Formation and Properties of Medium and High Molecular Weight Compounds of Elements of Groups 3, 4, and 5[**]

BY G. FRITZ [*]

The differences between compounds of carbon and of silicon are discussed, and the role of silicon as a fundamental structural component in inanimate nature is described. Starting with silicic acid and silicates, the structure and properties of the silicones and of compounds having Si–C–Si skeletons are described. The possibilities for the formation of high molecular-weight compounds between elements of Groups 3 and 5 of the periodic system are considered, with particular reference to boron nitride and to aluminum-phosphorus compounds.

1. Introduction

High molecular-weight substances have a special significance in nature. They are characterized by the linking together of numerous building components to form large composite structures. Their properties are very largely determined by the forces that hold the building units together. These forces may be purely electrostatic (as in ionic crystals) or metallic bonding forces (as in metal crystals and intermetallic compounds) or directional covalent bonds. It is necessary in many cases to assume that different types of bonds are involved, each type making a different contribution. These principles are found in the structural substances in inanimate nature, as well as in biologically important high molecular-weight substances such as proteins and polysaccharides. The structures of the latter are largely based on the ability of the carbon atom to form C–C bonds.

2. Differences Between Compounds of Carbon and of Silicon

A glance under the thin covering of the animate world shows that the earth's crust is built up from structural systems in which the element silicon, with its strong tendency to form the Si–O–Si grouping, plays a key part. Silicon is situated directly under carbon in the periodic table. In order to gain an insight into the diverse functions of these elements in nature, and so to establish general principles for the structure of inorganic high polymers, it seems advisable first to inquire into the reasons for the differences in the behavior of carbon and silicon atoms.

The ground state electronic configuration of carbon is $1s^2\,2s^2\,2p^2$, while that of silicon is $1s^2\,2s^2\,2p^6\,3s^2\,3p^2$. Unlike the C atom, the Si atom has a free 3d level, and is therefore capable of forming coordination compounds and of utilizing lone pairs of electrons of attached atoms to strengthen the bonding. While carbon can achieve stronger bonding by the formation of multiple bonds (π bonds), which at the same time satisfy the requirements for the polymerization and polyaddition reactions that are so important in carbon chemistry, silicon forms no corresponding multiple bond systems. The electronegativity of silicon is lower than that of carbon (Si 1.8; C 2.5), and the polar components in silicon compounds are consequently greater than in the corresponding carbon compounds. This and the ability of silicon to form coordination compounds largely determine the chemical behavior of this element. It is therefore understandable why CCl_4 is resistant to water, whereas $SiCl_4$ is very readily hydrolyzed with formation of the Si–O–Si grouping. Finally, the bond energies of compounds of silicon and of carbon differ appreciably in some cases (Si–Si 53, C–C 83, Si–O 108, C–O 85, Si–H 75, C–H 99 kcal/mole) [1].

[1] *T. Cottrell*: The Strength of Chemical Bonds. Butterworths, London, 1958, 2nd. Edit., p. 270–280.

The differences between silicon and carbon are particularly obvious in their oxides. CO_2 is a molecular compound, and free CO_2 molecules exist in the gaseous state. SiO_2, on the other hand, is a high molecular-weight substance, the formula of which merely indicates its stoichiometric composition. The Si atom is situated at the center of a tetrahedron with the oxygen atoms at the corners, and the various tetrahedra are joined to one another by a common oxygen atom.

3. Structure of Silicic Acid and Silicates

The structure of the silicates is also based on SiO_4 tetrahedra. The simplest silicic acid (and that with the highest oxygen content) is orthosilicic acid $Si(OH)_4$, which tends to lose water with formation of the Si–O–Si grouping (Fig. 1).

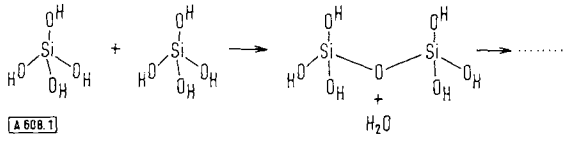

Fig. 1. Condensation of orthosilicic acid.

Isolated SiO_4^{4-} tetrahedra are found in the island structures, *e.g.* in olivine (Mg_2SiO_4). The nature of the linkage determines the type of silicate (Fig. 2).

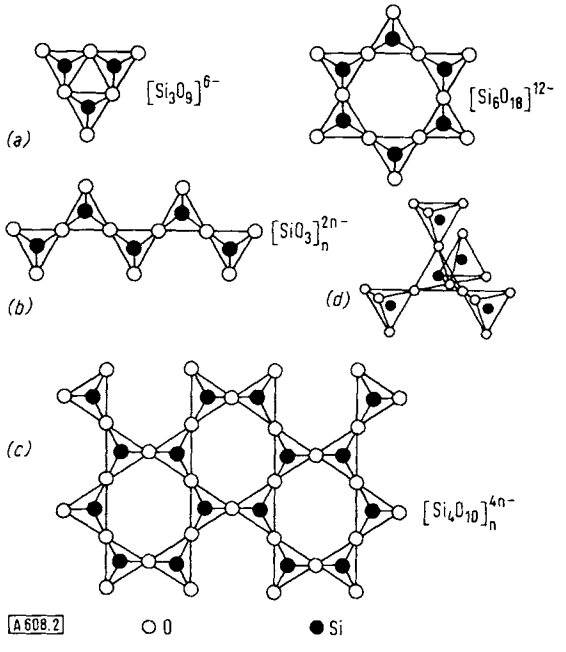

Fig. 2. Structures of the silicates:
(a) Ring structure $[Si_3O_9]^{6-}$; $[Si_6O_{18}]^{12-}$; (b) chain structure $[SiO_3]_n^{2n-}$; (c) layer structure $[Si_4O_{10}]_n^{4n-}$; (d) three-dimensional network structure. (Above each Si atom there is an O atom, which is not shown).

Nature gains an important variation in this structural principle by the replacement of the silicon ions by aluminum ions, since the radii of these two ions are very similar (Si^{4+} 0.41 Å; Al^{3+} 0.5 Å). The aluminum ion then assumes the 4-coordination of silicon. This results in an increase in the negative charge of the anionic skeleton by one unit per aluminum ion introduced. To compensate for these negative charges, cations are built into the open aluminosilicate anions, as is found *e.g.* in muscovite (Fig. 3).

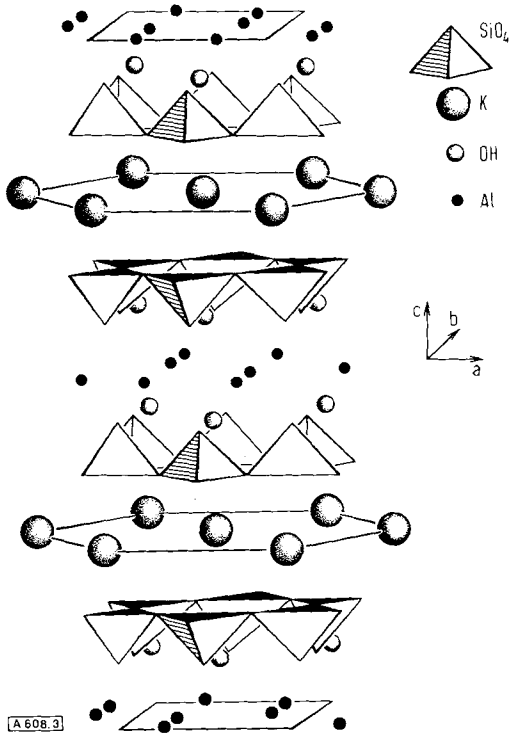

Fig. 3. Structure of muscovite ($KAl_2(OH)_2AlSi_3O_{10}$).

A particularly large group of natural aluminosilicates exists in three-dimensional lattice structures. This group includes the feldspars. A typical member is orthoclase $K(AlSi_3O_8)$.

The polymeric substances discussed so far are crystalline. The structure of the crystal is determined by the periodic arrangement of the structural units in the lattice. By breakdown of this regularity, it is possible to obtain glass-like substances. Figure 4 shows the arrangement of the SiO_4 tetrahedra in quartz glass (cf. the arrangement in crystalline quartz, Fig. 2c).

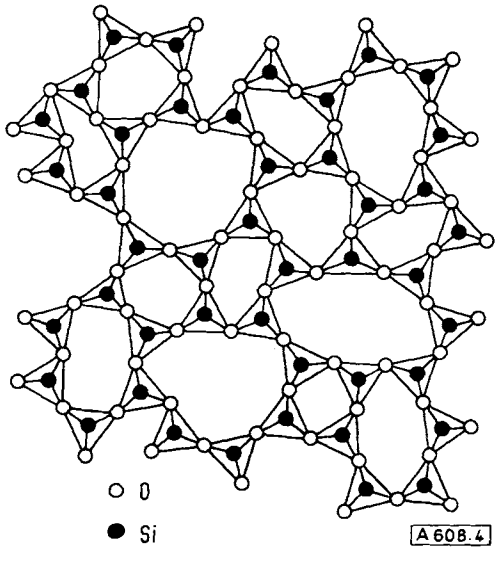

Fig. 4. Arrangement of the SiO_4 tetrahedra in quartz glass. (Above each Si atom there is an O atom, which is not shown.)

The vitreous state results from irregular linkages of the tetrahedra arising in the melt, which are retained on cooling because of its viscosity. Glasses are formed, not only by SiO_2, but also by B_2O_3, condensed phosphates, and oxides of arsenic, antimony, selenium *etc.*; many organic high polymers also occur as glasses. The vitreous state is unstable in relation to the crystalline state. In alkali metal and alkaline earth metal glasses, metal oxides are incorporated into the tetrahedral network (eq. (1)).

$$\text{Si–O–Si} + \text{CaO} \longrightarrow \text{Si–O Ca O–Si} \qquad (1)$$

This gives rise to points of fission, with the result that the softening temperature and the viscosity of the glass are lowered[2]. The more mobile the network becomes as a result of points of fission, the more readily do the components arrange themselves into the crystalline lattice. This process, which can be observed in all silicate glasses, is known as devitrification.

4. Structure of Silicones

The strength of the Si–O–Si linkage is responsible for the high stability of silicates and silicate glasses. However, the usefulness of these substances is limited by the fact that they are brittle and are fairly readily attacked by alkalis. If we imagine some of the oxygen atoms of the SiO_4 tetrahedra in a quartz glass of this type to be replaced by organic groups (*e.g.* CH_3), which can no longer link adjacent tetrahedra, certain units (*e.g.* long chains having an Si–O–Si skeleton) can be isolated from the SiO_2 glass. The resulting derivatives of the silicates still possess some of the characteristics of the silicate structure, but also have properties attributable to the $\equiv Si–CH_3$ groups. This relationship is illustrated in Figure 5.

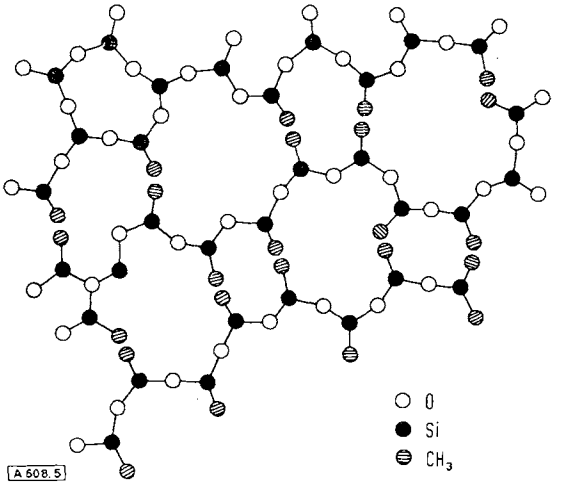

Fig. 5. Derivation of the structure of a silicone from the structure of a silica glass. (Above each Si atom there is an O atom, which is not shown.)

Compounds of this type are known as organosiloxanes or silicones[3,4]. This group of compounds cannot be obtained in the manner described, nor do they occur in nature. To obtain silicones, silicon must first be prepared by reduction of SiO_2 and then converted into alkylchlorosilanes. These can be prepared by reaction of $SiCl_4$ with methylmagnesium chloride, or preferably by "direct" synthesis. This involves the reaction of elementary silicon with methyl chloride, a reaction whose occurrence and course are strongly dependent on the catalyst. The reaction leads to the formation of a mixture of silicon halides, the most valuable of which is $(CH_3)_2SiCl_2$ (eq. (2)).

$$CH_3Cl + Si \xrightarrow[300\,^\circ C]{\text{cat.}} \begin{matrix}(CH_3)_2SiCl_2,\ CH_3SiCl_3,\ (CH_3)_3SiCl,\ SiCl_4\\ HSiCl_3,\ CH_3SiHCl_2,\ (CH_3)_2SiHCl,\ Si(CH_3)_4\end{matrix} \qquad (2)$$

This reaction, which is used on the industrial scale (Rochow synthesis), was observed independently and at about the same time[4] by *R. Müller* and *Rochow*.

As was previously mentioned, the SiCl grouping is readily hydrolyzed, the initial reaction products being silanols. Like orthosilicic acid, these compounds have a strong tendency to lose water with formation of the Si–O–Si grouping (eq. (3)), the resulting products, *e.g.* in the case of $(CH_3)_2SiCl_2$, being long chains.

$$\begin{matrix}CH_3\\ |\\ -O-Si-O-\\ |\\ CH_3\end{matrix}\left[\begin{matrix}CH_3\\ |\\ Si-O\\ |\\ CH_3\end{matrix}\right]_n\begin{matrix}CH_3\\ |\\ -Si-\\ |\\ CH_3\end{matrix} \qquad (3)$$

$(CH_3)_3SiCl$ can form only one such linkage, whereas CH_3SiCl_3 can form three. It is thus possible to obtain linear and crosslinked three-dimensional structures, and the physical properties of the condensation products can be widely varied in this way.

The linear silicones are oils or, where the chains are very long, rubbery substances. The highly crosslinked substances, *i.e.* the silicone resins, become increasingly like silica glass with increasing crosslinking. The silicones are now popular synthetic materials, since they combine the properties of the Si–O–Si bond of the silicates with typical characteristics of organic groups. The polar component of the Si–O–Si linkage is about 50%. The bonding is strengthened by π components as a result of interaction of the electrons from the oxygen with the 3d orbitals of the silicon. The Si–C bond in the $SiCH_3$ group is about 88% covalent and 12% polar. These facts explain the high thermal stability, the hydrophobic properties, and the solubility behavior of the silicones.

With silicone chemistry as a basis, it is possible to construct skeletons in which Si–O–Si groups are replaced *e.g.* by Si–O–Al, Si–O–Sn, Si–O–Ti, and Si–O–P[5].

5. Structure of Carbosilanes

The CH_2 group is isoelectronic with the O atom. Compounds in which the silicon atoms are linked by a single carbon atom (by a CH_2 group in chains or simple rings), which are known as carbosilanes, are mainly formed by free-radical reactions on thermal

[2] *A. Dietzl*, Naturwissenschaften *29*, 537 (1941); *31*, 22, 110 (1943); Z. Elektrochem. angew. physik. Chem. *48*, 9 (1942).

[5] *K. A. Adrianov*: Metal Organic Polymers. Interscience, New York 1965.

cleavage of tetramethylsilane and the methylchlorosilanes [6]. The thermal decomposition of $Si(CH_3)_4$ and of the methylchlorosilanes in the gas phase yields mixtures of oily, tarry, and even crystalline compounds, whose molecular skeletons consist mainly of alternate silicon and carbon atoms. Cyclic products are formed preferentially [7]. Figure 6 shows some of the low molecular-weight compounds of this class.

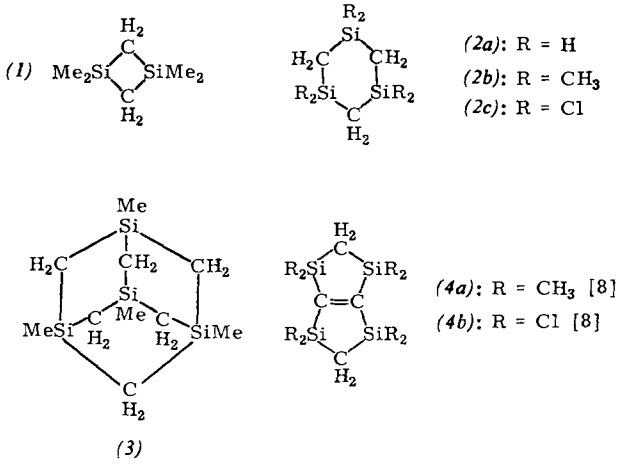

Fig. 6. Some low molecular-weight carbosilanes obtained by pyrolysis of $Si(CH_3)_4$ and the methylchlorosilanes. The compounds containing *SiH* groups were prepared from compounds containing SiCl groups by reduction with $LiAlH_4$. (Me = methyl.)

The formation of carbosilanes is due to the primary cleavage of the silicon-carbon bond in $Si(CH_3)_4$ at about 700 °C, which yields methyl and silyl radicals (eq. (4)). The methyl radicals react further in accordance with eq. (5). Combination of the radicals leads to the

$$(CH_3)_3Si{-}CH_3 \rightarrow (CH_3)_3Si^{\bullet} + CH_3^{\bullet} \quad (4)$$

$$(CH_3)_3Si{-}CH_3 + CH_3^{\bullet} \rightarrow (CH_3)_3Si{-}CH_2^{\bullet} + CH_4 \quad (5)$$

simplest member of the class $(CH_3)_3Si{-}CH_2{-}Si(CH_3)_3$. The structure of the medium and high molecular-weight substances, which have not yet been very extensively studied, is based on the same principle. These substances are particularly important since when heated they form compounds having still higher molecular weights, with no separation of silicon or carbon. An extremely wide variety of high molecular-weight compounds are formed, ranging from the simple $Si{-}CH_2{-}Si$ chain to silicon carbide.

The properties of the carbosilanes are very largely determined by the character of the Si–C bond. Accordingly, the fully methylated compounds are very inert, and are solvolyzed only under extreme conditions. The compounds containing SiCl bonds can enter into further reactions. Thus by hydrolysis of these SiCl groups, Si–C–Si skeletons can be linked by Si–O–Si groupings, or the SiCl groups may be converted into SiH groups, which can then be oxidized.

6. High Polymers with a Silicon Network

The tendency toward the formation of high molecular-weight compounds by free-radical reactions is very pronounced in the chemistry of silicon. This is seen in the formation of compounds whose skeletons consist of Si–Si bonds. Thus $(SiH)_x$ can be prepared from SiH_4 by heating [9]. $SiCl_4$ and H_2 react to form the higher silicon chlorides up to $(SiCl)_n$ [10]. $(SiCH_3)_x$ is obtained among other products from SiH_4 and ethylene [11]. In the high molecular-weight compounds $(SiH)_x$, $(SiCH_3)_x$, and $(SiCl)_x$, each silicon atom is directly bonded to three others.

The route to high molecular-weight compounds need not start with the small structural units (monomers) and lead by growth reactions (condensation, polymerization) to large structures. These can also be prepared with care from crystallographically definite structures of the desired basic skeleton. Thus $CaSi_2$ forms a layer structure (Fig. 7) [12].

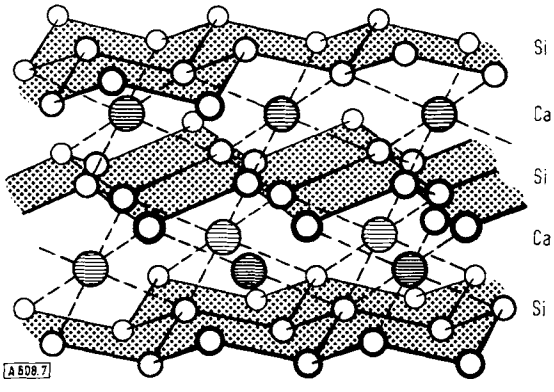

Fig. 7. Structure of $CaSi_2$.

To expose the silicon network, the calcium atoms connecting the layers must be dissolved out or replaced by monovalent atoms or by radicals. This is achieved by reaction of $CaSi_2$ with an $SbCl_3$ melt [13]. The silicon is first exposed in accordance with equation (6), but is unfornately chlorinated to a greater or lesser

$$3\,CaSi_2 + 2\,SbCl_3 \rightarrow 6\,Si + 2\,Sb + 3\,CaCl_2 \quad (6)$$

extent (eq. (7)), depending on the reaction conditions.

$$x\,Si + {}^1/_3\,x\,SbCl_3 \rightarrow (SiCl)_x + {}^1/_3\,x\,Sb \quad (7)$$

[13] *H. Kautsky* and *L. Haase*, Chem. Ber. *86*, 1226 (1953).

After conversion into SbI_3 with iodine, the liberated antimony can be removed from the reaction mixture with anhydrous organic solvent. As expected, the silicon left behind is extremely reactive; it reacts even with water, whereupon violent liberation of H_2 takes place. When heated, it changes into normal silicon. Direct reaction of $CaSi_2$ suspended in CCl_4 with chlorine or ICl also gives this form of silicon, as well as $(SiCl)_x$ formed by further chlorination [14, 15].

$$^1/_2\, x\, CaSi_2 + {}^1/_2\, x\, Cl_2 \xrightarrow[20-40\,^\circ C]{} (Si)_x + 1/2\, x\, CaCl_2 \qquad (8)$$

$$(Si)_x + 1/2\, x\, Cl_2 \xrightarrow[40\times 60\,^\circ C]{} (SiCl)_x \qquad (9)$$

The resulting $(SiCl)_x$ and its derivatives occur in the lepidoide form, *i.e.* ideally in a layer on which all the functional groups are situated on the surface of the insoluble substance, and are thus directly accessible to reactions.

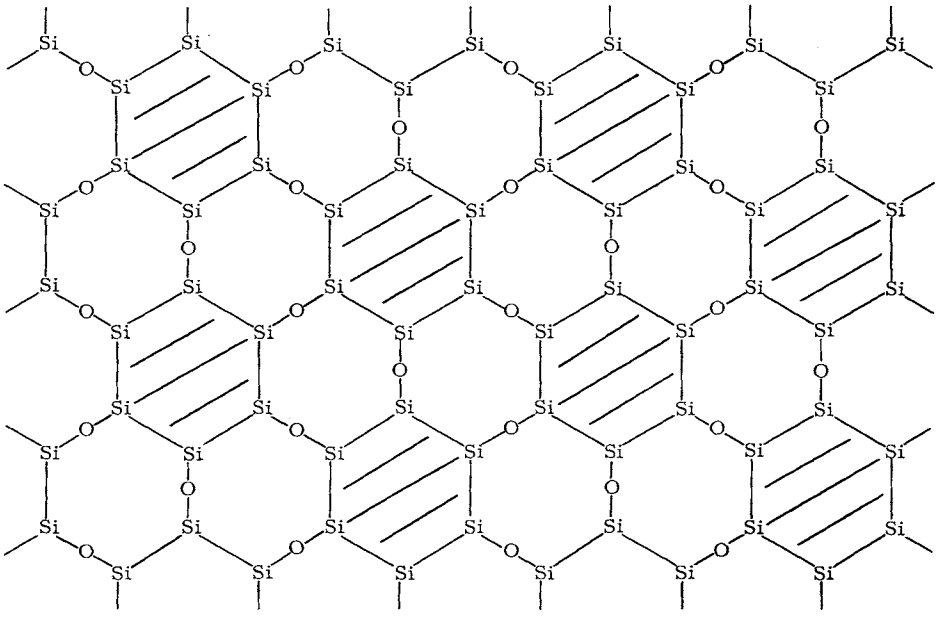
H. Kautsky [16] tried to dissolve the calcium out of the $CaSi_2$ layer lattice and to replace it by hydrogen atoms in order to separate the layers and so obtain the polymeric lepidoide $(SiH)_x$. However, this is not possible, since the anions of the acid and the oxygen of the solvent intervene in the replacement of calcium by hydrogen, so that a permutitic high polymer having the composition $(Si_6O_3H_6)_n$ is formed [16]. The silicon layer in this case consists of six-membered silicon rings joined by oxygen atoms. This substance reacts very rapidly and quantitatively with *e.g.* Br_2 to form surface compounds having a definite stoichiometric composition and having the same basic network structure. The reactions involve substitution of the SiH groups on the surface. The structure of the siloxene network is illustrated in Figure 8.

The layer therefore carries reactive groups, by means of which chemical reactions can be carried out on an ideal surface, offering the possibility of obtaining model substances. A second, very interesting characteristic of these compounds is their color and fluorescence [17]; for example, dibromosiloxene reacts with CH_3OH to form an orange derivative (two OCH_3 groups), while tetrabromosiloxene forms a red compound (four OCH_3 groups). The explanation of this phenomenon for the siloxene network and for the high molecular-weight silicon compounds should add considerably to our knowledge of color, fluorescence, and energy transfer on surfaces.

7. High Molecular-Weight Compounds between Elements of Groups 3 and 5

Graphite and boron nitride (Fig. 9) form very similar layer lattices.

The groups B–N and C–C are isosteric; unlike graphite, $(BN)_x$ is white and non-conducting. Its high thermal stability therefore makes it suitable for use as an insulator and lubricant at high temperatures. At 1400 °C and 7000 atm, boron nitride can be converted from the graphite-like structure to a diamond structure; in this form it burns only at 1900 °C and is as hard as diamond.



[A 608. 8]

Fig. 8. Structure of a siloxene network (the Si_6 rings are shaded). The fourth valence on the Si atom is occupied by H atoms, which can be replaced *e.g.* by halogens [16].

The chemistry of the low molecular-weight, boron-nitrogen compounds is similar in some respects to carbon chemistry. While the formation of molecular compounds between compounds of the group 4 ele-

[17] *H. Kautsky*, Kolloid-Z. *102*, 1 (1943); *E. Hengge*, Chem. Ber. *95*, 648 (1962).

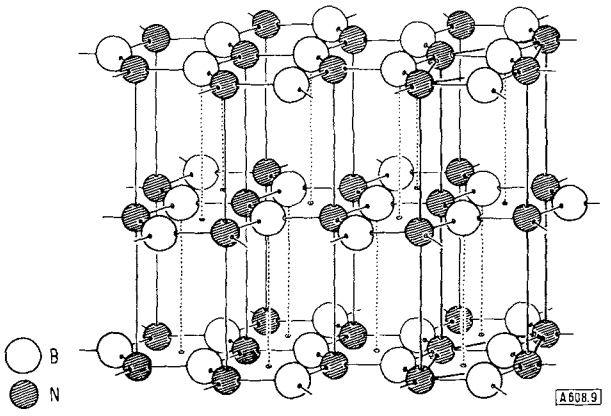

Fig. 9. Lattice of boron nitride.

ments is dominated by substitutions, condensations, and additions, the first reaction step in the case of compounds between elements of groups 3 and 5 is often adduct formation, owing to the electronic structure in these compounds. Interesting compounds can be formed from the adducts by removal of atoms and groups, as is illustrated by the formation of borazole [18] from B_2H_6 and NH_3 (eq. (10)).

$$3\ (BH_3)_2 + 6\ NH_3 \longrightarrow 2 \begin{array}{c} H \\ B \\ HN \quad NH \\ \| \quad \| \\ HB \quad BH \\ N \\ H \end{array} + 12\ H_2 \qquad (10)$$

This route is not satisfactory for the formation of compounds between aluminum and phosphorus, though the chemical behavior is still largely governed by the tendency toward adduct formation [19]. High molecular-weight compounds are obtained when the aluminum carries more than one group that is capable of coordination [20].

In these cases extensive crosslinking takes place, the degree of crosslinking being greatest when the aluminum carries three PR_2 groups.

In most of the classes of substances discussed, the bonding between the individual groups is predominantly homopolar, with a more or less pronounced polar component. This explains some of the properties,

such as the solubility, and the possibility of solvolysis. The stability is largely determined by the tendency toward formation of the oxygen compounds. The optimum stability is reached in the naturally occurring silicate skeletons. At the other end of the scale we find the aluminum-phosphorus compounds, which are very readily oxidizable, and most of which ignite spontaneously.

We started by comparing silicon and carbon as building elements in the skeletal substances of animate and inanimate nature. The modification of these natural structural systems offers the chemist a multitude of possibilities for the synthesis of high molecular-weight substances that are nowadays indispensable. These possibilities are still far from exhausted both theoretically and in their applications. We may therefore look forward to many interesting developments in the future.

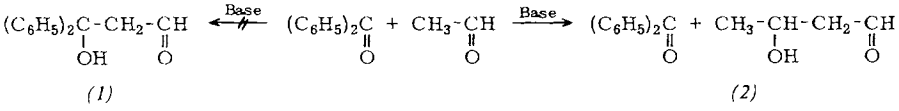
Directed Aldol Condensations

BY G. WITTIG AND H. REIFF [*]

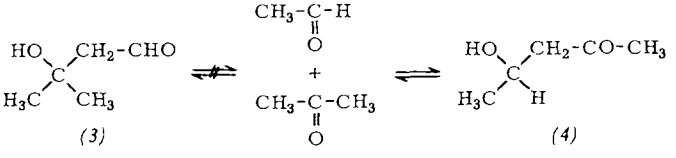
The present article describes the discovery of a new procedure for aldol condensations for the preparation of α,β-unsaturated carbonyl compounds[***]. *The scope of this process is demonstrated by many examples, including some from the natural products sector; at the same time, however, these examples also mark its limitations. The metalated Schiff's bases may be classified as ambident anions; this also explains acylations on the nitrogen. A comparison of the new directed aldol condensation with the formation of unsaturated carbonyl compounds through olefination via phosphorylids shows that the latter method fails when a ketone is used as the substrate. This is where the described procedure using metalated Schiff's bases proves its value.*

1. Introduction

Until a few years ago, the aldol addition could not be directed in such a way that an aldehyde having a hydrogen atom in the α position added to the carbonyl group of a ketone, since the preferred reaction is the self-addition of the aldehyde. For example, the reaction of acetaldehyde with benzophenone in the presence of the usual basic catalysts does not lead to the desired aldol adduct *(1)*, but to acetaldol *(2)* which loses water to form crotonaldehyde.



(1) *(2)*



(3) *(4)*

Even condensation with more reactive ketones such as acetone fails to yield the adduct *(3)*, but leads instead to compound *(4)* [1], since acetaldehyde has the more reactive carbonyl group and acetone has a more nucleophilic carbon atom after anionization.

It is not possible to remove first a proton from the acetaldehyde and then add the electrophile *e.g.* in the form of acetone. Generally the two components must be placed together in the reaction vessel, the base then being added dropwise. Moreover, the base cannot be chosen arbitrarily, since it must be such that it does not add to the carbonyl group.

These difficulties can be avoided by conversion of the carbonyl group of the aldehyde into the azomethine group, metalation of the resulting "protected" acetaldehyde (*e.g.* with lithium diisopropylamide) to obtain *(5)*, and reaction of *(5)* with acetone or benzophenone [2, 3].

Since the protective group can be readily removed after the aldol addition, this method opens new routes to aldol condensations by way of organometallic compounds.

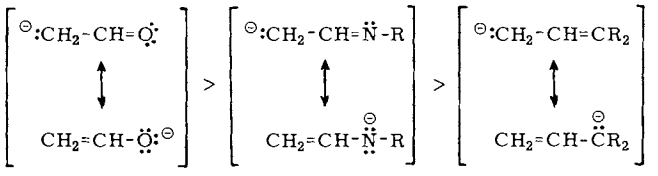
2. Theoretical Considerations

The new method of aldol addition *via* Schiff's bases seems plausible in retrospect, since the metalated Schiff's bases should have been expected to be intermediate in their reactivity between the allyl anions and the anionized carbonyl compounds.



Both the allyl and the enolate anions react readily with carbonyl compounds. It was therefore considered very probable that the anionized Schiff's bases would react in a similar manner. The feasibility of directed aldol condensations depended on whether the metalated Schiff's bases would add rapidly to the unmetalated species (as is the case with the anionized carbonyl compounds) or whether they would behave more like the allyl anions, which do not enter into additions of this nature.

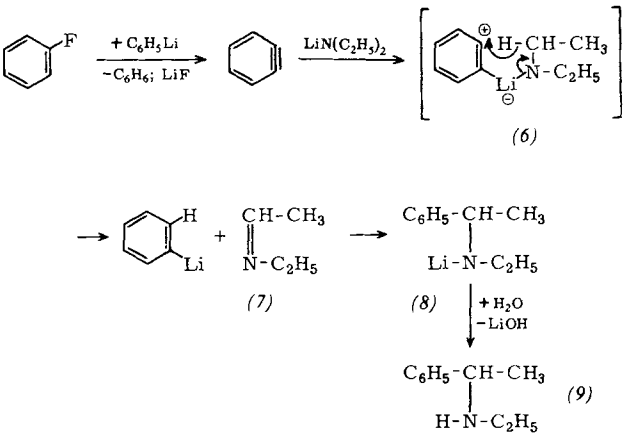
In fact, the electrophilicity of the azomethine group is so low that the self-addition can be suppressed by the procedure described in Section 4. The metalated Schiff's base, on the other hand, is sufficiently nucleophilic to attack even inert carbonyl groups, such as those of ketones. This effect contributes to the success of the new method.

3. Discovery of the Principle of the Directed Aldol Condensation

The foregoing theoretical considerations did not, however, precede the actual experiments. On the contrary, attention was directed toward the metalated Schiff's bases by unexpected experimental results.

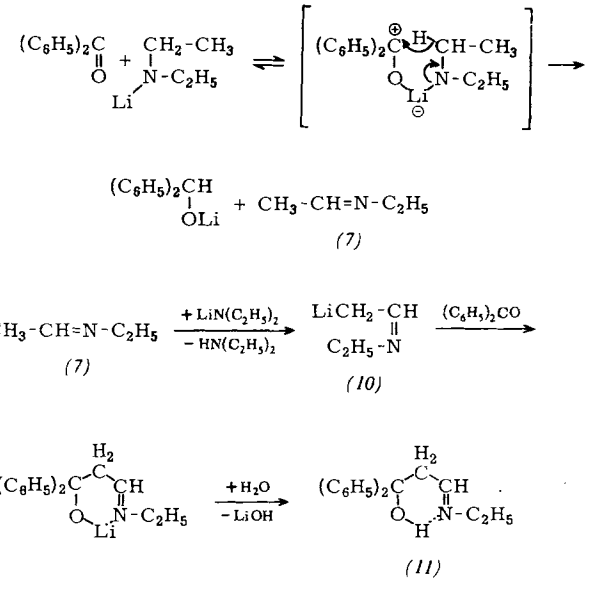
In the course of investigations on dehydrobenzene, phenyllithium was allowed to react with fluorobenzene in the presence of lithium diethylamide. In addition to the expected diethylaniline, the products also included α-phenyldiethylamine. Closer investigation [4] showed that the lithium diethylamide evidently adds to dehydrobenzene, formed as an intermediate, to give the ate-complex *(6)*, which has not been isolated. The anionic loosening of the ligand adjacent to the nitrogen leads to a hydride transfer, which results in the formation of phenyllithium and the Schiff's base *(7)*. These two compounds combine irreversibly by addition of the organolithium compound to the C=N group to form the lithium amide *(8)*, hydrolysis of which yields α-phenyldiethylamine *(9)*.

This ability of lithium diethylamide to act as a hydride donor led to further experiments. To verify that lithium diethylamide does in fact occur as the reducing



agent, it was allowed to act on benzophenone. We expected reduction to benzohydrol *via* the ate-complex, coupled with oxidation of the amine to form the Schiff's base *(7)*. Up to 35% of benzohydrol was actually isolated; however, a more complicated compound was obtained instead of ethylideneethylamine *(7)*. Careful determination of its structure [4], followed by synthesis, showed that this product was the Schiff's base *(11)*, *i.e.* an aldimine adduct.

Thus part of the benzophenone is evidently reduced to benzohydrol in a redox reaction, in which a corresponding quantity of the Schiff's base *(7)* is formed. After metalation of *(7)* by lithium diethylamide that is still present, the metalated Schiff's base reacts with unreduced benzophenone to form the aldimine adduct *(11)*. The surprising thing is that all these reactions proceed to completion within a minute at 0 °C.



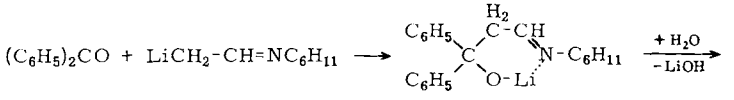
Since the end product *(11)* can be readily converted into β-phenylcinnamaldehyde by mineral acid, the overall reaction is an aldol condensation in which the methyl group of the acetaldehyde is specifically condensed with the carbonyl group of the ketone. This possibility of a directed aldol condensation was pursued further, particularly since it was soon found that the method can be generalized within wide limits and generally gives good results.

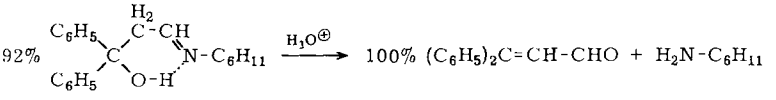
[4] *G. Wittig, H.-J. Schmidt*, and *H. Renner*, Chem. Ber. *95*, 2377 (1962).

4. Directed Aldol Condensations

The optimum conditions ("standard method") for the metalation or anionization of Schiff's bases on the one hand and the subsequent reaction with carbonyl compounds to form aldimine adducts on the other are described below. Cyclohexylamine was found to be suitable as the amine component of the Schiff's bases, since Schiff's bases having branched alkyl substituents on the nitrogen have less tendency toward self-addition than those with unbranched ligands[5]. For obvious steric reasons lithium diisopropylamide proved to be a particularly suitable metalating agent instead of lithium diethylamide.

Thus on reaction of ethylidenecyclohexylamine with lithium diisopropylamide in ether at 0 °C and, after





(12a)

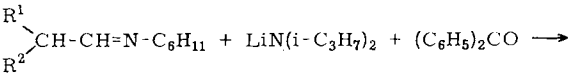
10 min, addition of benzophenone at −70 °C, hydrolysis gave the Schiff's base *(12a)* in 92% yield[2].

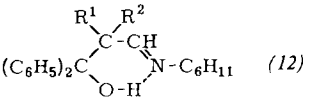
The favorable results are also due to the fact that the resulting lithium salts of the aldol adducts, as formulated above, exist as chelates. The IR spectrum in every case confirmed that the nitrogen of the aldimine group in the hydrolysis products is linked to the hydroxyl group by an intramolecular hydrogen bond. Broad absorption bands were observed at 3200 to 3100 cm^{-1} for KBr disks and at 3300 to 3200 cm^{-1} in $CHCl_3$ or benzene, no change being found in the solution spectra even at high dilutions.

It is interesting to note that methyllithium, which was used to convert the diisopropylamine into its lithium derivative, preferentially metalated ethylidenecyclohexylamine on the methyl group at −70 °C, and added only to a small extent to the C=N group. After the addition of benzophenone followed by hydrolysis, the aldimine adduct *(12a)* was isolated in 71% yield. Since the aldimine adduct could be converted almost quantitatively into β-phenylcinnamaldehyde, the problem of carrying out a directed aldol condensation on aromatic ketones was solved.

However, the directed aldol condensation, though proceeding particularly smoothly with aromatic ketones, is limited in its applicability. To determine the influence of the inductive and steric effects on the new procedure, the Schiff's bases of α-substituted acetaldehydes were metalated under the standard conditions with lithium diisopropylamide, and the aldimine adducts obtained with benzophenone were isolated[6]. The yields are given in Table 1.

Table 1. Directed aldol condensation: influence of inductive and steric effects on the formation of aldimine adducts.



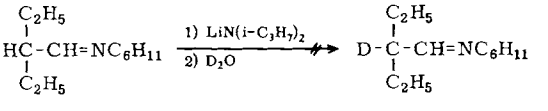


(12)

	R^1	R^2	*(12)* Yield (%)	M.p. (°C)
(12a)	H	H	92	127–128
(12b)	CH_3	H	91	82– 83
(12c)	C_2H_5	H	71	104–105
(12d)	CH_3	CH_3	29	107–108
(12e)	C_2H_5	C_2H_5	0	–

It can be seen that the yield decreases with increasing branching on the α-carbon of the Schiff's base. 2-Ethylbutylidenecyclohexylamine *(12c)* does not react.

The reason for this was shown by the following observations. When the Schiff's base *(13)* was treated for 2 hours with lithium diisopropylamide in ether (the Schiff's base of the unsubstituted acetaldehyde is immediately metalated in ether) and the product hydrolyzed with D_2O, *(13)* was recovered in 95% yield[6]. The IR and in particular the NMR spectra showed that the compound contained no deuterium, and so had not been metalated. *(13)* could not be metalated even by tritylsodium in ether or by tritylpotassium in ethylene glycol dimethyl ether; the solutions were still deep red after four weeks, and back-titration showed that they still contained 80 and 96%, respectively, of unreacted base[6].



(13)

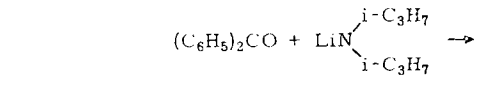
This also explains the fact that almost 50% of benzohydrol was detected on reaction of *(13)* with lithium diisopropylamide in the presence of benzophenone. The lithium diisopropylamide reacts with benzophenone instead of with *(13)*, hydride transfer taking place as formulated earlier to give benzohydrolate and the new Schiff's base *(14)*. *(14)* is metalated by lithium diisopropylamide and then enters into aldimine addition with unreacted benzophenone to give *(15)*.

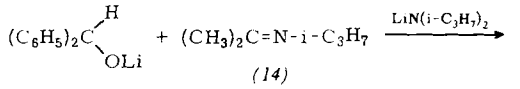
On subsequent hydrolysis and distillation *(15)* decomposed into benzophenone and *(14)*.

The decrease in metalation with increasing alkylation of the aldimine is probably due to the combined effects of the increasing steric hindrance and the hyperconjugation which decreases the mobility of the α-protons.

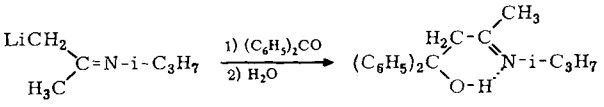
[5] *R. Tiollais*, Bull. Soc. chim. France *14*, 716 (1947).

[6] *H. Reiff*, Dissertation, Heidelberg University, 1966.



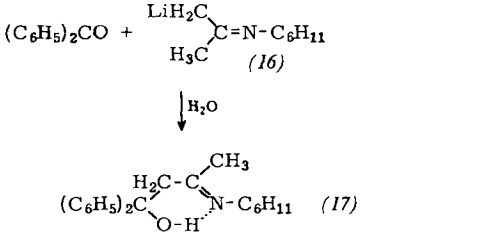


(14)

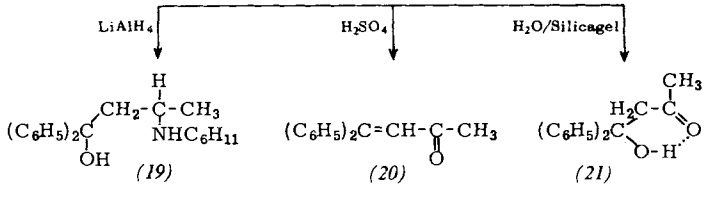


(15)

In this connection the reaction of *(14)* with the metalating agent and benzophenone was studied more closely. It corresponds to an aldol addition of acetone to benzophenone, which *A. Klages* and *E. Fanto* [7] had already unsuccessfully tried to achieve. Isopropylidenecyclohexylamine was metalated under the usual conditions to give *(16)*, which was then brought into contact with benzophenone. The aldimine adduct *(17)* could be isolated in 64% yield [8].



(16) (17)



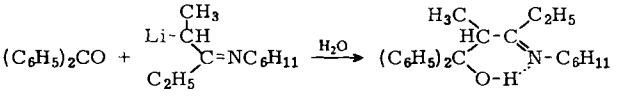
(19) (20) (21)

Reduction of *(17)* with $LiAlH_4$ (which at the same time established its constitution) gave the amino alcohol *(19)* in 81% yield. The IR spectrum of *(19)* no longer contained an azomethine band.

Decomposition of *(17)* with dilute sulfuric acid led to the unsaturated ketone *(20)* (78% yield), which was found to be identical with a comparison product prepared by a more laborious route. Even the nitrogen-free aldol adduct *(21)* could be obtained in 68% yield [8]. Thin-layer chromatography of *(17)* on silica gel gave two products; the compound having the higher R_f value was identified as benzophenone, while the other compound ($C_{16}H_{16}O_2$, m.p. 85 °C) was found, from the position of the NMR signals and the proton ratio ($CH_{arom.}:OH:CH_2:CH_3 = 10:1:2:3$), to be the previously unknown ketol *(21)*.

In the reaction of the Schiff's base of the homologous diethyl ketone with benzophenone, the ketimine adduct *(22)* could be isolated but the corresponding ketol could not be obtained by thin-layer chromatography [8].

The acidic decomposition of *(22)* also failed to yield the unsaturated ketone; both operations gave only benzophenone, the branching on the α-carbon atom in this case evidently again opposing the stability of the aldol adduct.

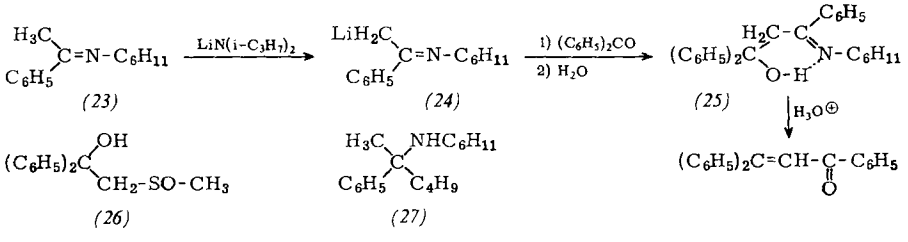


(22)

The Schiff's base *(23)* of acetophenone, on anionization with lithium diisopropylamide to give the deep yellow *(24)* and combination with benzophenone, gave the adduct *(25)* (55% yield), which was converted, on treatment with dilute mineral acid, into 1,1-diphenyl-2-benzoylethylene in 95% yield [6].

Variation of the metalation conditions in this case gave rise to a number of secondary reactions, of which we shall select only a few [6]. Potassium *tert*-butoxide in ether or tetrahydrofuran, instead of metalating *(23)*, cleaved the benzophenone present into benzoic acid in a Haller-Bauer reaction [9]. When the reaction was carried out in dimethyl sulfoxide, which, according to *D. J. Cram* [10], particularly favors anionization, the addition product *(26)* of the methylsulfinyl carbanion was obtained in 89% yield [11].

When *(23)* was treated with ethereal butyllithium in the absence of a ketone, 22% of *(23)* and 67% of *(27)* could be isolated after hydrolysis; this indicates that the organolithium compound had added preferentially to the C=N bond. A further insight into the reaction was afforded by hydrolysis with D_2O after the reaction of *(23)* with butyllithium [6].



(23) (24) (25) (26) (27)

The NMR spectrum of the recovered Schiff's base *(29)* showed that one hydrogen on the acidic methyl group and one in the ortho position of the benzene nucleus

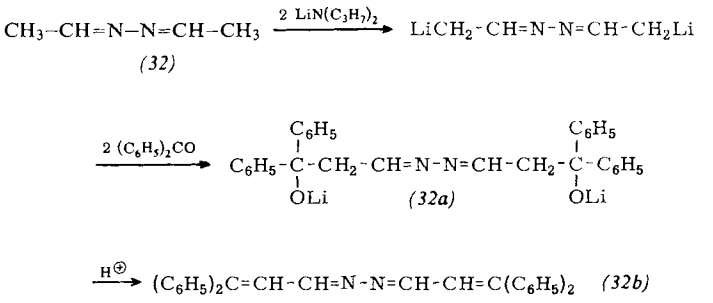
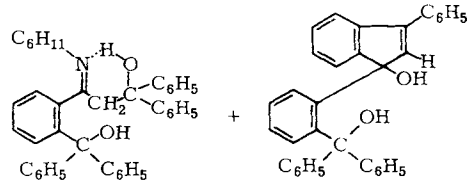
(28) (29) (28a) (30)



(32) (32a) (32b)

had been replaced by deuterium. Thus apart from a C=N addition, *(23)* was converted by butyllithium into the double metalation product *(28)*. In analogy with the formation of the dilithium derivative *(30)* on metalation of *N*-methylbenzamide with butyllithium, as observed recently by *C. R. Hauser* [12], we formulate our product as indicated in *(28a)* [6] to express the fact that the formation of a five-membered chelate ring has a decisive influence on the *o*-metalation.

Whereas metalation of *(23)* with lithium diisopropylamide followed by addition of benzophenone yielded the normal ketimine adduct *(25)* as described above, metalation of *(23)* with 2 moles of butyllithium in ether followed by reaction with benzophenone led to the expected bis-adduct *(31)* (16%), the main product,



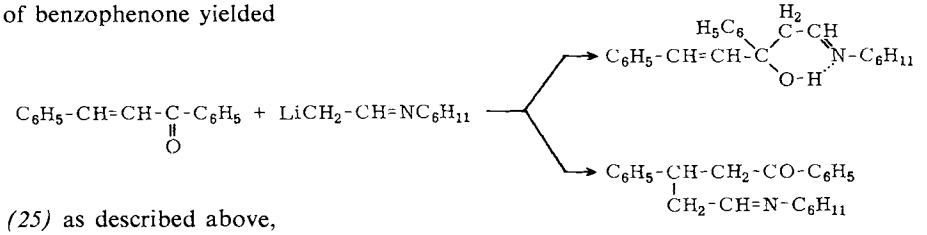
(31) (31a)

however, being the diol *(31a)* (48% yield). The determination of the structures and the interesting reactions of the two compounds on treatment with acids will not be discussed here [6].

On the other hand, an interesting question in connection with the dimetalation of *(23)* is whether the directed aldol condensation can also be extended to azines.

Preliminary experiments (metalation followed by hydrolysis) with the readily obtainable acetaldazine *(32)* showed that the α,ω-dimetalated compound is relatively stable at −70 °C. When two moles of benzophenone were added to the doubly metalated acetaldazine in ether at −70 °C, the bis-adduct *(32a)* of benzophenone could be isolated in 30% yield [6]. The crystalline compound *(32a)* (m.p. 182–183 °C) could be readily and quantitatively converted into β-phenylcinnamaldehydazine *(32b)*.

The dependence of the aldimine addition on the external conditions is shown by the behavior of metalated ethylidenecyclohexylamine toward unsaturated ketones such as benzylideneacetophenone. When the two components were brought together in ether at −70 °C, the 1,2-adduct *(33)* could be isolated in 51% yield, whereas reaction at room temperature gave only 32% of this adduct and 6% of the Michael adduct *(34)* [8].



(33) (34)

5. Metalated Schiff's Bases as Ambident Anions

Before discussing the particularly interesting aldimine additions that lead to natural products, we must first consider the question of structure and the mechanistic processes occurring in reactions with metalated Schiff's bases. NMR-spectroscopic studies by *J. D. Roberts* [13] show that the two methylene groups in the allyl Grignard compounds are indistinguishable. The simple AX_4 spectrum obtained can be reconciled only with a fast equilibrium.

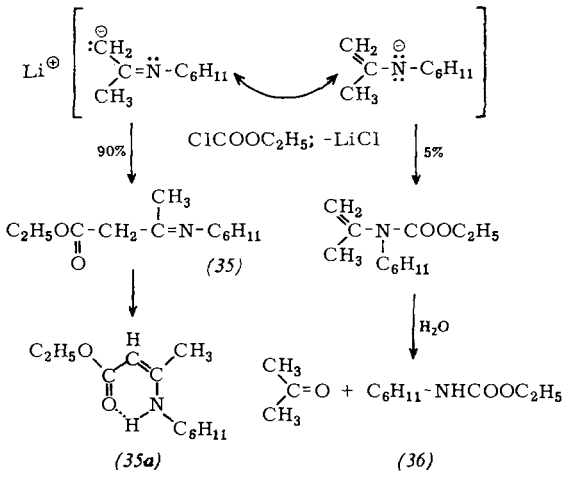
Electrophilic reagents can therefore attack at both ends of the resonance-stabilized allyl system. By analogy with this, it must be expected that the anionized Schiff's bases can also react in the resonance form having the negative charge on the nitrogen.

The reaction of the anionized Schiff's base of acetone with ethyl chloroformate yields 90% of *(35)*, the IR and NMR spectra of which indicate that it exists in its chelate form *(35a)* as ethyl β-cyclohexylaminocrotonate; 5% of *N*-cyclohexylurethane *(36)* is also obtained [6].

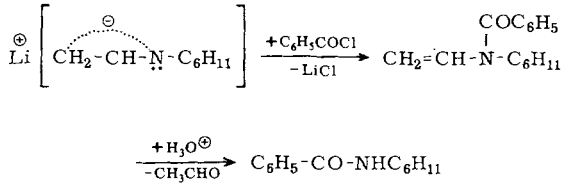
The ethoxycarbonyl group has therefore been introduced onto carbon and onto nitrogen, the ratio of the

[12] *W. H. Puterbaugh* and *C. R. Hauser*, J. org. Chemistry *29*, 853 (1964); *R. L. Vaulx*, *W. H. Puterbaugh*, and *C. R. Hauser*, *ibid. 29*, 3514 (1964).

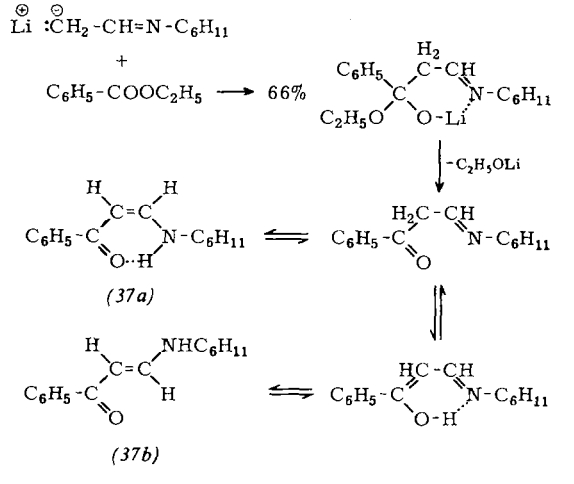
[13] *J. D. Roberts* and *J. E. Nordlander*, J. Amer. chem. Soc. *81*, 1769 (1959).



products being determined by the electrophilicity of the other reactant. The action of benzoyl chloride on lithium ethylidenecyclohexylamine gave 35% benzoylation on the nitrogen, together with oils and resins that were not examined further [6].



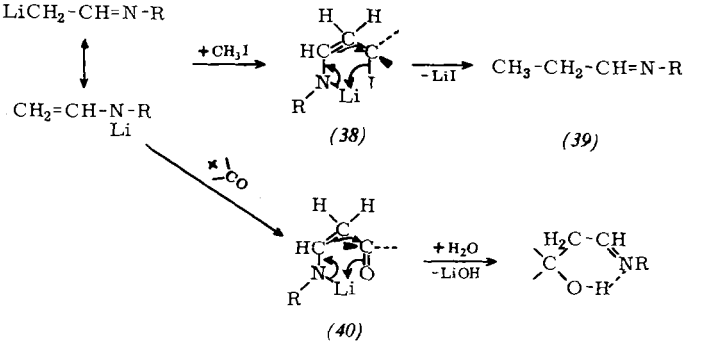
The analogous reactions with ethyl benzoate and with *N,N*-dimethylbenzamide, on the other hand, led to mixtures of *cis*- and *trans*-β-cyclohexylaminovinyl phenyl ketones *(37a)* and *(37b)* in 66 and 84% yields, respectively, *i.e.* to *C*-benzoylation products [8].



The configurations were assigned on the basis of IR and NMR spectra, which will not be discussed here.

Why should the reactions of metalated Schiff's bases with aldehydes or ketones (or even with alkyl halides) yield *C*-substituted products, whereas with reagents such as ethyl chloroformate or benzoyl chloride they undergo appreciable or predominant *N*-substitution? Metalated Schiff's bases may be regarded as ambident anions or, in other words, as bifunctional nucleophiles. As a rough simplification it may be said that halides such as methyl iodide that react in substitutions by an S_N2 mechanism, attack anions of this type [14] at the atom of the mesomeric system that has the lower electron density according to the electronegativity scale, *i.e.* at the carbon atom in this case, as we have found in a series of examples. On the other hand, halides that are solvolyzed by an S_N1 mechanism (*e.g. tert*-butyl iodide) are preferentially attacked by the atom of the ambident system that carries the greater electron density, *i.e.* the nitrogen.

This situation has been plausibly interpreted by *A. Brändström* [15]. In the metalated Schiff's base, the metal cation (*i.e.* the lithium in our case) preferentially resides on the most electronegative part of the molecule (*i.e.* on the nitrogen). Unionized reagents such as methyl iodide then approach in such a way as to give the six-membered ring transition state *(38)*, from which the product *(39)* can be formed by elimination of lithium halide.



The reaction with ketones, *i.e.* the directed aldol condensation itself, also appears to be readily explained as proceeding by this mechanism *via (40)*. The role played by the solvation of the electropositive metal cation in this reaction should not be overlooked.

On the other hand, with compounds that ionize relatively readily, the first step is rapid formation of lithium halide. The remaining cation then seeks out the point in the anion at which the electron density is greatest. Thus, as has already been mentioned, the reaction of lithium ethylidenecyclohexylamine with benzoyl chloride proceeds *via* the unstable enamine (*N*-vinylcyclohexylbenzamide) to give *N*-cyclohexylbenzamide as the main product.

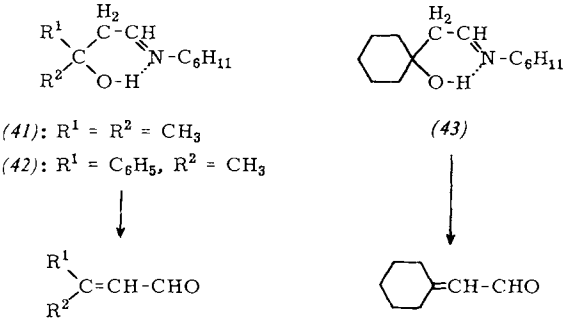
6. Conversion of the Aldol Adducts into the α,β-Unsaturated Carbonyl Compounds

It appeared at first that problems might arise in the use of the new procedure for the synthesis of natural products, since it was possible that with methyl ketones such as β-ionone, the $CO-CH_3$ system might

[14] Cf. *R. Gompper*, Angew. Chem. *76*, 412 (1964); Angew. Chem. internat. Edit. *3*, 560 (1964).

[15] *A. Brändström*, Ark. Kemi *6*, 155 (1954).

undergo transmetalation with the metalated Schiff's base. Model experiments with acetone, acetophenone, and cyclohexanone showed that the transmetalation could be substantially suppressed by operating under the standard conditions (see Section 4), *i.e.* the Schiff's base was metalated in ether at 0 °C and brought into contact with the ketone or aldehyde at −70 °C. After hydrolysis and recrystallization (preferably from petroleum ether), the new, well-crystalline Schiff's bases are always obtained in yields of between 50 and 90%.



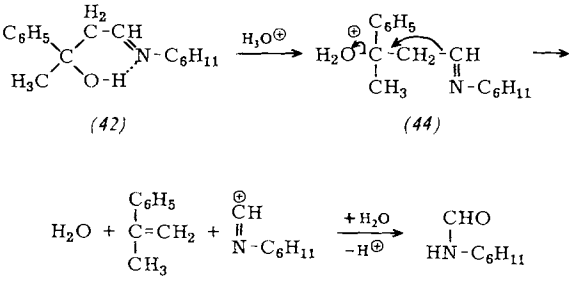
(41): $R^1 = R^2 = CH_3$

(42): $R^1 = C_6H_5$, $R^2 = CH_3$

(43)

These aldimine adducts can generally be converted into the α,β-unsaturated aldehydes or ketones in a single operation by steam distillation in the presence of oxalic acid; the final products distil over. Under the conditions described, the thermodynamically more stable product, *i.e.* the *trans*-olefin, is usually formed. Thus *(41)* gave 51% of β-methylcrotonaldehyde, *(42)* gave 71% of β-methylcinnamaldehyde, and *(43)* gave 60% of cyclohexylideneacetaldehyde.

Acid hydrolysis did not always lead to only one product. Thus the aldol adduct of lithium ethylidenecyclohexylamide and acetophenone gave 71% of β-methylcinnamaldehyde (identified as its semicarbazone) and 19% of α-methylstyrene, which was probably formed by fragmentation *via* compound *(44)*.



(42) *(44)*

7. Preparation of Natural Products

The procedure for the directed aldol condensation was finally used for the synthesis of α,β-unsaturated carbonyl functions in natural products and in compounds that are important intermediates in the preparation of natural products. The compounds listed in Table 2 can be prepared relatively easily by the new process [3,8].

The first crystalline sample of β-cyclocitrylideneacetaldehyde was obtained after synthesis by this method.

Table 2. Preparation of natural products by directed aldol condensation in accordance with the scheme.

$$R{-}CO{-}R' + LiCH_2{-}CH{=}NR + H_2O \rightarrow R{-}CR'{=}CH{-}CHO + LiOH + H_2NR$$

(R' = Alkyl, Aryl, H)

Carbonyl-component	Aldimine adduct M.p. (°C)	Yield (%) [a]	α,β-Unsaturated aldehyde B.p. (°C/torr)	Yield (%) [a]
Butyraldehyde	not isolated		2-Hexen-1-al 42—48/15	65
β-Cyclocitral	92—93	58	β-Cyclocitrylidene-aldehyde 72.5—75/0.1	50
6-Methyl-5-hepten-2-one	32—33.5	76	Citral (*cis-trans*-mixture) 68—74/0.5	64
β-Ionone	46—47	80	β-Ionylideneacet-aldehyde 115—120/0.001	42

[a] Yield based on carbonyl component used.

When precipitated from petroleum ether by cooling, it melts between −2 and +2 °C. The two aldehydes citral and β-ionylideneacetaldehyde are particularly important, in that they are intermediates in the synthesis of vitamin A and other carotenoids.

It may be asked whether these chain-lengthening processes with formation of α,β-unsaturated aldehydes or ketones could not be better carried out through olefination *via* phosphorylids. Though this method has found a wide range of applications and has been used by *S. Trippett* [16] for the preparation of α,β-unsaturated aldehydes, it is in this very application that its disadvantages become obvious. The scopes of the two methods are shown in Table 3.

Table 3. Preparation of α,β-unsaturated carbonyl compounds by directed aldol condensation and *via* phosphorylids; comparison of yields.

$CH_3{-}CH_2{-}CH_2{-}CH{=}CH{-}CHO$	65	81
$C_6H_5{-}CH{=}CH{-}CHO$	72	60
$(CH_3)_2C{=}CH{-}CHO$	40	0
$C_6H_5{-}C(CH_3){=}CH{-}CHO$	71	0
$(C_6H_5)_2C{=}CH{-}CHO$	78	0
$(C_6H_5)_2C{=}C(CH_3){-}CHO$	81	0
$(C_6H_5)_2C{=}CH{-}C(CH_3){=}O$	50	0

[a] Yields based on carbonyl component used.

[16] *S. Trippett* and *D. M. Walker*, J. chem. Soc. (London) *1961*, 1266.

According to Table 3, the olefination of aldehydes *via* phosphorylids also gives good results; however, this method is totally unsuccessful with ketones. This is where the new directed aldol condensation becomes really valuable.

It would be interesting in this connection to ex-amine the question of whether the imine derivatives of β-carbonylmethylenephosphoranes $(C_6H_5)_3P{=}CH{-}CH{=}NR$, like the metalated Schiff's bases, react with ketones in the desired manner.

The authors are grateful to the Stiftung Volkswagenwerk, the Deutsche Forschungsgemeinschaft, and the Badische Anilin- & Soda-Fabrik AG. for their support of the investigations.

Circular Dichroism and Optical Rotatory Dispersion – Principles and Application to the Investigation of the Stereochemistry of Natural Products [1]

BY G. SNATZKE [*]

The principles of circular dichroism and of optical rotatory dispersion are described. Examples are given to illustrate the use of these methods for the determination of the configurations and conformations of natural and synthetic products. Some limitations of the octant rule are mentioned.

1. History

The phenomenon of optical activity was discovered by *Arago* [2] in 1811 whilst experimenting with quartz, and was subsequently studied in some depth by *Biot*. In 1815, *Biot* [3] found that this property is not peculiar to crystals, but is also exhibited by liquids such as oil of turpentine or a solution of camphor in alcohol. Two years later [4] he reported that the angle of rotation becomes greater when the measurement is carried out at shorter wavelengths; this observation laid the foundation for spectropolarimetry. Though a few prominent chemists and physicists later used this method, it remained largely unknown to those not specialized in it until about 1953.

Lowry [5] attributes the long period of stagnation to the invention of the Bunsen burner (1866), which made it extremely easy to produce (practically) monochromatic light, *i.e.* that of the sodium D-line (589 nm). Instead of using a monochromator, which had been particularly troublesome in the previous century, one had only to hold a piece of rock salt into the flame if one wanted to measure the optical rotation of a substance. Owing to the simplicity of this method, nearly all the earlier workers ignored the much more valuable information of a complete rotatory dispersion curve, and it is quite surprising that so many stereochemical problems were solved by $[\alpha]_D$ measurements alone [6].

The Bunsen burner was thus responsible for the delayed development of spectropolarimetry, and it was left to *Carl Djerassi* in the USA to bring it back to life in 1953. Within a few years, he and his co-workers carried out measurements on more substances [7] than had been investigated in all the preceding 140 years. This was partly made possible by the first commercial spectral polarimeter [8], which had two important characteristics: firstly, it allowed measurements to be extended into the UV range, so that the optical rotatory dispersion (ORD) could be measured even within the absorption bands of many chromophores, and secondly, the instrument was extremely simple to operate. A number of automatic recording spectropolarimeters are now commercially available [9], and such instruments are an essential part of the equipment of any natural products institute.

Circular dichroism (CD) was first observed in amethyst by *Haidinger*[12] in 1847. Circular dichroism in solutions was studied in particular by *Cotton*[13], who also found the phenomenological connection between CD and ORD. Owing to the more sophisticated equipment needed, however, CD measurements were even less used than ORD measurements, and they became common only after the introduction, about six years ago, of the first commercial instrument. This was the Dichrographe, which made use of the electro-optical (Pockels) effect[14]. Various instruments are now also available for the measurement of CD[9].

2. Fresnel Theory and Measured Quantities

2.1. Fresnel Theory

Linearly polarized light is characterized in that its electric vector is propagated in the form of a planar cosine vibration (Fig. 1)[15]. According to *Fresnel*[16, 17], a beam of linearly polarized light may be thought of as resulting from the superposition of two circularly polarized rays with opposite directions of rotation, but having the same wavelength and intensity. A beam of circularly polarized light is characterized in that the tip of the electric vector describes a helix (Fig. 2). Thus

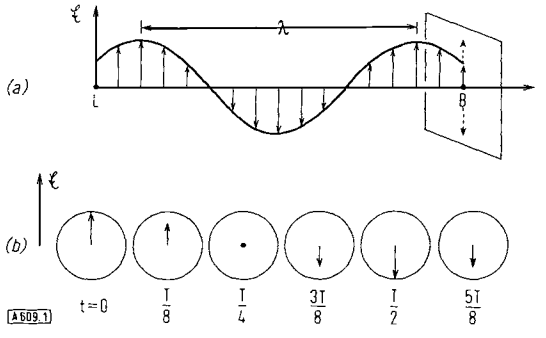

Fig. 1. Electric vector $\mathfrak{E}$ of a linearly polarized light beam. L is the ligh source, B the observer looking toward the light source. The straight line LB and its continuation beyond B is called the light path. (a) Dependence of the electric field strength $\mathfrak{E}$ on the distance at a given time t. (b) Dependence on time (at the observer's position B); T is the period of the vibration (defined by $T = \lambda/c$, c = velocity of light in vacuum).

an observer looking against a beam of linearly polarized light sees the vector varying its length in accordance with a cosine function, but vibrating always in the same

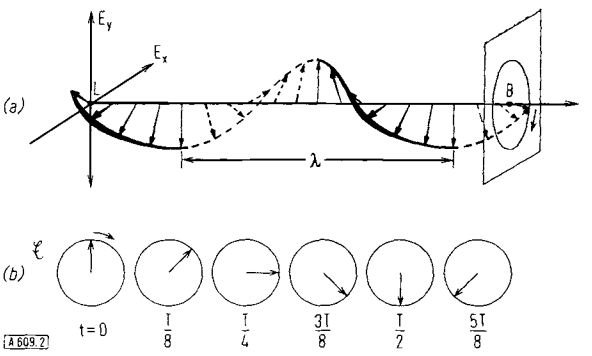

Fig. 2. Electric vector $\mathfrak{E}$ of a right-handed circularly polarized light beam. (a) Dependence of the field vector $\mathfrak{E}$, as well as its components E_x and E_y, on the distance at a given time t. (b) Dependence on time (at the observer's position B).

direction, whereas in the case of circularly polarized light the vector $\mathfrak{E}$ of constant length changes its direction proportional to time. For right-handed circularly polarized light, the tip of the vector runs clockwise, while for left-handed circularly polarized light it runs anticlockwise[18]. If the light source emits simultaneously in one direction coherent beams of left-handed and right-handed circularly polarized light of the same wavelength and intensity the superposition of the two produces a linearly polarized vibration. This can be shown easily either by calculation or by a vector diagram (Fig. 3).

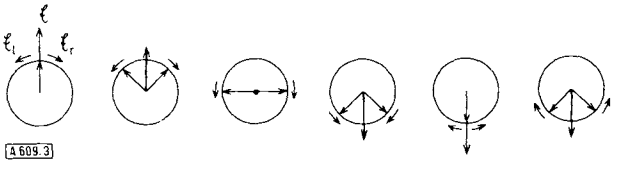

Fig. 3. Superposition of right-handed and left-handed circularly polarized light beams of same wavelengths and intensities emitted in phase by a light source. The sum of $\mathfrak{E}_l$ and $\mathfrak{E}_r$ gives a vector having the properties of a linearly polarized light beam.

If, on the other hand, the two beams propagate with different velocities (*i.e.* different wavelengths) through the medium under investigation, the resultant vector will not have a constant direction, but will make an angle with the original direction of vibration that increases with increasing distance traversed (Fig. 4).

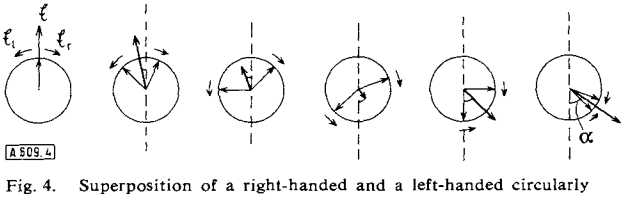

Fig. 4. Superposition of a right-handed and a left-handed circularly polarized light beam having different propagation velocities. As in Figure 3, these are all "snapshots" taken at the same time but at increasing distances from the light source. The right-handed circularly polarized beam is faster than the left-handed in this case.

Thus according to *Fresnel*, optical rotation is simply due to the difference in the velocities of right-handed and left-handed circularly polarized light in an "op-

[12] *W. Haidinger*, Poggendorfs Ann. *70*, 531 (1847).

[14] *M. Grosjean* and *M. Legrand*, C. R. hebd. Séances Acad. Sci. *251*, 2150 (1960).

[15] The plane in which the electric vector is propagated is generally known as the "vibration plane" of linearly polarized light. The corresponding magnetic vector is perpendicular to this plane.

[16] *A. Fresnel*, Memoirs No. XXVIII (1822), No. XXX (1823). However, most of this author's work was not published until the middle of the last century. See also [17].

[17] *P. Drude*: Lehrbuch der Optik. Hirzel, Leipzig 1900, p. 379.

[18] It can be seen from Figure 2 that the "screw" moves forward from L to B without turning, *i.e.* it is not screwed like a mechanical screw into its thread.

tically active medium", and the angle of rotation α (in radians) is given by the Fresnel equation

$$\alpha(\text{rad}) = \pi(n_l - n_r)l/\lambda_{vac}$$

(l: length of the tube, λ_{vac}: wavelength in vacuum, n_l and n_r: refractive indices for left-handed and right-handed circularly polarized light). The proportionality factor in this equation is called the "specific rotation", and conversion into degrees (which is more familiar to the chemist), taking into account the dependence on concentration in the case of solutions, gives

$$[\alpha]_\lambda^T = \alpha/(lc')$$

(l in dm, concentration c' in g/ml). λ and T are the wavelength and the temperature at which the measurement is carried out. In spectral polarimetry, however, it is customary to use the "molecular rotation" to

$$[\Phi] = ([\alpha] \times \text{molecular weight})/100$$

facilitate comparison *e.g.* of homologs.

2.2. Optical Rotatory Dispersion

If the angle of rotation α (or $[\alpha]$ or $[\Phi]$) is measured as a function of the wavelength, greater absolute values are obtained at shorter wavelengths (Fig. 5) – a behavior already found by *Biot*. This behavior is described as "plain curve" (normal ORD), and in spectral regions that are remote from the absorption bands, it can be expressed by a Drude equation

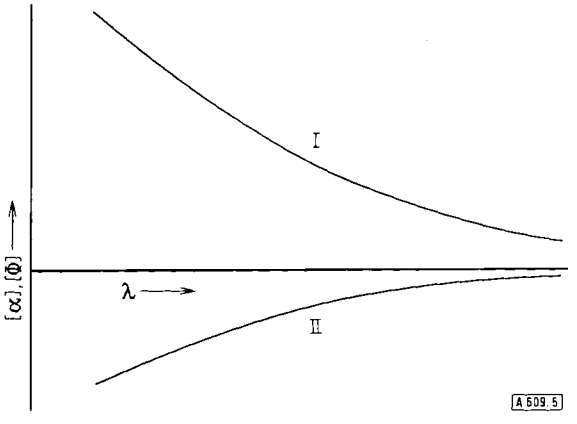

Fig. 5. Plain ORD curves of two optically active substances (I: dextrorotatory, II: levorotatory) in a spectral range in which no absorption takes place (schematic).

$$[\Phi] = \sum_i A_i/(\lambda^2 - \lambda_i^2)$$

(A_i and λ_i are constants).

2.3. Circular Dichroism and the Cotton Effect

In the region of an absorption band, left-handed and right-handed circularly polarized light are not only propagated with different velocities, but they are also absorbed to different extents. This behavior, which is known as "circular dichroism", is most simply described by the difference of the molar decadic absorption coefficients

$$\Delta\varepsilon = \varepsilon_l - \varepsilon_r$$

Calculations or a vector diagram similar to Figure 4 shows that as a result of circular dichroism, an S-shaped component is superimposed on the plain ORD curve in the region of the absorption band. A curve of this type is described as "anomalous ORD", and both effects, CD and anomalous ORD, are known as the "Cotton effect". If one of the two curves is known over the entire spectral range, the other can be calculated with the aid of the Kronig-Kramers transform [19].

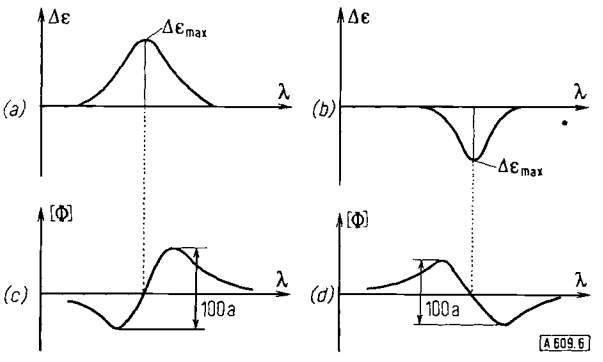

Fig. 6. Positive (a) and negative (b) CD with corresponding ORD partial curves (c) and (d).

Figure 6 shows that the maximum of a CD curve coincides with the point of inflection of the S-shaped part of the ORD curve; moreover, by going from long toward short wavelengths, in the case of positive CD the ORD curve first reaches a peak and then a trough, while for negative CD the trough appears before the peak [20] (*Natanson* [21] and *Bruhat* [22] rule).

Figure 7 shows the four possible types of Cotton effect ORD curves.

The CD is characterized by four quantities, *i.e.* $\Delta\varepsilon$ at the maximum ($\Delta\varepsilon_{max}$), λ_{max}, the sign, and the shape of the curve (*e.g.* fine structure). The same is true of an ORD curve, the magnitude in this case being described by the "amplitude", which is defined by

$$a = ([\Phi]_1 - [\Phi]_2)/100.$$

$[\Phi]_1$ in this expression refers to the extremum at longer wavelengths, $[\Phi]_2$ to that at shorter wavelengths of an anomalous curve. In the case of Gaussian-type CD curves, the approximation

$$a \approx 40\ \Delta\varepsilon_{max}$$

is valid.

[19] a) Cf., *e.g.*, *W. Moffit* and *A. Moscowitz*, J. chem. Physics *30*, 648 (1959); b) *C. A. Emeis, L. J. Oosterhoff*, and *G. de Vries*, Proc. Roy. Soc. (London) *A 297*, 54 (1967).

[20] To avoid confusion with UV curves, the terms peak and trough are used for ORD curves, and positive (or negative) maximum for CD curves.

[21] *L. Natanson*, Bull. Acad. Sci. (Kraków) *1908*, 764; J. Physique *8* [4], 321 (1909).

[22] *G. Bruhat*, Ann. Physique *3* [9], 232, 417 (1915); *13* [9], 25 (1920).

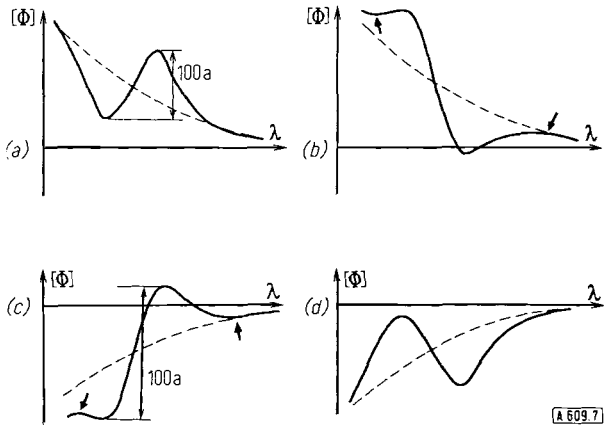

Fig. 7. The four possible types of actual ORD curve. (a) Positive and (b) negative Cotton effect with positive background rotation (plain ORD), (c) positive and (d) negative Cotton effect with negative background rotation. Arrows indicate "pseudo-extremes".

It can be seen by comparison of Figure 7 with Figure 6 that the distance from the peak to the trough of a real ORD curve does not exactly correspond to 100*a* (defined as shown in Figure 6); the difference in the background rotations at λ_1 and λ_2 should be introduced as a correction, but this is seldom done.

When a light beam that was originally linearly polarized leaves a medium that exhibits a Cotton effect in the range under investigation, it is elliptically polarized. This can be seen from the vector diagram (Fig. 8). Owing to the difference

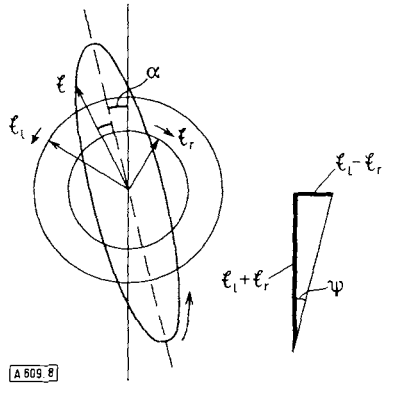

Fig. 8. Ellipticity. On emerging from a substance exhibiting circular dichroism, $\mathfrak{E}_l$ is different from $\mathfrak{E}_r$; the tip of the resultant vector consequently describes an ellipse (which is very narrow in practice). This representation shows the behavior of the resultant vector at a given point as a function of time. The principal axis of the ellipse forms the angle of rotation α with the original direction.

in the absorptions of left-handed and right-handed circularly polarized light, the vectors $\mathfrak{E}_l$ and $\mathfrak{E}_r$ now have different magnitudes (the intensity of a light beam is given by the square of its amplitude), and the tip of the resultant vector consequently follows an elliptical path. Its shape is decribed by the ellipticity ψ where *a* is the major axis and *b* the minor

$$\psi = \arctan(b/a)$$

axis of the ellipse. In analogy with the quantities related to rotation, one can define a specific ellipticity

$$[\psi] = \psi/lc'$$

and a molecular ellipticity

$$[\theta] = ([\psi] \times \text{molecular weight})/100$$

the latter being related to $\Delta\varepsilon$ by the equation

$$[\theta] \approx 3300\ \Delta\varepsilon_{max}.$$

Finally, mention must also be made of the rotatory (or rotational) strength, which is useful in quantitative calculations. It is defined [19] on the basis of the dipole strength [23] by

$$R = \frac{3\,hc\,10^3 ln\,10}{32\,\pi^3 N} \int \frac{\Delta\varepsilon}{\nu}\,d\nu$$

Thus a Cotton effect can be characterized either by measurement of an angle (determination of $[\Phi]_{peak}$ and $[\Phi]_{trough}$) or by a differential absorption measurement ($\Delta\varepsilon_{max}$). In all cases in which it is possible to make measurements in the region of absorption bands the interpretation of the CD is easier, since its half-band width is smaller than that of an anomalous ORD curve. In the investigation of chromophores that absorb in an inaccessible region, on the other hand, the ORD measurement must be used. The advantages and disadvantages of the two methods have been compared by several authors [24]; for details of equipment, the reader is referred to other reviews [11, 12, 25].

3. Relationship Between the Cotton Effect and Stereochemistry

3.1. Conditions for the Occurrence of a Cotton Effect

Pasteur [26] had already recognized that the condition for the occurrence of optical activity in solution is "molecular dissymmetry", *i.e.* that a molecule cannot be converted into its mirror image by mere rotation. A compound of this type is now described as "chiral" [27], the geometric condition for this being that the molecule (on time average in the case of a conformational equilibrium) should not have a rotation-reflection axis [28] S_p.

A Cotton effect is associated with the presence of a chromophore, and according to *Moscowitz* [29], it is possible to differentiate between two types of chromophores, *i.e.* "inherently (or intrinsically) dissymmetric" chromophores and chromophores having local symmetry, but being dissymmetrically perturbed. When light is absorbed, one electron is excited from a (doubly) occupied orbital into an unoccupied antibonding orbital, and if these two orbitals (owing to a suitable skeleton) are chiral, a strong Cotton effect is

[23] *R. S. Mulliken*, J. chem. Physics *7*, 14 (1939).

[28] This condition implies that the molecule must not contain either a reflection plane ($\equiv S_1$) or center of inversion ($\equiv S_2$).

[29] *A. Moscowitz*, Tetrahedron *13*, 48 (1961).

to be expected on interaction with the light beam. The rotatory strength of such inherently dissymmetric chromophores can assume a value of 10^{-38} cgs units. Some examples are shown in Figure 9.

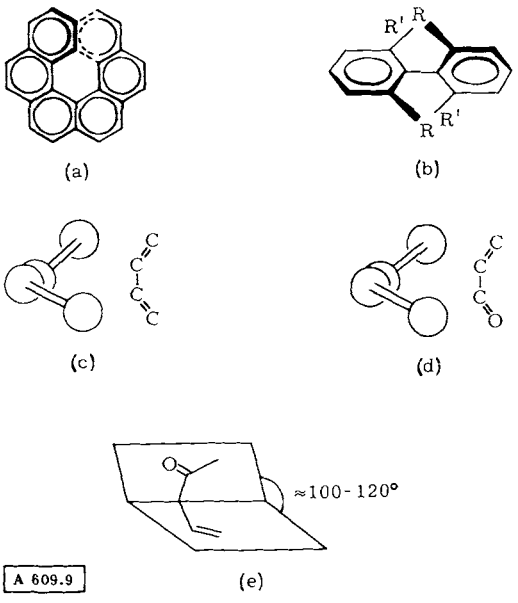

Fig. 9. Examples of inherently dissymmetric chromophores. (a) Hexahelicene, (b) biphenyl derivatives (conjugation band), (c) nonplanar conjugated dienes, (d) conjugated nonplanar enones (K-band), (e) β,γ-unsaturated ketones of suitable geometry (R-band).

For example, hexahelicene cannot have a planar structure, but must be helical. This means that the π system is also chiral, resulting in a $\Delta\varepsilon_{max}$ of over 100[30]. Biphenyls exhibit several bands, some of which correspond to local excitations (within the π system of one of the two rings), while others are due to the entire 12 π system. When the biphenyl skeleton is nonplanar, the compounds are also inherently dissymmetric[31]. A special case is that of β,γ-unsaturated ketones in which the π orbital of the C=C bond can overlap simultaneously and chirally with the p orbital and the π* orbital of the C=O group. These compounds have long been known to give enhanced extinction in the UV region[32], and the Cotton effect can again assume very high values[33].

However, most chromophores possess local symmetry (plane of symmetry). Their electron system is thus achiral, and should interfere equally with a beam of left-handed and right-handed circularly polarized light. If chromophores of this type (cf. Fig. 10) are incorporated into a chiral environment, however, as is *e.g.* the keto group in camphor, there is still at least some dissymmetric perturbance of the otherwise symmetric orbitals, which again gives rise to a Cotton effect. Chromophores of this type, some of which are shown in Figure 10, are known as "inherently symmetric but dissymmetrically perturbed" chromophores. Their rotatory strength does not generally exceed about 10^{-40} cgs units.

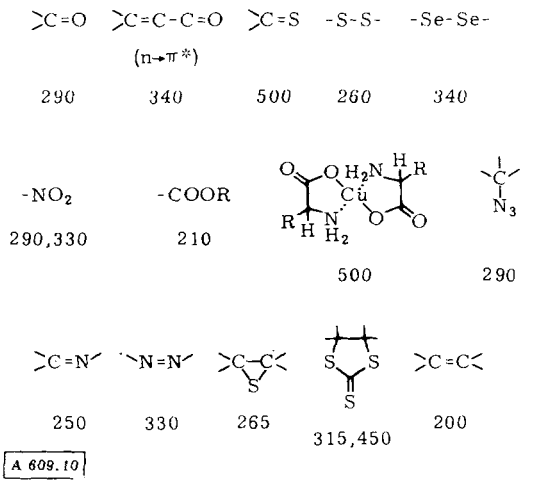

Fig. 10. Examples of inherently symmetrical but dissymmetrically perturbed chromophores. The numbers under the formulas indicate the absorption regions.

Finally, compounds having no chromophore (in the usual sense) can be successfully studied by conversion into derivatives that give a Cotton effect ("Cottonogenic derivatives"). Some of these are shown in Figure 11.

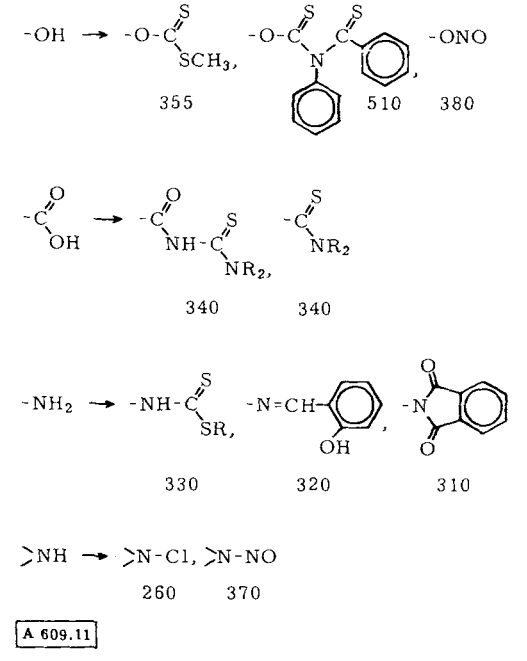

Fig. 11. Some "cottonogenic derivatives" of alcohols, acids, and amines. The numbers under the formulas indicate the absorption regions.

3.2. Sign of the Cotton Effect and Geometry of the Molecule

To find a relationship between the sign (and possibly the magnitude) of the Cotton effect and the geometry of the molecule, it is possible to proceed by one of three paths, one empirical, one semiempirical, and the third theoretical. Two examples will be given to illustrate the empirical procedure. We have found[34] that the salicylidene derivatives of 3-amino steroids

[30] *A. Moscowitz*, Dissertation, Harvard University 1957.

[34] *H. Ripperger*, *K. Schreiber*, *G. Snatzke*, and *K. Heller*, Z. Chem. *5*, 62 (1965).

give a positive CD around 320 nm when the NH_2 group is in the β position [*(1)*, *(2)*] and a negative CD when the NH_2 is in the α position [*(3)*, *(4)*], irrespective of whether the linkage of rings A and B is *cis* or *trans* (Fig. 12). Similarly, the stereochemistry of an OH group on C-20 of pregnan-20-ol derivatives can be established from the sign of the Cotton effect of the *O*-nitroso derivative at about 370 nm [35] (Fig. 13).

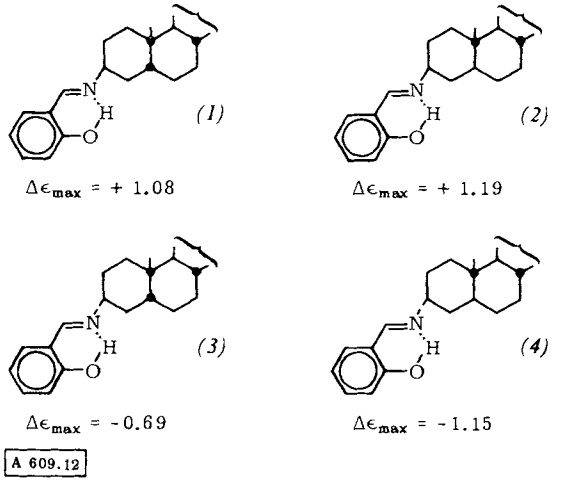

Fig. 12. $\Delta\varepsilon_{max}$ values for the 3-(salicylidenamino) steroids *(1)*–*(4)*.

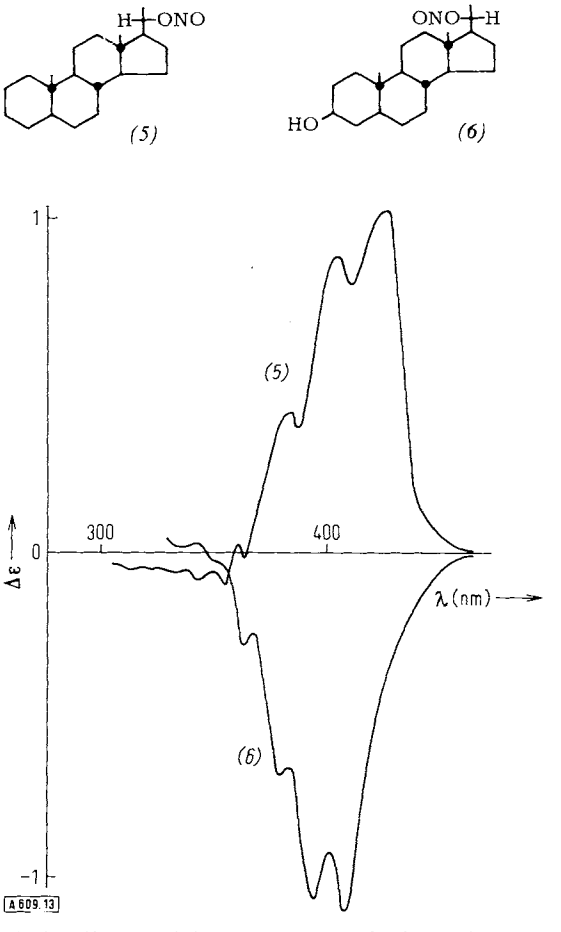

Fig. 13. CD of the nitrites of a 5α-pregnan-20α-ol *(5)* and a 5α-pregnan-20β-ol *(6)*.

[35] *M. Legrand* and *R. Viennet*, C. R. hebd. Séances Acad. Sci. *255*, 2985 (1962); *C. Djerassi, H. Wolf*, and *E. Bunnenberg*, J. Amer. chem. Soc. *85*, 2835 (1963).

The principle of the theoretical route can just be touched upon in this review. According to the theory of optical activity [36], the rotatory strength of a band is given by the equation

$$R = \mu_e \mu_m \cos\gamma$$

where μ_e is the electric and μ_m the magnetic transition moment vector during the excitation of the electron, and γ is the angle between these two moments. If these quantities can be calculated *ab initio*, it is possible to predict at least the sign of the Cotton effect for a given geometry, since it follows from the cosine function that parallel moments lead to a positive CD and antiparallel moments to a negative CD.

This calculation will be illustrated qualitatively for the α-helix of polypeptides or proteins [37]. Each turn of the α-helix contains 3.6 amide groups, and the direction of the transition moment vectors is known for the K-band of these amide groups (Fig. 14a).

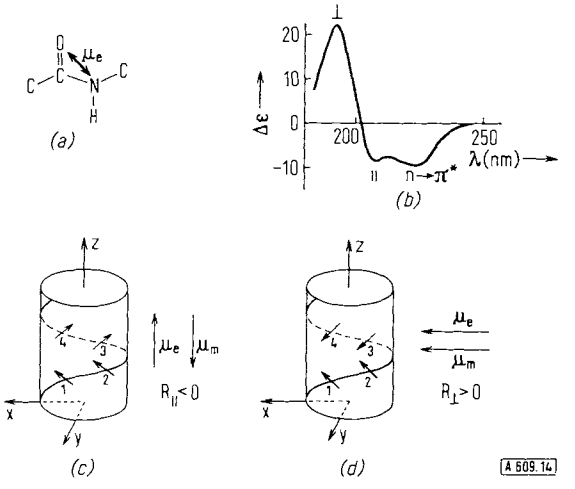

Fig. 14. Determination of the sign of the Cotton effect of the amide bands in an α-helix. (a) Direction of μ_e of the amide group [38], (b) observed CD of poly-L-glutamic acid at pH = 4.3 [39], (c) direction of the transition moment vectors for the band polarized parallel to the axis, (d) direction of the transition moment vectors for one of the two bands polarized perpendicular to the axis. (For details see text.)

According to exciton theory, the amide groups cannot be excited independently of one another, and coupling takes place over the entire chain. Only three coupled vibrations are possible: either all the transitions are in phase or the transitions of each adjacent pair are in phase opposition. This is indicated in Figures 14c and 14d by the direction of the arrows, each of which represents an amide unit. In 14d there are two possibilities, *i.e.* "1" and "2" upward and "3" and "4" downward, or else "2" and "3" upward and "4" and "1" downward. Only one case is shown in the diagram.

The electric transition moment vectors add up in 14c to give a resultant vector in the *z* direction, whereas in 14d they give a total moment perpendicular to the axis (*e.g.* in the *x* direction in this case). This displacement of electronic charges is associated with a magnetic transition moment vector. If one looks along the axis in 14c (in the positive *z* direction), the arrows are arranged anticlockwise; according to the right-hand rule, this corresponds to a magnetic moment vector

[36] *L. Rosenfeld*, Z. Physik *52*, 161 (1928); *E. Condon, W. Altar*, and *H. Eyring*, J. chem. Physics *5*, 753 (1937); *E. Hückel*, Z. Elektrochem. angew. physik. Chem. *50*, 13 (1944).

[37] This simplified description follows a rigorous derivation, which is given in a review by *A. D. McLachlan*, Proc. Roy. Soc. (London) *A 297*, 131 (1967). Further original literature is also cited in this review.

[38] *D. L. Peterson* and *W. T. Simpson*, J. Amer. chem. Soc. *77*, 3929 (1955).

that opposes μ_e. Thus in the case of a right-handed helix, as in Figure 14c, the above formula shows that the band, which is polarized parallel to the axis of the helix (since the total moment μ_e is parallel to this axis) must give a negative Cotton effect. A similar argumentation applied to 14d shows that in this case the two moments are parallel to each other, so that the two bands, which are polarized perpendicular to the axis, must have a positive sign.

The exciton theory also states that the bands polarized perpendicular to the axis must lie at shorter wavelengths than those polarized parallel to the axis, so that the CD curve of poly-L-glutamic acid, which is shown in Figure 14b[39], must correspond to a right-handed helix[40]. At a time when CD measurements were still difficult, *Moffitt*[41] deduced an equation for the ORD curve from these relationships:

$$[\Phi]_{pu}\frac{3}{n^2+2} = a_0\frac{\lambda_0^2}{\lambda^2-\lambda_0^2} + b_0\frac{\lambda_0^2}{(\lambda^2-\lambda_0^2)^2}$$

($[\Phi]_{pn}$: molecular rotation per amino acid unit, n: refractive index of the solvent; a_0, b_0, and λ_0 are constants), in which b_0 assumes a value of about -600 when the polypeptide is entirely in the form of a right-handed α-helix[42].

Great success has been achieved in the establishment of semiempirical rules that predict, on the basis of theoretical considerations, the change in the sign of the contribution of a substituent to the Cotton effect when the position of this group in relation to the chromophore is varied, and in which the sign itself is found from experimental data. This may be illustrated by the octant rule[43], although several *ab initio* calculations now exist for this rule.

Saturated ketones exhibit a weak band at about 300 nm due to an n → π* transition. The n orbital has a nodal plane, which is identical with the (x,z) plane. For the π* orbital, the (y,z) plane and another surface perpendicular to this, intersecting the O=C bond roughly in the middle, are nodal surfaces (Fig. 15). For the sake of simplicity, this third nodal surface is also drawn as a plane. These three surfaces divide the space around the ketone (in our example a cyclohexanone) into eight octants, the four more important rear octants of which are shown in Figure 15d in an "octant projection". The viewing direction is from the O toward the C of the carbonyl group. If the dissymmetric perturbance of the carbonyl chromophore, which is by itself symmetric, is due to Coulomb interactions of the incompletely screened nuclei of the molecule, the contributions to the Cotton effect of two substituents in adjacent octants must according to the theory[19a,44] have opposite signs.

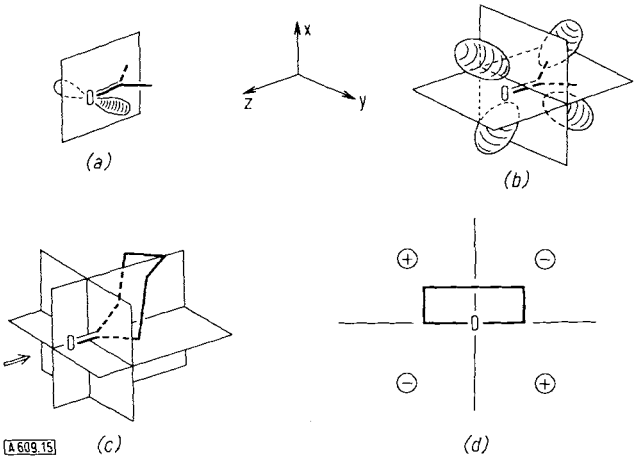

Fig. 15. Octant rule for saturated cyclohexanones (with c_s symmetry). (a) Nodal plane of the n orbital, (b) nodal surfaces of the π* orbital, (c) the eight octants formed by the three nodal surfaces, (d) signs for the four rear octants by projecting from O toward C of the carbonyl group.

The large volume of data available, which was obtained in particular in the laboratories of *Djerassi*, *Klyne*, and *Ourisson*, made it possible to establish the signs as shown in Figure 15d. These have also been deduced theoretically[19a,44]. Nevertheless, the octant rule is mentioned here as a semiempirical method, since other theoretical calculations lead only to a quadrant rule[45]. On the basis of the extensive material available, however, there can be no doubt about the change in sign on passage to the front octants.

Pao and *Santry*[46] very recently carried out another calculation that leads to division into twelve sectors. A further nodal surface is added to those already mentioned. Figure 16 shows a projection from above onto the (y,z) surface (*i.e.* not the usual octant representation), according to which the contribution of

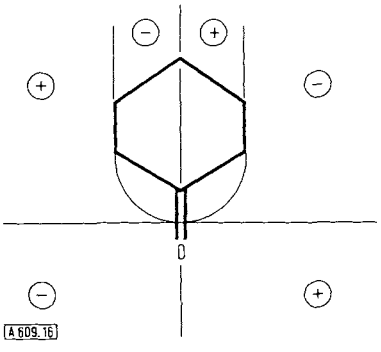

Fig. 16. Upper sectors for ketones according to *Pao* and *Santry* [46].

an axial substituent β to the carbonyl group should give a sign opposite to that found by the octant rule. Our investigations on optically active adamantanone derivatives[47] have now shown that a COOR group chlorine, bromine, or iodine in this position actually gives the "wrong" contribution. It is not yet known whether this means that the octant rule will have to be modified, or whether this "antioctant behavior" has to be attributed to the strong polarity of these groups.

[40] The band at 224 nm is due to a n→π* excitation of the amide group.

4. Examples from the Natural Products Field

The success of the octant rule will now be illustrated by a classical example[43] (Fig. 17). 5α-Cholestan-2-one *(7)* and 5α-cholestan-3-one *(8)* exhibit a positive Cotton effect, which is roughly twice as large for *(7)* as for *(8)*. This can be readily explained by the octant rule. In the 3-oxo compound *(8)*, the contributions of the atoms of rings A and C cancel out on grounds of symmetry, and the two methyl groups lie in the (*x*,*z*) nodal surface, so that only the methylene groups C-6 and C-7 (and the groups C-15 and C-16, which are very remote from the chromophore) contribute to the Cotton effect. According to Figure 15d, these contributions should be positive. In the 2-oxo compound *(7)*, on the other hand, all the C atoms except those of ring A (which are disregarded on symmetry grounds) and C-6 lie in the rear upper left octant, and so give rise to the high positive Cotton effect.

The Cotton effect is not always sufficiently large to permit a definite interpretation. Thus tetrahydroionone *(9)*[48] gives practically no effect at room temperature, since the side chain containing the chromophore can assume different conformations, which differ only slightly in their energy content, with the result that the contributions to the Cotton effect are

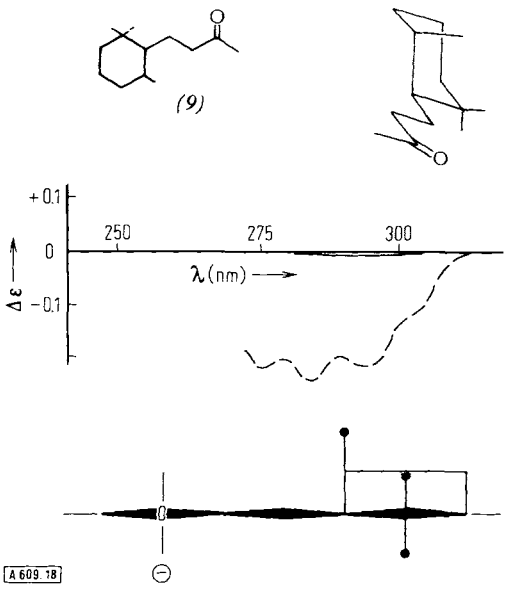

Fig. 18. Most stable conformation of tetrahydroionone *(9)* and its octant projection, as well as the observed CD at 20 °C (—) and −179 °C (– – –).

such as solvation complexes. Practically all our results for the variation of the CD with temperature support this assumption.

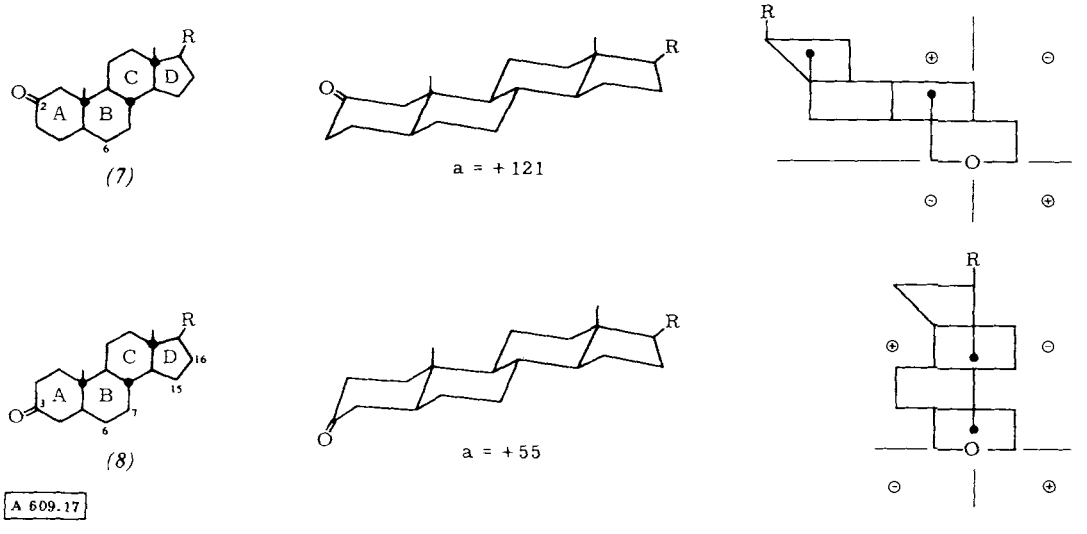

Fig. 17. Stereoformulas and octant projections of the steroids *(7)* and *(8)*.

substantially compensated. However, if the solution is cooled to a sufficiently low temperature, the population of the conformation with the lowest free energy must steadily increase[49], and a distinctly measurable CD was in fact found at −179 °C (Fig. 18). If the chair form of the ring and the equatorial position and zigzag form of the side chain are assumed to be most stable, a negative CD would actually be predicted by the octant rule. However, this interpretation is based on the assumption that the change in the CD with temperature is due only to the displacement of the conformational equilibria, and is not connected with other factors

A limiting case for the application of the octant rule is found in the compounds *(10)* through *(12)* (Fig. 19). Tetrahydropyranone *(10)*[48] exhibits a weak negative CD at room temperature, which increases by a factor of more than two when the temperature is lowered.

If one again assumes a chair conformation for the heterocyclic ring, there are two possibilities, *i.e.* an equatorial vinyl group and an axial methyl group and *vice versa*. If the vinyl group (at least on the fully substituted C atom) is assumed to be bulkier than the methyl group, one obtains a projection as shown in Figure 19 (R = vinyl as the equatorial substituent). The only group that can contribute to the Cotton effect is one of the two geminal methyl groups, which lies in a negative octant, in agreement with the observed negative CD.

However, it is doubtful whether the replacement of CH_2 by O in the ring itself has no appreciable effect. The CD of the

[48] I am grateful to Dr. *G. Ohloff*, Firmenich & Cie, Geneva, for supplying this substance. The sign of the Cotton effect of compound *(10)* has already been described by *M. Mousseron-Canet* and *C. Levallois*, Bull. Soc. chim. France *1965*, 1339.

[49] In an equilibrium between two conformers whose free energies differ *e.g.* by 0.65 kcal/mole (with $\Delta S = 0$), 25% of the less stable isomer are present at 25 °C, but only 1.9% at −190 °C, *i.e.* at this temperature the more stable isomer is present practically alone in the solution.

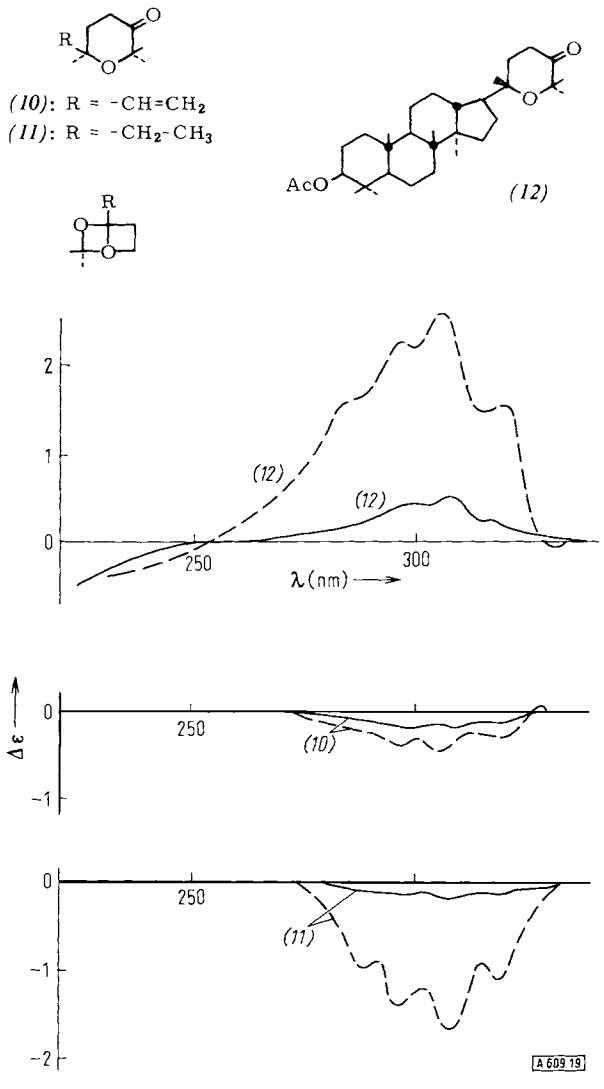

Fig. 19. CD of *(10)* through *(12)* at 20 °C (—) and −180 °C(— — —) and octant projection of *(10)* and *(11)*.

saturated compound *(11)* seems to support this, as the ethyl group now definitely occupies the equatorial position, and according to its greater size, the CD is greater in *(11)*. Even without the use of the octant rule, which is problematic in this case, it is possible to deduce from the positive CD of the degradation product *(12)* of dipterocarpol [50] that the configuration of the latter at the quaternary carbon adjacent to the ring oxygen is opposite to that of *(10)* and *(11)*; this supports the configuration assigned [50] to C-20.

A good insight into conformational equilibria was also provided by the perhydroazulene derivative *(13)* [51], which is closely related to the sesquiterpenes. It had been shown by X-ray analysis [52] that this molecule occurs in the crystal in a conformation having an equatorial bromine. According to the octant projection (Fig. 20), one should expect a positive CD for this compound. However, a negative CD is actually found in solution [51], the maximum occurring at 315 nm (in methylcyclohexane/isopentane 1:3 v/v), which indi-

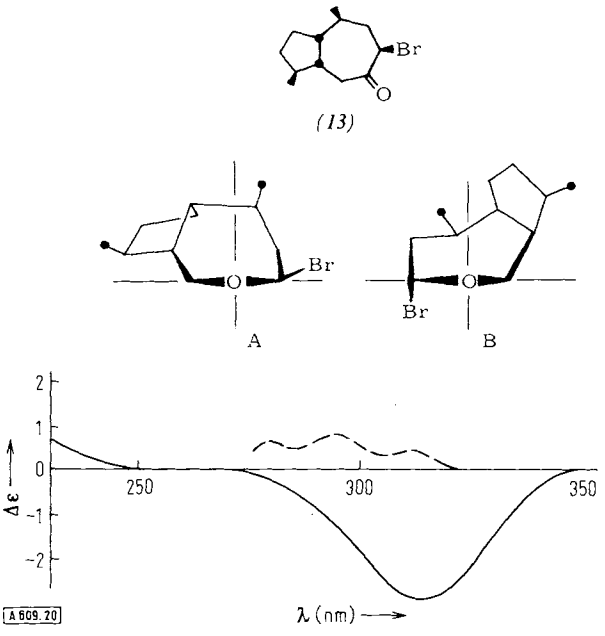

Fig. 20. CD of the bromo ketone *(13)* at +20 °C (—) and −180 °C (— — —) and octant projection of two conformers A and B.

cates that the bromine is axial [53]. According to the "axial α-haloketone rule" [54], this points to a conformation such as B (Fig. 20). The question now was whether the conformation A (Fig. 20) occurring in the crystal was really the most stable, or whether it was a somewhat less favorable arrangement stabilized *e.g.* by lattice forces. Measurement at −180 °C led to reversal of the sign of the CD with a simultaneous shift of λ_{max} to 294 nm, which is characteristic of equatorial bromine [53]. This CD, which is in agreement with the projection A, shows that A actually has the lower energy content; however, conformation B cannot be much less stable. The same conclusion could be reached from CD measurements in various solvents [51].

Though most of the investigations described so far have been concerned with ketones, the Cotton effect can also be used to determine the configurations or conformations of other chromophores. While the Cotton effect of saturated lactones cannot always be unequivocally deduced from the structure [55], the situation is much more favorable for unsaturated and epoxy lactones, since the findings for the corresponding ketones [56] are also applicable to these compounds [57]. It must be remembered, however, that the −C−CO−O- grouping is coplanar, as is shown by X-ray studies (in

the solid state)[58]. This may be illustrated by the case of parasorbic acid *(14)*, in which the methyl group is known from NMR measurements to be equatorial[59]. Figure 21 shows the projection of parasorbic acid;

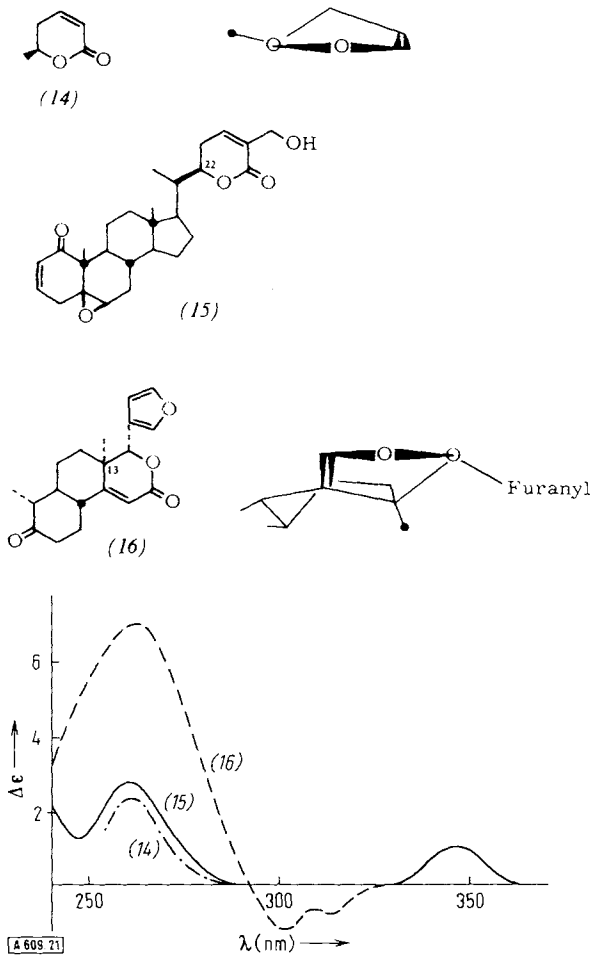

Fig. 21. Projection and CD (at 20 °C) of parasorbic acid *(14)* (—·—·—), CD of jaborosolactone A *(15)* (—), and projection and CD of odoratin *(16)* (— — —).

according to the corresponding rules for ketones[56], the chirality of the nonplanar enone systems gives a positive Cotton effect. A positive CD was also found[60] for jaborosolactone A *(15)*, in which the "steroid substituent" of the enelactone must again be equatorial; this fixes the stereochemistry at C-22 in the side chain[61]. Finally, the positive CD at 264 nm in odoratin *(16)* helped to establish the stereochemistry at C-13 (13α), which had already been deduced from biogenetic considerations[62].

Cyclopentenones show opposite signs for the CD of the n→π* band[56] to that of cyclohexenones of identical chirality of the enone system. This rule is again applicable to the corresponding enelactones[57], and was used to determine the absolute configuration of loliolide (digiprolactone) *(17)*[63] (Fig. 22)[57]. No sign could be predicted according to the octant rule from the CD of its oxidation product *(18)*, since the contribution of a methyl group had to be balanced against that of a lactone group.

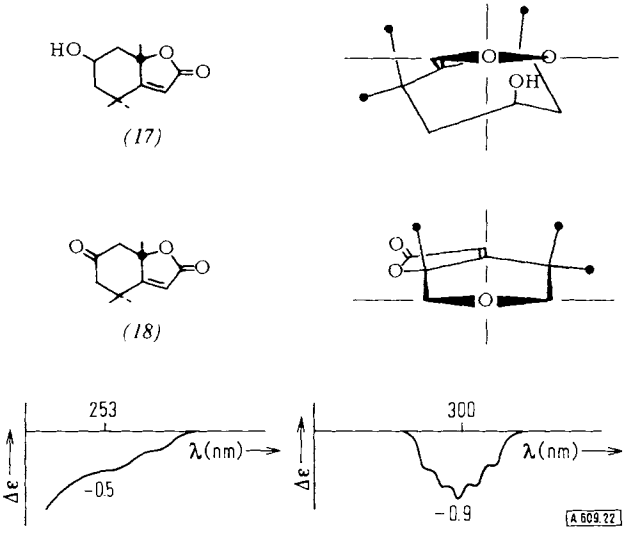

Fig. 22. Projection of loliolide (digiprolactone) *(17)* and its oxidation product *(18)*; CD of *(17)* (left) and of *(18)* (right).

In the above lactone examples, the conformation was known and the configuration was determined from the CD. The reverse was true in the case of verrucarin A *(19)*[64], in which the only detectable chromophore is a muconic acid unit. Molecular models indicate that the mobility of the large lactone ring is very restricted, and two bands are in fact found for *(19)* at 288 and 255 nm (Fig. 23)[65]. The first of these corresponds to the n→π* band of the muconic acid chromophore, which is not clearly recognizable in the UV spectrum, and the two ester groups may, to a first approximation,

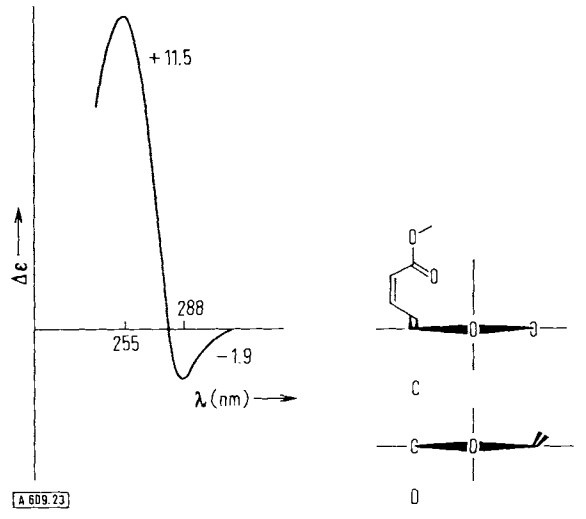

Fig. 23. Projection of the transoid (C) and the cisoid (D) enelactone group of the muconic acid part of verrucarin A *(19)* and CD of *(19)*. The deviation from coplanarity is exaggerated in C to facilitate drawing.

be regarded as separate partial chromophores. According to X-ray analysis [66], one of the enester groups is in the cisoid conformation (strongly angular), while the other is in the transoid conformation (almost planar). If we again apply the rules for the corresponding enones, we would expect a negative CD for both conformations, as is in fact found (Fig. 23). Conversely, it must be concluded from this value that the large ring in verrucarin A *(19)* (at least in the muconic acid region) has the same conformation in solution as in the crystalline state.

A chromophore that has been extensively studied both experimentally [67] and theoretically [68] is the nonplanar cisoid diene system. If this is arranged as a right-handed helix, it gives a positive Cotton effect, while a left-handed helix gives a negative Cotton effect. α-Phellandrene *(20)* seemed at first sight to be an exception to this rule, since it gives a negative Cotton effect [69], which would mean that the isopropyl group occupies a quasi-axial and not a quasi-equatorial conformation. It was therefore assumed that owing to the small difference in the energies of the two conformers, the less favorable conformation already had a higher population at room temperature; this assumption was supported by the temperature-dependence of the ORD amplitude between 10 and 90 °C [70]. It was therefore expected that the sign of the Cotton effect would be reversed at lower temperatures, as was in fact found below about −150 °C [71] (Fig. 24).

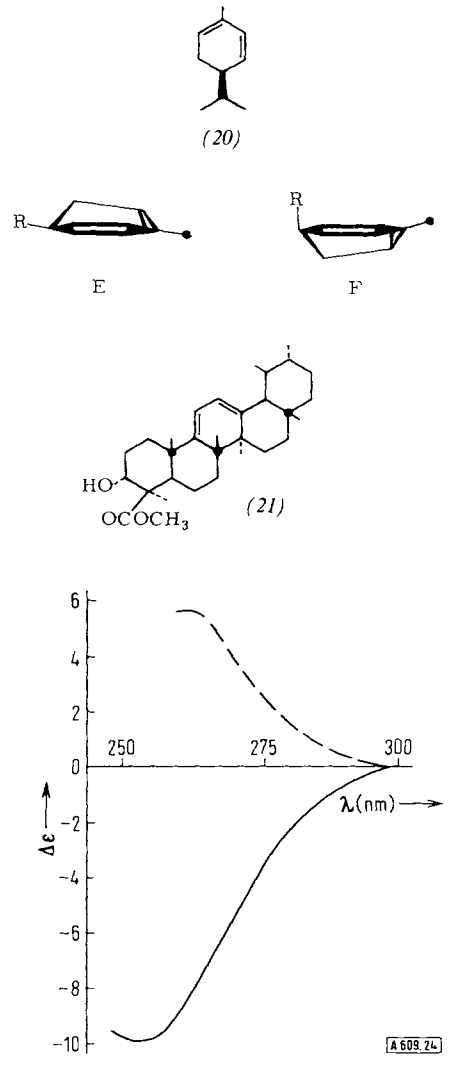

Fig. 24. Conformational equilibrium of α-phellandrene *(20)* and CD at 20 ° (—) and −177 °C (— — —). E gives a positive and F a negative Cotton effect. Formula of the rigid diene *(21)* shown for comparison.

This directly proves the postulated conformational equilibrium between the conformers E and F (Fig. 24). Since we had found an experimental $\Delta\varepsilon_{max}$ of +33 for the rigid diene *(21)* [72], it can be estimated to a rough approximation that 65 % of the less stable conformer F is present at room temperature, and only 42 % at −177 °C. The displacement of the equilibrium is thus not very great, despite a temperature difference of about 200 °C and the reversal of the sign of the CD.

The examples described show that configurations and conformations can be determined on an empirical or semiempirical basis with the aid of circular dichroism or optical rotatory dispersion, even without a rigorous theory. It has been necessary to omit any mention of applications in inorganic coordination chemistry [73], but it should be pointed out that these methods can be successfully used to locate bands that are often impossible to recognize in the UV spectrum, as was the case

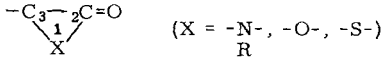
α-Lactams (Aziridinones)

BY I. LENGYEL AND J. C. SHEEHAN [*]

α-Lactams have often been postulated as intermediates in numerous processes. The isolation of the first α-lactam, N-tert-butyl-3-phenylaziridinone, was accomplished in 1962. Since then, further N- and C-3-substituted α-lactams have been synthesized. Most of these very reactive compounds undergo easy thermal decomposition; remarkable is the relative stability of 1,3-di-tert-butylaziridinone, which does not start to decompose below 140 °C. The α-lactam ring is opened by nucleophilic reagents. – The correlation of stability and substituents is discussed in the last section. An acyclic, planar or almost planar, charge-delocalized intermediate is suggested to explain the observed effects.

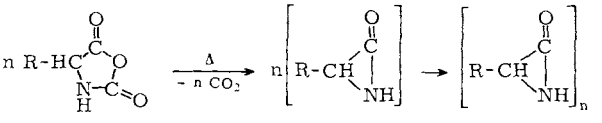
I. α-Lactams as Possible Intermediates; Unsuccessful Attempts at Preparation

α-Lactams [aziridinones] are the first and, to date, only representatives of the three-membered ring carbonyl compounds of general structure *(1)* to have been synthesized (see Section II).



(1)

It was *Leuchs* [1] who first proposed α-lactams as reactive intermediates. He observed that α-amino acid *N*-carboxy-anhydrides ("Leuchs-Anhydride") *(2)* rapidly lose carbon dioxide on heating to form polypeptides *(4)*. *Leuchs* postulated an α-lactam *(3)* as intermediate but it could not be isolated [2].



(2) *(3)* *(4)*

An α-lactam (*N*-phenylaziridinone) as a possible intermediate was also mentioned by *Sheehan* and *Izzo* [3], who isolated the β-lactam 1-phenyl-2-azetidinone during the reaction of phenyl isocyanate with diazomethane.

The possibility that certain α-haloamides may cyclize to α-lactams on dehydrohalogenation with bases has been investigated for two aromatic precursors of this class by two groups of workers [4]. In no case could an α-lactam be isolated or detected as intermediate.

The reaction of α-chloro-α,α-diphenylacetanilide *(5)* with sodium hydride [4b, 4c, 4f, 4g] gave 2-(3,3-diphenyl-2-indolinon-1-yl)-2,2-diphenylacetanilide *(6)* as the major product, together with smaller amounts of 3,3-diphenyl-2-indolinone *(7)* and 1,3-diphenyl-2-indolinone *(8)*. The formation of all three products can be explained through a common α-lactam intermediate *(9)* [4c, 4f].

[2] *Leuchs'* assumption that the decarboxylation of α-amino acid *N*-carboxy anhydrides leads to cyclic polymers, proved erroneous later: it was recognized (*R. B. Woodward* and *C. H. Schramm,* J. Amer. chem. Soc. *69,* 1551 (1947)) that the products are linear polypeptides and not cyclic α-lactam polymers.

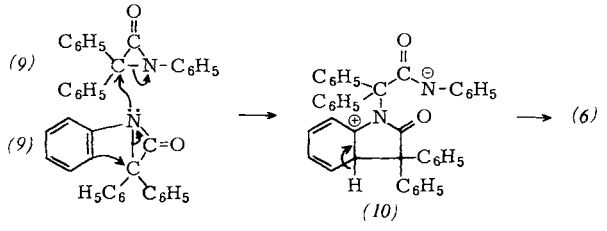
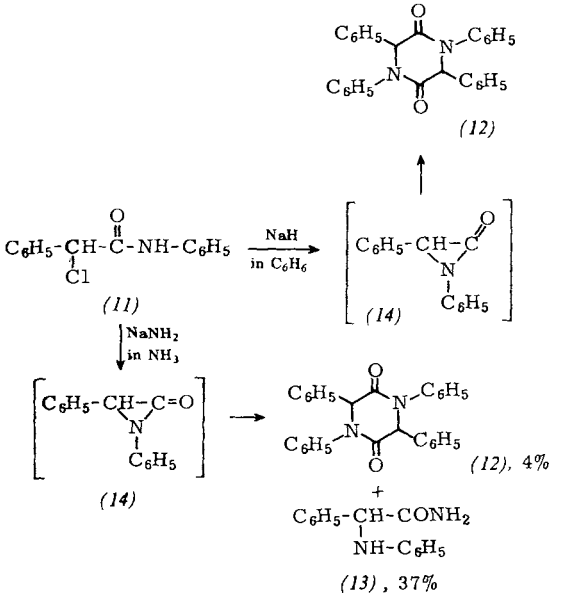
To explain the formation of the main product *(6)*, it has been suggested[4f] that *(9)* undergoes an unusual dimerization *via (10)*. The fact that the postulated α-lactam intermediate does not dimerize to the simpler symmetrical dimer, hexaphenylpiperazine-2,5-dione, is explained by *Sarel* and co-workers[4f] on steric grounds.

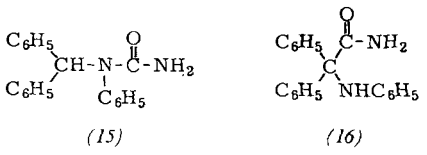


The analogous reaction of α-chloro-α-phenylacetanilide *(11)* with sodium hydride yields 1,3,4,6-tetraphenylpiperazine-2,5-dione *(12)* and a solid of uncertain structure. Here too, an α-lactam *(14)* has been suggested as an intermediate[4a,4b].

If sodium hydride is replaced by sodium amide, the rearrangement of *(11)* mainly into α-anilino-α-phenylacetamide *(13)* is observed[4a].

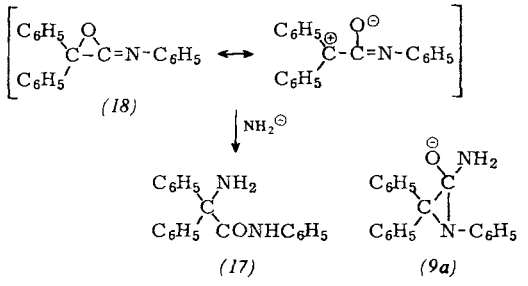


Interestingly, the course of the analogous reaction of *(5)* is fundamentally different: When α-chloro-α,α-diphenylacetanilide *(5)* is treated with sodium amide in liquid ammonia, *N*-benzhydryl-*N*-phenylurea *(15)*, α-anilino-α,α-diphenylacetamide *(16)*, and α-amino-α,α-diphenylacetanilide *(17)*, are formed in the ratio 5:1:1[4e]. (The reaction of *(5)* with NaH leads to *(6)*, *(7)*, and *(8)*.) It has been assumed[4e] that compounds *(15)* and *(16)* arise from the α-lactam intermediate *(9)* by reaction with $NH_2^{\ominus}$.



According to *Sarel et al.*[4a], product *(17)* may be formed either from the iminooxirane isomer *(18)* of the α-lactam[5] or by direct substitution of the α-chlorine atom in *(5)* by NH_2. The two phenyl substituents at the α-carbon facilitate the formation of a carbanion, derivable from the primary adduct *(9a)* of the α-lactam and $NH_2^{\ominus}$ through C–C fission, leading to benzhydrylurea *(15)* – the observed major product. C–N scission affords *(16)*. The α-lactam *(9)* could not be isolated or detected.

In 1962, *Sheehan* and *Lengyel* attempted to synthesize 1,3,3-triphenyl-2-aziridinone *(9)* *via* a photochemical route. The addition of diphenyl carbene to the CN double bond of phenyl isocyanate would, in principle, be the simplest synthesis of this α-lactam. Diphenyldiazomethane was selected as the source of diphenyl carbene. Since *Staudinger*[6] had already observed that diphenyldiazomethane does not react with phenyl isocyanate on simple mixing, *Sheehan* and *Lengyel* generated the diphenyl carbene photochemically and observed a smooth reaction with phenyl isocyanate[7]. This is the first example of the addition of a carbene to an isocyanate and the first photochemically initiated reaction of an isocyanate. However, no α-lactam could be isolated, but one of the products proved to be identical with the major product *(6)* of the reaction of α-chlorodiphenylacetanilide with sodium hydride. This product *(6)* possibly arises from an α-lactam intermediate *(9)* in the same way as was proposed for the formation of *(6)* from α-chlorodiphenylacetanilide[4f].



No authentic synthesis of 1,3-diphenylaziridinone *(14)* or 1,3,3-triphenylaziridinone *(9)* has been reported to date.

II. Preparation and Structure of α-Lactams

1. Dehydrohalogenation of *N*-Chloro- and α-Chloroamides

In 1961, *Baumgarten* and co-workers detected for the first time an α-lactam as an intermediate by a spectroscopic technique[8]. Studying the Favorskii-type rearrangement of *N-tert*-butyl-*N*-chloroamides by treatment with potassium-*tert*.-butoxide, they observed an

[5] Such an iminolactone intermediate was first suggested by *Sheehan* and *Lengyel* (see reference [25]).

[6] *H. Staudinger, E. Anthes*, and *F. Pfenninger*, Ber. dtsch. chem. Ges. *49*, 1928 (1916).

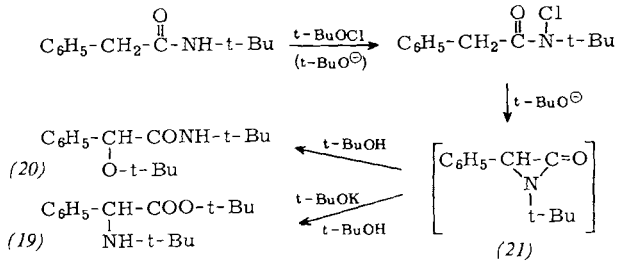
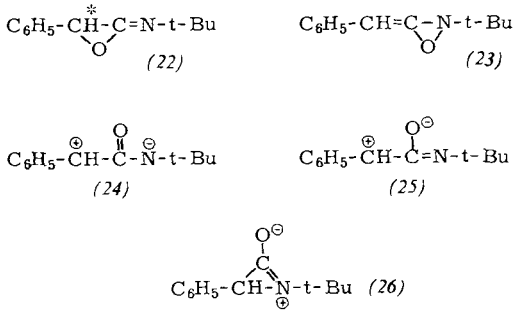
intermediate (which they could not isolate) that exhibited a carbonyl band at 1847 cm^{-1}. This wavelength is in full accord with theoretical expectations for an α-lactam [9].



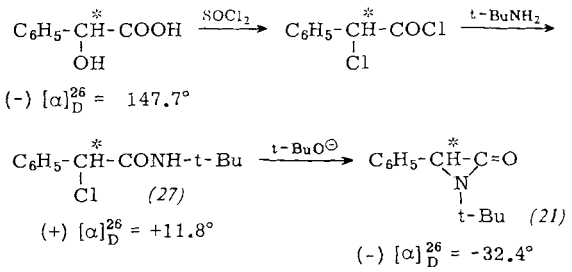
Furthermore, two different ring openings could be demonstrated through isolation of the end products, ester *(19)* and amide *(20)*. In 1962, *Baumgarten* starting with *N-tert*-butyl-*N*-chlorophenylacetamide (ν_{CO} = 1670 cm^{-1}) succeeded in isolating the α-lactam *(21)* (m.p. 32–33 °C) from the same reaction [10].

One year later, *Baumgarten* and co-workers reported [11] the synthesis of the same α-lactam, starting from *N-tert*-butyl-α-chlorophenylacetamide. The spectroscopic and analytical data were in agreement with the proposed structure.

Since, however, the reaction conditions, as well as the rearrangement observed by *Baumgarten*, strongly resembled those of the Favorskii-reaction of α-haloketones, the question arose whether the product may possibly have another structure. *Baumgarten* considered structures *(22)–(26)*. Structures *(24)–(26)* are analogous to those discussed by *House* [12]

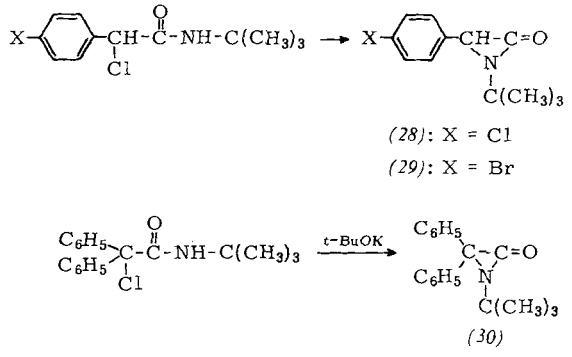


and *Fort* [13] for the "Favorskii intermediate". To elucidate the structure, *Baumgarten* and co-workers undertook the synthesis of an optically active form of *(21)* [11]. Since the precursor, the optically active (+)-*N-tert*-butyl-α-chlorophenylacetamide *(27)* easily racemizes, it was not possible to determine the optical purity of (–)-*(21)*. All mesomeric dipole structures [*e.g. (24)*, *(25)*, and *(26)*] with substantial charge separation require the α-carbon atom to be in sp^2 configuration, *i.e.* to be planar. The fact that the synthesis yields an optically active α-lactam, excludes both the dipole structures *(24)–(26)* and any charge-delocalized precursor. For the same reason, one could exclude another possibility,



the optically symmetrical oxazirane structure *(23)* simultaneously. To distinguish between the α-lactam and the iminolactone structure *(22)*, *Baumgarten* and co-workers have repeated the original synthesis [8] with *ca.* 50% ^{18}O-containing *N-tert*-butyl-*N*-chlorophenylacetamide and thus obtained an ^{18}O-labeled α-lactam. The IR spectrum of the starting material showed a carbonyl doublet at 1668 and 1645 cm^{-1} and that of the product at 1848 and 1827 cm^{-1}. The similarity of the two doublets was taken as evidence for the presence of an amide C=O group in both compounds. The three-membered ring amide structure received further corroboration from NMR measurements. The coupling constant for the α-^{13}C–H in the α-lactam *(21)* was 168.5 ± 0.5 Hz. This value is in excellent agreement with the $J^{13}CH$ values of other aziridine systems and corresponds to a 34% s character of the α-carbon atom.

By means of the same reaction, *i.e.* treatment of *N*-chloro- and α-chloroamides, respectively, with potassium *tert*-butoxide, the same workers later prepared three additional α-lactams in pure form [14], namely 1-*tert*-butyl-3-*p*-chlorophenylaziridinone *(28)*, (m.p. 35–36 °C) 1-*tert*-butyl-3-*p*-bromophenylaziridinone *(29)* (m.p. 56–57 °C), and 1-*tert*-butyl-3,3-diphenylaziridinone *(30)* (m.p.77–79 °C).These compounds are, in analogy to the other α-lactams known to date, low melting, highly reactive solids, exhibiting a carbonyl band in their IR spectra at about 1850 cm^{-1} [14].



Simultaneously and independently, *Sheehan* and coworkers (see [4c]) prepared a number of aliphatic *N*-alkyl-α-haloamides and studied their reaction with non-aqueous bases. α-Haloamides appeared better suited to the preparation of α-lactams than the corresponding *N*-haloamides, for two reasons: 1) Because of the greater solubility difference, it is easier to separate the α-lactam formed from an α-haloamide than from an *N*-haloamide; 2) the formation of an anion is more favored when the charge is situated on the nitrogen than when it is on the α-carbon; the reaction pathway (b) leading to the formation of an α-lactam appears to be more plausible starting with an α-haloamide. The

[9] Based on theoretical considerations one would expect α-lactams to show a carbonyl band between 1760 and 1840 cm^{-1}; γ-lactams absorb at 1700–1750 and β-lactams at 1730–1760 cm^{-1}. See, *e.g., L. J. Bellamy*: The Infrared Spectra of Complex Molecules. J. Wiley and Sons, Inc., New York 1958, p. 214.

[10] *H. E. Baumgarten*, J. Amer. chem. Soc. *84*, 4975 (1962).

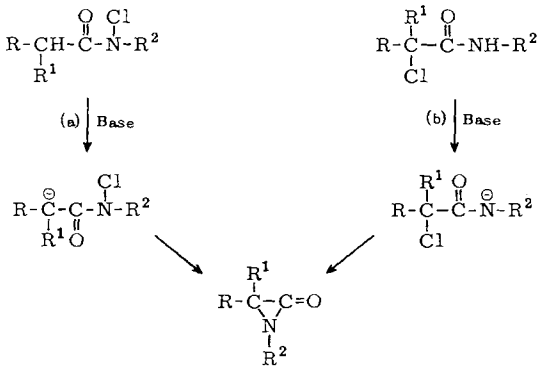
[11] *H. E. Baumgarten, J. J. Fuerholzer, R. D. Clark*, and *R.D. Thompson*, J. Amer. chem. Soc. *85*, 3303 (1963).

[12] *H. O. House* and *W. F. Gilmore*, J. Amer. chem. Soc. *83*, 3972, 3980 (1961).

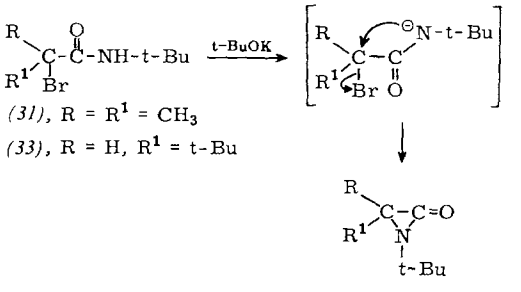
[13] *A. W. Fort*, J. Amer. chem. Soc. *84*, 2620 (1962); b) *ibid. 84*, 4979 (1962).

[14] *J. J. Fuerholzer*, Ph. D. Thesis, University of Nebraska, 1965.

choice of the precursor was further influenced by the known stabilizing effect of geminal alkyl substituents in the β-lactam [15] and β-thiolactone [16] series.



Starting from these considerations, *Sheehan* and *Lengyel* have dehydrohalogenated 2-bromo-2-methyl-*N*-*tert*-butylpropionamide *(31)* with potassium *tert*-butoxide or potassium metal at low temperature. The reaction yielded the desired α-lactam *(32)* [17,18], (m.p. 22–24 °C, carbonyl band at 1837 cm^{-1}, no NH-band at 3400 cm^{-1}) the first aliphatic representative of this class.



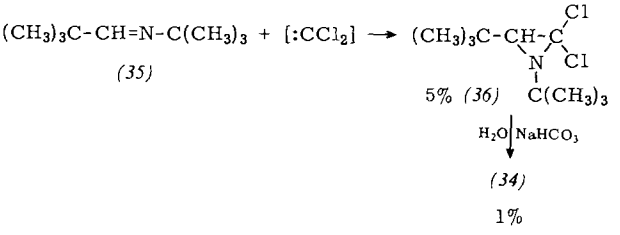
(31), R = R^1 = CH_3
(33), R = H, R^1 = t-Bu

(32), R = R^1 = CH_3
(34), R = H, R^1 = t-Bu

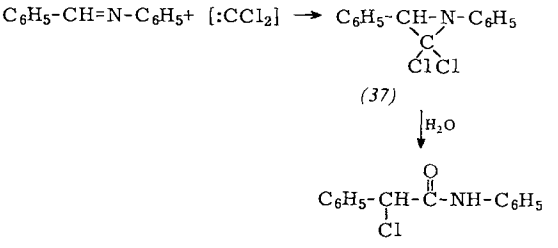
Using the same method, *Sheehan* and *Beeson* prepared in 1965 a new α-lactam, 1,3-di-*tert*-butylaziridinone *(34)* in almost quantitative yield [19,20]. This α-lactam has a far higher thermal stability and a much lower chemical reactivity than all other α-lactams known to date. It can be distilled at reduced pressure, survives gas chromatography under certain conditions, and can even be purified by column chromatography [19,20].

2. Preparation of an α-Lactam through Carbene Addition

1,3-Di-*tert*-butylaziridinone has also been prepared by *Sheehan* and *Beeson via* addition of dichlorocarbene to *N*-neopentylidene-*tert*-butylamine *(35)* and subsequent hydrolysis of the adduct *(36)*. This is the first successful conversion of a CCl_2 group in a three-membered heterocycle to a carbonyl group without ring opening [20]. The low yield of the addition is ascribed to the strong steric hindrance of the CN double bond of the imine.



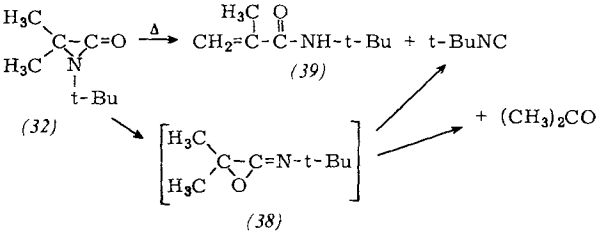
It was *Fields* and co-workers who first succeeded [21,22] in adding dichloro carbene to the CN double bond of Schiff's bases to form dichloroaziridines, which can be regarded as potential precursors of α-lactams. However, the 2,2-dichloro-3-phenylaziridine *(37)* prepared from benzalaniline yielded on hydrolysis no α-lactam but α-chlorophenylacetanilide. Similarly, the dichloroaziridines prepared from benzalanisidine and benzal-*p*-chloroaniline [22] gave on hydrolysis the corresponding α-chloroamides.



III. Reactions of α-Lactams

1. Thermal Decomposition

1-*tert*-Butyl-3,3-dimethylaziridinone *(32)* undergoes slow decomposition even at room temperature, and one hour's refluxing in ether effects complete destruction of the ring [18] to give the isomeric *N*-*tert*-butylmethacrylamide *(39)* as the major product [23]. Surprisingly, acetone and *tert*-butyl isocyanide are also produced [18]. It is assumed that the α-lactam *(32)*



(38)

[15] *J. C. Sheehan* and *E. J. Corey*: Org. Reactions *9*, 388 (1957).

[16] *J. C. Sheehan*, Ann. New York Acad. Sci. *88*, 665 (1960).

[17] *I. Lengyel*, Ph. D. Thesis, Massachusetts Institute of Technology, Sept. 1963.

[18] *J. C. Sheehan* and *I. Lengyel*, α-Lactams I, J. Amer. chem. Soc. *86*, 1356 (1964).

[19] *J. H. Beeson*, Ph. D. Thesis, Massachusetts Institute of Technology, June 1966.

[20] *J. C. Sheehan* and *J. H. Beeson*, α-Lactams IV, J. Amer. chem. Soc. *89*, 362 (1967).

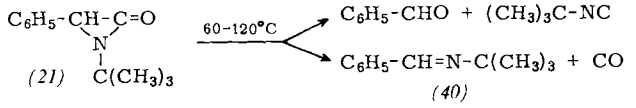
[21] *E. K. Fields* and *J. M. Sandri*, Chem. and Ind. *1959*, 1216.

[22] *A. G. Cook* and *E. K. Fields*, J. org. Chemistry *27*, 3686 (1962).

[23] The isomerization of α-lactam *(32)* to the α,β-unsaturated amide *(39)* seems to occur with particular ease because compound *(32)* possesses β-hydrogens for elimination. In α-lactams not having β-hydrogens (*e.g. (34)*) such isomerization cannot take place (see also summary).

partially rearranges on warming to the structurally isomeric iminolactone *(38)*, which fragments further to give a ketone and an isocyanide.

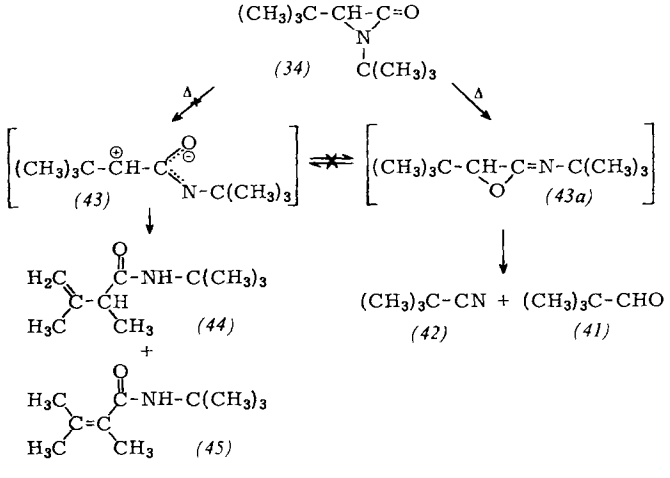
Nuclear magnetic resonance and mass spectrometric investigation of the pyrolysis products of 1-*tert*-butyl-3-phenylaziridinone (heated to 60–120 °C) showed [24] that the main path of decomposition leads to benzaldehyde and *tert*-butyl isocyanide. However, smaller amounts of *N*-benzylidene-*tert*-butylamine *(40)* and carbon monoxide were also detected, which indicates that the pyrolysis proceeds *via* at least two pathways.



(21) *(40)*

Whereas other α-lactams investigated to date decompose rapidly and completely at temperatures between 60 and 120 °C, decomposition of 1,3-di-*tert*-butylaziridinone *(34)* does not start below 140 °C [19,20]. Prolonged heating (12 h) of the compound at 175 °C in a sealed tube leads to a complex mixture, 60% of which is made up by pivalaldehyde *(41)* and *tert*-butyl cyanide *(42)*. It is assumed [19,20] that the *tert*-butyl cyanide arises from the originally formed *tert*-butyl isocyanide [18] by thermal isomerization. Gas-phase pyrolysis at 450 °C yields 93% of pivalaldehyde and *tert*-butyl cyanide.

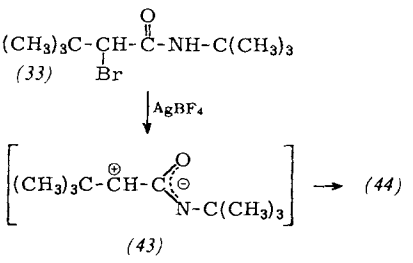
If this pyrolysis passed, at least in part, through a zwitterionic intermediate [*e.g. (43)*], one would expect to find in the pyrolysis mixture also products of a neopentyl rearrangement [*e.g. (44)* and *(45)*]. It has been



demonstrated by comparison with authentic substances [*(44)* and *(45)*] that such products are not formed in the pyrolysis.

The fact that treatment of 2-bromo-3,3-dimethyl-*N*-*tert*-butylbutyramide *(33)* with silver tetrafluoroborate does lead to a neopentyl rearrangement (most probably *via* the zwitterion *(43)* as intermediate) indicates that the iminolactone intermediate *(43a)* (postulated to explain the observed products) in the pyrolysis of α-lactam *(34)* does *not* arise *via (43)*,

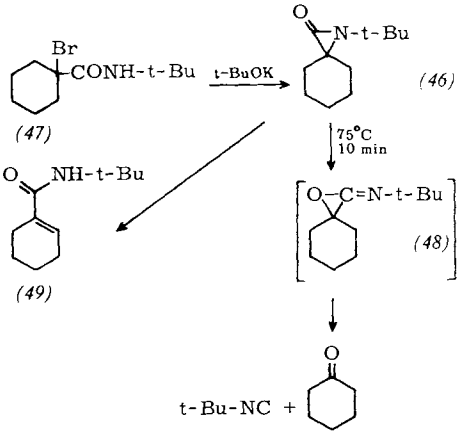
[24] Reference [14], p. 92.



or at least that *(43)* cannot have an appreciable lifetime.

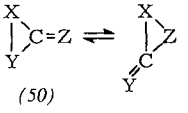
In 1964, *Sheehan* and *Lengyel* reported the thermal decomposition of spiro-α-lactam *(46)* [25]. This compound (isolated only in crude state from the reaction of 1-bromo-1-*N*-*tert*-butylcarboxamidocyclohexane *(47)* with potassium *tert*-butoxide) decomposed quantitatively within 10 min at 75 °C to give cyclohexanone and *tert*-butylisocyanide as major products, together with a smaller amount of *N*-*tert*-butyl-1-cyclohexanecarboxamide *(49)*.

This type of fragmentation [26] can best be explained again by assuming that, on heating, the spiro-α-lactam *(46)* rearranges



first to the isomeric iminolactone *(48)* which then fragments. Nevertheless, the experiment did not allow a decision to be made as to whether the by-product *(49)* was formed *via* an E_2 reaction directly from the starting material or, through a rearrangement, from the α-lactam. Similarly, the question of the mechanism of the rearrangement α-lactam *(46)* → iminolactone *(48)* has also remained unanswered.

As is well known, compounds of the general structure *(50)* are subject to thermal [27] X–Y bond rupture and/or isomerization [28]. An interesting example of



(50)

[25] *J. C. Sheehan* and *I. Lengyel*, α-Lactams II, J. Amer. chem. Soc. *86*, 746 (1964).

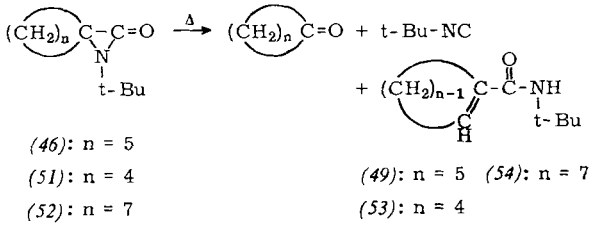
[26] While products of the ketone and isocyanide type are formed only in 12% yield in the pyrolysis of the α-lactam *(32)* [18], this type of fragmentation is the predominant one in the case of the spiro-α-lactam *(46)*: cyclohexanone and *tert*-butyl isocyanide are formed in 66% yield.

[27] *W. B. Hammond* and *N. J. Turro*, J. Amer. chem. Soc. *88*, 2880 (1966).

[28] *J. C. Shields, B. A. Shoulders, J. F. Krause, C. L. Osborn*, and *P. D. Gardner*, J. Amer. chem. Soc. *87*, 3026 (1965); *E. F. Ullman* and *W. J. Fanshawe*, J. Amer. chem. Soc. *83*, 2379 (1961).

this unusual rearrangement has been reported in the monochloroethyleneimine series by *Deyrup* and *Greenwald*[29].

The remarkable course of the "thermolysis" of *(46)*[25] awakened further interest in other spiro-α-lactams. *Sheehan* and *Beeson* investigated the thermal decomposition of 1-*tert*-butyl-tetramethylene- and heptamethylene-aziridinone *(51)* and *(52)*[19,30], prepared in the same manner. In these experiments, the two α-lactams were used as crude products.

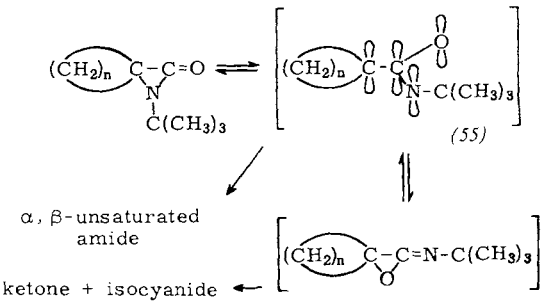


(46): n = 5
(51): n = 4
(52): n = 7

(49): n = 5 *(54)*: n = 7
(53): n = 4

Warming to 80–100 °C led, in analogy with the pentamethylene derivative *(46)*, to the formation of *tert*-butyl isocyanide, the corresponding cyclic ketone and an α,β-unsaturated amide [*(53)* and *(54)*, respectively]. The ratio of these products, however, was different in the four compounds investigated to date. From *(46)* ($n = 5$), amide and ketone are formed in the molar ratio 2.5:1; from *(51)* ($n = 4$) the ratio is 0.15:1[25]; and from *(52)* ($n = 7$) 14.0:1. On heating, the monocyclic α-lactam *(32)* affords amide and ketone type products in the molar ratio 5.4:1.

In the case of the tetramethylene and heptamethylene derivatives, it has been established that the unsaturated amides *(53)* and *(54)* do not arise during the α-lactam preparation from the bromoamides, but directly from the α-lactams on heating[30]. It is assumed[30] that the α-lactam pyrolysis



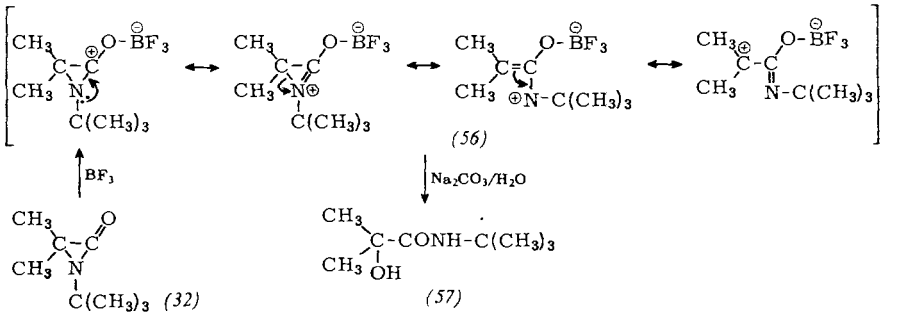
(55)

passes through a charge-delocalized transition state or "metastable intermediate" *(55)*, similar to that proposed for the Favorskii rearrangement of α-haloketones[12,13].

The results obtained hitherto for the α-lactam pyrolysis in the spiro series (such as the relative rates of formation of unsaturated amides *versus* ketones and *tert*-butyl isocyanide as a function of structure) are in qualitative agreement with this intermediate[30].

2. Salt- and Ylide-formation

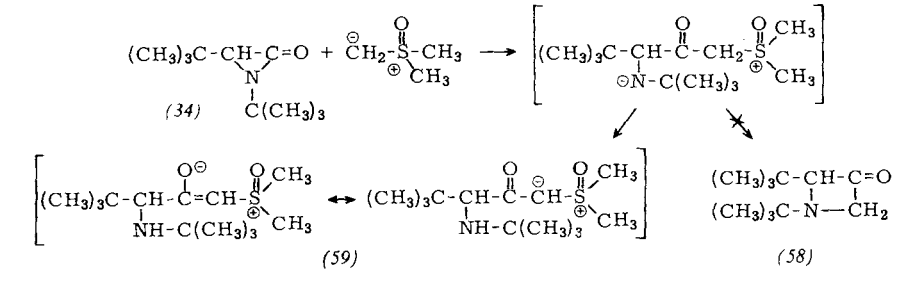
Treatment of 1-*tert*-butyl-3,3-dimethylaziridinone *(32)* with boron trifluoride yields a salt, $C_8H_{15}NO \cdot BF_3$[31]; polymerization is not observed. Sodium carbonate hydrolysis of the salt leads to *N*-*tert*-butyl-2-hydroxy-2-methylpropionamide *(57)* as the only product. The



(56) *(32)* *(57)*

salt may be formulated as a resonance hybrid of the dipolar structures *(56)*.

In the hope of obtaining a ring enlargement product *(58)*, *Sheehan* and *Beeson* treated α-lactam *(34)* with dimethyl sulfoxonium-methylide in DMSO at room



(34) *(59)* *(58)*

temperature. However, only a stable ylide *(59)* was formed[19,20].

Similar ylides are formed from ethyl propiolate, phenyl isocyanate, and diphenylketene with the same reagent[32].

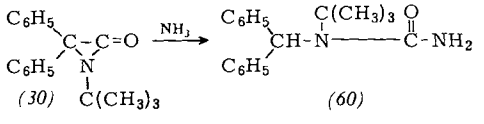
3. Reactions of α-Lactams with Nucleophilic Reagents

a) Reactions with Aprotic and Protic Reagents

In general, α-lactams are very reactive. Their properties lie between those of the "Favorskii-intermediates" and those of the very stable di-*tert*-butyldiaziridinone, prepared by *Greene* and *Stowell*[33]. The chemical reactivity of α-lactams is indeed closer to that of the former than to the latter. Except for the very stable and unreactive 1,3-di-*tert*-butylaziridinone *(34)*, all α-lactams isolated and investigated to date react completely with nucleophiles already at room temperature. Depending on the nucleophilie, a strong selectivity is observed in the type of ring opening. Reaction with proton-containing nucleophiles, *e.g.* water, alcohols, thiols, amines, and mineral acids (HZ) leads exclusively to amides, corresponding to an alkyl-nitrogen bond splitting. On the other hand, reaction of α-lactams with aprotic nucleophiles ($Z^{\ominus}$) gives amino acid derivatives as the only products, corresponding to a ring opening at the acyl-nitrogen bond[34].

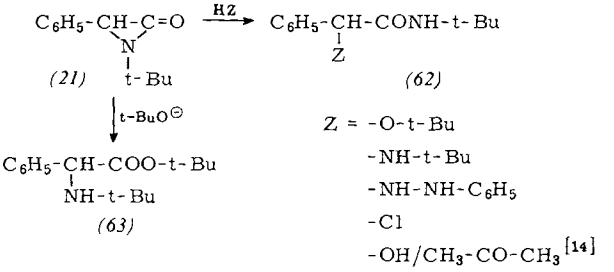
Products such as urethanes, urea derivatives, *etc.*, which could arise from α-lactams with nucleophiles *via* CC scission (the third possible way of opening the ring) have been observed only the in reaction of 1-*tert*-butyl-3,3-diphenylaziridinone *(30)* with liquid ammonia, in which *N*-benzhydryl-*N*-*tert*-butylurea *(60)* is the major product. Also, treatment of the same



(30) *(60)*

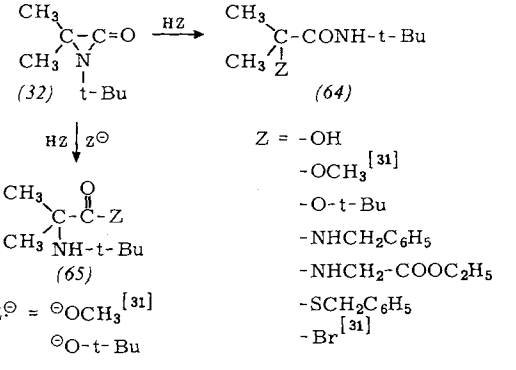
α-lactam with potassium *tert*-butoxide leads to benzhydryl-*tert*-butylamine *(61)* and not to an α-amino acid ester[35].

Reaction of 1-*tert*-butyl-3-phenylaziridinone *(21)* with *tert*-butyl alcohol, *tert*-butylamine, phenylhydrazine, or hydrochloric acid and solvolysis in different acetone/water mixtures gave the corresponding α-substituted *N*-*tert*-butylphenylacetamide *(62)*, whereas reaction of *(21)* with potassium-*tert*-butoxide produced *tert*-butyl *N*-*tert*-butylphenylglycinate *(63)* [10,11].



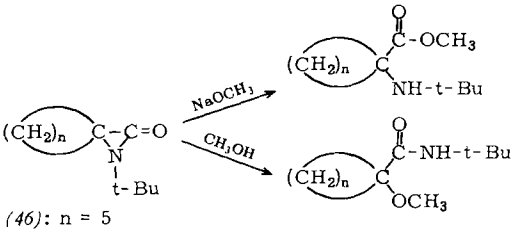
(21) *(62)* *(63)*

The α-lactam *(32)* was treated with water, methanol, *tert*-butyl alcohol, benzylamine, ethyl glycinate, 2-toluenethiol, and hydrobromic acid and from all these reactions the product was the corresponding α-substituted *N*-*tert*-butylisobutyramide *(64)* [17,18]. Sodium methoxide and potassium *tert*-butoxide converted the α-lactam *(32)* into the corresponding ester of *N*-*tert*-butyl-α-aminoisobutyric acid *(65)*.



(32) *(64)* *(65)*

The reaction of the three spiro-α-lactams *(46)*, *(51)*, and *(52)* with methanol or methoxide ion showed the same type of selective ring opening[30] as observed earlier[31] with the 3,3-dimethyl derivative *(32)*.



(46): n = 5
(51): n = 4
(52): n = 7

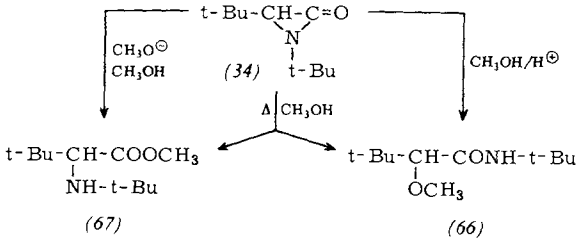
In contrast to the α-lactams *(21)* and *(32)*, 1,3-di-*tert*-butylaziridinone *(34)* is remarkably resistant toward nucleophiles (HZ). Several days' refluxing is necessary to solvolyze α-lactam *(34)* with methanol. The methanolysis products are amide *(66)* and ester *(67)* in the molar ratio 3:2[19,20]. This is the first recorded case in which an α-amino acid derivative was formed in the "uncatalyzed" solvolysis of an α-lactam. In

[33] *F. D. Greene* and *J. C. Stowell*, J. Amer. chem. Soc. *86*, 3569 (1964).

[34] The Favorskii reaction of α-chlorodibenzyl ketone is similarly selective: the 2,6-lutidine catalyzed methanolysis of this compound leads to the corresponding α-methoxy ketone; the sodium methoxide catalyzed methanolysis on the other hand gives the rearranged methyl ester [13].

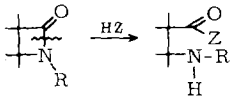
[35] *H. E. Baumgarten* and *R. D. Clark*, unpublished results; see reference [14], p. 88.

agreement with earlier findings for 1-*tert*-butyl-3,3-dimethylaziridinone, the α-lactam *(34)* gave only the ester *(67)* on treatment with sodium methoxide. Acid-catalyzed methanolysis led exclusively to amide *(66)*.

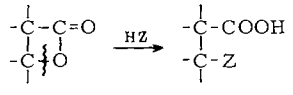


b) Nucleophilic Ring Opening of Other Small-ring Heterocycles

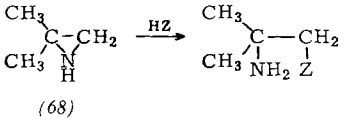
Monocyclic β-lactams are relatively stable compounds. They are solvolyzed only under drastic conditions and then yield products corresponding exclusively to scission of the amide bond [36].



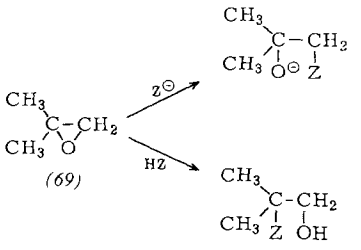
β-Lactones, on the other hand, are opened by nucleophiles preferentially at the alkyl-oxygen bond [37], a type of ring opening that resembles more that of α-lactams.



The type of ring opening of 2,2-dimethylaziridine *(68)* is also in sharp contrast to that of the α-lactams investigated to date. 2,2-Dimethylaziridine *(68)* is opened by protic nucleophiles (HZ) in such a way that substitution occurs exclusively at the primary carbon, *i.e.* nitrogen atom remains attached to the tertiary carbon [38].

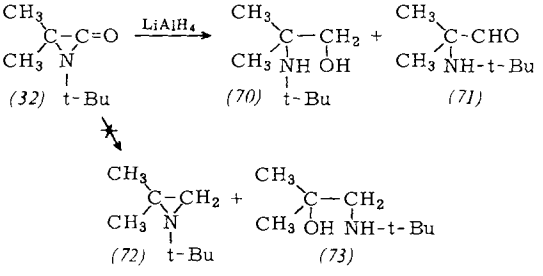


The observations made to date on the ring opening of α-lactams parallel the corresponding reactions of epoxides. Thus 2,2-dimethyloxirane *(69)* is opened by acids (HZ) to a primary alcohol and by bases or ionic nucleophiles to a tertiary alcohol [39].



c) Reduction of α-Lactams with $LiAlH_4$

Reaction of the α-lactam *(32)* with $LiAlH_4$ affords a mixture of 2-*tert*-butylamino-2-methyl-1-propanol *(70)* and 2-*tert*-butylamino-2-methylpropionaldehyde *(71)* [40]. Neither the anticipated 1-*tert*-butyl-2,2-dimethylaziridine *(72)* nor the structurally isomeric



amino alcohol, 1-*tert*-butyl-2-methyl-2-propanol *(73)*, could be detected in the product [40].

Applying the considerations [41] generally accepted for the reduction of acyclic tertiary amides to α-lactams with $LiAlH_4$ (and presuming a genuine α-lactam structure), three products are anticipated: a tertiary amine *(72)*; an *N,N*-disubstituted amino alcohol *(70)*; and a similar amino aldehyde *(71)*. In fact, the reaction produced only the last two. The possibility that the first product is indeed 1-*tert*-butyl-2,2-dimethylaziridine *(72)*, which is then converted into more stable secondary products, can be excluded since 2,2-dimethyl-*N*-alkylaziridines are known [42] to be stable even to an excess of $LiAlH_4$ when refluxed in ether.

d) Reduction of Larger Lactams with $LiAlH_4$

N-Aryl- and *N*-alkyl-β-lactams are reduced by an excess of $LiAlH_4$ to the corresponding *N,N*-disubstituted amino alcohol [43,44] in analogy to the α-lactam *(32)*. *N*-Alkyllactams

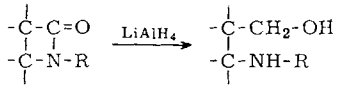
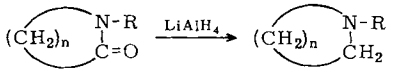
[44] It should be mentioned here that *N-unsubstituted* β-lactams can be reduced by an excess of $LiAlH_4$ in high yields to the corresponding cyclic imine [*E. Testa*, *L. Fontanella*, and *G. F. Cristiani*, Liebigs Ann. Chem. *626*, 114 (1959)]. In fact, this reduction serves as an excellent method for the preparation of 3,3-disubstituted azetidines.



R = Alkyl, Aryl

with five- to nine-membered rings normally give the corresponding heterocycles *(74)* in good yield on reduction with $LiAlH_4$[45].



n = 3-7 *(74)*

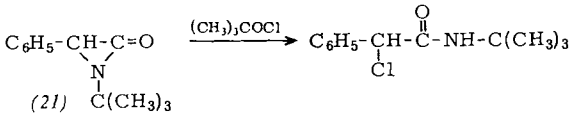
4. Miscellaneous Reactions of α-Lactams

a) Reaction with Diazomethane

In the hope of obtaining a ring-enlargement product, *Sheehan* and *Lengyel* treated 1-*tert*-butyl-3,3-dimethylaziridinone *(32)* with an ethereal solution of diazomethane at 0 °C[18]. No reaction was observed. *Baumgarten* and *Fuerholzer* attempted[46] to bring about a reaction between 1-*tert*-butyl-3-phenylaziridinone *(21)* and diazomethane in boiling ether; they could not, however, isolate or identify a product indicating a reaction.

b) Reaction with *tert*-Butyl Hypochlorite

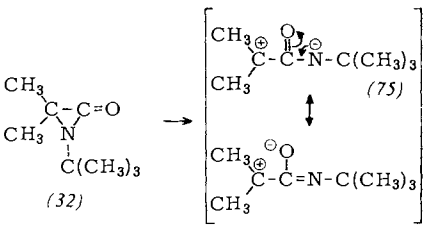
Addition of an ethereal solution of the α-lactam *(21)* to a solution of *tert*-butyl hypochlorite in ether initiates a rapid reaction[46]. One obtains *N*-*tert*-butyl-α-chlorophenylacetamide as the only product in 76% yield. In view of the polarization of *tert*-butyl hypochlorite ($tert\text{-}Bu\overset{\delta\ominus}{O}-\overset{\delta\oplus}{Cl}$), with the chlorine atom carrying a partial positive charge, the product obtained is surprising.



(21)

c) Reaction with Dimethyl Fumarate and Dimethyl Acetylenedicarboxylate

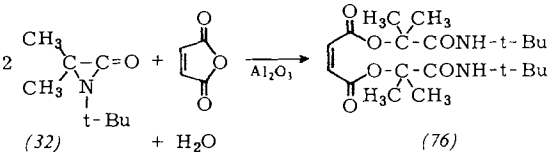
To examine the question whether α-lactams can function as 1,3-dipoles *(75)*[47], the α-lactam *(32)* was treated with dimethyl fumarate and dimethyl acetylenedicarboxylate, respectively[17,18]. No reaction was observed at 0 °C in chloroform solution. The α-lactam could be detected unchanged after two days.



(32) *(75)*

d) Reaction with Maleic Anhydride

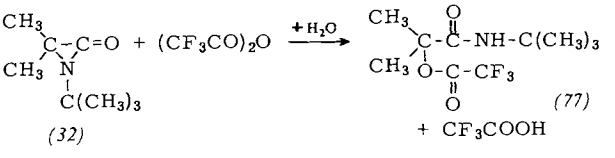
Surprisingly, the α-lactam *(32)* does react at 0 °C in chloroform with maleic anhydride. The product isolated after chromatography on alumina has been characterized[17] by elemental analysis, molecular-weight determination, and IR, UV, NMR, and mass spectrometry[48] as di[1-*tert*-butylcarbamoyl)-1-methylethyl)] maleate *(76)*.



(32) + H_2O *(76)*

e) Reaction with Trifluoroacetic Anhydride

α-Lactam *(32)* reacts vigorously with trifluoroacetic anhydride even at −5 °C to yield 1-(*tert*-butylcarbamoyl)-1-methylethyltrifluoroacetate *(77)*[48]. The mechanism has not been investigated.



(32) *(77)* + CF_3COOH

IV. Influence of the Substituents on Preparation, Stability, and Reactivity of α-Lactams

1. Variation of the Substituent on Nitrogen

As shown by *Sheehan* and *Lengyel*[17,18], the *N*-substituent decisively affects the reactivity of the "aliphatic" α-lactams. Exchanging the *N*-*tert*-butyl group in the starting amide for an *n*-propyl group *(78)* yielded the much more reactive α-lactam *(79)*, which has been detected by IR spectroscopy, but it reacted vigorously, even in the cold, with the potassium *tert*-butoxide present, thus precluding isolation. The two end products isolated were *tert*-butyl 2-methyl-2-*n*-propylaminopropionate *(80)* and 2-*tert*-butoxy-2-methyl-*N*-*n*-propylpropionamide *(81)*.

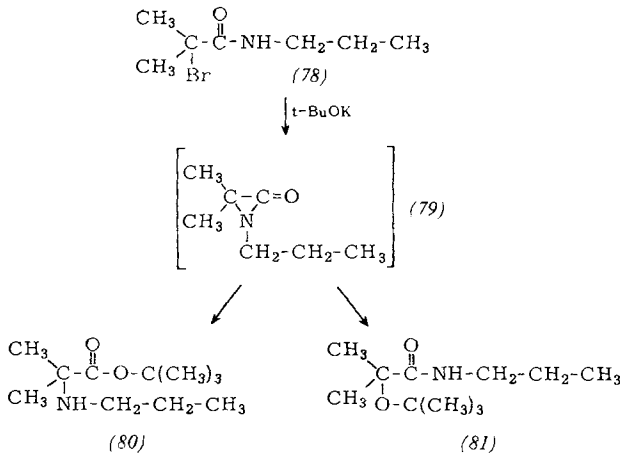
During the course of their attempts to prepare stable 3-phenyl-α-lactams[14,35] *Baumgarten* and co-workers also noticed the decisive influence of the *N*-substituent on ease of formation and stability of α-lactams.

[45] See, for example, a) *R. Lukes* and *J. Malek*, Chem. Listy *45*, 72 (1951); b) *P. G. Gassman* and *B. L. Fox*, J. org. Chemistry *31*, 982 (1966).

[46] Reference [14], p. 49.

[47] *R. Huisgen*, Angew. Chem. *75*, 604 (1963); Angew. Chem. internat. Edit. *2*, 565 (1963).

[48] *I. Lengyel*, unpublished results.



a) Replacement of the *N-tert*-Butyl Group in *(21)* by Secondary Alkyl Groups

Pure α-lactams could not be isolated from *N*-isopropyl-α-chlorophenylacetamide, *N*-isopropyl-α-bromophenylacetamide, *N*-cyclohexyl-*N*-chlorophenylacetamide, *N*-cyclohexyl-α-chlorophenylacetamide, or *N*-cyclohexyl-α-bromophenylacetamide [14]. The α-lactam was in most cases detected by IR, but in no case isolable because of its high reactivity. Replacement of the bulky *tert*-butyl group by primary and/or secondary alkyl or cycloalkyl groups – substituents with smaller steric requirement – in the starting amides also enhances the reactivity of the corresponding α-lactam.

b) Replacement of the *N-tert*-Butyl Group in *(21)* by *N*-2,6-Dimethylphenyl Group

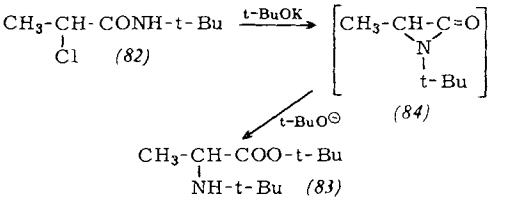
On the basis of the findings just described, one might expect that other bulky substituents on nitrogen would also lead to stable, moderately reactive α-lactams. In contrast to this expectation, it was found by *Baumgarten* and co-workers [14] that treatment of *N*-2,6-dimethylphenyl-α-bromophenylacetamide with potassium *tert*-butoxide in ether does not give an α-lactam; no IR band characteristic for an α-lactam could be detected in the spectrum of the reaction product, which was a yellow glassy mass that could not be identified.

This observation suggests that the ease of formation of an α-lactam (under otherwise identical conditions) is dependent not only on the degree of steric hindrance around the nitrogen, since both the *tert*-butyl and the 2,6-dimethylphenyl groups are bulky substituents with large steric requirements.

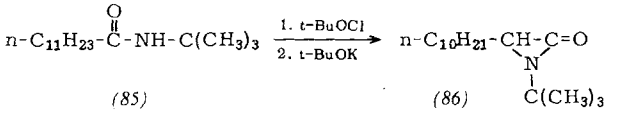
2. Variation of the Substituents on C-3

a) Aliphatic Series

Although the α-lactam formed from 2-bromo-2-methyl-*N-tert*-butylpropionamide with potassium *tert*-butoxide was stable enough to be isolated [17,18], replacement of one of the two methyl groups at C-3 by a hydrogen in the starting amide drastically changed the course of the reaction [18]. On treatment with potassium *tert*-butoxide, *N-tert*-butyl-α-chloropropionamide *(82)* gave a single product, *tert*-butyl-*N-tert*-butylalaninate *(83)*, in high yield. The intermediate α-lactam *(84)* could be detected by IR methods but was not isolated in pure form [18].

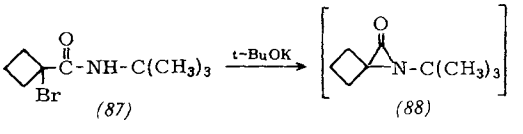


Attempts of *Baumgarten* and co-workers [14] to prepare a stable α-lactam from a long-chain fatty-acid amide were also unsuccessful. The reaction of *N-tert*-butyl-1-undecanecarboxamide *(85)* with *tert*-butyl hypochlorite and potassium *tert*-butoxide gave the α-lactam *(86)* (ν_{CO} = 1847 cm^{-1} in pentane) in such a low yield that it could not be isolated in pure form, since it is more reactive than the other components of the mixture and therefore decomposed on work-up. (For the formation of the unusually stable α-lactam *(34)* [19,20], compare Section III.1.)



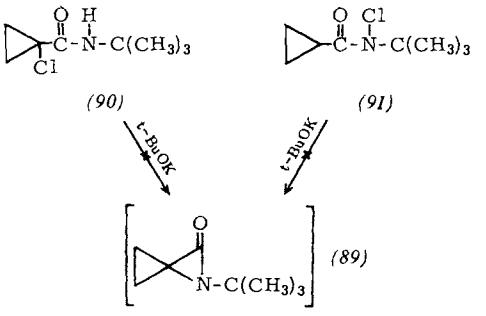
b) Variation of the Substituents on C-3 in Spiro-α-lactams

As mentioned in Section III.1., it was possible [19,25,30] to isolate – at least in crude form – α-lactams in good yield from *N-tert*-butyl-1-bromo-1-cycloalkane carboxamides with five-, six-, and eight-membered rings at C-3. However, decreasing the ring size of the spiro moiety in the starting amide produced a significant change in the reaction course: treatment of *N-tert*-butyl-1-bromo-1-cyclobutanecarboxamide *(87)* with potassium *tert*-butoxide in pentane at 0 °C gave – in low yield – the expected α-lactam *(88)*, but this was too reactive to be isolated [19].



Attempts [19] to prepare the interesting double-ring lactam *(89)* from the corresponding cyclopropyl precursors *(90)* and *(91)* on treatment with potassium *tert*-butoxide did not yield detectable quantities of compound *(89)* [19].

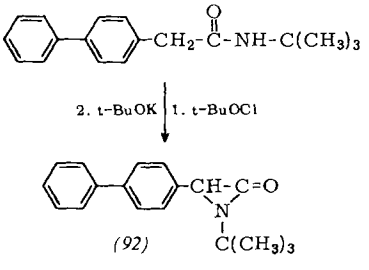
Only unchanged starting material was recovered from *(91)*, and starting with *(90)*, a mixture of unchanged starting material and *N-tert*-butylcyclopropane carboxamide was obtained.



c) Variation of the Substituents on C-3 in the Aromatic Series

As was mentioned in Section II.1., *Baumgarten* and co-workers prepared besides *N-tert*-butyl-3-phenylaziridinone *(21)*, the 3-*p*-chlorophenyl *(28)* and 3-*p*-bromophenyl *(29)* analogs. By using very fast work-up procedures they could also isolate 1-*tert*-butyl-3,3-diphenylaziridinone *(30)* [14].

Further attempts to prepare other α-lactams with aryl groups on C-3 did not lead to isolable quantities of the desired products [14]. Thus, it was not found possible to prepare or even to detect an α-lactam from *N-tert*-butyl-*p*-nitrophenylacetamide under the usual conditions. The reaction product was a dark-brown tar [14]. 1-*tert*-Butyl-3-(4-biphenylyl)aziridinone *(92)* could be prepared *via* the corresponding *N*-chloroamide only in impure form (m.p. 77–82 °C) [14].



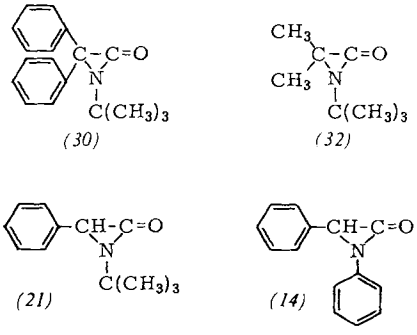
3. Thermal Stability and Chemical Reactivity of α-Lactams as a Function of Substitution Pattern

i) The greater the steric requirements of the substituents on N and on C-3 in the aliphatic series, the easier the preparation and purification of the α-lactam and the greater its thermal stability and lower the reactivity towards nucleophiles.

ii) Under otherwise identical conditions, C-3-disubstituted α-lactams are more stable than C-3-monosubstituted ones.

iii) The ease of thermal decomposition and the type of products formed is dependent not only on the steric factor but also on the presence or absence of at least one β-hydrogen in the alkyl group on C-3. α-Lactams possessing at least one such β-hydrogen in this alkyl group [such as *(32)*] decompose even on short warming in refluxing ether; the major products are α,β-unsaturated amides, formed *via* elimination of a β-hydrogen and subsequent rearrangement. α-Lactams that do not have a β-hydrogen in one of the alkyl groups on C-3 are more resistant to heating and give different products on thermal decomposition. Thus, the α-lactam *(21)* starts to decompose only at 105 °C [14], whereupon it fragments to benzaldehyde and *tert*-butyl isocyanide [14]. Similarly, the thermal decomposition of 1,3-di-*tert*-butylaziridinone *(34)*, which does not have a β-hydrogen and is further stabilized by the two bulky *tert*-butyl groups, does not start below 140 °C and leads to an aldehyde and a nitrile [19, 20].

iv) If the properties of α-lactams were determined and influenced only by steric factors, one would expect the α-lactam *(30)* to be more stable and easier to prepare than the α-lactam *(32)* because the two phenyl groups are bulkier than the two methyl groups. In fact, however, diphenyl-α-lactam *(30)* is the more difficult one to prepare. Furthermore, the α-lactams *(21)* and *(14)*

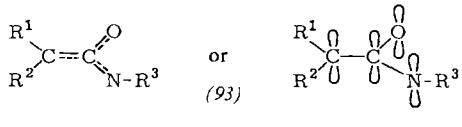


would then be expected to have a comparable stability, since the steric requirements of the *tert*-butyl and the phenyl group are not very different. In fact, the α-lactam *(14)* could not be prepared, in spite of considerable effort [4a,4b].

This leads to the conclusion that there are other factors (*e.g.* electronic effects) besides the steric one influencing the stability of α-lactams.

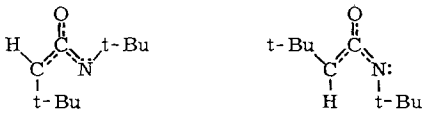
v) It appears reasonable to assume that both the preparation and the chemical and thermal reactions of α-lactams are decisively influenced by the geometry of an "acyclic" intermediate or transition state. The observations made hitherto concerning the properties of α-lactams can, at least qualitatively, be explained by invoking an intermediate or transition state of this type.

Such an intermediate *(93)* has recently been suggested by *Sheehan* and *Beeson* [30] (compare Section III.1.). This intermediate is acyclic, planar or quasi-planar,



and charge-delocalized. Substituents which contribute to the charge delocalization and thereby to the stabilization of this intermediate (or transition state), effect a destabilization of the real α-lactam ground state, *i.e.* render the preparation more difficult and enhance the reactivity of α-lactams.

Phenyl and aryl substituents considerably extend the charge delocalization of the transition state. In compounds with phenyl substituents on both C-3 and nitrogen [*e.g. (14)* and *(9)*], the π-electron system is extended throughout the whole molecule, thereby greatly facilitating formation of such an intermediate and enhancing its stability. This would explain why 1,3-diphenyl- and 1,3,3-triphenylaziridinone could not be prepared: the acyclic form is so stable that cyclization does not occur. Alkyl substituents, *e.g.* methyl [17,18] or *tert*-butyl groups [19,20], which do not significantly contribute to an extension of charge delocalization in the intermediate, destabilize this form and consequently enhance the stability of the α-lactam structure. As scale models clearly show, steric hindrance is very pronounced around the O–C–N atoms



in both possible conformations of the transition state of di-*tert*-butylaziridinone [20]. This may well explain the low reactivity and high thermal stability of this α-lactam.

We thank Dr. Helmut Seidl of the University of Munich, presently at the Department of Chemistry, M.I.T., for critically reading the German version of this manuscript. Our own work described here has been supported by the National Institutes of Health, Bethesda, Maryland (USA). We gratefully acknowledge this support.

The Photolysis of Iodoaromatic Compounds

BY R. K. SHARMA AND N. KHARASCH [*]

Under appropriate conditions, the photolysis of iodoaromatic compounds yields derivatives of biphenyl and phenanthrene, as well as organometallic compounds. Ring closures of o-terphenyls to triphenylenes and of benzanilides to phenanthridones are described. The formation of dehydrobenzene (benzyne) on photolysis of 1,2-diiodobenzene in solution has been established. The photolysis of various substituted iodoaromatic compounds or of substances such as CH_3I, ICN, ICH_3, COOH, or $RC{\equiv}CI$, provides a general method for the generation of a large variety of free radicals in solution. The potential uses of photochemically initiated exchanges of iodine in ArI for ^{131}I, Li, D, Cl, or Br are noted.

1. Introduction

There are many early references [1] to the photochemistry of iodoaromatic compounds in the published literature and the free-radical nature of such processes was early recognized, especially by *Bryce-Smith* and co-workers. However, the synthetic potentialities of these reactions were not realized until comparatively recently. This review summarizes the main features of recent work on photolysis of iodoaromatic and other iodo compounds (ICN, ICH_2COOH, CH_3I, *etc.*) as well as selected bromoaromatic compounds. The mechanism of the photolysis is also commented on.

The following compounds can be synthesized by the photolysis of iodoaromatic compounds

a) Substituted biphenyls
b) Phenanthrenes (from *o*-iodostilbenes)
c) Various radio-isotope labeled compounds (by exchange reactions)
d) Specifically labeled deuterium compounds (by exchange reactions)
e) Organometallic compounds
f) Benzynes in solution (from 1,2-diiodoaromatic compounds).

2. Light Sources and the Nature of the Excited State

Perusal of the literature relating to the photolysis of iodoaromatic compounds reveals that a variety of light sources, frequently without filters, have been used – especially in qualitative studies. Mercury lamps have been most popular, and a summary of the

various types of commercial lamps is available [2]. A modified version of a cold-cathode, low-pressure mercury-vapor lamp was described by *Heidt* and *Boyles*, and an adaptation of such a lamp, now commercially available as the "W–K lamp" [74], has been found to be especially effective in synthetic work [3]. Monochromatic light, though less often used, has provided important information about details of reaction mechanisms.

A complete description of the initial excited state attained by iodoaromatic compounds on absorption of a quantum of light, as well as of the state which culminates in the cleavage of the carbon-iodine bond, is available only for a few cases, and the general picture is not complete. *Iredale* and co-workers examined the spectra of a number of iodo-organic compounds [4–7]. The first absorption band of iodobenzene in cyclohexane solution has a maximum at 2560 Å ($\varepsilon = 665$), and the second has a maximum at 2320 Å ($\varepsilon = 10000$). The second band has been said to correspond to the 2100 Å band (N → V, or π-π^*) of benzene [5]. It has been suggested that the first band is not due to absorption of a light quantum by the π-electrons of the aromatic system, but to absorption by the carbon-iodine bond or one of the electrons of iodine. Excitation to the A-level takes place, leading to the loss of an iodine atom.

This suggestion is supported by the fact that under the influence of nitric oxide, which inhibits the back reaction

$$C_6H_5^{\bullet} + I^{\bullet} \rightarrow C_6H_5I$$

by means of the side-reaction

$$C_6H_5^{\bullet} + NO \rightarrow C_6H_5NO,$$

a quantum yield of approximately unity has been found for the photodecomposition of iodobenzene by light of wavelength 2500 Å to 1800 Å. Practically all the light-affected molecules must have absorbed by way of the carbon-iodine bond, and not in the π-electrons of the benzene ring, since it is very unlikely that NO would have reacted by way of excited molecules at room temperature [4,5].

Substitution in the aromatic ring changes the spectral characteristics of the molecule. It has been pointed out that a molecule may absorb in the same spectral regions in one or more ways, in one or another of different groups, and to an extent dependent upon transition moments in these groups and on the influence of these groups on one another [5].

Wilkinson has studied the photosensitized decomposition of 1-iodonaphthalene. Degassed solutions of 1-iodonaphthalene do not show appreciable decomposition at 3600 Å. However, in the presence of benzophenone as sensitizer (when the triplet state of 1-iodonaphthalene is formed at a quantum yield of 0.9) the quantum yield of iodine formation, Φ_{I_2}, is only about 0.05, *i.e.* about one-half of the value when iodonaphthalene itself is irradiated at 3100 Å. It was suggested, therefore, that the triplet state of 1-iodonaphthalene is capable of dissociation, but does not always do so [8].

3. Photochemical Aspects

3.1. The Free-Radical Nature of the Photolysis

On absorption of light of suitable wavelength, an iodo compound dissociates into a free radical and an iodine atom. The quantum yield of this process in the liquid phase or in solution is less than unity. This has been ascribed to the back reaction (2).

$$Ar{-}I \rightarrow Ar^{\bullet} + I^{\bullet} \quad (1)$$
$$Ar^{\bullet} + I^{\bullet} \rightarrow ArI \quad (2)$$
$$Ar^{\bullet} + I_2 \rightarrow Ar{-}I + I^{\bullet} \quad (3)$$
$$Ar^{\bullet} + O_2 \rightarrow ArO_2^{\bullet} \quad (4)$$
$$Ar^{\bullet} + NO \rightarrow ArNO \quad (5)$$

The formation of free radicals by photolysis of ArI compounds has been proposed by several workers. The principal evidence for the homolytic nature of the process can be summarized as follows.

a) If the photolysis is carried out in the presence of the radical scavengers oxygen or nitric oxide, which inhibit the back reaction, the quantum yield of the reaction increases. *Olaerts* and *Jungers* have shown that the presence of oxygen raises the quantum yield in the photodecomposition of iodobenzene ten-fold, as compared with the value in absence of oxygen [28]. It was also shown that the quantum yield was independent of the amount of iodine produced, so reaction (3) cannot be very significant [52]. Similarly, a quantum yield of almost unity has been achieved in the presence of nitric oxide [5].

b) When the photolysis is conducted in aromatic solvents, the isomer distribution in the arylation product is in good agreement with that obtained with thermally generated aryl radicals [9,10].

c) Free radicals are known to participate in abstraction reactions. When aryl radicals are produced photochemically, they can also abstract hydrogen, chlorine, and bromine from cyclohexane [3], carbon tetrachloride, and bromoform [11], respectively.

The photolysis of iodobenzene in fluorocarbon and hydrocarbon solvents at 77 °K has been studied by ESR methods. The results suggest the formation of "free" phenyl radicals on photolysis [12].

The carbon-iodine bond energy in ArI compounds is about 55 kcal/mole. The photolysis of these bonds can thus be achieved readily; and with proper precautions – under conditions which allow other sen-

sitive functional groups to remain intact – the photochemical decompositions of iodoaromatic compounds should provide a convenient source of free radicals of many different types.

3.2. Arylation by Photochemically Generated Aryl Radicals

It was shown by *Bryce-Smith* and co-workers that photolysis of iodobenzene, in isopropylbenzene [9] or as the neat liquid [13], leads to the phenylation of the isopropylbenzene or the iodobenzene. It was also found that hydrogen transfer to phenyl radical occurs on photolysis in isopropylbenzene.

Wolf and *Kharasch* have demonstrated that useful yields of substituted biphenyls and similar compounds can be obtained by this method [3] (see Table 1).

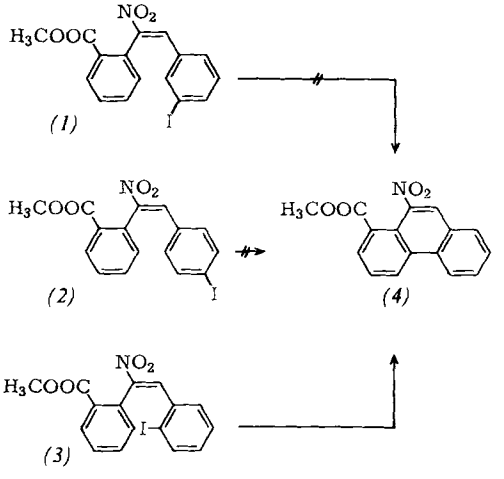
$$Ar{-}I + C_6H_6 \rightarrow Ar{-}C_6H_5 + {}^1/_2\, I_2 + [H] \qquad (6)$$

Table 1. Photolysis of aromatic iodo compounds in benzene.

Substrate	Conc. (M)	I_2 released (%)	Product	Yield (%)
Iodobenzene	0.03	98	Biphenyl	65
4-Iodobiphenyl	0.02	100	*p*-Terphenyl	91
1-Iodo-naphthalene	0.03	75	1-Phenyl-naphthalene	50
2-Iodotoluene	0.02	90	2-Methylbiphenyl	13
3-Iodotoluene	0.02	90	3-Methylbiphenyl	50
4-Iodotoluene	0.02	80	4-Methylbiphenyl	75
2-Iodothiophene	0.04	100	2-Thienylbenzene	70
2-Iodophenol	0.01	100	2-Hydroxybiphenyl	60
3,5-Diiodo-4-hydroxy-benzaldehyde	0.02	100	3,5-Diphenyl-4-hydroxy-benzaldehyde	25
2-Iodobenzoic acid	0.02	100	2-Phenylbenzoic acid	73
4-Iodobenzoic acid	0.03	100	4-Phenylbenzoic acid	80
4-Iodonitro-benzene	0.02	53	4-Nitrobiphenyl	–
2-Iodoaniline	0.01	60	2-Aminobiphenyl	20
4-Iodoaniline	0.02	75	4-Aminobiphenyl	38
2,4,6-Triiodophenol	0.015	100	2,4,6-Triphenylphenol	75

With many iodo substrates in aromatic solvents, iodine release is essentially quantitative. A plot of iodine release against time, however, shows a decrease in the rate of reaction in the later stages [14]. This may be due either to screening of light by the iodine released or to an increased amount of back reaction. Attempts have sometimes heen made to minimize such effects by carrying out the reaction in the presence of copper [16], silver [13], mercury [17], or silver trifluoroacetate [18]. In the photolysis of 1-iodo-2-phenylacetylene in benzene, the yield of diphenylacetylene was increased from 50 to 70 % when silver trifluoracetate was added. There are some problems caused by adherence of precipitated metallic iodides to the walls of the photolysis tube but satisfactory yields can generally be obtained in dilute solutions, even when the iodine released is not removed.

In the reaction, as carried out by *Wolf* and *Kharasch*, the incoming phenyl group always takes the position vacated by iodine; rearrangement of the aryl radical or the product has never been found. In those cases where a rearranged product has been isolated [19,20], the results can be attributed either to the isomerization of the iodo compound prior to the cleavage of the carbon-iodine bond or to rearrangement of the product subsequent to its formation. An ingenious experiment, which was planned to detect the slightest amount of rearrangement of the radical, while providing the greatest opportunity for it to do so, was conducted by *Kupchan* and *Wormser* [21]. It was shown that photolysis of methyl 3′-iodo-α-nitro-*cis*-stilbene-2-carboxylate *(1)* and methyl 4′-iodo-α-nitro-*cis*-stilbene-2-carboxylate *(2)* afforded no phenanthrene product, whereas the 2′-iodoisomer *(3)* gave the phenanthrene product *(4)* in 50 % yield.



Wynberg and *van Driel* [19], while attempting to use iodothiophene as a radical source, discovered that 2-phenylthiophene rearranges to 3-phenylthiophene on irradiation. In this paper, however, it was not made explicit whether isomeric products were isolated when iodothiophene was photolyzed in benzene.

The photochemical phenylation reaction has been extended to the direct synthesis of polyphenyl products. The synthesis of *(8)* and *(9)* from readily available 2,4,6-triiodophenol *(7)* further illustrates the scope of the photochemical technique [22].

A simple synthesis of *(10)* was achieved by *Nickon* and *Aaronoff* by the photolysis of 2,4-dimethyl-6-iodo-

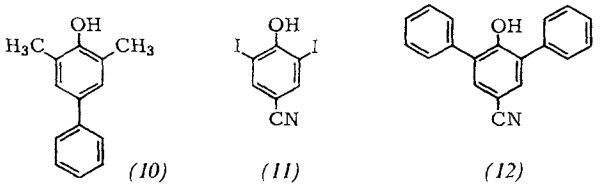
phenol in benzene[23], and recently the synthesis of 2,4,6-tri(pentadeuteriophenyl)phenol, in 45.5 % yield, by the photolysis of 2,4,6-triiodophenol in hexadeuteriobenzene has been reported by *Dimroth*, *Berndt*, and *Volland*[67].



(10) (11) (12)

Ioxynil *(11)*, a herbicide and molluscicide, is more toxic to plants in the light than in the dark. Since ioxynil undergoes photolytic reaction in benzene solution to give a phenylated product *(12)*, it has been suggested that the toxic action might be due to the free radicals produced in the cell on exposure to light, which seriously interfere with the reactions essential for the life of the plant[24].

Table 2. Some other synthetic results in the photolysis of iodo compounds in benzene [25].

Substrate	Time (h)	Product	Yield (%)
1-Iodo-2-phenylacetylene	12	Diphenylacetylene	50
1-Iodo-2-tolylacetylene	12	Tolylphenylacetylene	62
Benzoyl iodide	60	Benzophenone	12 [a]
2-Iodobenzaldehyde	48	2-Phenylbenzaldehyde	95 [a]
4-Iodobenzaldehyde	48	4-Phenylbenzaldehyde	90 [a]
Monoiodoacetic acid	24	Phenylacetic acid	67
Cyanogen iodide	10	Benzonitrile	50 [b]

[a] As 2,4-dinitrophenylhydrazone.

[b] As benzoic acid.

The phenomenon of photolytic decomposition in benzene is not limited to aryl iodides. *Kharasch* and *Göthlich* have shown that the reaction can be extended to other types of organic iodides to give fair to good yields of substituted benzenes (cf. Table 2)[25].

Photolysis of methyl iodide in benzene leads to the formation of toluene in 66 % yield, but with ethyl iodide and isopropyl iodide the yields of alkylation products are low[26]. Photolysis of benzyl iodide[17] in isopropyl benzene and of benzyl iodide and allyl iodide[27] in benzene also result in poor yields. In general, radicals that are not very susceptible to disproportionation can be produced effectively, and used for synthetic purposes, by photolysis of the appropriate iodo compounds.

3.3. Effect of Oxygen

Reference was made earlier to the fact that the presence of oxygen increases the quantum yield of decomposition of iodobenzene[28]. In the photolysis of iodoacetic acid in hexane, it was found by *Hacobian* and *Iredale*[29] that $\Phi_{I_2} = 0.49$ when no special efforts were made to remove oxygen. After an extensive removal of oxygen by transferring the solution under vacuum from one vessel to another by evaporation and condensation at least six times, the iodine release on photolysis was negligible ($\Phi_{I_2} = 0$) although the amount of light absorbed was practically the same as in the presence of oxygen. Similarly, the photolysis in hexane of such iodides as methyl, ethyl, isoamyl, iodobenzene, and *p*-iodotoluene gave $\Phi_{I_2} = 0.5$ in the presence of oxygen and $\Phi_{I_2} = 0.05$ after its extensive removal.

$$p\text{-}C_6H_5\text{-}C_6H_4\text{-}I \rightleftharpoons p\text{-}C_6H_5\text{-}C_6H_4^{\bullet} + I^{\bullet}\ (1/2\ I_2) \quad (7)$$

$$p\text{-}C_6H_5\text{-}C_6H_4^{\bullet} + C_6H_6 \longrightarrow p\text{-}C_6H_5\text{-}C_6H_4\text{-}C_6H_6^{\bullet} \quad (8)$$

$$p\text{-}C_6H_5\text{-}C_6H_4^{\bullet} + p\text{-}C_6H_5\text{-}C_6H_4\text{-}C_6H_6^{\bullet} \longrightarrow C_6H_5\text{-}C_6H_5 + p\text{-}C_6H_5\text{-}C_6H_4\text{-}C_6H_5 \quad (9)$$

$$p\text{-}C_6H_5\text{-}C_6H_4\text{-}C_6H_6^{\bullet} + \tfrac{1}{2}I_2 \longrightarrow p\text{-}C_6H_5\text{-}C_6H_4\text{-}C_6H_5 + HI \quad (10)$$

$$p\text{-}C_6H_5\text{-}C_6H_4^{\bullet} + HI \longrightarrow C_6H_5\text{-}C_6H_5 + I^{\bullet} \quad (11)$$

$$2\ I^{\bullet} \rightleftharpoons I_2 \quad (12)$$

The effect of oxygen on the product distribution in the arylation of benzene has been demonstrated by *Kharasch* and *Sharma*[30]. It was found in the photolysis of 4-iodobiphenyl in benzene that the yield of the hydrogen-transfer product (biphenyl) increased at the expense of the arylation product (*p*-terphenyl) with

more efficient removal of oxygen by freeze-pump-thaw cycles. The ratio of biphenyl/*p*-terphenyl increased from 0.1 when the solution was not degassed to 0.5 when the solution was rigorously degassed. The decrease in the yield of biphenyl in the presence of oxygen has been explained in terms of the ability of oxygen to interfere with hydrogen transfer processes (equations (9) and (11)).

As mentioned earlier, oxygen can trap the radicals formed. In the above photolysis, 4-hydroxybiphenyl was formed in up to 26 % yield if the solution was kept saturated with oxygen during photolysis. The route to the phenol can be visualized as proceeding *via* a hydroperoxide, which is cleaved by the hydrogen iodide.

3.4. Arylation in Other Media

Bryce-Smith and co-workers, and *Kharasch* and *Naylor* [31], have studied the isomer distributions in the photochemical phenylation of various aromatic solvents. The results show that the isomer distribution is characteristic of "normal" free radicals, since a "hot" radical would have shown less selectivity. Thus any excess energy associated with the radical when first formed is rapidly dissipated in the condensed phase.

Badger and *Whittles* have photolyzed 1-iodonaphthalene in molten naphthalene. The products found were 1,1-binaphthyl, 1,2′-binaphthyl and small amounts of perylene *(13)* and benzofluoranthene *(14)* [32]. A control experiment showed that perylene is not formed by cyclodehydrogenation of 1,1′-binaphthyl.

(13)   *(14)*

Photolysis of 2-, and 3-, and 4-iodobiphenyl in biphenyl has been studied by *Hutchinson*, *Hudson*, and *Doss* in order to determine partial rate factors for substitution of biphenyl by biphenylyl free radical [33].

The photolysis of iodobenzene in thiophene gives 2- and 3-phenylthiophene, besides 2,2′-bithienyl and 2,3′-bithienyl [34]. In view of the recently established isomerization of 2-phenylthiophene to 3-phenylthiophene, the low yield of 3-phenylthiophene is rather surprising.

Preliminary experiments in our laboratory indicated that in the photolysis of 4-iodobiphenyl in 1-hexene an appreciable addition of 4-biphenylyl radicals to the double bond of 1-hexene occurs. This addition of a photochemically generated radical to a double bond has now been further studied toward developing a general synthesis of carboxylic acids from olefins.

Carboxymethyl radicals produced by photolysis of iodoacetic acid add to 1-hexene to give a mixture of saturated and unsaturated C_8 acids. Extraction with dilute sodium carbonate, acidification, and hydrogenation gives a 60 % yield of *n*-octanoic acid. A similar photolysis in cyclohexene gives 1- and 2-cyclohexenylacetic acid (24 %), cyclohexylacetic acid (3 %), and acetic acid (29 %) [35]. However, when bromoacetic acid was photolyzed in 1-hexene and in cyclohexene, *n*-octanoic acid and cyclohexylacetic acid were obtained in 60–70 % yields; unsaturated acids were not found in these cases.

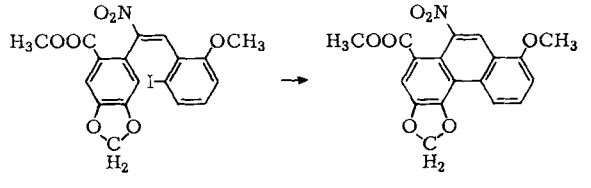
3.5. Intramolecular Arylation

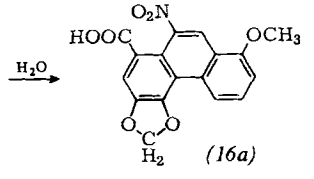
Based on the general studies of *Wolf* and *Kharasch*, *Kupchan* and *Wormser* have developed a general synthesis of substituted phenanthrene derivatives, which uses substituted 2-iodostilbenes in an intramolecular reaction to effect photocyclization [21].

(15)  *(16)*

$R^1 = R^2 = H$, 90 %
$R^1 = CH_3$, $R^2 = H$, 96 %
$R^1 = H$, $R^2 = COOCH_3$, 71 %
$R^1 = CH_3$, $R^2 = COOCH_3$, 62 %
$R^1 = H$, $R^2 = NO_2$, 40 %
$R^1 = COOCH_3$, $R^2 = NO_2$, 45 %

The effectiveness of this method for the synthesis of nitrophenanthrenes that are not readily accessible by other approaches is illustrated by an elegant synthesis of the naturally occurring tumor inhibitor, aristolochic acid *(16a)*.





(16a)

In the presence of dissolved oxygen or iodine, *cis*-stilbenes give phenanthrenes on photolysis in solution [36]. It was suggested that the cyclization proceeds through an unorthodox *trans*-dihydrophenanthrene derivative, and strong evidence for this has been presented [37, 38]. Photolysis of methyl α-nitro-*cis*-stil-

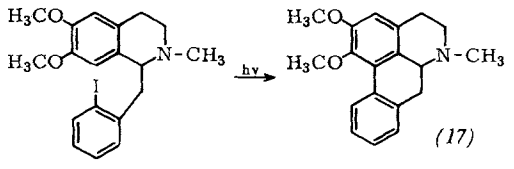
[37] *W. M. Moore*, *D. D. Morgan*, and *F. R. Stermitz*, J. Amer. chem. Soc. *85*, 829 (1963).

[38] *G. S. Hammond*, *J. Saltiel*, *A. A. Lamola*, *N. J. Turro*, *J. S. Bradshaw*, *D. O. Cowan*, *R. C. Counsell*, *V. Vogt*, and *C. Dalton*, J. Amer. chem. Soc. *86*, 3197 (1964).

bene-2-carboxylate fails to effect cyclization in the presence of oxygen or iodine, whereas the 6- or 2'-iodo compound gave the cyclization product in 45 % yield. This makes the intermediacy of a dihydrophenanthrene in the photocyclization of 2-iodostilbene very unlikely and an intramolecular cyclization *via* a free radical path seems the more likely route. It should be noted that on irradiation *trans*-stilbenes isomerize to *cis* compounds and may therefore be used as starting materials in some syntheses.

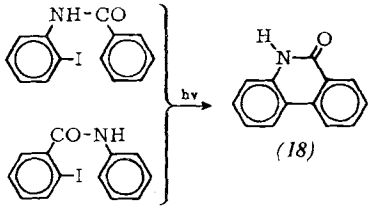
The method has been extended to the photochemical synthesis of noraporphines and of aporphines, by photolysis of 1-(2-iodobenzyl)-1,2,3,4-tetrahydroisoquinoline derivatives. Photolysis of suitable precursors gave DL-nuciferine *(17)*. It was found that the yield



(17)

was much better when the hydrochloride salt was photolyzed in aqueous solution [39]. While photolyses in aqueous solutions have not been generally studied, a report of the photolysis of 2-iododeoxyuridine in aqueous media has been made by *Prusoff* in a study of considerable chemical and biochemical interest.

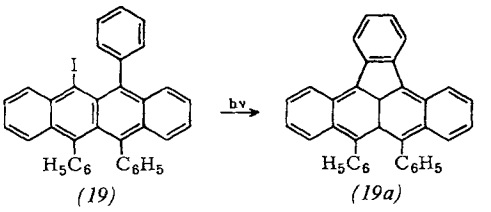
Similar intramolecular cyclizations leading to heterocyclic systems have been effected by *Kharasch* and coworkers [40]. For example, 2-iodo-*N*-benzoylaniline or 2-iodo-*N*-phenylbenzamide gave phenanthridone *(18)* on photolysis in benzene solution. Of special interest was the finding that benzanilide itself could undergo photocyclization to give phenanthridone in even better yields than from the iodo compounds.



(18)

The stereochemistry for the ring closures in these reactions would be favored on starting from the lactim forms of the amides. Further studies of the photolysis of sulfonamides are in progress to define these points more fully.

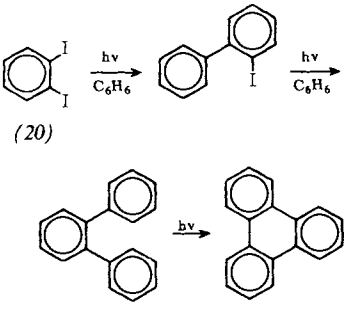
Formation of a five-membered ring – the first intramolecular cyclization to be effected by photolysis of an iodoaromatic substrate – was reported in 1942 by *Badoche* [1] who converted compound *(19)* into compound *(19a)*.



(19) *(19a)*

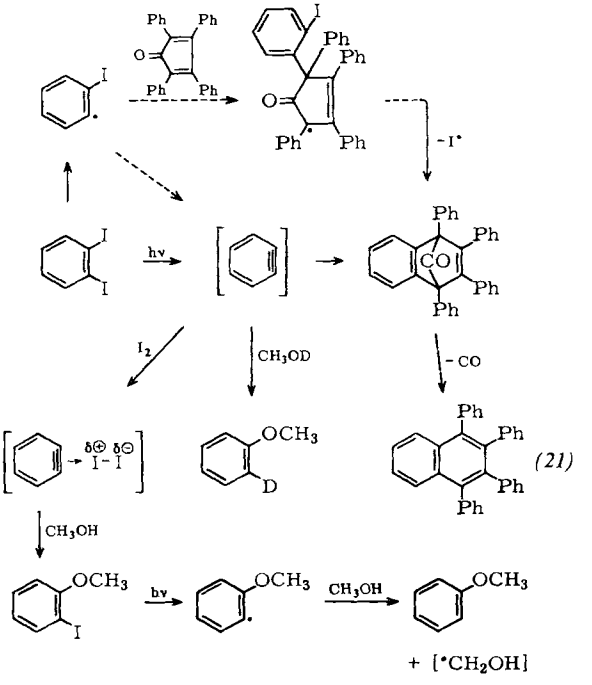
3.6. Polyiodo Compounds

Photolysis of *o*-diiodobenzene in benzene gave mainly 2-iodobiphenyl and small amounts of biphenyl and triphenylene [41]. Recent work has clearly demonstrated that triphenylene is formed by cyclodehydrogenation of *o*-terphenyl [42].



(20)

There is, of course, the interesting possibility that both iodine atoms will be lost on photolysis of diiodobenzene giving rise to benzyne. In the case of *o*-diiodobenzene, it was shown independently by *Kampmeier* and *Hoffmeister* and by *Kharasch* and *Alston* [43] that photolysis in the presence of tetracyclone gives the expected Diels-Alder adduct of benzyne and tetracyclone, *i.e.* 1,2,3,4-tetraphenylnaphthalene.



(21)

[43] See footnote 14 in reference [41].

It is, however, conceivable that the adduct is formed in a two-stage radical process without involving benzyne at all. Further evidence has now been obtained by performing the photolysis in CH_3OD. Mass spectral analysis of the anisole formed showed it to contain 63.8 % of monodeuterated anisole, which can be interpreted as arising through the intermediacy of benzyne [15].

The formation of 2-iodoanisole was unexpected, and presents another possible route to anisole by reductive removal of iodine. Its formation in such amounts by solvolysis of 1,2-diiodobenzene seems quite unlikely, and a more reasonable route, involving a π-complex of iodine with benzyne, is suggested.

Presuming that *m*- and *p*-benzynes would also add methanol to give anisole, formation of appreciable amounts of anisole on photolysis of *m*- and *p*-diiodobenzene in methanol would indicate the presence of these transitory intermediates. However, only traces of anisole (< 0.1 %) were formed when the experiment was carried out. It was felt that anisole is formed by secondary solvolytic processes and that *m*- and *p*-benzynes are not involved [44–46].

As pointed out earlier, photolysis of other diiodo- and triiodobenzene derivatives in benzene gives rise to the expected phenylation products. Thus, 2,4,6-triiodophenol leads to 2,4,6-triphenylphenol and thence to 2,4,6-triphenylphenoxy radicals. This opens a route to the general synthesis of substituted phenoxy radicals, whose properties could then be studied in detail. Other polyiodo compounds have also been studied (Table 1), but much further work remains to be done. It may also be pertinent to mention here that photolysis of methylene iodide in solution has recently been shown to give carbene [47].

3.7. Steric Effects

Eliel [48] has pointed out that whereas biphenyl itself has a strong absorption maximum at 249 nm, $\varepsilon = 15000$, because of an excited state involving conjugation of the two benzene rings, the introduction of even a single methyl group in the *ortho* position shifts the absorption maximum to 237 nm and lowers the extinction coefficient to 10500. When there are two methyl groups in the *o,o'* positions, the biphenyl band disappears and the absorption spectrum of the molecule resembles that of *m*-xylene. The reason for this is that the excited state deviates from a planar conformation and the extended resonance is greatly dampened. From the ultraviolet spectrum of *o*-iodobiphenyl there is also some evidence that the substitution of iodine at the *o*-position forces the molecule out of the planar conformation [6]

It seems, therefore, that 2-iodobiphenyl should photolyze faster than 4-iodobiphenyl, since loss of iodine from a molecule of 2-iodobiphenyl would allow the resulting 2-biphenylyl radical to assume a more stable planar structure. It has, however, been observed that although the photolysis of 4-iodobiphenyl in benzene is more than 90 % complete, the similar photolysis of 2-iodobiphenyl proceeds to an extent of 45 % only [49]. It appears that iodine competes favorably with benzene for the 2-biphenylyl radical and that steric factors in formation of the transition state for the conversion to *o*-terphenyl may be decisive in determining the course of the reaction. This is also reflected in the photolysis of an equimolar mixture of 2- and 4-iodobiphenyl in benzene, where it is found that *p*-phenylation is 26 times faster than *o*-phenylation. For the latter case, however, the differences in the light absorption by the two compounds might also be responsible for the observed yields of the phenylation products.

3.8. Exchange

It was reported by *Noyes* [50] that hexane solutions of iodobenzene undergo exchange reaction on illumination with visible light, whereas duplicate solutions stored in the dark underwent no more than 1 % of exchange. A direct substitution by an iodine atom was suggested as a mechanism of this exchange reaction [51]. A recent study by *Anbar* and *Rein* [52], utilizing a high-pressure mercury lamp and cut-off filters at 2850 Å and 3400 Å, reports that in the case of isotopic exchange with iodine the rate of de-iodination is independent of the concentration of molecular iodine and that the rate of isotopic exchange varies as the square root of the iodine concentration.

The observed square root dependence of the rate of exchange on iodine concentration is in accord with a mechanism *via* (13) and (14).

$$I_2 \xrightarrow{h\nu} 2\,I^{\bullet} \qquad (13)$$

$$I^{\bullet} + PhI \longrightarrow PhI + I^{\bullet} \qquad (14)$$

The exchange reaction appears to be distinctly faster than the corresponding exchange of ethyl iodide [57], while the rate of reaction with sodium suggests that the relative rates of exchange by a displacement of iodine which results in the formation of a radical would be in the opposite order. Moreover, the fact that the rate of de-iodination is independent of the iodine concentration suggests that reaction (15) is of little importance at the iodine concentration employed.

$$C_6H_5{-}I + I^{\bullet} \longrightarrow C_6H_5^{\bullet} + I_2 \qquad (15)$$

$$C_6H_5I \xrightarrow{h\nu} C_6H_5^{\bullet} + I^{\bullet} \qquad (16)$$

$$C_6H_5^{\bullet} + I_2 \longrightarrow C_6H_5I + I^{\bullet} \qquad (17)$$

Exchange *via* reaction (16) and (17) would require a first order dependence on the iodine concentration.

It may be pointed out that although the contribution of a reaction such as (17) is considered to be negligible during the exchange, the reaction can occur under appropriate conditions, the iodine then acting as a radical trap [57].

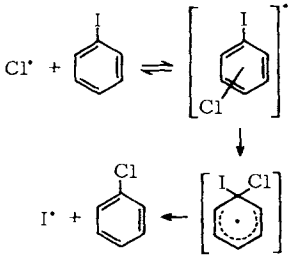
The displacement of iodine by chlorine or bromine atoms under illumination has also been studied.

$$Ar{-}I + Cl^{\bullet} \rightarrow ArCl + I^{\bullet} \quad (18)$$

$$Ar{-}I + Br^{\bullet} \rightarrow ArBr + I^{\bullet} \quad (19)$$

The reactions proceed smoothly in carbon tetrachloride or other inert solvents at room temperature on illumination with visible light, but do not take place at a noticeable rate in the dark. When a substituent is present, the entering halogen atom invariably occupies the position of the atom displaced. Dissociation of iodoarene followed by subsequent reaction with the halogen, or a mechanism involving a displacement on halogen to give an aryl radical are considered to be unlikely; direct displacement on carbon is favored. This may proceed through the formation of a π- or σ-complex intermediate[54]. Formation of complexes between aromatics and halogen atoms is indirectly supported by the selectivity studies of *Russell*[55] and *Walling* and *Mayahi*[56].



3.9. Abstraction Reactions

Replacement of iodine by hydrogen has been effected by conducting the photolysis in cyclohexane[3] or methanol[53]; in most cases the yield is good[53]. Water, methyl iodide, and dimethoxymethane were also identified among the reaction products. The following sequence of reactions has been proposed for the reductive de-iodination process.

$$ArI \rightarrow Ar^{\bullet} + I^{\bullet} \quad (20)$$

$$Ar^{\bullet} + CH_3OH \rightarrow ArH + {}^{\bullet}CH_2OH \quad (21)$$

$${}^{\bullet}CH_2OH + I \rightarrow (ICH_2OH) \rightarrow HI + H_2C{=}O \quad (22)$$

$$CH_3OH + HI \rightarrow CH_3I + H_2O \quad (23)$$

$$H_2C{=}O + 2\,CH_3OH \rightarrow H_2C(OCH_3)_2 + H_2O \quad (24)$$

These reactions especially when perdeuterioacetone is used as a solvent provide a general synthesis of specifically labeled deuterium compounds from iodo precursors.

The photolysis of chloro or bromo compounds under conditions where exchange of hydrogen for halogen can occur was reported by *Szychlinski*[58].

Using a procedure similar to that of *Bridger* and *Russell*[59], photolysis of 4-iodobiphenyl in a mixture of benzene and other solvents containing hydrogen has been initiated. The purpose of such a study is to compare the hydrogen-donating abilities of various solvents. Preliminary studies show that the differences in hydrogen-donating abilities of the various solvents can be demonstrated, *e.g.* with methanol and cyclohexane, but further study is required before quantitative predictions can be made.

When the photolysis of 4-iodobiphenyl is carried out in carbon tetrachloride, 4-chlorobiphenyl is formed. However, the yield of this product diminishes as the photolysis progresses, probably because Cl or CCl_3 (which are present under conditions of photolysis) attack 4-chloro- or 4-iodobiphenyl converting them into other products. Bromine can also be abstracted when bromoform is used as the solvent in the photolysis. The yield of the bromobiphenyl was 93 %, and only about 1 % of hydrogen abstraction takes place, as measured by biphenyl formation[60]. This result is in excellent agreement with the findings of *Cadogan et al.*[66], who studied the similar reaction with bromoform of the thermally generated phenyl radical from benzoyl peroxide.

3.10. Synthesis of Organometallic Compounds

Formation of organometallic compounds by the attack of organic free radicals on a suitable substrate is known. The availability of a variety of free radicals by the photolyses of aryl iodides offers an attractive route for such syntheses and it has been effectively utilized in the synthesis of organophosphorous and organoboron compounds. *Griffin* and co-workers[61,62] have shown that the photolysis of iodobenzene, in a three- to five-fold excess of trimethyl phosphite at $-3\,^{\circ}C$, yields dimethylphenylphosphonate in quantitative yield. A mechanism involving the attack of phenyl radical on trimethyl phosphite has been proposed.

$$\begin{aligned} C_6H_5I &\xrightarrow{h\nu} C_6H_5^{\bullet} + I^{\bullet} \\ C_6H_5^{\bullet} + P(OR)_3 &\longrightarrow C_6H_5P^{\bullet}(OR)_3 \\ C_6H_5P^{\bullet}(OR)_3 + I^{\bullet} &\longrightarrow [C_6H_5P(OR)_3]^{\oplus}I^{\ominus} \\ [C_6H_5P(OR)_3]^{\oplus}I^{\ominus} &\longrightarrow C_6H_5P(O)(OR)_2 + RI \\ R = CH_3 & \end{aligned} \quad (22)$$

The phosphonium salt *(22)* has been isolated. Vinyl iodide has also been shown to undergo photolysis with formation of dialkyl vinyl phosphonate.

Recently *Drawe* and *Caspari* [63] have shown that gamma-irradiation (Co-60 source) of mixtures of aryl halides with triphenylphosphine or triphenylarsine gives phosphonium or arsonium halides. Although photolyses of aryl iodides have not been carried out in the presence of triphenylarsine, formation of arsonium iodides, and hence of carbon-arsenic bonds, in this manner should be feasible. Photolysis of iodobenzene with phosphorous trichloride and tribromide is reported to give phenylphosphorous dichloride and the dibromide, respectively, after irradiation for 50–53 hours [20].

It was found by *Bowie* and *Musgrave* [20] that photolysis of iodobenzene in the presence of boron halides results in the formation of phenylboron dihalides and diphenylboron halides by free-radical substitution reactions. Hydrolysis of the products gives the corresponding boronic or borinic acids, the yields decreasing in the series $BI_3 > BBr_3 > BCl_3$. Boron tribromide is used most frequently; and by using suitable iodo compounds a variety of boronic and borinic acids or anhydrides has been obtained. There is also some evidence that BBr_2 radicals are also present in the above photolyses.

The reaction of 1-iodonaphthalene gives rise to a 2-naphthyl derivative that is formed by rearrangement of the 1-naphthyl radical or of the intermediate 1-naphthylboron dibromide. The rearrangement of the 1-naphthyl radicals seems ruled out, particularly in view of the study of *M. S. Kharasch* and *Danenberg* [64], who found that isomerization of this radical to 2-naphthyl radical does not occur in boiling carbon tetrachloride. Since it is known that ionic paths are available for isomerizations of 1-naphthyl to 2-naphthyl compounds, it seems that such a path may be involved for the rearrangement of 1-iodonaphthalene or of 1-naphthylboron dibromide under the conditions of the experiment.

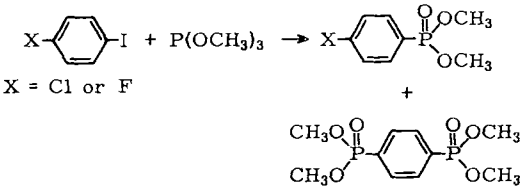
Bowie and *Musgrave* [20] also attempted the photolysis of iodobenzene in the presence of silicon tetrabromide or stannic bromide but could not isolate any definitive products.

3.11. Photolysis of Other Halides

As the strength of the carbon-halogen bond increases, the photolysis is expected to proceed with increasing difficulty. This is borne out by the results of the photolysis of 4-halobiphenyls [65]. Whereas the photolysis of 4-iodobiphenyl is more than 90 % complete, under the same conditions 4-fluorobiphenyl and 4-chlorobiphenyl decompose only to the extent of 1–2 %. 4-Bromobiphenyl, however, photolyzes to the extent of 70–80 %, under conditions where 4-iodobiphenyl photolysis is essentially complete, to yield the following products: *p*-terphenyl, biphenyl, and hydrogen bromide (20–30 %), and bromobenzene (1 %). Recently, *Matsura* and *Omura* have been able to obtain biphenyl derivatives in 20–40 % yields by photolysis of variously substituted bromobenzenes in benzene [68]. (The photolysis of chloro- and bromoarenes under reductive conditions [58] was mentioned in Section 3.9.)

A recent report by *Joschek* and *Miller* [69] indicates that a steady irradiation of 4-bromophenol in deaerated water with a low-pressure mercury-vapor lamp gives 4,4'-dihydroxybiphenyl and hydroquinone. Similar results are obtained with 2- and 3-bromophenols.

Although there is little significant photochemical cleavage of C–Cl and C–F bonds in aryl halides, *Obrycki* and *Griffin* have reported that photolysis of *p*-chloroiodobenzene and *p*-fluoroiodobenzene in the presence of trimethyl phosphite gives an appreciable amount of *p*-phenylenebisphosphonate *(23)* as well as the expected *p*-chlorophenyl-or *p*-fluorophenylphosphonate.



(23)

This unexpected lability of the carbon-chlorine and carbon-fluorine bonds has been ascribed to the activating influence of the dimethoxyphosphono group in the *ortho* or *para* position [70].

The predominant process in the photolysis of oxygen-free aqueous solutions of fluorobenzene is the one that leads to the disappearance of the absorption band of fluorobenzene in the 260 nm region. This photochemical change has a quantum yield of 0.2 and is almost entirely reversible on admission of oxygen. A similar phenomenon is observed in ethanol or *n*-heptane solutions. The quantum yield of the process has a first-order dependence on concentration. In view of these results, formation of a dimer has been proposed [71]. It is interesting to note that vapor-phase photolyses of hexafluorobenzene has been reported to give hexafluoro(Dewar benzene) [72, 73].

The authors wish to thank the National Science Foundation and the National Institutes of Health for support of their studies on photolysis of iodoaromatic and related compounds. One of us (R.K.S.) is also indebted to the Intra-Science Research Foundation for a study grant for the academic year 1966–1967.

The Cool Flames of Hydrocarbons

BY A. FISH [*]

This review describes the properties of the cool-flame and two-stage ignition processes that characterize the gaseous oxidation of hydrocarbons and discusses the chemical reactions that are responsible for these phenomena. Cool flames result from a chain-thermal acceleration of reaction rate. It is probable that the free-radical chain involved is propagated by the reaction of an alkyl radical with oxygen to give an alkylperoxy radical which isomerizes to a hydroperoxyalkyl radical. The decomposition of this radical produces a hydroxyl radical, which attacks the hydrocarbon rapidly and unselectively to regenerate an alkyl radical. Branching probably results from the pyrolysis of mono- and dihydroperoxides, from the oxidation of aldehydes, and from radical-molecule reactions. This reaction scheme explains the existence of a low-temperature ignition peninsula and the relation of the extent and shape of this peninsula to the molecular structure of the hydrocarbon. The chemical relevance of cool flames to abnormal combustion phenomena, such as knock, in gasoline engines is discussed.

1. Introduction

The gaseous oxidation of a hydrocarbon is a complex free-radical chain reaction which involves a multiplicity of chain carriers and branching agents with widely different lifetimes and modes of reaction. The resulting variation with temperature and pressure of the reaction rate leads to a complex pressure/temperature ignition profile that exhibits distinct high-temperature and low-temperature regions with an intermediate region of negative temperature coefficient of reaction rate.

The low temperature region of ignition is associated with cool flames; in this region, ignition is a two-stage process, the propagation of a cool flame being followed by that of a hot flame. These two stages are evident both in "static" experiments, in which the two flames pass in succession through the stationary mixture of gases, and in flow experiments, in which each flame can be stabilized at a given point in a flowing gas. In the latter type of experiment, the cool flame appears as a pale blue reaction zone upstream from the bright hot flame; it exhibits many of the properties of a true flame. In static experiments, at pressures too low for ignition, cool flames still propagate; the properties of these flames are continuous across the ignition boundary [1,2] showing that the isolated cool flame and the first stage of two-stage ignition are one and the same phenomenon. In contrast, ignition in the high-temperature region is a one-stage process; no cool flame precedes the hot flame and no cool flames propagate at pressures too low for ignition.

In addition to being readily distinguished from one-stage ignition, the region of cool-flame and two-stage ignition may itself be divided into several parts. The pressure/temperature locus of the limiting condition for ignition exhibits fine structure. As temperature is increased, the necessary pressure for ignition passes through several minimum and maximum values; the region surrounding a particular minimum is referred to as a "lobe". The existence of several lobes shows that the cool-flame region is a very complex kinetic system, several successive increases and decreases of reaction rate occurring within a quite narrow temperature region. Further evidence of this kinetic complexity is provided by the formation of periodic cool flames. In fuel/oxidant mixtures of suitable pressure, temperature, and composition, several cool flames may propagate, one following another after a discrete time interval during which little non-isothermal reaction occurs. Cool-flame reaction is, therefore, one of the few examples of periodic phenomena in chemistry.

The régime of two-stage ignition is of considerable practical significance. It is established [3] that a close qualitative relationship exists between the tendency of a pure hydrocarbon fuel to cause knock in an engine and the shape and extent of its low-temperature ignition profile.

2. The Properties of Cool Flames

2.1. The Pressure/Temperature Ignition Profile

The nature of the ignition profile of the oxidation of a hydrocarbon has been discussed in general terms in the Introduction. All the phenomena described are exemplified by the oxidation of 2-methylpentane [2], a typical alkane having primary, secondary, and tertiary C–H bonds. The pressure/temperature (p_o/T_o) ignition profile for the reaction of this alkane with twice the molar quantity of oxygen is shown in

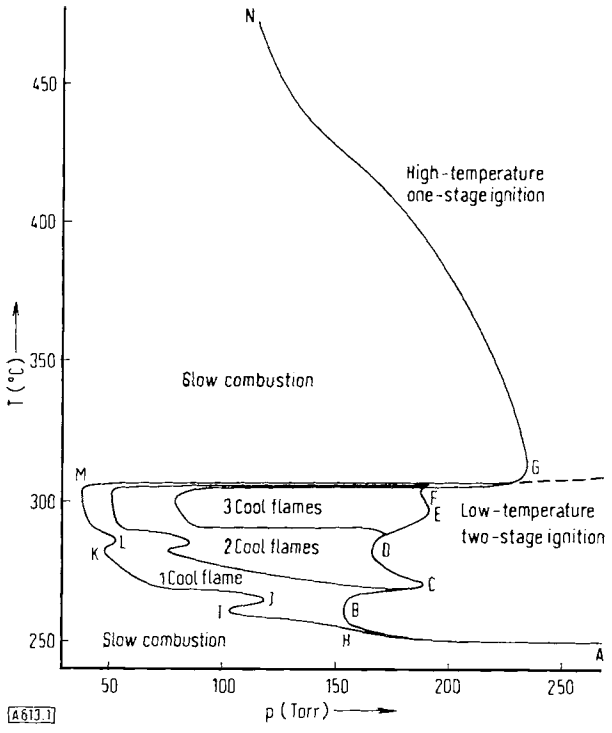

Fig. 1. Pressure/temperature ignition profile for 2-methylpentane/O_2 in a molar ratio of 1:2 (spherical Pyrex vessel of 450 ml capacity) [2].

Figure 1. Oxidation proceeds slowly and almost isothermally at temperatures below 250 °C.

The rate of reaction increases with temperature, and at 250 °C and at approximately 170 torr, is sufficient to lead to two-stage ignition; at lower pressures, cool flames propagate. This kind of behavior persists in the temperature range 250–307 °C, the low-temperature ignition peninsula (ABCDEFG, Figure 1) consisting of three lobes (ABC, CDE, and EFG). Similarly, three corresponding lobes (HIJ, JKL, and LMF) comprise the limiting condition for cool flames. Periodic cool flames are formed at sufficiently high temperatures and pressures within the cool-flame region. At 307 °C, the rate of reaction falls quite sharply with further increase of temperature, *i.e.*, the temperature coefficient of reaction rate is negative. As a result the limiting pressure for ignition increases sharply. As temperature is increased still further, the rate of reaction again increases but the resulting ignition (GN, Fig. 1) is one-stage.

The precise nature and position of the pressure/temperature ignition profile depend, of course, on the experimental conditions. The nature and amount of oxidant, the nature and extent of the surface, and the molecular structure of the fuel all affect the ease and extent of cool-flame reaction.

2.1.1. The Oxidant

Cool flames are formed during the oxidation of hydrocarbons in air or oxygen (and also during certain other reactions of hydrocarbons, such as nitration by nitrogen dioxide). The temperature range involved is, in general, slightly higher for the reaction of a given fuel with air than for reaction with oxygen, but the major difference between the two oxidants is the pressure range within which the limiting profiles of two-stage ignition and of cool flames lie.

Hydrocarbon/oxygen systems at suitable temperatures produce cool flames at pressures which can be as low as 0.05 atm. The minimum total pressure at which cool flames can be observed in 2:1 mixtures of oxygen with 2-methylpentane, for example, is 40 torr (Figure 1) while that in 4:5 mixtures of oxygen with hexane is 20 torr [4]. The limiting pressures even for two-stage ignition of such mixtures are much less than 1 atm, being about 155 torr and 175 torr respectively in these two cases. Cool flames are formed in hydrocarbon/air systems only at considerably greater pressures, however. Thus, for mixtures of air with pentane having $O_2:C_5H_{12} = 6.4:1$ (*i.e.* containing 0.8 × the stoichiometric quantity of oxygen) the lower pressure limit of cool flames is about 1 atm and of two-stage ignition is about 3.5 atm [5]. Mixtures of similar stoichiometry of the reactive fuel heptane with air [6] produce cool flames at about 100 torr total pressure but ignite only at pressures of about 1 atm.

Nevertheless, the cool flames of hydrocarbons in air and in oxygen are similar phenomena [7].

The properties of cool flames are affected not only by the nature of the oxidant but also by the amount. The mixture composition affects the cool flame intensity (defined in section 2.2.) which, in general, increases with the proportion of fuel present. This is to be expected from chemical considerations; the intensity is related to the amount of heat released and hence to the reaction rate of the oxidation. For hydrocarbons, this rate is a more sensitive positive function of fuel concentration than it is of oxygen concentration [8]. (It should be noted that for the oxidation of aldehydes, the opposite is true [1].)

Although the quantitative properties of cool flames are dependent upon the nature of the oxidant and the mixture composition, the basic chemical processes involved are independent of these factors, as is shown in Section 4.

2.1.2. The Surface of the Reaction Vessel

The nature and extent of reaction vessel surfaces have a profound effect on the rates of gaseous oxidation reactions. At low pressures, the predominant chain-termination steps in such reactions are heterogeneous, involving the removal at the wall of chain carriers and branching agents to give inactive products.

Thus, for example, it is well established that base- or salt-coated vessels destroy HO_2 radicals efficiently but boric acid-coated vessels do not [9]. Again, the destruction of hydrogen peroxide at the surface to give inactive products is inefficient

in a boric acid-coated vessel, having an activation energy of about 5 kcal mole^{-1}, but is much more efficient in copper vessels[10], in which the activation energy is less than 3 kcal mole^{-1}.

The natures and amounts of the minor products can also depend to a marked extent on the nature of the reaction vessel surface[11]. The extent of the vessel surface, which is usually expressed as the ratio of surface to volume, S/V, also affects the rate of these heterogeneous processes. Diffusion-controlled wall reactions have rate constants which depend on the inverse square of the effective radius of the vessel[12], whereas those of kinetically-controlled wall reactions depend on the inverse first power of the effective radius[13]. These wall effects can produce dramatic changes in ignition profiles.

The one-stage ignition limits of heptane depend on both the nature and the extent of the surface, the primary factor involved probably being the mode of control of the termination steps[10]. The cool flames of heptane are inhibited in vessels coated with lead oxide but are unaffected by potassium chloride coatings[14]; those of cyclohexane are inhibited by both boric acid and sodium hydroxide[15]. Again, multiple cool flames characterize the oxidation of butane by oxygen between 280 °C and 320 °C in a silica vessel but are strongly inhibited when the vessel walls are coated with metal oxides (PbO, NiO, Cu_2O, Fe_2O_3, Pb_3O_4) or metal halides ($MnCl_2$, $NiCl_2$, $CuCl_2$, $PbCl_2$, KCl, and KI)[16]. In the presence of these coated surfaces, the ignition limits are much higher than in silica vessels. The most effective inhibitor studied was lead oxide; there seems little reason to doubt that the mode of action involves an increase in the rate of heterogeneous chain termination or in the rate of heterogeneous destruction branching agents. In contrast, however, etching the Pyrex reactor with hydrofluoric acid and/or coating it with potassium chloride does not materially affect the cool flame region of the oxidation of 1:1 propane/oxygen mixtures[17].

Although the nature and extent of the vessel surface profoundly affect the morphology of the two-stage ignition region by altering the kinetic balance of the reactions involved, it seems likely[18] that they do not alter qualitatively the predominant chemical routes by which oxidation occurs.

2.1.3. The Molecular Structure of the Fuel

The profound effect of the molecular structure of a fuel on the ease with which cool flames are formed during its oxidation was evident from the first published study of these phenomena.

Perkins[19], in 1882, described the "blue lambent flames" which could be obtained in air from the vapours of certain organic fuels. He noted that as the molecular weight of a paraffinic fuel was increased, the tendency to give such flames increased. A similar result was obtained from a series of aliphatic acids, but no such flames could be obtained for simple aromatic hydrocarbons, aromatic acids, or phenols.

More recent studies have shown that the nature and position of the low-temperature ignition diagram is a sensitive function of molecular size and shape. The two-stage ignition limit (cf. curve ABCDEFG, Fig. 1) may be divided into a maximum of three lobes; for some hydrocarbons, certain of these are absent. In other words, the "fine structure" of the low-temperature ignition diagrams is related to molecular structure.

If the lobes are designated L_1, L_2, and L_3 in order of increasing temperature[3], *n*-alkanes with four or more carbon atoms exhibit all three lobes, although L_3 is sometimes ill-defined. Propane, however, shows two lobes only and the temperatures at which these occur show that they are L_2 and L_3. Ethane shows L_3 only and methane is unique in this series in possessing no low-temperature region. (Methane does exhibit a two-stage ignition limit at temperatures of *ca.* 500 °C[20] but the mechanism of this combustion is not the same as that of the low-temperature ignition of higher hydrocarbons[21].) Some branched-chain alkanes also have certain lobes absent.

Although 2-methylpentane and 2,2-dimethylbutane have all three lobes, isobutane exhibits L_2 and L_3 only, while 2,3-dimethylbutane shows no well-defined low-temperature ignition régime. Neopentane has L_2 and L_3 lobes but the latter is at a high temperature and is probably not a real lobe at all but corresponds to the two-stage ignition of methane[21].

Cyclic hydrocarbons also have "incomplete" diagrams. Cyclohexane exhibits only two lobes, as does methylcyclopentane; there is disagreement about the nature of the low-temperature ignition diagram of cyclopentane. It is difficult meaningfully to compare ignition diagrams for different hydrocarbons obtained under different conditions of oxidant, fuel:oxidant ratio, and vessel size and material.

The available data do suggest, however, that the complexity of the low-temperature ignition diagram varies with molecular structure in a systematic way and that it is not merely a function of experimental conditions. These data are summarized in Table 1.

The lower pressure/temperature limit of cool-flame formation (see curve HIJKLM, Fig. 1) also exhibits lobes. Fewer detailed studies of the relation of these to molecular structure have been made than for the ignition limit, but it seems likely that the numbers of lobes in the cool-flame limit and in the ignition limit correspond.

2.2. Pressure Change

The propagation of a cool flame in a reacting hydrocarbon-oxygen mixture is accompanied by a rise in pressure, Δp_{cf}. The use of transducers to detect this

pressure change is one of the most common methods of studying cool-flame reactions. If the gases behave ideally, the magnitude of this rise in a constant volume reactor is given by the equation

$$\Delta p_{cf} = p_o \left(\frac{\bar{n}\bar{T}}{n_o T_o} - 1 \right)$$

where p_o, T_o, n_o are the pressure, temperature, and molecular concentration of the unchanged mixture and $\bar{T}$, $\bar{n}$ are the mean temperature and molecular concentration at the instant when the pressure rise is Δp_{cf}.

At low concentrations of oxidant, the pressure falls, after the cool flame has passed, to a value only slightly greater than the original value, p_o (Fig. 2a); in other words, $\bar{n}$ is not significantly greater than n_o and the transient pressure rise is

largely due to the exothermic character of the reaction ($\bar{T} > T_o$). At higher oxidant concentrations, however, Δp_∞ is quite large (Fig. 2b); it is evident that both $\bar{n}$ and $\bar{T}$ exceed the values n_o and T_o.

If the pressure is sufficiently high, the passage of a cool flame may be followed by that of a hot flame, giving an overall pressure/time record as in Fig. 2c. The passage of the cool flame is followed by a further induction period and a rapid non-isothermal increase in pressure, which is defined as the hot flame. Subsequently the pressure falls exponentially from its maximum value until the contents of the reaction vessel are again in thermal equilibrium with their surroundings. The final pressure change, Δp_∞, is considerable, showing that a substantial increase in molecular concentration has occurred during hot ignition. If the pressure and temperature are sufficiently high, the "second-stage" induction period is so short that no intermediate decrease in pressure between the two stages of ignition is noticed (Fig. 2d).

For a given fuel and oxidant in a mixture of given stoichiometry the relationships between $\bar{n}$ and n_o and $\bar{T}$ and T_o will be functions of pressure; it should therefore be possible to express Δp_{cf} as a function of p_o alone. It has been shown [1,6] that the relation

$$\Delta p_{cf} = Cp_o + Kp_o^2$$

where C and K are constants, holds for iso-octane/air mixtures. Approximately, then,

$$\Delta p_{cf} = kp_o^m$$

where $1 < m < 2$ and k is constant. The accuracy of this empirical relationship is illustrated for 2-methylpentane/oxygen mixtures [2,18] in Figure 3, from which it is evident that for this system $m \simeq 1.65$. This value compares quite closely with that for the iso-octane/air system [6], for which $m \simeq 1.5$. Moreover, this kind of relationship holds not only for different hydrocarbon/oxidant systems under similar conditions but also for a given fuel under very widely different conditions (see Section 4).

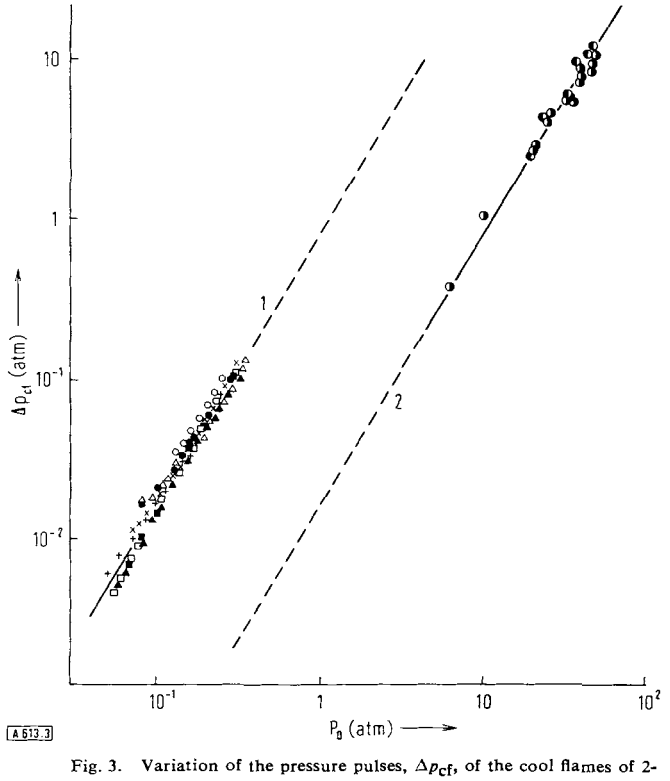

Fig. 3. Variation of the pressure pulses, Δp_{cf}, of the cool flames of 2-methylpentane with initial pressure p_o [18].

○, 260 °C; ●, 269 °C; ×, 275 °C; +, 282 °C;
■, 289 °C; □, 291 °C; ▲, 299 °C; △, 306 °C.

2: Rapid compression machine
◑, $RH:O_2:N_2 = 1:19:76$, 433 °C;
◐, $RH:O_2:N_2 = 1:30.6:122$, 457 °C.

The relationship between Δp_{cf} and p_o is a measure of the intensity I_{cf} of the cool flame:

$$I_{cf} = (p_o + \Delta p_{cf})/p_o$$

The intensities of cool flames in different hydrocarbon-oxidant systems are quite similar. For example, those of the first cool flame of heptane in air [34] are 1.04 to 1.35 while those for the first cool flame of 2-methylpentane in oxygen [2] are 1.1 to 1.4. The intensities of the second-stage hot flames, which may be defined similarly, have values from about 2.5 to 4.0 [2,34].

A further important parameter which may be derived from the pressure change accompanying the propagation of a cool flame is the maximum rate of pressure increase, $(dp/dt)_{max,cf}$. Whereas Δp_{cf} is not a good kinetic measure of the chemical reactions occurring during a cool flame, $(dp/dt)_{max,cf}$ is, because it is proportional to $(d\bar{T}/dt)_{max}$ (where T is the average temperature at time t) which is in turn related to the rate of liberation of heat per unit volume of the reactor and hence to the rate of chemical transformation [1]. It is likely, therefore, that if the complex low-temperature ignition limit is related to the rate of chemical transformation in the cool flame, it will be related to $(dp/dt)_{max,cf}$. This is indeed so [2,34]. For the first cool flame of the 2-methylpentane/oxygen system, for example, the variation of $(dp/dt)_{max,cf}$ with temperature and pressure exhibits a system of three "lobes", the positions of which correspond well with those of the lobes in the loci of the limiting conditions for ignition and for cool flames (Fig. 4). The complex dependence on p_o and T_o of the *limiting* conditions for igni-

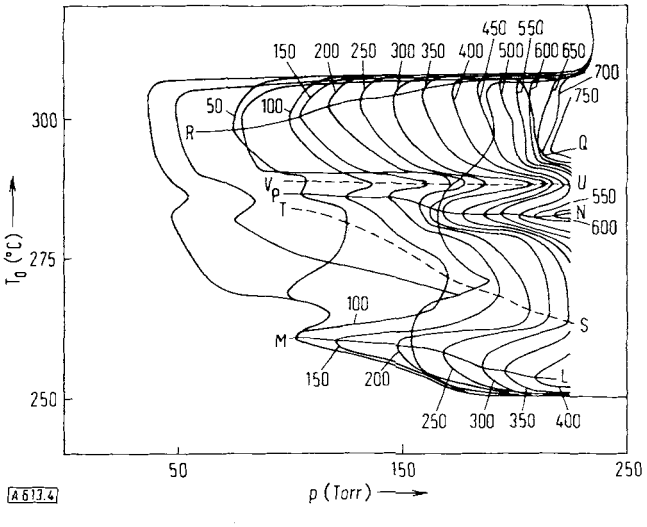

Fig. 4. Pressure/temperature "contour" map of the rate of pressure rise during the first cool flame in 2-methylpentane/oxygen ($RH:O_2 = 1:2$). LM, NP, and QR are loci of maximum rate; ST and UV are loci of minimum rate; contours are lines of equal rate (torr/sec) [2].

tion is closely related, therefore, to the rate of the overall chemical reaction responsible for the cool-flame step.

2.3. Induction Periods

The induction period for two-stage ignition is divisible into two parts, τ_{cf} and τ_{hf} (see Fig. 2c), the relative magnitudes of which depend on stoichiometry, pressure, and temperature.

Some authors [1] distinguish three stages, denoting τ_{cf} as the time from the completion of the filling of the vessel to the beginning of the sharp pressure rise, Δp_{cf}; the "second stage" is then the time for cool-flame propagation, *i.e.* the time elapsing during this sharp change in pressure, and the third stage is τ_{hf}. At low pressure, this alternative definition of τ_{cf} does not substantially affect its measured variations with the independent variables, as the time for cool-flame propagation is relatively small, corresponding to an average flame velocity of about 30 cm/sec, and does not vary markedly [1].

As p_o is increased at constant T_o, τ_{cf} becomes shorter, obeying the equation

$$\tau_{cf} = k' p_o^{-n} + c'$$

where n is positive and k' and c' are constants. This equation holds both at low [1,2,18] and at high [18,34] pressures. The value of n varies with T_o in a way that reflects the shape of the ignition limit [2,34]. At temperatures at which the limiting value of p_o for ignition is minimized, so is the value of n.

The effects of p_o and T_o on τ_{hf} are complex. Two factors may be distinguished, *viz*: the effects of p_o and T_o themselves on the second-stage ignition process and their effects on cool-flame intensity which cause the actual values of pressure and temperature under which the second stage occurs to vary. In general, the second effect is more important at the lower temperatures within the two-stage ignition régime (*i.e.*, where Δp_{cf} is highest [2]) and the first effect more important at higher temperatures [1].

At high pressures, for iso-octane cool flames [34], τ_{hf} is related to p_o by a power law similar to that which holds for τ_{cf} and, for hot flames, n also exhibits maximum and minimum values as T_o is altered. The temperatures at which these values occur, however, are not identical with those at which n for cool flames exhibits turning values. For the cool flames of hexane at high pressures [37], τ_{cf} depends primarily on temperature and τ_{hf} primarily on pressure. The variation of $\ln\tau_{cf}$ with $1/T_o$ has been used to calculate an "effective activation energy", E_{eff}, for the cool flame process [1,34]. In the case of many fuels, this plot is linear over a considerable range of temperature and the values of E_{eff} obtained correlate quite well with the octane numbers of those fuels [1]. In other cases, however, the plot of $\ln\tau_{cf}$ against $1/T_o$ is non-linear [2,34]. In view of the chemical complexity of the overall cool flame process, the precise significance of E_{eff} is not clear.

[37] *W. Jost* and *A. Martinengo*, Soc. of Automotive Engineers Mid-year Meeting, Detroit 1966, paper 660347.

2.4. Temperature Change

As has been mentioned, the pressure increase attendant upon the passage of a cool flame is associated with an increase in the temperature of the gases due to the heat liberated by their chemical reaction. In a "static" reactor, this temperature increase can be measured directly by suitably positioning the hot junction of a thermocouple in the reactor and comparing the output of this with that of a second thermocouple, the hot junction of which is maintained at the temperature of the reactor wall [38,39]. Similarly, in a flow system, the difference in temperature of the inlet and exhaust gases can be measured [40]. This thermometric technique is a useful one for distinguishing cool-flame reaction from slow combustion; although slow combustion is not entirely isothermal, the rate of temperature change is much less than that of cool-flame reaction. The variation of ΔT with T_o exhibits a sharp maximum in the cool-flame region [40]; at a given temperature T_o,

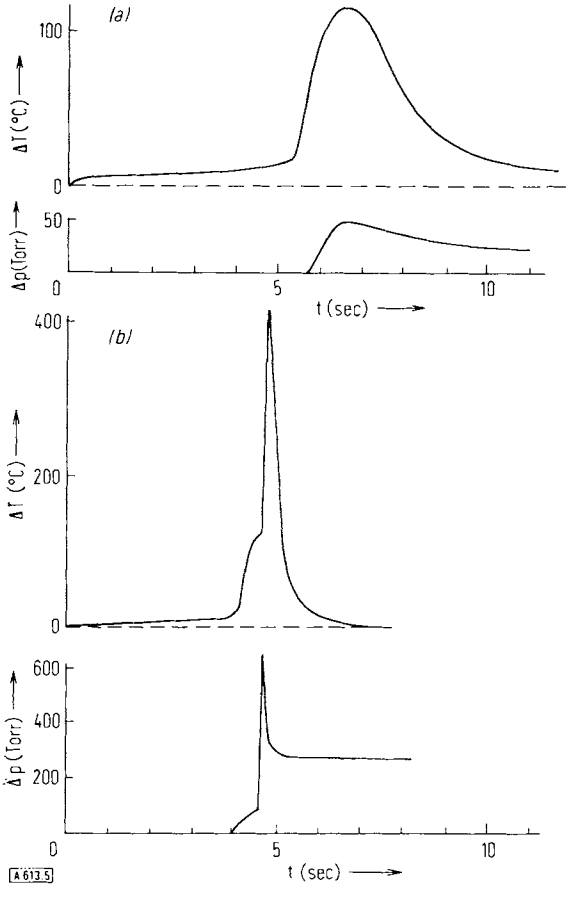

Fig. 5. Changes in pressure and temperature during the oxidation of neopentane (T_o = 310 °C, RH:O_2 = 1:2).
(a) Cool flame reaction at p_o = 200 torr;
(b) Two-stage ignition at p_o = 260 torr [33].

[38] *M. Vanpée*, Bull. Soc. chim. Belgique *64*, 235 (1955).
[39] *R. H. Burgess* and *J. C. Robb*, Trans. Faraday Soc. *54*, 1015 (1958).
[40] *G. H. Meguerian*, J. physic. Chem. *67*, 1020 (1963).

ΔT_{cf} varies with the reactant concentrations according to the equation

$$\Delta T_{cf} = k''[RH]([O_2] - [O_2]_c)$$

where $[O_2]_c$ is a critical concentration of oxygen below which non-isothermal reaction does not develop.

As would be expected, the changes in temperature and in pressure during the propagation of a cool flame and of two-stage ignition run closely parallel (Fig. 5) [33]. At low concentrations of oxidant, comparison of the measured ΔT_{cf} with that calculated from Δp_{cf} using the ideal gas law and assuming negligible change in molecular concentration gives agreement within 15%.

The magnitude of ΔT_{cf} varies from about 10 °C to about 200 °C, being higher for fuel/oxygen mixtures than for fuel/air mixtures because of the lower thermal capacity per mole of fuel of the former. For a given system, ΔT_{cf} is highest at high pressures but low temperatures.

It has been suggested that low-temperature two-stage ignition results solely because the increase in temperature ΔT_{cf} raises the temperature of the reacting mixture so that it reaches the high-temperature one-stage ignition curve GN (Figure 1). If this were so, GN would describe the pressure locus of $(T_o + \Delta T_{cf})$ for reactions of which the T_o/p_o relationship is BCDEFG. In fact, the locus of $(T_o + \Delta T_{cf})$ generally lies above GN; it would appear that the thermal effect of cool flames on the conditions for the second-stage ignition is considerable but that there is a marked chemical effect too.

2.5. Light Emission

The passage of a cool flame is accompanied by the emission of light [41]. The detection of this radiation, with the aid of a photomultiplier, has been used as a diagnostic test of cool-flame formation [42,43], although a faint light emission may accompany slow combustion also [44]. The source of this chemiluminescence is excited formaldehyde [45–47]. It is very difficult to envisage a radical-molecule reaction which would give formaldehyde with an energy of 77 kcal mole^{-1} in excess of the ground electronic state. It is likely, therefore, that a radical-radical reaction is involved. Studies of the thermal decomposition of alkyl nitrites and nitrates [48] have suggested that alkoxy radicals are involved; a possible reaction is

$$RCH_2O^{\bullet} + {}^{\bullet}OH \rightarrow H_2CO^{*} + ROH, \quad \Delta H = -75 \text{ kcal mole}^{-1}.$$

As the concentrations of radicals in cool-flame systems are fairly low, it would be expected that radical-radical reactions would be infrequent. It is consistent with this that the extent of the conversion of fuel to excited formaldehyde in the cool flame is very low indeed. During the oxidation of butane [42] about 5×10^{15} molecules react per quantum emitted; the corresponding figure during the oxidation of acetaldehyde is 3×10^6 molecules/quantum [49]. The light emission from cool flames is unlikely, therefore, to provide information regarding the nature of the major chemical paths by which the fuel is oxidized.

An interesting, recently discovered aspect of light emission during hydrocarbon oxidation occurs during slow combustion of mixtures in which the mole fraction of oxygen is low, at temperatures just too low for cool-flame formation. A sudden acceleration of the variation of pressure with time occurs [26,50] in the last stages of the slow oxidation. Simultaneously, a sharp jump in the emission of light occurs [43,50] (the *pic d'arrêt*) after which the reaction stops very quickly. The *pic d'arrêt* is probably due to radical-radical reactions when the oxygen is nearly all consumed.

2.6. The Chemical Products of Cool Flames

Oxidation in the cool-flame region is a very unselective process, producing a wide variety of stable or moderately stable products. It has been shown gas-chromatographically that the products of alkane cool flames include alkenes, alcohols, saturated and unsaturated aldehydes and ketones, and O-heterocyclic compounds (Table 2) [51].

A further class of compounds which are important in cool-flame products is that of the organic peroxides. Although some of these can be analyzed satisfactorily by gas chromatography [52], it is difficult to effect an estimation under conditions that are suitable for analyzing products with other functional groups. Peroxides have usually been analyzed, therefore, by chemical means or by paper chromatography. The latter technique [53] has shown that, in addition to alkyl monohydroperoxides, peracids, and hydrogen peroxide, the products of oxidation in the cool flame region contain unsaturated hydroperoxides [15] and alkyl dihydroperoxides [14]. This last class of compounds can, indeed, become the major peroxidic

component of the product mixture [14]. In addition to the many organic products of cool-flame oxidation, oxides of carbon and water are formed, the amounts increasing with the availability of oxygen.

The natures of the products do not change suddenly at the boundaries between slow combustion and cool flames but change gradually with experimental conditions.

Thus, in the oxidation of 2-methylpentane [51], the yield of titratable peroxide is high during slow combustion at low temperatures (near H, Fig. 1) but decreases along HIJKLM, being very small at M. The yields of certain other products are, however, low in low-temperature slow combustion but increase with temperature and reach maximum values in the cool-flame region. In the oxidation of hexane, the yields of 2,5-dimethyltetrahydrofuran, 2-ethyl-4-methyloxetane, and 2-methyl-3-propyloxirane all maximize under cool-flame conditions [4] (Fig. 6).

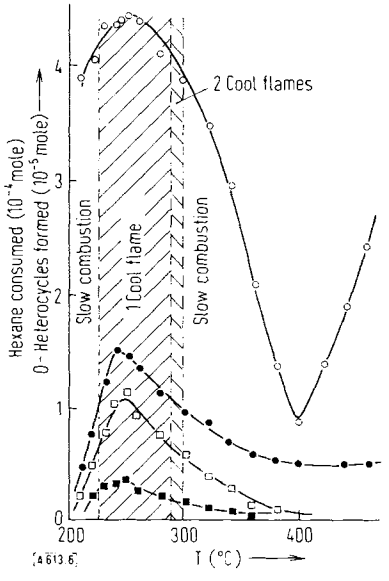

Fig. 6. Amount of fuel consumed during the oxidation of hexane with oxygen (75:60 torr) and yield of O-heterocycles as a function of temperature.
○, *n*-hexane; ●, 2,5-dimethyltetrahydrofuran;
□, 2-ethyl-4-methyloxetane; ■, 2-methyl-3-*n*-propyloxirane [4].

Even within the cool-flame region itself, significant changes in the relative yields of various products occur with change in temperature and can be tentatively related to the fine structure of the region. These variations thus provide a clue to the nature of the subtile mechanistic changes which lead to the formation of several lobes (Fig. 7) [51]. The reactions leading to a given product can be assigned to a given lobe (or lobes). Thus, in Figure 7, reactions producing 2,4-dimethyltetrahydrofuran are most important in lobes

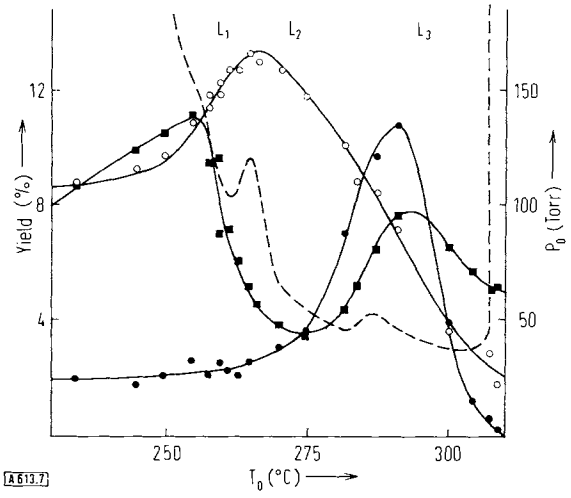

Fig. 7. Examples of the yields of products from slow combustion just outside the cool flame limit in 2-methylpentane/O_2 (1:2).
○, 2,4-dimethyltetrahydrofuran; ●, 2,2-dimethyl-3-ethyloxirane(×10); ■, acetone; – – – p_0/T_0 locus of cool flame limit (HIJKL, Fig. 1) [51].

L_1 and L_2, those producing 2,2-dimethyl-3-ethyloxirane are most important in L_3, and those producing acetone in L_1 and L_3.

At temperatures above the maximum temperature for cool-flame formation, the yields of oxygenated organic products gradually decrease while those of alkenes and of hydrogen peroxide increase.

The products of ignition are very different from those of cool flames. During the highly exothermic second stage of ignition, the wide variety of oxygenated products produced in the cool-flame stage is largely destroyed. The concentrations of water, of oxides of carbon, and of certain hydrocarbons of low molecular weight increase, however. In fuel-rich mixtures, extensive cracking of the excess fuel occurs, giving high yields of simple aliphatic and of aromatic hydrocarbons and, in very rich mixtures, depositing soot.

Techniques, such as electron paramagnetic resonance spectroscopy, for identifying and estimating radicals in the gas phase are as yet insufficiently sensitive to deal with the low radical concentrations and complex mixtures found in the early stages of hydrocarbon oxidation. Indirect evidence, based upon the natures of the more stable products and on known modes of radical reaction to give such products, suggests strongly, however, that chain reactions involving alkyl, alkylperoxy, hydroperoxyalkyl, and hydroxyl radicals are important in the cool flame region.

2.7. The Periodicity of Cool Flames

Multiple cool flames have often been observed at pressures below those necessary for two-stage ignition. These non-isothermal events occur at intervals during an otherwise isothermal oxidation reaction. As many as seven successive cool flames have been observed during the oxidation of propane [24,50]; similarly, the oxidations of pentane [50] and butane [25] are characterized by a maximum of five cool flames. Other fuels for which multiple cool flames have been observed include hexane [4], heptane [14], 2-methylpentane [2], acetaldehyde [54], and butanone [55].

Periodic phenomena of this sort are rare in chemistry [56] and are not well understood. It has been commonly supposed that a cool flame occurs when some intermediate product reaches a critical concentration [57]; the concentration of the product involved should decrease precipitously during the passage of the cool flame. Peroxides do indeed exhibit this behavior in some systems [15,25,51,55]; dihydroperoxides, for example, are the major peroxidic product of the pre-cool-flame reaction of heptane with an equimolar quantity of oxygen at 160 torr and 255 °C, but are completely destroyed when the cool flame passes [14]. As these compounds have been considered to be the agents of degenerate branching of slow combustion at relatively low temperatures, it appears that cool flames are mechanistically similar to slow combustion and should not be regarded as side processes. Aldehydes, which also act as agents of degenerate branching during hydrocarbon combustion, are similarly instrumental in the formation of cool flames [58–60]. It seems, then, that the normal course of slow combustion can lead to a non-isothermal event and that this can occur several times in the same system. Two explanation of this have been advanced.

The "chain-thermal" theory [12,61] attributes the oscillations to the effect of the rise in temperature resultant from the cool flame on the rates of formation and destruction of a single intermediate (X) [55,58,59].

This intermediate product X can lead, under suitable conditions of p_0 and T_0, to multiple cool flames if its formation and destruction reactions, *viz.*

$$\text{reactants} \xrightarrow[E_1]{\Delta H_1} \text{X}$$

$$\text{X} \xrightarrow[E_2]{\Delta H_2} \text{products}$$

are such that $\Delta H_2 > \Delta H_1$ and $E_2 > E_1$. As X accumulates, the second reaction becomes more rapid; this increases the rate of liberation of heat and hence increases the temperature. The second reaction is therefore accelerated relative to the first, as $E_2 > E_1$, and [X] falls. When [X] becomes small, the temperature falls again and the first reaction is accelerated relative to the second leading to another increase in [X], and so to a periodic thermokinetic phenomenon.

The alternative explanation is that odd-numbered cool flames and even-numbered cool flames are due respectively to the production of critical concentrations of different intermediate products X and Y, each of which is involved in branching reactions [12,62]. This "two-product" explanation is therefore purely kinetic.

The necessary reaction scheme

$$\text{A} + \text{X} \xrightarrow{k_3} \text{B} + 2\,\text{X},$$

$$\text{X} + \text{Y} \xrightarrow{k_4} \text{B} + 2\,\text{Y},$$

$$\text{A} + \text{Y} \xrightarrow{k_5} \text{B}$$

(where A and B represent reactant and final product respectively) gives the rate equations

$$\mathrm{d}[\mathrm{X}]/\mathrm{d}t = k_3[\mathrm{A}][\mathrm{X}] - k_4[\mathrm{X}][\mathrm{Y}],$$

$$\mathrm{d}[\mathrm{Y}]/\mathrm{d}t = k_4[\mathrm{X}][\mathrm{Y}] - k_5[\mathrm{A}][\mathrm{Y}].$$

When [X] reaches the critical value $k_5[\mathrm{A}]/k_4$, $\mathrm{d}[\mathrm{Y}]/\mathrm{d}t$ becomes positive and [Y] increases at the expense of [X]. When [Y] in turn reaches the critical value $k_3[\mathrm{A}]/k_4$, $\mathrm{d}[\mathrm{X}]/\mathrm{d}t$ becomes negative and [X] will eventually fall below the value $k_5[\mathrm{A}]/k_4$. [Y] will then begin to fall in turn and when [Y] becomes less than $k_3[\mathrm{A}]/k_4$, [X] will rise again. If, therefore, the criterion for the first, third, *etc.* cool flames is that [X] exceeds a critical value and for the secund, fourth, *etc.* is that [Y] exceeds a critical value, the periodic phenomenon is explicable. It has been suggested [62,63] that the reaction X + Y → B + 2 Y is a condensation reaction which catalyzes the decomposition of hydroperoxide (X) to aldehyde (Y).

It is noteworthy that each of these explanations depends on the competition between two reactions, the first being dependent on the relative magnitudes of E_1 and E_2 and the second on those of k_3 and k_5. If, indeed, Y could be associated with the heat evolved by the reactions of X [64], the two theories could become quite similar. Neither of these theories explains satisfactorily all the features of cool-flame periodicity.

The two-product theory does not show why periodic phenomena occur in non-isothermal regions of oxidation but not in isothermal ones. The chain-thermal theory, however, demands that, owing to the gradual consumption of reactants,

the intensities of successive cool flames must decrease, whereas the two-product explanation demands only that those of odd-numbered cool flames decrease and that those of even-numbered cool flames decrease. In certain systems, the "two-product" explanation of cool flames is supported by the fact that successive cool flames are not equivalent. Thus, for example, during the non-isothermal oxidation of butane[25], the passage of the second cool flame at 284 °C is accompanied by a precipitous decline in the concentration of peroxides, whereas that of the first cool flame is not. Again, comparison of the decreases in concentrations of products during the passage of each cool flame of 2-methylpentane[51] suggests that some are associated with reactions of peroxides and others with reactions of aldehydes.

3. Mechanism of Cool-Flame Formation

3.1. Elementary Steps in the Gaseous Oxidation of Hydrocarbons

The slow oxidations of hydrocarbons, in both gaseous and liquid phases, are the best-known examples of degenerately branched chain reactions. In such reactions, the four kinds of step involved are initiation, propagation, termination, and branching. If the branching process is to be truly degenerate, then the reciprocal of Φ (the net branching factor) must exceed the average lifetime of the chain-carrying radicals, *i.e.* branching must be slow. Hydrocarbon oxidation is thus characterized by very slow initiation, a reasonably rapid primary linear chain process leading to a metastable product P (the agent of degenerate branching), and slow breakdown of, or further reaction of, P to branch the chain. When the reaction conditions are such that Φ exceeds zero (or, more accurately, a small positive value, in order to overcome reactant consumption) the concentrations of chain carriers will increase exponentially and the mixture will increase in temperature, leading to chain-thermal ignition. At low temperatures, the first non-isothermal stage of such ignition is cool-flame reaction.

3.1.1. Initiation

The initial attack on saturated hydrocarbons by oxygen usually involves the abstraction of a hydrogen atom to yield an alkyl radical and a hydroperoxy radical:

$$RH + O_2 \rightarrow R^\bullet + HO_2^\bullet \qquad (1)$$

As the activation energies of such abstraction reactions are high (40–55 kcal mole^{-1}), they are both slow and selective. As would be expected from the strengths of C–H bonds in various intramolecular environments, the tertiary hydrogen atoms are by far the most vulnerable and the primary atoms are least readily attacked. Thus, the attack by oxygen on a typical hydrocarbon molecule such as isopentane, $(CH_3)_2CHCH_2CH_3$, produces a mixture of four alkyl radicals, but $(CH_3)_2\dot{C}CH_2CH_3$ predominates. These differences are most marked, of course, at low temperatures.

3.1.2. Propagation

Alkyl radicals may decompose, recombine, disproportionate, isomerize, or react with either fuel or oxygen. In the presence of large concentrations of oxygen, the last of these reactions is sufficiently rapid to occur to the virtual exclusion of the others. The first step in the interaction of $R^\bullet$ with O_2 must be the formation of some species which may be formally written as $R^\bullet....O_2$. This may be a fairly stable free radical which can exist for relatively long periods of time or it may be merely a collision complex which breaks down within the period of a single vibration. It is generally believed that at low temperatures (< 300 °C) $RO_2^\bullet$ radicals are quite stable but that at higher temperatures (> 400 °C) the initial collision complex breaks down almost immediately to give an HO_2 radical and an alkene. The competition between the reactions (2) and (3) is partly responsible for the observed influence of temperature on the pattern of product formation.

$$R^\bullet + O_2 \rightarrow RO_2^\bullet \qquad E = 0 \qquad (2)$$

$$R^\bullet + O_2 \rightarrow HO_2^\bullet + \text{alkene}, \quad E = 7\text{–}10 \text{ kcal mole}^{-1} \qquad (3)$$

The primary propagation process at low temperatures must be completed, therefore, by reactions of $RO_2^\bullet$ which lead eventually to the abstraction of hydrogen from another fuel molecule to regenerate an alkyl radical, $R^\bullet$. If the $RO_2^\bullet$ radicals formed at low temperatures have an appreciable lifetime, there are various fates which they can undergo.

The first of these is reaction (4) with the fuel to form a hydroperoxide; abstraction of tertiary hydrogen predominates as the activation energies for the rupture by $RO_2^\bullet$ of tertiary, secondary, and primary C–H bonds are 8, 10·5, and 14 kcal mole^{-1} respectively.

$$RO_2^\bullet + RH \rightarrow ROOH + R^\bullet \qquad (4)$$

This reaction is important in liquid-phase oxidation. In gas-phase oxidation, there is evidence for the formation of small amounts of ROOH from certain compounds RH[65,66] but such products may sometimes result from relatively unimportant side reactions and not from one of the main chain-propagation steps.

Thus, in the oxidations of ethane and isobutane[67,68] the corresponding hydroperoxides arise from the termination reaction (5),

$$RO_2^\bullet + HO_2^\bullet \rightarrow ROOH + O_2 \qquad (5)$$

and methyl hydroperoxide is formed during the oxidation of methane[69,70] by $CH_3O_2^\bullet$ radicals attacking formaldehyde

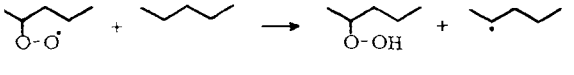
(and not methane). Furthermore, during the oxidation of isopentane no monohydroperoxides can be detected [71].

It is now generally believed that at fairly low temperatures $RO_2^{\bullet}$ radicals are formed which react further in such a way as to enable chains to be propagated without the $RO_2^{\bullet}$ radicals themselves reacting with a fuel molecule. Thus, they may isomerize by the transfer of hydrogen from a carbon atom to the outer oxygen of the peroxy group (reaction (6)).

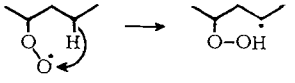
$$C_nH_{2n+1}OO^{\bullet} \rightarrow {}^{\bullet}C_nH_{2n}OOH, \quad E = 8\text{–}24 \text{ kcal mole}^{-1} \qquad (6)$$

This reaction is, in general, sufficiently rapid to compete successfully with intermolecular hydrogen abstraction at sub-atmospheric pressures and at temperatures of about 600 °K.

Consider, for example, the competition between reactions (4a) and (6a).



(4a)



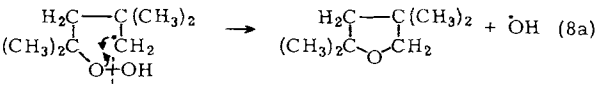
(6a)

The ratio of the rates of intramolecular and intermolecular H-abstraction by $RO_2^{\bullet}$ is $k_{6a}/k_{4a}[RH]$. When the partial pressure of RH is 200 torr, $[RH] = 10^{18.5}$ molecules cm^{-3}. If it is assumed that there is free rotation in the transition state of reaction (4a), $k_{4a} \simeq 10^{-13}e^{-10500/RT}$ cm^3 molecules^{-1} sec^{-1}. (If it is assumed that there is no free rotation, a considerably lower value is obtained.) As reaction (6a) involves transfer of secondary hydrogen around a six-membered ring, $k_{6a} \simeq 10^{11}e^{-11100/RT}$ sec^{-1}. At 600 °K, then, $k_{6a}/k_{4a}[RH] \simeq 10^{5.3}$ and intramolecular abstraction predominates. Even for less favored intramolecular H-transfer reactions, such as the transfer of the primary H around a five-membered ring, this ratio is as high as 10^2.

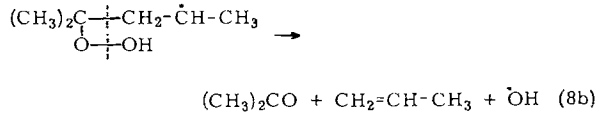
It has been amply demonstrated experimentally [4, 18, 51, 72–80] that this isomerization reaction is a major chain-propagating step during gaseous oxidation. Similarly, isomerization by transfer of an alkyl group occurs (reaction (7)) [51, 72, 77, 78], although this is much less common.

$$C_nH_{2n+1}OO^{\bullet} \rightarrow {}^{\bullet}C_{n-m}H_{2(n-m)}OOC_mH_{2m+1} \qquad (7)$$

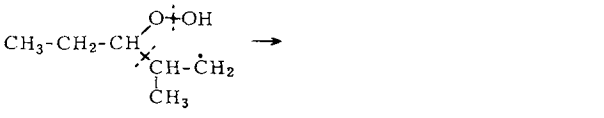
The hydroperoxyalkyl radical produced by reaction (6) may decompose in one of several ways or may react with further oxygen. The modes of decomposition of such radicals have been enumerated previously [51, 72]; only a few examples need be given here (reactions (8a)–(8e)).



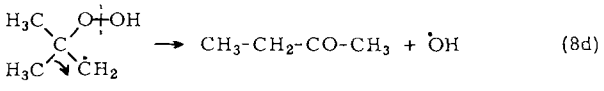
(8a)



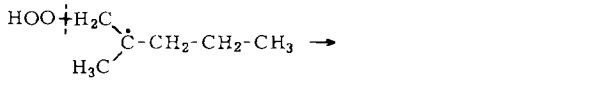
(8b)

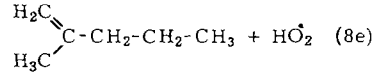


(8c)



(8d)





(8e)

It is evident from these examples that carbonyl compounds, alkenes and O-heterocycles (oxiranes, oxetanes, tetrahydrofurans, and tetrahydropyrans) are among the important products of decomposition of the hydroperoxyalkyl radicals. Moreover, as the O–O bond is the weakest in the decomposing radical, the radical usually (although not invariably) produced is the hydroxyl radical. The corresponding breakdown of the alkylperoxyalkyl radicals produced by the infrequent reaction (7) gives alkoxy radicals (and hence alcohols).

The hydroxyl radical attacks the hydrocarbon fuel molecule, abstracting a hydrogen atom to form water and thus regenerating an alkyl radical and completing the primary chain process. This abstraction reaction has a low activation energy (1–2 kcal mole^{-1}) [81]; attack by $^{\bullet}OH$ on the fuel molecule is, therefore, much less selective than attack by $RO_2^{\bullet}$ or $HO_2^{\bullet}$. When $^{\bullet}OH$ is the predominant chain-propagating entity, the formation of tertiary alkyl radicals will no longer predominate and the products of oxidation will include, in significant amounts, products of the further reaction of each possible alkyl radical derived from the fuel.

In oxidation régimes where isomerization is the usual fate of alkylperoxy radicals and decomposition of the

hydroperoxyalkyl radicals so formed occurs readily, the primary linear chain process may be represented:

$$C_nH_{2n+1}^{\bullet} + O_2 \rightarrow C_nH_{2n+1}OO^{\bullet} \quad (9a)$$

$$C_nH_{2n+1}OO^{\bullet} \rightarrow {}^{\bullet}C_nH_{2n}OOH \quad (9b)$$

$${}^{\bullet}C_nH_{2n}OOH \rightarrow \text{products} + {}^{\bullet}OH \quad (9c)$$

$${}^{\bullet}OH + C_nH_{2n+2} \rightarrow H_2O + C_nH_{2n+1}^{\bullet} \quad (9d)$$

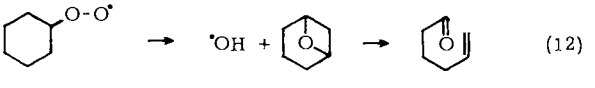
The further oxidation of hydroperoxyalkyl radicals, reaction (10), competes with their decomposition, becoming particularly important in the case of α-hydroperoxyalkyl radicals[51]; the hydroperoxyalkylperoxy radicals so formed may abstract hydrogen

$${}^{\bullet}C_nH_{2n}OOH + O_2 \rightarrow {}^{\bullet}OOC_nH_{2n}OOH \quad (10)$$

from a fuel molecule to give dihydroperoxides, propagating the chain, or may decompose to branch the chain. The formation of dihydroperoxides by a route involving intramolecular H-transfer is supported by the results of studies[14,82] in which a compound (HBr) with a readily-abstractable hydrogen was added to the system. Under these conditions, intermolecular H-transfer competes with intramolecular H-transfer, and monohydroperoxides, not dihydroperoxides, are formed.

Isomerization is not the only fate of alkylperoxy radicals during gaseous oxidation. In the presence of substantial amounts of alkenic products, addition of $RO_2^{\bullet}$ to these species may lead to oxiranes as products (*e.g.* reaction (11)) and it has been suggested[71,78] that $RO_2^{\bullet}$ may decompose without prior isomerization (*e.g.* reaction (12)).

$$RO_2^{\bullet} + R^1R^2C{=}CR^3R^4 \rightarrow R^1R^2\dot{C}\text{-}\underset{\underset{OOR}{|}}{C}R^3R^4 \rightarrow R^1R^2C\text{-}\underset{\diagdown O \diagup}{C}R^3R^4 + RO^{\bullet} \quad (11)$$



(12)

Each of these steps will also propagate the chain.

At higher temperatures, where alkyl radicals react with oxygen predominantly to give an olefin and an $HO_2^{\bullet}$ radical, some reaction of $HO_2^{\bullet}$ must be responsible for completing the primary chain. This radical abstracts a hydrogen atom from an alkane to give hydrogen peroxide (reaction (13));

$$HO_2^{\bullet} + RH \rightarrow H_2O_2 + R^{\bullet} \quad (13)$$

the activation energy has not been measured accurately but is probably[10,83] in the region of 6–14 kcal mole^{-1}. Attack of RH by $HO_2^{\bullet}$ is therefore more selective than attack by $^{\bullet}OH$ and, if reaction (13) becomes important at higher temperatures, the selectivity should increase with temperature.

It has been suggested[83], however, that the reaction of $HO_2^{\bullet}$ with alkenes (which are formed in the same propagation step as is $HO_2^{\bullet}$) to give α-hydroperoxyalkyl radicals is sufficiently rapid to become the major chain-propagating reaction of this radical in the temperature range 300–400 °C. The chain cycle (14) has thus been proposed[83]:

$$HO_2^{\bullet} + R_2C{=}CR_2 \rightarrow R_2\dot{C}\text{-}C(OOH)R_2 \quad (14a)$$

$$R_2\dot{C}\text{-}C(OOH)R_2 + O_2 \rightarrow R_2C(OO^{\bullet})C(OOH)R_2 \quad (14b)$$

$$HO_2^{\bullet} + R_2C(OO^{\bullet})C(OOH)R_2 \rightarrow R_2C(OOH)C(OOH)R_2 + O_2 \quad (14c)$$

$$R_2C(OOH)C(OOH)R_2 \rightarrow 2\,R_2CO + 2\,\dot{O}H \quad (14d)$$

$${}^{\bullet}OH + R_2CHCHR_2 \rightarrow R_2\dot{C}CHR_2 + H_2O \quad (14e)$$

$$R_2\dot{C}CHR_2 + O_2 \rightarrow R_2C{=}CR_2 + HO_2^{\bullet} \quad (14f)$$

In this cycle, $^{\bullet}OH$ is again the entity which attacks the fuel molecule and oxidation is unselective. It seems that unless (14d) is very fast step (14c) should properly be regarded as a termination step and step (14d) as a branching step, rather than each as a propagation step. This being so, scheme (14) does not represent a chain-propagation process but is merely a slow mechanism for conversion of $HO_2^{\bullet}$ to $^{\bullet}OH$. A true propagation process would result if the step (14g) were substituted for (14b–d) inclusive or if step (14h) were substituted for (14c–e) inclusive.

$$R_2\dot{C}\text{-}C(OOH)R_2 \rightarrow R_2C\text{-}\underset{\diagdown O \diagup}{C}R_2 + \dot{O}H \quad (14g)$$

$$R_2CH\text{-}CHR_2 + R_2C(O\dot{O})\text{-}C(OOH)R_2 \rightarrow R_2C(OOH)\text{-}C(OOH)R_2 + R_2\dot{C}\text{-}CHR_2 \quad (14h)$$

In this event, schemes resembling the propagation scheme involving alkylperoxy radical isomerization are produced, except that the hydroperoxyalkyl radicals involved necessarily have the hydroperoxy group and the unpaired electron on adjoining carbon atoms.

3.1.3. Degenerate Branching

Several types of compound produced in the propagation steps discussed above are capable of acting as agents of degenerate branching. Two kinds of branching reaction are possible, the first involving non-radical reactants (including molecular oxygen) only and the second involving radicals. The latter family of reactions, being of lower activation energy than the former, are probably important only in régimes of rapid reaction.

The pyrolysis of peroxides has frequently been postulated as a degenerate branching reaction in the oxidation of alkanes. Monohydroperoxides decompose to

[82] *L. V. Karmilova, N. S. Enikolopyan, A. B. Nalbandyan,* and *N. N. Semenov,* Ž. fiz. Chim. *34,* 562 (1960).

[83] *J. H. Knox,* Combust. and Flame *9,* 297 (1965).

give an alkoxy radical and a hydroxyl radical (reaction 15) with activation energies of *ca.* 35–40 kcal/mole^{-1} (*e.g. tert*-butyl hydroperoxide[84], $E = 37.8 \pm 0.7$ kcal mole^{-1}). Dihydroperoxides decompose similarly, by homolysis of both O–O bonds; in α-dihydroperoxides this scission process will be accompanied by that of a C–C bond, leading to two carbonyl compounds and two OH radicals (reaction (16)) whereas β-, γ-, or δ-hydroperoxides will decompose to dicarbonyl compounds (reaction (17)).

$$ROOH \rightarrow RO^{\bullet} + {}^{\bullet}OH \qquad (15)$$

$$HOO(R^1R^2)C\text{-}C(R^3R^4)OOH \longrightarrow R^1R^2C{=}O + R^3R^4C{=}O + 2\,{}^{\bullet}OH \qquad (16)$$

$$R^1R^2C(O\text{-}OH)\text{-}CH_2\text{-}C(O\text{-}OH)R^3R^4 \longrightarrow R^1C(=O)\text{-}CH_2\text{-}C(=O)R^3 + {}^{\bullet}R^2 + {}^{\bullet}R^4 + 2\,{}^{\bullet}OH \qquad (17)$$

Hydrogen peroxide decomposes with the assistance of a second body (reaction 18), the process having[85] an activation energy of 45 kcal mole^{-1}. This branching

$$HOOH + M \rightarrow 2\,\dot{O}H + M \qquad (18)$$

process is therefore likely to be important at temperatures somewhat higher than those at which organic peroxides decompose.

The attack by molecular oxygen on moderately stable products with weak C–H bonds is considerably faster than the corresponding attack on alkanes, (*i.e.* than the initiation reaction) and will act, therefore, as a degenerate branching reaction. By far the best example of such a class of products is the aldehydes; reaction (19) has frequently been supposed[58–60] to fill this role. For formaldehyde[82], $E_{19} = 32$ kcal mole^{-1} whereas for acetaldehyde[86] E_{19} may be as low as 14 kcal mole^{-1}. Higher aldehydes, including branched and unsaturated aldehydes, are in general less reactive than acetaldehyde[87].

$$RCHO + O_2 \rightarrow HO_2^{\bullet} + R\dot{C}{=}O \qquad (19)$$

The pyrolysis of peroxides and the oxidation of aldehydes are certainly the two best-established modes of degenerate branching during the oxidation of alkanes. Branching reactions involving free radicals as reactants have received less attention but it has recently been realized that these may play a considerable part. In the oxidation of heptane[14], for example, the hydroperoxyheptylperoxy radicals formed may decompose (reaction (20)) sufficiently rapidly to compete with hydrogen abstraction to give a dihydroperoxide. Also, the reactions of free radicals with molecules (*e.g.* reactions (21) and (22)) can lead to branching.

$$CH_3CH(OOH)CH_2CH(OO^{\bullet})C_3H_7 \rightarrow 2\,{}^{\bullet}OH + (CH_3)_2C{=}O + C_3H_7^{\bullet} + CO \qquad (20)$$

There is an important analogy between such reactions and the equation $X + Y \rightarrow B + 2\,Y$ involved in the two-product explanation of cool flames (section 2.7.).

$$RO_2^{\bullet} + R'CHO \rightarrow RO^{\bullet} + {}^{\bullet}OH + R'\dot{C}{=}O \qquad (21)$$

$$RO_2^{\bullet} + R''OOH \rightarrow RO^{\bullet} + {}^{\bullet}OH + R''O_2^{\bullet} \qquad (22)$$

3.1.4. Termination

Termination of chains in gaseous oxidation systems occurs in two ways. Radicals may react together in the gas phase to produce species which are inactive as chain-propagating agents, or may diffuse to the walls where they are either captured or converted to inactive products. During slow combustion the concentrations of radicals are low; homogeneous termination processes, which have rates proportional to the product of two radical concentrations, are therefore slow and heterogeneous termination predominates. At higher radical concentrations, such as those characteristic of non-isothermal oxidation, homogeneous termination by disproportionation of radicals having relatively long lifetimes, such as $RO_2^{\bullet}$ and $HO_2^{\bullet}$, may become appreciable, however. The effects of surface on the kinetics of the overall reaction provided evidence for the mode of termination.

The important homogeneous termination reactions during the gaseous oxidation of alkanes are

$$2\,C_nH_{2n+1}OO^{\bullet} \rightarrow C_nH_{2n+1}OOH + C_nH_{2n} + O_2 \qquad (23)$$

$$C_nH_{2n+1}OO^{\bullet} + HO_2^{\bullet} \rightarrow C_nH_{2n+1}OOH + O_2 \qquad (24)$$

$$2\,HO_2^{\bullet} \rightarrow H_2O_2 + O_2 \qquad (25)$$

Heterogeneous termination occurs by diffusion to, and destruction at, the walls of chain carriers and branching agents (*e.g.* $HO_2^{\bullet}$, $C_nH_{2n+1}OO^{\bullet}$, ${}^{\bullet}C_nH_{2n}OOH$, ${}^{\bullet}OH$, H_2O_2, ROOH). These processes can be controlled either by the efficiency of the wall reaction (kinetic control) or by the rate of diffusion of species to the wall (diffusion control)[10,12].

3.2. The Steps Operative in the Cool Flame Region

The temperature region in which cool flames are formed (250–400 °C) is such that both modes of reaction of alkyl radicals with oxygen must be considered as

[84] *A. D. Kirk* and *J. H. Knox*, Trans. Faraday Soc. *56*, 1296 (1960).

propagation steps. The particularly low selectivity of oxidation in the cool-flame region shows that, if the primary chain-propagating cycle be represented by the general equations

$$RH + X^{\bullet} \rightarrow R^{\bullet} + XH$$

$$R^{\bullet} + O_2 \rightarrow P + X^{\bullet}$$

then it is evident that the species X that predominates in the cool-flame region is different from that predominating at other temperatures and attacks RH less selectively. It is likely therefore that $X \equiv OH$ at cool-flame temperatures whereas at other temperatures $RO_2^{\bullet}$ or $HO_2^{\bullet}$ radicals act as X.

Two propagation schemes (schemes (9) and (14)) in which $X \equiv OH$ have been discussed. The basic difference between these is that the hydroperoxyalkyl radicals in scheme (14) are necessarily α-hydroperoxyalkyl radicals, whereas β-, γ-, and δ-hydroperoxyalkyl radicals, as well as α-hydroperoxyalkyl radicals, are formed in scheme (9). If only scheme (14) operates, the O-heterocyclic products with carbon skeletons corresponding to that of the fuel molecule will be oxiranes exclusively, whereas, if scheme (9) operates, oxiranes, oxetanes, tetrahydrofurans, and tetrahydropyrans can all be formed. The latter is found experimentally to be true, particularly in the cool-flame region [4, 18, 33, 51, 72, 90, 91].

The primary chain-propagation process during cool-flame oxidation of alkanes is thus probably (9), although the chain (14a, 14g, 14e, 14f) and the reaction sequence (11) may each contribute to the formation of oxiranes and the sequence (14b, 14h, 16) may increase the yields of carbonyl scission products. A detailed study [51] of this reaction scheme has shown that it is consistent with the complex product distribution resulting from the cool-flame oxidation of 2-methylpentane. It is probable that the chain (14a, 14g, 14e, 14f) competes quite effectively with the chain (9) during the oxidation of smaller alkanes such as isobutane and ethane.

The rate-determining step in cycle (9) is the alkylperoxy radical rearrangement reaction, reaction (9b). As the activation energies of the different modes of rearrangement differ, it is possible that this reaction explains the complex variation of the properties of cool flames with temperature and also the variation of the shape and extent of the low-temperature ignition diagram with the molecular structure of the fuel [3]. Two factors affecting the activation energy in question may be distinguished, namely, the strength of the C–H bond broken and the strain energy involved in forming the cyclic transition state.

Correlation of the temperature region in which the yield of each product maximizes during the cool-flame oxidation of 2-methylpentane [51] with the mode of rearrangement involved in the formation of the product shows that the three lobes of the two-stage ignition régime are predominantly associated, in order of increasing temperature, with 1:5, 1:6, and 1:4 H-transfer respectively, suggesting that the transition-state strain energy is the predominant factor. A given mode of H-transfer cannot be assigned exclusively to a given lobe, however. In particular, there is considerable intermixing of 1:5 and 1:6 H-transfer in the two lower lobes.

The strain energies involved in four-, five-, six-, seven-, and eight-membered cycloalkane rings are, respectively, 26, 6.5, 0.6, 6.5, and 10 kcal mole^{-1}. If it is assumed that the strain energies of transition-state rings of similar sizes run parallel to these, 1:5 H-transfer in alkylperoxy radicals should occur at the lowest temperature, followed by 1:6 and 1:4 H-transfer and, in turn, 1:7 H-transfer. The energetic requirements of the decomposition reactions of the hydroperoxyalkyl radicals so formed may, however, be sufficiently large to alter the effective sequence. For example, considerable strain energy is involved in reaction (8a), in which a ring is formed which has two fewer members than the ring involved in the corresponding reaction (6). Radicals which have been formed by the easy 1:5 H-transfer will decompose therefore only slowly, as a four-membered ring is involved, and this step may become rate-determining. The decomposition of radicals formed by 1:6 H-transfer involves, however, a five-membered ring and will be relatively rapid. Such considerations may explain the "mixing" of 1:5 and 1:6 H-transfer in the lobes L_1 and L_2 of the 2-methylpentane system and may, indeed, cause overall reactions involving 1:6 H-transfer to occur, in general, at lower temperatures than those involving 1:5 H-transfer.

The variation of the shape of the low-temperature ignition peninsula with the molecular structure of the fuel can be explained reasonably satisfactorily in chemical terms by considering the number of hydrogens which can be transferred around rings of a given size in each and every alkylperoxy radical derived from the fuel skeleton and adding these to give a picture of the properties of the fuel (see Table 1). It is necessary to consider every alkylperoxy radical derived from the fuel skeleton because $^{\bullet}OH$ attacks fuel unselectively.

For example, two alkylperoxy radicals can be derived from butane, *viz*, 1-butylperoxy and 2-butylperoxy. The 1-butylperoxy radical has two hydrogens available for 1:4 H-transfer, two for 1:5 H-transfer, and three for 1:6 H-transfer. The 2-butylperoxy radical has, respectively, five, three, and zero such hydrogens. The propensities (irrespective of energy requirements) of butane to react *via* propagation steps involving, respectively, 1:4, 1:5, and 1:6 H-transfer, are therefore in the ratios 7:5:3. The ignition limit of this fuel should therefore exhibit all three lobes. Ethane, however, gives only one alkylperoxy radical and this can isomerize only by 1:4 H-transfer. Only one lobe should therefore be present. Similarly, neopentane should exhibit one lobe only, corresponding to 1:5 H-transfer.

The predictions of this theory, if it is assumed that 1:6 and 1:5 H-transfer account respectively for lobes L_1 and L_2 and that 1:4 H-transfer (together with 1:n H-transfer where $n > 6$) accounts for L_3, are compared with experiment in Table 1. The increasing number and position of lobes as the molecular weight of an *n*-alkane is increased are correctly predicted, as are the "incomplete" diagrams of isobutane and neopentane. For 3-methylpentane, however, the theory predicts the existence of more lobes than have been found.

2,3-Dimethylbutane is a particularly interesting case; isomerization of alkylperoxy radicals by 1:6, 1:5, and 1:4 H-transfer is possible but it is doubtful whether such radicals will be formed. An alkyl radical derived from this fuel necessarily has a tertiary hydrogen atom attached to a carbon atom in a position α to the carbon atom bearing the free valency. The abstraction by oxygen of this hydrogen atom (reaction (3)) will be easy and may well compete successfully

[90] *H. C. Bailey* and *R. G. W. Norrish*, Proc. Roy. Soc. (London), Ser. A, *212*, 311 (1952).

[91] *G. Kyryacos*, *H. R. Menapace*, and *C. E. Boord*, Analytic. Chem. *31*, 222 (1959).

with the addition of oxygen. If this is so, the low-temperature ignition region of 2,3-dimethylbutane will be either non-existent or very small, in agreement with experiment.

Cyclic hydrocarbons probably have "incomplete" diagrams because of the highly strained configuration of the transition state complex necessary to alkylperoxy radical rearrangement. In the oxidation of cyclohexane, 1:5 H-transfer occurs, leading to 5-hexen-1-al[78], and 1:6 H-transfer is possible in the boat form but 1:4 H-transfer is unimportant. Cyclopentylperoxy radicals, indeed, may not isomerize easily at all. In Table 1, isomerization reactions of cycloalkylperoxy radicals that may be excluded for this reason have been placed in parentheses and discounted in predicting the occurrence of lobes.

The alkylperoxy radical rearrangement theory describes quite successfully, then, both the natures of the products of cool flames of alkanes and the variation of the fine structure of the two-stage ignition region with molecular size and shape. Similarly, the variation with molecular structure of the oxidation characteristics of ketones and esters can be described by the theory[92]. The branching reactions involved in the cool-flame régime doubtless include both the pyrolysis of peroxidic compounds and the oxidation of aldehydes, both of which are found as products (see Sections 2.5 and 2.6).

Thus, the cool flames of butanone[55] and of cyclohexane[15] have been said to represent the pyrolytic explosion of accumulated peroxide. On the other hand, the opinion has been expressed[60] that the cool flames of oxidizing hydrocarbons correspond to the cool flames of aldehydes. The possible role of peroxides and aldehydes in a two-product explanation of the formation of cool flames is dependent on the existence of a mechanism for their interconversion. Branching by the homogeneous decomposition of peroxide/aldehyde addition compounds may also play some part, as may radical reactions such as (20), (21), and (22).

The probable mechanistic reasons for the changes in rate and selectivity of the gaseous oxidation of alkanes with temperature may therefore be summarized as follows. At low temperatures, alkyl radicals react with oxygen to give alkylperoxy radicals which, in turn, attack fuel molecules selectively to produce hydroperoxides. Branching results from the pyrolysis of the hydroperoxides. As the temperature is increased, the mode of reaction of alkylperoxy radicals changes and this is the basic reason for the formation of cool flames. Homogeneous isomerization reactions predominate, producing hydroperoxyalkyl radicals. The different activation energies of the various modes of this reaction may be responsible for the fine structure of the cool-flame region. The hydroperoxyalkyl radicals decompose, both directly and after addition of further oxygen, producing a wide variety of stable or moderately stable products. These decomposition reactions lead to the OH radical as the predominant chain-propagating entity; the resulting attack on the fuel molecule is rapid and unselective. The chain is branched by reactions of aldehydes, hydroperoxides, and dihydroperoxides. The existence of an upper temperature limit of cool flames is probably a result of the mode of attack of alkyl radicals by oxygen changing from addition to abstraction. At temperatures above those of cool flames, it is likely that the hydroperoxy radical propagates the chain, producing hydrogen peroxide and resulting in an increase in selectivity and a decrease in rate. Branching probably results from the homogeneous decomposition of the hydrogen peroxide so formed.

4. Cool Flames and Combustion Processes in Engines

The properties of the self-ignition of hydrocarbon fuels at high pressures (> 15 atm) and temperatures ($> 700\,^{\circ}K$) are of primary importance in understanding abnormal combustion phenomena in internal combustion engines. Thus, self-ignition of the end-gas is widely held[93–95] to be responsible for knock in the gasoline engine and accounts also for the phenomenon of run-on. Again, in the diesel engine, the normal operation of the engine is determined by the length of the ignition delay period and the pattern of heat release during ignition. A close qualitative relationship exists between the tendency of a pure hydrocarbon fuel to cause knock in a gasoline engine and the shape and extent of its low-temperature ignition diagram[3, 72]. It would seem then that the two-stage ignition process is maintained even at pressures far into the ignition zone. Recent direct experimental work has shown that this is so.

Although the ignition delay is reduced, when the pressure is increased from about 1 to about 15 atm, by a factor of 10^3 to 10^4, the general shape of the ignition limit is reflected in the shape of isolag curves at high pressure[96], although the "fine structure" of the low-temperature limit is lost (Fig. 8a). Division of the total delay to ignition at high pressure of a stoichiometric mixture with air of 60% iso-octane + 40% heptane into τ_{cf} and τ_{hf}, and extrapolation of the pressure/temperature loci of the conditions $\tau_{hf} = 0$, τ_{total} = minimum, and τ_{hf} = maximum to the pressures and temperatures characteristic of the ignition limit, produces curves which reflect even the fine structure of the limit, as illustrated in Figure 8 (b) and (c). This relationship between two-stage ignition at low pressures and under engine conditions is reflected also in the indices n and m in the equations $\tau_{cf} = k'p^{o-n} + c'$ (Section 2.3.) and $\Delta p_{cf} = kp_o^m$ (Section 2.2.) which describe the variations of induction period and pressure rise with initial pressure. For the cool flames of 2-methylpentane, the index n at pressures relevant to combustion in engines (10–50 atm) is similar to the minimum value of n at the ignition limit[18]; the equality of m under these two widely different conditions of initial pressure is striking (Fig. 3).

A most dramatic demonstration of the similarity between two-stage ignition at low pressures and that under engine conditions has resulted from the analysis of the chemical products of the cool-flame step in each case[18].

(c) Extrapolation of loci of turning values of τ to the limiting conditions for ignition.

I = cool flame limit; II = ignition limit [96].

The cool flames of 2-methylpentane were isolated under two sets of conditions which differed very widely, low-pressure experiments being performed in a conventional Pyrex reactor and high-pressure experiments in a rapid-compression machine. A 15-fold range of reactant ratio was involved; the reactors differed by a factor of 100 in effective radius (calculated in terms of molecular mean free paths), the pressures were different by a factor of 5×10^2 and the induction period measured differed by a factor of 10^4. Despite these very large differences in conditions, the chemical products of the first stage of two-stage ignition are sufficiently similar in the two régimes for there to be little doubt that a common phenomenon is involved. Of 42 organic species in the products, no less than 39 are common to the two combustion régimes; this pattern is sufficiently complex to ensure that its duplication in the two régimes is mechanistically significant. The products of the cool-flame oxidation of 2-methylpentane at high pressures include dimethyltetrahydrofurans, which are diagnostic of the occurrence of alkylperoxy radical isomerization, in considerable quantities. The very low surface availability (radius of reactor about 10^6 mean free paths) and short reaction time (about 10^{-3} sec) ensure that isomerization is not (as has been suggested [11,83]) an unimportant wall reaction, but occurs homogeneously and is capable of propagating the chain. The high-pressure experiments have been extended to the cool-flame combustion of 2-methylpentane in a motored Ricardo E6 experimental engine [18]; again, the products are similar. Nor is the similarity peculiar to 2-methylpentane as a fuel. The preflame reaction products of iso-octane in a motored engine contain large amounts of 2,2,4,4-tetramethyltetrahydrofuran and 2-*tert*-butyl-3-methyloxetane [97]. These ring ethers, together with 2-isopropyl-3,3-dimethyloxetane and 2-*tert*-butyl-3,3-dimethyloxirane, are also present in the end products of slow oxidation of the end gas during the spark-ignited combustion of iso-octane in an engine [98]; small quantities of these products even survive the passage of the flame itself [99,100].

The relationship of the knock rating of a fuel to its low-temperature ignition diagram is hardly surprising for the same chemical paths which determine the latter are involved in the early stages of the autoignition process which leads to knock. A circle of correlation has therefore been established between the molecular structure of a fuel, the ease of formation of and subsequent isomerization of the alkylperoxy radicals derived from it, the shape and extent of its low temperature ignition diagram, and its octane rating.

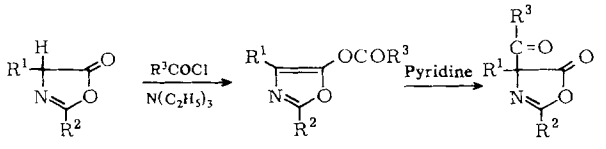
5-Acyloxyoxazoles and their Rearrangement to 4-Acyloxazol-5-ones

By *W. Steglich* and *G. Höfle* [*]

4-Substituted 2-phenyl-4*H*-oxazol-5-ones, on reaction with aliphatic carboxylic acid chlorides in the presence of one molar equivalent of triethylamine, give 2,4-disubstituted 5-acyloxyoxazoles *(1)* in high yield. As example we cite the reactions of 4-methyl-2-phenyloxazol-5-one with acetyl chloride or methyl chloroformate, in which 5-acetoxy-4-methyl-2-phenyloxazole *(1a)* and 4-methoxycarbonyloxy-4-methyl-2-phenyloxazole *(1b)*, respectively, are formed.

(1a): Yield 93 %; b.p. 140 °C/0.4 mm, m.p. 52 °C; IR (film) 1789 (vs), 1748 (s), 1718 (s), 1656 (vs), 1548 cm^{-1} (m); UV (in hexane, fine structure maximum with bands at 300, 286, 280, 275 (ε = 18600), 269 nm; NMR (in CCl_4) δ = 2.06 (singlet, 3 protons), 2.22 (singlet, 3), 7.3 (multiplet, 3), 7.9 ppm (multiplet, 2).

(1b): Yield 97 %; b.p. 150 °C/0.4 mm; IR (film) 1779 (vs), 1661 (s), 1548 cm^{-1} (m); NMR (in CCl_4) δ = 2.10 (singlet, 3 protons), 3.85 (singlet, 3), 7.3 (multiplet, 3), 7.9 ppm (multiplet 2).



(1) *(2)*

(a), $R^1 = R^3 = CH_3$, $R^2 = C_6H_5$
(b), $R^1 = CH_3$, $R^2 = C_6H_5$, $R^3 = OCH_3$

When kept or when warmed for a short time in pyridine, *(1a)* rearranges to 4-acetyl-4-methyl-2-phenyloxazol-5-one *(2a)*.

(2a): Yield 80 %; b.p. 135 °C/0.4 mm; IR (film) 1818 (vs), 1718 (s), 1639 cm^{-1} (s); NMR (in CCl_4) δ = 1.63 (singlet, 3 protons), 2.20 (singlet, 3), 7.5 and 8.0 ppm (multiplet, 5). Methyl 4,5-dihydro-4-methyl-5-oxo-2-phenyloxazole-4-carboxylate *(2b)* is obtained analogously from *(1b)* and is identical with a product obtained by another route [1].

Acylation of the oxazolone anion with acid chloride and triethylamine thus leads to the *O*-acyl derivative in a kinetically controlled reaction, whereas under the usual conditions of the Dakin-West reaction [2] (acetic anhydride and pyridine) only the thermodynamically more stable *C*-acyl derivatives have hitherto been isolated [3]. To establish whether 5-acyloxyoxazoles are formed also as intermediates in the classical Dakin-West reaction needs further study.

Huisgen and *Knorr* [4] detected 5-acetoxyoxazolium salts as the first stage of the Dakin-West reaction of mesoionic 3-alkyloxazolones. When *(1a)* is warmed with glacial acetic acid cleavage to *N*-benzoyl-DL-alanine occurs, whereas simultaneous addition of pyridine leads to formation of 3-benzoylamino-2-butanone.

Since 4-acyl-4*H*-oxazol-5-ones *(2)* are cleaved to α-acylamino ketones by acid hydrolysis, the sequence of reactions now described constitutes a method for the conversion of aliphatic halides into α-acylamino ketones in good yield.

Preparation of 2,4-Disubstituted 5-Acyloxyoxazoles (1): 50 mmoles of the acid chloride is added dropwise and with stirring into an ice-cooled solution of 50 mmoles of oxazolone and 7 ml of triethylamine (50 mmoles) in 70 ml of tetrahydrofuran. After 2 h the mixture is evaporated in a vacuum and the residue is partitioned between ether and N HCl. The ethereal phase is dried with $MgSO_4$ and, after removal of the ether in a vacuum, is distilled.

Preparation of 2,4-Disubstituted 4-Acyloxazol-5-ones (2): 20 mmoles of 5-acyloxyoxazole *(1)* is heated in 40 ml of anhydrous pyridine for 30 min at 95 °C. The pyridine is evaporated and the residue is distilled, both operations being carried out in a vacuum.

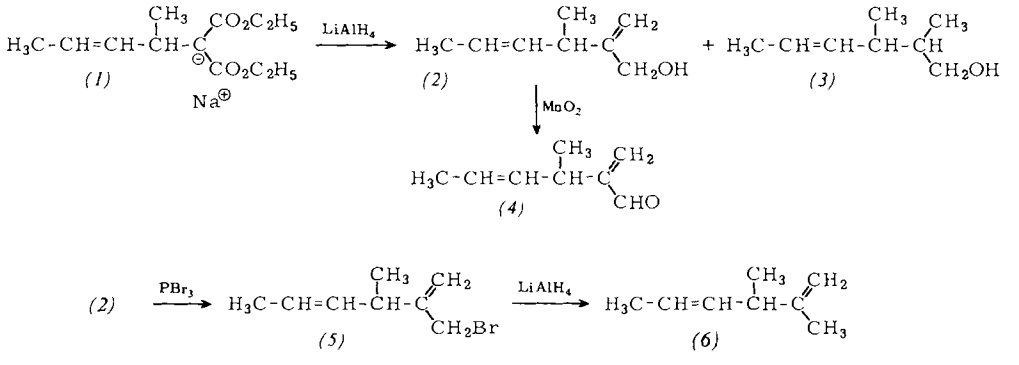
Preparation of 1,4-Dienes by Reduction of Sodioallylmalonic Ester with Lithium Aluminum Hydride

By *W. Sucrow* [*]

1,4-Dienes are conveniently accessible if one applies to sodioallylmalonic ester the reduction process described by *Marshall et al.* [1] for substituted sodiomalonic esters. The single previous example of this type appears to be the reduction of a tricyclic malonic ester lactone in the synthesis of alantolactone [2]. An experiment with a model *(1)* (chosen with a view to synthesis of a steroid containing an unusual side chain [3]) showed that reduction occurs also with open-chain sodioallylmalonic esters, yielding the nonconjugated diene without isomerization. Further, the 1,4-diene-alcohol can be converted into the aldehyde or the hydrocarbon without isomerization.



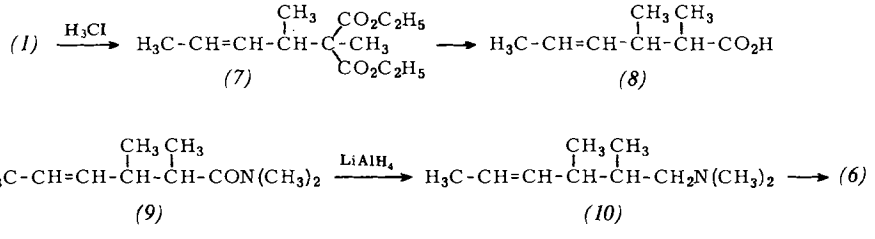
(1) *(2)* *(3)* *(4)* *(5)* *(6)*

Experimental:

The sodium salt *(1)* from 10 g of diethyl (1-methyl-2-butenyl)-malonate[4] is heated with 5.25 g of $LiAlH_4$ in 65 ml of dimethoxyethane for 20 min, thus giving 74% of a *ca.* 5:1 mixture of 3-methyl-2-methylene-4-hexen-1-ol *(2)* [b.p. 80 °C/18 mm; IR, $=CH_2$ 3090, 1650, 905, $-CH=CH-$ 968 cm^{-1}; NMR, $H_3C-C\leqslant$ (d) δ = 1.12; $H_3C-C=$ (split d) 1.65; $HC\leqslant$ (dq) 2.8; $-CH_2O-$ (broad s) 3.96; $=CH_2$ (m) 4.82, (m) 4.97; $-CH=CH-$ (m) 5.1–5.6 ppm; 3,5-dinitrobenzoate, m.p. 44 °C] and 2,3-dimethyl-4-hexen-1-ol *(3)*, which appears from its NMR spectrum to be a mixture of the *threo*- and the *erythro*-form. Compounds *(2)* and *(3)* can be separated by gas chromatography (20% Carbowax/Chromosorb W, H_2, 180 °C).

Oxidation of *(2)* with manganese dioxide gives a 60% yield of 3-methyl-2-methylene-4-hexenal *(4)* [b.p. 60 °C (bath temp.)/18 mm; UV, 212.5 nm (ε = 6800) in ether; IR, $=CH_2$ 3100, 1629, 941, $-CHO$ 2700, 1702, $-CH=CH-$ 972 cm^{-1}; NMR, $H_3C-C\leqslant$ (d) δ = 1.13, $H_3C-C=$ (split d) 1.65, $HC\leqslant$ (m) around 3.3, $-CH=CH-$ (m) around 5.3, $=CH_2$ (m) 5.85, (m) 6.10, $-CHO$ (s) 9.42 ppm; dinitrophenylhydrazone, m.p. 137 °C]. With PBr_3 in petroleum ether *(2)* affords 2-bromomethyl-3-methyl-1,4-hexadiene *(5)* [b.p. 80 °C (bath temp.)/18 mm; IR $=CH_2$ 3095, 1641, 912, $-CH=CH-$ 970 cm^{-1}; NMR, $H_3C-C\leqslant$ (d) δ = 1.16, $H_3C-C=$ (d) 1.67, $HC\leqslant$ (m) 2.8–3.3, $-CH_2Br$ (s) 3.90, $=CH_2$ (m) 4.94, (m) 5.13; $-CH=CH-$ (m) around 5.3 ppm], and thence by 3.5 hours' boiling with $LiAlH_4$ in ether an 80% yield of 2,3-dimethyl-1,4-hexadiene *(6)* [b.p. 107 °C; IR, $=CH_2$ 3090, 1642, 892; $-CH=CH-$ 970 cm^{-1}; NMR, $H_3C-C\leqslant$ (d) δ = 1.06, $H_3C-C=$ (m) 1.65 (6 H), $HC\leqslant$ (m) 2.4–3.0, $=CH_2$ (m) 4.62 (2 H), $-CH=CH-$ (m) around 5.3 ppm; mass spectrum, M^+ at *m/e* = 110.10996, fragments at *m/e* = 95 ($M-CH_3$, m* = 82.0), 93 ($95-2H$, m* = 91.0), 91 ($93-2H$, m* = 89.0), 67 ($95-C_2H_4$, m* = 47.3), 41 ($67-C_2H_2$, m* = 25.1), 39 ($41-2H$, m* = 37.1)].

For control, compound *(6)* was also prepared by the following route: Methylation of *(1)* gives the dialkylmalonic ester *(7)* [b.p. 100 °C (bath temp.)/0.1 mm; NMR new (s) δ = 1.23, no longer (d) at 3.08 ppm], which was hydrolyzed (m.p. 142 °C) and then decarboxylated to *(8)* [b.p. 100 °C (bath temp.)/18 mm; IR, $-COOH$ 1710, $-CH=CH-$ 969 cm^{-1}]. Reduction of the derived dimethylamide *(9)* [b.p. 50 °C (bath temp.)/0.1 mm; IR, $-CON\leqslant$ 1650, $-CH=CH-$ 970 cm^{-1}] leads to *N,N*-dimethyl-2,3-dimethyl-4-hexenylamine



(10) [b.p. 90 °C (bath temp.)/18 mm]. The NMR spectrum of *(10)* [4 doublets from CH_3 on saturated C at δ = 0.73, 0.75, 0.84, 0.93 ppm; $H_3C-C=$ (d) 1.61; $-N(CH_3)_2$ (s) 2.08; $-CH=CH-$ (m) around 5.3 ppm] shows that *(8)*, *(9)*, and *(10)* occur as mixtures of *threo*- and *erythro*-forms. Oxidation of *(10)* to the amine oxide and Cope degradation[5] gives *(6)* [40% yield calculated on *(1)*]. IR and NMR spectra were measured for CCl_4 solutions.

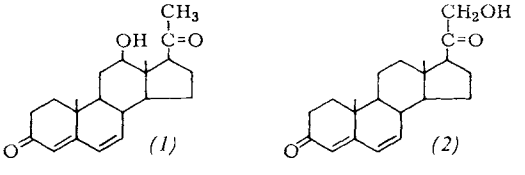
Protective Materials in the Secretion from the Prothoracic Protective Gland of a Mexican Cybister Species [1]

By *H. Schildknecht* and *W. Körnig* [*]

During an excursion by boat on the water ditches of the floating garden of Xochimilco (Mexico City) we were able to catch four *Cybister* (as well as many *Hydrophylidae*). We succeeded in bringing three of the water beetles alive to Heidelberg. Their milky cervical secretion was sucked up in glass capillaries. 1.5 mg of a crystalline substance of m.p. 196 °C was isolated from this secretion by repeated preprarative thin-layer chromatography on silica gel (GF_{254} Merck) with 1:1 cyclohexane/ethyl acetate.

Since we had found cybisterone[2] as protective material in the corresponding secretion of *Cybister lateralimarginalis* occurring, above all, in Southern Europe, we assumed that the ingredient of the prothoracic gland of this, as yet inexactly characterized, Mexican *Cybister* would also be a steroid. This was at once confirmed by the absorption maximum at 284 nm in ethanol and the absorption bands at 1655 cm^{-1} ($\nu_{C=O}$), 1612 cm^{-1} ($\nu_{C=C}$), and 1580 cm^{-1} ($\nu_{C=C}$). Further, a band at 1680 cm^{-1} ($\nu_{C=O}$) indicated a second carbonyl group, this one exocyclic. In agreement with this we found a positive Cotton effect with two circular dichroism maxima at 363 and 303 nm. A hydroxyl group, identified by acetate formation, was evidenced by a strong absorption band at 3350 cm^{-1} (ν_{O-H}) and ν_{C-OH} vibrations at 1038 cm^{-1} (s) and 1070 cm^{-1} (m). A molecular weight of 328 (calculated from the mass spectrum) showed that the protective material from the Mexican *Cybister*, like cybisterone, is in fact a C_{21} steroid. The fragmentation pattern in the mass spectrum showed that the side chain of the steroid must be a CH_3CO group. These results suggest the presence of a 4,6-pregnadiene-3,20-dione hydroxylated in ring C.

The 11β- and 12α-position for the OH can be excluded since such steroids do not form acetates in pyridine/acetic anhydride. Comparison of the IR spectra of 11α-hydroxy-4,6-pregnadiene-3,20-dione and the natural product excludes further the 11α-position. Finally, study of the absorption data of *Heller*[3] for numerous hydroxylated progesterones showed the *Cybister* steroid to have the structure of a 12β-hydroxy-4,6-pregnadiene-3,20-dione *(1)*. We propose the name cybisterol for this new insect steroid, of which the beetle can store more than 1 mg.



Alongside this material, we isolated from the prothoracic protective glands traces of 21-hydroxy-4,6-pregnadiene-3,20-dione *(2)*, which was identified spectroscopically after isolation by thin-layer chromatography.

Sulfur Dichloride (Chlorosulfonyl)imide and *N,N'*-Hydrazodisulfonyl Difluoride[1]

By *H. W. Roesky*[*]

Reaction of chlorosulfonamide *(1)* and thionyl chloride *(2)* affords sulfur dichloride (chlorosulfonyl)imide *(3)*.

$$\underset{(1)}{ClSO_2NH_2} + 2\ SOCl_2 \longrightarrow \underset{(3)}{ClSO_2\text{-}N{=}S(Cl)Cl} + 2\ HCl + SO_2$$
$$\qquad\qquad (2)$$

Compound *(3)* can also be obtained by boiling amidosulfuric acid *(4)* and *(2)* under reflux for 5 days, the yield being 35%.

$$\underset{(4)}{HOSO_2NH_2} + 3\ SOCl_2 \rightarrow (3) + 3\ HCl + 2\ SO_2$$

Experimental:

0.1 mole of *(1)* and 0.22 mole of *(2)* are heated (oil-bath temperature 100 °C) under reflux for 12 h. HCl and SO_2 are given off as gaseous products and a brown residue formed, which on fractional distillation affords compound *(3)* in 70% yield. Compound *(3)* is a yellow liquid, b.p. 72 °C/0.2 mm (65–66 °C/0.02 mm), which reacts with a little water to yield crystalline amidosulfuric acid as a precipitate. With an excess of anhydrous hydrogen fluoride at 80 °C the product *(3)* affords fluorosulfonamide *(5)*

$$\underset{(3)}{ClSO_2N{=}S(Cl)Cl} + 5\ HF \longrightarrow \underset{(5)}{FSO_2NH_2} + SF_4 + 3\ HCl$$

With sodium fluoride in TMSO, *(3)* reacts at 100–120 °C to give chlorosulfonyl fluoride and thiazyl fluoride, NSF.

The IR spectrum of compound *(3)* (capillary film) in the NaCl and KBr region shows bands at 1800 w, 1395 vs, 1170 vs, 1110 vs, 980 w, 678 vs, 585 vs, 548 s with shoulders at 523 w, and 440 vs cm^{-1} [2]. These are provisionally allotted to the following vibrations: ν_{as}(SO) 1395, ν_s(SO) 1170, ν(S=N) 1110, ν(SN) 678, ν(SCl) 585, 548, 440.

When a mixture of 1.0 mole of *(5)* and 1.0 mole of *(2)* is boiled under reflux, for 24 h, *N,N'*-hydrazodisulfonyl difluoride *(6)* is precipitated and can be separated by filtration from the sulfur oxide (fluorosulfonyl)imide, FSO_2NSO (24.5 g), and sulfur dichloride (fluorosulfonyl)imide, FSO_2NSCl_2, that are also formed. Compound *(6)* (yield as above, 11 g) is a yellow solid, m.p. 77 °C, that is soluble in methanol with decomposition. The ^{19}F–NMR spectrum measured at 100 °C contains a singlet at $\delta_F = -54.4$ ppm (CCl_3F as external standard). In the ^1H–NMR spectrum there is a sharp triplet (relative intensities 1:1:1) at $\delta_H = 6.18$ ppm, $J_{H-N} = 54$ Hz [$(CH_3)_4Si$ as external standard], probably caused by spin coupling of the nitrogen. The IR spectrum of *(6)* was measured in Kel-F oil at 4000–1350 and in Nujol at 1350–400 cm^{-1}: 3100 vs, 1400 vs, 1360 vs, 1175 vs, 1060 s, 840 s, 765 s, 740 s, 550 vs cm^{-1} [2].

$$(5) + SOCl_2 \longrightarrow \underset{(6)}{FSO_2\text{-}\overset{H}{N}\text{-}\overset{H}{N}\text{-}SO_2F}$$

Preparation of *N*-(Trifluoromethyl)fluorosulfonamide and its Salts [1]

By *H. W. Roesky*[*]

N-(Dichloromethylene)chlorosulfonamide *(1)*, prepared by treatment of chlorosulfonyl isocyanate with phosphorus pentachloride[2], reacts with anhydrous hydrogen fluoride[3] to give *N*-(trifluoromethyl)fluorosulfonamide[4] *(2)*.

$$\underset{(1)}{ClSO_2N{=}C(Cl)Cl} + 4\ HF \longrightarrow \underset{(2)}{FSO_2\text{-}\overset{H}{N}\text{-}CF_3} + 3\ HCl$$

Experimental:

0.3 mole of *(1)* and 2.2 mole of HF are condensed in a 300-ml Monel cylinder. After thawing to room temperature, the cyclinder is warmed to 80 °C for 2 h; then it is cooled to 0 °C and most of the HCl formed is allowed to escape. The crude product is poured into a second cyclinder containing 2 moles of dry sodium fluoride and left overnight (absorption of the excess of hydrogen fluoride). The product *(2)* is obtained by pumping off and condensation in a high vacuum (methanol/solid carbon dioxide). For further purification, compound *(2)* is fractionally distilled through a 20-cm long column. Yield: 11 g (crude product 21 g); b.p. 100–101 °C.

Compound *(2)* is a water-clear liquid that can be distilled undecomposed in glass apparatus. It is very soluble in water and on titration with 0.1 N NaOH it takes up two equivalents of alkali. The fluorine atom on the sulfonyl group is hydrolyzed by dilute sodium hydroxide solution. With tetraphenylphosphonium and tetraphenylarsonium chloride it gives the salts

$[(C_6H_5)_4P]^{\oplus}[FSO_2NCF_3]^{\ominus}$, m.p. 192 °C and
$(C_6H_5)_4As]^{\oplus}[FSO_2NCF_3]^{\ominus}$, m.p. 190 °C (dec.),

which are precipitated as white solids.

The IR spectrum of compound *(2)* (capillary film) in the NaCl and KBr region shows bands at 3130 s, 1460 vs, 1410 vs, 1265 vs, 1205 vs, 1170 vs, 990 m (?), 860 m, 810 vs, 712 w, 606 vs, 537 m, 425 m cm^{-1} [5] [*(2)* decomposes KBr disks]. These are provisionally assigned to the following vibrations: 3130 ν (NH), 1460 or 1410 ν_{as} (SO) (in the IR spectra of the salts the two bands appear shifted to lower wavelengths, at 1350 and 1322 cm^{-1}), 1265 ν_s (SO), 1205 ν_{as} (CF), 1170 ν_s (CF), 810 ν (SF), 606 ν (SN).

The ^{19}F–NMR spectrum contains for the CF_3 group two doublets at $\delta_F = 58.0$ ppm (CCl_3F as external standard) with coupling constants $J_{F-SF} = 6$ Hz and $J_{F-H} = 3$ Hz. The FSO_2 group gives rise to two quartets at $\delta_{SF} = -55.4$ ppm with coupling constants $J_{SF-H} = 4$ Hz and $J_{F-SF} = 6$ Hz. The doublet:quartet intensity ratio 3:1. The ^1H–NMR spectrum contains a broad signal at $\delta_H = 7.45$ ppm [$Si(CH_3)_4$ as external standard]. The NMR data accord with structure *(2)*. According to the IR and NMR spectra the isomeric form $F-OS(OH)=NCF_3$ is unlikely.

Formation of Dialkoxycarbonium Ions from Ketals by Removal of Alkyl Groups by means of Carbonium Ions [1]

By *S. Kabuss* [*]

Whereas dialkoxycarbonium salts *(1)* are, in general, obtained in good yield from orthocarboxylic esters by the action of Lewis acids [2], monoalkoxycarbonium salts *(2)* are only exceptionally accessible by the analogous reaction of ketals with Lewis acids [2b].

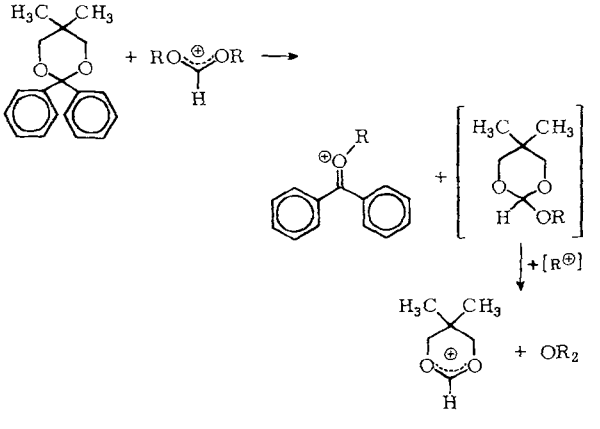
[a] Only traces of 2-ethyl- or 2-*n*-pentyldioxolanylium salts could be detected by NMR spectroscopy.

[b] As well as 25% of the *p*-tolyl derivative (analysis by NMR spectroscopy).

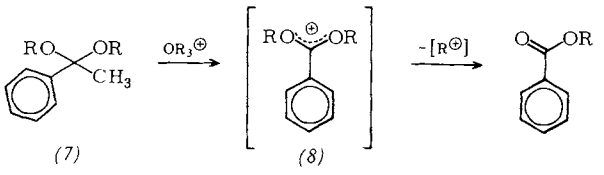
[c] As well as 45% of the phenyl derivative (analysis by NMR spectroscopy).

We have observed that ketals disproportionate under the influence of Lewis acids ($SbCl_5$ or BF_3) in CH_2Cl_2 or SO_2 even below room temperature, with intermolecular alkyl migration that leads to dialkoxycarbonium ions, *i.e.* carboxylic acid derivatives, and ethers of tertiary alcohols. Under the reaction conditions these ethers are converted into olefins, which are obtained as dimers or oligomers. When cyclic ketals, *e.g. (3)* or *(5)*, are used, the dialkoxycarbonium salts, *e.g. (4)* or *(6)*, are isolated in crystalline form. The disproportionation is also caused by the action of strong alkylating agents such as trialkyloxonium or dialkoxycarbonium salts [3] or alkyl halide-$AgBF_4$ mixtures [4] on ketals.



The yield of dialkoxycarbonium salt depends on the structure of the ketal. Reaction is particularly smooth with ketals of acetophenone, from which exclusively the methyl group is transferred. Yields are lower with the homologs containing larger alkyl groups. Removal of a secondary alkyl group, *e.g.* from 2-isopropyl-2-phenyldioxolane, can be effected only to a limited extent. Ketals of dialkyl ketones all give cyclic 2-alkyldialkoxycarbonium salts in only moderate yield. With ketals of unsymmetrical di-*n*-alkyl ketones the larger alkyl group is transferred preferentially. Benzophenone ketals are cleaved by alkylating agents into ketonic and alcoholic components [5], which can both react further with the alkylating agent.

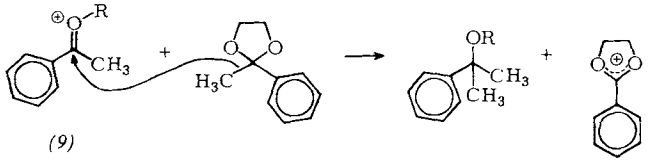
Open-chain ketals, *e.g. (7)*, also undergo disproportionation on reaction with trialkyloxonium salts; crystalline dialkoxy-



(7) (8)

carbonium salts such as *(8)* have not, however, yet been isolated since they react further as strong alkylating agents with ketals and ethers[3]; 20–30% yields of the dealkylation products are isolated, *i.e.* the carboxylic esters.

Ketonium salts, such as *(9a)* or *(9b)*, although not isolated, may be intermediates in the disproportionation of the ketals; they would react further with the excess of ketal undergoing alkyl fission[6].



(9) *(4)*

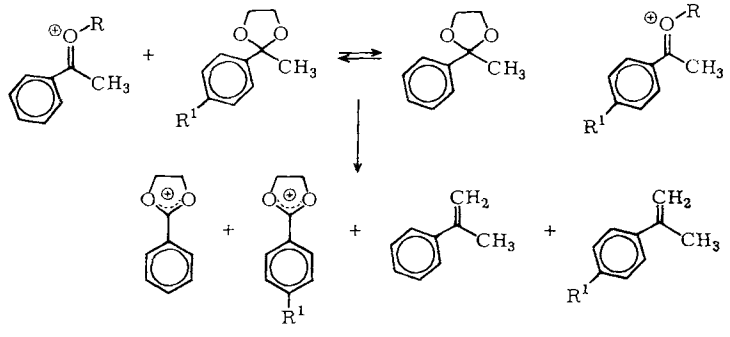
(a) R = $-CH_2-CH_2-OSbCl_5^{\ominus}$

(b) R = $-CH_2-CH_2-OC_2H_5$

(c) R = Alkyl

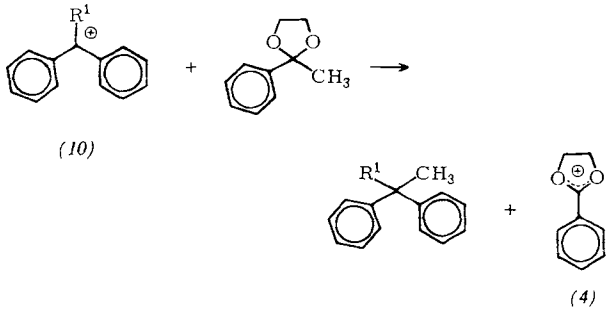
Dialkoxycarbonium salts may be obtained from ketals analogously by use of *O*-alkylketonium salts *(9c)*, which are obtainable in pure crystalline form by alkylation of ketones with dialkoxycarbonium salts[3].

The removal of the alkyl group can be regarded formally as a new type of electrophilic substitution on a saturated C atom, wherein carbonium ions constitute both the attacking and the leaving group. The weaker electrophile *(4)* is replaced by the stronger *(9)* with fission of a C–C bond.



If the ketonium salt and the ketal are derived from two different ketones, then generally both the starting materials yield a dialkoxycarbonium salt as well as an olefin. Alongside alkyl-transfer occur a series of alkoxy-transfers[7] leading to rapid exchange of functional groups[8].

Other stable carbonium ions, react like the alkoxycarbonium ions *(9)*, *e.g.* diphenylcarbonium ions *(10)* described by *Volz* and his co-workers[9] react with ketals with loss of alkyl[10].



(10) *(4)*

Alkyl fission, however, has not yet been achieved with triphenylcarbonium salts.

[4] *H. Meerwein, V. Hederich*, and *K. Wunderlich*, Arch. Pharm. *291/63*, 541 (1958).

[5] Fission into ketonic and alcoholic components occurs also as competitor during the disproportionation. It is to be considered as dealkylation of the ketonium salt.

[6] *Meerwein et al.* [4,7] described the reaction of acetals, occuring with hydride transfer, that is analogous to disproportionation of ketones. These authors assume a direct transfer of the hydride to the alkyl group of the alkylating agent; however, it can be shown that this reaction is also a disproportionation, since in the reaction of 2-phenyldioxolane with triethyloxonium salt, apart from dioxolanylium salt *(4)*, derivatives of benzyl alcohol are formed. The reaction proceeds *via* alkoxycarbonium (aldehydium salts), which react with excess acetal with hydride removal.

[7] *H. Meerwein, V. Hederich, H. Morschel*, and *K. Wunderlich*, Liebigs Ann. Chem. *635*, 1 (1960).

[8] Such alkoxy-transfer occurs even at −40 °C, as may be shown by NMR spectroscopy. Alkyl fission is immeasurably slow at that temperature.

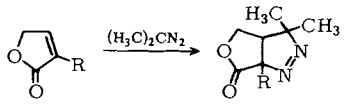
Synthesis of *gem*-Dimethylcyclopropanes by means of 2-Diazopropane

By *M. Franck-Neumann*[*]

Corey and *Jautelat*[1] recently reported the introduction of *gem*-dimethylcyclopropane units be means of diphenylsulfonium isopropylide. The action of 2-diazopropane[2] on electrophilic C=C double bonds is a further method for introduction of this group and we have studied its possibilities[3].

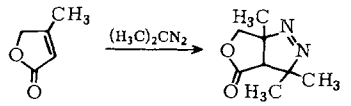
The butenolides[4] *(1a)* and *(1b)* react with 2-diazopropane at room temperature, yielding the expected[5] adducts *(2a)* (yield 90%; m.p. 74 °C, decomp.) and *(2b)* (yield 60%; m.p. 87 °C, decomp.). The diazo compound adds in the reverse direction to *(1c)*, yielding *(2c)* (yield 27%; m.p. 78 °C). The rate of reaction decreases rapidly on passing from *(1a)* to *(1c)*.

In their IR spectra the pyrazolines *(2a)* to *(2c)* show bands at 1775 cm^{-1} (γ-lactone) and 1555 cm^{-1} (azo group), and in the UV region they absorb at 322 nm (ε = 263), 327 nm (ε = 197), and 323 nm (ε = 190), respectively (in chloroform).



(1) *(2)*

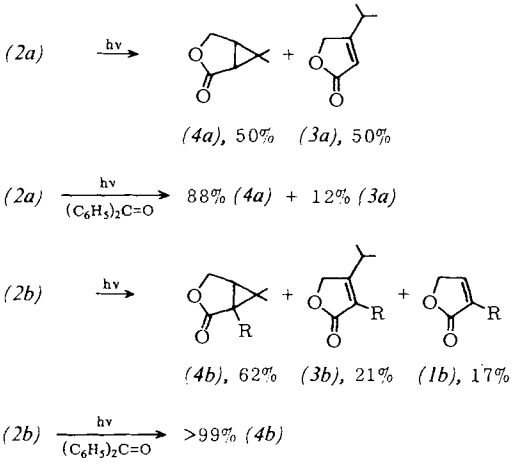
(a), R = H
(b), R = CH_3



(1c) *(2c)*

The NMR spectra (Table 1) are in agreement with the structures assigned.

In contrast to the relatively high thermal stability of the pyrazoline *(2c)*, compounds *(2a)* and *(2b)* decompose slowly from 70 °C upwards. Decomposition of *(2a)* in boiling benzene gives exclusively the 2-isopropylbutenolide *(3a)*, whereas a mixture of 80% of the butenolide *(3b)* with 20% of the cyclopropane derivative *(4b)* arises from *(2b)*. The yields of cyclopropane derivatives are higher on photolysis in benzene[6]. In this reaction *(4a)* and *(3a)* are obtained in a 1:1 ratio from *(2a)*, and a mixture of *(4b)* 62%, *(3b)* 21%, and *(1b)* 17% is formed from *(2b)*. Formation of *(1b)* is formally a 1,3-dipolar retrocycloaddition[7].



(4a), 50% *(3a)*, 50%

(2a) $\xrightarrow[(C_6H_5)_2C=O]{h\nu}$ 88% *(4a)* + 12% *(3a)*

[a] J = 7 Hz.

We have now found that the proportion of cyclopropane to olefin is increased if the photolysis is sensitized by benzophenone. Also removal of nitrogen is about ten times faster than in absence of the sensitizer.

All the thermal and photochemical removals of nitrogen afford quantitative crude yields. The compositions assigned to the mixtures were determined by gas chromatography (polypropylene glycol column 190 °C). The structures of the products that were separated by preparative gas chromatography were supported by the following spectroscopic data:

(3a) shows, in its IR spectrum, the double band at 1750 and 1780 cm^{-1} characteritic of butenolides[8] and absorption by the double bond at 1635 cm^{-1}; *(3b)* absorbs at 1770 and 1680 cm^{-1}; *(4a)* and *(4b)* show only the strong bands at 1775 cm^{-1}; the protons in the three-membered ring give rise to a weak band at 3010 cm^{-1}. UV spectra in methanol: *(3a)*, λ_{max} = 209 nm (ε = 15600); *(3b)*, λ_{max} = 214 nm (ε = 15400); *(4a)*, λ_{max} = 207 nm (ε = 2800); *(4b)*, only end absorption.

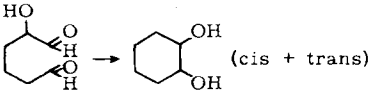
1,6-C–C Linkage on Pressure-hydrogenation of α-Hydroxyadipaldehyde

By *H. Feichtinger* and *H. Noeske*[*]

Pressure-hydrogenation of aqueous solutions of α-hydroxyadipaldehyde *(1)* over Raney nickel at 85 °C and 100 atm gives 1,2,6-hexanetriol in 84% yield[1]. Almost quantitative yields can be obtained by using a continuous process[2] with a Ni–MgO solid-bed catalyst.

However, if a 20% aqueous solution of *(1)* is hydrogenated batchwise in an autoclave with magnetic stirring and in the presence of Ni–MgO catalyst[3] for 1.5 h at 105 °C and then for 4 h at 145 °C with a hydrogen pressure of 110 atm, subsequent filtration, evaporation, and distillation of the residue afford a fraction (some 20% of the total amount of product) that passes over at 76–86 °C/0.7 torr and solidifies in the receiver (softening point about 50 °C). After recrystallization from ether/petroleum ether, the above fraction melts at 63–77 °C. It was found to be a mixture of *cis*- and *trans*-1,2-



(1)

cyclohexanediol. In the hydrogenation of *(1)* under pressure the α-hydroxyl group had thus been eliminated and a ring had been formed by 1,6-C–C linkage.

The composition of the mixture was ascertained by oxidation with alkaline permanganate solution and detection of adipic acid by paper chromatography. The isomers were separated by way of the benzylidene derivative[4] of the *cis*-compound and were compared by IR spectroscopy with the same compounds obtained from pyrocatechol by hydrogenation over the same Ni–MgO catalyst. Finally the phenylurethane derivatives[5] of both isomers were prepared by means of phenyl isocyanate; they agreed in melting points and IR spectra with data recorded in the literature and found for the derivatives obtained by hydrogenation of pyrocatechol.

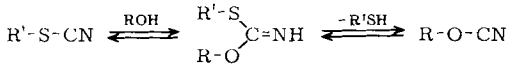
Cyanic Esters from Thiocyanates

By *W.-D. Habicher* and *R. Mayer* [*]

Iminothiocarbonates *(2)*, which are readily accessible from alcohols and thiocyanates *(1)* [1], can, as we have found, be converted into cyanic esters *(3)* [2] in good yield, with loss of a thiol, preferably in presence of a thiol-trapping agent.



(1) *(2)* *(3)*

R′ may be aliphatic, cycloaliphatic, arylaliphatic, or aromatic. Aliphatic and arylaliphatic groups are particularly suitable for use as R groups.

Examples: From ethyl thiocyanate *(1)*, R′ = C_2H_5, were obtained 76% yields of *n*-butyl *(3)*, R = *n*-C_4H_9, n_D^{25} = 1.4009, and 84% yields of *n*-pentyl *(3)*, R = *n*-C_5H_{11}, n_D^{25} = 1.4101, and isopentyl *(3)*, R = *iso*-C_5H_{11}, n_D^{25} = 1.4089.

General Procedure:

An iminothiocarbonate *(2)* (0.1 mole) is vigorously stirred in ether for 2–3 h at 0 °C in presence of a thiol-trapping agent (*e.g.* a mixture of 27 g of HgO and 20 g of anhydrous $MgSO_4$). Then the mixture is filtered, the solvent removed at 0 °C in a vacuum, and the residue distilled in a vacuum at a bath temperature not exceeding 30 °C. The cyanic esters *(3)* are condensed in a cold trap.

Synthesis and Pyrolysis of 3-Azaquadricyclane Derivatives. — A New Azepine Synthesis [1]

By *H. Prinzbach*, *R. Fuchs*, and *R. Kitzing* [*]

The oxepine synthesis that starts from furan and acetylene derivatives and consists of the Diels-Alder addition *(1a)* → *(2a)*, photochemical valence isomerization *(2a)* → *(3a)*, and the pyrolysis *(3a)* → *(4a)* has repeatedly proved its value [2]. We have prepared, by an analogous route, the first derivatives [*(3b)* and *(3c)*] of the thermally labile 3-azaquadricyclane system, and thence the azepines *(4b)* and *(4c)*.

[a] The weak maxima of the toluenesulfonyl group are not listed.

[b] Measured at *ca.* 36 °C. The spectrum shows the temperature-dependence expected from hindered rotation around the C–N bond.

Pyrrole derivatives containing a strong electron acceptor as *N*-substituent [*(1b)* and *(1c)*] react with dimethyl acetylenedicarboxylate, to afford the 7-azanorbornadienes *(2b)* and *(2c)* in 30–40% yield [3]. As in the UV spectra of 7-oxa and 7-methylene analogs [4], in the region 280–290 nm, maxima or shoulders are found, more or less pronounced according to the polarity of the medium, that may arise from interaction between the homoconjugated C=C double bonds.

Direct excitation of the electron transitions responsible for these absorptions by light of wavelength > 290 nm induces almost quantitative conversion of *(2)* into the tetracyclic amides *(3b)* and *(3c)*. These amides can be isolated in pure crystalline form and then characterized; isomerization to the azepines *(4b)* and *(4c)* occurs in solution at 20 °C at measurable rates [$t_{1/2}$ (40 °C, $CDCl_3$) *ca.* 30 min for *(3c)*, *ca.* 120 min for *(3b)*]. As in the case of the ether *(3a)*, the thermal "forbidden" [5] reversal *(3)* → *(2)* of the photo process cannot be detected (NMR). Further, the azepines *(4b)* and *(4c)* containing methoxycarbonyl substituents dimerize [6] in solution slowly even at 20 °C, *(4c)* faster than *(4b)*.

We have carried out numerous reactions, including cycloadditions and acid-catalyzed rearrangements [7], with the azaquadricyclane [*(3b)*, *(3c)*] and azepine derivatives [*(4b)*, *(4c)*]; these reactions, when considered together with the spectroscopic data, leave no doubt as to the correctness of the structures assigned [8].

Experimental:

An O_2-free ethereal solution of *(2b)* (500 mg) in anhydrous ether (200 ml) is irradiated at −30 to −40 °C (Pyrex filter, Philipps-HPK-125 lamp or Hanau-TQ-81 high-pressure lamp). The product *(3b)* is allowed to crystallize out slowly or is isolated (yield > 90%) after the solvent has been distilled off; *(4b)* is obtained pure (yield *ca.* 50%) when *(3b)* is heated for a short time in benzene (80 °C), and the whole is chromatographed on silica gel (benzene/CH_2Cl_2). The same conditions are used for *(4c)* except that pyrolysis is carried out in boiling ether.

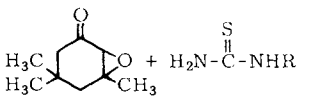
2,4,5,6-Tetrahydro-5,5,7-trimethylbenzimidazole-2-thiones, a New Group of Benzimidazole Derivatives [1]

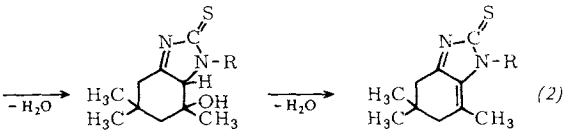
By *H.-D. Dell* [*]

In connection with investigations of dihydroisophorone we have attempted to convert the related epoxide *(1)* into the episulfide. Conversion of epoxy compounds into their S analogs can be effected with thiourea [2], such reactions being known also for cyclohexene epoxides [3].

However, warming equimolar amounts of *(1)* and thiourea in methanol (2 h, 70 °C) gives 2,4,5,6-tetrahydro-5,5,7-trimethylbenzimidazole-2-thione *(2)*, R = H, needles (from methanol), m.p. 189–190 °C (yield 70%).



(1)



(2)

Monosubstituted thioureas also undergo this reaction; *e.g.* *N*-phenylthiourea gives *(2)*, R = C_6H_5, crystals, m.p. 125 to 127 °C (from ethyl acetate); *N*-(1-naphthyl)thiourea gives *(2)*, R = 1-naphthyl, m.p. 178–180 °C. Use of thiosemicarbazide leads to an amino derivative *(2)*, R = NH_2, needles (from ethyl acetate), m.p. 163–164 °C. Reaction with dicyanodiamide or urea does not, however, afford the corresponding 2-imino or 2-oxo derivative.

The weakly acidic H atom of the NH group of *(2)*, R = H, can be replaced by Na when the compound is warmed with $NaNH_2$ in an inert solvent. The structure assigned accords with the IR spectrum and the chemical behavior. Compounds of this new type may be of interest as antimetabolites.

Binding of the Substrate in Yeast Pyruvate Decarboxylase [1]

By *A. Schellenberger* and *G. Hübner* [*]

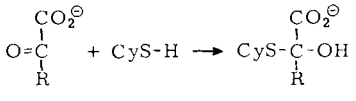
In order to study the function of the SH groups in yeast pyruvate decarboxylase (PDC; 2-keto acid carboxylase, 4.1.1.1), we have caused *N*-(*N*-acetyl-*p*-sulfamoylphenyl)-maleimide (ASPM) [2] to act on PDC or apo-PDC under the conditions set out in the Table. Inactivation of the enzyme in the presence of a large excess of the SH reagent is a first-order reaction in both cases.

Table 1. Half-reaction times for inactivation of apo-PDC and PDC by ASPM. Buffer: 0.1 M maleate, pH 6.6. Concentrations: ASPM 1.43×10^{-2} M; pyruvate 3.43×10^{-2} M; thiamine pyrophosphate (TPP) 3.57×10^{-3} M; Mg^{2+} 10^{-2} M.

Reactants	Half-reaction time (min)
Apo-PDC	2.5
Apo-PDC + TPP	2.5
Apo-PDC + Mg^{2+}	3.0
Apo-PDC + pyruvate	3.0
PDC	15
PDC + pyruvate	> 120

That the enzyme is protected by its substrate from attack by SH reagents was already known [3]. The results recorded in the Table show that the substrate is bound to an SH group of the enzyme before reaction with the coenzyme (TPP).

It might, however, also be the case that the SH groups involved in the enzyme action are protected by binding of the substrate to some other group in the active center before reaction with the relatively large ASPM molecule. We have therefore studied, as a model reaction, the reaction of pyruvate *(1)*, R = CH_3, and of trimethylpyruvate *(1)*, R = $C(CH_3)_3$, with cysteine, using spectroscopy in the region of the $n \rightarrow \pi^*$-transition at pH 7.4; we found that the extinction of a pyruvate solution at 314 nm is reversibly decreased by cysteine, but not that of other amino acids (glycine, alanine, serine). This result indicates formation of a hemiacetal *(2)* between pyruvate and cysteine.



(1) *(2)*

Stuart models show that for steric reasons trimethylpyruvate cannot form a hemiacetal. This explains why trimethylpyruvate is not decarboxylated by PDC and also why it does not act as a competitive inhibitor of the PDC reaction[4].

Apo–PDC reacts appreciably faster than holo-PDC with ASPM, neither the coenzyme nor Mg^{2+} ions protecting the apoenzyme from reaction with the SH reagent. We conclude from this, in agreement with earlier ideas derived from kinetic measurements[5], that the sites of binding for TPP and Mg^{2+} in the apoenzyme are at first free and relatively far removed from the site of binding of the substrate. Only on recombination to give the holoenzyme does a structural rearrangement of the protein components occur that draws the cysteine into the active center.

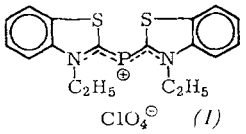
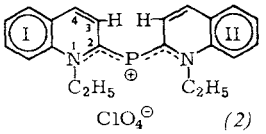
Crystal Structure of Bis-(1-ethyl-2-quinolyl)-phosphamethinecyanine Perchlorate

By *I. Kawada* and *R. Allmann*[*]

Some time ago the structure of 1-ethyl-2-[(1-ethylbenzothiazolin-2-ylidene)phosphino]benzothiazolium perchlorate *(1)* was determined[1], whereupon participation of the doubly bonded phosphorus in the π-electron system of the cyanine was established. On replacement of the benzothiazole by quinoline, steric causes (too close approach of the H atoms on C-3) should prevent formation of a planar cyanine cation *(2)*. This has in fact been confirmed by a structural study of 1-ethyl-2-[(1-ethyl-1,2-dihydroquinolin-2-ylidene)phosphino]-quinolium perchlorate *(2)*[2].



$ClO_4^{\ominus}$ *(1)*



$ClO_4^{\ominus}$ *(2)*

As the Figure shows, the two quinoline planes I and II are rotated by 40° and 24°, respectively, around the C–P bonds and out of the cyanine plane. The normals to planes I and II enclose an angle of 60°. Therefore resonance in the cyanine cation is hindered, which results in a noticeable lengthening of the C–P bonds: 1.81 and 1.77 Å as compared with 1.76 in *(1)* (but C–P = 1.83 Å in triphenylphosphine).

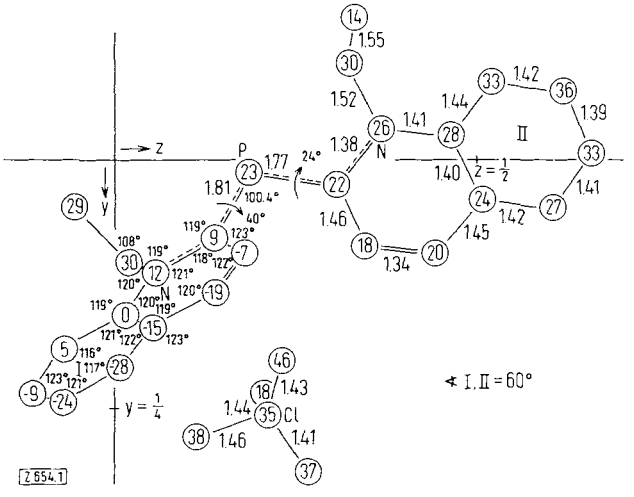


Fig. 1. *y,z*-Projection of a perchlorate anion and a phosphacyanine cation *(2)* with mean distances (Å) and bond angles. *x*-Coordinates in *a*/100 are given in the circles.

The slight asymmetry of *(2)* in the crystal indicates partial shift of the positive charge to side I of the cyanine cation. This is shown, not merely by the differences in the torsion angles and in the C–P bond lengths, but also in the shorter distance of the half-molecule I from the perchlorate anion; the only intermolecular atomic separations less than 3.4 Å are $N_I \cdots O$ 3.20 Å and $C\text{-}2_I \cdots O$ 3.26 Å.

In other respects the halves I and II are identical within the calculated standard deviations (σ = 0.01–0.02 Å for distances and 1–2° for angles). Therefore the distances and angles given in the Figure are the means of those determined for the two half-molecules. Attention is directed to the almost isolated double bond [(C-3) = (C-4) = 1.34 Å].

Crystallographic parameters for *(2)* are:

$a = 7.997 \pm 13$ Å	Space group $P2_1/c$
$b = 19.546 \pm 21$ Å	D_m (pycn.) = 1.36 ± 1 g cm^{-3}
$c = 14.157 \pm 28$ Å	$D_x = 1.34$ g cm^{-3}
$\beta = 93.67 \pm 0.16°$	$Z = 4$

The structure determination for *(2)* is based on 2560 independent reflections (of which 374 were unobservable) and was carried out in the same way as that of *(1)*. With isotropic individual temperature factors, the reliability factor between observed and calculated structure factors (excluding H atoms) was reduced to $R = 16.3\ \%$.

Iron Derivatives of Five-membered Carbon-Nitrogen Heterocycles

By *F. Seel* and *V. Sperber*[*]

Dedicated to Professor B. Eistert on his 65th Birthday

By treating pyrazole *(1)*, imidazole *(2)*, and 1,2,4-triazole *(3)* with penta- or tetra-carbonyliron, mercury tetracarbonylferrate(II), ferrocene, or dicarbonylcyclopentadienyliron in the presence or absence of a solvent (benzene, toluene, or mesitylene) we have been able to prepare the almost colorless iron(II) derivatives of these nitrogen-heterocycles, namely, $Fe(N_2C_3H_3)_2$ from *(1)*, $Fe(N_2C_3H_3)_2 \cdot 0.5\ N_2C_3H_4$ from *(2)*, and $Fe(N_3C_2H_2)_2$ from *(3)*. In the case of imidazole, the synthesis can be effected even with iron powder. In the reaction of dicarbonylcyclopentadienyliron, cyclopentadiene and cyclopentene are by-products;

$$[C_5H_5Fe(CO)_2]_2 + 4\ N_2C_3H_4 \rightarrow 2\ Fe(N_2C_3H_3)_2 + C_5H_6 + C_5H_8 + 4\ CO$$

The deep brownish-red iron(III) derivative $Fe(N_2C_3H_3)_3$ is formed on reaction of dicarbonylcyclopentadienyliron chloride with *(1)*, together with dicarbonylcyclopentadienyliron which can be separated by extraction with toluene:

$$4\ C_5H_5Fe(CO)_2Cl + 10\ N_2C_3H_4 \rightarrow 2\ Fe(N_2C_3H_3)_3 + [C_5H_5Fe(CO)_2]_2 + 4\ CO + 4\ N_2C_3H_5Cl + 2\ C_5H_6$$

The iron(III) derivative of *(1)* is obtained in moderate yield by reaction of iron(III) chloride with the potassium salt in liquid ammonia. Also, reaction of the iron(II) compounds with silver salts of the heterocycles gives the iron(III) compounds:

$$Fe(N_2C_3H_3)_2 + AgN_2C_3H_3 \rightarrow Fe(N_2C_3H_3)_3 + Ag$$

The iron derivatives of the five-membered carbon-nitrogen heterocycles *(1)*, *(2)*, and *(3)* are clearly not aza analogs of ferrocene, but are coordination polymers. As such they dissolve in other substances only with decomposition. The iron(II) compounds are very sensitive to air, but the iron(III) compounds are not. A change in the type of chemical bonding is indicated in particular by the fact that the sandwich complex, π-cyclopentadienyl-π-pyrrolyliron ("azaferrocene")[1] can be converted into ferrocene by cyclopentadiene, whereas the iron(II) derivatives of the five-membered heterocycles *(1)*, *(2)*, and *(3)* with two or more nitrogen atoms do not undergo this reaction. Complexes of the type FeL_4I_2 [L = *(1)* or *(2)*], which were obtained from tetracarbonyliron(II) iodide, show that the coordination number of the metal atom is four in the iron(II) derivatives of *(1)* and *(2)* as well as in the poly-(1-pyrazolyl)iron(II) borates[2].

The behavior of pyrrole deviates to a remarkably large extent from that of heterocycles with two or more nitrogen atoms. It and its *N*-methyl derivative react with $Fe(CO)_4I_2$ to give coordination compounds of type FeL_2I_2 ($L = C_4H_4NH$ or $C_4H_4NCH_3$). Synthesis of the still unknown dipyrrolyliron(II) is apparently difficult because it can exist, if at all, only as an unstable sandwich complex ("diazaferrocene") and not as the more stable coordination polymer. In view of the stability of the coordination polymers $\{Fe(N_2C_3H_4)_{4/2}\}_G$ it is intelligible that the only pyrrole-iron compound isolated to date is $[Fe(NC_4H_4)_4]K_2$[3].

Complex compounds of the type $C_5H_5Fe(CO)_2L$ ($L = NC_4H_4$, $N_2C_3H_3$, or $N_3C_2H_2$) have been obtained by treating dicarbonylcyclopentadienyliron chloride with the potassium salts of all the five-membered nitrogen heterocycles in liquid ammonia. Of these, however, only the pyrrole derivative could be converted into the dumbbell complex $C_5H_5FeNC_4H_4$[4].

Experimental:

In order to prepare the iron(II) derivative of imidazole from ferrocene the two starting materials, mixed in the weight proportion 10:1, were warmed slowly to 250 °C in an highly evacuated sealed tube. An orange-colored solution resulted in the temperature region 90 °C [m.p. of *(2)*] to 120 °C. At 180 °C reaction begins, with lightening of the color of the melt and separation of a yellow crystalline precipitate. After 3 h the contents of the tube are allowed to solidify and then the excess of imidazole is sublimed off at 70 °C in a vacuum over a period of several hours, leaving a quantitative yield of $Fe(N_2C_3H_3)_2 \cdot 0.5\ N_2C_3H_4$ as yellowish-brown needles, 3 mm in length.

For preparation of the iron(III) derivative of pyrazole from dicarbonylcyclopentadienyliron chloride, the two components in the weight ratio 3:1 were dissolved in just sufficient toluene and boiled under reflux in an atmosphere of nitrogen. The solution changes from red to reddish-brown even before it boils, and a precipitate begins to separate. After 2 h the solvent is distilled off and the residual mixture is extracted with 50 ml of toluene per g of substance with exclusion of air. The brown residue is the desired product. It is washed with 0.05 N hydrochloric acid in the air.

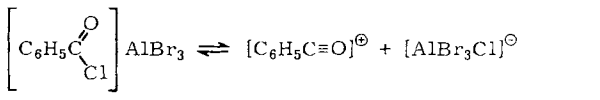
Identification of the Benzoylium Cation by IR Spectroscopy

By *H.-H. Perkampus* and *W. Weiss*[*]

In recent years numerous complexes between acid halides and Lewis acids have been studied by IR spectroscopy[1–3,5], and a new band around 2300 cm^{-1} was ascribed to an oxocarbonium ion. Repeated attempts were made to detect a corresponding band for the complex between a benzoyl halide and a Lewis acid[2,4]. Ionic complexes were obtained only from benzoyl fluoride and SbF_5 or AsF_5[3] and on treatment of methylbenzoyl chlorides with Lewis acids[2,5]. On the basis of conductivity measurements for the complex benzoyl chloride/$GaCl_3$ in the liquid state *Greenwood* and *Wade*[6] postulated an ionic structure $[C_6H_5CO]^{\oplus}[GaCl_4]^{\ominus}$, and *Oulevey*[7] demonstrated an exchange reaction between $AlCl_3$ and benzoyl chloride by means of radioactive chlorine, from which he deduced that the complex exists partly in an ionic form.

Our measurements were carried out with a cuvet described previously[8], wherein the substances can be measured directly as solids or as liquid films. Benzoyl chloride and $AlBr_3$ were placed in the cuvet at −196 °C and the spectrum was recorded from 2350 to 2100 cm^{-1} while the specimen was warmed cautiously. The substance film began to melt at about 0 °C, and at +7 °C a sharp band of low intensity appeared in the spectrum at 2209 cm^{-1}. The intensity of this band increased with rising temperature and reached a maximal value between 40 and 50 °C. After cooling, the bands had disappeared, but they reappeared on repeated increase in temperature. It is thus demonstrated that a temperature-dependent equilibrium between a coordinate and an ionic complex exists also in the system benzoyl chloride/$AlBr_3$.



Cation bands were also measured for the following solid systems (temperatures in parentheses are those up to which the samples were warmed; samples were later refrozen):

$CH_3COCl + AlBr_3 \rightarrow [CH_3CO]^{\oplus} + [AlBr_3Cl]^{\ominus}$: 2293 cm^{-1} (−28 °C)

$C_2H_5COCl + AlBr_3 \rightarrow [C_2H_5CO]^{\oplus} + [AlBr_3Cl]^{\ominus}$: 2264 cm^{-1} (−42 °C)

$C_2H_5COCl + GaCl_3 \rightarrow [C_2H_5CO]^{\oplus} + [GaCl_4]^{\ominus}$: 2264 cm^{-1} (−100 °C)

Preparation of Octametaphosphates, $M^I_8[P_8O_{24}]$

By *U. Schülke* [*]

When lead tetrametaphosphate tetrahydrate, $Pb_2[P_4O_{12}]\cdot 4\,H_2O$ *(1)* is heated, one obtains a mixture of the hitherto unknown crystalline lead octametaphosphate $Pb_4[P_8O_{24}]$ *(2)* (70 %) and high-molecular crystalline lead polyphosphate *(3)* (30 %), as well as traces of lead mono-, di-, and triphosphate.

Quantitative evaluation of paper chromatograms of samples taken at various stages of the dehydration, as well as Guinier photographs, rate of water loss, and differential thermal analysis, show that, during the heating up and while the temperature is kept at 350 °C, dehydration and thermal rearrangement of *(1)* occur by the stages:

a) crystalline $Pb_2[P_4O_{12}]\cdot 2\,H_2O$;

b) ring-hydrolysis of the tetrametaphosphate anion by the residual crystal water, to give a mixture of lead mono-, di-, and tri-phosphate;

c) condensation of the hydrolysis products to *(3)* and anhydrous crystalline lead tetrametaphosphate *(4)*;

d) conversion of *(4)* into *(2)*.

The steps c) and d) occur simultaneously.

When $Pb(H_2PO_4)_2$ is heated, only a poor yield of *(2)* is formed, together with *(3)*. The appearance of the octameric compound in the dehydration products of $Pb(H_2PO_4)_2$ was observed previously by *Thilo* and *Grunze* [1] who, however, on the basis of the position of the octametaphosphate spot on a one-dimensional paper chromatogram, assumed that this material was a polyphosphate.

When the mixture formed by heating *(1)* is treated with alkali-metal sulfide or carbonate solutions, crystalline alkali-metal salts of octametaphosphoric acid are obtained, *e.g.* $Na_8[P_8O_{24}]\cdot 6\,H_2O$ *(5)*.

Preparation of (5):

5–10 g of compound *(1)*, prepared by mixing solutions of $Pb(NO_3)_2$ and $Na_4[P_4O_{12}]\cdot 4\,H_2O$ in water, is heated in a shallow dish, first at 110 °C for 30 min, and then at 350 °C for 30 min. 100 g of the dehydration product is made into a slurry in 200 ml of water and treated, with stirring, with a solution of 70 g of $Na_2S\cdot 9H_2O$ in 600 ml of water. After 15 min the precipitated PbS is filtered off, *ca.* 100 ml of ethanol is added to the filtrate with stirring, the precipitated sodium polyphosphate is removed, and the sodium octametaphosphate is caused to crystallize by addition of *ca.* 900 ml of ethanol and is then sucked off, washed with 50 % ethanol, and dried in the air. For further purification the sodium salt can be recrystallized by adding ethanol to its aqueous solution.

The cyclic nature of the octametaphosphate anion is shown by the following facts:

1. The ratio $M^I:P = 1:1$ in the crystalline Na, K, Ag, and Ca salts, which corresponds to the general formula $M^I_n(PO_3)_n$ for metaphosphates.

2. The acid-base titration curve of octametaphosphoric acid which, referred to one POH group, corresponds to the curve for a strong monobasic acid; weakly acidic end groups, such as are present in polyphosphates, were not found (a dilute aqueous solution of octametaphosphoric acid can be prepared by reaction of its sodium salt with Wofatit KPS in the H form).

3. The ^{31}P–NMR spectrum of the aqueous solution of *(5)* consists of only one signal; the chemical shift is 21.2 ± 1 ppm [2], referred to 85 % H_3PO_4, in the region of shifts observed for metaphosphates [3].

4. The position of the octametaphosphate spot in the two-dimensional paper chromatogram characterizes it as a member of the homologous series of metaphosphates with an anion that is larger than that of hexametaphosphate.

The ring size (the number of PO_3 groups per anion) was determined by the same method as was employed in the case of the recently isolated penta- and hexa-metaphosphates *i.e.* by alkaline ring fission in 0.2 N NaOH [4]; the cyclic anion of the octametaphosphate was in this way first cleaved to the octaphosphate with a chain-like anion, which was identified by paper chromatography.

Fission of the sixteen-membered cyclic anion is, however, so slow that most of the octaphosphate formed is degraded to low-molecular polyphosphates and trimetaphosphate before all the octametaphosphate is cleaved.

The octametaphosphates, thus first available in quantity, resemble the high-molecular polyphosphates more than they do the tri- or tetra-metaphosphates. For instance, in solution they show good ability for complex formation, similar to that of triphosphate and higher-molecular polyphosphates. However, in the resistance to nucleophilic reagents the octametaphosphates are the equal of the very stable hexametaphosphates [4,5].

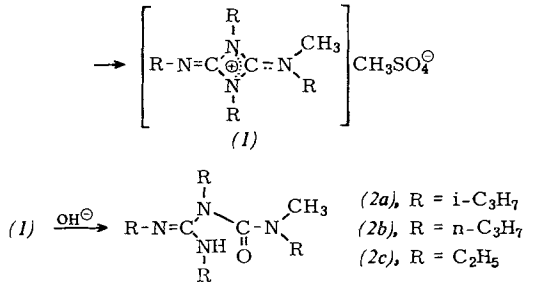
Dimerization of Carbodiimides[1]

By *K. Hartke* and *F. Rossbach*[*][2]

Aliphatic carbodiimides react readily with alkylating agents such as dimethyl sulfate. If equivalent amounts of the two compounds are mixed and kept at room temperature without a solvent being present, the ν-N=C=N stretching vibration of diisopropylcarbodiimide disappears in 5 days, of di-*n*-propylcarbodiimide in 30 h, and of diethylcarbodiimide in 16 h. NMR spectra indicate in each case reaction of two molar equivalents of carbodiimide with one of dimethyl sulfate to yield *N*-alkyl-*N*-methyl-1,3-dialkyl-2-alkylimino-1,3-diazetidine-4-iminium methyl sulfates *(1)*.

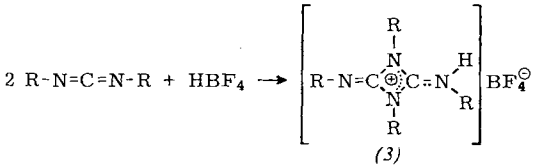


(1)

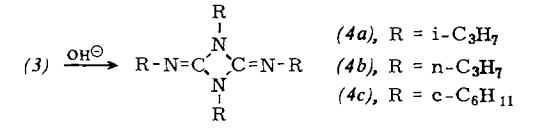
(2a), R = i-C_3H_7
(2b), R = n-C_3H_7
(2c), R = C_2H_5

The salts *(1)* are isolated as oils; they are soluble in water and on addition of an excess of aqueous sodium hydroxide are at once hydrolyzed to *N,N',N''*-trialkyl-*N*-(*N*-alkyl-*N*-methylcarbamoyl)guanidines *(2)*, which, being sparingly soluble, are then precipitated. Compound *(2a)* is crystalline, has m.p. 102–103 °C, is formed in 81 % yield, and has a molecular weight 286 (acidimetric); in the IR spectrum (KBr) νNH 2.99 μ, νCO 6.09 μ, νC=N 6.22 μ, and in the NMR spectrum ($CDCl_3$) doublets at 1.10 ppm [3 $C(CH_3)_3$] and 1.29 ppm [1 $C(CH_3)_2$], a singlet at 2.68 ppm (1 $N-CH_3$), and a broad singlet at 3.4 ppm (NH). The compounds *(2b)* and *(2c)* are liquid and have not yet been obtained analytically pure.

An analogous dimerization of aliphatic carbodiimides to salts of structure *(3)* is observed on admixture with 0.5 molar equivalent of anhydrous ethereal tetrafluoroboric acid[3] in anhydrous methylene chloride. IR spectroscopic studies showed that the reaction is complete within only a few minutes at room temperature.



(3)

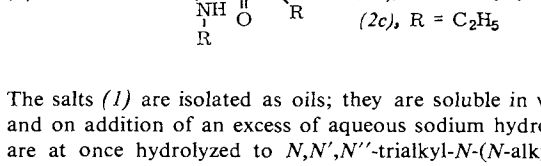


(4a), R = i-C_3H_7
(4b), R = n-C_3H_7
(4c), R = c-C_6H_{11}

The salts *(3)* were not isolated but were converted into the 1,3-dialkyl-2,4-bis(alkylimino)-1,3-diazetidines *(4)* by cautious neutralization with aqueous sodium hydroxide or by filtration through a column of basic Al_2O_3 [*(4a)*: m.p. 52 °C, yield 90 %. *(4b)*: b.p. 90 °C/0.05 torr, yield 70 %. *(4c)*: m.p. 122.5 °C, yield 95 %]. The structure *(4)* was proved by elemental analysis and spectroscopic data: *e.g.*, for *(4a)*: molecular weight 252 (acidimetric), 252 (mass spectrometric); IR (KBr) νC=N 5.96 μ; NMR (CCl_4) doublets at 1.12 ppm [2 $C(CH_3)_2$] and 1.29 ppm [2 $C(CH_3)_2$]. Dimeric aliphatic carbodiimides were previously almost unknown[4]. They are stable indefinitely at room temperature, but when warmed decompose partly into the monomers. Thus in the mass spectrum of *(4a)* one observes the molecular ion and fragments with mass numbers greater than that of the monomer only when the evaporation temperature is low. Moreover, some di-*n*-propylcarbodiimide is detectable by IR spectroscopy in the fresh distillate of *(4b)* but disappears after a few days.

Aromatic carbodiimides also dimerize, within a few minutes, on addition of 0.5 molar equivalent of anhydrous tetrafluoroboric acid in anhydrous methylene chloride; however, they afford in this reaction substituted quinazolinium salts of structure *(5)*, from which the 3-aryl-2-arylamino-4-aryliminoquinazolines *(6)* [*(6a)*, m.p. 181–185 °C[5], yield 85 %; *(6b)*, m.p. 246 °C, yield 82 %], are obtained by means of bases.

(5)



(6a), R = H
(6b), R = p-CH_3

The structure *(6)* was proved by IR, NMR, and mass spectral results. The compound *(6a)* was previously prepared by *McCoy* (1897) from chloro-*N,N'*-diphenylformamidinium chloride by means of aluminum chloride[6].

Preparation of Halogeno- and Acetato-organoplumbates(IV)[1]

By *F. Huber* and *E. Schönafinger*[*]

A large proportion of the covalent bond energy in the total free energy of the relevant system[2,3] is an important condition for the possibility of synthesis, and for the stability,

of lead(IV) compounds, which, in contrast to analogous compounds of other elements of the fourth Group, are almost all to be considered as intramolecular redox systems. Organolead(IV) halides, $R_{4-n}PbX_n$ ($X \neq F$), are thus more stable than the tetrahalides PbX_4.

We have now tried to prepare organosubstituted halogenoplumbates(IV) of the general formula $M^I_m[R_{4-n}Pb^{IV}X_{n+m}]$, since we wished to discover whether a corresponding stabilizing effect is to be seen among the organolead complex anions of which little was previously known. In view of the non-existence of purely inorganic hexabromo- and hexaiodoplumbates(IV), studies of the preparability of bromo- and iodo-organoplumbates(IV) were of particular interest.

For the series $M^I[R_3PbX_2]$ we mixed hot ethanolic solutions of triphenyllead chloride or bromide with the appropriate tetramethylammonium halide and, on cooling the solutions, obtained colorless crystalline precipitates.

$$(C_6H_5)_3PbX + (CH_3)_4NX \rightarrow [(CH_3)_4N][(C_6H_5)_3PbX_2] \quad (1)$$

(1a), X = Cl; m.p. 298 °C (decomp.)

(1b), X = Br; m.p. 277 °C (decomp.)

An analogous reaction with cesium bromide gave $Cs[(C_6H_5)_3PbBr_2]$, m.p. 209 °C (decomp.). Attempts to prepare the iodine compound failed; in these we isolated only starting materials.

Hills and *Henry*[4] mention briefly a product corresponding to *(1a)* but without characterizing its properties more closely. Compounds *(1a)* and *(1b)*, like the other compounds described here, are not sensitive to air or hydrolysis and are very difficultly soluble in the usual organic solvents. The solubility does not suffice for determination of exact molecular weights, but does suffice for conductivity measurements; *ca.* 10^{-3} M solutions in methanol at 20 °C have a conductivity about 100 times that of pure methanol [molar conductivity of *(1a)* $\mu_{20\,°C} = 122$ ohm^{-1} mole^{-1} cm^2], which we attribute to electrolytic dissociation of the compounds. In the solid state they may be built up, salt-like, of complex ions.

As example of compounds of type $M^I_2[R_3PbX_3]$ and as the as-yet sole alkyllead derivative, we were able to obtain the compound $[(CH_3)_4N]_2[(CH_3)_3PbCl_3]$ (decomp. 86 °C) by mixing solutions of trimethyllead chloride and tetramethylammonium chloride in ethanol at room temperature and extracting unchanged starting materials by ethyl acetate from the resulting precipitate. In all attempts to prepare other alkyl-substituted halogenoplumbates(IV) of this type, either the starting materials were recovered or, particularly on warming, the alkyl groups were removed with formation of halogenoplumbates(II).

Representatives of the series $M^I[R_2PbX_3]$ were provided by the colorless complex salts *(2)* precipitated when ethanolic solutions of diphenyllead dihalides or diacetate and of $(CH_3)_4NX$ (X = Cl, Br, or CH_3COO) were heated together:

$$(C_6H_5)_2PbX_2 + (CH_3)_4NX \rightarrow [(CH_3)_4N][(C_6H_5)_2PbX_3] \quad (2)$$

(2a), X = Cl; m.p. 301 °C (decomp.)

(2b), X = Br; m.p. 262 °C (decomp.)

(2c), X = CH_3COO; m.p. 223 °C (decomp.)

Under the same conditions cesium acetate and diphenyllead diacetate give the compound

$Cs[(C_6H_5)_2Pb(CH_3COO)_3]$, m.p. 274 °C (decomp.).

In the analogous reaction of cesium bromide with diphenyllead dibromide in ethanol the phenyl groups were removed quantitatively with formation of bromoplumbate(II). In anhydrous acetone, however, the compound

$Cs[(C_6H_5)_2PbBr_3]$, m.p. 223 °C (decomp.)

was obtained.

The reaction of iodides – which, like the other reactions, occurred independently of the molar ratio of starting materials used – led to the yellow salt

$[(CH_3)_4N]_2[(C_6H_5)_2PbI_4]$, m.p. 333 °C (decomp.)

which is an example of the type $M^I_2[R_2PbX_4]$.

Mixed compounds

$[(CH_3)_4N][(C_6H_5)_2PbX_{3-n}X'_n]$

were obtained from diphenyllead dihalides and $(CH_3)_4NX$ containing different halogens, n in the product formula depending on the exchange equilibrium. From a solution of diphenyllead dichloride and tetramethylammonium bromide (molar ratio 1:2) in ethanol there separated, *e.g.* after heating for 10 min, a product of formal composition

$[(CH_3)_4N][(C_6H_5)_2PbBr_{1.7}Cl_{1.3}]$

All attempts to convert dialkyllead dihalides by $(CH_3)_4NX$ or cesium halides into halogenodialkylplumbates(IV) resulted, after intermediate complex formation in solution, in quantitative elimination of the alkyl group R from the lead, and lead(II) compounds separated with evolution of gas, *e.g.*:

$$(CH_3)_2PbBr_2 + (CH_3)_4NBr \rightarrow [(CH_3)_4N][PbBr_3] + C_2H_6.$$

According to gas-chromatographic analyses the gas evolved consisted exclusively of dimerized alkyl groups only in the reactions of dimethyllead compounds (giving ethane). Removal of higher alkyl groups gave complex mixtures of alkanes and alkenes.

We have not yet been able to prepare compounds of type $M^I_m[RPbX_{3+m}]$. In place of the non-existent monorganolead trihalides we tried to combine phenyllead triacetate with $(CH_3)_4NX$ to give compounds with a halogenomonophenylplumbate(IV) anion; however, we isolated only lead(II) compounds, *e.g.* tetraethylammonium triiodoplumbate(II) from phenyllead triacetate and tetraethylammonium iodide.

The phenyl-substituted plumbates(IV) prepared are more stable than the unsubstituted analogs; the alkyl-substituted plumbates(IV) are less stable or cannot be isolated at all. In addition to the unexpectedly large effect of the group R, the influences of the anions and also of the cations and solvent on the stability are of not inconsiderable importance. An unfavorable summation of these factors can labilize a compound to such an extent that organic groups are cleaved from the lead and Pb(IV) is converted into Pb(II). This is a further example of the result of the "inert-pair" effect (cf.[3]), whose influence on the stability and chemistry of organometallic derivatives of the heavy elements of the third to the fifth Main Group has been little considered hitherto and which we are now investigating.

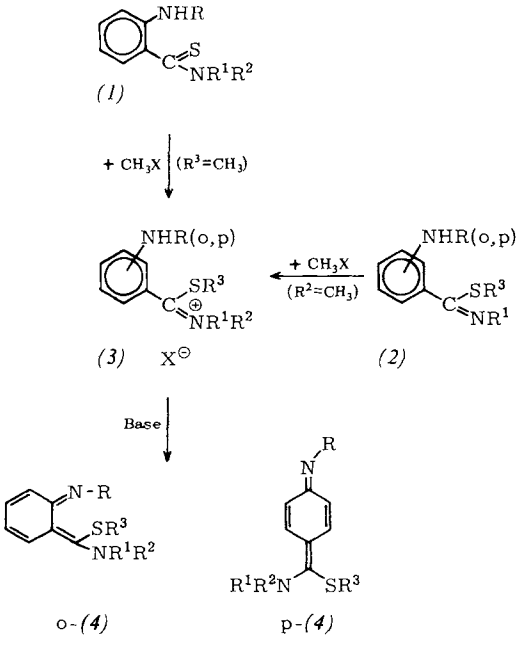
Quinone Methide Imines

By *R. Gompper* and *H.-D. Lehmann* [*]

Quinone methide imines cannot be prepared from aromatic amines and carbonium salts by processes analogous to those that have proved valuable for preparation of quinone methides [1] and quinodimethanes [2]. We have developed three methods for the synthesis of these compounds which, except for the stable *N*-phenylimine of fuchsone [3], have previously been only assumed [4], or proved by spectroscopy [5], to exist as intermediates; we here describe two of our methods.

1. *N,N*-Disubstituted thioanthranilamides *(1)* and corresponding *S,N*-disubstituted *o*- and *p*-aminothiobenzimidic esters *(2)* (so far we have used only 2-[*o*(*p*)-aminophenyl]-benzothiazole) react with methyl iodide or methyl *p*-toluenesulfonate (CH_3X), giving smoothly the salts *(3)*, whence HX can be removed by bases, *e.g.*, triethylamine, with formation of the stable quinone methide imines *(4)*.



(150 ml) is boiled under reflux for 2 days. The CS_2 is then distilled off, chloroform (200 ml) is added, and thereafter sodium carbonate solution is added gradually. The chloroform phase is separated, washed with water, and dried with calcium chloride. Distilling off the solvent leaves a yellow oil, which crystallizes when rubbed with a little acetone.

Preparation of N,N-Dialkyl-N-[o-(benzenesulfonylamino)-phenyl-α-(methylthio)benzylidene]ammonium Iodides (3), R = $SO_2C_6H_5$; R^1, R^2 = Alkyl:

0.1 mole of *(1)* is heated under reflux with 0.15 mole of methyl iodide in 100 ml of acetone for 15 min. Even during the boiling, the iodide separates in analytically pure form.

Preparation of N-(Benzenesulfonyl)-7-(dimethylamino)-7-(methylthio)-o-quinone methide imine (4), R = $SO_2C_6H_5$; R^1, R^2,R^3 = Methyl:

4.6 g of *(3)*, R^1, R^2, R^3 = CH_3, is suspended in 3 ml of anhydrous acetonitrile and treated with 0.7 g of *N*-ethyldiisopropylamine. Dissolution occurs with a yellow coloration. The mixture is covered with 1 ml of petroleum ether, and acetone is added to achieve homogeneity. The pale yellow, analytically pure *o*-quinone methide imine crystallizes out.

2. The action of diazomethane on *(1)*, R = $SO_2C_6H_5$, gives a mixture of *o-(4)* and *(5)*. The compound *o-(4)*, R = $SO_2C_6H_5$, R^3 = CH_3, R^1R^2N = morpholino, crystallizes from the ethereal solution in 76% yield and is easily separated from *(5)* (22%) in this way. The yield of *o-(4)* depends to a large extent on the nature of R^1 and R^2: from the pyrrolidide, $R^1 + R^2 = -(CH_2)_4-$, only 49% of *o-(4)* is obtained; from

[a] In chloroform. — [b] In acetonitrile. — [c] With decomposition.

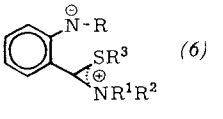
The starting materials *(1)* are accessible from *N*-substituted *o*- and *p*-aminobenzoyl chlorides or isatoic anhydrides by way of the amides which are then treated with P_2S_5. Compounds *(2)*, $R^1 + R^2$ = *o*-C_6H_4, can be prepared from the corresponding acid derivatives and *o*-aminothiophenol.

Preparation of N^1,N^1-Dialkyl-N^2-(benzenesulfonyl)thioanthranilamides (1), R = $SO_2C_6H_5$; R^1, R^2 = Alkyl:

A well-stirred suspension of N^1,N^1-dialkyl-N^2-(benzenesulfonyl)anthranilamide (0.1 mole) and P_4S_{10} (22.2 g) in CS_2

the piperidide, $R^1 + R^2 = -(CH_2)_5-$, only 29%; and from the dimethylamide, $R^1 = R^2 = CH_3$, none.

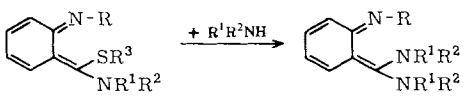
The quinone methide imines listed in the first Table are stable indefinitely if moisture is excluded. They show negative



(6)

solvatochromy, which indicates relatively great participation of the resonance structure *(6)* in the ground state.

Reaction of *o-(4)*, $R^3 = CH_3$, with secondary amines affords the *o*-quinone methide imines *(7)*.



o-(4) *(7)*

Cpd.	R	R^1	R^2	M.p. (°C)	λ_{max} (nm)	log ε	Yield (%)
(7)	$SO_2C_6H_5$	CH_3	CH_3	231	353	3.35	96
	$SO_2C_6H_5$	$-(CH_2)_2-O-(CH_2)_2-$		223	360	3.4	68
	$SO_2C_6H_5$	$-(CH_2)_4-$		219	—	—	32
	$SO_2C_6H_5$	$-(CH_2)_5-$		192	355	3.53	

The NMR spectra of *(7)*, $R^1 = R^2 = CH_3$, are temperature-dependent. For a solution in liquid SO_2 at −40 °C the signal due to the NCH_3 protons appears as a doublet (τ = 2.28 and 2.75), but at 37 °C as a singlet (τ = 2.48). The NCH_3 signal is also split (τ = 2.77 and 3.01) in the NMR spectrum of *o-(4)*, $R^1 = R^2 = CH_3$ (liquid SO_2, −40 °C). Most of the compounds *(4)* and *(7)* fluoresce strongly in the solid state.

When *o-(3)*, $R = C_6H_5$, is treated with K *tert*-butoxide in dimethylformamide a deep blue solution results. The *o*-quinone methide imine that is obviously formed could not be isolated but was proved to exist by cycloaddition of phenyl isocyanate and phenyl isothiocyanate.

N,P-Organometalated Phosphine Imines from Aminophosphines

By *O. J. Scherer* and *G. Schieder* [*]

N-Organometalated phosphine imines can be prepared from alkyl- or aryl-phosphines and organometal azides [1]. On treatment with an excess of ammonia in ether at *ca.* −50 °C di-(*tert*-butyl)chlorophosphine [2] [b.p. 49–50 °C/5 torr; $J(^{31}PCCH)$ = 12.0 Hz] gives an 81 % yield of aminodi-(*tert*-butyl)phosphine *(1)* as a water-clear liquid that is sensitive to oxygen and to moisture and does not condense to give $\{[(CH_3)_3C]_2P\}_2NH$ when kept for four weeks in a closed vessel.

$$[(CH_3)_3C]_2P-Cl + x\ NH_3 \rightarrow [(CH_3)_3C]_2P-NH_2 + NH_4Cl$$
(1)

(1): b.p. 33–34 °C/2 torr; m.p. −1 to +1 °C; ^1H–NMR spectrum (Varian A-60, 60 MHz; 10 % solution in benzene; tetramethylsilane as external standard), $J(^{31}PCCH)$ = 11.0 Hz.

An etheral solution of *(1)* is smoothly metalated by *n*-butyllithium in hexane at 0 °C. Reaction of *N*-phosphinyllithium amide *(2)* with chlorotrimethyl-silane or -germane affords di-(*tert*-butyl)phosphinyltrimethylmetal amides *(3)*.

$$(1) + n\text{-}C_4H_9Li \xrightarrow{-\,n\text{-}C_4H_{10}} [(CH_3)_3C]_2P\text{-}NH\text{-}Li \quad (2)$$

$$\xrightarrow[-\,LiCl]{(CH_3)_3MCl} [(CH_3)_3C]_2P\text{-}NH\text{-}M(CH_3)_3 \quad (3)$$

(M = Si, Ge)

(3a): M = Si; b.p. 39–40 °C/1 torr; m.p. −4 to −2 °C; yield 80 %; ^1H–NMR spectrum, $J(^{31}PCCH)$ = 11.0, $J(^{31}PNSiCH)$ = 0.6 Hz.

(3b): M = Ge; b.p. 49–50 °C/1 torr; m.p. −6 to −4 °C; yield 72 %; ^1H–NMR spectrum, $J(^{31}PCCH)$ = 11.0, $J(^{31}PNGeCH)$ = 0.3 Hz.

Further metalation of compounds *(3)* [*(3a)* at room temperature; *(3b)* at −40 °C] in ether with *n*-butyllithium affords compounds *(4)* whose existence is proved by treatment with chlorotrimethylsilane or -germane.

$$(3) + n\text{-}C_4H_9Li \xrightarrow{-\,n\text{-}C_4H_{10}} [(CH_3)_3C]_2P\text{-}NLi\text{-}M(CH_3)_3 \quad (4)$$

$$\xrightarrow{+(CH_3)_3M'Cl} \left[\begin{array}{c} M'(CH_3)_3 \\ | \\ [(CH_3)_3C]_2P^{\oplus}\text{-}NLi\text{-}M(CH_3)_3\ Cl^{\ominus} \end{array}\right] \quad (5)$$

$$\xrightarrow{-\,LiCl} \begin{array}{c} M'(CH_3)_3 \\ | \\ [(CH_3)_3C]_2P{=}N\text{-}M(CH_3)_3 \end{array} \quad (6)$$

(6a): M = Si, M′ = Ge; sublimes at *ca.* 90 °C/0.1 torr; yield 87 %; ^1H–NMR spectrum, $J(^{31}PCCH)$ = 14.3, $J(^{31}PGeCH)$ = 4.4, $J(^{31}PNSiCH)$ = 0.4 Hz.

(6b): M = Ge, M′ = Si; sublimes at *ca.* 80 °C/0.1 torr; yield 75 %; ^1H–NMR spectrum, $J(^{31}PCCH)$ = 11.9, $J(^{31}PSiCH)$ = 2.2, $J(^{31}PNGeCH)$ = 0 Hz.

Although the ^1H–NMR spectrum of the phosphine imine *(6a)* with its P–Ge/N–Si bond before as well as after sublimation gives no indication of existence of the isomer *(6b)*, the compound *(6b)* slowly rearranges to *(6a)* during sublimation [the isomer mixture contains *ca.* 25 % of *(6a)* and 75 % of *(6b)* after the first sublimation; *ca.* 60 % of *(6a)* and 40 % of *(6b)* after a second sublimation; identified by ^1H–NMR spectroscopy].

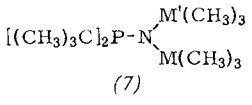
Heating at 120–130 °C for several hours is necessary for quantitative conversion of *(6b)* into *(6a)*. Keeping a benzene solution of the isomer mixture at room temperature for several days does not lead to enrichment of *(6a)*.

$$\begin{array}{c} Si(CH_3)_3 \\ | \\ [(CH_3)_3C]_2P{=}N\text{-}Ge(CH_3)_3 \end{array} \xrightarrow{\Delta} \begin{array}{c} Ge(CH_3)_3 \\ | \\ [(CH_3)_3C]_2P{=}N\text{-}Si(CH_3)_3 \end{array}$$
(6b) *(6a)*

The two phosphine imines *(6)* are readily soluble in ether, petroleum ether, and benzene; they react with CCl_4 [as does *(3)*]. Compounds *(3a)* and *(6a)* react to form $[(CH_3)_3C]_2P(Cl){=}N{-}Si(CH_3)_3$ (b.p. 42 °C/1 torr; m.p.

−13 °C; yield 90 %; ^{1}H–NMR spectrum: $J(^{31}PCCH)$ = 17.3, $J(^{31}PNSiCH)$ = 0.5 Hz; IR: P=N 1340 cm^{-1}). *(6a)* has a strong P=N band at 1320 cm^{-1} in its IR spectrum.

That the new class of *N,P*-organometalated phosphine imines *(6)* is formed by way of the intermediate addition product *(5)* and not by a rearrangement of *Michaelis-Arbuzov* type involving the intermediate *(7)* was proved by our experiments [*(4a)* M = Si + $(CH_3)_3GeCl$; *(4b)* M = Ge + $(CH_3)_3SiCl$]; if *(7)* had been formed, then the same



(7)

product or mixture of isomers would have resulted in the two cases.

Compound *(3)* exists exclusively in the aminophosphine form, this being proved by the IR spectrum (absence of a P=N band) and by oxidation with sulfur.

CONFERENCE REPORTS

Second International Meeting on Fuel Cells

held in Brussels (Belgium) on June 19–23, 1967

Some 350 participants attended this Meeting which was arranged by the Belgian Research Organisation S.E.R.A.I. (Société d'Etudes de Recherches et d'Applications pour l'Industrie). They came from 22 countries and represented 190 firms and Institutes. This shows that fuel cells have not lost their fascination as direct converters of chemical into electrical energy. However, there has been no easing of the difficulties connected with direct electrochemical oxidation, particularly of organic fuels. The following report presents a selection from the total of 55 papers.

1. Studies of the Course of Reaction

In porous electrodes, conversion of the reactant gases takes place near the electrolyte meniscus that is formed in the pores of the electrode. However, there is as yet no general answer to the question whether the reaction route involves (i) adsorption on the dry pore walls, (ii) surface diffusion to those parts of the pores that are filled with electrolyte and subsequent charge transfer, or (iii) diffusion through an electrolyte film of about 1 μ thickness above the visible meniscus before adsorption and charge transfer. To clarify this problem, *F. G. Will* (General Electric Company, Schenectady, U.S.A.) had studied an enlarged model of a meniscus covered with an electrolyte film. He covered a plane horizontal platinum foil, 40 cm long (the pore wall), with an electrolyte layer of 0.5, 1, or 2 mm thickness (the enlarged electrolyte film). Hydrogen, as reactant gas, streamed over the sulfuric acid electrolyte. The reference electrodes were platinized platinum points dipping into the electrolyte layer at distances of 2 cm from one another. It was thus possible to measure, for each region, the potential and the change in concentration by means of the resistance between neighboring platinum points. The changes in resistance during the anodic oxidation were smaller by orders of magnitude than those calculated. The cause was found to be convection (which was demonstrated by means of pigment particles) resulting from gradients in the surface tension. Further, there was additional water transport through the gas phase; this was shown very impressively when the surface of the liquid was covered with Teflon foil, water transport being more strongly hindered than that of H_2. Mathematical derivation of the polarization curve at limiting current gave good agreement with experiment. Since the curves for half-immersed electrodes and for technical gas-diffusion electrodes showed the same characteristics, *Will* concluded that the model provides a good picture of the pore function, *i.e.* that a "film mechanism" is involved.

The effect of adsorption layers on electrode processes was discussed in many papers. For instance, on platinum electrodes oxidation of CO in alkaline solution is hindered by the oxygen adsorption layer formed from +800 mV (against the reversible H_2 electrode).

As *H. Binder*, *A. Köhling*, and *G. Sandstede* (Batelle-Institut, Frankfurt/M, Germany) showed, a sulfur film, in contrast to an oxygen film, is stable on platinum even in the region of the H_2 potential. Current curves, measured potentiodynamically, show oxidation of the sulfur film to SO_2 in aqueous potassium hydroxide at +450 mV (70 °C), in dilute sulfuric acid at +650 mV (70 °C), and in concentrated phosphoric acid at +550 mV (150 °C). When dipped into a solution containing H_2S, porous electrodes with Raney nickel as active component receive a defined sulfur film. A slow stream of reactant gas was passed over such electrodes at a gas pressure of 0.6 atm. The S sorbate had only negligible influence on the oxidation of ethylene in dilute sulfuric acid or on that of CO in alkaline solution, but the oxidation of CO in acid solution was accelerated; in experiments with a sulfur coverage of 1 with a CO:H_2O mixture = 1:1 in 44 N H_3PO_4 at 155 °C the oxidation current was increased by a factor as high as 5. However, with saturated hydrocarbons in acid or unsaturated hydrocarbons in alkali the reaction velocity was diminished approximately proportionally to the sulfur coverage. There is as yet no explanation for the different behavior of carbon monoxide and of saturated and unsaturated hydrocarbons.

The exchange current per unit area of electrode is often given as a measure of the utility of an electrocatalyst. *G. Richter* (Siemens AG, Erlangen, Germany) explained how the exchange current can be measured also for powder catalyst present in powder form in the electrolyte if care is taken to achieve good electrical contact between the particles and a lead electrode. The exchange current was calculated from the initial current-potential curve and referred to the amount of the catalyst. The specific surface in m^2/g and values proportional to the surface, such as the double layer capacity and the chemisorption capacity, have utility only for the same support material. According to the method of preparation and after-treatment, values of the chemisorption capacity of unsintered Raney nickel (at potentials between 0 and +10 mV) were found to lie between 0.3 to 0.54 A s/g and for the specific exchange current between 0.2 and 1.7 A/g; the corresponding values for platinum black were 0.8 A s/g and 8 A/g[1].

M. Bonnemay, G. Bronoel, E. Levart, and *G. Peslerbe* (Laboratoire d'Electrolyse du CNRS, Mendon-Bellevue, France) have studied the influence of the structure of catalytic metals on their activity. The distances between platinum atoms in the lattice were altered by applying a tension or a compression and the rate of oxidation of hydrogen was measured. At 50 mV overvoltage a four-fold greater current was observed at a platinum sample that was under mechanical tension than at one that was not under tension. It seemed appropriate to replace the external tension by an internal one and to disturb the structure by alloying with small concentrations of a foreign element. Structural hardening is achieved by adding 0.5 % of Si to platinum. Such a sample proved to be appreciably more active if quenched from 1000 °C than after slower cooling. However, addition of alloying elements has also an electronic influence.

2. Low-temperature and Medium-temperature Cells

An effective gas electrode was obtained by *H. P. Landi, W. A. Barber, J. D. Voorhies*, and *R. G. Haldeman* (American Cyanamid Company, Stamford, U.S.A.) from carbon coated with catalyst and with Teflon as binder. The peculiarity is the use of fibrous Teflon (5 wt.-%), which confers high mechanical strength combined with good flexibility on the electrode. The new structure has proved valuable as an H_2/O_2 as well as an air electrode. At 25 °C platinum was more active in the cathode than was palladium or palladium-silver. With 1.1 mg of Pt per cm^2 of electrode surface, in aqueous potassium hydroxide with air as oxidant, an electrode potential of −0.06 V was measured at 20 m A/cm^2, and one of −0.21 V at −100 mA/cm^2 (potentials against the Hg/HgO electrode).

To provide current for balloons, which are released in large numbers and periodically questioned by a satellite, *J. Lemaignen* and *Ph. Demange* (Compagnie Francaise Thomson Houston, Hotchkiss Brandt, France) developed hydrogen-oxygen batteries that are stated to give an average output of 80 mW for 6 months. Higher impact loading is made possible by a nickel-cadmium accumulator connected in parallel. Longer life is achieved by using exchange membrane cells with fluorinated cation-exchangers. Because of the extreme conditions of pressure (below 350 mbar) and temperature (down to −60 °C) the battery is built into a steel cylinder and is thermally insulated. A total weight of 1800 g is expected. The O_2 supply is contained in a 0.8-l pressure vessel which is made of fiber-glass reinforced resin to save weight. The corresponding H_2 vessel has a capacity of 1.6 l.

As explained by *A. Winsel* (Varta AG, Frankfurt/M., Germany), the Varta company constructs H_2/O_2 cells with DSK electrodes[1] containing Raney nickel as active component in the anode and, in the cathode, Raney silver or silver precipitated by a special process. Electrodes functioning on one side are used in 50 W batteries which are designed to operate at 50–60 °C. For higher performance, Janus electrodes are preferred that can be charged on both sides and are sealed after lamination with epoxide resin. A pressure electrolysis apparatus with valve electrodes is stated to compensate for gas losses from the cells on long storage. Further, gas production can be achieved by catalytic decomposition of hydrazine, boranate, or peroxide by using Janus electrodes that have inactive fine-pored covering layers and a catalytically active middle layer.

In their paper *P. Dubois* and *J. Jacquelin* (Compagnie Générale d'Electricité, Marcoussis, France) described a 1 kW battery for hydrogen and oxygen. The modules are constructed of 12 double-sided electrodes which are sintered from nickel and silver (33 wt.-%). The battery contains 32 modules. The stated performance is reached at a working temperature of 55 °C. The cells alone weigh 70 kg. They are not yet optimized. Attempts are under way to replace the 2 mm thick sinter electrodes by thinner ones; this should reduce the Ag content to a few percent.

H. J. R. Maget (General Electric Company, Lynn, U.S.A.) described air-operated cells with ion exchange membranes onto both sides of which electrodes containing noble metal are pressed. For the membrane material a polymer from sulfurized α,β,β-trifluorostyrene is used, which is appreciably more resistant to oxidation than the sulfurized styrene used previously. It is chemically stable at temperatures up to 70 to 90 °C. The cathode is made hydrophobic with 10 % Teflon; thus the water produced is in the form of droplets which are not carried away immediately in the stream of air. The air becomes heated on the electrode, so that circulation is favored by a chimney effect. The operational efficiency amounts to 50 %. The current density can reach 120 mA/cm^2. A fuel cell battery with a nominal performance of 300 W has been run for 8000 hours with an output of 15 W.

3. Cells with Dissolved Fuel

W. Vielstich (University, Bonn, Germany) divides catalysts for anodic oxidation of hydrazine into three groups. Raney metals give rise to a potential more negative than that of the hydrogen electrode and they afford a measurable current even at the hydrogen potential. Noble metals such as platinum set up the hydrogen potential, but silver, gold, and active charcoal lead to anodic currents only at very positive potentials. – Two mechanisms can be considered for the oxidation of hydrazine: according to one of them a mixed potential is set up, and according to the other there is elimination of H before passage of the current. An attempt to differentiate between the two possible mechanisms by analyzing the gases formed at a defined anodic current strength was unsuccessful. However, the disturbance of an O_2 cathode by hydrazine can be explained as due to formation of an O_2/N_2H_4 mixed electrode.

H. H. von Döhren, D. Sparbier, and *G. Wolf* (Varta AG, Kelkheim, Germany) reminded the audience that skeletal nickel is useless for acceleration of the oxidation of methanol below 80 °C. However, with platinum on carbonylnickel as carrier in 8 N KOH at 18 mA/cm^2 a cell potential of 0.4 V is obtained. A 55 W battery contains 15 cells, arranged in electrical series, with silver-catalyzed O_2 electrodes. Janus cathodes permit use of a higher O_2 pressure (about 1 atm) whereby the output can be increased. Whereas formaldehyde reacts very rapidly on this catalyst, the intermediate formate produced becomes enriched in the electrolyte during discharge and is converted only as the methanol concentration decreases.

M. Futterer, H. G. Plust, and *C. G. Telschow* (Brown Boveri & Cie, Baden, Switzerland) have also chosen platinum on porous nickel for anodes in methanol batteries, using, however, a hydrophobized charcoal-air electrode as cathode. The selectivity of this electrode for reduction of O_2 was so much improved that the self-discharge corresponds to a current of only 18–20 μA/cm^2. Prolonged output from 20 W methanol-air batteries is effected with 1 to 5 mA/cm^2. Thermal insulation of the batteries permits operation at external temperatures down to −30 °C.

4. Cells with Molten Carbonate as Electrolyte

If Al_2O_3 is heated with an excess of Li_2CO_3 at 650 °C, a molten electrolyte is formed with lithium aluminate as matrix, which according to *A. Salvadori, M. Louichon*, and *C. Lebras* (Gaz de France, La Plaine Saint Denis, France) has considerable advantages over the paste-form electrolytes used so far. Even at this high operating temperature natural gas cannot be oxidized directly but must first be reformed. Nickel is the active constituent of the anode. On the cathode side, copper oxide mixed with active silver prevents the undesirable increase in granule size.

[1] DSK electrodes are double skeleton catalyst electrodes.

The solubility of O_2 is interesting because of the chemical short-circuit that it may cause, even in molten electrolytes. *M. Schenke* and *G. H. J. Broers* (C.T.I.–T.N.O., Amsterdam, Netherlands) have determined the solubility by amperometric titration with solid Na_2SO_3. A concentration of 0.4×10^{-6}mole of oxygen per cm^3 was found in alkali carbonate mixtures at 700 °C under 1 atm pressure of oxygen. During studies of cathode corrosion the solubility of silver and of copper oxide was determined and also estimated by calculation. The solubility of the Ag^+ ion is about 4×10^{-5} g/cm^3 at 700 °C, which is in approximate agreement with the calculated value. The solubility of CuO is lower than that of Ag^+ but higher than its estimated value.

5. Fuel Cells with Reformer

W. Frie (Siemens A.G., Erlangen, Germany) has calculated the thermodynamic equilibria that can exist during the production of hydrogen by treatment of methanol with steam. The following components were taken into account: H_2, CH_4, CH_3OH, CH_2O, HCOOH, CO_2, CO, H_2O, $(CH_3)_2O$, and carbon. The selectivity of a catalyst can not be calculated thermodynamically. However, the curves reproduce the experimental findings satisfactorily even though methane and carbon are not taken into account.

M. Prigent, C. Dezael, and *O. Bloch* (Institut Francais du Pétrole, Rueil-Malmaison, France) have compared direct oxidation of methanol with oxidation after previous steam-reformation. Complete conversion of the methanol was achieved even at 200 °C with copper chromite and ferrite as catalyst. Owing to the low reaction temperature the CO content of the reformate is between 0.2 and 0.8 %. The authors believe it possible to attain an efficiency of 70 % for the reformer, of 60 % for the fuel cell, and thus of about 40 % for the complete set-up with a weight of 30 kg/kW. This should be compared with a direct methanol-oxidation cell which with a cell potential of 0.4 V has an efficiency of about 30 % and a weight of about 33 kg/kW. A comparison of the amounts of platinum used in the anodes also comes out in favor of the cell with the reformer.

F. L. Gray (Texas Instruments Inc., Dallas, Texas, U.S.A.) has studied steam reformation and partial oxidation as preliminary processes before introduction of the fuel gas into cells containing eutectic carbonate melts and oxide matrices. The new cells with double-sided cathodes produce 20 mW/cm^2. A 500 W battery is attached to a propane reformer. Partial oxidation of petroleum gas is to be tested in a 1 kW fuel cell apparatus. It seems possible to achieve a life of 1000 h for the battery. The starting up time from the cold amounts to 40 min, and the overall efficiency to 15 %.

Rapid Chemical Separations for the Study of Short-lived Atomic Nuclei

By *G. Herrmann* [*]

Extremely neutron-rich atomic nuclei of about 40 elements may be obtained by nuclear fission. For examination of their properties these nuclides, whose half-lives amount to a few seconds, must be isolated by rapid chemical separations. To achieve this one may either speed up the usual methods of chemical analysis or utilize special nuclear-chemical effects.

The first method was illustrated by the following examples: Precipitation reactions are replaced by isotope- and ion-exchange on preformed precipitates, for instance, of halogen nuclides on silver halides or of alkali nuclides on salts of heteropolyacids. Solvent extractions may be accelerated by placing the extracting solvent on a finely divided powder through which the aqueous solution is then rapidly sucked; protactinium isotopes (in concentrated hydrochloric acid) can be separated in this way from a large excess of fission products when diisobutyl carbinol is used as solvent. Also, the formation of volatile hydrides of arsenic, selenium, antimony, and tellurium occurs very rapidly on addition of zinc to their acid solutions under suitable conditions – small volumes of concentrated hydrochloric acid and large amounts of fine zinc powder. Nuclear-chemical effects that can be used for rapid separations include β-recoil from solid surfaces,through which the materials produced from short-lived β-emitters leave a sample and are deposited on a foil; the yields admittedly depend more on the recoil energy than on the chemical properties. More specific are chemical reactions between recoil atoms and gaseous reactants when these yield volatile compounds, *e.g.* reaction of fission iodine with methane to give methyl iodide.

The applications of these procedures to the study of short-lived nuclides was illustrated by means of work carried out on neutron emitters present in fission products. After pulsed irradiation in the Mainz reactor, new neutron emitters of half-life down to 0.8 sec (^{140}I) were detected, and their contributions – as well as the contributions of known neutron emitters – to delayed neutron emission on fission of uranium-235 by thermal neutrons was measured [1].

Recent Findings in the Organic Chemistry of Tin and Lead

By *W. P. Neumann* [*]

Recent development of the organic chemistry of tin is characterized by surprising possibilities of effecting reactions with compounds containing Sn–H, Sn–N, and Sn–O groups. Interest has centered more and more on the use of organotin compounds for syntheses in organic chemistry and on the study of reaction mechanisms [1].

The long Sn–H bond (1.70 Å) is not strongly polar but is readily polarizable, thus permitting three types of reaction: *Hydride transfer* is the first step in the smooth 1,4-addition that yields ketene *N*-stannylimines *(1)* (where Y is, *e.g.*, NR_2, OR, H, Cl, or NO_2), which react with numerous compounds of the type ROH, RX, and R–COX:

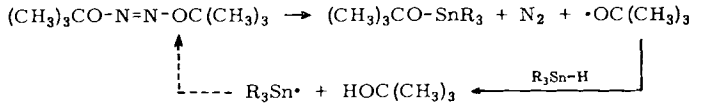
$$p\text{-Y}-C_6H_4-CH=C(CN)_2 + R_3Sn-H \rightarrow p\text{-Y}-C_6H_4-CH_2-C(CN)=C=N-SnR_3 \quad (1)$$

Many hydrostannations proceed by *radical mechanisms*. The Sn-H group is here disclosed as a very powerful radical trapping agent:

$$R'\text{-}CH=CH_2 + R_3Sn\cdot \longrightarrow R'\text{-}\dot{C}H\text{-}CH_2\text{-}SnR_3 \xrightarrow{R_3SnH} R_3Sn\cdot + R'\text{-}CH_2\text{-}CH_2\text{-}SnR_3$$

The hydrogen is eliminated as a *proton* in condensations with stannyl compounds $R_3Sn^{\delta\oplus}-X^{\delta\ominus}$, where advantageously $X = -N(C_2H_5)_2$.

The radical decomposition of diacyl peroxides is extremely powerfully induced by stannyl radicals. As shown by ^{18}O labeling, they attack the O–O bridge, the more readily the more the bridge is deprived of electrons by the influence of substituents. Radical decomposition of numerous azo compounds, R–N=N–X–R or R–X–N=N–X–R, is also powerfully induced, *e.g.*:



Here again electron deficiency on X is important. In every case investigated the mechanism is synchronous (S_R2).

Now experimental difficulties have been overcome, the organic chemistry of lead is developing rapidly[2]. On the basis of the observation that negative substituents, X, on lead can be readily replaced[2], sensitive organolead hydrides are no longer prepared in the pure state but are formed *in situ* by the following equilibria:

$$R_3Pb-CH_2-CH=CH_2 + R_3'SnH \rightleftarrows R_3'Sn-CH_2-CH=CH_2 + R_3PbH$$

$$(R_3Pb)_2O + 2\,R_3'SnH \rightleftarrows (R_3'Sn)_2O + 2\,R_3PbH$$

They are valuable for specific hydrogenations and are useful for additions to C=C, C≡C, SCN-, and OCN-groups (with conjugated systems 1,4-addition is possible), and also as catalysts for polyadditions.

N,N-Dialkylplumbylamines (*e.g.*, $R_3Pb-N(C_2H_5)_2$) can also undergo numerous 1,2- or 1,4-additions, *e.g.*, to isocyanates, nitriles, isocyanides, aldehydes, or carbodiimides. In this way –O–Pb– or new –N–Pb– groups are formed and further syntheses become readily accessible.

Nuclear Resonance Studies of Molecular Movements and Phase Changes in Solid Organic Substances

By *W. Müller-Warmuth* [*]

Toluene is an example of a system with several solid phases. Its properties can be continuously varied, by careful supercooling, over a wide range from the mobile to the highly viscous glassy phase. A crystalline phase also exists. Transition of the phases into one another can be followed by the temperature-dependence of the spin-lattice relaxation and by the second moments of the nuclear resonance curves.

Hindered rotation of the methyl group was studied for a number of solid ethers[1]. Many ethers are crystalline, some are glassy, and some exist in several phases side by side, depending on the thermal treatment. The marked narrowing of the ^1H–NMR lines that is observed on phase transition from the glassy to the crystalline state well below the melting point can be interpreted as isotropic movements of whole molecules.

Although rotation of the methyl groups normally leads to line narrowing and maxima in the relaxation rates only at elevated temperatures (usually above 77 °K), the second moment for all three xylenes was lower by a factor of 2 than that expected for a rigid lattice, even at very low temperatures (2 °K)[2]. Relaxation studies gave a similar surprising result[2]. With a working frequency of about 14 MHz, maxima in the spin-lattice relaxation occurred at 77 °K (*o*-xylene), 51 °K (*p*-xylene), and 16 °K (*m*-xylene). The values for the relaxation decreased only very slowly with decreasing temperatures. This behavior can be explained as due to reorientation processes of the methyl group by a tunnel effect. This mechanism is effective even at very low temperatures for the torsion ground state. In the relaxation, restrictions to energy transfer between various degrees of freedom in the organic solid can be noticed. A cosine law with two terms for the contributions with six-fold and three-fold symmetry serves as potential function. The potential barriers lie between 0.2 and 2.3 kcal/mole.

Investigation of Proton-Transfer Processes by Electrochemical Relaxation Techniques

By *H. W. Nürnberg* [*]

The dissociation and recombination of carboxylic acids in aqueous solution is an important example of proton-transfer processes that are of significance in many chemical and biochemical reactions. The rate constants of these very fast reactions ($\tau_{1/2} \approx 10^{-6}$–$10^{-8}$ sec) can, for example, be determined by suitable voltammetric techniques when the equilibrium

$$HA \underset{k_r}{\overset{k_d}{\rightleftharpoons}} H^{\oplus} + A^{\ominus}$$

is displaced by means of the coupled electrode process of hydrogen evolution at mercury

$$H^{\oplus} + e^{\ominus} \rightarrow {}^1/_2\,H_2$$

and the velocity is measured *via* the current passing the electrode or a component of this current.

The rate constants k_d and k_r can be determined from the limiting current values that are obtained from the resulting current-voltage curve (polarogram) provided that the current is measured so fast ($t_1 \approx 30$–1 μsec) that it is not merely the rate of diffusion of the reaction components that determines the value of the current. The method of High Level Faradaic Rectification[1] enabled satisfactory measurements to be made for the first time in the μsec range and thus made possible the determination of kinetic data for 17 structurally different carboxylic acids[2]. The results are corrected for the influence of double layer effects at the electrode[3] and are therefore the true values in 1 M lithium halide solution.

On the basis of the results obtained, the following conclusions may be drawn: In many cases the carboxylic acids behave normally, *i.e.* recombination is diffusion controlled in each case with the same k_r value, and k_d is proportional to the equilibrium constant K_c. The order of the values of k_d and K_c is in general agreement with the extent of inductive and mesomeric effects arising from the structure of the respective acid.

Deviations from normal behavior exist (i) in the case of α- and *ortho*-hydroxy acids because of the tendency toward formation of intramolecular hydrogen bonds with the carboxyl group in the acid anion and (ii) in the case of acids having an alkyl group in the γ or the *ortho* position. These hydrophobic groups render the structure of the water in their neighborhood more rigid and thus make more difficult the reorientation of the water molecules to form hydrogen-bond systems, between the acid anion and the hydrated proton ($H_9O_4^{\oplus}$), that are suitable for proton transfer. In 1 M lithium halide solution, the value of $k_r = 3.7 \times 10^{10}$ indicates that this intermolecular hydrogen-bond system extends on average over 13.5 Å, *i.e.* over about five water molecules.

In general, these results confirm the view first put forward by *Eigen*[4] that an intermolecular hydrogen-bond system extending over several water molecules is of decisive importance for proton transfer in the course of dissociation and recombination. This hydrogen-bond system also plays an important role in the reduction of $H^{\oplus}$ ions at an electrode, *i.e.* in the transfer of a proton to the electrode surface immediately preceding the rate-determining charge-transfer step.

The linear $k_d - K_c$ relationship that is characteristic of normal behavior corresponds to a linear entropy relationship since the measurements were made within a temperature range (*ca.* 20 °C) where $-\log K_c$ goes through a flattened maximum where $\Delta H \approx 0$ and $\Delta H_d^{\ddagger} \approx H_r^{\ddagger}$.

The significance of the entropy, and consequently of the orientation of the solvent molecules in the initial, transition, and final states of dissociation, is thus clearly emphasized. In general, the more hydrophilic an acid is (*i.e.* the lower the decrease in entropy of the system acid molecule plus surrounding solvent molecules on dissociation), the more rapidly and completely will it dissociate. The influence of inductive and mesomeric effects arising from the structure of the respective acid corresponds to this entropy relationship and is in fact its cause.

SELECTED ABSTRACTS

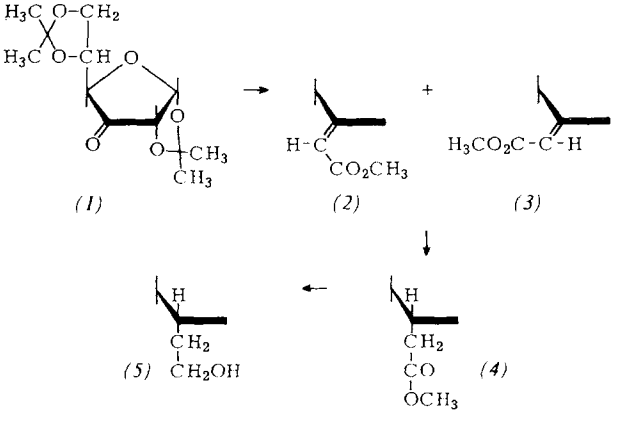
Tris(triphenylphosphine)cobalt dihydride, $H_2Co(P(C_6H_5)_3)_3$, *(1)*, a complex that binds molecular nitrogen, has been prepared by *A. Misono, Y. Uchida, T. Saito,* and *K. M. Song*, by the reaction of Co(III) acetylacetonate, triphenylphosphine, and triisobutyl-aluminum in ether at 10 °C in the presence of H_2; yellow crystals, 50 % yield. The complex is very sensitive to air and decomposes at 77 °C under vacuum, with liberation of H_2 and benzene. Under nitrogen, the color of the benzene solution changes from brown to red, and orange crystals of $N_2Co(P(C_6H_5)_3)_3$ can be precipitated with petroleum ether. *(1)* takes up CO in exchange for hydrogen, and hydrogenates ethylene at room temperature. / J. chem. Soc. (London) C *1967*, 419 / –Ma. [Rd 729 IE]

7-, 8-, and 9-membered silacyclic hydroxy and oxo compounds containing functional groups were synthesized for the first time by *R. A. Benkeser* and *R. F. Cunico*. Pyrolysis (400–500 °C) of dimethylbis(3-carbomethoxypropyl)silane in the presence of $ThCl_4$ gave 1,1-dimethylsilacyclooctan-5-one (2,4-dinitrophenylhydrazone: m.p. 134.5–135 °C). Acyloin ring closure of dimethylbis(3-carbomethoxypropyl)silane with sodium in toluene gave a mixture of 1,1-dimethyl-6-hydroxysilacyclononan-5-one and 1,1-dimethylsilacyclononan-5-ol (yield 47 %).The acyloin ring closure of dimethylbis(2-carbomethoxyethyl)silane gave 1,1-dimethyl-5-hydroxysilacycloheptan-4-one (yield 28 %), which yielded 1,1-dimethylsilacycloheptan-4-one on reduction (treatment with propanethiol, $ZnCl_2$, and HCl gas in benzene, then with $HgCl_2$–$CdCO_3$ in aqueous acetone). / J. org. Chemistry *32*, 395 (1967) / –Ma. [Rd 686 IE]

Xanthine oxidase from milk is catalytically active even in anhydrous organic solvents. *F. R. Dastoli* and *S. Price* measured the oxidation of crotonaldehyde by methylene blue, which is catalyzed by the xanthine oxidase, in a series of solvents in which the salt-free lyophilized enzyme was completely insoluble. The reaction rates (V_{max}) were higher than 10 % of the rate in water (for 0.05 M potassium phosphate; pH= 7.5); large differences in the Michaelis constants for crotonaldehyde were found (water: K_M = 3 mM; acetone: K_M = 1; *o*-dichlorobenzene: 8; furan: 8; benzene: 17; thiophene: 20; pyridine: 70; toluene: 120). / Arch. Biochem. Biophysics *118*, 163 (1967) / –Hö. [Rd 709 IE]

The conversion of phenylalanine into lignin-forming glucosides has been observed by *K. Freudenberg* and *J. Torres-Serres* following the administration of the ^{14}C-labeled compound to young spruce branches. Gluco-*p*-coumaryl alcohol, coniferin, and syringin were formed in a few days. Two other labeled compounds were presumably glucosides of piceatannol. / Liebigs Ann. Chem. *703*, 225 (1967) / –Ma. [Rd 722 IE]

A new route to branched sugars by a modified Wittig reaction with ketoses is reported by *A. Rosenthal* and *L. (Benzing) Nguyen*. When *e.g.* 1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose *(1)* in DMF at 0 °C is made to react with an ice-cold solution of trimethyl phosphonoacetate and K *tert*-butoxide in DMF (20 hours, 20 °C), followed by



reduction of the sugars *(2)* and *(3)* to the methoxycarbonylmethyl derivative *(4)* and reduction of *(4)* with $LiAlH_4$, the product obtained is 3-deoxy-3-*C*-(2-hydroxyethyl)-1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose *(5)*. / Tetrahedron Letters *1967*, 2393 / –Ma. [Rd 724 IE]

Insertion of dihalogenocarbenes into Si-Hg and Ge-Hg bonds, according to *D. Seyferth, R. J. Cross,* and *B. Prokai,* occurs in the reaction of bromodichloromethyl- (or dibromochloromethyl)phenylmercury with bis(trimethylsilyl)- or bis(trimethylgermyl)mercury (molar ratios 2:1; in benzene at 65–75 °C; 70 min). The principal products are trihalogenovinyltrimethylsilane or -germane, which are obtained in yields of 43 or 63 % respectively (filtration; gas-liquid partition chromatography). A plausible reaction sequence is given, but it is not yet certain whether the rate-determining step is a bimolecular reaction between the two Hg compounds or the decomposition of $C_6H_5HgCCl_2Br$.

$$((H_3C)_3Si)_2Hg + H_5C_6Hg{-}CCl_2Br \xrightarrow[-H_5C_6HgBr]{} (H_3C)_3Si{-}Hg{-}CCl_2{-}Si(CH_3)_3$$

$$(H_3C)_3Si{-}Hg{-}CCl_2{-}Si(CH_3)_3 \xrightarrow{+H_5C_6HgCCl_2Br} (H_3C)_3Si{-}Hg{-}CCl_2{-}CCl_2{-}Si(CH_3)_3 \longrightarrow$$

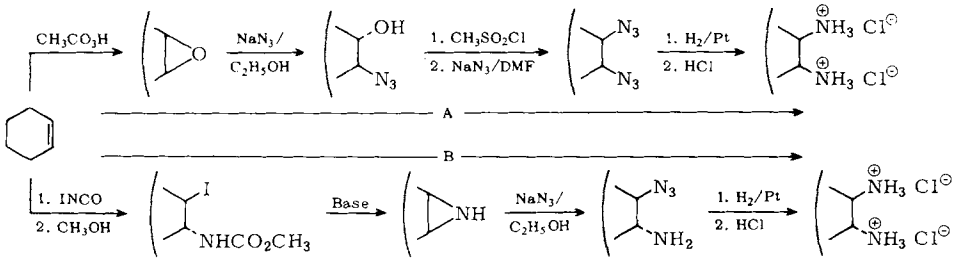
$$(H_3C)_3SiHgCl + (H_3C)_3Si{-}CCl{=}CCl_2$$

$$\downarrow$$

$$(H_3C)_3SiCl + Hg$$

/ J. organometallic Chem. *7*, P 20 (1967) / –Jg. [Rd 744 IE]

A method for the stereospecific synthesis of vicinal diamines has been developed by *G. Swift* and *D. Swern* using sterically pure compounds in stereospecific reactions that proceed in good yields. Routes A and B, which lead to the stereoisomers, can be illustrated for cyclohexene:



This method represents an important advance, particularly in the stereospecific synthesis of aliphatic vicinal diamines. *meso*-3,4-Diaminohexane dihydrochloride (route B) and *threo*-3,4-diaminohexane dihydrochloride were obtained from *trans*-3-hexene in yields of 72 and 35 % respectively. Since both *cis*- and *trans*-4-methyl-2-pentene could be used in the pure state, it was possible to check that all the reactions of routes A and B proceed smoothly and specifically; of the four products the pairs obtained by opposite routes are identical in all their properties (yield: 62–71 % by route A, 59–60 % by route B). / J. org. Chemistry *32*, 511 (1967) / –Jg. [Rd 747 IE]

A precursor of the biosynthesis of insulin has been isolated by *D. F. Steiner* and *P. E. Oyer* from incubates with human tumor tissue (tumor of the Langerhans' islets). They detected the incorporation of [^{3}H]-leucine and [^{3}H]-phenylalanine into insulin and a high molecular weight protein. The latter has a molecular weight of about 10800 (insulin 6000) and an N-terminal phenylalanine (as does the B chain of insulin), and exhibits immunological relationship to insulin. Unlike insulin, however, the protein is not split into two chains by sulfitolysis. Treatment of this high molecular weight protein with small quantities of trypsin yields a product that behaves chemically and immunologically like insulin. This observation supports the hypothesis that the two polypeptide chains of insulin are synthesized as a single chain. The proteolytic attack would then take place after the configuration of insulin has been formed. / Proc. nat. Acad. Sci. USA *57*, 473 (1967) / –Scha. [Rd 726 IE]

The tricyanovinylation of aromatic compounds without electropositive substituents, according to *R. Henderson* and *W. A. Sheppard,* can be achieved with tetracyanoethylene (TCNE) if the latter is made more electrophilic by complex formation with $AlCl_3$. Benzene, toluene, fluorobenzene, and naphthalene react in this way (see table), but durol (sterically hindered) and chlorobenzene do not. The benzene derivative, for example, is obtained by heating of a deep red-brown TCNE/$AlCl_3$ solution (molar ratio 1:1) in benzene for 1 hour, chromatographic separation on Al_2O_3, recrystallization from benzene or acetonitrile, and sublimation.

Ar	Ar–C(CN)=C(CN)$_2$	
	m.p. (°C)	yield (%)
C_6H_5	98.3–99.2	35
p-CH_3–C_6H_4	115.5–117	23
p-F–C_6H_4	122–123	17
β-naphthyl	174–178	20

/ J. org. Chemistry *32*, 858 (1967) / –Jg. [Rd 749 IE]

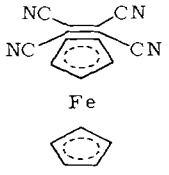
Two L-asparaginases (L-asparagine amidohydrolase, EC 3.5.1.1), of which only one exhibits antitumor activity, have been isolated by *H. A. Campbell et al.* from *Escherichia coli* B. L-Asparaginase has been known for some time as the effective antitumor agent in guinea-pig serum, while this enzyme from yeast or *Bacillus coagulus* is ineffective. The two new enzymes differ in their solubility properties, their chromatographic behavior, and their activity as a function of pH. The authors purified the antitumor fraction by a factor of 90; a glutaminase activity of 2 % appears to be a characteristic of the enzyme. / Biochemistry *6*, 721 (1967) / –Scha. [Rd 725 IE]

The vapor pressure above the calcium carbide phase has been determined by *R. H. Flowers* and *F. C. W. Pummery* between 1250 and 1950 °K for equilibrium conditions by the Knudsen effusion method:

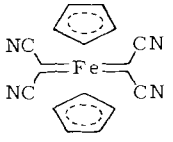
$$4.575 \log p = (-49000 \pm 950)/T + (13.3 \pm 0.6).$$

Pure calcium carbide, $CaC_{2.05 \pm 0.03}$, was prepared from graphite and calcium (purity: 99.9 %; impurities Mg and Al) in a helium atmosphere. The gas phase consists almost entirely of monoatomic Ca (target quantities: 1 to 20 μg); carbon does not vaporize in appreciable quantities. In the range CaC_2 to $CaC_{3.5}$, the vapor pressure is independent of the excess of carbon, *i.e.* an independent C phase is present for Ca:C > 1:2. Since the heat of vaporization of Ca (L_{298} = 42.4 ± 0.4 kcal mole^{-1}) and the specific heat of CaC_2 are well known, the standard heat of formation of CaC_2, $-(\Delta H^0_{298} - L_{298}) = -13.1 \pm 1.5$ kcal mole^{-1} (SrC_2: −20.2 ± 3, BaC_2: −19.5 ± 3) can be calculated very accurately from the average of the enthalpies of formation (according to the 2nd and 3rd laws), $\Delta H^0_{298} = 55.5 \pm 1.5$ kcal mole^{-1} for the reaction CaC_2 (solid) → Ca(gas) + 2 C (solid). / J. inorg. nuclear Chem. *29*, 311 (1967) / –Jg. [Rd 727 IE]

The bonding in the ferrocene-tetracyanoethylene (TCNE) adduct (1:1) has been elucidated by *R. L. Collins* and *R. Pettit* by Mössbauer spectroscopy of the ^{57}Fe nucleus (10 mCi source; ^{57}Co in Cu). Since 1962, both the ferrocenium tetraethylide and the charge-transfer structures had been considered possible. The spectra of free ferrocene and of the TCNE adduct at 77 °K are extremely similar (isomeric shift: + 0.475 ± 0.01 and 0.465 ± 0.01 mm/s, in relation to iron; quadrupole splitting: 2.400 ± 0.02 and 2.397 ± 0.02 mm/s; Karyagin effect: 1.14:2 and 0.81: 1), whereas ferrocenium dichlorodicyano-*p*-benzosemiquinoide, which is known to be a ferrocenium salt, has a quite different structure.



(1)



(2)

The Fe nucleus is therefore only slightly influenced by the TCNE. A symmetrical and salt-like structure *(2)* can therefore be ruled out in favor of a charge-transfer structure *(1)*, in which the TCNE interacts "from the outside" with only one benzenoid ring. / J. inorg. nuclear Chem. *29*, 503 (1967) / –Jg. [Rd 728 IE]

The ion-exchange properties of a titanium hexacyanoferrate(II) complex having the approximate composition $[(TiO_2)(OH)HFe(CN)_6 \cdot 4H_2O]_n$ have been examined by *K. H. Lieser, J. Bastian, A. B. H. Hecker,* and *W. Hild.* The gel-like product, which can be dried (after which it still contains a total of 21 % of H_2O) and sieved (grain sizes 0.1 to > 1 mm) and is insoluble in water, is obtained by precipitation from 0.5 M $TiCl_4$ + 2 M HCl solution with a 0.4 M acid solution of $K_4[Fe(CN)_6]$ or hexacyanoiron(II). Properties: in contact with H_2O, pH ≈ 3; exchange capacity 1.4 to 1.5 m-eqt/g (theoretical 2.3 m-eqt/g, *i.e.* a maximum of 1 exchangeable proton per $Fe(CN)_6$ unit); specific area 185 m^2/g; stable in 2 M HCl, decomposes slowly in 5 M HCl; above pH = 4 (titration with NaOH), decomposes into $Na_4[Fe(CN)_6]$ + titanium dioxide gel. The selectivity for Cs is very high; the selectivities for the alkali and alkaline earth metals at concentrations of 10^{-8} to 1 mole/l decrease in the order Cs > Rb > K > NH_4 > Na > Li and Ba > Sr > Ca > Mg > Be. Separation factors for some 1:1 solutions at pH = 2.1 to 2.4: Cs/Rb = 5.5, Cs/NH_4 = 42.8, Cs/Li = 23; K/NH_4 = 9.4; Na/Li = 12; Ba/Sr = 4.7, Ba/Be = 27; Sr/Ca = 1.2, Sr/Mg = 9.3. The exchange proceeds rapidly ($\tau_{1/2}$ ≈ 2 min); and is followed by two slower processes having $\tau_{1/2}$ ≈ 10 min and 20 h, respectively. In the pH range between 2.5 and 0, the partition coefficients change by factors of 10 to 1000. / J. inorg. nuclear Chem. *29*, 815, 872 (1967) / –Jg. [Rd 740 IE]

A new process for the synthesis of aminals and enamines has been found by *H. V. Hirsch* in the reaction of tris(dimethylamino)- trispiperidino-, or tris-(1-pyrrolidinyl)arsine with aldehydes or ketones. Aminals are formed if there is no vicinal hydrogen present (eq. (a)); otherwise, dialkylamine is eliminated to form enamines (eq. (b)).

$$2\ As(N(CH_3)_2)_3 + 3\ R{-}CO{-}R' \xrightarrow[-As_2O_3]{} 3\ R{-}C(N(CH_3)_2)_2{-}R' \qquad (a)$$

$$2\ As(N(CH_3)_2)_3 + 3\ R_2CH{-}CO{-}R' \xrightarrow[-As_2O_3]{-3\ HN(CH_3)_2} 3\ R_2C{=}CR{-}N(CH_3)_2 \qquad (b)$$

Examples of compounds prepared are:

Aminals	B.p. (°C/mm)	Yield (%)
ω,ω-Bis(dimethylamino)toluene	51/2	73
Bis(dimethylamino)methane	77	84
Enamines		
1-Piperidinocyclohexene	70/2	75
α-(1-Pyrrolidinyl)styrene	75/1	25
4-Dimethylamino-*N*-methyl-Δ^3-piperideine	76/10	83

/ Chem. Ber. *100*, 1289 (1967) / –Jg. [Rd 745 IE]

All the fluorotelluric acids $TeF_n(OH)_{6-n}$ have been prepared by *L. Kolditz* and *I. Fritz*, those with $n = 1$ to 4 were obtained from telluric acid and hydrofluoric acid, while pentafluorotelluric acid, was obtained from barium tellurate and fluorosulfuric acid. The solid mixture of fluorotelluric acids can be resolved by paper or column chromatography at 0 °C on cellulose (eluent: 75 ml of propanol + 25 ml of H_2O + 5 g trichloroacetic acid), the R_f values being as follows:

$n = 5$	$n = 4$	$n = 3$	$n = 2$	$n = 1$	$n = 0$
0.980	0.854	0.745	0.577	0.365	0.264

The main products, di- and tetrafluorotelluric acids, are more strongly acidic than $Te(OH)_6$; they are monobasic to weak bases (*e.g.* pyridine, quinoline) and dibasic to strong bases. The reaction of $Te(OH)_6$ with KF in aqueous solution without further acidification yields a product $Te(OH)_6 \cdot 2KF$, which is stable even in contact with the solution. Since (a) the IR spectrum does not contain H_2O bands, (b) all the fluorine can be titrated with $ZrOCl_2$, and (c) a mixture of $Te(OH)_6$ + KF can be ruled out by X-ray analysis, the product is evidently a complex in which the coordination number of Te is increased. / Z. anorg. allg. Chem. *349*, 175, 184 (1967) / –Jg. [Rd 741 IE]

The fluorination of cyanogen chloride, according to *J. B. Hynes, B. C. Bishop,* and *L. A. Bigelow*, leads under mild conditions to interesting fluorination products containing both Cl and N. In the direct process, ClCN diluted with N_2 was injected into pure F_2 at 94 °C (F:ClCN:N_2 = 5.3:1:10); in the indirect process a Cl_2-ClCN mixture (1:6 to 2:1) was condensed on an excess of AgF_2 at –196 °C, and the autoclave was brought to room temperature over a period of 20 hours. In both cases the mixture was resolved by rectification and gas chromatography.

CF_3NClF	b.p. –32.8 °C; colorless stable gas; first "organic" compound having the formula RNClF; typical mass-spectrometric component: ClN^+
$CClF_2NF_2$	a little; colorless stable gas; typical mass-spectrometric components: CF^+, Cl^+, CF_2^+, CF_3N^+, $CClF_2^+$, CF_4N^+
$CF_3N{=}NCClF_2$	b.p.5.8 °C; yellow liquid; heat of dilution = 5.86 kcal $mole^{-1}$ Trouton const. = 21.0 cal deg^{-1} $mole^{-1}$
CF_3NCl_2	b.p. 14.9 °C; heat of dilution = 6.1 kcal $mole^{-1}$; very stable to dilute alkali; photolyzes to $CF_3N = NCF_3$

/ Inorg. Chem. *6*, 417 (1967) / –Jg. [Rd 746 IE]

Neuere Methoden der Präparativen Organischen Chemie. (New methods of preparative organic chemistry). Edited by *W. Foerst*. Verlag Chemie, Weinheim/Bergstr., Vol. IV. 1066. viii, 304 pp. 2 figures, 44 tables, bound DM 38.–; Vol. V 1967, viii, 280 pp., numerous figures and tables, bound DM 38.–.

After the appearance of the first volume in 1944, "Neuere Methoden" made its mark within a short time, and was used, not only as a convenient and very useful source of information to the chemist engaged in preparative work, but also by advanced students preparing for examinations. This tradition was carried on in 1960 by the second and third volumes [1], and the present review deals with Volumes IV and V. Like the earlier volumes, they contain a selection of articles from recent volumes of Angewandte Chemie, and deal exclusively with important and recent methods of preparative organic chemistry.

Volume IV: α-Additions to isonitriles, triple additions, and four-component condensations (*I. Ugi* 1962 [2], revised 1965); the text has been rearranged, the nomenclature has been partly improved, and nsiderable supplementary material has been added in places. Isonitrile syntheses (*I. Ugi et al.* 1965, revised 1965). Reactions of sodium hydrazide with organic compounds (*Th. Kaufmann et al.* 1964, revised 1965); a number of new findings and numerous procedures have been added. Ethynation reactions (*W. Ried* 1964, revised 1965); Parts I and II have been combined, and supplementary material has been added in places. Syntheses with nascent quinones (*H. W. Wanzlick* 1964), cyclization of dialdehydes with nitromethane (*F. W. Lichtenthaler* 1964, revised 1965). Use of complex boron hydrides and of diborane in organic chemistry (*E. Schenker* 1961, revised 1965). This article has been completely rearranged, and now contains 1700 references instead of 865 and 49 procedures instead of 22. This contribution is a most valuable review of this extremely important and rapidly developing method.

Volume V: New reactions of alkylidenephosphoranes and their preparative uses (*H. J. Bestmann* 1965); the three parts, which were originally published separately, have been combined. Syntheses with heterocyclic amides (azolides) (*H. A. Staab* and *W. Rohr* 1962, revised 1966); many results from recent years and 11 procedures have been added. Organic syntheses with imides of sulfur dioxide (*G. Kresze* and *W. Wucherpfenning* 1967). Syntheses of naturally occurring fatty acids by sterically controlled olefination of carbonyl compounds (*L. D. Bergelson* and *M. M. Schemjakin* 1964, revised 1965). Syntheses with *s*-triazine (*Ch. Grundmann* 1963, revised 1965). Silylation as an aid in organic synthesis (*L. Birkhofer* and *A. Ritter* 1965, revised 1965). Organosodium and organopotassium compounds (*M. Schlosser* 1964, revised 1965); Parts I and II have been modified and combined, and some of the procedures have been revised.

All the contributions now contain very useful procedures, either in the body of the text or at the end, which may be used directly. Each volume again contains an index of reactions and compounds. The articles are very readable, since they are clear and not too long. The authors have spared no effort to present their own fields in a convenient form. The formulas and the presentation are very good, and printing errors are rare (*e.g.* IV, p. 172). The printed area of Angewandte Chemie has been halved horizontally. Those who regret that this again makes the books wider than they are high (21×18.5cm), so that they spoil the appearance of the row of books on the shelf, can console themselves with the modest price that can be achieved in this way.

Many may think that an important preparative method would be better described in a detailed monograph or handbook. However, there are many points in favor of the publication and continuation of this series. These are not subjects that can already be found in specialized books, but new developments, which ought to be made known as soon as possible. In this way, many interesting points can be presented for which a complete and final description is not as yet worth while.

Readers of Angewandte Chemie may think that they have no need for these volumes, but a given preparation will be easier to find in Neuere Methoden than in Angewandte Chemie, and in addition will contain more recent information.

Another advantage is the collection of unrelated topics. The study of these volumes must be recommended to every chemist and postgraduate student. They provide a broad view of progress in preparative organic chemistry, and are also excellently suited for revision by subscribers to Angewandte Chemie before examinations. *H. Musso* [NB 685 IE]

[2] Year in which the article appeared in Angewandte Chemie.

Mikromethoden für das klinisch-chemische und biochemische Laboratorium (Micromethods for the Clinical Chemistry and Biochemistry Laboratory). By *H. Mattenheimer*. Verlag Walter de Gruyter & Co., Berlin 1966. 2nd Edit., x, 223 pp., 35 figures, plastic cover DM 30.

The publication of a second revised and enarged edition of "Mikromethoden" is very welcome. The micromethods, developed more than 30 years ago by *K. Linderstrøm-Lang* and *H. Holten*, are finding increasing application in clinical chemistry and biochemistry laboratories wherever it is necessary to investigate small quantities of material. The book describes apparatus and general procedures, then deals with special procedures for chemical and enzymatic determinations, determinations of enzyme activities in the biological fluids and in tissue samples, and finally with ultramicro methods for the determination of enzymes. The methods described are nearly all colorimetric, with the emphasis on "optical tests" for the determination of metabolites and enzyme activities.

The book is a valuable aid in the laboratory, particularly for technical personel. The reviewer would recommend that a subject index be compiled for later editions, and that the simplified method given in the appendix for the clinical-chemical determination of glucose in blood should be omitted, since it does not stand up to critical examination.

B. Hess [NB 584 IE]

Der Arbeitnehmer als Erfinder. Seine Rechte und Pflichten. (The Employee as Inventor. His Rights and Obligations.) By *O. Röpke*. W. Kohlhammer Verlag, Stuttgart-Berlin-Köln-Mainz 1966. 1st Edit., 176 pp., paperback, DM 16.80.

The author has succeeded in providing an ex remely clear explanation of the rights and obligations of the employee (and employer) as they are to be found in legislation and general guiding principles concerning employees' inventions. It must, however, be pointed out that, in particular, the problems of industrial law will cause much difficulty to the employee-inventor, who generally has little experience in such matters, and he may easily be led to false conclusions. The book deals with inventions made in the course of employment, and with free-lance inventions, in the light of important decisions made by the German Federal Supreme Court and the recommendations of the Arbitration Committee for Employees' Inventions. The guiding principles for the remuneration of such inventions are also considered. Further, a summary is given concerning patent and utility model appli-

cations for free-lance inventions, the utilization of these protective rights, and the general treatment of employees' suggestions. The book closes with a section on tax concessions for the remuneration of employees' inventions, for income from free-lance inventions, and for bonuses for suggested improvements. In the voluminous appendix, the relevant legislation, ordinances, and guiding principles are given and various forms are also reproduced. The book can also be recommended to employers and to those whose profession it is to advise inventors. *V. Vossius* [NB 628 IE]

The Chemistry of Technetium and Rhenium. By *R. D. Peacock*. Topics in Inorganic and General Chemistry, Monograph 6. Edited by *P. L. Robinson*. Elsevier Publishing Company, Amsterdam-London-New York 1965. 1st. Edit. ix, 137 pp., 14 Figures, 29 Tables. 55s; 27.50 Dfl.

The main purpose of the monograph, which is a review of the present knowledge of rhenium and technetium, is to be found in the comparison of the chemistry of these homologous elements. The author not only describes the various classes of compounds but explains the material in the light of modern transition-metal chemistry. Understandably, the greater part of the book is devoted to the chemistry of rhenium. The literature is covered up to the middle of 1965; however, various omissions have been made, even in the better documented chemistry of technetium. For example, one searches in vain for information concerning the technically and scientifically remarkable inhibition of corrosion exhibited by pertechnate ions. Nevertheless, the book assists the reader in gaining a deeper understanding of the chemistry of these transition elements and will prove stimulating reading for chemists interested in inorganic and radiochemistry.

K. Schwochau [NB 620 IE]

Introduction to Nuclear Chemistry. By *D. J. Carswell*, Elsevier Publishing Co., Amsterdam-London-New York 1967, 1st Edit., ix, 279 pp., 69 figures, 23 tables, Dfl. 32.50.

This book is based on lectures which the author gave over the course of many years at the University of New South Wales in Australia. It deals with the structure of the atom and of the nucleus, the laws of radioactive decay, nuclear reactions, types of decay, the use of physical nuclear methods in chemistry, such as the Mössbauer effect and nuclear magnetic resonance, detectors and their mode of action, radiation chemistry, mass spectrometry, isotope separation, neutron sources, accelerators, the actide elements, and the application of radioisotopes in industry and research. The concluding chapter lists 16 simple experiments which, without substantial outlay of time or money, provide an experimental insight into radiochemistry and nuclear chemistry.

The book is very simply written. Mathematical and abstract treatment is largely avoided, sometimes with adverse effects. For example, the reviewer thinks it unlikely that the description of isotope dilution analysis can really be understood. In a demanding chapter, in which several electronic circuits are described and in which the mode of action of a diode or triode is compared with that of a transistor by means of a circuit diagram, the statement of Ohm's law is too trivial. In the chapter "Actinides" the description of the stability of the individual actinide valences appears to need revision, as well as a better presentation.

Despite these drawbacks, the book should be particularly suitable for students who wish to acquire some overall knowledge of nuclear chemistry and who have no opportunity to attend lectures on nuclear and radiochemistry. A big help in understanding the subject matter is the short summary given at the end of each chapter. On the other hand, the price of about £ 3.0.0 seems a little high for this introductory book. *C. Keller* [NB 649 IE]

Nobel Lectures Chemistry 1901–1921 and 1922–1941. Issued by the Nobel Foundation, Elsevier Publishing Company, Amsterdam-London-New York, 1966. Volume 1901–1921, xii, 409 pp., several illustrations, Dfl 80.–; Volume 1922–1941: 53 pp. several illustrations, Dfl. 80.–.

The first Nobel prizes were awarded in 1901. They were, and in a certain sense still are, a present from the nineteenth century to the twentieth, for *Alfred Nobel* died in 1896. It must have been particularly difficult at the time to find among the many eminent chemists the one who deserved to be the first awarded this great distinction. *Cannizzaro*, *Gibbs*, *Thomsen* and *Berthelot*, *Arrhenius*, *Ostwald* and *A. von Bayer*, *Emil Fischer*, and *Moissan* were considered, and some of them received the prizes in later years. The majority of the votes (11 of 20) went to *van't Hoff* in 1901. It is a pleasure to read his Nobel lecture today, more than 65 years later. *van't Hoff* deals with osmotic pressure and chemical equilibria and it is of interest to note that neither here nor in the motivation for awarding the prizes is there an indication of the discovery of the asymmetric carbon atom. This work is mentioned only in the eulogy – in one sentence. One becomes acutely aware of the fact that the material that we learn today in the first few semesters as something self-evident was by no means self-evident at the beginning of the century.

In 1902 *Emil Fischer* received the prize for his fundamental work on sugars and purines, and in 1903 it was *Arrhenius*' turn for his theory of electrolytic dissociation (who can envisage the time when talk of the *theory* of electrolytic dissociation was the order of the day?). In 1904 *Ramsay* was honored for his discovery of the inert gases, in 1906 *Moissan* for his discovery of fluorine, in 1907 *Buchner* for his demonstration of cell-free fermentation. Self-evident truths today, but were they 60 years ago?

Anyone with a sense of history will find his money well spent on the two volumes of Nobel lectures that have now been issued by Elsevier. The reader will encounter many important men who have shaped our modern thinking, but will meet them in a way different from that in textbooks. One could say he will meet them on a more personal level.

H. Grünewald [NB 643 IE]

Biological Chemistry. By *H. R. Mahler* and *E. H. Cordes*. Harper and Row (Publishers) New York-London 1966. 1st Edit., xv, 872 pp., numerous figures and tables, 63 s.

The outstanding contribution made by American workers to biochemistry during recent years is very largely the result of this subject gaining a firm place a long time ago in both medical and natural science faculties of American universities. In chemistry, as in medicine and biology, biochemistry has become a pillar of a modern syllabus admittedly with different aims. While biochemistry (physiological chemistry) in the field of medicine is characterized by the functions and pathology of organs, in chemistry it is the fundamental set of chemical and physicochemical principles of the life-determining processes. Although all aspects of biochemistry are interdependent, they can be developed better independently of one another if the curriculum is adapted to achieve this aim in the optimum manner. It is clear that a rapid advance in one section will promote a similar speeding up in another. This subdivided responsibility somewhat resembles a technique applied for difficult ascents during mountain climbing. Two ropes are needed for climbing overhanging rocks. One is used to pull while it runs through the hook fixed above the climbers, and the second is carried loosely. After the fixing of the next hook, the second rope in turn takes up the pull. The above general remarks seemed necessary in order to characterize the place and importance of this new work. The book has been written for chemists by chemists. The authors have done splendidly, and in many respects have achieved a breakthrough for biochemistry in the part it occupies in chemical teaching. The book reproduces fairly accurately

the two-semester course of lectures given at Indiana University for graduate students. Since a thorough background in organic and physical chemistry is assumed, certain traditional sections of biochemistry textbooks have been eliminated. For example, there is no chapter on carbohydrate chemistry. The structure of coenzymes is likewise discussed only as far as its function in enzymatic reactions makes this necessary. The difficult problem of protein and nucleic acid structure, relegated to the later chapters in most textbooks, is placed right at the beginning. It is characterized by a thoroughness and breadth normally found only in large reference books and survey articles. Two similarly detailed chapters on the thermodynamics and kinetics of enzyme reactions follow to provide the prerequisite basis for the discussion of the mechanism of enzyme action (in a separate chapter). Enzyme action here signifies the catalytic action of protein, not the chemical principles of coenzyme activity. The latter is dealt with in detail for each coenzyme in the next chapter.

The first half of the book, which is devoted to theoretical principles and general aspects, concludes with a chapter about the structure of cells and the organization of enzymatic activities in cell fractions and particles. The second half deals with the dynamics of the chemical events in the cell. A sequence of chapters of conventional nature is found: carbohydrate metabolism, amino acids, nucleic acids, oxidation of fatty acids, and decomposition of complex lipids, and also chapters on the tricarboxylic acid cycle, biological oxidation, an extensive chapter on photosynthesis, and finally two chapters on biosynthesis (lipids and proteins).

As is to be expected in a first edition, some aspects are unbalanced. This is often due to the fact that in some fields there are gaps in the literature references. It will be possible to make the necessary improvements in the new editions, which will no doubt soon be forthcoming. In particular, reference may be made to the chapter "Quaternary structure of proteins", which has in no way been given the detailed treatment that is devoted later to the model of allosterism as a controlling principle in enzyme activity. Many decisive facts, such as the relationship between the number of subunits and the number of coenzyme binding sites, particularly in dehydrogenases, have been omitted entirely. The spontaneous association of subunits to form typical structures and active complexes likewise depends on the interactions determining the structure of higher order, and characterizing the allosteric transformations. The literature references attached to each chapter are most welcome, survey articles and papers to which special progress can be attributed being listed separately. The German reader will note that original work from German periodicals is rarely mentioned, and, when it is, with mutilated names. The subject of biochemistry in natural science faculties will receive a strong impetus through this work, and it is hoped that the book will achieve the widest possible distribution. *K. Wallenfels* [NB 639 IE]

Organic Compounds with Nitrogen-Nitrogen Bonds. By *C. G. Overberger, J.-P. Anselme*, and *J. G. Lombardino*. From the Series "Modern Concepts in Chemistry". The Ronald Press Company, New York 1966. 1st Edit., vi, 115 pp., $ 7.00.

The authors of the present work have succeeded admirably in presenting a concise survey of the vast field of compounds with NN bonds. In addition to the subject and author index, the book contains a theoretical introduction and chapters on the following topics: Hydrazines, azomethines having NN bonds (hydrazones, azines, osazones), azo compounds, diazo compounds (aromatic diazonium salts, diazoalkanes, diazirines), hydrazides, *N*-nitrosamines (*N*-nitramines), azides (tetrazenes, triazenes). Each chapter is carefully subdivided and completed by a literature register in which particular emphasis is placed upon review articles and surveys. The literature is covered up to 1965.

It is only to be expected that in 115 pages the information given is in a concentrated form and that a somewhat subjective choice of material has been made. Nevertheless, the authors have made such a good selection that the reader has no difficulty in obtaining a good idea of the preparation and reactions of these compounds and, particularly, of the work carried out with them during the last decade.

E. Fahr [NB 619 IE]

The Encyclopedia of Chemistry. Edited by *G. L. Clark* and *G. G. Hawley*. Reinhold Publishing Corporation, New York 1966. 2nd Edit., xxi, 1144 pp., numerous illustrations, $ 25.00.

The appearance of a second edition of an "Encyclopedia" exceeding 1000 pages within nine years can be described as an achievement. It may be expected that work has meanwhile been carried on to eliminate out-of-date information, to collect together scattered pieces of information, and to cut down verbosity. Unfortunately, these expectations have not been entirely fulfilled.

A cursory glance through the volume gives an excellent impression. There is hardly a subject that is not discussed (admittedly some entries, such as Carbene, Cobalamine, and Tacticity, are absent the printing is pleasant, the illustrations are large and clear. Careful reading of the text, however, reveal that the quality of the articles varies. Side by side with good, modern, and clearly written contributions (*e.g.* on crystal field theory and nuclear reactors), there are others which provide out-of-date information, engage in long, pointless argument, or are poorly coordinated. For example, information about nucleic acids is contained in three different places. Four authors are named, and there is no indication that they had previously agreed on who is to say or write what.

On the library shelf the book will often be useful and sometimes annoying. There is a long way to go before the editors and the authors achieve a true encyclopedia.

H. Grünewald [NB 645 IE]

Interpretation of Mass Spectra. By *F. W. McLafferty*. W. A. Benjamin, Inc., New York-Amsterdam 1966. 1st ed., xvii, 229 pp., several figures, bound $ 9.00.

The ever-increasing importance of mass spectrometry in science and industry has made it necessary to systematize the interpretation of mass spectra, *i.e.* to classify them according to significant aspects. While the hitherto published books confine themselves to the decomposition mechanisms of classes of organic compounds, the author of this treatise attempts to instruct the reader in the interpretation of mass spectra by the use of spectra of unknown organic substances. Problems of instrumentation are therefore merely touched on in the introduction.

The elucidation of reactions leading to molecular fragmentation and hence conclusions regarding the type and structure of a compound form the predominant content of the interpretation of mass spectra. Certain fundamental rules are set up for the treatment of decomposition mechanisms and the reactions are classified in few general groups. Although certain simplifications are necessary, this systematization does represent an aid for evaluating mass spectra.

The method with which the author introduces the student and scientist to the problems of the interpretation of mass spectra is interesting. Progress from initially simple decomposition mechanisms to ever more complicated ones enables the student to test his understanding on unknown spectra and to compare his solution with that given in the final chapter. One advantage of this method is that it also provides practice in interpretation. *H. Krone* [NB 635 IE]

The Structure and the Function of Gangliosides[**]

BY H. WIEGANDT[*]

Dedicated to the memory of Richard Kuhn

Gangliosides are found in the brain and other organs, and are composed of sphingosine, fatty acids, hexoses, and sialic acid. Types of gangliosides differ in the fatty acids and the sugar residues. The carbohydrate residue in the quantitatively predominating brain gangliosides is ganglio-N-tetraose, a tetrasaccharide. In these gangliosides, this residue combines with one or more molecules of sialic acid. The oligosaccharide part is a carrier of serologic properties. Gangliosides are characteristic lipid components of some neuronal membranes in the central nervous system, and can be localized on the synaptic apparatus of nerve cells in the cerebral cortex. Their site of occurrence and physiological action point to their participation in the transmission of impulses. It was in the brains of the mentally ill that gangliosides were first discovered, and indeed their pathologic accumulation can possibly be attributed to congenital defect of enzymes involved in their synthesis or metabolism. Gangliosides are produced from their components by acceptor-specific transferases.

1. Introduction

Work began on a new type of acidic lipids having a high carbohydrate content when *Klenk*[1] characterized a substance he isolated from the brains of patients suffering from amaurotic familial idiocy and Nieman-Pick disease, the existence of these lipids having earlier been detected by *Landsteiner* and *Levene*[2] and by *Thierfelder* and *Walz*[3] on account of the formation of characteristic dyes by these compounds with *p*-dimethylaminobenzaldehyde and orcinol. *Blix*[4] found in 1938 that these lipids regularly occur also in the normal brain. *Klenk* suspected that "Substance X" was localized in ganglial cells, and therefore named it ganglioside[5].

The identification of gangliosides as sphingolipids[*] and the determination of their constituents date back to the fundamental work of *Klenk et al.* Gangliosides are composed of sphingosine *(1)* [(2*S*:3*R*)-2-amino-*trans*-4-octadecene-1,3-diol], fatty acids, hexoses, and a sialic acid, *i.e.* an *N*-acylated or an *O*-acylated neuraminic acid *(2)* (5-amino-3,5-didesoxy-D-*glycero*-β-D-*galacto*-nonulosonic acid), mostly *N*-acetyl- or *N*-glycolylneuraminic acid (NANA or NGNA).

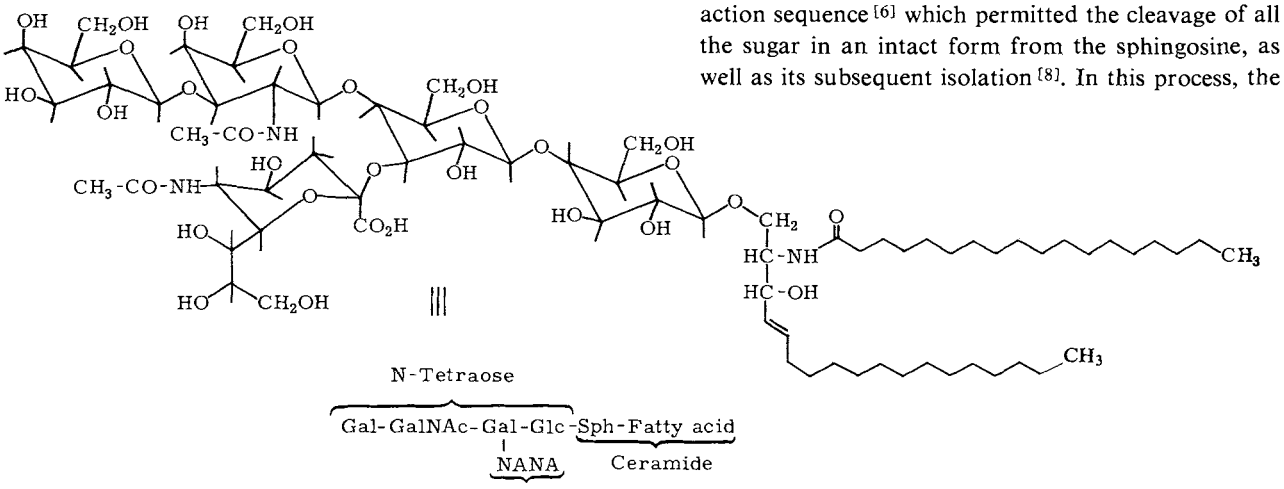
[*] Sphingolipids are fatty substances containing sphingosine as the basic component.

2. Structure of Gangliosides

Gangliosides were isolated and obtained in the pure form by the use of chromatographic methods. The elucidation of the chemical structure of the ganglioside $G_{GNT}1$ *(3)* (see below) isolated from the brain was attempted first, as this compound was available



N-Tetraose

Gal-GalNAc-Gal-Glc-Sph-Fatty acid

NANA Ceramide

Sialic acid = *N*-acetylneuraminic acid

$G_{GNT}1$ *(3)*

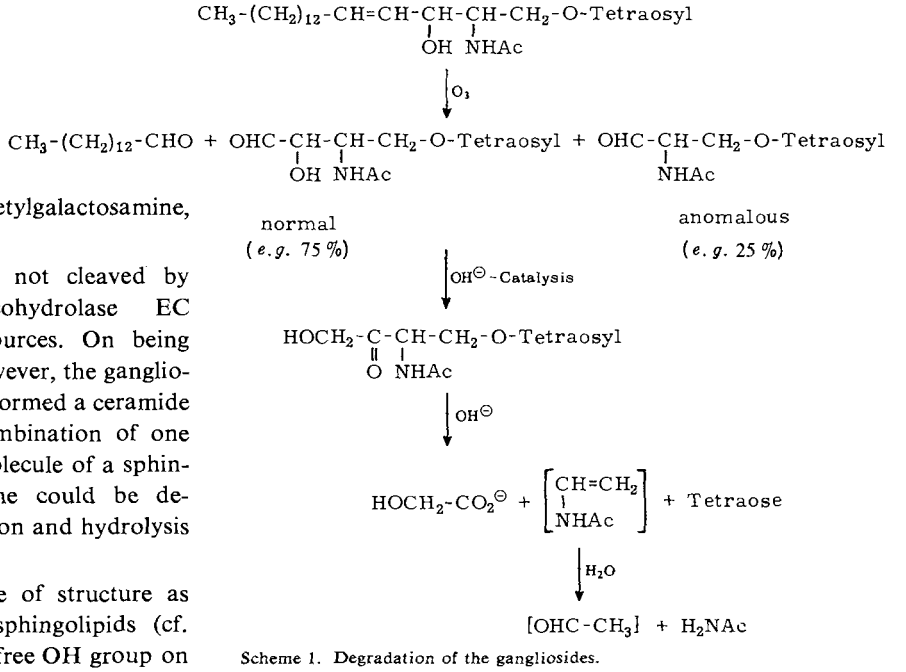
in the pure state in a sufficiently large amount. After exhaustive hydrolysis, quantitative analysis revealed a molecular ratio of 1:1:1:2:1:1 between sphingosine, fatty acid, glucose, galactose, *N*-acetylgalactosamine, and *N*-acetylneuraminic acid.

The sugar-sialic acid linkage was not cleaved by neuraminidase (neuraminate-glycohydrolase EC 3.2.1.18) samples from various sources. On being heated with dilute mineral acids, however, the ganglioside $G_{GNT}1$ lost its sialic acid and formed a ceramide tetrasaccharide. (Ceramide is a combination of one molecule of a fatty acid and one molecule of a sphingosine base.) 3-*O*-Methylsphingosine could be detected after the exhaustive methylation and hydrolysis of ceramide tetrasaccharide.

Gangliosides exhibit the same type of structure as that characteristic of other glycosphingolipids (cf. Table 2): a sphingosine base with a free OH group on C_3 carries a fatty acid molecule linked by an amide to the 2-amino group. A carbohydrate is linked by a glycoside to the OH group on the C_1 atom of the ceramide. The sialic acid characteristic of the gangliosides is bound to the sugar residue by a ketoside linkage. In a strongly acidic medium, the Des-NANA-$G_{GNT}1$ is further cleaved, giving rise to several free and still ceramide-bound sugars.

In the degradation of gangliosides with glacial acetic acid/acetic anhydride and catalytic amounts of conc. sulfuric acid [6] however, sialic acid is cleaved from the ganglioside only partially (but the ceramide is liberated), so that one obtains free oligosaccharides in which the linkage to the sialic acid remains intact.

The elucidation of the structure of gangliosides made a big step forward after the introduction of a new reaction sequence [6] which permitted the cleavage of all the sugar in an intact form from the sphingosine, as well as its subsequent isolation [8]. In this process, the C=C double bond in the sphingosine is split oxidatively with *e.g.* ozone, periodate and OsO_4 [9], or *m*-chloroperbenzoic acid [10]. The resulting substances can be fragmented by treatment with a weak base in such a way that the sugar residue is liberated [*]. The route shown in Scheme 1 has been proposed [7] for this reaction sequence.



Scheme 1. Degradation of the gangliosides.

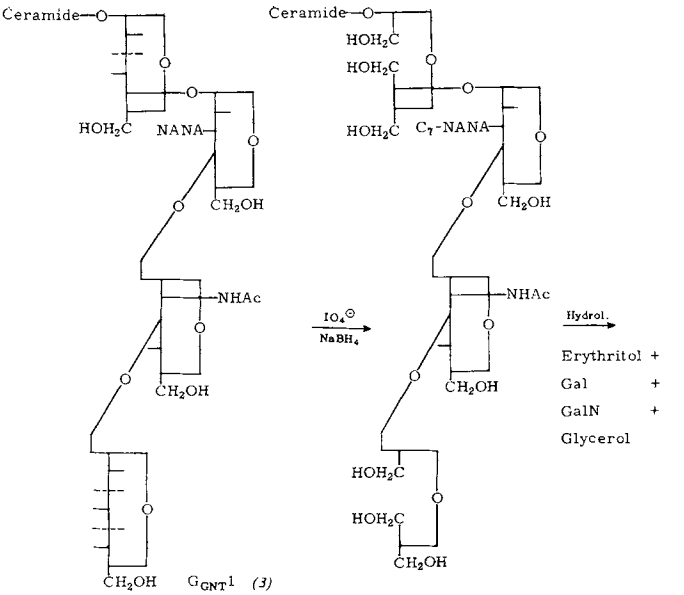
[10] *H. Wiegandt*, unpublished.

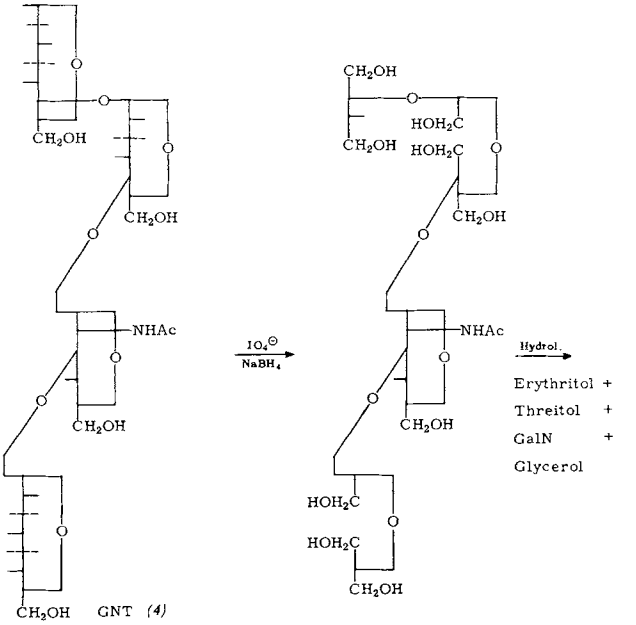
[*] When $OsO_4/IO_4^{\ominus}$ or *m*-chloroperbenzoic acid is used, the carbohydrate moiety should first be protected by peracetylation. The *O*-acetyl groups are cleaved off in the alkaline fragmentation.

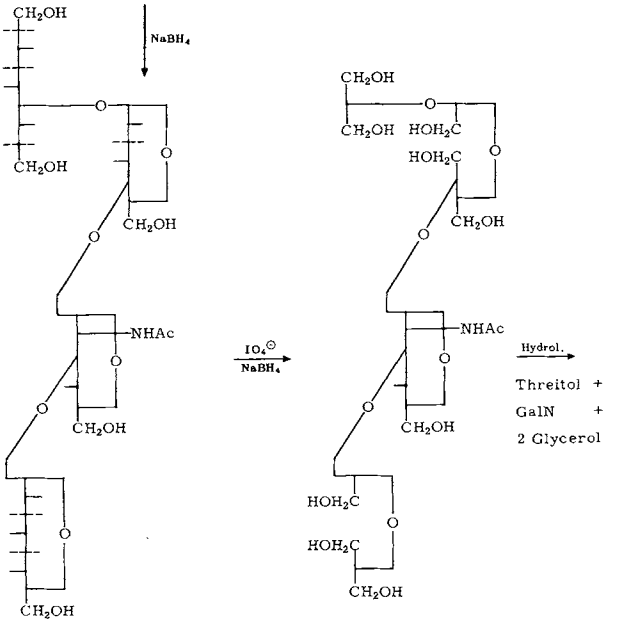
This method has been used to obtain the sialic acid-containing sugar residue from the neuraminidase-resistant ganglioside $G_{GNT}1$. The cleaving-off of sialic acid by careful acidic hydrolysis with 0.1 N H_2SO_4 at 80 °C gave the base sugar ganglio-*N*-tetraose. Further partial hydrolysis with the same medium at 100 °C permitted the isolation and characterization of two trisaccharides GNTrI and GNTrII and all three possible disaccharides GNBI, GNBII, and Lact.

The known nitrogen-containing tetrasaccharides can be easily separated paper chromatographically. Paper chromatographic "fingerprinting" of the products formed in the partial hydrolysis or the alkaline degradation represents another method of characterizing these saccharides on the microscale [19].

Ganglio-*N*-tetraose, GNT *(4)*, and $G_{GNT}1$ were cleaved with periodate, and the aldehydic fragments were reduced with $NaBH_4$. The comparison of the results showed that the sialic acid (here NANA), which cannot be cleaved off enzymatically, is linked to the C_3 of the second sugar residue of GNT.







3. Determination of the Components of Gangliosides

The differences between the gangliosides lie mainly in their carbohydrate moiety, but the sphingosine bases and the fatty acids may also vary. The gangliosides so far prepared in the pure state are uniform only as regards their sugar residue, and yet it is this residue that is essentially responsible for the differences in the chromatographic, chemical, and physiological properties.

Apart from sphingosine *(1)*, such chromatographically pure gangliosides from human and bovine brain contain another base which is homologous to the sphingosine *(1)*, but has a C_{20} chain instead of a C_{18} chain [11]. The sphingosines are saturated to an extent of about 10 %, *i.e.* about 10 % of the molecules do not contain C=C double bonds [12]. The C_{18}/C_{20} weight ratio varies with age: C_{18} predominates in the fetal brain, C_{20} greatly predominating in the brain of adults [13]. The C_{18}-sphingosine is the main component in the gangliosides isolated from the spleen [14].

There is also a variation in the fatty acids that are linked to the sphingosine. In each case, one of the fatty acids present is found in a particularly high concentration, the nature of this fatty acid depending on the source of the ganglioside; thus, it is stearic acid in the case of brain gangliosides, and lignoceric acid in the case of spleen gangliosides.

Glucose, galactose, *N*-acetylglucosamine, *N*-acetylgalactosamine, and fucose have so far been identified amongst the basic components of neutral oligosaccharides of the gangliosides. The neutral sugar linked to the ceramide moiety of the known gangliosides contains a maximum of four such sugar molecules forming a

tetrasaccharide *e.g.*, ganglio-*N*-tetraose in brain ganglioside and lacto-*N*-neotetraose in bovine erythrocytic or spleen ganglioside [15], but gangliosides with mono-, di-, and trisaccharides have also been isolated.

Gangliosides obtained from human erythrocytes and spleen contain mainly *N*-acetylneuraminic acid (NANA), while *N*-glycolylneuraminic acid (NGNA) is the predominating sialic acid (accompanied by NANA) in the gangliosides extracted from the erythrocytes and the spleen of other primates [16], as well as the horse and cattle.

Gangliosides may carry one or more molecules of sialic acid [17]. Sialic acid molecules are linked to the sugar in the ganglioside either singly or after they have been interconnected *via* 2 → 8 bonds [18]. When sialic acids are connected with another sialic acid molecule by a ketoside linkage in the 8-position, an inner ester is formed with particular ease. The resulting lactones are very unstable; they are easily cleaved by hydrolysis and can be detected by titration, reaction with hydroxamic acid, and paper electrophoresis.

The electrophoretic migration rate of gangliosides and their constituent sialic acid-containing oligosaccharides is greatly affected by the position in which the sialic acid is linked to the sugar residue. When two sialic acid molecules are interconnected, only one is strongly acidic in the paper electrophoresis at various pH values [19].

Of the α- and the β-ketosides of sialic acids, only the α-anomers are attacked by neuraminidase [20]. The linkage of the sialic acid must always be α-ketosidic here, since neuraminidase cleaves all the sialic acid molecules in the known gangliosides, though sometimes only after a certain hindrance has been eliminated [21]. This can be done *e.g.* in the case of $G_{GNT}1$ by removing the galactose and the *N*-acetylgalactosamine from the end of the sugar residue through partial acidic methanolysis or partial acetolysis, and then treating the resulting $G_{Lact}1$ with neuraminidase.

The gangliosides are generally detected by the colorimetric determination of the sialic acids with orcinol (*Bial*'s reagent [22]), *p*-dimethylaminobenzaldehyde (*Ehrlich*'s reagent [23]), thiobarbituric acid [24], diphenylamine [25], or 3,5-diaminobenzoic acid [26]. Sialic acids are relatively strong acids with p*K* 2–3, and therefore the gangliosides can be titrated acidimetrically.

The following techniques have been proposed for the identification and the quantitative determination of the sphingosine bases: Chromatographic identification of the base either in the free form or as the 2,4-dinitrophenyl derivative after the hydrolysis of the glycosphingolipid and isolation of the base (methanolic 1 N H_2SO_4 followed by ether extraction at pH > 7) [27]. The sphingosines can also be separated gas chromatographically after trimethylsilylation, and can be characterized with the aid of a mass spectrometer [28]. Furthermore, sphingosines may be characterized by the gas-chromatographic determination of the aldehydes or the fatty acids (as methyl esters) formed by the oxidative cleavage of the C=C double bond with ozone, $OsO_4/IO_4^{\ominus}$, or periodate/permanganate [11b, 29].

The fatty acids are analyzed by gas chromatographing the methyl esters after acidic methanolysis of the gangliosides.

3.1. Nomenclature of the Gangliosides [30]

Trivial or semitrivial names [30] are used to denote the oligosaccharides. The letter N attached to an oligosaccharide denotes a nitrogen-containing sugar. Trisaccharides and disaccharides that can be derived from one and the same tetrasaccharide are distinguished by I, II, *etc.*, I describing the sugar that originates from the non-reducing end of the tetrasaccharide (cf. Table 1).

Table 1. Abbreviations for oligosaccharides.

Oligosaccharide	Short designation	Abbreviation
Ganglio-*N*-tetraose	Gal(β1,3)GalNAc(β1,4)Gal(β1,4)Glc	GNT
Ganglio-*N*-triose I	Gal(β1,3)GalNAc(β1,4)Gal	GNTr I
Ganglio-*N*-triose II	GalNAc(β1,4)Gal(β1,4)Glc	GNTr II
Ganglio-*N*-biose I	Gal(β1,3)GalNAc	GNB I
Ganglio-*N*-biose II	GalNAc(β1,4)Gal	GNB II
Lacto-*N*-tetraose	Gal(β1,3)GlcNAc(β1,3)Gal(β1,4)Glc	LNT
Lacto-*N*-neotetraose	Gal(β1,4)GlcNAc(β1,3)Gal(β1,4)Glc	LNnT
Lacto-*N*-neotriose I	Gal(β1,4)GlcNAc(β1,3)Gal	LNnTr I
Lacto-*N*-triose II	GlcNAc(β1,3)Gal(β1,4)Glc	LNTr II
Lacto-*N*-neobiose I	Gal(β1,4)GlcNAc	LNnB I
Lacto-*N*-biose II	GlcNAc(β1,3)Gal	LNB II
Globo-*N*-tetraose	GalNAc(β1,3)Gal(β1,4)Gal(β1,4)Glc	GloNT

In abbreviations, G stands for ganglioside. The subscript, as in G_{GNT}, designates the sialic acid-free oligosaccharide. The Arabic numeral affixed to the abbreviation gives the number of sialic acid molecules. Different sialic-acid position isomers are distinguished by attaching a, b, *etc.* to the Arabic numeral (*e.g.* $G_{GNT}2a$ and $G_{GNT}2b$). If the sialic acid in a ganglioside is not NANA, but NGNA, this is specified by adding (NGNA) to the description.

4. Occurrence of Gangliosides

On the basis of quantitative determinations, gangliosides represent the following proportions of the total lipids [30, 31]:

one-day-old human brain	7.46 %
adult human brain	3.49 %
adult human *substantia grisea*	8.65 %
adult human *substantia alba*	4.16 %

After the separation of the *substantia alba* (white matter) into myelin and microsomes [32], the gangliosides are mainly present in the latter, in which the ganglioside content reaches 0.4 % of the dry weight. The concentration of the gangliosides in the *substantia grisea* (gray matter) of the frontal lobes of the brain and the *nucleus caudatus* (large ganglia of the brain stem) is about 1.2–1.6 % on dry weight (0.4 % lipid-NANA). This corresponds to a ganglioside-NANA content of about 10.4×10^{-12} g per ganglial cell [33].

Gangliosides occur in high concentrations also in the spleen (*e.g.* they form 3.3 % of the total lipids in human spleen [31]). The brain gangliosides are qualitatively the same in all the species investigated so far [man, cattle, rabbit, rat, hedgehog, chicken, crab (eye stalk) [10]], but the spleen gangliosides show strong interspecific variations, and so do the gangliosides of the visceral system in general.

Gangliosides are also found in the erythrocytes, leukocytes, serum, kidneys, adrenal glands, placenta, milk, blood-vessel walls, intestines, lungs, and in the lens of the human eye.

5. Chemical and Physical Properties

Gangliosides are colorless crystallizable substances melting with decomposition (*e.g.* the melting point of $G_{GNT}1$ is 189–190 °C, decomp.). They are insoluble in non-polar solvents, and their solubility in polar ones (water, alcohols, *etc.*) increases with the size of their sugar residue and their sialic acid content. In aqueous solutions, gangliosides form micelles having a molecular weight of about 200,000–250,000 [34]. In dimethylformamide or tetrahydrofuran, on the other hand, they form molecular solutions characterized by a molecular weight of 1000–3000 [35].

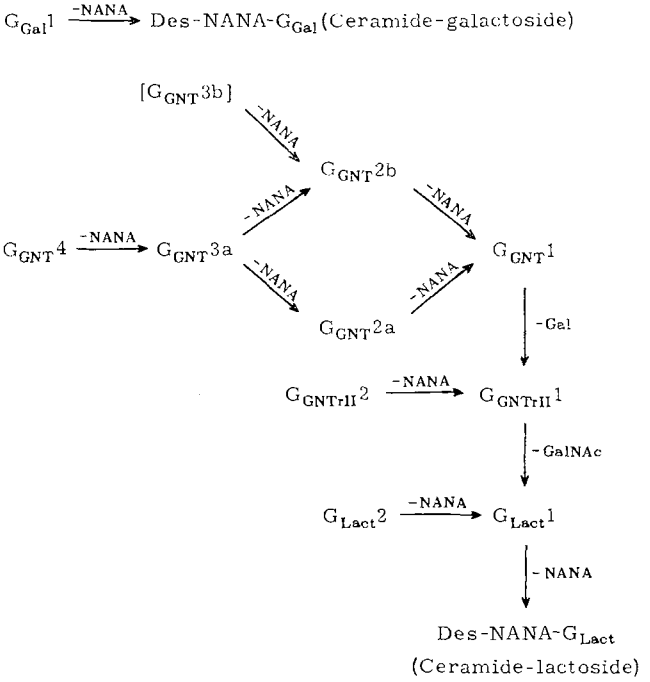
Gangliosides may form a lipid film on water. The minimum area required by a ganglioside molecule at the air/water interface of such a film at 30 dyne/cm [*] is 63 Å^2 for $G_{GNT}1$ and 95 Å^2 for a disialoganglioside [36]. Sphingomyelin, consisting of sphingosine and phosphorylcholine and containing mainly stearic acid as the fatty acid component, has an area requirement of 40 Å^2/molecule.

Urged by the concept that psychochemicals and local anesthetics can alter the physicochemical properties of biological membranes, *Van Deenen* [37] investigated a model system consisting of ganglioside films on water containing the substances mentioned above, and found that the latter penetrated through the films to various extents and modified the surface tension of the gangliosides.

Acidic lipids such as the gangliosides have a strong affinity for alkaline earth metal ions, but the fixation of $^{45}Ca^{2\oplus}$ on ganglioside films on water at pH 5.5 is considerably less pronounced than on phospholipid films [36]. Similarly to phospholipids (triphosphoinositide and phosphatidylserine), gangliosides have a higher affinity for $Ca^{2\oplus}$ than for $Mg^{2\oplus}$ ions in binary mixtures such as the chloroform/methanol/water system [38].

6. Brain Gangliosides

The main gangliosides in the brain are as follows: $G_{GNT}1$, $G_{GNT}2a$, $G_{GNT}2b$, and $G_{GNT}3a$. The first indication concerning their structural connection came from enzymatic degradation with neuraminidase [17]. By successive enzymatic cleavage of single sialic acid residues, it was possible to convert several gangliosides into $G_{GNT}1$, whose sialic acid could no longer be cleaved off by the enzyme (cf. the transformation of $G_{GNT}4$ to $G_{GNT}1$ in Scheme 2). The main



Scheme 2. Structural relationships between brain gangliosides.

brain gangliosides thus differ only in the number and/or the position of the sialic acid groups. In the case of the gangliosides $G_{GNT}1$ and $G_{GNTrII}1$, which are not cleaved by neuraminidase, the action of the enzyme is presumably obstructed by large substituents in the neighborhood [6]. The base carbohydrate carrying

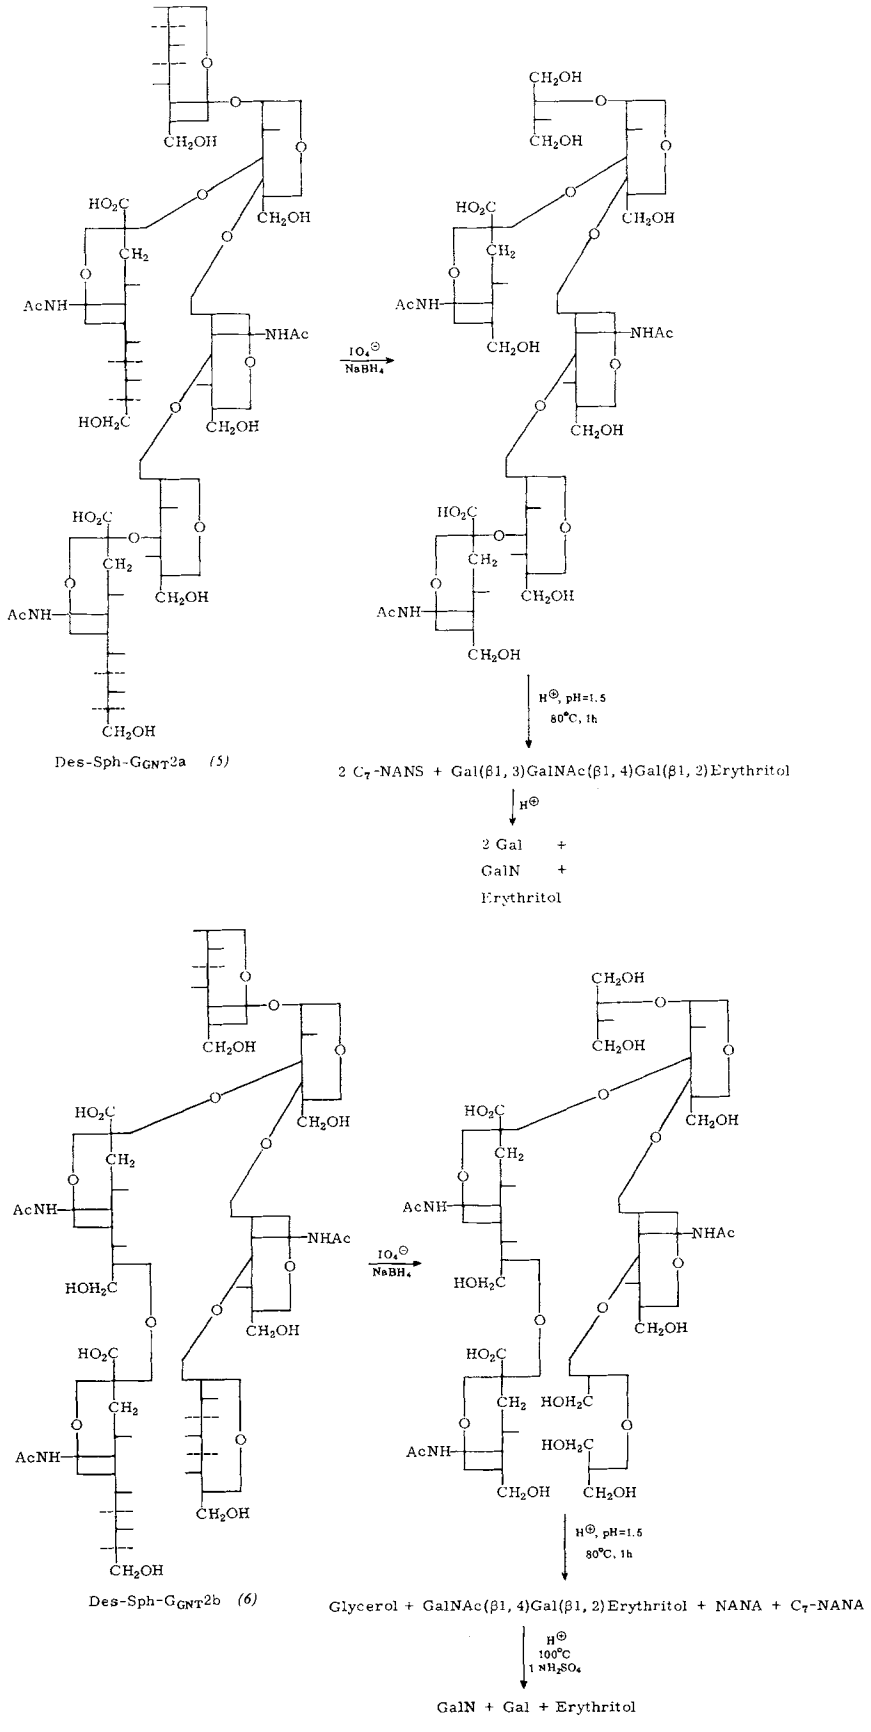
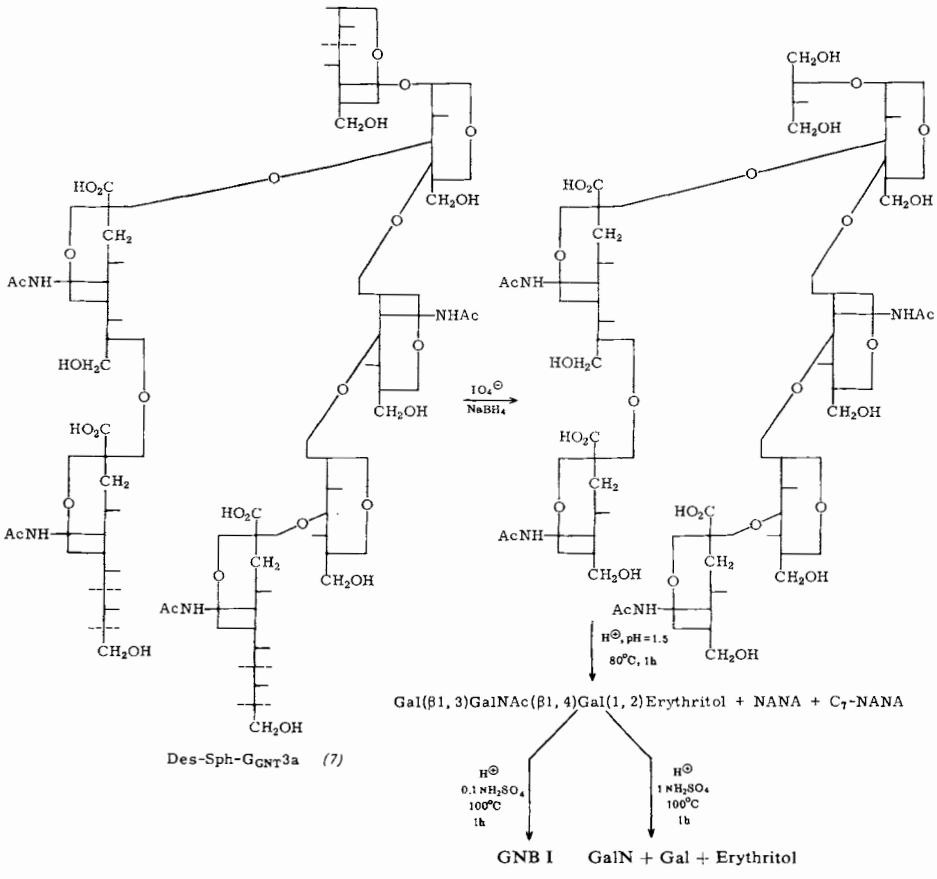
[38] *R. Quarles* and *J. Folch-Pi,* J. Neurochem. *12,* 543 (1965).

the sialic acid in these brain gangliosides is ganglio-*N*-tetraose *(4)*.

The determination of the points of attachment of NANA in the sialic acid-rich GNT gangliosides $G_{GNT}2a$, $G_{GNT}2b$, and $G_{GNT}3a$ was accomplished by the periodate oxidation[18] of Des-Sph-$G_{GNT}2a$ *(5)*, Des-Sph-$G_{GNT}2b$ *(6)*, and Des-Sph-$G_{GNT}3$ *(7)*, followed by acid hydrolysis.

In the ganglioside $G_{GNT}2a$, each of the two galactose molecules of the ganglio-*N*-tetraose at C_3 carries a NANA molecule. In the isomer $G_{GNT}2b$, on the other hand, the two sialic acid molecules are interconnected by a 2 → 8 keto-side linkage, and are attached to the 3-position of the front





galactose residue. The building units of $G_{GNT}2a$ and $G_{GNT}2b$ are combined in ganglioside $G_{GNT}3a$. These observations have recently been confirmed by *Klenk et al.*[39].

Besides these main components, several other gangliosides normally present in the brain in smaller quantities have been isolated, and their chemical structure has been determined[6, 40]. The ganglioside $G_{GNTrII}1$[6], earlier denoted by G_0, differs from $G_{GNT}1$ only in the absence of a terminal galactose residue. Therefore, it contains ganglio-*N*-triose II as the base carbohydrate. Owing to an enzyme defect in the biological synthesis or degradation, this ganglioside is accumulated in the infantile form of amaurotic idiocy of the Tay-Sachs type, and is therefore often referred to as Tay-Sachs ganglioside.

Other brain gangliosides contain ganglio-*N*-triose II with two NANA molecules ($G_{GNTrII}2$), or they contain lactose with one or two NANA molecules. The smallest ganglioside, $G_{Gal}1$, contains only one molecule of galactose, substituted by NANA at the 3-position. The structural relationships between the brain gangliosides are shown in Scheme 2, which also illustrates a path of the biological degradation.

7. Gangliosides in the Spleen and the Erythrocytes

Much less work has been done on the gangliosides of the visceral system than on those of the brain. In man, cattle, and the horse, the main ganglioside is $G_{Lact}1$. It has been possible to isolate several other higher gangliosides from the spleen and the erythrocytes of man and cattle, but the structure of these has not yet been elucidated. In these compounds, galactosamine is accompanied by glucosamine. A glucosamine-containing ganglioside $G_{LNnT}1$(NGNA) found in the red cells and the spleen of cattle contains lacto-*N*-neotetraose as the base carbohydrate, this compound having so far been known only as a component of human milk[15]. It cannot be excluded that parenchymatous organs contain also gangliosides that can be derived from glycosphingolipids carrying no sialic acid molecules, for such lipids are present in these organs (cf. Table 2). This is supported by the presence of $G_{Lact}1$ and the recent isolation of a hitherto unknown ganglioside from intestinal tissues and the lens of the human eye that comprises sphingosine, fatty acids, sialic acid, glucose, and galactose in a ratio of 1:1:1:1:2[41a].

The question arises whether the specific structure of certain lipid-bound or protein-bound oligosaccharides

Table 2. Glycosphingolipids containing no sialic acid molecules occurring in erythrocytes, spleen, kidneys, *etc.*

are characteristic of certain cell structures such as cell surfaces for example. Available data suggest that compounds containing ganglio-*N*-tetraose are basically confined to the central nervous system, while compounds containing globo-*N*-tetraose are restricted to parenchymatous-stromatic elements of the body.

8. Accumulation Diseases

In sphingolipidoses, which are rare hereditary diseases transmitted *via* a recessive autosomal mechanism, sphingolipids are stored in the brain and often also in other organs such as the spleen, the kidneys, and the liver. This indicates that the enzymes involved in the metabolism of sphingolipids are not produced by the body, because the structural gene governing these enzymes suffers from a hereditary defect. In fact, a deficiency of such enzymes has already been observed in some of these diseases. Table 3 lists a number of such diseases, the main stored lipids, and – whenever known – the missing enzymes.

Table 3. Data for various forms of sphingolipidosis [a].

Name of disease	Main lipid stored	Missing enzyme
Amaurotic idiocy infantile form (Tay-Sachs type)	$G_{GNTrII}1$	specific hexosaminidase?
Late-infancy form (biochem. special form?)	$G_{GNT}1$	specific galactosidase?
Niemann-Pick disease	sphingomyelin	sphingomyelinase
Gaucher's disease	Cer-Glc	specific glucosidase
Metachromatic leukodystrophy	Cer-Gal-SO_3^-	sulfatase
Globoid cell leukodystrophy (type Krabbé)	Cer-Gal	specific cerebrosidesulfotransferase
Fabry's disease	Cer-Glc-Gal-Gal	specific galactosidase

[a] The gangliosides show a pathologic picture also in the juvenile and the adult forms of amaurotic idiocy, in gargoylism, and in Krabbe's disease (diffuse infantile familial sclerosis).

Changes in the gangliosides are by far the greatest in infantile amaurotic idiocy of the Tay-Sachs type. Lipid-bound sialic acid in this case exceeds the normal quantity by a factor of 2–3, and about 80 % of it is present in accumulated ganglioside $G_{GNTrII}1$, which under normal conditions features only in small amounts. All other mono-, di-, and trisialogangliosides constituting about 1 % of the dry weight exhibit a normal level [42].

In another form of lipidosis occurring in late infancy, the ganglioside picture is modified in such a way that about 80 % of all the ganglioside-NANA is contained in the ganglioside $G_{GNT}1$ [43], as compared to the normal value of about 18 %.

Whereas the ganglioside pattern is more or less normal in the juvenile and the late infantile forms of amaurotic idiocy, two monosialogangliosides (probably $G_{Gal}1$ and $G_{Lact}1$) show abnormally high levels in gargoylism, the Niemann-Pick disease, and Gaucher's disease [44].

An abnormally high level is also often found for the corresponding sialic acid-free ceramide oligosaccharides in all these diseases. The specific storage of gangliosides is thus accompanied by a more general disruption of the whole glycolipid metabolism in most cases of neurolipidoses.

9. Biosynthesis and Metabolism of Gangliosides

Sphingosine *(1)* is synthesized by the body from palmitaldehyde and serine:

$$CH_3\text{-}(CH_2)_{14}\text{-}CHO + HO_2C\text{-}\underset{\displaystyle NH_2}{\underset{|}{C}}H\text{-}CH_2OH \longrightarrow \longrightarrow$$

$$CH_3\text{-}(CH_2)_{12}\text{-}CH{=}CH\text{-}\underset{\displaystyle OH}{\underset{|}{C}}H\text{-}\underset{\displaystyle NH_2}{\underset{|}{C}}H\text{-}CH_2OH$$

(1)

Dihydrosphingosine, which is first formed, is subsequently dehydrogenated. According to recent investigations, each hexose molecule is attached in turn to the backbone molecule. For each monosaccharide, there is a separate class of transferases. They are used for the transfer of the same sugar-nucleotide, but they differ in their acceptor-specificity (cf. Table 4).

Table 4. Transferases.

Enzyme	Source	Acceptor	Product
NANA-transferases	*E. coli*	$(NANA)_n$	colominic acid
	Rat mammae	Lact	3′-NANA-Lact
	Goat colostrum	Lact	6′-NANA-Lact
	Submaxillary region of sheep	desialomucin	NANA(2→6)GalNAc-protein
	Chick embryo brain	ceramide lactoside (des-NANA-G_{Lact})	$G_{Lact}1$
	Chick embryo brain	$G_{GNT}1$	$G_{GNT}2a$
Galactose-transferases	Rat mammae	Glc	Lact
	Cow's colostrum and tissues	GlcNAc	*N*-acetyllactosamine
	Cow's colostrum and tissues	GlcNAc-protein	Gal-GlcNAc-protein
	Chick embryo brain	$G_{GNTrII}1$	$G_{GNT}1$

The stepwise synthesis of brain gangliosides $G_{GNT}2a$ and $G_{GNT}3a$ is shown in Scheme 3 [45].

The steric hindrance observed in cleavage by neuraminidase appears to play a part also in the biosyn-

thesis. When GalNac is already bound to the 4-position of the front galactose of GNTrII or GNT, sialic acid does not become attached to the same galactose at the 3-position. This also applies in the stepwise biochemical degradation of *e.g.* Cer-Glc-Gal-(NANA)-GalNAc-Gal-NANA ($G_{GNT}2a$). First the terminal NANA residue is split off, and then the next galactose residue. The GalNAc, which is now the end group, must become detached before the next group (NANA) can be eliminated, and so on.

10. Subcellular Localization and the Biological Properties of Gangliosides

To obtain more information concerning the function of gangliosides in the cell, the localization of these lipids inside the cell has been studied, and the results suggest that they occur in the neuronal membranes in the cell body, dendrites, axons, and synaptic junctions, *i.e.* in exactly those elements which are involved in the transmission of nerve impulses.

When *substantia grisea* is homogenized with great care, it is possible to retain some of the nerve endings (synaptosomes) which become detached from the nerves. These nerve endings can be purified by differential and density-gradient centrifugation [46] (cf. Fig. 1a). Basically, they consist of an outer membrane and inner small mitochondria and vesicles characteristic of synapses. The synaptic vesicles contain the chemical substances responsible for the transmission of impulses across nerves. They occur in greatly increased numbers on the direct synaptic contact sites, namely on presynaptic membranes. When lysis is conducted in a hypotonic medium [47], the synaptosomes burst and release their contents. The resulting fragments can be separated by centrifugation (Figs. 1b and 1c). Contrary to earlier assumption [48], the gangliosides are found not in the synaptic vesicles, but in the membrane components originally belonging to the outer membrane of the nerve endings, as shown by electron micrographs. No gangliosides have been found in the mitochondria [49].

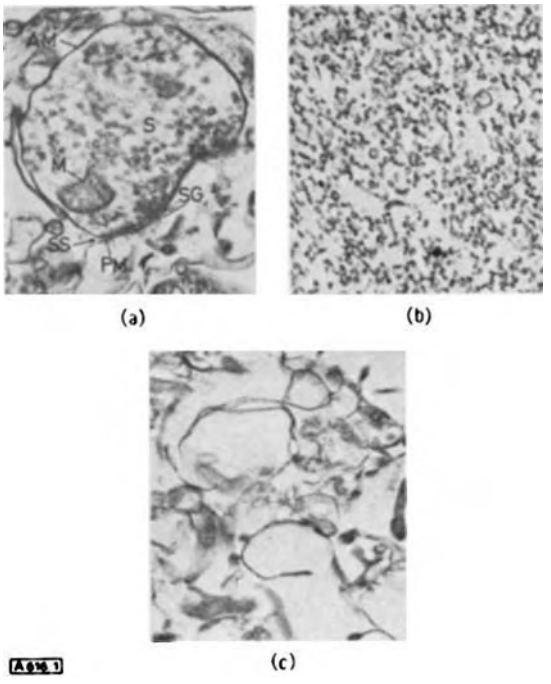

Fig. 1. a) Electron micrograph of a nerve ending isolated from bovine cerebral cortex (contrast coating with OsO_4 embedding in Vestopal W), × 45000. AM = outer membrane; S = synaptic vesicle; M = mitochondrion; SS = synaptic gap; PM = postsynaptic membrane; SG = subsynaptic web.

b) Electron micrograph of isolated synaptic vesicle material (× 40000).

c) Electron micrograph of ganglioside-containing membranes from nerve endings (× 40000).

Another possibility of concentrating ganglioside structures in subcellular fractions consists in treating the latter with the neutral detergent Triton X 100 (isooctylphenoxypolyethoxyethanol) [10], which dissolves gangliosides out of the membranes only to a small extent.

When the total microsome fraction from gray matter or the osmolyzed nerve ending fraction freed from mitochondria and synaptic vesicles is suspended in weakly alkaline Triton X 100, the various types of membranes are attacked with different intensities. Analysis of the membrane components that remain undissolved shows that they are the ones with a high ganglioside content.

Electron micrographs of nerve endings show structures rich in acidic carbohydrates on the outside of axonal membranes and in particular directly at the synaptic

gap [50]. Even the localization of gangliosides suggests that these typically membrane-forming amphiphile lipids, which indeed also carry electric charges, are involved in the impulse-conduction of neurons, and many observations on the physiological action of these lipids support this hypothesis.

Tetanus toxin is known to be fixed by gangliosides [51], at high toxin concentrations *e.g.* $G_{GNT}3$ fixing about 0.6 mole of the toxin (M.wt. $\approx$ 70,000). The action of tetanus toxin is thought to lie in blocking the inhibition synapses, *i.e.* impeding the liberation of neurotransmitter substances [52]. *Wolfe* has shown that the distribution of γ-aminobutyric acid – the presumed transmission substance at the inhibitory synapses – resembles that of the gangliosides [53].

The participation of gangliosides in the transmission of excitation is further supported by the following observation: After 5 h in a tris-buffered glucose Ringer solution at 0 °C, brain tissues no longer show extra respiration on electrical stimulation, but this cold treatment does not affect the normal respiration [55]. The addition of gangliosides to such a damaged system restores up to 80 % of the extra respiration. The author, *McIlwain*, attributed this to histones leaving the cell nuclei in the cold medium and reaching and blocking ganglioside sites.

When injected into the blood, gangliosides may provoke the formation of antibodies against themselves. The serologic specificity of gangliosides is localized in their carbohydrate moiety, the sialic acid also playing an essential part. The gangliosides in the $Rh_0(D)$ antigen-antibody system are found to be carriers of blood group properties [54]. In serologic tests, lacto-*N*-neotetraose from ganglioside $G_{LNnT}1$(NGNA) shows a specificity as regards the nature of the pneumococcus type XIV polysaccharide.

According to *McIlwain* [56], furthermore, the gangliosides lower the concentration of sodium and potassium in the non-inulin space by reducing the sodium space, increasing the potassium space, and depressing the concentration of potassium in the potassium space.

5-Hydroxytryptamine (serotonin) is thought to be a neurotransmitter in the central nervous system. According to *Wooley* and *Gommi* [57], the serotonin-receptor must contain sialic acid, and is probably a ganglioside. These authors demonstrated on a fundus preparation that the serotonin-sensitivity is disturbed by treatment with neuraminidase, but it can be restored by adding gangliosides, particularly $G_{Lact}2$, which fixes serotonin the most strongly. It seems probable that an equimolecular complex is formed in this process [58]. No complex is formed between a ganglioside and serotonin in the presence of $Ca^{2\oplus}$ ions, since gangliosides fix the latter even more strongly. Reserpine, too, liberates serotonin from the complex.

All these results suggest that gangliosides are involved in important functions of the central nervous system, and perhaps in the operations of membranes in general. The next task is to find a connection between the structure and the function of these compounds.

The author wishes to thank Professor Dr. P. Karlson for carefully reading through the manuscript and making valuable suggestions.

Recent Results in the Field of Liquid Crystals

BY A. SAUPE[*]

Thermotropic mesomorphous phases such as occur in the melts of many organic substances are considered. Though mesomorphous melts were first observed by Reinitzer in 1888, fundamental structural problems regarding such melts have not, as yet, been completely solved. Part I of this article deals mainly with such structural problems and with the theories of crystalline organic liquids. Part II describes the use of nematic solvents for magnetic resonance studies on oriented molecules. Examples are given to illustrate the possibilities offered by this procedure, and some of the results obtained so far are reviewed.

Introduction

Liquid crystals, or crystalline liquids, are obtained when most organic substances are melted; they are formed at that stage of the melting when insufficient heat has been supplied to bring about the transition into the normal isotropic liquid. They are phases that are strongly anisotropic in some of their properties (a characteristic normally found only in solid crystals), though the phases themselves may be as mobile as water. These thermotropic crystalline phases are separated from the normal liquid and from the crystal by first-order transition points. A given substance may have several mesomorphous phases, and, so far as can be gathered from observations, these are then separated from one another by first-order transition points.

A second group of crystalline liquids occurs in solutions; these are more accurately described as lyotropic crystalline liquids. The best-known representatives of this group are aqueous soap solutions. The molecular structures of the soap-water systems have recently been studied in some detail. The reader is referred to the latest article[1] in a long series of reports[2] on this topic.

Several reviews[3–6] and a book[7] on crystalline liquids have appeared during the last ten years, and several recent articles deal with mesomorphous states in biological systems[8]. All the organic substances known through 1959 to possess mesomorphous properties have been listed by *Kast*[9], and the results of dielectric and refractometric measurements have been collected by *Maier*[10,11].

I. Structures, Theories, and Properties of Crystalline Liquids

1. Types of Crystalline Liquids

There are three principal types of crystalline liquids, which are described by the terms proposed by *Friedel*[12], *i.e.* nematic, cholesteric, and smectic. (A notable exception is formed by the mesomorphous melt of diisobutylsilanediol, which cannot be classified according to this scheme[13].) Molecules that form mesomorphous phases are more or less elongated. Figure 1 shows the schematic structures of the

mesomorphous phases. The order in all mesomorphous phases is characterized by the more or less complete orientation of the molecules with their long axes parallel. This orientation is apolar, *i.e.* a given molecular orientation and the orientation obtained from it by rotation through 180° are equally probable. Crystalline liquids are thus not ferroelectric. However, doubt is cast on this general conclusion by a number of recent investigations [14–16].

a) Nematic Liquids

Nematic liquids differ structurally from normal isotropic liquids only in the spontaneous orientation of the molecules with their long axes parallel (Fig. 1). In the absence of special measures, the preferred direction of the long axes is not constant over large areas, but varies (generally continuously) with position. Nematic liquids are characterized by the thread-like structures that can often be observed in thin films under the polarization microscope (Fig. 2). These are

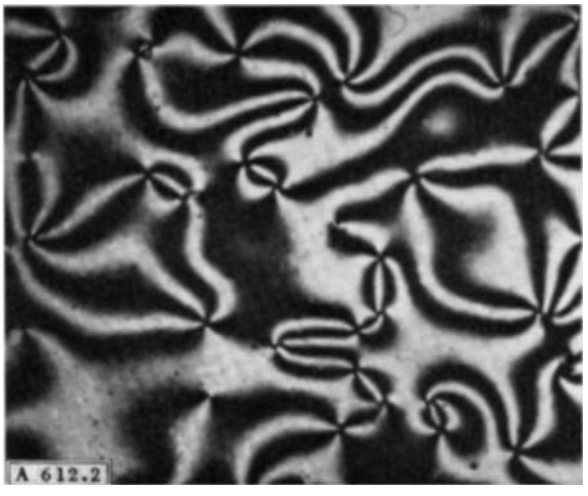

Fig. 2. Nematic fiber texture of 1,4-bis(*p*-ethoxybenzylidene)cyclohexanone. Crossed Nicols, magnification 100× (According to *Sackmann* and *Demus*).

striae resulting from a particularly strong dependence of the preferred direction on position in the vicinity of the axis of the thread. There may no longer be any definite preferred direction in the axis of the thread itself. Homogeneously aligned layers, *i.e.* layers having a constant preferred direction, behave optically in the same way as uniaxial crystals exhibiting positive birefringence, *i.e.* the ordinary ray has the lower refractive index. The optical axis coincides with the preferred direction of the long axis of the molecule.

The molecular orientation is not completely parallel, owing to the thermal motion pf the molecules. The parallelism is measured by the expression

$$S = (1/2) \langle 3 \cos^2 \Theta - 1 \rangle \qquad (1)$$

where θ is the angle between the long axis of a molecule and the preferred direction. The angular brackets indicate that the expected value, *i.e.* the average value of $\cos^2 \theta$, is to be used. For perfectly parallel orientation, *i.e.* for ideally nematic order, $S = 1$, while for the isotropic phase $S = 0$. In nematic liquids S is strongly temperature-dependent and increases with falling temperature. According to existing results, the value of S at the clear point, *i.e.* the transition point to the isotropic phase, is between 0.3 and 0.5. The highest S values observed in nematic liquids are about 0.8 (see Fig. 7, Section I.3).

Nematic liquids can readily be homogeneously oriented. Large samples are most easily oriented by magnetic fields of several thousand gauss [17]; the optical axis becomes parallel to the field axis. Thin films between glass plates can be oriented by boundary effects [18, 19]. By suitable surface treatment, it is possible to obtain two different homogeneous orientations *e.g.* with 4,4′-bis(methoxy)azoxybenzene. Rubbing of the surfaces of the glass in a given direction leads to "planar layers" in which the optical axis lies in the plane of the film and parallel to the rubbing direction; "erected layers", in which the optical axis is perpendicular to the plane of the film, are obtained by careful cleaning of the surfaces *e.g.* with sulfuric acid/bichromate.

b) Smectic Liquids

A given substance may give one or more smectic phases as well as a nematic phase. The smectic phases always occur – in agreement with the higher order – at lower temperatures. However, a smectic phase can also occur as the only mesomorphous phase. According to observations on homogeneously oriented erected smectic layers, smectic liquids, like nematic liquids, behave optically in the same way as uniaxial crystals having positive birefringence.

In thin, nonhomogeneously oriented films, smectic liquids can be recognized microscopically from their characteristic textures, which can be used for classification purposes [20]. Some examples are shown in Figures 3 and 4. The polygon texture in Figure 4 is a special case of the focal conic texture, which was studied and explained by *Friedel* [12].

The focal conic texture is characterized by ellipses, each with a corresponding hyperbolic branch, and which, like the nematic threads, can be seen because of the very strong dependence of the preferred direction on position in their vicinity. There is probably no longer a preferred direction on the ellipses and hyperbolic branches. An ellipse and the corresponding hyperbola lie in two mutually perpendicular planes, the major axis of the ellipse lying in the intersection of the two planes. The ellipse passes through the foci of the hyperbola, and the hyperbola (of which only one branch is visible) runs through the foci of the ellipse. In the region between the curves, the preferred directions lie along the

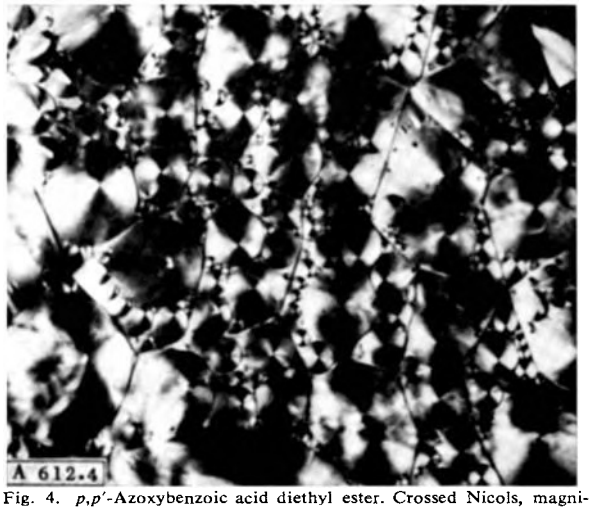

Fig. 4. *p,p'*-Azoxybenzoic acid diethyl ester. Crossed Nicols, magnification 100×, focusing on upper side of sample, 120°C. Smectic polygon structure. (According to *Sackmann* and *Demus*.)

straight lines running from the ellipse to the visible branch of the hyperbola. Equidistant parallel surfaces can be placed perpendicular to these lines (Dupin cyclides). In the polygon texture, the boundary faces show ellipses, which are gathered into groups within polygons (Fig. 4).

The classification of smectic phases has been studied in detail by *Sackmann*, *Arnold*, and *Demus* [20–25]. Their investigation of the miscibility of mesomorphous phases indicates the existence of at least three types of smectic phases, which are denoted by A, B, and C.

Most of the smectic phases observed belong to type A, which corresponds to the structure shown in Figure 1c [21]. Comparison with the nematic phases shows the existence of an additional optical principle in this case, *i.e.* the arrangement of the centers of gravity of the molecules in planes perpendicular to the preferred direction of the long axis of the molecule, and hence perpendicular to the optical axis. In type A, the distribution within the planes is irregular.

Smectic liquids of type B have been observed only in substances in which at least type A also occurs. Type B always occurs in the lowest temperature range. It probably differes from type A in that the arrangement of the centers of gravity of the molecules in the plane is hexagonal close-packed [26]; however, X-ray analyses have been carried out for only a few cases [27]. If type C and type A occur together, type C always exists at lower temperatures. This type C has a more highly ordered structure than type A, though it is not yet known in what respect.

Table 1 shows some recent results obtained by *Arnold* [26, 28, 29] for the heats of transition for transitions into and between mesomorphous phases. It can be concluded from the temperature-dependence and the magnitude of the birefringence [11] that the S values of smectic liquids vary only slightly with temperature and are higher than those of nematic liquids. IR measurements for the determination of S have been reported for 4,4'-bis(*n*-heptyloxy)azoxybenzene (type C); the value obtained was 0.9 [30].

c) Cholesteric Liquids

A cholesteric phase occurs only in optically active substances. It may be regarded as a special case of a nematic phase, since its molecular structure corresponds to a twisted nematic layer (cf. Fig. 1). In a homogeneously oriented layer, the preferred direction is no longer constant over the entire volume; there

are instead parallel planes in which the preferred direction is constant. Thus though their order is no higher than that of true nematic liquids, these "cholesteric-nematic" liquids have a layer structure, which leads in many respects to behavior similar to that of smectic liquids. As one proceeds along a line perpendicular to the planes of constant preferred direction, the preferred direction rotates uniformly. The pitch of this rotation (rotation through 2π) varies widely, is usually temperature-dependent, and is generally between 0.2 and 20 μ. The temperature-dependence may be positive or negative.

The twisting cannot be detected directly by X-ray studies [31], which merely seem to confirm that the arrangement of the molecules over small regions containing only a few molecules is almost the same as that in the isotropic liquid. This is also true of nematic liquids [32, 33]. The twisting of the cholesteric liquids can be seen in the unusual optical behavior of homogeneously ordered layers:

1. On irradiation parallel to the axis of rotation, over a small wavelength range about $\lambda_R = pn$, where p is the pitch of the rotation and n is the average refractive index, only one circularly polarized beam is transmitted while the other is totally reflected; however, no reversal of the direction of rotation takes place in contrast to reflection from a metallic surface.

2. Outside this range, a strong optical rotatory power (up to 100 rotations per millimeter) can be observed on perpendicular irradiation [10]. The total reflection range separates wavelength ranges with opposite rotation directions.

If λ_R lies in the visible region, the total reflection gives rise to a bright color. Since p is strongly dependent on temperature for many substance, the color observed may also be strongly temperature-dependent. Thin homogeneously oriented layers of such substances can therefore be used to show directly the temperature distribution on a surface [34–37]. Another application is based on the dependence of p, and hence of the reflection color, on dissolved substances.

For example, the reflection color of a cholesteric mixture of 20 % of cholesteryl chloride and 80 % of cholesteryl nonanoate changes from the normal green to red on absorption of benzene and to blue on absorption of chloroform. The color changes are so sensitive that they can be used to detect even traces of vapors [34].

The twisting of the molecular structure of cholesteric liquids was deduced by *Friedel* [12] from observations made on their optical behavior. This conclusion is confirmed by more recent theoretical studies by *de Vries* [38] who investigated the optical properties of

continuously twisted anisotropic layers for strong twisting with illumination only along the axis of rotation. He found that layers of this type have the same unusual properties as are observed in cholesteric liquids. Quantitative experimental checks were carried out by *Cano* and *Chatelain*[39], who studied the optical rotatory power of cholesteric mixtures as a function of the structural twisting.

Planar homogeneously oriented cholesteric layers, *i.e.* layers having a uniform axis of rotation, can be relatively easily produced between two plates of glass or mica. The axis of rotation is perpendicular to the plane of the layer. If, in wedge-shaped layers, the preferred direction at the interfaces is fixed by boundary effects, regular fringes (Grandjean fringes) are observed. The fringes follow the lines of constant thickness. The increase in thickness from one fringe to the next is equal to $p/2$; these fringes can be explained as resulting from the twisting[40].

Nonhomogeneously oriented cholesteric layers, like smectic liquids, can have the focal conic texture. In this case the parallel equidistant surfaces presumably coincide with the surfaces of uniform preferred direction and their normal directions with the straight axes of rotation[5,6]. They therefore differ from homogeneous layers in that the direction of the axis of rotation varies with position, but the twisting should otherwise be the same. However, no direct evidence of twisting is observed in the optical behavior of nonhomogeneous layers of this type. For example, they exhibit no unusual reflecting power, probably because of the nonuniform orientation of the axes of rotation.

Homogeneous, non-birefringent layers can also be obtained by cooling from the isotropic phase[7]; the focal conic texture develops in these layers only on further cooling. In this context, mention should also be made of another question that has not yet been answered. During viscosity measurements on cholesteryl stearate, *Porter* and *Johnson*[41] found no sudden change at the transition point from the cholesteric to the smectic phase. However, the authors could not establish whether a phase transition actually occurred in the sample examined.

No experimental details are known about the fluctuation of the molecular axes about the preferred direction in cholesteric liquids. The molecules are probably oriented to about the same extent as in true nematic liquids.

Optically active substances can form smectic phases as well as (or instead of) a cholesteric phase. The smectic phases then always exist at lower temperatures. These smectic phases show no peculiarities as compared with those of inactive substances. The criteria that the centers of gravity of the molecules should be arranged in equidistant planes and that the preferred directions should be perpendicular to these surfaces are not compatible with the twisting that characterizes the cholesteric liquids.

2. Theories of Nematic Liquids

a) Swarm Theory

Thick layers of nematic liquids appear cloudy, and are reminiscent of emulsions. The turbidity is due to the fact that samples of this type are not homogeneously oriented unless special measures are taken. However, distinct turbidity, *i.e.* strong light scattering, is still found when the orientation is made homogeneous *e.g.* by means of a magnetic field. It may therefore be concluded that molecules in regions up to 0.1 μm in diameter exhibit random changes in orientation[42].

The strong light scattering is one of the main pieces of evidence in favor of the swarm theory, which was advocated in particular by *Ornstein* and *Kast*[43], and which is still favored for the interpretation of experimental results. This theory is essentially as follows. The molecules of nematic liquids group together to form swarms containing on average about 10^5 molecules. Within these swarms, the molecules lie parallel to one another. The directional component of the interaction between the swarms is small, so that the orientation of the axes of the swarms in relation to one another is random unless a uniform orientation is imposed by external agencies. The swarms have only a limited life, and are constantly being broken down and then reformed.

The assumption that only weak orienting forces exist between the swarms has not been confirmed. Observations on thin layers (<0.3 mm), some of which will be described in the next section, contradict this idea, as do *Maier*'s observations[17] on the behavior of thick layers. Complete orientation of the liquid in thick layers can be achieved even with relatively low magnetic field strengths (1000–2000 gauss). This is illustrated by Figure 5, which shows the dielectric anisotropy of 4,4'-bis(methoxy)azoxybenzene. The ascending part of the saturation curve is not shown, since the experimental reproducibility is poor. After the magnetic field has been switched off it may take

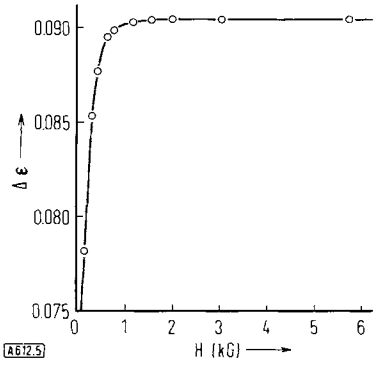

Fig. 5. Dielectric anisotropy of nematic liquid 4,4'-bis(methoxy)azoxybenzene according to *Zindel* [44]. Temperature 134.7 °C, measuring frequency 100 kHz, ε_1 dielectric constant parallel to the magnetic field, ε_2 perpendicular to the magnetic field, $\Delta\varepsilon = \varepsilon_2 - \varepsilon_1$.

[44] *D. Zindel*, unpublished.

several minutes before the system regains its initial state [17]. The deorientation of independent swarms should be much faster for nematic 4,4′-bis(methoxy)-azoxybenzene, owing to its low viscosity. The form of the saturation curve should also be different if the magnetic field has to orient independent swarms in opposition to the effects of thermal motion. This is shown by the fact that the dielectric anisotropy does not disappear completely even in the absence of external fields [17].

The alignment by a magnetic field can be equally easily explained without reference to any swarm structure. In the nematic liquid, which is aligned at the interfaces by boundary effects and in the body of the liquid by convection currents [17], the application of a magnetic field leads to uniform alignment of the molecules owing to the diamagnetic anisotropy of the volume elements and the free mobility of the molecules. The imposed alignment is such that the axis along which the diamagnetic susceptibility is lower lies parallel to the magnetic field. The saturation field strength will therefore obviously depend on the experimental conditions, *i.e.* on the strength and nature of the preorientation by boundary effects and convection currents, and is not a constant characteristic of the liquid. The alignment in the magnetic field is not associated with any appreciable change in entropy (see Fig. 5).

The small effect of a magnetic field on the thermal motion of the molecules was shown particularly impressively by *Chatelain* [45]. This author found that, in a layer more than 0.5 mm thick of 4,4′-bis(methoxy)-azoxybenzene that was homogeneously aligned by boundary effects, a 20000 gauss magnetic field parallel to the optical axis does not appreciably influence the birefringence, and so has less effect on the variation of the orientation of the molecules than a temperature change of 0.02 °C. The variation of the orientation is also substantially unaffected by boundary effects. The birefringence was found to be constant for layer thicknesses of 2 μm to 0.7 mm [45].

The structure of nematic liquids is more continuous than the original swarm theory assumed. Nevertheless, there is some justification for the imaginary breakdown of the liquid into swarms as a model for the description of collective random variations of orientation. One example of the use of this model is *Chatelain*'s treatment of light scattering [42].

b) Continuum Theory

When thin layers of nematic liquids are examined under the microscope, the liquid appears to be clear, and one gains the impression of one continuous structure. Observations of this nature form the main basis of the continuum theory, which is due to *Zocher* [46] and *Oseen* [47]. This theory is not confined to nematic liquids, but is also applicable to cholesteric and smectic liquids. It was recently revised and presented in a simple form by *Frank* [48].

The continuum theory is based on the assumption that at every point in an undisturbed crystalline liquid, there is a definite preferred direction for the orientation of the longitudinal axes. This preferred direction is assumed to vary continuously with position, except possibly at a few special surfaces or lines, where the preferred direction is naturally no longer definite.

As a consequence of these assumptions, crystalline liquids must be expected to have elastic flexible structures, since the preferred direction and its variation can be determined only if it affects the free energy and if the latter has a minimum for the prevailing boundary conditions. Following a small external disturbance, the molecules will return to the previous orientation.

The change in free energy as a result of a deformation, *i.e.* the deformation energy, can be calculated with the aid of elastic constants. In particular, a maximum of four constants [48] should be required to describe the deformation energy for small deviations from the homogeneous orientation in nematic liquids. Three of these constants belong to the fundamental deformations defined by *Zocher* [46] (Fig. 6). In the case of the twisting, the deformation energy is given by equation (2).

$$E_{\mathrm{def}} = \frac{1}{2} K_{\mathrm{d}} \varphi'^2 \qquad (2)$$

where K_{d} is the deformation constant and φ' is the derivative of the angle of rotation along the axis of rotation. Similar equations are valid for other fundamental deformations.

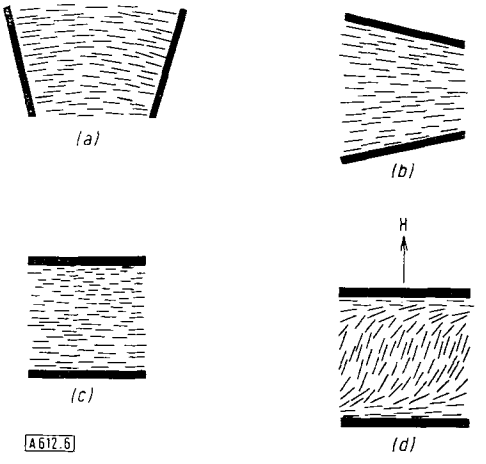

Fig. 6. Deformations of a nematic liquid. (a)–(c) Fundamental deformations: longitudinal bending, transverse bending, and twisting; (d) deformation of a planar layer in a magnetic field.

Experimental studies on bending behavior have so far been carried out only for nematic liquids, the properties observed being as expected. In these studies, a magnetic field was used to deform nematic layers that had been homogeneously oriented by boundary effects (Fig. 6), and the change in the optical properties

was observed [49]. When the magnetic field is switched off, the molecules resume their original homogeneous orientation. The three constants of the fundamental deformations can be relatively easily determined by this procedure, but absolute determinations of the three constants have been reported only for 4,4′-bis(methoxy)azoxybenzene [50, 52]. The constants are strongly dependent on temperature, but their ratio remains constant [52]. The calculated deformation energies are low, even for considerable deformations.

Consider for example a nematic layer of 4,4′-bis(methoxy)azoxybenzene having imposed twisting. With $K_d = 3.7 \times 10^{-7}$ dyne at 125 °C [52] and for a pitch of 1 cm ($\varphi' = 2\pi$), the deformation energy is only 0.7×10^{-5} erg·cm^{-3}.

For a pitch of 1 μm, *i.e.* twisting of the same order of magnitude as the spontaneous twisting of many cholesteric liquids, the deformation energy increases to 730 erg·cm^{-3}, *i.e.* 0.004 cal·mole^{-1}.

It is interesting to compare this deformation with the energy liberated by spontaneous parallel orientation of the longitudinal axes. On the basis of the theory described in Section I.3, it can be estimated that for 4,4′-bis(methoxy)azoxybenzene at the same temperature this energy is about 300 cal·mole^{-1}, *i.e.* almost 10^5 times as great. The comparison suggests that in the statistical description of cholesteric liquids, the twisting may, to a good approximation, be disregarded in the treatment of the parallel orientation of the molecular axes, and that cholesteric liquids behave in the same way as normal nematic liquids in this respect.

A comparison of the energies also explains why a strongly twisted structure may be favored by optically active molecules and why normal nematic liquids also assume a cholesteric character when optically active substances are added, since even slight changes in the interaction between the molecules is sufficient to cause twisting.

3. Degree of Order and Statistical Treatment of the Nematic State

The degree of order $S = (1/2) \langle 3 \cos^2 \Theta - 1 \rangle$, which gives the average deviation of the orientation of the molecular axes, can be determined experimentally by various methods. It can be found from the principal refractive indices or from the principal diamagnetic susceptibilities [51, 53–55]. Other possibilities are the use of IR or UV dichroism [30, 54, 55], nuclear resonance spectra [56–58], or X-ray scattering [32]. Comparison and critical examination of the S values found by various methods for 4,4′-bis(methoxy)azoxybenzene [55] shows that the results agree to within the experimental error. Thus nematic liquids have a well-defined degree of order, which can be determined experimentally.

For a statistical treatment of the nematic state, it appears convenient to apply a long-range order theory similar to the Weiss theory of ferromagnetism as the simplest approximation; *Born* [59] attempted this as early as 1916. In this treatment we consider only the rotational degrees of freedom of the molecules and assume that the interactions between the molecules, in so far as they affect the orientation of an individual molecule, may be replaced by an internal field. Thus each molecule has assigned to it a potential energy $D = f(S, V, \Theta)$, which depends in the case in question on the angular position Θ of its longitudinal axis, the degree of order S, and the molar volume V. It is assumed in this treatment that the anisotropy of the molecules perpendicular to their longitudinal axes is negligible. Application of Boltzmann statistics then gives eq. (2a).

$$S = \frac{3}{2} \cdot \frac{\int_0^{\pi/2} \exp(-D/kT) \cdot \cos^2\Theta \cdot \sin\Theta \, d\Theta}{\int_0^{\pi/2} \exp(-D/kT) \sin\Theta \, d\Theta} - \frac{1}{2} \qquad (2a)$$

This gives S as a function of the temperature and of the molar volume if the expression for D is known explicitly.

If, in the determination of D, it is assumed that the nematic order is mainly due to dispersion forces, restriction to the pure dipole-dipole component [60] gives eq. (2b). The quantity A is as yet unknown.

$$D = -\frac{1}{2} \cdot \frac{A}{V^2} S (3 \cos^2 \Theta - 1) \qquad (2b)$$

It is not possible to list here the many assumptions involved in the statistical method and in the expression for D. Comparison of calculated and experimental data, and particularly a comparison of the S values, shows that these assumptions are justified, and that a qualitatively satisfactory description of the nematic state is obtained.

The quantity A, which is a characteristic of the substance, can be calculated from the transition temperature if the molar volumes of the nematic and of the isotropic liquid at the clear point are known. It must be assumed for this calculation that the molecular structure does not change during the phase transition. The available empirical data [60] indicates that, owing to the relatively small change in volume at the clear

point, eq. (2c) is approximately satisfied. In this equation, T_K is the clear point (°K) and $V_{n,K}$ is the molar volume of the nematic phase at the clear point.

$$A/kT_K V_{n,K}^2 = 4.55 \quad (2c)$$

It is convenient to introduce a reduced temperature τ, where V_n is the molar volume of the nematic phase at

$$\tau = T\, V_n^2/T_K V_{n,K}^2 \quad (2d)$$

the absolute temperature T. According to eq. (2c), a plot of S as a function of τ gives a curve which is generally valid.

Figure 7 shows the experimental values of S for various nematic liquids plotted against $T_{red} = 100\ T/T_K$ instead of against τ; this is permissible for a qualitative comparison. The curve shown is that calculated for 2,4-nonadienoic acid. The agreement is almost perfect for this substance and for 2,4-undecadienoic acid [54], which is not shown. On the other hand, the experimental S values are higher for 2,4-decadienoic acid (not shown) and for most other substances. One exception is 4,4′-bis(methoxy)azoxybenzene, which gives lower S values. It is interesting to note that 4,4′-bis(methoxy)azoxybenzene and 4,4′-bis(ethoxy)azoxybenzene, though differing only slightly in structure, differ considerably in their S values (Fig. 7). Two other higher homologs that have been studied by IR spectroscopy [30], *i.e.* 4,4′-bis(hexyloxy)azoxybenzene and 4,4′-bis(heptyloxy)azoxybenzene, have S values approximately equal to those of 4,4′-bis(ethoxy)azoxybenzene.

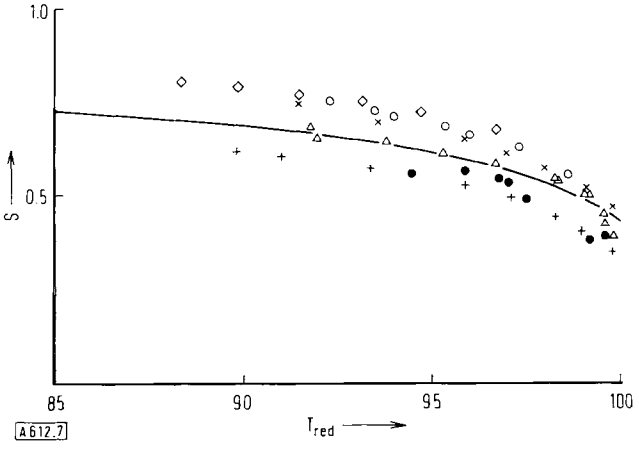

Fig. 7. S values of nematic liquids.
2,4-Nonadienoic acid (clear point 53 °C): Δ from IR data[54], continuous curve from theory [54, 60];

4,4′-bis(ethoxy)azoxybenzene (clear point 168 °C):
○ from NMR data, × from refractive indices [*];
4-*n*-hexyloxybenzoic acid (clear point 154 °C):
◇ from NMR data [58].

[*] The S values were recalculated by the method described in [55] from experimental data reported by *Chatelain* and *Germain* [61]. The crystals were treated as optically uniaxial for the calculation of the internal field, *i.e.* the two somewhat different lower refractive indices were replaced by the average value $\bar{n}$:

$$\frac{\bar{n}^2-1}{\bar{n}^2+2} = \frac{1}{2}\left(\frac{n_p^2-1}{n_p^2+2} + \frac{n_m^2-1}{n_m^2+2}\right)$$

It was also assumed that the arrangement of the molecules in the crystal corresponds to ideal nematic order (*i.e.* $S = 1$ in the crystal).

In view of the rough manner in which the intermolecular interactions were taken into account and the very simple statistical approximation used, the agreement with the theory is good on the whole (In this context, the reader is referred to further applications [52, 61–64].) However, this theory does not permit a quantitatively correct description of the nematic state.

4. Dielectric Properties of Nematic Liquids

The behavior of crystalline liquids in electric fields has been the object of numerous experimental and theoretical investigations. It was hoped that these studies would lead to some elucidation of important structural problems [14–17, 65–71].

As has been mentioned, nematic liquids in thick layers (>0.1 mm) can be homogeneously oriented by magnetic fields. Homogeneously oriented layers of this type can be used for the measurement of the two principal dielectric constants, ε_1 parallel to the optical axis and ε_2 perpendicular to this axis; the first accurate measurements were carried out in 1954 by *Maier*, *Barth*, and *Wiehl* [65]. Further experimental studies have more recently been carried out on nematic and on some smectic liquids in the radio frequency [66] and microwave regions [67–69]. In the smectic phase, measurements could be carried out on partly oriented layers obtained by cooling isotropic or nematic layers in a magnetic field [66, 67].

A theoretical study by *Maier* and *Meier* [70] deals with the dependence of the static ε_1 and ε_2 values on the degree of order of the nematic liquid and on the molecular properties (*e.g.* on the magnitude and orientation of the permanent electric dipole moment in the molecule and on the polarizability anisotropy). Applications to nematic liquid 4,4′-bis(alkoxy)azoxybenzenes and 4,4′-bis(alkoxy)azobenzenes show that the dielectric anisotropy of the nematic phase and the values of ε_1 and ε_2 are understandable as a consequence of the average orientation described by the degree of order S [70]. At a measuring frequency of 100 kHz, the

transition from the isotropic into the nematic phase is not accompanied by any appreciable change in the average contribution of the orientation polarization, from which it could be concluded that a specific and very pronounced dipole association occurs in the nematic phase. An obvious conclusion is that there is no ferroelectric or antiferroelectric short-range order in these liquids.

In all the substances that have been studied, ε_1 and ε_2 exhibit a normal Debye relaxation in a range of frequencies around 10^{10} Hz. A Debye relaxation of the isotropic liquid phases is also found in the same frequency range. However, the measurements on 4,4′-bis(*n*-alkoxy)azoxybenzene derivatives in the radio frequency range [66] led to the discovery of an additional relaxation region, which occurs only in the mesomorphous phases and affects ε_1, whereas ε_2 shows no dispersion between 100 kHz and 4 MHz.

The lower-frequency relaxation is assigned to the dipole moment of the azoxy group, or more precisely to the component of the dipole moment parallel to the longitudinal axis of the molecule. This component can be aligned with the optical axis simply by rotation of the molecule about a transverse axis. For this to happen, it is necessary to overcome a potential barrier associated with the parallel orientation in the mesomorphous phases. It is therefore understandable that the corresponding relaxation time becomes greater.

In contrast to the azoxy compounds, no low-frequency relaxation could be observed for the azo compounds [66]. This is in agreement with the above interpretation, since the azo group has no permanent dipole moment, and hence no dipole component that can be aligned simply by rotation about a transverse axis of the molecule.

Theoretical studies [71] based on an extended Debye expression show how the retardation of the relaxation is related to the angular distribution function of the molecules. Since the ε_1 relaxation times are found to increase by a factor of 10^2 to 10^3, it may be concluded that the probability of the perpendicular orientation of the molecules ($\Theta = 90\,^\circ$) is only about 1 % to 0.1 % of the value for a uniform distribution (isotropic phase). The height of the potential barrier can also be estimated. However, more detailed assumptions concerning the analytical form of the angular distribution function are then necessary.

From the expression $f(\Theta) = \sin\Theta \cdot \exp(C \cdot \cos^2\Theta / kT)$ for the angular distribution function, the factor g by which the dielectric relaxation time is increased by the nematic order is found to be given by equation (3) [71].

$$g = \frac{kT}{C}\,(e^{C/kT} - 1) \approx \frac{kT}{C}\,e^{C/kT} \qquad (3)$$

The height of the potential barrier found for 4,4′-bis-(methoxy)azoxybenzene [71], with the experimental value $g = 100$ at 121 °C, is $C = 5.1$ kcal/mole. (C = difference between the free energies in the perpendicular and parallel molecular orientations.) This potential can also be estimated from the degree of order found by experiment. By definition,

$$S = (3/2)\int_0^{\pi/2} \cos^2\Theta\, f(\Theta)\cdot d\Theta \Big/ \int_0^{\pi/2} f(\Theta)\cdot d\Theta - 1/2$$

With $S = 0.56$ at 121 °C for 4,4′-bis(methoxy)azoxybenzene, as follows from the diamagnetic susceptibilities [55], and with the above expression for the angular distribution function, $C = 3.2$ kcal/mole. (The statistical theory described in Section I.3 gives $C = 3.3$ kcal/mole.)

The main reason for the difference in the two experimental estimates is that the correlation of the rotational motions of adjacent molecules, which is of the utmost importance to the dielectric relaxation behavior, was not taken into account. Despite the differences, however, it is confirmed that the peculiarities of the dielectric relaxation behavior can be explained as resulting from the parallel orientation.

Whereas the dielectric properties of nematic liquids at frequencies above 100 kHz now seem to be essentially understandable, their behavior in static electric fields and in alternating fields having very low frequencies is still largely unexplained. The orienting action, at least in very low-frequency fields and in static fields, is not determined entirely by the dielectric anisotropy, as might have been expected.

More recent studies on this point have been carried out on macroscopic samples [58, 68] and on thin layers [14–16, 72–76].

Carr [68] has measured the dielectric losses in the microwave region in macroscopic samples, and so studied the orienting effect of low-frequency electric fields and of static electric and magnetic fields. Other studies on macroscopic samples were carried out by *Rowell*, *Phillips*, *Melby*, and *Panar* [58], who examined the nuclear magnetic resonance spectra of the samples. *Carr* [68] noted that the orientation behavior in very low-frequency or static electric fields is strongly dependent on impurities. He therefore assumed that this behavior is influenced by the conductivity, which is also strongly dependent on impurities.

In thin layers, the action of electric fields can be observed optically [14, 72–74] (Fig. 8) or can be studied by measurement of the IR dichroism [76]. The polarizability of thin nematic layers in very low-frequency electric fields can be extremely high and may exhibit hysteresis [15, 16, 75]. The behavior of the layers is thus similar to that of ferroelectric crystals.

Williams [14] discovered that thin nematic layers can form fairly regular patterns under the influence of a homogeneous electric field having a very low frequency and lying perpendicular to the plane of the layer. Photographs of some of these patterns are shown in Figure 8. *Williams* and *Heilmeier* believe that this behavior of thin layers points to ferroelectric properties [15]. These phenomena, which have not yet been explained, may be connected with currents set up in nematic liquids by static or low-frequency alternating electric fields. However, no satisfactory explanation has yet been proposed for these currents themselves.

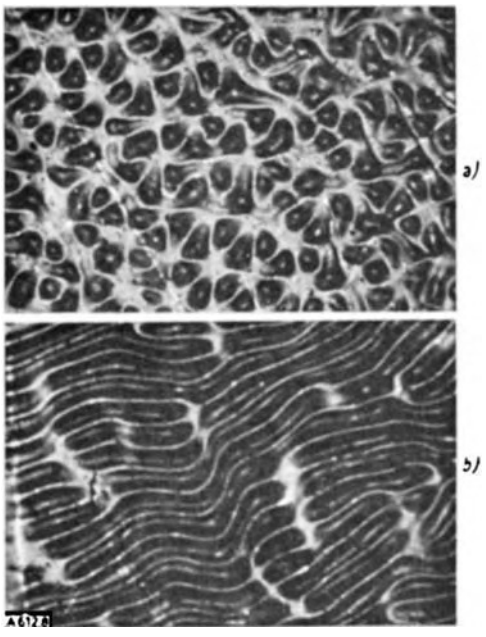

Fig. 8. Nematic liquid layers in an electric field. Layer thickness about 50 μm. Photographs taken with linearly polarized light at a magnification of 100—150× according to *Kassubeck* [74].

a) 4,4′-Bis(methoxy)azoxybenzene at 120 °C in a d.c. field. (1.6 kV/cm). The "flower pattern" can occasionally be observed shortly after the application of the field; a pattern of intertwined fringes is later formed.

b) 4,4′-Bis(methoxy)azoxybenzene at 120 °C in an alternating field (30 Hz, 1.6 kV/cm). Normal fringe pattern, typical of nematic liquid 4,4′-bis(alkoxy)azoxybenzene derivatives in low-frequency alternating fields.

II. Crystalline Liquids as Solvents for Magnetic Resonance Studies

1. Introduction

Crystalline liquids, and particularly those of the nematic type, can have solvent properties almost as good as those of isotropic liquids. However, the solubility depends in a different way on the properties of the solute. Differences in the molecular shape or in the polarizability anisotropy can have strong effects.

A greater dependence of the solubility on the molecular properties is of interest in chromatographic separations. Gas-chromatographic studies on disubstituted benzenes have in fact confirmed [77, 78] that crystalline liquids have a remarkable separating power. For example, *m*- and *p*-xylenes can be completely separated with a mesomorphous 4,4′-bis(alkoxy)azoxybenzene derivative as the separating liquid.

Solute molecules in mesomorphous solutions experience some orientation in the anisotropic environment. It therefore seems obvious to use nematic liquids that can readily be uniformly oriented by a magnetic field, or in thin layers by boundary effects, as solvents for experiments with oriented molecules, and particularly for spectroscopic investigations.

IR and UV absorption measurements with polarized light [30, 54, 76, 79–81] and Raman measurements [82] have been carried out on pure nematic liquids, with the following results. The vibrational spectra of the molecules in the mesomorphous phases are practically the same as the spectra of the isotropic liquid phase. No marked frequency shifts or changes in intensity are found in the electronic transitions in the visible and near UV regions. Thus the spectra give no indication of specific associations of the molecules in the mesomorphous phase or of any change in the molecular structure. The degree of order of nematic and smectic phases was calculated from the pronounced dichroism in some frequency ranges [30, 54, 55, 76]. The polarization of the transitions can also be determined, and this facilitates the assignment of the transitions. Although crystalline liquids have not yet been used as solvents for IR or UV absorption measurements, their usefulness for this purpose will probably be limited by their own strong absorption.

Nematic crystalline liquids are fairly versatile solvents for nuclear magnetic resonance [80] and electron spin resonance studies [81]. The reader is referred to reviews [83, 84] and important theoretical articles [84–86] on this topic. The anisotropic components of the spin interactions are easy to observe in such solvents and generally cause very marked changes in the magnetic resonance spectra as compared with the normal solution spectra. In deuteron resonance the quadrupole interactions between the nucleus and the electron cloud become the dominant terms, and in fluorine and proton resonances the direct magnetic dipole-dipole interactions between the nuclei, whereas these interactions have no influence on the position and intensity of the resonance lines in isotropic solutions. In the ESR spectra of radicals, the differences between the spectra of isotropic and of nematic solutions are less pronounced. However, the splitting in the 9-line spectrum of the tetracyanoethylene anion changes at the transition point from 1.58 gauss in isotropic liquid 4,4′-bis-(methoxy)azoxybenzene to 0.94 gauss in nematic liquid 4,4′-bis(methoxy)azoxybenzene [87]. The number of resonance lines may be doubled in the case of biradicals [88].

2. Proton and Fluorine Resonance Spectra in Nematic Solutions

Magnetic resonance spectra of nuclei having spin 1/2, *e.g.* ^{1}H or ^{19}F, are determined by the interactions of the magnetic dipole moments of the nuclei with the external magnetic field and by the magnetic dipole-

dipole interactions of the nuclei with one another. If the mobility of the molecules is high, the interactions are decreased in isotropic liquids and solutions. Thus the spin Hamiltonian operator, which determines the frequencies and intensities of the transitions, has the form given in equation (4).

$$\mathbf{H}_1 = -\frac{h H_o}{2\pi} \sum_p \gamma_p (1-\sigma_p) I_{zp} + h \sum_{\substack{p,q \\ p>q}} J_{pq} \mathbf{I}_p \mathbf{I}_q \qquad (4)$$

H_0 is the external magnetic field, which is assumed to be parallel to the z direction; $\mathbf{I}_p$ and $\mathbf{I}_q$ are the vectorial spin operators of the nuclei p and q; I_{zp} is the z component of the spin operator, and γ_p is the gyromagnetic ratio of p; the z component of the dipole moment is therefore given by $h\gamma_p/4\pi$.

The local magnetic field of the nuclei $H_0\ (1 - \sigma_p)$ differs from the external magnetic field, owing to screening by the electron sheath. For diamagnetic molecules, the screening constant σ_p is a small positive number ($\sigma_p \approx 3\times10^{-5}$ for protons), which depends on the orientation with respect to the magnetic field. The screening constant found in isotropic liquids is the average over all orientations, and is equal to one third of the trace of the screening tensor.

The magnetic resonance frequencies are given by eq. (5), provided that the second sum in (4), which contains the magnetic coupling of the nuclei with one another, is negligible.

$$\nu_p = \frac{H_o}{2\pi} (1-\sigma_p)\gamma_p \qquad (5)$$

σ_p depends on the nature of the chemical bond; the resonance frequencies are therefore subject to "Chemical shifts". However, the couplings generally lead to further splitting, so that the coupling constants J_{pq} involved in the splitting can be determined, as well as the chemical shifts, by analysis of the spectra. These are both important data for the determination of structures.

The magnetic interactions between the nuclei depend even more than the chemical shifts on the orientation of the molecule. The interactions may be direct or indirect (electron-coupled). The direct interactions may be visualized by consideration of the local magnetic fields. A nucleus p having spin 1/2 changes the field strength at q by the component of its magnetic dipole field in the H_0 direction:

$$\Delta H_{loc} = \pm \gamma_p \frac{h}{4\pi} \left(\frac{3\cos^2\Theta_{pq}-1}{r_{pq}^3} \right) \qquad (6)$$

where r_{pq} is the distance from p to q.

The positive sign in (6) applies to parallel orientation and the negative sign to antiparallel orientation of the spin p with respect to H_0; Θ_{pq} is the angle between r_{pq} and H_o. (H_o is assumed to be large in relation to the dipole fields of neighboring nuclei. The components perpendicular to H_o may therefore be disregarded.)

If we ignore the indirect interaction, the previously single resonance line of q should be split, according to the mean local field, into two lines at $\nu_q \mp B_{pq}^{dir}$, where B_{pq}^{dir}, is the average value defined in eq. (7)

$$B_{pq}^{dir} = -\frac{h\gamma_p\gamma_q}{4\pi^2} \cdot \frac{1}{2} \left\langle \frac{3\cos^2\Theta_{pq}-1}{r_{pq}^3} \right\rangle \qquad (7)$$

This calculation of the splitting frequency is based on the assumption that $\nu_p - \nu_q \gg B_{pq}^{dir}$. It is therefore generally useful only for qualitative studies.

B_{pq}^{dir}, and hence the direct interaction, disappears in isotropic liquids, since the degree of order of the internuclear axis, $S_{pq} = \langle 3\cos^2\Theta_{pq} - 1\rangle/2$, is zero. The "scalar" coupling constants J_{pq} are the average values of the indirect interactions, which are propagated mainly along the chemical bonds and are passed on by the magnetic couplings between the nucleus and the electrons. "Scalar" coupling constants generally occur only between nuclei that are separated by only a few bonds. They are smaller than 30 Hz for $^1H^1H$, $^1H^{19}F$, and $^{19}F^{19}F$ couplings in organic molecules.

For oriented molecules, owing to the additional couplings, the spin Hamiltonian operator becomes $\mathbf{H} = \mathbf{H}_1 + \mathbf{H}_2$. The first term has the form given in eq. (4); only the screening constants have changed. $\mathbf{H}_2$ is given by eq. (8)

$$\mathbf{H}_2 = h \sum_{\substack{p,q \\ p>q}} B_{pq}(3_z I_{zp} I_q - I_p I_q) \qquad (8)$$

The "anisotropic" coupling constant B_{pq} is the sum of an indirect component B_{pq}^{indir} and the direct component B_{pq}^{dir} given by eq. (7).

The mean direct interaction between adjacent molecules in solid crystals cannot be disregarded. The nuclei throughout the crystal are therefore magnetically coupled with one another. The resulting nuclear magnetic resonance spectrum consists of an absorption signal several kiloherz wide, often with no structure, so that no coupling constants can be found from the spectrum.

There is no fixed spatial order in nematic liquids. The molecules can diffuse as rapidly as in the normal isotropic liquids. For intermolecular interactions, therefore, B_{pq} becomes disappearingly small, owing to its dependence on distance and on angle. For intramolecular interactions, on the other hand, B_{pq} does not have a disappearingly small average value, owing to the partial orientation of the molecules. This averaging is based on the facts that the molecules still have a high rotational mobility despite the partial orientation, and that the nematic solution is uniformly oriented by the magnetic field. Thus the use of the average values in the Hamiltonian operator is justifiable only if these values are reached by averaging, even over a short time, irrespective of the starting position of the molecule in question. The corresponding correlation times in the present case must therefore be shorter than 10^{-6} sec [89].

[89] *A. Abragam*: The Principles of Nuclear Magnetism. Oxford University Press, Oxford 1961.

The proton resonance spectra in Figure 9 show the effect of the orientation obtainable in nematic solutions on the spectra, the example chosen in this case being benzene. The spectra shown were recorded with non-spinning samples.

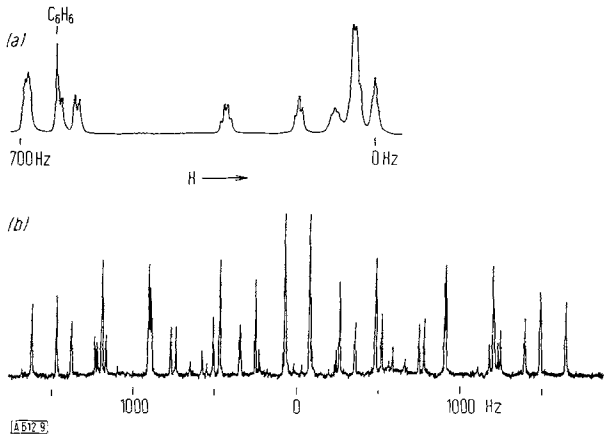

Fig. 9. Proton resonance spectra of benzene in a solvent mixture of 60 % of heptyloxy-4'-ethoxyazobenzene and 40 % of 4-hexyloxy-4'-ethoxyazobenzene at 100 MHz. (a) isotropic solution, 120 °C, (b) nematic solution, 50 °C.

The spectrum of the isotropic liquid solution above the clear point is a normal solution spectrum, in which only one sharp resonance line is observed for benzene. The total splitting of about 700 Hz is mainly due to the difference between the chemical shifts of aliphatic and aromatic protons. In the solvent molecules the couplings give rise to numerous closely spaced signals, so that no really sharp individual lines can be observed.

The spectrum of the nematic solution contains only benzene lines; of the 76 transitions allowed by symmetry [90], more than 50 can be recognized. The total splitting is more than 3000 Hz. It is due to the direct couplings. For the spectrum shown, $B_{12} = 435.7$ Hz, $B_{13} = 82.3$ Hz, $B_{14} = 54.5$ Hz, and the degree of order S of the principal axis of symmetry is $S = -0.11$.

The nuclear magnetic resonance in nematic liquids may be observed by the same measuring technique as is used for isotropic solutions. The homogeneous orientation of the sample is produced by the constant magnetic field H_0, the only other function of which is to provide the Zeeman splitting of the spin levels. However, the sample cannot rotate about an axis perpendicular to H_0 to compensate for field inhomogeneities, since this would disturb the alignment of the molecules. The unavoidable field inhomogeneities therefore have a much stronger effect on the line widths of proton and fluorine resonances in nematic solutions than in isotropic solutions. The half-value widths in proton and fluorine resonance spectra in nematic solutions are a few Hz, so that resolution is still good, but the signal/noise ratio deteriorates because of the greater line width.

[90] *A. Saupe*, Proc. XIII Colloque Ampère 320 (1964); Z. Naturforsch. *20a*, 572 (1965).

At high resolution, the resonance frequencies in the nematic solution are strongly dependent on the temperature and on the concentration of the solution. The temperature and concentration in the measuring volume must therefore be constant if the line width is to be uniformly small over the entire spectrum. These two conditions are not easy to satisfy. The solvent used for the spectra in Figure 9 was a eutectic mixture with a particularly low melting point. Mixtures having even lower melting points have recently been found [91, 92]. A mixture of 4'-ethoxy-4-hexyl-oxyazo(or azoxy)-benzene (20 mole-%) and butyl 4-ethoxyphenyl terephthalate may be used as a nematic solvent for measurements at room temperature [91].

The proton resonance spectrum of the nematic carrier substance should also consist of sharp lines. Recent studies on pure nematic liquids [58, 85] led in a few cases (particularly that of 4,4'-bis(methoxy)azoxybenzene) to spectra with differentiated fine structures. In general, however, a broad signal with no appreciable structure is obtained owing to the large numbers of protons. The proton resonance spectra of oriented molecules are still simple enough for resolution into individual lines only in systems having a small number of interacting nuclei (up to about eight per molecule). Solvent molecules containing large numbers of protons are therefore advantageous for ^{1}H–NMR studies in nematic solutions, since the spectra of simpler solute molecules can then be observed without appreciable disturbance against the broad background signal of the solvent (see *e.g.* Figs. 9 and 10).

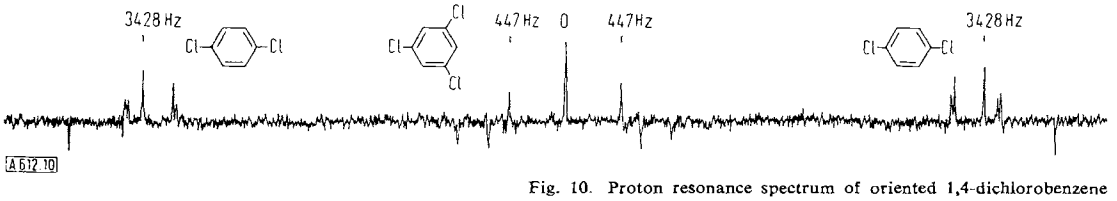

Fig. 10. Proton resonance spectrum of oriented 1,4-dichlorobenzene and 1,3,5-trichlorobenzene in nematic liquid 4,4'-bis(*n*-hexyloxy)azoxybenzene (60 MHz, 70 °C). The lines pointing downward are side bands at a distance of 4036 Hz from the main signals.

The structure of the spectra of oriented molecules is strongly dependent on the molecular geometry. Figure 10 shows the spectra of 1,3,5-trichlorobenzene and of 1,4-dichlorobenzene recorded in the same solution. In isotropic solutions the proton resonance spectra of both substances consist of single resonance lines, which are only slightly displaced in relation to the benzene line.

The symmetrical three-line spectrum having the intensity ratio 1:2:1 (middle part of Fig. 10) is characteristic of an oriented three-proton system in which all the coupling constants are the same, *i.e.* of a three-proton system with a threefold axis of symmetry. The distance between the lines is equal to 3 B_{pq}. In the spectrum shown, $B_{pq} = 149$ Hz.

The three anisotropic coupling constants of 1,4-dichlorobenzene ($B_{23} = B_{56} = 2240$ Hz, $B_{25} = B_{36} = -131.3$ Hz, $B_{26} = B_{35} = +8.3$ Hz) show that C–C four protons in the molecule are situated at the corners of a

[91] *H. Spiesecke* and *J. Bellion-Jourdan*, Angew. Chem. *79*, 475 (1967); Angew. Chem. internat. Edit. *6*, 450 (1967).

[92] *D. Demus*, Z. Naturforsch. *22a*, 285 (1967).

rectangle whose sides are in the ratio 1:1.72 [93]. The ratio found experimentally differs only slightly from $1:\sqrt{3}$, which is the value calculated on the assumption that all the bond angles are 120° and that all C–C distances are equal. The coupling constants found for benzene show that the protons are arranged at the corners of a regular hexagon.

The deduction of the geometric data is based on the assumption that B_{pq}^{indir} is negligible in comparison with B_{pq}^{dir}. Thus B_{pq} is equated to B_{pq}^{dir}. On this assumption, eq. (9) is valid for "rigid" molecules.

$$B_{pq} = -\frac{h}{4\pi^2}\,\gamma_p\gamma_q\,\frac{S_{pq}}{r_{pq}^3} \tag{9}$$

r_{pq} is really an average distance, which differs somewhat from the equilibrium distance mainly because of zero-point vibrations.

If r_{pq} is known, the degree of order S_{pq} can be calculated from eq. (9). No other method is known at present for the reliable determination of S_{pq}; consequently, (9) cannot be used directly for the determination of internuclear distances. However, it is possible to determine bond angles and ratios of internuclear distances, since the various S_{pq} values are interdependent (see eq. (11a)).

The mean orientation of a rigid molecule can generally be described by a matrix having a maximum of five elements, which are independent of one another within certain limits [85].

To define the order matrix, we denote the axes of a molecularly fixed system of coordinates by ξ, η, and ζ, while Θ_ξ, Θ_η, and Θ_ζ are the angles of these axes with respect to the optical axis of the nematic liquid (Fig. 11). The matrix elements are given by the average values defined in eq. (10).

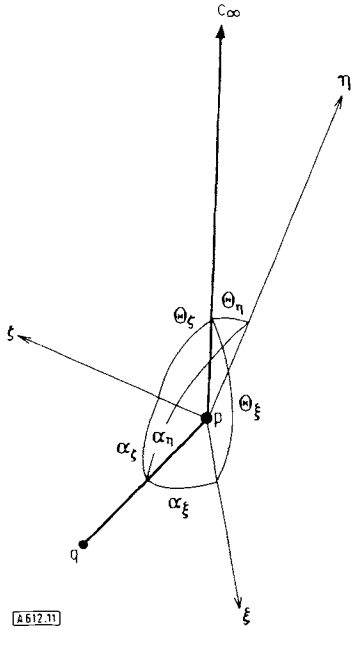

Fig. 11. ξ, η, ζ: Molecularly fixed system of cartesian coordinates. $\Theta\xi$, $\Theta\eta$, $\Theta\zeta$: Angles with respect to the spatially fixed optical axis. α_ξ, α_ζ, α_ζ: Angles with respect to the molecularly fixed p,q axis.

[93] *A. Saupe*, Molecular Crystals *1*, 527 (1966).

$$S_{ij} = (1/2)\,\langle\, 3\cos\Theta_i\cos\Theta_j - \delta_{ij}\,\rangle\;;\; i,j = \xi,\eta,\zeta$$
$$\delta_{ij} = 0 \text{ for } i \neq j;\ \delta_{ii} = 1 \tag{10}$$

The matrix is symmetrical by definition, and $S_{\xi\xi} + S_{\eta\eta} + S_{\zeta\zeta} = 0$. Thus there remain only five independent elements.

If α_ξ, α_η, and α_ζ are the angles between the pq axis and the ξ, η, and ζ axes of the coordinate system (Fig. 11), the degree of order of the pq axis is given by eq. (11a).

$$S_{pq} = \sum_{i,j} \cos\alpha_i \cos\alpha_j\; S_{ij} \tag{11a}$$

The relationship between the S_{pq} values is implicit in this equation. To determine the structure, the S_{pq} values for an assumed molecular structure are determined from the coupling constants B_{pq} by means of equation (9), and the S matrix is calculated with some (at most five) of these values. The remaining S_{pq} values can then be calculated once more from eq. (11a). The results are used to check the assumed molecular structure by comparison with the values found from B_{pq}.

The procedure is very easy to use in the case of symmetrical molecules, since the S matrix can be brought into the diagonal form by principal axis transformation. In 1,4-dichlorobenzene, for example, the principal axes are determined by symmetry (2,3 axis, 2,6 axis, normal to the plane of the molecule). In this case, according to eq. (11a),

$$S_{25} = (r_{23}^2/r_{25}^2)\,S_{23} + (r_{26}^2/r_{25}^2)S_{26}$$

Since $r_{25}^2 = r_{23}^2 + r_{26}^2$, we find, from eq. (9), a relationship between the ratio of the internuclear distances r_{23}/r_{26} and the coupling constants:

$$B_{25}\,(1 + \rho^2)^{5/2} = B_{23} + \rho^5 B_{26}\;(\rho = r_{23}/r_{26}).$$

Molecules having an at least threefold axis of symmetry are easiest to deal with. If the axis of symmetry is chosen as the ζ axis, the S matrix is in the diagonal form, and $S_{\xi\xi} = S_{\eta\eta} = -S_{\zeta\zeta}/2$. Eq. (11a) simplifies to (11b).

$$S_{pq} = \frac{1}{2}\,(3\cos^2\alpha_\zeta - 1)\,S_\zeta \tag{11b}$$

Thus all the axes in the molecular plane of benzene and of 1,3,5-trichlorobenzene have the same degree of order. It follows that in benzene, for the assumed planar structure, $B_{12}:B_{13}:B_{14} = 1:0.1925:0.1250$. On the other hand, the coupling constants given above for Figure 9 lead to 1:0·1912:0·1251. The differences are within the limits of accuracy of the measurements. Though real differences are undoubtedly present owing to the vibrational motions of the protons, they have not yet been reported.

According to the results for benzene, the assumption that $B_{pq} = B_{pq}^{dir}$ is permissible for $^1H,^1H$ couplings. On the other hand, B_{pq}^{indir} cannot be completely neglected in $^{19}F,^{19}F$ couplings. Measurements on hexafluorobenzene in nematic solutions show that B_{pq}^{indir}

contributes several percent to B_{pq} [94, 95]. Consequently, accurate structural data cannot be obtained from anisotropic fluorine couplings.

In $^{13}C,^{1}H$ couplings, B_{pq}^{indir} again seems to be so small that no appreciable error is introduced by the use of $B_{pq} = B_{pq}^{dir}$ in structural determinations. Thus the molecular structure of pure hydrocarbons can be determined to within the unit of measurement if the $^{13}C,^{1}H$ coupling constants are known as well as the $^{1}H,^{1}H$ coupling constants. The natural abundance of ^{13}C is too low to give isotope lines in the spectra obtained by a single pass, as in Figures 9 and 11. It is necessary to use compounds enriched in ^{13}C. If a data store is used, the natural abundance of ^{13}C is sufficient [96]. This gives a practicable procedure for the determination of structures in a liquid phase.

Table 2 shows a comparison of the H–C–H bond angles of CH_3 groups, as calculated from ^{1}H–NMR measurements in nematic solutions on the assumption that B_{pq}^{indir} was negligible, with the values found from microwave data. The agreement is good in view of the facts that (i) the bond angles are averages, (ii) the two methods correspond to different averages, and (iii) the microwave data refer to gases and the ^{1}H–NMR data to nematic solutions

Table 2. Bond angles of CH_3 groups determined in nematic solutions from proton resonance spectra [97, 98] and in dilute gases from microwave spectra [99–101].

[a] *p-n*-Octyloxy-benzoic acid; [b] 4,4′-Bis(*n*-hexyloxy)azoxybenzene.

The results obtained by *Snyder* and *Meiboom* [96] for tetramethylsilane and neopentane in nematic solutions are interesting in this connection. These molecules, which are assumed to have tetrahedral symmetry, should not exhibit any orientation effects and should give only single sharp lines; however, splittings of up to 15 Hz have been observed. The molecules must therefore be deformed in the solution; the bond angles change by up to about one tenth of a degree [96].

The signs of the coupling constants J_{pq}, which are important for theoretical studies, can also be determined by measurements in nematic solutions. Analysis of the nuclear resonance spectra, as in isotropic solutions, gives only the relative signs of the coupling constants, since the spectra remain unchanged when the signs of all the coupling constants are changed. Thus even the signs of the S values are unknown at first. In many cases, however, preferred orientations can be established with sufficient certainty from the molecular structure. For example, very elongated molecules, which do not form associates, preferentially have their long axes parallel to the optical axis, so that the S value of the longitudinal axes is positive. In planar molecules, the parallel orientation of the planes is preferred for similar reasons; the S value of the normal to the plane of the molecule is therefore negative. The signs of nearly all the S values given in this article have been determined by considerations of this nature.

A qualitative knowledge of the preferred orientation of the molecules leads directly to a knowledge of the signs of at least some coupling constants B_{pq}. It is then also possible to determine the absolute sign of scalar coupling constants J_{pq}, provided that the relative signs are known from the analysis of the spectrum.

Another property that can be determined experimentally only with difficulty or not at all, and which is of interest in connection with bond properties and magnetic screening, is the anisotropy of the chemical shift.

In nematic solutions, the screening constant differs from its value in isotropic solutions by the amount given by eq. (12a).

$$\sigma_p(\text{nem}) - \sigma_p(\text{iso}) = \frac{2}{3} \sum_{i,j} S_{ij}\, \sigma_{ij} \qquad (12a)$$

σ_{ij} denotes the components of the screening tensor in the molecularly fixed coordinate system. For molecules having a three- or more-fold axis of symmetry, eq. (12a) simplifies to eq. (12b) if the axis of symmetry is again chosen as the ζ axis.

$$\sigma_p(\text{nem}) - \sigma_p(\text{iso}) = \frac{2}{3} S_{\zeta\zeta}(\sigma_{\zeta\zeta} - (\sigma_{\xi\xi} + \sigma_{\eta\eta})/2) \qquad (12b)$$

Table 3 shows experimental results for the anisotropy of the chemical shifts of protons and of fluorine. The chemical shifts were measured above the clear point in isotropic solution and at lower temperatures in nematic solution. $\Delta\sigma = \sigma_{\xi\xi} - (\sigma_{\xi\xi} + \sigma_{\eta\eta})/2$ can be calculated, using eq. (12b), from the differences of the

chemical shifts and the values of the degree of order S of the nematic solution. Tetramethylsilane was used in both solutions as the internal standard. It may be assumed that the weak orientation effects observed for tetramethylsilane in nematic solutions[96] have no appreciable influence on the screening of the protons.

The S values in Table 3 present an idea of the degree of order reached with these molecules. The orientation is strongly dependent on the temperature and concentration. The lowest orientation that can be reached in the neighborhood of the clear point can be up to 30 % lower than the values indicated, and the highest orientation at low concentrations and low temperatures up to 30 % higher. No marked dependence of the orientation on nematic solvents is to be expected for these molecules.

Systematic studies on the orientation behavior of chlorinated benzene derivatives[93] show that their mean orientations are substantially independent of the nature of the nematic solvent. The electric dipole-dipole interactions between chlorobenzenes and solvents are relatively unimportant to the orientation. On the other hand, the directional components of the dispersion interactions appear to be decisive.

3. Deuteron Resonances

Whereas proton and fluorine resonances (which involve nuclei having spin 1/2, and hence having no quadrupole moment) in nematic solutions can be used for the study only of relatively small molecules, owing to the strong magnetic coupling of these nuclei with one another, this limitation practically disappears in the case of deuteron magnetic resonance. Deuterons have spin 1 and possess a quadrupole moment; no coupling with other nuclei is observed in most cases. The resonance spectra are then easy to analyze, since they consist of a superposition of doublets corresponding to deuterons with different effective quadrupole interactions.

The spin Hamiltonian operator, including the quadrupole interactions, can be expressed as the sum of three terms: $\mathbf{H} = \mathbf{H}_1 + \mathbf{H}_2 + \mathbf{H}_3$, where $\mathbf{H}_1$ and $\mathbf{H}_2$ are defined in equations (4) and (8) and $\mathbf{H}_3$ in eq. (13)

$$H_3 = h \sum_p B_{pp} I_{zp}^2 \tag{13}$$

$\mathbf{H}_3$ contains the interactions between the electric quadrupole moments of the nuclei with the electron cloud and the adjacent nuclei. A strong magnetic field is assumed, *i.e.* all terms that are not interchangeable with $\Sigma_p I_{zp}$ are neglected.

If the magnetic interactions with other nuclei are negligible, the spectrum of a nucleus having spin 1 consists of a doublet with a distance $2B_{pp}$ between the lines. For nuclear spin 1, B_{pp} is given by (14a)

$$B_{pp} = \frac{1}{2h} eQ_p \sum_{i,j} V_{ij}^p S_{ij} \tag{14a}$$

In this equation, eQ_p is the electric quadrupole moment and V_{ij}^p represents the second derivative of the electrostatic potential V_p that acts on the nucleus p $\left(V_{\xi\xi}^p = \frac{\partial^2 V_p}{\partial \zeta^2},\ V_{\zeta\eta}^p = \frac{\partial^2 V_p}{\partial \xi \partial \eta}, \ldots\right)$.

In the evaluation of the measurements described below, it was assumed that the tensor V_{ij} is rotationally symmetrical about the axis of the corresponding CD bond. If the ζ axis is taken parallel to the bond, the situation for the corresponding ^2H is given by eq. (14b).

$$B_{pp} = -\frac{3}{4\pi} eQ_p V_{\zeta\zeta}^p S_{\zeta\zeta} \tag{14b}$$

^2H–NMR spectra of partly deuterated nematic liquid 4,4′-bis(alkoxy)azoxybenzenes and alkoxybenzoic acids have been studied, as have the ^2H–NMR spectra of deuterated benzene, toluene, naphthalene, stilbene, and benzoic acid[58,105]. S values can be calculated from the observed splittings; the quadrupole coupling constants for ideal orientation were measured in crystalline powders at low temperatures.

The D–C–D angle of the CD_3 group in deuterated toluene was determined on the assumption that the quadrupole couplings for the aromatic deuteron in the p position and for the deuterons of the CD_3 group are the same and that the quadrupole tensors are rotationally symmetrical with respect to the axes of the C–D bonds. The value found for the C–D–C angle was 111.9 °[58].

4. Electron Spin Resonances

ESR measurements in nematic solutions are easier to carry out than nuclear magnetic resonance studies, partly because the ESR transitions are much more intense, and partly because the homogeneity of the magnetic field is not very important, owing to the greater natural line widths. However, the method is limited by the fact that it can be used only for the study of radicals that are sufficiently stable in mesomorphous solvents. Measurements on diphenylpicrylhydrazyl, the tetracyanoethylene anion[87], Coppinger's radical[106], perinaphthenyl[107,108], and two biradicals[88], *i.e.* bis(2,2,6,6-tetramethylpiperidyl oxide-4-yl) glutarate *(1)* and terephthalate *(2)*, have been reported so far.

[108] *H. R. Falle* and *G. R. Luckhurst,* Molecular Physics *11,* 299 (1966).

The anisotropic coupling constants between unpaired electron spin and the nuclei can be determined from the ESR spectra of the nematic solutions. The spin Hamiltonian operator is of the same form for monoradicals in the two liquid solutions, but the values of the coupling constants change. The effective anisotropic coupling components are obtained from the coupling constants observed in nematic solutions by subtraction of the scalar coupling constants. The magnitudes of the scalar coupling constants can be reliably determined in the isotropic solution above the clear point.

To calculate a degree of order from an experimentally determined anisotropic coupling component, the corresponding coupling tensor must be known, *e.g.* from theoretical studies or from independent measurements. As in the case of nuclear magnetic resonances, the sign of a scalar coupling can be determined if the preferred orientation is known. The results obtained for the tetracyanoethylene anion, for example, confirm the positive sign of the scalar coupling to the nitrogen [87].

In the case of biradicals, the magnetic dipole-dipole interaction between the impaired electrons is no longer completely balanced out in nematic solutions. An additional coupling therefore occurs and this leads to the splitting of the resonance lines [82].

Glarum and *Marshall* [107] carried out particularly comprehensive studies on the perinaphthenyl radical. A comparison of the observed scalar and anisotropic coupling constants with calculated values showed good agreement. The g tensor was determined: $g_\xi = g_\eta = 2.00278$ and $g_\zeta = 2.00226$ (ζ axis perpendicular to the plane of the molecule). g_ζ is roughly equal to the g value of the free electron, $g_e = 2.00232$. The planar radical is highly oriented in nematic liquid 4,4′-bis(methoxy)azoxybenzene. On average, the parallelism of the plane to the magnetic field is as good as that of the longitudinal axes of the solvent molecules.

I am grateful to Prof. Dr. R. Mecke, the director of the Institut für Elektrowerkstoffe, for his support of our work on crystalline liquids. Sincere thanks are due to Frau E. Maier for the use of the collection of reprints left by her late husband Prof. Dr. W. Maier. I am also grateful to Dr. G. Meier for stimulating discussions and for his readiness to help, to Prof. Dr. Sackmann for the photographs to Fig. 2–4, to Dr. B. Stark for her assistance with the literature, and to the Deutsche Forschungsgemeinschaft for financial support.

Direct Synthesis of Organohalogenosilanes

BY V. BAŽANT, J. JOKLÍK, AND J. RATHOUSKÝ [*]

The direct synthesis of organohalogenosilanes, particularly methyl- and phenylchlorosilanes, is the main process for the production of the monomers required for silicone polymers. This complex heterogeneous catalytic reaction involves the interaction of a gaseous component (the organic halide) with two solid components (silicon and copper), the relative quantities of which change as the reaction proceeds. The mechanism of the direct synthesis has not yet been conclusively established. The free-radical mechanism originally proposed supposes the formation of organic free radicals. On the other hand, the chemisorption mechanism suggested later postulates the dissociative adsorption of the organic halide on the silicon-copper double center (the silicon and the copper being joined by a chemical bond). The results obtained so far indicate that the chemisorption mechanism is of decisive importance, but it is not impossible that both mechanisms operate simultaneously.

1. Introduction

The keystone of modern processes for the production of organosilicon compounds is the direct synthesis of monomeric organohalogenosilanes, the starting materials for the polymerization. This direct synthesis was discovered by *Rochow* [1,2] in 1940, and independently by *Müller* [3] and *James* [4] somewhat later. The rapidly growing demand for silicones led to fast development of this method, which is technologically and economically much better than the older processes based on the Grignard synthesis. However, because of

the difficulties encountered in scaling up the reactor for the direct synthesis and the extremely poor reproducibility of the preparation of the active contact mass, further improvements are still necessary. The interest being attracted by the development of the direct synthesis of organohalogenosilanes is shown by the large number of publications and patents on this topic, which have been discussed in reviews [5–7a].

2. Reaction with Hydrogen Chloride

The reaction of hydrogen chloride with silicon, which was already known in the last century [8–10], may be regarded as the forerunner of the direct synthesis of organohalogenosilanes. It is interesting to note that, even at that time, copper was used as a catalyst in a number of cases, though this reaction, unlike the direct synthesis of organochlorosilanes, will also proceed without a catalyst. *Fischer* and *Wolf* [11] derived equations from which the equilibrium composition of the reaction mixture can be calculated as a function of the temperature and pressure. Three papers deal with the kinetics of this reaction [12–14].

3. Reaction with Methyl Chloride

The reaction of methyl chloride with silicon in the presence of copper at about 300 °C yields methylchlorosilanes. On stoichiometric grounds, the only product should be dimethyldichlorosilane:

$$2\ CH_3Cl + Si \xrightarrow[300°C]{Cu} (CH_3)_2SiCl_2 - 40\ kcal \qquad (1)$$

However, partial pyrolysis of the methyl groups at the temperature of the reaction leads to a mixture of products, in which, as a whole, more chlorine atoms than methyl groups are attached to silicon. Apart from dimethyldichlorosilane, methyltrichlorosilane is also obtained as a main product, and trimethylchlorosilane, methyldichlorosilane, tetramethylsilane, trichlorosilane, and tetrachlorosilane are formed in smaller quantities (cf. Table 1).

Table 1. Main products of the direct synthesis of methylchlorosilanes [18].

Compound	B.p. (°C)
$(CH_3)_4Si$	26.6
$HSiCl_3$	31.8
$(CH_3)_2HSiCl$	36.0
$(CH_3)HSiCl_2$	41.0
$(CH_3)_3SiCl$	57.7
$SiCl_4$	57.6
CH_3SiCl_3	65.7
$(CH_3)_2SiCl_2$	70.0

The methylchlorosilanes are difficult to separate, partly because of the small differences in their boiling points, and partly because of the formation of the azeotropic trimethylchlorosilane/tetrachlorosilane mixture (1:1; b.p. 54.5 °C) [15]. Apart from the azeotropic mixture, the methylchlorosilanes can be separated by distillation in a column having 60–100 theoretical plates [16, 17].

In addition to these substances, the reaction mixture contains a large variety of by-products with and without Si; according to *Rochow* [19], 41 compounds are formed alongside dimethyldichlorosilane. The crude product contains 5–10 wt.-% of compounds whose boiling points exceed that of $(CH_3)_2SiCl_2$. This fraction consists mainly of compounds of the type $\equiv SiOSi\equiv$, $\equiv SiSi\equiv$, and $\equiv SiCH_2Si\equiv$ (some have been identified and are listed in Table 2). Silicon-free products include hydrogen, methane, ethane, and ethylene [22],

Table 2. Some by-products containing Si and boiling above 70 °C that are obtained in the direct synthesis of methylchlorosilanes [21].

Compound	B.p. (°C/torr)
$(CH_3)(C_2H_5)SiCl_2$	101/749
$C_2H_5SiCl_3$	97.9/760
$(C_2H_5)_2HSiCl$	100.5/760
$(CH_3)(C_3H_7)SiCl_2$	119/737
$C_3H_7SiCl_3$	122/740
$(CH_3)_2ClSi-O-SiCl(CH_3)_2$	139/739
$(CH_3)Cl_2Si-O-SiCl_2(CH_3)$	138/760
$(CH_3)_2ClSi-O-SiCl_2(CH_3)$	142/739
$(CH_3)_2ClSi-O-SiCl_3$	147/735
$(CH_3)Cl_2Si-SiCl_2(CH_3)$	158–760
$(CH_3)_3Si-SiCl_2(CH_3)$	–
$(CH_3)_2ClSi-SiCl_2(C_2H_5)$	181/744
$(C_2H_5)_2ClSi-SiCl_2(C_2H_5)$	187/731
$(CH_3)Cl_2Si-CH_2-SiCl_2(CH_3)$	187/734
$(CH_3)_2ClSi-CH_2-SiCl_2(CH_3)$	189–192/760
$(CH_3)Cl_2Si-CH_2CH_2-SiCl_2(CH_3)$	209/746

as well as 2- and 3-methylpentanes, 2- and 3-methylhexanes [23], and other aliphatic and aromatic hydrocarbons [24].

It was formerly thought that the nonvolatile reaction products deposited on the contact mass consist mainly of carbon formed by the decomposition of the methyl radicals

$$\bullet CH_3 \rightarrow C + 3/2\ H_2 \quad (2)$$

However, it was recently shown [25] that these products consist predominantly of polymethylenes, which are formed by the interaction of methyl radicals adsorbed on the surface of the catalyst:

$$CH_3Cl_{(g)} \rightarrow \bullet CH_{3(ads)} + \bullet Cl_{(ads)} \quad (3)$$

$$2\ \bullet CH_{3(ads)} \rightarrow \overset{\bullet}{\underset{\bullet}{}}CH_{2(ads)} + CH_{4(g)} \quad (4)$$

$$n\ \overset{\bullet}{\underset{\bullet}{}}CH_{2(ads)} \rightarrow [CH_2]_{n(s)} \quad (5)$$

In spite of its complex course, the direct synthesis of methylchlorosilanes can be made very selective by a suitable choice of the reaction conditions, and it is possible to obtain in the liquid condensate 70–90 % of dimethyldichlorosilane [26, 27]. The optimum temperature depends on the activity of the contact mass, and lies between 250 and 380 °C. The decomposition of the methyl groups generally becomes more pronounced with rising temperature [22], and the overall chlorine content of the products increases. This is economically unfavorable since methyltrichlorosilane is less desirable than dimethyldichlorosilane. This effect of higher temperatures can be countered to some extent by the use of higher flow rates of methyl chloride. Since the reaction rate is proportional to the partial pressure of methyl chloride, it is advantageous to increase the pressure; the optimum pressure [28] is between 5 and 7 atm. The reaction of methyl chloride with silicon is strongly exothermic [29], and effective removal of heat is therefore essential.

Methyl chloride may contain various, generally undesirable, impurities (water, methanol, dimethyl ether, dichloromethane, vinyl chloride, *etc.*), depending on how it is prepared [30, 31]. The catalytic activity of the copper used depends on the quality of its surface. Stamped copper or copper powdered in a ball mill, the crystal lattice of which is highly disordered, has proved most suitable. Chemically precipitated copper may also be used, whereas electrolytic copper has proved to be less suitable. While methyl chloride and copper having reproducible properties can be prepared without difficulty, the properties of silicon depend, not only on its chemical composition, but also on its phase structure, which strongly influences the rate of the reaction and the composition of the product. In the heterogeneous system, silicon reacts rather slowly with methyl chloride, because of oxidic passivity of the surface [7].

The contact mass generally used in the direct synthesis of methylchlorosilanes consists of 90 wt.-% of Si and 10 wt.-% of Cu. This catalyst mass may be prepared *e.g.* by pelletizing powdered silicon and copper, the pellets being sintered in an atmosphere of hydrogen at temperatures below the melting point of copper [32]. In another process, water glass [33] or hydrolyzed ethyl silicate [34] is used as a binder for silicon and copper. These pelletized catalysts have the disadvantage of poor heat removal, and a simple mechanical mixture of silicon and copper or a finely powdered Si–Cu alloy is therefore used in industrial manufacture.

The addition of metals or salts to the contact mass, both to improve the reproducibility of the course of the synthesis and to increase the yield of one of the products, has been the subject of innumerable publications.

Addition of Al, Zn, or Mg [35] increases the content of trimethylchlorosilane in the reaction product from 3 to 10 %. On the other hand, small quantities of Zn (<0.5 %) or zinc halides increase the content of dimethyldichlorosilane [36]. *Golubtsov et al.* [37, 38] found that Sb is an activator up to a certain low concentration, but poisons the catalyst when present in higher concentrations. As, $ZnCl_2$, and P in the presence of Sb also function as activators, while P, Pb, S, Be, Bi, and Ti act as inhibitors. *Dvořák*, *Šnobl*, and *Čermák* [39] emphasize the favorable effect of Mg (< 1 %) on the reaction arte and on the dimethyldichlorosilane yield. *Rossmy* [40] studied the effect of metals incorporated into semiconductor silicon as electron donors or acceptors; he claims that the elements of Group VA of the periodic system favor the formation of methyltrichlorosilane, whereas In and Zn favor that of dimethyldichlorosilane.

The addition of various gases (nitrogen[41], hydrogen[42], chlorine[43], and hydrogen chloride[44,45]) has also been studied as a means of influencing the composition of the reaction product. Hydrogen increases the yield of methyldichlorosilane[42]; an equimolar mixture of hydrogen and methyl chloride at 390 °C gives a product having a methyldichlorosilane content of 15–17 % instead of the usual content of 1–2 %. Addition of hydrogen chloride increases the contents of methyltrichlorosilane[41,42] and of methyldichlorosilane[45–47] in the reaction product.

The kinetics of the direct synthesis of methylchlorosilane has received relatively little attention[39,48–51]. According to *Joklík*, *Kraus*, and *Bažant*[48], who studied the reaction of methyl chloride with silicon as a heterogeneously catalyzed reaction in a closed system at pressures up to 1000 torr, the kinetics of this reaction can be expressed by the general relationship

$$r = \frac{k K_A p_A}{[1 + \sqrt{K_A p_A} + K_R p_R]^2} \quad (6)$$

deduced by *Hougen* and *Watson*[52]. In this equation, r is the reaction rate (*i.e.* the number of molecules of methyl chloride that react per hour per kg of contact mass), k is the rate constant, K_A is the equilibrium adsorption coefficient of methyl chloride, K_R is the equilibrium adsorption coefficient of dimethyldichlorosilane, p_A is the partial pressure of methyl chloride, and p_R is the partial pressure of dimethyldichlorosilane. It can be seen, therefore, that the adsorption of the methyl chloride is accompanied by dissociation and that the surface reaction is the rate-determining step. A relationship of the same form has also been derived for the reaction of methyl bromide with Si[53]. Equation (6), which was calculated for pressures up to 1.3 atm, has been applied successfully to reactions in a flow system, in one case for pressures up to 9 atm[49], and in another case[51] even up to 41 atm. *Dvořák* and *Čermák* recently determined the rate of reaction of methyl chloride with an Si–Cu alloy in a flow reactor[39] and obtained substantially the same results.

4. Reaction with Ethyl Chloride and Higher Alkyl Halides

Ethyl chloride[1,2,54–59] reacts more readily than methyl chloride with silicon in the presence of copper, but the selectivity of the reaction for the formation of the bifunctional dialkyldichlorosilane is lower. In addition to diethyldichlorosilane and ethyltrichlorosilane, an appreciable percentage of ethyldichlorosilane is formed; the main products of the direct synthesis of ethylchlorosilanes are shown in Table 3.

Table 3. Main products of the direct synthesis of ethylchlorosilanes [18].

Compound	B.p. (°C)
$HSiCl_3$	31.8
$SiCl_4$	57.6
$(C_2H_5)HSiCl_2$	74.8
$C_2H_5SiCl_3$	97.9
$(C_2H_5)_2HSiCl$	99.7
$(C_2H_5)_2SiCl_2$	129.0
$(C_2H_5)_3SiCl$	143.5
$(C_2H_5)_4Si$	154.0

Table 4. Some by-products containing Si and boiling above 154 °C that are obtained in the direct synthesis of ethylchlorosilane.

Compound	B.p. (°C/torr)
$(C_3H_7)_2SiCl_2$	172/730
$(C_2H_5)Cl_2Si-O-SiCl_2(C_2H_5)$	186/726
$(H)Cl_2Si-CH_2CH_2-SiCl_3$	189/742
$Cl_3Si-CH_2CH_2-SiCl_3$	201/745
$[Cl_2Si-CH_2CH_2]_2$	219/740
$(C_2H_5)Cl_2Si-CH_2CH_2-SiCl_3$	226–227/730
$(C_2H_5)Cl_2Si-CH_2CH_2-SiCl_2(C_2H_5)$	248–249/730

Substances that boil above the boiling point of tetraethylsilane are also formed (see Table 4)[60,61]. According to *Krylov et al.*[54], the formation of ethylchlorosilane is a first order reaction (activation energy 22 kcal/mole). The kinetics of this reaction have also been studied by *Bažant* and *Kraus*[57] with the purpose of elucidating its mechanism.

The reactions of higher alkyl chlorides have received less attention. The dialkyldichlorosilane content in the reaction product decreases rapidly with the increasing chain length of the organic residue, while the content of alkyldichlorosilane, alkyltrichlorosilane, tetrachlorosilane, and trichlorosilane increases. The reactions studied were those of propyl and isopropyl chlorides [62] and of butyl and isobutyl chlorides [63].

Among the reactions of the unsaturated aliphatic halides, that of vinyl chloride with silicon is important. This reaction proceeds only very slowly in the presence of Cu [64], and other catalysts were therefore sought. Those studied included Mg, Sn [65], and Ni [66,67], of which Ni proved to be the best. Unlike vinyl chloride, allyl chloride reacts readily with silicon [64].

5. Reaction with Polyhalogenoparaffins

The reactions of silicon with organic halides whose molecules contain more than one halogen atom [68–82] are very complex. A large number of interesting compounds are formed that are otherwise difficult to obtain [6,83].

Petrov et al. concluded from the reaction behavior of several chloroalkyltrichlorosilanes [84–89] that chloroalkyltrichlorosilanes do not occur as intermediates in the reaction of dihalogenoalkanes with silicon, because both halogens react almost simultaneously. The only case in which the second halogen could be retained was the reaction of 1,3-dichloro-2-butene [85] with silicon at low temperatures, which yielded 3-chloro-2-butenyltrichlorosilane and 3-chloro-2-butenyldichlorosilane; the chlorine atom attached to the double-bonded carbon atom also reacted at higher temperatures.

6. Reaction with Aryl Halides

Next to methylchlorosilanes, phenylchlorosilanes [2] are the most important components of polymeric silicone products produced on an industrial scale.

In the reaction with aryl halides, the catalyst (Ag, Cu, Fe, Ni, Pt, or Sb) is used either as a mechanical mixture or as an alloy with silicon. Ag [90] gives a more selective reaction course than other catalysts (as in the synthesis of methylchlorosilanes, "selectivity" refers here to the highest possible yield of diaryldichlorosilane). Cu increases the reaction rate, and consequently also the reactor capacity, because the rate of feed of chlorobenzene can be very substantially increased without excessively decreasing the conversion. It can thus be appreciated that despite its lower selectivity, Cu is probably the only catalyst suitable for use in direct synthesis on an industrial scale.

If no other reaction activators are added, side reactions become so important in this case that at most only about half of the chlorobenzene reacts to form phenylchlorosilanes. An Si–Cu alloy has been found to be unsuitable, since chlorobenzene, unlike methyl chloride, probably does not cause the intermetallic compound Cu_3Si to decompose. For this reason it is preferable to use a mechanical mixture of silicon and copper in a weight ratio of between 7:3 and 8:2.

The reaction is carried out on an industrial scale with technical silicon, whose principal impurities are Al and Fe. The presence of Al in the contact mass leads to more pronounced decomposition [91], the main products being benzene,

biphenyl, and hydrocarbon-like products, which are deposited on the catalyst. Al promotes the formation of diphenyldichlorosilane, particularly in the early stage of the reaction, and shortens the induction period; however, its effect on the course of the direct synthesis of phenylchlorosilanes has not been fully explained. The aluminum chloride formed in the reaction causes the decomposition of phenylchlorosilanes during the distillation of the reaction product. Attempts have therefore been made to complex the aluminum chloride, *e.g.* in the form of the nonvolatile adduct $NaAlCl_4$, which has a smaller tendency to cleave the Si-phenyl bond [92]. In contrast to Al, Fe has practically no effect on the course of the reaction. Ni, Pt, and Sb (10 %) have not proved to be effective as catalysts. Like the metal chlorides, the contact surface itself can act as a Lewis acid by adsorption of chlorine atoms [93], and it can then attack the Si-phenyl bond.

Since the copper-catalyzed direct synthesis of phenylchlorosilanes from silicon and chlorobenzene has not led to satisfactory yields, attempts have been made to improve the course of the reaction by the addition of solid components to the contact mass or by the addition of volatile substances to chlorobenzene.

It was found that Zn and Sn inhibit the side reactions and favor the formation of diphenyldichlorosilane, whereas Pb or lead chloride, Sb, and Mg have no appreciable effect. Addition of $SnCl_4$ and of $TiCl_4$ does not increase the quantity of phenylchlorosilanes formed, but rather inhibits the favorable action of Sn and Zn; $SiCl_4$ and $SiHCl_3$ suppress the side reactions and promote in particular the formation of phenyltrichlorosilane. Hydrogen chloride [90,95] shortens the induction period of the reaction and increases the yield of phenylchlorosilanes; the addition of 30 to 50 mole-% of hydrogen chloride to chlorobenzene suppresses the side reactions that lead to the formation of carbon [*], and so prevents the loss of reactivity of the contact mass [94]. Hydrogen also inhibits the side reactions leading to biphenyl and chlorinated biphenyls. However, the content of benzene in the products simultaneously increases as a result of the reaction of hydrogen with the phenyl groups. Raising the reaction temperature favors side reactions and decreases the selectivity of the reaction [97,98], as in the direct synthesis of methylchlorosilanes. This undesirable effect can be countered to some extent by an increase in the flow rate of chlorobenzene.

Pyridyl chloride [99] and naphthyl chloride [100] have also been used instead of chlorobenzene for the reaction with silicon.

The reactions of aromatic bromides were studied mainly for theoretical reasons, because these compounds react better and more selectively; the compounds used were bromobenzene [101], *o*-, *m*-, and *p*-bromotoluene [102], and *p*-fluoro-, *p*-chloro-, *p*-isopropyl-, and *p*-*tert*-butylbromobenzene [103].

The reaction of bromobenzene with Si/Cu to give diphenyldibromosilane is heterogeneously catalyzed [52], and the rate-determining step is the surface reaction, which involves two dissociatively adsorbed bromobenzene molecules [101]. A comparison of the reactivities of bromobenzene and the isomeric bromotoluenes [102] shows that methylation in the benzene ring leads to a decrease in the reactivity of the aryl bromide; the least reactive of these compounds is *o*-bromotoluene, probably because of the steric effect of the methyl group.

The initial reaction rates of *p*-substituted bromobenzenes have been correlated with the aid of the Hammett constants [103]. A similar correlation was obtained for the relative specific adsorption capacities of bromobenzene, *m*- and *p*-bromotoluene, *p*-ethylbromobenzene, and *p*-fluorobromobenzene (adsorption of the aryl bromides on the contact mass was measured gas-chromatographically by the pulse technique [104]). It may be concluded from the high values of the correlation coefficient ($\approx$ 0.98) that the substituent exerts an inductive effect.

7. Mechanism of the Direct Syntheses

Joklík and *Bažant* [13] deduced the probable mechanism of the reaction of hydrogen chloride with silicon from kinetic studies. While the main product in the reaction of methyl chloride with silicon is the bifunctional dimethyldichlorosilane, the corresponding reaction of hydrogen chloride leads to the trifunctional trichlorosilane

$$Si + 3\,HCl \rightarrow SiHCl_3 + H_2 \qquad (7)$$

The formation of trichlorosilane can be explained by dissociative adsorption of hydrogen chloride on the contact mass followed by recombination of the hydrogen atoms to form hydrogen molecules, which are desorbed from the contact surface. The chlorine atoms react to form ($SiCl_2$), which reacts in turn with further hydrogen chloride to form trichlorosilane:

$$Si + 2\,HCl \rightarrow 2\,H + (SiCl_2) \qquad (8)$$

$$2\,H \rightarrow H_2 \qquad (9)$$

$$(SiCl_2) + HCl \rightarrow SiHCl_3 \qquad (10)$$

Hurd and *Rochow* [105] proposed the following reaction scheme for the direct synthesis of methylchlorosilanes:

$$2\,Cu + CH_3Cl \rightarrow CuCl + CuCH_3 \quad (11)$$

$$CuCH_3 \rightarrow {}^{\bullet}CH_3 + Cu \quad (12)$$

$$Si + CuCl \rightarrow (SiCl) + Cu \quad (13)$$

$$(SiCl) + {}^{\bullet}CH_3 \rightarrow (CH_3SiCl) \quad (14)$$

$$(SiCl) + CuCl \rightarrow (SiCl_2) + Cu \quad (15)$$

The reaction continues up to the formation of the volatile methylchlorosilanes, which are then desorbed leaving an unoccupied surface. This scheme accounts for the dissociation of methyl chloride on copper, the activation of silicon by the chlorine atom of copper(I) chloride, and the transfer of the free methyl radical with the aid of methylcopper. *Krahé* and *Rochow* [106] recently used gold as the catalyst instead of copper, and observed the formation of volatile, unstable organogold compounds. *Müller* and *Gümbel* [107] confirmed the validity of the free-radical mechanism, but also stressed the need for the presence of aluminum chloride or ferric chloride, which accelerate the reaction

$$CH_3Cl + Cu \xrightarrow{AlCl_3} CuCl + CH_3^{\bullet} \quad (16)$$

However, they were unable to detect the existence of methylcopper.

Czernotzky [108] studied the interaction of free methyl radicals with dimethyl ether added to the ingoing stream of methyl chloride in the direct synthesis, and on the basis of his results he supports the free-radical mechanism. *Setínek*, *Bažant*, and *Šorm* [109] investigated the inhibition of the direct synthesis of methylchlorosilane by nitrous oxide. These authors interpret the results by assuming the presence of two types of methyl radical in the reaction zone: a small number is present in the gas phase, and their reaction leads to the formation of silicon-free by-products; however, most of the methyl radicals are bound to the surface of the contact mass, and their further reactions yield methylchlorosilanes.

Several objections have been raised against the free-radical mechanism. One of the most important arguments is the fact that the direct synthesis can be carried out very selectively (yield: 80 to 90 % of dimethyldichlorosilane); such high selectivities have not so far been observed in free-radical reactions. Another objection [110] to the reaction course proposed by *Hurd* and *Rochow* is that the direct synthesis of some alkyl- and alkenylchlorosilanes can be carried out at temperatures below 260 °C, whereas it is only at this temperature that the chlorination of silicon by copper(I) chloride begins.

As an alternative to the free-radical mechanism, *Klebanskiĭ* and *Fichtengolz* [110] and *Trambouze* [111] suggested a chemisorption mechanism. According to these authors, the intermetallic compound Cu_3Si ("η phase") must first be formed in the contact mass, (i) by melting Cu and Si, (ii) by sintering the compressed powdered mixture in a current of hydrogen, or (iii) by the reaction of copper(I) chloride with silicon; methylchlorosilanes are formed only by the reaction of Cu_3Si with methyl chloride. Owing to its dipole moment, methyl chloride is adsorbed on the surface of the intermetallic compound with the methyl group situated on silicon and the chlorine atom on copper. However, this does not result in the formation of copper(I) chloride, since the copper carrying the halogen remains in the crystal lattice. Chlorine bound in this way is more reactive than that in copper(I) chloride, and this is why some direct syntheses proceed at temperatures below 260 °C.

This view is supported by *Voorhoeve* and *Vlugter* [27, 112, 113], who studied the composition of the reaction product at the beginning of the reaction as a function of the contact mass, which in one case (a) contained only silicon and the intermetallic compound, and in the second case (b) copper also. In case (a), the condensate contained 90 % of dimethyldichlorosilane from the very beginning of the reaction, while in case (b) the dimethyldichlorosilane content gradually increased from 60 to 90 %; thus (b) required an induction period for the formation of the intermetallic compound from the free copper and silicon. The authors therefore concluded that the presence of Cu_3Si in the contact mass is essential to the formation of dimethyldichlorosilane, and that free copper is responsible for the pyrolysis of the methyl groups. To verify this assumption, they added hydrogen sulfide to the methyl chloride. Hydrogen sulfide should bind free copper as the sulfide, but should not react with the intermetallic compound. The dimethyldichlorosilane content in the reaction product increased slightly; however, the reaction of hydrogen sulfide with methylchlorosilanes evidently was not taken into account in the evaluation of this experiment. The question of whether methyl chloride is adsorbed with the methyl group on silicon and with chlorine on copper was also investigated with the aid of a series of silicides with decreasing positive charge on the metal (Ca, Cu, Cr, Fe). The ratio of methyl groups to chlorine atoms in the reaction mixture, as expected, decreased with the decreasing positive charge on the metal atom of the respective silicide.

Krylov and co-workers [54, 114] found that both active and inactive copper alloys contain Cu_3Si. The intermetallic compound decomposes rapidly in the active alloys during the reaction, but only slowly or not at all in the less active alloys. The authors conclude that the true catalyst is copper in the active form, which is formed only on decomposition of the intermetallic compound.

According to *Golubtsov, Andrianov, et al.* [115–117], the reaction of copper(I) chloride with silicon yields volatile dichlorosilene, which then reacts with methyl chloride adsorbed on copper to form methylchlorosilanes.

$$2\,CuCl + Si \rightarrow SiCl_2 + 2\,Cu \quad (17)$$

$$(SiCl_2) + CH_3Cl{\cdot}Cu \rightarrow (CH_3SiCl_2) + CuCl \quad (18)$$

$$(CH_3SiCl_2) + CH_3Cl{\cdot}Cu \rightarrow (CH_3)_2SiCl_2 + CuCl \quad (19)$$

Zuckerman [6] mentioned the possibility of a relationship between the semiconductor properties of silicon and the reactivity of silicon in the direct synthesis of methylchlorosilane. *Dragojević* [118] presented theoretical arguments for this possibility while *Rossmy* [40] adopted an opposite view.

Some n type (foreign element P, O) and some p type (foreign element B, Al) semiconductor silicons have been examined in this connection by *Joklík* and *Bažant* [119]. Silicon doped with aluminum reacted best, the material containing phosphorus was poorer and reacted only at higher temperatures, and the samples with boron and with oxygen were practically nonreactive. It follows that there is no relationship between the semiconductor properties of silicon and its reactivity in the direct synthesis of methylchlorosilanes. The reason for the observed reactivity of the samples in question is the ability of methyl chloride to react with those impurity elements that can replace silicon in the crystal lattice or can be deposited at higher concentrations at the lattice dislocations. These experiments do suggest that the reaction of methyl chloride with silicon proceeds *via* the dislocations in the silicon crystal.

Experiments with ethyl chloride and silicon in a flow reactor (with provision for the removal of gas samples at various points along the reactor) [57] showed that ethylchlorosilanes are formed by parallel reactions. Addition of hydrogen chloride to the ethyl chloride does not lead to an increased yield of ethyldichlorosilane. Thus contrary to the view that has prevailed in the past, ethyldichlorosilane is not formed by the reaction steps

$$C_2H_5Cl \rightarrow HCl + CH_2{=}CH_2 \quad (20)$$

$$C_2H_5Cl + HCl + Si \rightarrow C_2H_5SiHCl_2 \quad (21)$$

and ethyl chloride is not decomposed into ethylene and hydrogen chloride on copper under the conditions in question. The experimental results can be interpreted as follows. Ethyl chloride is first dissociatively adsorbed on the surface of the contact mass. The next step is the adsorption of the second carbon atom of the ethyl group on the adjacent center, with elimination and adsorption of hydrogen. The ethylene biradical is then either desorbed as ethylene or else forms a compound having the skeleton $\equiv SiCH_2CH_2Si\equiv$. The hydrogen atom may be desorbed as molecular hydrogen or it may react with the ethyl radical to form ethane, or form an Si–H bond. An excess of chlorine atoms on the contact surface leads to the formation of ethyltrichlorosilane, ethyldichlorosilane, tetrachlorosilane, and trichlorosilane.

Hurd and *Rochow* [105] believe that the mechanism of the direct synthesis of phenylchlorosilanes is similar to that of the direct synthesis of methylchlorosilanes, and assume that free radicals are involved. However, this mechanism does not explain the formation of appreciable quantities of benzene and biphenyl. The first reaction step

$$C_6H_5Cl + 2\,Cu \rightarrow C_6H_5Cu + CuCl \quad (22)$$

should be followed by the decomposition of phenylcopper into free phenyl radicals, which would be a fast step; these radicals should then react in the gas phase with the excess of chlorobenzene to give chlorinated hydrocarbons. This assumption was verified by a model experiment with phenyl radicals produced by the pyrolysis of benzil. From an analysis of the reaction products of the direct synthesis it was found, however, that chlorobiphenyl and higher aromatic chlorides are formed in much smaller quantities than benzene and biphenyl. *Vavruška* [120] used this observation to explain the formation of benzene, biphenyl, and the higher hydrocarbons by surface reactions between the phenyl groups adsorbed on the copper.

$$^{\bullet}C_6H_5 + {}^{\bullet}C_6H_5 \rightarrow (^{\bullet}_{\bullet}C_6H_4) + C_6H_{6(ads)} \quad (23)$$

$$^{\bullet}C_6H_5 + {}^{\bullet}C_6H_5 \rightarrow C_{12}H_{10(ads)} \rightarrow C_{12}H_{10(g)} \quad (24)$$

$$2\,{}^{\bullet}C_6H_5 + (^{\bullet}_{\bullet}C_6H_4) \rightarrow C_{18}H_{14(ads)} \rightarrow C_{18}H_{14(g)} \quad (25)$$

$$^{\bullet}C_6H_5 + (^{\bullet}_{\bullet}C_6H_4) \rightarrow (^{\bullet}_{\bullet}C_6H_3) + C_6H_{6(ads)} \quad (26)$$

$$C_6H_{6(ads)} \rightarrow C_6H_{6(g)} \quad (27)$$

The course of the direct synthesis of phenylchlorosilanes has been quantitatively followed as a function of time for various chlorobenzene feed rates and at various temperatures [97]. The composition of the product becomes constant after the induction period. However, the increase in the reactivity of the contact mass is related, not only to the increase in the surface of the contact mass, but mainly to the increase in the number of active sites. During the induction period, the surface gradually becomes occupied by phenyl radicals and chlorine atoms formed by dissociative adsorption of chlorobenzene. The chlorine atoms react with silicon; the adsorbed phenyl radicals can form bonds with silicon (which is activated by partial chlorination), thus yielding diphenyldichlorosilane

and phenyltrichlorosilane, or they can also react with one another on the contact surface to form benzene, biphenyl, and polyphenylenes.

All these reactions proceed simultaneously. The extent to which they compete with one another depends primarily on the temperature.

It is extremely difficult at the present stage to prove conclusively the validity of any one mechanism. The chemisorption mechanism appears more likely, though a series of observations and many of the compounds formed suggest that the two mechanisms can operate simultaneously, *i.e.* the chemisorption mechanism may be accompanied to a small extent (depending on the reaction conditions) by the free-radical mechanism.

The Mechanism of the Wolff-Kishner Reduction, Elimination, and Isomerization Reactions[**]

BY H. H. SZMANT[*]

The mechanism of the Wolff-Kishner reaction is discussed in the light of accumulated information about the kinetics, thermodynamics, and solvent effects of the process. Wolff-Kishner reduction under normal conditions is thought to involve the trans hydrazone anion, which, in the rate-determining step, exhibits a more or less concerted proton capture at the carbanion terminal and undergoes a solvent-induced proton loss at the nitrogen terminal. The stereochemistry of the Wolff-Kishner reduction is believed to be affected by the presence of "ortho" substituents and by a change to a nonpolar, aprotic reaction medium. The mechanism elaborated for the Wolff-Kishner reduction is extended to the Wolff-Kishner elimination and isomerization reactions. Conformational analysis of the intermediates permits correlation of the competitive reduction and elimination processes with the structures of acyclic systems.

1. Introduction

The information available concerning the Wolff-Kishner reduction in protic solvents[1], in a polar aprotic solvent such as dimethyl sulfoxide[2] (DMSO), and in a nonpolar solvent such as toluene[2d], permits the elaboration of a self-consistent mechanistic pattern for the three Wolff-Kishner processes (reduction, elimination, and isomerization). As in previous publications[1,2b] on this subject, the discussion is limited to base-catalyzed, homogeneous Wolff-Kishner reactions; pyrolytic reactions catalyzed by platinum[3] are not included. In the first part of this paper, the mechanism of the Wolff-Kishner reduction is discussed, first for protic conditions, and then when other types of solvents are employed. In the later sections the mechanism of the Wolff-Kishner reduction is extended to include the competitive side reactions such as elimination and isomerization,

2. The Mechanism of Wolff-Kishner Reduction

In the Wolff-Kishner reaction, a ketone (or an aldehyde) is first converted into the hydrazone which decomposes to yield the corresponding hydrocarbon and nitrogen when heated at about 200 °C with sodium alkoxide in anhydrous alcohol.

Seibert[4] was the first to suggest that the formation of the hydrazone anion *(2)* is the initial step of the Wolff-Kishner reaction, but the first-order dependence of the rate on the concentration of base catalyst was only demonstrated in a subsequent kinetic study[1a]. This base-dependence is maintained in all solvents investigated so far, although the reported[3c] success of some Wolff-Kishner reductions carried out with an excess of hydrazine, indicates that hydrazine is a sufficiently strong base to function as a catalyst.

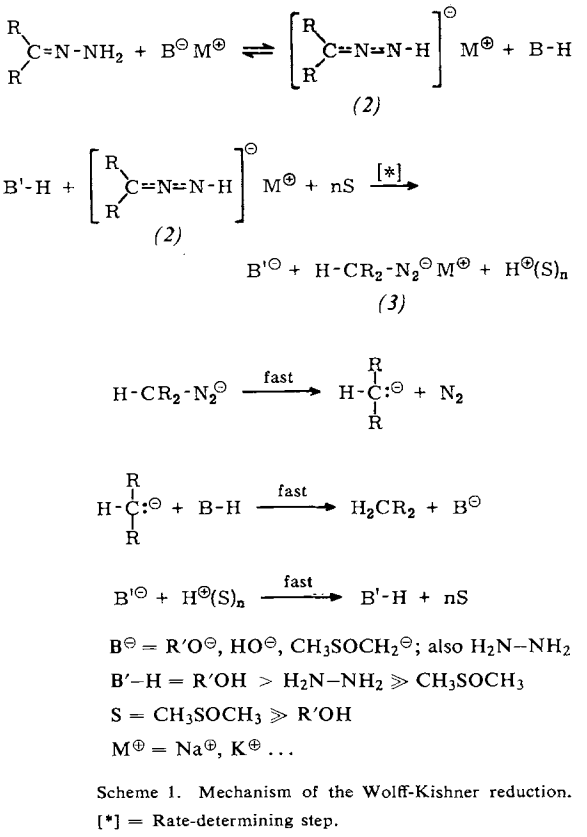
While the formation of the hydrazone anion is undoubtedly the first step of the Wolff-Kishner reaction, it cannot be the rate-determining step, since benzophenone hydrazone can be converted into its anion in anhydrous DMSO by means of the anion derived from DMSO without any appreciable evolution of nitrogen [2c]. The results of our investigations [2b], namely that the rate of the reaction depends also on the concentration of a hydroxylic solvent, and that the association of the hydroxylic solvent with the hydrazone anion is temperature dependent, support the idea that the formation of a new C–H bond at the carbon terminal in the delocalized hydrazone anion is an essential part of the rate-determining step of the Wolff-Kishner reaction.

If the latter conclusion is correct, then one should expect the reaction to fail when the carbon terminal of the hydrazone anion resists the acquisition of the negative charge. This may be precisely the reason why the hydrazone of 2-phenylbenzo-3-tropone *(1)* fails to produce a Wolff-Kishner reaction in

(1)

spite of prolonged heating at 200 °C in the presence of base catalyst. The distribution of electrons expected in such a system may also be responsible for a considerable decrease in the acidity of the N–H bonds and the consequent reluctance to form the hydrazone anion [5a]. For other non-Wolff-Kishner behavior of substituted tropolones see the work of *Mukai et al.* [5b].

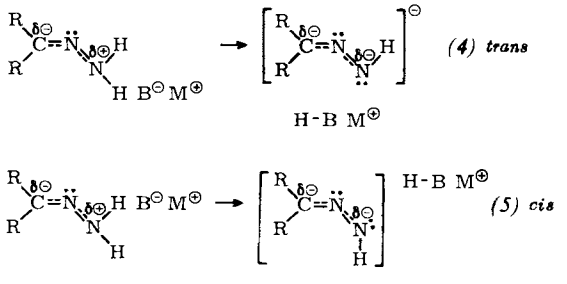
However, the following evidence suggests that the capture of a proton by the carbanion terminal in the hydrazone anion is only a part of the rate-determining step: (i) the nonlinear Hammett relationship established [1b] for the Wolff-Kishner reduction of a large series of hydrazones; (ii) the gradual lowering of the enthalpy of activation [2b] by DMSO in a concentration range (6.75 – 9 M) in which its effect can no longer be attributed merely to a change in the dielectric constant of the hydroxylic reaction medium; and (iii) the pronounced influence of "*ortho*" substituents on the rate of the Wolff-Kishner reaction [1,4]. On the basis of this evidence it is concluded that, as a general rule, in the rate-determining step of the Wolff-Kishner reduction of ordinary hydrazones the proton capture at the carbon terminal in the hydrazone anion is coupled, in a more or less concerted fashion, with a solvent-induced proton abstraction at the nitrogen terminal to form *(3)*. Recent work by *Kosower* and *Huang* [6] not only provides evidence for the existence of the elusive diimide structure *(3)*, but also demonstrates its ease of ionization. The latter observation supports the view that a nucleophilic solvent participates in the formation of the diimide ion in the rate-determining step of the Wolff-Kishner reduction by promoting the ionization of the N–H bond. Scheme 1 depicts the mechanism of the Wolff-Kisher reaction.



Scheme 1. Mechanism of the Wolff-Kishner reduction. [*] = Rate-determining step.

It is noteworthy that the observed [2b] favorable response of the rate to an increase in the dielectric constant of the reaction medium agrees with the postulated rate-determining step since the charge of the hydrazone anion becomes localized as the diimide ion is formed, and additional ionic species are generated as well.

The stereochemistry in the formation of the hydrazone anion is of interest even when one is dealing with a symmetrical hydrazone, $R_2C{=}N{-}NH_2$, in view of the nonequivalence of the two N–H bonds. *A priori*, it can be assumed that the base attacks preferentially at the hydrogen farthest removed from the lone pair on the central nitrogen atom. Thus the *trans* anion *(4)* is believed to be formed rather than the *cis* anion *(5)*.



(4) trans

(5) cis

This preferential formation of the *trans* anion should be greatest in the presence of protic solvents which can be expected to form a hydrogen bond to the carbon terminal of the hydrazone anion to a greater extent than in the case of simple carbanions [7] because of the cooperative effect of the nonbonding electrons

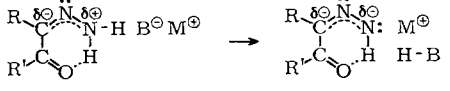
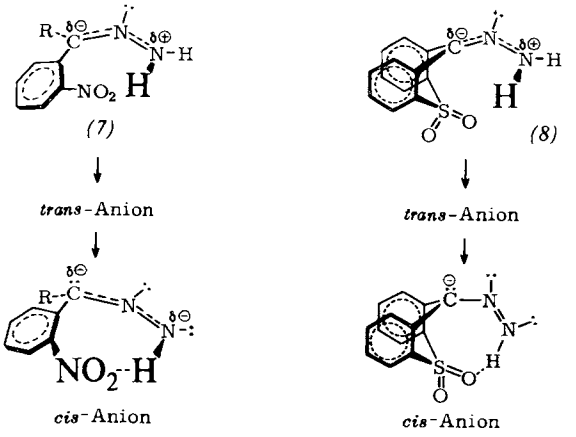
on the nearby nitrogen atom. There is no reason to suppose that the difference between the geometrical isomers of the hydrazone anion is less real than the isomerism of the allylic carbanions [8]. The geometry of the latter is determined by the structure of the starting material, their stability depends on the degree of delocalization (coplanarity), and each geometrical isomer gives a different olefinic product. On the other hand in the case of the isomers of hydrazone anions, the predominance of one of the geometrical isomers is subject to kinetic control, their stability depends not only on delocalization but also on the mutual repulsion of the neighboring nitrogen atoms, and, while both isomers lead to the same product, their geometry may modify somewhat the mechanism of the reaction.

A substituent capable of promoting a strong intramolecular hydrogen bridge with the terminal nitrogen of the hydrazone should also induce the formation of the *cis* hydrazone anion. A suitable substituent for this purpose is an α-carbonyl group [9]; another substituent, the α-hydroxyimino group, is discussed in the last section of this paper. In the case of the α-carbonyl hydrazones, the coplanarity and appropriate ring size of the system combine to create an ideal situation for the generation of a *cis* anion *(6)*. A similar situation may also exist in the hydrazones of 2-pyridyl carbonyl compounds [1b].



(6)

Since the hydrazone anion is, generally speaking, a relatively long-lived species [2c], one can also visualize the possibility of a *trans-cis* isomerization, with the subsequent participation of the *cis* isomer in the rate-determining step. Such an isomerization should take place when a substituent is present which can form an intramolecular hydrogen bond with the *cis* anion but not with the hydrazone proper. This type of situation exists, for example, in hydrazones of aromatic carbonyl compounds containing an *o*-nitro or *o*-carbonyl group, and in structures in which a transannular hydrogen bond is formed. The difference between the hydrazone and its anion resides in the lower coplanarity of the anion in which the carbon terminal of the hydrazone moiety acquires considerable carbanion character and thus approaches sp^3 hybridization. The localization of the negative charge at the carbon terminal is favored by the strong electron-withdrawing nature of the majority of the substituents which form intramolecular hydrogen bonds. The isomerization under discussion may be illustrated by the hydrazone of an *o*-nitroarayl carbonyl compound *(7)* and the hydrazone of thioxanthone dioxide *(8)*.



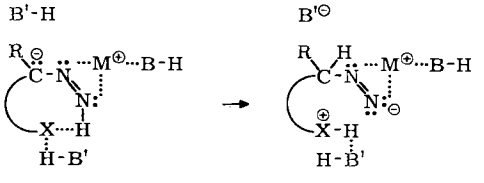
(7) *(8)*

trans-Anion *trans*-Anion

cis-Anion *cis*-Anion

Both of these systems [1b,4,10] as well as the monohydrazones of α-dicarbonyl compounds [4], are reduced at exceptionally low temperatures in protic solvents by the Wolff-Kishner method. This property is attributed to a combination of two circumstances: (i) the relatively strong carbanion character of the carbon terminal in the hydrazone anion, and (ii) the "internal solvation" of the N–H terminal by the functional groups enumerated above.

Regardless of the details of the isomerization of the hydrazone anion, the fact that *ortho* substituents capable of hydrogen bonding with the N–H terminal cause a significant lowering of the enthalpy of activation of Wolff-Kishner reduction is considered as strong evidence in favor of the conclusion that the breaking of the N–H bond is part of the rate-determining step. The rate-determining step with the participation of an *ortho* substituent (X) is represented in Scheme 2.



Scheme 2. Rate-determining step of the Wolff-Kishner reduction of the hydrazone of an "*ortho*" substituted compound. X = α-Carbonyl, α-hydroxy, *o*-carbonylaryl, *o*-nitroaryl, 2-pyridyl, transannular SO_2, *etc.* See Scheme 1 for the meanings of abbreviations.

The role of the different types of solvents in the Wolff-Kishner reduction can now be examined, starting with the most common reaction medium, namely hydroxylic solvents [11].

In an exclusively hydroxylic solvent, the mechanism of the Wolff-Kishner reduction, leading to and including the rate-determining step, can be formulated as shown in Scheme 3.

When a hydroxylic solvent and DMSO are present together in such concentrations that both solvent molecules participate in the rate-determining step, then each solvent performs the function for which it is best suited.

The most important difference between the rate-determining steps when ROH and R'OH + DMSO are

[8] *D. H. Hunter* and *D. J. Cram*, J. Amer. chem. Soc. *86*, 5478 (1964).

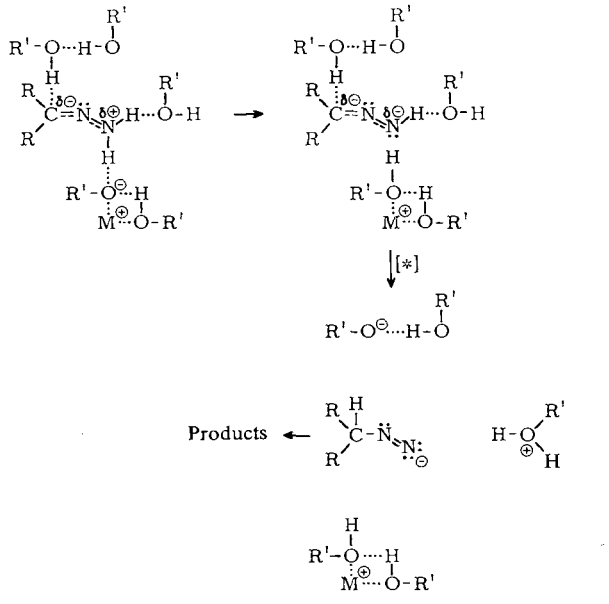
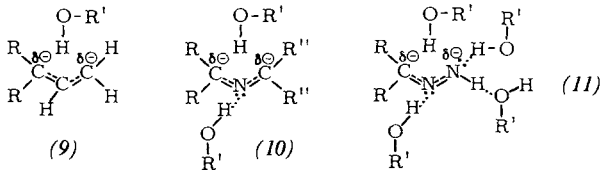


Scheme 3. Wolff-Kishner reduction in a hydroxylic solvent [12].
[*] = Rate-determining step.

used as solvents is the participation of DMSO in the breaking of the N–H bond and in the solvation of the metal cation. The former effect is believed to predominate in the concentration range 6.75–9.00 M and to account for the gradual lowering [2b] of the enthalpy of activation. The simultaneous increase [2b] in the negative entropy of activation must be the result of an increase in the organization of the DMSO molecules caused by the ionic products of the rate-determining step.

It is noteworthy that the intermolecular proton transfer suggested in Scheme 3 is analogous to the mechanism of the base-catalyzed isomerization of imines [13], and differs from the intramolecular proton transfer demonstrated by *Cram* and *Uyeda* [14] for the base-catalyzed isomerization of allylic hydrocarbons. However, the comparison of the respective anions *(9)–(11)* of Scheme 4 reveals that the increasing number of nonbonding electrons available for solvation with protic solvent molecules must necessarily promote the intermolecular proton transfers.

When the hydrazone anion is generated in an aprotic polar solvent such as DMSO by means of an alkoxide, then the newly formed alcohol must serve as the



Scheme 4. Solvation in allylic, imine, and hydrazone anions.

[12] Only the minimum number of solvent molecules is shown in this diagram. The R'OH molecules should be visualized either above or below the plane of the hydrazone.

[14] *D. J. Cram* and *R. T. Uyeda*, J. Amer. chem. Soc. *86*, 5466 (1964).

proton source at the carbanion terminal. Judging by the absence of a kinetic isotope effect in the alkoxide-catalyzed exchange reaction of hydrocarbons when DMSO is employed [15] as the solvent, the diffusion of alcohol molecules must be a slow process, and thus the Wolff-Kishner reaction has to depend on a proton transfer by the newly formed alcohol.

The intramolecular proton transfer under these circumstances resembles the proton transfer in the allylic hydrocarbons [14], and explains the observation [2c] that the generation of an alcohol molecule within the solvent cage that encloses the hydrazone anion is more effective than the addition of relatively large amounts of alcohol to a solution of the hydrazone anion in DMSO. Also, the slow migration of the alcohol toward the carbanion terminal, and the known capacity of DMSO molecules to capture the alcohol through hydrogen bonding, explains the relatively high degree of azine formation when the Wolff-Kishner reduction is carried out in DMSO [2a, 2d].

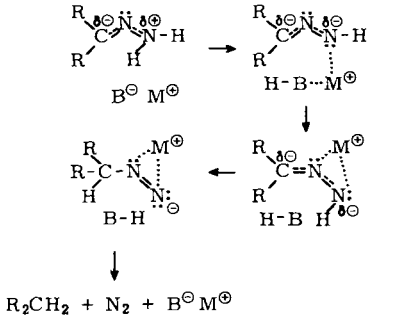
Next to be considered is the Wolff-Kishner reaction in anhydrous DMSO [2c] in which the hydrazone anion is generated by means of the anion derived from DMSO. It is now known [2c] that the addition of benzophenone hydrazone to a solution of dimsylsodium in DMSO causes a rapid (k_2 at 25 °C *ca.* 10^{-3} lmole^{-1} sec^{-1}) formation of the benzophenone hydrazone anion which gives a characteristic absorption maximum at 3930 Å ($\varepsilon = 2\times10^4$). In the absence of oxygen the solution of the hydrazone anion is stable over a period of several days. Thus it is apparent that the Wolff-Kishner reaction fails to occur in DMSO free of hydroxylic components and this behavior must be attributed to the low acidity of DMSO (pK_a 31.3) [16] as compared with the acidity of either the carbon or nitrogen acids derived from the benzophenone hydrazone anion. The weaker of the two acids, namely the carbon acid in benzhydryldiimide, should have a pK_a value lower than that reported for diphenylmethane in DMSO (28.6) [16] because of the electron-withdrawing effect of the diimide group, and thus the proton donating ability of DMSO turns out to be too small for the formation of the new C–H bond in the rate determining step of the Wolff-Kishner reaction. The failure to observe a Wolff-Kishner reaction of the hydrazone anion in a truly aprotic medium also excludes the possibility of an intramolecular proton transfer from the nitrogen to the carbon terminal.

Finally, the mechanism of the Wolff-Kishner reduction in an essentially aprotic, nonpolar solvent such as toluene [2d] may be considered. In view of the limited solvating capacity of such a medium, the ionic species will tend to exist as intimate ion pairs, and, following the formation of equimolar quantities of hydrazone anion and alcohol, the metal cation can be expected to coordinate both species in a tightly held complex. This situation should favor a rapid proton

[15] *J. E. Hofmann*, *A. Schriesheim*, and *R. E. Nickols*, Tetrahedron Letters *1965*, 1745.

[16] *E. C. Steiner* and *J. M. Gilbert*, J. Amer. chem. Soc. *87*, 382 (1965).

capture by the carbanion terminal, and this expectation is indeed realized in view of the greater velocity [2d] of the Wolff-Kishner reaction in toluene than in DMSO. However, one must still account for the breaking of the N–H bond in the hydrazone anion when the solvent is unable to participate in the rate-determining step. The choice is between the alkoxide ion shuttling back to the N–H bond following proton capture at the carbanion terminal or the more plausible alternative of a *trans-cis* isomerization of the hydrazone anion aided by the chelating capacity of the metal cation and the subsequent intramolecular proton transfer depicted in Scheme 5.

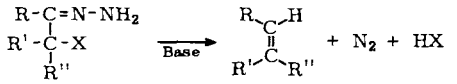


Scheme 5. Wolff-Kishner reduction in nonpolar, aprotic solvents.

Regardless of the solvent conditions, the final step of the Wolff-Kishner reduction is the collapse of the diimide anion in the presence of a proton source into the hydrocarbon and a nitrogen molecule. This step is identical with that studied by *Cram et al.* [17] in connection with the stereochemistry of carbanions. These authors found that the retention of the configuration in the transition state increases when the "leaving group" is a nitrogen molecule (as compared with carbon, oxygen, or hydrogen "leaving groups"), and also that the degree of retention depends on the proton-donating capacity of the medium and its dielectric constant. Applying these results to the collapse of the diimide anion in the Wolff-Kishner reduction, we conclude that this step is a rapid one, either because of a rear attack by the protic solvent, or because the formation of the nitrogen molecule creates a "low pressure region" in the liquid structure which assists in "pulling in" the carbanion and proton donor from opposite directions. The conclusion with regard to the fast base-catalyzed collapse of diimide is born out by recent work of *Kosower* [6] on phenyl- and *tert*-butyldiimides.

3. The Mechanism of the Wolff-Kishner Elimination

The elimination which occurs in the course of a Wolff-Kishner reduction has been known since the days of *Kishner* [18], who observed the formation of 2,5-dimethyl-2-octene during the attempted reduction of 2,6-dimethyl-2-hydroxy-3-octanone. However the conditions propitious for the Wolff-Kishner elimination to form *(12)* have never been properly defined, and



(12)

the occurrence of the elimination remained somewhat erratic.

Thus, while the Wolff-Kishner elimination was shown [19] to be strongly dependent on the ring size of cyclic ketones (subjected to the Huang-Minlon procedure [11]) and on the conformational equilibria in acyclic ketones, it was reported to occur with great reluctance [20] with either type of ketone in spite of the presence of excellent leaving groups [11]. Several groups of investigators [21] found that the elimination takes place in the course of the Wolff-Kishner reduction of steroidal ketones, and *Turner et al.* [22] suggested some of the stereochemical requirements for the elimination process without dwelling on the details of the competition between the elimination and reduction paths.

The strict stereochemical requirements for the Wolff-Kishner elimination suggests that the critical step of this reaction occurs after the original trigonal carbon (of the ketone or hydrazone) has assumed the tetrahedral configuration. This implies that the reaction follows the general pattern of a *trans* elimination, and that the proton capture at the carbanion terminal of the hydrazone anion determines the orientation of the nitrogen moiety. The data on the Wolff-Kishner elimination in steroids offer substantial support for this conclusion. In most of the examples in which the elimination predominates, the hydroxyl next to the carbonyl group has an axial orientation. Thus, solvation of this hydroxyl group by protic solvents is expected to promote an equatorial proton capture at the carbanion terminal of the hydrazone anion, and, in the final analysis, the hydroxyl and the nitrogen moiety are *a,a-trans* with respect to each other in an ideal orientation for the *trans*-elimination [23]. This process is illustrated in Scheme 6 for the 5-hydroxy-6-oxo steroid system which is common to several investigations [21d, 21e]. A similar situation exists in the 9-hydroxy (or epoxy)-11-oxo steroids [21e], and in both systems the Wolff-Kishner reaction follows the elimination path almost exclusively. In the 11-hydroxy-12-oxo steroids such as *(13)* [21e], on the other hand,

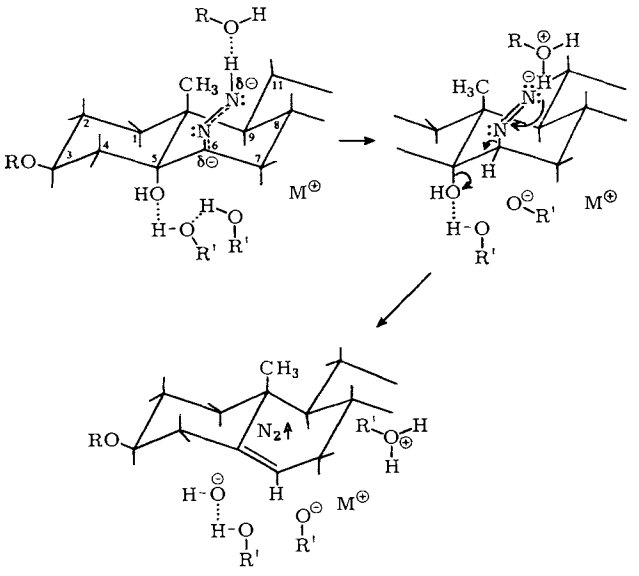
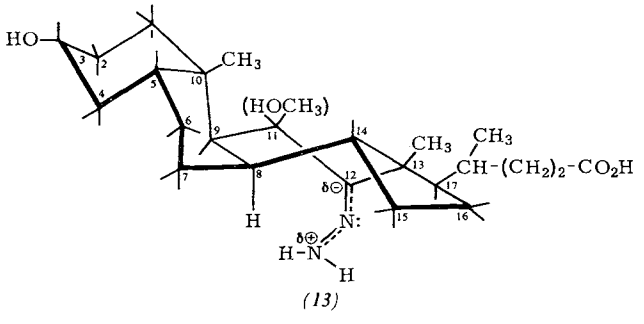


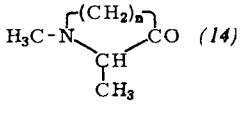
Scheme 6. Wolff-Kishner elimination in 5-hydroxy-6-oxo-steroids.

the elimination and reduction processes occur in nearly equal proportions regardless of whether the hydroxyl group is oriented alpha or beta. This can be understood by examining the stereochemistry of the steroidal C ring. Because of the *cis*-junction of the C ring with the 5-membered D ring, and because of the repulsive interactions between the axial substituents at C-13 and C-17, the C ring will tend to assume a twisted conformation. As a result, the hydroxyl group at C-11 is oriented either semi-axially or semi-equatorially, and in this ambiguous situation some of the stereospecificity in the proton capture step is lost.



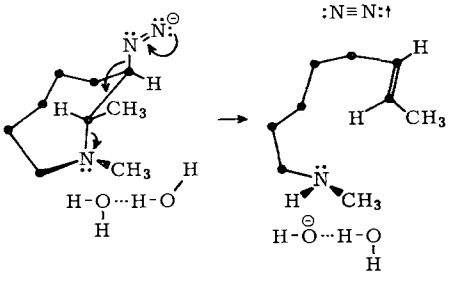
(13)

On the basis of these results, the relative reluctance of the 2-halogen substituted cholestanones [20] to undergo a Wolff-Kishner elimination can be attributed to the equatorial orientation of the potential "leaving groups". Also the interesting differences in the behavior of the cyclic oxoamines [19] can be explained on the basis of the relative ease with which a *trans* orientation of the critical moieties can be achieved. Thus, in the



(14)

system *(14)* no elimination could be detected when $n = 3$, while the yield of the elimination product increased from 44 % to 99 % as the value of n changed from 4 to 5. These results agree with the release of tension in the conformation as the size of the ring increases (see Scheme 7).



Scheme 7. Wolff-Kishner elimination in cyclic systems.

The results obtained for acyclic α-substituted ketones are more difficult to rationalize because these systems possess a large degree of rotational freedom. Following the guidelines established for the relatively rigid cyclic systems, one must search for a correlation between conformational preferences and the *trans* orientation of the diimide ion moiety and the potential "leaving group", which is assumed to be a structural requirement for the elimination process.

Let us consider first the conformation of the hydrazone in which the potential "leaving group" X and the hydrazone moiety are oriented *cis* with respect to each other. This conformation follows the pattern established for unsaturated molecules [24] and permits a high degree of solvation at both polar groups. The solvation by protic solvents determines the stereo-

chemistry of proton capture at the carbanion terminal in the hydrazone anion, as shown in Scheme 8, in accord with the relative size of the substituents R′ and R″ at the carbon atom containing the potential "leaving group". The diimide ion which results from this process has an unfavorable eclipsed conformation, and its destiny will depend on the relative stability of the two conformations in which either the group R or the nitrogen moiety are oriented *trans* with respect to the potential "leaving group" X. An examination of a number of individual cases (see Table 1) reveals that, barring the effect of factors which are enumerated below, the Wolff-Kishner reduction path is suppressed to the extent to which the repulsion between the *gauche* oriented groups R, R′ and R′, R″ increases. This is apparent from the first six entries in Table 1, in which the "leaving groups" (X) are similar, and on relating the nature of the groups R″ and R to the decrease in the yield of the reduction product.

It is apparent that the reduction path is suppressed the most when both R′ and R″ are aromatic groups, and in the combination of one alkyl and one aryl group the repulsion seems to be greater when the aryl group is located near the diimide anion. In the last seven entries in Table 1, the structural variation resides only in the nature of the X group. The first four of these entries illustrate [18] the partial dependence of the yield of the elimination product on the strain at the nitrogen atom of the "leaving group" while the last three entries, together with the other cases where X = OH or OR, illustrate the suppression of the reduction path when X is a superior "leaving group".

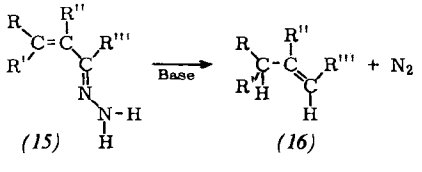
Grundon et al. [2d] have recently demonstrated the nearly complete absence of the Wolff-Kishner elimination when a toluene solution of the hydrazone of 3,3-dimethyl-1,2′-methylpiperidinobutan-2-one is treated with potassium *tert*-butoxide. The same hydrazone gave a 38 % yield [19a] of the elimination product under protic reaction conditions.

The observation of *Grundon et al.* fits the mechanisms evolved here for the Wolff-Kishner reaction in aprotic, nonpolar solvents and for the Wolff-Kishner elimination. It is clear that the 1:1 complex of the highly polar hydrazone anion and of the alcohol will tend to be coordinated by the metal cation into a tight complex when these species are surrounded by solvent molecules of low polarity such as those of toluene, and this situation is not conducive to the migration of the alcohol toward the potential "leaving group" for the purpose of hydrogen bonding to the latter. Thus, the nitrogen is expelled from the diimide ion, and the resulting carbanion and nearby alcohol molecule collapse to the final hydrocarbon product, in preference to an elimination process.

Apart from the conformational factors mentioned above, the reluctance of the Wolff-Kishner reaction investigated by *Wharton et al.* [20] to give elimination products can also be attributed to the relatively nonprotic reaction medium employed (1,2-dimethoxyethane plus 2 to 3 equivalents of 95 % hydrazine in the absence of any other base catalyst). Assuming that the hydrazone anion is formed satisfactorily under these conditions, the limited quantity of protic components of the reaction mixture will tend to form hydrogen bonds with the ether linkages of the solvent rather than participate in the elimination process.

4. The Mechanism of the Wolff-Kishner Isomerization

The Wolff-Kishner isomerization consists in the migration of a double bond during Wolff-Kishner reduction [*e.g. (15)* → *(16)*].

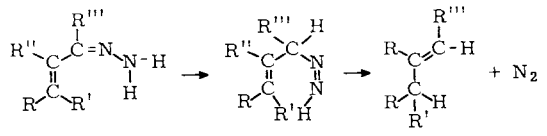


(15) *(16)*

The reaction was first observed by *Lardelli* and *Jeger* [25] who also suggested a cyclic mechanism for this transformation (see Scheme 9).

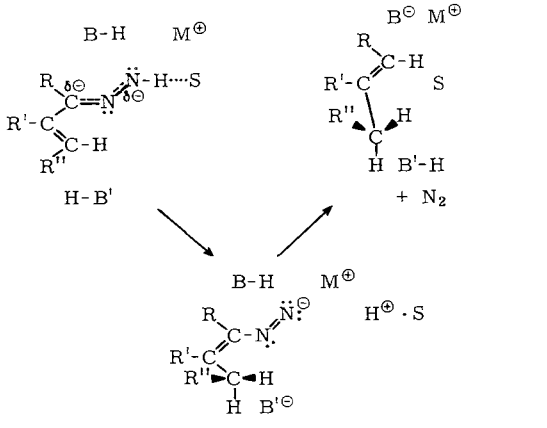
This mechanism does not seem satisfactory because it does not clarify the conversion of the hydrazone to

[25] a) *G. Lardelli* and *O. Jeger*, Helv. chim. Acta *32*, 1817 (1949); b) *R. Fischer, G. Lardelli*, and *O. Jeger, ibid. 33*, 1335 (1950); *34*, 1577 (1951).



Scheme 9. Wolff-Kishner isomerization according to *Lardelli* and *Jeger* [25].

the diimide, and because it attributes to the double bond the capacity to induce the *cis* structure in the diimide. Even though hydrogen bonding to olefinic π electrons is not unknown [26], it is doubtful that this phenomenon can be responsible for the stereospecificity suggested above, and it is therefore preferable to attempt to interpret the isomerization within the framework of the general mechanism of the Wolff-Kishner reactions. The improbability of the mechanism in Scheme 9 is further supported by the complete suppression of isomerization when the Wolff-Kishner reaction is carried out in toluene [2d]. In the absence of competitive hydrogen bonding between the hydrazone or its anion and the solvent molecules, the intramolecular association assumed in the "cyclic mechanism" should be favored and hence also the isomerization process. The contradicting results point to an active participation of the protic solvent in the isomerization, and a mechanism for the latter is suggested in Scheme 10.



Scheme 10. Newer conceptions about the Wolff-Kishner elimination.

Steric interference between the substituents at the olefinic bond and the solvated N–H terminal casts serious doubts on the possibility of extending the delocalization of the hydrazone moiety to include the olefinic system while the nitrogen and olefinic systems are pointing toward each other; for this reason the *anti* hydrazone structure is assumed.

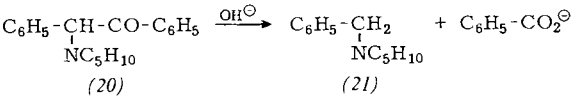
A novel isomerization has been observed [34] in the course of the Wolff-Kishner reaction of the tetracyclic ketone *(17)*. In addition to the expected reduction product *(18)* there was also 15 % of an isomeric product *(19)* isolated. The formation of the latter can be considered to result from a competitive protonation of the intermediate carbanion (during the collapse of the hydrazone anion in the final phase of the Wolff-Kishner mechanism) at one of carbon atoms neighboring the original carbonyl group: These carbon atoms exhibit an olefin-like character associated with the presence of the cyclopropane ring system. One is tempted to predict that the isomeric product *(19)* would be suppressed if the Wolff-Kishner reaction were to be carried out in an essentially aprotic medium.

(17) *(18)* *(19)*

A not dissimilar ring opening occurs [35] during the Wolff-Kishner reduction of α,β-epoxy ketone. As may well be expected, the intermediate carbanion suffers a unidirectional opening of the neighboring epoxide with the resulting formation of an allylic alcohol.

5. Side Reactions During the Wolff-Kishner Reaction

In the course of attempted or partially successful Wolff-Kishner reactions side reactions are encountered that have no bearing on the mechanism of the process as such [27]. One of these is the base-catalyzed cleavage of certain α-substituted ketones illustrated by the cleavage [19] of α-phenyl-α-piperidinoacetophenone *(20)* to *N*-benzylpiperidine *(21)* in 25 % yield,



(20) *(21)*

The same type of reaction accounts for the isolation of benzoates from the attempted [28] Wolff-Kishner reduction of α-hydroxyiminopropiophenone hydrazone, and the formation [29] of 8-benzhydryl-1-naphthoic acid in the attempted Wolff-Kishner reduction of 2,2-diphenyl-1-acenaphthenone.

Another such side reaction occurring in conjunction with the Wolff-Kishner elimination reaction consists of the reduction of the expected olefin to the saturated hydrocarbon. The Huang-Minlon procedure [11] favors this side reaction because an excess of hydrazine is used; probably the atmospheric oxidation of hydrazine to diimide [30] leads to the hydrogenation of the olefin. An example of the occurrence of this side reaction is the isolation [19] of *p,p'*-dimethoxybibenzyl instead of the corresponding stilbene from the Wolff-Kishner elimination of 4-methoxy-α-4'-methoxyphenyl-α-(α'-phenylethylamino)acetophenone hydrazone and another is the isolation [31] of cholestane instead of 2-cholestene during

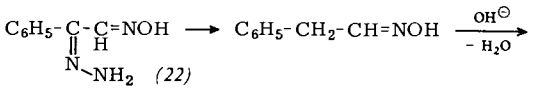
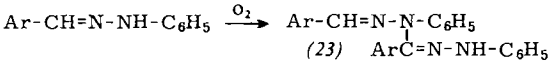
the Wolff-Kishner elimination reaction of 2-acetoxy-3-cholestanone.

Finally, the possibility exists of the decomposition of an aldehyde derivative in which the attack of the base upon the aldehydic hydrogen can be accompanied by the departure of a suitable "leaving group". This situation is illustrated by the isolation[28] of phenylacetic acid in 78% yield from the Wolff-Kishner reduction of α-hydroxyiminoacetophenone hydrazone *(22)*.



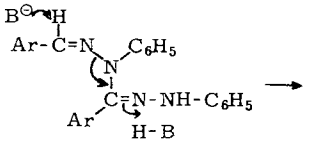
(22)

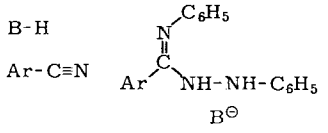
A similar reaction is the base-catalyzed decomposition of some phenylhydrazones of aromatic aldehydes[32]. The base-catalyzed decomposition is preceded by an oxidative coupling of the phenylhydrazone to a hydrazidine *(23)*; the final



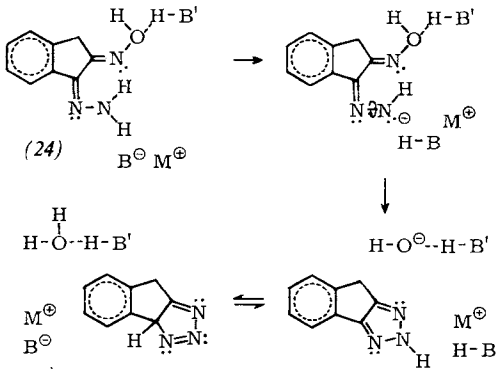
(23)

elimination reaction occurs with the latter species in which an excellent "leaving group" is now available:





A side reaction which does have a direct bearing on the Wolff-Kishner reaction is the formation[28] of *vic*-triazoles observed during the reaction of some α-hydroxyiminoketones. The acyclic representatives undergo a normal Wolff-Kishner reduction to the corresponding oximes (unless one of the side reactions described above happens to interfere), but the α-hydroxyiminoketone hydrazones *e.g. (24)* in which both functional groups are forced into coplanarity produce a *vic*-triazole. This result seems to confirm the hypothesis that the hydrazone anion is a relatively long-lived species even in the presence of protic molecules, since an intramolecular displacement reaction (see Scheme 11) can occur in



(24)

Scheme 11. Triazole formation on the Wolff-Kishner reduction of α-hydroxyimino hydrazones.

competition with a proton capture typical of the Wolff-Kishner reduction. Since *(24)* contains an "*ortho*" substituent capable of strong intramolecular hydrogen bonding, it is assumed that the *cis*-hydrazone anion is formed in preference to the *trans* isomer, and the fact[28] that the yield of *vic*-triazoles decreases to 1 and 0% when a methyl or phenyl substituent is introduced at the terminal nitrogen atom is strong evidence that the formation of the *cis*-hydrazone anion is indeed the initial step of the reaction[32]. Once the *cis*-anion is formed, the repulsion of the nonbonding electron pairs on the vicinal nitrogen atoms aids *cis-trans* isomerization, and then a nucleophilic attack of the hydrazone anion terminal on the nitrogen of the oxime produces ring closure. The nucleophilic character of the hydrazone anion is not unexpected if one considers that a hydrazone proper is able to cause a nucleophilic displacement of a nitro group in certain *o*-nitroarylketone hydrazones[33], and that nucleophilic attack on the nitrogen of a variety of derivatives of oximes occurs during the acid-catalyzed cyclizations of α-hydroxyiminoketohydrazones to *vic*-triazoles[27].

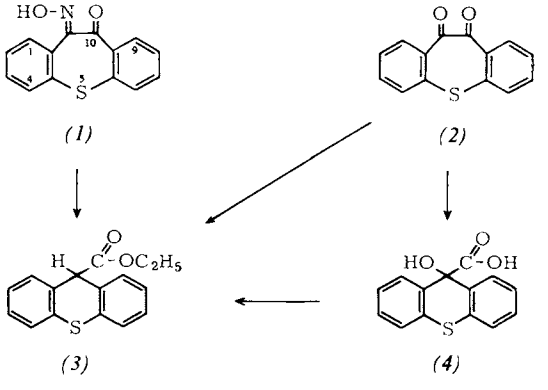
Acid-catalyzed Ring Contraction of Dibenzothiepin-10,11-dione

By *A. Lüttringhaus* and *G. Creutzburg*[*]

On acid hydrolysis of dibenzothiepin-10,11-dione monoxime *(1)* in aqueous ethanol we obtained, instead of the expected diketone *(2)*, ethyl 9 *H*-thioxanthene-9-carboxylate *(3)*, which was formed in more than 70% yield by ring contraction and reduction. The diketone *(2)* prepared by a different route[1] is converted into *(3)* under similar conditions. 9-Hydroxythioxanthene-9-carboxylic acid *(4)*, accessible from *(2)* by a normal base-catalyzed benzilic acid rearrangement, is converted into *(3)* even faster than are *(1)* and *(2)* under the same conditions.



(1) *(2)* *(3)* *(4)*

The ester *(3)* formed in each case is identical with a sample obtained by esterification of the authentic 9 *H*-thioxanthene-9-carboxylic acid[2] as regards mixed melting point and IR and NMR spectra (8 aromatic protons give a multiplet at $\tau = 2.6$; a benzylic proton gives a singlet at $\tau = 4.9$; CH_2 quadruplet at $\tau = 5.8$, $J = 7.5$ Hz; CH_3 triplet at $\tau = 8.9$, $J = 7.5$ Hz; TMS as internal standard, in $DCCl_3$).

Under the same conditions no reaction occurs with dibenzothiepin-10,11-dione *S,S*-dioxide, with benzil, with phenanthraquinone, or with 5 *H*-dibenzo[*a,d*]cyclohepta-1,4-diene-10,11-dione. We consider this to be evidence that the sulfur atom, with its free electron pairs, is concerned in the reaction mechanism (cf.[3]).

Preparation of (3):

1.45 g of dibenzothiepin-10,11-dione monoxime *(1)* is dissolved in a warm mixture of 100 ml of ethanol and 30 ml of concentrated hydrochloric acid (or 50% sulfuric acid) (red coloration) and then boiled for 3 h. On addition of 100 ml of water and cooling, colorless crystals of *(3)* separate, m.p. 100 °C (ethanol/water); mixed m.p. with authentic *(3)*, 100 °C; yield 1.1 g (71.4%). Conversion of *(2)* and *(4)* into *(3)* is carried out analogously. If during the reaction a current of nitrogen is passed through the solution into an ice-cooled receiver containing a little water, the acetaldehyde formed can be trapped as 2,4-dinitrophenylhydrazone, m.p. 147 °C.

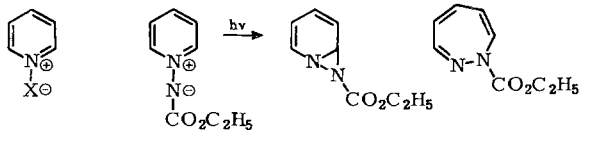
Photochemical Synthesis of Ethyl 1 *H*-Diazepine-1-carboxylate

By *J. Streith* and *Jean-Marie Cassal*[*]

Mesoionic pyridinium derivatives of type *(1)*, X = O, CR_2, or NR, can be considered as aromatic 1,3-dipoles[1]. Whereas pyrrole derivatives are obtained by UV irradiation of pyridine *N*-oxides or pyridinium dicyanomethylide[2], we have established that the compound *(2)* synthesized by *Hafner*[3] undergoes photochemically induced ring expansion to ethyl 1*H*-diazepine-1-carboxylate *(4)*.

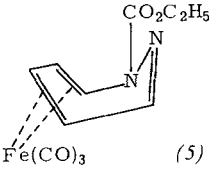
UV irradiation of a 10^{-2} M solution of the *N*-(ethoxycarbonylamino)pyridinium derivative *(2)* by means of a mercury high-pressure lamp with a Pyrex filter leads in a few hours to complete disappearance of the starting material, while the solution becomes dark red. Removal of the solvent, chromatography on silica gel and distillation of the red oil thus obtained provides a homogeneous red product (yield 95%), b.p. 50 °C/0.5 torr, $n_D^{25} = 1.5302$, whose mass spectrum[4], microanalysis, and spectral data indicate structure *(4)*.



(1) *(2)* *(3)* *(4)*

The UV spectrum of compound *(4)* in *n*-hexane [$\lambda_{max} = 217$ ($\varepsilon = 10000$), 362 nm ($\varepsilon = 230$)] is very similar to that of ethyl azepine-1-carboxylate[5]. The IR spectrum (film) contains bands at 2950, 1700, and 1600 cm^{-1}. As well as the expected ethyl multiplets at $\tau = 8.65$ (triplet) and 5.68 (quartet), the NMR spectrum contains signals for five olefinic protons, at $\tau = 2.6$, 3.42, 3.75, 3.82, and 4.25, whose chemical shifts exclude bicyclic isomeric structures.

If a solution of compound *(4)* in petroleum ether is treated with $Fe_2(CO)_9$[6] at room temperature, the carbonyliron complex *(5)*, m.p. 115–116 °C (after chromatography on silica gel and sublimation), is obtained. As is to be expected, the NMR spectrum of the complex *(5)* contains, besides signals for the ethyl protons, signals at higher magnetic field ($\tau = 6.68$, 4.90, 5.43, and 3.69) for the protons H-4, H-5, H-6, and H-7, a result that was obtained also by *E. O. Fischer* for the carbonyliron complex of ethyl azepine-1-carboxylate[7].



(5)

The conversion of *(2)* into *(4)* can be considered as a two-stage reaction, namely, 1,3-dipolar ring closure to the diaziridine *(3)* followed by valence-tautomerization to *(4)*.

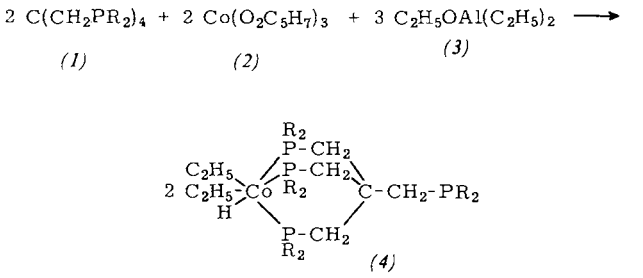
Preparation and Properties of a Bicyclic Hydridodiethylcobalt Complex [1]

By *J. Ellermann* and *W. H. Gruber*[*]

Recently we reported the synthesis of spiroheterocyclic alkylzinc complexes[2] incorporating tetrakis(diphenylphosphinomethyl)methane *(1)* that, in general, functioned as a doubly bidentate ligand[3,4]. We have now found that on reduction of tri(acetylacetonato)cobalt(III) *(2)* by ethoxydiethylaluminum *(3)*[5] in the presence of *(1)* a bicyclic hydridodiethylcobalt complex *(4)* is formed and not a spiroheterocyclic complex. The compound *(1)* thus here functions only once as a tridentate ligand[6].

Since the reaction of $P(C_6H_5)_3$ with *(2)* and *(3)* in a N_2 atmosphere leads to $N_2 \cdot Co[P(C_6H_5)_3]_3$[6a], it seems remarkable that the above reaction, which is also carried out in a N_2 atmosphere, shows no sign of the formation of an analogous N_2-containing complex.



(1) (2) (3) (4)

+ 2 C_2H_4 + 3 $C_2H_5OAl(O_2C_5H_7)_2$

R = C_6H_5

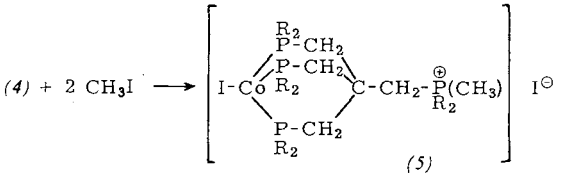
Experimental:

1 mmole each of *(1)* and *(2)* are dissolved in 10 ml of anhydrous, N_2-saturated benzene and treated with 1.5 mmoles of *(3)* slowly and with stirring at room temperature. Ethylene is evolved and the color changes within 30 min from green to dark brown. The small amounts of decomposition products that are formed during the reaction are filtered off, and the filtrate is concentrated in a vacuum to 3–5 ml and treated with 20 ml of ether. The brown crystals of 4-(diphenylphosphinomethyl)-1,1-diethyl-1-hydrido-2,2,6,6,7,7-hexaphenyl-2,6,7-triphospha-1-cobaltabicyclo[2.2.2]octane *(4)*, which separate within an hour, are filtered off, washed twice with 10 ml of diethyl ether, and dried in a vacuum. Compound *(4)* is extremely sensitive to air, soluble in benzene, acetone, or chloroform, and insoluble in petroleum ether, cyclohexane, or diethyl ether.

The composition and structure of *(4)* are proved by elemental analysis, cryoscopic determination of molecular weight in benzene, and the IR spectrum (νCo–H 1912 cm^{-1} w–m; characteristic absorptions[7] of the $Co(C_2H_5)_2$ group (cm^{-1}); νC–H 2985, 2970, 2910, 2875 (all w–m); $\delta_s CH_3$ 1169 m; ρCH_3 914 w–m, 891 s–m, 846 m, (?) 821 m; ρCH_2 647 m–st; νCoC_2 565 m, 548 w). Compound *(4)* is diamagnetic and has a UV spectrum such as is to be expected from a *cis* octahedral Co(III) complex (point group C_s)[8] [λ_{max} 28550 cm^{-1} (w–m, broad), 16750 cm^{-1} (m, broad)]. The intensity ratios of the νCoC_2 vibrations are also in accord with the assumptions.

When heated, compound *(4)* melts at 204 °C with decomposition, C_2H_6 and C_2H_4 being formed. IR spectroscopic examination of the pyrolysis residue suggests that a cobalt hydride complex is formed simultaneously.

In contrast to the hydride complexes H_3CoL_3 [L = $P(C_6H_5)_3$, $P(C_6H_5)_2C_2H_5$][9] and $H_2Co[P(C_6H_5)_3]_3$[10], compound *(4)* does not exchange its hydrogen for nitrogen. When the benzene solution of *(4)* is heated with an excess of CH_3I for one hour at 70 °C, methane, ethylene, and ethane are evolved (determined gas-chromatographically) and the pale brown cobalt(I)-phosphonium iodide complex *(5)* separates. Its



(4) + 2 CH_3I → *(5)* + CH_4 + C_2H_4 + C_2H_6

R = C_6H_5

composition and structure are proved by elemental analysis, magnetism (at 20 °C, μ = 2.5 B.M., corresponding to two unpaired electrons), conductivity in DMF (v = 1120 liter $mole^{-1}$, μ = 72 ohm^{-1} cm^2 $mole^{-1}$), and IR spectrum [$\nu\overset{\oplus}{P}-CH_3$ 660 w–m; $\nu_1\overset{\oplus}{P}-C_6H_5$ 1109 m–s; no absorption due to $HCo(C_2H_5)_2$ group]. The formation of methane is explained by reaction between hydride hydrogen and methyl carbonium ions. The simultaneous appearance of C_2H_4 and C_2H_6 is due to dismutation of the two ethyl groups[2]. Since *n*-butane is not seen to be formed, a radical mechanism is excluded.

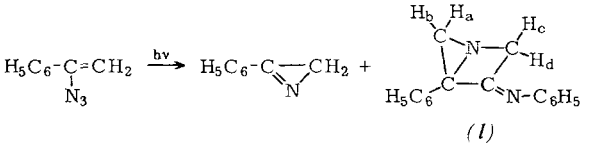
Formation of an Azabicyclopentane Derivative on Photolysis of α-Azidostyrene

By *F. P. Woerner*, *H. Reimlinger*, and *D. R. Arnold*[*]

Pyrolysis[1] and photolysis[2] of vinyl azide derivatives lead to azirine derivatives. In some cases ketene imines are formed as by-products.

After irradiating an approximately 6 % solution of α-azidostyrene in anhydrous benzene with filtered light from a mercury high-pressure lamp[3], we isolated 2-phenylazirine as main product (yield > 85 %) and a 10 % yield of 4-phenyl-3-phenylimino-1-azabicyclo[2.1.0]pentane *(1)* which is a derivative of a new heterobicyclic system.



(1)

A solution of α-azidostyrene (2.5 g) in anhydrous benzene (45 ml) was irradiated through a 2-mm thick Pyrex filter until gas evolution ceased (*ca.* 5 h), then the solvent was distilled off in a vacuum. The residue was cooled until crystals were formed. These were washed with cyclohexane [yield, 0.2 g of analytically pure *(1)*, m.p. 137–140 °C].

Elemental analysis and spectral results (NMR, mass spectrum, IR, and UV) indicate structure *(1)*. In the NMR spectrum[4] one sees two singlets with half-band width *ca.* 2 Hz at τ = 7.2 (H_a; relative intensity 1) and at τ = 8.38 (H_b; relative intensity 1). This accords with the coupling constant of the geminal protons of phenylaziridine[5]. The signals for the AB system H_c–H_d are at τ = 4.9 and 5.2 (relative intensity 2)

with a coupling constant of 16 Hz. The signal of the phenyl protons *ortho* to the imino nitrogen atom is a multiplet centered at τ = 2.4 (relative intensity 2); and that of the remaining aromatic protons is a multiplet centered at τ = 2.8 (relative intensity 8). Analogous substances[6] provide an indication of the shift of signals of the CH_2 protons on the four-membered ring to lower field owing to the neighboring nitrogen atom. Further, we also derive structure *(1)* from the mass spectrum, specifically from the appearance of the ion M−42 and of a fragment at *m/e* 42 ($H_2C{=}N{-}CH_2$). The compound is found to have molecular weight 234. The UV spectrum (in alcohol) includes an absorption band at 244 nm (ε = 12200). In the IR spectrum (KBr) the C=N absorption is at 6.2 μm and, remarkably, three absorption bands occur between 9.98 μm and 10.16 μm.

It is tempting to ascribe the formation of *(1)* to addition of ketene phenyl imine to phenylazirine. According to *Smolinsky*[1], phenylazirine and ketene phenylimine coexist after pyrolysis of α-azidostyrene. The characteristic ketene imine absorption[1] at 5 μm in the IR spectrum of our reaction mixture after photolysis can be explained by presence of a small amount of ketene phenyl imine. However, no trace of *(1)* is to be found in the gas chromatogram after pyrolysis of α-azidostyrene at 350 °C. Nor is any trace of *(1)* to be found in the mixture obtained on addition of azidostyrene to boiling phenylazirine (*ca.* 180 °C). From our results, together with the observation that *(1)* is also formed on photolysis of phenylazirine, we conclude that it is formed by photochemical and not by thermal activation. This is thus the first case of intermolecular photocycloaddition to a carbon-nitrogen double bond.

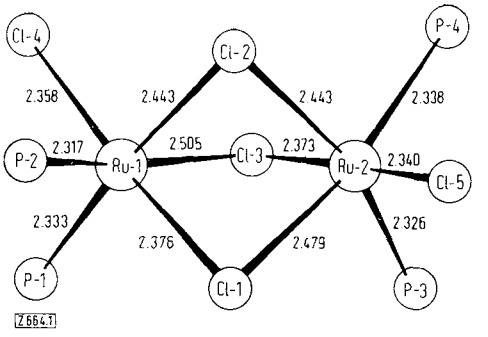
X-Ray Structure Analysis of Tri-μ-chlorobis[bis(tri-*n*-butylphosphine)-ruthenium Chloride]

By *G. Chioccola, J. J. Daly*, and *J. K. Nicholson*[*]

The synthesis of $Ru_2Cl_5[P(n\text{-}C_4H_9)_3]_4$ has been described recently and the results of chemical investigations suggest[1] the structure *(1)*. The complex has a magnetic moment of 0.75 B.M. per ruthenium atom[2] corresponding to one unpaired electron in the molecule.

The dark red crystals are monoclinic, space group $P2_1/c$ with a = 13.866, b = 16.003, c = 30.545 Å, β = 110.0°. There are four molecules in the unit cell and the observed density gives a molecular weight of 1170.7 (theoretical 1188.8). The intensities were measured on a linear diffractometer[3] and the structure was determined by Patterson and Fourier methods. A least squares refinement of 3776 planes gives a current *R*-factor of 0.083. The standard deviations of the Ru–Cl and Ru–P bond lengths are 0.0052 and 0.0054 Å respectively.



(1)

The X-ray analysis confirms the structure *(1)* and the Ru–Cl and Ru–P distances are shown in the figure. The coordination round the ruthenium atoms is approximately octahedral (the largest angular distortion is 12.4°) and the environments of these atoms are very similar. The Ru···Ru distance is 3.115 Å, and is thus much longer than that found in the metal (2.650 Å)[4]. The Ru–Cl distances fall into two groups: those *trans* to other Ru–Cl bonds are considerably shorter (2.340–2.376 Å) than those (2.444–2.505 Å) *trans* to Ru–P bonds.

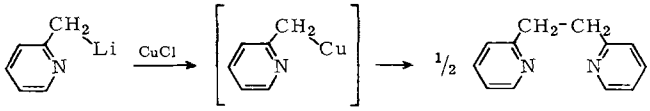
Dimerization of Azaallyl, Diazaallyl, and Oxaazaallyl Groups by Way of Copper-containing Intermediates[1]

By *Th. Kauffmann, G. Beissner, E. Köppelmann, D. Kuhlmann, A. Schott*, and *H. Schrecken*[*]

We are studying systematically the dimerization of organic compounds by way of organo copper derivatives, a reaction whose unusually wide applicability[2] is not yet fully recognized[3,4].

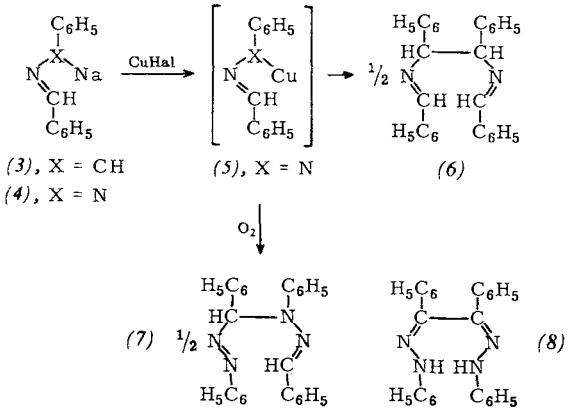
We observed dimerization of the 3-azaallyl group contained in *(1)* when treating the compound[5] with 1 molar equivalent of CuCl or $CuBr_2$ in tetrahydrofuran/ether (1:1) under nitrogen at 60 °C. The product *(2)* was formed in, respectively 72 and 78 % yield with separation of Cu or CuBr[6].



(1) *(2)*

When CuI in dimethoxyethane at 85 °C is treated with 1 molar equivalent of the deep red compound *(3)* (formed by the action of $NaNH_2$ on *N*-benzylidenebenzylamine), the 2-azaallyl group of *(3)* dimerizes analogously, yielding compound *(6)* (58 % yield) specifically in the *meso*-form (m.p. 163 °C; lit.[7], 164 °C).

The 1,2-diazaallyl group in *(4)* is also coupled by successive action of 1 molar equivalent of CuCl and oxygen in dimethoxyethane at 60 °C, to give a known[8] product of m.p.

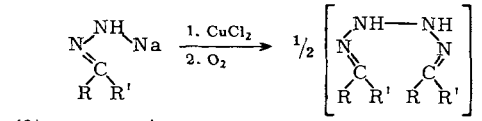


(3), X = CH
(4), X = N
(5), X = N
(6)

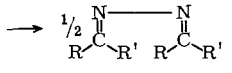
(7)
(8)

191 °C (yield 59 %), to which structure *(7)* applies[9]. Compound *(8)*, which is obtained on oxidation of benzaldehyde phenylhydrazone by iodine[10], is not formed. The Cu(I) compound *(5)* arising as intermediate is thermally stable but very sensitive to oxygen; it was isolated[11] as a colorless crystalline substance and converted into *(7)* by way of a thermally labile green Cu(II) compound.

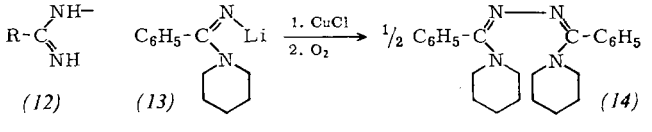
Treating compounds *(9)* and *(10)* analogously with $CuCl_2/O_2$ led to *ca.* 40 % yields of the corresponding azines. The compounds *(11)*, or the derived copper compounds, that are to be assumed as primary dimerization products apparently undergo secondary changes.



(9), R = H; R' = C_6H_5
(10), R = R' = CH_3
(11)

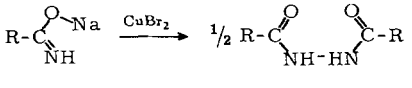


Here circumstances are thus similar to those in the case of the dimerization of 1,3-diazaallyl groups of the type *(12)* by means of $CuCl/O_2$, where substituted *s*-triazoles result from secondary reactions[3,12]. In this connection it is of interest that successive action of one molar equivalent each of CuCl and oxygen on *(13)* in dimethoxyethane at 65–75 °C affords a product *(14)* in 75 % yield.



(12)
(13)
(14)

The 1,3-oxaazaallyl group of *(15)* was not dimerized, to yield *(17)*, when *(15)* was treated with CuCl or $CuCl/O_2$ in tetrahydrofuran. However, *(17)* was obtained when *(15)* was treated with one molar equivalent of $CuBr_2$ in tetrahydrofuran, though the yield was only 26 % calculated on the benzamide taken (43 % calculated on the benzamide consumed). Addition of oxygen barely increased the yield. In the analogous dimerization of the 1,3-oxaazaallyl groups of *(16)* with $CuBr_2$, product *(18)* was formed in 30 % yield



(15), R = C_6H_5
(16), R = $(CH_2)_4$-CH_3
(17), R = C_6H_5
(18), R = $(CH_2)_4$-CH_3

calculated on the hexanamide taken (49 % calculated on the hexanamide consumed).

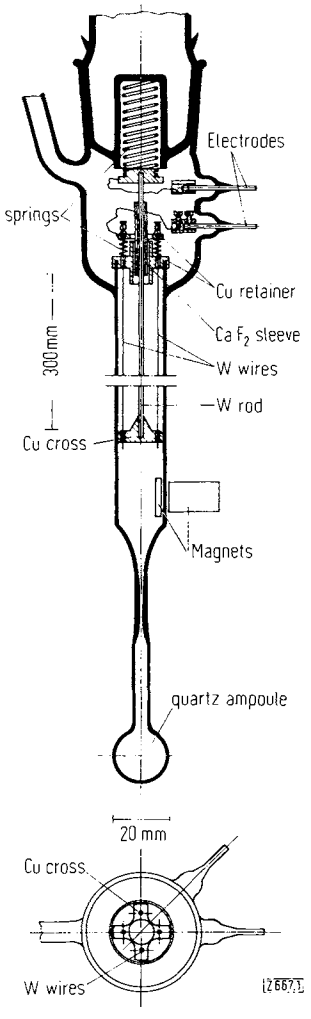
Preparation of Tungsten Pentafluoride

By *J. Schröder* and *F. J. Grewe*[*]

Not only tungsten hexafluoride but also lower tungsten fluorides play an appreciable part in the chemical transport reactions by means of which fluorine leads to homogenization of tungsten filaments in incandescent lamps[1]. The fluorides dissociate to tungsten and fluorine on tungsten filaments whose temperatures exceed 2000 °C, and tungsten is transported from the colder to the hotter zones of the glowing body until the temperature of the hot filament is completely homogeneous. At lower temperatures, lower fluorides of tungsten are formed and these disproportionate in the gas space or on the walls of the vessel into tungsten metal and its hexafluoride. However, if the wall of the vessel is cooled, the lower fluorides can be trapped out of the gas space and can be thus isolated.

For the synthesis of tungsten pentafluoride the carefully baked out quartz apparatus (Fig.) was filled with 500 torr of WF_6 and plunged into a cooling bath at −50 to −60 °C. The WF_6 condensed in the quartz ampoule and a WF_6 vapor pressure of *ca.* 10 torr was set up in the gas space. The four tungsten wires were heated to 500 to 700 °C; WF_5 then separated on the cold quartz wall as a yellow crystalline substance; after the excess of WF_6 had been pumped off, the



pentafluoride was transferred to the ampoule by manipulation of the magnetic rod.

WF_5 can be kept undecomposed in a closed quartz vessel. At room temperature the vapor pressure amounts to *ca.* 1 torr and the substance can be sublimed from 20 to −30 °C without decomposition.

WF_5 is exceedingly hygroscopic and decomposes at once in the air. It reacts with dilute NaOH + H_2O_2 to give a clear solution of tungstate and fluoride. Analyses for fluorine and tungsten give a ratio F:W = 5:1. Determination of the oxidation number gives W^{5+} required for WF_5. Analyses of the sublimed material give the same result. At 50 to 70 °C, WF_5 disproportionates to WF_6 and a dark grey solid that also reacts with dilute NaOH + H_2O_2 to give tungstate and fluoride. Analysis of the decomposition product gives a F:W ratio of 4:1 and oxidation state W^{4+}.

The equation

$$2\ WF_5 \rightarrow WF_6 + WF_4$$

is derived from the amounts of WF_5 used, of WF_6 produced, and of the dark grey decomposition residue.

The dark grey decomposition product has the empirical formula WF_4 and is amorphous to X-rays, whereas WF_5 gives sharp X-ray diagrams with the following *d* values: 7.879 (w); 7.120 (vw); 5.205 (m^+); 4.493 (w^+); 4.218 (s^+); 3.958 (s); 3.683 (w); 3.567 (m); 3.355 (s); 3.271 (w^+); 3.112 (vw); 3.059 (s^+); 2.941 (vw); 2.867 (w); 2.772 (s); 2.731 (s); 2.652 (vw); 2.581 (vw); 2.532 (vw); 2.447 (s); 2.401 (m); 2.374 (m); 2.302 (s); 2.216 (s); 2.195 (vw); 2.130 (m); 2.009 (s^+); 1.992 (m); 1.975 (m); 1.926 (w); 1.911 (w); 1.871 (s); 1.802 (vw); 1.777 (m); 1.738 (vw); 1.723 (m^+); 1.690 (m); 1.673 (m); 1.652 (w); 1.637 (vw); 1.611 (w); 1.591 (w); 1.558 (w); 1.495 (s); 1.483 (w); 1.471 (w); 1.463 (vw); 1.428 (s^-); 1.414 (m^+); 1.397 (m^+); 1.383 (m^+); 1.368 (m^+).

Preparation and Structure of Methylpotassium

By *E. Weiss* and *G. Sauermann*[*]

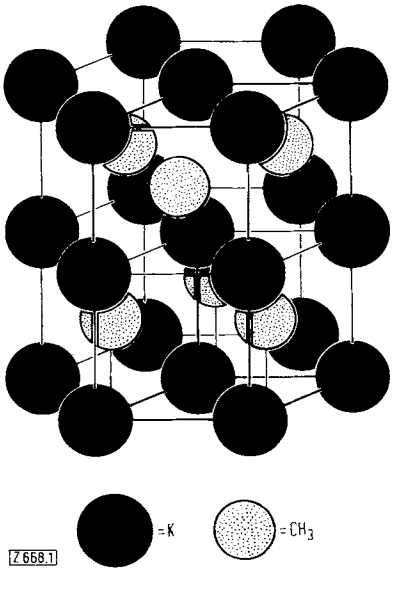
Continuing our studies of alkyl derivatives of the alkali metals[1] we have worked out new methods of preparing CH_3K and have determined its crystal structure. We obtained CH_3K (a) by reaction of dimethylmercury dissolved in pentane with a liquid K–Na alloy in excess and (b) by double decomposition of CH_3Li and K *tert*-butoxide dissolved in ether at −10 °C.

$$\text{(a)}\ (CH_3)_2Hg + K/Na \rightarrow CH_3K + Na/K/Hg$$

$$\text{(b)}\ CH_3Li + (CH_3)_3COK \rightarrow CH_3K + (CH_3)_3COLi$$

Reaction of alkyllithiums with alkali-metal *tert*-butoxides in hexane or heptane has been used previously only for preparation of organylsodiums containing rather large alkyl groups and has given impure products when applied to organylpotassiums[2]. We found that the reaction can also be effected in ether and is then suitable for, *inter alia*, the preparation of methylpotassium. It is, however, necessary to work fast and with cooling in order to avoid ether cleavage by the very reactive CH_3K. Also the CH_3Li is used in slight excess since alkyllithiums have a stabilizing effect on ethereal solutions of higher alkyl-alkali metals[3]. The products therefore contain small amounts of Li, but they give X-ray diagrams identical with those of CH_3K prepared by method (a).

When dry, the preparations are highly pyrophoric, colorless, microcrystalline powders whose X-ray diagrams can be indexed on a hexagonal structure with lattice constants $a_0 = 4.27_8$ and $c_0 = 8.28_8$ Å. The structure is of the NiAs type (space group $P6_3/mmc$) with two formula weights in the unit cell and an X-ray density of 1.37 g cm^{-3}.



Whereas CH_3Li[4], and very probably also CH_3Na[5], form tetrameric structural units with an inner metal tetrahedron surrounded by four methyl groups, CH_3K provides the first case with isolated methyl groups in the lattice, these groups being each surrounded by six nearest K atoms in trigonal-prismatic arrangement. Isolated ethyl groups occur in ethyl-sodium which forms a layer structure[5].

Since the H atoms have only feeble scattering power their location is difficult. Two ν-C–H frequencies (at 2805 and 2740 cm^{-1}) in the IR spectrum of CH_3K (KBr disks) indicate the possibility of a trigonal-pyramidal structure of the methyl groups which may then be built as methyl anions into a cation lattice.

Preparation of *N*-Aminoaziridines and Rearrangements to Hexulose Hydrazones[1]

By *H. Paulsen* and *D. Stoye*[*]

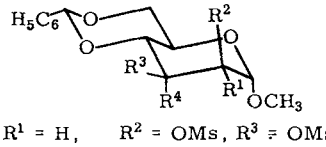
Reaction of terminal-vicinal di-*O*-mesyl groups such as are present in 3-*O*-benzyl-1,2-*O*-isopropylidene-5,6-di-*O*-mesyl-D-glucofuranose *(1)* with hot anhydrous hydrazine (4 h at 70 °C) gives the *N*-aminoaziridine *(3)*, which can be obtained as a syrup ($[\alpha]_D^{20} = -78.3°$; $c = 1.4$ in $CHCl_3$) in 80 % yield by extraction of by-products into ether and shaking of the residual solution with chloroform. The product *(3)* forms crystalline hydrazones with carbonyl compounds in the presence of a trace of acid; *e.g.* with benzaldehyde the hydrazone *(4)* [m.p. 70–73 °C, $[\alpha]_D^{20} = -103.7°$, $c = 1.0$ in $CHCl_3$; NMR of *(4)*: $\tau = 7.5$ (H-5), $\tau = 7.89$ (H-6), $\tau = 8.00$ (H-6'), $J_{5,6} = 7.5$, $J_{5,6'} = 5.0$. $J_{6,6'} = 1.0$ Hz] is formed. In *(3)* two protons are exchangeable, but in *(4)* none.

Reaction of *(3)* occurs by nucleophilic substitution on C-6 of *(1)*, leading to the 6-deoxy-6-hydrazino-5-*O*-mesylate *(2)*, which reacts further by a neighboring group reaction to give the *N*-aminoaziridine *(3)*. Grob fragmentation[2] of *(2)* occurs as a competing reaction to the extent of 16 % and affords the unsaturated sugar *(5)*[3] as olefinic fragment. Fragmentation is the main reaction of α-*O*-mesylhexurono-hydrazides and leads to sugar ketenes[4].

Hydrogenation of *(3)* with Raney nickel and hydrazine in ethanol at 50 °C affords a 5-amino-5,6-dideoxy-sugar *(6)* with the L-*ido*-configuration by selective ring opening at C-6. After removal of the solvent by distillation and purification by column chromatography (silica gel; benzene/ethanol = 9:1), the product *(6)* is obtained in 65 % yield as a syrup ($[\alpha]_D^{20} = -38.9°$; $c = 1.5$ in $CHCl_3$). The route *via* the *N*-amino-aziridines is thus a simple method for synthesis of 5-amino-5,6-dideoxy-sugars. If the D-*allo*-[5] or D-*gulo*-compound[6] corresponding to *(1)* is treated with hydrazine, one obtains *via* a L-*talo*- or L-*manno*-*N*-aminoaziridine the 5-amino-5,6-dideoxy-sugars corresponding to *(6)* but with, respectively, the L-*talo*-configuration (54 % yield; syrup; $[\alpha]_D^{20} = +108.3°$, $c = 1.2$ in $CHCl_3$; crystalline *N*-acetyl derivative, m.p. 106–107 °C, $[\alpha]_D^{20} = +80.3°$, $c = 0.9$ in $CHCl_3$) or the L-*manno*-configuration (syrup; $[\alpha]_D^{20} = +57.9°$, $c = 1.0$ in $CHCl_3$; crystalline *N*-acetyl derivative, m.p. 77–81 °C, $[\alpha]_D^{20} = +42.2°$, $c = 0.6$ in $CHCl_3$).

Whe *(3)* is warmed in pyridine/acetic anhydride (100 °C, 48 h) a new type of rearrangement occurs, yielding the 6-deoxy-5-ulose acetylhydrazone *(7)* (61.5 % yield, m.p. 114–118 °C, $[\alpha]_D^{20} = -72.5°$, $c = 1.1$ in $CHCl_3$). The ring opening is again selective, with migration of hydrogen from C-5 to C-6. This reaction affords a simple route to 6-deoxy-5-ulose derivatives.

Vicinal di-*O*-mesyl groups attached to a ring (*e.g.* to the six-membered ring) behave differently in the reaction with hydrazine and do not give bicyclic *N*-aminoaziridines. All the possibilities of reaction were investigated with the methyl 4,6-*O*-benzylidene-2,3-di-*O*-mesyl-D-hexopyranosides *(8)*–*(11)*.



manno *(8)*, R^1 = H, R^2 = OMs, R^3 = OMs, R^4 = H

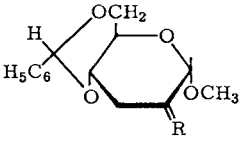
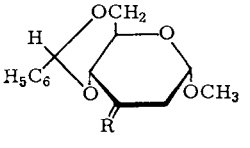
gluco *(10)*, R^1 = OMs, R^2 = H, R^3 = OMs, R^4 = H
altro *(11)*, R^1 = H, R^2 = OMs, R^3 = H, R^4 = OMs

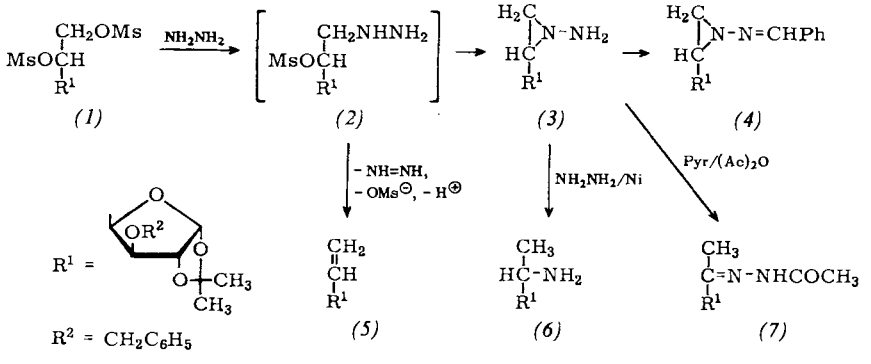


(12), R = H_3CCONH-N=
(13), R = O=



(14), R = H_3CCONH-N=
(15), R = O=

A primary *trans*-elimination is the main reaction when compounds with a hydrogen atom and an *O*-mesyl group in *trans*-diaxial relation are heated with hydrazine, even at 70 °C (4 h). In the case of the *manno*-compound *(8)*, elimination of the axial *O*-mesyl group from C-2 leads to the 2,3-enol 3-mesylate; cleavage and rearrangement thereof gives a



3-keto compound which reacts with hydrazine to give the hydrazone, which was isolated as acetate *(14)* (85 % yield; m.p. 132–135 °C, $[\alpha]_D^{20} = +135°$, $c = 0.7$ in $CHCl_3$). The *allo*-compound *(9)* eliminates the axial *O*-mesyl group from C-3, giving the 2,3-enol 2-mesylate, whose further analogous reaction and acetylation affords a 3-deoxy-2-ulose acetylhydrazone *(12)* (55 % yield; m.p. 212–214 °C, $[\alpha]_D^{20} = -23.8°$, $c = 0.9$ in $CHCl_3$).

The *gluco*- and *altro*-compounds *(10)* and *(11)* cannot undergo *trans*-elimination. Thus, in these cases, nucleophilic substitution again becomes the reaction with hydrazine (at 140 °C, 5 h). The α-hydrazino-*O*-mesylates formed with inversion as primary products contain *trans*-hydrogen atoms and *O*-mesylate groups, so that elimination follows as a secondary reaction, leading to alkenylhydrazines which can be isolated, after acetylation, as rearranged deoxy-ulose acetylhydrazones. Reaction of *(10)* and *(11)* in this way yields a mixture of *(12)* and *(14)*, wherein *(12)* preponderates since nucleophilic attack on C-2 is apparently easier than on C-3. Transhydrazonization of *(12)* and *(14)* with benzaldehyde in weakly acidified dioxane solution makes accessible the 3-deoxy-2-ulose derivative *(13)* (53.7 % yield, m.p. 112–113 °C, $[\alpha]_D^{20} = +93.8°$, $c = 1.2$ in $CHCl_3$), and the 2-deoxy-3-ulose derivative *(15)* (75 % yield, m.p. 172 to 173 °C, $[\alpha]_D^{20} = +129°$, $c = 1.2$ in $CHCl_3$ [7]).

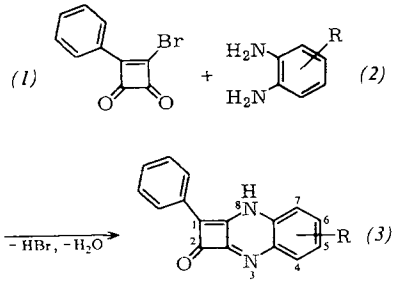
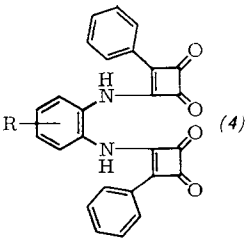
Synthesis of Cyclobuta[*b*]quinoxalines [**]

By *W. Ried* and *W. Kunstmann* [*]

1-Phenylcyclobuta[*b*]quinoxalin-2(8*H*)-ones *(3)* are formed on reaction of 1-bromo-2-phenyl-1-cyclobutene-3,4-dione *(1)* [1] with *o*-phenylenediamines *(2)*.



In no case are isomers obtained. The position of the substituents is determined by the fact that the most basic amino group in *(2)* attacks the other reactant *(1)* at position 1. Thus with symmetrical *o*-diamines (*o*-phenylenediamine, 2,3-naphthylenediamine) a by-product *(4)* is found which, on the basis of its composition, must arise from *(1)* and *(2)* in the ratio 2:1 (yield < 5 %).



R	*(4)*, m.p. (°C)	Properties	νC=O	(cm⁻¹)
H	235 (CH_3OH)	Pale red platelets	1770	1730
4,5-Benzo	259 (CH_3CN)	Pale red needles	1770	1730

No unsymmetrical *o*-diamine affords an analogous by-product.

Indications in favor of the structure of the new compounds will be adduced for the case of 1-phenylcyclobuta[*b*]quinoxalin-2(8*H*)-one *(3)*, R = H: Elemental analyses are in exact agreement with theory. A molecular weight of 246 (theor., 246.3) is found from the mass spectrum. Study of the NMR spectrum is not yet concluded; the spectrum shows only aromatic protons. It is not yet clear whether failure to find the N–H proton is due to technical causes (*e.g.* low solubility) or intermolecular association. The IR spectrum favors the latter explanation; it contains a very broad band around 3000 cm^{-1} for which the NH group is responsible. As expected, this band is not present in the spectrum of the 8-CH_3 derivative. At 1760 cm^{-1} there is a very strong carbonyl band, which is typical of comparable cyclobutenones [1,2]. The characteristic bands at 1670 cm^{-1} and 1610 cm^{-1} can be ascribed to stretching vibrations of the C=N and C=C double bond, respectively, of the four-membered ring.

The structure of the by-products *(4)* was proved by comparison with the 1-anilino-2-phenyl-1-cyclobutene-3,4-diones that are formed from *(1)* and aromatic mono- and *p*-diamines under the same conditions.

Experimental: Synthesis of compounds (3)

2.4 g (0.01 mole) of *(1)* is dissolved in 50 ml each of tetrahydrofuran and glacial acetic acid. 0.01 mole of *(2)* dissolved in 20 ml each of tetrahydrofuran and glacial acetic acid is added in one portion with stirring at room temperature.

[a] Decomposition usually occurs at the melting point of these compounds.

(Diamine salts are introduced in as concentrated aqueous solution as possible with addition of the appropriate amount of sodium acetate.) The solution immediately becomes deep red or black; after a short time it becomes turbid; a yellow precipitate is formed. The mixture is stirred for some hours further, then the product is sucked off, washed with meth-

anol, and recrystallized as indicated in the Table. Yields: 20–30 %.

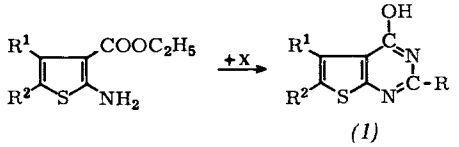
New 4-Hydroxythienopyrimidines

By *W. Ried* and *R. Giesse* [*]

Hitherto, little was known about 4-hydroxythienopyrimidines and they were accessible only by relatively complicated methods [1]. We have found that 4-hydroxythienopyrimidines can be obtained, some of them in good yield, from 2-amino-3-thiophenecarboxylic esters [2] and 3-amino-2-thiophenecarboxylic esters [3] by reaction with nitriles or their derivatives such as imidic esters, amidines, amidoximes, and acid amides; the products mostly crystallize as colorless needles.

4-Hydroxythieno[2,3-*d*]pyrimidines *(1)* are obtained from 2-amino-3-thiophenecarboxylic esters.

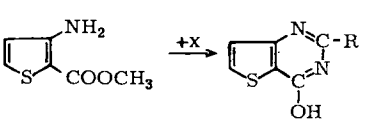


(1)

R	R^1	R^2	*(1)*, m.p. (°C)	*(1)*, yield (%)	X	Conditions
C_6H_5	H	C_2H_5	214	25	C_6H_5–C(NH)OC_2H_5	14 h/160 °C
Cl_3C	CH_3	CH_3	248	40	Cl_3C–C(NH)OCH_3	2 h/130 °C
Cl_3C	H	C_2H_5	220	50	Cl_3C–CN	8 h/50 °C
C_6H_5–CH_2	–$(CH_2)_4$–		260	30	C_6H_5–CH_2–CN	15 h/$AlCl_3$/b.p.
H	H	C_6H_5	260	95	H_2N–CHO	15 h/b.p.

4-Hydroxythieno[3,2-*d*]pyrimidines *(2)* are obtained from 3-amino-2-thiophenecarboxylic esters.

Decisive for occurrence of the reaction is sufficient basicity of the nitrogen in the aminothiophenecarboxylic ester in respect of the carbonium C atom of the nitrile or the nitrile derivatives. This condition is satisfied by use of the polar solvent pentyl alcohol and of anhydrous aluminum chloride or concentrated sulfuric acid as catalyst, or by reaction of the components without a solvent or catalyst at higher temperatures. Intermediates could not be isolated.



(2)

R	*(2)*, m.p. (°C)	*(2)*, yield (%)	X	Conditions
p-H_3C–C_6H_4	276	45	*p*-H_3C–C_6H_4–C(NH)OC_2H_5	15 h/160 °C
Cl_3C	234	90	Cl_3C–C(NH)OCH_3	12 h/165 °C
H	220	50	H_2N–CHO	12 h/b.p.

Preparation of 4-hydroxythieno[2,3-d]pyrimidines (1):

0.01 mole of 2-amino-3-thiophenecarboxylic ester and an equimolar amount or slight excess of imidic ester, nitrile, or formamide were allowed to react under the conditions stated. After the reaction had occurred, the mixture was cooled for some time (the product often crystallized from the hot mixture), added to a little ether, and filtered with suction. The product was washed with ether and then recrystallized, with addition of active charcoal, from alcohol or dioxane.

Preparation of 4-hydroxythieno[3,2-d]pyrimidines (2):

1.57 g (0.01 mole) of methyl 3-amino-2-thiophenecarboxylate and a slight excess of imidic ester or formamide were allowed to react under the stated conditions. Crystallization began even during the heating of the reaction mixture. The mixture was then cooled for a short time and the crystalline residue was filtered off. A second crop of crystals was obtained by heating the filtrate again for a couple of hours. The combined crystals were washed with ether and recrystallized from alcohol or dioxane with addition of active charcoal.

PH_3 – A New Ligand in a Transition Metal Complex

By *E. O. Fischer, E. Louis,* and *R. J. J. Schneider* [*]

Previous experiments have shown that the binuclear complex compound $[V(CO)_4PH_2]_2$ containing two PH_2 bridges is the exclusive product when $V(CO)_6$ reacts with PH_3, hydrogen being evolved during the process [1]. We have now succeeded in incorporating PH_3 as a unidentate ligand photochemically into a metalcarbonyl compound, by exchange of CO for PH_3.

We obtained tricarbonylcyclopentadienylphosphinevanadium(I), π-$C_5H_5V(CO)_3PH_3$, by UV irradiation of a solution

of π-$C_5H_5V(CO)_4$ in tetrahydrofuran or benzene under a phosphine atmosphere for several hours at room temperature[**].

$$\underset{(1)}{\pi\text{-}C_5H_5V(CO)_4} + PH_3 \xrightarrow{h\nu} \underset{(2)}{\pi\text{-}C_5H_5V(CO)_3PH_3} + CO$$

In agreement with the low symmetry of *(2)* three sharp bands appear in the ν_{CO} region of the IR spectrum (*n*-hexane solution) at 1975 (s), 1901 (s), and 1876 (vs) cm^{-1}. The ^1H–NMR spectrum of *(2)* in C_6D_6 shows two doublets at τ = 5.72 (int. 5, C_5H_5) with $J_{P-V-C_5H_5}$ = 1.5 Hz and τ = 6.81 (int. 3, PH_3) with J_{P-H} = 324 Hz[5].

From the position of the ν_{CO} frequencies (Table 1) it follows that the d_π–d_π back-donation in the PH_3 complex must be stronger than in $P(Alkyl)_3$ or $P(Aryl)_3$ ligands. According to a recent classification of P-containing ligands of metal carbonyls according to their π-acceptor strengths[4], this would correspond approximately to that of a $PCl(Aryl)_2$ group.

Table 1. ν_{CO} bands (cm^{-1}) of $C_5H_5V(CO)_3PX_3$ complexes and of $C_5H_5V(CO)_4$ in hexane.

$C_5H_5V(CO)_3PH_3$	1975 (s)	1901 (s)	1876 (vs)
$C_5H_5V(CO)_3P(C_4H_9)_3$ [1]	1951	1874	1854
$C_5H_5V(CO)_3P(C_2H_5)_2C_6H_5$ [2]	1958	1880	1851
$C_5H_5V(CO)_3P(C_6H_5)_3$ [3]	1962	1884	1865
$C_5H_5V(CO)_4$	2031	1931	1901

The ^1H–NMR spectrum of free PH_3 in C_6D_6 shows a doublet at τ = 9.13 with a coupling constant J_{P-H} = 186.5 Hz[5]; liquid PH_3 shows J_{P-H} = 182.2 ± 0.3 Hz[6]. The considerable increase in J_{P-H} in the complex is in agreement with the decisive effect of the backdonation metal → phosphorus on linkage of PH_3 that follows from the ν_{CO} frequencies.

Preparation of (2):

All operations must be conducted with care under an inert gas. Even small amounts of oxygen yield explosive mixtures with PH_3, and these are self-inflammatory at low pressures.

One gram (4.38 mmoles) of tetracarbonylcyclopentadienylvanadium(I) *(1)* is dissolved in 30 ml of tetrahydrofuran or benzene contained in a 500 ml single-necked flask fitted with two taps. The first of these is connected *via* a three-way tap with a low-pressure and a high-pressure manometer; the second is connected with a 200 ml cold trap containing *ca.* 68 mmoles of PH_3 condensed by means of liquid N_2. While intense cooling is maintained (the reaction flask at −78 °C, the cold trap at −196 °C) the system is evacuated to water-pump vacuum and then closed. The cooling baths are then removed from the flask and trap. After complete evaporation of the PH_3 and consequent saturation of the solvent there remains a slight positive pressure (10–30 torr) in the apparatus. The solution is irradiated for 8 h with UV light from a high-pressure lamp (Q 81, Quarzlampen GmbH., Hanau). During irradiation the solution is shielded from the heat developed by the UV lamp and is subjected to vigorous magnetic stirring.

By the end of the reaction the solution has turned from orange-red to brownish-red. All the gas in the flask is removed by means of N_2, and the solution is filtered over filterwool on a G3 sinter and evaporated to dryness. The residue is purified by column chromatography (Al_2O_3 S neutral active, 5 % H_2O; Riedel) with hexane as eluant. Unchanged *(1)* (yellow zone) is followed by *(2)* as a red zone; the latter is collected separately, recovered by evaporation in a vacuum, and recrystallized from pentane. After being dried for 5 h in a high vacuum, *(2)* is obtained as red-brown platelets of m.p. 110 °C (decomp.) (yield *ca.* 45 %). The product *(2)* dissolves readily in benzene to give a red solution and moderately readily in hexane or pentane to give an orange-red solution. The solutions are decomposed by air within a few minutes.

Deprotonation of Glycine Amide in a Ternary Copper(II)-Complex[1]

By *H. Sigel*[*]

In Cu^{2+} peptides, and presumably also in Cu^{2+} proteins, the deprotonated amide group plays an important part in binding metal ions[2a]. Deprotonation of the amide group in binary Cu^{2+} peptides and peptide-like complexes has been studied repeatedly (cf., *e.g.*[2]). We have investigated deprotonation of such a group in a ternary Cu^{2+} complex that resembles an enzyme/metal-ion/substrate complex. As ligands we chose 2,2′-bipyridyl (Bipy) and glycine amide (HL).

Three protons are liberated on titration[3] of a 1:1 solution of Cu^{2+} and glycine amide hydrochloride. The first of these is derived from the ammonium group of the protonated glycine amide, the second from the amide group, and the third from a hydrate water molecule[4]. On titration of a solution that contains the Cu^{2+}-2,2′-bipyridyl 1:1 complex (this complex is formed to the extent of more than 94 % under the titration conditions) in place of hydrated Cu^{2+} only two protons are liberated, the second being again derived by deprotonation of the amide group. Liberation of a further proton does not take place because there is no hydrate water molecule within the smaller coordination sphere of a Cu^{2+} bound in this way.

The difference in stabilities

$$\log K^{CuBipy}_{CuBipyHL} - \log K^{Cu}_{CuHL} = -0.4$$

between the ternary and the binary Cu^{2+} complex is of the order to be expected[1,5] for addition of an O–N ligand to Cu^{2+}-Bipy (the amide group coordinates first through the oxygen[2a]). The acidity of the proton of the amide group in the ternary Cu^{2+} complex is, it is true, smaller by 0.7 pK unit than that of the binary complex, which has $pK^{H}_{CuBipyHL}$ = 7.71 ± 0.06, but it is nevertheless very high. The lower acidity depends mainly on the somewhat lower stability of the ternary complex (cf. also[1]).

The important result of our investigation is thus that Cu^{2+} bound to one ligand but containing two further hydrated coordination positions can coordinate with a further ligand containing an amide group and that this group can still be deprotonated in the physiological pH range. Accordingly there is the possibility that an enzyme is at least partly coordinated by way of deprotonated proteinamide groups even in enzyme/Cu^{2+}/substrate complexes.

Stability and acidity constants of the ternary Cu^{2+}—2,2'-bipyridylglycine amide complex and of the binary Cu^{2+}-glycine amide system ($I = 0.1$; $NaClO_4$; $t = 25\,°C$) [a,b].

Formation of 3,4-Diaza-1,3,5-hexatrienes from Alkenylamines and Diazoalkanes

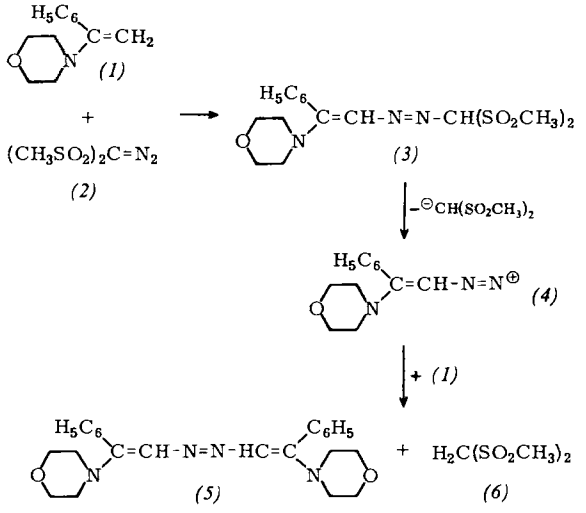
By *U. Schöllkopf, E. Wiskott*, and *K. Riedel*[*]

Reaction of alkenylamines with the usual diazoalkanes appears either not to occur or to be extremely sluggish[1]. We have now found that reaction occurs readily with those diazoalkanes that have pronounced diazonium character. Transfer of the diazo group and subsequent coupling thus lead to 3,4-diaza-1,3,5-hexatrienes.

For instance, if dimesyldiazomethane *(2)* in chloroform is allowed to react with two equivalents of α-morpholinostyrene *(1)* for 24 h at room temperature, there is formed, besides dimesylmethane *(6)* (84 % yield), a *ca.* 65 % yield of 1,6-dimorpholino-1,6-diphenyl-3,4-diazahexatriene *(5)*, m.p. 210 to 212 °C (decomp.) (after precipitation from chloroform or tetrahydrofuran by methanol); NMR ($DCCl_3$, τ): 2.6 (m, 10 H); 3.16 (s, 2 H); 6.3 (q, 8 H); 7.0 (q, 8 H); UV (λ_{max}, nm, CH_3OH or C_6H_{12}): 261 or 254 (8800), 431 or 401 (28000) [2].

For isolation of *(5)* the mixture is evaporated to small bulk and filtered; *(5)* is then precipitated from the filtrate by methanol. Bis(phenylsulfonyl)diazomethane and ethyl nitrodiazoacetate [3] react in the same way as *(2)*, but ethyl diazoacetate itself and diphenyldiazomethane do not react.

Presumably *(1)* and *(2)* first yield the azo compound *(3)* which then reacts further with a second molecule of α-morpholinostyrene *(1)* – perhaps in a S_N1-like reaction by way of the vinyldiazonium ion *(4)* [4] – to give *(5)* and *(6)*.



As shown by the comparatively simple NMR and electron spectra, only one of the six stereoisomers theoretically possible for *(5)* is formed; but it is not yet known which.

(5) dissolves in 2 N HCl with shift of λ_{max} from 261 to 248 nm and from 431 to 346 nm. Protonation probably occurs on the nitrogen atom of the morpholine group where, according to HMO calculations [5], the π-electron density is greatest. If *(5)* is set aside in 1 N hydrochloric acid for 24 h it is hydrolyzed to the phenacylhydrazone *(7)* of phenylglyoxal.

Mass-spectrometric Study of the Synthesis of NH_3 on Iron Tips[1]

By *W. A. Schmidt*[*]

In spite of the great importance of heterogeneous catalytic processes and of the large amount of work devoted to its study, the surface processes occurring on the catalyst are not yet satisfactorily clarified. We have attempted to apply, in the case of NH_3 synthesis, the results of field ion mass spectrometry on ionization of NH_3 and N_2/H_2 mixtures on iron to the solution of this problem. Field ionization makes it possible to ionize molecules that are interacting with a metal (tips) from the gas phase (pressure of *ca.* 10^{-4} torr) and to analyze them mass-spectrometrically. In view of the high sensitivity of the mass spectrometer, it seems reasonable to expect that even ions formed from molecules adsorbed on the metal surface will be detectable.

The apparatus used was a 60° sector field mass spectrometer[2]. The residual gas pressure was reduced to $\leq 10^{-9}$ mm; there was no disturbance from water vapor during the mass spectrometric measurements.

Table 1. Types of ions and intensities in the field ion mass spectrum of NH_3 on an iron tip.

Type of ion	Intensity (arby.) [a]	Type of ion	Intensity (arby.)	Type of ion	Intensity (arby.)
N_2^+	≤ 1.0	N_3^+	3.5	NH_3^+	2.3×10^4
N_2H^+	5.0×10^3	N_3H^+	2.5	NH_4^+	1.0×10^6
$N_2H_2^+$	3.5×10^1	$N_3H_2^+$	6.5	$NH_4^+\cdot NH_3$	2.85×10^3
$N_2H_3^+$	1.0×10^2				
$N_2H_4^+$	1.0×10^1	$N_3H_4^+$	1.5	N_4^+	1.2
$N_2H_5^+$	3.3×10^1	$N_3H_5^+$	1.0	N_4H^+	1.0
$FeN_2H_n^+$		$FeN_3H_n^+$		$FeN_4H_n^+$	
n=0,1,..,6	1.0—10.0	n=0,1,..,9	1.0—10.0	n=0,1,..12	1.0—10.0

[a] arby. = arbitrary (scale units).

Table 1 shows the types of ions and their intensities for the field ion mass spectrum of NH_3 on an iron tip. The field strength was a few 10^7 V/cm, and the NH_3 pressure was 4×10^{-4} torr; tip and gas were at room temperature.

As well as NH_3^+ (the parent molecular ion), NH_4^+ and $NH_4^+\cdot NH_3$ occurred more strongly depending on the field strength. The high intensities of NH_4^+ and $NH_4^+\cdot NH_3$ are to be explained by the fact that, since ammonia is a polar gas, ionization results from a condensed layer formed on the tip surface owing to the inhomogeneous field. This layer is thicker than a monomolecular layer. Ionization by the tunnel effect is accompanied by self-dissociation, which is promoted by the field and which leads to formation of NH_4^+ and, by association, $NH_4^+\cdot NH_3$. A similar behavior has already been observed for water vapor[2, 3].

The absence of NH_2^+, NH^+, and N^+ ions is remarkable. The observed intensity of NH_4^+ would suggest that NH and NH_2 are enriched in the absorption layer. In fact, the reactions occurring in the layer lead to structures containing molecular nitrogen as well as associates with three of four N atoms although, according to estimates and comparisons of ionization potentials, ionization of, *e.g.*, NH appears possible.

The lower part of Table 1 shows groups of ions that are analogous to those in the upper part but still contain iron. Detection of these ions permitted direct analysis of the chemisorption structures. No structures occurred containing atomic nitrogen.

Table 2 gives results of field ionization of a N_2/H_2 mixture (proportions *ca.* 1:3; pressure 5×10^{-4} torr; tip and gas at room temperature) on an iron tip at two field strengths. At the lower field strength N_2H^+ ions were found as well as the molecular ions H_2^+ and N_2^+. At the higher field strength N_2H^+ was not present, because ionization occurs before the molecules can enter into equilibrium with the metal surface.

Table 2. Field ion mass spectrum of a N_2/H_2 mixture on an iron tip at two field strengths.

Mass	Field strength 195 MV/cm		Field strength 135 MV/cm	
	Intensity (arby.)	Assignment	Intensity (arby.)	Assignment
1	10	H^+	—	—
2	75	H_2^+	0.2	H_2^+
28	3500	$^{14}N_2^+$	7.5	$^{14}N_2^+$
29	25	$^{14}N^{15}N^+$	0.5	$^{14}N_2H^+$
	$\frac{\text{Intensity mass 28}}{\text{Intensity mass 29}} = \frac{140}{1}$ [a]		$\frac{\text{Intensity mass 28}}{\text{Intensity mass 29}} = \frac{15}{1}$	

[a] The ratio $^{12}N_2^+$: $^{14}N^{15}N^+$ amounts to 138.4:1 on the basis of the natural isotope ratio.

Even if the iron tip is at a higher temperature (*ca.* 200 °C) the field ion-mass spectrum of N_2 contains only N_2^+ and no N^+ ion.

These results indicate that nitrogen enters the surface structures only in molecular form. If this result is applied to NH_3 synthesis, non-dissociative chemisorption of nitrogen should be the first step. *Shvachko et al.*[4] came to the same conclusion when they found FeN_2 adsorption complexes on iron under the conditions of NH_3 synthesis up to more than 400 °C. Furthermore, the specific adsorption of N_2 on {111} surfaces of iron, as found by *Brill, Richter,* and *Ruch*[5], also necessitates the adsorption of nitrogen in molecular form.

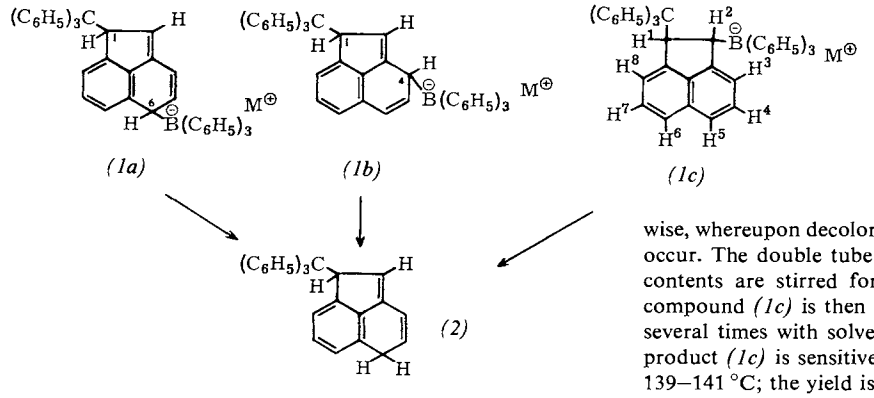
Structure and Hydrolysis of the ate-Complex from Tritylsodium, Acenaphthylene, and Triphenylborane

By *G. Wittig, W.Tochtermann,* and *B. Knickel*[*]

When polymerization of acenaphthylene is initiated by tritylsodium and terminated by triphenylborane, subsequent acid hydrolysis affords 1,5-dihydro-1-tritylacenaphthylene *(2)*[1]. It has not been possible previously to decide whether the product *(2)* arose by 1,6-addition of the Lewis base/Lewis acid pair tritylsodium/triphenylborane to acenaphthylene with subsequent hydrolysis of the complex *(1a)* in a S_E2 reaction, or whether a 1,4- or 1,2-addition to acenaphthylene occurred, leading to *(1b)* or *(1c)*, whereupon acid hydrolysis then gave rise, respectively, to a single or double allylic shift (S_E2' reaction).

In order to answer this question[2] it was essential that the ate-complex *(1)* be isolated and its structure elucidated by means of NMR spectroscopy (a method that was not available at the time of the earlier publication[1]). The product *(1)* could be isolated in either of two ways: Tetramethylammonium bromide precipitates the sparingly soluble tetramethylammonium derivative *(1)* [M = $N(CH_3)_4$, decomp. 154 to 155 °C (recrystallized from acetone/ethanol)] from an aqueous solution of the sodium salt *(1)* [M = Na[1]]; it is, however, better to prepare the complex with tritylpotassium in 1,2-dimethoxyethane[3], from which the potassium salt



(1), M = K, decomp. 139–141 °C, is precipitated directly. We have used the second method to prepare analogous complexes from 1,2-dideuterio-,4,7-di-*tert*-butyl- and 5,6-dichloro-acenaphthylene[1,4].

The ^{1}H–NMR spectrum[5] of *(1)*, M = K, shows the aromatic protons as a multiplet at τ = 2.6–3.4 and three signals at τ = 3.55 (J = 7 Hz), 3.70 (J = 8 Hz), and 4.13 (J = 7 Hz) (each 1 H, probably H^4, H^8, and H^3[6]). It contains also a broad singlet at τ = 4.29 (1 H, half-width *ca.* 5 Hz) and a structureless broad signal at τ = 6.2 (1 H)[7]. On the basis of a comparison with 1-tritylacenaphthene *(1c)*, H in place of $^{\ominus}B(C_6H_5)_3$[1] [τ (H^1) = 4.55; X part of an ABX system, *cis*-coupling J_{AX} = 7.8 Hz, *trans*-coupling J_{BX} = 2.2 Hz[8], analyzed according to AMX], we assign the singlet at τ = 4.29 to the proton H^1, and the signal at τ = 6.2 to the proton that is on the carbon atom in the α-position to the boron[9].

These results can be accounted for only by structure *(1c)*, for the following reasons:

1. In the spectrum of the complex from 1,2-dideuterio-acenaphthylene[4] there is no signal at τ = 4.29 (H^1) or 6.2. In other respects the spectrum corresponds to that of the non-deuterated complex. Thence it follows that the signal at τ = 6.2 belongs to the proton H^2 and that boron is attached to C-2 of the acenaphthene system.

2. The spectrum of the complex from 5,6-dichloroacenaphthylene[1] is very similar to that of *(1)* [multiplet at τ 2.3–3.4; doublets at τ = 3.46 (H^4), τ = 3.84 (H^8), and τ = 4.08 (H^3), J = 8 Hz in each case[6]; τ = 4.44 (H^1), τ = 6.18 (H^2)]. This is because the signals of H^5 and H^6 in the spectrum of *(1c)* appear within the broad aromatic multiplet, so that replacement of the two hydrogen atoms by chlorine does not change the appearance of the spectrum appreciably.

3. The same is true for the spectrum of the complex from 4,7-di-*tert*-butylacenaphthylene[1], in which the three doublets are merely replaced by two singlets at τ = 3.77 (3 H, presumably H^5, H^6, and H^8) and τ = 4.06 (H^3)[6]. Further signals are a multiplet at τ = 2.3–3.5, τ = 4.53 (H^1), τ = 6.25 (H^2), and *tert*-butyl resonances at τ = 8.9 and 9.0. The fact alone that such a complex is formed contraindicates 1,4- or 1,6-addition, since entry of triphenylborane in *ortho*-position to a *tert*-butyl group is not very likely.

4. The finding that the signal for H^1 in the spectrum of *(1)* does not have a large coupling constant suggests that H^1 is *trans* to H^2[8], *i.e.* *trans*-addition of the trityl group and of triphenylborane occurs, with formation of *(1c)*.

Thence it follows that acid hydrolysis of *(1)* to *(2)* and triphenylborane is a S_E2' reaction. Since it has been shown in several other cases that allylic shifts do not occur in such decompositions[10], this is the first case to our knowledge where hydrolysis of such a borate complex is to be regarded as a 1,5–S_E2' cleavage[2].

Experimental: Triphenylborane (0.9 g, 3.7 mmoles) is dissolved in benzene (30 ml) in one arm of a double Schlenk tube fitted with a sinter, and acenaphthylene (0.57 g, 3.7 mmoles) in anhydrous ether (100 ml) is added to it. After 10 minutes' stirring, a 0.175 M solution (17 ml) of tritylpotassium in 1,2-dimethoxyethane[3] is rapidly added dropwise, whereupon decoloration and deposition of *(1c)*, M = K, occur. The double tube is then sealed in a vacuum and the contents are stirred for 12 h with exclusion of light; the compound *(1c)* is then filtered off on the sinter and washed several times with solvent that is distilled on to it. The dry product *(1c)* is sensitive to light and air and decomposes at 139–141 °C; the yield is 1.6 g (63 %).

[5] Measured in [D$_6$]acetone with the Varian HA 100. We thank Dr. *J. C. Jochims* and Miss *G. Taigel* of the Max-Planck-Institut für Medizinische Forschung, Heidelberg, for measuring these spectra. All the complexes prepared from tritylpotassium gave also the methylene and methyl signals of 1,2-dimethoxyethane at τ = 6.54 and 6.72 since these products contain varying amounts of this solvent, *e.g.* 2 molar equivalents in *(1c)*.

[6] This assignment is based on allocation of the signal at highest field strength to H^3 because of its proximity to the boron atom. Additionally, it was shown by spin decoupling that H^3 couples with H^4.

[7] This broadening is probably to be attributed to the influence of the boron.

[8] Cf. *M. J. S. Dewar* and *R. C. Fahey*, Angew. Chem. *76*, 320 (1964); Angew. Chem. internat. Edit. *3*, 245 (1964).

[9] The tetramethylammonium salt *(1)*, M = N(CH$_3$)$_4$, prepared *via* the Na salt, gives the same signals for the ate part of the molecule. Only the signals for 1,2-dimethoxyethane are missing; in their place appears the singlet of the N(CH$_3$)$_4$ protons at τ = 6.76.

Dehydration of Gaseous [2-D]-2-Butanol over $CaSO_4$[1]

By *P. Bautista, M. Hunger*, and *H. Noller*[*]

It is usually assumed that dehydration of a gaseous alcohol over a solid catalyst involves β-elimination, but this has not previously been proved. We have studied the dehydration of 2-butanol and [2-D]-2-butanol over $CaSO_4$ (annealed at 150 °C under air (1 torr) for 11 hours) between 270 and 420 °C by microcatalysis and mass spectroscopy (catalyst volume *ca.* 0.5 cm^3 of powder; carrier gas helium; streaming velocity 40 ml/min; CEC 21–620 mass spectrometer).

In the temperature range used, the conversion of [2-D]-2-butanol was on an average 2 % less than that of the non-deuterated alcohol. The activation energy of the deuterated butanol (10.9 kcal/mole) is about 4 % greater than that of the non-deuterated butanol (10.5 kcal/mole). The low value – or perhaps complete absence – of the secondary kinetic isotope effect accords with the assumption of a β-elimination. A somewhat larger effect would perhaps be expected, but barely more than 15 %.

Distribution of the butenes formed as primary products at 270 and 406 °C, respectively, was 1-butene 23.5 and 33.5 %, *trans*-2-butene 21.5 and 26.5 %, and *cis*-2-butene 55 and 40 %. As in similar heterogeneous eliminations more 2- than 1-butene is formed (Saytzeff rule), and the *cis*-isomer predominates greatly. However, the relatively large proportion of 1-butene is divergent from previous results [2]; it even exceeds the amount of *trans*-2-butene. The thermodynamically most stable butene (*trans*-2-butene) is thus primarily the most disfavored. The deuterated and the non-deuterated alcohol give the same primary distribution of butenes.

90 % of the deuterium present in the [2-D]-2-butanol can be detected in the butenes. The deuterium loss is distributed as follows among the three butenes: *cis*-2-butene 15 %; *trans*-2-butene 8 %; 1-butene 0 %. Thus 1-butene arises by a pure β-elimination

$$H_3C{-}CDOH{-}C_2H_5 \rightarrow H_2C{=}CD{-}C_2H_5 + H_2O$$

Partial α-elimination (with subsequent migration of hydrogen) cannot be excluded for the 2-butenes

$$H_3C{-}CDOH{-}CH_2CH_3 \rightarrow H_3C{-}CH{=}CH{-}CH_3 + HDO.$$

Presumably, however, the loss of deuterium is due to the structure of the intermediate carbonium ion, which then should not be considered as a classical carbonium ion.

The differences can perhaps be interpreted as follows: the formation of 1-butene occurs in a pure concerted reaction, whereas elimination to yield 2-butene has some E-1 character caused by the differing acidities of the protons at the end and in the middle of the chain. Furthermore, the elimination to give *cis*-2-butene must have more E-1 character than that leading to the *trans*-isomer. This could indicate that the probability of conversion into the *cis*-isomer increases with the lifetime of the carbonium ion; but then chance of losing deuterium must increase correspondingly.

Butenes with two or more deuterium atoms were not detectable.

Passivation of Raney Nickel by Nitriles. – Hydrogenation in Acid Solution

By *P. Tinapp* [*]

In connection with a study of the possibilities of hydrogenating nitriles at various pH values it has been found that dissolution of Raney nickel in dilute non-oxidizing mineral acids can be prevented by addition of a nitrile. The activity of the Raney nickel is retained in this very acid medium. Contrary to previous assumption, hydrogenations with Raney nickel are thus, in general, possible in the presence of dilute mineral acid.

Experimental:

Benzonitrile (51.5 g, 0.5 mole) was dissolved in a mixture of tetrahydrofuran (180 ml), water (20 ml), and 96 % sulfuric acid (50 g) and, after addition of *ca.* 10 g of Raney nickel, was hydrogenated at room temperature and normal pressure. Uptake of hydrogen had ceased after about 5 h. Without having been filtered from the catalyst, the mixture was poured into water (*ca.* 600 ml), and the benzaldehyde formed was extracted with ether. The combined extracts were washed once with water and dried over sodium sulfate. Subsequent distillation gave 41 g (79 %) of benzaldehyde.

The procedure can be applied to other aromatic nitriles. To what extent the influence of solvent or substituents must be taken into account is the subject of further study.

Nothing is yet known about the origin of the passivation effect. The amount of nitrile necessary for passivation depends on the amount of Raney nickel and on the nature of the nitrile. α,β-Unsaturated and aromatic nitriles hinder most strongly the dissolution of the Raney nickel. Passivation may thus perhaps arise by π-complex formation at the CN group. Complexes of this type have already been described [1].

Table 1. Passivation of Raney nickel by nitriles. 1 g of Raney nickel was suspended in 25 ml of 25 % aqueous-ethanolic sulfuric acid, and the nitrile was added dropwise until evolution of hydrogen had ceased. The value found for benzonitrile was taken as unity and the values for the other nitriles were referred to this on a molar basis.

Nitrile	Activity of nitrile referred to benzonitrile = 1 (average value)
Cinnamonitrile	0.7
Acrylonitrile	1.03
m-Tolunitrile	1.1
o-Tolunitrile	1.18
n-Hexyl cyanide	1.69

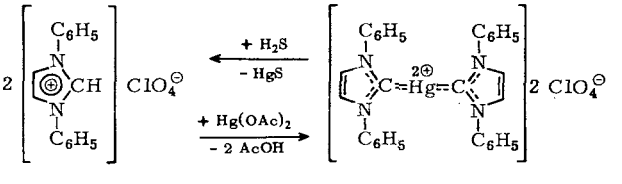
Direct Synthesis of a Mercury Salt-Carbene Complex [1]

By *H.-W. Wanzlick* and *H.-J. Schönherr* [*]

Transition-metal-carbene complexes have hitherto been obtained only indirectly: suitable ligands are converted into carbene ligands with retention of the existing bond to the central atom [2,3]. Nucleophilic carbenes, which are similar to isocyanides [4], should be suitable for direct synthesis of such complexes. That is the case, as we have shown by a first example: In view of the results obtained by *Schöllkopf et al.*, with Hg^{2+} as central atom [3,3a], we treated 1,3-diphenylimidazolium perchlorate *(1)* with mercury(II) acetate in dimethyl sulfoxide (DMSO) and obtained the carbene complex *(3)* [5]. It was unnecessary to add a base to produce the carbene *in situ*. Bis(1,3-diphenylimidazolio)mercury diperchlorate *(3)* [crystallizes from DMSO as colorless plates, m.p. *ca.* 370 °C (decomp.), which darken above *ca.* 250 °C] is formed with liberation of acetic acid in almost quantitative yield. It is stable to acids but is immediately reconverted into



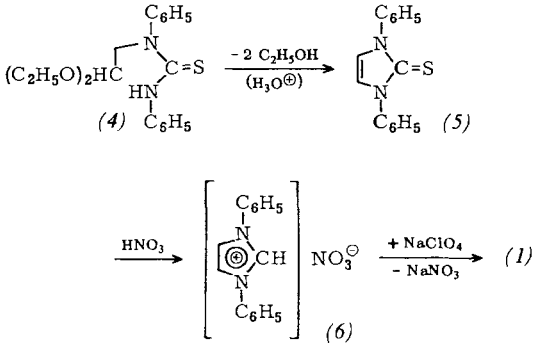
(1) *(3)*

(1) by hydrogen sulfide (in DMSO) with separation of mercury sulfide. The carbene fragment forms the base peak (m/e = 220) in the mass spectrum[6].

The NMR spectra (measured in [D_6]-DMSO as solvent) of *(1)* and *(3)* prove the structure of *(3)*. The "*meta*-coupling" shown by the salt *(1)*[7] naturally is absent for the complex *(3)*. The signals of the phenyl protons, and particularly of the protons on C-4 and C-5, are shifted upfield on conversion of *(1)* into *(3)*.

	H(1)	H(4), H(5)	H_{phenyl}
(1)	τ = −0.29 (t) (J = 1.5)	τ = 1.47 (d) (J = 1.5)	τ = 1.95–2.5 (m)
(3)	—	τ = 1.71 (s)	τ = 2.2–2.7 (m)

The salt *(1)* was prepared as follows:



Experimental:

A mixture of *N*-(2,2-diethoxyethyl)aniline and phenyl isothiocyanate (molar ratio 1:1.1), when kept for 4 days at room temperature, gave the thiourea derivative *(4)*, m.p. 94 °C (yield 88 %), which afforded the thione *(5)*, m.p. 161 °C (yield 66 %), when heated with conc. hydrochloric acid. Heating *(5)* with 36 % nitric acid (d = 1.220) gave an almost quantitative yield of the nitrate *(6)* (very hygroscopic), which was converted into *(1)*, m.p. 169 °C (yield 94 %), by dissolution in dilute nitric acid and addition of alcoholic sodium perchlorate solution.

Complex salt (3): 4 g of the salt *(1)* and 2 g of mercury(II) acetate were shaken in *ca.* 7.5 ml of DMSO at 80 °C for 10 min. When the solution cooled to room temperature crystals separated; crystallization was completed by addition of *tert*-butyl alcohol. When recrystallized from a little DMSO the complex is obtained in well-formed rectangular plates.

Compounds with Si–Ti Linkages

By *E. Hengge* and *H. Zimmermann*[*]

We have obtained compounds with the hitherto unknown Si–Ti linkage by treatment of triphenylsilylpotassium with titanium halides. The stability of the Si–Ti bond is appreciably increased by neopentane structures, which are particularly stable in compounds of elements of the fourth main group, or by substituents that are π-bonded to the titanium.

A characteristic example is the formation of tetrakis(triphenylsilyl)titanium from $TiCl_4$ and $(C_6H_5)_3SiK$:

$$TiCl_4 + 4\ (C_6H_5)_3SiK \rightarrow Ti[Si(C_6H_5)_3]_4 + 4\ KCl$$

Ethereal solutions of $(C_6H_5)_3SiK$ and $TiCl_4$ are simultaneously added dropwise to ether at 0 °C with stirring. Stirring is continued overnight, then the mixture is poured on ice plus 2 N HCl; the water and ether are then separated off and the precipitate is washed with methanol/water and ether and recrystallized from xylene (yield 44 %).

Tetrakis(triphenylsilyl)titanium is a pale yellow substance that melts at 395–400 °C with decomposition. It is very sparingly soluble in xylene, toluene, or benzene, and insoluble in all other solvents. Its particular stability may depend above all on the strong shielding of the phenyl groups in the neopentane structure, and on the high symmetry. Aqueous alkali decomposes the compound slowly, causing evolution of hydrogen:

$$Ti[Si(C_6H_5)_3]_4 + 8\ H_2O \rightarrow Ti(OH)_4 + 4\ (C_6H_5)_3SiOH + 4\ H_2$$

The amount of hydrogen evolved corresponds to theory ($Si:H_2$ = 1:1).

The IR spectrum shows, besides the usual CH, phenyl, and Si-phenyl bands, a new band at 900–940 cm^{-1}. This vibration may be associated with the neopentane skeleton since similar bands appear for similar compounds such as $[(CH_3)_3Si]_4Si$.

$(C_6H_5)_3SiK$ reacts also with $Cl_2Ti(\pi\text{-}C_5H_5)_2$ forming a Si–Ti bond:

$$(\pi\text{-}C_5H_5)_2TiCl_2 + 2\ KSi(C_6H_5)_3 \rightarrow (\pi\text{-}C_5H_5)_2Ti[Si(C_6H_5)_3]_2$$

The reaction is carried out in diglyme (diethylene glycol dimethyl ether) with ice cooling. The resulting reddish-brown solution is evaporated and the resulting residue is extracted with chloroform. On addition of pentane to the extract, yellow bis(triphenylsilyl)di(π-cyclopentadienyl)titanium is precipitated and is purified by sublimation at 280 °C (yield 35 %).

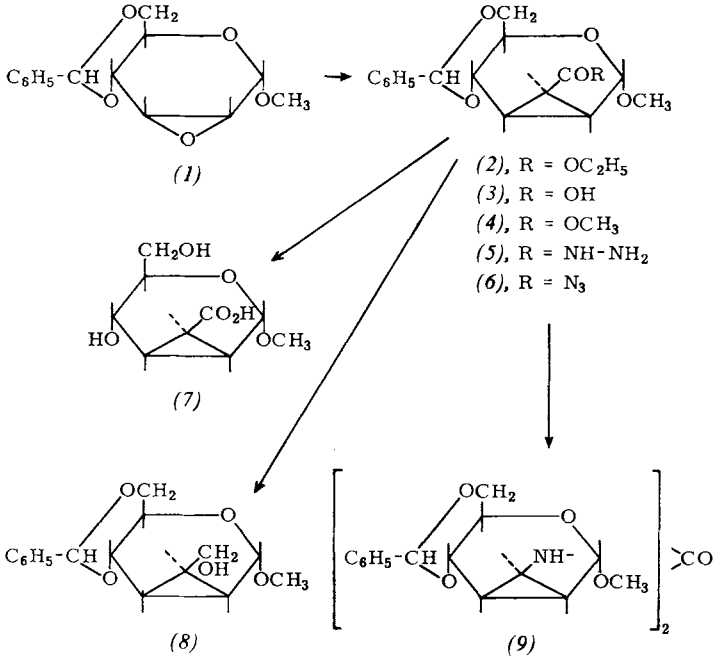
Synthesis of Methyl 4,6-*O*-Benzylidene-2,3-(2′-hydroxyethylidene)-α-D-mannopyranoside, a Cyclopropane Sugar

By *W. Meyer zu Reckendorf* and *U. Kamprath-Scholtz*[*]

PO-Activated olefination, as described by *Horner*[1], has seldom been used for the preparation of sugars with a branched carbon skeleton. Its application to the preparation of cyclopropane derivatives from epoxides of the sugar series has not previously been described.

We treated the epoxide *(1)*[2] with ethyl diethoxyphosphorylacetate[3], $(C_2H_5O)_2PO\text{–}CH_2COOC_2H_5$, and NaH in di-

oxane. After a sufficiently long reaction time (3 days at 80 °C) most, but not all, of the compound *(1)* was consumed Since separation of the product was difficult we hydrolyzed the mixture *(1)* + *(2)* cautiously (1 N NaOH/acetone at room temperature), whereupon the unchanged epoxide *(1)* remained unattacked and we obtained the acid *(3)* in 46 % yield; it has m.p. 191–192 °C and $[\alpha]_D^{20} = +57°$ (c = 1 in $CHCl_3$). Esterification with diazomethane gave the methyl ester *(4)* (> 90 % yield), m.p. 164–166 °C, $[\alpha]_D^{20} = +57°$ (c = 1 in $CHCl_3$). The configuration assigned follows from the NMR spectrum[4] (100 MHz, in $CDCl_3$, ppm with reference to TMS): H-1, δ = 4.83 (singlet, $J_{1,2} = 0$[5]); H-2, δ = 1.83; H-3, δ = 2.12 ($J_{2,3}$ = 9.1 Hz, *cis*); H-4, δ = 3.50 ($J_{3,4}$ = 1.9 Hz); H-7, δ = 1.68 ($J_{3,7}$ = 4.6 Hz, *trans*; $J_{2,7}$ = 5.0 Hz, *trans*). In C_6D_6: H-4, δ = 3.14; H-5, δ = 3.75 ($J_{4,5}$ = 9.0 Hz, diaxial).



Of the wealth of reactions that are possible with *(3)* and *(4)* we have investigated the following: Treating *(4)* with hydrazine hydrate in ethanol (16 h, reflux) gives the hydrazide *(5)* [quantitative yield, m.p. 236–238 °C, $[\alpha]_D^{20} = +42°$ (c = 1 in $CHCl_3/CH_3OH$ 9:1)]. Reaction of *(3)* with chloroformic ester, triethylamine, and sodium azide[6] afforded the azide *(6)* [85 % yield, m.p. 100–101 °C, $[\alpha]_D^{20} = +52°$ (c = 1 in $CHCl_3$)], which yielded the urea derivative *(9)* [91 % yield, m.p. 241–245 °C, $[\alpha]_D^{20} = +59.5°$ (c = 1 in $CHCl_3$)], when heated in anhydrous toluene for 1 h, treated with water, and boiled for a further 16 h. Further hydrolysis of the acid *(3)* proceded only as far as compound *(7)* [yield 80 %, m.p. 133–134 °C, $[\alpha]_D^{20} = +5°$ (c = 1 in CH_3OH)]. The glycosidic linkage is stable to 5 N HCl. Reducing the ester *(4)* with $LiAlH_4$ in tetrahydrofuran (1.5 h, reflux) gave the alcohol *(8)* [74 % yield, m.p. 140–142 °C, $[\alpha]_D^{20} = +72°$ (c = 1 in $CHCl_3$)].

CONFERENCE REPORTS

Chemistry of Organic Peroxides

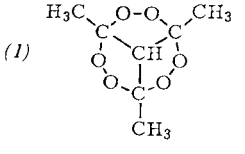
The International Symposium on "The Chemistry of Organic Peroxides" was held in Berlin-Adlershof during 13–15th September 1967. It was arranged by the Institut für Organische Chemie of the Deutsche Akademie der Wissenschaften zu Berlin and by the Chemische Gesellschaft in der DDR. Thirty-two papers were read and 250 participants from 20 countries were present.

Peroxide Synthesis

In a review paper *A. Rieche* (Berlin-Adlershof) reported the synthetic principles used by the Adlershof school for the preparation of numerous peroxy compounds.

1. Addition of hydrogen peroxide or alkyl hydroperoxides to carbonyl compounds, nitriles, Schiff's bases, or ketene acetals. With hydrogen peroxide in the presence of mineral acid, triacetylmethane affords triacetylmethane peroxide *(1)*, which formed the symbol of the peroxide symposium.

(1)



2. Reactions of mesomerically stabilized carbonium ions with H_2O_2 or HOOR. They lead particularly smoothly to peroxides containing α-situated N or O functional groups.

3. Reactions of electrophilic agents such as halogens or Hg(II) acetate with olefins in the presence of hydrogen peroxide.

4. Substitution of $R-OO^{\ominus}$ for functional groups (Cl, OR, OH, NH_2) in organometallic compounds of Sn, Ge, Pb, As, or Sb.

Bond-breaking Reactions; Trioxides, Tetroxides

According to *P. D. Bartlett* (Cambridge, Mass.) *t*-butyl hydroperoxide and lead(IV) acetate at −95 °C give a solution of di-*t*-butyl tetroxide *(2)*, which is in equilibrium with the hydroperoxy radical ($K = 5 \times 10^{-5}$ at −95 °C, heat of dissociation 6 kcal/mole). At higher temperatures the tetroxide

evolves oxygen, and radical recombination leads to di-*t*-butyl trioxide *(3)*, which is stable up to −35 °C.

$$Bu{-}OOH \rightarrow BuOO\cdot \rightleftarrows Bu{-}O{-}O{-}O{-}O{-}Bu \quad (2)$$

$$Bu{-}O{-}O{-}O{-}O{-}Bu \rightarrow 2\,BuO\cdot + O_2 \quad (2)$$

$$BuO\cdot + \cdot O{-}O{-}Bu \rightleftarrows Bu{-}O{-}O{-}O{-}Bu \quad (3)$$

Above −35 °C oxygen and di-*t*-butyl peroxide are formed as stable end products. Following the radical concentration by ESR spectroscopy over the whole temperature range shows minima in the region where the tetroxide and trioxide exist.

N. A. Milas (Cambridge, Mass.) found that iodobenzene is formed without evolution of oxygen on reaction of diacetoxy iodobenzene with *t*-butyl hydroperoxide at −80 °C, so that the tetroxide *(2)* must be present in these solutions. Cautious warming leads at −70 °C to evolution of oxygen and formation of the trioxide *(3)*, whence oxygen is again evolved between −45 and −20 °C.

$$C_6H_5{-}I(O{-}Ac)_2 \xrightarrow[-80°C]{Bu{-}OOH} C_6H_5I + Bu{-}O{-}O{-}O{-}O{-}Bu \quad (2)$$

$$\xrightarrow{-70°C} Bu{-}O{-}O{-}O{-}Bu + {}^1/_2\,O_2 \xrightarrow{-45/-20°C} {}^1/_2\,O_2$$
$$(3)$$

The temperature ranges in which the tetroxide and trioxide appear agree well with those found by *P. D. Bartlett*.

In the discussion there were various references to the importance of spin conservation for reaction mechanism. For instance, a one-stage decomposition of the tetroxide *(2)* must produce the O_2 molecule as a singlet. However, *T. G. Traylor* (San Diego, California) was able to exclude this one-stage mechanism by comparison with the decomposition of di-*t*-butyl hyponitrite *(4)*. Compound *(4)* exists in the *trans*-form and cannot yield an O–O bond in one step; yet the almost identical proportion of Bu–O–O–Bu among the decomposition products from *(2)* and *(4)* indicates analogous decomposition mechanisms.

$$(2)\quad BuO(O{-}O)OBu \xrightarrow{?} Bu{-}O{-}O{-}Bu \;(O{=}O)$$

$$(4)\quad BuO{-}N{=}N{-}OBu \rightarrow\rightarrow Bu{-}O{-}O{-}Bu + N_2$$

In the papers by *Bartlett*, *Traylor*, and *Hiatt* formation of O_2 and a radical pair was assumed in place of a one-stage decomposition of the tetroxide *(2)*. Here the spin conservation rule permits formation of singlet O_2 with a singlet radical pair or formation of (normal) triplet O_2 and a triplet radical pair:

$$(2)\ Bu{-}O{-}O{-}O{-}O{-}Bu \rightarrow \begin{cases} BuO\cdot\downarrow\ O{=}O\ \uparrow\cdot OBu \\ BuO\cdot\downarrow\ O{=}O\ \downarrow\cdot OBu \end{cases}$$

P. D. Bartlett pointed out that an experimental decision between the two possibilities was not yet possible, since reversal of spin in the radical pairs is faster than coupling of the radicals or their diffusion away, as shown by the identical cage effects of "singlet" and "triplet" pairs of methyl or cumyl radicals.

G. A. Russell (Ames, Iowa) pointed out in his paper that oxygen in the triplet ground state cannot add to a carbanion in a one-stage reaction, since this would break the spin conservation rule. His observation that triphenylmethyl and diphenylmethyl anions nevertheless add oxygen very rapidly requires a multistage mechanism for its interpretation:

Electron transfer $\quad R{:}^{\ominus} + O_2^{\uparrow\uparrow} \rightarrow R^{\cdot\uparrow} + O_2{\cdot}^{\ominus\uparrow}$

Spin reversal $\quad R^{\cdot\uparrow} + O_2{\cdot}^{\ominus\uparrow} \rightarrow R^{\cdot\uparrow} + O_2{\cdot}^{\ominus\downarrow}$

Coupling $\quad R^{\cdot\uparrow} + O_2{\cdot}^{\ominus\downarrow} \rightarrow R{-}OO{:}^{\ominus\uparrow\downarrow}$

According to the acidity of the hydrocarbon, either the anion formation (*e.g.* diphenylmethane) or the reaction of the anion with O_2 (fluorene) is rate-determining.

Owing to spin conservation, the occurrence of singlet oxygen would be expected in reactions where oxygen is evolved, which involve a polar mechanism. For instance, the singlet oxygen ("doubly bonded" O_2) that is evolved on reaction of bromine with hydrogen peroxide as reported by *W. A. Waters* (Oxford, England) could attack olefins with shift of the double bond or undergo 1,4-addition to 1,3-dienes or to hydrocarbons of the anthracene type. Singlet oxygen is thus

$$H{-}\overset{\curvearrowright}{O}{-}O{-}\overset{\curvearrowright}{H}\quad Br{-}\overset{\curvearrowright}{Br} \rightarrow O{=}O$$

to be considered the key compound in the photosensitized reactions of O_2 discovered by *G. O. Schenck*.

Connections with co-carcinogenesis were also referred to.

Mrs. *S. K. Maizu*, (Moscow, USSR) dealt with the role of alkyl hydroperoxides and peroxy radicals in the liquid-phase oxidation of organic compounds. For the process yielding radicals, not only the decomposition of an alkyl hydroperoxide must be considered, but also the reaction

$$RH + ROOH \rightarrow R\cdot + RO\cdot + H_2O$$

as indicated by the dependence of the decomposition of the hydroperoxide on the strength of the C–H bond in RH. The influence of the reaction medium and of homogeneous catalysts (salts of metals of variable valence) was discussed. Complexes of alkyl hydroperoxides with other components of the reaction mixture play an important part. Studies of the formation of epoxides in co-oxidation of olefins and organic compounds showed that acylperoxy radicals are the epoxidizing agents.

W. Pritzkow (Merseburg, DDR) deduced from competition experiments that tertiary C–H bonds on the cyclohexane ring are autoxidized faster by a factor of at least 2 when in equatorial than in axial positions. *L. Novotný* (Prague, CSSR) discussed the formation, by way of peroxidic intermediates, of α,β-unsaturated five-membered ring lactones in plants (various *Petasites* species).

According to *A. G. Davies* (London, England), autoxidation of organometallic compounds occurs by way of a radical chain:

$$ROO\cdot + M{-}R \rightarrow R{-}OO{-}M + R\cdot$$
$$R\cdot + O_2 \rightarrow R{-}OO\cdot$$

When R is optically active α-methylbenzyl and M is boron complete racemization results, which makes direct introduction of O_2 unlikely. An addition-elimination mechanism was proposed.

In a review paper *G. A. Razuvayev* (Gorki, USSR) gave an insight into his own, very numerous, investigations of new homolytic reactions of peroxy compounds. Many organometallic compounds react with diacyl peroxides even below the decomposition temperature of the peroxides, the acylperoxy radical then not undergoing decarboxylation.

$$R_nM + (R'COO)_2 \rightarrow R_{n-1}M{-}O{-}CO{-}R' + R'COOR$$

$$2\,R_nM + (R'COO)_2 \rightarrow 2\,R_{n-1}M{-}O{-}CO{-}R' + 2\,R\cdot$$

(M = Al or Tl)

Metal-metal bonds are cleaved by diacyl peroxides.

$$R_3M{-}MR_3 + (R'COO)_2 \rightarrow 2\,R_2M{-}O{-}CO{-}R'$$

(M = Sn or Pb)

$$(R_2M)_2M' + (R'COO)_2 \rightarrow 2\,R_3M{-}O{-}CO{-}R' + M'$$

(M = Si or Ge; M' = Hg, S, Se, or Te)

Dialkyl peroxides have appreciably greater difficulty in reacting with organometallic compounds; at room temperature only the following reaction with trialkylaluminum occurs:

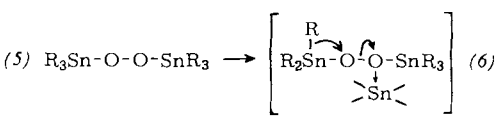
$$2\,Alk_3Al + t\text{-}Bu_2O_2 \rightarrow 2\,Alk_2Al{-}O{-}Bu\text{-}t + 2\,Alk\cdot$$

Stable organometallic compounds such as tetraalkyl compounds of silicon and germanium react with dialkyl or diacyl peroxides or peresters only above the decomposition temperatures of the latter. Then a reaction of the alkyl groups with the free radicals occurs that involves attack on the C–H bonds.

Peresters of the type $R_3M{-}CH_2{-}CH_2{-}CO{-}OOBu\text{-}t$ were prepared with M = Si or Ge, and the reactions of the radicals formed on their thermal decomposition were studied. Further, peroxides of composition $RHgOOR'$ and R_2TlOOR' have been synthesized for the first time and studied.

For organic peroxy derivatives of tin and lead, *V. A. Shushunov* (Gorki, USSR) showed that alkylperoxy derivatives of the type $R_3M{-}OO{-}R'$ decompose homolytically only above 100 °C. However, heterolytic decomposition of acylperoxy derivatives of type $R_3M{-}OO{-}CO{-}R'$ (M = Sn or Pb) is rapid even at room temperature. Both reactions follow a kinetic law of the first order. The influences of the substituent, the metal, and the solvent on the decomposition reactions were studied.

J. Dahlmann (Berlin-Adlershof, DDR) reported the synthesis and decomposition of bis(organometallyl) peroxides $R_3M{-}OO{-}MR_3$ (M = Ge, Sn, or Pb). In the decomposition of tin peroxides, which occurs even below room temperature, the kinetics and the influences of substituents, solvent, and added tin compounds show that the decomposition is induced by diorganotin oxides formed in the decomposition.

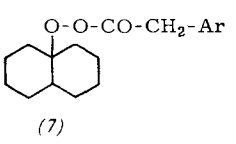


$$\rightarrow R_2SnO + R_3SnOR$$

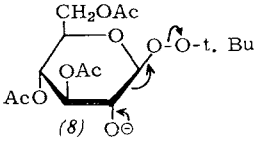
W. P. Neumann (Giessen, Germany) reported the reaction of diacyl peroxides with organotin hydrides. It results from attack of R_3Sn radicals on the peroxidic oxygen and chain propagation by the acyloxy radicals thus formed. The stannyl radical is nucleophilic and always attacks the electron-poorer peroxidic oxygen.

A kinetic study of the reaction of amines with dibenzoyl peroxide (*O. A. Tschaltykjan*, Jerewan, USSR) showed that amines are of two types, namely, those that react with the O–O bond either mainly heterolytically or mainly homolytically.

C. Rüchardt (München, Germany) studied the thermal decomposition of substituted 9-decalyl perphenylacetates *(7)* in polar and apolar solvents. By following the consumption of the perester and the formation of radicals (trapping by galvinoxyl) kinetically, he found that heterolysis and homolysis of the O–O bond of *(7)* are truly competitive reactions. Radical formation is favored by electron-donor substituents (*e.g.* $p\text{-}OCH_3$).



(7)

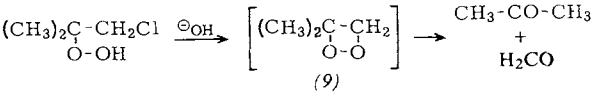


(8)

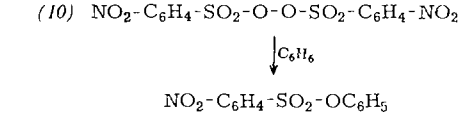
M. Schulz (Berlin-Adlershof, DDR) studied fragmentation of the system *(8)*, his examples being the base-catalyzed decomposition of acylated *t*-butyl peroxyglycosides, sugar azohydroperoxides, and acetylated sugar peroxy esters. The five-center fragmentation of peroxyglycosides has preparative importance as a sugar degradation reaction.

E. Schmitz (Berlin-Adlershof, DDR) gave several examples of heterolysis of nitrogen-containing peroxides, whose fragmentation is started by presence of a basic N atom or a deprotonated amide nitrogen in the γ-position to the peroxy group.

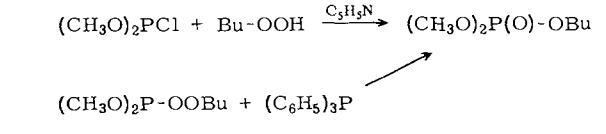
W. H. R. Richardson (San Diego, California) discussed the decomposition of monochlorinated *t*-butyl hydroperoxide by bases to yield acetone and formaldehyde by way of an intermediate *(9)* containing a four-membered ring. Kinetic data were adduced in favor of neighboring group participation by the peroxide group.



R. L. Dannley (Cleveland, Ohio) studied electrophilic substitution of aromatic compounds by nitrobenzenesulfonyl peroxides *(10)*. The reaction leads to phenols, in good yield, by way of sulfonic esters.



According to *G. Sosnovsky* (Milwaukee, Wisconsin) reaction of monochloro derivatives of tervalent phosphorus with *t*-butyl hydroperoxide in pyridine gives a phosphate ester, which is also obtained from the perphosphate ester and triphenylphosphine.



Reactions of Ozone; Ozonides

P. S. Bailey (Austin, Texas) reviewed reactions of ozone with organic compounds. Four types of reaction were distinguished: 1. Cycloaddition to olefins, yielding primary ozon-

ides; 2. electrophilic attack, for instance on phosphines and amines; 3. nucleophilic attack, for instance on Schiff's bases; and 4. 1,3-dipolar insertions into C–H bonds, for instance with benzaldehyde. *R.W. Murray* (Murray Hill, New Jersey) discussed the route from primary ozonide to ozonides on the basis of extensive experimental material. The Criegee mechanism needs some extensions. The intermediate stages *(11)* and *(12)* were brought into the discussion on the basis of stereochemical and crossing experiments, as well as labeling experiments with deuterium or ^{18}O.

(11) 
 *(12)*

R. Criegee (Karlsruhe, Germany) showed that aldozonides from styrene and substituted styrenes are cleaved to aldehyde and acid by some solvents, particularly rapidly by methanol. A diozonide isomerizes under acid catalysis to a compound that contains two peroxide groups and two acetal oxygen atoms.

The Kinetic Principle of Excitable Systems

By *W. Seidel*[*]

About 70 years ago *W. Ostwald*[1] noted in the behavior of the system Fe/HNO_3 remarkable analogies to phenomena that were known in excitation physiology. This finding suggested that a chemical kinetic principle exists that is capable of generalization and is not confined to living systems. In fact, many such, so-called "kinetic" model systems are known, and the analogies of their functioning to that of living systems that can undergo excitation is so astonishingly extensive that "no biological phenomenon of excitation is known that cannot be simulated by a kinetic model"[2].

The most obvious characteristic of all these systems is an "either-or" behavior that results from the ability of the system to exist in two different (stationary) states. Like the living systems, the models are open systems in the thermodynamic sense; a stationary state arises only if an inward flow from the environment compensates the outward flow from the system. These flows are caused by driving forces that originate from an energy or a potential difference. A superposition of the relations between flow and driving force for the system and for its surroundings should make it possible to interpret the behavior observed.

It can be clearly shown[3] how, for instance, superposition of a "load line" on a non-monotonic N-shaped characteristic of a system leads to the existence of two stable stationary states which are separated by an unstable one. If the characteristic of the system can shift relative to the characteristic of the evironment, because of the chemical kinetics, then an "either-or" behavior can be explained.

In the nerve-cell membrane the phenomenon of excitability is of electrochemical nature[4]. Like most model systems, the Fe/HNO_3 system, later called the Ostwald-Lillie nerve model, also belongs to electrochemistry[5]. As a typical electrode having a passivating film, iron shows the requisite non-monotonic course in its current-potential characteristic. The Fe/HNO_3 model can be used to simulate the most varied biological excitation phenomena[6]. In all other cases a non-monotonic characteristic of the system is found to be significant. Doubtless, occurrence of such characteristics is not confined to the particular set, "current-potential". On the contrary, excitable systems are to be expected whenever a non-monotonic course of any flow-driving force relation is the kinetic principle.

Condensation of D-Glucose with Aromatic Systems in Liquid Hydrogen Fluoride

By *F. Micheel*[*]

High polymers are formed by condensation, in nucleophilic reactions, of polycyclic aromatic hydrocarbons[1] with aldoses in liquid HF at room temperature. The site of substitution can be determined by condensation with [1-^{14}C]-D-glucose and oxidation to carboxylic acids. Carbazole gives a polymer-homologous series of condensation products; C–C bonds occur in all of these, and the OH groups of the sugar residue can be acetylated.

Being aromatic systems, coals of various ages also give condensation products (labeling with [1-^{14}C]-D-glucose; glycosidically bound D-glucose is removed by hydrolysis)[2]. Moreover, very pure graphite (99.999 % of C) condenses with formation of covalent bonds (0.6–1.8 % of [1-^{14}C]-D-glucose)[3]. All the condensation products are free from water-soluble self-condensation products of D-glucose. Benzene and [1-^{14}C]-D-glucose afford, amongst other condensation products, triphenylmethane whose labeled tertiary C atom is derived from the D-glucose (yield: 15 %, calc. on D-glucose). Toluene and [1-^{14}C]-D-glucose yield, as well as a methylanthracene, a hydrocarbon $C_{24}H_{24}$, $[\alpha]_D = -44°$ (in benzene), which fluoresces blue in solution and contains aliphatic groups (yield: *ca.* 4 %, calc. on D-glucose).

Individual Steps in the Chemisorption of Gases on Metals

By *W. M. H. Sachtler*[*]

The chemisorption of gases on metals is determined primarily, not by the collective parameters of the metallic state – Fermi level, holes in the d-band, *etc.* – but by the chemical

properties of the individual surface atoms and by those of the atoms of the gaseous molecule. Just as in complex chemistry, the chemical properties of an adsorbing atom are modified by its neighbors. A study has been made of the role played in chemisorption by the geometry (*e.g.* the size of the adsorbed atoms, number of adsorption sites on the surface) in comparison with the stoichiometry, *i.e.* the number of valence electrons of the surface atoms.

Chemisorption of gases of the type H_aX on pure Ge or Si surfaces follows stoichiometric laws[1]; each molecule dissociates into a H atoms and one X atom, each H atom saturates one surface atom, and each X atom saturates a surface atoms; thus, in sum, $2a$ surface atoms are saturated per H_aX molecule. The surface atoms behave as univalent species, since of each four valence electrons of each Ge atom three electrons are used for covalent bonding to the three nearest neighbors; the fourth electron is available for chemisorption, as a "dangling bond".

Stoichiometry also determines chemisorption by typical metals. However, in contrast to covalent crystals (such as Ge) metals do not confine themselves to the "dangling bonds"; instead, all the valence electrons are available for bonding with the adsorbate.

As a result chemisorption causes marked demetalization of the surface atoms and is therefore dissociative in two respects: the bonds within the gas molecule and also those within the surface can be broken. By using the field ion microscope it has been shown[2] that the surface atoms can even leave their original positions in the lattice and move to more favorable positions between or even above the adsorbate atoms. Such rearrangements can occur even at the temperature of liquid nitrogen. Since each atom that leaves its position in the lattice leaves a vacancy, which can then move into the interior of the crystal, the injection of vacancies caused by chemisorption is an additional phenonemon which has been verified experimentally.

Chemisorption often occurs in three successive stages:

1. Chemi-adsorption (surface atoms remain in their original places in the lattice).

2. Corrosive chemisorption (rearrangement of the atoms of the surface and of the adsorbate).

3. Ligand chemisorption (the metal atoms or ions that have migrated in process (2) complete their coordination number by further chemisorption).

Formation and Properties of Molecular Complexes in the Excited State

By *A. Weller*[*]

The fluorescence spectrum of a solution that contains electron-acceptor (A) as well as electron-donor molecules (D) can disclose the formation of excited charge-transfer complexes A^-D^+ (heteroexcimers) by the appearance of a long-wave fluorescence emission that is structureless and unaccompanied by a corresponding change in the absorption spectrum. The molecular complexes, which are unstable in the ground state, are formed in accord with

$$\overset{*}{A} + D \rightarrow A^-D^+ \text{ or } \overset{*}{D} + A \rightarrow D^+A^-$$

in diffusion-controlled reactions between an excited and an unexcited molecule with an enthalpy of formation ($-\Delta H$) of several kcal/mole; at higher temperatures this enthalpy can be measured from the temperature-dependance of the relative fluorescence intensities, if back-reaction occurs.

The wave number of the maximum of the complex emission is governed by the simple energy relationship:

$$h\nu_{max} = IP_D - EA_A - (C + U) - H^{solv}_{A^-D^+} - E_{rep}$$

where IP_D is the ionization energy of the donor molecules, EA_A is the electron affinity of the acceptor molecules, $C + U$ is the Coulomb + resonance energy in the complex, $H^{solv}_{A^-D^+}$ is the solvation energy of the complex and E_{rep} is the repulsion energy between A and D in the ground state of the complex. The validity of this relation has been tested for a large number of acceptor-donor systems by using substituted and unsubstituted aromatic compounds and numerous solvents; this work confirms the assumptions made about the charge-transfer character of the excited molecular complexes. Moreover, it now becomes possible to estimate the resonance energy U, which can be ascribed to participation of localized excited structures

$$\overset{\bullet}{A}D \leftrightarrow A^-D^+ \leftrightarrow A\overset{\bullet}{D}$$

in the complex.

In the system naphthalene (D)/*p*-dicyanobenzene (A) at high concentrations, formation of excited triple complexes $(DD)^+A^-$ can be observed, which dissociate partly when the temperature is increased, yielding D and D^+A^- (excited).

The significance of these studies lies on the one hand in the possibility of studying the diffusion-controlled kinetics of molecular complex formation in relation to various parameters (solvent, temperature, pressure, *etc.*), and on the other in the fact that the heteroexcimers, which are readily detected by means of their characteristic properties, can appear as intermediates in redox reactions.

Fine Structure of Ruthenium(III) Bromide

By *K. Brodersen*[*]

$RuBr_3$ crystals are rhombic (space group D^{13}_{2h})[2] and not, as hitherto assumed[1], hexagonal with the TiI_3 structure (space group D^3_{6h}). The unit cell (a = 6.47 Å, b = 11.205 Å, c = 5.855 Å) contains 4 formula units ($D_{X\text{-ray}}$ = 5.34 g cm^{-3}; $D_{pycn.}$ = 5.42 g cm^{-3}).

X-ray determination of the structure by Patterson and Fourier syntheses (refinement of the parameters by the method of least squares) shows characteristic $(Ru_2Br_3)Br_{6/2}$ groups as the structural unit with the Ru atoms in an approximately octahedral environment. The points in space group D^{13}_{2h} are occupied as follows:

4 Ru in 4 (e) with $x = 0.254_5$ and $z = 0.016_5$
4 Br_I in 4 (f) with $x = 0.587$ and $y = 0.599$
4 Br_{II} in 4 (f) with $x = 0.089$ and $y = 0.405_5$
2 Br_{III} in 2 (a) with $x = 0.571$
2 Br_{IV} in 2 (b) with $x = 0.945$

The magnetic moment is much depressed (to $\chi_{mol} = 108 \times 10^{-6}$ at 20 °C, temperature-independent) by the formation of Ru_2 groups. The interatomic distances are: Ru–Ru = 2.73 Å (shortest distance between two Ru_2 pairs in the chain = 3.12

Å); Ru–Br (within the Ru_2Br_3 group) = 2.46 Å; Ru–Br (to the 6 linking Br atoms) = 2.52 and 2.54 Å; Br–Br (shortest separations) = 3.38, 3.47, and 3.53 Å.

$RuBr_3$ with the grouping $(M_2X_3)X_{6/2}$ contributes to completion of the scheme set up by *Schäfer* and *Schnering* for the structures of transition-metal halides [3].

Structure of β-$RuCl_3$, RuI_3, $IrBr_3$, and IrI_3

By *K. Brodersen* [*]

Comparison of powder diagrams shows that RuI_3 and β-$RuCl_3$ have the same structure as $RuBr_3$ [1]. Calculation of the intensities on the X-ray diagrams of RuI_3 and β-$RuCl_3$ gives good agreement between the calculated and the expermental intensities if the atomic parameters of the $RuBr_3$ structure are used [$(Ru_2X_3)X_{6/2}$ units]. The structure given by *Fletcher* [2] for β-$RuCl_3$ must therefore be refined analogously to the $RuBr_3$ structure; this is also supported by the splitting of the Ru–Cl bands in the IR spectrum [2], which is in agreement with the D_{2h} symmetry found by us [1]. The molar susceptibilities [1,2] correspond only to a temperature-independent paramagnetism, and not to the temperature-dependent paramagnetism expected for the d_ε^5-configuration of Ru^{3+}.

$IrBr_3$ and IrI_3 (single crystals obtained by "chemical transport": 900 → 450 °C or 1000 → 400 °C [3]) crystallize in the monoclinic form with lattice constants: $IrBr_3$, a = 6.30 Å, b = 10.98 Å, c = 6.34 Å, and β = 108.7 °; IrI_3, a = 6.74 Å, b = 11.75 Å, c = 6.80 Å, and β = 108 °.

$IrBr_3$ has the $AlCl_3$ structure, but strongly disordered [3]. Model calculations indicate that these dislocations are to be attributed to shift of complete Br–Ir–Br layers, the cubic close packing of the Br atoms being retained during the shift. The $AlCl_3$ and $CrCl_3$ types now appear to be only special cases of a type of structure having cubic close packing of anions and an ordered distribution of the cations within one layer [3].

The resolution of racemates on optically active polymers has been studied by *G. Manecke* and *W. Lamer.* Chlorosulfonyl-substituted polystyrene (bead polymer, 200–400 mesh; with 2% of divinylbenzene) was first linked to L-arginine, L-α-phenylethylalanine, or L-ephedrine in dioxane or dioxane/water *via* sulfonamide bridges. 50 to 500 mg of DL-mandelic acid or DL-α-aminophenylacetic acid could be partially resolved on these polymers on columns 80 cm long and 1 cm in diameter (elution rate 6 to 12 ml/h; 1.5 ml fractions). Fractions containing an excess of the D-antipode are always eluted first; the results obtained on resolution of 70 mg of DL-mandelic acid on resin containing L-arginine are shown in the table.

ml of eluate after breakthrough	Concentration (mg/ml)	Specific rotation $[\alpha]_{313}$ (°)	Activation (%)
1.5	0.51	–55	6
4.5	3.07	–39	4.3

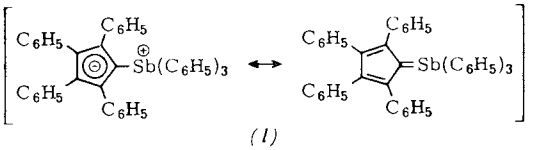
A crystalline antimony ylide, tetraphenylcyclopentadienylidene triphenylstiborane *(1)* has been synthesized for the first time by *D. Lloyd* and *M. I. C. Singer* by heating diazotetraphenylcyclopentadiene in molten triphenylstibine under N_2 at 140 °C (isolation by the addition of ether); m.p. 196–198 °C, ochre crystals, soluble in mineral acids, λ_{max} = 349 nm



(1)

(benzene). *(1)* is converted by prolonged heating mainly into tetraphenylcyclopentadiene. / Chem. and Ind. *1967*, 787 / –Ma. [Rd 721 IE]

The preparation and properties of boranocarbonates have been investigated by *L. J. Malone* and *R. W. Parry*. The structure of the anion corresponds to that of a carbonate in which one oxygen atom is replaced by the isoelectronic H_3B group. Potassium and calcium boranocarbonates are obtained in good yields as air-stable, water-soluble salts by the following reactions:

$$H_3BCO + 2\,KOH \xrightarrow{\text{alcohol}} K_2H_3BCO_2 + H_2O$$

$$H_3BCO + CaO \xrightarrow[H_2O\ (\text{trace})]{25\,^\circ C} CaH_3BCO_2$$

The H_3BCO, which may be prepared from the two condensed components B_2H_6 and CO, is not isolated in the pure state, but is introduced into the reaction in the form of an $H_3BCO/CO/B_2H_6$ mixture. IR investigations show the boranocarbonate ion to possess the symmetry of the acetate ion; the acid $H_2(H_3BCO_2)$ is rather weaker than carbonic acid. When treated with 85 % H_3PO_4, the boranocarbonates give H_3BCO of extremely high purity. / Inorg. Chem. *6*, 817 (1967) / –Sch. [Rd 761 IE]

The preparation of aziridines by reduction of α-chloronitriles with $LiAlH_4$ is reported by *K. Ichimura* and *M. Ohta*. The procedure is simple and leads to good yields. Rather more than one equivalent (≈ 1:1.3) of a suspension of $LiAlH_4$ in ether is added dropwise at −5 to 0 °C to a solution of α-chloronitrile in ether. After a few hours, the excess of $LiAlH_4$ is decomposed with alkali. No piperazines (which occur as by-products when Grignard compounds are used instead of $LiAlH_4$) or β-chloroamines are formed.

$$R\text{-}CHCl\text{-}CN \xrightarrow{LiAlH_4} RHC\!-\!CH_2 \quad (N\text{–}H)$$

R	B.p. (°C/mm)	Yield (%)

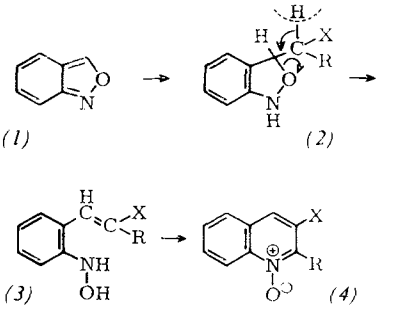
A one-stage synthesis of aliphatic nitriles was achieved by *J. A. Findlay* and *C. S. Tang*, starting from aldehydes. If a solution of aliphatic aldehydes, aldehyde trimers, or aldehyde-bisulfite compounds is boiled with hydroxylamine hydrochloride and a few drops of hydrochloric acid in 95 % ethanol for six hours under reflux, the corresponding nitrile is obtained in a practically quantitative yield. For example:

n-octanal	→	octanenitrile (83% yield)
n-tetradecanal	→	n-tetradecanenitrile (90% yield)
n-octadecanal bisulfite	→	n-octadecanenitrile (89% yield)
octadecanal trimer	→	n-octadecanenitrile (87% yield)

/ Canad. J. Chem. *45*, 1014 (1967) / –DK. [Rd 758 IE]

The use of dipotassium tetraisothiocyanatocobaltate(II) enables the detection of oxygen-containing organic molecules to be carried out more comprehensively and simply than previously (*e.g.* with iron(III) thiocyanate, or with CO formation at 1100–1500 °C over carbon). According to *F. Buscaróns* and *M. Pareira*, the microtest (mg range) depends upon the fact that $K_2Co(SCN)_4 \cdot 4H_2O$ rapidly turns blue on contact with a large number of liquid organic compounds (or solid compounds that can be heated up to the melting point without decomposition). Investigations conducted with 500 compounds showed that the test is negative for hydrocarbons and halogenated hydrocarbons of all types, and for mercaptans, thioethers, thiones, amines, heterocycles, and azo compounds. Positive reactions were obtained with ethers, alcohols and phenols, aldehydes and ketones, carboxylic acids and their esters, carboxylic amides halides, and anhydrides, quinones, and nitro compounds. Nitriles although oxygen-free, also react, while thymol, furan, and compounds that themselves are reagents for Co, such as imidodioxines and α-nitroso-β-naphthol do not react. / Analyt. chim. Acta *37*, 490 (1967) / –Jg. [Rd 784 IE]

The ring expansion of benzoxazole to form quinoline 1-oxides *(4)* in reactions with a number of active methylene compounds, such as $NC\text{–}CH_2\text{–}R$ and $C_2H_5O_2C\text{–}CH_2\text{–}R$, has been observed by *E. C. Taylor* and *J. Bartulin*. Thus the reaction of benzoxazole *(1)* with malonodinitrile in the presence of a catalytic quantity of piperidine is exothermic and leads to 2-amino-3-cyanoquinoline 1-oxide (yield 99 %). Less reactive methylene compounds are best used in the form of their alkali metal salts. The reaction probably proceeds



(1) *(2)* *(3)* *(4)*

via (2) and *(3)*. Examples: ethyl cyanoacetate → 3-cyano-1-hydroxy-1,2-dihydroquinolin-2-one (97 %); phenylsulfonylacetonitrile → 2-amino-3-phenylsulfonylquinoline 1-oxide (82 %). / Tetrahedron Letters *1967*, 2337 / –Ma. [Rd 723 IE]

A new type of compound of sulfuryl diamide was reported by *D. Zoellner* and *A. Meuwsen*. When dry HCl is passed into a cold suspension of sulfuryl diamide in acetonitrile, compound *(1)* is obtained as odorless, non-hygroscopic crystals (m.p. 160–162 °C (decomp.), 64 % yield). Compound *(1)* may be

$$CH_3\text{–}CN + (H_2N)_2SO_2 + HCl \rightarrow CH_3\text{–}C(=NH_2^{\oplus}Cl^{\ominus})\text{–}NH\text{–}SO_2\text{–}NH_2 \quad (1)$$

recrystallized from hot glacial acetic acid, and is readily soluble in cold anhydrous methanol but practically insoluble in ether, ethyl acetate, acetone, $HCCl_3$, CCl_4, C_6H_6, and boiling CH_3CN. The reaction of a cold methanolic solution of *(1)* with a similar solution of KOH gives a 55 % yield of

$$(1) + KOH \rightarrow CH_3\text{–}C(=NH)\text{–}NH\text{–}SO_2\text{–}NH_2 + KCl + H_2O \quad (2)$$

(2) in the form of crystals which are stable in air, melt at 125–130 °C (decomp.), and can be recrystallized from boiling CH_3CN. Compound *(2)* is soluble in cold methanol or ethanol; in water it is slowly hydrolyzed to acetamide and sulfuryl diamide. / Z. anorg. allg. Chem. *349*, 19 (1967) / –Sch. [Rd 764 IE]

Complexes of trivalent manganese have been prepared by *H. Funk* and *H. Kreis* by slow addition of fresh, anhydrous, ethereal $MnCl_3$ solutions (from manganese dioxide + HCl) to the other component at −40 and −5 °C. The complexes are

Complex	Color/stable up to (°C)	Remarks
$MnCl_3$·3 amine	brown/20	amine = NH_3; $C_nH_{2n+1}NH_2$ (n = 1 to 4; $(CH_3)_2NH$; $(C_2H_5)_2NH$
$MnCl_3$·3 R_3N	dark brown or dark green	R = C_2H_5; $C_6H_5CH_2$
$MnCl_3$·3 Z	green/100	Z = pyridine, quinoline

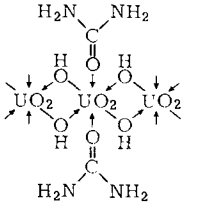
The cofactor requirement of collagen-proline hydroxylase has been determined by *J. J. Hutton*, *A. L. Tappel*, and *S. Udenfriend*. It was found that iron(II) ions, α-ketoglutarate, and ascorbate are required in addition to oxygen. The Michaelis constants were 3×10^{-5}, 3×10^{-6}, and 2×10^{-4} in a standard mixture containing 10^{-4} M iron(II) ion, 10^{-4} M α-ketoglutarate, and 5×10^{-4} M ascorbate. The α-ketoglutarate is assumed to have a regulating function. Though α-ketoglutarate was consumed in the tests, no correlation could be detected between this consumption and the formation of hydroxyproline. The enzyme from chick embryo was purified to such an extent that the cofactor requirement was "absolute", but this gave only a small increase in specific activity; moreover, the purity was not sufficient to explain the stoichiometry. The enzyme catalyzes the hydroxylation of certain proline residues in polypeptides that are rich in proline but poor in hydroxyproline and which can be broken down by collagenase.

$$\text{Peptidylproline} + \text{ascorbate} + O_2 \xrightarrow[Fe^{2+}]{\text{α-ketoglutaric acid}} \text{peptidylhydroxyproline} + \text{dehydroascorbate} + H_2O.$$

The measurement of the hydroxylase activity is based on the determination of tritium in the water of the reaction mixture on hydroxylation of [3,4−T_2]-proline in peptides. These peptides are obtained from chick embryos or are synthesized. The triple-helix structure of collagen is not essential to its suitability as a substrate for the hydroxylase. / Arch. Biochem. Biophysics *118*, 231 (1967) / −Hö. [Rd 708 IE]

The structure of the dihydroxyuranyl-urea complex, which was first prepared in 1958 and isolated as the urea uranate, has been elucidated by *W. Dembiński* and *A. Deptuła*. Whereas true uranates (polyuranates) are precipitated from uranyl salt solutions by strong bases such as NaOH or $Ba(OH)_2$, urea (the tendency of $UO_2^{2\oplus}$ to assume a coordination number of 6 and to form O and HO bridges is well known) gives the dihydroxyuranyl complex *(1)*, for the following reasons: a) the IR region around 3000 cm^{-1} is so little wider than that of free urea that only OH−NH_2 bridges are conceivable; there are no $-NH_3^{\oplus}$ bands at about 1050 cm^{-1}; the C=O band, which normally occurs at about 1680 cm^{-1}, is displaced by 55 cm^{-1} toward longer wavelengths,

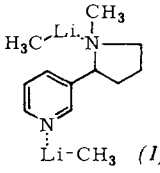


(1)

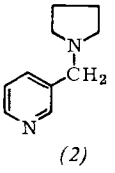
indicating CO−U coordination (Cr(III)- or Ti(IV)-urea complexes behave similarly). b) Thermal decomposition begins only 30 °C above the melting point of free urea; numerous decomposition products point to covalent bonding of the components. c) Even bases 10^4 times as strong, such as aniline or quinoline, do not form salts, but precipitate $UO_3\cdot2H_2O$. d) NH_3 is displaced from its complexes by the weaker base urea. e) The "cation": U ratio is only 1:1 even for stronger bases, but is 2:1 in this case. f) The molar volumes of $UO_2(OH)_2$, $UO_2(OH)_2\cdot H_2O$, $UO_2(OH)_2\cdot[CO(NH_2)_2]_2$, $UO_2(OH)_2\cdot[CONH_2NHCH_3]_2$ are linearly related to the molar volumes of their components. / J. inorg. nuclear Chem. *29*, 799 (1967)/− Jg. [Rd 742 IE]

The synthesis of *N*-(*t*-butyloxycarbonyl)amino acids, which are important components for peptide syntheses, has been optimized by *E. Schnabel* with respect to reaction rate and yield by the use of the correct pH value (pH-stat reaction; autotitrator). Free as well as sterically hindered or *N*-benzyl- and *N*-carbobenzoxy-substituted amino acids (Ala, Arg(NO_2) Arg(Tos), Asp (NH−NH−Boc), Glu(NH_2), Ile, Lys(Z), Met, Sar, Thr(Bu^t) *etc.*) react smoothly and in yields of 80 to 100% with a 10 % excess of *t*-butyl azidoformate in dioxane/water (1:1), water, or acetone within a few hours; examples of suitable bases are Na_2CO_3, $NaHCO_3$, $N(C_2H_5)_3$, NaOH, or MgO (pH = 8.5 to 12, generally 9.8). The *N*-(*t*-butyloxycarbonyl = Boc)amino acids or their Na salts are generally obtained in a very pure and crystalline state; they can be purified *via* the dicyclohexylammonium salts. / Chem. Ber. *702*, 188 (1967) / −Jg. [Rd 743 IE]

***para*-Substitution on Ziegler-Zeiser alkylation** was observed for the first time by *F. Haglid* and *J. O. Norén*. In contrast to pyridine, nicotine and *N*-(3-picolyl)-pyrrolidine *(2)* were also methylated in position 4 by methyllithium in ether/toluene. The ratio of substitution in positions 2, 4, and 6 was trace:1:5 in the case of nicotine and 5:1:2.75 in the case of *(2)*; different values were obtained with other solvents.



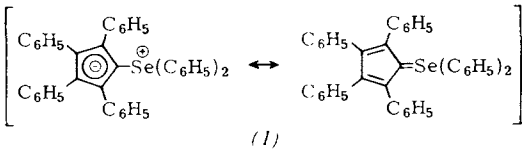
(1)



(2)

It is assumed that 4-alkylation occurs with nicotine and *(2)* *via* a methyllithium primary complex, as shown in *(1)* for nicotine. The preference for position 2 in *(2)* may be explained by the low steric hindrance for this position in comparison with nicotine. / Acta chem. scand. *21*, 329, 335 (1967) / –WG.
[Rd 766 IE]

The synthesis of a selenium ylide has been described for the first time by *D. Lloyd* and *M. I. C. Singer*. When diazotetraphenylcyclopentadiene was heated at 140 °C (10 min) in diphenylselenide under N_2, dilution of the cooled green solution with ether/petroleum ether gave yellow crystals of



(1)

diphenylselenonium-tetraphenylcyclopentadienylide *(1)*, m.p. 188–190 °C (decomp.), in 93 % yield. The IR spectrum is very similar to that of the sulfonium analog. *(1)* is stable in air in the absence of light, is only weakly basic, and is insoluble in HCl. / Chem. Commun. *1967*, 390 / –Ma.
[Rd 730 IE]

The monomer of the fd phage coat protein has a molecular weight of only 5163 and consists of 49 amino acid units, according to *G. Braunitzer et al.* The protein coat of the phage is built up of approximately 1900 of these units. The protein sequence has been almost completely determined. Because of the particularly high proportion of helical structures, the protein is highly resistant to attack by peptidases. The chain contains no cysteine, histidine, or arginine. At the carboxyl end there are five lysine units next to one another. The only proline unit is at position 6 from the amino end. Apart from the peptide hormones, the phage protein is the smallest functional protein yet known. In view of its small size, the methods now available (*e.g.* the Merrifield synthesis) make its total synthesis, and thereby the partial synthesis of a phage, appear possible. / Hoppe-Seylers Z. physiol. Chem. *348*, 725 (1967) / –Hö.
[Rd 773 IE]

Micrococcus nuclease has been investigated by *H. Feldmann* with regard to its suitability for the sequence analysis of oligonucleotides. The (crystallized) enzyme splits off predominantly the 5′ terminal dinucleoside diphosphate and the 3′terminal dinucleoside phosphate.

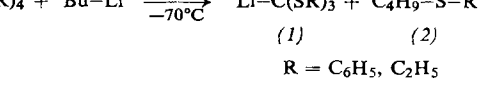
For this reason, tetranucleotides are mainly cleaved at the middle.

Pentanucleotides give the central nucleotide and the two terminal dinucleotides. In certain combinations of nucleotides other bonds are attacked, *e.g.* the internucleotide bonds in ApAp, CpCp, and CpG appear to be particularly labile. Clear results appear to be obtained only from pentanucleotides downward; for example, it appears that the bonds of heptanucleotides are first attacked endonucleolytically, and then the shorter oligonucleotides are degraded according to the above scheme. Once formed, dinucleotides appear to be stable. Despite these limitations the enzyme promises to be a useful tool for sequence analysis. / European J. Biochem. *2*, 102 (1967) / –Hö.
[Rd 774 IE]

Hexagonal diamond, a new modification of carbon, is formed from graphite at a static pressure of over 130 kbar and at a temperature greater than 1000 °C. As *F. B. Bundy* and *J. S. Kasper* show, it is necessary to start from well-crystallized graphite, in which the *c* axes of the crystallites are parallel to one another and to the direction of compression. During the conversion, the electrical resistance in the direction of the graphite *c* axis increases by a factor of about 4, and at right angles to this it increases by a factor of 10 to 200, depending on the completeness of the graphite lattice. The crystal structure of the product is hexagonal, with $a = 2.52$ Å and $c = 4.12$ Å. / J. chem. Physics *46*, 3437 (1967) / –Hz.
[Rd 782 IE]

The distortions of IR bands as a result of finite spectral slit width are corrected by *R. N. Jones*, *R. Venkataraghavan*, and *J. W. Hopkins* with the aid of a mathematical process which they call "pseudo-deconvolution". The requirements are a spectrophotometer with digital output, a digital computer, and a digital-analog converter for plotting the corrected spectra. A distortion of the true spectra occurs because the transmission measured at a given wavelength also includes contributions from light of neighboring wavelengths, the extent of this being determined by the dispersion of the prism or lattice and by the slit width. In mathematical terms, the spectrum measured is the result of the "convolution" (folding) of the true absorption spectrum with the slit functions, *i.e.* the degree of transmission of the slit in the neighborhood of the measuring wavelength. Reversal of this convolution is a highly complex mathematical process. It is, however, possible to convolute the measured spectrum further with the slit function (which is assumed to be triangular or Gaussian), by integrating the product of the sample transmission and the slit transmission twice with the wavelength as the integration variable. To a good approximation, the spectrum thus obtained deviates twice as strongly from the true spectrum as the measured one. The true spectrum can thus be reconstructed. The method was tested with simulated spectra (both isolated and overlapping bands with Lorentz profile). The increase in resolution is the same as that obtained by halving the spectral slit width. / Spectrochim. Acta *23* A, 925, 941 (1967) / –Hz.
[Rd 783 IE]

Carbanion formation from esters of orthothiocarbonic acid was observed by *G. A. Wildschut*, *H. J. T. Bos*, *L. Brandsma*, and *J. F. Arens* when the esters were allowed to react with butyllithium in THF at –70 °C. As a result of nucleophilic attack at the sulfur, the metalated triester of orthothioformic acid *(1)* and the corresponding butyl sulfide *(2)* were formed



(1) *(2)*

R = C_6H_5, C_2H_5

Compound *(1)* is smoothly alkylated with alkyl iodide or allyl bromide [CH_3–$C(SC_6H_5)_3$: 88–90 %, m.p. 146–148 °C; CH_2=CH–CH_2–$C(SC_2H_5)$: 76 %, b.p. 77–92 °C/0.45 torr], and is carboxylated with gaseous CO_2 [$(C_6H_5S)_3C$–COOH: 82 %, m.p. 97–100 °C]. If alkylation does not take place, then tetrakis(phenylthio or ethylthio)ethylene *(5)* is formed (R = C_6H_5: 45 %, m.p. 154–156 °C; R = C_2H_5: 68 %, m.p. 153–156 °C); carbenes *(4)* must be an intermediate product in this conversion. They are formed in an equilibrium reaction from *(1)* by the elimination of lithium thiolate *(3)*. Compound *(5)* is only obtained easily if *(3)* is removed from the equilibrium mixture by alkylation.

$$\underset{(1)}{2\ Li{-}C(SR)_3} \rightleftharpoons \underset{(3)}{2\ Li{-}S{-}R} + \underset{(4)}{2{:}C(SR)_2} \rightarrow \underset{(5)}{(RS)_2C{=}C(SR)_2}$$

Compound *(1)* may also be prepared from orthothioformic esters and butyllithium. / Mh. Chem. *98*, 1043 (1967) / –DK. [Rd 755 IE]

The dimer-monomer equilibrium of triethylaluminum in *n*-hexadecane solution was determined calorimetrically by *M. B. Smith* in a specially developed apparatus (quantities: approx. 160 ml *n*-hexadecane, a few ml of $Al(C_2H_5)_3$; ΔT determination with a resistance thermometer to within 10^{-4} °C); the values were determined experimentally from 60 to 150 °C, and by extrapolation up to 0 and 210 °C. The total heat of dilution Q_T can be resolved mathematically into the heat of dissociation Q_D and the heat of mixing Q_M (which decreases linearly with increasing mole fraction of $Al(C_2H_5)_3$). The calculation of the thermodynamic data (computer program for a nonlinear least-squares relationship for Q_T) is based on the following assumptions: (a) only dimers and monomers are present (K_D = monomer²/dimer); (b) K_D is the same in liquid $Al(C_2H_5)_3$ and in *n*-hexadecane solutions of various concentrations (same behavior as for a mixture of two hydrocarbons); (c) the temperature dependence of Q_D is negligible.

$$\Delta H_D^\circ = 16.9_{30} \pm 0.2_{30}\ \text{cal·mole}^{-1}$$

$$\Delta S_D^\circ = 32.1_9 \pm 0.6_3\ \text{cal·deg}^{-1}\text{·mole}^{-1}$$

$$\log K_D = 7.03_{44} = 370_{0.4}/T$$

From this it follows that K_D (0 °C) = 3.072×10^{-7} and K_D(210 °C) = 0.2374. On the other hand, molecular-weight determinations show that $Al(C_4H_9)_3$ and $Al(C_6H_{13})_3$ are already considerably dissociated at 0 °C. / J. physic. Chem. *71*, 364 (1967) / –Jg. [Rd 788 IE]

The existence of the tetrafluoroammonium cation has been definitely proved, according to *K. O. Christe, J. P. Guertin, A. E. Pavlath*, and *W. Sawodny*. The structure $NF_4^\oplus AsF_6^\ominus$ had already been assumed for the adduct $NF_3{\cdot}AsF_5{\cdot}F_2$, prepared in 1966 from an $NF_3/AsF_5/F_2$ mixture by glow discharge, on the basis of thermal stability and X-ray data. The following proofs can now be produced for two highly symmetrical ions: from the NMR spectrum (94 MHz, $CFCl_3$ as external standard; 25 °C, HF solution) the authors obtained δ_{As-F} = 69.5 ppm (Q) and J_{As-F} = 870 Hz (similar values for the structures $Ag^\oplus AsF_6^\ominus$ and $NO^\oplus AsF_6^\ominus$) and also δ_{N-F} = –213.5 ppm (T; half-width max. 10 Hz) and J_{N-F} = 234 Hz. The triplet and the low half-width indicate a symmetrical electric field around the ^{14}N nucleus (I = 1; T_d); $N_2F_3^\oplus$, $N_2F^\oplus$, $NF^\oplus$, $NF_3^\oplus$, *etc.*, give much broader signals. The infrared and Raman spectra, recorded for the crystal or in hydrofluoric acid solution, showed all the bands that would be expected for $AsF_6^\ominus$ [709(F_{1u}), 687(A_{1g}), 581(E_g), 406(E_{1u}), 378(F_{2g}), 147(F_{2u})] and for $NF_4^\oplus$ [1159(F_2), 813–815(A_1), 611(F_2), 488(E)]. A bond order of 0.85 is derived for the N–F bond in $NF_4^\oplus$ from the force constants. / Inorg. Chem. *6*, 533 (1967) / –Jg. [Rd 787 IE]

Volatile silanes can be halogenated in stages with silver chloride or bromide, as *R. P. Hollandsworth, W. M. Ingle*, and *M. A. Ring* have shown. Chloro- and bromogermanes have already been prepared in a similar manner. The silane (1–2.2 mmole) is passed over layers of silver halide (approximately 22.5 g), which are retained by layers of glass wool, in a Pyrex tube at 90–280 °C; the experiment is carried out in a vacuum apparatus. Up to the present, the systems given in the table have been converted according to eq. (a) or (b).

$$\text{Si–H} + 2\ AgCl \longrightarrow \text{SiCl} + HCl + 2\ Ag \qquad (a)$$

$$\text{SiH} + AgBr \longrightarrow \text{SiBr} + {}^1/_2\ H_2 + Ag \qquad (b)$$

System	Yield (%) monochlorinated product	dichlorinated product
$SiH_4/AgCl$	38	7.5
$CH_3SiH_3/AgCl$	60.5	8
$(CH_3)_2SiH_2/AgCl$	37	18.5
$(CH_3)_3SiH/AgCl$	39	–
$SiH_4/AgBr$	31.5	3
$Si_2H_6/AgCl$	30	(5.5)

The method is now being tested for the synthesis of disilanes. / Inorg. Chem. *6*, 844 (1967) / –Jg. [Rd 786 IE]

Isotope-exchange experiments to determine the mechanism of the enzymatic phosphoenolpyruvate (PEP) synthesis are proposed by *R. A. Cooper* and *H. L. Kornberg*. The reaction (1) which is catalyzed by PEP synthase from *Escherichia coli*, takes place in stages (2), (3), and (4).

(1) ATP + pyruvate ⇌ AMP + phosphate + PEP

(2) Enzyme + ATP ⇌ enzyme pyrophosphate + AMP

(3) Enzyme pyrophosphate + H_2O ⇌ enzyme phosphate + phosphate

(4) Enzyme phosphate + pyruvate ⇌ enzyme + PEP.

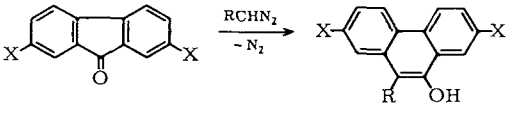
The formulation of reaction (2), (3), and (4) is supported by the following isotope-exchange reactions: (a) ^{14}C–AMP is rapidly incorporated into ATP on incubation with the enzyme, $MgCl_2$, and ATP; ADP has no influence on this reaction, but it is inhibited by fluoride and ethylenediaminetetraacetate (EDTA); (b) ^{32}P-phosphate is incorporated into ATP on incubation of ATP with enzyme, $MgCl_2$, and AMP; pyruvate is not necessary, but AMP must be present; (c) ^{14}C-pyruvate is incorporated into PEP if PEP is incubated with enzyme and $MgCl_2$; phosphate, ATP, and AMP are not necessary. These reactions are inhibited by EDTA but not by fluoride. Reactions (2)–(4) are more rapid than the forward reaction of (1). There is no proof for a direct phosphate transfer from ATP to pyruvate. / Biochim. biophysica Acta *141*, 211 (1967) / –Hö. [Rd 775 IE]

***N*-Acetyl-phenylalanyl-tRNA** is the starter for the polyuridylic acid-controlled synthesis of polyphenylalanine, according to *J. Lucas-Lenard* and *F. Lipmann*. The most important prerequisite for a starter appears to be the blocked amino group, since dipeptidyl-tRNA is also active. *N*-Formylmethionyl-tRNA generally functions as a starter in intact biological systems. In polyphenylalanine synthesizing systems from *Pseudononas fluorescens*, at lower (4 mM) magnesium-ion concentrations two further factors, f_1 and f_2, are involved in the start mechanism; they have been recovered from ribosomes by washing with 1 M ammonium chloride. They bind the *N*-acetyl-phenylalanyl-tRNA to the ribosomes; the cofactor for this reaction is GTP. The two factors are not identical with one of the three enzyme fractions G, T_s, T_u, which are also necessary for polypeptide synthesis. / Proc. nat. Acad. Sci. U.S.A. *57*, 1050 (1967) / –Hö. [Rd 770 IE]

Copper is a catalytically active component of cytochrome c oxidase from ox heart muscle. The copper content of the enzyme was already known, but the non-specific redox behavior of copper made its biological function appear questionable. *P. M. Nair* and *H. S. Mason* showed that removal of the copper from the enzyme caused a loss of enzymic activity, and that the enzyme could be reactivated with Cu(I). The copper was removed by means of 2,9-dimethyl-4,7-diphenyl-1,10-phenanthrolinedisulfonic acid ("bathocuproinsulfonic acid"), but only under anaerobic conditions in the presence of reduced cytochrome c. On incubation of the deactivated enzyme with equimolecular amounts of Cu(I)-acetonitrile perchlorate ($Cu(CH_3CN)_4ClO_4$), 3 to 4 fold stimulation over the initial activity was obtained. The assumption that the normal enzyme preparations are deficient in copper is supported by the fact that untreated cytochrome c oxidase is also activated by a factor of about 3 on treatment with Cu-acetonitrile. / J. biol. Chemistry *242*, 1406 (1967) / –Hö.

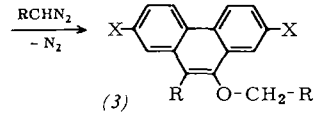
[Rd 776 IE]

Ring expansion of fluorenones to phenanthryl ethers was achieved by *B. Eistert* and *M. A. El-Chahawi* with diazomethane or diazoethane.



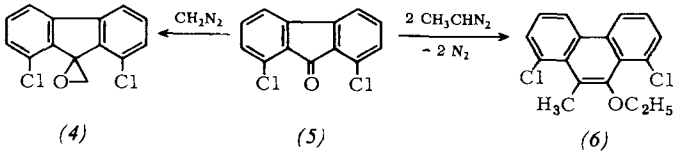
(1) *(2)*

(a): R = X = H
(b): R = H, X = Br



(3)

Fluorenone *(1a)* and dibromofluorenone *(1b)* react to give alkoxyphenanthrenes *(3)* only if pure distilled diazomethane or diazoethane solutions are used, the yields being respectively 90 and 75 %. If diazomethane is produced *in situ* from *N*-nitroso-*N*-methylurethane, as suggested by *R. F. Schultz et al.*, then then main product is the non-alkylated phenanthrol *(2a)* (30 %), with only a little *(3a)* (1.5 %). 1,8-Dichlorofluorenone *(5)* also reacts with diazoethane to give a



(4) *(5)* *(6)*

ring expansion product [*(6)*, m.p. 103–104 °C], but with diazomethane it gives the epoxide *(4)* (m.p. 240 °C). / Mh. Chem. *98*, 941 (1967) / –WG.

[Rd 767 IE]

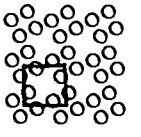
Catalase from human erythrocytes crystallizes in the form of tubes, as shown by micrographs taken by *N. A. Kiselev C. L. Shpitzberg*, and *B. K. Vainshtein.* The tube walls are formed from a monomolecular layer. The diameter of the tubes is 420 Å and the wall thickness is approximately 65 Å. The molecules (molecular weight 250000) are arranged in two parallel strands, each 75–80 Å in width, which form a helix. Thus the pitch of the helix is 150–160 Å; each turn of each strand contains about 23 molecules. The coordination number of the individual molecules is 6. The crystals studied were obtained from 1.5M ammonium sulfate solution at pH 6.5–7. Catalase obtained from ox liver crystallizes in the same form under these conditions, but with slightly different dimensions. / J. Molecular Biol. *25*, 433 (1967) / –Hö.

[Rd 768 IE]

Diagonal electrophoresis techniques, interesting and simple variations of paper electrophoresis, were used by *R. N. Perham* and *G. M. T. Jones* to resolve problems in the analysis of amino acid sequences. In this method, the mixture of substances is subjected to two successive electrophoreses under identical conditions but in directions at right angles to one another; a diagonal of substance spots is obtained. If a component or a group of components is chemically modified between the two electrophoreses, preferably on the electrophoresis paper, the modified substances will not lie on the diagonal after the second electrophoresis. For amino acid sequence analyses, proteins with trifluoroacetylated ε-amino groups in the lysine residues are cleaved with peptidases. After the first electrophoresis of the fragments, the paper is treated with gaseous ammonia, which liberates the amino groups. After the second electrophoresis all the lysine-containing peptides will not lie on the diagonal. / European J. Biochem. *2*, 84 (1967) / –Hö.

[Rd 769 IE]

Ribosome crystals are formed in chick embryo cells at temperatures below the normal physiological levels (5–15 °C). The arrangement of ribosomes in the crystals was studied by *B. Byers*, using an electron microscope. In interphase cells, layers are formed which are one ribosome thick and which may be bent into the form of closed cylinders. In mitotic cells, three-dimensional crystals are formed by the superposition of such layers. The ribosomes (diameter approx. 24 nm) are arranged as follows: the "unit cell" is a square,



the length of whose side is 57.3 nm. The layers may crystallize on a matrix or together with a structure-forming substance, since in cross-sectional pictures of the layers it is always possible to distinguish an optically denser and an optically less dense side to each layer. The particle weight of the ribosomes is approximately 4 million. / J. molecular Biol. *26*, 155 (1967) / –Hö.

[Rd 771 IE]

Chemotaxonomy der Pflanzen. Eine Übersicht über die Verbreitung und die systematische Bedeutung der Pflanzenstoffe. (Chemotaxonomy of Plants. A survey of the distribution and the systematic significance of plant substances). Volume 4, Dicotyledons: Daphniphyllaceae to Lythraceae. Chemical Series. Textbooks and Monographs in the Field of the Exact Sciences. Birkhäuser Verlag, Stuttgart-Basel 1966. 1st Edit., 551 pp., DM 106.–.

Of the six projected volumes of this already very well introduced work, Volume 4 is now available. It deals with the essential substances contained in a total of 71 dicotyledonous plant families, namely (in alphabetical order) Daphniphyllaceae to Lythraceae. Approximately 28000 species are included. The families Euphorbiaceae, Gesneriaceae, Labiatae, and Lauraceae are particularly large; the important family Leguminosae is left for a later volume.

The plan and the presentation of the subject matter follows the customary scheme. With supplements, the literature is covered to about the end of 1965 and includes many difficultly accessible references. Misprints and factual errors are rare, and the printing and presentation are as usual excellent. The scientist interested in the results of phytochemical research will find the volume very rewarding. *Hegnauer*'s conclusions in regard to the systematic inclusion of debatable genera are careful and conservative. Conclusions concerning the families that are discussed often include sentences such as: "For the time being the available data permit only a superficial chemotaxonomic assessment...". The situation is likely to alter as soon as sufficient detailed chemotaxonomic investigations become available. *C. H. Eugster* [NB 650 IE]

Die wissenschaftlichen Grundlagen des Pflanzenschutzes. By *H. Martin*. Based on the 5th Edit. (1964) of: *The Scientific Principles of Crop Protection*, translated and supplemented by *K. J. Schmidt*. Verlag Chemie GmbH., Weinheim/Bergstr. 1967. 1st Edit., xii, 696 pp. and 3 tables, DM 68.–.

The present book is divided into 16 chapters, the first of which introduces the subject matter. Chapters II, III, and IV deal with the resistance of plants to pathogenic agents and pests, the influence of external factors on the susceptibility of plants, and the methods of biological pest control. Chapters V to XVI discuss the chemical and physical agents and methods for the protection of plants, the problems that arise in their use, mechanisms of action, and special questions concerning the treatment of infection centers and vectors. The translation has been supplement by valuable references to recent publications, *e.g.* to recent German works on biological pest control, to the "ultralow volume" technique, which involves the spraying of highly concentrated substances, to new methods for the production of insecticidal aerosols, to the antibiotics Blasticidin-S and Kasugamycin, to the phosphorus insecticides, which are not discussed in the English text, to the mercury-free seed dressing Voronit, and the use of simulated bat cries to scare insects. Tables giving the Latin, German, and English names of important arthropods and fungi, as well as data on their classification, are included as an appendix. The book ends with comprehensive subject and author indexes.

The translation contains a number of shortcomings and printing errors, which should be corrected in a new edition. Thus the fungicide "Nirit" is referred to as "Nitrit", Dinocap sometimes appears as "Dinocab", Prometryn as "Prometrin" and Ametryn as "Ametrin". The statement that the herbicide Linuron was "placed on the market in 1960 by DuPont Nemour Inc." should also be corrected, since Linuron is a product of Farbwerke Hoechst AG. (*Scherer et al.*, German Patents, 1956 and 1958). The alkali metal and ammonium salts of "3,5-dinitro-*o*-cresol" are not "soluble in all proportions in water"; the solubility of the sodium salt at room temperature is only 5 %. DDT is not readily soluble "in most organic solvents". Gamma-HCH contains no "cyclodiene grouping".

The common names recommended by the International and the British Standards Organisations (ISO and BSI) are occasionally confused with trade names of crop protection agents, *e.g.* in the cases of Carbaryl ("the B.S. trade name is Carbaryl"), DNOC, and Dioxathion. In many cases the common names used in English, *e.g.* Azinphos, Fenthion, and Trichlorfon, are replaced in the translation by trade names, while in other cases substances, such as Monuron, Diuron, Neburon, and Linuron, are referred to by the common names but not by trade names. This disorderly use of names makes the book unnecessarily difficult to use. The chemical names should all be formed in accordance with the IUPAC nomenclature rules in the next edition.

The German translation of the article will be warmly received, since the English author has succeeded brilliantly in providing the biologically and agriculturally oriented reader with a clear picture of the physico-chemical and toxicological aspects of crop protection, and at the same time offering chemists and toxicologists working on the synthesis and testing of crop protection agents an insight into the biological problems encountered in crop protection. *H. Maier-Bode* [NB 686 IE]

Methoden der organischen Chemie (Methods of Organic Chemistry) (Houben-Weyl), Vol. VI, Part 3, Oxygen Compounds I, Edited by *Eugen Müller*. Georg Thieme Verlag Stuttgart 1965. 4th Edit., xlvii, 832 pp., 4 figures, 70 tables, DM 212.–.

The present Volume VI, Part 3, Oxygen Compounds I, of Houben-Weyl continues the sequence of monographs on the methods of preparative organic chemistry in the accustomed thorough manner.

The book begins with chapters on the preparation and transformation of ethers, acetals, orthocarbonates and oxonium salts; the literature references for the ethers embrace those up to and including 1962, and those for the remaining three classes of substances to 1963.

These chapters, written by *H. Meerwein*, leave nothing to be desired in respect of clarity of expression, completeness of the synthetic procedures, and the amount of personal experimental experience incorporated.

The following chapters deal with methods of preparing and transforming epoxides, oxetanes, and dihydro- and tetrahydrofuran derivatives, with literature references up to 1963. These chapters too are characterized by a strict systematic arrangement and admirable thoroughness of treatment.

The chapter "Ethers" is subdivided into purely aliphatic, aryl aliphatic, purely aromatic, and unsaturated ethers, so that the variations of comparable procedures can be viewed against the reactivities of the individual classes of substances. It should be emphasized that the methods of sugar alkylation are dealt with in a comprehensive manner; the biochemist engaged in preparative work should derive particular benefit from this aspect. The methods of ether transformation embrace all the oxidation, cleavage, and rearrangement reactions observed in ethers in systematic order. Consideration has been given to the generally neglected steric factors in the addition of alcohols to unsaturated ethers (p. 42).

The chapter on the methods of preparing acetals and ketals lays particular emphasis on the universally applicable procedures with orthoesters. Procedures for preparing spiroketals, which are basic to a number of natural substances (cf. *F. Bohlmann et al.*, Chem. Ber. *94*, 3193 (1961)), may perhaps be missed but they can be found later in a different connection (pp. 552 and 699ff).

Ketene acetals should also be included in a subsequent edition; a single example only is referred to in the chapter "Epoxides" (p. 484).

Under the subject "Conversions of oxonium salts" synthetic methods involving pyrylium salts are mentioned briefly (pp. 352–358 and 363–365). On the other hand, acid- and base-catalyzed ring-opening reactions of epoxides are described twice (p. 42ff. p. 448ff.). Perhaps this is inevitable in a work written by several authors. Among the transformation reactions of epoxides, the preparatively interesting removal of the oxygen atom by triphenylphosphine with the formation of an olefin may deserve a comment. In the treatment of the methods of oxetane preparation by cycloaddition of olefins to ketones (p. 503) there is no mention of the photochemical formation of oxetanes (Paterno-Büchi reaction) from olefins and carbonyl compounds; this method is of preparative interest and in many cases proceeds stereospecifically. In relation to the dihydrofuran-diene adducts (p. 559) in the chapter on the preparation of five-membered cyclic ethers, some remarks concerning the stereochemistry of the adducts, such as have been made in the case of similar compounds on page 641, would be entirely appropriate.

Further, it would seem useful to the reviewer to adopt the IUPAC nomenclature (pp. 559, 641, 643, 647), because finding of the compounds discussed in collected works from the subject index would then be made easier.

These few critical remarks are the only ones to have occurred to the reviewer during a careful reading, in which he was assisted by Dr. *H.-D. Scharf*. In view of the abundance of the material presented and discussed, this is proof of the quality of the work. The volume is a rich mine of chemical knowledge.

F. Korte [NB 640 IE]

Biochemie der Vitamine (Biochemistry of the Vitamins). By *Th. Bersin*. Akademische Verlagsgesellschaft, Frankfurt/Main 1966. 1st Edit., vii, 296 pp., 16 figures, DM 44.–.

The author, who was compelled to undertake this venture by his early work on the subject, attempts to describe the biochemical function and the therapeutic use of vitamins for the benefit of physicians and dieticians. Such a work cannot be more than a literature review, with more or less successful attempts at systematization, and certainly cannot be original. The book is divided into a general part, in which much of the material is distorted though not actually incorrect, and a special part, in which the various vitamins are discussed in an old-established manner. A large quantity of material, divided into biosynthesis, mode of action, therapeutic action, and analogs, is compressed into a relatively small space, but the discussion is frequently not sufficiently critical. In many cases matters cannot be regarded in such an unambiguous and schematic way. It would indeed be delightful if they were as certain as they appear to be from this presentation to the uninitiated reader (*e.g.* in the methionine synthesis and the mode of action of mercaptopurine). No definite function of vitamin B_{12} has been established in higher plants; the vitamins formed by intestinal bacteria are scarcely a source of self-provision.

The unbalanced treatment of the material is a particularly striking weakness. Trivia are given importance by a few words (orbitals, nonpolar, translational motion); Americanisms (absorption instead of resorption) and non-standard units (γγ, mcg) are simply adopted. Strange nomenclature (isoalloxazinebenzopteridine, pyridoxaminium-5′-phosphate) and interpretations (mongolism as mutation) seem dubious. Apart from incorrect references (*Wolley, Jacobs, etc.*) the references to the authors own work (*e.g.* Function of the nucleic acids: Vitalstoffe *8* (1963) 5) and the style are irritating.

On the other hand, the book contains a great deal of carefully collected and useful material. The medical material will seem interesting to the chemist and the chemical material to the physician.

L. Jaenicke [NB 586 IE]

Kurze Anleitung zur Berechnung von π-Elektronensystemen (A Short Introduction to the Calculation of π-Electron Systems). By *J. D. Roberts*. An extended translation of "Notes on Molecular Orbital Calculations" by *F. Wille*. S. Hirzel-Verlag, Stuttgart 1966. 1st Edit., xi, 165 pp., paperback, DM 19.80.

The "lecture notes" type of textbook, with its economic presentation, whose availability up to recent times has been unfortunately restricted predominantly to English-speaking countries, is here available in an exemplary form. The didactically sovereign, easily understandable, and sometimes unorthodox manner, which follows that of the basic *Roberts* lectures, including those given in Munich in 1962, introduces the student to the Hückel molecular orbital theory (HMO) as the simplest quantum-mechanical approximation procedure – "to be able to make MO calculations while swinging in a hammock beside a mountain lake". No extensive mathematical knowledge is assumed, and numerous exercises provide an opportunity of becoming familiar with quantities such as charge and bonding order, free valence, and delocalization energies. Further chapters deal with the application to aromatic, heteroatom-containing, or nonplanar electron systems, and to the prediction of chemical reactivities. In conclusion, the quantities neglected by the HMO theory are discussed critically. There is an appendix consisting of worked examples, two original publications, and a bibliography. The German text is lucid; the number of misprints is tolerable (*e.g. cis*-butadiene (p. 55) is always treated as linear in the HMO scheme without making additional assumptions, "$>$" on p. 93 should be "$<$". The chapter dealing with determinant factorization with the help of group theory has been extended to the general case, although only two-digit symmetry elements are used. A successful introduction to determinant algebra has been added as a further appendix. Numerical solutions of all exercises and an introduction to the use of the now available HMO tables would have been equally desirable. The book, provided with a preface by *R. Huisgen*, can also be recommended to the beginner as a simple introduction to HMO theory and its application to organic compounds.

H. Bock [NB 638 IE]

Techniques in Protein Chemistry. By *J. Leggett Bailey*. Elsevier Publishing Company, Amsterdam-London-New York 1967. 2nd Edit., xiv, 406 pp., 118 figures, 53 tables, Dfl. 55.–.

The very rapidly developing methodology of protein chemistry reached a comprehensive level a few years ago. Standard methods are now available for characterizing and purifying the proteins themselves and their degradation products. In many cases these may have to be combined in different ways or even modified, but when used together they generally succeed in elucidating structure. Some of these procedures may well be replaced by superior techniques, but this book attempts to select several proved and particularly well developed methods. Moreover, it chooses procedures which are applicable to research where purification or sequence analysis is only occasionally employed.

The limitation to reliable manipulative techniques such as paper chromatography, ion-exchange chromatography, and fingerprint procedures for amino acids and peptides, N- and C-terminal sequence determination, column chromatography, strip electrophoresis, dialysis, and molecular sieve separation of proteins, splitting of disulfide bonds and sulfhydryl determination in protein together with certain important basic methods such as protein, nitrogen and tryptophan determination, finds expression in an arrangement hardly changed from the first edition. The final chapter deals with methods of synthesizing simple peptides such as the enzymologist selects as substrates.

New developments in this field account for the substantial increase in size of the second edition. Here again *J. L. Bailey* has succeeded in selecting successful and reliable new devel-

opments and in describing them in a comprehensive manner, while giving a short account of promising, but as yet little tested techniques.

The individual chapters are very detailed, and are well suited for providing information to workers in other fields. Quite deliberately, attention has been directed to the preparation or purely chemical analysis of protein and peptide mixtures that can be accomplished without the need for elaborate instrumentation – with the possible exception of amino-acid analysis. Physicochemical methods have been left in the background. A somewhat wider-based presentation of the radioactive labeling of proteins would perhaps be desirable, for example with enzyme substrates, and also the analysis of the peptides and amino-acids of their labeled derivatives. Where several proved methods are available for achieving a particular aim, as for the determination of N-terminal sequences, all are described with equal thoroughness.

The book has been produced with care, and the printing, the high-quality illustrations, and the arrangement combine to make it very lucid. The abundance of material which it presents recommends it highly to everyone interested in protein methodology. *H. Fasold* [NB 633 IE]

Microbial Transformations of Steroids. By *A. Čapec, O. Hanč*, and *M. Tadra*. Translated from the Czech by *O. Macek, L. Urbanek* and *O. Hanč*. Dr. W. Junk, Publishers, Den Haag 1966. 1st Edit., iv, 253 pp., bound Dfl. 25.00/$ 6.95.

The conversion of steroids by microbial enzymes has been intensively investigated by numerous groups of workers during the past decade, and has led not only to scientifically interesting information but also to practically useful results. Although no detailed classification of papers published in scientific periodicals, reviews, and patents has yet been carried out, the present monograph attempts to rectify this omission. The brief introduction is followed by a discussion of the types of microbiological reactions and of reaction mechanisms. In this, the authors have not relied on speculations. Next comes a brief discussion of the influence exerted by the steroids on microorganisms. The practical hints concerning fermentation are very helpful. A detailed treatment of the analytical methods, identification, and constitution-determination methods is unnecessary, because all these are well known. No fundamentally new aspects arise in bacterially produced steroids. The necessity for determining physical data such as the melting point, optical rotation, and light absorption is taught to every student at the outset of his practical organic chemistry course, and in addition the treatise "Steroid Reactions" by *C. Djerassi* (1963) provides exhaustive information about chemical methods in steroid chemistry.

The sections that classify the microorganisms according to their reactions are very useful, as are the lists of steroid metabolites (together with physical data and the nature of their preparation) and the comprehensive bibliography (unfortunately reaching only to the end of 1963) which includes patent literature. This carefully produced work will render valuable service to both expert and outsider wishing to employ microbiological reactions. *Ch. Tamm* [NB 648 IE]

Growth, Function, and Regulation in Bacterial Cells. By *A. C. R. Dean* and *Sir C. Hinshelwood*. Clarendon Press: Oxford University Press, Oxford 1966. 1st Edit., xii, 439 pages, 120 figures, 29 tables, 2 plates, 84s.

In 1946, *Sir C. Hinshelwood* published a book entitled "The Chemical Kinetics of the Bacterial Cell". The present volume is based on the same material with the contents brought up to date. It would probably have been better to retain the old title, instead of arousing unfounded hopes by a title that does not agree with the contents. The book is by no means an introduction to the problems of the growth, function, and regulation of the bacterial cell. Nowadays, these problems can no longer be discussed without recourse to the chemical and morphological principles of bacteria as a basis.

The great value of this book lies in the detailed treatment of the biophysical aspects of bacteriology, which will become increasingly important with further research. The biophysical side of the various problems of bacteriology is familiar to very few microbiologists, so that this book is also a very welcome addition to the literature on bacteriology. The problems discussed are taken largely from the fields in which the authors work: this on the one hand is a guarantee of authenticity, but on the other leads to a rather unbalanced selection of material.

Both authors give a neat account of the biophysical principles of the intact bacterial cell, hardly touching on the biophysical problems of molecular biology. In their opinion the situation prevailing in intact cells must be elucidated before one can proceed into the molecular-biological domain. The idea that the reverse route may also be possible is evidently familiar only to the younger generation. *H. Zähner* [NB 606 IE]

Carbocyclic Non-Benzenoid Aromatic Compounds. By *D. Lloyd*. Elsevier Publishing Company, Amsterdam-London-New York 1966. 1st Edit., x, 220 pages, 2 figures, Dfl. 35.00.

The present monograph is intended as a concise presentation of the existing knowledge on non-benzenoid carbocyclic aromatic compounds. In the introduction (15 pages), a recapitulation of the historical development of the concept of "aromaticity" is followed by a description of the results of the molecular orbital theory that are of greatest importance to the preparative organic chemist. The next few chapters deal with derivatives of cyclopropene (19 pages), cyclobutadiene (20 pages), cyclopentadiene (43 pages), tropylium salts (19 pages), tropone and tropolones (45 pages), cyclooctatetraene and cyclononatetraene derivatives as well as annulenes (19 pages), and polycyclic compounds (35 pages), in particular the azulenes. The choice of material is generally reasonable, though the space devoted to the various classes of substances is not always in keeping with their importance. For example, the fulvenes are dismissed in 6 pages, whereas 45 pages are given to the tropones and tropolones.

In each section, the author describes in a readily understandable manner the methods of preparation, properties, chemical reactions, and principal spectral data. Each chapter is followed by a list of references, the total number of entries for the book being about 1000 (literature up to 1965). In comparison with other books on the same subject, a particularly pleasing feature is the clear formulation of the reactions, though no preparative details are given and the spectroscopic findings are not discussed. The inclusion of spectra of some characteristic compounds would undoubtedly have been helpful.

No previous theoretical knowledge is required in order to read the book, which can be recommended to chemists who wish to gain a general picture of recent results in the field of carbocyclic non-benzenoid aromatic compounds.

M. Neuenschwander [NB 608 IE]

Methods of Elemento-Organic Chemistry. Edited by *A. N. Nesmeyanov* and *K. A. Kocheshkov*. Vol. 1: The Organic Compounds of Boron, Aluminum, Gallium, Indium, and Thallium. By *A. N. Nesmeyanov* and *R. A. Sokolik*. North Holland Publishing Company, Amsterdam 1967. 1st Edit., xiii, 628 pp., 40 illustrations, 27 tables, Dfl. 87.–.

The first volume of this new series was published in 1964 by Nauka Press in Moscow and has been partly revised for translation into English. The various sections (*e.g.* boron 362 pp.; Al 140 pp.) of the book are mostly arranged according to methods of synthesis; for boron and aluminum, compounds without a metal-carbon bond are included. In a few sections, *e.g.* chapters 10–12 and 15 on boron compounds and in chapter 8 on aluminum compounds, division is

according to the substances described. An article on analytical methods for each element discussed is also included.

The book is intended above all for the chemist engaged in preparative work in organometallic chemistry and it will help him in his search for the best preparative method for a given compound by providing him with a wealth of procedures. However, because of the division by methods the same class of compound is often described in several places, and then the necessary cross-references are lacking so that the required data is not always very easy to find. In spite of the large amount of information given, much work is often required of the reader in selecting what is best suited to his needs.

The value of the individual chapters varies because of the different treatments of the literature – in some cases covered up to 1965, but mostly up to 1962/63. Whereas many sections, *e.g.* the synthesis of organoboranes by means of organometallic reagents, are relatively clear and uniform, others deal with too heterogeneous a material. It is, for instance, unintelligible why "symmetrization reactions" of boron compounds (p. 179ff.) is followed by a section on "exchange reactions" (p. 199ff.). Moreover, other analogous reactions are spread over several chapters.

It is unfortunate that not all the chapters have been carefully revised. The printing of formulas is often technically unsatisfactory. Interchanged headings, even of large subchapters (pp. 70 and 75), are to be found as well as numerous misprints and false references. In a number of cases, the inclusion of more recent knowledge would have greatly improved the selection of experiments described.

In spite of these failings, the book does provide a useful review of this complicated material although critical evaluation is still required of the reader. If this volume were thoroughly revised by the authors and editors it would fulfil a useful purpose among the literature of preparative organometallic chemistry. *R. Köster* [NB 656 IE]

Progress in Reaction Kinetics, Vol. 3. Edited by *G. Porter.* Pergamon Press, Oxford 1965. 1st Edit., vii, 515 pp., several figures, 100 s.

The editor has managed to bring out the third volume surprisingly quickly after the first two [1] of the series and also the cumulative index of the reactions whose kinetics form the subject of these three volumes. Substantially more than 1000 reactions are cataloged in the three groups "Reactions in gases", "Surface reactions", and "Reactions in condensed phases"; the arrangement and subdivision permits rapid successful searching.

The present, third, volume contains 10 contributions: *K. J. Laidler* and *J. C. Polanyi* present the theory of the kinetics of bimolecular reactions for advanced students (54 pp., 169 references). This is followed by a survey of "Reactions of hydrogen atoms in the gas phase" by *B. A. Thrush* (30 pp., 162 references), in which combination and transfer reactions are discussed. *R. Wolfgang* gives an introduction to "The chemistry of hot atoms in the gas phase", *i.e.* an indication of possible reaction paths for atoms containing kinetic energy in excess of the activation energy (70 pp., 162 references). In Chapter 4, *B. G. Gowenlock* discusses "The inhibition of radical chain reactions in the gas phase (25 pp., 133 references), with emphasis on the results of research of the past decade. The chapter by *A. W. Read* on "Vibration relaxation in gases" (30 pp., 141 references), which is fundamentally a progress report on the past five years, concludes the subject of the gas phase.

L. M. Dorfman and *M. S. Matheson* present a chapter on "Pulse radiolysis" (60 pp., 165 references), which is a very important technique for fast reactions, and treat the experimental methods in a welcome, detailed manner. *W. G. Burns* and *R. Barber* are the authors of a chapter on correlations of dose efficiency, linear energy transfer (= differential energy loss along the path of an ionized particle), and product yield during ionizing irradiation of nonaqueous systems, using the diffusion models that have proved themselves for aqueous systems (60 pp., 131 references). *E. J. Land* describes electron spectra and the kinetics of aromatic radicals (30 pp., 132 references). The assignment of the spectra is explained in exemplary fashion; ESR investigations are included in the references.

The last two contributions deal with polyreactions. *R. C. P. Cubbon* and *D. Margerison* discuss the organolithium-induced polyreactions of vinyl monomers (40 pp., 101 references). (Inexplicably, the authors have made a mistake in the interpretation of the kinetic formulas by a German group of workers. The problem stated on p. 427 has been solved.)

"The investigation of radical polymerization in solution" by *G. M. Burnett* concludes the volume. Here the presentation is unusually short (18 pp., 58 references) and the proportion of references that are older than 10 years is very high. Nevertheless, this chapter, like the others, documents the present state of knowledge and indicates possible lines of research. The presentation of the book is faultless. It is self-evident that this volume (like its predecessors) is a must in every chemical library and even more so in the personal library of all chemists concerned with kinetics. *H. Sinn* [NB 631 IE]

Histoire Brève de la Chimie (A Short History of Chemistry) by *L. Velluz.* Librairie Maloine, Paris 1966. 1st Edit., 115 pp., paperback F 14.–.

No one who is interested in the long and eventful journey of mankind to the point of understanding science can be indifferent to the flowering and the extraordinary development of chemistry. Is there a more beautiful masterpiece of logic than the theory of matter, built up patiently on experience, to which modern physics merely had to add details at the start of the twentieth century? On 115 pages *L. Velluz* surveys the development of fundamental ideas and recreates the leading actors of the drama.

The attempt by man to resist decay, and dreams of riches through transmutation of elements led to alchemy, a pseudoscience which clothed its unskilful metallurgical procedures in phantastic formulations. True chemistry did not begin until the end of the seventeenth century, still entirely as an appendix to philosophy. *Stahl* forged the first link between apparent and related facts with his phlogiston theory. These tenets, in turn, prevented *Priestley* about a hundred years later from drawing the correct conclusions from his discovery of oxygen. It was left to *Lavoisier* to discover the general principle of oxidation by developing precise weighing methods. The general awakening of interest in science early in the nineteenth century favored the initial successes of chemistry. This was the age when the educational system in Europe was established under the influence of *Liebig* and *Dumas*, when *Chevreul* recognized the existence of definite organic compounds, and when careful analyses were performed by *Berzelius* to establish the foundation of quantitative chemistry. This promising beginning was followed by the era of "lack of gratitude" of *ca.* 1840, reverberating with polemics and producing a generation of devoted chemists who resolved the conflicts founded in the dualistic views of *Berzelius*. Following the discovery of the laws of substitution by *Laurent*, this turbulent but fruitful period saw the triumphant type theory of *Gerhardt* and, *ca.* 1850, the origin of the chemical symbols, so devotedly defended by *Wurtz*.

The understanding of molecular architecture did not come about until after the discovery of the universal principle of molecular asymmetry by *Pasteur*. One chapter describes the stages in *Pasteur*'s discovery, soon to be completed by the work of *Le Bel*, *vant'Hoff*, *Kekulé*, and others. Modern structural chemistry had been established, and chemistry stood at the threshold of the promised land. *Mendeleev*'s classification of the elements, the discovery of radioactivity by *Pierre* and *Marie Curie*, and the progress in synthetic

[1] For a review of Volume 2 see Angew. Chem. *77*, 435 (1965); Angew. Chem. internat. Edit. *4*, 454 (1965).

chemistry became the basis of soaring chemical research, emphasized by the founding of the first dyestuff factory. Only a few reflections are devoted to the subsequent stormy and restless era. How many surprises does the future hold – perhaps the creation of psychological chemistry enabling man to act on his psyche?

The author has had a difficult task in condensing the historical development into so little space and yet giving the most important events their due attention. Critical selection became essential, and the author has succeeded by interposing anecdotes and by the use of a flowing style to make the actors of the exciting drama appear before our eyes in the atmosphere of their own age.

This small volume will instruct the layman in a friendly manner and will relate many new things or put old ones in perspective to the initiated. Once begun, the book will not be put down before the last page is read.

J. Rigaudy [NB 655 IE]

Solvent Effects on Reaction Rates and Mechanisms. By *E. S. Amis*. Academic Press, New York/London 1966. 1st Edit., xi, 326 pp., numerous figures and tables, $ 10.50.

Although *M. Berthelot* and *L. de St. Gilles* observed and studied the effect of solvents on the rate of chemical reactions as long ago as 1862, and *N. Menshutkin* stated in a fundamental work published in 1887 that "a reaction is inseparable from the medium in which it takes place", no critical compilation of the extensive experimental and theoretical work on the effects of solvents on reaction rates and mechanisms has appeared until the present monograph by *E. S. Amis*.

The first four chapters form theoretical attempts to interpret the effect of solvents on reactions involving different electric charges (reactions between ions, dipolar molecules, dipolar molecules and ions, and also electron exchange reactions between ions). Chapter V is devoted to the effect of external and internal pressure (cohesion) in addition to the comparison between gas-phase and solution reactions, and also the effect of solvent viscosity on the above types of reactions. Insofar as they describe the effect of the solvent on the reaction rate empirically, linear free energy relationships are listed in the following chapter.

The last two chapters deal with the qualitative solvation model proposed by *E. D. Hughes* and *C. K. Ingold* and also with further special solvent effects such as selective solvation, cage effects, primary and secondary salt effects, and hydrogen bonding.

The presentation of the often complex material is interspersed with numerous examples, 26 illustrations, and 30 tables. Theoretical physical aspects are emphasized rather than chemical ones. Considering the scope of the subject, it is perhaps inevitable that some aspects of particular importance to the organic chemist have been left out. No indications are given of the great importance which the dipolar, aprotic solvents have achieved in nucleophilic and electrophilic substitution reactions (*A. J. Parker*), or of the control of the reactivity of ambident anions and cations by the solvent (*N. Kornblum*). The value of the detailed bibliography (about 500 references, in part complete to 1965) is unfortunately marred by numerous misprints (*e.g.* references 16, 18 (p. 29); 33 (p. 57); 48, 56, 59, 65, 74 (pp. 119–120); 4, 6, 11, 15, 36, 41 (pp. 145–146); 8, 43 (pp. 181–182); 24, 25, 80, 108, 110, 113, 135, 136, 153, 157, 166 (pp. 251–255)). Some equations are badly set out typographically or actually wrong (*e.g.* eqs. 2.67; 5.16; 7.16; 7.17; 7.18; 7.124; 7.132; 7.143 and 7.144). No strict differentiation is made between mesomerism and equilibrium arrows.

In all, the book is suitable both as an introduction and for further study by inorganic and organic chemists. Its use is facilitated by good author and subject indexes, and it can serve as a valuable aid to discussing the rates and the mechanisms of chemical reactions in solution.

C. Reichardt [NB 647 IE]

Oxidation in Organic Chemistry. Edited by *K. B. Wiberg*. From the series of monographs "Organic Chemistry", Vol. 5. Part A. Academic Press, New York-London 1966. 1st Edit., xi, 443 pages, $ 14.00.

Those who are familiar with the excellent reviews in "Neuere Methoden der präparativen organischen Chemie" will welcome this English-language collection of critical reviews of the literature on selective methods. Oxidizing agents are still among the most important reagents of organic chemistry, and a general need will be filled by the two volumes (the second is in preparation) devoted to this field by the publishers of "Organic Chemistry", a collection of monographs published since 1964.

The first part of this book includes oxidation with permanganate (*R. Stewart*), with chromic acid and chromyl compounds (*K. B. Wiberg*), with vanadium(v), cobalt(III), and manganese(III) (*W. A. Waters* and *J. S. Littler*), with cerium ions (*W. H. Richardson*), and with lead tetraacetate (*R. Criegee*), as well as the cleavage of glycols (*C. A. Bunton*). All the known experimental results are included, as well as the theoretical principles, the solvents and reaction conditions used, and the inorganic and particularly the organic substrates to be oxidized. In some cases extensive tables of kinetic data, and occasionally even laboratory procedures, are given. The largest sections are naturally those dealing with topics of interest to the preparative organic chemist. The present volume may therefore be described as the most up-to-date and comprehensive work of its kind, and will prove a valuable aid to any chemist. The uniform layout of the six chapters and the detailed subject and author index are excellent.

G. Anner [NB 616 IE]

Encyclopedia of Polymer Science and Technology. Plastics, Resins, Rubbers, Fibers. Edited by *H. F. Mark*, *N. G. Gaylord*, and *N. M. Bikales*. Vol. 2: Amino Resins to Casein. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney, 1965. 1st Edit., xiii, 871 pp., many illustrations and tables, single copies 375s; subscription price 300s.

The second volume of this handbook [*] contains 41 contributions; most of the authors are active in industry in the United States. The diversity of the subject matter is demonstrated by the following details.

"Amino Resins" is the heading of an admirably illustrated article (94 pp., 101 references), which deals not only with the basic reactions of this class of compounds, but also delves deeply into the technical side of the subject. The production of polymers is treated in the sections entitled "Anionic Polymerization" (143 references; important advances made in 1963 and 1964 are unfortunately omitted), "Block and Graft Copolymers" (44 pp., 254 references, preparation, properties, and uses of these copolymers), "Cage Effect" (6 pp. paying special attention to phenomena which appear during polymerization), and "Bulk Polymerization" (24 pp., 82 references). In the last named article the heat of polymerization of vinyl chloride is given as 14.4–16.7 kcal mole^{-1} without any comment of the sort that one would expect to accompany such a wide range of values; furthermore, the table of densities of monomers leaves much to be desired.

The contribution headed "Antibodies and Antigens" is rather brief (only 12 pages) in view of the general importance of this field of study. On the other hand, the wealth of well-arranged material in "Biocides" make this contribution really exemplary. The copious list of commercially available stabilizers in the article "Antioxidants" is also very welcome; a similar list is missed in "Antistatic Agents" (25 pp.). Although "Aqueous Polymerization" (144 references, 37 pp.) gives a good summary of the widely varying types of initiators, information concerning the water solubility of the monomers at various temperatures is rather sparse.

[*] Cf. Angew. Chem. *78*, 156 (1966); Angew. Chem. internat. Edit. *5*, 148 (1966).

Problems of a more technical nature are covered in the sections headed "Annealing" (rather brief, having only 13 pages), "Automotive Applications" (12 pp.), "Bag Molding" (17 pp.), "Belting" (12 pp.), "Biaxial Orientation" (34 pp., several illustrations), "Bituminous Materials" (36 pp., 18 tables), "Bleaching" (46 pp., much information concerning apparatus), "Blowing Agents" (detailed information concerning the applicability of various classes of compound as foaming agents), "Building and Construction Applications" (with several illustrations taken from practice), "Calendering" (19 pp.), and "Casein" (13 pp.).

Special polymers are dealt with in the contributions headed "Bicycloheptene and -heptadiene Polymers" (the tabular summaries are worthy of praise; the literature is covered up to the end of 1964), "Butadiene Derivatives, Polymeric" (12 pp., 87 references), "Butadiene Polymers" (76 pp., 262 references), "Butylene Polymers" (40 pp., 79 references), and "*N*-Carboxyanhydrides". Strangely, the copolymers are not mentioned at all in the section on butadiene derivatives and only very briefly in that on butylene polymers; the table of r-values of the copolymerization of butadiene could well be more complete. In the articles concerned with individual polymers the reviewer missed lists of trade names and would therefore venture to suggest that the following editions should include tables in which the various polymers are listed alphabetically, both under their commercial designations and their systematic names.

Information about auxiliary agents for polymerization and for the polymerizate is given under the headings "Antiozonants" (8 pp.), "Azo Catalysts" (very detailed tables listing characteristic properties of 71 azo compounds), "Antifoaming Agents" (8 pp.), and "Brighteners, Optical" (9 pp.). The definitions of terms such as "A-Stage" and "B-Stage", which refer to the production of thermosetting resins, are given in merely 2 and 4 lines, respectively (without examples). The diffusion of gases through polymer films is treated in "Barriers, Vapor" (13 pp.). Finally, mention should be made of the chapters entitled "Boron Compounds" (16 pp., many pieces of information about the compounds of boron), "Bagasse" (5 pp.), and "Carbon" (18 pp. devoted to a discussion of the most important types of soot).

Apart from the main headings listed above there are of course others; for example, in the present work alone, the contribution "Biocides" is given under a further four headings. This kind of subdivision greatly facilitates use of the book.

O. Fuchs [NB 623a IE]

Encyclopedia of Polymer Science and Technology. Plastics, Resins, Rubbers, Fibers. Edited by *H. F. Mark, N. G. Gaylord,* and *N. M. Bikales.* Volume 3: Casting to Cohesive Energy. Interscience Publishers, a division of John Wiley & Sons, New York-London-Sydney 1965. 1st Edit., xiii, 862 pp., numerous illustrations and tables. Single copies 375 s; subscription price 300 s.

More than half of the third volume (28 contributions from 48 authors) of this work is devoted to cellulose and its derivatives. The treatment of cellulose itself covers 97 pages and includes 436 references; the most important physical and chemical properties are well presented in 56 figures and 18 tables. Some overlapping does, however, occur between this article and those entitled "Cellulose, Biosynthesis" (13 pages, 43 references), "Cellulose, Graft Copolymers" (44 pages, 81 references, including impressive photomicrographs and author's [*Immergut*] unpublished results), "Cellulose Derivatives" (17 pages, in which only the "non-classical" cellulose derivatives such as deoxy-, aminodeoxy-, halogenodeoxy-cellulose, *etc.* and oxidized cellulose and derivatives are treated), "Cellulose, Microcrystalline" (7 pages), and "Cellulose, Analytical Methods" (too short with 5 pages). If such repetition had been avoided, much more space could have been devoted to other sections.

Cellulose foil is dealt with in the chapter entitled "Cellophane" (20 pages, 150 references, production, applications); the firm [*Kalle*] which owns the trade mark *Cellophan*, is not mentioned although the names of three American manufacturers are given. Further subject headings are: "Cellulose Esters, Inorganic" (18 pages on nitrates, half a page on other esters; no table showing the dependence of solubility on the degree of nitration is given). "Cellulose Esters, Organic" subdivided into "Manufacture" (28 pages, 102 references, good tabular summaries), "Plastics" (66 pages, 74 references; although emphasis is placed on technological aspects, properties are summarized in large tables), "Fibers" (56 pages describing production and applications, 58 references; tables extending over many pages give trade names – a feature that is often neglected), and "Miscellaneous Cellulose Esters" (4 pages). "Cellulose Ethers" (91 pages, 181 references) with the main divisions ethyl, methyl, hydroxyalkylmethyl, hydroxyethyl, sodium carboxymethyl, cyanomethyl, and carbamoylethyl-cellulose, as well as other cellulose ethers; most of these contributions do not contain a clear representation of the solubility and plasticizing properties that are so important in practice.

Material concerning the manufacture of polymers and polymerization kinetics is provided in the sections "Cationic Polymerization" (25 pages, 66 references; although the mechanism is treated thoroughly only a selection of catalysts is given), "Catalysis" (short description of methods for the production of macromolecules, 9 pages), "Ceiling Temperature" (too short with one page, only four examples, literature not covered beyond 1958), "Chain Reaction Polymerization" (26 pages, 112 references; in this section and in the one entitled "Catalysis" Ziegler catalysts are treated briefly but a full treatment will not appear until the last volume), "Chain Transfer" (30 pages, 126 references; determination of transfer constants with results, special technical applications), and "Chemically Resistant Polymers" (30 pages, 57 references including many from the years 1963 and 1964, particular attention being given to polymers suitable for use in rocket technology).

Applications of a technical nature are dealt with in the sections entitled Casting" (20 pages, contains superfluous illustrations), "Coating Methods" (69 pages, comprehensive descriptions of methods involved, 89 illustrations), and "Cellular Materials" (51 pages, 152 references, processes, statistical data, properties). The individual types of polychloroprenes are described in "2-Chlorobutadiene Polymers" (36 pages, 79 references, production, applications, *etc.*).

Analytical methods are given in the following sections: "Characterization of Polymers" (21 pages, 77 references, some characteristic structural features such as branching, sequence length distribution in block copolymers, problems of determining chemical non-uniformity, head to head structures, foreign groups, and networks are merely touched upon, if mentioned at all), "Chemical Analysis" (34 pages, 197 references, physical methods such as IR and NMR spectrometry and differential thermal analysis are given in addition to chemical methods), and "Chromatography" (32 pages, 76 references, methods, examples). "Castor Oil" (6 pages) and "Chitin" (11 pages) are treated as individual compounds. A section headed "Cohesive-Energy Density" (30 pages, 75 references covering the literature up to 1964, tables of solubility parameters for low and high molecular-weight compounds, special cases of compounds containing strongly polar groups) concludes the volume under review.

To summarize it may be said that this volume, like its predecessors, contains a wealth of data from the field of polymer science, which can otherwise be found only by searching the specialized literature. In view of the rapid development of the science and technology of macromolecular materials the encyclopedia represents a valuable source of information for workers in this field.

O. Fuchs [NB 623b IE]

Guaianolides and Germacranolides. By *F. Šorm* and *L. Dolejš*. Monograph in the series "Chemistry of Natural Products", edited by *E. Lederer*. Holden-Day, Inc. (Publishers), San Francisco 1966. 1st Edit., 153 pages, $ 10.75.

This book is an excellent review of the principal results obtained over the past eight years in the field of these two groups of substances of the sesquiterpene series. The reader is first acquainted with the basic structures guaiane and dimethylisopropylcyclodecane (germacrane) and with the physiological effects of these bitter plant constituents. The next chapter gives a short historical account of guaianolides, followed by a description of the individual groups of substances. The description of the lactones from the artabsine group of substances is followed by that of the ketolactones from the matricarin group. Lactones with abnormal skeletons are then described, and mention is also made of guaianolides whose structures are not yet certain.

The second chapter deals with the germacranolides, the detailed investigation of which is due to the authors of this monograph. Like the guaianolides, these occur only in plants of the *Compositae* family, and have recently attracted special interest because some of them have a carcinostatic action. The physical properties of all the guaianolides and germacranolides known at present are collected in an appendix, and special mention should be made of the inclusion of 25 IR spectra. A book dealing with a narrow specialized field obviously cannot appeal to a large public; however, the present work will prove an excellent reference work and review to the chemist who is interested in this topic. Steps should be taken in subsequent editions to correct a few minor printing errors (an oxygen atom is missing from the acetal group in formula 71, and the CH_3 groups on C-5 are missing from the formulas of ambrosin and damsin on p. 110) as well as the incorrect arrangement of the IR spectra of the guaianolides under the germacranolides and *vice versa*. The presentation of the book, the clear print, and the clear formulas are exemplary. On the whole, this book is recommended as an addition to the natural-product chemist's library.

E. Klein [NB 603 IE]

Electroanalytical Chemistry, Vol. 1. By *A. J. Bard*, Marcel Dekker, Inc., New York 1966. 1st Edit., x, 426 pp., 42 figures, $ 15.75.

The aim of the editor of the new series is to introduce electroanalytical methods in the widest possible sense. The review articles are intended to provide information about established techniques as well as about more recent developments.

The first contribution, by *D. E. Smith*, is entitled "AC Polarography and Related Techniques" (155 pp.). Alternating-current polarography has been studied since the middle of the nineteen-forties, but has lately received particular impetus from developments in second-harmonic polarography, phase-sensitive amplification, and RF polarography. In the theoretical section, *Smith* deals systematically with diffusion-dependent waves, quasi-reversible reactions, systems with coupled chemical reactions of first, second, and higher order, and multi-step charge transfer and adsorption – some detailed derivations are included.The section on instrumentation is much shorter, and is directed to the use of operational amplifiers. Fundamental knowledge of electrode kinetics and AC circuits is assumed. The analyst expecting a compilation of methods of determination or even simply ideas for practical analysis is going to be very disappointed. On the other hand, the article is of great value to all those who wish to participate in the introduction of alternating-current methods in the analytical laboratory.

The arrangement of the second article on "Applications of Chrono-potentiometry to Problems in Analytical Chemistry" (40 pp.) by *G. Davies* likewise relies on the nature of the rate-determining step. A very careful description of instrumentation and the decisive electrode pretreatment follows. Examples are given of application in adsorption, and in chemical and electrode kinetics, as well as a tabular compilation of analytical determinations together with source references.

In the contribution "Photoelectrochemistry and Electroluminescence" (44 pp.), *T. Kuwana* deals only with photoeffects at electrodes immersed in solution. The photopotentials in organic systems (including photopolarography), on oxide surfaces and semiconductors, the irradiation of metal electrodes in nonabsorbing solutions, and the luminescence on electrodes are described. The article can be recommended as an introduction to a field that is still in a state of flux.

The article "The Electrical Double Layer, Part I, Elements of Double Layer Theory" (169 pp.) has been written by *D. M. Mohilner*. Both in electrode kinetics and in electroanalysis, particularly in trace analysis, failure to allow for double-layer effects can lead to serious errors in the evaluation of experimental results. The present, very clearly written, first part develops the thermodynamic theory of electrocapillarity, explains the fundamental postulates concerning the structure of the double layer, and in this way establishes the basis for the treatment of kinetics planned for the second part.

Methods and Results of Optical Investigations on Semiconductor Interfaces

BY K. H. BECKMANN [*]

Measurement of the state of polarization of reflected light (ellipsometry) permits the determination of the thickness and refractive index of thin layers formed on a surface. The IR absorption spectra of such thin layers, which can be measured by means of internal reflection spectroscopy (IRS), provide information about their chemical composition. These methods have been used to study adsorption processes and the formation of reaction layers at semiconductor interfaces, and may also be used for measurements of free charge carriers in the space-charge region and in surface states. Results of such investigations are given in this article.

1. Introduction

The expansion of semiconductor research in recent years has been accompanied by intensified investigation of the surfaces of these substances. The growing use of solid-state components in electronics presented a need for the recognition and elimination of troublesome surface effects, while at the same time semiconductors offer the advantage that more informative measuring methods can be used in fundamental research on interfaces. (For the charge and potential distributions at semiconductor-electrolyte interfaces, see [1].)

The present article deals with methods of investigation and the results that they provide. In the methods in question, information about the electric and chemical state of these surfaces is obtained from changes in optical quantities, such as radiation intensity and state of polarization, on interaction of light with the semiconductor surface. As far as possible, changes produced by light, particularly in the electric state of the semiconductor surface (*e.g.* formation of charge-carrier pairs, surface photoeffect), will not be taken into account in this article. The wavelength and intensity of the light used for the measurements must therefore be so chosen that its effect on the electric and chemical processes under investigation is minimal.

2. Methods

The optical methods to be discussed here permit the determination of the refractive index n and the absorption constant k of a reflecting medium. If the reflecting interface is covered with a thin film of a third material, the thickness d and the optical constants n and k of this layer can be measured; However, only two of these quantities can be determined from any one measurement. In certain circumstances n and k provide information about the chemical composition of the layer, while d is important in connection with reaction kinetics. However, more detailed information about the chemical constitution can be obtained by measurement of the IR absorption which is made possible even for very thin films by a special technique.

2.1. Methods using Polarized Light

A method developed by *P. Drude* [2] before the turn of the century permits the detection of a very thin film ($\leq$ 1 Å) on the surface of a solid if the layer and the substrate differ in their optical constants. It is also possible by this method to follow the growth of a layer up to thicknesses of several tens of thousands of Ångströms. If the film absorbs light of the wavelength used, this process can be used only so long as the penetration depth of the light is at least of the same order of magnitude as the thickness of the film.

[2] *P. Drude*, Ann. Physik Chem. *36*, 865 (1889).

The reflection of polarized light at the interface between two media having different optical constants is described by the Fresnel equations. The light vector E is split into the components E_p, which is polarized parallel to the plane of incidence, and E_n, which is polarized normal to the plane of incidence. The change in these vectors on reflection is given by

$$E_p^{(r)} = r_p \cdot E_p^{(i)} \qquad E_n^{(r)} = r_n \cdot E_n^{(i)} \tag{1}$$

where $E^{(r)}$ is the vector of the reflected light and $E^{(i)}$ that of the incident light. r_p and r_n are the Fresnel amplitude reflection coefficients. If the light is incident from medium "0" (see Fig. 1a) and the refractive index of the adjacent medium is n_1, then

$$r_n = \frac{n_0 \cos\varphi_0 - n_1 \cos\varphi_1}{n_0 \cos\varphi_0 + n_1 \cos\varphi_1} \qquad r_p = \frac{n_1 \cos\varphi_0 - n_0 \cos\varphi_1}{n_1 \cos\varphi_0 + n_0 \cos\varphi_1} \tag{2}$$

where φ_0 is the angle of incidence and φ_1 the angle of refraction in medium 1. Since the refractive indices of nonabsorbing media are real and those of absorbing media are complex, r_n and r_p may also be either real or complex. A complex r means that phase differences that are not equal to zero or π exist between $E^{(i)}$ and $E^{(r)}$.

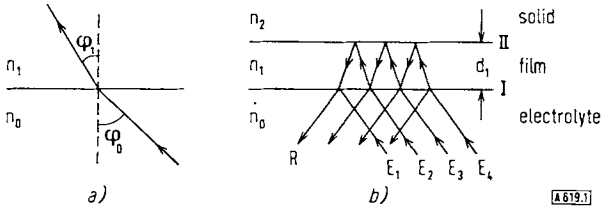

Fig. 1. (a) Refraction of light at an interface: n = refractive index; φ_0, φ_1 = angles of incidence and of refraction, respectively.

(b) Reflection of light at a surface covered with a film; d_1 = thickness of layer; E = incident beam; R = reflected beam.

If two media 0 and 2 are separated by a layer whose thickness is small in relation to the length of coherence of the light, and which absorbs the incident radiation only weakly or not at all, multiple reflections are possible in this thin film. As is indicated in Figure 1b, not only does the component of the incident ray E_1 reflected at the interface I contribute to the reflected ray R, but the incident rays E_2, E_3, *etc.* also contribute to R, since after traversing the thin film several times, they leave the layer with an amplitude determined by the reflection losses. This is substantially true of all the points of the interface I on which the beam falls.

If the thickness of the layer is uniform in the irradiated region, then in addition to the beam reflected at surface I, there will be contributions at every point due to other beams that have traversed the thin film two, four, or more times, and because of coherence, these beams superimpose there in magnitude and phase. The result is that the reflected light also has a uniform, definite state of polarization. Calculation of this superposition leads to the following expression for the amplitude reflection coefficient $\boldsymbol{R}$ of a thin film [3]:

$$\boldsymbol{R} = \frac{r_I + r_{II} \cdot \exp\left\{-\frac{4\pi i}{\lambda} n_1 d_1 \cos\varphi_1\right\}}{1 + r_I \cdot r_{II} \cdot \exp\left\{-\frac{4\pi i}{\lambda} n_1 d_1 \cos\varphi_1\right\}} = R \cdot e^{i\delta} \tag{3}$$

In this equation, r_I and r_{II} are the Fresnel coefficients of the interfaces I and II respectively; n_1 is the refractive index and d_1 the thickness of the film, φ_1 is the angle of refraction in the layer, λ is the wavelength, in vacuum, of the radiation used, R is the magnitude and δ is the argument of $\boldsymbol{R}$, and $i = \sqrt{-1}$. Insertion of r_n and r_p for r_I and r_{II} in accordance with equation (2) gives $\boldsymbol{R}_n$ and $\boldsymbol{R}_p$.

Equation (3) shows that $\boldsymbol{R}$ will generally be a complex number, even when all three of the media in question are non-absorbing and so have real optical constants. This means that when linearly polarized light falls on the coated interface, the reflected light is generally elliptically polarized.

For simplicity, linearly polarized light whose plane of vibration is inclined at 45 ° to the plane of incidence is used in reflection experiments of this type. In this case

$$E_n^{(i)} = E_p^{(i)}$$

After reflection, the amplitudes are

$$\boldsymbol{E}_n^{(r)} = \boldsymbol{R}_n \cdot E_n^{(i)} \qquad \boldsymbol{E}_p^{(r)} = \boldsymbol{R}_p \cdot E_n^{(i)} \tag{4}$$

Since $\boldsymbol{R}_n$ and $\boldsymbol{R}_p$ are different complex numbers, there is a phase difference between $\boldsymbol{E}_n^{(r)}$ and $\boldsymbol{E}_p^{(r)}$, and the two components differ in magnitude after reflection.

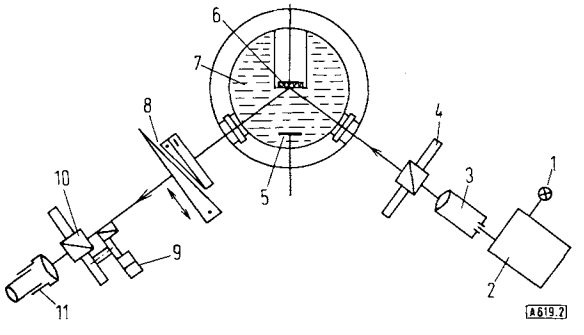

Fig. 2. Ellipsometer for the measurement of the growth of films on electrodes; 1. light source, 2. monochromator, 3. collimator, 4. polarizer, 5. counterelectrode, 6. sample, 7. electrolyte, 8. compensator, 9. half-shade device, 10. analyzer, 11. telescope.

These changes in the state of polarization of the reflected light can be measured with the apparatus shown in Figure 2, by means of which the growth of a layer on solid electrodes can be followed. A monochromator supplies monochromatic light which leaves the collimator as a parallel beam and is then linearly polarized. This polarized light then passes through the quartz window into the measuring cell, where it proceeds through the electrolyte to fall on the surface under examination, is reflected at this surface, and leaves the cell again through a second window. A platinum counterelectrode is

[3] *H. Mayer*: Physik dünner Schichten. Part I, Wissenschaftliche Verlagsgesellschaft mbH., Stuttgart 1950, p. 145ff.

situated opposite the sample for electrochemical polarization, and a calomel reference electrode also dips into the cell for measurement of the potential.

After leaving the cell, the reflected light passes through a Soleil-Babinet compensator, by means of which it is possible to obtain any desired phase difference between the components of the light vector polarized normal to and parallel to the plane of incidence. The compensator is adjusted in such a way as to convert the elliptically polarized light into linearly polarized light, and the magnitude of the phase difference is determined in this way. The adjustment is made on the basis of observations with a telescope, an analyzer, and a Tronstad [4] elliptic half-shade device, the half shade providing an accurate criterion of whether the light is elliptically or linearly polarized.

If we form the ratio of equations (4), taking into account (3), we find that since $E_n^{(i)} = E_p^{(i)}$,

$$\frac{E_p^{(r)}}{E_n^{(r)}} = \frac{R_p}{R_n} = \frac{R_p \cdot e^{i\delta_p}}{R_n \cdot e^{i\delta_n}} = \tan\psi \cdot e^{i\Delta} \qquad (5)$$

The quantity Δ is the phase difference between the components of the electric vector, and ψ is the angle between the plane of the restored linear polarization and the normal to the plane of incidence. This angle is found by measurement of the azimuth of the linearly polarized light leaving the compensator by means of a Lippich half shade.

The set-up described here may be modified. Thus instead of visual observation, a photoelectric cell may be used as an indicator. The optical compensator may be replaced by a $\lambda/4$ plate [5]. (For other methods for the determination of the state of polarization of reflected light see [6, 7].) Various kinds of information can be obtained from such measurements depending on the nature of the problem. We are interested in the case in which the optical constants of the substrate (medium 2 in Fig. 1b) and of the medium 0, from which the light is incident, are known, and the optical constants of the thin film (medium 1) and its thickness are to be determined.

It can be seen from equations (5), (3), and (2) that the quantities ψ and Δ depend in a complicated manner on the optical constants of the media 0, 1, and 2. The only practically possible method of evaluation, even for nonabsorbing layers, is therefore to calculate the values of ψ and Δ for various constants n_0, n_1, d_1, and n_2 by means of a computer. The calculated values of ψ and Δ are seen to be unique functions of the refractive index n_1 of the film and its thickness d_1 for practically all values of these quantities [8]. Ambiguity can arise only with very large values of n_1, but such high refractive indices are generally found only in the neighborhood of strong absorption lines. Further difficulties arise in measurement and evaluation in these regions in any case, since it would then be necessary to determine three unknowns (d_1, n_1, and the absorption constant k_1) from the two measured quantities Δ and ψ.

For very thin films ($d_1 < 100$ Å), it is possible to use approximate solutions in which Δ and ψ vary linearly with the thickness d_1 of the layer [9] and the proportionality factor depends on the refractive indices of the media involved.

The ellipsometric measurements discussed here allow the determination of even very small film thicknesses. According to *Archer* and *Gobeli* [9], the maximum sensitivity is 0.07 Å, which is less than the thickness of a monolayer. It should be possible to have layers one monolayer thick and with an incomplete coverage of the surface of the substrate, but not a layer whose thickness is much less than that of a monolayer. However, a layer that contains (evenly distributed) only a fraction Θ of the number of particles required for a monolayer behaves optically in the same way as a layer of thickness $\Theta \cdot d_0$, where d_0 is the thickness of the monolayer [10,11]. This theoretical deduction was confirmed by *Bootsma* and *Meyer* for the adsorption of noble gases on germanium. They determined the surface coverage volumetrically and the thickness of the adsorption layers ellipsometrically [12].

During the adsorption of polar organic molecules on metal surfaces, the layer thickness was determined ellipsometrically and with isotopes [13]. The results of the two methods agreed down to effective layer thicknesses considerably less than the thickness of a monolayer.

Owing to the periodic variations of Δ and ψ with d_1, the accuracy is different in different ranges of film thickness; however, it is always better than 1 %. The smallest layer thickness that could be measured with our apparatus by visual observation was 1 Å. An area of 0.2–1 cm² is illuminated for the measurement.

2.2. Measurement of the IR Absorption by Internal Reflection Spectroscopy (IRS)

Detailed information about the chemical composition of thin films can be obtained by measurement of the IR absorption. The great sensitivity of this process permits spectroscopic measurements with a single transmission of the beam through the layer, even for thicknesses of several 100 Å (depending on the strength of the absorption). Since all semiconducting substances, unless they are too highly doped, are transparent to IR radiation, the layers to be studied can be left on the semiconductors on which they have grown. However, a single transmission is not sufficiently sensitive for very thin layers.

Spectroscopic measurements can be carried out even on layers as thin as a few Å by a method given by *Harrick* [14]. A specially shaped semiconductor covered

by the thin film on two opposite sides is used. Monochromatic infrared radiation falls from the semiconductor onto one of the coated surfaces (see Fig. 3) in such a way that total reflection takes place at this

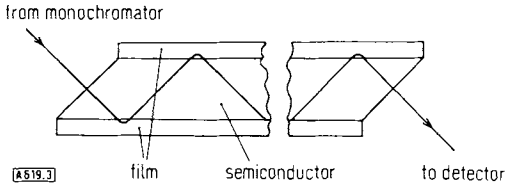

Fig. 3. Principle of the measurement of the IR absorption of thin films by internal reflection spectroscopy (IRS).

interface. This is nearly always possible, since semiconducting materials generally have very high refractive indices. The radiation penetrates a short distance (of the order of the wavelength) into the rarer medium (the film), and can thus interact with the molecules of the layer. According to the law of conservation of energy, the energy that is not absorbed in the layer must return to the semiconductor, and the process is repeated at the opposite face, as shown in Figure 3. In this way the absorption process is repeated several times in succession, with the result that the absorption signal is intensified. The number of reflections, and hence the number of absorption processes, depends on the length and thickness of the semiconductor on which the layer is situated. Figure 4 shows a comparison of the absorption spectrum obtained by the normal transmission method for a germanium oxide film containing hydride with the spectrum obtained by internal reflection spectroscopy with 50 reflections. (The semiconductor consisted of intrinsic germanium.)

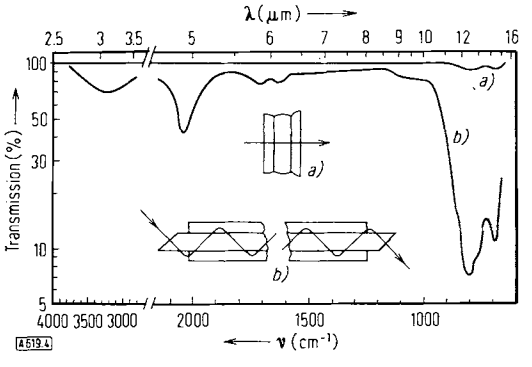

Fig. 4. IR spectrum of a film of germanium oxide containing hydride (on intrinsic germanium).
(a) transmission,
(b) with internal reflection (50 reflections).

To record absorption spectra, chopped light is usually passed through the sample. With objects that absorb only weakly, this means that relatively large signals are received by the detector, whereas the variations in these signals due to absorption are very small. The sensitivity can be considerably increased in the case of an absorption process whose intensity can be altered by means of external factors (*e.g.* electric fields). Unchopped light is passed through the object, and the alternating light component obtained by modulation of the absorption is measured at maximum amplification (effect modulation).

A correspondingly large increase in sensitivity can be achieved by difference methods for objects whose absorption cannot be influenced by external parameters. This involves the measurement of the difference between the signals produced after the splitting of the beam into two; one of the resulting beams is unattenuated and is allowed to fall on one detector while the other beam, which is attenuated by absorption, falls onto a second detector. These voltages, which are very small for weak absorptions, can then be amplified.

3. Results

3.1. Adsorption Processes on Semiconductor Surfaces

Archer and *Gobeli*[9,15] used ellipsometric methods to study the adsorption of oxygen on silicon. The samples were prepared by cleavage of single crystals of silicon in a high vacuum (5×10^{-10} torr). At this pressure, the reflection behavior of the cleavage face did not change during the first 10–15 min after cleavage. It was only on addition of oxygen that it became possible to record the changes in phase difference shown in Figure 5, which were interpreted as resulting from the formation of a monomolecular adsorption layer. The detection sensitivity was 0.07 Å.

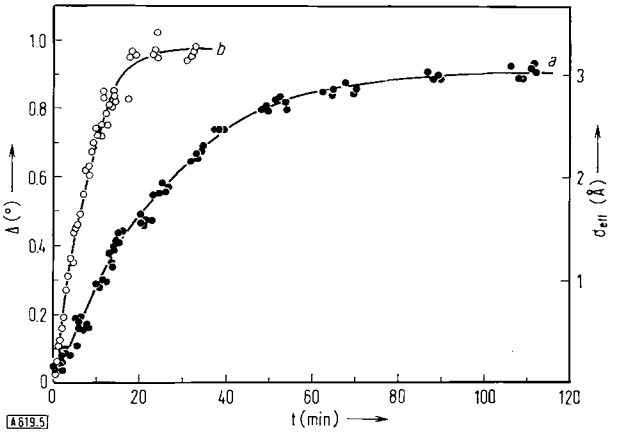

Fig. 5. Ellipsometric measurement of the adsorption of oxygen on silicon surfaces (obtained by cleavage of single crystals) at room temperature (after [9]).
(a) $P_{O_2} = 3.6\times10^{-7}$ torr
(b) $P_{O_2} = 1.8\times10^{-6}$ torr.

Since the measured quantity ψ remains practically constant for such small changes in the thickness, only one unknown can be determined. The phase difference Δ varies in proportion to the degree of coverage. The fact that a constant phase difference is reached after a long time is interpreted by the authors as indicating that the formation of the monolayer is complete, and that the adsorption then becomes considerably slower. The sticking coefficients were determined from the resulting data by comparison with the number of molecules impinging on the semiconductor surface. The values obtained

[15] *R. J. Archer* [7], p. 255.

are an order of magnitude lower than those found by other methods; the authors attribute this difference to the fact that they used cleavage faces of high surface perfection. Further growth to form a triple layer is also approximately proportional to the logarithm of time.

Archer[15] also reported on the adsorption of vapors on silicon surfaces that were covered with a 15–20 Å layer of silicon oxides and hydrides formed as a result of etching (with various HF/HNO_3 mixtures). The surface of this layer could be made hydrophilic by immersion in HF/HNO_3, so that the adsorption of water vapor was intensified. (For measurement of the adsorption of organic molecules on silicon, see also [16].)

Becker and *Gobeli*[17] used internal reflection spectroscopy to study the IR absorption of hydrogen adsorbed on the surface of silicon crystals. The surfaces of these samples were cleaned by bombardment with argon ions at 5×10^{-4} torr and heating to 1000 to 1200 °K in an ultrahigh vacuum. A pressure of 10^{-6} torr of hydrogen was established, and atomic hydrogen, which was produced by means of a glowing tungsten filament, was chemisorbed on the surface of the silicon. With the aid of a difference method, the authors were able to detect the resulting Si–H bond by its IR absorption. After about 45 min, the thickness of the adsorption layer became constant despite the continued action of atomic hydrogen, and the coverage did not decrease even in a high vacuum. The authors assume that this coverage must be at most monatomic, since it could be removed by a relatively short bombardment with argon ions. Bombardment of the silicon surface with hydrogen ions in a gas discharge led to the formation of thicker silicon hydride layers.

3.2. Investigations on the Formation of Reaction Layers on Semiconductor Surfaces

Archer[18] used ellipsometric measurements to follow the growth of oxide layers on germanium and silicon in air at room temperature after specified etching and rinsing of the polished surfaces. After etching in mixtures of acetic, hydrofluoric, and nitric acids, layers 12 Å thick were found on silicon and layers 16 Å thick on germanium. After 30 hours, the thickness of these layers had increased to about 30 Å. The growth of the layers followed the Elovich equation, according to which the layer thickness is proportional to the logarithm of time. The measured refractive indices agreed well with those of the oxides of these semiconducting substances.

Andreeva and *Shishakov*[19] studied the absorption of air and the subsequent oxidation of the surfaces of vapor-deposited germanium films. They allowed air to act on the surface for periods of 20–30 min, alternating with six-hour periods during which the sample container was evacuated. The 10–30 Å layer that was formed in air partly disappeared on evacuation; an additional layer was formed under the further action of air, and this could again be partly removed by evacuation. On evacuation for 6 hours, films that had taken 34 days to grow to 80 Å were reduced in thickness to 46 Å. These phenomena are explained by the vaporization or decomposition of the oxide formed. The oxidation of vapor-deposited germanium films was much slower in dry oxygen than in moist air. Freshly evaporated germanium films adsorbed water only very slowly. While the growth of the layer formed in air on polished single crystals of germanium and silicon was found to be proportional to $t^{1/2}$, film thicknesses of between 30 and 80 Å (Si) or even 135 Å (Ge) could be detected on etched surfaces of both materials immediately after etching, but further growth of these layers was only very slight, and some actually became thinner.

Stricha and *Kiltschizkaja*[20] determined ellipsometrically the reflection parameters for uncoated germanium and silicon surfaces which had been formed by cleavage at 10^{-9} torr. These quantities were then used to evaluate reflection measurements on germanium and silicon after etching in various solutions. For example, silicon has a 60 Å film after etching in HF solution, a 35 Å film after mechanical polishing, and a 50 Å film after cleavage in air. With germanium they found a 25 Å film after etching in H_2O_2, and a 35 Å film after cleavage in air (the time taken for layer formation is not given).

Archer[21] used polarization measurements to follow the growth of layers on silicon during corrosion. The corroding electrolyte consisted of 20 M aqueous hydrofluoric acid containing nitric acid, sodium nitrite, or nitric oxide in concentrations of 10^{-1} to 10^{-3} M. The growth of the layer was determined as a function of the concentration of the additives and as a function of the type and magnitude of the conductivity of the semiconductor sample. Simultaneous measurement of the refractive index (see also [8]) showed that it evidently depended on the type and value of the conductivity. Whereas the refractive index of the layer was generally 2.7 in the cases of n-type and p-type material, the value for p-type Si having specific resistances of 0.1 to 0.001 ohm·cm was about 4.1. Moreover, the formation of the film was five times as fast within this resistance range as for samples having other resistance values.

Chemical studies[22] had shown that similar films, which also have a high chemical reactivity, can be produced on silicon by anodic polarization in hydrofluoric acid. On the basis of the chemical behavior of these layers, it was thought that they consist either of very reactive elemental silicon or of silicon hydrides. Owing to the high refractive index of 4.1, *Archer* concluded that layers of elemental Si are formed on

p-type material having specific resistances of 10^{-1} to 10^{-3} ohm·cm, while layers of silicon hydrides are formed when the material has a specific resistance outside this range. However, IR studies [23] showed that their approximate composition ranges between $SiOH_2$ and $SiO_{1.5}H$, *i.e.* that they contain an appreciable amount of oxygen. No relationship was found between the chemical composition of the layer and the resistance of the semiconductor. A similarly high oxygen content was also found by proton-activation analysis [24], and the relationship found by *Archer* [21] between the rate of growth of the film and the conductivity of the silicon used was confirmed.

We investigated the properties of reaction layers of similar composition produced on p-type silicon by anodic polarization in strong aqueous solutions of hydrofluoric acid [23]. Curve a in Figure 6 shows the transmission spectrum of the layer produced on a silicon disk in a deuterium-enriched solution. The absorption with maxima at 2135, 2115, and 2090 cm^{-1} is assigned to the stretching vibrations of SiH_x groups, and the absorption with maxima at 1560, 1530, and 1520 cm^{-1} to the stretching vibrations of SiD_x groups. The magnitude of the frequency shift confirms this assignment. The broad band at 1070 cm^{-1} shows that some Si–O bonds are also present. After the layer had been exposed to the action of 30 % H_2O_2 for 16 hours, we found a large number of OH groups (absorption at about 3400 cm^{-1}, curve b). The very large decrease in transmission at this point indicates an increase in the number of SiOH groups.

This absorption could also be due to H_2O incorporated in the layer. However, this possibility can be ruled out in view of the absence of the corresponding deformation vibration at 1600 cm^{-1}. Moreover, the intensity of the band at about 1100 cm^{-1} has increased greatly. This absorption is due to the stretching vibrations of the SiO_x groups and/or the stretching vibration

ν(Si–OH) of the SiOH groups. ν(Si–OH) is the vibration in which the OH group vibrates toward the Si atom.

Figure 7 shows the changes in the transmission spectrum of a thinner film after additional treatments. Whereas freshly formed layers (curve a) react explosively with 65 % HNO_3, a layer that has been preoxidized in H_2O_2 (curve b) can be further oxidized by nitric acid (curve c). The number of SiOH groups increases; the intensity of the SiH_x stretching vibrations remains practically unchanged (see below), but the bands are partly displaced toward higher wave numbers. The increase in absorption at 1070 cm^{-1}, in conjunction with the intensification of the band at 870 cm^{-1}, points to the formation of chains having the chemical composition Si_2O_6. The SiOH and SiH groups suffer substantial decomposition during heat treatment at 1000 °C, and the absorption at 810 cm^{-1} (curve d) suggests that the layer then consists of SiO_2 with a disordered arrangement of the SiO_4 tetrahedra such as occurs in amorphous quartz.

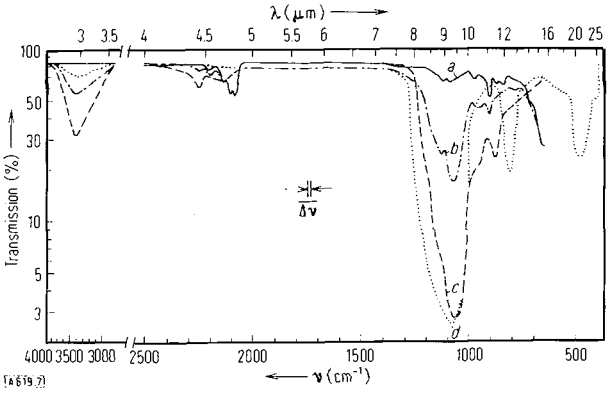

Fig. 7. Influence of oxidation processes on the transmission spectrum of an anodically produced reaction layer on p-type silicon (after [23]). Electrolyte: 10 N aqueous hydrofluoric acid.

(a) Immediately after layer formation.

(b) After treatment for 16 h with 30 % H_2O_2.

(c) After additional treatment for 10 s with 65 % HNO_3.

(d) After subsequent annealing in air at 1000 °C for 5 min.

Quantitative evaluation of these spectra showed that the freshly prepared layers have approximately the composition $SiH_{1.5}$, *i.e.* that they consist of polymerized silicon hydrides. Oxidation with H_2O_2, subsequent oxidation with HNO_3, and oxidation in air have practically no effect on the integrated absorption strength due to the SiH_x stretching vibrations (Fig. 8); as the original band at 2100 cm^{-1} decreases in intensity a new band appears at 2275 cm^{-1}. In conjunction with the simultaneous increase in the number of SiO oscillators, this means that the $-(SiH_2)-(SiH_2)-$ chains are gradually converted into $-(SiH_2)-O-(SiH_2)-$ chains. The displacement of the $(SiH)_x$ stretching vibration is due to the change in the SiH force constant as a result of the attachment of oxygen to the silicon. The absorption bands below 900 cm^{-1}, which are particularly noticeable in curve a of Figure 6, could not be assigned. They could be due to the presence of SiF bonds, but this assumption has not been proved.

The question of how reaction layers of this nature can be formed on anodic polarization has not yet been answered. Though the individual steps in the anodic dissolution of silicon in hydrofluoric acid have been studied[25], the formation of silicon hydrides cannot yet be explained.

Reaction layers having comparable chemical compositions can also be formed on germanium in etching solutions containing nitric acid or hydrogen peroxide as well as hydrofluoric acid[26]. IR analysis of the layers was carried out by internal reflection spectroscopy, since they are very thin. An HF/HNO_3 mixture (40 % HF/65 % HNO_3, 7:3 v/v) gave essentially GeO_2, which could be readily determined from

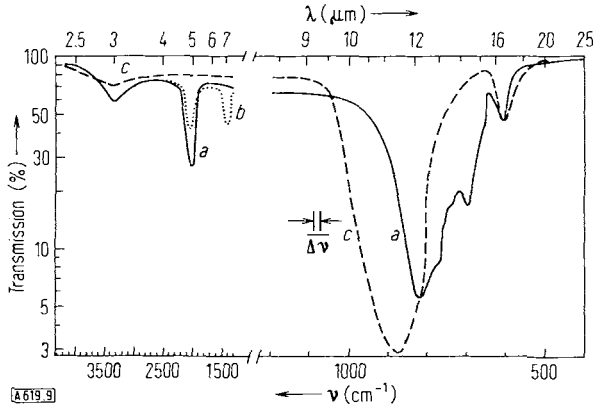

Fig. 9. (a) IRS-transmission spectrum of a layer formed on intrinsic germanium in an etching solution consisting of 40 % HF and 30 % H_2O_2 (10:1 v/v).
(b) Partial spectrum of the layer formed in the same solution enriched in deuterium.
(c) Transmission spectrum of the layer of (a) after annealing in air at 500 °C for 8 min (after [26]).

the absorption. The strongest absorption for layers formed in HF/H_2O_2 (40 % HF/30 % H_2O_2, 10:1 v/v) occurred at 825 cm^{-1} (see Fig. 9). The wave number of this vibration was too far from the characteristic frequencies of the GeO_2 modifications to allow assignment to one of these modifications without further investigation. It was only after formation of such a layer in an ^{18}O-enriched solution ($[^{16}O]/[^{18}O] = 8.5$) that this absorption could be assigned to a GeO stretching vibration on the basis of the transmission spectrum shown in Figure 10.

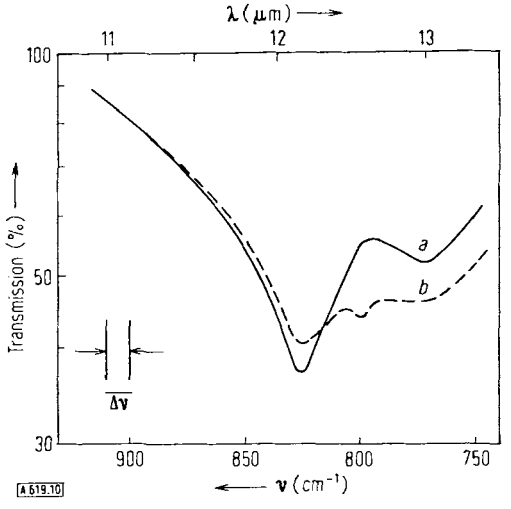

Fig. 10. Absorption band of the GeO_x stretching vibration of a reaction layer formed on germanium by etching as described in Fig. 9 (after [26]).
(a) Layer contains only ^{16}O.
(b) Layer also contains ^{18}O ($[^{16}O]/[^{18}O] = 8.5$).

Since the added ^{18}O is probably present in the layer in the form of ^{16}O–Ge–^{18}O groups, we found that curve a (only with ^{16}O) was replaced by curve b with an additional absorption at 800 cm^{-1} due to vibration of the ^{16}O–Ge–^{18}O group corresponding to that occurring at 825 cm^{-1} in the case of ^{16}O–Ge–^{16}O. This displacement by 25 cm^{-1} corresponds to the calculated isotope effect, and this confirms the assignment of the absorption at 825 cm^{-1} to the GeO stretching vibration.

Moreover, the short-wavelength part of the spectrum of curve a in Figure 9 shows that some OH groups (3300 cm^{-1}) and a larger number of GeH bonds (2000 cm^{-1}) are present. The latter assignment is confirmed by the appearance of the GeD stretching vibration after deuteration (curve b). Heating for 8 min at 500 °C leads to the disappearance of these hydride bonds, and the GeO stretching vibration is displaced to 860 cm^{-1}, which is also its known position in the soluble modifications of GeO_2. Quantitative estimation of the absorption intensities from curve a gave the approximate composition $GeOH_2$ for the original reaction layer.

While these surface films formed on germanium in HF/H_2O_2 have a certain similarity to the corrosion layers formed on silicon in HF/HNO_3, and while similar layers can be produced on silicon by anodic polarization in HF solution, anodic formation of such films on germanium was found to be impossible. In the film-forming range, silicon goes into solution in a bivalent state[25], whereas germanium always gives a tetravalent state on anodic dissolution in hydrofluoric acid solutions of various concentrations[27].

[27] *G. Schwandt*, unpublished.

Ellipsometric studies on the formation of a layer on germanium anodes in alkaline electrolytes showed the potential-dependent film growth illustrated in Figure 11 [28]. This current density-potential curve is explained by the fact that OH^- ions from the electrolyte are required for the anodic dissolution of germanium, but owing to the relatively high concentration of the conducting salt, these ions are replenished only by diffusion to the semiconductor surface. The concentration gradient of the OH^- ions in front of the semiconductor surface reaches a maximum at a potential of about −400 mV; if the potential is raised further, the diffusion current remains constant, and the anodic dissolution consequently cannot be increased. Water reacts directly with germanium only above +100 mV, so that a steep increase in current begins at this point.

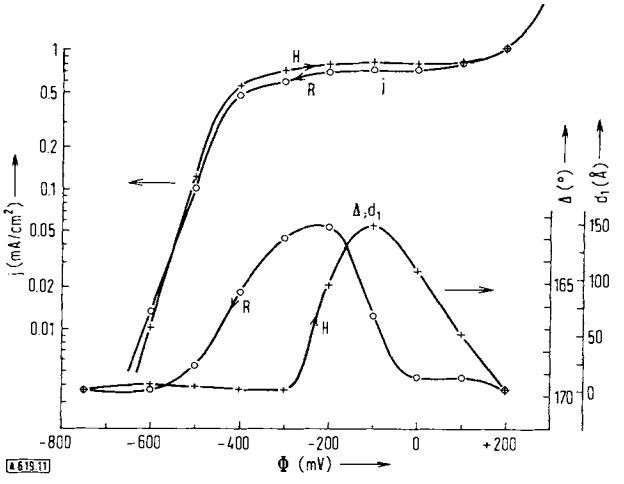

Fig. 11. Characteristic of a p-type germanium electrode (ρ = 10 Ω cm) in alkaline electrolyte with conducting salt (upper curves) and ellipsometrically measured film growth (lower curves) as a function of the potential Φ (after[28]).Electrolyte:3×10⁻² M KOH,0.6 M KBr,1.1×10⁻² M GeO_2, potential against saturated calomel electrode, angle of incidence 50°, wavelength of the light λ = 565 nm. H = forward run, R = reverse run.

The potential-dependent film growth shown in Figure 11 was observed in the region of this limiting diffusion current. Figure 12 shows the increase in the thickness of the layer at a constant potential as a function of time. In this case Δ is plotted against ψ (cf. eq. (5)] with time as the parameter. Corresponding relationships with the film thickness were calculated by computer for various refractive indices of the layer and plotted in Figure 12. For film thicknesses greater than 700 Å, the experimental curve follows the calculated curve for $n_1 = 1.5$ with an accuracy of $\delta n_1 = \pm 0.01$. The thickness of the layer increases almost linearly with time, and it is therefore concluded that the layer is fairly porous.

Figure 13 shows the Δ (ψ) curve for a layer formed in an electrolyte in which the alkali metal is cesium. The experimental curve, unlike that in Figure 12, is unsymmetrical and is not closed. Curves calculated for absorbing layers are therefore shown in Figure 13; the experimental curve agrees more closely with these.

[28] *K. H. Beckmann*, Ber. Bunsenges. physik. Chem. *70*, 842 (1966).

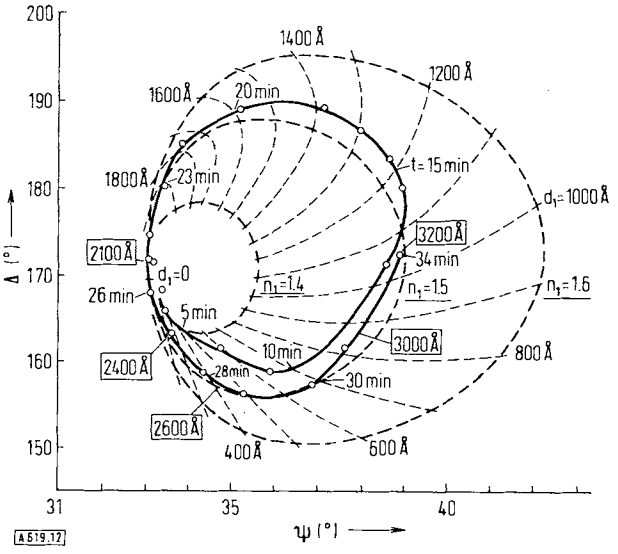

Fig. 12. Comparison of the quantities Δ and ψ measured in the forward run H at a constant potential of −100 mV (full curve) with values calculated for various thicknesses (d_1) and refractive indices (n_1) of the layer (after [28]). Electrolyte and other data as in Fig. 11. The lines of equal thickness are valid only for the first tracing of the experimental curve.

The refractive index of the layer is found from this plot to be $n_1 \approx 1.43 - i\,0.15$. It can therefore be seen that the reaction products formed on anodic dissolution of germanium depend partly on the alkali metal ion present in the electrolyte. The alkali metal ion is very probably incorporated into the layer. This assumption was confirmed by IR studies, since the IR spectrum corresponded to that of the acidic germanates. The layer thus had a composition such as $NaHGeO_3$ or $CsHGeO_3$; however, the exact formula cannot be given.

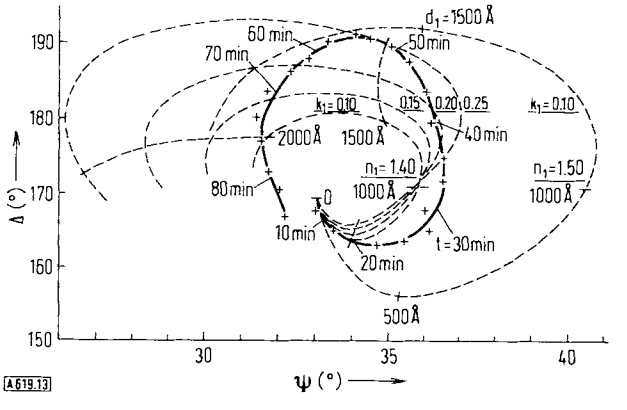

Fig. 13. Comparison of the quantities Δ and ψ measured in the forward run at a constant potential of −200 mV (——) with the values calculated for various thicknesses (d_1) and refractive indices (n_1, k_1) of the layer (after [28]). Sample and optical data as in Fig. 11. Electrolyte: 3×10⁻² M CsOH, 1 M CsBr, 1.1×10⁻² M GeO_2.

Thermally produced oxides are very important in industry as passivating substances on the surfaces of semiconductors, particularly silicon. Many optical investigations have been carried out to establish the structure and chemical composition of these films. *Sládková* [29] studied the growth of thermally produced SiO_2 layers on silicon as a function of the temperature.

[29] *J. Sládková*, Czechoslov. J. Physics *13B*, 452 (1963).

Below 950 °C, the thickness of the layer increased linearly with time, while between 950 and 1000 °C it increased parabolically in accordance with $d_1 \propto \sqrt{t}$. This means that the layers formed at higher temperatures are more dense, so that the rate of diffusion of the oxygen in the silicon dioxide layer is rate-determining.

The same growth pattern was found by *Claussen* and *Flower*[30] for thermal oxidation at 1200 °C in dry and in moist oxygen as well as in moist argon, the proportionality constant varying with the composition of the gas. The oxidation of the surface of Si is slowest in dry oxygen and in argon saturated with water at 28 °C, and fastest in oxygen saturated with H_2O. The same growth law was found by *Edagawa et al.*[31] from IR measurements; the activation energies for the oxidation in various atmospheres were determined from the temperature dependence.

Revesz and *Zaininger*[32] determined the compactness of SiO_2 films on silicon relative to amorphous quartz from the ellipsometrically measured refractive indices of the films by comparison of the refraction $(n^2 - 1)/(n^2 + 2)$ with that of the quartz. It was found that SiO_2 layers formed anodically in methylacetamide reach a density of only 77 % of that of amorphous quartz. *Pliskin* and *Lehman*[33] also found that the refractive index of SiO_2 layers increases with increasing density, and also with increasing concentration of oxygen vacancies. Increasing concentration of oxygen vacancies is also accompanied by a displacement of the SiO stretching vibration toward lower wave numbers. The authors also used similar optical methods as well as etching processes to study silicon dioxide layers formed by thermal oxidation, vapor deposition, pyrolysis of tetraethoxysilane $Si(C_2H_5O)_4$, catalysis of the reaction of oxygen with silicon by lead oxide, sputtering, and anodic polarization in the electrolyte. When the films obtained at lower temperatures were subsequently "densified" in a moist atmosphere at about 980 °C, their optical properties became practically the same as those of the thermally produced oxide.

IR measurements on silicon nitride (Si_3N_4) layers produced on silicon surfaces by sputtering or pyrolytic deposition from a mixture of SiH_4 and NH_3 have also been reported[34,35]. The frequency of the Si–N stretching vibration varies slightly according to the method of production of the layer.

Very few optical investigations have been carried out on interfaces of compound semiconductors. *Saxena*[36] used ellipsometry to study film-free indium antimonide surfaces in order to determine the refractive index of this semiconductor. Values of 3.5 to 4.1 were obtained, depending on the surface treatment. *Zaininger* and *Revesz*[37] found that the oxide layers formed on thermal oxidation of GaAs surfaces are possibly inhomogeneous and their composition is so complex that evaluation of the measured quantities after stepwise etching gives values of the optical constants that vary with the thickness of the film. The authors concluded from this and from the results of other investigations that arsenic is deposited at the interface between the semiconductor and the layer during oxidation.

3.3. Optical Studies on the Space-Charge Region and on Surface States

The electric and electrochemical behavior of semiconductor interfaces depends strongly on the properties of the space-charge region immediately under the semiconductor surface[1]. By application of a voltage between the semiconductor surface and a counterelectrode, it is possible to vary the potential drop across this space-charge region and hence the energy of the electrons in this region (band bending), and since their density follows the Fermi distribution, the number of electrons and holes present also changes. The counterelectrode may consist of a metal plate situated at a very short distance away from the semiconductor electrode, with which it forms a condenser. In certain circumstances the semiconductor may be immersed in an electrolyte, and the voltage required for bending of the energy bands may be applied between the semiconductor and a platinum counterelectrode.

The free electrons or holes in the semiconductor absorb infrared radiation in a characteristic manner. In the range in which we are interested, with radiation energies $h\nu$ smaller than the distance between bands $E_g = E_c - E_v$ (see Fig. 14), this absorption leads to an increase in the energy of the absorbing carriers, which either remain in their band or pass into another conduction or valence band. However, this absorption is so weak that measurable signals are obtained only at very high carrier densities.

Even in internal reflection spectroscopy measurements with 100 reflections, the number of additional free carriers present in the space-charge region is still too small to be measured. However, a measurable signal is obtained if the measurements are carried out with unchopped light and effect modulation. The band bending can be modulated between U_{R1} and U_{R2} (see Fig. 14) by application of an alternating field between the sample and the counterelectrode. The densities of the electrons and holes then change in accordance with the Fermi distribution given in Figure 14c, which is plotted on the same energy scale. The quantity f is the ratio of the number of electrons present in the band in question at this energy to the

number of possible sites. The quantity $(1 - f)$ is the corresponding number for the holes in the valence band. It can be seen from Figure 14 that for band bending by U_{R1} at the surface (Fig. 14a), the valence band contains more holes and the conduction band fewer electrons than in the case of U_{R2} (Fig. 14b). The infrared beam, which passes through the space-charge region immediately before and after each total reflection, is therefore weakened to various extents by absorption in the two modulation half-waves, depending on the carrier densities. It is only this small change that is electronically amplified and recorded after the beam reaches the detector.

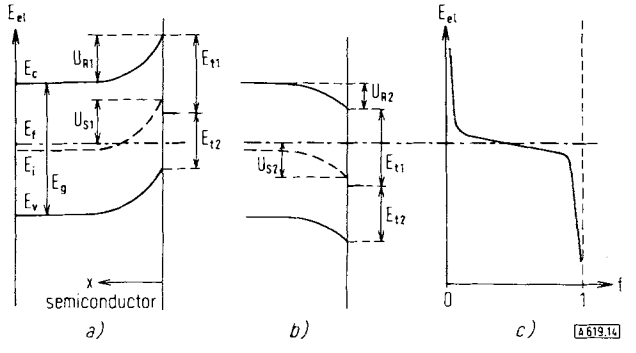

Fig. 14. (a), (b) Variation of the electronic energy (band model) near the semiconductor surface for two different band bendings.

(c) Fermi distribution on the same energy scale.

E_C: bottom of the conduction band; E_V: top of the valence band; E_F: Fermi level; E_i: middle of the forbidden zone; U_R: band bending at the surface; E_t: energy of the surface state; E_{el}: energy of the electrons; x: perpendicular distance from the surface; E_g: band gap; U_S: surface potential.

In addition to this absorption by free carriers, another process is also possible. There may be surface states situated in the forbidden zone between the two bands. This means that there are energy states within the band gap at the surface that can be occupied by electrons. These states or centers are due to attached foreign atoms or even simply to the breakdown of the properties of the periodic lattice at the surface. The occupation of these centers also follows the Fermi distribution; centers below the Fermi level E_F (see Fig. 14) are almost totally occupied by electrons, while those above the Fermi level are mostly empty. The change in the energy of the electrons in both bands as a result of the application of an electric field between the semiconductor and the counterelectrode (change of band bending) is the same as the change in the energy of the electrons in surface states. This means that the center is always situated at a distance E_{t1} from the conduction band and at a distance E_{t2} from the valence band, irrespective of the magnitude and direction of U_R. Thus if the magnitude of U_R is such that the energy of the center is above E_F (see Fig. 14a), the center is substantially unoccupied, and it may be occupied by an electron from the valence band by absorption of a light quantum $h\nu_2 = E_{t2}$ by this electron. Conversely, if the center lies below E_F (Fig. 14b), the occupied center may be emptied by absorption of a quantum $h\nu_1 = E_{t1}$, the electron being raised into the conduction band. If the band bending caused by the direct current is such that the energy of the surface state coincides with the Fermi level, there is a constant change in the occupancy of this state, even at small amplitudes of the applied alternating voltage, and hence in the optical absorption due to the charge carriers occupying or leaving this surface state. Since E_{t1} and E_{t2} (see Fig. 14) are generally different, changes in absorption will be observed at two wavelengths if the probabilities of the above transitions are sufficiently high, and these changes will then also differ in phase.

Harrick [38] carried out measurements of this type between 1.1 and 5.4 μm on n-type silicon surfaces that had been thermally oxidized in an atmosphere of wet oxygen. The sample was always kept at a positive potential with respect to the counterelectrode by means of a DC voltage (bending up of the band), and an alternating voltage was superimposed on this direct voltage. With large positive DC voltages, the magnitude of the observed absorption change increased approximately with λ^2. This spectral behavior demonstrates the absorption by free holes in silicon. Since the absorption by free holes is stronger than that by free electrons, no absorption due to the change in the density of the free electrons with the applied AC voltage could be observed at low bias voltages ($U_R \approx 0$). At wavelengths shorter than 4 μm, absorption changes appeared whose magnitude and sign are strongly dependent on the applied DC voltage. These changes were assigned to transitions of the charge carriers into or from the surface states. A broad distribution of surface states was deduced from the spectral behavior of the magnitude and phase of these changes, and in the range in which measurements were possible, the density of these states was found to decrease from the center of the band to zero at the upper edge of the valence band. The physical or chemical nature of these centers is not yet known.

Figure 15 shows the absorption spectra of free holes (curve a) and of free electrons (curve b), the density of which was modulated by variation of the band bending over the space-charge region in intrinsic germanium. In this measurement the semiconductor was immersed in an electrolyte; the bending of the band could be changed by means of the applied alternating field. Since the absorption cross section of the free holes is very much greater than that of the free electrons at these wavelengths, the band bending at the surface had to be changed to a greater extent for curve b in order to obtain roughly equal modulation. The resulting change in the number of charge carriers per cm² of surface, as calculated from the change ΔI in the incident intensity I_0 and the known absorption cross sections of holes and electrons, are $\Delta P \approx 4\times10^{11}$ cm^{-2} and $\Delta N \approx 4\times10^{12}$ cm^{-2}. The variation of the carrier densities as a result of this change in band bending can be calculated with the aid of the Fermi distribution and the Poisson equation. The values obtained agree very closely with the experimental results.

[38] *N. J. Harrick*, Physic. Rev. *125*, 1165 (1962).

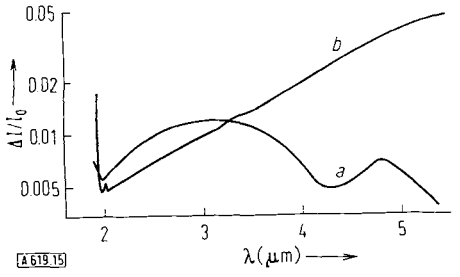

Fig. 15. Relative change in transmission on modulation of the hole density (a) for upward bending of the bands ($U_R \approx -100$ meV) and of the electron density (b) for downward bending of the bands ($U_R \approx 250$ meV) in intrinsic germanium. The approximate changes in the carrier densities are:
(a) $\Delta P \approx 4 \times 10^{11}$ cm^{-2}
(b) $\Delta N \approx 4 \times 10^{12}$ cm^{-2}.

The fast increase in $\Delta I/I_0$ below 2 μm is due to another effect. At these wavelengths the absorption of the radiation increases very rapidly in the case of germanium, since the incident energies ($h\nu \approx E_g = E_c - E_v$, see Fig. 14) are sufficient to raise electrons from the valence band into the conduction band. If strong electric fields are present, as is the case at the surface, they favor the transition, *i.e.* they effectively decrease the band gap (Franz-Keldysh effect), so that the absorption increases even at greater wavelengths (see *e.g.* [39]).

Samoggia et al. [40] observed transitions from surface states into the conduction band in n-type germanium (see Fig. 16). The bending of the bands U_{S0} (surface potential) is given by the distance of the middle of the forbidden zone on the surface from the position of the Fermi level in units of kT (see Fig. 14).

Curve A was recorded with upward bending of the bands. The intensity change ($\Delta I/I_0$) due to the superimposed AC voltage corresponds to the absorption spectrum of the free holes. Curve B, which was obtained with less pronounced upward bending of the bands, shows smaller changes in the hole density as a function of the AC voltage, as well as an additional absorption shifted in phase by 180° in a narrow energy range around 0.44 eV. The absorption signal of the free holes in this case is due to the fact that the upward bending of the bands is stronger, and the hole density on the surface is therefore greater, in the positive than in the negative half-wave of the superimposed alternating voltage. The fact that the signal β is opposite in phase means that this absorption takes place in the negative half-wave. The restriction of this additional signal to a narrow energy range indicates that a discrete state is involved in the transition. Corresponding to the observations concerning Figure 14, it follows from the opposite phase that this signal is due to a transition from the occupied state into the conduction band. The transition reaches its maximum rate at a surface potential $U_{S0} = +1.8$. Thus at this band bending, the center coincides in its energy with the Fermi level. The center is therefore situated 0.045 eV above mid gap. The broad selective absorption band denoted by α can be assigned to a continuum of surface states distributed about an energy of 3.5 kT above mid gap. If the band is bent further downward we finally obtain the absorption spectrum of the free electrons (curve g). Another absorption band opposite in phase to β should now occur as a result of transitions from the valence band into the same state. However, the authors believe that the quantum-mechanical transition probabilities are too low for this band.

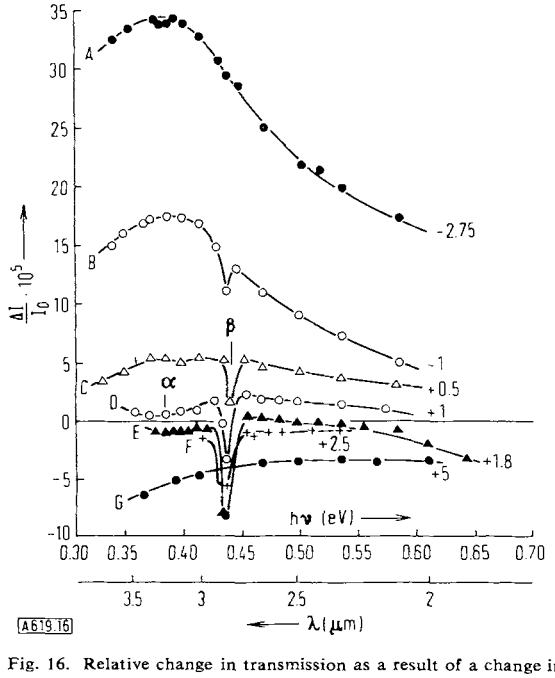

Fig. 16. Relative change in transmission as a result of a change in the density of the free charge carriers in the space-charge region and in the occupancy of the surface states (after [40]). The band bending in units of kT is given at the right hand end of each curve.

It has been shown by the examples that the optical measuring methods are suitable for use in the study of film-forming processes down to monolayers. However, the chemical compositions found for the reaction layers by optical investigations in the chemical and electrochemical studies sometimes do not agree with the models proposed for the dissolution of these substances. The reason for this discrepancy is probably that the layers in question are formed only in a secondary reaction of the dissolved semiconductor atoms. The layers therefore do not provide any insight into the actual dissolution process.

Definite results concerning the formation of surface compounds in electrochemical reactions should be provided by studies with effect modulation. The term "surface compounds" here refers to the compounds formed between the surface semiconductor atoms, whose bonds to the solid may already be weakened, and atoms from the surrounding medium. If the density of these surface molecules changes sufficiently rapidly, *i.e.* with a time constant smaller than 0.1 s, with the potential, these changes with effect modulation should permit the observation of absorption bands in the IR spectrum at the characteristic frequencies of these molecules.

New Methods of Preparative Organic Chemistry VI[**]

Reactions with *N*-Carbonylsulfamoyl Chloride

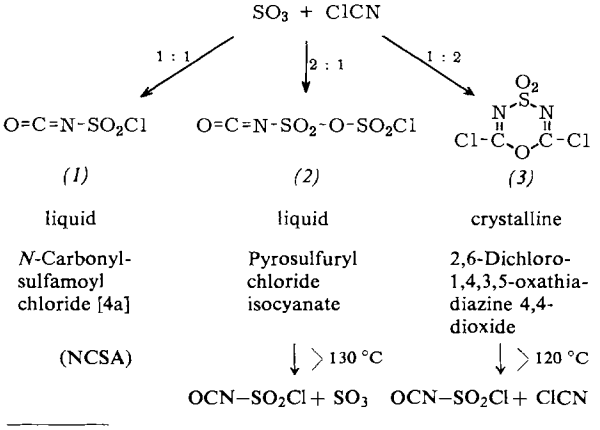
BY R. GRAF [*]

N-Carbonylsulfamoyl chloride (NCSA) is an intermediate that can be obtained from cyanogen chloride and sulfur trioxide, and which reacts with many compounds, via electrophilic substitution, much more readily than other isocyanates. Reactions with compounds containing hydroxyl, amino, or carboxyl groups lead to N-chlorosulfonyl-urethanes, -ureas, and -amides, respectively. This group of products also includes the parent substance sulfamoyl chloride (amidosulfonyl chloride). The reaction of N-carbonylsulfamoyl chloride with olefins provides an easy route, not only to derivatives of β-amino acids and unsaturated carboxylic acids, but also to many β-lactams. New, very reactive sulfonylisocyanates of several types can be obtained by further reactions of primary products obtained from N-carbonylsulfamoyl chloride and by the reaction of N-carbonylsulfamoyl chloride with olefins in the presence of free-radical formers. When allowed to react with a number of compounds, NCSA undergoes loss of carbon dioxide to form products containing the grouping =N–SO₂Cl.

1. General

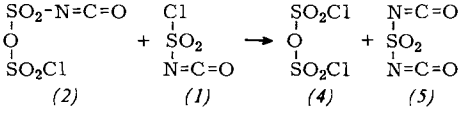
1.1. Preparation[1-4]

The reaction of sulfur trioxide with cyanogen chloride at a temperature not exceeding 0 °C leads to the formation of compounds *(1)*, *(2)*, and *(3)* by combination of the components in the ratios 1:1, 2:1, and 1:2.



Whereas NCSA is thermally stable up to 300 °C, *(2)* and *(3)* decompose slightly above 100 °C to give *(1)* and sulfur trioxide or *(1)* and cyanogen chloride respectively; the sulfur trioxide and cyanogen chloride react to form *(1)*. This explains why by far the most abundant product obtained on reaction of sulfur trioxide with cyanogen chloride above 130 °C is *N*-carbonylsulfamoyl chloride.

A roughly equimolar mixture of pyrosulfuryl chloride *(4)* and sulfonyl diisocyanate *(5)* is formed as a by-product (1–2%, based on the reacted cyanogen chloride); this remains behind as a high-boiling residue on fractionation of the crude *(1)* under reduced pressure, and is probably formed from *(1)* and *(2)*.



The boiling points of *(4)* and *(5)* are too close to each other to permit a complete separation by distillation. Reaction with cyanogen chloride at high temperatures converts this mixture into the more readily separable components chlorine, sulfur dioxide, NCSA *(1)*, and sulfonyl diisocyanate *(5)* [5].

Technical *N*-carbonylsulfamoyl chloride sometimes contains traces of sulfonyl diisocyanate and pyrosulfuryl chloride, but these are generally not objectionable. On the other hand, even a very small quantity of sulfur trioxide has extremely undesirable effects, particularly in the reaction with olefins. NCSA containing sulfur trioxide rapidly darkens the walls of polyethylene vessels. Cyanogen chloride in small quantities (at most a few tenths of one per cent) is advantageous in the NCSA, since this ensures the absence of free sulfur trioxide.

[2] *R. Graf*, Chem. Ber. *89*, 1071 (1956).

[3] *R. Graf*, Org. Syntheses *46*, 23 (1966).

[4] *R. Graf*, German Pat. 944009, Farbwerke Hoechst AG (1953); Chem. Zbl. *1958*, 2246.

[4a] Instead of the name "*N*-carbonylsulfamoyl" chloride one often finds in the literature the designation "chlorosulfonyl isocyanate", as well as the abbreviation "NCSA".

[5] *R. Graf*, German Pat. 1084714, Farbwerke Hoechst AG (1959); Chem. Zbl. *1961*, 4519.

Physical Properties: *N*-Carbonylsulfamoyl chloride is a colorless liquid (m.p. −44 to −43 °C; b.p. 107–108 °C/760 torr, 38 °C/50 torr; $d_4^{20} = 1.626$; $n_D^{27} = 1.4435$), which fumes slightly in air, has a choking smell, and undergoes thermal decomposition only above about 300 °C.

Storage: Glass stoppers of bottles used for storage of NCSA stick fast after a short time, even when coated with silicone grease. Glass bottles with rubber stoppers covered with polythene film are suitable for storage for short periods. Polyethylene bottles with screw caps are best for longer storage times (a few weeks). NCSA can be kept indefinitely in sealed glass ampuls.

Handling: NCSA reacts explosively with water to form sulfamic acid, hydrogen chloride, and carbon dioxide. Otherwise the same precautions must be taken as for chlorosulfuric acid, oleum, or thionyl chloride. In cases of contact with the skin, the area should at once be washed thoroughly with water. No specific toxic effect other than the caustic action has so far been observed.

Solvents and Diluents: The choice of inert solvents is limited by the high reactivity of NCSA. Suitable solvents include saturated aliphatic hydrocarbons (more or less limited solubility below 0 °C), aromatic hydrocarbons such as benzene and toluene, chlorinated hydrocarbons such as CH_2Cl_2, $CHCl_3$, CCl_4 and chlorobenzene, diethyl ether, diisopropyl ether, and acetonitrile. Liquid sulfur dioxide is particularly favorable, since it increases the reactivity of NCSA still further. Substances such as acetone or ethyl acetate can be used to a limited extent, but only at low temperatures. Tetrahydrofuran is unsuitable, as are members of all the classes of compounds mentioned below, which react with *N*-carbonylsulfamoyl chloride.

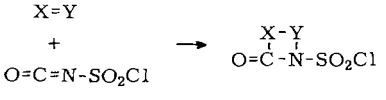
1.2. General Chemical Behavior

N-Carbonylsulfamoyl chloride is the most reactive isocyanate known. This appears to be due to the particularly high degree of electropositive polarization as a result of the direct attachment of the isocyanate group to the strongly electron-attracting SO_2Cl group. The isocyanate group generally reacts more rapidly than the sulfonyl group. The three main types of reactions of NCSA are illustrated below.

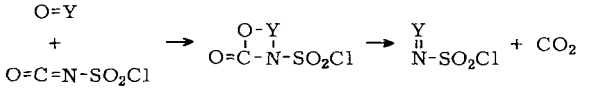
I. Compounds, X–H, containing reactive hydrogen add to NCSA, the H adding to the nitrogen and the residue X to the carbonyl group:

$$O{=}C{=}N{-}SO_2Cl + XH \rightarrow X{-}CO{-}NH{-}SO_2Cl$$

II. Compounds containing a double bond, X=Y, can add to NCSA to form a four-membered ring:



If X is oxygen, carbon dioxide is readily eliminated:



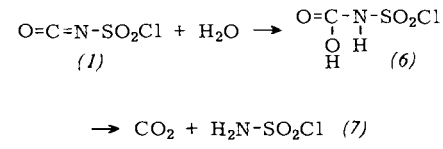
III. Under special conditions, or with compounds X–Y that cannot react with an O=C=N group, the sulfonyl chloride group reacts:

$$O{=}C{=}N{-}SO_2Cl + X{-}Y \rightarrow O{=}C{=}N{-}SO_2X + YCl$$

2. Special Reactions of NCSA

2.1. Water (Reaction Type I)

When concentrated (aqueous) hydrochloric acid is added dropwise to a solution of liquid sulfur dioxide containing NCSA, the NCSA reacts with 1 mole of water to form *N*-chlorosulfonylcarbamic acid *(6)*, which readily decomposes into sulfamoyl chloride *(7)* [6,7] and carbon dioxide.



This method can also be carried out on a large scale, and gives a colorless, extremely pure product. *R. Appel* and *G. Berger* used anhydrous formic acid as the water donor [8].

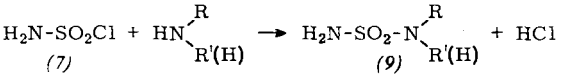
Sulfamoyl chloride (amidosulfonyl chloride) *(7)* decomposes with elimination of hydrogen chloride on prolonged heating at 80–100 °C, and can be distilled only in very small quantities under high vacuum. Compound *(7)*, which can be readily recrystallized from methylene chloride by intense cooling, reacts extremely vigorously with water to form amidosulfuric acid and hydrogen chloride.

Sulfamoyl chloride *(7)* offers a variety of possibilities as an intermediate:

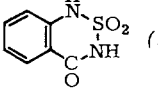
2.1.1. It reacts with sodium alkoxides or alcohols in the presence of tertiary amines to form esters *(8)* of sulfamic acid [9]:

$$\underset{(7)}{H_2N{-}SO_2Cl} + ROH \rightarrow \underset{(8)}{H_2N{-}SO_3{-}OR} + HCl$$

2.1.2. Reaction with primary or secondary aromatic amines leads to derivatives *(9)* of sulfamide [7,10]:



E. Cohen and *B. Klarberg* [11] described the reaction with methyl anthranilate to form 3,4-dihydro-1*H*-2,1,3-benzothiadiazin-4-one 2,2-dioxide *(10)*.



(10)

They also studied the cleavage of *o*-nitrophenylsulfamide *(11)* and the transfer reaction with aniline

[6] *R. Graf*, German Pat. 937645, Farbwerke Hoechst AG (1952); Chem. Zbl. *1956*, 9008.

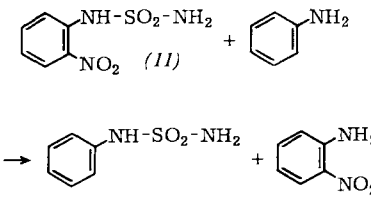
[7] *R. Graf*, Chem. Ber. *92*, 509 (1959).

[8] *R. Appel* and *G. Berger*, Chem. Ber. *91*, 1339 (1958).

[9] *R. Appel* and *W. Senkpiel*, Angew. Chem. *70*, 504 (1958).

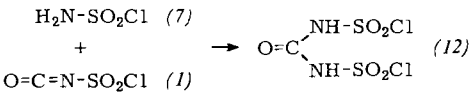
[10] *R. Graf*, German Pat. 947554, Farbwerke Hoechst AG (1953); Chem. Zbl. *1957*, 5416.

[11] *E. Cohen* and *B. Klarberg*, J. Amer. chem. Soc. *84*, 1994 (1962).



Derivatives of the compound NH_2-SO_2-NR-SO_2-NH_2 are readily obtained by reaction of *(7)* with aliphatic amines. *R. Appel* and *G. Berger* obtained bissulfamoylhydrazine NH_2–SO_2–NH–NH–SO_2–NH_2 by reaction of *(7)* with anhydrous hydrazine in acetonitrile [8].

2.1.3. NCSA slowly adds on amidosulfonyl chloride with formation of urea-*N,N'*-bissulfonyl chloride *(12)* [12].



2.1.4. Reaction with aromatic hydrocarbons and $AlCl_3$ gives amides of aromatic sulfonic acids *(13)* [13]:

$$RH + ClSO_2–NH \xrightarrow[AlCl_3]{} R–SO_2–NH_2 + HCl$$

2.1.5. Amidosulfonyl chloride reacts with potassium fluoride in boiling acetonitrile to form amidosulfonyl fluoride [14], which, unlike amidosulfonyl chloride, can be distilled without decomposition and is not hydrolyzed rapidly by water below about 60 °C. Amidosulfonyl fluoride can also be obtained from *N*-carbonylsulfamoyl fluoride (cf. Section 2.15) by reaction with an equimolar quantity of water (cf. formation of amidosulfonyl chloride) [15].

2.2. Alcohols, Phenols, Thiols (Reaction Type I)

Alcohols, phenols, or thiols react with NCSA to form (thio)esters of *N*-chlorosulfonylcarbamic acid *(14a)* or *(14b)* [16, 17]

$$\underset{(1)}{R–XH + O=C=N–SO_2Cl} \rightarrow \underset{\begin{matrix}(14a),\ X = O\\(14b),\ X = S\end{matrix}}{RX–CO–NH–SO_2Cl}$$

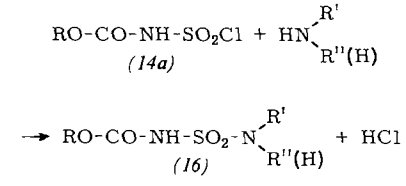
which are in turn capable of undergoing many further reactions. Owing to the violence of the reaction, diluents are used with lower alcohols, and to avoid side reactions only the equivalent quantity of the alcohol is used. The *N*-chlorosulfonylurethanes *(14a)* crystallize well and are stable on storage, whereas the esters of *N*-chlorosulfonylthiocarbamic acid decompose more or less rapidly on storage.

2.2.1. Hydrolysis of *(14a)* leads *via* the free *N*-sulfonic acids, with elimination of hydrogen chloride and sulfuric acid, to the ester *(15)* of carbamic acid. This reaction greatly simplifies the preparation of urethanes from alcohols and phenols.

$$\underset{(14a)}{RO–CO–NH–SO_2Cl} + 2\,H_2O \rightarrow \underset{(15)}{RO–CO–NH_2} + H_2SO_4 + HCl$$

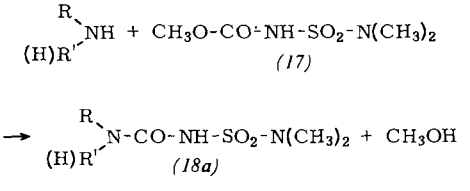
When the hydrolysis is carried out in alkaline solution, it leads to the mono- or bisalkali metal salts [*] of the urethane-*N*-sulfonic acids. The bisalkali metal salts are more stable on storage, dissolve more readily, and give a more strongly alkaline reaction than the monoalkali metal salts. On the other hand, the monoalkali metal salts of arylurethane-*N*-sulfonic acids, which are derived from phenols, decompose rapidly even in weakly alkaline solution into the phenol, sulfamic acid, and carbon dioxide [17].

2.2.2. Amines containing reactive hydrogen give stable acyl-substituted sulfamides *(16)* [17, 18].



It is possible in this way to link any alcohol or phenol to any amine *via* the $-CO-NH-SO_2-$ group; for example, the herbicide dodecyl *N*-(phenylsulfamoyl)-thiocarbamate can be obtained by reaction of NCSA with dodecyl mercaptan and aniline, *via* *S*-dodecyl *N*-chlorosulfonylthiocarbamate [19]. This and similar compounds containing the grouping $-CO-NH-SO_2-$, which will be repeatedly encountered in the following sections, act as monobasic acids and form stable alkali metal salts.

2.2.2.1. Methyl *N*-dimethylsulfamoylcarbamate *(17)* reacts with primary and secondary aliphatic and aromatic amines with liberation of heat and elimination of methanol to give substituted sulfamides *(18a)* [12]:



Compounds of this type are also formed as described in Section 2.3.2. if the reaction of the more nucleophilic aliphatic amines with NCSA in accordance with Section 2.3 cannot be stopped at the stage of the sulfonyl chloride R–NH–CO–NH–SO_2Cl.

[17] *R. Graf*, Chem. Ber. *96*, 56 (1963).

[*] The bis-salts are $RO–CO–\overset{\ominus}{N}–SO_3^{\ominus}\ 2\,M^{\oplus}$ (the mono-salts are $RO–CO–NH–SO_3^{\ominus}\ M^{\oplus}$) (cf. Chem. Ber. *96*, 57 (1963)).

[18] *R. Graf*. German Pat. 940292, Farbwerke Hoechst AG (1952); Chem. Zbl. *1956*, 12973.

[19] *E. H. Sheers*, US-Pat. 3113857, American Cyanamid Corp. (1961).

2.2.3. When the sulfonyl chlorides *(14a)* derived from phenols are heated above 80 °C (preferably in the presence of an excess of NCSA), HCl is eliminated to form sulfonyl isocyanates *(19)*, which contain the group $-O-SO_2-N=C=O$ attached to an aromatic residue [20]:

$$\underset{(14a)}{ArO-CO-NH-SO_2Cl} \rightarrow \underset{(19)}{ArO-SO_2-N=C=O} + HCl$$

The same products are obtained directly when aromatic compounds containing one or more phenolic groups are heated above 80 °C with at least one mole of NCSA per equivalent of OH.

$$\underset{(1)}{Ar-OH + Cl-SO_2-N=C=O} \rightarrow \underset{(19)}{ArO-SO_2-N=C=O} + HCl$$

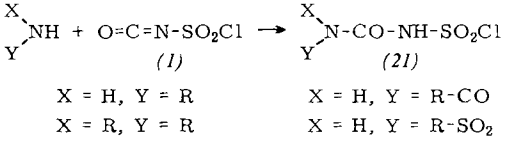
Trichloroethanol has also been converted in good yield into $CCl_3-CH_2-O-SO_2-N=C=O$ by this method.

2.2.4. Reaction with alcohols (even in the absence of HCl acceptors) or phenols (in the presence of HCl acceptors) yields esters *(20)* of urethane-*N*-sulfonic acids [17]:

$$\underset{(14a)}{RO-CO-NH-SO_2Cl} + R'OH \rightarrow \underset{(20)}{RO-CO-NH-SO_2-OR'} + HCl$$

2.3. Amines (and Amides) (Reaction Type I)

Primary and secondary aromatic amines, amides of carboxylic and sulfonic acids, imides, or lactams add to NCSA with formation of *N*-chlorosulfonylureas *(21)* [16]:



To minimize further reaction in accordance with 2.3.2, *(1)* is dissolved in a diluent and a solution of the equivalent quantity of amine is added with cooling and vigorous stirring. This precaution is unnecessary with amides and, for example, with the less nucleophilic nitroanilines. The more strongly nucleophilic aliphatic amines, and to some extent even *e.g.* anisidine, react further in accordance with 2.3.2, despite this precaution, and a more or less large quantity of the compounds $R-NH-CO-SO_2NHR$ is formed as well as the sulfonyl chloride. Ammonia gives the ammonium salt of ureasulfonimide [21].

2.3.1. Hydrolysis of *(21)* leads *via* the unstable *N*-sulfonic acids to substituted ureas *(22)* [12]:

$$\underset{(21)}{X-NH-CO-NH-SO_2Cl} + H_2O \rightarrow \underset{(22)}{X-NH-CO-NH_2} + H_2SO_4 + HCl$$

X = R, R–CO, $R-SO_2$

Hydrolysis in alkaline media leads to the mono- or to the more readily soluble bisalkali metal salts of the *N*-sulfonic acids (cf. Section 2.2.1).

2.3.2. Further reaction of *(21)* with amines yields substituted sulfamides *(18)* [18], which are generally very stable and form neutral salts.

$$\underset{(21)}{X-NH-CO-NH-SO_2Cl} + HN\begin{matrix}R'\\R''(H)\end{matrix} \rightarrow \underset{(18)}{X-NH-CO-NH-SO_2-N\begin{matrix}R'\\R''(H)\end{matrix}} + HCl$$

X = R, R–CO, $R-SO_2$

2.3.3. Reaction with alcohols, even in the absence of hydrogen chloride acceptors, yields esters *(23)* of substituted urea-*N*-sulfonic acids [12]:

$$\underset{(21)}{X-NH-CO-NH-SO_2Cl} + R'OH \rightarrow \underset{(23)}{X-NH-CO-NH-SO_2-OR'} + HCl$$

X = R, R–CO, $R-SO_2$

2.4. Carboxylic Acids (Reaction Type I)

NCSA reacts with carboxylic acids to form *N*-chlorosulfonylamides *(24)* of carboxylic acids, with elimination of carbon dioxide [22]:

$$\underset{(1)}{R-COOH + O=C=N-SO_2Cl} \rightarrow \underset{(24)}{R-CO-NH-SO_2Cl} + CO_2$$

This reaction proceeds readily with saturated and unsaturated fatty acids, aliphatic dicarboxylic acids, or benzoic acid, but is retarded or prevented by electron-attracting substituents (Cl, NO_2). The primary product of the reaction of formic acid with NCSA decomposes into sulfamic acid, carbon monoxide, and carbon dioxide.

The thermal stability and storage stability of the *N*-chlorosulfonylamides *(24)* are generally lower than those of the compounds obtained as described in Sections 2.2 and 2.3, and this must be borne in mind in their preparation and further treatment.

2.4.1. Hydrolysis of *(24)* leads *via* the unstable *N*-sulfonic acids to amides, and provides a very simple method for the conversion even of unstable unsaturated carboxylic acids into their amides [12]:

$$\underset{(24)}{R-CO-NH-SO_2Cl} + 2\,H_2O \rightarrow R-CONH_2 + H_2SO_4 + HCl$$

Hydrolysis in alkaline media gives stable alkali metal salts of amide-*N*-sulfonic acids. In this series of compounds, the bisalkali metal salts are again more readily soluble and more stable on storage than the mono salts.

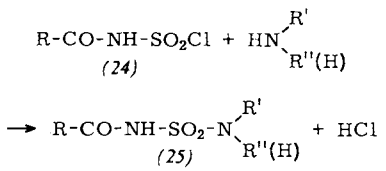
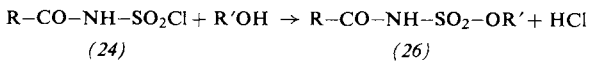
[22] *R. Graf*, German Pat. 931225, Farbwerke Hoechst AG (1952); Chem. Zbl. *1956*, 3995.

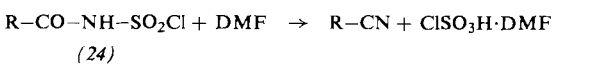
2.4.2. Acylated sulfamides *(25)* can be obtained by reaction with amines [23]:



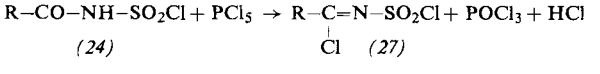
2.4.3. Reaction with alcohols, even in the absence of hydrogen chloride acceptors, gives esters *(26)* of acylated sulfamic acids [12]:



2.4.4. The extremely smooth elimination of chlorosulfuric acid with dimethylformamide (DMF) is a simple and generally applicable method for the preparation of nitriles [24]:

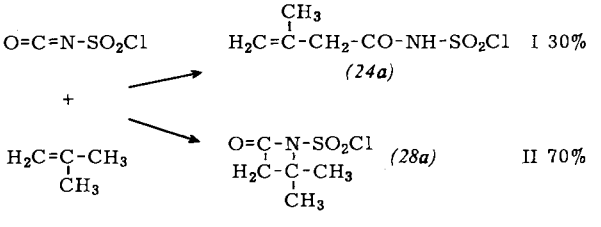


2.4.5. Reaction with PCl_5 leads to *N*-chlorosulfonylcarbimidyl chlorides *(27)* [12]:



2.5. Olefins (Reaction Types I and II)

The cryptoionic reaction with olefins is undoubtedly one of the most interesting reactions of *N*-carbonylsulfamoyl chloride. The products are an unsaturated *N*-chlorosulfonylamide, *e.g. (24a)*, and a β-lactam-*N*-sulfonyl chloride, *e.g. (28a)*, as is shown below for the reaction with isobutylene [25–28].

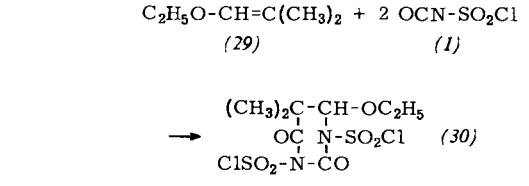


The ratio of the conversions by routes I and II is determined by the constitution of the olefin. This ratio cannot generally be altered by changing either the solvent or the reaction temperature. Route II generally predominates, but in some cases the only product is the open-chain amide *(24)* (cf. Section 2.6).

In accordance with the Markownickoff rule, the nitrogen in NCSA, which carries a partial negative charge, adds on to the carbon atom carrying the smallest number of hydrogens in the olefin.

The *N*-chlorosulfonylamides formed from olefins and NCSA are derived (so far as is known at present) from β,γ-unsaturated carboxylic acids. In the reaction of *n*-1-hexene with NCSA, it has been shown that the *N*-chlorosulfonylamide formed in addition to 4-*n*-butyl-2-oxoazetidine-*N*-sulfonyl chloride is derived from an *n*-heptenoic acid [12]. The mother liquor remaining after hydrolysis of the reaction mixture of *n*-1-hexene and NCSA followed by extraction of the β-lactam gave an unsaturated carboxylic acid on acidification with concentrated hydrochloric acid and steam distillation. Hydrogenation of this unsaturated acid (PtO_2) *via* the chloride ($SOCl_2$) gave an amide, whose melting point, mixed melting point, and IR spectrum showed that it was identical with heptanamide. Thus in the formation of the *N*-chlorosulfonylamide, the CO group of NCSA again attacks the terminal C atom of the olefinic double bond.

Enol ethers do not react in the same way as simple olefins. 3,4-Dihydro-2*H*-pyran reacts smoothly with NCSA in ether to form *N*-chlorosulfonyl-5,6-dihydro-4*H*-pyran-3-carboxamide [29]. However, while ethyl vinyl ether and NCSA also give the unsaturated amide $C_2H_5O-CH=CH-CO-NH-SO_2Cl$ [29], ethyl isobutenyl ether *(29)*, even when present in excess, reacts



directly with two moles of NCSA to form the dihydrouracil derivative *(30)*, which can be oxidized by chromic acid to dimethylbarbituric acid after removal of the sulfonyl chloride groups [30].

Certain diolefins, such as dipentene (*dl*-limonene) [27] and 1,4-dimethylenecyclohexane [31] give bis-β-lactams.

E. J. Moroconi and *J. F. Kelly* [32] recently described the reaction of allenes with NCSA. In addition to unsaturated *N*-chlorosulfonylamides *(24)*, this reaction gives *N*-chlorosulfonyl-β-lactams having an exocyclic methylene group, *e.g. (28b)*. The allenes *(31a)–(31c)*

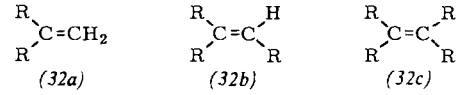
(31a) (31b) (31c)

react in a similar way. Olefins having the constitution *(32a)–(32c)*, in which at least one of the double-bonded C atoms is attached to two alkyl groups, react



(32a) (32b) (32c)

rapidly, *i.e.* the reaction is strongly exothermic at room temperature and is practically complete within a period of a few seconds to a few minutes.

α-Olefins [33] $RCH=CH_2$ and olefins having a non-terminal double bond RCH=CHR [34] react much more slowly with NCSA [27].

The unsaturated hydrocarbons styrene [27], bicyclo-[2.2.1]hept-2-ene [27], and 1,2-dihydronaphthalene [35], which formally belong to the latter group of olefins, are more like the first group in their reaction behavior.

Electron-attracting substituents on the hydrocarbon residue lower the reaction rate, as is shown by the behavior of 4-chlorostyrene, esters of methallylcarboxylic acid, and methallyl alkyl and methallyl aryl ethers [27]. Methallyl chloride reacts even more slowly [31].

The large difference in the rates of reaction of NCSA with olefins with and without branching on the double bond can be utilized for the separation of olefins of these types [27,36,37].

N-Chlorosulfonyl-β-lactams *(28)* are generally relatively stable, though their stabilities, like their rates of formation, can differ very widely in their order of magnitude. On prolonged storage or on heating, for example, they generally undergo primary rearrangement into unsaturated *N*-chlorosulfonylamides *(24)*. The unsaturated *N*-chlorosulfonylamides tend to decompose further. Thus when 4,4-dimethyl-2-oxoazetidine-*N*-sulfonyl chloride *(28a)*, which is obtained from isobutylene, is heated at 100 °C, it decomposes within a few minutes with liberation of heat and formation of tarry products. The thermal rearrangement of *N*-fluorosulfonyl-β-lactams is easier to follow kinetically, since the sulfonyl fluorides are much more stable and do not tend to enter into ill-defined decomposition reactions [27].

It should be emphasized at this point that the *N*-chlorosulfonyllactams *(28)* and the open-chain *N*-chlorosulfonylamides *(24)* are formed independently and simultaneously from isobutylene and homologous olefins, *i.e.* the *N*-chlorosulfonylamide found in the reaction products is not formed *e.g.* by further reaction of the initially formed *N*-chlorosulfonyllactam [27]. This has been clearly shown by IR spectrographic observation of reacting mixtures [38]. The ratio in which the two products are formed remains constant from the beginning to the end of the reaction.

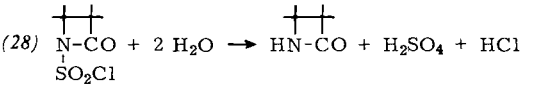
An exception to this rule is found in the case of α-methylstyrene, which gives only the unsaturated *N*-chlorosulfonylamide on normal working-up of the reaction mixture. When the reaction is followed IR-spectrographically, it is found that a β-lactam is in fact formed, but rearranges rapidly into the amide [38].

In general, the monosubstituted *N*-chlorosulfonyl-β-lactams having lower alkyl residues in position 4 have the lowest thermal stabilities; the stability increases with increasing substitution on C-3 and C-4. One of the most stable *N*-chlorosulfonyl-β-lactams is 3-*tert*-butyl-4,4-dimethyl-2-oxoazetidine-*N*-sulfonyl chloride, which is obtained from 2,4,4-trimethyl-2-pentene and which showed no change on storage for 15 years or on being heated at 100 °C. 3,3-Dimethyl-4-phenyl-2-oxoazetidine-*N*-sulfonyl chloride showed no depression of its equilibrium melting point after repeated melting and resolidification, whereas 4-phenyl-2-oxoazetidine-*N*-sulfonyl chloride undergoes partial rearrangement into *N*-chlorosulfonylcinnamamide on melting; this leads to a rapid depression of the equilibrium melting point [27].

The unsaturated *N*-chlorosulfonylamides *(24)*, which can react in accordance with Sections 2.4.1.–2.4.4., differ from the corresponding *N*-chlorosulfonyl-β-lactams *(28)* in their much higher rates of hydrolysis; this difference often facilitates the separation of these compounds [27].

The *N*-chlorosulfonyl-β-lactams enter into an extremely wide variety of reactions, the most important of which appears to be their conversion into the free β-lactams.

2.5.1. The rates of hydrolysis of the *N*-chlorosulfonyl-β-lactams varies with the substituents over a very wide range. In some cases (substitution by one or two small aliphatic residues), hydrolysis to the free lactam takes place with simultaneous neutralization of the acid liberated without further measures [39]:



(28) $+ 2\,H_2O \rightarrow$ $+ H_2SO_4 + HCl$

However, even in the *N*-chlorosulfonyllactams that are more stable to water, the SO_2Cl group can be readily removed *via* unstable *N*-sulfinic acids by the action of reducing agents such as zinc dust or iron powder in aqueous-alcoholic suspension, or, more elegantly, with simultaneous neutralization of the liberated acid in the presence of a small quantity of an iodide, which catalyzes the hydrolysis of the *N*-sulfonyl chloride by a redox reaction [27,40].

When the molten mixture of *N*-chlorosulfonyllactam *(28a)* and unsaturated *N*-chlorosulfonylamide *(24a)* obtained by

[33] *H. Biener*, Belg. Pat. 662257, Farbwerke Hoechst AG (1964).

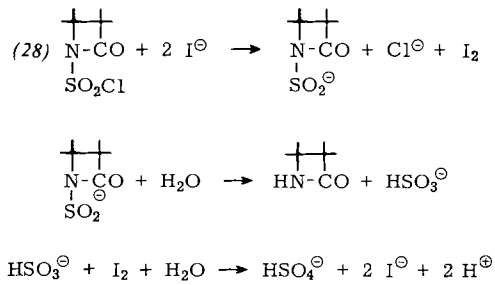
[38] *K. Clauss*, Farbwerke Hoechst AG, unpublished results.

[39] *R. Graf*, German Pat. 1116228, Farbwerke Hoechst AG, (1958); Chem. Zbl. *1964*, 16-2261.

[40] *R. Graf*, German Pat. 1086234, Farbwerke Hoechst AG (1958); Chem. Zbl. *1961*, 6684.



continuous reaction of NCSA and isobutylene in the absence of solvents is hydrolyzed at pH = 5–7, approximately half of the *(24a)* is converted into 3-methyl-3-butenonitrile $CH_2=C(CH_3)-CH_2CN$ by the action of the free lactam formed from *(28a)* (cf. Section 2.4.4). The remainder of the compound *(24a)* is found in the hydrolysis mixture in the form of the salt $CH_2=C(CH_3)-CH_2-CONH-SO_3Na$. When the mother liquor remaining after extraction of the lactam is heated close to its boiling point for a short time after addition of concentrated sodium hydroxide solution, large quantities of the less soluble salt $(CH_3)_2C=CH-CONH-SO_3Na$, which is formed by rearrangement, crystallize out as large shiny platelets on cooling.

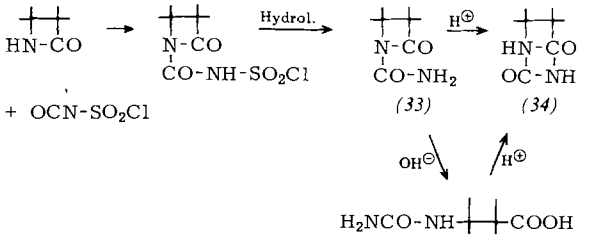
The crude 4,4-dimethyl-2-azetidinone obtained by extraction of the hydrolysis mixture with chloroform contains small quantities of 3-hydroxy-3-methylbutanonitrile $(CH_3)_2C(OH)-CH_2CN$ as well as the unsaturated amide and nitrile. This hydroxy nitrile cannot be separated from the lactam by fractional distillation, and is as stable as the lactam toward permanganate. It appears in the gas chromatogram as a sharp peak before the lactam, and remains in the mother liquor on recrystallization of the permanganate-treated and vacuum-fractionated lactam *e.g.* from diisopropyl ether at −40 °C. After the ready cleavage of any remaining β-lactam with sulfuric acid, the hydroxy nitrile can be isolated from concentrated residual mother liquors by extraction with chloroform. It was identified as the urethane $NC-CH_2-C(CH_3)_2-O-CONH_2$ [colorless needles, m.p. 90–91 °C (from dilute aqueous methanol), obtained by reaction with NCSA followed by hydrolysis in accordance with Section 2.2.1] by comparison (mixed melting point) with the compound [12] obtained in the same way from an authentic sample of the hydroxy nitrile [41].

The special advantage of this synthesis of β-lactams from olefins and *N*-carbonylsulfamoyl chloride, which can also be carried out on the industrial scale, is that it gives β-lactams having unsubstituted NH groups, many of which can be very readily polymerized in the presence of alkaline catalysts and under very mild conditions into high molecular-weight, fiber-forming products; these are characterized by a remarkable stability to oxygen even at high temperatures [42].

The liberation of heat on cleavage of a β-lactam with concentrated hydrochloric acid served as a reliable test for the presence of a β-lactam (in addition to the IR spectrum, which contains CO bands at 5.6–5.7 μm). The failure of this reaction to take place with the lactam obtained from camphene gave the first indication that this was not a β-lactam; the product was in fact found to be a γ-lactam [43].

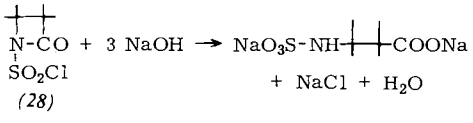
The ready availability of the β-lactams led to the investigations of a series of ring-cleavage and substitution reactions of this class of compounds. Of these reactions, only that with NCSA will be reported here.

2.5.1.1. As internal amides with a free NH group, β-lactams react with NCSA in accordance with the reaction given in Section 2.3. The *N*-carbamoyl-β-lactams *(33)* obtained by hydrolysis of the reaction products can be converted into dihydrouracils *(34)* [12]:



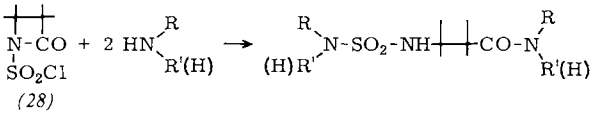
The easy and almost quantitative conversion into the extremely stable, readily crystallizing, sparingly soluble dihydrouracils, which have relatively high and sharp melting points, can be used for the characterization of liquid β-lactams. The intermediate *N*-carbamoyl-β-lactam need not be isolated.

2.5.2. *N*-Chlorosulfonyl-β-lactams *(28)* are cleaved between the nitrogen and the CO group by strongly nucleophilic reagents.



To carry out this reaction, the *N*-chlorosulfonyllactams are added to excess caustic alkali solution [27,44]. When heated in acidic solution, the salts lose sulfuric acid and form salts of β-amino acids.

2.5.3. The reaction of *(28)* with excess aliphatic or aromatic amine results in the introduction of two amine residues into the molecule [27,45].



The products are insoluble in sodium carbonate solution and are only very slowly cleaved by boiling hydrochloric acid.

With aromatic amines having strongly electron-attracting substituents X (*o*-nitroaniline, chloronitroaniline) in the presence of tertiary bases, the β-lactam ring remains intact and only one mole of the amine reacts to give compounds of the type *(35)* [12].

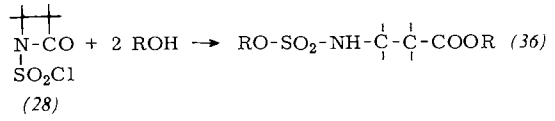
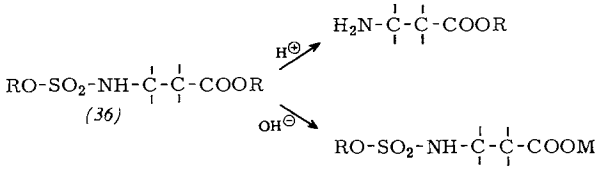
[45] *R. Graf*, German Pat. 1004189, Farbwerke Hoechst AG (1954); Chem. Zbl. *1957*, 9805.

2.5.4. Reaction with alcohols or phenols in the presence of alkoxides (phenoxides) or tertiary amines gives bis-esters *(36)* [27,46]:



(28)

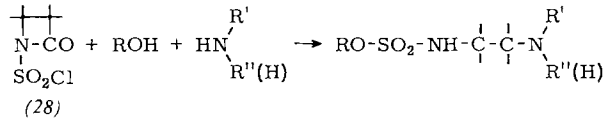
2.5.4.1. The bis-esters *(36)* give different products on hydrolysis by acids and by bases [27]:



(36)

It is possible in this way to obtain esters of β-amino acids directly after working up from *N*-chlorosulfonyl-β-lactams (addition to alcoholic alkoxide solution, introduction of hydrogen chloride, and heating for about 1 hour).

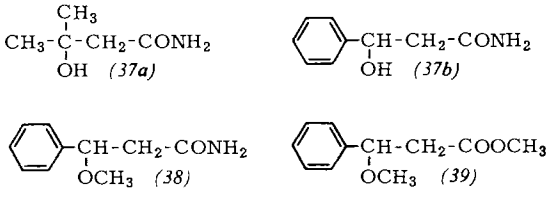
2.5.5. On reaction with an amine in alcohol (phenol), the alcohol residue becomes attached to the SO_2 group and the amine residue to the CO [27].



(28)

On hydrolysis of the products in acidic media, the sulfonate group is split off, and amides of β-amino acids are formed.

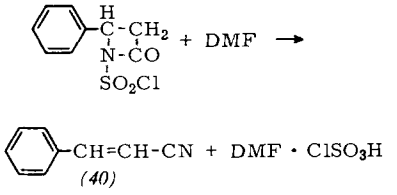
2.5.6. When *N*-chlorosulfonyl-β-lactams are hydrolyzed without neutralization of the liberated acid, amides of β-hydroxy acids are sometimes formed in good yields, whereas alcohols give amides or, under more vigorous conditions, esters of β-alkoxycarboxylic acids, *e.g. (37)*, *(38)*, and *(39)* [47].



(37a) *(37b)* *(38)* *(39)*

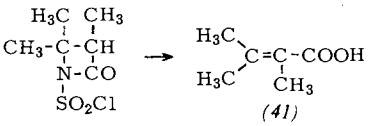
In other cases the hydrolysis of chlorosulfonyllactams is more complicated; the reaction may yield an unsaturated nitrile, together with cleavage back into the olefin, unsaturated acids or amides, or even a lactone (from 2,3,3-trimethyl-2-butene) [27].

2.5.7. Reaction with dimethylformamide gives nitriles of unsaturated acids [48], *e.g. (40)*.



(40)

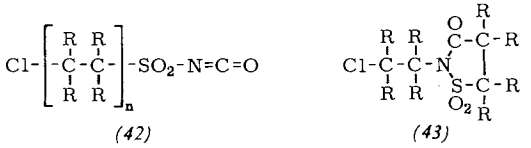
2.5.8. Dissolution in concentrated sulfuric acid followed by pouring into water sometimes leads to high yields of unsaturated acids (*e.g.* cinnamic acid, β,β-dimethylacrylic acid, α,β,β-trimethylacrylic acid *(41)*) [12].



(41)

When the reaction mixture is poured into water, the residue $>N-SO_2Cl$ appears as sulfamic acid. Saturated and unsaturated *N*-chlorosulfonylamides *(24)* can also be converted into carboxylic acids in this way.

2.5.9. *D. Günther* and *F. Soldan* [49] found that the reaction of NCSA with olefins proceeds differently under the action of UV radiation or in the presence of free-radical formers. On the one hand, the olefin adds on with formation of alkyl-substituted 2-chloroethylsulfonyl isocyanates and their lower telomers *(42)*, and on the other, NCSA reacts with two moles of olefin to form alkyl-substituted *N*-2-chloroethyl-3-oxothiazolidine 1,1-dioxides *(43)*.



(42) *(43)*

Olefins of all types, including ethylene, react in this way. This has made available a large number of new sulfonyl isocyanates with a wide range of possible further reactions.

2.6. Other Examples

Many compounds of the type RH enter into electrophilic substitutions with *N*-carbonylsulfamoyl chloride or fluoride to give *N*-chloro- or *N*-fluoro-sulfonylamides R–CO–NH–SO_2Cl(F), which can react further as described in Sections 2.4.1.–2.4.5. Some examples of the possible groups R are listed in Table 1.

The reaction generally proceeds at 20–40 °C, though in the case of anthracene a temperature of about 80 °C is necessary for fast reaction (in toluene).

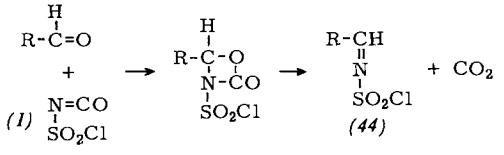
When the *N*-chlorosulfonylamides are dissolved in concentrated sulfuric acid and the solution poured into water, the free carboxylic acids are formed, as in the case of *N*-chlorosulfonyllactams (cf. Section 2.5.8).

Benzene and toluene can be made to react with NCSA in the presence of $AlCl_3$ at 20–30 °C; hydrolysis of the primary product leads to benzamide or toluamide[55].

2.7. Aldehydes

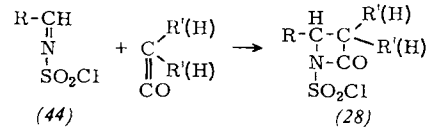
After the addition of NCSA to the carbonyl group (Reaction Type II), carbon dioxide is eliminated and azomethine-*N*-sulfonyl chlorides *(44)* are formed [27,56].



(1) *(44)*

The primary formation of unstable adducts of NCSA and aldehydes has been experimentally verified in some cases by the observation of crystalline products, which decomposed with liberation of CO_2. Azomethine-*N*-sulfonyl chlorides in which R = aryl crystallize particularly readily. They are rapidly cleaved by water to give the starting aldehydes, amidosulfuric acid, and hydrogen chloride.

2.7.1. The azomethine-*N*-sulfonyl chlorides very readily add on ketene or substituted ketenes, such as dimethylketene, to form *N*-chlorosulfonyl-β-lactams *(28)* [27,57].

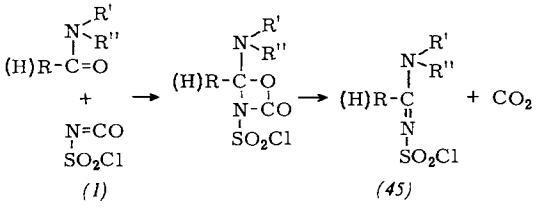


(44) *(28)*

Hydrolysis of these *N*-chlorosulfonyl-β-lactams in accordance with the reaction given in Section 2.5.1. led to a series of new lactams, only some of which could be obtained from the olefin.

2.8. *N,N*-Dialkylamides

N,N-dialkylamides of carboxylic acids, as well as the constitutionally similar *N*-alkyllactams, piperidides of carboxylic acids, *etc.*, add on NCSA in a Type II reaction to give unstable adducts, which readily lose carbon dioxide to form N^2-chlorosulfonylamidines *(45)* [58].



(1) *(45)*

The products can react as described in Sections 2.2.1.–2.2.3. Hydrolysis gives the free amidines [59] *via* the free amidine-*N*-sulfonic acids, which, in some cases, are isolable.

2.9. Ketene

Ketene reacts with NCSA in ether at low temperatures in a Type II reaction to give *N*-chlorosulfonyl-2,4-azetidinedione *(46)*, which can be readily converted into malonic acid derivatives [60,61].

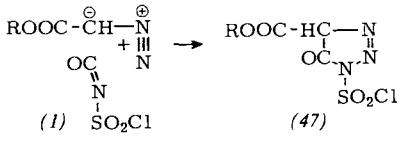
[61] *E. Mundlos* and *R. Graf*, Liebigs Ann. Chem. *677*, 108 (1964).

(46) cannot be isolated since it readily decomposes.

2.10. Diazoacetic Ester

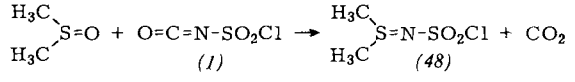
Reaction with diazoacetic ester leads to the ester of 1-chlorosulfonyl-5-oxo-Δ^2-triazoline-4-carboxylic acid *(47)* [31].



(1) *(47)*

2.11. Dimethyl Sulfoxide

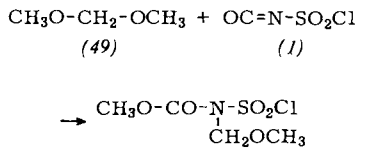
Dimethyl sulfoxide reacts with NCSA with loss of CO_2 and formation of *N*-chlorosulfonyldimethylsulfimide *(48)* (Reaction Type II) [62].



(1) *(48)*

2.12. Bismethoxymethane (Methylal)

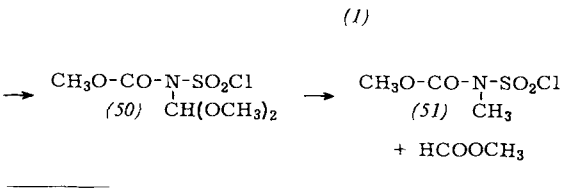
Bismethoxymethane (methylal) *(49)* adds smoothly and exothermally to NCSA in a Type I reaction (the residue $-CH_2OCH_3$ taking the place of H in this case) [12].



(49) *(1)*

2.13. Ortho Esters

NCSA adds to ortho esters, and particularly readily to trimethyl orthoformate, with elimination of formate and formation of esters of *N*-alkyl-*N*-chlorosulfonylcarbamic acid [*e.g. (51)*]. The intermediate *(50)* has not yet been isolated [63,64]



(1) *(50)* *(51)*

[62] *R. Appel* and *H. Rittersbacher*, Chem. Ber. *97*, 852 (1964).

[63] *H. Biener*, German Pat. 1186044, Farbwerke Hoechst AG (1963).

[64] *H. Biener*, Liebigs Ann. Chem. *686*, 102 (1965).

2.14. Pyridine

The addition product of NCSA with pyridine [65], like the SO_3-pyridine adduct, reacts with alkali to give the sodium salt of glutacondialdehyde, which can be detected as the dianil derivative. The NCSA-pyridine adduct reacts only slowly with ice water with loss of CO_2, and certain reactions of NCSA that normally proceed only in anhydrous media can be carried out (though in poor yields) with this adduct in aqueous suspension: an example of such a reaction is the reaction with aniline as described in Section 2.3.2. [12].

2.15. Sodium Fluoride, Hydrogen Fluoride

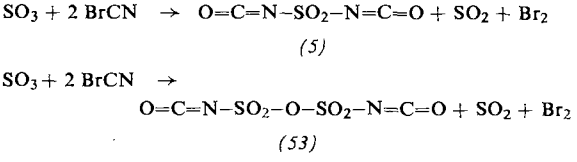
NCSA reacts with NaF or HF in a Type III reaction to give *N*-carbonylsulfamoyl fluoride *(52)* (CSF) [15, 66,67]. Of all the isocyanates, CSF is closest in its behavior to NCSA. It can in principle be used in the

(1) *(52)*

same way as NCSA, but generally reacts a little more slowly [27]. The *N*-sulfonyl fluorides obtained in reactions with *(52)* are generally much more stable to hydrolysis and to heat than the *N*-sulfonyl chlorides [68].

2.16. Pyrolysis of NCSA to Sulfonyl Diisocyanate

The reaction of cyanogen bromide with sulfur trioxide leads *via* thermally unstable sulfonyl bromides, with elimination of bromine and sulfur dioxide, to sulfonyl diisocyanate *(5)* or disulfuric acid diisocyanate *(53)*, depending on the conditions. These two reactions may be represented by the overall equations [69]:



(5)

(53)

NCSA can be converted, in the gas phase at about 400 °C, or more readily and more smoothly in the presence of catalysts containing $FeCl_3$ [70], into sul-

[65] *R. Graf*, German Pat. 1000807, Farbwerke Hoechst AG (1955); Chem. Zbl. *1957*, 8365.

fonyl diisocyanate, chlorine, and sulfur dioxide in excellent yields:

$$\underset{(1)}{2\ O{=}C{=}N{-}SO_2Cl} \rightarrow \underset{(5)}{SO_2(-N{=}C{=}O)_2} + Cl_2 + SO_2$$

At about 400 °C in the presence of catalysts containing $FeCl_3$, sulfonyl diisocyanate is formed directly from SO_3 and cyanogen chloride [71]:

$$2\ SO_3 + 2\ ClCN \rightarrow SO_2(-N{=}C{=}O)_2 + SO_2 + Cl_2$$

Sulfonyl diisocyanate is also formed on prolonged boiling of NCSA with silver cyanate [72].

Sulfonyl diisocyanate appears to be rather less reactive than NCSA, but reacts with the above-mentioned classes of compounds, including olefins, to give products similar to those obtained with NCSA. Many of these reactions can be controlled to give predominant reaction of both isocyanate groups or of only one isocyanate group [30].

The Degradation of Poly(ethylene terephthalate)[**]

BY L. H. BUXBAUM [*]

The penetration of new markets by polyester fibers has emphasized the need for increased stability of the polyester toward a variety of degradative reactions. Extensive studies of the nature of the thermal, hydrolytic, oxidative, and radiation-induced degradation reactions have been reported. The interpretation of kinetic investigations and the identification of the reaction products have been facilitated by using suitable esters as model compounds in place of the polymeric species.

1. Introduction

Poly(ethylene terephthalate) has the reputation of being a polymer of great resistance to environments which might be expected to limit its useful life as a fiber, film, or other end product. However, even the small amount of decomposition occurring under normal manufacturing and processing conditions is important to the manufacture of a uniform product. Polyester fibers and films, although of excellent durability, can be affected by hydrolysis, aminolysis, and various kinds of radiation.

To avoid a gradual deterioration of the physical properties of the product, such degradation reactions must be inhibited or retarded. In turn, successful stabilization must be based on an understanding of the precise mechanism by which each type of degradation occurs. Much research in this direction has been conducted by the polyester producers and by textile research institutes.

Akron, Ohio (USA)

1.1. Preparation of Poly(ethylene terephthalate)

Poly(ethylene terephthalate) is prepared in two stages from dimethyl terephthalate and ethylene glycol. In the first stage a precondensate is formed which chiefly consists of the diglycol ester together with a certain amount of oligomers (up to the tetramers).

This trans-esterification, which is catalyzed by small amounts of metal salts (Zn, Mn, Cd, Pb, Ca, Mg, *etc.*), is carried out at 200 °C, the methanol formed being continually removed by distillation. The complete removal of the methanol is most important since it can drastically interfere with the formation of sufficiently long chains; as a monofunctional alcohol it forms stable end groups and thus prematurely stops chain growth.

In the second stage, polycondensation of the precondensate is carried out at *ca.* 280 °C in high vacuum (< 1 torr) and with addition of a heavy metal salt (usually Sb), the glycol formed being continually removed.

Concentration of catalyst and temperature control are very significant factors in determining the stability of the resulting polyesters. Additionally, of course, stabilizers (usually P-compounds) can also be added.

1.2. Properties of Poly(ethylene terephthalate)

Poly(ethylene terephthalate) exhibits a number of interesting physical, and chemical, properties, only the most important of which shall be briefly mentioned here. On account of the hydrophobic nature of this polymer (absorption of water at 20 °C and at a relative humidity of 25 % is less than 0.5 %) its mechanical properties are almost uninfluenced by water (*i.e.*

it has a high wet strength, and there is no "flat spotting" of the polyester tire cord). Poly(ethylene terephthalate) is very resistant to attack by most organic solutions and reagents, especially acids, and also to biological degradation. It is much more stable toward the effect of light and atmospheric conditions than most of the other polymers.

Poly(ethylene terephthalate) fibers are distinguished by their excellent resilience and by their dimensional stability. Up to a temperature of *ca.* 150 °C the properties of the fiber deteriorate very little. Other properties which are responsible for the popularity of poly(ethylene terephthalate) fiber in the textile industry are its good permanent-set property and high melting point (260 °C).

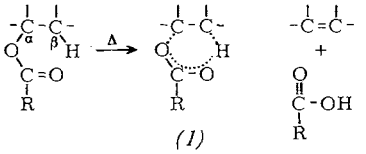
The excellent electrical properties of poly(ethylene terephthalate), such as high specific resistance, high dielectric strength, together with its thermal stability and small moisture absorption, make it a very good insulating material.

2. Thermal Degradation

The nature of thermal degradation of polyesters is not entirely clear. The primary fission of the ester linkage in the polymer is probably not a homolytic reaction, since thermal degradation cannot be inhibited by free radical trapping agents. The close agreement between the behavior of poly(ethylene terephthalate) (PET) and model ester compounds (see Section 2.2) suggests that the mechanism for polymer degradation is probably similar to that for simple ester pyrolysis.

2.1. Thermal Degradation of Carboxylic Esters in General

The mechanism by which esters containing at least one β-hydrogen atom decompose pyrolytically to give olefins and acids is generally considered to involve a cyclic transition state *(1)* [1].



(1)

In *(1)*, the C–H bond and the alkoxy C–O bond are partly broken, while the olefinic C=C bond and the O–H bond are partially formed. Previous work [2] has shown that the C–O bond breakage is heterolytic and that the alpha-carbon atom develops some carbonium-ion character in the transition state. It appears that for a given ester at a fixed temperature, the rate of decomposition is determined more by the stability of the breaking alkoxy C–O bond than by the breaking C–H bond or the forming C=C bond [3].

Maccoll [4] proposed that the reaction is a pseudo bimolecular electrophilic substitution, (E_2), involving nucleophilic attack of the carbonyl oxygen atom on the β-hydrogen atom.

This field has been widely but unsystematically studied. A good survey of the earlier literature up to about 1928 has been presented by *Hurd* [5]. *Ritchie* [6] has summarized nine of the breakdown routes which occur most frequently.

2.2. Thermal Degradation of Model Compounds

Difficulties in studying the polyester itself suggested the use of simplified model systems representing specific segments of the intact PET chain, segments with terminal hydroxyethyl groups and representing the known incorporation of occasional ether linkages. Ethylene dibenzoate *(2)*, 2-hydroxyethyl benzoate *(3)* and diethylene glycol dibenzoate *(4)* have been chosen most often for such studies. The degradation of *(2)*

$C_6H_5–CO–O–CH_2–CH_2–O–CO–C_6H_5$

(2)

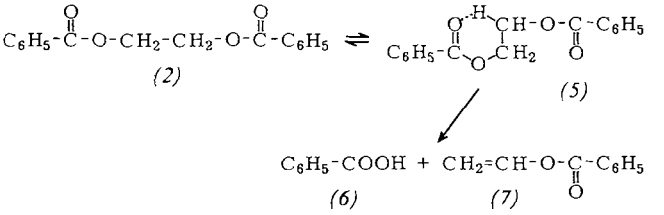
$C_6H_5–CO–O–CH_2–CH_2OH$

(3)

$C_6H_5–CO–O–CH_2–CH_2–O–CH_2–CH_2–O–CO–C_6H_5$

(4)

between 250 °C and 350 °C has been well studied [2, 7, 9], and is thought to proceed *via* a cyclic transition state. Benzoic acid *(6)* and vinyl benzoate *(7)* are formed.



(2) *(5)* *(6)* *(7)*

Ritchie [6] also reported benzophenone as a reaction product, although there is no confirmation of this product by other workers. It is possible that this difference in product formation may have resulted from the use of different temperatures in the pyrolysis.

3-Oxapentylene dibenzoate *(4)* decomposes by a similar route to give benzoic acid and 2-vinyloxyethyl benzoate *(8)*.

$C_6H_5–CO–OCH_2–CH_2–OCH=CH_2$

(8)

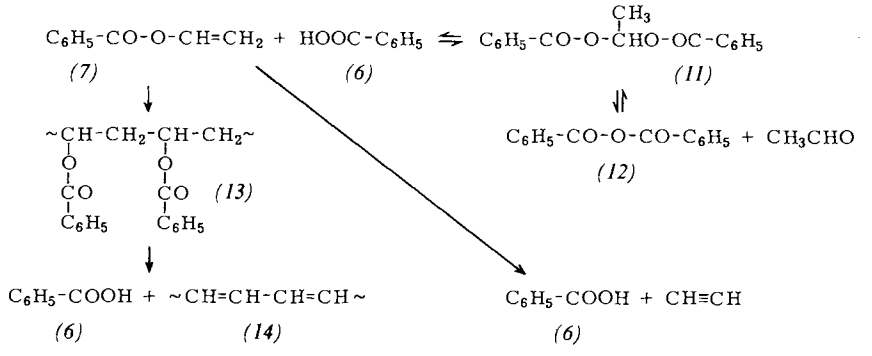
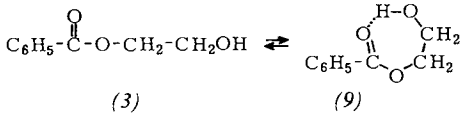
[9] *G. Challa*, Makromolekulare Chem. *38*, 138 (1960).

Despite the importance of 2-hydroxyethyl esters in the formation of PET, few studies with model compounds such as 2-hydroxyethyl benzoate *(3)* have been performed. *Iengar* and *Ritchie*[8] studied the pyrolysis of *(3)* at temperatures between 375 °C and 500 °C and proposed a complex degradation mechanism. Our results, which were obtained at 280 °C, suggest a different mechanism involving a seven-membered ring

The vinyl compounds formed during these reactions react further to give a complex mixture of end products. The pyrolysis of vinyl benzoate *(7)* has been studied extensively and it has been shown, that, as expected, this vinyl compound reacts very rapidly at 280 °C. After 30 min at this temperature *(7)* yielded a black mass in which benzoic acid *(6)*, benzoic anhydride *(12)* and a diene *(14)* could be detected.



(9) as transition state and the formation of an active species *(10)*[14]. This mechanism explains the low activation energy found for this reaction (28 kcal/mole) and the formation of ether linkages. (The dehydration reaction is not significant at 280 °C, as could be shown with ethylene glycol[9].)



A transesterification reaction takes place also, and at 280 °C the equilibrium 2 *(3)* ⇌ *(2)* + ethylene glycol is established in *ca.* 10 min.

Figure 1 shows the thermal degradation of *(2)*, *(3)*, and *(4)*.

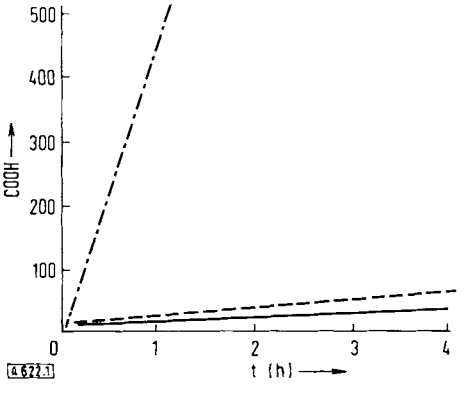


Fig. 1. Thermal degradation of ethylene dibenzoate *(2)* ——, 3-oxapentyl enedibenzoate *(4)* – –, and 2-hydroxyethyl benzoate *(3)* – · – · – at 280 °C under nitrogen.

The following facts can be given as proof that the intermediates *(11)* and *(13)* are formed in the reaction: Ethylidene dibenzoate *(11)* could be isolated from the reaction mixture containing compounds *(6)* and *(7)* by gas chromatography and was identified by IR- and NMR-spectroscopy. Starting from compound *(11)* an equilibrium is once again set up at 280 °C between *(7)* and *(6)* as well as with *(12)* and acetaldehyde. Polyvinyl benzoate *(13)* (prepared from vinyl benzoate and a radical chain initiator) similarly gives compounds *(6)* and *(14)* at 280 °C; the presence of *(14)* was confirmed by IR- and UV-spectroscopy.

Recently *Zimmermann* and *Leibnitz*[10] investigated the influence of catalysts on a number of the individual reactions. The primary chain splitting reaction of ethylene dibenzoate *(2)* to benzoic acid *(6)* and vinyl benzoate *(7)*, as well as the reaction of *(7)* with alcohols and the polymerization of *(7)*, are accelerated *e.g.* by zinc acetate. It was found that the catalysts zinc acetate and lead acetate have no influence on the thermal degradation of polyvinyl benzoate *(13)* to *(6)* and *(14)* or on the formation of acetaldehyde and *(12)* from *(7)* and *(6)*.

2-Vinyloxyethyl benzoate *(8)*, the first degradation product of 3-oxapentylene dibenzoate *(4)*, decomposes further to benzoic acid *(6)*, acetaldehyde, and acetylene at temperatures above 350 °C[8]. At 280 °C, however, another reaction is of importance: in the presence of benzoic acid the diester *(2)* is formed, the "acylal" *(15)*, which is known to form in the reactions of other vinylethers[11], probably occurring as intermediate. At 280 °C at least 50% of the carboxyl groups formed in the degradation of *(4)* react with the vinyl ether *(8)* to give *(2)* and acetaldehyde[14].

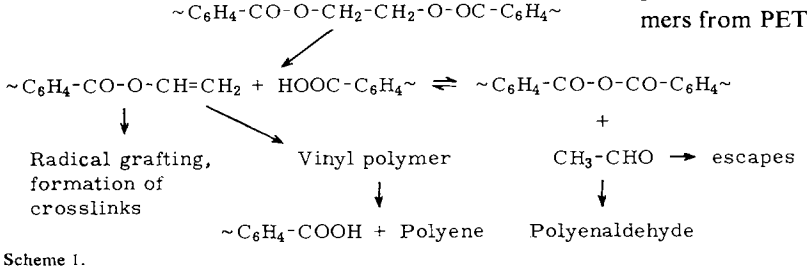
In general, caution is necessary in correlating the results obtained from studies with model compounds with the reactions of the polymer itself. However, it has been found that in this case model compound reactions do not differ much from the reactions taking place during the thermal degradation of PET, especially at temperatures between 200 °C and 300 °C.

2.3. Thermal Degradation of Poly(ethylene terephthalate)

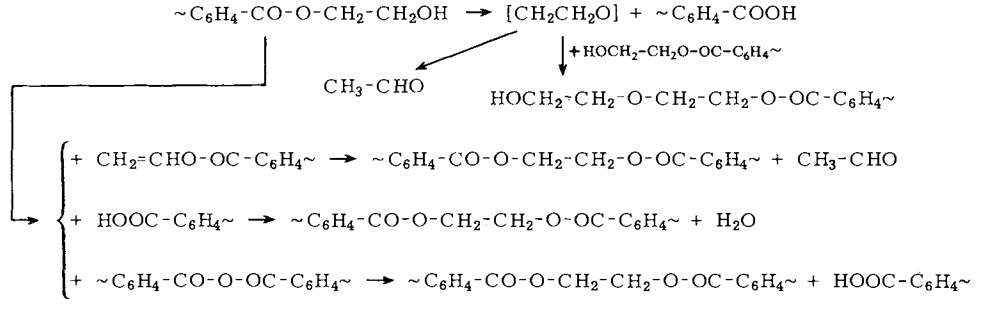
Various research teams have studied the thermal degradation of polyester during the last few years [6,7, 10–13]. From their results and from extensive studies with model compounds we know that PET breaks down by a molecular mechanism with random chain scission at the ester links. Although a radical mechanism has been proposed [12], no evidence for such a mechanism could be established.

Pohl [13] proposed that the principal point of weakness in the polyester chain is the β-methylene group. The main reactions in the thermal degradation of PET are summarized in the following scheme:



Scheme 1.

If 2-hydroxyethyl end groups are present in the polymer the following reactions take place also:



Scheme 2.

Thus, as long as free hydroxyl end groups exist in a PET melt, every broken polymer link will be reformed. When most of the hydroxyl end groups have been consumed, the molecular weight will begin to fall.

2.3.1. Products of Thermal Degradation

When PET is maintained in a molten state under nitrogen at about 280 °C, it decomposes slowly to gaseous and to solid, low molecular weight products; the functional groups react with one another, and the polymer becomes colored.

2.3.1.1. Gaseous Products

A gaseous mixture with the following composition (concentration in mole-%) is formed at temperatures between 280 °C and 306 °C [7]: CO = 8.0; CO_2 = 8.5; H_2O = 0.8; CH_3CHO = 79.5; C_2H_4 = 2.0; 2-methyldioxolane = 0.4; CH_4 = 0.4; C_6H_6 = 0.4. Although this composition varies appreciably with temperature acetaldehyde is always the major product.

2.3.1.2. Non-gaseous Products, Oligomers

During melt spinning of PET a white "dust" is formed and covers various parts of the spinning apparatus [15a]. A similar sublimate can be produced in the laboratory by bubbling nitrogen through molten polyester. This sublimate consists primarily of terephthalic acid and acidic oligomers [7, 14].

Cyclic oligomers (mainly the trimer) are also formed during the thermal degradation of PET. A kind of equilibrium between the cyclic oligomers and the polymer seems to exist. After extracting these oligomers from PET and heating the extracted polymer for about one hour at 280 °C, the same amount of cyclic oligomer is again formed [16]. It is not known how these oligomers are formed in the polymer, although a transesterification involving end groups can be assumed.

Goodings [7] isolated a number of compounds, mainly derivatives of substituted benzoic acids and biphenyldi- and monocarboxylic acids, from extensively pyrolyzed PET. However, these materials were found in very low concentration (0.005–0.09 wt.%).

2.3.1.3. Reactions of Functional Groups

PET has an average molecular weight of 25000 (intrinsic viscosity $[\eta] = 0.68$ dl g^{-1}). The concentration of carboxyl groups depends on the catalyst and is of the order 10–50 equiv/10^6 g of polymer. The concentration of hydroxyl end groups is about 60 equiv/10^6 g. During thermal degradation, the concentration of hydroxyl groups tends to fall and the carboxyl group content of the polymer increases. Anhydride groups can be formed; they begin to accumulate when most of the hydroxyl end groups have been consumed [7]. The anhydride groups are formed by the reaction of vinyl end groups with carboxyl groups and by dehydration of two carboxyl groups. *Goodings* [7] reported that PET which had been degraded at 306 °C for 65 hours under nitrogen gave an IR-spectrum indicating that anhydride and carboxyl groups were present in the ratio 1:2.6.

2.3.1.4. Discoloration

Discoloration is a serious problem in the production of PET since the consumer of white polyester goods demands a brilliant white color. As PET degrades, its color changes first to yellow, then to brown, and finally to black. Since the chromophoric substances involved are very difficult to isolate, contradictory results have been reported about their nature and composition. At least part of the chromophore seems to be chemically bonded to the polymer. The chromophore is believed to be a highly unsaturated aliphatic molecule with a molecular weight of about 300–1000 [7, 14]. Two routes leading to color formation in PET are discussed in the literature. *Goodings* [7] assumes the formation of polyenaldehydes from acetaldehyde. *Zimmermann* [10, 15], on the other hand, has shown that unsaturated, color forming molecules are formed from polyvinyl esters. Our own studies show that both reactions contribute to color formation; the precise polymerization conditions will determine which reaction sequence predominates.

2.3.2. Kinetics

Investigations on the kinetics of simple esters [3–5] show that their decomposition reactions are homogeneous, follow first order kinetics in both the vapor and the liquid phase, and are unaffected by radical scavengers. The activation energy found for ester pyrolysis was about 40 kcal/mole; on a theoretical basis pure chain scission of the ester link would require an activation energy of almost 60 kcal/mole. The lower value observed indicates a mechanism probably involving a cyclic transition state *(I)*.

The rate of thermal degradation of PET can be measured in terms of: a) the products formed, b) the rate of change of molecular weight of the polymer (as measured by the melt viscosity or the intrinsic viscosity), or c) the rate of change in concentration of end groups. Table 1 shows reaction rate constants and activation energies found by different authors using one or more of the methods mentioned above. It is interesting that all the rate constants have the same order of magnitude.

The effect of molecular weight (or intrinsic viscosity) on the thermal degradation of PET per unit time, and at various temperatures, is shown in Figure 2.

Table 1. Reaction rate constant and activation energy of the thermal degradation of PET.

k and E_a calculated from	$k(h^{-1} \cdot 10^3)$ at 282 °C	E_a (kcal/mol)

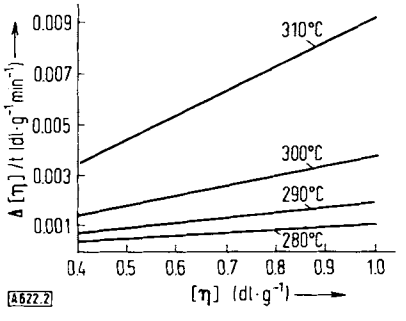

Fig. 2. The thermal degradation of PET per minute as a function of $[\eta]$ at different temperatures.

3. Oxidation

The degradation of PET in various oxygen-nitrogen mixtures between 280 °C and 325 °C has been investigated by *Marshall* and *Todd* [12]. The rate of degradation (measured by the decrease in the melt viscosity) increased linearly with increasing oxygen content. Passing oxygen through molten polyester causes rapid degradation, noticeable by color formation, an increase in carboxyl content and a decrease in molecular weight [14].

3.1. Course of Oxidation

No generally accepted concept for the course of the oxidation of PET has been reported. In previous studies, the mechanism developed by *Bolland et. al* [19] for the oxidation of hydrocarbons has generally been referred to and adopted in the interpretation of the oxidation of polymers [18].

The high molecular weight of PET and the influence of the physical structure make it difficult to study the oxidation of the polymer directly. Consequently,

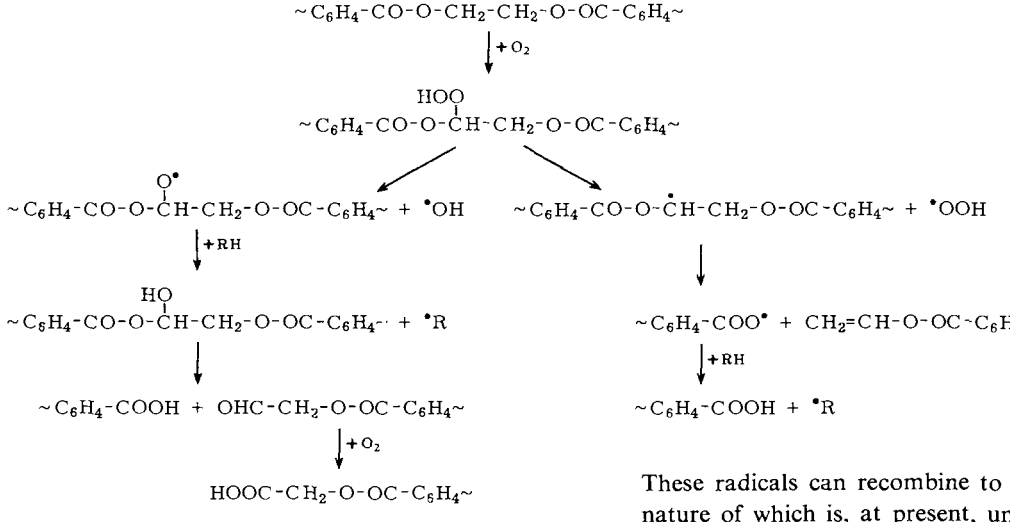
[18] *W. L. Hawkins*, SPE Trans. July *1964*, 187.

[19] *J. L. Bolland*, Quart. Rev. chem. Soc. (London) *3*, 1 (1949).

studies with model compounds have provided most of the mechanistic information available. 3-Oxapentylene dibenzoate *(4)* oxidizes readily at 130 °C[20] to give 2-benzoyloxyethyl benzoyloxyacetate, 2-benzoyloxyethyl formate, benzoyloxyacetic acid, benzoic acid, formic acid and water. Ethylene dibenzoate *(2)*, and 2-hydroxyethyl benzoate, *(3)*, can not be oxidized at 130 °C; above 200 °C decomposition occurs, but this is probably a combination of oxidative and thermal degradation. The mechnism of the oxidation of these two model compounds is therefore inaccessible to direct study. When comparing the degradation of these compounds under oxygen and under nitrogen at 210 °C, the higher carboxyl-group content and the darker color of the samples heated under oxygen suggest a breakdown to acidic and color forming species similar to those obtained from *(4)*.

The results from these model compound studies are in good agreement with results obtained with PET.

Diethylene glycol links lower the stability of polyester toward oxidation. The reaction sequences shown in Scheme 3 have been proposed as an interpretation of the oxidation of PET:



Scheme 3. RH = PET

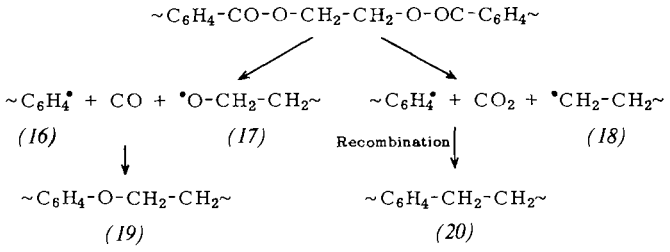
4. Degradation by Radiation

4.1. Photolysis

Generally speaking poly(ethylene terephthalate) is very stable toward ultraviolet light; however, some long term degradation occurs especially when it is exposed to light of wavelength 3000–3300 Å[21a]. There seems to be a threshold photon energy of about 3 eV below which no damage is done[21].

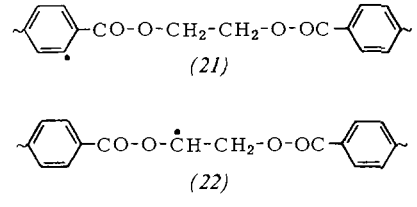
The present understanding of the photodegradation of polyesters is very rudimentary since most reports on this subject are of "weathering" experiments, in which oxygen and moisture play an important role in the degradation.

Stephenson et al.[21] and *Marcotte et al.*[21a] showed that the polymer turns to an amber color, becomes brittle, evolves gas (mainly CO and CO_2), and becomes partly insoluble in trifluoroacetic acid, after it has been exposed to monochromatic light of wavelengths 2537 and 3130 Å. From their results the reaction sequences shown in Scheme 4 seem probable:



Schema 4.

Hydrogen abstraction from neighboring molecules leads to the formation of radicals such as *(21)* and *(22)*.



These radicals can recombine to form crosslinks, the nature of which is, at present, unknown. The formation of polyphenyl systems, in which reactions involving the radical *(22)* (see section 4.2.) seem to be of little importance, has also been suggested[22].

For practical purposes, "weathering" experiments give a good picture of the performance of PET in specific outdoor applications. Under these conditions the ether content of the polymer is of extreme importance. *Coleman*[22] exposed copolymers of PET containing polyoxyethylene glycol to ultraviolet light. After 300 hours of exposure, a yarn containing 17% by weight of polyoxyethylene glycol (MW = 2800) showed a 40% decrease in intrinsic viscosity while pure PET was not affected. Therefore this copolymer was not

accepted on the market even though the dyeability of fibers of this material was much superior to that of fibers prepared from the homopolymer.

4.2. Degradation by High Energy Ionizing Radiation

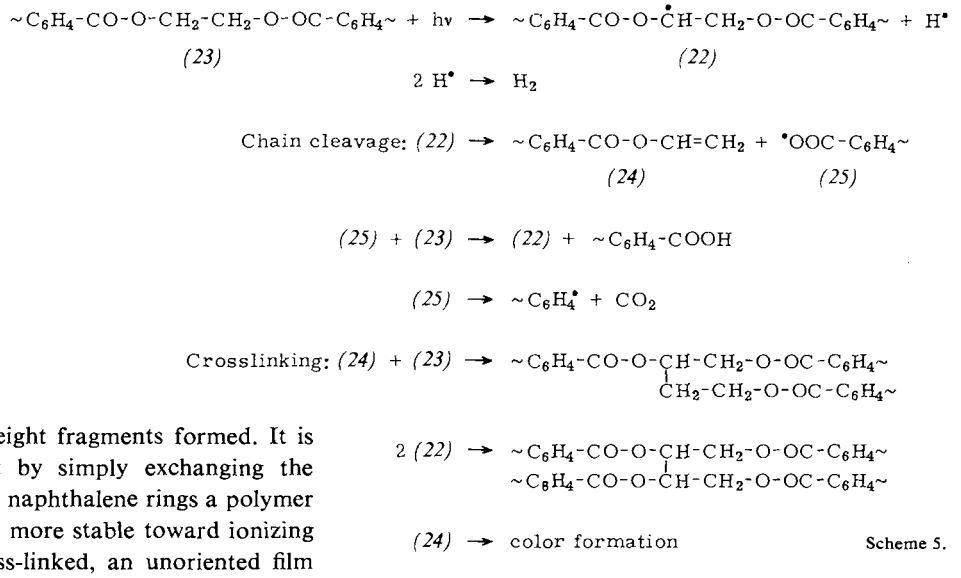
The mechanical properties of PET fibers are relatively unchanged by moderate doses of high energy radiation. When subjected to doses of more than 50 Mrad the tensile strength and ultimate elongation of the PET begin to decrease considerably and deteriorate rapidly when the dose reaches the 100–500 Mrad range. Radiation doses exceeding 1000 Mrad [23] lead to the lowering of the glass transition temperature, which probably results from the lowering of the molecular weight by chain cleavage and from plasticization by the low molecular weight fragments formed. It is interesting to note that by simply exchanging the benzene rings in PET for naphthalene rings a polymer is formed which is much more stable toward ionizing radiation. Although cross-linked, an unoriented film of poly(ethylene 2,6-naphthalene dicarboxylate) was still tough and flexible after 1000 Mrad of gamma radiation [40].

Rather contradictory results have been reported concerning the reactions occurring during high energy irradiation. Both crosslinking [24,26] and chain cleavage [25] have been claimed to be predominant; the former claim was based upon partial insolubilization of the polymer, while the latter was based upon complete solubility, a steady decrease in molecular weight with increasing dose, and physical evidence of chain cleavage.

More recent evidence suggests that both chain cleavage and crosslinking occur and that the reaction conditions determine which process is predominant. Dose rate, kind of radiation, temperature, crystallinity, and impurities, such as water [26] or oxygen, are examples. At low dose rates of gamma-rays, carboxyl groups are formed – and no gel formation has been observed. At higher dose rates (over 5000 Mrad) a network is formed in the polymer [29] and fewer carboxyl groups are formed.

Some investigations have been carried out using high speed electrons [26,28] instead of gamma-rays [27]. The results of these experiments were expected to be different since electrons are known to cause a temperature increase in the polymer (electron microscopy) and are reported to destroy crystallinity in PET by changing the steric conformation of the chain [28]. No gel formation has been observed at temperatures up to 175 °C for doses of up to 2000 Mrad [29a]; at temperatures above 200 °C rapid gelation occurs even with low doses.

ESR studies of free radicals formed by gamma-irradiation of PET [29] support the suggestion of the reaction sequences shown in Scheme 5 as being the primary steps in the degradation:



Scheme 5.

The differences between photolysis of PET and degradation by high energy radiation can be summarized as follows:

Photolysis:

Primary reaction products:

$\sim C_6H_4\cdot + CO + {}^{\bullet}OCH_2-CH_2-O-OC-C_6H_4 \sim$;
Only few carboxyl groups, and no hydrogen, are formed.

Crosslinking occurs.

Degradation by high energy radiation:

Primary reaction products:

$\sim C_6H_4-CO-O-\dot{C}H-CH_2-O-OC-C_6H_4 \sim + H^{\bullet}$
Hydrogen and carboxyl groups are formed.

No gelation occurs (up to 2000–5000 Mrad).

5. Hydrolytic Degradation

In contrast to other polyesters, PET is very resistant to attack by water, acids, and bases; this is due, presumably, to its aromatic character and to the tight packing of its chains. Nevertheless, it does hydrolyze at temperatures above 100 °C. Of the forms of degradation discussed thus far, hydrolysis is by far the most troublesome reaction. The hydrolysis of PET at 100°–120 °C and 100% relative humidity proceeds 10000 times faster than that of thermal degradation and 5000 times faster than that of oxidation in air in the same temperature range [31].

It is known that dry PET adsorbs moisture rapidly and that the extent of adsorption is dependent upon the time of exposure, the particle size, crystallinity, and relative humidity.

5.1. Neutral-, and Acid-Catalyzed Hydrolysis

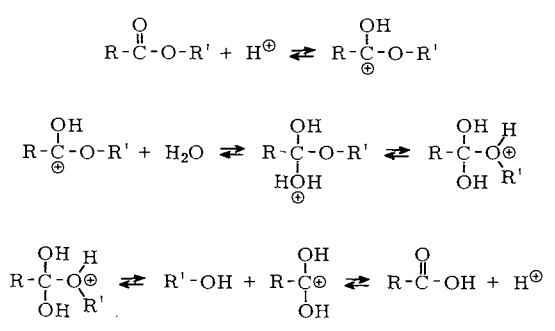
5.1.1. Adsorption and Diffusion of Water

The hydrolysis of ester bonds must proceed *via* (i) the adsorption of water on the surface of the polymer and (ii) diffusion to the interior of the polymer from the point of attack. Knowledge of the rates of adsorption and diffusion are of practical and theoretical importance. The adsorption of water by dry PET cubes of length 3/16″ (or 0.4762 cm) amounts to 0.025% after $^1/_2$ h, and, by dry PET powder (40 mesh), to *ca.* 0.125%.

The influence of the diffusion of moisture on the rate of hydrolysis has been considered by several groups of workers, but the results are contradictory. *Golike* and *Lasoski* [30] and *McMahon et al.* [31] assume that the diffusion of moisture into the polymer is the rate-controlling step. However, the rate of diffusion of water into PET at temperatures above 100 °C is at least 1000-fold higher than the rate of hydrolysis [32, 33]. The observed differences are probably due to differences in morphology and molecular geometry of the polymers studied.

5.1.2. Course of Hydrolysis

The hydrolysis of esters in neutral or acid media generally proceeds according to the reactions shown in Scheme 6:



Scheme 6.

The reaction rate depends on both the proton concentration and the amount of water. This is in agreement with the observation that the hydrolysis rate for PET depends on the relative humidity. The adsorption isotherm [33] shows that the rate of hydrolysis is directly proportional to the concentration of water in the polymer.

The influence of proton concentration on the hydrolysis rate is evident in the hydrolysis of PET in hydrochloric acid [33–36,42–44]. The rate is only slightly influenced by acid concentrations below 3 N but increases rapidly at concentrations above this value. *Ravens* [34] explains this by considering the acid concentration not in the aqueous phase, but in the polymer itself. Because of the low dielectric constant of PET (< 4), one can assume that the acid in the polymer is only slightly dissociated. This is in agreement with the work of *Sheard* [35], who observed that ammonia will diffuse through films of PET whereas ammonium ions will not. The importance of the dielectric constant is further emphasized by the fact that the rate of acid hydrolysis is slower in drawn fibers than it is in undrawn fibers.

In drawn fibers the crystallinity is of a higher order than it is in undrawn fibers. During crystallization, the molecules assume a *trans*-configuration; hence, the polymer has a smaller dipole moment and therefore a smaller dielectric constant. This in turn leads to a decrease in the degree of dissociation of the hydrochloric acid, so that the proton concentration within the polymer is lower than that in the surrounding medium.

Organic acids, *e.g.* adipic acid [45], also catalyze the hydrolysis of PET [36]. Terminal carboxyl groups of a polyester, which enter into all reactions characteristic of carboxylic acids, also have a catalytic effect. From investigations on polymers with initial carboxyl-group concentrations of from 8 to 97 equiv./10^6 gram of polymer, *Ravens* and *Ward* [33] concluded that the hydrolysis rate can be expressed by

$$d[-COOH] / dt = k[-COOH]^{1/2}$$

where the square root term arises from the weakly acidic nature of the carboxyl group of the polymer. This is a catalytic effect and is not due to adsorption of water in the polymer at carboxyl end groups only, since the adsorption isotherm is independent of the carboxyl end group concentration [33].

5.2. Base Catalyzed Hydrolysis

Very little has been published about the base catalyzed hydrolysis of PET. This is especially important in view of the potential interactions between polyester fibers and various organic and inorganic bases used in dyeing, aftertreatment, and washing.

Sodium or potassium hydroxide solutions normally attack only the surface of a PET fiber; however, changes in the fine structure of the inner part of the fiber after such treatment have been observed recently [37]. The dielectric properties of the polymer and the formation of carboxylate ions on the fiber surface presumably present a barrier to the penetration of the polymer by hydroxyl ions. The formation of a skin around the fiber and the fact that the rate constant for base catalyzed hydrolysis of esters of dibasic acids is smaller than the rate constant for acid hydrolysis is taken as further evidence for the greater stability of polyester fibers in alkaline solutions than in acid solutions.

The degradation of PET in the presence of amines is accompanied by the formation of amide bonds. The final formation of the terephthalic acid diamide takes place *via* oligoester amides and oligoamides [37, 38]. The morphology of the polymer is again of great importance. Thus *Farrow*, *Ravens*, and *Ward* [39] have shown that a fiber sample with high orientation and crystallinity was unattacked after 16 hours in aqueous methylamine, whereas samples having other morphological properties were considerably degraded. The attack by methylamine takes place in three stages: The initial attack is in the amorphous regions; in the second stage, scission produces more low molecular weight material and gives rise to an increase in the degree of crystallinity of the polymer; the third stage, distinguished by a gradual decrease in the rate of reaction, is attributed to a decrease in the rate of attack on both crystalline and amorphous regions.

The rate of aminolysis in the presence of primary and secondary amines is of the same order of magnitude as the rate of alcoholysis [37]. Tertiary amines react with polyester only at higher temperatures; but these reactions are not, as yet, fully understood. For example, the products of the thermal degradation of PET seem to react with the tertiary amine; the products of this reaction and the amine itself are subject to further thermal and oxidative degradation. The known catalytic effect of hydroxyl compounds on the aminolysis of esters [41] further complicates the picture.

Formation and Properties of Solvated Electrons

BY U. SCHINDEWOLF [*]

In the formulation of many chemical reactions, electrons are regarded as readily transferable particles, though their participation in these reactions cannot be directly observed. However, the discovery that electrons can be produced in various ways in suitable solutions and that they are stabilized by solvation and can thus be studied directly has recently led to a rapid growth of interest in these, the simplest and most reactive particles of chemistry. The solvated electron has physical properties that permit its detection by various methods even at very low concentrations, so that it is also possible to follow its many reactions, most of which are extremely fast.

1. General

It has been shown in recent years that dissolved electrons [1, 2] occur as reaction intermediates in the course of many energy-consuming chemical processes. They are formed on radiolysis, photolysis, and electrolysis of aqueous and other polar systems. They also occur in the base-promoted ionization of hydrogen in solution, and probably in some redox processes. However, dissolved electrons are by no means a very recent discovery, but were observed more than a hundred years ago on dissolution of alkali metals in

liquid ammonia [3]; they were recognized as such and some of their properties established fifty years ago as a result of investigations on such metal solutions.

In view of the many ways in which dissolved electrons are formed, it is likely that they take part in numerous chemical processes, such as metabolism, photosynthesis, and biological radiation damage.

It is not easy to detect the participation of dissolved electrons in these processes, since the high reduction potential of the electrons makes them extremely reactive toward many dissolved ions, free radicals, and neutral molecules, as well as toward the solvent molecules themselves, so that they are generally short-lived (lifetime in pure water < 1 msec) and are consequently present in the solutions only in very low concentrations. The electrons can be stabilized, however, by inhibition of their reactions in frozen solvents. In the absence of impurities, they have a relatively long life even at room temperature in solutions of metals in ammonia, so that these solutions are particularly suitable for the study of the physical properties of dissolved electrons (rate of decomposition of highly purified sodium-ammonia solutions $< 1\%$ per day).

The electrons naturally do not exist in solution as free particles, but, as the common term "solvated electron" implies, they are solvated, *i.e.* bound by the solvent; they therefore possess properties similar to those of ions in solution. Nevertheless, the solvation of electrons must be distinguished from that of ions. For example, with a hydrogen ion, which is localized within a small volume element because of its great mass, ion-dipole interactions lead to the firm attachment of one or more solvent molecules (H_3O^+ or $H_9O_4^+$). The dissolved electron, on the other hand, has a small mass and a low momentum, and is therefore "smeared out" over a large volume in accordance with the uncertainty principle. The field extending from the small spatial charge density of the "smeared out" electron is too weak for the formation of a firm solvation sheath; it is nevertheless sufficient to polarize the surrounding solvent molecules (electronic and orientation polarization) to such an extent that the electron is trapped in the resulting polarization field of the solvent.

Repulsion between the captured electron and the electrons of the solvent molecules leads to a displacement of the latter with formation of a cavity [9, 10] (in ammonia this cavity has a volume of 110 to 180 Å^3, corresponding to a radius of 2.95 to 3.40 Å). The electron is naturally not confined to this cavity, but the probability of its being found outside the cavity is small; this probability decreases with increasing distance.

According to the above model, which was developed in general terms by *Landau* [11] and was applied to dissolved electrons by *Davydov* [12] and *Deigen* [13], and finally in a refined form by *Jortner* [14], there is a resemblance between dissolved electrons and F centers in ionic crystals [15], *i.e.* electrons trapped in anion vacancies. Since the ions in the crystal are immobile, the electrons, produced *e.g.* by irradiation, cannot create space for themselves, and stabilization of these electrons consequently depends on the presence of anion vacancies in the crystal.

The most outstanding physical property of dissolved electrons is their high light absorption in the red to infrared region of the spectrum, as a result of which they appear blue and can be detected in concentrations as low as 10^{-8} mole/l. They are paramagnetic, give a one-line ESR spectrum, and have a mobility three to four times as high as that of normal solvated ions in an electric field.

The electrons exist in this state only at low concentrations. At higher concentrations they tend to undergo spin compensation with formation of diamagnetic electron pairs (e_2^{2-}) analogous to the F′ centers in ionic crystals. If the concentration of the electrons can be further increased, the solutions assume a metal-like character (free electrons), with high conductivities and metallic luster. These transitions can be represented by the equilibria (1a,1b), which are displaced toward the right with increasing concentration.

$$e^- \rightleftharpoons 1/2\, e_2^{2-} \rightleftharpoons e_{met}^- \qquad (1a, 1b)$$

2. Formation

2.1. Solutions of Metals

Solutions of electrons in ammonia and its derivatives (methylamine, dimethylamine, ethylamine, ethylenediamine, hexamethylphosphoramide) can be relatively easily prepared by dissolution of alkali metals, alkaline earth metals, and certain rare earth metals, which spontaneously dissociate:

$$M \rightarrow M^+ + e^- \qquad (2)$$

The equilibria (1) between the solvated electrons (which predominate at concentrations lower than 0.001 M), the spin-compensated electron pairs, and the

free electrons of the near-metallic state (above 1 M) can be followed particularly readily in solutions of alkali metals in ammonia, since a wide range of concentrations can be covered owing to the high solubility of the metal (cf. the phase diagram of the sodium-ammonia system in Fig. 1). The transition to the metallic state is associated at low temperatures with a miscibility gap [16–19].

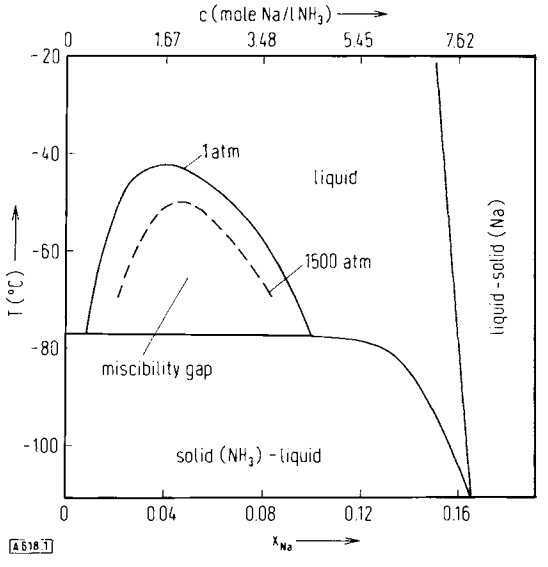

Fig. 1. Part of the phase diagram of the system sodium-ammonia with eutectic and miscibility gap (cf. [8]); the miscibility gap is displaced toward lower temperatures and higher concentrations by increased pressure (broken curve) [19].

In amines, in which the solubility of the metals is generally considerably lower, probably ion pairs such as $(Na^+ \cdot e^-)$, $(Na \cdot e_2)^-$, and $(Na^+ \cdot e^-)_2$ also occur, as deduced from light absorption and ESR spectra of these solutions.

The solubility of alkali metals in some aliphatic ethers such as tetrahydrofuran, dimethoxyethane, and dioxane is three to five orders of magnitude lower than that in ammonia [20–22]. Like the solutions in ammonia and in amines, these solutions are blue; however, they are diamagnetic, probably because of the formation of higher ion pairs or spin-compensated electron pairs. Above 0 °C these solutions become colorless.

Solutions of alkali metals in water and in alcohols cannot be obtained, owing to the fast reaction of the solvated electrons that are probably formed during the dissolution process. However, evidence of the formation of electrons on dissolution of alkali metals in water is provided by the chemical behavior of dissolved nitrous oxide [23], a specific reagent for dissolved electrons ($N_2O + e^- + H_2O \rightarrow N_2 + OH + OH^-$). Attempts to confirm the observation [24] that supercooled water-alcohol mixtures turn blue when metallic sodium is added have been unsuccessful.

However, it is possible to obtain condensates that are blue owing to solvated electrons by condensation of water or alcohol vapor together with alkali metal vapor on a cold surface at 70 °K [25–26]. Solvated electrons can be produced in solid ammonia in the same way [27], whereas liquid metal-ammonia solutions separate on cooling into solid metal and solid ammonia [28].

2.2. Radiolytic Processes

Many radiation-chemical reactions in water, alcohols, and other polar solvents proceed *via* solvated electrons (which are formed after thermalization of the high-energy electrons produced by the Compton effect, the photoelectric effect, and by electron impact) [1, 2, 29–32], *e.g.* in accordance with,

$$H_2O \rightarrow H_2O^+ + e^- \qquad (3)$$

in which the relaxation time of solvation is less than 5×10^{-10} sec [32a]). The radiolytic yield on irradiation of aqueous solutions with X-rays or with electrons is 2.5 electrons per 100 eV of energy absorbed [33a]. It follows that the absorption of 1 rad (1 rad = 6.25×10^{13} eV of energy absorbed per g of irradiated substance) is sufficient for the formation of 1.56×10^{12} electrons per ml of aqueous solution.

If, by means of pulse techniques, this dose is supplied in an interval of time that is short (< 10 μsec) compared with the lifetime of the solvated electrons, one obtains an initial electron concentration of 2.6×10^{-9} M. Doses of more than 10^4 rad can be produced within a few μsec by pulsed operation of electron accelerators, so that the dissolved electrons formed can be detected by fast-recording optical methods and their reactions can be followed kinetically. A schematic representation of an arrangement suitable for the production of solvated electrons by pulse radiolysis and for their optical detection is given in Fig. 2.

The doses obtainable with continuous radiation sources (irradiation times > lifetime of dissolved electrons) are much smaller because of the strong heating effect, so that the electron concentrations attainable are also much lower (with an arrangement of favorable geometry, a 15000 curie

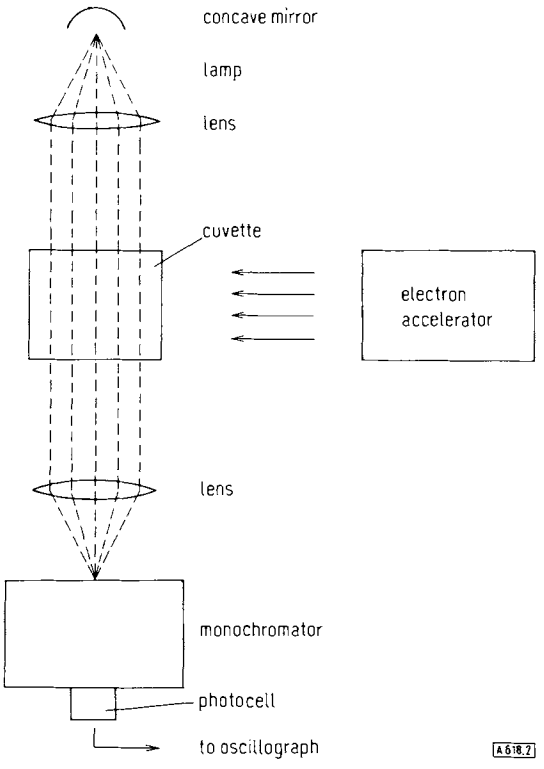

Fig. 2. Arrangement for the production of solvated electrons by pulse radiolysis with fast electrons. The solvated electrons are detected with a quick-response photocell, which records the change in the optical density of the irradiated solution in the red part of the spectrum.

^{60}Co γ source produces, in pure water, a stationary electron concentration of 10^{-8} M [34]).

The secondary reactions of the electrons are so strongly inhibited in vitrified solvents below 100 °K that the electrons can accumulate during irradiation until the glass turns blue [26, 30, 35–37]. According to recent observations, when large radiation doses are absorbed, *i.e.* at high electron concentrations, the electrons form electron pairs [38] according to eq. (1a).

The vitreous state is essential for the stabilization of electrons in frozen solvents [26, 35–37]; in a crystalline matrix electron can also be detected but the attainable concentrations are much lower [37a].

2.3. Photochemical Processes

Solvated electrons also take part in many photochemical reactions in aqueous and alcoholic solutions [39]. However, the electrons in photochemical reactions, unlike those in radiolytic reactions, are formed, not by ionization of the solvent, but by ionization of photochemically active solutes (*e.g.* Hal^- [40–42], OH^- [40–42], $[Fe(CN)_6]^{3-}$ [42,43], SO_4^{2-}, CO_3^{2-} [43a], and many aromatic compounds having electron-donating groups [44]).

Within wide limits, the yield of electrons produced in this way is proportional to the intensity of the light used and to the concentration of the photochemically active solutes. The yield increases with rising temperature [39], suggesting that the electron is emitted thermally from the excited state, *e.g.*

$$I^- \underset{}{\overset{h\nu}{\rightleftharpoons}} I^{*-} \xrightarrow{\text{therm.}} I + e^- \qquad (4)$$

As a result of solvation, the energies involved are changed in such a way that the emission of electrons often requires less energy in solution than in the gas phase.

The UV illumination of metals, *e.g.* mercury, in aqueous solutions leads to the formation of solvated electrons which can be traced by the photocurrent [44a,44b].

2.4. Dissociation of Hydrogen

The pH-dependence of the chemical behavior of dissolved electrons and of dissolved hydrogen atoms in water [45–49] shows that the equilibrium

$$H \rightleftharpoons H^+ + e^- \qquad (5)$$

is established between the two particles; this corresponds to an acid-base equilibrium with the hydrogen atom as the acid and the solvated electron as the base. The dissociation constant is approximately 10^{-10} mole/l [50, 51]. In alkaline solution the hydrogen atoms are completely dissociated:

$$H + OH^- \rightarrow H_2O + e^- \qquad (6a)$$

The corresponding reaction of fluoride ions

$$H + F^- \rightarrow HF + e^- \qquad (6b)$$

also yields solvated electrons [51a].

Not only hydrogen atoms, but also hydrogen molecules, can dissociate in the presence of strong bases to give solvated electrons [52, 53].

The reaction in liquid ammonia,

$$1/2\ H_2 + NH_2^- \rightleftharpoons NH_3 + e^- \qquad (7)$$

which is very fast, has an equilibrium constant of 2×10^{-5} $(mole/l)^{1/2}$. At constant hydrogen concentration, the equilibrium is displaced to the right with rising temperature and to the left with rising pressure (Fig. 3).

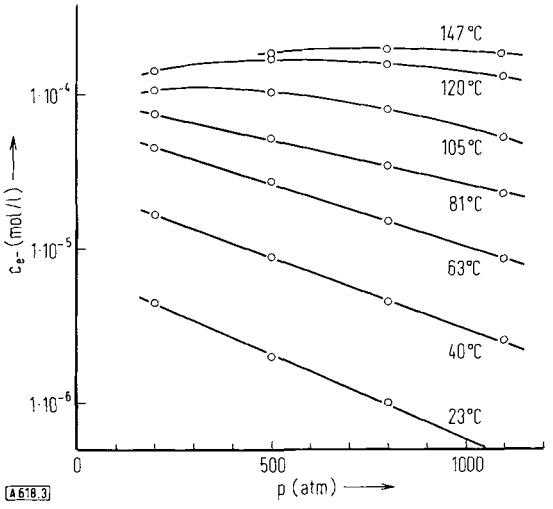

Fig. 3. Pressure-dependence and temperature-dependence of the equilibrium concentration of the solvated electrons in a 0.23 M solution of potassium amide in liquid ammonia saturated with 100 atm of hydrogen [53].

The heat of reaction as calculated from the temperature-dependence of the equilibrium constant is 12–16 kcal/mole, while the pressure-dependence gives a value of 64 ± 3 ml/mole for the volume increase associated with the reaction [53].

The equilibrium reaction (7) permits the investigation of dissolved electrons at extremely low concentrations even at high temperatures (up to the supercritical state of ammonia [53]), at which the electrons are normally no longer stable owing to reactions with the solvent or with impurities.

2.5. Electrolysis

It was observed some 70 years ago [54] that when solutions of alkali metal salts in ammonia are electrolyzed they attain the blue color of solvated electrons at the cathode. The thermodynamically favored formation of hydrogen at the cathode is completely suppressed because of the high overvoltage. The reaction inhibition leading to the hydrogen overvoltage may be due to the slow reaction of dissolved electrons with ammonia.

Electrolysis of aqueous solutions of alkali metal salts probably also results initially in the formation of solvated electrons, but these have not yet been definitely detected, owing to fast secondary reaction with water. Indication of the electrolytic production of solvated electrons is provided from the presure dependence of the discharge current of a hydrogen electrode at constant overvoltage [54a]. The reduction behavior of dissolved nitrous oxide on electrolysis [23] and the change in the light absorption at the cathode [55] also indicate the intermediate formation of dissolved electrons. Definite spectroscopic detection should be possible with the aid of pulse electrolysis (discharge of a highly charged condenser through an electrolyte solution having a low ohmic resistance), in which high concentrations of dissolved electrons should be present for short periods.

3. Physical Properties

3.1. Apparent Molar Volume

The cavity model mentioned in the introduction is based mainly on the observation that solutions of metals in ammonia occupy a volume greater than the sum of the volumes of the pure components, *i.e.* that the volume of the metals is greater in the dissolved state than in the solid state [56–60]. For example, the apparent molar volume of sodium at −33 °C and at concentrations between 0.05 M (at lower concentrations the density measurements are too inaccurate) and 0.5 M is 61 ± 1 ml/mole (Fig. 4), whereas the molar volume of solid sodium is 23 ml/mole.

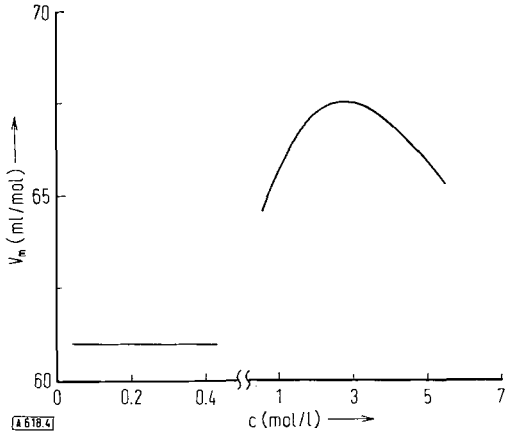

Fig. 4. Apparent molar volume (V_m) of sodium dissolved in liquid ammonia as a function of concentration at −33 °C [56–60].

[60] *S. R. Gunn* [7], p. 76; J. chem. Physics *47*, 1174 (1967).

This increase in the apparent molar volume must be due to the special state of the electrons in solution, since positive volume effects of this order of magnitude are not found in solutions of other substances; on the contrary, the volume frequently decreases in the case of ionic solutes because of electrostriction.

The volume occupied by the dissolved electrons as calculated from the apparent molar volume of dissolved sodium, taking into account the molar volume of the sodium ions and the electrostriction effects due to these ions (which cannot be determined directly by experiment), is 65 to 95 ml/mole [5, 14a, 61]. This value, however, is valid only for electron pairs, since the density measurements, on which this calculation was based, were carried out on relatively concentrated solutions in which the electrons are mainly in the spin-compensated state.

Values found from density measurements for the volume of electrons in more dilute solutions, in which unpaired electrons predominate, are inconsistent (the molar volume of dissolved sodium, according to *Ogg* [10], is 700 ml/mole; according to *Evers* [59] it passes through a minimum value of 50 ml/mole at 0.02 M; according to *Gunn* [60], the value is 60 ml/mole, and is independent of the concentration).

However, the volume can be estimated indirectly from the volume change associated with the equilibrium reaction (7) between hydrogen and electrons (concentration $< 10^{-4}$ M), which can be calculated from the pressure-dependence of the equilibrium constant [53]. From this volume change and the molar volumes of the other substances taking part in the reaction, the volume occupied by the unpaired electrons at −33 °C is found to be 84 ± 15 ml/mole.

According to these measurements, the electrons in the unpaired state have the same volume as the spin-paired electrons. This is supported by the observation, based on magnetic measurements, that the equilibrium between unpaired and paired electrons is practically independent of pressure [62]. On the other hand, electrons in the metallic state have a greater volume, as is shown not only by density measurements on metallic solutions [56–58] (Fig. 4), but also by the displacement of the equilibrium (1b) toward the nonmetallic state by pressure. This displacement is revealed by the decrease in the electric conductivity of concentrated metal solutions [63] and by the shift of the miscibility gap of these solutions under the influence of pressure [19] (Fig. 1).

The value of 65 to 95 ml/mole for the volume of electrons dissolved in ammonia, which corresponds to 110 to 160 Å^3/electron, naturally has nothing to do with the size of the electrons. It simply indicates the loosening of the structure of ammonia by the electron, which is interpreted in the cavity model by displacement of the ammonia out of reach of the short-range forces of the electron. The average radius of the cavity as given by the above volume is 2.95 to 3.40 Å. *Jortner*'s theoretical treatment [14] of the solvated electron by the cavity model leads, in conjunction with optical measurements, to similar values. As is also shown by optical measurements, an increase in pressure leads to compression of the cavity and a rise in temperature to expansion of the cavity [64].

No reliable data can be given for the size of the electron cavities in water and in alcohols, since solutions of sufficiently high concentrations for density measurements cannot be prepared. Optical measurements indicate that the cavities in these systems are smaller than those in ammonia.

The observation that solvated electrons can readily be obtained radiolytically in vitreous frozen solvents, but only to a small extent in crystalline frozen solvents [26, 35–37a], also indicates that space is required for the stabilization of the electrons. The regular structure of the crystals does not provide cavities of sufficient size, nor can they be created by the electrons owing to the immobility of the structural units of the crystal. Amorphous glasses, on the other hand, already contain enough vacancies to accommodate electrons, and the presence of these vacancies may be favored by the addition of electrolytes.

3.2. Light Absorption

Dilute solutions of the alkali metals in ammonia and its derivatives, in some ethers, and in vitreous frozen aqueous and alcoholic solutions are blue because of their absorption of light in the red part of the spectrum. Similar colors are seen in metal-free deep-frozen water and alcohol glasses on irradiation with X-rays or with electrons. Irradiation of liquid water, alcohol, ammonia, *etc.* leads to a similar, though transient, blue color. The obvious explanation for the blue color in all these systems is the absorption of light by dissolved electrons.

As can be seen from Figure 5 for water [31, 34, 65–68] (on irradiation with electrons) and ammonia [69–73] (with low concentrations of dissolved alkali metals) and from Table 1 for a number of other solvents, the absorption spectra are found to exhibit certain characteristic features. The spectrum of dissolved electrons consists of a single asymmetric absorption region extending from the blue to the near infrared region, with a half-width of *ca.* 0.5 to 1 eV. The area under the absorption curve yields an oscillator strength of nearly unity. The position and height of the absorption maximum depend on the solvent.

The absorption maximum occurs at lower energies for ammonia and its derivatives than for water and alcohols. Mixed

solvents, *e.g.* water-ammonia, exhibit, not the two absorption maxima characteristic of the two solvents, but only one maximum in an intermediate position, this position depending on the composition of the solvent [31, 70, 71, 77]. The absorption maximum is displaced toward higher energies by deuteration [35, 78, 79] and by the addition of electrolytes [73, 80], as well as by an increase in pressure or by a decrease in temperature.

In solutions of metals in ammonia or in amines, an increase in concentration leads to a small displacement of the absorption maximum toward lower energies [72, 73]; in the case of the amines, this is accompanied by the appearance of further maxima in the higher energy range, the positions and heights of which depend on the metal [70, 71, 74, 81, 82]. The displacement is attributed to the formation of electron pairs, which absorb at a longer wavelength, and the new maxima to the formation of ion pairs. The metallic solutions of high concentration are highly reflecting [83] to light of the infrared to red region of the spectrum, thereby appearing bronze-colored. The high reflectivity gives support to the contention that free electrons are present in the solutions.

The absorption of the solvated electron, like that of F centers, is interpreted as being due to a $1s \rightarrow 2p$ transition of a caged electron [14]; the transition energy is a function of the size of the cavity and of the potential that acts on the electron. With the simplified assumption of a square-well potential, the transition energy is inversely proportional to the square of the cavity radius R:

$$E_{2p} - E_{1s} = h\nu \approx R^{-2} \qquad (8)$$

This relationship is very satisfactorily obeyed in F centers, in which the size of the lattice vacancies occupied by the electrons is defined by the lattice parameters [84].

Some of the characteristics of the spectrum of dissolved electrons can be qualitatively explained with the aid of eq. (8). Since no rigid structure and hence no uniform radius can be assumed for the cavity containing the electron, no sharp spectral line should be expected according to eq. (8). The fact that the spectrum extends over a wide range of energies is probably due to a wide scatter of the size of the cavities about a preferred mean value. The absorption spectrum of F centers is considerably narrower than that of solvated electrons, since the size of the cavities in the former case varies only with the vibration of the lattice points, whereas the size in the case of solvated electrons is influenced, not only by the vibration, but also by the rotation of the solvent molecules.

According to eq. (8), the displacement of the absorption maximum toward higher energies with increasing

pressures is due to compression of the cavity, and the displacement toward lower energies with rising temperature is due to the thermal expansion of the cavity.

Application of eq. (8) to the position of the absorption maximum in various solvents leads to the conclusion that the size of the cavities depends mainly on the solvating groups $-OH$ or $>NH$ of the solvent, whereas the substituents on these groups (H, CH_3, *etc.*) exert only a small effect. This means that the size of the cavities is independent of the size or bulk of the solvent molecules and of their macroscopic dielectric constants or their surface tension. In solvent mixtures, the cavity size assumes a value intermediate between the values for the pure solvents; this shows that the cavity is formed from the molecules of all the solvent components, *i.e.* that there is no preference for solvation by any one solvent.

The assumption on which eq. (8) is based, *i.e.* that the electrons move in a square-well potential, is an oversimplification. However, a more accurate treatment of the cavity model based on a coulombic potential also predicts that the energy of the optical transition increases with decreasing size of the cavity [14].

3.3. Magnetic Properties

The experimental evidence for the equilibrium (1a) between single electrons and spin-compensated electron pairs is based primarily on the concentration-dependence of the molar paramagnetic susceptibility of dissolved alkali metals in ammonia (Fig. 6) [57,85].

In very dilute solutions, in which the dissolved metal may be assumed to be completely dissociated into metal cations and electrons, the molar susceptibility, χ, is about 1500×10^{-6} cm³/mole at -33 °C; this is the value expected for paramagnetic particles having a magnetic moment $\mu = 1$ Bohr magneton ($\chi = N\mu^2/kT$, N = Avogadro's number). Since the cations are diamagnetic, the paramagnetism must be attributed to the electrons (spin paramagnetism). The molar susceptibility decreases rapidly with increasing concentration (to 50×10^{-6} cm³/mole in 0.5 M solution) because of the formation of spin-paired electron pairs. The temperature-dependence of the molar susceptibility at concentrations up to 0.5 M shows that the dissociation equilibrium $e^{2-} \rightleftharpoons 2\,e^-$ is displaced toward the right with rising temperature, *i.e.* that energy is absorbed during the dissociation (4.5 kcal/mole) [86]. On the other hand, the dissociation equilibrium is not affected by pressure, as is shown by the fact that the magnetic properties are independent of the pressure [62].

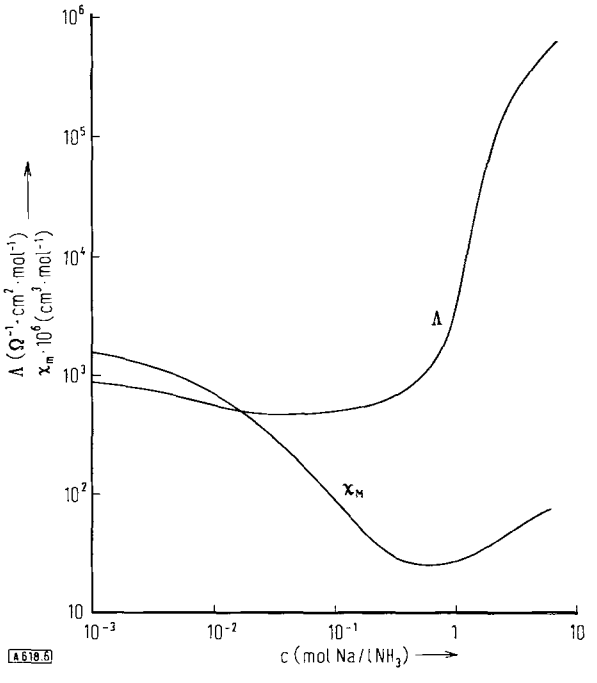

Fig. 6. Magnetic susceptibility χ_m [56, 82] and equivalent electric conductivity Λ [4, 90] of solutions of sodium in liquid ammonia at -33.5 °C as a function of concentration.

The magnetic measurements and their interpretation are confirmed by ESR measurements [87]. The ESR spectrum of the dissolved electrons contains a single, extremely sharp line (half-width 0.05 gauss; g-factor 2.0012). The absence of any hyperfine splitting, and the line sharpness, indicate that there is no strong magnetic interaction between the electron and the solvent molecules of an ordered solvation sheath, but that the solvation sheath forming the cavity must instead be very loosely bound. The spin-compensated electron pairs do not give an ESR signal.

Numerous magnetic measurements have also been carried out on solutions in other amines [82,88–90]. The interpretation of these measurements is complicated because of the additional occurrence of electron-ion pairs in these solutions. It has not yet been possible to carry out measurements on irradiated liquid systems, owing to the short lifetime of the electrons.

Blue condensates of alkali metal vapor and water- or alcohol vapor and irradiated vitreous frozen solvents in which the electrons have accumulated sufficiently to turn the glass blue exhibit essentially the same magnetic behavior [25, 26, 30, 35–37]; the ESR spectra contain several lines, but only one of these can be assigned to the captured electrons, the others probably being due to free radicals formed from the solvent. The signal assigned to the electrons decreases in intensity at the same rate as does the blue color on heating and on exposure to light. When the material is heated, the electrons are taken up by the solvent or by free radicals; on exposure to light, they are probably promoted into a higher energy level, since the blue color and the ESR signal of the electrons return when the exposed sample is carefully heated [36].

Ortho-para hydrogen conversion. Like all paramagnetic particles, dissolved electrons catalyze the ortho-para

hydrogen conversion [91,92]. However, measurements on highly purified, amide-free solutions of sodium in ammonia show that the rate of conversion is several orders of magnitude higher than would be expected from *Wigner*'s theory [93] for paramagnetic particles having a radius of about 3 Å (rate constant of the conversion by paramagnetic particles proportional to r^{-4}; r = collision radius).

3.4. Electric Mobility

Data on the mobility of dissolved electrons can be obtained from conductivity studies of their solutions [4, 94]. The limiting value of the equivalent conductivity of highly dilute solutions of sodium in ammonia is about 1020 Ω^{-1}cm^{2}mole^{-1} at −33 °C (Fig. 6). Taking into account the mobility of the sodium ions (130 Ω^{-1} cm^{2}mole^{-1}), we find that the mobility of the dissolved electrons is about 900 Ω^{-1}cm^{2}mole^{-1} [95]. When the concentration is increased to the range in which electron pairs are formed, the equivalent conductivity of the solutions decreases slightly. Thus the marked decrease in the molar magnetic susceptibility on formation of electron pairs has no parallel in the conductivity behavior; the course of the curve shows that the mobility of the electron pairs is only slightly lower than that of the unpaired electrons, if the slight decrease in conductivity is not entirely due to slight ion-pair formation.

The transition to the metallic state is marked by the strong increase in conductivity above 0.5 M. The equivalent conductivity of a saturated solution of sodium in ammonia is comparable to that of mercury or of pure sodium. Over the entire concentration range, the conductivity increases with rising temperature [94] and decreases with rising pressure [63].

Solutions of metals in amines [96,97] and in ethers [22] have much lower equivalent conductivities, owing to incomplete dissociation. Data on the mobility of the electrons in these solutions are not available.

On pulse radiolysis of aqueous solutions a transient increase in conductivity is observed which may be attributed to the radiolytically generated electrons and the ionic decomposition products of water [98,99]. The mobility of electrons in water at room temperature, as found from the increase in conductivity, taking into account the conductivity component of the ions, is 177 ± 20 Ω^{-1}cm^{2}mole^{-1} [44a,99]. Thus the mobility of electrons in water is only about one fifth of the mobility in ammonia.

If a normal migration mechanism (*i.e.* movement of the charged particle with its solvation sheath through the viscous solvent) is assumed, this difference in the mobilities of dissolved electrons in water and in ammonia could be due to the difference in the viscosities of the two solvents (η_{H_2O} (25 °C) = 0.894 cP; η_{NH_3} (−33 °C) = 0.255 cP) in accordance with the Walden rule $l \sim 1/\eta \cdot r$ (l = mobility, r = radius of the charged particle, η = viscosity of the solvent). However, since the mobility of charged particles is also inversely proportional to their size, the mobility of the large solvated electron should be lower than that of normal ions, whereas the mobility of electrons in water and ammonia is two to five times as great (for comparison, the mobilities of Na^+ and Cl^- ions in water at 25 °C are 50 and 76 resp.; in ammonia at −33 °C they are 130 and 179 Ω^{-1}cm^{2}mole^{-1} resp.). It therefore seems unlikely that the electrons migrate exclusively by a normal mechanism.

In view of the small mass of the electron, tunneling may be a possible explanation for the high mobility [100]. Thus it is conceivable that the electron "jumps" from its cavity into an adjacent solvent zone in which a chance arrangement of the molecules provides the conditions required for the accommodation of an electron. The anomalous thermoelectric properties [101] of dilute solutions of metals in ammonia (direction of heat transport opposite to that of the electron movement, owing to the polarization energy released on the collapse of an abandoned cavity) support the assumption that tunneling is involved.

The effects of temperature and pressure on the conductivity of dilute solutions can be interpreted in this context by a change in the probability of tunneling due to dilatation or compression of the solvent.

Further information about the mechanism of conduction by dissolved electrons should be provided by transport measurements on dilute solutions of metals [102,103] and by conductivity measurements on deep-frozen condensates of metal vapor and water- or ammonia vapor, in which the contribution of the metal ions and the ions of the solvent itself to the conductivity should be negligible.

3.5. Thermodynamic Quantities

The thermodynamic data for dissolved electrons are not known very accurately, since they are generally obtainable only indirectly, *e.g. via* cyclic processes, and their determination involves more or less arbitrary assumptions. They can therefore be used only with certain reservations for further calculations.

Standard potential. The standard potential of dissolved electrons E_e^0 in ammonia, with respect to the standard hydrogen electrode, was determined polarographically[104], and is -1.95 ± 0.1 V at 25 °C (overall reaction $H^+ + e^- \rightarrow {}^1/_2\,H_2$). It is more positive than the standard potentials E_M^0 of metals (overall reaction $H^+ + M \rightarrow 1/2\,H_2 + M^+$) that dissolve in ammonia to form solvated electrons (*e.g.* $E_{Li}^0 = -2.24$ V, $E_K^0 = -1.98$ V[105]). The dissolution of these metals ($M \rightarrow M^+ + e^-$) is associated with a loss of free energy ($E_M^0 - E_e^0 < 0$). Metals having a more positive standard potential (*e.g.* Mg; $E_{Mg}^0 = -1.74$ V[105]) have very low solubilities or are insoluble since the dissolution process is accompanied by an increase of free energy ($E_M^0 - E_e^0 > 0$). However, if the required free energy is supplied from an external source, *e.g.* in the form of electric energy, then Mg, Be, and Al[106] as well as Sm, La, and Ce[107] also dissolve with formation of dissolved electrons (anodic dissolution).

For aqueous solutions, the standard potential is given by the sum of the free enthalpies of the various reaction steps[108]

$(e^-)_s + (H_2O)_l \rightarrow$	$(H)_s + (OH^-)_s$	$\Delta G° =$	8.4 kcal/mole
$(H)_s \rightarrow$	$1/2\,(H_2)_g$	$\Delta G° =$	−53.1 kcal/mole
$(H^+)_s + (OH^-)_s \rightarrow$	$(H_2O)_l$	$\Delta G° =$	−19.1 kcal/mole
$(e^-)_s + (H^+)_s \rightarrow$	$1/2\,(H_2)_g$	$\Delta G° =$	−63.8 kcal/mole

(the subscripts g, s, and l denote the gaseous, solvated, and liquid states). The free enthalpy of the first reaction is found from the equilibrium constant which is calculated from the ratio of the rate constants of the forward[50] and reverse[51] reactions ($k_{forw.} = 16$ l·mole^{-1}·sec^{-1}, $k_{rev} = 1.8 \times 10^7$ l·mole^{-1}·sec^{-1}). The free enthalpy of the second reaction consists of the free enthalpy of dissociation of hydrogen and the free enthalpy of solvation of hydrogen atoms[109]. The free enthalpy of the third reaction is given by the dissociation equilibrium of water. The value found from the free enthalpy of the overall reaction for the standard potential of electrons dissolved in water at 25 °C is −2.78 V.

Since the standard potential of electrons in aqueous solutions is more positive than those of most of the alkali and alkaline earth metals, the formation of solvated electrons during the dissolution of these metals in water is possible, at least thermodynamically.

Heat of solvation. The heat of solvation of electrons, *i.e.* the energy liberated when an electron passes from a vacuum into a solution, can be calculated for ammonia by means of a Born-Haber cycle applied to solutions of metals in liquid ammonia ($(M)_{solid} \rightarrow (M)_g \rightarrow (M^+)_g + (e^-)_g \rightarrow (M^+)_s + (e^-)_s \rightarrow (M)_{solid}$) involving the heat of sublimation and the heat of ionization of the metal, the estimated heat of solvation of the metal ions, and the experimental heat of solution of the metal[14a]. The heat of solvation of electrons in ammonia is found from the data for the alkali and alkaline earth metals to be $\Delta H_{e^-} = -36 \pm 4$ kcal/mole. In agreement with this, a value of −34 kcal/mole is obtained from a similar cycle including the exothermic reaction[110]

$$(e^-)_s + (NH_4^+)_s \rightarrow (NH_3)_l + 1/2\,(H_2)_g \quad \Delta H = -43 \text{ kcal/mole}$$

as well as the dissociation and ionization of hydrogen and the solvation of the protons (heat of solvation ≈ −285 kcal/mole). A value of $\Delta H_{e^-} = -39$ kcal/mole is found by another route for the heat of solvation of electrons in water.

The heats of solvation of electrons in water and in ammonia are considerably lower than those of simple monovalent negative ions. This is due to the low charge density of electrons in the solvated state. The empirical relationship between the heat of solvation and the radius of simple negatively charged ions in water gives a radius of about 3 Å for the mean charge distribution of the electron[109].

The standard potential and the heat of solvation of electrons can be used to determine the equilibrium constant and the heat of reaction for certain reactions. Thus the standard potential of electrons in ammonia and the self-dissociation constant of ammonia give a value of 4×10^{-6} (mole/l)$^{1/2}$ for the equilibrium constant of reaction (7) at 25 °C. Though this is approximately three orders of magnitude lower than the experimental value[52,53], one could scarcely expect a better agreement in view of the uncertainty in the standard potential of electrons and in the dissociation constant of liquid ammonia (uncertain by a factor of 100). The heat of reaction is found by calculation to be $\Delta H = 17$ kcal/mole, in fairly good agreement with experiment.

The equilibrium constant found in this way for the corresponding reaction in water

$$1/2\,H_2 + OH^- \rightarrow H_2O + e^- \qquad (9)$$

is so small that it seems pointless to try to detect the electrons formed at room temperature. However, since the heat of reaction is probably very high, *i.e.* the equilibrium is displaced to the right with rising temperature, it may be possible to obtain and to study solvated electrons in equilibrium with hydrogen at elevated temperatures even in water[*].

The reverse reactions (7) and (9) formally describe the exothermic decomposition reactions of electrons (at low concentrations) with the pure solvents. The reaction is relatively fast in water, but extremely slow in ammonia. This difference in behavior of the electrons in the two solvents is due to the different enthalpies of the respective endothermic first reaction steps leading to atomic hydrogen.

$$(e^-)_s + (NH_3)_l \rightarrow (H)_s + (NH_2^-)_s \quad \Delta H = 33 \text{ kcal/mole} \qquad (10)$$

$$(e^-)_s + (H_2O)_l \rightarrow (H)_s + (OH^-)_s \quad \Delta H = 6 \text{ kcal/mole} \qquad (11)$$

The heat of reaction in ammonia is so high that the reaction cannot proceed at, or below, room temperature.

4. Models

The theoretical treatment of the solvated electron is not strictly possible unless its structure is known. The treatments published so far[14,111,112] are based on

[112] *L. Raff* and *H. A. Pohl* [1], p. 173.

various, sometimes contradictory assumptions regarding the structure of the solvation sheath; however, they all include the assumption that the electron is not strongly localized, but moves within a relatively large volume.

Jortner's model [14], which was mentioned earlier, will now be described in somewhat greater detail, since it copes well with the diffuse structure deduced for the solvation sheath on the basis of experimental results. According to this model the electron is bound in the polarization field due to the solvent molecules, which have been oriented and polarized by the field of the electron.

By means of the SCF theory the energy of the electron in the 1s ground state and in the optically excited 2p state, and hence the energy of the transition responsible for the absorption of light ($h\nu = E_{2p} - E_{1s}$) can be calculated as a function of the diameter of the cavity. This relates two quantities that can be determined experimentally, at least in the case of liquid ammonia, so that the theory can be checked. Alternatively, if the energy of the optical transition in other solvents is known, the theory can be used to obtain a rough estimate of the size of the cavities occupied by the electrons.

According to the rules of quantum mechanics, the total energy of the system consisting of a dissolved electron and the polarized dielectric (in relation to the energy of the resting electron in a vacuum and the unpolarized dielectric) is equal to the expectation value of the Hamiltonian operator of the Schrödinger equation given by the electronic wave

$$E_i = \int \psi_i^* \left[-\frac{h^2}{8\pi^2 m} \nabla^2 + \frac{e}{2}\left(1 - \frac{1}{D}\right) f_i \right] \psi_i \, d\tau \qquad (12)$$

function ψ. (The subscript i refers to the i-th state of the electron; D = static dielectric constant of the solvent, h = Planck's constant, m = mass of the electron, e = electronic charge, ∇^2 = Laplace operator; the integration is to be carried out over the entire space.) The potential f_i due to the diffuse electronic charge without the dielectric is given by the Poisson equation

$$\nabla^2 f_i = 4\pi e |\psi_i|^2 \qquad (13)$$

The polarization field acting on the electron as a result of the polarization of the dielectric is $(1 - 1/D) f_i$.

The potential f_i and the wave function ψ_i are consistent with each other only if ψ_i is an eigenfunction of the Schrödinger equation formed with $f_i(\psi_i)$. E_i then assumes a minimum value.

A hydrogen-like, one-parameter wave function

$$\psi_{1s} = \left(\frac{\lambda^3}{\pi}\right)^{1/2} e^{-\lambda r} \qquad (14)$$

is assumed for the ground state (1s state) of the electron. The parameter λ (dimension cm^{-1}) is the reciprocal of the radius of maximum charge density. Equations (13) and (14) lead to the potential f_{1s}

$$f_{1s} = -\frac{e}{r} + \frac{e(1 + \lambda r)\exp(-2\lambda r)}{r} \qquad (15)$$

For large distances r, f_{1s} is a pure Coulomb potential, but it shows positive deviations at small distances. The potential is assumed to be constant inside the cavity ($f_{r < R} = f_R$, R = radius of the cavity).

Insertion of (14) and (15) in (12) gives the energy of the 1s electron as a function of the size of the cavity and the parameter λ. The value of λ to be used is found from $(dE/d\lambda)_R = 0$ by the variation method.

The energy of the excited 2p state is calculated in the same way with the aid of the assumed wave function:

$$\psi_{2p} = \left(\frac{\mu^5}{\pi}\right)^{1/2} r\, e^{-\mu r} \cos\Theta$$

In this case, however, it must be remembered that the excited state is not an equilibrium state, since the orientation polarization of the solvent cannot adapt itself to the changed charge distribution of the 2p state on excitation (Franck-Condon principle): the orientation polarization of the 2p state is therefore determined by the charge distribution of the electron in the ground state. Electronic polarization, of course, follows the change in the charge distribution on excitation.

The calculations were carried out for two values of the radius of the cavities, *i.e.* for the value $R = 3.3$ Å estimated from density measurements on solutions of metals in liquid ammonia and for the limiting value $R = 0$ Å. The transition energies found for these two cases from the macroscopic data for water (dielectric constant and refractive index) are 0.93 and 1.35 eV. As expected, the transition energy increases with decreasing cavity size, though not so rapidly as is suggested by eq. (8) on the assumption of a square-well potential. In agreement with experiment, calculations of the oscillator strength in both cases give values of the order of 1, as is to be expected for allowed transitions.

Since the energies found in this way depend only slightly on the macroscopic data for the solvent (they differ by less than 5% for water and ammonia), they can be compared directly with the transition energies found experimentally in various solvents. The calculated results for ammonia and its derivatives (for $R = 3.3$ Å) agree fairly well with experiment (cf. Table 1). Thus in conjunction with theory, the optical measurements confirm the value found by another route for the cavity size. For water and alcohols, comparison indicates an infinitesimally small cavity for the dissolved electrons (but according to the theory, the electron is still distributed over a finite volume; the radius of maximum charge density $1/\lambda$ is about 1.7 Å for $R = 0$ and about 2.6 Å for $R = 3.3$ Å).

It is probably an exaggeration to say that the cavities in water and in alcohols are infinitesimally small. However, this result cannot be refuted so long as the volume occupied by the solvated electrons in these solvents cannot be measured either directly or indirectly (determination of the densities of suitable solutions, the pressure-dependence of the position of the absorption maximum, the pressure-dependence of the position of the equilibrium or of the rate of suitable reactions). However, it is necessary to refute the assumption that the infinitesimally small cavity in water is due to the surface tension of water, which is high in comparison with that of liquid ammonia, and which must be overcome in the formation of the cavity. Thus in spite of the lower or even negligible surface tension, the cavity sizes found from optical measurements are approximately the same in methanol [76, 77] as in water, and the same in supercritical ammonia [53] as in liquid ammonia.

Jortner's cavity model, in which the solvation sheath has a diffuse structure, contrasts with two other models, which involve distinct short-range order. *Natori* and *Watanabe* [111] assume a tetrahedral structure of the cavities in water, which would follow from the regular structure of ice if a central water molecule were replaced by an electron, the four water molecules at the vertices of the tetrahedron being arranged with one hydrogen atom of each pointing toward the center. In the model proposed by *Raff* and *Pohl* [112], two oppositely oriented solvent dipoles, in which the positive pole is a hydrogen atom, are held together by the charge of the electron situated between them, *e.g.*

$H-O-H\cdots e^-\cdots H-O-H$

This structure can be described more simply by a hydrogen molecule-ion interacting with two anions of the solvent, *i.e.* in this case OH^- ions:

$HO^-\cdots H_2^+\cdots OH^-$

The transition energies calculated from both of these models roughly agree with those found experimentally. However, the assumed short-range order should give a multiline ESR spectrum, owing to the magnetic interaction with the protons bound in a fixed geometric arrangement, whereas such a spectrum has not yet been observed (except in the case of alkali metal-water condensates at −140 °C)[25,113]. Moreover, these two models cannot explain the broad absorption spectrum, which can be readily interpreted in *Jortner*'s model as being due to a broad radius distribution.

5. Chemical Properties

As is to be expected from their strongly negative redox potential, solvated electrons can react with many substances in solution. The reactions are generally so fast that they can be followed only with the aid of special methods (*e.g.* pulse radiolysis or flash photolysis to produce the electrons and flash spectroscopy to detect them). Though the rate constants have been measured for most of the reactions studied[114], the primary products are still largely uncertain, so that conclusions regarding the reaction mechanism can be reached in only a few cases.

Some characteristics of the reactions of solvated electrons are illustrated by the following examples.

Highly purified solvents. The instability of solvated electrons in water can be attributed to the following reactions, all of which yield hydrogen:

	Rate constant ($l \cdot mole^{-1} \cdot sec^{-1}$)	Activation energy ($kcal \cdot mole^{-1}$)	
$e^- + H_2O \rightarrow H + OH^-$	16 [50]	—	(16)
$2\,e^- + 2\,H_2O \rightarrow H_2 + 2\,OH^-$	4.5×10^9 [49, 115]	5.2 [75]	(17)
$e^- + H^+ \rightarrow H$	2.1×10^{10} [65, 115, 116]	3.2 [117, 118]	(18)

(The electrons formed *e.g.* by radiolysis also react with the other primary and secondary products OH, O^-, H_2O_2, *etc.*) Reaction (18) predominates in acidic to neutral solutions. In alkaline solution, the main reaction at low electron concentrations is reaction (16), which is first order with respect to the electrons, while the second-order reaction (17) becomes predominant at higher electron concentrations. Molecular hydrogen is formed directly only in reaction (17).

Reaction (16), which has also been studied in aqueous ethylenediamine containing dissolved alkali metal[119], is the slowest reaction of electrons in water that has been studied so far. The rate constant given may be only an upper limit, since contamination with reactive compounds even at a concentration of 10^{-8} M interferes with the kinetic measurements. For the same reason, 4.55 $kcal \cdot mole^{-1}$ [117] is probably only a lower limit for the activation energy of this reaction, particularly since the reaction enthalpy is about 6 $kcal \cdot mole^{-1}$ according to eq. (11).

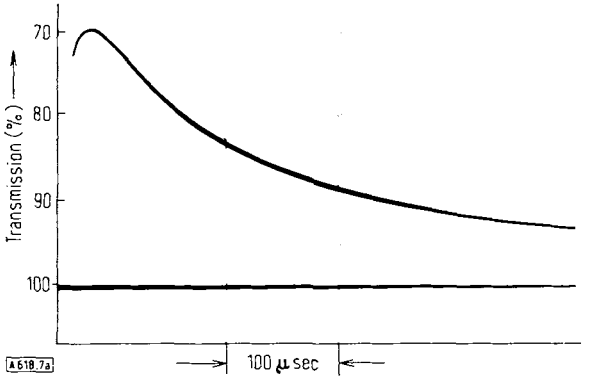

Fig. 7a. Change in the light transmission at 0.7 µ as a result of the formation and reaction of solvated electrons in heavy water (0.01 M NaOD, saturated with D_2 at 1 atm) on pulse radiolysis with fast electrons (10 MeV, 0.5 A, 5 µsec; optical path 6 cm) [79]. Owing to secondary processes, the maximum concentration of solvated electrons is reached only 50 µsec after the end of the pulse.

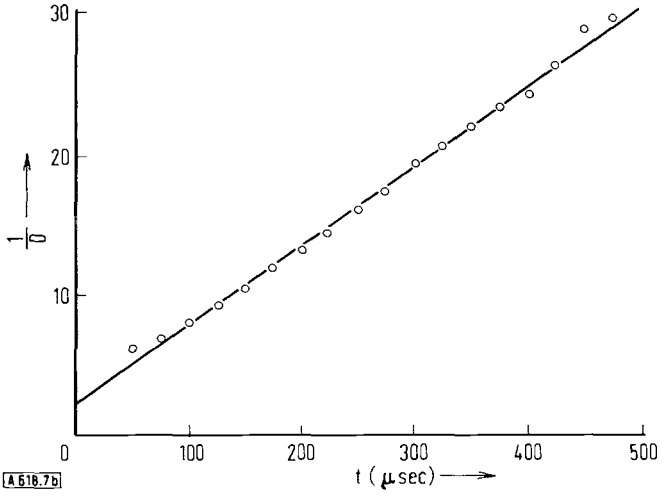

Fig. 7b. A plot of the reciprocal of the optical density *D* from Fig. 7a against time gives a straight line (second-order reaction according to eq. (17)), whose slope gives the rate constant (5.4×10^9 $l \cdot mole \cdot sec^{-1}$) and whose intercept on the ordinate gives the total concentration of the solvated electrons formed (6×10^{-6} M).

Few details are available as yet concerning the reactions corresponding to equations (16) to (18) in other solvents[25,119a]. In the absence of H^+ ions, the life-

time of the electrons in solution decreases in the order liquid ammonia, amines, water (lifetime < 1 msec) methanol (< 5 μsec)[120]. Since the volume occupied by the electrons also decreases in this order (cf. Table 1 in conjunction with eq. (8)), the dependence of the lifetime of the electrons on the solvent may be attributed to the solvent-dependence of the cavity size. When an electron reacts with a solvent molecule, the cavity disappears, so that the formation of the activated complex is associated with a decrease in volume, the change in volume increasing with the size of the cavity.

Thus the activation volume, *i.e.* the difference in volume between the activated complex and the starting materials, is much more negative in the reaction of electrons with ammonia than in the reaction with water. The empirically observed[121] and theoretically justifiable linear relationship between the activation volume and the entropy of activation $\Delta S^{\neq}$, which, according to the transition state theory, determines the activation energy E_a along with the rate constant k_r of a chemical reaction

$$k_r = \frac{kT}{h} \cdot e^{\Delta S^{\neq}/R} \cdot e^{-E_a/RT}$$

consequently shows that the stability of the electrons is many orders of magnitude greater in ammonia, and a few orders of magnitude less in alcohols, than in water. The difference in the activation volumes suggests that the reaction in ammonia should be much more strongly accelerated by pressure than the reaction in water[*].

Simple neutral molecules. The reaction of solvated electrons with simple molecules, such as $O_2 \rightarrow O^-$, $I_2 \rightarrow I_2^-$, $CO \rightarrow CHO$, $CO_2 \rightarrow COOH$, $H_2O_2 \rightarrow HO + OH^-$, $N_2O \rightarrow N_2 + OH$, $NO \rightarrow NHO$, $CS_2 \rightarrow CS_2H$, $CCl_4 \rightarrow CCl_3 + Cl^-$, $C(NO_2)_4 \rightarrow C(NO_2)_3 + NO_2^-$, have rate constants $> 10^9$ l·mole^{-1}·sec^{-1} [66, 115, 117, 122, 123]. They are therefore close to the limit of diffusion-controlled reactions. Hydrogen, nitrogen, and the noble gases are inert to solvated electrons.

Cations. All metal cations apart from alkali, alkaline earth, and bivalent rare earth metal ions[66, 117] are reduced by solvated electrons to an oxidation state one unit of charge lower, *e.g.* $Ag^+ \rightarrow Ag$, $Cd^{2+} \rightarrow Cd^+$, $Tm^{3+} \rightarrow Tm^{2+}$. The resulting unstable ions react further. In the series of bivalent metal ions[66] Mn^{2+}, Fe^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Cr^{2+}, Cd^{2+} and the trivalent rare earth metal ions[117] Lu^{3+}, Pr^{3+}, La^{3+}, Tb^{3+}, Dy^{3+}, Gd^{3+}, Nd^{3+}, Tm^{3+}, Sm^{3+}, Yb^{3+}, Eu^{3+}, the rate constant increases from 10^8 to 4×10^{10} l·mole^{-1}·sec^{-1}. It is not yet possible to establish any clear relationship between the rates of these reactions and the properties of the ions.

The rate of reaction of metal ions with solvated electrons is sometimes considerably increased by complexing of the metal ions[66, 124]; the promotion of the reaction by the ligands is attributed partly to their ability to capture an electron and pass it on to the central cation, and partly to the change in the electron density of the cation due to complex formation. The effectiveness of ligands for such processes increases in the order OH^-, CN^-, NH_3, H_2O, F^-, Cl^-, and I^- [124].

Anions. Anions with completely filled valence shells, such as F^-, Cl^-, Br^-, I^-, CN^-, CNO^-, CNS^-, N_3^-, and OH^-, do not react with solvated electrons[117]. The following nonmetallic oxo anions are also inert to solvated electrons in their highest oxidation state[117]: $B_4O_7^{2-}$, CO_3^{2-}, HCO_3^-, ClO_4^-, HPO_4^{2-}, PO_4^{3-}, SO_4^{2-}. On the other hand, the oxo anions of metals[117], *e.g.* MnO_4^- and $Cr_2O_7^{2-}$, as well as all the oxo anions of nitrogen, bromine, and chlorine (except ClO_4^-)[117, 124] are highly reactive.

For a number of the above mentioned reactions, the rate constants obtained by pulse radiolysis are confirmed by electrochemical measurements[44a].

Aliphatic compounds. Saturated hydrocarbons, alcohols, amines, ethers, and their fluorine derivatives show little tendency to react with solvated electrons in water ($k < 10^7$ l·mole^{-1}·sec^{-1})[122]. The anions of lower fatty acids and simple hydroxy acids, as well as some of the acids themselves, do not react (formate, acetate, lactate, succinate ions; oxalic, citric, and lactic acids)[122]. Some of these compounds are also stable to solutions of metals in liquid ammonia. Olefins (particularly those with conjugated double bonds), aldehydes, and ketones (but not their hydrates) are mostly very reactive[115, 122, 124, 125].

Halogenated hydrocarbons and fatty acids (except fluorinated compounds) react extremely rapidly with solvated electrons[126]. The reaction rate increases in the order Cl, Br, I derivatives. The reactions result in the removal of halide ions:

$$R{-}X + e^- \rightarrow R\cdot + X^-$$

The reactivity of the halogen substituent is further increased by adjacent electron-attracting substituents; this effect can be very satisfactorily described by the Taft substituent constant σ^* [127], which characterizes the efficiency of the substituents in withdrawing electrons from the halogen through the aliphatic chain (inductive effect). This supports the assumption that the electrons attack at the halogen atom.

Aromatic compounds. In contrast to the saturated aliphatic hydrocarbons, the aromatic hydrocarbons,

owing to their particular electron system, can readily accept an additional electron. This results in the formation of aromatic radical-anions, which are very stable, at least in nonaqueous solutions. They can be prepared in solutions of alkali metals in liquid ammonia [128], amines [129], and ethers [130–132] by the addition of aromatic compounds. The rate of the addition reaction is again appreciable. Rate constants of 1×10^7 to about 5×10^9 l·mole^{-1}·sec^{-1} [125, 126, 133] have been found by pulse radiolysis for the addition of solvated electrons to benzene, naphthalene, anthracene, biphenyl, and terphenyl in aqueous and alcoholic solutions.

As in the halogenated hydrocarbons, substitution in the aromatic ring leads to variation of the reaction rate within wide limits [126] (phenol $k = 4 \times 10^6$, fluorobenzene 6×10^7, chlorobenzene 6×10^8, iodobenzene 4×10^9, nitrobenzene 3×10^{10} l·mole^{-1}·sec^{-1}). This variation of the reactivity of substituted aromatic compounds toward solvated electrons is similar to that shown by the aromatic compounds toward nucleophilic reagents, which can be described by the Hammett σ function [134]. This parallelism suggests that dissolved electrons attack the ring system in exactly the same way as nucleophilic reagents.

The activation energies of about 20 exothermic reactions with rate constants between 10^5 and 10^{11} l·mole^{-1}·sec^{-1} are all about 4 ± 1 kcal/mole [118, 135–137], so that the rates of these reactions, like those of the reactions with the pure solvents, are determined by the change in entropy on formation of the activated complex. This result cannot be generalized until a greater number of slow reactions of electrons have been studied. However, it appears to be of general significance to the reactions of dissolved electrons.

The investigation of reactions of electrons with rate constants $< 10^7$ l·mole^{-1}·sec^{-1} in water is unfortunately very difficult because of the reaction of the electrons with the water molecules. Consequently, further studies should be carried out on substances that react only slowly in liquid ammonia, in which the electrons are stable but in other respects react in the same way as in water.

It can be seen from these examples that the reactions of electrons have been more thoroughly studied, from the kinetic point of view, than those of any other reactive particle. Nevertheless, there is still much ground to be covered before it will be possible to explain the many reactions of electrons on the basis of a single consistent theory. However, it is to be hoped that the evaluation of the kinetic studies, supplemented by investigations in other solvents, will lead to a deeper understanding of the relationship between the structure or electron distribution of molecules and their chemical reactivity.

The Discovery, Isolation, Elucidation of Structure, and Synthesis of Antamanide [1]

BY TH. WIELAND

IN COLLABORATION WITH G. LÜBEN[5], H. OTTENHEYM[2], J. FAESEL, J. X. DE VRIES, A. PROX, AND J. SCHMID[*]

Dedicated to Professor A. Butenandt on the occasion of his 65th birthday

Antamanide is the name we have given to a constituent of the fungus Amanita phalloides. This substance counteracts the lethal action of the Amanita toxins phalloidine and α-amanatine if administered to the white mouse before, or simultaneously with, the poisons. Its concentration in the fungus is, however, so low that the toxic action of the latter predominates. Antamanide is a cyclic decapeptide formed from the L-amino acids alanine, phenylalanine, proline, and valine in the molar ratio 1:4:4:1. The amino-acid sequence was determined by a combination of gas chromatography and mass spectrometry. The structural formula assigned was confirmed by synthesis according to a classic route of peptide chemistry.

1. Discovery

Since the summer of 1962 we have been busy with the investigation of the extremely small amounts of lipophilic components of the constituents of the bulbous leaf fungus, *Amanita phalloides*. By consequential chromatography we were able to obtain two hitherto unknown materials in pure form, phallin B, a toxic component belonging to the phallotoxine family, and a non-poisonous cyclopeptide, phallin A, which consists[3] of alanine, glycine, proline, phenylalanine, and valine (in the molar ratio 1:1:1:2:1). The fraction 1b mentioned in reference[3], which was obtained by a complicated purification procedure followed by chromatography on silica gel, was found to be non-poisonous when administered to mice despite its content of the poisonous phallin B. This led us to consider the possibility of the fraction 1b containing an antitoxic principle, which neutralized the toxic action of phallin B. With doses of 50 mg of the fraction 1b per kg of white mouse, the absolute lethal action of 5 mg of phalloidine per kg (LD_{50} = 2.0 mg/kg) could be completely counteracted. All attempts to enrich the antitoxin resulted in a preparation, whose thin layer chromatogram showed the presence of six components. 5 mg of this mixture per kg of white mouse was found to be a sufficient dose for complete protection against 5 mg phalloidine per kg. The amount of the antitoxic preparation available was, at this stage of our investigations, too small to permit further enrichment and characterization experiments to be carried out. This limitation and lack of time, compelled us to momentarily shelve our investigations.

2. Isolation

At this point in time *D. Rempel*[4] began his working up of the fungus harvest of 1963. Like his predecessors he used chromatographic methods for the separation of the numerous components, but instead of using a cellulose powder chromatographic column, as was used by previous workers, he used a column of dextran gel Sephadex G-25. Partition chromatography on such a column with a mixture of butanone, acetone, and water (20:6:5 v/v = solvent F) permitted the separation of the toxic and the non-toxic peptide constituents, the non-toxic components, because of their lipophilic character, leaving the chromatographic column ahead (pre-toxic fraction) of the toxic components.

At a later date, our group utilized the solubility of the non-toxic peptides in acetone in that we extracted the part of "primary material" LA that is soluble in solvent F with acetone and used the acetone-soluble LLA for the further working up of these peptides. From 125 kg of *A. phalloides*, approx. 40 g of the lipophilic non-toxic mixture could be obtained, which on being administered to a white mouse at a dose of

50 mg/kg proved sufficient to prevent certain death from 5 mg/kg of phalloidine. Further enrichment of the antitoxic principle[5] was achieved by column chromatography using methanol, or a methanol/water mixture, on Sephadex G-25 in earlier experiments and on Sephadex LH-20 in later work.

The anti-toxic substance absorbs in the UV-region and therefore its presence in the eluate from the chromatographic column is registered by a Uvicord; however, it does not give a specific color reaction and each of the fractions from the column had to be tested in experiments with mice in order to establish their preventative action against phalloidine.

Because of the large number of similar products present in the mixture, thin layer chromatography proved most effective after a certain degree of enrichment had already been achieved. At the same time the peptides were rendered visible (dark blue coloration) by *N*-chlorination with *tert*-butyl hypochlorite followed by treatment with tolidine[6]. After the first run, using methanol, the total activity was contained in a tenth of the amount by weight of the starting material; its concentration was found to be such that a dose of 5 mg/kg was sufficient protection against 5 mg/kg phalloidine. After a second run in methanol/water (1:1) (see Fig. 1) the amount by weight of the active portion had been reduced by a factor of 10 % resulting

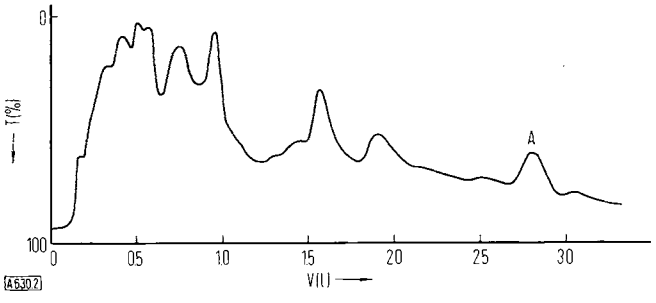

Fig. 1. Uvicord chart obtained on chromatographing [Sephadex LH-20 column (4 × 200 cm); eluant: methanol-water (1:1 v/v)] crude antamanide (1.5 g) isolated by preliminary chromatography. Antamanide at A.
Ordinate: Transmission T (%).
Abscissa: Volume V (l).

in an increase in activity such that a dose of 0.5–1 mg/kg proved to be sufficient protection against 5 mg/kg phalloidine. The thin layer chromatogram showed the presence of an almost pure active substance.

Preparative thin layer chromatography, on silica gel HF_{254} and using a mixture of *sec*-butanol/ethyl acetate/water (13:12:5) as solvent, formed the last purification step. After elution of the layer (at $R_F \approx 0.5$) containing the antitoxic substance, traces of dissolved silica gel could be removed by passage of the solution through a Sephadex LH-20 column. By using the above purification technique *ca.* 250 mg of pure antamanide were obtained from 40 g of a mixture of the acetone-soluble lipophilic components extracted from *A. phalloides*. The pure antamanide crystallized out on rubbing with acetone or butanone and was recrystallized from these solvents (see Fig. 2). It sinters at 167 °C and melts at 172 °C, is extremely soluble in methanol, acetone, ethyl acetate or pyridine, is readily soluble in higher alcohols and butanone, moderately soluble in ethyl acetate, slightly soluble in benzene, and almost insoluble in water and in paraffins.

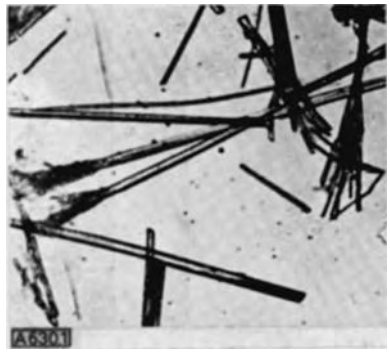

Fig. 2. Antamanide, crystallized from butanone.

In the white mouse the protective dose (PD) of pure antamanide against 5 mg/kg phalloidine amounts to 0.5 mg/kg. If the amount of poison is increased to 10 mg/kg (*i.e.* 4 × LD_{50}), complete protection can be achieved with 1.5 mg/kg of antamanide. A dose of 5 mg/kg of antamanide is sufficient protection against 25 mg/kg phalloidine. Whilst phalloidine administered to unprotected mice leads to the destruction of the endoplasmic reticulum of the liver cells within 15–30 minutes after injection (*O. Wieland* and *F. Miller*, *L. Fiume*, and *R. Laschi*; see ref.[7]), the liver of mice protected by antamanide remains completely normal. The slowly operating action of 1 mg (per kg body weight) of the ten times more poisonous α-amanitine, which attacks the nucleus of the liver cell, can be offset by repeated doses of 10 mg/kg of antamanide administered over a period of a few days.

3. Elucidation of Structure

3.1. Attempted Elucidation of Constitution by Classical Means

On hydrolysis with acetic acid/hydrochloric acid (1:1) for 12 h at 110 °C antamanide decomposes to the amino acids alanine, phenylalanine, proline, and valine in the molar ratio 1:4:4:1. Further, since antamanide is electrophoretically neutral and gives a negative ninhydrin test it must be considered as being a cyclopeptide. Mass spectrographic analysis showed the presence of a molecular ion at $m/e = 1146$, which is in accord with a cyclic decapeptide derived from the above mentioned amino acids in the given ratio. A new micromethod[8] was used for establishing the con-

[6] *R. H. Mazur*, *B. W. Ellis*, and *P. S. Cammarata*, J. biol. Chemistry *237*, 1619 (1963).

[7] *Th. Wieland*, Fortschr. Chem. org. Naturstoffe *25*, 214 (1967).

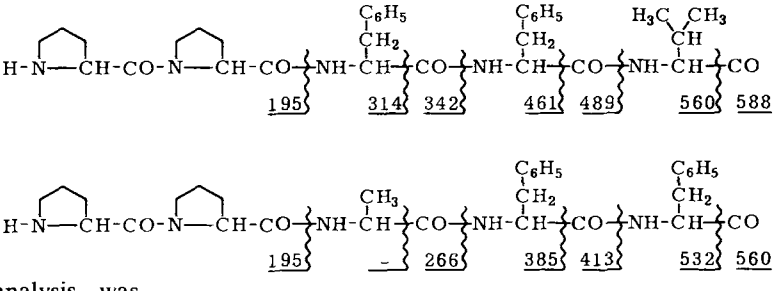
figuration of the structural units. This involved the micro-chromatographic, or electrophoretic isolation of the amino acids to be investigated from the hydrolyzate and their subsequent coupling with the azide of a suitable benzyloxycarbonyl-(= Z-) L-amino acid to form the Z-dipeptide. The presence of the L-forms gives rise to the formation of isochiral (L-, L-) Z-dipeptides; if a D-amino acid is present then a diachiral L-D-compound is also formed. A good separation [9] of the diastereoisomers can be obtained on a cellulose powder layer using pyridine/water (82:18 v/v) as solvent, provided that the group Z is first removed. This can be achieved on the micro-scale by gently applying spots of a 0.1 % solution of $PdCl_2$ in methanol to the initial drops of Z-dipeptide on the thin-layer plate and then placing the plate in a hydrogen atmosphere whereupon catalytic reduction occurs. It was subsequently established by chromatography, using the solvents mentioned above, that every one of the amino acids derived from the antamanide hydrolyzate gave rise to a spot of the L-L dipeptide only, thus suggesting that all the structural units have the L-configuration. The determination of the amino acid sequence presented hitherto unknown difficulties. The first step in our investigations was the examination of the possibility of cleaving the peptide ring in only one position by acid hydrolysis. *G. Lüben* obtained a mixture of peptides that gave a positive ninhydrin test (*i.e.* a mixture of linear peptides) together with the unchanged cyclopeptide, by treatment with glacial acetic acid /12 N hydrochloric acid at 40 °C for 24 h. This mixture could be separated by preparative thin layer chromatography. The quickest migrating component, which, according to the amino acid analysis, was composed of two phenylalanine, one alanine, one valine, and four proline units, was stepwise degraded (in a way that was modified in order to take into account the lipophilic nature) according to the method of *Edman*. The results obtained indicated the series Phe–Phe–Ala–Val–Pro–Pro–(Pro–Pro). Since the two missing phenylalanine units can only be accommodated at the beginning of the chain, we proposed the structural formula (–Phe_4–Ala–Val–Pro_4–) for antamanide and proceeded to synthesize a corresponding linear decapeptide. On chromatographic analysis of the synthetic product, a large discrepancy appeared between the R_F value of the synthesized octapeptide Phe–Phe–Ala–Val–Pro–Pro–Pro–Pro and that of the degradation peptide of the same assumed formula that had been subjected to sequence analysis; the latter migrated considerably farther. The unexpected lipophilic nature of the degradation peptides from antamanide was quite remarkable, and yet there seemed no reason to doubt the results of the Edman degradation, which had been carried out in the customary manner. It was not until later that we ascertained that the degradation peptide investigated, as well as other peptides isolated from the product of partial hydrolysis of antamanide, exhibited a certain peculiarity insofar as they all yielded two ninhydrin-positive products on incubation with methanolic ammonia; these products proved separable on thin-layer chromatography. This peculiarity has not yet been explained.

After it had become clear that the classic methods of sequence analysis could not be applied to the problem in hand, we resorted to mass spectrometric analysis.

3.2. Elucidation of the Structure by Mass Spectrometry

In agreement with the amino acid structure, the molecular ion of antamanide appears in the mass spectrum at *m/e* 1146. Its high intensity is suggestive of a cyclopeptide. A remarkable feature of the spectrum is the absence of intense fragment ions above *m/e* 588 and *m/e* 560, the only exception being an ion at M–91 (91 = benzyl). On the basis of these ions it was possible to derive formally two pentapeptide sequences, each containing the sequence Pro–Pro at their N-terminal end. This derivation takes into consideration the majority of the fragment ions that are observed (Scheme 1).



Scheme 1. Suggested fragmentation patterns for two pentapeptides.

The formation of analogous fragment ions with an N-terminal H–Pro–Pro sequence had already been observed during the mass-spectrometric decomposition of a cyclononapeptide [10]. The absence of characteristic fragment ions between *m/e* 588 and *m/e* 1055 (M–91) is readily explained by the immediate decomposition of the antamanide molecule into two pentapeptides, which then proceed to decompose stepwise. The structure of antamanide should thus result from the coupling of the two sequences Pro–Pro–Phe–Phe–Val and Pro–Pro–Ala–Phe–Phe.

A combination of gas chromatography and mass spectrometry was used to confirm the sequence [11].

[9] *Th. Wieland* and *H. Bende* Chem. Ber. *98*, 504 (1965).

[10] *F. Weygand* and *A. Prox*, unpublished.

[11] *A. Prox* and *F. Weygand*: Peptides. Proc. 8th Europ. Peptide Sympos., Nordwijk 1966. North-Holland Publ. Comp., Amsterdam 1967, p. 158.

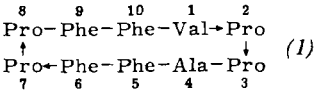
Since fragments were detected that had been formed by transannular transpeptidation, the procedure adopted in this part of the structure elucidation is briefly described below.

Antamanide (10 mg) was partially methanolized by treatment with 8.5 N methanolic hydrogen chloride solution for 5 h at 70 °C. The methyl esters of the peptides were separated gas chromatographically as the *N*-trifluoroacetyl compounds and were then analyzed mass spectrometrically. Over 30 components were obtained, a characteristic selection of which is given in sequence form in Table 1.

Table 1. Sequence derivation from the partial sequences of the N-trifluoroacetyl peptide methyl esters separated by gas chromatography.

1	2	3	4	5	6	7	8	9	10	(11	12)
Val	Pro	Pro	Ala								
		Ala	Phe	Phe							
			Phe	Phe	Pro						
				Phe	Pro	Pro					
					Pro	Pro	Phe				
							Phe	Phe	Val		
									Phe	Val	Pro
Val	Pro	Pro	Ala	Phe	Phe	Pro	Pro	Phe	Phe	(Val	Pro–)

The results of this precise analysis thus indicate the new structure *(1)* for antamanide (see also Scheme 2).

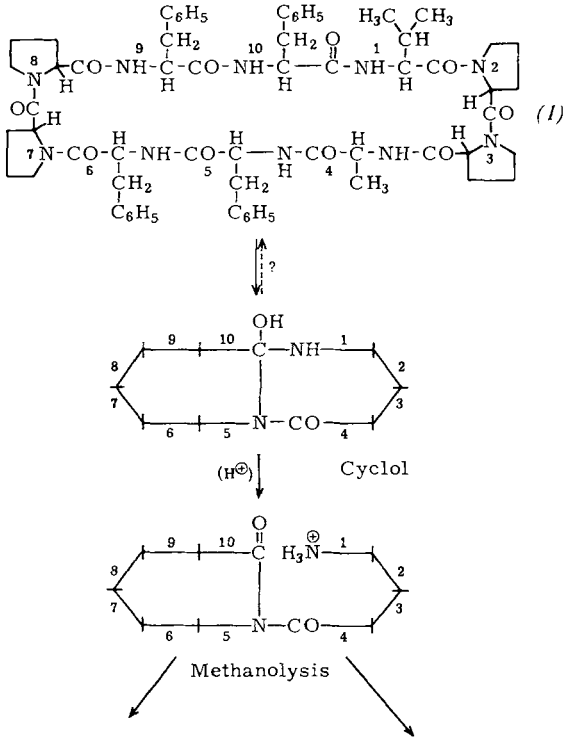


(1)

In addition to the peptide methyl esters listed in Table 1, others were found whose sequences were not consistent with the series given above, *e.g.*, Phe–Val–Phe, Phe–Phe–Ala, Phe–Val–Ala, and Phe–Phe–Phe. Their occurrence can be explained by the assumption of transannular interactions during the process of H^+-catalyzed methanolysis. A cyclol structure[12], formed by the reaction of an amide group with a CO group, can undergo ring cleavage thus giving rise to a peptide ring of reduced size that bears a linear polypeptide side chain. The side chain is split off from the resulting diacylimide by methanolysis and is degraded further. (If the side chain consists of only two units, it can be cleaved off as the diketopiperazine.) On partial methanolysis of the contracted peptide ring, peptide esters can be formed whose sequence is not present in the original peptide but arises as a result of rearrangement. This process is formulated in Scheme 2 for the "artificial" tripeptide Phe–Phe–Phe, but it can apply – *mutatis mutandis* – for the other three new peptides.

4. Synthesis of Antamanide

The synthesis of antamanide was accomplished *via* the cyclization of a linear decapeptide. Of the ten isomers that are possible in principle, we prepared one in a way that readily permitted variations to be made. On the basis of recent findings it proved unnecessary to observe the basic approach that had previously been adopted. Hitherto, the danger of racemization had prohibited the use of the usual activation methods[13] except in the case of amino acids protected by urethane groups; the only method permitted was the azide method. According to the latest work of *G. W. Anderson et al.*[14], the simplest method of peptide synthesis (with mixed alkyl carboxylic anhydrides[15]), however,



Phe-Phe-Phe-OCH_3 (9 10 5)

Val-Pro-Pro-Ala-OCH_3 (1 2 3 4)

+ Phe-Pro-Pro-OCH_3 (6 7 8)

and other esters

Scheme 2. Possible rearrangement in acid-catalyzed degration of antamanide *(1)*.

proceeds without racemization if certain bases, *e.g.* *N*-methylmorpholine, are used in place of triethylamine. Our synthesis of the methyl ester of the *N*-*tert*-butyloxycarbonyl-(BOC) compound from pentapeptides I (6–10) and II (1–5), as shown in Scheme 3, was conducted mainly according to the anhydride method although other common coupling methods[13] were also used.

The ester of pentapeptide I was converted into the acid by hydrolysis with sodium hydroxide solution in dioxane, and the derivative of pentapeptide II was converted into the ester having a free amino group by acid-catalyzed removal of BOC. The two components could then be coupled by the anhydride method to form the methyl ester of the BOC-decapeptide.

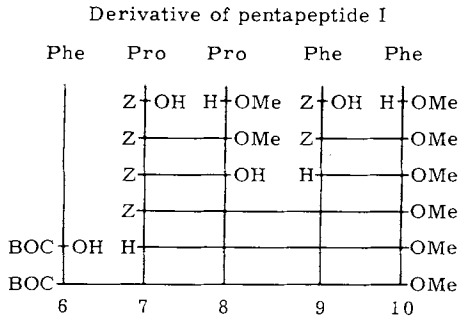
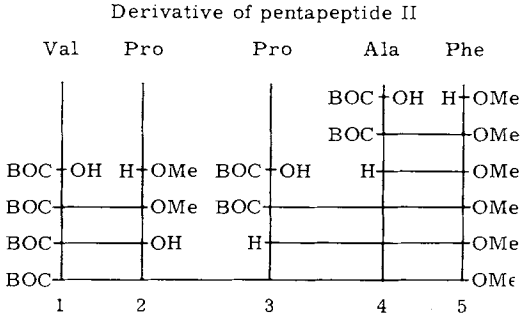
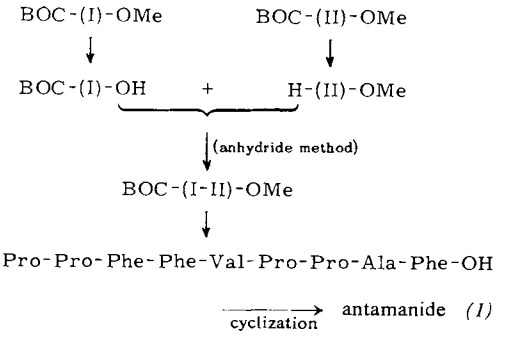




Scheme 3. Synthesis of the derivatives of pentapeptides I and II. Z = benzyloxycarbonyl group, BOC = *tert*-butoxycarbonyl group, Me = CH_3.

The terminal protecting group was removed from the decapeptide and cyclization of the free decapeptide was then accomplished by means of the anhydride method [16]. The yield was improved by additional protonation of the free amino terminal during anhydride formation [17]. Antamanide was obtained in *ca.* 30 % yield (with reference to the linear zwitterionic decapeptide). The compound crystallized out when its solution was seeded with the natural substance. In mouse experiments a dose of 0.5 mg per kg body weight, administered subcutaneously, was found to be effective against 5 mg of phalloidine per kg.



The authors are grateful to Fräulein Ch. Carstens and Fräulein A. Schmitz, who work in the laboratory of Dr. H. Wick (C. H. Boehringer Sohn, Ingelheim/Rhein), for toxicity determinations, to H.-J. Knorr and E. Lantzsch, of the same company, for their skillful preparative work and their help in the isolation of the natural product, and to Frau H. Schiefer, who obtained pure antamanide from the fungus harvest of 1966. Professor E. Lederer and Dr. M. Senn, Gif-sur-Yvette, carried out the first mass spectrometric analyses. The investigations were supported financially by the Deutsche Forschungsgemeinschaft. Dr. de Vries wishes to thank the Alexander-von-Humboldt-Stiftung for a study grant.

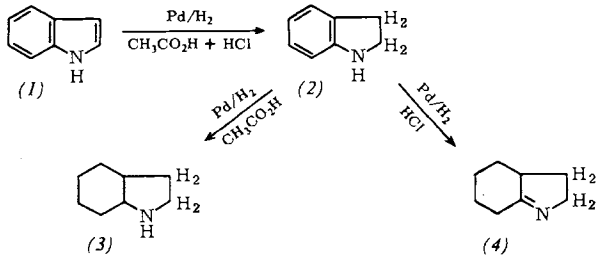
COMMUNICATIONS

Catalytic Hydrogenation of Indole

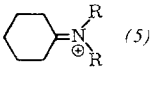
By *I. Butula* and the late *R. Kuhn* [*]

Willstätter and *Jaquet* [1] hydrogenated indole *(1)* over platinum in glacial acetic acid, obtaining octahydroindole *(3)*. If the hydrogenation was interrupted after absorption of one molar equivalent of hydrogen, then indoline *(2)* was isolated as well as *(3)*. *Adkins* and *Leonradt* [2] obtained *(2)* in 60% yield on hydrogenation of *(1)* over copper chromite at 170–190 °C and 250 atm, and *(3)* from *(1)* in 80% yield on hydrogenation over Ni at 250 °C and 250 atm.

If indole is hydrogenated in glacial acetic acid over $Pd(OH)_2/BaSO_4$ at 18 or 60 °C, dark products are formed with an H_2-absorption of 3–4 molar equivalents. If hydrochloric acid is added and hydrogenation is effected at 60 °C, 1 molar equivalent of hydrogen is taken up rapidly and reduction then ceases. Indoline can be isolated in 80% yield. This product is hydrogenated in glacial acetic acid over the same catalyst at 60 °C to give octahydroindole *(3)* (80%). However, if *(2)* is hydrogenated in 1 N hydrochloric acid at 60 °C, 3,3a,4,5,6,7-hexahydro-2*H*-indole *(4)* is obtained in 64% yield.



Under these conditions *Kuhn* and *Haas* [3] obtained cyclohexanone from aniline and suggested that the hydrogenation proceeds by way of the immonium compound *(5)*. If *(2)* is regarded as a substituted aniline, the appearance of the



(5)

imine *(4)* confirms *Kuhn* and *Haas*' suggestion. The structure of *(4)*, which was prepared by a different route *i.e.* as intermediate in the synthesis of erythrinane [4], was proved by IR [5] and NMR spectra.

Indoline (2): 2 g of $Pd(OH)_2/BaSO_4$ [6] was prereduced in 50 ml of glacial acetic acid, then 2.34 g of indole in 20 ml of 2 N HCl was added, and the mixture was hydrogenated in a shaking-apparatus at 60 °C and atmospheric pressure for

1.5 h. The catalyst was filtered off, the filtrate evaporated to dryness, and the residue dissolved in dilute sodium hydroxide solution and extracted with chloroform. After removal of the solvent and distillation of residue, 2.1 g (90%) of *(2)* was obtained. The IR spectrum was in accord with the Sadtler spectrum No. 22446.

Octahydroindole (3): 2.1 g of compound *(2)* was hydrogenated in 40 ml of glacial acetic acid over 2 g of $Pd(OH)_2/BaSO_4$ for 14 h at 60 °C. Working up as above afforded 1.7 g (80%) of *(3)*. Picrate, m.p. 135–137 °C ([1]: 137–139 °C).

3,3a,4,5,6,7-Hexahydro-2H-indole (4): 4 g of $Pd(OH)_2/BaSO_4$ was prereduced in 50 ml of distilled water, 3.6 g of *(2)* in 100 ml of 1 N HCl was added, and the mixture was hydrogenated at 60 °C and atmospheric pressure for 20 h (H_2 uptake: 2.4 molar equivalents). The crude product (strong $-\overset{\oplus}{H}N=C\diagdown$ absorption band at 1684 cm^{-1} in the IR spectrum) was dissolved in dilute aqueous sodium hydroxide, extracted with $CHCl_3$, and distilled. 64% (2.3 g) of compound *(4)* was obtained alongside a little *(3)*. Picrate, m.p. 132–133 °C ([4]: 132–133 °C).

A New Alkenynylamine Synthesis

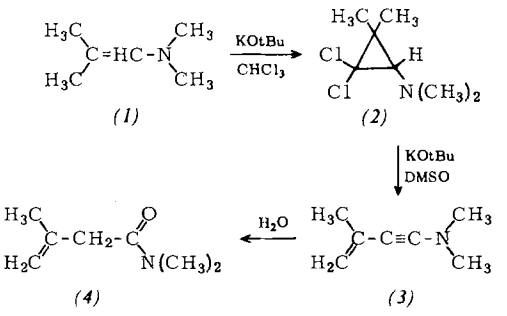
By *T. C. Shields*, *W. E. Billups*, and *A. N. Kurtz* [*]

Alkynylamines have been prepared [1] and stimulated considerable interest recently. We wish to report the extension of a simple route for alkenynes [2] to the synthesis of alkenynylamines.

Treatment of isobutenyldimethylamine *(1)* with chloroform and an excess of potassium *tert*-butoxide in pentane results in (2,2-dichloro-3,3-dimethylcyclopropyl)dimethylamine *(2)* in 32% yield [3]. Its NMR spectrum consists of four sharp singlets at τ = 7.73 (6 H, $(CH_3)_2N$ group), 8.38 (1 H, cyclopropyl proton), and 8.73 and 8.77 (3 H each, $C(CH_3)_2$ group).

Dehydrochlorination of *(2)* with potassium *tert*-butoxide in dimethyl sulfoxide at 25–40 °C for five hours affords a 20–30% yield of dimethyl-(3-methylbut-3-en-1-ynyl)amine *(3)*. The NMR spectrum of *(3)* shows a multiplet at τ = 5.24 (2 H, $=CH_2$ group), a sharp singlet at 7.30 (6 H, $(CH_3)_2N$ group), and a three line pattern centered at 8.23 (3 H, $C(CH_3)$ group). The molecular weight was determined mass spectrometrically (molecular ion at *m/e* = 109 with other significant fragments at *m/e* = 94, 79, and 53). The ultraviolet spectrum ($\lambda_{max.}^{C_6H_{12}}$ = 257 nm, ε = 8100, in cyclohexane) and infrared absorption [4.53 μ, $-C\equiv C-N(CH_3)_2$], along with elemental analysis, confirm the structure of *(3)*.

In water, compound *(3)* is hydrolyzed to *N,N*-dimethyl-3-methylbut-3-enamide *(4)* which shows NMR multiplets at τ = 5.19 and 5.31 (1 H each, $=CH_2$ group), a singlet at τ = 7.03 (6 H, $(CH_3)_2N$ group), and multiplets at 7.14 (2 H, CH_2 group) and 8.25 (3 H, $C(CH_3)$ group).



The mechanism of the conversion of compound *(2)* into *(3)* is not clear; however, attempts to trap a cyclopropene intermediate with nucleophiles have failed [4].

Synthesis of compound (2):

Isobutenyldimethylamine (121.0 g; 1.22 moles) in *n*-pentane (500 ml) is combined with chloroform (150.4 g; 1.26 moles) and cooled to 5 °C. Potassium *tert*-butoxide (179.5 g; 1.6 moles) is added slowly with stirring under a nitrogen atmosphere. Additional *n*-pentane (100 ml) is added during this period to reduce the viscosity of the reaction mixture. After an additional 1.6 hour's stirring, the mixture is quenched in ice water and the organic phase dried over Na_2SO_4. The *n*-pentane is removed and the product rapidly distilled through a short-path column whereupon 71 g (32% yield) of product, b.p. ~22 °C/0.7 torr, are obtained. The kettle temperature should be kept below about 60 °C since the contents are liable to explode if overheated. Redistillation of the product is uneventful except for a small amount of decomposition. Analysis by VPC is not practical due to extensive decomposition in the instrument; however, the compound is shown to exist in a very high state of purity by NMR spectroscopy.

Synthesis of compound (3):

Compound *(2)* (18.2 g; 0.10 mole) is added slowly to a solution of potassium *tert*-butoxide (44.9 g; 0.40 mole) in dimethyl sulfoxide (300 ml), with stirring, under nitrogen. The temperature (exothermic reaction) is maintained below 40 °C. After five hours total reaction time the mixture is quenched in ice water and extracted with *n*-pentane. The extract is dried over Na_2SO_4, concentrated, and distilled through an 8″ Vigreaux column. About 3.5 g of product (20–30% yield) is obtained. Purification is easily accomplished *via* preparative gas chromatography using an 8 ft. 10% SE-30 silicone gum rubber column.

Hydrogen-substituted Cyclotriphosphazenes Formed by NH→PH Tautomerization [1]

By *A. Schmidpeter* and *J. Ebeling* [*]

1-Amino-3-iminodiphosphazenes [**] condense readily with compounds that contain two replaceable nucleophilic substituents on the central atom, yielding six-membered phosphazene heterocycles [2]. 1-Amino-3-imino-1,1,3,3-tetraphen-

yldiphosphazene removes 2 molar equivalents of phenol from triphenyl phosphite *(2a)*. The diphenyl alkylphosphonites *(2b)* [3] and *(2c)* react similarly.

The products correspond in composition to the expected cyclotriphosphazadienes *(3)* but do not have the sensitivity to oxidation expected for such compounds; they are unchanged by atmospheric oxygen. The couplings that occur in the ^{31}P- and ^{1}H–NMR spectra, especially the high P–H coupling show unambiguously that the reaction products are the tautomers *(4)* that have arisen by migration of the proton from nitrogen to phosphorus.

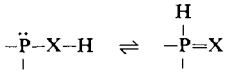
A direct P–H coupling from phosphorus bound to nitrogen has not hitherto been known. However, values for coupling constants can be estimated from $L_{PH} \approx 100\ (\Sigma\chi_S - 3)$ Hz. χ_S are here the electronegativities of the substituents (other than the hydrogen) bound to the phosphorus. Agreement of the calculated values [670 Hz for *(4a)*; 570 Hz for *(4b)* and *(4c)*] with the experimental values can be taken as confirmation of structure *(4)*.

Whereas for X = O the tautomeric equilibrium



always lies exclusively to the right-hand side, all the amino and imino derivatives so far prepared from phosphorus in the oxidation state +3 (X = N–) are stable only in the NH form, and not in the phosphazene form [4]. The compounds *(4)* are thus also the first hydrogen-substituted cyclophosphazenes. The factors governing the phosphazane/phosphazene tautomerism are currently being investigated.

Experimental:

An equimolar mixture of the diphosphazene *(1)* and the phosphonite *(2)* is slowly heated at 0.2 torr for one hour in a flask arranged for distillation. The phenol released distills into the receiver. The residue is recrystallized from benzene or acetonitrile, affording the cyclotriphosphazene *(4)* as colorless needles in 70–80 % yield.

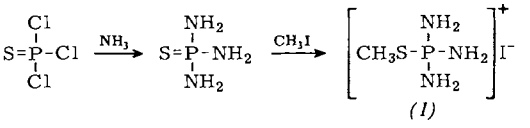
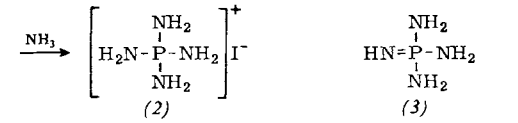
Preparation of Tetraaminophosphonium Salts by Ammonolysis of the Triamino(methylthio)-phosphonium Ion [1]

By *A. Schmidpeter* and *C. Weingand* [*]

Ammonolysis of PCl_5 is always accompanied by condensation and leads to amino-di- [2], -tri- [3,4], -tetra- [3], and -polyphosphazenes [3]. The imidophosphoric triamide *(3)* that is assumed as unstable monophosphazene intermediate [5] cannot be isolated in such experiments. It is obtained as its hydriodide *(2)* if the trifunctional $SPCl_3$ is used as starting material, instead of the tetra- or penta-functional PCl_5, for the ammonolysis, the sulfur function that remains in the resulting $SP(NH_2)_3$ [6] is activated by alkylation [7], and the fourth amino group is introduced by further, mild, ammonolysis.

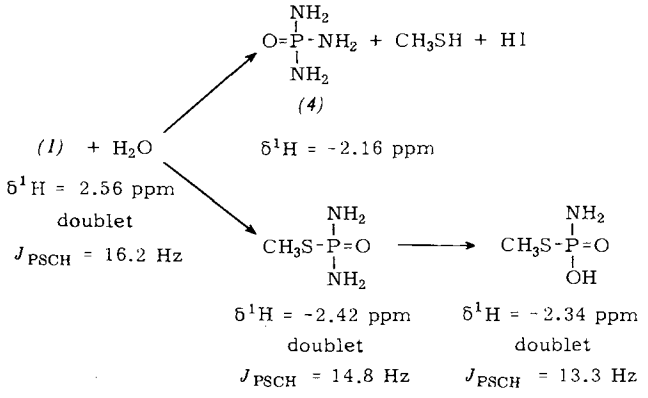


(1)



(2) *(3)*

The compound *(1)*[8] obtained from thiophosphoric triamide and methyl iodide is insoluble in organic solvents except aniline. In contrast to $SP(NH_2)_4$ it is rapidly decomposed by aliphatic amines, alcohols, and water. The half-reaction time for hydrolysis at 0 °C was determined by ^1H–NMR spectroscopy as approximately 20 minutes for a 40% solution in D_2O. The hydrolysis does not proceed uniformly; the methylthio group is only partly removed from the phosphorus atom, a somewhat smaller proportion remaining attached thereto. At room temperature hydrolysis is complete within a few minutes.



Chemical shifts in D_2O relative to TMS as external standard.

NH_3 reacts less fast, but removes methanethiol quantitatively. In methylene chloride ammonolysis of *(1)* leads smoothly to *(2)*, no condensation accompanying the substitution. This compound is unexpectedly stable thermally: it is altered only above 210 °C, and then without melting. It is soluble only in liquid ammonia (6 g/100 ml) and water. When warmed, the cation is rapidly hydrolyzed to $OP(NH_2)_3$, but in cold water it is stable to a considerable extent in contrast to the middle members[9] of the series $[(C_6H_5)_nP(NH_2)_{4-n}]^+$. It can be precipitated from aqueous solution as reineckate $[P(NH_2)_4]Cr(SCN)_4(NH_3)_2$ (pink, analytically pure) and as tetraphenylborate $[P(NH_2)_4]B(C_6H_5)_4$ [containing $NH_4B(C_6H_5)_4$ as impurity]. Further, by reaction with BiI_3 and HgI_2, pale red $[P(NH_2)_4]BiI_4$ and yellow $[P(NH_2)_4]_2HgI_4$ were obtained from *(2)*, and brown $[CH_3SP(NH_2)_3]BiI_4$ and yellow $[CH_3SP(NH_2)_3]_2HgI_4$ from *(1)*.

It has not yet been possible to obtain the underlying base *(3)*, the aza analog of phosphoric acid, from *(2)*. The base *(3)* does not come into question as an intermediate in the ammonolysis of PCl_5 since it is apparently a stronger base than NH_3. But use of an extremely high NH_3/PCl_5 ratio might lead to formation of its hydrochloride $[P(NH_2)_4]Cl$.

Triamino(methylthio)phosphonium iodide (1):

$SP(NH_2)_3$ (28 g, 0.25 mole) was stirred for 6 days at room temperature with CH_3I (45 g, 0.32 mole) and CH_3Cl (60 ml). The deposit was sucked off and washed with ether. The yield (63 g) is quantitative and the product is analytically pure. M.p. 161–162 °C with loss of CH_3SH lit.[8]: 159–160 °C.

Tetraaminophosphonium iodide (2):

A fast stream of NH_3 is passed into a vigorously stirred suspension of *(1)* (2.00 g) in CH_2Cl_2 (30 ml) for 2 h. On removal of the solution there remained 1.71 g of pure *(2)* (yield 98%). Incompletely reacted products can be purified by washing quickly with methanol warmed to 40 °C.

Radiospirometric Determination of the Oxidation *in vivo* of [17α-^{3}H]Testosterone and its Esters at C-17

By *M. Wenzel*, *L. Pitzel*, and *P.-E. Schulze*[*]

With the aid of "metabolism-labile" labeling by deuterium or tritium it has proved possible to elucidate the oxidation in a specific position of organic compounds within an organism by measuring the activity of the water in the expired air[1,2]. We used this method to determine the minimal oxidation of [17α-^{3}H]-testosterone and the minimal oxidation and rate of hydrolysis of its 17β-esters, testosterone acetate and heptanoate, in rats. The determination is based on the following reactions:

$$\text{[17α-}^3\text{H]Testosterone} + \frac{\text{DPN}}{\text{TPN}} \xrightarrow[\text{dehydrogenase}]{\text{17β-Steroid-}}$$

$$\text{4-Androstene-3,17-dione} + \frac{^3\text{H-DPN}}{^3\text{H-TPN}} \xrightarrow[\text{cycle}]{\text{Respiration}}$$

H^3HO in body water

The [17α-^{3}H]testosterone esters must be hydrolyzed in the organism before the testosterone can be oxidized.

If the amount of radioactivity injected, the weight of the experimental animal, and thus the total body water[2a] are known, then measuring the specific tritium activity in a distilled sample of body water permits the amount of steroid oxidized to be determined by means of the following calculation:

$$\frac{\mu\text{Ci per ml of distilled body water}}{\mu\text{Ci of injected steroid per ml of body water}} \cdot 100 = \text{minimal oxidation in \%}$$

Fig. 1 shows the rate of oxidation of [17α-^{3}H]testosterone[3], and of its 17β-acetate and 17β-heptanoate, determined in this way in an apparatus described previously[1,2].

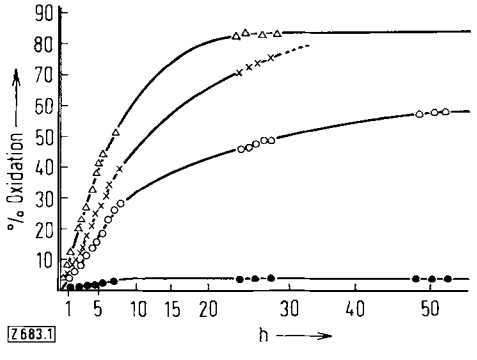

Fig. 1. Oxidation, *in vivo*, of [17α-^{3}H]testosterone (—Δ—Δ—), its acetate (—×—×—) and heptanoate (—O—O—), and of [7-^{3}H]testosterone (—•—•—) in male rats.
Injection of the steroids dissolved in propylene glycol and physiological saline (1:1); 0.5 ml intramuscularly.
Ordinate: % oxidation at C-7 or C-17.

According to these results, testosterone (at a dosage of 0.4 μmole/kg rat) is oxidized to the 17-ketone to the extent of at least 85% within 24 hours, whereas the acetate (0.35 μmole/kg) and heptanoate (0.6 μmole/kg) are hydrolyzed and oxidized to the 17-ketone only to the extent of 70 and 40%, respectively, during the same period.

These results are difficult to reconcile with concepts about the extended duration of action of hormone esters (*e.g.*, 28–30 days for testosterone heptanoate). The cause may be that in *Junckmann* and *Witzel*'s experiments[4] 1 to 5 mg of hormone per animal (12 to 60 μmole/kg) were injected, sometimes in oily suspension. It is possible that resorption, hydrolysis, and oxidation are reduced under these circumstances. We showed previously that the proportion oxidized decreases with increasing steroid dosage, even before the capacity of the 17β-hydroxysteroid dehydrogenase is exhausted[2].

If [7-^{3}H]testosterone (0.11 mg/kg) is injected into rats, no oxidation occurs at C-7 and therefore very little tritium is found in the body water (Fig. 1). This low labilization of tritium may be caused by a partial hydroxylation at C-7[5].

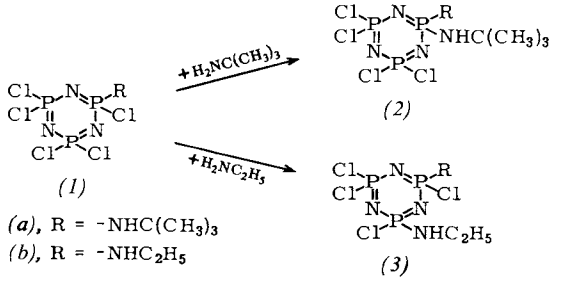
The Structure of the Products of Aminolysis of Aminopentachlorocyclotriphosphazenes

By *R. Keat*[*] and *R. A. Shaw*[**]

The pattern of replacement of the chlorine atoms in hexachlorocyclotriphosphazene by a number of different primary and secondary amines has been studied in some detail[1]. Widely differing replacement patterns have been observed with different alkylamines, even when members of the same class of amine were involved. In this connection we have studied the factor which determines the structure of the aminolysis product in the case of the amino derivatives *(1)*. The *tert*-butylamino-derivative *(1a)* gives with further *tert*-butylamine the geminal diamino-derivative *(2a)*[1f] whilst the monoethylamino-derivative *(1b)* yields with further ethylamine a non-geminal compound *(3b)*[1d].

On treatment of compound *(1a)* with ethylamine, a diamino-derivative, m.p. 68–70 °C, is obtained. When these two substituents are introduced in the reverse order, *i.e.* when *(1b)* is treated with *tert*-butylamine a diamino-derivative having m.p. 104–105 °C results. If the amino group already attached to the ring determines the point of entry of the second amino group then the lower melting isomer should be the geminal, and the higher melting isomer the non-geminal compound. In fact, the opposite is the case, *i.e.* the compound having m.p. 68–70 °C has the structure *(3a)* whilst the substance of m.p. 104–105 °C has the structure *(2b)*. This suggests that the nature of the nucleophile is, at least in the reactions reported here, a major structure determining factor.



(a), R = $-NHC(CH_3)_3$
(b), R = $-NHC_2H_5$

All compounds reported here had satisfactory analyses and their structures were determined by ^{1}H–NMR spectroscopy (cf. ref.[2]). Thin-layer chromatography showed that, in general, the compounds reported could be obtained in yields of more than 85%. Methods for the synthesis, the separation, and the determination of structure of this type of compound have been described previously[1e–1h, 2].

Trimethylsilyl Derivatives of Germanium and Tin. — Electron-balance Bonds of Silicon

By *H. Bürger* and *U. Goetze*[*]

Investigation of the electron-excess compounds of type $(R_3Si)_2E(VI)$ *(1)* and $(R_3Si)_3E(V)$ *(2)* [R = H or CH_3; E(VI) = O, S, Se, or Te; E(V) = N, P, As, or Sb] by structural analysis or spectroscopy has shown that the elements O and N use approximately sp- and sp^2-hybridized orbitals, respectively, whereas the other elements use preponderately p-orbitals for their bonds with the Si atom[1]; thus the valence parameters in the series *(1)* and *(2)* cannot be compared directly. However, in the electron-balance compounds $(R_3Si)_4E(IV)$ *(3)* the E atom is sp^3-hybridized; comparative observations for compounds of type *(3)* are thus not falsified by differences in the s-character of the Si–E bonds.

We have completed the series *(3)* by preparing the compounds $[(CH_3)_3Si]_4Ge$ *(3c)* and $[(CH_3)_3Si]_4Sn$ *(3d)* and have examined them by IR, Raman, and ^{1}H–NMR spectroscopy in conjunction with $[(CH_3)_3Si]_4C$ *(3a)*[2] and $[(CH_3)_3Si]_4Si$ *(3b)*[3]. Compounds *(3c)* and *(3d)* were prepared similarly to *(3a)*[2] and *(3b)*[3]:

$$Cl_4E(IV) + 8\,Li + 4\,(CH_3)_3SiCl \xrightarrow{THF} 8\,LiCl + (3)$$

When E(IV) = Ge or Sn the reduction

$$Cl_4E(IV) + 4\,Li \rightarrow E(IV) + 4\,LiCl$$

also occurs, so that 50% of the Ge used or 80% of the Sn used is recovered as metal. Calculated on the proportion of reaction that leads to linkage, the yields are 70% for *(3c)* and 50–60% for *(3d)*. Like *(3a)* and *(3b)*, the compounds *(3c)* and *(3d)*, which are spherical top molecules, colorless, crystallizing well from CH_3CN, and subliming at 60 °C/10^{-4} torr, have unusually high melting points and volatility. They are decomposed by KOH to $(GeH_2)_x$ and Sn, respectively. Alcohol and H_2O attack them more slowly than in the case of *(3b)*.

	$[(CH_3)_3Si]_4E$(IV) E(IV) =	M.p. (°C) [a]	^{1}H–NMR $\delta \pm 0.01$	$J(^1H^{13}C) \pm 0.5$ (Hz)	$J(^1H^{29}Si) \pm 0.1$ (Hz)	$J(^1HE(IV))$ (Hz)
(3a)	C	305–307 [2]	0.23 [b] 0.2 [2]	119.5	6.3	^{13}C (1.4 [c])
(3b)	Si	319–321 [3]	0.21	120.0	6.5	^{29}Si: 2.2 ± 0.1
(3c)	Ge	295	0.24	120.5	6.7	—
(3d)	Sn	235–236	0.29	120.7	6.7	^{119}Sn: 22.2 ± 0.2 ^{117}Sn: 21.5 ± 0.2

[a] In molten capillaries.
[b] 25% Solution in CCl_4, TMS and cyclohexane as internal standards, Varian A 60.
[c] Limit of resolution power.

The ^{1}H–NMR spectra show a steady progression of all δ- and *J*-values and no irregularities as for compounds *(1)* and *(2)*. The vibrations of the Si_4E(IV) skeleton obey the selection rules for ideal tetrahedrons. The fundamentals ν_1 to ν_4 are at the following frequencies (in $cm^{-1} \pm 2\ cm^{-1}$):

	ν_1	ν_2	ν_3	ν_4
(3a)	382	151	673	176
(3b)	328	90	457	101
(3c)	319	68	361	89
(3d)	311	58	330	73

The positions of the stretching vibrations confirm qualitatively that, in spite of the lower polarity, the (sp^3)Si-(sp^3)Sn σ-bond in *(3d)* (ν = 326 cm^{-1}) is stronger than the (sp^3)Si-(sp^3)Sb bond in $[(CH_3)_3Si]_3Sb$ (ν = 319 cm^{-1}), whereas the Si–C bond in *(3a)* is appreciably weaker than the Si–N bond in $[(CH_3)_3Si]_3N$ because the former has less s-character and less polarity and no π-contribution to strengthen it. We shall report the force constants of *(3a)–(3d)* together with the complete analysis of the vibration spectra in a future communication.

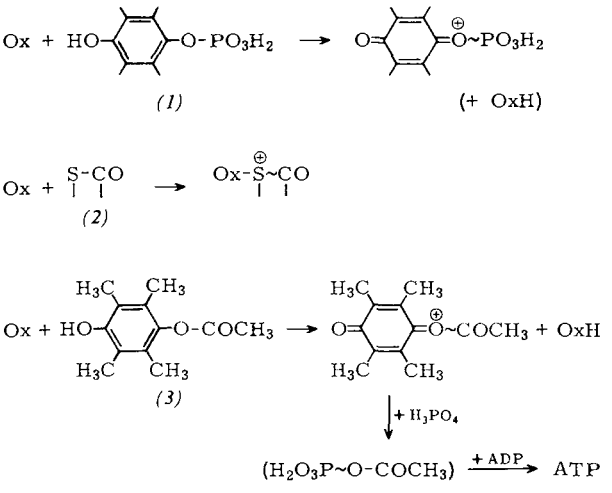
Formation of Adenosine Triphosphate (ATP) from Adenosine Diphosphate (ADP) and Phosphate during Oxidation of Durohydroquinone Monoacetate[1]

By *Th. Wieland* and *H. Aquila*[*]

We have demonstrated the conversion of oxidation energy into a high group-transfer potential[2] for the case of formation of an energy-rich phosphoryl linkage, H_2O_3P–X, during oxidation of *S*-phosphoryl thiols[3] or hydroquinone monophosphoric esters *(1)*[4]. Energy-rich acyl groups (which can transfer their acyl group to phosphoric acid) are formed similarly during the action of oxidizing agents on *S*-acyl compounds such as thiolactones *(2)*[2,5].

The use of hydroquinone for oxidative formation of activated acyl groups also makes it possible to obtain ATP from ADP and phosphate. In our reaction system the energy-rich acetyl group produced by oxidizing durohydroquinone monoacetate *(3)* with bromine or tetrabromo-*o*-benzoquinone reacts with phosphate (or ADP) to give acetyl phosphate (or acetyl-ADP), which reacts with ADP (or phosphate) to give ATP.



Formation of acetic anhydride on oxidation of 2-methyl-1,4-naphthohydroquinone-1-acetate by *N*-bromosuccinimide in glacial acetic acid has recently been described by *Thanassi* and *Cohen*[6].

We obtained durohydroquinone monoacetate *(3)* in *ca.* 35% yield by acetylation of durohydroquinone at 0 °C with acetyl chloride in pyridine, together with the diacetate from which it was separated by utilizing its slower rate of migration on chromatography on silica gel with chloroform as eluant. Recrystallization from ethanol/water and then from benzene gave material melting at 146.5–147.5 °C.

For oxidative phosphorylation 48 mg (0.1 mmole) of ADP·$3H_2O$ (C.F. Boehringer und Soehne, Mannheim-Waldhof), 0.87 ml of a 0.115 M solution of 85% phosphoric acid in dioxane, and 5 ml of a 0.1 M solution of tetrabutylammonium hydroxide in propan-2-ol (Merck, Darmstadt) were placed in a 50-ml flask and evaporated on a rotary apparatus in a vacuum. The residue was moistened with ethanol and the latter was then removed. After this procedure had been repeated several times, the residue was dried for 5 h at oil-pump vacuum over P_2O_5 and solid KOH in a desiccator; it was then dissolved in 5 ml of pyridine (dried over CaH_2) and, after addition of 20.8 mg of durohydroquinone monoacetate, treated with 0.014 ml (0.25 mmole) of bromine or 47 mg (0.11 mmole) of tetrabromo-*o*-benzoquinone with ice cooling and magnetic stirring. The mixture was stirred in the ice-bath for half an hour and for a further 1.5 h at 20 °C then evaporated in a vacuum. The residue dissolved wholly in 2.0 ml of methanol. 0.5 ml of this solution was placed on a 20 cm × 20 cm thin-layer plate (0.5 mm of silica gel HF_{254}, Merck), and the chromatogram was developed first with chloroform/methanol (10:3), then dried with a fan, and fur-

ther developed with propan-1-ol/conc. ammonia/water (6:3:1). After drying, the lower fluorescence-quenching ATP zone was removed and the silica gel was eluted with 25 ml of 0.05 M Tris buffer (pH = 7.55). The yields of ATP determined enzymically [7] and referred to the ADP used were: on oxidation with bromine 6.0 and 6.8%; on oxidation with tetrabromo-*o*-benzoquinone 9.5%; without oxidizing agent 0.0%; and without acetyldurohydroquinone monoacetate 0.0%.

Syntheses by Means of 1-Alkylidene- and 1-(Arylalkylidene)-3-pyrazolidone *N,N*-Betaines, a New Type of Stable Azomethine Imine

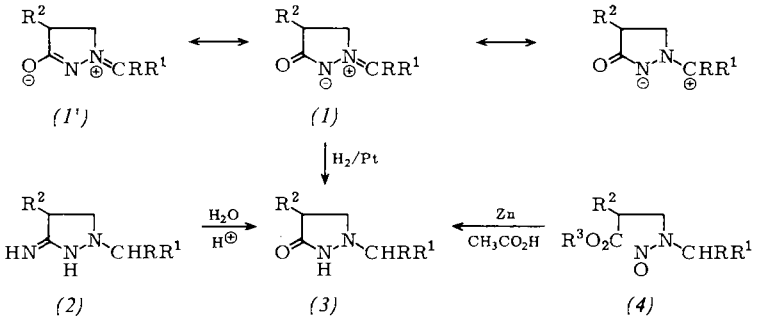
By *H. Dorn* and *A. Otto*

Azomethine imines have, it is true, been postulated as intermediates in the formation of hexahydro-1,2,4,5-tetrazines from 1,2-disubstituted hydrazines and aldehydes [1], but they have been isolated in only two cases, namely, as deep blue "anhydro bases" from *N*-(arylamino)pyridinium iodides [2] and as orange-red products from arenediazo cyanides and diazofluorene [3]. We have found that stable azomethine imines are obtained very simply from 3-pyrazolidone and carbonyl compounds in 80–90% yield. This reaction is generally applicable; it takes place exothermally and either without a solvent or in methanol. The crystalline azomethine imines *(1)* are dried in a vacuum over P_4O_{10} and then recrystallized from alcohols or dioxane. They are colorless unless substituents R^1 are introduced that deepen color (NO_2, 4-dialkylamino).

Because of their molecular weights and their chemical behavior the products *(1)* cannot be either hexahydro-1,2,4,5-tetrazines or β-lactams. Their acid-catalyzed hydrolysis regenerates the starting materials quantitatively. Catalytic hydrogenation (methanol, Adams Pt, atmospheric pressure) leads to quantitative yields of 1-substituted 3-pyrazolidones *(3)*. Since 3-pyrazolidone [4] and its *C*-alkyl derivatives [5] have recently become readily accessible, this reaction offers a very simple synthesis of 1-substituted 3-pyrazolidones [6].

The position of CRR^1 in *(1)* and *(3)* follows from synthesis of *(3a)* and *(3b)* by way of the 3-amino-*N*-nitrosopropionic ester *(4)* and of *(3c)* by acid hydrolysis of 1-benzyl-3-iminopyrazolidine *(2c)* which is obtained by cyclization of 1-benzyl-1-(2-cyanoethyl)hydrazine [7].

In agreement with the azomethine imine structure, the IR spectra of *(1)* contain intense bands at 1670 and 1600 cm^{-1}, of which the latter, more intense, band is to be assigned to the carbonyl vibration. Their shift to lower frequencies compared with the bands of the corresponding pyrazolidones indicates participation of the limiting structure *(1')*. The NMR spectra of *(1a)*, *(1c)*, and *(1e)*, and of compounds analogous to *(1b)* that are synthesized from 2,2,6,6-tetradeuteriocyclohexanone correspond to the azomethine imine structure *(1)*; *(1a)* (in $CDCl_3$) shows two singlets at $\tau = 7.62$ and 7.73 for the two methyl groups.



(1') *(1)* *(2)* *(3)* *(4)*

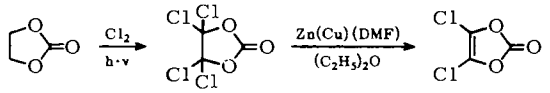
Syntheses by Means of Dichlorovinylene Carbonate (4,5-Dichloro-1,3-dioxol-2-one) as Dienophile and Photocyclophile [**]

By *H.-D. Scharf*, *W. Droste*, and *R. Liebig* [*]

We have prepared the hitherto unknown dichlorovinylene carbonate (4,5-dichloro-1,3-dioxol-2-one) *(3)* in good yield by the following route:

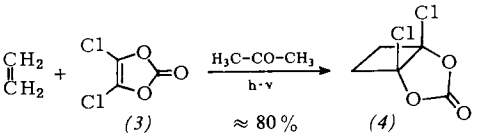


(1) *(2)* *(3)*

Exhaustive chlorination of the readily accessible ethylene carbonate *(1)* by *Ellingboe* and *Melby*'s method [1] leads to the tetrachloro-derivative *(2)* which reacts with a copper-zinc couple in ether in presence of catalytic amounts of dimethylformamide to give the compound *(3)* with loss of chlorine. This product is a colorless, lachrymatory liquid of b.p. 39–40 °C/10 torr, $n_D^{28} = 1.4602$, which crystallizes below room temperature. Its IR carbonyl vibration [2] is at 1890 cm^{-1}. The molecular weight, determined mass-spectrometrically, is 154, corresponding to the formula $C_3O_3Cl_2$ for the chlorine isotope 35.

Photocycloaddition to ethylene:

On irradiation [3], *(3)* reacts with ethylene [4] in acetone at room temperature, giving the cycloadduct *(4)* smoothly:

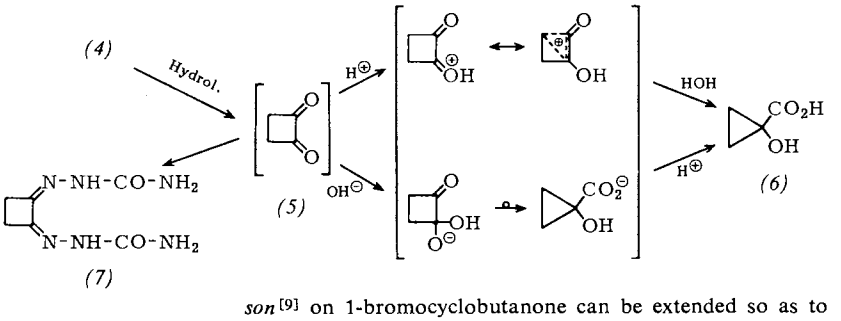


(3) ≈ 80 % *(4)*

1,2-Dichloro-1,2-cyclobutylene carbonate (3a,5a-dichloro-3a,4,5,5a-tetrahydrocyclobuta[*d*]-[1,3]-dioxol-2-one) *(4)* forms colorless crystals (m.p. 50 °C). The expected AA'BB' NMR spectrum of the four protons [5] collapses to a singlet at $\tau = 7.05$ because the shielding of the proton pairs above and below the ring is apparently comparable. The spin coupling type [6] can be recognized by scale expansion of the signal. IR absorption [2] (CCl_4): γ_{CO} at 1885 cm^{-1}. The C–H skeletal vibrations correspond to the values given by *Mery* and *McCleon* [7] for the cyclobutane ring; namely, C–H stretching vibration at 3010 and 2960 cm^{-1}, deformation vibration of the H–C–H angle at 1420 cm^{-1}, deformation vibration of the four-membered ring at 1230 cm^{-1}.

On dissolution of *(4)* in cold dilute KOH and subsequent acidification, or on its dissolution in HCl, 1-hydroxycyclopropanecarboxylic acid *(6)* is formed as sole product.

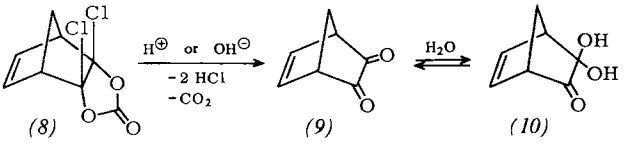
Since this reaction corresponds formally to a Favorskii rearrangement but takes place in both pH ranges, the observations made by *Conia* and *Ripoll* [8] and by *Rappe* and *Knutson* [9] on 1-bromocyclobutanone can be extended so as to indicate that the dione *(5)* is formed as intermediate and rearranges in acid by way of a dicyclobutonium ion but in alkali by the benzilic acid mechanism. The diketone *(5)* can be trapped as bissemicarbazone *(7)* [10], which is in agreement with the above assumptions.



(4) *(5)* *(6)* *(7)*

Compound *(6)* has m.p. 106 °C. Its structure was proved by comparison of its ^1H–NMR spectrum with the data of *Wiberg* and *Nist* [11].

Diels-Alder reaction with cyclopentadiene:



(8) *(9)* *(10)*

The thermal diene reaction of *(3)* with cyclopentadiene in boiling dioxane gives the *endo*-bicyclo[2.2.1]heptene derivative *(8)*, which forms colorless crystals of m.p. 147 °C. Its structure follows from the ^1H–NMR spectrum [5]. This spectrum shows three triplets of equal area at $\tau = 3.6$, 6.4, and 7.85, which are to be assigned to the olefinic, tertiary, and methylene protons. The methylene protons here do not constitute an AB system because of the comparable shielding.

Treating *(8)* with hydrochloric acid or alkali affords the hitherto unknown bicyclo[2.2.1]heptene-2,3-dione *(9)*, which

is formally a homo-*ortho*-quinone. After distillation, the dione *(9)* is a yellowish-red oil which slowly crystallizes. The yellow crystals melt at 35 °C[12]. The ^{1}H–NMR spectrum[5] of the diketone shows a triplet at $\tau = 3.55$ for the two olefinic protons, a quintuplet at $\tau = 6.8$ for the two tertiary protons, and for the two methylene protons an AB system with shielding parameters $\tau = 7.1$ and 7.5 and a geminal coupling of 11 Hz; the B part of the system is split by 2-Hz coupling with the tertiary protons.

In D_2O the signals are changed in a characteristic way. The olefinic protons now form an AB system, whose components are centered at $\tau = 3.35$ and 3.73. The vicinal coupling of the two protons amounts to 6 Hz. Each component is again split by a 3-Hz coupling, which one finds again in the two, now separated multiplets for the tertiary protons at $\tau = 6.73$ and 6.85. The two methylene protons appear as a singlet at $\tau = 7.6$, which is split by a long-range coupling (*ca.* 1 Hz) with the two tertiary protons and the A component of the olefinic protons.

On addition of water a hydroxyl-proton signal appears at $\tau = 5.15$, which indicates that a carbonyl group of the diketone *(9)* is hydrated in aqueous solution, giving compound *(10)*. In this way we explain the reversible thermochromic behavior of dilute aqueous solutions of *(9)*, which are colorless *(10)* at 0–5 °C but deep yellow *(9)* at 80 °C.

The dione *(9)* is formally a Diels-Alder adduct of cyclopentadiene with dicarbon dioxide O=C=C=O, which is so far known only in derivatives[13]. This unknown carbon oxide occurs masked in the dichlorovinylene carbonate *(3)*, so that its thermal and photochemical cycloadditions can be simulated by *(3)*.

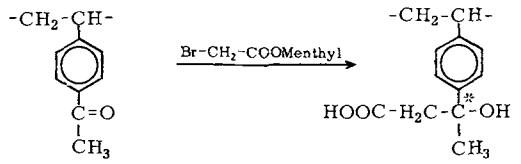
Asymmetric Reduction of Polyvinylacetophenone[**]

By *Rolf C. Schulz*[***] and *H. Mayerhöfer*[*]

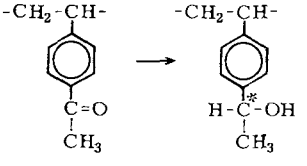
Asymmetric syntheses have so far been described only for compounds of low molecular weight. We have applied such reactions to macromolecular substances, in order to obtain optically active polymers.

The Reformatsky reaction between menthyl bromoacetate and acetophenone described by *Reid* and *Turner*[1] was applied to polyvinylacetophenone *(1)*. It could be shown by IR spectroscopy that the reaction took the expected course; however, since only insoluble polymers resulted, no value for the optical rotation or the optical yield could be determined.



(1)

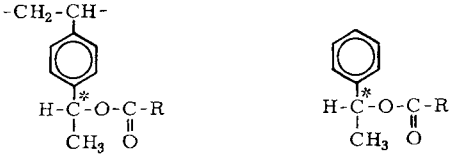
Since reduction of *(1)* by lithium aluminum hydride led to soluble poly-[4-(2-hydroxyethyl)styrene] *(2)*, an attempt was made to direct this reaction sterically. Products from $LiAlH_4$ and chiral alcohols [2,3] came into consideration as reducing agents. We used 1,2-*O*-cyclohexylidene-α-D-glucofuranose[2a] or quinine. In model reactions with acetophenone the optical yields of α-methylbenzyl alcohol were 15 % and 48 %, respectively.



(1) *(2)*

Spectroscopy and elemental analysis of derivatives of the reduction product *(2)* showed that all the keto groups were reduced. The asymmetric reagents could be separated by dialysis or precipitation from the polymers that were soluble in tetrahydrofuran or methanol. When the glucose derivative was used, the polymer *(2)* obtained was levorotatory. Reduction with $LiAlH_4$/quinine proved more advantageous; it afforded a dextrorotatory polymer *(2)*: $[\alpha]_{589} = +3.86$, $[\alpha]_{500} = +5.92$ ($c = 3.000$ in THF). If one assumes that the optically pure polymer has the same rotation as (+)-α-methylbenzyl alcohol ($[\alpha]_{589} = +43.3$, homogeneous; $[\alpha]_{500} = +65.5$, homogeneous)[4], then an optical yield of 9 % can be calculated.

To confirm this finding, derivatives of *(2)* and (+)-α-methylbenzyl alcohol were prepared. The *p*-nitrobenzoate *(3a)* of the polymer and of (+)-α-methylbenzyl alcohol *(4a)* have small negative rotations. However, the rotation of the polymer and of (+)-α-methylbenzyl alcohol are approximately doubled on reaction with phenyl isocyanate.



(3) *(4)*

(a), R = *(b)*, R =

(3b): $[\alpha]_{589} = +6.58$ ($c = 1.0$ in THF)
$[\alpha]_{500} = +9.8$ ($c = 1.0$ in THF)

(4b): $[\alpha]_{589} = +101.5$ ($c = 4.864$ in benzene) [5]
$[\alpha]_{589} = +40.8$ ($c = 4.88$ in benzene) 40.3 % optical purity
$[\alpha]_{500} = +57.4$ ($c = 4.88$ in benzene) 40.3 % optical purity
$[\alpha]_{500} = +39.8$ ($c = 4.88$ in THF) 40.3 % optical purity

From the rotations of the urethanes *(3b)* and *(4b)* the optical yield for the asymmetric reduction of polyvinylacetophenone *(1)* is 9.8 %. The agreement between the optical yields leads

to the conclusion that an asymmetric synthesis of the polymer has in fact been achieved.

These results demonstrate a new method for the synthesis of optically active polymers.

Experimental:

Polyvinylacetophenone was prepared according to *Kenyon*[6], and (+)-α-methylbenzyl alcohol according to *Červinka*[3] with $[\alpha]_{589} = +19.5°$ (homogeneous), in 45–48 % optical yield.

(+)-Poly-[4-(2-hydroxyethyl)styrene] *(2)*:

$LiAlH_4$ (2.112 g, 0.0553 mole) was suspended in tetrahydrofuran (250 ml), quinine ($[\alpha]_D = -172°$; 16.2 g, 0.05 mole) was added, and the mixture was boiled for 10 min. A solution of *(1)* (4 g, 0.0274 unit mole) in tetrahydrofuran (50 ml) was added dropwise during 10 min and the whole boiled under reflux for 6 h. The polymer was precipitated by pouring the mixture into 3 % sulfuric acid and was reprecipitated from tetrahydrofuran by 3 % sulfuric acid and then from tetrahydrofuran by saturated sodium hydrogen carbonate solution and water. Yield 2.5 g.

Formation of Polymethyl(methylene)aluminum

By *H. Sinn*[*], *H. Hinck*[*], *F. Bandermann*[*], and *H. F. Grützmacher*[**]

Complex formation between biscyclopentadienyltitanium(IV) compounds (Cp_2TiCl_2 and $Cp_2TiClCH_3$) and trimethylaluminum has a half-reaction time of $< 10^{-2}$ seconds even at −45 °C. In both cases the complex formation is accompanied by a very slow reaction. This is indicated by development of an absorption band at 460 nm which is at first synchronous with an evolution of methane. It thus seemed likely that the reaction should be considered as formation of the compounds with CH_2 bridges between Ti and Al that *C. Feay*[1] had isolated.

However, we observed that further methane was evolved after the band at 460 nm had developed; the reaction was therefore studied without use of a solvent and with a large excess of $Al(CH_3)_3$. The rate of initial evolution of methane followed the rate law:

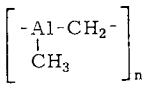
$$d[CH_4]/dt = k[Ti][Al(CH_3)_3]^{0.5}$$

If the initial molar ratio $Cp_2TiCl_2/Al(CH_3)_3$ was 1:100, the evolution of methane increased after *ca.* 100 hours at room temperature. The viscosity of the mixture increased from 0.9 cp to > 100 cp; after 350 hours the reaction mass solidified, yet slowly evolved more methane. In sum, almost 1 mole of methane was liberated per mole of $Al(CH_3)_3$.

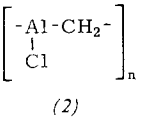
The solidified mass does not dissolve in petroleum ether, and swells in benzene; components of low molecular weight and products formed from the titanium compound are removed by extraction in a glass Soxhlet apparatus with benzene. The residue is a pale greyish powder with the composition C_2H_5Al. It reacts quantitatively with deuterium chloride:

$$C_2H_5Al + 3\,DCl \rightarrow AlCl_3 + D_2CH_2 + DCH_3$$

We therefore propose formula *(1)*, where *n* is probably about 100. (If this were not so, more DCH_3, would be formed by reaction with the end groups.)



(1)



(2)

In this connection the compound *(2)* that was obtained by *H. Lehmkuhl* and *R. Schaefer*[2] by a quite different route should be noted.

Before the extraction, the reaction mass evolves only traces of $Al(CH_3)_3$ in a high vacuum. It dissolves in tetrahydrofuran. Viscosity determination (on the basis of the Staudinger relation that is valid for polystyrene) gave a mean degree of polymerization $P_n = 1/(1-p) = 20$, corresponding to a degree of reaction $p = 0.95$, whereas we expected $p = 0.85$ to 0.90 on the basis of the amount of methane evolved.

The extraction residue, swollen and suspended in benzene, reacts with titanium tetrachloride with formation of a voluminous, almost black, mass. A suspension of this compound in hydrocarbons is an efficient catalyst for the polyreaction of ethylene and α-olefins.

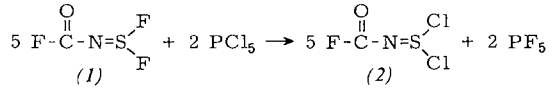
N-(Fluoroformyl)iminosulfur Dichloride and *N*-(Chloroformyl)iminosulfur Dichloride

By *H. W. Roesky* and *R. Mews*[*]

As part of our study of sulfur-nitrogen compounds[1] we have prepared iminosulfur dichlorides $-N{=}SCl_2$ from the corresponding fluoro derivatives. *N*-(Fluoroformyl)iminosulfur difluoride *(1)* [2] reacts with phosphorus pentachloride at room temperature, giving *N*-(fluoroformyl)iminosulfur dichloride *(2)* and phosphorus pentafluoride.



(1) *(2)*

33 g of *(1)* is added dropwise with ice cooling to 23.1 g of PCl_5. The mixture is then stirred for 2 h at 0 °C and for 24 h at room temperature. The volatile products are removed in a

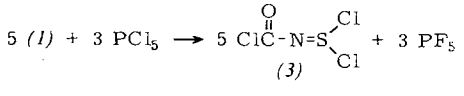
high vacuum at room temperature and trapped at −80 °C (acetone/Dry Ice) and −196 °C (liquid nitrogen). The contents of the (−80 °C)-trap (31.6 g) were fractionated at water-pump vacuum through a 25-cm packed column: b.p. 42 to 44 °C/12–14 mm; yield 26 g (61 %); molecular weight 162 (cryoscopic in benzene; theor. 164).

Compound *(2)* is a pale yellow liquid, which reacts with V4A steel with decomposition. The compound *(1)* reacts also with aluminum trichloride to give *(2)*, but in this case only a low yield of product is obtained.

The IR spectrum (capillary film) in the NaCl and KBr region includes bands at 1800 (vs), 1240 (vs), 1120 (with shoulder, vs), 838 (vs), 760 (vs), 655 (m), 628 (w), 590 (w), 535 (w), 495 (m), and 440 (vs) cm^{-1}.

The ^{19}F–NMR spectrum includes a singlet at $\delta_F = -19.8$ ppm against CCl_3F as external standard.

Reaction of *(1)* with PCl_5 at 40 to 60 °C gives *N*-(chloroformyl)iminosulfur dichloride *(3)*:



$$5\ (1) + 3\ PCl_5 \longrightarrow 5\ ClC(=O)-N=SCl_2\ (3) + 3\ PF_5$$

27 g of *(1)* is added slowly with ice cooling to 28 g of PCl_5. The mixture is then stirred for 12 h at 40 °C and for 10 h at 60 °C. A clear solution results which is worked up as described above. B.p. 32 °C/1.5 torr; m.p. −7 °C (great tendency to supercooling); yield 19 g (51 %); molecular weight 181 (cryoscopic in benzene; theor. 180.5). Compound *(3)* is a yellow liquid. The IR spectrum shows bands at 2300 (w), 1740 (vs), 1255 (m), 1170 (vs), 947 (s), 755 (s), 670 (m), 540 (w), and 425 (s) cm^{-1}.

Tentative assignments for *(2)* and *(3)* are: vibrations at 1800 and 1740 ν(CO), 1240 and 1170 ν(N=S), 1120 ν(CF), 947 ν(CCl), and 440 and 425 cm^{-1} ν(SCl).

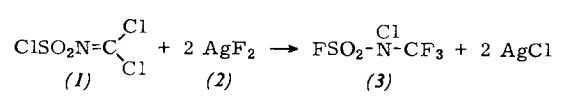
N-Chloro-*N*-(trifluoromethyl)-fluorosulfonamide [1]

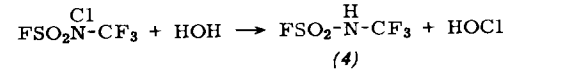
By *H. W. Roesky* [*]

N-(Dichloromethylene)chlorosulfonamide *(1)* [2] reacts with silver difluoride *(2)* to give *N*-chloro-*N*-(trifluoromethyl)-fluorosulfonamide *(3)* in 22% yield.



$$ClSO_2N=C(Cl)Cl\ (1) + 2\ AgF_2\ (2) \longrightarrow FSO_2-N(Cl)-CF_3\ (3) + 2\ AgCl$$

The compound *(3)* is a slightly yellow liquid having an unpleasant pungent odor. It liberates bromine from aqueous potassium bromide solution. The first step in the hydrolysis of *(3)* is the formation of hypochlorous acid.



$$FSO_2N(Cl)-CF_3 + HOH \longrightarrow FSO_2-N(H)-CF_3\ (4) + HOCl$$

N-Trifluoromethylfluorosulfonamide *(4)* could be isolated as the tetraphenylphosphonium salt [2].

The temperature-dependence of the vapor pressure of *(3)* between −20 and +15 °C gives the vapor pressure equation

$$\log p_{torr} = (-1503/T) + 7.31$$

The heat of vaporization of *(3)* is $\Delta H = 6850$ cal/mole and the Trouton constant is approximately 22.2 cal/deg. The extrapolated boiling point found from the vapor pressure curve is 33.9 °C, while the experimental value is 31–33 °C [3].

Elemental analysis verifies the composition of *(3)*. The mass spectrum shows fragments [4] at $m/e = 166$ (FSO_2NCF_3), 147 (FSO_2NCF_2 or SO_2NCF_3), and 83 (FSO_2 or NCF_3).

The ^{19}F–NMR spectrum of *(3)* gives a doublet at $\delta_F = 61.6$ ppm for the CF_3 group and a quartet at $\delta_F = -44.8$ ppm for the SO_2F group against CCl_3F as the external standard. The intensity ratio is 3:1. The coupling constant J_{FF} is 6.5 Hz. The following absorptions occur in the NaCl and KBr region of the IR spectrum (capillary film with AgCl plates): 1630 (w), 1595 (w), 1578 (w), 1480 vs), 1420 (w), 1280 (vs), 1250 (s), 1210 (vs), 1160 (vs), 1090 (w), 975 (vs), 930 (w), 810 (vs), 740 (w), 600 (vs), 565 (w), 525 (w), and 490 (w) cm^{-1} [5].

Procedure:

0.2 mole of *(1)* is added dropwise from a dropping funnel to an excess of silver difluoride in a two-neck flask, with stirring by a magnetic stirrer. The second neck of the flask carries a distillation head with a collecting flask followed by two condensation traps (cooled with acetone/Dry Ice). A yellow liquid collects in the receiver and in the first trap. NO_2 and SO_2F_2 are present as impurities. After the first trap has warmed to room temperature, the liquids are combined and fractionated in a packed column 30 cm long.

Simple Synthesis of Oligomeric Phenyl-phosphines and -arsines

By *H. Schumann, A. Roth*, and *O. Stelzer* [*]

Oligomeric organo-phosphines and -arsines of defined composition have hardly been known hitherto. As well as tetra-organo-diphosphines and -diarsines and cyclic oligomers, only pentaphenyltriphosphane [1] has been described, though the possible formation of a tris(diphenylphosphino)arsine [2] has recently been mentioned. We have now found, in treatment of organostannylphosphines and organostannylarsines with phenylphosphorus chloride or phenylarsenic chloride, a simple process that makes readily accessible good yields of pure stable compounds with 2, 3, or 4 phosphorus or arsenic atoms linked to each other.

Tris(trimethylstannyl)-phosphine and -arsine in ethereal solution under an argon atmosphere react at room temperature with diphenylphosphorus chloride or diphenylarsenic chloride with elimination of trimethyl tin chloride and

formation of tris(diphenylphosphino)-phosphine *(1a)* and -arsine *(1b)* or tris(diphenylarsino)-phosphine *(1c)* and -arsine *(1d)*, respectively:

$$[(CH_3)_3Sn]_3R + 3\,(C_6H_5)_2XCl \rightarrow \underset{\displaystyle X(C_6H_5)_2}{\overset{\displaystyle (C_6H_5)_2X \quad X(C_6H_5)_2}{R}} + 3\,(CH_3)_3SnCl$$

(1)

	X	R	M.p. (°C)	Yield (%)
(a)	P	P	118–120	85
(b)	P	As	120–123	59
(c)	As	P	169–172	60
(d)	As	As	143–147	51

After being stirred for 6 h the ethereal solutions were evaporated in a vacuum, and the products were precipitated by addition of pentane. Trimethyltin chloride can be isolated in quantitative yield from the filtrate. The compounds *(1a)–(1d)*, obtained in pure form after repeated reprecipitation from ether/pentane, are extremely sensitive to oxygen and decompose with yellow coloration immediately on access to air; after decomposition of *(1a)*, triphenylphosphine, tetraphenyldiphosphine, and yellow phenylphosphine $(C_6H_5P)_n$ were isolated.

Analogously, reaction of diphenylphosphorus chloride or diphenylarsenic chloride with phenyl bis(trimethylstannyl)-phosphine or phenylbis(trimethylstannyl)arsine[3] afforded syntheses of the new compounds bis(diphenylarsino)phenylphosphine *(2a)*, bis(diphenylphosphino)phenylarsine *(2b)*, and bis(diphenylarsino)phenylarsine *(2c)*; reaction of diphenylphosphorus chloride with diphenyl(trimethylstannyl)-arsine gave (diphenylphosphino)diphenylarsine *(3)*:

$$[(CH_3)_3Sn]_2RC_6H_5 + 2\,(C_6H_5)_2XCl \rightarrow \underset{\displaystyle C_6H_5}{\overset{\displaystyle (C_6H_5)_2X \quad X(C_6H_5)_2}{R}} + 2\,(CH_3)_3SnCl$$

(2)

	X	R	M.p. (°C)	Yield (%)
(a)	As	P	155–158	90
(b)	P	As	125–129	66
(c)	As	As	185–190	65

$$(CH_3)_3Sn{-}As(C_6H_5)_2 + (C_6H_5)_2PCl \rightarrow (C_6H_5)_2P{-}As(C_6H_5)_2 + (CH_3)_3SnCl$$

(3), m.p. 115–117 °C, yield 71 %

The properties of compounds *(2a)–(2c)* and *(3)* are the same as those of three-fold substituted phosphines and arsines, but the sensitivity to oxygen decreases in the order $RX_3 \rightarrow RX_2 \rightarrow RX$, also with increasing substitution of the central atom R by phenyl groups.

In the pure state all the compounds are colorless crystalline substances that are found to dissolve without decomposition in diethyl ether, cyclohexane, and aromatic hydrocarbons. Their structures were proved by complete elemental analyses, cryoscopic determinations of molecular weight, and IR spectra[4]. In the IR spectra are found, not only the vibration bands of the phenyl nuclei dependent on the P and As substituents, but also the bands required by the C_{3v} symmetry $\nu_{as}RX_3$ and ν_sRX_3 at 486 and 427 cm^{-1} *(1a)*, 357 and 280 cm^{-1} *(1b)*, 311 and 274 cm^{-1} *(1c)*, and 285 and 262 cm^{-1} *(1d)*, the bands required by the C_{2v} symmetry $\nu_{as}RX_2$ and ν_sRX_2 at 354 and 282 cm^{-1} *(2a)*, 311 and 293 cm^{-1} *(2b)*, and 293 and 262 cm^{-1} *(2c)*, as well as the bands required for the C_s symmetry ν P–As at 353 cm^{-1} *(3)*.

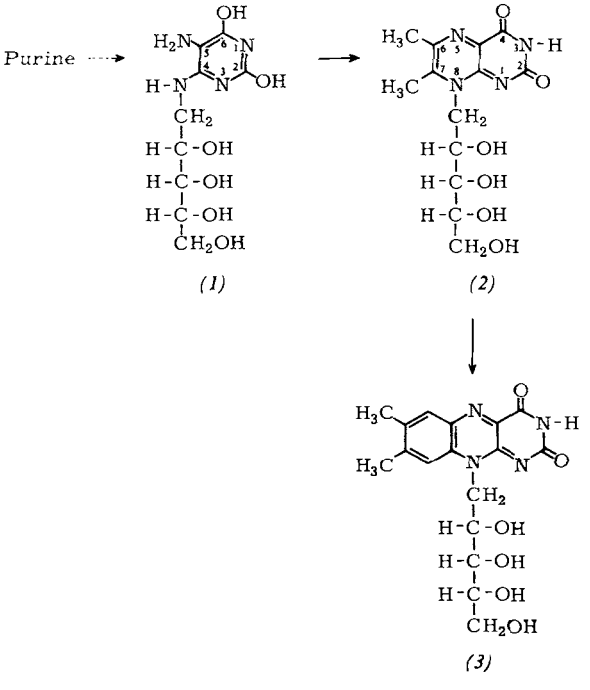
Accumulation of 2,5-Diamino-6-hydroxy-4-ribityl-aminopyrimidine in a Riboflavin-deficient Mutant of *Saccharomyces cerevisiae*

By *A. Bacher* and *F. Lingens*[*]

The biosynthesis of riboflavin *(3)* leads from a purine compound[1] by way of several intermediates to 5-amino-2,6-dihydroxy-4-ribitylaminopyrimidine *(1)*[2] and then to 6,7-dimethyl-8-rityllumazine *(2)*[3]. 4,5-diaminopyrimidine compounds were expected to be precursors of *(1)*.



We have shown that a riboflavin-deficient mutant of *Saccharomyces cerevisiae*, HK 859[4], forms an intensely blue-green fluorescing compound on incubation in minimal medium supplemented with biacetyl. This product, which is not formed in absence of biacetyl, was isolated as follows: The yeast was grown in minimal medium[4] supplemented with yeast extract, peptone, and riboflavin, centrifuged off, and incubated with fresh minimal medium containing 0.8 ml biacetyl per liter. The cell-free medium was placed on a column of Magnesiumsilikat "Woelm". The column was washed with deionized water and eluted with acetone/4 N ammonia (2:1). The eluate was evaporated to dryness in a vacuum and placed on a column of Dowex 50 Wx 8 (NH_4^+ form). The column was washed with deionized water and

eluted with 0.1 N phosphate buffer (pH = 7). The green-fluorescing fractions were combined and once more adsorbed on Magnesiumsilikat "Woelm" (elution as described above). Further purification was by chromatography on a column of CM-Sephadex C-25 (Na^+ form, elution with distilled water). The green-fluorescing fractions were combined and lyophilized. All operations were conducted in dim light in a darkroom.

The yellow compound thus obtained decomposed in aqueous solution in sunlight with separation of colorless crystals, which were identified as 2-amino-4-hydroxy-6,7-dimethylpteridine *(6)* by comparative thin-layer chromatography with six different solvents. Hydrolysis of the accumulated substance in 6 N HCl at 115 °C (24 h) yielded 6,7-dimethyllumazine *(7)*, which was identified in the same way. The UV spectrum of the accumulated substance closely resembled that of 2-amino-4,8-dihydro-6,7,8-trimethyl-4-oxopteridine. Measurement of the optical rotatory dispersion and the mass spectrum revealed close similarity to 6,7-dimethyl-8-ribityllumazine *(2)*. We thus assign to the accumulated compound the structure 2-amino-4,8-dihydro-6,7-dimethyl-4-oxo-8-ribitylpteridine *(5)*. Compound *(5)* was synthesized[5] and proved identical with the accumulated compound in UV and IR spectra and in R_F values in four different solvents.

These results lead us to the conclusion that the mutant investigated originally accumulates 2,5-diamino-6-hydroxy-4-ribitylaminopyrimidine *(4)*.

We assume that *(4)* or a phosphoric ester of *(4)* is an intermediate in riboflavin biosynthesis and is converted by enzymatic deamination into the 5-amino-2,6-dihydroxy-4-ribitylaminopyrimidine *(1)* previously detected[2]. We further assume that riboflavin is formed from a guanine compound rather than from a xanthine compound as supposed hitherto[6].

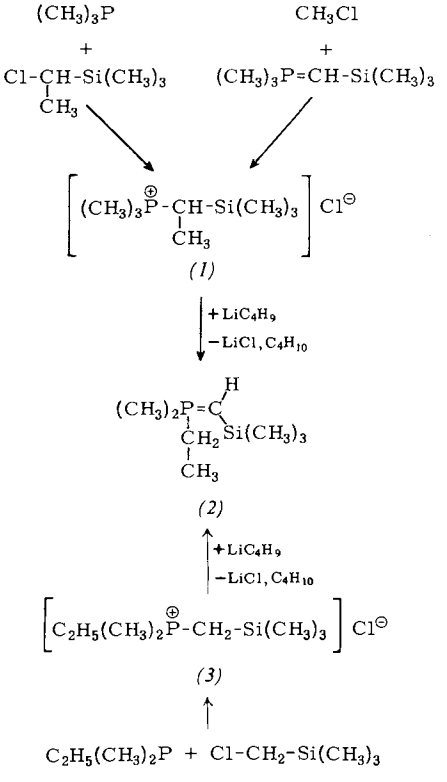
Silyl Shift in Phosphorus Ylides

By *H. Schmidbaur* and *W. Tronich* [*]

The ylide function in trialkylalkylidenephosphoranes is stabilized by silyl residues and destabilized by alkyl residues[1]. While examining the combined effects of silyl and alkyl ligands on an ylide C atom in alkylidenephosphoranes, we discovered a new type of 1,3-silyl shift.

1-(Trimethylsilyl)ethyltrimethylphosphonium chloride *(1)* can be obtained from trimethylphosphine and 1-chloroethyltrimethylsilane under mild conditions (8 days, < 50 °C). The same product is obtainable in quantitative yield from trimethyl(trimethylsilylmethylene)phosphorane[1] and methyl chloride (1 day, −30 °C). Volatile impurities are removed in a vacuum to leave colorless crystals of *(1)*, decomp. 180–185 °C.

Deprotonation of this phosphonium salt *(1)* with *n*-butyllithium at 20 °C in suspension in diethyl ether/*n*-hexane, followed by filtration to remove the precipitated LiCl and distillation under vacuum, surprisingly leads to ethyldimethyl(trimethylsilylmethylene)phosphorane *(2)*, b.p. 83–84 °C/14 torr, m.p. −32 to −30 °C, 65% yield. The structure of *(2)* is established by the ^1H-NMR spectrum[1] and by independent synthesis from ethyldimethylphosphine and chloromethyltrimethylsilane. The structures of *(1)* and *(3)* were also verified by NMR spectroscopy.



The formation of *(2)* from *(1)* on deprotonation with *n*-C_4H_9Li is interpreted as a silyl transfer from an ethyl group attached to phosphorus onto one of the methyl groups at the phosphorus, and corresponds to an exchange of a proton and a trimethylsilyl cation. Experiments with homologous compounds have shown that the silyl shift is a general phenomenon.

Stereospecific *cis* Addition of Dichloroketene to *cis*- and *trans*-Cyclooctenes

By *R. Montaigne* and *L. Ghosez* [*]

The reaction of dichloroketene with olefins and dienes yields readily 1:1 cycloadducts [1], mechanistic alternatives being a synchronous or a two-step dipolar process. We now describe the stereochemistry of the cycloaddition.

Dichloroketene (liberated *in situ* from dichloroacetyl chloride and triethylamine at room temperature) reacts smoothly with *cis*-cyclooctene to yield the compound *cis*-10,10-dichlorobicyclo[6.2.0]decan-9-one *(1a)* (yield 50 %; b.p. 91 °C/0.4 torr; n_D^{25} = 1.5128) and with *trans*-cyclooctene to form the *trans*-isomer *(1b)* (yield *ca.* 100 %; b.p. 79.5 °C/0.2 torr; n_D^{25} = 1.5077). Intercontamination is estimated, gas chromatographically, to be lower than 4 % [2].

Both adducts show a strong absorption band at 1805 cm^{-1} indicative of an α,α-dichlorocyclobutanone. The structural assignments are supported by the ^1H–NMR spectra (60 MHz; CCl_4; TMS as internal standard):

(1a) τ = 6.4 (1H); 7.07 (1H); 7.75–8.25 (4H); 8.25–8.82 (8H)

(1b) τ = 6.63 (1H); 7.39 (1H); 7.62–9.1 (12H).

Dechlorination of *(1a)* and *(1b)* with tributyltin hydride in refluxing cyclohexane containing catalytic amounts of azobisisobutyronitrile yields respectively the parent ketones: *cis-(2a)* (yield 56 %; b.p. 51–52 °C/0.2 torr; n_D^{25} = 1.4859; $\nu_{C=O}$ = 1772 cm^{-1}) and *trans-(2b)* (yield 77 %; b.p. 59–61 °C/0.3 torr; n_D^{25} = 1.4821; $\nu_{C=O}$ = 1772 cm^{-1}).

The configurations of *(1a)*, *(1b)*, *(2a)*, and *(2b)* can be deduced from the comparison of their IR spectra in the 1500 to 1400 cm^{-1} region with those of *cis*- and *trans*-cyclooctenes and their carbene-adducts: the *cis* compounds show two main bands in this region whereas the *trans* configurations show only one [3].

	νCH_2 (cm^{-1})		
	cis		*trans*
Cyclooctene	1469	1444	1452
9,9-Dichlorobicyclo[6.1.0]nonane	1470	1450	1445
Bicyclo[6.1.0]nonane	1472	1445	1458
10,10-Dichlorobicyclo[6.2.0]decan-9-one	1465	1448	1450
Bicyclo[6.2.0]decan-9-one	1463	1447	1452

The addition of dichloroketene onto olefins is thus a *cis* stereospecific cycloaddition [4]. Furthermore, as we obtained the same results using either pentane or acetonitrile as solvent, the stereochemical course of the reaction is entirely independent of the dielectric constant of the reaction medium. The experimental evidence cited above leads to the following conclusions:

1. The reaction makes available a two-step method of synthesis of cyclobutanones having the same configuration as the olefins from which they are derived.

2. A rotating intermediate being excluded, the addition appears to occur in a single step. This indicates that the selection rules for concerted cycloaddition reactions [5] cannot be applied as such to the cycloaddition of ketenes.

The Absolute Configuration of Chlorophyll [1]

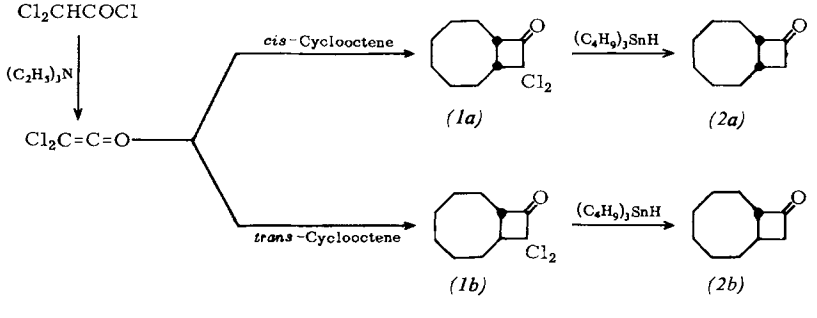
By *H. Brockmann jr.* [*]

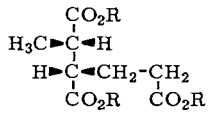
Tri-*p*-bromophenacyl (+)-*threo*-dihydrohematinate *(1)* [3], m.p. 108.5–109 °C, was obtained by *Fleming* [2] from (−)-α-santonin, and thus has the absolute configuration(2*S*,3*S*) [2]. Tri-*p*-bromophenacyl (−)-*threo*-dihydrohematinate *(2)* is formed from crystalline (+)-*threo*-dihydrohematinic acid *(3)*, which was first prepared by *Fleming* [2] by hydrolysis of synthetic dextrorotatory *threo*-dihydrohematinimide *(4)*, ($[\alpha]_D^{20}$ = +67 °). (+)-*(4)* consequently has the absolute configuration (2*R*,3*R*).

A levorotatory oily *threo*-dihydrohematinimide ($[\alpha]_D^{20}$ = −46 ° in methanol), which did not give a crystalline product on hydrolysis, but whose crystalline benzylamine salt gave an IR spectrum identical with that of the benzylamine salt of the racemic imide, and which gave no melting point depression with this salt, was obtained by *Ficken et al.* [4] and earlier by *H. Fischer* [5] by oxidative degradation of pyropheophorbide-*a*, a derivative of chlorophyll-*a*. Comparison of the rotation values of dihydrohematinimides prepared by different routes indicated that chlorophyll-*a* has the absolute configuration (7*S*,8*S*) [2].

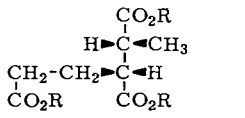
The degradation product from (−)-α-santonin had not yet been directly compared with a degradation product of chlorophyll.

Repetition of the oxidative degradation of methylpheophorbide-*a* with chromium trioxide in sulfuric acid [5], hydrolysis of the acidic degradation products with hydrochloric acid, and esterification with *p*-bromophenacyl bromide, followed by chromatography on silica gel with chloroform gave a moderate yield of crystalline dextrorotatory tri-*p*-bromophenacyl *threo*-dihydrohematinate, m.p. 109 °C, $[\alpha]_D^{20}$ = +2.6 ±0.3 °, $[\alpha]_{436}^{20}$ = +9.5 ± 0.4 °, *c* = 1.1 in chloroform. This product gave no melting point depression with *(1)* from

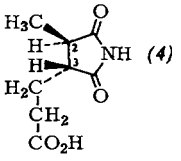




(1), R = $CH_2COC_6H_4$-p-Br



(2), R = $CH_2COC_6H_4$-p-Br
(3), R = H



(4)

(−)-α-santonin[6], and had the same R_f value in the thin layer chromatogram (silica gel HF_{254}, chloroform) as *(1)*, *(2)*[6], and the racemic ester. A simultaneously crystallized mixture of *(1)* from chlorophyll-*a* and *(2)* [from *(4)*] melts at 119 °C, and the melting point is not depressed by the addition of racemic ester.

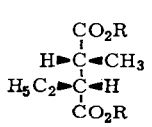
The Absolute Configuration of Bacteriochlorophyll[1]

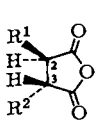
By *H. Brockmann jr.*[*]

Racemic *threo*-3-ethyl-2-methylsuccinic acid *(1)* was first resolved by *Berner* and *Leonardsen*[2]. The configuration of (+)-*(3)* was related to that of (+)-*(4)* and (+)-*(5)* by comparison of the optical rotations of acids, esters, and cyclic anhydrides at the sodium D line[2]. The absolute configuration of (+)-2,3-dimethylsuccinic anhydride *(4)* was very reliably[3] deduced by the application of the Kirkwood rule[4] on the basis of the known absolute configuration of (2*R*)-(+)-methylsuccinic anhydride *(6)*[3], which was established by X-ray diffraction[5]. Thus (+)-*threo*-3-ethyl-2-methylsuccinic acid is supposed to have the absolute configuration (2*R*,3*R*).

Like *Berner* and *Leonardsen*[2], we resolved racemic *(1)* into the enantiomers with strychnine, and prepared the di-*p*-bromophenacyl ester *(2)* (m.p. 115 °C, $[\alpha]_D^{20} = -49.4 \pm 3°$, $c = 1.3$ in chloroform) in good yield (86%) from the dextrorotatory acid *(1)*.



(1), R = H
(2), R = $CH_2COC_6H_4$-p-Br



(3), R^1 = CH_3, R^2 = C_2H_5
(4), R^1 = R^2 = CH_3
(5), R^1 = R^2 = C_2H_5
(6), R^1 = CH_3, R^2 = H

Levorotatory ester *(2)* (m.p. 112–113 °C, $[\alpha]_D^{24} = -37°$) was obtained by *Golden et al.*[6] by the oxidative degradation of a bacteriochlorophyll derivative, whose configuration in ring II must therefore be (3*R*,4*R*).

Bacteriochlorophyll *(7)* has already been converted by *Fischer*[7] into a derivative of chlorophyll-*a*[8], and so[9] has the same absolute configuration as chlorophyll-*a* at C-7 and C-8, which was recently recognized by *Fleming* as (7*S*,8*S*)[1,10]. If the 10-methoxycarbonyl group is assumed to occupy the energetically more favorable *trans* position with respect to the 7-propionic acid side chain, as has been found for derivatives of chlorophyll-*a*[11] and -*b*[12], then formula *(7)* represents the constitution and the absolute configuration at all the carbon atoms of bacteriochlorophyll[13].

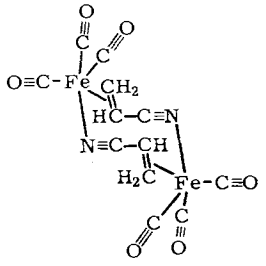
Acrylonitrile as a Hard and Soft Base in Di-μ-acrylonitrilebis(tricarbonyliron)

By *M. L. Ziegler*[*]

Three complexes having the compositions σ-$Fe(CO)_4AN$ *(2)*, π-$Fe(CO)_4AN$ *(3)*[1], and σ,π-$[Fe(CO)_3AN]_2$ *(1)*[2] have been isolated from the system $Fe(CO)_5$/acrylonitrile (AN). In

(2), the acrylonitrile molecule is bound *via* the nitrogen atom, and the trigonal bipyramid of the $Fe(CO)_5$ is axially substituted. In *(3)*, the olefinic double bond is coordinated, and the bipyramid is equatorially substituted.

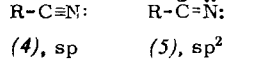
According to the HSAB concept [3], acrylonitrile is both a soft and a hard base, depending on whether the molecule reacts *via* the olefinic double bond or *via* the free electron pair on the nitrogen. It should therefore be possible to distinguish between a hard and a soft "position" in $Fe(CO)_5$, since hard ligands always substitute in the axial position [2]. X-ray structural analysis of *(1)* has shown that acrylonitrile is coordinated both as a hard and as a soft base in this complex. *(1)* contains



a ring system in which both of the iron atoms and both of the acrylonitrile molecules take part.

Each of the iron atoms is coordinated to one of the acrylonitrile molecules *via* the nitrogen atom and to the other *via* the olefinic double bond. The configuration at the iron atoms is a compromise between a trigonal bipyramid and a tetragonal pyramid. If the configuration is regarded as a distorted trigonal bipyramid, the olefinic double bonds have replaced an equatorial CO group and the nitrogen atoms an axial CO group, as must be expected from *(2)* and *(3)*.

According to the existing results, the $C\equiv N \rightarrow Fe$ linkage is not linear. This is understandable if the nitrogen is assumed to be sp^2 hybridized. In free nitriles, the resonance hybrids



(4), sp *(5)*, sp^2

(4) and *(5)* are present in roughly the same amounts [4], so that sp^2 hybridization may be assumed in *(1)*.

The compound *(1)* crystallizes in the triclinic system with the space group $C_i^1-P1_1^-$, with one molecule in the unit cell. The lattice constants are $a = 6.40$ Å, $b = 9.57$ Å, $c = 6.51$ Å, $\alpha = 93.0°$, $\beta = 106.6°$ $\gamma = 105.4°$. The structure was determined by three-dimensional Patterson and Fourier syntheses. The provisional *R* value is 20 %.

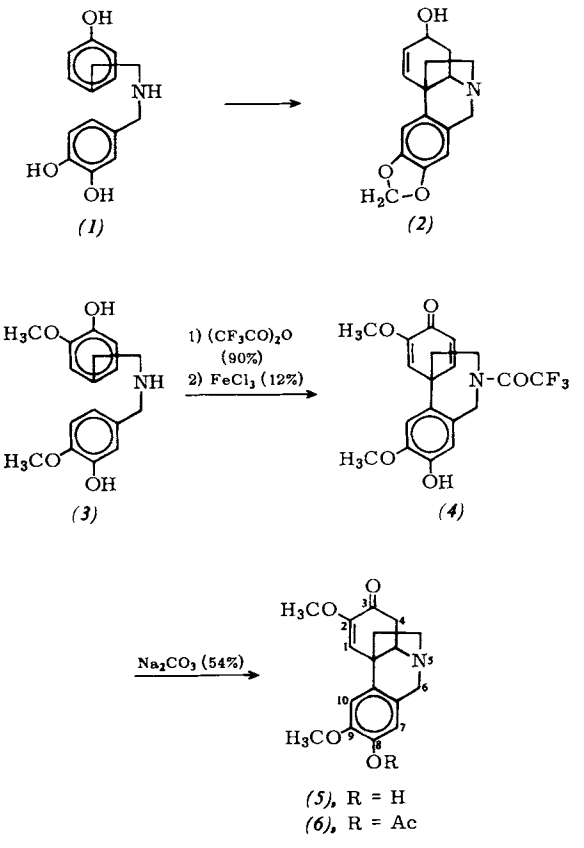
Model Reaction for the Biosynthesis of the Crinin Alkaloids [1]

By *B. Franck* and *H. J. Lubs* [*]

Crinin *(2)* and about thirty similar alkaloids from Amaryllidaceae are formed in the plant cell by oxidative condensation of norbelladin *(1)*, according to a hypothesis advanced by *Barton* [2] and verified by isotope experiments [3]. On the basis of this biosynthetic path, we found the ring system *(5)* of the crinin alkaloids particularly easy to prepare from a norbelladin derivative *(3)*.



Methoxy-*O*-methylnorbelladin *(3)* [4] was *N*-trifluoroacetylated and then oxidized for 48 hours at 20 °C in the two-phase system $CHCl_3$/1N $FeCl_3$ (1:1). Chromatography of the reaction mixture (ethyl acetate/benzene, 1:1, on silica gel G) gave the dienone *(4)* in 12 % yield. This underwent a second intramolecular condensation on hydrolysis with $CHCl_3$/2 N Na_2CO_3 (20 °C) to give the amine *(5)* $C_{17}H_{19}NO_4$, m.p. 232–234 °C (dec.), which takes up 1 mole of H_2 on hydrogenation with H_2/Pd in CH_3OH. The structure *(6)* is verified for the monoacetate $C_{19}H_{21}NO_5$, m.p. 210 °C, by the following spectroscopic data: IR spectrum in KBr: 1760 (ester), 1695, 1625 cm^{-1} (enone); NMR spectrum in $CDCl_3$ (TMS = 0): $\delta = 2.30$ ($COCH_3$), 3.75, 3.88 (2 OCH_3), 6.47, 6.75, and 6.98 (H on C-1, 7, 10); mass spectrum at 70 eV: $m/e = 343$ (91 %, $M^{\oplus}$), 301 (base peak, $M-CH_2=C=O$), 286 (301 − CH_3), 272 (301 − CHO), 258 (286 − CO), 227 (258 − CH_3).

Slow Inversion at Pyramidal Nitrogen: Isolation of Diastereomeric 7-Chloro-7-azabicyclo-[4.1.0]heptanes at Room Temperature

By *Dorothee Felix* and *A. Eschenmoser*[*]

The question of the existence of stereoisomerism at room temperature due to slow inversion at pyramidal nitrogen is a classical problem of stereochemistry[1]. On the basis of simple steric strain arguments it had been suggested[2] many years ago that this type of stereoisomerism might be found most likely in highly strained ethylene imine derivatives. Recent NMR studies on aziridine[3], oxaziridine[4] and diaziridene[5] derivatives support this suggestion, especially for the last case[6]. Today, an additional working hypothesis in the search for noninverting amines is based on the argument[7] that a higher σ-electronegativity of the ligands at nitrogen should be associated with a higher s-character of the nonbonding lone-pair orbital at nitrogen, and thus – *ceteris paribus* – with a higher inversion barrier. In fact, the amines known to invert most slowly among the acyclic series[8] are derivatives of hydroxylamine[9], and the barriers of oxaziridines and diaziridines[4,5] are higher than those of corresponding aziridines. On the other hand, repulsion between the nonbonding electron pairs of nitrogen and the adjacent hetero atom (conjugative destabilization) might primarily be responsible for the enhancement of the barriers in these systems[9,3e]; however, the relative importance of these inductive and conjugative factors has not yet been evaluated experimentally. Parallel with investigations on the structural requirements of high inversion varriers[10] we came upon the aziridine system named in the title; the diastereoisoisomerism exhibited by this system at room temperature presents a drastic illustration of the influence of electronegative ligands on the inversion barrier of amines.

N-chlorination[11] of 7-azabicyclo[4.1.0]heptane *(1)*[12] with sodium hypochlorite in water at 0 °C affords about 90 % of a product, the thin layer chromatographic analysis (silica gel/benzene-ethyl acetate/iodine) of which showed the presence of a stable major component A and a slow-moving labile component B. A clean separation of the two components could be achieved by column chromatography on silica gel (pentane/diethyl ether) at *ca.* 10 °C (yield ratio A:B *ca.* 4:1); rapid distillation at room temperature (0.05 torr) yielded the analytically (combustion analysis) pure liquids. Whereas samples of the component A isolated in such a manner are thin-layer chromatographically and NMR-spectroscopically homogeneous, samples of the labile component B contain small amounts (NMR: *ca.* 5 %) of component A. Compound A can be distilled unchanged at higher temperatures (b.p. 57–58 °C/11 torr) whereas component B is converted wholly, or partly, depending on the duration of heating, into component A. Both compounds release a molar equivalent of iodine from an acetic acid solution of potassium iodide and, on reduction with sodium hydrogen sulfite (in aqueous methanol/0 °C/10 min), revert to 7-azabicyclo[4.1.0]heptane *(1)* (yields 87 and 72 % resp.).

On the basis of their mode of formation, the thermal conversion of B into A, the re-reduction of B and A to *(1)*, as well as the analytical and spectroscopic data reproduced in the Table and Figures 1 and 2, we conclude that compounds A and B are the diastereoisomers *(2)* and *(3)* of 7-chlorobicyclo[4.1.0]heptane. We assume that the presumably more strained *endo*-configuration *(3)* belongs[13] to the labile, more dense, more highly refracting isomer B. In the NMR spectrum of this isomer the multiplet signals that are ascribed to the two bridgehead hydrogens occur at 2.1 ppm, *i.e.*, approximately 0.2 ppm[14] upfield from the corresponding multiplet in the spectrum of isomer A (cf. Fig. 1).

In the spectra of mixtures of isomers A and B these multiplets can be integrated separately; this affords a simple means of following the course of the conversion B → A with time. In benzene solution (*ca.* 6 wt.-% of B) at 29.5 °C the epimerization clearly follows the first order rate law with a rate constant $k = 4.3 \times 10^{-5}$ sec^{-1} (halflife 4.5 h). Under these conditions the conversion is complete within about a day, *i.e.*, it leads to the NMR-spectroscopically homogeneous isomer A. The completeness of this conversion can also be observed from the change in the IR spectrum with time; the two isomers can be clearly differentiated by the position and intensity of a band at 600 cm^{-1} that is ascribed to the (N–Cl)-stretching vibration[14] (cf. Fig. 2).

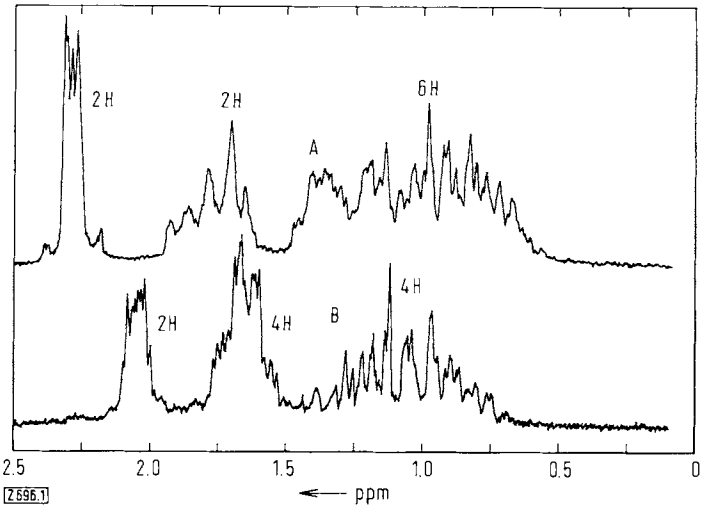

Fig. 1. NMR-Spectra of A and B, Varian HA–100, in deuteriobenzene, 20 °C.

So far as we know the above example is the first case of a "voluntary"[1b] nitrogen-inversion stereoisomerism at room temperature that has been demonstrated by isolation[**]. It appears to result from a favorable accumulation of factors that would be expected to raise the nitrogen inversion barrier, *i.e.*, (i) the increased ring strain of the three-membered ring in the planar inversion transition state relative to the pyramidal

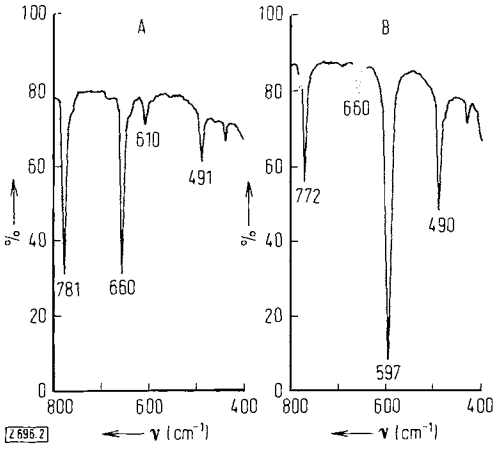

Fig. 2. IR-Spectra of A and B, liquid, KBr-cell.

ground state, (ii) the greater s-character of the lone-pair nitrogen orbital in the three-membered ring (possibly enhanced by the inductive influence of the chlorine) relative to a normal amine, and (iii) the conjugative destabilization of the planar inversion transition state (relative to the pyramidal ground state) resulting from the proximity of the formally non-bonding electron pairs of the nitrogen and chlorine. The type of structure displayed by the aziridines [15] that are electronegatively substituted on the nitrogen obviously affords an especially suitable model system for the experimental study of the influence of these factors on the inversion at nitrogen. Experiments in this direction are being carried out with investigations of other properties of the diastereomeric pair A/B and the kinetic determination of the inversion-activation parameters [16].

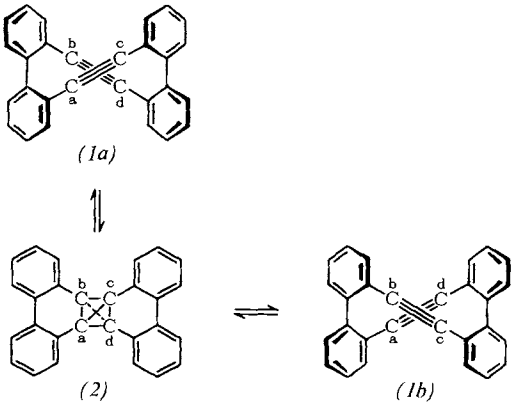
Synthesis of 9,10,19,20-Tetradehydrotetrabenzo-[*acgi*]cyclododecene

By *H. A. Staab* and *E. Wehinger* [*]

9,10,19,20-Tetradehydrotetrabenzo[*acgi*]cyclododecene *(1)*, whose fixed crossed triple bonds had attracted our attention [1], was obtained by metalation of bi(2-bromophenyl)-acetylene with *n*-butyllithium at −40 °C and subsequent cyclization of the metalated species with anhydrous copper(II) chloride. Compound *(1)* (m.p. 221–222 °C, from ligroin 60–70 °C) was isolated by thin layer chromatography (silica gel HF_{254}; ligroin, 60–70 °C/benzene 1:1) of the reaction product. The mass-spectrometrically determined molecular weight (M^+ at *m/e* 352) and hydrogenation (Pd/C, benzene) to 9,10,19,20 - tetrahydrotetrabenzo[*acgi*]cyclododecane [2] provide proof of structure. The UV absorption of *(1)* at remarkably short wavelengths [λ_{max} = 240 nm (ε = 72600); 222 nm (73700)] is explained as a result of twisting of the aromatic rings.

Consideration of models shows that *(1)* has a completely rigid carbon skeleton in which the four carbon atoms of the two triple bonds occupy the apexes of a distorted tetrahedron. With regular valence angles, the triple bonds, whose effective radii are assumed to be 1.6 Å [3], would have to approach each other to within 2 Å. Nevertheless, *(1)* exists unequivocally as a diacetylene and not as the tetrahedrane *(2)* since the most intense Raman absorption is ν′(C≡C) at 2220 cm^{-1} [4]. However, regarding the prevailing stereochemical conditions, we would not rule out the possibility of thermal or photochemical valence isomerization of *(1)* to the tetrahedrane *(2)*. Because of the chirality of the mole-



cule, the formation of *(2)* as an intermediate should involve a racemization as well as a novel rearrangement of the carbon skeleton *(1a)* ⇌ *(1b)*. Experiments to settle this question are in progress.

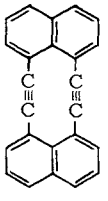
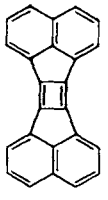
Attempted Preparation of 7,8,15,16-Tetradehydrodinaphtho[1,8-*ab*; 1,8-*fg*]cyclodecene

By *H. A. Staab*, *A. Nissen*, and *J. Ipaktschi* [*]

In connection with investigations of intramolecular interactions between triple bonds[1,2], our interest became centered on 7,8,15,16-tetradehydrodinaphtho[1,8-*ab*; 1,8-*fg*]-cyclodecene *(1)*, whose triple bonds should be even more rigidly fixed in a parallel arrangement than those of 1,8-diethynylnaphthalenes[1]. This should particularly favor overlapping of the in-plane π electrons, which in the extreme case would lead to a cyclobutadiene system *(2)* with rehybridized σ bonds.

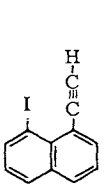


(1)

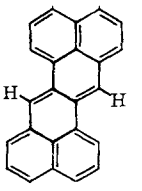


(2)

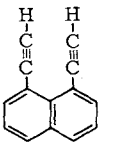
1-Ethynyl-8-iodonaphthalene *(3)*, m.p. 75–76 °C, was obtained from 8-iodo-1-naphthoyl chloride[3] *via* 1-acetyl-8-iodonaphthalene and 1-(1-chlorovinyl)-8-iodonaphthalene. However, coupling of the copper compound of *(3)* in pyridine (8 h, 115 °C) yielded not *(1)*, but a compound (yield 50 %) containing two more hydrogen atoms that was identified as zethrene *(4)*[4].



(3)



(4)



(5)

It appears that compound *(4)* is formed from *(1)*, which is not stable under the conditions of reaction, for the presence of compound *(4)* was also established during an attempt to prepare *(1)* by coupling of the dicopper compound of 1,8-diethynylnaphthalene *(5)* with 1,8-diiodonaphthalene. Compound *(5)*, m.p. 75 °C, was obtained in very good yield from 1,8 - divinylnaphthalene[5] *via* the tetrabromide (m.p. 127–129 °C) after dehydrobromination with potassium *tert*-butoxide in tetrahydrofuran.

The reactions of compound *(5)* also evidence special intramolecular interactions between the spatially proximate triple bonds. Thus hydrogenation with Lindlar catalyst gives predominately (50 % yield) 1,2-dimethylacenaphthylene *(6)*. Evidence for the intermediacy of 1,2-dimethyleneacenaphthene *(7)* was obtained when *(7)* was trapped during hydrogenation of *(5)* (Lindlar catalyst, tetrahydrofuran) in the presence of maleic anhydride as the 1:1 adduct (m.p. 191–195 °C, 30 % yield[6].

Ninth Lyons-Tübingen Chemical Meeting

The Ninth Lyons-Tübingen Chemical Meeting took place on September 27–29, 1967, at Tübingen on the invitation of the Tübingen Academic Chemical Staff. Three plenary lectures and twenty-five short papers were read.

Extracts from the lectures and papers:

The Structure of Some Fluorides, Oxides, and Oxide Fluorides: the $RbNiCrF_6$ Type

By *D. Babel* (Lecturer), *G. Pausewang*, and *W. Viebahn*[*]

Among the oxide systems there are compounds AM_2O_6 that crystallize in the perovskite lattice with only half the A cation sites occupied, *e.g.*, $CaNb_2O_6 = Ca_{0.5}NbO_3$. An analogous structure was at first expected for corresponding fluorides $A^IM^{II}M^{III}F_6$ where A^I = large alkali ions, M^{II} and M^{III} = small ions, in particular of the first transition series, since many of the components required, *e.g.*, $KNiF_3 + CrF_3$, are already known to crystallize with the perovskite lattice or with closely related structures.

A number of new compounds $A^IM^{II}M^{III}F_6$ were prepared, where A^I = K, Rb, or Cs, M^{II} = Mg, Ni, Cu, Co, Fe, or Mn, and M^{III} = Al, Ga, Cr, Fe, or V, by heating mixtures of the binary fluorides $AHF_2 + MF_2 + M'F_3$ in stoichiometric amounts under an inert atmosphere. However, X-ray structure analysis of the crystalline powders showed that these were not perovskites but belonged to a hitherto unknown face-centered cubic structure type ($RbNiCrF_6$ type).

Further, numerous oxides $A^IM^{V'}M^{VI}O_6$ with A^I = K, Rb, or Cs, as well as oxide fluorides have this structure, whose relations to the perovskite type on the one hand and to the pyrochlore type on the other were illustrated.

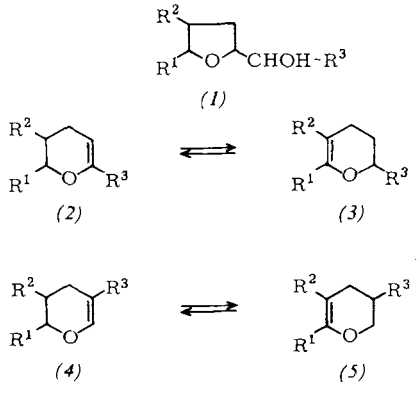
Catalytic Elimination and Isomerization Reactions of *O*-Heterocycles

By *G. Descotes*[*]

The mechanism and stereochemistry of ring-expansion of α-alkylfurfuryl alcohols *(1)* are determined by the number, position, and steric relations of the substituents. The cation



(with the positive charge on a carbon atom) that is adsorbed on aluminum oxide as intermediate usually undergoes heterolysis of the C–O bond. However, for conformations that are only slightly hindered sterically and thus favor *trans*-elimination, cleavage of C–C occurs. On heterolysis of *threo-(1)* ($R^1 = R^2 = H$; $R^3 \neq H$) the latter applies exclusively and leads to dihydropyrans *(2)* and *(3)*, as well as *(4)* and *(5)*.

The isomerizations *(2)* ⇄ *(3)* and *(4)* ⇄ *(5)* depend on complex intra- and inter-molecular migrations of hydride ions which are hindered if the substituents are bulky or are in *cis*-relation to the hydroxylated chain.

Analogous isomerizations are observed among tetrahydropyrans.

A New Method for Estimating Thermodynamic Properties of Crystalline Substances: Alkali Halides and Hydrides (NaCl System)

By *J. Bousquet, J. Cl. David* (Lecturer), *M. Diot*, and *A. Guillon*[*]

The dependence of the following thermodynamic parameters (referred to the standard state) on molar volumes was studied: lattice energy, enthalpy of formation, entropy of formation (1. elements in the ideal monoatomic gas state; 2. alkali elements in the standard state, halogens in the gas state), and free energy of formation. Linear functions of the logarithm of the molar volume resulted; the lines representing them are, in general, characteristic of each cation.

For the alkali hydrides, which crystallize in the NaCl system, the representative points lie distinctly off these lines and it is assumed that the hydrides occur as trimers $M^+(M_2H_3)^-$. With such assumptions it is possible to supplement and interpret the experimentally observed thermodynamic results. Agreement with previously estimated analogous values is very good.

Some Properties of 3-Phenoxyacrolein

By *R. Gelin* (Lecturer) and *D. Makula*[*]

3-Phenoxyacrolein is a stable starting material for preparation of malonaldehyde:

$$C_6N_5O\text{–}CH{=}CH\text{–}CHO \xrightarrow{H_2O} [HOCH{=}CH\text{–}CHO \rightleftharpoons OHC\text{–}CH_2\text{–}CHO] + C_6H_5OH$$

Hydrochlorides of the corresponding imino enamines are obtained quantitatively on reaction with hydrochlorides of primary aromatic amines:

$$[Ar\overset{\oplus}{N}H{=}CH\text{–}CH{=}CH\text{–}NHAr]Cl^{\ominus}$$

With alcohols and a catalyst diacetals of malonaldehyde (1,1,3,3-tetraalkoxypropanes) are obtained.

Other nucleophilic reagents (organomagnesium compounds, secondary amines, and Na derivatives of compounds with active methylene groups) react with addition-elimination. With organomagnesium compounds α,β-unsaturated aldehydes result; Na derivatives of compounds with active methylene groups afford quantitative yields of dienolates:

$[XYC{=}CH{-}CH{=}CHO^{\ominus}]\ Na^{\oplus}$

Microcalorimetric Investigation of Heterogeneous Catalytic Reactions

By *P. C. Gravelle* [*]

In a catalytic reaction at least one reactant is adsorbed on the surface of the catalyst. The adsorbed species takes part in surface reactions, and the final step in the reaction cycle is desorption of the reaction product. All the partial processes deliver or take up energy and can thus be followed directly by calorimetry.

An apparatus was described for measurement of the heat of adsorption of small quantities of gas. The curve showing the dependence of the differential heats of adsorption on the degree of occupation of the surface at a given temperature are characteristic of the adsorbed gas on the one hand and of the solid adsorbent on the other. Calorimetry discloses the change of surface activity of a catalyst with respect to a gas on variation, particularly, of the temperature of adsorption and of the surface structure. The same applies to chemisorption processes occurring on the surface. The calorimetric results are refined by thermochemical cyclic processes, and reaction mechanisms and kinetic conclusions are derived from them.

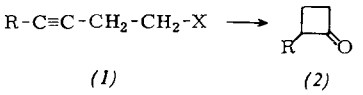
Conversion of Acetylene Compounds into Small-Ring Compounds

By *M. Hanack* (Lecturer), *I. Herterich*, *V. Vött*, and *H. Ehrhardt* [*]

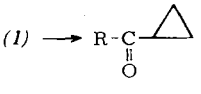
The C–C triple bond shows an unexpected readiness to take part in carbonium ion reactions, and this makes possible novel types of synthesis of small-ring compounds.

If acetylene derivatives of structure *(1)* (R = CH_3, C_2H_5, or i-C_3H_7; X = *m*-$OSO_2C_6H_4NO_2$) are solvolyzed in media of high ionizing power (*e.g.* formic or trifluoroacetic acid), they are converted completely into 2-alkylcyclobutanones *(2)*.



(1) *(2)*

The direction of rearrangement can be controlled by changing the reaction conditions: if acetylenes *(1)* are solvolyzed with addition of catalytic amounts of Hg(II) salts, then alkyl cyclopropyl ketones *(3)* are the preponderant products isolated.



(3)

Cyclization is not the only result of solvolysis of *(1)* when R = H; the cyclobutanones are then accompanied by esters of analogous structure.

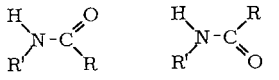
cis-trans-Isomerism of *N*-Monosubstituted Amides

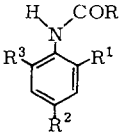
By *H. Kessler* [*]

N-Monosubstituted amides exist mainly in the *trans*-form (b) [1]. The *cis*-form (a) takes part in the equilibrium only to the extent of < 1 % (the activation energy of the equilibration (a) ⇌ (b) amounts to *ca.* 15–23 kcal/mole). But with formamides alone (R = H) (a) is preferred.



cis *trans*

(a) *(b)*



(1)

R = H, CH_3, C_2H_5, i-C_3H_7, *tert*-C_5H_9
R^1, R^2, R^3 = CH_3, C_2H_5, i-C_3H_7 or *tert*-C_4H_9

The position of the equilibrium and the height of the energy barrier (a) ⇌ (b) have been studied by NMR spectrometry for nuclear-substituted anilides *(1)*. In contrast to the case with acetanilide (R = CH_3; R^1 = R^2 = R^3 = H) appreciable amounts of (a) are found in *ortho*-substituted acetanilides [2]; the proportion of (a) increases with the size of the *ortho*-substituent [for 2,4,6-tri-*tert*-butylacetanilide the equilibrium mixture contains (a):(b) = 45:55].

Simultaneously, the free activation enthalpy of establishment of equilibrium increases with increasing steric hindrance. For the tri-*tert*-butylacetanilide it amounts to 24 kcal/mole, sufficing to enable (a) and (b) to be isolated in quantity by thin-layer chromatography at 0 °C, and thus constituting the first separation of *cis*- and *trans*-forms of a *N*-monosubstituted amide.

Increase in the size of the group R (from H to *tert*-C_4H_9) decreases the proportion of (a).

The effects observed are explained by twisting of the benzene ring relative to the plane of the amide bond by means of the *ortho*-substituents. The steric effect of the phenyl ring is reduced in the twisted form.

Polarimetric Study of Simple and Mixed Metal-Amino Acid Complexes

By *M. R. Pâris* (Lecturer) and *M. Petit-Ramel* [*]

The optical rotation is changed when an optically active ligand is coordinated to a metal ion. The specific rotation of a species is an additive property (in the same way as, for example, absorption). The pH-dependence of the optical

rotation permits determination of the stability constants and the specific rotation of each of the complexes that are successively formed. For this purpose the pH values and the rotations of solutions ($HClO_4/NaClO_4$ at constant ionic strength 0.5) containing originally the metal ion and the complex-forming agent are measured simultaneously during progressive neutralization with NaOH. For determination of the stability constants and specific rotations the graphical method of *Fronaeus-Yatsimirskii*, plus the analytical method of least squares, were applied, this being their first use in polarimetry. Studies to date have been concerned with simple complexes of Cu, Zn, Cd, and Ni with D-alanine, D-valine, and L-proline, and mixed complexes of Cu with these amino acids and with glycine, the last named complex showing no rotation.

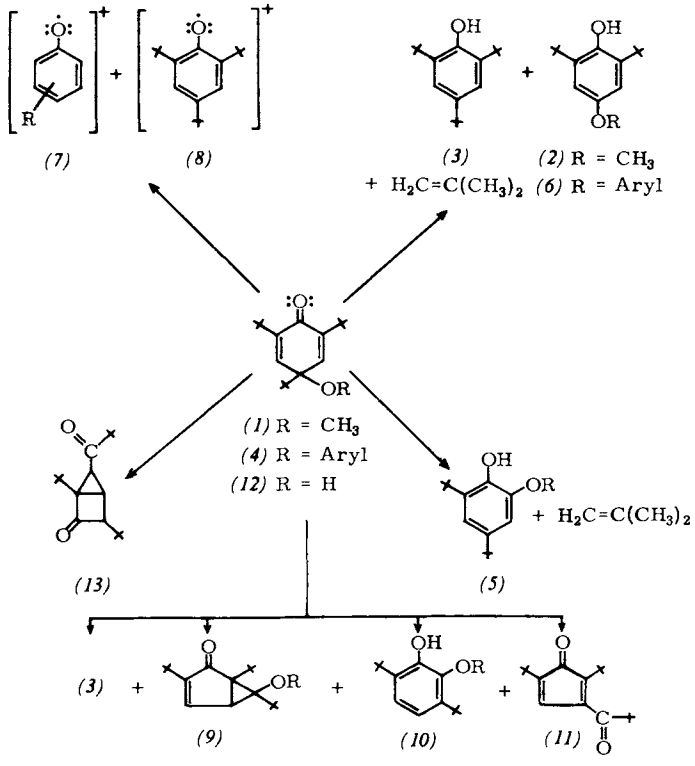
Specific Fragmentation of Cyclohexadienones

By *A. Rieker*[*]

Aliphatic ethers of *para*-quinol *(1)* decompose on pyrolysis, on acid fission, or in the mass spectrometer into isobutene, 2,4,6-tri-*tert*-butylphenol *(3)*, and the *p*-hydroxyphenyl ether *(2)* as main products. Aryl ethers of type *(4)*, however, are cleaved by pyrolysis into *o*-hydroxydiphenyl ethers *(5)* and isobutene, on acid fission into *(5)* or *(6)* according to the conditions, and in the mass spectrometer into the radical components *(7)* and *(8)*.



Photolysis of *para*-quinol derivatives proceeds quite differently: thus compounds *(3)*, *(9)*, *(10)*, and *(11)* are formed from *(1)* in ether (254 nm), whereas irradiation of *(12)* affords two stereoisomeric bicyclo[2.1.0]pentan-2-one derivatives having, probably, the structure *(13)*.

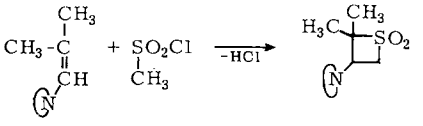
Formation of Sulfenes from Aliphatic Sulfonyl Chlorides and Trialkylamines

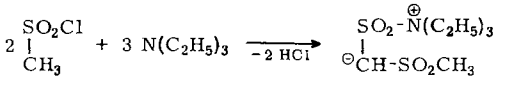
By *K. Rieth*[*]

S,S-Dioxides of thioaldehydes are formed as intermediates on reaction of tertiary bases with primary sulfonyl chlorides. They can be detected indirectly by trapping with suitable cycloaddition reagents (olefins with strongly polar double bonds, such as enamines and ketene acetals). Derivatives of thietane *S,S*-dioxide result.



The reactions are preferentially carried out in ether at room temperature. Cycloaddition of thioketone *S,S*-dioxides from secondary sulfonyl chlorides does not occur under these conditions, but it takes place smoothly in acetonitrile at −40 °C.

Mesylsulfene is formed from methanesulfonyl chloride and triethylamine under these conditions, and is detected as the triethylamine adduct.



The steric course of the cycloaddition of mesylsulfene to *cis*- and *trans*-1-butoxy-1-butene can be recognized from the ^1H–NMR spectra.

Ternary Oxides of Rutile Structure: Systems containing WO_2, MoO_2, VO_2, or TiO_2

By *W. Rüdorff* (Lecturer) and *H. Kornelson*[*]

The dioxides VO_2, MoO_2, and WO_2 crystallize in a monoclinic deformed rutile structure. In this structure the M–M pair has a remarkably short separation (Mo–Mo = 2.50 Å) in the direction of the *c*-axis. These dioxides have only a small, temperature-independent paramagnetism (TIP), which indicates direct metal-metal bonding. The authors have studied whether

a) the monoclinic structure is retained on formation of mixed crystals among themselves or with TiO_2,

b) M–M bonds still occur in the mixed crystals, and

c) electron transfer (change of valence) occurs between the cations.

There is a complete series of mixed crystals having monoclinic structure in the series MoO_2–WO_2. The TIP is retained, *i.e.*, Mo–Mo, W–W, and Mo–W pairs occur.

TiO_2 and WO_2 form a tetragonal rutile phase $(Ti_xW_{1-x})O_2$ with $1 > x > 0.42$, the magnetic behavior indicating that the W atoms still occur mainly in pairs.

In the system VO_2–WO_2, however, $x = 0.95$ to about 0.33 for the tetragonal rutile phase $(V_xW_{1-x})O_2$, but at $x < 0.33$ the structure passes continously into the WO_2 structure. At the composition $(V_{0.67}W_{0.33})O_2$ $(= V_2WO_6)$ the substance has the trirutile structure with V^{III} and W^{VI}; at the same time the conductivity reaches a minimum. This compound is antiferromagnetic, like the trirutiles Cr_2WO_6, $(VCr)WO_6$, $(FeV)WO_6$, and Cr_2TeO_6. At the transition trirutile-rutile

which occurs by inclusion of VO_2 or TiO_2 into $(V^{III}_{0.67}W^{VI}_{0.33})O_2$, the paramagnetism increases greatly since the magnetically active M^{3+} ions no longer occupy neighboring sites.

Galvanic Metal—Non-metal Elements

By *J. P. Soulier, D. Bouquet,* and *J. Gauthier* (Lecturer) [*]

The reaction

Metal + Non-metal → Salt $\qquad \Delta H < 0$

in galvanic elements was studied for many combinations of elements by means of suitable electrolytes. The EMF is independent of the concentration and to a certain extent also of the nature of the electrolyte; it depends only on the solubility product of the resulting difficultly soluble salt. EMF measurements thus permit exact determination of solubility products.

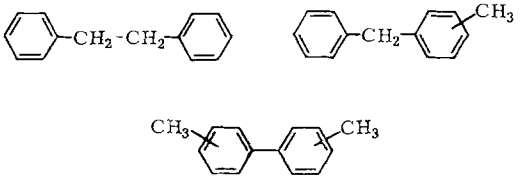
Organic Syntheses in the Plasma of High Voltage Discharges

By *H. Suhr* [*]

When vapors of organic compounds are led at pressures of a few torr through the plasma of cold discharges, various processes can take place. The molecular ions that are primarily formed may recombine, decompose into smaller fragments, or undergo chemical reactions with neighboring neutral molecules. At 25–50 V/cm and pressures of 1–10 torr reaction with neutral molecules predominates. The behavior, in the glow discharge, of a great number of different types of substance with molecular weights of 50 to 150 has been studied: most of the compounds give mixtures in which dimerization products (formed from molecular ions and neutral molecules) predominate. From the proportions of the isomers formed from, *e.g.*, toluene, information about the lifetime of the molecular ions and about their reactive



behavior can be obtained. If vapors of different compounds are fed together through the discharge tube, the proportions in which the products are formed gives information about the selectivity of the molecular ions.

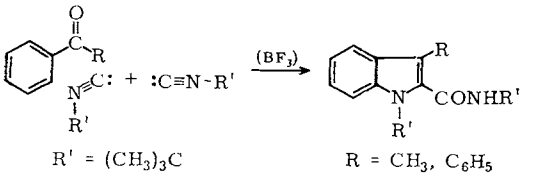
A New Synthesis of Indole Derivatives

By *B. Zeeh* [*]

Ketones are activated by Lewis acids such as BF_3 (the polarity of the carbonyl group is greatly increased) and can then react with nucleophilic reagents. If the nucleophile is an isocyanide, a series of unexpected reactions is observed, in which always two molecules of isocyanide react with one of ketone. When an aromatic ring is present, indole derivatives are formed.

tert-Butyl amides of 2-indolecarboxylic acids are formed from aromatic ketones, such as acetophenone or benzophenone, and *tert*-butyl isocyanide:



$R' = (CH_3)_3C$ $\qquad$ $R = CH_3, C_6H_5$

If, however, the aromatic substituent is in the isocyanide component (*e.g.*, phenyl isocyanide), cycloaliphatic ketones afford 2-indoleninecarboxanilides [1]. [VB 128 IE]

Quantum-mechanical Prediction of the Existence and Properties of the Unknown Molecule BeH_2

By *W. Kutzelnigg* and *R. Ahlrichs* [*]

Quantitative predictions of the properties of unknown molecules by "*ab initio* calculations" have so far been rarely possible because of the extraordinarily complicated quantum-mechanical equations to be solved. (By *ab initio* calculations we mean those in which only the number and kind of the nuclei and the number of electrons are put in, and in which, for instance, the equilibrium geometry of the molecule comes out of the calculation.)

Almost all *ab initio* calculations are based on the "independent particle model". This means that one orbital (one one-electron wave function) is associated with each electron and that the interaction between the electrons is calculated as the electrostatic repulsion between the electron clouds that correspond to the orbitals. Since, however, the electrons are not smeared charge distributions, and only a probability distribution of all the electrons has any physical meaning, this description in which the "electron correlation" is neglected cannot be quite correct. However, it permits certain properties, such as dipole moments, equilibrium distances and angles, and force constants, to be obtained surprisingly well. The independent particle model is, however, quite insufficient to permit calculation of bond energies and electron excitation energies.

A method developed by the authors [1] for calculation of a major part of the electron correlation – the "electron pair correlation" – now makes *ab initio* calculation of bond energies possible. The procedure has been applied with success to some known small molecules and then to the unknown molecule BeH_2.

The BeH_2 molecule is linear and symmetrical in the ground state. The equilibirum Be–H separation (1.35 ± 0.01 Å) is almost the same as in the known [2] BeH molecule (1.343 Å); valence force constants are also similar [f_r = 2.23 (BeH_2) and 2.26 (BeH) mdyn/Å]. The Be atom is in almost the same valence state in the two molecules. In accord therewith the dissociation energy for separation of one H atom from BeH_2 (consideration being given to zero point vibrations) at 89 ± 6 kcal/mole is distinctly greater than that for separation of the second H atom (53 ± 6 kcal/mole) because bonding of

a further H atom to BeH requires no additional "promotion energy".

The calculated limits of error in our results arise mainly because the "interpair correlation energy", although small, is not negligible and so far can only be estimated rather than calculated.

BeH_2(gas) is exothermic with respect to BeH + $^1/_2$ H_2 or Be(gas) + H_2, but endothermic (by 38 ± 6 kcal/mole) with respect to Be(solid) + H_2 or (by 48 ± 6 kcal/mole) with respect to the known[3,4] solid BeH_2 which, however, apparently does not consist of BeH_2 molecules but is high-polymeric. The BeH_2 molecule cannot be obtained by heating solid BeH_2 since at the temperature at which this decomposes into the elements[3] (about 400 °K) the BeH_2 equilibrium pressure amounts to only $10^{-18\pm3}$ atm. However, reaction of metallic Be and H_2 ($p \geq 1$ atm) at temperatures between 1000 and 1500 °K should afford BeH_2 molecules in measurable concentration.

Behavior of Molecules in High Electric Fields and at Surfaces

By *J. H. Block*[*]

In extremely high electric fields (> 10^7 V/cm) molecules are so strongly polarized that an electron can tunnel out, whereby an ion arises. This process of field ionization is utilized in studying the behavior of molecules in high electric fields by means of mass spectrometry.

These high fields can be established only on surfaces, for instance in the field ion microscope of *E. W. Müller*. Field-ion mass spectrometry can thus be used for studying certain surface reactions.

The energies induced in molecules at field strengths of 10^6 to 10^7 V/cm cause a perceptible change in the chemical behavior of, particularly polar, substances. For instance, association reactions of dipolar molecules become field-dependent. This dependence can be demonstrated by field pulse methods. For this purpose an electric field (< 10^7 V/cm) is first created so as to produce a desired species, which is then ionized by a pulse of short duration and analyzed directly in the mass spectrometer. It can thus be shown that the HCOOH molecule, whose polar monomer is associated to the nonpolar dimeric form, becomes stabilized in the monomeric form in high electric fields.

Field pulse methods, coupled with direct mass spectrometric analysis of the resulting ions, also makes it possible to study surface reactions kinetically. By varying the pulse frequency from 1 sec to 10^{-5} sec, products of surface reactions can be analyzed that have been formed within very short times. This procedure provides a very direct method of investigating heterogeneous catalysis, interpretation of the results being made difficult only by field-induced processes. The molecular ions produced by field ionization are of particular interest. Owing to their very low excitation, they show peculiar chemical behavior most impressively.

New Developments in the Crystal Chemistry of Multicomponent Oxides

By *E. Kordes*[*]

An astonishing tolerance for isomorphous replacement of cations, even if of different valence, is often observed, not only with complicated, but also with simple lattices. As long ago as 1935 formation of a continuous series of mixed crystals was established for MgO, $LiFeO_2$, and Li_2TiO_3[1] (all three with NaCl structure), and more recently of MgO or NiO and $LiFeO_2$ (all with NaCl structure) with the rhombohedral $LiCrO_2$ (deformed NaCl structure with ordered cationic distribution[2]), and also between MgO and $LiVO_2$ (isotypic with $LiCrO_2$). Cubic compounds Li_3NbO_4 and Li_3TaO_4, isotypic with MgO, are also known. These two mixed oxides give further continuous series of mixed crystals with MgO, Li_2TiO_3, and $LiFeO_2$; these are thus cases of coupled isomorphous replacement of $(Li^+)_9(M^{5+})_3$ by $(Mg^{2+})_{12}$ or $(Li^+)_8(Ti^{4+})_4$ or $(Li^+)_6(Fe^{3+})_6$.

Stable homogeneous mixed crystals with the composition

$$Li_{10}MgFe^{III}Ti^{IV}M^{V}M'^{VI}O_{15}$$

(M = Nb on Ta; M' = W or Mo)

and NaCl structure have also been prepared.

The oxidic spinel lattice shows a similar tolerance for cation replacement. The alkali spinel $LiAl_5O_8$ can be derived from the very similar spinel $Mg_2Al_4O_8$ by the replacement 2 $Mg^{2+} \rightarrow Li^+Al^{3+}$; a corresponding derivation applies to the analogous spinel $LiFe_5O_8$. Surprisingly, $LiFe_5O_8$ gives a continuous series of mixed crystals with the rhombohedral $LiCrO_2$ or $Li_4Cr_4O_8$ (deformed NaCl structure) that is not isotypic with it: an excess of cations is accommodated in the spinel lattice of the $LiFe_5O_8$.

Cu^I ions can also be accommodated in spinels. $LiFe_5O_8$ and $CuFe_5O_8$, for instance, give a continuous series of mixed crystals. 20 mole-% of Li^+ in $LiIn^{III}Cr^{III}_4O_8$ can be replaced by Cu^+.

Cu_2O also forms compounds with the oxides of the lighter trivalent rare-earth metals; for instance, new mixed oxides $CuLaO_2$, $CuPrO_2$, $CuNdO_2$, $CuSmO_2$, and $CuEuO_2$ have been obtained that are isotypic with one another and crystallize with the rhomobedral $NaHF_2$ lattice.

New Results in the Chemistry of Complex Compounds of Metals in Lower Oxidation States

By *H. Behrens*[*]

Oxidation by iodine of $Na_2[Cr_2(CO)_{10}]$, which is isoelectronic with $Mn_2(CO)_{10}$, leads stepwise to $[Cr(CO)_5I]^-$, $Cr_2(CO)_{10}I$, and $Cr(CO)_5I$[1,2]. The binuclear anionic complex $[Cr_2(CO)_{10}I]^-$, which is not accessible by this route, is formed when the binuclear neutral complex is reduced with sodium amalgam in THF[3]. The IR spectra of $(OC)_5Cr-I-Cr(CO)_5$ and $[(OC)_5Cr-I-Cr(CO)_5]^-$ indicate a double octahedral arrangement of the ligands with I as common apex and linear Cr–I–Cr linkage[4]. The ionic Cr^I complex $[Cr(CO)_2(NH_3)_4]I$, in which the CO groups are *trans* to one another, can be obtained from $Cr(CO)_5I$ and liquid NH_3. $Cr(CO)_5I$ generally reacts with other uni- or bidentate N or P ligands by oxidation to elemental iodine and reduction to penta- or tetra-carbonylchromium(0) compounds[5].

In the series $Cr(CO)_5X$, $[Cr(CO)_5X]^-$, $Cr_2(CO)_{10}X$, and $[Cr_2(CO)_{10}X]^-$ (X = CN, SCN, or OCN)[3,6,7] the pseudohalogen of the binuclear complexes is in the bridge position, as is iodine in the iodine derivatives. Like $[Cr(CO)_5NCS]^-$, $Cr(CO)_5NCS$ is an isothiocyanate compound with a Cr–N bond[4].

M^0 compounds can be synthesized from cyanometalates(0)[8] as well as from pure dicyclopentadienyl complexes(π-$C_5H_5)_2M$ (M = V, Cr, Fe, Co, or Ni) and mixed cyclopentadienylmetal-carbon monoxide complexes[9,10]. Particular mention may be made of the preparation of the trigonal-bipyramidal $Fe(CO)_2$tripy from $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$ and 2,2′:6′,2″-terpyridyl (tripy)[11].

Whereas $Co_2(CO)_8$ disproportionates with Lewis bases to Co^{II} and Co^{I-}, the compounds

$[Co^{I}(bipy)_3]\,[Co^{-I}(CO)_4]$ and $[Co^{I}(phen)_3]\,[Co^{-I}(CO)_4]$ [12]

are formed on treatment of $(C_6H_8)_2Co_2(CO)_4$ (C_6H_8 = 1,3-cyclohexadiene) with 2,2′-bipyridyl (bipy) or 1,10-phenanthroline (phen), respectively.

However, the norbornadiene in $(nor\text{-}C_7H_8)_2Co_2(CO)_4$ can be replaced according to the equation:

$$(nor\text{-}C_7H_8)_2Co_2(CO)_4 + 2\,L \rightarrow Co_2(CO)_4L_2 + 2\,nor\text{-}C_7H_8$$

(L = bipy, phen, or $[(C_6H_5)_2PCH_2]_2$)

these being the first cobalt carbonyl derivatives to be obtained in which four CO groups are replaced by N or P ligands[12]; they have the same structure as $Co_2(CO)_8$.

The compounds $Co_2(CO)_4L_2$ are oxidized by I_2 to the covalent pentacoordinated $ICo(CO)_2L$, but are reduced by sodium to the salt-like tetracoordinated $Na[Co(CO)_2L]$[12].

Valence Force Constants of Various Phosphorus Compounds

By *J. Goubeau*[*]

The author's method of calculating "force constants" was described. By examining systematically selected examples from various transition series of the type PX_3–PX_2Y–PXY_2–PY_3 and similar series with quadri- and quinque-valent phosphorus the important bases for changes of force constants (differences of up to nearly 200 %) were established as:

1. differences in hybridization,
2. differences in electronegativity of the components,
3. multiple bonding ($d\pi$–$p\pi$), and
4. polar valence contributions.

The force constants increase markedly with increasing s-contribution to the σ-bonds, in phosphorus chemistry as in other combinations of elements. Force constants of certain phosphorus compounds become larger with increase in electronegativity of the other components when other bonding conditions are unchanged (hydrogen bonds are understandably an exception). In both these cases the maximum change in the force constants is of the order of 30–40 %.

The greatest changes are due to contributions from multiple bonds: as an example, the PS force constants in tetraligated SPXYZ were discussed; the bond order varies between 2.0 and 1.3 according to the electronegativity of the ligands. The influence of polar contributions to the bonding, which weaken the force constants, was explained for the cases of some fluorine, chlorine, and cyanide derivatives of phosphorus; with these examples the effect of variation in force constant on the reactivity of the compounds could be demonstrated.

Mechanism of Eliminations over Solid Catalysts

By *H. Noller*[*]

Static and dynamic studies have been carried out, particularly by the microcatalytic method, with C_2 to C_4 alkanes between 100 and 400 °C. The catalysts were salts and oxides; metals are ineffective. Alkaline-earth salts have much greater activity than alkali salts, doubtless because of their higher cationic charge. The activity of cations with the same charge increases with decreasing radius. The activity of the anions approximately parallels their basicity.

Reactivity decreases in the substituent series Cl, Br, OH, NH_2, C_6H_5. Methyl and, in particular, phenyl substitution on C_α increases the reactivity appreciably. Methyl substitution on C_β is without influence, but this does not apply to phenyl substitution. Deuterium introduced on C_α remains in the molecule (indicating β-elimination), although not always on C_α. The secondary kinetic isotope effect, if present at all, is < 5 %.

Reactions are always of the first order. It is impossible to decide kinetically between E1 and E2 mechanisms, but this can be done by considering the distribution of primary products. On alkaline-earth salts the primary products from 1-halogenobutanes (X = Cl or Br) are the same as from 2-halogenobutanes; 2-butenes always largely preponderate (Saytzeff rule), and among these in the lower temperature region often the (thermodynamically less stable) *cis*-2-butene. This indicates an E1 mechanism that operates through the same 2-butyl cation. Lithium salts are highly selective; with 2-halogenobutanes they give primarily *cis*-2-butene, and with 1-halogenobutanes they yield primarily 1-butene.

The stereoselectivity of the catalysts follows from the *cis*/*trans* proportions of the 2-halogeno-2-butenes that are formed from the *meso*- and DL-forms of 2,3-dihalogenobutanes. The series of catalysts with decreasing selectivity KBO_2, K_2CO_3, K_3PO_4, K_2SO_4, $BaCO_3$, $Ca(BO_2)_2$, $Ba_3(PO_4)_2$, $CaCl_2$ covers the whole range of almost complete stereoselectivity (KBO_2: *cis*/*trans* from *meso* = 97:3, from DL 9:91, at 250 °C), *i.e.*, *trans*-elimination, to vanishing stereoselectivity ($CaCl_2$: *cis*/*trans* from *meso* = *cis*/*trans* from DL = 17:83, at 200 °C),

i.e., pure carbonium ion mechanism. Interpretation is provided by the relative strengths of the interaction between cation and halogen on the one hand and between anion and H on the other. If the two interactions are comparable in strength, the E2 mechanism is found to operate; if interaction between cation and halogen is the stronger, the E1 mechanism is observed.

Stereoselectivity decreases with rise in temperature.

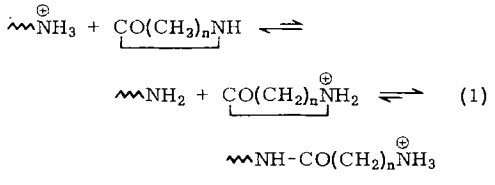
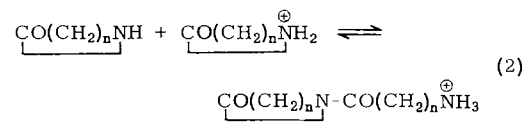
Cationic Polymerization of Lactams

By *M. Rothe* [*]

Polymerization of lactams by Brønsted acids (protic acids, ammonium salts, H_2O) and by Lewis acids[1,2] can be assigned similar types of mechanism in which the active end of the chain is always an ammonium ion[3]. Chain growth can occur after proton exchange with lactams; the lactam cation that is formed acylates the amino group thus freed.



Differences in the course of polymerization with different initiators can be ascribed to the mechanism of the corresponding starting reactions as well as to side reactions brought about by the different end groups formed [(a) carboxyl, (b) *N*-acyllactam, (c) amidine groups[4]]; such end groups can contribute to different types of chain growth (a, b) or lead to chain termination (c). Also of importance are ring size and substitution of the lactam: 5- and 6-membered lactams give only short-chain oligomers; *N*-methylcaprolactam does not react, but *N*-methylaminocaproic acid forms the lactam quantitatively with cationic initiators; 8- and higher-membered lactams, on the contrary, give polymers almost quantitatively because termination with amidine formation, which must lead to rings of medium size, does not occur. Polymerization with protic acids (halogen hydrides, various phosphorus and sulfonic acids, picric acid, CF_3COOH) occurs with acylation of the lactam by the corresponding lactam salt to form the *N*-(ω-aminoacyl)lactam salt.



This and the next higher oligomers were detected, as previously with caprolactam[1], during polymerization of the other lactams mentioned by IR spectroscopy and by electrophoresis with help of the hydroxamic acid reaction. Model reactions with oligomers confirm the mechanism assigned. Acyllactams react with ammonium groups with fission of lactam[5] (chain growth on the C-terminal end); this is indicated by a decrease in the acyllactam content of the polymer during polymerization, as determined titrimetrically and by IR spectroscopy.

The amidine formation was demonstrated chromatographically in the oligomer region, which is easier to study, for $H_2N(CH_2)_5CO-[NH(CH_2)_5CO]_2-NHCH_2C_6H_5 \cdot HCl$; at temperatures above 190 °C, this compound cyclizes partially at the terminal NH_2 group with loss of water.

Lewis acids (BF_3, P_2O_5) and lactams give adducts that acylate monomers in accord with eq. (2). However, polymerization occurs only in presence of cocatalysts (H_2O), the $H[BF_3OH]$ formed acting as protic acid.

Thermokinetic Measurements

By *F. Becker* [*]

The principle of thermokinetic measurements is to follow the progress of a chemical reaction by means of its evolution of heat. Apart from the fact that it gives heats of reaction as well as velocity constants, the method has the advantage that the output dQ_R/dt can be recorded as a function of the heat of the reaction Q_R as the reaction proceeds; and the rate laws are thus evaluated directly in their simple differential form. For a reaction of the first order the function $dQ_R/dt = f(Q_R)$ is a straight line with the slope k_1; its intercept with the abscissa represents the heat of reaction for complete conversion. For a reaction of the second order with equal initial concentrations, recording the function $[dQ_R/dt]^{1/2} = f(Q_R)$ gives a straight line that can be evaluated equally simply.

Two methods were used for experimental realization of this measuring principle. The first is isothermal calorimetry with controlled Peltier cooling, in which the cooling current from a semiconductor Peltier battery in thermal contact with the reaction vessel is controlled so as to provide a cooling output equivalent at each moment to the heat output of the reaction, whereby the initial temperature of the calorimeter is unchanged. The measuring signal is then a voltage proportional to the cooling current i_k, which is recorded by a two-coordinate pen as function of the integral $\int i_k \, dt$ provided by an electronic integrator. The second method is "quasi-isothermal" heat flow calorimetry, in which the temperature difference ΔT between the calorimeter and the thermostat liquid, which is proportional to the heat flow dQ/dt, is used as measuring signal and a function analogous to $dQ/dt = f(Q)$ is recorded, again by means of an electronic integrator and, when required, a root function generator. Sufficient heat flow is provided so that ΔT remains < 0.05 deg, whereupon the temperature-dependence of the rate constants can be neglected. A theoretical study was made of the conditions under which the relation of heat flow dQ/dt to total heat removed Q has the same mathematical form as the thermokinetic rate law $dQ_R/dt = f(Q_R)$.

Examples of reactions were provided to show that these methods enable rate constants to be determined within ± 1 % and reaction enthalpies within ± 2 %, 25 ml of 0.02–0.04 molar solutions of reactants and reaction times of 5–10 min sufficing for this purpose.

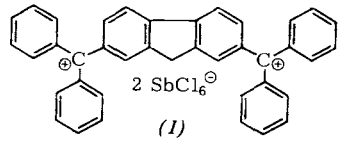
Studies with Stable Carbonium Ions

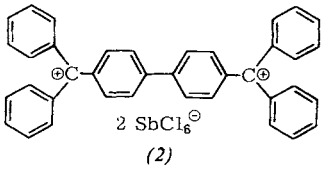
By *H. Volz* [*]

According to HMO calculations the cyclopentadienyl cation in the ground state should have an open molecular shell and triplet character. If the Jahn-Teller effect intervenes, the character of the open molecular shell is retained but the ground state should show singlet character. ESR studies of pentaphenylcyclopentadienyl hexachloroantimonate [1] indicate that the molecule has singlet character in the ground state. An open molecular shell is also obtained by HMO calculation for the indenyl and the fluorenyl cations [2], whose thermodynamic stabilities are accordingly appreciably less than those of the isoelectronic diarylmethyl and triarylmethyl cations, as is shown by study of the chloride ionization equilibria. On account of its electronic instability the fluorenyl cation itself cannot be isolated, even at −70 °C; but the 9-chlorofluorenyl cation can be obtained; the reason for this is probably on the one hand the electron-donating effect of the chlorine [3], and on the other the fact that chlorine in the 9-position is not removed as Cl^+ whereas in the fluorenyl cation the H in the 9-position can be easily removed as H^+.

The acceptor strength of carbonium ions should be raised by introduction of a second or third positive charge into the molecule, owing to mutual action of the positive centers. HMO calculations and chloride ionization experiments show, however, that the acceptor strength of the dication *(1)* is about the same as that of the triphenylmethyl cation.



(1)



(2)

X-Ray structure analysis [5] of single crystals [4] of the dication *(2)* show that the two positive centers (sp^2-hybridized) lie in the same plane as the four aryl carbon atoms attached to them. The two hexachloroantimonate anions are regular octahedrons and the shortest distance between one of the positively charged C atoms and a Cl atom of the $SbCl_6$ amounts to 3.5 Å.

Transformation Processes in Fiber Keratins

By *G. Ebert* [*]

A differential calorimeter operating on the principle of differential thermal analysis has been used to study order-disorder transitions in fiber keratin which is gradually heated in water or concentrated electrolyte solutions, attention being paid to the position of the transition temperature, the sharpness of the transition, and the heat of transformation. Also the contraction of the fiber under the conditions of heating used was measured and correlated with the caloric effects.

The influence of cystine bridges on these processes was determined by stepwise reduction of the cystine content (reduction with sodium mercaptoacetate and blocking or elimination of SH groups by $C_2H_4Br_2$ or CH_3I); the transformation temperature and the half-width of the peak are altered only when the cystine content has been reduced to below 25 % of its original value; thus the major portion of the cystine present contributes little to the thermal stability of the ordered region. This is in agreement with the fact that most of the cystine is contained in the amorphous matrix. The cooperative character of the transformation process decreases very rapidly only after degradation of the last of the cystine bridges to be attacked, these bridges being responsible for stabilization of the ordered region and possibly linking the chains. Sulfide cross-links (introduced by treating partially reduced keratin with 1,2-dibromoethane) shift the process to higher temperatures. The same is true within limits for alkali-treated keratin of increased lanthionine content.

In concentrated LiBr solutions (3.5 to 12 molar) an exothermic process is observed which is shifted to higher temperature linearly with rising concentration. The assumption that this is connected with sorption of electrolytes on the keratin fiber, this sorption being hindered below certain temperatures, was confirmed titrimetrically and by conductivity measurements. Causes of the hindrance are to be sought (i) in the structure of highly concentrated electrolytes and (ii) in hindrance of diffusion through cuticula and through cross-linkages in the fiber stock.

The contraction and the exothermic process are linked in such a way that contraction occurs only after the peak has reached its maximum. Essential for the contractive effect are: (i) a not too large cation, which apparently is sorbed onto the polar groups, increases the hydrophilicity of this region, and weakens the stabilizing hydrogen bridges; and (ii) a large, singly charged anion, which is probably sorbed near the hydrophobic groups, disturbs the structure of the water in the neighborhood, and thus makes easier the cleavage of the hydrophobic linkages.

Study of Surface Reactions by Diffraction of Low-energy Electrons

By *G. Ertl* [*]

The method of diffraction of slow electrons (LEED) was used in the classical experiment of *Davisson* and *Germer* for demonstration of the wave nature of electrons, but only recently has it been developed into a useable tool for study of processes occurring on clean surfaces.

If a monochromatic beam of electrons with energies between *ca.* 20 and 300 eV impinges perpendicularly on a single-crystal surface, then because of the slight penetration only diffraction on the uppermost layers of atoms occurs. Thus, after post-acceleration of the elastically scattered electrons, diffraction spots can be seen on a fluorescent screen and from their positions the unit cell of the surface structure can be derived. Exact determination of the structure is unfortunately not yet possible because the nature of the scattering process is not yet completely understood.

Adsorption of gases on clean surfaces often leads to appearance of additional, new spots in the diffraction picture, showing that the adsorption layer is an ordered two-dimen-

sional superstructure. In favorable cases plausible structural models can be given; the adsorption of ethylene on a (110) surface of copper may be cited as an example. Covering of a surface can extend in various ways: for instance, by formation of several different two-dimensional phases with different degrees of coverage, which in the transition area can exist next to one another as large islands (O_2 on (110)-Cu); or with a more or less continuous increase in the (microscopic) degree of coverage and continuous change in position of the diffraction spots (O_2 on (110)-Pd). The successive action of different types of particle can in certain circumstances lead to expulsion or to formation of ordered mixed phases (C + O_2 + (100)-Cu). Decomposition reactions can be followed by means of changes in the diffraction picture (C_2H_4 on (110)-Ni). Quantitative kinetic information can be obtained by measuring the intensity of a specific diffraction spot (reaction $O_{ad} + CO_2 \rightarrow CO_{2,g}$ on (110)- and (100)-Cu).

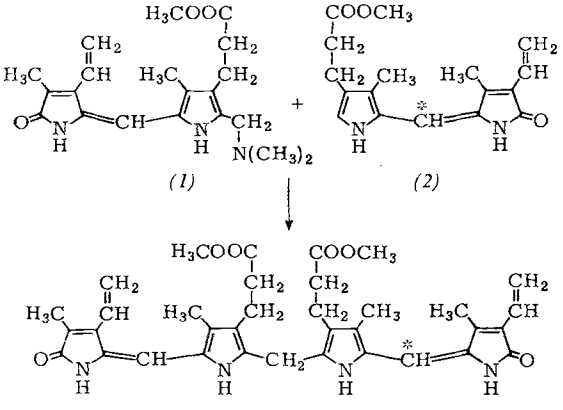
Syntheses in the Pyrrolone and Pyrrole Series[**]

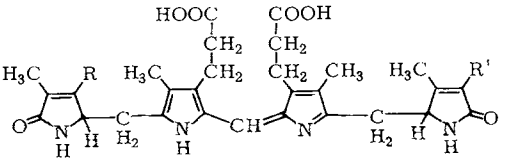
By *H. Plieninger*[*]

The decisive step in a new high-yielding synthesis of bilirubin is the linking of a Mannich base of type *(1)* with an oxodipyrromethene of type *(2)* by the action of acetylenedicarboxylic ester[1] (the formation of bilirubin dimethyl ester is shown schematically below). The reaction is suitable as a general synthesis of unsymmetrical biladienes, *e.g.*, mesobilirubin.



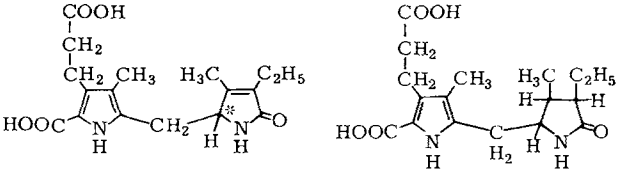
(1) *(2)*

Radioactive bilirubin is easily obtained by using a compound *(2)* labeled by ^{14}C on the methine bridge (asterisk). The linkage of *(1)* to *(2)* is proved because the specific activity in the bilirubin dimethyl ester agrees with that of the component *(2)*; this proof was necessary because it was found that under the same conditions *(1)* can dimerize without addition of *(2)*.



(3), R = $-CH=CH_2$, R' = $-C_2H_5$
(4), R = $-C_2H_5$, R' = $-CH=CH_2$

Further, the synthesis of two vinyl-substituted urobilins *(3)* and *(4)* was described. Compounds of this type are excreted in optically active form in feces after administration of antibiotics.



(5) *(6)*

We have achieved the first resolution of pyrrolone derivatives of type *(5)* and the corresponding pyrrolidone derivatives *(6)*. The compounds are to be used for synthesis of optically active urobilins and stercobilins.

Lecture at München (Germany) on November 14, 1967 [VB 127 IE]
German version: Angew. Chem. *80*, 242 (1968)

69 Heidelberg, Tiergartenstrasse (Germany)

[**] The experimental work was carried out by Mr. *F. El-Barkawi*, Dr. *U. Lerch*, and Messrs. *R. Steinsträsser*, *U. Oswalt*, *J. Ruppert*, and *A. Tapia*.

SELECTED ABSTRACTS

$As_4(NCH_3)_6$ has an adamantane structure. The structure proposed by *H. Nöth et al.* for the compound which they had synthesized was confirmed by *J. Weiss* and *W. Eisenhuth* by a Weissenberg photograph, three-dimensional Patterson synthesis, and three-dimensional Fourier syntheses. An *R* value of 0.153 was obtained. The compound crystallizes monoclinically in the space group C_{2h}^5–$P2_1/n$ with lattice constants a = 7.523 Å, b = 16.696 Å, c = 11.907 Å, β = 93.1°. The unit cell contains four molecules. The four arsenic atoms form a tetrahedron (mean distance 3.271 ± 0.007 Å; edge length of the tetrahedron) and the six nitrogen atoms form an octahedron (edge length 4.110 ± 0.01 Å). Both are completely regular, whereas the six carbon atoms of the CH_3 groups occupy the corners of a highly distorted octahedron. The mean length of the arsenic-nitrogen bond, 1.867 Å, is in good agreement with the calculated value of 1.87 Å. / Z. anorg. allg. Chem. *350*, 9 (1967) / –Sch.

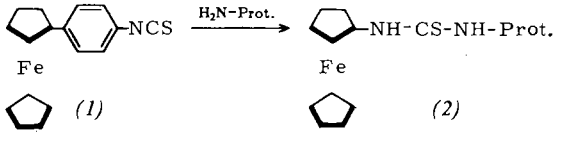
[Rd 762 IE]

Acid-base titrations on powdered quartz and also powdered vitreous silica (Vitreosil) and flint glass (particle sizes 20–10, 10–4, 4–2, and 2 µm; titration in deionized water with 0.1 N NaOH and HCl at 20–22 °C within 10–15 min) led *S. S. Jørgensen* and *A. T. Jensen* to the following conclusions. For quartz (approximately 2.6 acid groups per 100 Å^2) and for vitreous silica the acid-base properties are determined almost entirely by the outer surface, *i.e.* the protolysis capacity (equivalents of acid or base used per 100 g of powder over a defined pH range) increases linearly with specific surface area. The titration curves (pH 3–11) are S-shaped and can be divided into three regions (pH 3–5, 5–9, 9–11); the flatter end regions have the greater protolysis capacities (and thus greater buffer capacities) and show hysteresis effects. On washing the quartz with HCl (removal of the Fe, *ca.* 0.03 %), the protolysis capacity decreases in the acid region and increases in the alkaline region; on washing with HF (removal of the limited crystalline surface), the protolysis

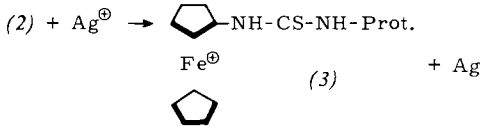
capacity shows an overall decrease. In 1 N NaCl solution the alkaline protolysis capacity is greater than in pure water, and the buffer range is at a lower pH value. The time and hysteresis effects are due to "latent" acidity (dissolution of the silica), though this is obscured by an instantaneous and reversible acidity. The protolysis capacity of flint glass lies completely above pH 4.5 and is about ten times greater than those of quartz and vitreous silica; however, it is not dependent on the specific surface area. In this case there must therefore exist protolytically active inner surfaces. / J. physic. Chem. *71*, 745 (1967) / –Jg. [Rd 785 IE]

The preparation of eleven labeled trinucleotides on a preparative scale is described by *G. Högenauer*. The radioactive trinucleotides, which were required for the investigation of codon-anticodon interactions, were obtained from *E. coli* and bakers' yeast that had been grown in nutrient media containing ^{32}P phosphate. The total RNA was hydrolyzed enzymatically (pancreatic extract), the oligonucleotide mixture was subjected to preliminary purification on a DEAE-cellulose column, and the trinucleotides were separated. Paper electrophoresis and chromatography in the other direction of the paper led to an extensive separation of the nucleotides, GGU, AAU, GGC, and AAC being obtained pure. If the RNA was hydrolyzed with ribonuclease T1, the preliminary purification was unnecessary. Electrophoresis und chromatography gave as final products pure ACG, CAG, AAG, CCG, UUG, UAG, and AUG. The trinucleotide components were identified by high-voltage electrophoresis of the fragments obtained on hydrolysis. / Mh. Chem. *98*, 494 (1967) / –DK. [Rd 754 IE]

Ferrocene-labeled proteins *(2)* have been prepared by *H. Franz* by way of the *p*-ferrocenylphenyl isothiocyanate *(1)* (m.p. 133–135 °C; IR: 2150 cm^{-1}) which he has synthesized.



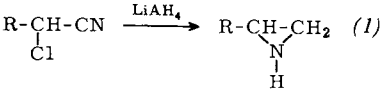
(1) *(2)*



(3)

It is thus possible to label proteins with heavy metals whilst avoiding disturbing complex association. Under the mild conditions of this reaction, the proteins largely retain their immunobiological properties. The author suggests that a further reaction of *(2)* with silver ions, giving *(3)* with separation of silver, could be used for electron-optical investigations. Compound *(1)* is obtained in a yield of 70 % by coupling ferrocene with diazotized *p*-nitraniline, reduction of the nitro compound to *p*-ferrocenylaniline, and further reaction with thiophosgene. / Naturwissenschaften *54*, 339 (1967); Z. Chem. *7*, 235 (1967) / –DK. [Rd 756 IE]

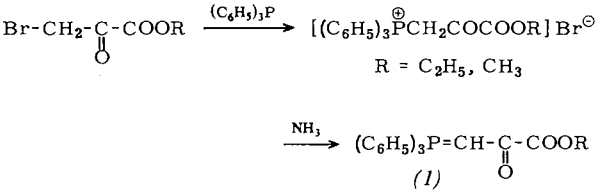
2-Monosubstituted aziridines can be obtained, according to *K. Ichimura* and *M. Ohta*, under very mild conditions in a new synthesis of general importance. The reduction of α-chloronitriles with $LiAlH_4$ at –5 to 0 °C proceeds *via* a reaction which is initially exothermic to give the corresponding aziridine *(1)* in good yield and without by-products.



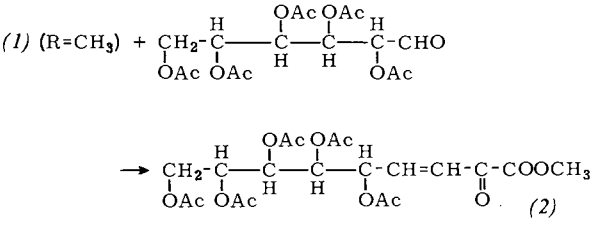
(1)

Thus, for example, 2-(*n*-propyl)aziridine is obtained from α-chloropentanenitrile in 82 % yield (R = n-C_3H_7; b.p. 114–118 °C). / Bull. chem. Soc. Japan *40*, 432 (1967) / –DK. [Rd 757 IE]

(Triphenylphosphoranylidene)pyruvic acid esters *(1)* were prepared for the first time by *Yu. A. Zhdanov* and *L. A. Uzlova* by the reaction of α-bromopyruvic esters with triphenylphosphine and NH_3 (m.p. 169–171 °C).



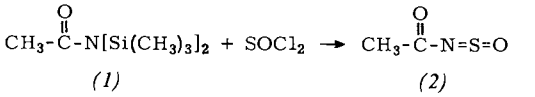
(1)



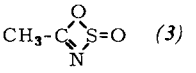
(2)

Wittig reaction of *(1)* (R = CH_3) with D-galactose pentaacetate gave the methyl ester of pentaacetyl-3,4-didehydro-3,4-dideoxy-D-galactononulonic acid *(2)* (m.p. 141–143 °C) in 52 % yield. The reaction thus gave a carbohydrate with an additional three carbon atoms, and thereby provides a means for the preparation of higher sugars and their derivatives, for example those found in lipids, gangliosides, *etc.* / Žh. obšč. Chim. *36*, 1211 (1966); Engl. translation: J. general Chem. USSR *36*, 1225 (1966) / –DK. [Rd 759 IE]

***N*-Thionylacetamide** *(2)*, attempts to prepare which from acetamide and $SOCl_2$ or by "transthionylation" had previously only given acetonitrile and SO_2, was obtained by *O. J. Scherer* and *R. Schmitt* in 70 % yield by the reaction of *N*-(bistrimethylsilyl)acetamide *(1)* with $SOCl_2$. Compound *(2)*, which is the first representative of a new group of compounds of thionylcarboxamides, is a yellow liquid (b.p. 36–37 °C/11 torr) that is insoluble in petroleum ether, readily soluble in ether, CCl_4, $CHCl_3$, and CH_2Cl_2, and reacts explosively with H_2O and alcohols. The possibility of a four-membered ring structure *(3)* was excluded on the



(1) *(2)*



(3)

basis of the IR band at 1740 cm^{-1} (C=O). / Z. Naturforsch. *22b*, 224 (1967) / –DK. [Rd 760 IE]

Novel manganese(II) complexes with the coordination number 8 were obtained by *K. C. Dash* and *D. V. R. Rao* by the reaction of dihalobispyridinemanganese(II) complexes with thiourea in methanol.

$$[Mn{\cdot}py_2{\cdot}X_2] + 4\ NH_2{-}CS{-}NH_2 \rightarrow [Mn{\cdot}py_2{\cdot}(NH_2{-}CS{-}NH_2)_4{\cdot}X_2]$$

(1)

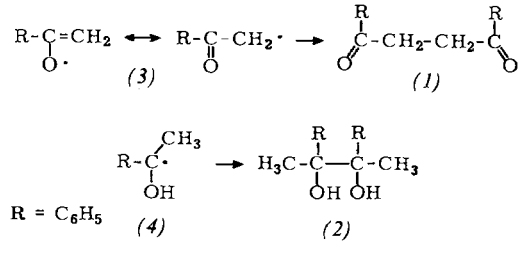
(1a): X = Cl, m.p. 177 °C, white platelets that are soluble in alcohol, nitrobenzene, and acetone. The compound is a weak electrolyte in acetone, and in the solid form it is paramagnetic (χ = 17770, μ_{eff} = 6.6 B.M.). *(1b)*: X = Br, m.p. 167 °C, white platelets with the same properties as *(1a)*, (χ = 15655, μ_{eff} = 6.1 B.M.). / Z. anorg. allg. Chem. *350*, 207 (1967) / –Sch.

[Rd 765 IE]

The mechanism of tRNA degradation by polynucleotide phosphorylases was studied by *M. N. Thang*, *W. Guschlbauer*, *H. G. Zachau*, and *M. Grunberg-Manago*. The enzyme cleaves the ribopolynucleotides by phosphorolysis, thus liberating 5′-nucleoside diphosphates. If ^{32}P phosphate is introduced, the diphosphates are labeled in the β-position. Phosphorolysis of tRNA is complete only above 45 °C, since at this point the chains are denatured, but not at, for example, 42 °C. At temperatures below 45 °C intact tRNA molecules remain, which are only very slowly decomposed. The degradation takes place as follows: (1) addition of the enzyme to the 3′-OH end; (2) step-by-step movement of the enzyme along the nucleotide chain with liberation of nucleoside diphosphates; (3) regions with secondary structure (base pairing) are only attacked very slowly; and (4) the enzyme does not separate from the substrate until it reaches the 5′-OH end. Polynucleotide phosphorylase is well known for its reverse reaction; it provided the first means of synthesizing polyribonucleotides and thereby the means for the beginning of the elucidation of the genetic code. / J. molecular Biol. *26*, 403 (1967) / –Hö.

[Rd 772 IE]

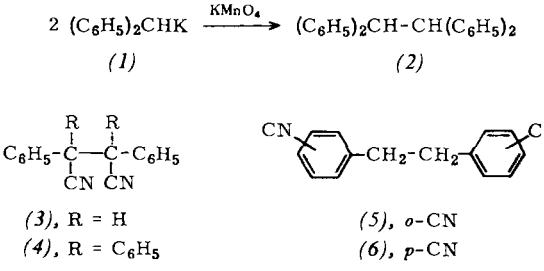
A new photochemical reaction of acetophenone is described by *H.-D. Becker*. When liquid acetophenone is irradiated with UV light in the presence of catalytic amounts of phenol (Hg high-pressure lamp, Pyrex filter), 1,2-dibenzoylethane *(1)* is formed in 86 % yield (calculated on the acetophenone reacted) together with a mixture of stereoisomeric acetophenone pinacols *(2)*. Methyl-substituted acetophenones react in the same way; the phenol may be replaced by certain substituted phenols, though these are less effective. It is assumed that the acetophenone undergoes a photochemical enolization catalyzed by phenol, and that the resulting product undergoes disproportionation to give a phenoxy *(3)* and a semipinacol



radical *(4)*, which then dimerize to give the reaction products *(1)* and *(2)*. / J. org. Chemistry *32*, 2140 (1967) / –Ma.

[Rd 777 IE]

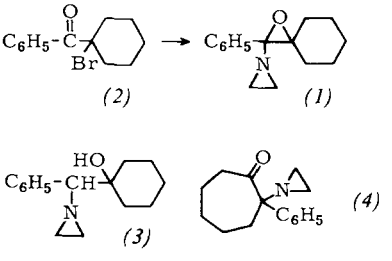
The oxidative dimerization of carbanions is described by *E. M. Kaiser*. The carbanions were prepared by means of alkali metal amides, and were dimerized rapidly and smoothly with oxidizing agents in liquid NH_3, the only impurity being the starting material. Solid $KMnO_4$ reacts with diphenylmethylsodium to give 1,1,2,2-tetraphenylethane *(2)* in 42 % yield, and with the potassium compound *(1)* to give *(2)* in 69 % yield; lower yields are obtained with $CuBr_2$, $K_2Cr_2O_7$, $KClO_4$, or air. The reaction is not limited to hydrocarbons; the potassium salts of phenylacetonitrile and diphenylacetonitrile react with $KMnO_4$ to give the dimers *(3)* and *(4)* in 67 and 77 % yields, and the potassium salts of *o*- and *p*-



tolunitrile give *(5)* and *(6)* in yields of 50 and 47 %. / J. Amer. chem. Soc. *89*, 3659 (1967) / –Ma.

[Rd 778 IE]

Epoxyamines are a new class of organic compounds. The first stable representative of this class, 2-(1-aziridinyl)-2-phenyl-1-oxaspiro[2.5]octane *(1)*, was synthesized by *C. L. Stevens* and *P. M. Pillai* by the action of the lithium salt of ethylenimine on α-bromocyclohexyl phenyl ketone *(2)* in ether at room temperature (b.p. 90–95 °C/0.001 torr; m.p. 20–22 °C; yield 70–75 %). Acid hydrolysis of *(1)* gave α-hydroxycyclohexyl phenyl ketone, reduction with $NaBH_4$ gave 1-[α-(1-aziridinyl)-benzyl]cyclohexanol *(3)*, and catalytic hydrogenation gave 1-(α-*N*-ethylaminobenzyl)cyclohexanol. When *(1)* was heated in boiling *o*-dichlorobenzene under nitrogen, ring expansion occurred with the formation of 2-(1-aziridinyl)-2-phenyl-



cycloheptanone *(4)*. / J. Amer. chem. Soc. *89*, 3084 (1967) / –Ma.

[Rd 779 IE]

Reactive aromatic heterocycles containing tetravalent sulfur have been identified by *R. H. Schlessinger* and *I. S. Ponticello*, and also by *M. P. Cava*, *N. M. Pollack*, and *D. A. Repella*. 1,8-bis(hydroxymethyl)naphthalene reacted with P_2S_5 in CS_2 to give the sulfide *(1)* (85 %, m.p. 102 °C), which was then oxidized with $NaIO_4$ to give the sulfoxide *(2)* (m.p. 230 °C; decomp.). Compound *(2)* reacted with *N*-phenylmaleimide in acetic anhydride to give the Diels-Alder adduct *(3)*. The mass spectrum of *(3)* contained a peak at *m/e* = 184, which was assigned to the retrodiene product naphtho[1,8-*c*,*d*]thiapyran *(4)*. Acenaphtho[5,6-*c*,*d*]thiapyran *(5)* was detected in an analogous reaction starting from 5,6-bis(hydroxymethyl)-acenaphthene. The trapping of *(4)* by dienophiles offers a simple method for the preparation of pleiadene derivatives.

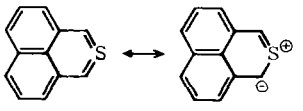
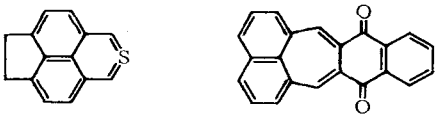
(2) X = SO

(3)



(4)

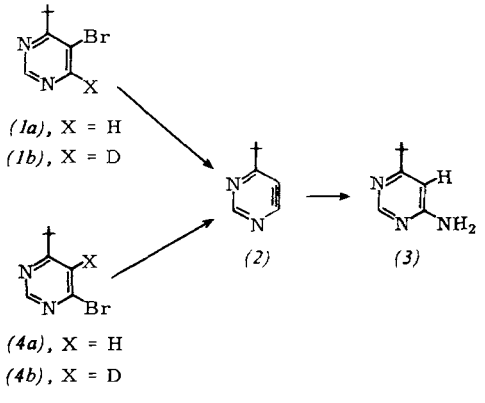


(5) (6)

For example, if the starting materials were *(2)* and 1,4-naphthoquinone, it was possible to prepare the unusually stable benzo[*l*]pleiadene-8,13-quinone *(6)* in the form of brown needles of m.p. 247–248 °C. / J. Amer. chem. Soc. *89*, 3640, 3641 (1967) / –Ma. [Rd 780 IE]

Mono-Na acetonitrile and homologous compounds, which are assumed to be the intermediates in many condensation reactions of nitriles with α-H atoms and in alkylation reactions of such nitriles, are reported by *C. Krüger* to be obtainable by the reaction of Na bis(trimethylsilyl)amide with acetonitrile or similar nitriles in ether at –40 to –60 °C (to avoid self-condensation of the nitrile). $NaCH_2CN$ adds only to polar double bonds (CO, CN); however, it also acts as a carbene precursor, particularly in the presence of cyanide acceptors. For example, after heating the compound in cyclohexene it is possible to demonstrate (by gas chromatography) the presence of norcarane (2 %). / J. organometallic Chem. *9*, 125 (1967) / –Ma. [Rd 781 IE]

The existence of the heteroaryne 6-*tert*-butyl-4,5-didehydropyrimidine *(2)* has been established by *H. C. van der Plas, P. Smit,* and *A. Koudijs.* Reaction of *(1a)* with KNH_2/NH_3 at –33 °C affords 6-amino-4-*tert*-butylpyrimidine *(3)* in 14 % yield. Under the same conditions, the isomer *(4a)* gives *(3)* in quantitative yield.



(1a), X = H
(1b), X = D

(2) (3)

(4a), X = H
(4b), X = D

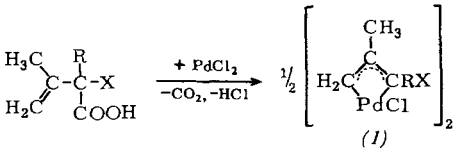
The results of experiments conducted with the deuterated compounds *(1b)* and *(4b)* ruled out other possible reaction courses, such as attack by the amide ion at the electron-depleted 6-position of *(1a)* and subsequent hydride shift, or addition/elimination reaction of *(4a) via* a resonance-stabilized anion. The reactions yielded compound *(3)* only, and not [5-D]-6-amino-4-*tert*-butylpyrimidine. / Tetrahedron Letters *1968*, 9 / –Kr. [Rd 830 IE]

Formation of methylenecyclohexadiene derivatives on dimerization of di- and triarylmethyl radicals has been established by *H. Lankamp, W. Th. Nauta,* and *C. Maclean.* On the basis of chemical properties and spectra, the authors deduce that there are two kinds of radical dimers: ethane derivatives, which only decompose slowly, if at all, into radicals (*e.g.* di-, (unsubstituted) tetra-, and pentaphenylethanes, as well as all tetraphenylethanes bearing a moderate number of *o*-alkyl groups). On the other hand, dimers that are in equilibrium with the free radicals in solution have a methylenecyclohexadiene structure. Examples:

	R^1	R^2	R^3	R^4	M.p. (°C)
(1)	CH_3	CH_3	H	H	120
(2)	CH_3	CH_3	H	CH_3	115
(3)	CH_3	CH_3	CH_3	CH_3	137
(4)	$(CH_3)_3C$	H	H	H	–

In solution, *(1)*, *(2)*, and *(4)* dissociate to approximately the same extent. Compound *(3)* is completely dissociated in solution; it can only be prepared from dimesitylmethanol with V^{2+} or Cr^{2+} in acetone/H_2SO_4 at low temperature. The UV and NMR spectra of *(1)* through *(4)* are in agreement with the structures assigned. For purposes of comparison, the ethane derivatives *(1a)* and *(3a)* corresponding to *(1)* and *(3)*, respectively, were prepared from the diarylmethanol with an excess of V^{2+} or Cr^{2+} at room temperature (yield 10–20 %). *(1a)*, m.p. 227–228 °C, and *(3a)*, m.p. 230–231 °C, rearrange to form the radical-containing equilibrium mixture or the radicals corresponding to *(3)* if they are heated for a short time at 220–240 °C and then quenched. *Gomberg*'s "hexaphenylethane" apparently also exists in the form of a methylenecyclohexadiene derivative. / Tetrahedron Letters *1968*, 249 / –Kr. [Rd 831 IE]

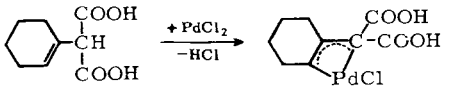
A new method for the preparation of π-allylpalladium chloride complexes *(1)*, which carry a carboxyl, an ester, an acid amide, or a nitrile group on C-1 and a CH_3 group on C-2, is reported by *R. Hüttel* and *H. Schmid.* The complexes are formed on reaction of unsaturated derivatives of malonic acid with $PdCl_2$ under mild conditions.



(1)

Examples: *(1a)*, R = CH_3, X = COOH, yield 97 % (as compared to a yield of 13 % when prepared from trimethylacrylic acid and a yield of 3 % of a mixture of isomers when prepared from isopropenylpropionic acid); *(1b)*, R = CH_3,

X = CN, yield 78 %; and *(1c)*, R = C_2H_5, X = $COOC_2H_5$, yield 70 %. In order to investigate the competition between proton loss and decarboxylation when the proton and the carboxyl group are both attached to the same C atom, 1-cyclohexenylmalonic acid was used as starting material in place of the unknown isopropenylmalonic acid. The formation of compound *(2)* proves that the highly activated α-

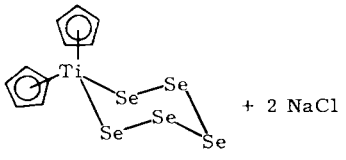


(2)

hydrogen atom is split off preferentially. / Chem. Ber. *101*, 252 (1968) / –Kr. [Rd 832 IE]

Di-π-cyclopentadienyltitanium(IV)pentaselenide *(1)* has been prepared by *H. Köpf, B. Block*, and *M. Schmidt*. They made use of the following reaction in aqueous acetone:

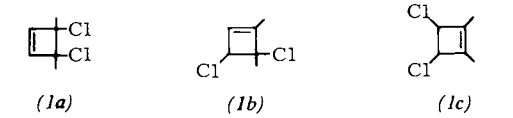
$(\pi\text{-}C_5H_5)_2TiCl_2 + Na_2Se_5 \longrightarrow$



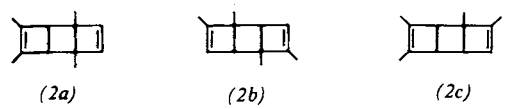
(1)

Compound *(1)*, dark violet crystals of m.p. 211 °C, is insoluble in water, difficultly soluble in ether or benzene, and moderately soluble in H_2S or dimethyldisulfide. *(1)* is stable in air. Its ^1H–NMR spectrum is temperature dependent: when recorded at room temperature, the spectrum contains two signals of equal intensity, irrespective of which solvent is used; as the temperature increases these signals (measured in dimethyldisulfide) broaden reversibly and finally coalesce. Above 100 °C, compound *(1)* reacts irreversibly with the solvent. The temperature dependence of the spectrum is interpreted as inversion of the six-membered ring, whose conformation is fixed. The ^1H–NMR spectrum of the known analogous pentasulfide, red-violet needles of m.p. 201–202 °C, shows the same temperature dependence. / Chem. Ber. *101*, 272 (1968) / –Kr. [Rd 833 IE]

"Dimers of 1,2-dimethylcyclobutadiene" *(2a)—(2c)* have been obtained by *R. Criegee, W. Eberius*, and *H.-A. Brune* on dechlorination of a mixture of the dichlorides *(1a)–(1c)* that is formed by addition of HCl to dimethylenecyclobutene. On dechlorination with lithium- or sodium amalgam, the compounds *(2a)–(2c)* were always formed in the molar



(1a) *(1b)* *(1c)*



(2a) *(2b)* *(2c)*

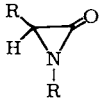
(3a) *(3b)*

ratio 1:1.4:5.4, irrespective of the molar ratio of the isomers *(1)*. Their pyrolysis to tetramethylcyclooctatetraenes served as proof of structure. In *(2c)* the rings are *syn*-fused, as the ozonization shows. The formation of *(2a)–(2c)* can be interpreted as a Diels-Alder synthesis from two molecules of 1,2-dimethylcyclobutadiene: *(2a)* and *(2b)* could be formed from one molecule each of *(3a)* and *(3b)*, and *(2c)* from two molecules of *(3a)* or *(3b)*. It is assumed that *(3a)* and *(3b)* are tautomers. / Chem. Ber. *101*, 94 (1968) / –Kr. [Rd 834 IE]

An unusually stable α-lactam that is derived from adamantane has been prepared by *E. R. Talaty, A. E. Dupuy jr.*, and *A. E. Cancienne jr.* 1-Adamantylacetyl chloride forms the bromine derivative *(1)* which yields the bromoamide *(2)* on reaction with 1-aminoadamantane (2 mole). Reaction of *(2)* with potassium *tert*-butoxide in ether at 0 °C affords the α-lactam *(3)*, m.p. 180 °C, 72 % yield. Compound *(3)* sublimes at

$R\text{-}CH_2\text{-}COCl \longrightarrow R\text{-}CHBr\text{-}COCl$ *(1)*

$\longrightarrow R\text{-}CHBr\text{-}CONH\text{-}R \longrightarrow$ *(2)*

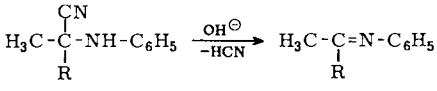


(3) R = 1-Adamantyl

105–110 °C/0.025 torr, and does not decompose in boiling xylene; decomposition in boiling methanol is not complete until a period of 30 h has passed. / J. heterocyclic Chem. *4*, 657 (1967) / –Ma. [Rd 835 IE]

Ketanils and ketimines may be prepared *via* α-cyanamines *(1)*, according to *J. S. Walia, L. Heindl, H. Lader*, and *P. S. Walia*. The compounds *(1)* are formed in excellent yields on reaction of ketones with aniline and $CN^{\ominus}$ ions in the presence of acetic acid. Reaction of *(1)* with methanolic KOH at room temperature affords ketaniles *(2)*. The reaction presumably proceeds by way of the base-catalyzed elimination of HCN from *(1)*. Examples:

R	Yield of *(1)* (%)	Yield of *(2)* (%)
Phenyl	87	94
p-Chlorophenyl	98	99
2-Thiophenyl	82	95
2-Pyridyl	89	72
Styryl	97	80



(1) *(2)*

/ Chem. and Ind. *1968*, 155 / –Ma. [Rd 836 IE]

The molecular structure of gaseous disulfane has been determined by *M. Winnewisser* and *J. Haase*, who combined the results obtained from electron diffraction experiments and microwave spectrometry. The electron diffraction data obtained by the sector microphotometer method indicated

the interatomic distances d(S–S) = 2.055 ± 0.001 Å and d(S–H) = 1.352 ± 0.010 Å and the angle (HSS) = 91° 57′ ± 30′. The H–H distance, and thus the dihedral angle between the two half molecules, could not be determined by electron diffraction because of the low scattering power of the H atom; for this reason the dihedral angle was established by microwave spectroscopy. For the molecule in question, it was possible to determine only differences in the rotation constants from which a value of 90°37′ ± 3′ can be calculated for the dihedral angle. / Z. Naturforsch. *23a*, 56 (1968) / –Hz.
[Rd 837 IE]

The use of tetrakis(triphenylphosphine)platinum(0) as initiator for radical polymerizations has been suggested by *C. H. Bamford, G. C. Eastmond,* and *K. Hargreaves.* It is used in combination with a suitable halogen compound (*e.g.* CCl_4). Since the activation energy for the initiation of the polymerization of methyl methacrylate amounts to only 11.2 kcal/mole, the combination is effective at temperatures between below room temperature and 80 °C. The unusually low frequency factor is assumed to result from steric hindrance to the formation of a transition complex with the monomer or the solvent. No inhibition occurs at high halogen concentrations. / Trans. Faraday Soc. *64*, 175 (1968) / –Hz.
[Rd 838 IE]

The absorption spectra of liquids in the millimeter range have been measured by *J. E. Chamberlain, H. A. Gebbie, G. W. F. Pardoe,* and *M. Davies* by means of Fourier transformation of interferograms. If an indium antimonide detector that is cooled by liquid helium is used, the long-wave limit of interferometry can be extended to 5 mm. The range of application of the method thus overlaps with that of microwave spectroscopy. The authors consider that the advantage of their method lies in the fact that broad absorption bands – such as are encountered with dielectric liquids in this spectral region – can be recorded better than with microwaves, since the tuning of microwaves over a wide range is very difficult. The spectra of water and of chlorobenzene as obtained by the new method are given as examples. / Chem. Physics Letters *1*, 523 (1968) / –Hz.
[Rd 839 IE]

The oxidation of phenylhydroxylamine by OH radicals in dilute (approx. 5×10^{-4} M) solutions saturated with N_2O, has been followed by pulse radiolysis by *A. Wigger, A. Henglein,* and *K.-D. Asmus.* The following reactions and data are deduced from the dime-dependence of the absorption spectra (0 to 20 μsec after the pulse):

$$C_6H_5NHOH + OH \rightarrow C_6H_5NHOH(OH) \quad (a)$$
$$\lambda_{max} = 440, 350, 270\ \mu m$$

($k = 1.2\times10^{10}$ to 1.5×10^{10} l·mole^{-1}·sec^{-1}, independent of pH between 3.7 and 11.5).

$$C_6H_5NHOH + e_{aq} \rightarrow C_6H_5NHOH(e_{aq}) \quad (b)$$

($k = 1.4\times10^{9}$ to 1.8×10^{9} l·mole^{-1}·sec^{-1}, *i.e.* slower than expected for a diffusion-controlled reaction).

$$C_6H_5NHOH(OH) \rightarrow C_6H_5NOH + H_2O \quad (c)$$
$$\lambda_{max} = 450, 270\ \mu m$$

($k = 1.8\times10^{5}$ sec^{-1}; $\tau_{1/2} \approx 5$ μsec at pH 4.5 to 7, ≈ 1 μsec at pH = 2 and 10)

$$C_6H_5NOH \rightarrow C_6H_5NO^- + H^+ \quad (d)$$
$$\lambda_{max} = 450, 290\ \mu m$$

($pK_a = 11.7$)

$$2\ C_6H_5NOH \rightarrow C_6H_5NO + C_6H_5NHOH \quad (e)$$
$$\lambda_{max} = 330\ \mu m$$

($k_{max} = 4\times10^{7}$ l·mole^{-1}·sec^{-1} at pH = 11.5).

BOOK REVIEWS

Massenspektrometrische Strukturanalyse organischer Verbindungen. Eine Einführung. (Mass Spectrometric Structural Analysis of Organic Compounds. An Introduction). By *G. Spiteller.* Verlag Chemie GmbH., Weinheim/Bergstr. 1966. 1st Edit., xii, 355 pp., 91 illustrations, 2 tables, DM 44.–.

Now that this work has been published, we have at our disposal a German-language book that presents the principles of this modern physical technique which, during the last decade, has achieved immeasurable importance for structural analysis of organic molecules; the book also enables the reader to use the method practically. Combinations with gas chromatography, thin-layer chromatography, and pyrolysis, together with the insights thereby obtained into fragmentation processes, have converted mass spectrometry into a specialist area with great possibilities for interpretations over a wide section of chemistry as a whole. The appearance of a monograph of this kind is thus particularly welcome.

The first section treats briefly the physical principles and details of apparatus. It is to be welcomed that attention is paid to practical directions for addition of samples, relative quantities, purity of samples, evaluation of spectral quantities, *etc.* This is of great value because, in the reviewer's experience, the difficulties of the beginner start with reading the graph that emerges from the mass spectrometer.

In the second section the mechanisms of ion formation and degradative reactions of organic molecules in the mass spectrometer are explained in great detail.

In the third section there follow descriptions and explanations of the mass spectra of the most important classes of chemical compounds. Here it has proved valuable to divide substances into aliphatic hydrocarbons and those with substituents of class 1 and 2, aromatic types of compounds, heterocyclic compounds, and aliphatic compounds containing several functional groups. Numerous examples are given, by means of which the key fragments typical of a class of compounds are clearly set out.

The fourth section contains mass spectra of natural products. Typical decomposition reactions are presented by means of characteristic examples and with references to the literature.

The fifth and final section is devoted to an introduction into the evaluation of mass spectra of substances of unknown composition. It contains very helpful and useful tables showing the neutral fragments split off in the first stage of decomposition and also the key fragment ions. Experimental details are also given for chemical reactions on the micro scale which are particularly useful since they permit pre-

paration of those derivatives that are most suited to mass spectrometric work.

The author's great experience in mass spectrometric structural analysis is evident from the many valuable and practical directions. The book provides an excellent foundation for chemists who have to deal with mass spectrometry of organic compounds. *K. Heyns* [NB 662 IE]

Grundlagen der Synthese von Zwischenprodukten und Farbstoffen (Principles of the Synthesis of Intermediates and Dyestuffs). By *N. N. Woroshzow*, Translated into German by *E. Baumann* and *F. Bahr*. Akademie-Verlag, Berlin 1966, 1059 pp., 26 illustrations and 12 charts, DM 135.–.

After an interval of several decades a major work has appeared in which the principles of the synthetic methods of interest in dyestuff chemistry are discussed in detail. The present book contains a wealth of material collected from the literature and critically surveyed. An introductory chapter, treating in particular the principles of aromatic electrophilic and nucleophilic substitution, is followed by 14 chapters concerned with sulfonation, nitrosation, introduction of halogen, introduction of amino groups, replacement of the sulfo group by a hydroxyl group, replacement of halogen by other substituents, interconversion of amino and hydroxy compounds, diazotization, acylation, oxidation, and sulfuration, reduction of compounds containing nitrogen-free functional groups, condensations, and rearrangements.

The individual chapters treat the synthetic principles in general first, then the mechanistic principles, and finally the preparative and sometimes the technical operations, as well as special cases. Every chapter is characterized by an extraordinarily large number of references to the old and new literature; the many references to Russian papers are sure to be of particular importance to readers in the Western hemisphere. One can point, for instance, to the discussion of the kinetics of alkali melts (p. 351) where it is shown that the experimental proof, usually attributed to *J. F. Bunnett*, for the two-stage mechanism of nucleophilic aromatic substitution by means of *Bodenstein*'s equation for the stationary state, was given as early as 1938 by *Woroshzow jun.* for alkali melts of aromatic sulfonic acids.

On the other hand, a remarkable feature of this book is that sections presented in a very modern way are often placed next to problems that are discussed in the manner of the 1920's. In spite of this limitation, *Woroshzow*'s book is a mine of knowledge, not only for the dyestuff chemist, but also for all chemists who are interested in the principles of aromatic chemistry. It shows again how many interesting basic problems advanced by the technical development of dyes during the past hundred years still await detailed investigation. *H. Zollinger* [NB 660 IE]

Zuckerchemie. Eine Einführung (Sugar Chemistry. An Introduction). By *G. Henseke*. Akademie-Verlag, Berlin 1966. 1st Edit., 167 pp., 3 tables, 3 charts, DM 25.–.

This little book follows a mainly conventional pattern. The author has succeeded in collecting a very large amount of the wide area of carbohydrate chemistry in a small space; the book consequently bears some resemblance to a dictionary. Corresponding to their importance, the significant classes of compound and the fundamental reactions are discussed, their arrangement being easy to follow. In this respect the book fulfils its purpose and provides a rapid survey for all who are interested and particularly for readers who are not chemists. The numerous formulas are clear and have been prepared with great care; however, most of them are drawn with the sugar chain vertical, whereas in recent years presentation by means of ring formulas and, whenever possible, by stereochemical formulas has been preferred because these lead to a better understanding of the actual molecular shapes and the course of reactions. It is only in the latter way that the reader can readily appreciate how considerations of mechanisms developed in the past decade and modern methods of measurement apply also to carbohydrate chemistry. The relation of reaction mechanism to stereochemistry, questions of conformational analysis, and the importance of NMR spectroscopy for determination of structure could well have been more strongly emphasized. *H. Paulsen* [NB 663 IE]

Kunststofftechnisches Wörterbuch (Plastics dictionary), Vol. III, French-German. By *A. M. Wittfoht*. Carl Hanser Verlag, München 1966. 1st Edit., xvi, 768 pp., plastic cover, DM 124.–.

The previously published Volume 4 (German-French) has been warmly recommended because of the very good compilation and excellent explanation of individual words, often supported by most useful drawings and diagrams.

The same can be said about the present volume. As such, the dictionary is exemplary in arrangement and typography, and hence very lucid as well as convenient to use. The fields of application of plastics dealt with in Volume 4, *e.g.* adhesives, reinforced plastics and foams, have been expanded to include the latest developments. Novel chemical processing and processing machinery, *e.g.* winding techniques and heat insulation by ablation, have been added. The inclusion of units and standards employed in plastics testing is welcome. A further feature is the inclusion of size-reduction machinery, winding techniques, glass fibers, coating, dryers, welding and a section on "plastic pipes" in the illustrated section previously comprising shaping, presses, molds, processing and mixers.

A very high standard has been achieved through the collaboration of numerous German and French specialists, particularly *Max Windsor*, whose name appears as co-editor. The book has become the standard work in the plastics field for technologists, businessmen, and translators alike, and can be warmly recommended to all interested in this field. *O. Horn* [NB 653 IE]

Zur Viskosimetrie (Viscometry). By *L. Ubbelohde*. Completely revised by *G. H. Gottner* and *W. Weber*. S. Hirzel Verlag, Stuttgart 1965. 7th Edit., xii, 75 pp., 15 illustrations and 19 tables, DM 18.60.

The seventh edition of this standard work, which has been thoroughly revised, differs from the previous editions in introduction of the standard value 1.002 cP for the viscosity of water at 20 °C.

The book is divided into three parts: a general part, a theoretical part, and tables for conversions and calculations. A pleasing feature is the concise and clear exposition, which strives towards a general presentation of the problems of viscometry and yet remains close to everyday practice.

The book has won for itself a wide readership among research and industrial workers, although in this edition specialization on the requirements of the petroleum industry has been avoided. *K. F. Elgert* [NB 681 IE]

Handbuch der mikrochemischen Methoden (Handbook of Microchemical Methods). Edited by *F. Hecht* and *M. K. Zacherl*. Vol. 4: Elektronenstrahl-Mikroanalyse (Electron Beam Microanalysis). By *H. Malissa*. Springer-Verlag, Vienna-New York 1966. 1st Edit., viii, 154 pp., 79 illustrations, linen DM 49.–/Subs. price DM 39.60.

In this volume of the Handbook, theory, technique, and uses of electron beam microanalysis are described in detail. The main section includes X-ray emission analysis with ex-

citation of the X-radiation by a focused electron beam. Other techniques such as those involving electron and X-ray absorption, electron scattering, and X-ray and electron diffraction are treated more briefly because of their lesser analytical importance. Electron microscopy is omitted.

The presentation is illustrated by means of many examples that are taken from the literature or from the authors' own researches. An exhaustive list of references is added to each of the five chapters; in particular, the last chapter, which concerns actual examples from research, has a literature appendix containing 238 references, arranged according to subjects. In view of the wide range of material considered, and the fact that it is partly new, it is not surprising that a few errors occur, *e.g.* the explanation and numerical values for resolving power on p. 61 and some formulas and dimensions in section b on pp. 83–89. An author index and a (regrettably too short) subject index are attached. The book will be a valuable help to all engaged in electron and X-ray microanalysis. *H. Massmann* [NB 678 IE]

[1] Cf. Angew. Chem. *75*, 239 (1964).

Kernmagnetische Resonanz (Nuclear Magnetic Resonance). By *H. Sillescu*. Springer-Verlag, Berlin-Heidelberg-New York 1966. 1st Edit., viii, 136 pp., illustrations, DM 32.–.

Nuclear magnetic resonance spectra, particularly high-resolution spectra of organic liquids, present the chemist with clear relations to the parameters of a given molecule; the former assumption that theoretical calculations would be fruitful in this field has indeed proved accurate during recent years. However, for a thorough understanding the chemist needs knowledge of sections of theoretical physics that had to be sought out tediously from textbooks written for physicists. In this area the present book fills a gap for German-speaking chemists, in that the classical relations are briefly summarized and applied to the operator formalism of quantum mechanics, thence are derived the consequences that apply to nuclear resonance spectroscopy, and indeed in a breadth and with a detail that do not use a phrase such as "a short calculation shows that" to fob off the chemist who is not always very proficient in mathematics.

The theory of broad line nuclear resonance spectroscopy, as well as that of high-resolution techniques, are treated very thoroughly, but the double resonance methods that are so important for the organic chemist are barely mentioned. Chapters on quadrupole coupling and relaxation phenomena complete the physical section. However, the mathematical appendix is likely to be too brief for the chemist who has had only the minimum of training. In spite of its didactically precise construction the book requires concentrated reading by the beginner; for the expert it will be a welcome revision. The production is good, but in the interest of a lower price it could have been more economical.

E. G. Hoffmann [NB 667 IE]

Reaktionen an und in Festen Stoffen (Reactions on and in Solid Substances). By *K. Hauffe*. Anorganische und Allgemeine Chemie in Einzeldarstellungen (Inorganic and General Chemistry), Volume II. Springer-Verlag, Berlin-Heidelberg-New York 1966. 2nd revised Edit., xii, 968 pp., 525 illustrations, DM 148.–.

The first edition of this book was reviewed in this Journal [*] over ten years ago. Since that time, "on and in", as this book is called in the laboratory, has proved a reliable guide to research in the field of solid-state reactions, and what was said then still applies today. The work rests on two foundations: disorder theory and diffusion theory. Great progress has meanwhile been made in both areas, also in their relation to solid-state chemistry, and not least through two symposia, severally in Amsterdam and Munich. It is thus not surprising that the author has wished to modernize his book; but it is surprising that he has found the time and strength for such an undertaking; the shear increase in size from 700 to 1000 pages shows how much had to be done. However, the increased range and the increased documentation promotes the book from the ground state of a textbook for students into the conductivity band of a handbook for the active research worker.

The general layout of the book has not changed. After a general chapter on defect phenomena, defects in ionic and covalent crystals are treated as special cases, and boundary-layer phenomena receive particular emphasis. Then follows the extensive chapter on diffusion, and thus the ground is prepared for discussion of special groups of phenomena: oxidation (scaling), formation of higher ionic compounds (additions), reduction, and roasting. A final chapter briefly collects together what has not yet been discussed in the book: ceramics and metal ceramics, photography, catalyst carriers, passivity, deformability, crystal growth, epitaxy.

Treatment of this very varied material is brought up to date in the present edition. The means by which this was done are as follows. The theoretical part of the chapter on diffusion has been completely revised by *C. Seyfert*, a former collaborator of the author and now in Karlsruhe; it now provides solutions for the most varied geometries and boundary conditions. Except for a number of additions, the atomistic part of this chapter has undergone little change. The electrochemistry of ionic crystals has been included at appropriate places in the text; progress since the first edition makes it now possible to obtain some information about defects and carrier activities from potential measurements on solid-state cells.

New results on the interaction of gases with semiconductors are discussed in the hope that these phenomena will become more important to catalysis and to the reduction of ores, though progress in these directions is not yet remarkable. Much new material has been added concerning oxidation of metals and reduction of ores.

This book thus bears witness to steady progress in solid-state chemistry with the help of solid-state physics, but progress is not marked by spectacular breakthroughs. An impression, admittedly a fleeting one, was formed by the reviewer that the first edition, conceived originally as a whole, has not absorbed the newer experimental material quite homogeneously, but that the latter has been treated more in the form of abstracts and thus creates a kind of disturbance. This was probably unavoidable and will certainly not stop "on and in" from being, in the future as hitherto, a faithful and indispensible aid for all solid-state chemists.

G.-M. Schwab [NB 676 IE]

Der Stoffwechsel im Zentralnervensystem (Metabolism in the Central Nervous System). By *N. Seiler*. Verlag Georg Thieme, Stuttgart 1966. xi, 139 pp., 23 illustrations, 11 tables, paperback, DM 24.–.

This volume in the monograph series "Biochemie und Klinik" (Biochemistry and the Clinic) gives a welcome survey of present views on basic dynamic biochemistry, exemplified for the central nervous system in physiological and pathological states. General metabolic processes, as they occur in other organs, are first described as an essential preliminary for understanding of special functions, and then the peculiarities of the central nervous system are set out. In this way the metabolic problems such as anoxia, narcosis, and mental illnesses which are so typical for the brain are explained. The author describes in particular detail the metabolic disturbances that so often lead to mental illness.

Although the most recent knowledge is not considered in all the chapters, a particular merit of this book is the consistently brief presentation of the most important results in this field, a presentation that is based on an underlying knowledge of the literature. The book provides a worthwhile foundation for all who may be occupied with the special questions of the functions of nerves or brain. Further, the text is everywhere so richly provided with references that it eases the way to further information for those interested in greater detail.

H. Wiegandt [NB 661 IE]

Die Entwicklung der Chemie in der neueren Zeit (The Development of Chemistry in Modern Times) by *H. Kopp*. Geschichte der Wissenschaften in Deutschland, Band X (History of Science in Germany, Vol. 10). Johnson Reprint Corp., New York. Georg Olms Verlagsbuchhandlung, Hildesheim 1966. Reprographic reprint of the 1873 Munich edition. xx, 854 pp., DM 118.–.

The Development of Chemistry constitutes Volume 10 of the "Geschichte der Wissenschaften in Deutschland – Neuere Zeit" (History of Science in Germany – Modern Times), issued by the Historical Commission of the Royal Academy of Sciences in Munich under the patronage of Maximilian II, King of Bavaria. Other volumes included *Karmarsch*, "The History of Technology" (Vol. 11, 1872) and *Hirsch*, "The History of Medicine" (Vol. 22, 1893). This series, to which the reprint unfortunately makes no reference, was a continuation of a similarly conceived encyclopedia entitled "A history of arts and sciences from the Renaissance to the end of the 18th century", including contributions by *J. F. Gmelin* on chemistry (1797–1799), *Poppe* on technology (1807–1811), and *Haeser* on medicine (1846–1860). These form the subject of an earlier review[1].

The present work, entitled "Development" by the author in order to "eliminate the possibility of confusion with my earlier [1843–47] 'History of Chemistry' " is interesting for two reasons. Shortly after the proclamation of the Empire in 1871, which put an end to the multiple-state system in Germany, *i.e.* in a strongly national, even emphatically nationalistic epoch, *Kopp* wrote in a preface "chemistry belongs ... to those branches of knowledge which neither in regard to the subject matter, nor in the treatment, nor in the form in which the results obtained are expressed, can be property of a particular nation". For this reason "the historian must consider himself as having no particular home, and as a citizen of no particular country". In complying with this premise, *Kopp* did not write a history which put the development of chemistry in Germany in the foreground, but one in which the individual national contributions were given a status according to their importance. On the other hand, *Kopp*'s "Development", which records the results up to around 1858, is to a large extent a contemporary account of the origins of the "knowledge now becoming important". Although the author did not himself set out to present this, he had to report on its origin. Thus, only about the first 200 pages of the book lead the reader from the chemical knowledge of antiquity to the general acceptance of the antiphlogiston system of Lavoisier. The major part of the book is taken up by discussion concerning the development of the theoretical aspects of chemistry, above all progress in organic chemistry up to about the time of *Laurent*, *Gerhardt*, and *Kolbe*; *Kekulé*'s treatise "On the constitution and the metamorphoses of chemical compounds" [1858] forms the conclusion, because "these reflections belong to the chemistry of the present ... and should not form the subject of a historical essay".

Both *Kopp*'s "History" and "Development" are standard works in the history of chemistry; a reprint of the latter is therefore very welcome. *W. Ruske* [NB 654 IE]

[1] *W. Ruske*, Angew. Chem. *79*, 587 (1967); Angew. Chem. internat. Edit. *6*, 578 (1967).

Actions Chimiques et Biologiques des Radiations. (Chemical and Biological Action of Radiation.) Edited by *M. Haissinsky* with contributions by *E. J. Hart*, *C. Ferradini*, *T. J. Hardwick*, and *A. Chapiro*. 10th series. Masson & Cie. Editeurs, Paris 1966. 1st Edit., 324 pp., 78 figures, 49 tables, F 120.–.

This new volume in the series, which is intended as an exchange of information between radiochemists and radiobiologists, again contains four authoritative reviews of the latest developments in certain fields of radiochemistry.

The first article is on the hydrated electrons formed on radiolysis of water (*E. J. Hart*, English, 88 pp., 150 references). A short introduction on their discovery is followed by a description of the experimental methods that are used for their production and detection. The physical properties and the structure of the hydrated electrons are then described, as are their reactions with free radicals and with stable inorganic and organic substances. The rate constants of the reactions discussed are tabulated in a 12-page appendix. It would have done no harm to mention in connection with the discovery of hydrated electrons that they were first observed and identified in irradiated frozen aqueous systems in a German radiochemical laboratory.

The content of the second article, "Reaction Rates of Free Radicals in the Radiolysis of Water" (*C. Ferradini*, French, 35 pp., 120 references), follows on from that of the first. It deals with the rates of the reactions of the other radicals OH, H, HO_2, and $O^{\ominus}$, formed by the action of radiation on water, with one another and with other inorganic and organic substances (13 pages of tables giving rate constants).

In the next article, "Radiolysis of Liquid Hydrocarbons" (*T. J. Hardwick*, English, 61 pp., 120 references), an attempt is made in the introduction to explain the processes that precede the actual chemical reactions when ionizing radiation passes through a liquid system. This is followed by an outline of the radiolysis of saturated and unsaturated aliphatic compounds and of aromatic compounds, in which reaction mechanisms and yields are given and discussed.

The last contribution is devoted to the interesting but as yet unexplained "Radiation-Induced Polymerization in the Solid Phase" (*A. Chapiro*, French, 125 pp., 230 references). The author confines his discussion to the polymerization of vinyl derivatives, a few heterocyclic compounds, and aldehydes and nitriles. Discussion of the kinetics of the reactions is deliberately avoided, but an attempt is made to apply the general principles of radiochemistry to the reactions.

Since the coverage of the latest literature is very comprehensive, these very readable articles should provide valuable information for all chemists and biologists working in related fields. *U. Schindewolf* [NB 684 IE]

Polyolefins. Structure and Properties. By *H. von Boenig*. Elsevier Publishing Company, Amsterdam-London-New York 1966. 1st. Edit., ix, 319 pp., 80 illustrations, 117 tables, Dfl. 47.50.

As can be seen from the subtitle, the author has set himself the aim of accounting for the properties of the olefins on the basis of their molecular structure, which immediately determines their crystalline, supermolecular structure (single crystals, spherolithic aggregates) which in turn plays an important role in the industrial applications of these compounds. The choice and subdivision of the material, which is presented in a condensed form, corresponds to this aim.

A short consideration of the historical development in the first chapter is followed by a treatment of the structure of the polyolefins in the Chapter 2. The latter deals with the steric regularity, the helix conformation, and the connected problem of crystallization from solution and from the melt.

In the third chapter the author considers in detail the dependence of some properties on the density; a topic which permits far-reaching conclusions to be drawn regarding the molec-

ular structure and also gives some indication of the tensile strength, stiffness, hardness, and modulus of elasticity. Polyethylenes are therefore expediently classified as being of low, medium, or high density.

In the remaining five chapters the connections are investigated which exist between the structure of polyolefins and their physical, chemical, electrical, and thermal properties and their behavior on being processed. The last chapter is particularly important for people interested in the technology of plastics. Great emphasis is placed upon the relation between structure and rheology, the melt flow index being stressed as a suitable parameter. When the molecular weight distribution, which determines *inter alia* the shrinkability and distortion tendency, is taken into account, the melt flow index proves a good numerical indication of the workability, as well as of the shock and breaking behavior of formed objects. The progress which has been made in the extrusion of polymers is alluded to and phenonema such as melt fracture are discussed.

Boenig's book should appeal to both researchers and technologists. The fruitfulness of the cooperation of these two groups of workers is evidenced by the spectacular advances made in the field of polyolefins during the last decade. The book may well make an important contribution to this continuing development.

The book is comprehensibly written, comprehensively subdivided, richly furnished with illustrations and tables, and contains a wealth of references to the original literature.

H. Weber [NB 624 IE]

Electrophilic Additions to Unsaturated Systems. By *P. B. D. de la Mare* and *R. Bolton*. Reaction Mechanisms in Organic Chemistry, Monograph 4. Edited by *C. Eaborn* and *E. D. Hughes*. Elsevier Publishing Company, Amsterdam-London-New York 1966. 1st Edit., x, 284 pp., numerous schemes and tables, Dfl. 40.00.

The present monograph, which is the fourth in the series "Reaction Mechanisms in Organic Chemistry", deals with electrophilic additions to unsaturated systems. One of the authors, Professor *de la Mare*, has himself made numerous experimental contributions in this field.

The book is divided into 13 chapters. A short introduction and a chapter on the chemistry of carbonium ions are followed by a discussion of the principal electrophilic additions. These include hydration, the addition of weak acids, of mineral acids, and of halogens, epoxidation, and the addition of sulfenyl halides and of compounds containing electrophilic nitrogen, phosphorus, or arsenic. The final chapter deals with electrophilic additions to acetylenes, allenes, conjugated dienes, and to other systems such as C=O, C=N, S=O, and N=N double bonds.

The content of the book, which is built up on a purely theoretical basis, is extremely rich; the literature is covered up to the end of 1964.

No procedures are given for the execution of electrophilic additions, nor are any to be expected in view of the very concise presentation.

The book is very well written, and as a valuable contribution to theoretical organic chemistry it makes an excellent companion to the volumes published earlier.

F. Asinger [NB 583 IE]

Introduction to Practical High Resolution Nuclear Magnetic Resonance Spectroscopy. By *D. Chapman* and *P. D. Magnus*. Academic Press Inc., London-New York 1966. 1st Edit., ix, 112 pp., 30 illustrations, numerous tables, 25 s/$ 4.25.

This book is intended to provide a first introduction to nuclear magnetic resonance spectroscopy and its potentialities for students and for chemists engaged in structure determinations of organic molecules; its particular aim is to introduce them to carrying out these studies in practice. For this reason the authors intentionally desist from any form of theoretical derivation.

The fundamental ideas such as chemical shift and spin-spin coupling are introduced in a few words and are clearly explained by means of examples. Reference is made to detailed monographs for deeper study. The section on experimental technique is somewhat more expansive. The use of ^{19}F, ^{31}P, ^{14}N, and ^{13}C nuclear resonance in organic structural analysis, and five well chosen examples, close the first part.

The second part consists of 37 very clearly arranged tables of τ values and coupling constants from recent literature.

This book can be recommended as a brief introduction into the methods and experimental technique, and into the analysis of spectra, for chemists who wish to use nuclear resonance spectroscopy for determination of structure.

H. Friebolin [NB 665 IE]

Advances in Alicyclic Chemistry. Edited by *H. Hart* and *G. J. Karabatsos*. Academic Press Inc., London-New York 1966. 1st Edit., x, 395 pp., numerous illustrations and tables, bound $ 16.50.

This book is the first volume of a new series in which it is intended regularly to report the most recent results in the chemistry of alicyclic compounds. The reviewer agrees with the editors that the explosive growth of the original literature justifies a further new series.

The editors have been successful in obtaining for this volume competent authors who in their own papers have contributed important material to the fields which they treat here. Considered as a whole, the book provides a balanced and in parts highly critical survey.

J. Meinwald and *Y. C. Meinwald* report on bicyclo[*n*.1.1]-alkanes and related tricyclic systems. It would be welcomed by the reviewer if the nomenclature rules for bicyclic and tricyclic bridged compounds given by the authors in their introduction were generally adopted. The main discussion of the bicyclic compounds is devoted to the bicyclo[2.1.1]hexane and the bicyclo[1.1.1]pentane system, their syntheses and reactions, and rearrangements of their derivatives. A special section is devoted to consideration of highly strained tricyclic compounds (tricyclopentane, -hexane, and -octane).

The chemistry of cyclopropenes is surveyed by *G.L.Closs*. He discusses in detail, not only the synthetic possibilities for cyclopropene and its derivatives, but also their reactions, the spectral properties, and the bonding. The peculiar "aromatic" properties of the cyclopropenyl cations and of the cyclopropenones are treated in depth.

A detailed chapter (*A. J. Waring*) is devoted to cyclohexadienones. The author brings together the extensive and widely scattered material with great care. Of the 121 pages of this chapter, 53 pages are reserved for the varied ways of forming cyclohexadienones; other parts describe their transformations and reactions. A special section is reserved for the photochemistry of cyclohexadienones.

In the next chapter *K. F. Koch* surveys the photochemical rearrangements of monocyclic tropolones and benzotropolones, and of colchicine and isocolchicine. The structures of the "lumi"-products are discussed in detail with reference to their UV, IR, and NMR spectra.

In spite of two previous reviews of "reactions at a bridgehead" [1], the chapter by *R. C. Fort* and *P. v. R. Schleyer* on the same theme contains much new experimental material that has become available only during the last five years. Besides containing a theoretical section, this chapter collects

[1] *D. E. Applequist* and *J. D. Roberts*, Chem. Reviews, *54*, 1065 (1954); *U. Schöllkopf*, Angew. Chem. *72*, 147 (1960).

together the reactions of bridgehead carbenium ions, carbanions, and free radicals.

One can only hope that the same high level will be maintained in the further volumes planned for this series. The editors and authors will then have given us a good "Advances" series. *M. Hanack* [NB 668 IE]

High Resolution Nuclear Magnetic Resonance Spectroscopy. By *J. W. Emsley, J. Feeney,* and *L. H. Sutcliffe.* Pergamon Press, Oxford 1965 and 1966. 1st Edit., 2 volumes, xxiii, 1154 pp., numerous illustrations and tables, linen 105 s.

The two volumes of this work begin with a detailed description of the physical principles underlying NMR techniques, which is followed by two chapters (together 79 pp.) on the calculation of chemical shifts and coupling constants in accord with various theories. The individual parts of a spectrometer are described for the experimentalist, as are the practical methods of preparing the sample, of standardization, and of the actual measurement; information on these subjects had previously to be searched out from different sources and supplemented by personal experience. The chapter on spectral analysis, *i.e.* on determination of δ- and J-values from measured spectra occupies 200 pages, which constitute almost a third of volume 1. The theory is used to develop expressions needed for the analysis of all the important spin systems and gives indications for their evaluation. Spectroscopic effects of chemical equilibria and fast reactions are placed in a special chapter.

The whole of volume 2 is devoted to special applications of the method to chemical problems, the voluminous material being arranged according to the atomic nuclei under study (^{1}H 205 pp., ^{19}F 97 pp., other nuclei 139 pp.) and within each such section according to the chemical classes of compounds. Although the literature has not been completely covered up to 1963, this collection of material, with its many clear tables, is an imposing performance by the authors. It is a pity that two whole years passed before publication of this work! The appendix to the book must also be recognized as very useful; it contains, *inter alia*, the contributions of a benzene ring to the shielding of a neighboring proton (according to *Johnson* and *Bovey*) and *Tiers*' tables of τ values which were hitherto of limited availability.

The work reviews mainly the results and opinions in the original papers and generally refrains from new interpretations of the material reported. Evaluations, if made at all, are expressed in very restrained language; for instance one does not read "The authors' measurements are valueless" but, instead, "It is difficult to assess the theoretical significance of their measurements".

The opportunity to unify definitions, terms, and symbols has not been exploited; on the contrary, the usage, *e.g.* for chemical shift, for line width, or for mean lifetime, changes according to what was used in the paper being reviewed. Some equations in volume 1 (particularly on pages 481 to 491) contain errors which can mislead the user; and in these places the conscientious reader may need many hours to recognize errors as such.

Naturally it is not difficult, with a work of this range, to find items that have been incompletely or incorrectly described, particularly as this is a field of study that touches on a series of different scientific disciplines – from theoretical physics to the chemistry of natural products. Thus no author – and also no reviewer – will be able to master the whole of the material. All the greater, therefore, is it to the authors' credit that they have provided a comprehensive book. It is not conceived as an introduction to the method; but it can be recommended to every NMR spectroscopist for advanced, critical study. Further, these volumes are likely to be essential to everyone as a reference work; for this purpose they may be considered as a new edition of *Pople, Schneider,* and *Bernstein*'s standard work that appeared in 1959.

A. Mannschreck [NB 671 IE]

Indole Alkaloids. An Introduction to the Enamine Chemistry of Natural Products. By *W. I. Taylor.* Vol. XXVIII of the series: A Course in Organic Chemistry, Advanced Section. Pergamon Press, Oxford 1966. 1st Edit., 148 pp., numerous figures, paper back 25/–.

On 140 pocket-book pages, half of which are filled with structural formulae, an attempt is made to treat the chemistry of the indole alkaloids unconventionally deductively by emphasizing the reactions of the indole system and biogenetic considerations. This method, the fulfilment of which has become possible only as a result of the rich volume of data collected during the last 10 years (the principle is due to Sir *Robert Robinson*) assures the reader of continuity, while the individual facts do not appear overwhelming. In his search for (generally biogenetic) inter-relationships the author has not hesitated to formulate hypothetical intermediate stages and as yet undiscovered alkaloid variants. Occasionally more remote analogies are resorted to in order to explain the course of reactions (*e.g.* Lycorine-neostrychnine on p.79). By adhering to this method the author succeeds in including, although sometimes only briefly, a large number of preparative and physicochemical details.

As a result of its recent date of publication, and the concepts that are consequently involved, the book is somewhat more modern than other works on alkaloids. Numerous results of the last few years appear to have been summarized here for the first time. Entries such as picraline, echitamine, copsine, vindoline, vincamine, voacamine, schizozygine, burnamicine, and also skytanthine as a mevalonoid nonindole alkaloid, characterize part of the developments revealed by the author. In general, the biogenetic postulates are based on mevalonic acid, although at the time of writing the book no confirmatory labeling experiments had been carried out.

Although the book could be recommended as a summary, or to those who wish to gain a brief overall picture of the more recent classes of alkaloids, a certain degree of familiarity is taken for granted. Compared with the books by Bentley, Boit, or Manske-Holmes, it is not really suitable as an introduction. The formulas are well presented, misprints are rare, and the price is not unreasonable. *H.-J. Teuber* [NB 637 IE]

Treatise on Analytical Chemistry. Edited by *I. M. Kolthoff* and *P. J. Elving.* Part II, Vol. 4: Analytical Chemistry of Inorganic and Organic Compounds. Interscience Publishers, a Division of John Wiley and Sons, New York-London-Sydney 1966. Part II, Vol. 13: Analytical Chemistry of Inorganic and Organic Compounds. 1st Edit., xxi, 528 pp., 14 illustrations, 29 tables, bound 160 s.

Two very different volumes of *Kolthoff* and *Elving*'s Handbook of Analytical Chemistry are now available for review, Volume 4 of Part II of this work[*] deals with the analysis of the elements silver (*E. P. Przybylowicz* and *C. W. Zuehlke*), gold (*N. Herz*), calcium (*K. K. Turekian* and *E. Bolter*), strontium and barium (*K. K. Turekian* and *E. Bolter*), radon and radium (*J. Sedlet*), and aluminum (*G. H. Farrah* and *M. L. Moss*). This volume, like its predecessors, is written by experts in the analysis of the elements that they treat, and it is in line with the usual careful work that is known from previous volumes.

Volume 13 deals with the determination of functional groups in organic compounds. The two preceding volumes 11 and 12 dealt with methods of elemental analysis of organic compounds, *i.e.* the determination of carbon, hydrogen, nitrogen, phosphorus, oxygen, sulfur, the halogens, boron, silicon, *etc.* The present volume describes the analytical methods used for determining functional groups in organic compounds, *i.e.* typical structural features that can be used for characterization or for quantitative determination of organic compounds. Chemical and physical methods (IR, UV, Raman, NMR, and mass spectrometry, as well as chromatographic methods of

[*] Cf. Angew. Chem. 76, 739 (1963).

separation) are here treated side by side and frequently their values are compared. The individual authors have written their sections with excellent knowledge of their subjects; this volume in particular can be recommended as reference work for all concerned with structural analysis of organic compounds.

An introduction about functional groups is given by *J. Mitchell*. The section on determination of active hydrogen was contributed by *F.T. Weiss*, analysis of the C–CH_3 group by *K. G. Stone*. Analysis for carbonyl groups is treated by *J. G. Hanna* and *S. Siggia*, that of the carboxyl group by *S. Veibel*. The volume closes with two sections on phosphorus functional groups (*D. N. Bernhart*) and on functional groups containing bivalent sulfur, –SH, –S–, –S–S–, *etc.* (*J. H. Karchmer*).

It is hoped that the further volumes on the determination of functional groups will soon appear and that they will supplement the present volume at the same high level.

H. Kienitz [NB 682 IE]

Organic Photochemistry. Edited by *O. L. Chapman*. Marcel Dekker Inc., New York 1967. Vol. 1. 1st Edit., ix, 339 pp. numerous illustrations, $ 15.75.

The ever increasing number of original papers that appear each year in the field of organic photochemistry illustrate the present preparative and theoretical importance of this subject. The bewildering profusion of new photochemical reactions makes it difficult even for the investigator active in this area to keep informed about the many new facts. It is therefore to be welcomed that an attempt is being made to collect the many facts from original papers into the series entitled "Organic Photochemistry" and to arrange them in a critical manner. In accordance with this aim, the present volume is not a textbook, but is a collection of reviews intended in the first place for the chemist engaged in syntheses.

The titles of the seven contributions are: Photochemical Transformations of Cyclohexadienones and Related Compounds (*P. J. Kropp*); Photochemical Transformations of Small-ring Carbonyl Compounds (*A. Padwa*); Photo-Fries Reaction and Related Rearrangements (*V. I. Stenberg*); Photochemistry of Troponoid Compounds (*D. J. Pasto*); Photochemistry of Olefins (*G. J. Fonken*); The Photocyclization of Stilbenes (*F. R. Stermitz*); and Photocycloaddition Reactions (*O. L. Chapman* and *G. Lenz*).

The authors, who are all distinguished in their fields, have achieved a competent presentation of their material. The titles show, however, that the subject has been divided according to classes of compound as well as according to type of reaction. Thus some duplication has been inevitable. The rearrangement carvone $\xrightarrow{h\nu}$ carvonecamphor is shown in formulas no fewer than three times (pp. 82, 240, and 296), as also is the photocycloaddition of 2-cyclohexenone to isobutene (pp. 81, 240, and 299); the list of such examples could be considerably extended (*e.g.*, p. 79 → p. 294; p. 80 → p.180; p. 216 → p. 315).

With new scientific books at their present price, such duplications are not a welcome feature. It is to be hoped that, when continuing the series, the editors will coordinate the contributions of the various authors more carefully and thus ensure for the series the success that it deserves.

The Reduction of Organic Compounds with Chromium(II) Salts

BY J. R. HANSON[*] AND E. PREMUZIC[**]

Chromium(II) salts can be used for a variety of reductions in organic chemistry; for example, alkyl halides and suitably substituted olefins may both be reduced to alkanes, and alkynes may be converted into trans-olefins. Several epoxyketones are reduced to α,β-unsaturated ketones or β-hydroxyketones, and a nitro steroid was found to give a hydroxy(hydroxyimino) compound. The reduction of alkyl halides is reported to proceed by a free-radical mechanism; the halogen atom that is set free forms a bridge between two chromium atoms.

1. Introduction

In 1916, *Traube* and *Passarge* reported[1] that an acidic aqueous solution of chromium(II) chloride in an inert atmosphere reduces maleic acid and fumaric acid to succinic acid. On treatment of a chromium(II) chloride solution with sodium hydroxide, a suspension of chromium(II) hydroxide was obtained, which reduced cinnamic acid to β-phenylpropionic acid. Nitrous oxide was quantitatively reduced by alkaline and acidic solutions of chromium(II) salts to ammonia. Nitrites, on the other hand, were not reduced. An oxime, benzaldoxime, was reduced under alkaline conditions at 100 °C to benzylamine.

During the 1920's, titanium(III), chromium(II), and vanadium(II) salts were shown to be efficient agents for the generation of free radicals. For example, *Conant* and *Sloan*[2] prepared free radicals from triphenylmethylpyrylium chloride and phenylxanthenol in the presence of acidic vanadium(II) chloride. Thus one-electron transfer to the carbonium ion derived from triphenylmethanol gives the triphenylmethyl radical.

$$(C_6H_5)_3C^+ + e \rightarrow (C_6H_5)_3C^\bullet$$

Dimeric products were often observed, for example, in the reduction of aromatic α,β-unsaturated ketones[3,4]. In 1930, *Hein*, *Farl*, and *Baer* reported[5] the action of chromium(II) halides on diethyl ether and established the existence of compounds of the type $CrX_2OC_2H_5$ (X = Cl, Br, or I) containing trivalent chromium.

$$2\ CrX_2 + 2\ C_2H_5OC_2H_5 \rightarrow 2\ CrX_2OC_2H_5 + C_4H_{10}$$

Similar compounds are formed with dioxane and benzyl ethyl ether. However, aromatic ethers such as phenetole and anisole are unreactive at room temperature. Aniline, pyridine, and piperidine produce diamino complexes of the type $CrX_2OC_2H_5(amine)_2$.

In 1934, *v. Braun* and *Rudolph* used chromium(II) chloride for reduction of carbonimidoyl chlorides to Schiff's bases[6]. Eleven years later, *Cole* and *Julian*[7]

described the use of acidic chromium(II) chloride for the dehalogenation of 5,6-dibromo-3-keto steroids. *Royer* [8] used acidic chromium(II) sulfate to prepare 5,5-biacridyl from 5-chloroacridine. More recent applications of the reagent include its use in the reduction of epoxyketones [9]. A better knowledge of the inorganic chemistry of the system and, in particular, the importance of bridging complexes [10] has been reflected in a clearer understanding of the mechanism of the reduction [11–15].

Chromium(II) chloride and acetate are readily prepared by the zinc and hydrochloric acid reduction of chromium(III) chloride. The acetate is a relatively insoluble salt prepared by the addition of sodium acetate to chromium(II) chloride. Both may be handled quite easily at room temperature in a nitrogen or carbon dioxide atmosphere.

2. The Role of Bridging Ligands in Reductions by the Chromium(II) Ion

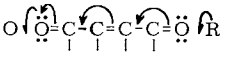
Chromium(II) salts react with a variety of ions of the type $[Co(NH_3)_5X]^{2+}$, which serve as the oxidizing agent *via* a quantitative transfer of X to the reducing agent [10]. For the system where X = Cl, the transfer takes place without an exchange with chloride ion in solution. This suggests that the activated complex for the electron transfer reaction has a configuration in which X is bonded simultaneously to Cr and Co to form a Co···X···Cr complex. There is further evidence [16] for this in the exchange reaction between Cr^{2+} and $CrCl^{2+}$. Such bridge-activated complexes are also formed by other ions and atoms, *viz.* Ti^{2+}, Ti^{3+}, Ti^{IV}, V^{2+}, V^{3+}, V^{IV}, V^{V}, and Cr^{2+}. The nature of the bridging group plays an important part in determining the rates of these exchange reactions. Thus in the Cr(II)/Cr(III) system, where the bridging group in the intermediate $(H_2O)_5Cr^{3+}\cdots X\cdots Cr^{2+}(OH_2)_5$ forms a part of the inner coordination shell of both ions, the rate decreases by a factor of 10^7 along the series $X = Br^- > N_3^- > Cl^- > OH^- > F^- > NCS^- > NCS^- > H_2O$ [17].

Organic anions can serve as bridging groups in oxidation-reduction reactions of this type. Again the nature of the coordination shell is important; for example, free oxalate is rapidly reduced to glycolate by chromium(II) perchlorate, whereas oxalate bound to Cr(III) is reduced very slowly by Cr(II) [18].

Sebera and *Taube* have conducted [19] a kinetic study of the reactions of the chromium(II) ion with complex ions of the type $[(NH_3)_5Co(III)L]^{2+}$, where L is an organic ligand such as succinate, succinate monomethyl ester, fumarate, fumarate monomethyl ester, or one of the three isomers of phthalic acid. The system is suitable for study since cobalt(III) complexes have an absorption band at 350 nm ($\varepsilon = 53-79$) which may be used to follow the course of this series of reactions. The net changes of the system are represented by

$$[(NH_3)_5CoL]^{2+} + Cr^{2+} + 5\ H^+ \rightarrow Co^{2+} + CrL^{2+} + 5\ NH_4^+$$

and a chromium(III) complex is formed. The mechanism involves attack by the chromium(II) ion at a carboxyl adjacent to Co(III), except in the case of fumarate, monomethyl fumarate, and terephthalic acid where there is conjugation between the free carboxyl group and that bearing the Co(III) center. The electron transfer reaction between solvated Cr^{2+} and $[(NH_3)_5CoL]^{2+}$ then takes place through an attack by the reducing species at the free carboxyl group [20]. An interesting mechanism of electron conduction by the conjugated systems was described by *Taube* and co-workers:



Many organic ligands, both aromatic and heterocyclic, can serve as bridging groups for electron transfer. In a further study, *Gould* and *Taube* [21] have shown that the rates of reduction also depend on the substituents on the ligand itself and the stability of the complex formed. Their experiments have also demonstrated the formation of free radicals during the course of these reductions and the influence that they exert on the rates of reaction. For example, in the reduction of pyridine-2- and -4-carboxylate ions the ligands are thought to facilitate the electron transfer by permitting delocalization of the reducing electron in the pyridine ring, with the formation of a radical-ion intermediate.

Other investigations [22] have revealed the formation of 2,5-dihydroxy-*p*-benzoquinone complexes with chromium(II) ions.

3. The Formation of Organo-Chromium Complexes

Anet and *Leblanc* [11] investigated spectroscopically the reaction of benzyl halides with aqueous chromium(II) perchlorate in perchloric acid, and were thus able to establish the existence of benzylpentaaquochromium(III) perchlorate. On heating in the absence of oxygen, this complex gave bibenzyl through the formation of benzyl radicals. However, in the presence of oxygen the main product was benzaldehyde. Reduction of

benzyl chloride with chromium(II) chloride in aqueous hydrochloric acid gave toluene. The complex $[Cr(H_2O)_4ClCH_2C_6H_5]^{2+}$ formed initially contains a chloride ion as well as water molecules in the coordination sphere of the metal ion. In this position the chloride ion favors reduction by bridging with a further chromium(II) ion in the reducing agent. The chromium(II) complex thus formed can dissociate to benzyl anions, which in turn react with the solvent to give toluene. Allyl chloride and phenacyl chloride are likewise reduced by chromium(II) perchlorate.

In a further study, *Anet* [23] investigated the reduction of chloroform by chromium(II) perchlorate in aqueous solution and established the presence of chloropentaaquochromium(III) perchlorate and of $[Cr(H_2O)_5CHCl_2]^{2+}$, whose structure is analogous to

$$CHCl_3 + 2\,Cr^{2+} + 10\,H_2O \rightarrow Cr(H_2O)_5Cl^{2+} + Cr(H_2O)_5CHCl_2^{2+}$$

that of the complex $[Cr(H_2O)_5CH_2C_6H_5]^{2+}$ obtained [11] from benzyl chloride.

The structure of these complexes, like that of other chromium complexes, involves octahedral coordination in which five water molecules and the dichloromethyl anion form the ligands. The stability of these organochromium ions is consistent with the substitution inertness of chromium(III) complexes [24].

Although the benzyl complex decomposes on heating to give bibenzyl, the dichloromethyl complex does not give tetrachloroethane or its reduction product, dichloroethylene; instead, chloride ions are formed. Furthermore, the dichloromethyl complex does not react with oxygen, sulfur dioxide, mercuric chloride, nor is it reduced by hydrogen in the presence of palladium catalyst; it thus behaves differently from its benzyl analog [11].

The reduction of chloroform could involve the following steps. Firstly, a one-electron reduction in which there is a direct transfer of a chlorine atom to chromium.

$$CHCl_3 + Cr^{2+} + 5\,H_2O \rightarrow [Cr(H_2O)_5Cl]^{2+} + {}^{\bullet}CHCl_2$$

Two processes may then occur: the free radicals may either dimerize, or react further with chromium(II) ion present to give organochromium ion:

$${}^{\bullet}CHCl_2 + Cr^{2+} + 5\,H_2O \rightarrow [Cr(H_2O)_5CHCl_2]^{2+}$$

If the latter step is fast, less dimerization will be observed.

Investigations by *Kochi* and *Rust* [14] have shown that the reaction may not be as simple as this. The reaction of *tert*-butylhydroperoxide with a reducing metal in aqueous solution produces methyl radicals

$$(CH_3)_3COOH + M^{n+} \rightarrow (CH_3)_3CO^{\bullet} + M(OH)^{n+}$$
$$(CH_3)_3CO^{\bullet} \rightarrow CH_3COCH_3 + {}^{\bullet}CH_3$$

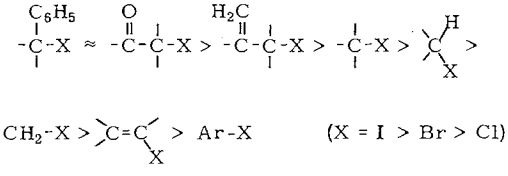
For example, if titanium(III) chloride is the reducing agent [cf. [25]] then the relative yields of ethane and methane depend on the presence of added metal ions. In particular, the ions of the transition metals are effective in promoting dimerization of methyl radicals. Even traces of such ions in the reducing agent may affect the results.

There is a further consequence of the existence of metal ion-free radical complexes. Such complexes may have a longer lifetime than simple alkyl radicals and a lesser tendency to abstract hydrogen from, for example, the solvent.

4. The Reduction of Alkyl Halides

The reduction of alkyl halides by chromium(II) salts represents one of the best known uses of these reagents. Some examples of the systems that have been studied are presented in Table 1.

The reactivity of the various types of halide decreases in the following order [26]:



From the results shown in Table 1 it is clear that a number of products are possible. For example monohalides give mainly the products of reduction or dimerization. On the other hand, halides with an adjacent halogen, hydroxyl, or other anionic substituents give rise to olefins. With suitably oriented α,β-unsaturated ketones cyclization can also occur.

The formation of these products can be rationalized in mechanistic terms. In investigations on the reduction of carbonium ion to a free radical by strongly reducing transition metal salts in their low valency states, the influence of added halide ions was particularly noted. It was shown [13] that chromium(II) salts alter the course of reactions of the 1,1-diphenylethyl cation to give dimeric products instead of the radical, provided halide ions are present. The interpretation placed on these results was that an intermediate organic halide was required. It has been subsequently suggested [15] that halide ions are beneficial but not mandatory – in their absence, the reaction merely proceeds more slowly.

The first step in the reduction of an alkyl halide may be envisaged as the attack of the chromium(II) ion on the halogen atom. The second stage involves a migration of the alkyl residue to form a new carbon-chromium bond. This process is accompanied by a one-electron transfer from a second chromium(II) ion through a bridging anion. The subsequent decomposition of this intermediate by elimination, protonolysis, or attack on unchanged organic halide, can account for the majority of the products.

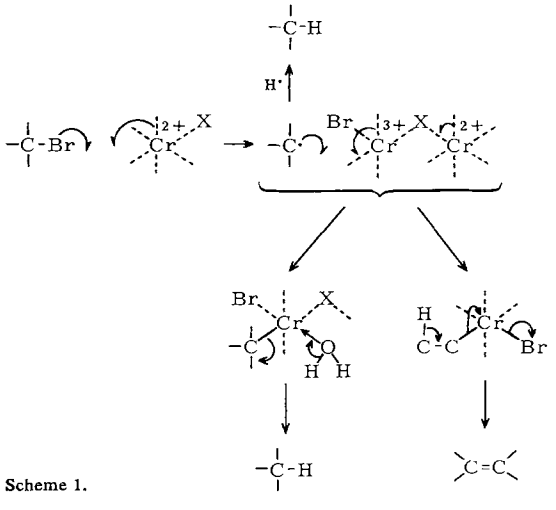
	$Cr(CH_3COO)_2$ n-C_4H_9SH	DMSO			

The intervention of a free-radical stage prior to the formation of the carbon-chromium bond is supported [12,29] by the action of hydrogen-donor reagents such as *n*-butanethiol, 1,4-cyclohexadiene, 1-benzyl-1,4-dihydronicotinamide, *etc.* In the presence of these reagents, the reduction of 9β-bromo-11β-hydroxy steroids by chromium(II) halides rapidly yields the 11β-hydroxy steroids. These pathways may be summarized according to Scheme 1.

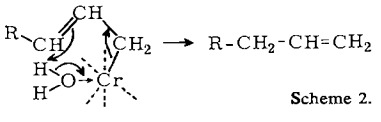


Scheme 1.

There are a number of interesting consequences of this reaction.

For example chromium(II) chloride reduction of 9α-bromo-$\Delta^{1,4}$-3-keto steroids and their 1,2-dihydro analogs, gives rise to 5,9-cyclosteroids – a Grignard type addition of the organochromium derivative occurring to the α,β-unsaturated ketone. The intervention of a bridged complex in the second one-electron transfer step and hence the obvious influence of other groups in the coordination sphere of the chromium ion, suggest a reason for dependence of the reaction on the anion associated with the chromium ion and the influence of the solvent.

The formation of a complex may also account for double-bond isomerizations which have been observed [26] (Scheme 2).



Scheme 2.

The reduction of geminal and vicinal dihalides follows a similar pattern. The dehalogenation of vicinal dihalides by chromium(II) ion proceeds [26] much faster

[27] *F. A. L. Anet* and *E. Isabelle*, Canad. J. Chem. *36*, 589 (1958).

[28] *G. Rosenkranz, J. Pataki, J. Gatica*, and *C. Djerassi*, J. Amer. chem. Soc. *72*, 4081 (1950); *J. J. Beereboom, C. Djerassi, D. Ginsburg*, and *L. F. Fieser, ibid. 75*, 3500 (1953).

[29] *D. H. R. Barton* and *N. K. Basu*, Tetrahedron Letters *1964*, 3151; *C. H. Robinson, O. Gnoj, E. P. Oliveto*, and *D. H. R. Barton*, J. org. Chemistry *31*, 2749 (1966).

than that of the corresponding monohalides and leads to the formation of the corresponding olefins. In the absence of a radical trapping agent this parallels the reduction of α-hydroxy- and α-aminoalkyl halides [27, 30]. There have been a number of preparative uses of this reaction in the introduction and protection of double bonds in the steroid series [31, 32]. (It was not possible to selectively remove the bromine atom from 1,2-bromofluorides.) The possibility of double bond migration is again also present. Indeed the method permits a smooth sequence in the conversion of Δ^5-3-hydroxy steroids to Δ^4-3-ketones by addition of bromine, oxidation to the ketone, and reductive elimination with chromium(II) chloride [33].

The rate of formation of the corresponding olefins follows the sequence [26]

C_6H_5–CHBr–CH_2Br > CH_3–CHBr–CHBr–CH_3 > $BrCH_2$–CH_2Br ≈ CH_2=CBr–CH_2Br > CH_3CHCl–$CHClCH_3$ > $ClCH_2$–CH_2Cl > *o*-dibromobenzene > BrCH=CHBr.

Competitive rate studies support the suggestion of participation by the neighboring halogen in facilitating the reaction. Thus the following relationship was found:

$$\frac{k(\text{1,2-dichloroethyl})\text{benzene}}{k(\text{1-chloroethyl})\text{benzene}} = 20$$

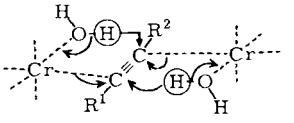
A bromine atom further facilitates reaction, presumably by the easier formation of a bridging system.

$$\frac{k(\text{1-chloro-2-bromoethyl})\text{benzene}}{k(\text{1-chloroethyl})\text{benzene}} = 50$$

However, allylic halides with a second halogen substituent on the vinylic carbon do not show any marked rate enhancement.

5. The Reduction of Unsaturated Systems

There are a number of examples of the reduction of multiple bonds by the low-valency states of transition metal ions. The reduction of alkynes by chromium(II) sulfate in dimethylformamide leads to *trans*-substituted olefins [34]. The ease of reduction depends on the presence of an accessible coordination site in the molecule. The specific reduction of an α-hydroxyallene to an olefin has also been reported in a vitamin A synthesis [35]. A study of the reduction of alkynes suggests that reversible formation of a chromium(II)-alkyne complex is followed, in the rate determining step, by the attack of a second chromium(II) ion on this complex. A transition stage of the type shown in Scheme 3 has been postulated.



Scheme 3.

Appropriately substituted olefins can be reduced to alkanes by chromium(II) sulfate in aqueous dimethylformamide. For reduction to occur in acidic solution the olefin must form part of an enedione or an α,β-unsaturated ketone attached to an aromatic ring. In the majority of cases the yields [36] are high although coupling products have been isolated [2] in certain cases. There are plenty of examples in the alicyclic series in which simple α,β-unsaturated ketones are not attacked by acidic solutions of the reagent. Recently, ammoniacal solutions of chromium(II) ions have been shown to rapidly reduce α,β-unsaturated ketones to the saturated ketones [37]. An extension of this type of reagent uses [38] chromium(II) ion complexed with ethylenediamine. Some examples of the systems that have been studied are given in Table 2.

Table 2. The reduction of unsaturated systems with chromium(II) ions.

Compound	Reducing agent	Solvent	Product	Yield (%)	Ref.
$HOCH_2$–C≡C–CH_2OH	$CrSO_4$	H_2O	*trans*-2-Butene-1,4-diol		[34]
C_6H_5–C≡C–CO_2H	$Cr(OH)_2$	Petroleum ether	C_6H_5–CH_2–CH_2–CH_2H		[1,3]
C_6H_5–CH=CH–CO_2H	$CrCl_2$ or $CrSO_4$	H_2O/DMF	C_6H_5–CH_2–CH_2–CO_2H	89	[1,36]
Maleic acid	$CrSO_4$	H_2O	HO_2C–CH_2–CH_2–CO_2H	86	[1,36]
Fumaric acid	$CrSO_4$	H_2O	HO_2C–CH_2–CH_2–CO_2H	91	[1,36]
C_6H_5–CH=CH–CO–CH_3	$CrCl_2$	C_2H_5OH/H_2O	C_6H_5–CH–CH_2–CO–CH_3 C_6H_5–CH–CH_2–CO–CH_3		[2]
$(CH_3)_2$C=CH–CO–CH_3	$CrCl_2/NH_3$	NH_3/H_2O	$(CH_3)_2$CH–CH_2–CO–CH_3		[37]

The mechanism of the reduction of unsaturated systems probably involves the formation of an olefin-metal complex which is subsequently attacked by a second chromium(II) ion [36]. In the ammoniacal system, species of the following type have been invoked [37].

[30] *F. Fried* and *E. Sabo*, J. Amer. chem. Soc. *79*, 1130 (1957).

Related to this is the reduction[39] of oxalate to glycolate by chromium(II) perchlorate.

6. Reduction of Epoxides

A number of α,β-epoxy ketones have been reduced by acidic solutions of chromium(II) chloride or acetate. Whereas chromium(II) chloride leads to the formation of the α,β-unsaturated ketone, use of chromium(II) acetate under less acidic conditions enables the β-hydroxyketone to be isolated. The main application of this reduction has been in the steroid series. For example reduction of 16α,17α-epoxyprogesterone with chromium(II) chloride gives 16,17-didehydroprogesterone whilst with chromium(II) acetate 16α-hydroxyprogesterone is formed[40]. Chromium(II) chloride has been regularly used[41] in the deoxygenation of the limonoid group of triterpenes in which ring D bears an α,β-epoxy-δ-lactone.

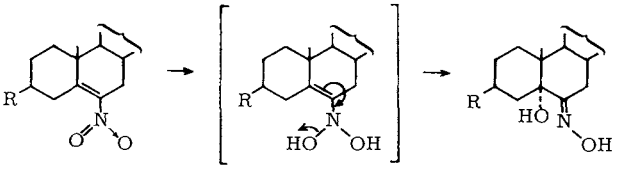
[40] *W. Cole* and *P. L. Julian*, J. org. Chemistry *19*, 131 (1954).

7. Reduction of Nitro Compounds

The early observation[1] that chromium(II) chloride does not reduce nitrites and hydroxylamine has not yet been explained. Reduction of a nitroolefin, 6-nitrocholesteryl-acetate *(1)*, and some related 5-chloro-6-nitro steroids with acidic solutions of chromium(II) chloride resulted[42] in the formation of the 5α-hydroxy-6-hydroxyimino steroids.



(1)

The above survey illustrates the wide range of application of the chromium(II) ion, whose reducing properties often complement those of the hydrides or dissolving metals.

Problems and Possibilities of Modern Trace Analysis[**]

BY H. SPECKER[*]

As a result of the development of measuring techniques, analytical chemists can now determine very small quantities as well as trace concentrations of the order of 10^{-8} % with good accuracy. In exceptional cases it is even possible to detect 10^5 atoms of an element. In this review, definitions of important analytical terms are outlined and a critical appraisal of the principal methods of trace analysis is given.

1. Introduction

During the past two decades, inorganic analytical chemistry has been especially concerned with the problems and methods of trace determination. One reason for this is the importance of trace elements, only recently recognized in biological problems, in the chemistry of very pure substances, in the prevention of pollution of air and water, and in the catalysis of chemical and biological processes.

[*] Prof. Dr. H. Specker

Present address: Institut für Spektrochemie
46 Dortmund, Bunsen-Kirchhoff-Str. 11 (Germany)

[**] Based on plenary lectures to the 2nd International Symposium on Very Pure Substances in Dresden, 1965, and to the Fachgruppentagung Analytische Chemie 1966 in Lindau.

In trace detection and determination, the analyst has at his disposal only very small quantities of the trace elements, which occur in the original substance together with large excesses of other elements, the principal components. The ratio of principal components to trace components is by definition at least 10^3, and in extreme cases 10^{10} or even higher. The analytical problem of trace determination is immediately obvious from this ratio; the methods or the procedures devised must permit the accurate determination of very small quantities of one substance in the presence of large excesses of others. Since classical gravimetric and volumetric methods are clearly unsuitable for determination of such small quantities, only physical methods can be considered. These are:

1. electrochemical methods,
2. photometry and fluorescence analysis,

3. spectrochemical analysis in the broad sense,
4. activation analysis,
5. mass spectroscopy, and
6. catalytic detection reactions.

Electrochemical, photometric, and catalytic methods always require chemical preparation, whereas the other three methods permit examination of the sample as submitted for analysis. Direct analysis offers important advantages; these will be discussed in detail.

2. Definitions

Before discussing the possibilities and limitations of the various methods and analytical principles, we shall first define three terms used in trace determination and present examples to illustrate them:

1. the sensitivity of an analytical method,
2. the detection limit of an analytical procedure, and
3. the limit of guarantee for purity.

The use of the term "sensitivity" has lead to many misunderstandings in analytical chemistry. In modern analysis, *i.e.* in electrochemical methods, photometry, spectrochemistry, and activation analysis the sensitivity of an analytical method is measured by the slope of the calibration line. This definition is particularly clear in photometric analysis where it is well known that the slope of the calibration line is given by:

$$\Delta E/\Delta c = \varepsilon \cdot d$$

(E = extinction, c = concentration, ε = extinctivity, d = thickness of absorption cell).

This is illustrated in Figure 1 for the reactions used in the photometric determination of iron [1]. It can be seen that the method using *o*-phenanthroline (line 2) is about five time as sensitive as that using 2,6-pyridinedicarboxylic acid (line 3). In both cases the thickness of the cell was 1 cm. As can be seen from the equation, the sensitivity of any photometric determination can in principle be increased by increasing the thickness of the absorption cell.

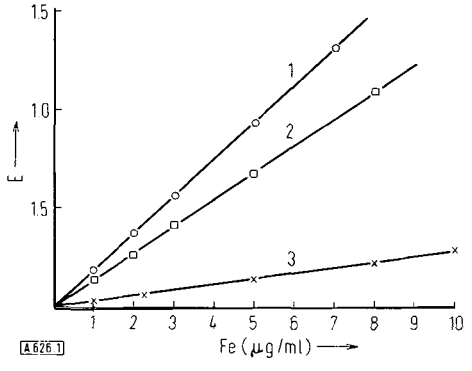

Fig. 1. Calibration lines for the photometric determination of iron (definition of sensitivity). Line 1: with 2-pyridinealdoxime, $\Delta E/\Delta c$ = 0.18; line 2: with *o*-phenanthroline $\Delta E/\Delta c$ = 0.14; line 3: with 2,6-pyridinedicarboxylic acid, $\Delta E/\Delta c$ = 0.028. The thickness of the cell is 1 cm. Ordinate: Extinction. Abscissa: Iron concentration.

[1] *H. Specker*, Z. Erzbergbau Metallhüttenwes. *17*, 132 (1964).

Another example illustrating the sensitivity of a detection reaction is the determination of lead and copper by inverse voltammetry with a hanging drop of mercury (Fig. 2). The slope of the calibration line for copper is much less steep than that for lead. This is because a complexing agent (pyridine) must be added during the determination of copper to separate the redissolution potential of copper from that of mercury. The abscissa in Figure 2 is calibrated in micrograms and not in molarities. Conversion of the results into molarities shows that the inverse voltametric determination of lead is about seven times as sensitive as the determination of copper.

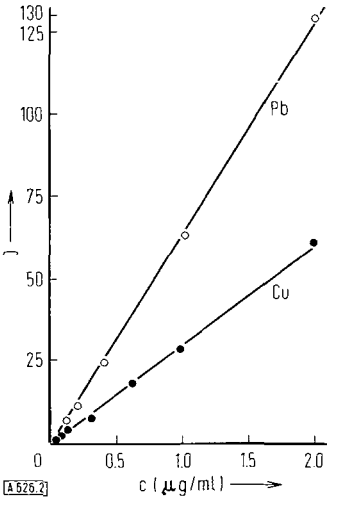

Fig. 2. Calibration lines for the inverse voltammetric determination of lead and copper (definition of sensitivity). Ordinate: I in scale divisions. Abscissa: Concentration (µg/ml). Pb line: dI/dc = 66 (scale divisions/µg); Cu line: dI/dc = 29 (scale divisions / µg).

A careful distinction must be made between the sensitivity of a method and the detection limit of an analytical procedure [*]; the detection limit of an analytical procedure was introduced in its present form by *Kaiser* [2] for spectrochemical analysis, and was later extended to all analytical procedures [3]. The detection limit is a characteristic numerical value (figure of merit) for an analytical procedure; it can be objectively determined, and has a definite significance. In each case it refers to a definite "complete analytical procedure" used for the solution of a given analytical problem in accordance with a precisely established set of instructions. There is no such thing as a general detection limit, *e.g.* for spectrochemistry, photometry, or mass spectroscopy.

The detection limit is derived from the standard deviation of the blank values. Many blank determinations (at least 25) are carried out by the procedure in question; *e.g.* for a photometric detection reaction, all the reagents must be present except the element to be determined, and the standard deviation of the blank values is calculated from the results. The value

[*] For definition of detection power, see Section 4.

[2] *H. Kaiser*, Spectrochim. Acta *3*, 40 (1947/48).

[3] *H. Kaiser* and *H. Specker*, Z. analyt. Chem. *149*, 46 (1956).

of the measured quantity at the detection limit is then given by

$$\underline{x} = 3\,\sigma_{Bl} + \bar{x}_{Bl}$$

(σ_{Bl} = standard deviation of the blank values, $\bar{x}_{Bl}$ = average of the blank values). The factor 3, *i.e.* a probability of error of only 0.14 %, is chosen to ensure that only one value is really necessary in all cases of practical importance, even when the results deviate from the normal distribution. The concentration $\underline{c}$ at the detection limit is found from the analytical function $c = f(x)$ to be

$$\underline{c} = f(\underline{x}).$$

The value of the blank is of no importance; the deciding factor is the scatter of the blank values, from which the standard deviation can be calculated. A constant blank value, whatever its magnitude, can always be eliminated by means of a correction. This is also true of the constant component of fluctuating blank values, which is given by the statistical mean $\bar{x}_{Bl}$ of the values. The significance of the detection limits found in this way is shown by Figure 3 for the photometric determination of iron with *o*-phenanthroline. The value of $\underline{c}$ was found to be 0.04 μg Fe/ml.

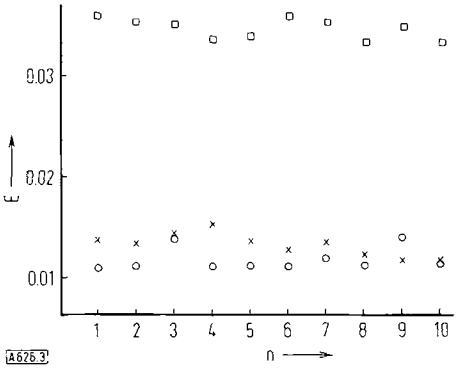

Fig. 3. Detection limit $\underline{c}$ of the photometric determination of iron with *o*-phenanthroline. ○ = blank value, × = 0.02 μg of Fe/ml, □ = 0.1 μg of Fe/ml. $\underline{c}$ = 0.04 μg of Fe/ml. Ordinate: Extinction. Abscissa: Number of measurements (measurements carried out at the Institut für Spektrochemie, Dortmund).

The extent to which the detection limit for an accurately defined procedure can depend on the external conditions may be illustrated by two examples. The indicated value of 0.04 μg of Fe/ml for the detection limit of iron was determined by more than 100 blank measurements in unpurified laboratory air. When the experiments were repeated in a dust-free room, the detection limit with the same reagents was 0.013 μg of Fe/ml. The poor detection limit in the first case was due to the unavoidable presence of dust particles (which contained iron) from the air around the industrial area of Dortmund. These stray dust particles increased the standard deviation of the blank values, and so gave a poor detection limit.

The detection limit is improved only slightly, if at all, by an increase in the thickness of the cell; this can be seen from Figure 4, which shows the blank values for the photometric determination of nitrate in water at cell thicknesses of 1 cm (left) and 5 cm (right). The detection limit at 1 cm is 0.3 mg/l, while that at 5 cm

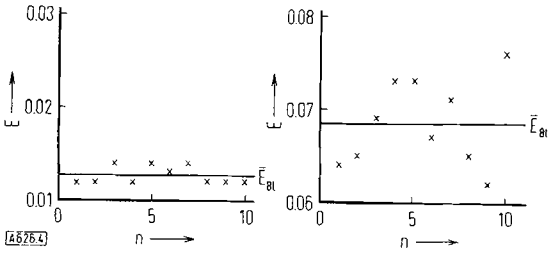

Fig. 4. Blank values for the photometric determination of nitrate with α-naphthylamine and sulfanilic acid. Left: thickness of the cell d = 1.002 cm, detection limit $\underline{c}$ = 0.3 mg of NO_3^-/l; right: d = 5 cm, $\underline{c}$ = 0.27 mg of NO_3^-/l. $\bar{E}_{Bl}$ are the average blank values.
Ordinate: Extinction. Abscissa: Number of measurements.

is 0.27 mg/l. The sensitivity, on the other hand, increases in proportion to the cell thickness, as was mentioned earlier. In the examples given, and in general in processes involving chemical pretreatment, the variations in the blank values are due, not to the measuring apparatus, but to the reagents and to stray components introduced from the atmosphere. The only variations caused by a photometer are about two orders of magnitude smaller, and are not significant in such determinations [4]. For this reason, lower (*i.e.* better) detection limits are achieved in processes that can be carried out without chemical preparation. In these cases, the scatter of the results, and hence the standard deviation of the blank values, is due only to the measuring apparatus. All experimental work in modern trace analysis is aimed at the improvement of the detection limits, *i.e.* at the reduction of the scatter of the blank values and in general of the "noise level" of a procedure.

The "limit of guarantee for purity" is a relatively new concept in trace analysis. It is required when an analysis leads to a negative result, *i.e.* when the experimental result x is smaller than the value $\underline{x}$ at the known detection limit. In such cases, the analyst is asked what purity he can guarantee for the sample. The obvious answer is to say that the concentration in the sample is definitely below the concentration $\underline{c}$ at the detection limit. However, this is wrong, since it is quite possible for a concentration slightly above $\underline{c}$ to give an experimental result smaller than $\underline{x}$ owing to a strong chance fluctuation, so that this experimental value cannot be accepted as correct. The reason for this state of affairs is known in mathematical statistics as an "error of the second type".

The significance and statistical derivation of the "limit of guarantee for purity" was first formulated by *Nalimov et al.* [5,6], and later by *Roos* [7]. This concept was subsequently discussed in detail mainly at the instigation of *Ehrlich* [8], and has been described in a clear and understandable manner by *Kaiser* [8]. According

[7] *J. B. Roos,* Analyst *87,* 832 (1962).

[8] *H. Kaiser,* Z. analyt. Chem. *209,* 1 (1965).

to this author the limit of guarantee for purity is given by

$$c_G = \bar{x}_{Bl} + 6\,\sigma_{Bl}$$

where $\bar{x}_{Bl}$ is again the mean of the blank values and σ_{Bl} is the standard deviation of the blank values. The analyst can guarantee with "certainty" that the concentration of a given element in the sample is not higher than c_G when the analysis gives a negative result.

We shall again compare the "detection limit" of an analytical procedure ($\underline{c}$) and the "limit of guarantee for purity" of a sample (c_G)

1. What is the lowest content in a sample that can be "reliably" detected by the analyst? Answer: $\underline{c} = f(\bar{x}_{Bl} + 3\,\sigma_{Bl})$.

2. What purity can be guaranteed with "certainty" if a substance that might be present cannot be detected (experimental value smaller than the value at the detection limit)? Answer: $c_G = f(\bar{x}_{Bl} + 6\,\sigma_{Bl})$.

3. Enrichment Processes

Chemical and physical enrichment processes have proved very useful for the improvement of detection limits. If the introduction of impurities can be avoided in chemical enrichment processes, the detection limits, as with physical enrichment, can generally be improved by one to two powers of ten. Interference is decreased by the removal of the principal components, and the absolute quantity of the trace components subjected to analysis is also increased.

The following is a simple example from spectrochemical analysis. In a directly excited sample of aluminum, approximately 10 mg are analyzed. If this sample contains *e.g.* 10^{-4} % of copper, the analytical signal is based on 10^{-6} g of copper. If, on the other hand, we begin with 1 g of sample, remove the aluminum, and quantitatively excite the trace element, then 10^{-4} g of copper are available for the analytical signal. In *Pohl*'s procedure[9], the trace elements are separated from the principal component by precipitation and solvent extraction, and are then determined spectrochemically.

Another interesting example of chemical concentration of trace components by extraction of the trace elements was described by *Wunderlich*[10]. Very pure germanium chloride (50 to 100 g) is extracted directly with 6 N hydrochloric acid; the two phases are immiscible. Several cations, including arsenic, can then be determined down to 0.01 ppm. The danger of accidental contamination in this case is extremely low, since the 6 N hydrochloric acid can be prepared in a very pure state.

Physical enrichment processes generally do not involve dissolution of the sample, and so are not subject to chemical sources of interference. Such methods are particularly suitable for combination with spectrochemical analysis and X-ray fluorescence analysis.

With the aid of zone melting, *Abakumov* and *Konovalov*[11] obtained detection limits of 10^{-6} to 10^{-7} % for Ag, Cu, and Tl in very pure bismuth. The vaporization method presents two possibilities: (i) vaporization of the principal component and (ii) vaporization of the trace components, which are then collected. In case (i), the matrix is often removed by chlorination or fluorination; thus by vaporization of V, B, and Si in the form of the chlorides 5×10^{-5} % of W, 10^{-6} % of Ta, and 2×10^{-8} % of Mn can be detected spectrochemically in samples of a few grams of these substances.

In a method described by *Geilmann*[12] and *Neeb*[13], the sample is heated in a furnace, and the volatile components are carried by a current of gas through a nozzle onto a cold collecting surface; this collector is then excited directly. The *Geilmann* process has proved very useful for the determination of Tl, Zn, As, Bi, and Cd. Simultaneous concentration of several trace elements in tungsten oxides was achieved by *Lounamaa*[14]. In this process, the tungsten is first converted into the extremely nonvolatile tungsten carbide at low temperatures. It was possible by this procedure to improve the detection limits of 15 elements by two powers of ten.

4. Possibilities and Limitations of the Various Methods

We shall now consider the limits of the various methods in the light of the present position of trace analysis. The question of the absolute limit of a method or of an analytical principle is not very meaningful, since there are processes used in nuclear physics by which it is possible to detect individual atoms or elementary particles. However, one would hardly call these analytical procedures. Consequently, one can only consider an idealized analytical procedure isolated from the apparatus available at any given time, and ask oneself if it approaches the limit imposed by the quantized nature of energy.

Considerations of this type are already important in connection with the detection power[*] of X-ray fluorescence and spectrochemical analysis. Only a small number of investigations that can be accurately evaluated have been carried out on the detection power of modern electrochemical processes[15]. In inverse voltammetry on the hanging mercury drop and on the graphite electrode, we found that the detection power for lead, cadmium, and silver was 0.2 ng/ml, *i.e.* approximately 10^{-9} M solutions. Modern polarographs are also capable of detection in the nanogram range. According to the latest publications and the manufacturers' data, some cations and anions

[14] *N. Lounamaa*, Suomalaisen Tiedeakatemian Toimituksia (Ann. Acad. Sci. fenn.) Ser. A II *63*, 1 (1955).

[*] In accordance with a suggestion by *Kaiser*, the term "detection sensitivity" or "sensitivity" that was frequently used in the past is replaced by "detection power". This means that the term "sensitivity" is now reserved exclusively for the measured value/scale division, *i.e.* in analysis, for the slope of the calibration line.

[15] *R. Neeb*, Article in Reinststoffanalytik, 2. Internationales Symposium „Reinststoffe in Wissenschaft und Technik". Vol. 2, Akademie-Verlag, Berlin 1966, p. 573.

can be determined in solutions as dilute as 10^{-9} to 10^{-10} M.

To emphasize clearly the distinction between the terms used, we again stress that the detection power referred to here is not to be confused with the statistically defined detection limit of a complete analytical process. The detection power applies to an analytical principle embodied in an "idealized" procedure that is not subject to interference by external influences. It is usually one to two powers of ten lower than the detection limit.

4.1. Photometry

Owing to the chemical pretreatment of the sample and the reagents required, the detection limit in photometry, as was mentioned earlier, depends on the reagents and on the scatter of the blank values due to the outside atmosphere. We have been able to achieve detection limits of 0.008 to 0.02 μg of metal/ml by the use of specially purified reagents in a dust-free room. In the present state of photometric measuring techniques, this is the order of magnitude of the detection power of this analytical principle, which is determined by the extinctivity [16]. With few exceptions [17] ε_{max} is given by

$$\varepsilon_{max} = 9 \cdot 10^{19} \cdot P \cdot a \leqq 10^5$$

if the entire system contains only one chromophore. In this equation, P is the probability of transition, and a is the square dimension of the chromophore. The extinctivities in the photometric procedures used for the determination of trace elements are between 10000 and 30000, and between 50000 and 80000 for dithizonates. If one assumes that an extinction of 0.01 can still be reproducibly measured, it can be deduced from the well known equation

$$E = \varepsilon \cdot c \cdot d$$

that by making use of all possibilities, it is just possible to carry out an accurate measurement on a 10^{-7} M solution. Thus trace contents of less than 10^{-5} % cannot be determined photometrically without previous enrichment. This limit was determined for absorption photometry; it is not valid for fluorescence analysis, in which visual and photometric measurement is still possible in some cases for 10^{-10} to 10^{-12} M solutions. However, routine fluorescence analysis is not particularly popular in inorganic chemistry, owing to its susceptibility to interference.

4.2. Spectrochemical Analysis

The most important method of inorganic trace analysis at present is emission and absorption atomic spectroscopy. This method has the following advantages over other methods [18].

The samples can be analyzed directly, *i.e.* without chemical preparation. The spectrochemical methods are specific, and the identification of the element is conclusive. For these reasons, many elements in the same sample can be determined qualitatively and quantitatively at the same time. Low detection limits can be achieved, and the accuracy (standard deviation) is satisfactory over wide concentration ranges; moreover, only small quantities of material are required (sometimes as little as 1 μg is sufficient). Once a procedure has been established, the time taken for preparation of the sample and analysis is short. Combination of spectrochemical analysis with enrichment processes, though not so universally applicable, leads to very low detection limits and relatively high accuracies [18].

The problem of the detection limit and its improvement has received more attention in recent years in spectrochemistry than in any other analytical method [18]. The detection power of this analytical principle has been discussed by *Mandel'stam* and *Nedler* [19]. Because of the simplifications and assumptions made, the authors regard their treatment as qualitative rather than as quantitative. They calculate the spectrochemical detection power for individual elements in absolute quantities, and conclude that 10^{-12} g can be detected in an arc and 10^{-13} g in a hollow cathode. The corresponding concentrations are 10^{-9} and 10^{-10} % respectively. This means that 10^9 atoms can be detected in a sample with the aid of the hollow cathode, and 10^{10} atoms with the aid of an arc.

That these limits have occasionally almost been reached in practice is illustrated in Table 1, where column a) refers to analysis of pure solutions and column b) to the analysis of U_3O_8 with a carrier. The Table clearly shows the difference between the detec-

Table 1. Spectrochemically detectable quantities (after *Korovin* [19a], abridged) (a) in pure solutions, (b) in technical U_3O_8 (enrichment of the sample by fractional distillation with a carrier).

tion limits in pure solutions and those in an industrial analytical sample.

Of the many spectrochemical investigations that have been carried out, we shall consider only one interesting piece of work on the analysis of very pure substances. *Haftka*[20] studied the purification of high-purity aluminum by zone melting, with particular reference to the elements magnesium and silicon. The detection limits in this case are about 10^{-6} %. Some trace elements that could not be detected spectrochemically in the initial bar were very obvious after zone melting. *Haftka* followed the purification of zone-refined bismuth spectrochemically and by conductance measurements. Whereas the conductance along the bar changed only by a factor of 2, concentration changes of several powers of ten were found spectrochemically. Thus spectrochemical analysis is much more suitable for purity control in this case.

An even more recent spectrochemical method of trace analysis is atomic absorption spectroscopy[21]. This method developed surprisingly rapidly after the first investigations by *Walsh*[22]. The analytical principle is simple, and the apparatus inexpensive. A hollow cathode made from the element that is to be determined is caused to emit radiation (a continuum may also be used), which is then passed through the vaporized sample. The atoms of the element to be determined absorb in particular at the wavelengths of their resonance lines, and this absorption is measured. Since the number of atoms absorbing the light determines the detection limit, the latter may be decreased by increasing the optical path or the residence time of the atoms present in the gaseous phase. This second alternative was realized by *L'vov*[23] by means of the graphite cell. When the sample or the solution is introduced directly into a graphite tube about 10 cm long and heated to a high temperature it evaporates, and the atoms remain for a long time in the gas space. The versatility and handling of the absorption cell was recently considerably improved by *Massmann*[24]. By this technique, it was possible to obtain detection limits of 10^{-11} g of aluminum and 10^{-12} g of zinc in atomic absorption spectroscopy. The detection power as defined in Section 4 is about 10^{-14} g for favorable elements. Though atomic absorption spectroscopy cannot achieve the importance of emission spectral analysis, it has gained a firm place in optical spectral analysis because of its very low detection limits and the relatively inexpensive apparatus required. However, a number of technical difficulties still remain to be overcome before it can be used for routine analysis on a large scale.

4.3. Activation Analysis

The trace analysis method having the best detection power is activation analysis. The reasons for this are the high specificity (due to specific half-lives and specific radiation energies), the possibility of the simultaneous determination of several elements, the ease of separation by carriers, and the absence of blank values, since the sample is irradiated without preliminary treatment and any surface impurities can be removed by etching after activation.

Thermal neutrons are the particles most frequently used in activation analysis. When a sample is irradiated with neutrons or other particles, the number of atoms A activated is

$$A = Nf\sigma\,(1-e^{-\lambda t})$$

N is the number of atoms present, f is the neutron flux, σ is the effective cross section (which is a measure of the probability of capture of the particles by the element in question), λ is the half-life, and t is the irradiation time. The effective cross section differs from one element to another by several powers of ten. This difference and the difference in the half-lives give rise to the different detection limits for the various elements under otherwise identical conditions. Some idea of the detection limits found is given in Table 2. By increasing the neutron flux by one to two powers of ten, which is now possible, the detection limits given here can be further improved, and short-lived activated emitters can be determined more readily. Thus *Neeb et al.*[27] were recently able to determine 10^{-10} % of gold in high-purity aluminum at a neutron flux of 8×10^{13} n cm^{-2} sec^{-1}.

Table 2. Detection limits for activation analysis by neutron radiation in a flux of 10^{13} n cm^{-2} sec^{-1}.

10^{-11} g	10^{-12} g	10^{-13} g	10^{-14} g
Sb	As	Lu	Eu
Ar	In	Dy	—

Ga	Re	—	—
Hf	Sm	—	—
Co	Sc	—	—
Cu	Tb	—	—
La	Tm	—	—
Li	W	—	—
Na	Yb	—	—

The activation analysis of high-purity substances has recently been reviewed by *Alimarin et al.*[28] (see Table 3). The detection limits for most impurities, irrespective of the matrix, are between 10^{-6} and 10^{-8} %. (For further reviews on detection limits for 70 elements by this analytical principle, see the articles by *Lukens*[25] and *Jule*[26].)

Activation analysis is not confined to the use of slow neutrons. Fast neutrons, protons, deuterons, α-particles, ^{3}He, and γ-radiation can also be used for activation. "Inverse" activation is also possible. Owing to its high neutron capture cross section, boron (0.1 to 0.008 %) can be determined indirectly in steel from the reduced ^{59}Fe activity.

In addition to the advantages mentioned, activation analysis also has certain disadvantages. It cannot be used to obtain a general picture of the composition of a sample, as can spectrochemical analysis or mass spectroscopy, since the elements to be determined must be known in advance. Another disadvantage is the high cost of production and manipulation of radioactive elements. Nevertheless, activation analysis must be used whenever the most rigorous demands of the chemistry of pure substances have to be met. It is in fact indispensable in certain special cases.

4.4. Mass Spectroscopy

One of the great advantages of spectrochemical analysis is that it can be used for very fast, rough analysis to gain a general picture of the composition of a sample. The same possibility is offered by mass spectroscopy. This method again requires no chemical preparation of the sample. Consequently, contamination by the outside air and by reagents is reduced, and the detection power is accordingly greatly improved. The ion source used almost exclusively in inorganic mass-spectroscopic analysis is the high-frequency high-vacuum spark type, in which the composition of the ion beam corresponds closely to the composition of the sample. On the basis of this assumption, it is possible to determine all components directly to within an uncertainty factor of 3, and without special calibration. The ions of the elements present are generally recorded on a photographic plate. Mass spectroscopy is finding increasing use, particularly in the analysis of very pure substances. Table 4 lists the detection power for the impurities in very pure silicon as determined by such a method.

Table 4. Detection limits $\underline{c}$ for mass spectrographic trace determinations in high-purity silicon [28a].

Element	$\underline{c}$ (Atom-ppb)	Element	$\underline{c}$ (Atom-ppb)
Bismuth	1	Arsenic	3
Lead	2	Gallium	6
Gold	10	Zinc	5
Tungsten	3	Copper	5
Tantalum	30	Nickel	50
Europium	2	Iron	30
Cerium	100	Manganese	1000
Antimony	2	Chromium	10
Tin	3	Calcium	10
Indium	30	Chlorine	10
Silver	6	Phosphorus	10
Molybdenum	10	Magnesium	10
Niobium	3	Boron	3

[28a] The data are taken from AEI Technical Information Sheet A 16.

In a fundamental study, *Ehrlich* and *Mai* [29] have accurately determined detection limits in the analysis of very pure substances on a statistical basis. In semiconductor silicon, the detection limits for about 50–60 elements are less than or about 10 atom-ppb (billion $\equiv 10^9$), and for a further 10 elements between 10 and 100 ppb; only three elements have detection limits between 100 and 200 ppb in the mass-spectroscopic analysis of high-purity silicon. By very careful elimination of the strong background blackening in the neighborhood of the principal lines of the matrix (cut-outs are made in the photographic plates and the interfering ions of the principal components pass through), *Mai* [30] achieved detection limits of 0.3 ppb for favorable elements in high-purity aluminum. Conversion of the values given here into absolute quantities, *i.e.* the quantities that fall on the photographic plate and give rise to the analytical signal, shows that as little as 10^{-12} to 10^{-16} g can be recorded mass-spectroscopically; thus 10^5 atoms can be detected. This brings us into a range that is also reached in special cases by activation analysis.

However, it should be mentioned that the results of mass spectroscopic analysis can be falsified by external influences. Sources of error include contaminants from the outside air, contacts made during transport, materials entrained through the ion source, and particularly the "memory effect" (errors due to remaining traces of the previous analytical sample). Moreover, the performance of accurate inorganic analysis of solids is still very difficult, and requires extensive cooperation between chemists and physicists. A great deal of fundamental research and improvement of the equipment will be required before routine inorganic mass-spectroscopic analysis in the ppb range will become practicable.

[30] *H. Mai*, J. sci. Instruments *42*, 339 (1965).

4.5. Catalytic Detection Reactions

Catalytic or kinetic analytical methods make use of the dependence of catalytic reactions on the concentration of the catalyzing element. These reactions can be divided into three groups [31, 32, 32a]

1. activation of the reactant by coordination,
2. formation of a charge transfer complex between the catalyst and the reactant, and
3. activation of the reactant by conversion into the free radical form.

The first group consists mainly of reactions of elements that occur in only one oxidation state. The increase in the reaction rate is generally slight and the detection power is of the order of 10^{-4} to 10^{-7} g/ml. A well known example is the catalytic determination of iodide ions with hydrogen peroxide in the presence of molybdenum, zirconium, hafnium, niobium, and tantalum, all of which form complexes with hydrogen peroxide.

The formation of a charge transfer complex requires overlapping between the free orbitals of the reactant and the occupied orbitals of the catalyst or *vice versa*. For this reason, the favored elements are those with partly occupied d shells, *i.e.* those which form characteristic complexes of this type with aromatic anions and phenols. It is possible in such reactions to attain a detection power of 10^{-9} to 10^{-12} g/ml.

If a catalyst is to form free radicals, it must be readily oxidizable or reducible, with loss of or acceptance of an electron. The radicals formed are extremely reactive, a fact which leads to a very marked increase in the reaction rate and consequently to an extremely good detection power (in the picogram range). Some examples are the catalytic detection reactions with hydrogen peroxide in alkaline media, the oxidation of thiosulfate to tetrathionate, and the reduction of peroxodisulfate to sulfate.

Catalytic detection reactions are known at present for 35 elements. The only elements for which specific reactions exist are copper [33] and cobalt. Copper(II) salts react specifically with *p*-dimethylamino-α-benzoylaminocinnamic acid, a compound which exhibits green fluorescence in the presence of copper. By means of such a process it is possible to determine 0.001 μg of Cu/ml and it is used at present for the determination of very low copper contents in high-purity hydrochloric acid and chlorosilanes.

The number of selective catalytic detection reactions is greatly increased if selectivity is related to the same reaction for three to five other elements. Reactions of this type exist for chromium, molybdenum, tungsten, uranium, manganese, rhenium, iron, nickel, ruthenium, palladium, vanadium, platinum, gold, mercury, fluorine, bromine, iodine, sulfur, selenium, and tellurium. Less selective reactions are known for titanium, zirconium, hafnium, thorium, niobium, tantalum, zinc, cadmium, germanium, silicon, and phosphorus. Selectivity for some of the elements in the last group can be greatly increased by preliminary complexing of one of the accompanying elements.

This and other recent results show considerable promise for the future of trace determination by catalytic detection reactions, particularly in trace analysis of high-purity substances.

Conductance of Electrolyte Solutions

BY J. BARTHEL [*]

The present article deals with methods and results of conductance studies with special reference to nonaqueous solvents, e.g. ethanol, dioxane, dimethylformamide, acetonitrile, nitromethane, and acetone, in some cases mixed with water, as well as NH_3, SO_2, I_2, etc. On the basis of a model in which the ions are represented as charged spheres and the solvent as a homogeneous isotropic medium, the conductance theory can (at least for low electrolyte concentrations) give a more or less complete representation of the problem. A new statistical treatment of the transport problem confirms important results of this representation. The present state of the investigation is finally outlined in a review of recent publications.

1. Introduction

Conductance measurements are among the most accurate of all electrochemical measurements. The investigation of conductance as a function of concentration gives the conductivity at infinite dilution, the ion mobilities, the dissociation constants of ionogens, the association constants of ionophores, ionic radii, and in many cases information about the structure of the electrolyte solutions in the vicinity of the ions. Parameters available in studies of this nature include the temperature, the pressure, and the strength and frequency of the external electric field, as well as the properties of the ions and of the solvent. In the theoretical treatment, there is no fundamental difference between water and nonaqueous solvents.

Ionophores [2] (true electrolytes [1]) are substances which in the pure state already exist as ionic crystals, *e.g.* the alkali metal halides. Ionogens [2] (potential electrolytes [1]), such as acetic acid, form ions only by chemical reaction with solvent molecules.

Ionophores are completely dissociated in solution; however, in solvents with sufficiently low dielectric constants, Coulomb forces between oppositely charged ions lead to the formation of associates, which, in symmetrical electrolytes (charges on cation and on anion equal in magnitude), cannot transport current, *e.g.*

$$Na^+ + Cl^- \underset{CH_3COCH_3}{\rightleftharpoons} [Na^+Cl^-]^0$$

The reaction of ionogens with the solvent to form ions does not proceed to completion

$$CH_3COOH + H_2O \rightleftharpoons CH_3COO^- + H_3O^+$$

Both processes are described by the thermodynamic equilibrium constants K_A (association constant) or K_D (dissociation constant) [**].

[**] The symbols used are given in the following list in the approximate order in which they occur.

K_A	= association constant [l/mole]
K_D	= dissociation constant [mole/l]
Λ	= molar conductance [ohm^{-1} cm^2 mole^{-1}]
Λ_c	= equivalent conductance [ohm^{-1} cm^2 equiv^{-1}]
Λ_0	= limiting conductance for $c \to 0$
σ, σ_c	= specific conductance [ohm^{-1} cm^{-1}]
σ_L	= specific conductance of the solvent
n_e	= electrochemical valence of electrolyte $[K^{z+}_{\nu+}A^{z-}_{\nu-}]$ $n_e = \nu_+ z_+ = \nu_- z_-$
R, R_L	= resistance [ohm] also hydrodynamic ionic radius R, R_∞, R^+, R^- [cm]
A	= cell constant [cm^{-1}] also coefficient of the Fuoss-Onsager theory
$\vec{P}(\vec{r})$	= establishment of a point by the vector $\vec{r}$
n_i, n_ν, n_+, *etc.*	= analytical concentration [ions/ml] of i ions ν ions, cations, *etc.*
$n_{ij}(\vec{r_1}, \vec{r_{21}})$	= density of j ions at a distance $\vec{r_{21}}$ from an i ion at $\vec{P}(\vec{r_1})$
D	= relative dielectric constant
η	= viscosity [poise]
$n^0_{ij}(r)$	= density of j ions at a distance r from an i ion in spherically symmetrical non-disturbed equilibrium distribution
z_i, z_ν, z_+, *etc.*	= valence of an i ion, an ν ion, a cation, *etc.*
$f_{ij}(\vec{r_1}, \vec{r_{21}}), f^0_{ij}(r)$	= distribution functions; for definition, see eq. (2) and eq. (3).
$\psi_i(\vec{r_1}, \vec{r_{21}}), \psi'_i(\vec{r_1}, \vec{r_{21}}), \psi^0_i(r)$	= electrostatic potentials
ρ, ρ_i	= charge density
e_0	= electronic charge = 4.80223×10^{-10} e.s.u.
k	= Boltzmann constant = 1.38026×10^{-16} erg deg^{-1} molecule^{-1}
N_ν	= occupancy in the Wicke-Eigen and Falkenhagen-Kelbg theories
μ, μ_i, μ_0	= chemical potential
f_i, γ_i, y_i	= activity coefficients
$f_\pm$, $\gamma_\pm$, $y_\pm$	= mean activity coefficients of electrolytes
x	= mole fraction
m	= molality [mole/1000 g of solvent]
c	= molarity [mole/l]
τ	= for definition cf. eq. (10)
$\varkappa$	= parameter in the Debye-Hückel theory, for definition see eq. (11)
b	= parameter of the Bjerrum theory, for definition see eq. (10)
a, a_i, a_J, a_K, *etc.*	= ionic radii (distance parameters)
Λ_I	= relaxation term
Λ_{II}	= electrophoretic term

(This footnote is continued on opposite page)

The theory of electrolytes is primarily concerned with completely dissociated electrolytes. The results of this treatment are then extended to account for the behavior of the free ions of associating ionophores or ionogens.

2. Measurement of the Concentration-Dependence of the Conductance of Electrolytes

The determination of the properties of electrolytes from the dependence of their electric conductance on concentration demands very accurate experimental data. To obtain an accuracy of 0.01 % in the determination of the limiting conductance Λ_0 by extrapolation, the measurement of the individual Λ values and of the corresponding concentrations in dilute solutions (10^{-4} to 10^{-2} mole/l) must be equally accurate. Association constants $K_A \geqslant 10$ can be determined with this accuracy; values found for association constants much lower than this are not meaningful, owing to the limits of accuracy of K_A.

An accuracy of 0.01 % for the individual values can be achieved even in nonaqueous solvents. The prime requirement in this case is that the solvents used should be so pure that no correction of the electrolytic conductance is necessary. This is often possible only if all preparations (chemical purification, distillation) of the solvent and of the electrolyte, as well as the measurements themselves, are carried out under a carefully purified protective gas.

The concentration-dependence of the electrolytic conductance can be determined by three methods:

1. independent preparation of each sample and subsequent introduction into the measuring apparatus,

2. stepwise dilution of a concentrated electrolyte solution in the apparatus shown in Fig. 1,

3. stepwise concentration, starting with the pure solvent, by addition of the pure electrolyte or of a concentrated stock solution in the apparatus shown in Fig. 2.

In our experience, the stepwise concentration method (Fig. 2) has certain advantages over the dilution method. The sample used in the measurement of the conductance of the solvent is that used for the preparation of all the solutions. The quantity of solvent is small, however large the number of concentration steps, and the accuracy of measurement, which is to be identified with the accuracy with which the concentration of the most dilute solution is known, is higher than in a dilution method, in which the error increases from the most concentrated to the most dilute solution. (For other measuring arrangements of this type see [5,6].)

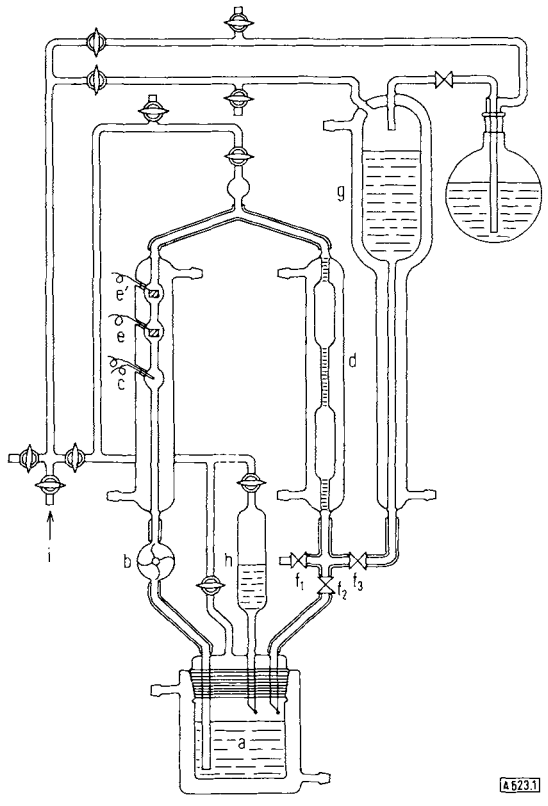

Fig. 1. Recirculation apparatus for the determination of the concentration dependence of electrolytic conductance under a protective gas by the stepwise dilution method [7]:

a electrolyte container; b recirculating pump; c thermistor; e,e' large-surface cylindrical electrodes in the measuring segment; d burette (a known quantity of electrolyte solution is run out through the valve f_1 with f_2 closed, and is replaced by pure solvent from the solvent reservoir g through the valve f_3); h concentrated stock solution; i protective gas inlet. All tubes are thermostatted or insulated.

To achieve an accuracy of 0.01 %, the temperature in the measuring cell must be kept constant to within about 0.001 °C. The resistance is measured by a bridge arrangement (for a discussion of the effects of the measuring cell, the measuring bridge, and the recorded reading in precision measurements cf. [3,7,8]; for the phase jump method cf. [6,9]). The electrolytic conductor obeys Ohm's law.

The cell constant ($A[\mathrm{cm}^{-1}] = l/q$) of the measuring cell is the ratio of the length (l) of the electrolytic conductor to its cross section (q). It is generally found with the aid of the equation $A = R \cdot \sigma_c$ by measurement of the resistance (R) of an electrolyte whose specific conductance $\sigma_c = \Lambda_i \cdot c \cdot n_e 10^{-3}$ is known, and can then be used to determine the specific

S, E', J_1, J_2, L, A, F = coefficients of the Fuoss-Onsager theory

a electrolyte container and mixing vessel with stirrer; a' stirrer motor; z measuring cell with large-surface annular electrodes e,e' facing narrow conduction paths (capillary ring d); g,g' glass rings to protect the electrodes; h,h' stirrers; k stirrer motor. The mixing vessel contains the solution up to the level n_1, and the measuring cell is filled (new level n_2 in a) and emptied by inert gas pressure. A stock solution may be introduced into b from a weighing burette (tip of the burette shown), or the electrolyte may be introduced through the cap c; i protective gas inlet.

conductance σ_c or the equivalent conductance Λ_c of any electrolyte solution from resistance measurements. When the solvent used is not completely pure, the resistance value R_{exp} found for the solution must be corrected by means of the formula $1/R = 1/R_{exp} - 1/R_L$, where R_L is the resistance found for the solvent used. This correction allows only for additivity of the conductance values, and its validity is therefore often doubtful (cf. Section 7.4).

Since conductance measurements on electrolyte solutions are generally referred to standard KCl solutions, it is necessary to ensure that the accuracy of these with respect to the cell constant is compatible with the desired accuracy in Λ_c. If the usual standard solutions[18] (1 N, 0.1 N, 0.01 N KCl) cannot be used because their electrolyte concentration is too high, it is advantageous to use aqueous KCl solutions having $c < 0.01$ mole/l, which satisfy the equation

$$\Lambda_c = 149.93 - 94.65c^{1/2} + 58.74c \log c + 198.46c \qquad (1)$$

with an accuracy of 0.01 %[10]. The cell constant should be independent of concentration in the range in which measurements are carried out.

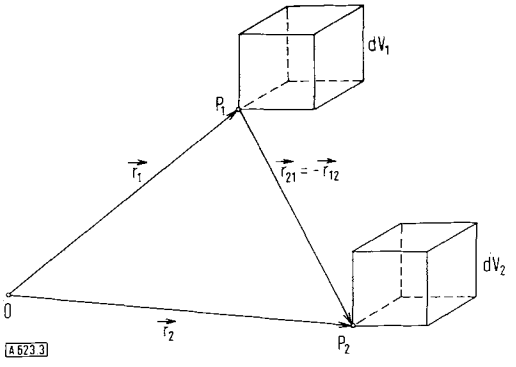
3. Distribution Functions

The theory of electrolytes is built up around the distribution functions of the ions. Electrolytes in solution give ions of the types 1,2,....*i*,*j*,...*m* in the concentrations $n_1, n_2, \ldots n_i, n_j, \ldots n_m$ ions/ml. The distribution of the ions in the solution depends on the forces acting between all the particles, ions and solvent molecules. External forces are also involved in the description of transport properties. The distribution of ions is described by distribution functions[11] (cf. also [2, 17, 18]).

$$f_{ij}(\vec{r}_1, \vec{r}_{21}) = n_i(\vec{r}_1) n_{ij}(\vec{r}_1, \vec{r}_{21}) = n_j(\vec{r}_2) n_{ji}(\vec{r}_2, \vec{r}_{12}) = f_{ji}(\vec{r}_2, \vec{r}_{12}) \qquad (2)$$

In this equation, $n_{ij}(\vec{r}_1, \vec{r}_{21})$ represents the density of *j* ions [ions/ml] at a distance $\vec{r}_{21}$ from an *i* ion at $P_1(\vec{r}_1)$ (cf. caption to Fig. 3).



A 623.3

Fig. 3. Derivation of the distribution function eq. (2).
To find the ion distribution, let an observer at a point 0 record the population of *i* ions in a volume element dV_1 and the population of *j* ions in a volume element dV_2 over a period Δt. The two volume elements with their solvent-permeable and ion-permeable walls are immovably fixed in relation to the observer at the positions $P_1(\vec{r}_1)$ and $P_2(\vec{r}_2)$ in the solution. The observer notes a time Δt_i for the residence of an *i* ion in dV_1. This is proportional to the particle density n_i, the size of the volume element dV_1, and the observation period Δt, *i.e.* $\Delta t_i = \alpha n_i\, dV_1\, \Delta t$ (where α is the proportionality factor). Similarly, he records a time $\Delta t_j = \alpha n_j\, dV_2\, \Delta t$ for the residence of a *j* ion in dV_2. He also determines a time $\Delta t_{ij} = \alpha n_{ij}\, dV_2\, \Delta t_i$ for the presence of a *j* ion in dV_2 with the condition that there is also an *i* ion in dV_1, and finally a time $\Delta t_{ji} = \alpha n_{ji}\, dV_1\, \Delta t_j$. Since $\Delta t_{ij} = \Delta t_{ji}$, we obtain eq. (2) (cf. also [2]).

As is confirmed *e.g.* by the behavior of KCl in aqueous solution at low concentrations, a small group of ionophores exists in solution almost entirely as free cations and anions, and can therefore be used for the direct experimental investigation of the properties of an electrolyte that is theoretically completely dissociated.

In the absence of external forces, the ions assume a spherically symmetrical equilibrium distribution, in which n_i is independent of position P_1 and $\vec{r}_{12} = r$, and which is described by the function

$$f_{ij}^0(r) = n_i\, n_{ij}^0(r) = n_j\, n_{ji}^0(r) = f_{ji}^0(r) \qquad (3)$$

The ions exert long-range Coulomb forces on one another, which are stronger than the induction and

[11] *L. Onsager*, Physik. Z. *28*, 277 (1927).

dispersion forces acting between all the particles in the solution. There is as yet no theory that takes into account all intermolecular forces.

In the classical model of an electrolyte solution, the ions (valences $z_1 \ldots . z_m$) are represented as charges in a homogeneous and isotropic solvent (dielectric constant D, viscosity η). If $\psi_i^0(r)$ is the electric potential at a distance r from an ion i in the absence of external forces, and if it is assumed that only Coulomb forces act between the ions, the position-dependent concentration of j ions in the vicinity of the i ions is obtained as a result of a Boltzmann distribution in the form of eq. (4).

$$f_{ij}^0 = n_i n_j \exp\left[\frac{e_0 z_j \psi_i^0(r)}{kT}\right] = n_i n_j \sum_{\nu=0}^{\infty} \frac{1}{\nu!}\left[\frac{e_0 z_j \psi_i^0(r)}{kT}\right]^\nu \quad (4)$$

In the Debye-Hückel theory[12], the expansion of the series is stopped after the linear term

$$f_{ij}^0 = n_i n_j \left[1 - \frac{e_0 z_j \psi_i^0(r)}{kT}\right] \quad (5)$$

For symmetrical electrolytes, the further expanded distribution function (6) leads to the same Poisson

$$f_{ij}^0 = n_i n_j \left[1 - \frac{e_0 z_j \psi_i^0(r)}{kT} + \frac{1}{2}\left(\frac{e_0 z_j \psi_i^0(r)}{kT}\right)^2\right] \quad (6)$$

equation (8) as equation (5), since the charge density

$$\rho_i = \frac{1}{n_i} \sum_{j=1}^{m} f_{ij}^0 e_0 z_j$$

for electrolytes of this type contains no powers with even exponents.

Higher powers in the expansion (4) were taken into account, though only for a binary electrolyte in solution, in the work of *Gronwall, Sandved*, and *La Mer*[13] for symmetrical electrolytes up to $\nu = 5$ and of *La Mer, Gronwall*, and *Greiff*[14] for unsymmetrical electrolytes up to $\nu = 3$.

According to *Wicke* and *Eigen*[15], contrary to the Boltzmann distribution, the volume occupied by the ions should restrict the sites available for the ν ions in a unit volume to a number N_ν. For this case, *Falkenhagen* and *Kelbg*[16] give a distribution function

$$f_{ij}^0 = n_i n_j \frac{\exp\left[\frac{e_0 z_j \psi_i^0(r)}{kT}\right]}{1 + \sum_{\nu=1}^{m} \frac{n_\nu}{N_\nu}\left[\exp\left(\frac{e_0 z_\nu \psi_i^0(r)}{kT}\right) - 1\right]} \quad (7)$$

which changes into the form previously given by *Eigen* and *Wicke* for $m = 2$ and equal occupancies for the cation and the anion, and into equation (4) for infinitely large occupancies.

Each of the electrostatic potentials $\psi_i^0(r)$ of equations (4) to (7) satisfies a Poisson equation

$$\Delta\psi_i^0(r) = -\frac{4\pi}{D}\cdot\rho_i = -\frac{4\pi}{Dn_i} \sum_{j=1}^{m} f_{ij}^0 e_0 z_j \quad (8)$$

and can be determined from this and the boundary conditions of the problem.

If the charge on the ions in solution is assumed to be built up from zero to its full value, $\psi_i^0(r)$ can be used to find the activity coefficients f_i, γ_i, or y_i of the species i (solvent index $i = 0$), which explain the thermodynamic properties of the electrolyte solution in the range of validity of the distribution function in question (cf. *e.g.*[1,17,18]) according to

$$\mu_i = \mu_i^{0(x)} + RT \ln x_i f_i = \mu_i^{0(m)} + RT \ln m_i \gamma_i = \mu_i^{0(c)} + RT \ln y_i c_i$$
$$\mu_i^{0(x)} = \lim_{x_0 \to 1} [\mu_i - RT \ln x_i]\,; \quad \lim_{x_0 \to 1} f_i = 1 \quad (9)$$

The mean activity coefficient $y_\pm$ that occurs in the conductance equation of associating ionophores and ionogens is discussed in connection with this equation. For point ions (ions with zero radius), the activity coefficient of a binary electrolyte in dilute solution, which is the one encountered most frequently, is found from the distribution (5) to be

$$-\ln y_\pm = \tau = \frac{1}{2} ba\varkappa\,, \quad b = \frac{|z_+ z_-| e_0^2}{aD\,kT} \quad (10)$$

$$\varkappa^2 = \frac{4\pi e_0^2 Nc}{1000\,D\,kT}(\nu_+ z_+^2 + \nu_- z_-^2) \quad (11)$$

In this article we give only the basic principles that lead to conductance equations in the classical theory of electrolytes. For the calculation of the thermodynamic properties of electrolyte solutions by statistical-mechanical methods, the reader is referred to recent summaries[20,21].

4. The Conductance of Completely Dissociated Electrolytes

With the exception of a limiting law, conductance equations have been derived only for solutions containing a single binary electrolyte. In these equations the specific conductance σ [ohm^{-1} cm^{-1}], or more frequently the molar conductance $\Lambda = 1000\ \sigma/c$ [ohm^{-1}cm^2 mole^{-1}] or the equivalent conductivity

$\Lambda_c = \Lambda/n_e$ [ohm^{-1} cm^2 equiv^{-1}] is expressed as a function of the electrolyte concentration c.

$$\Lambda_c = f\,[c;\,\Lambda_0,a,D,\eta,T]$$

In addition to c, this function contains the limiting values ($c \rightarrow 0$) of the equivalent conductance Λ_0, a parameter a that is generally taken to represent the ionic radius, and the viscosity η, dielectric constant D, and temperature T of the solution. The influence of the frequency and strength of the applied field are not shown in this equation. The dependence on c is frequently written as a dependence on the parameter $\varkappa$ (cf. eq. (11)) of the Debye-Hückel theory.

No experimental confirmation can be found for an equation $\Lambda = \Lambda_0$, such as that on which Ostwald's Law for ionogens is based. The main inhibiting effects are defined by a relaxation term Λ_I, resulting from the unsymmetrical charge distribution about a migrating ion due to the external field, and an electrophoretic term Λ_{II}, due to the migration of this ion in relation to the solvent, which is displaced in countercurrent by the ion cloud.

$$\Lambda_c = \Lambda_0 - \Lambda_I\,(c;\,\Lambda_0,a,D,T) - \Lambda_{II}\,(c;\,a,D,\eta,T) \tag{12}$$

In the form

$$\Lambda_c = \Lambda_0 - Sc^{1/2} + E'c\ln c + J_1c - J_2c^{3/2} \tag{13}$$

which was first established in the Fuoss-Onsager theory [23,24], all the coefficients S, E', J_1, and J_2 contain components due to both effects.

The disturbed ion distribution due to the external field is described by the unsymmetrical function

$$f_{ij}(\vec{r}_1,\vec{r}_{21}) = f_{ij}^0(r) + f'_{ij}(\vec{r}_1,\vec{r}_{21}) \tag{14}$$

to which is assigned, for pure Coulomb interaction between the ions, a potential

$$\psi_i = \psi_i^0(r) + \psi'_i(\vec{r}_1,\vec{r}_{21}) \tag{15}$$

in accordance with eq. (8) and

$$\Delta\psi'_i = -\frac{4\pi}{Dn_i}\sum_{j=1}^{m} f'_{ij}e_0z_j \tag{16}$$

The continuity equation for the stationary case

$$\mathrm{div}_2(f_{ij}\vec{v}_{ij}) + \mathrm{div}_1(f_{ji}\vec{v}_{ji}) = 0 \tag{17}$$

where the velocities $\vec{v}_{ij}(\vec{r}_1,\vec{r}_{21})$ and $\vec{v}_{ji}(\vec{r}_2,\vec{r}_{12})$ ($\vec{v}_{ij}$ = velocity of a j ion out of the vicinity of the i ion) are related to the forces responsible for the unsymmetrical distribution (cf. [18]), and *via* these to the potential $\psi'_i(\vec{r}_1,\vec{r}_{21})$, can be used together with the Navier-Stokes equation for the movement of spherical ions to calculate the components [25,27] Λ_I and Λ_{II} or the coefficients [2,23,33] S, E', J_1, and J_2.

The information that can be provided by a conductance equation therefore depends

1. on the form of the ion distribution f_{ij}^0 on which it is based,

2. on the form of the boundary conditions of the problem,

3. on the approximations used in the calculation of ψ'_i, and

4. on the nature of the factors affecting ion mobility that are also taken into account.

The limiting equation (*Onsager* [11,22], *Debye* and *Falkenhagen* [26]) with

$$\Lambda_I = \frac{|z_+z_-|e_0^2}{3\,D\,kT}\,\frac{q}{1+\sqrt{q}}\,\Lambda_0\,\varkappa \tag{18}$$

$$\Lambda_{II} = (|z_+| + |z_-|)\,\frac{\mathfrak{F}\,e_0\,10^8}{6\pi\eta C}\,\varkappa \tag{19}$$

$$q = \frac{|z_+z_-|}{|z_+| + |z_-|}\,\frac{l_{0+} + l_{0-}}{|z_+|l_{0-} + |z_-|l_{0+}} \tag{20}$$

is the simplest solution of the conductance problem for point ions (ionic radius $a = 0$) obtained with the distribution (5).

Consideration of (11) leads directly to a form

$$\Lambda = \Lambda_0 - S_{(\Lambda)}\,c^{1/2} \tag{21}$$

whose coefficient $S_{(\Lambda)}$ has the value S given in Table 1, for 1,1 electrolytes since $q = {}^1/_2$.

With $a \neq 0$, *Onsager* and *Fuoss* [29] obtained an electrophoretic term Λ_{II} which, for symmetrical electrolytes, contains the factor $(1 + \varkappa a)^{-1}$ that is not present in eq. (19). Also for $a \neq 0$, *Kaneko* [30] gives a relaxation term Λ_I that also contains the factor $(1+\varkappa a)^{-1}$ not present in (18) on linear approximation of the exponential function $\exp[(1-\sqrt{q})\varkappa a]$ occurring in the Kaneko expression. This result explains an equation proposed by *Robinson* and *Stokes* [3,31]

$$\Lambda = \Lambda_0 - S_{(\Lambda)}\,(1 + \varkappa a)^{-1}\,c^{1/2} \tag{22}$$

The validity of the limiting law is often confined to such low ion concentrations in nonaqueous solutions that it is outside the range of accurate measurement. The experimental data can be reproduced over a wider range with the aid of eq. (22).

Conductance equations in the complete form (13) or equations of similar and corresponding content in the form (12) have been obtained on revision of the

[*] The value of the Faraday constant $\mathfrak{F}$ in absolute coulomb/equivalent and that of the electronic change in esu must be used in the equations of the coefficients in this Table, in agreement with the work of *Fuoss* and *Onsager*. The equations can also be applied to symmetrical electrolytes having ions of higher valences by taking the magnitude of the charge into account in the coefficients.

approximations for the relaxation term and the electrophoretic term, taking into account extended distribution functions and the formulation of appropriate boundary conditions [*].

The first equation (13), which was proposed by *Fuoss* and *Onsager* [23], is based on the distribution (6); the boundary conditions are taken as

$$\left(\frac{\delta\psi_i'}{\delta r}\right)_\infty = 0\ ;\ \psi_i'(a-0) = \psi_i'(a+0)\ ;\ \left(\frac{\delta\psi_i'}{\delta r}\right)_{a-0} = \left(\frac{\delta\psi_i'}{\delta r}\right)_{a+0}; \tag{23a}$$

$$([f_{ij}\vec{v}_{ij} - f_{ji}\vec{v}_{ji}]\vec{r})_{r=a} = 0 \tag{23b}$$

The conditions (23a) describe the behavior of the disturbing potential at the field boundaries, while (23b) states that the ions, as rigid spheres, move with only a tangential velocity component on meeting. The terms S, E', J_1, and J_2 contain two components: both the contributions of the electrophoretic effect and the evaluation of the relaxation term by an approximation that takes the velocity field completely into account (in the limiting law, only the component in the field direction is considered). Though it does not include all the terms that are linear in the concentration dependence [23,25], this equation [2] takes into account a conductance-increasing kinetic effect that results in the accumulation of ions behind the migrating ion. A viscosity component to allow for the change in the viscosity of the solution on introduction of the electrolyte can be taken into account by means of the Einstein relation [32]. Λ in eq. (13) is then replaced by the quantity $\Lambda_\eta = \Lambda(1 + Fc)$, where $F = 6.308\times 10^{21} R^3$ (R = hydrodynamic radius of the ion), or else eq. (13) takes the form [48]:

$$\Lambda = \Lambda_0 - Sc^{1/2} + E'c \ln c + J_1 c - Fc\Lambda_0 + O(c^{3/2}) \tag{24}$$

A term J_2 for the Fuoss-Onsager theory is given by *Fuoss* and *Berns* [33] and in a revised form by *Justice* [33a]. However, this term is used by *Fuoss et al.* only in rare cases in the evaluation of experimental data, and in the conductance theory it is discussed only in the residual term $O(c^{3/2})$ of (13) or (24) in view of the incompleteness of J_1 [34]. *Fuoss, Onsager,* and *Skinner* [35] have reported a new equation resulting from further revision [36] of the fundamental principles; this equation will be discussed in Section 5.

The extended distribution function (4) for symmetrical electrolytes [13] forms the basis of the conductance equation proposed by *Pitts* [37]. Here the boundary conditions are postulated in a different manner and additional effects are not taken into account. The equation, which has a claimed validity range of up to 0.1 N for 1,1 electrolytes in aqueous solution, was deduced as a complex expression with the aid of tabulated functions, but was modified to the form (13) by *Fernández-Prini* and *Prue* [38].

[*] Equations in this section of the present article are formulated so as to be valid for 1,1 electrolytes.

Falkenhagen, Leist, and *Kelbg*[39] give a conductance equation based on the Eigen-Wicke distribution function[15], in which an a parameter is also taken into account in the boundary conditions. *Leist*[40] attacked the problem again, using the generalized distribution (7) given by *Falkenhagen* and *Kelbg*, and with a viscosity correction for 1,1 electrolytes.

Kelbg[41] introduced the boundary condition (23) in the derivation of another conductance equation (see also[25,27]). The equations are obtained in the form (12). The Kelbg equation for symmetrical electrolytes[25] then contains

$$\Lambda_I = \frac{e_0^2}{6\,D\,kT} \cdot \frac{(2-\sqrt{2})\,\Lambda_0\,\varkappa}{(1+\varkappa a)\,(1+\frac{1}{2}\sqrt{2}\,\varkappa a+\frac{1}{6}\,\varkappa^2 a^2)} \qquad (25)$$

$$\Lambda_{II} = \frac{e_0^2\,N\cdot 10^{-11}}{27\,\pi\eta} \cdot \frac{\varkappa}{1+\varkappa a}$$

(Compare with the equation given by *Fuoss* and *Onsager*, see[25]).

In all extensions of the Onsager limiting law, the short-range forces in the neighborhood of an ion are taken into account by the a parameter. The stipulation of a rigid sphere by means of the boundary conditions corresponds to the simplest form of a repulsion potential[34]. The importance of the distribution function f_{ij}^0 becomes clear in the new conductance equation given by *Fuoss, Onsager,* and *Skinner* (cf. Section 5).

Only a few experimental data have been evaluated by several equations. In these cases, the experimental values for aqueous solutions with $c < 0.02$ mole/l can be reproduced equally well by the Fuoss-Onsager, Pitts, Leist, and Kelbg equations, though with different a values[25,42]. The viscosity correction of the Leist equation permits the description of the experimental data up to the saturation range of 1,1 electrolytes[40]. By far the majority of the experimental results were evaluated with the Fuoss-Onsager equation. This equation has also been repeatedly confirmed by experimental results in nonaqueous solutions.

Important results of the classical theory of electrolytes are confirmed by a new treatment of the conductance problem, which is based on the statistical-mechanical theory of irreversible processes, and is independent of the basic principles of the foregoing description. The limiting law is confirmed by the theories of *Friedmann*[43], *Falkenhagen* and *Ebeling*[44], and *Résibois et al.*[45]. *Falkenhagen* and *Kremp*[46] give a new conductance equation of the form (13). The coefficients of this equation are shown in Table 1; the electrophoretic term S_2 is written in a form of the classical limiting law that differs from the form given in the original article.

The conductance equations cannot be easily applied to solutions containing more than two ionic species[17,29,47]. Though the electrophoretic term Λ_{II} for each individual ion in the limiting law for electrolyte mixtures is independent of the nature of the other ions, the relaxation term Λ_I depends in a complex manner on the nature and concentration of all the ions in the solution.

5. Conductance of Ionogens and Associating Electrolytes

In charge transport, ion pairs formed by symmetrical electrolytes

$$K^+ + A^- \rightleftharpoons [K^+\,A^-]^0 \qquad K_A = \frac{[K^+\,A^-]^0}{[K^+]\,[A^-]} \qquad (26)$$

behave in the same way as the undissociated molecules of ionogens.

$$KA \rightleftharpoons K^+ + A^- \qquad K_D = \frac{[K^+]\,[A^-]}{[KA]} \qquad (27)$$

The association constant K_A of ionophores and the dissociation constant K_D of ionogens are related to the degree of dissociation α [$(1-\alpha)$ is thus the degree of association] by

$$K_A = K_D^{-1} = \frac{(1-\alpha)y_0}{\alpha^2 c y_\pm^2} \qquad (28)$$

where $y_\pm$ is the mean activity coefficient of the dissociated electrolyte; the activity coefficient y_0 of the associate or of the undissociated molecule can generally be taken as equal to unity ($y_0 = 1$).

Only the free ions of ionogens and of associated ionophores contribute to their conductance. Since the concentration of these ions in the solution is $c' = \alpha c$, the conductance equation for electrolytes of this type is

$$\Lambda = \alpha\,[\Lambda_0 - \Lambda_I(c') - \Lambda_{II}(c')] \qquad (29)$$

or

$$\Lambda = \alpha\,[\Lambda_0 - Sc'^{1/2} + E'c'\ln c' + J_1 c' - J_2 c'^{3/2}] \qquad (30)$$

based on eqs. (12) and (13) of Section 4. Eq. (30) can be related to the law of mass action (28), and it then gives the conductance equation reported by *Fuoss*[2,48–50] for associating electrolytes ($J_1 = J$, and J_2 is disregarded).

$$\Lambda = \Lambda_0 - S(\alpha c)^{1/2} + E'\alpha c \ln(\alpha c) + J\alpha c - K_A y_\pm^2\,\Lambda\alpha c + O(c'^{3/2}) \qquad (31)$$

Table 2. Dependence of the association constants on the activity coefficients used [51]. Alkali metal ethoxides in ethanol (25 °C), $10^{-4} < c < 10^{-3}$ mole/l, water content of the ethanol about 0.001 %.

The equation for the activity coefficient $y_{\pm}$ depends on the concentration range. It must be remembered in this connection that the association constant depends to a certain extent on the activity coefficient used (Table 2). The constants $K_A^{(1)}$, $K_A^{(2)}$, and $K_A^{(3)}$ are based on

$$-\ln y_{\pm}^{(1)} = \tau = 4.202 \times 10^6 \cdot (DT)^{-3/2} (\alpha c)^{1/2} \quad \text{(cf. (10))} \tag{32}$$

$$-\ln y_{\pm}^{(2)} = \tau(1 + \varkappa a)^{-1} \tag{33}$$

$$-\ln y_{\pm}^{(3)} = \tau(1 + \tau)^{-1} \tag{34) [52, 53]}$$

Eqs. (30) and (31) can be deduced from any conductance equation of the form (13). They were derived and discussed by *Fernández-Prini* and *Prue*[54] for the Pitts equation. An equation of the form (29) was derived by *M. Leist* [40] from her equation for completely dissociated electrolytes and related to the law of mass action using an activity coefficient that takes into account the volume occupied by the ions.

The work involved in the use of the complete equation (31) can be avoided for strongly associated electrolytes and nearly always for ionogens since the concentration of free ions in the solution in these cases is so small that it falls within the range of application of the Onsager limiting law. For incompletely dissociated electrolytes this law is written in the form

$$\Lambda = \alpha\,[\Lambda_0 - S(\alpha c)^{1/2}] \tag{35}$$

or

$$\Lambda = \Lambda_0 - S(\alpha c)^{1/2} - K_A y_{\pm}^2\,\Lambda\alpha c\,; \quad -\ln y_{\pm} = \tau \tag{36}$$

An acceptable guiding figure for the use of these equations is an association constant $K_A = 10^4$ ($K_D = 10^{-4}$) in aqueous solution.

Among the extensions of the Onsager limiting law, the equation given by *Marshall* and *Grunwald*[55] could also be mentioned.

$$\Lambda = \Lambda_0 - \frac{S(\alpha c)^{1/2}}{1 + \tau} - K_A y_{\pm}^2 \Lambda\alpha c\,; \quad -\ln y_{\pm} = \frac{\tau}{(1 + \tau)^{3/2}} \tag{37}$$

Limiting law	(36)	49.47	100	20.54	1238
Marshall and *Grunwald*	(37)	49.51	130	20.53	1275
Fuoss and *Onsager*	(31)	49.47	65	20.39	1090

The Ostwald dilution law $\Lambda = \Lambda_0 - K_A\Lambda\alpha c$ with $\alpha = \Lambda/\Lambda_0$ is nearly always an inadequate approximation [55a].

Under conditions that do not permit the use of the limiting law, most experiments are evaluated with the aid of the Fuoss equation.

The Leist equation, *e.g.* with $a = 1.8$ Å, gave $K_A = 220$ and $\Lambda_0 = 44.8$ for $AgNO_3$ in ethanol in the concentration range $c < 0.6$ mole/l [40]. According to *Parfitt* and *Smith*[56], the values obtained with the aid of the Fuoss-Onsager method ($c < 0.02$ mole/l) are $K_A = 210$, $\Lambda_0 = 44.88$ and, $a_J = 3.85$ Å.

If the dissociation constant K_D of the ionogen and the association constant K_A of the ionophore are introduced into the conductance equations in the same way, *via* the postulated law of mass action, no allowance is made for the essential difference between these two quantities. The dissociation of ionogens results from the breaking of a nonpolar bond, whereas the association of ionophores (and sometimes also ionogens) is a consequence of the distribution of the ions in a given solvent. The ions retain their identity in the associate. The association constant can be calculated from the forces that determine the distribution of the ions.

For oppositely charged ions, the number w_{ij} of j ions at a distance between r and $r + \Delta r$ from an i ion

$$w_{ij} = 4\pi r^2\,\Delta r\,nj \exp\left(-\frac{z_i z_j e_0^2}{DkTr}\right) \tag{38}$$

has a minimum at

$$r = q = -\frac{z_i z_j e_0^2}{2\,D\,kT} \tag{39}$$

This minimum moves toward greater distances r as the dielectric constant of the solvent decreases (Fig. 4). According to *Bjerrum*[57], ions at a distance $r < q$ apart are to be regarded as associated, so that the

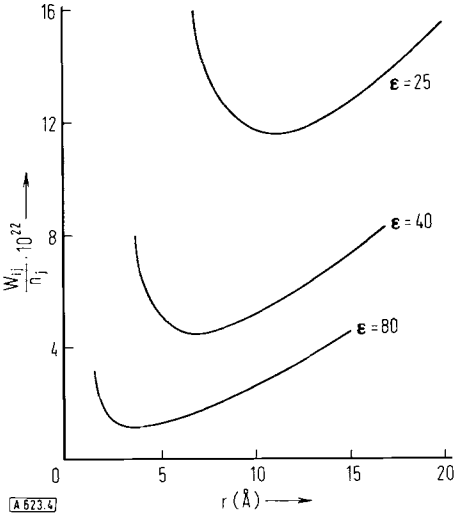

Fig. 4. Number of negative ions in a spherical shell ($\Delta r = 0.1$ Å) at a distance r from a positive central ion in solvents of different dielectric constants ($\varepsilon = D$).

degree of association (1 - α) of a binary electrolyte (for definition of b see equation 10) is

$$(1-\alpha)=\frac{4\pi Nc}{1000}\int_{a}^{q} r^2 \exp(ba/r)\,dr=\frac{4\pi Nca^3b^3}{1000}Q(b) \qquad (40)$$

$$Q(b)=\int_{2}^{b} x^{-4}e^{x}dx$$

The function $Q(b)$ has been tabulated [1,18]. In dilute solutions ($\alpha^2 \approx 1$, $y_{\pm} \approx 1$), it is found that

$$K_A=\frac{1-\alpha}{c}=\frac{4\pi Na^3b^3}{1000}Q(b) \qquad (41)$$

The Bjerrum association theory, in principle, correctly reproduces the change in K_A with the dielectric constant and temperature of the solvent [1,18,58,59] when there are no specific interactions between ions and solvent molecules, but sometimes leads to anomalies with respect to the a parameter. In eq. (40), *Fernández-Prini* and *Prue* [54] take the dielectric saturation in the field of the ions into account by inclusion of a position-dependent dielectric constant in the Boltzmann factor. This leads to much better agreement of the a parameter with the crystallographic radii of the ions in the cases studied by the authors. *Prue* [60] also raises the question of whether the Bjerrum distance q for which the potential energy of the ion pair becomes $2kT$, really takes into account the ions that cannot contribute to the charge transport; as a result of the consideration of this question, he replaces the upper integration limit in eq. (40) by an arbitrary distance d, which is discussed as a further parameter on the basis of the experimental data.

Fuoss [61] interprets the association constant by counting the contact pairs (according to *Prue* [60], $d = 4a/3$):

$$K_A=\frac{4\pi Na^3}{3000}e^{b} \qquad (42)$$

From thermodynamic considerations, *Denison* and *Ramsay* [62] had found $K_A = e^b$, and *Gilkerson* [63] extended this relationship by inclusion of the entropy component from the partition functions of the free and associated ions. A specific solvation in the association process is taken into account in this equation.

With E_s as the molar free energy of solvation (free ions → ion pair), it is found [61,63,64] that

$$K_A = K_0\, e^{b}\, e^{E_s/RT}, \text{ and according to } Fuoss\ K_0=\frac{4\pi Na^3}{3000} \qquad (43)$$

The mass-action constant of the ion-pair formation required in the *ad-hoc* hypothesis is no longer necessary in a new conductance equation given by *Fuoss*, *Onsager*, and *Skinner* [35] for symmetrical ionophores. The retention of the complete Boltzmann factor in the distribution function (4) gives an expression $A(a)$ for the decrease in conductance due to ion contact pairs, which asymptotically approaches the value of K_A given by eq. (42) with decreasing dielectric constant of the solvent.

$$\Lambda=\Lambda_0-Sc^{1/2}+E'c\ln\tau^2+L(a)c-A(a)\Lambda_0 c\,e^{-2\tau} \qquad (44)$$

τ is as defined in eq. (10). Eq. (44) covers the equation (31) given by *Fuoss* [48] in 1959 as a limiting form. For low concentrations, and since $\tau^2 = 6E'_1c$, equation (44) can be converted into eq. (31) with $L+E'\ln 6E'_1 = J$ in the low dielectric constant range. In dilute solutions with higher dielectric constants, on the other hand, $e^{-2\tau} \approx 1$, and collection of the linear terms as $J = L(a)-\Lambda_0A(a)+E'\ln 6E'_1$ leads to the 1957 Fuoss-Onsager equation [23] (13) for unassociated electrolytes [34]. Since it is the only conductance equation for ionophores, eq. (44) is the solution of an old theoretical problem.

In the new statistical treatment of the problem, again without postulation of the law of mass action, *Ebeling*, *Kraeft*, and *Kremp* [65] derived a form

$$K_A=\frac{4\pi Na^3}{1000}\,\frac{e^{b}}{b} \qquad (45)$$

which is obtained by asymptotic expansion of the function $Q(b)$ in eq. (41).

The distance parameter a can be determined in three ways from the conductance data for associating electrolytes: First from the J or L term in accordance with Table 1 as $a_J(a_L)$; secondly from K_A as a_K; and finally, in conjunction with Stokes law, as a_Λ from Λ_0. However, the relationship $a_K = a_J = a_\Lambda$ is generally not satisfied. The observed deviations form the starting point for the discussion of the structure in the immediate neighborhood of the ions.

In solvents having low dielectric constants ($D < 12$), another ion can arrange itself in the field of the ion pair dipole of 1,1 electrolytes to form an ion triplet [66] (cf. also [1,18,67]).

$$[K^+A^-]^0 + K^+ \rightleftharpoons[K'_3] [K^+A^-K^+]^+$$

$$A^- + [K^+A^-]^0 \rightleftharpoons[K''_3] [A^-K^+A^-]^-$$

On the assumption of spherical ions with spherically symmetrical charge distributions, $K'_3 = K''_3 = K_3$. The ion triplets contribute to the charge transport and have a limiting conductance $\Lambda_0^{(3)}$; however, this conductance cannot be directly determined by experiment. No complete theoretical treatment of the conductance problem including ion triplets or even higher associates has yet been carried out. The equation

$$\Lambda=\Lambda_0 K_A^{-1/2}c^{-1/2}+\Lambda_0^{(3)}K_3K_A^{-1/2}c^{1/2} \text{ (see ref. [66])}$$

as a functional type correctly reproduces the observed concentration dependence. It gives the observed minimum of Λ and its displacement with the dielectric constant of the solvent. K_A and K_3 can be determined from the position of the minimum and an assumption [18] regarding $\Lambda_0^{(3)}$, *e.g.* $\Lambda_0:\Lambda_0^{(3)} = 1:3$.

6. Evaluation of the Experimental Data

6.1. Graphic Methods

For completely dissociated electrolytes, the values of Λ_0 and J_1 are obtained from a plot of

$$\Lambda = \Lambda_0 - Sc^{1/2} + Ec \log c + J_1 c\,; \quad E = 0.4343\,E' \tag{46}$$

An approximate value ${}_0\Lambda_0$ is found by extrapolation in the Λ-$c^{1/2}$ diagram or with the aid of equation (51), and S and E' from Table 1 are used to calculate a function

$$\Lambda_1 = \Lambda + Sc^{1/2} - Ec \log c \tag{47}$$

$$S = 0.8204\times10^6\,\Lambda_0/(DT)^{3/2} + 82.501/\eta(DT)^{1/2} \tag{48}$$

$$E = 6.7747\times10^{12}\,\Lambda_0/(DT)^3 - 0.9977\times10^8/\eta(DT)^2 \tag{49}$$

A plot of $\Lambda_1 = \Lambda_0 + J_1 c$ gives an improved extrapolated value ${}_1\Lambda_0$, with which the rapidly converging process is repeated [2]. J_1 is found from the slope of the linear function (Fig. 5). A nest method may be used to find a_J from $J_1^{(exp)}$.

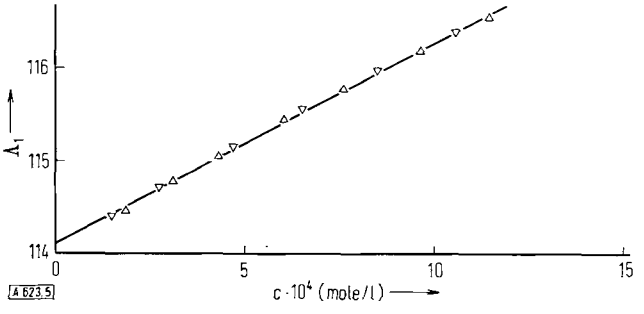

Fig. 5. Determination of Λ_0 and J in accordance with eq. (46). $CsOCH_3$ in CH_3OH (25 °C) [69]; Δ and ∇ are points obtained for different sets of experiments; $\Lambda_0 = 114.11$, $J = 2120$.

Two values a' and a'' are chosen such that $J_1(a') < J_1^{(exp)} < J_1(a'')$. The difference between a' and a'' is narrowed in the subsequent steps. The complete equation (13) with J_2 is best evaluated numerically.

Evaluation with the aid of the limiting law would give Λ_0. *Shedlovsky* [68] has shown that the function

$$\Lambda_0^c = \frac{\Lambda + S_2 c^{1/2}}{1 - S_1 c^{1/2}} \tag{50}$$

calculated from (21) does not give constant Λ_0 values even in very dilute solutions, and that this approximation is reached only by linear extrapolation of the Λ_0 value after plotting the experimental Λ_0^c values as

$$\Lambda_0^c = \Lambda_0 + Bc \tag{51}$$

The equation (22) given by *Robinson* and *Stokes* can also be used for extrapolation from higher concentration ranges [31].

The conductance equation for incompletely dissociated electrolytes

$$\Lambda = \Lambda_0 - S(\alpha c)^{1/2} + E\alpha c \cdot \log(\alpha c) + J_1 \alpha c - K_A y_\pm^2 \Lambda \alpha c \tag{52}$$

can be evaluated graphically [2,49,70]; an estimated or extrapolated ${}_0\Lambda_0$ value is taken, and the quantity

$$\Lambda' = \Lambda + S(\alpha c)^{1/2} - E\alpha c \log(\alpha c) \tag{53}$$

is used to construct a function $y = (\Lambda' - \Lambda_0)(\alpha c)^{-1}$. When plotted against $x = y_\pm^2 \Lambda$ by a graphic nest method to find Λ_0, this function gives an equation

$$y = J_1 - K_A x \tag{54}$$

that is suitable for iteration (Fig. 6).

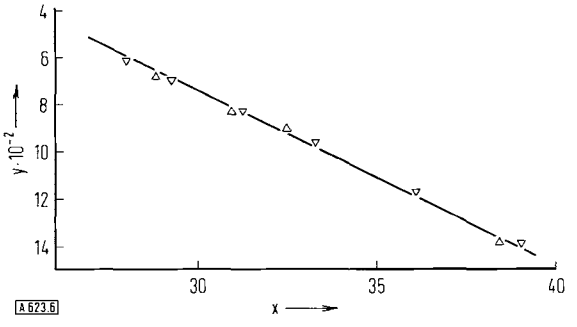

Fig. 6. Determination of conductance data by the x–y method. $CsOC_2H_5$ in C_2H_5OH (25 °C) [71]; Δ and ∇ are points for different sets of experiments; $\Lambda_0 = 49.49$, $J = 1460$, $K_A = 73$.

Apart from the first iteration step, in which one takes $\alpha = \Lambda/{}_0\Lambda_0$, it is necessary to determine α iteratively from equation (30) (with $J_2 = 0$) for each subsequent step in the determination of Λ_0, J_1, and K_A for each experimental value, so that the process is very time-consuming.

A procedure described by *Fuoss* and *Kraus* [72] can be used for evaluations in accordance with the limiting law

$$\Lambda = \alpha[\Lambda_0 - S(\alpha c)^{1/2}] \tag{55}$$

With an auxiliary variable $z = {}_0\Lambda_0^{-3/2}(\Lambda c)^{1/2}S$ and a corresponding tabulated function [73] $F(z) = 1\text{-}z[1\text{-}z[1\text{-}...]^{-1/2}]^{1/2}$ equation (55) can be written in conjunction with the law of mass action as

$$\frac{F(z)}{\Lambda} = \frac{1}{\Lambda_0} + \frac{K_A}{\Lambda_0^2}\,\frac{c\,\Lambda y_\pm^2}{F(z)} \tag{56}$$

Λ_0 and K_A are obtained in a rapidly converging iteration process on plotting of $F(z)\Lambda^{-1} = f(c\Lambda y^{2+}\,[F(z)]^{-1})$. A process described by *Shedlovsky* [74] using an auxiliary function that has also been tabulated [75] is based on an empirical extension of the limiting law. A comparison of the two procedures is described by *Fuoss* and *Shedlovsky* [76]. The sensitivity of this

[76] *R. M. Fuoss* and *Th. Shedlovsky*, J. Amer. chem. Soc. *71*, 1496 (1949).

process to fluctuations of the experimental values and solvent corrections was described by *Kortüm et al.* [77, 230].

The extrapolation to Λ_0 is sometimes inaccurate for weakly dissociated electrolytes; in cases of this type, it is advantageous to obtain Λ_0 from the additivity of the ion mobilities [78, 79].

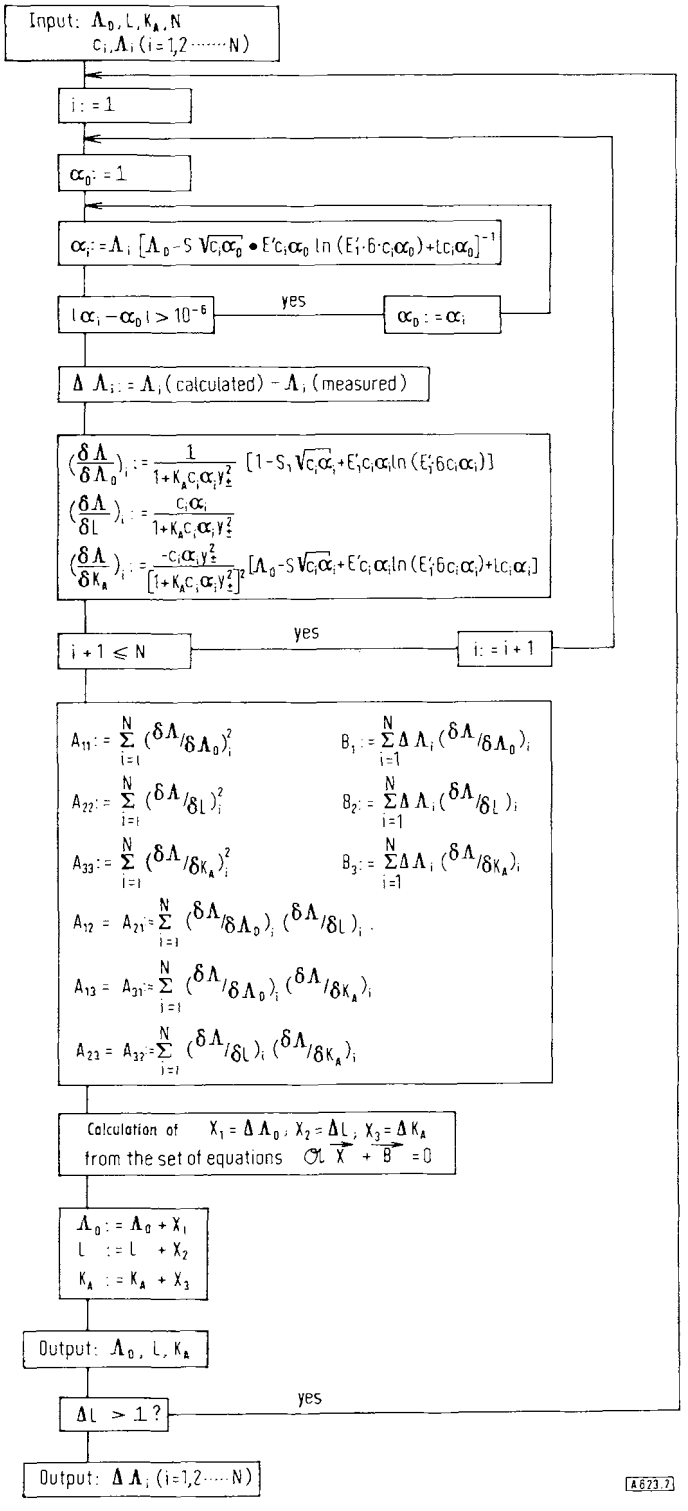

Fig. 7. Flow diagram for the evaluation of experimental data in accordance with eq. (44) in the form

$$\Lambda = \Lambda_0 - S(\alpha c)^{1/2} + E'\alpha c \ln(6E'_1\alpha c) + Lc - K_A\Lambda\alpha c y_\pm^2$$

for associated electrolytes. N = number of pairs of values c_i, Λ_i. For higher association constants ($K_A > 500$), it is preferable to start with α_0: = Λ_i/Λ_0. The equation

$$\mathfrak{A}\vec{X} + \vec{B} = 0$$

is solved by the Gauss-Banachiewicz method [*].

6.2. Numerical Methods

The basic principles for the establishment of a numerical compensation ("adjustment of observations") process were deduced by *Kay* [80, 81]. The conductance equation in the form (13) or in a similar form is expanded in accordance with

$$\Lambda({}_0\Lambda_0 + \Delta\Lambda, {}_0J_1 + \Delta J_1 \ldots) = \Lambda({}_0\Lambda_0, {}_0J_1 \ldots) + \frac{\delta\Lambda}{\delta\Lambda_0}\Delta\Lambda_0 + \frac{\delta\Lambda}{\delta J_1}\Delta J_1 + \ldots \quad (57)$$

using preselected approximate values ${}_0\Lambda_0$, ${}_0J_1$, *etc.* Iterative improvements $\Delta\Lambda_0$, $\Delta J_1 \ldots$ are calculated with the aid of a compensation program until the improvements fall below a predetermined limit. Figure 7 shows the flow diagram of a general process of this type used by us for the evaluation of experimental data and as an example of the use of equation (44). The predetermined limit in this case is $\Delta L < 1$. Differing from *Kay* we prefer to calculate the coefficients J_1, J_2, *etc.* from the conductance data of a direct calculation of a, since these coefficients are the same for all equations (cf. Table 1). The a parameters are determined from these quantities with the aid of special programs. Computer programs for the treatment of conductance equations are also given by *de Maine* and *Seawright* [82].

7. Results of Recent Conductance Investigations

The foregoing sections described the conductance theory and the hydrodynamic and electrostatic continuum model on which it is based. This model and the conductance equations derived from it, with a few exceptions that can be seen from the text, form the basis of the following investigations. As with any model, there exists the difficulty of assigning the parameters of the equations to the molecular dimensions of the solvent-electrolyte system; however, it is possible by a systematic series of experiments to demonstrate functional relationships which, sometimes in conjunction with results obtained by other methods, enable one to draw correct conclusions concerning the true molecular data, the structure of the electrolyte solutions, and reactions in solutions.

In the discussion of the results, no special role has been assigned to water as a solvent, and concentrated aqueous solutions have been completely disregarded (cf. [89]).

Contributions to this problem have also been made in Russian publications, but we have not been able to make systematic use of these.

Work on electrolytic conductance up to 1964 was reviewed in reports by *Fischer, Winkler,* and *Jander* (1958) [83], *Prue*

7.1. Conductance and Association of 1,1 Electrolytes

In agreement with the Bjerrum association theory, 1,1 ionophores generally exist exclusively as free ions in aqueous solutions at low concentrations; association is generally observed in solvents having a dielectric constant of about 50.

Hawes and *Kay*[5] carried out very accurate measurements in ethanol-water mixtures, and found $K_A = 3 \pm 0.4$ for CsCl at $D = 54.9$ and for KCl at $D = 43.3$. The corresponding values in pure ethanol ($D = 24.3$, $\sigma_L \approx 10^{-8}$) are $K_A(CsCl) = 158.1 \pm 0.6$ and $K_A(KCl) = 95 \pm 3$. In an extensive study of alkali metal halides in dioxane-water mixtures, *Fuoss et al.*[90] found no measurable association above $D = 50$. LiCl and $AgNO_3$ are associated in dimethylformamide ($D = 36.7$), whereas KI and perchlorates are not[91]. *Bury* and *Justice*[92] do not give association constants for $KClO_4$ in dioxane-water mixtures above $D = 25.3$; at $D = 25.3$, K_A has a value of 15.3. In the same solvent mixture, *Accascina* and *D'Aprano*[93] observed a similar behavior for $KClO_3$ ($K_A = 18$ at $D = 28.5$). 1,1 Electrolytes are not associated in formamide ($D = 109.5$)[94]. *Hoover*[95] found abnormally low a values for KCl in *N*-methylpropionamide ($D = 176$), and regarded this specific solvent effect as evidence of slight association.

Accascina et al. found an anomaly at low dielectric constants: $LiClO_4$ exhibits no association in dioxane-water mixtures[96] down to a dielectric constant of 10, in which *e.g.* LiCl[90] and $LiClO_3$[97] are strongly associated ($K_A \approx 1000$), or in methanol-butanol mixtures[98] down to a dielectric constant of 18, though it is associated in acetone ($K_A \approx 5000$)[99]. In solvents of low dielectric constant, in agreement with theory, this nonassociating electrolyte showed the second intersection ($c_1 = 0$, $c_2 = 10^{-J/E}$) of the limiting line $\Lambda = \Lambda_0 - Sc^{1/2}$ with the complete function $\Lambda = \Lambda_0 - Sc^{1/2} + Ec \log c + Jc$, which is situated too close to c_1 in solutions having higher dielectric constants[100]. For comparison, $K_A = 268$ at $D = 15.7$ for $KClO_4$ in dioxane-water[92]; $KClO_4$ and $NaClO_4$ are completely dissociated in methanol[101], in dimethylformamide[91], and in dimethylacetamide[102].

The validity of rules concerning the relationship between the properties of the electrolyte and the solvent and the magnitude of the association constant is only limited. *Fuoss et al.*[90] found in their studies on the conductance of alkali metal halides in dioxane-water mixtures that, for a given anion, the association constant increases with the atomic weight of the cation (as a result of decreasing solvation), while for a given cation, the association constant decreases with increasing atomic weight, *i. e.* with increasing volume, of the anion. On re-evaluation of earlier data for alkali metal salts in other solvents with the aid of the conductance equations (13) and (31), *Kay*[80] found partial agreement with the above rule. In methanol ($D = 32.6$), only CsCl ($K_A = 15$; subsequent redetermination[103] gave $K_A = 8.9$) is weakly associated, whereas all the nitrates studied are associated ($10 < K_A < 40$). The alkali metal picrates[104] also deviate from the Fuoss rule. *Evans*, *Zawoyski*, and *Kay*[105] report that the association constant for ion pair formation in the approximately isodielectric solvents ($D = 36$) acetonitrile, nitromethane, and nitrobenzene and in acetone ($D = 20.5$) increases with decreasing crystallographic radius of the ions. LiCl and LiBr are strongly associated in sulfolane[54] ($D = 43.3$ at 30 °C) the values of K_A being 1.4×10^4 and 278 respectively, whereas alkali metal iodides and other alkali metal salts exhibit only slight association. LiCl[106] and NaCl[107] are not associated in water-glycerol mixtures. NaCl is also unassociated in water-ethylene glycol mixtures[108].

Janz, Marcinkowsky, and *Ahmad* [121] studied the electric conductance and viscosity of $AgNO_3$ in acetonitrile and benzonitrile up to a concentration of 6 moles/l; these authors observed ion pair formation, and at higher salt concentrations ion triplet formation. The results were evaluated with the aid of the semi-empirical conductance equation given by *Wishaw* and *Stokes* [122], which is applicable at high salt concentration when a viscosity correction [25] is applied.

Large ions having a central charge, such as tetraalkylammonium and tetraphenylborate ions, are characterized in many series investigations by constancy of the a parameter.

Among the tetraalkylammonium halides R_4NX (R = CH_3, C_2H_5, C_3H_7, C_4H_9, X = Cl, Br, I), tetrabutylammonium iodide is associated in water ($K_A \approx 3$). This behavior is due to the structure of the environment of the large hydrophobic ions rather than to direct electrostatic interaction of the charge carriers [123]. Low association constants have also been found for tetraalkylammonium salts by *Quintin, Justice*, and *Justice* [124]. *Davies* and *Taylor* [125] found that R_4NX, $R_3(n\text{-}C_{18}H_{37})NX$, $R_2(n\text{-}C_{12}H_{25})_2NX$, and $R_2(n\text{-}C_{12}H_{25})(n\text{-}C_{18}H_{37})NX$ (R = CH_3, C_2H_5, C_3H_7, C_4H_9, X = Cl, I, NO_3, Pi (picrate)) behaved normally in hydrocyanic acid (18 and 25 °C), *i.e.* the experimental values agreed with the eq. (13) for unassociated electrolytes.

Information about the limiting range for association (methanol at 25 and 10 °C) is given in a comprehensive report by *Kay, Zawoyski*, and *Evans* [126], which contains results of measurements on 23 tetraalkylammonium salts of type R_4NX and $(iso\text{-}C_5H_{11})_3RNX$ (R = CH_3, C_2H_5, C_3H_7, C_4H_9, $n\text{-}C_5H_{11}$, $iso\text{-}C_5H_{11}$; X = Cl, Br, I, Pi, $B(C_6H_5)_4$). $(C_4H_9)_4NB(C_6H_5)_4$ is the most strongly associated salt ($K_A = 37$); the association is uncertain for some of the salts in this series. A similar situation is found in acetonitrile [105, 127], and in nitrobenzene the occurrence of association cannot be definitely established in many cases. Association is pronounced, however, in acetone ($(CH_3)_4NF$ with $K_A = 1140$). (For further data on tetraalkylammonium salts and borates, alkylsulfonates, phosphonium salts, and other salts, see [120, 128–148, 191–193].)

Since the sizes of the cation and the anion are approximately equal, $(C_4H_9)_4NB(C_6H_5)_4$ can be used as the reference electrolyte for the determination of ion mobilities in accordance with

$$l_{0+} = l_{0-} = 1/2\,\Lambda_0 \qquad (58)$$

with an accuracy of about 1 % [128]. $(iso\text{-}C_5H_{11})_3(C_4H_9)NB(C_6H_5)_4$ is equally suitable [130] and $(iso\text{-}C_5H_{11})_4NB(iso\text{-}C_5H_{11})_4$ even gives an accuracy of

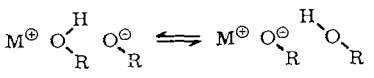
0.1 %[129]. (For other ion mobility measurements, also by other methods, see[120,125,149–159].)

Investigations with D_2O as the solvent have been carried out by *Kay* and *Evans*[160] on tetraalkylammonium halides, by *Horne* and *Johnson*[161] on KCl between −2 and +12 °C, and by *Swain* and *Evans*[162] on other salts.

Barthel et al.[4,51,69] were able to evaluate accurate measurements on alcoholic solutions containing bases (MOR) in low concentrations by means of the new conductance equations (13), (31), and (44). The variation of the association constant, which had not previously been observed in salts (decreasing from LiOR to KOR and increasing again from KOR to CsOR (R = C_2H_5, C_3H_7) cf. Table 2) is explained by ion pair formation according to two possible mechanisms:

1. the partial or complete penetration of the solvent sheaths by ions, generally accepted for salts, or
2. as a consequence of protolysis of a solvate molecule.



The second effect is more significant with small cations. The alkali metal methoxides are not associated in methanol[69].

7.2. Conductance and Association of Polyvalent Electrolytes

The normal limiting region of association for symmetrical electrolytes generally occurs at higher dielectric constants for electrolytes containing ions of higher valence. Mg, Ni, and $Cu(en)_2$ sulfates exhibit no association in formamide (D = 110)[163]. $MgSO_4$, MgC_2O_4, $CaCrO_4$[164], and many other 2,2 electrolytes are associated in water, and $MgSO_4$ is associated even in formamide-dioxane mixtures having a dielectric constant (D = 81, K_A = 88) higher than that of water[165]. However, the Ca salts of disulfonic acids do not form associates in water[166]. *Staples* and *Atkinson*[167] used benzenesulfonates (BS^-), *p*-benzenedisulfonates (BDS^{2-}), 4,4′-biphenyldisulfonates ($BPDS^{2-}$), and 4,4′′-terphenyldisulfonates ($TPDS^{2-}$) to study the association of polyvalent electrolytes having widely separated charge centers (bolaform electrolytes) in dioxane-water mixtures. The 1,1-electrolyte KBS and the 1,2 electrolytes K_2BDS and K_2BPDS are associated only in mixtures containing 50 % of dioxane, whereas K_2TPDS is weakly associated even in water.

In the treatment of unsymmetrical electrolytes, it is necessary to take into account conducting ion pairs of the type $[K^+A^{2-}]^-$ as well as $[K^+A^{2-}K^+]^0$. A conductance equation for bolaform electrolytes is given by *Fuoss* and *Edelson*[182].

Dawson, *Vaughn*, *Lester*, *Pruitt*, and *Sears*[183] found that polyvalent electrolytes and complex salts of the transition elements are completely dissociated in *N*-methylacetamide.

The association limit is further displaced for 3,3 electrolytes, such as $La[Co(CN)_6]$. $La[Co(CN)_6]$ is associated (K_A = 243) in formamide, whereas the conductance data of unsymmetrical electrolytes such as $[Co(NH_3)_6]Cl_3$ can be represented by eq. (13)[184]. For other studies on polyvalent electrolytes, see[168–181].

7.3. Higher Associates

On the basis of nonlinearity of the Shedlovsky plot, *Little* and *Singleterry* [185] concluded that higher associates are formed by cesium dinonylnaphthalenesulfonate (CsDNNS) in nitromethane, nitropropane, ethanol, *n*-butanol, and methyl isobutyl ketone and by LiDNNS in nitroethane, nitropropane, acetone, and methyl isobutyl ketone. LiDNNS forms only ion pairs in methanol, ethanol, and butanol, as does CsDNNS in acetone.

Beard and *Plesch* [186] observed minima in the concentration dependence of the conductance of $(CH_3)(C_2H_5)_3NI$ in CH_2Cl_2 down to low temperatures (−55 °C), and deduced ion triplet formation constants based on the assumption that $\Lambda_0^{(3)} = \Lambda_0/3$. *Strohmeyer*, *Seifert*, and *Landsfeld* [187] studied the effect of the ligands R on the electrolytic conductance of organometallic compounds of the type MR_2. Compounds MgR_2 form ion triplets in diethyl ether and tetrahydrofuran, whereas dialkylzincs do not; the cyclopentadiene derivatives of zinc behave similarly to the dialkylmagnesiums. Sodium tetracarbonylcobaltate associates in tetrahydrofuran to form ion pairs and higher associates [188]. *Vreugdenhil* and *Blomberg* [189] studied the conductance of Grignard compounds in diethyl ether.

According to *Bearcroft* and *Nachtrieb* [190], several associates are involved in charge transport in the system I_2 (liq.)/KI, as follows:

$$nI_2 \rightleftharpoons I^+ + I_{2n-1}^-, \quad K^+I^- \rightleftharpoons K^+ + I^-, \text{ and } K^+I^- + K^+ \rightleftharpoons K_2I^+$$

7.4. Interaction of the Electrolyte and the Solvent

This group of problems was first studied by *Walden*, who expressed his findings in the rule

$$\Lambda_0 \eta = \text{const.} = \frac{e_0^2 N \times 10^{-11}}{54\pi}\left(\frac{1}{R^+} + \frac{1}{R^-}\right) \tag{59}$$

Equation (59) is the form for 1,1 electrolytes (R^+, R^- = hydrodynamic radii of the ions). It can be deduced from Stokes' law and the definition of ion mobility. The accuracy with which it is satisfied generally increases with increasing size of the ions and with decreasing tendency of the solvent toward association. In addition to eq. (59), the relationship

$$l_{0j}\eta = \text{const.} = \frac{|z_j| e_0^2 N \times 10^{-11}}{54\pi} \cdot \frac{1}{R_j} \tag{60}$$

is also valid under the same conditions.

The Walden rule can be used for the estimation of a first Λ_0 value, such as is required *e.g.* in the iteration process. It provides information about the movement of spherical ions in a hydrodynamic continuum, and has been used in many of the investigations mentioned above for the estimation of the interaction of the ion with its surroundings. Examples are to be found in the work of *Fuoss* [90, 208, 209, 211, 212] and of *Kay et al.* [160, 191–193].

The approximation of the Walden rule is improved if the ionic radius R is expressed as depending on the dielectric constant of the solvent [194] (s = empirical constant)

$$R = R_\infty \left(1 + \frac{s}{D}\right) \tag{61}$$

This takes into account the orientation of the solvent dipoles by the migrating ion. *Boyd* [195] and *Zwanzig* [196] have provided a theoretical basis for the semiempirical equation (61). For a discussion of the limiting conductance on the basis of a kinetic theory see Section 7.6.

A second group of investigations was concerned with the discussion of the association constants as $\ln K_A = f(1/D)$ in accordance with $K_A = K_0 e^b$ (cf. eq. (43)). The results obtained in series of solvents were often satisfactorily reproduced by this relationship. Deviations from linearity in the $\ln K_A - 1/D$ diagram can be explained by $E_s \neq 0$ (cf. eq. (43)), and have even been quantitatively explained in a few cases (cf. *e.g.* [63]). For a complete understanding it is necessary to introduce a variable dielectric constant for the continuum surrounding the ion [54, 197] or to take into account the molecular structure of the solvent [60].

In another group of investigations, a further polar component is added to the solvent-electrolyte system, this component interacting with one of the ions to form an ion-dipole associate whose formation constant competes with K_A. The association of tetrabutylammonium picrate in dioxane/*p*-nitroaniline mixtures differs considerably from that in isodielectric mixtures (D = 13.2) of dioxane with water, methanol, and acetonitrile [198]. The picrate anion forms an associate with *p*-nitroaniline [199]. *Treiner*, *Quintin*, and *Fuoss* [200] concluded from conductance measurements that the phenol component of binary mixtures of acetonitrile with picric acid, *p*-, *m*-, and *o*-nitrophenol, and *p*-methoxyphenol adds on to quaternary ammonium ions as the phenoxide, with liberation of a proton, and that small ions such as Br^- in the mixtures are preferentially solvated by phenols.

The investigations mentioned above are concerned with complex formation between the anion of the electrolyte and an electrophile. Interactions of the

cation with nucleophiles have been described in a series of articles by *Gilkerson et al.* [201–203]. The cation of tertiary ammonium salts, in this case $(C_4H_9)_3HNPi$, forms 1:1 complexes with added amines in chlorobenzene and *o*-dichlorobenzene, the stability of these complexes increasing in the order 4-cyanopyridine < acetonitrile < tri-*n*-butylamine < pyridine < 4-methylpyridine. The methyltri-*n*-butylammonium cation (introduced as the perchlorate or iodide) associates with triphenylphosphine oxide in *o*-dichlorobenzene and ethylene dichloride. The addition of picric acid to tri-*N*-*n*-butylhydroxylammonium picrate in *o*-dichlorobenzene leads to a considerable decrease in conductance, while the addition of pyridine leads to an increase in conductance.

Specific ion-solvent interactions have also been found by *Day*, *Barnes*, and *Cox* [204] in conductance measurements on $Na[Al(C_2H_5)_4]$ and $Na[Al(iso\text{-}C_4H_9)_4]$ in diethyl ether and toluene. The conductance of $AlCl_3$ in acetonitrile (L) is due to the ions $[AlCl_2L_4]^+$ and $[AlCl_4]^-$, which are formed by complex disproportionation [205] in accordance with

$$2\ AlCl_3(s) + 4\ L \rightarrow [AlCl_2L_4]^+ + [AlCl_4]^-$$

In the same solvent, $CoCl_2$ forms the ions $[CoL_6]^{2+}$ and $[CoCl_3L]^-$ [206], and according to other investigations $[CoCl_4]^{2-}$ [207]. (For investigations that include other types, see [208–212].)

Ebeling, *Falkenhagen*, and *Kraeft* [213] interpret the decrease in conductance with increasing concentration of a neutral component (such as sugar, glycerol, mannitol) with the aid of a molecular theory in which the decrease in conductance is mainly due to the volume occupied by the ions and by the neutral molecules.

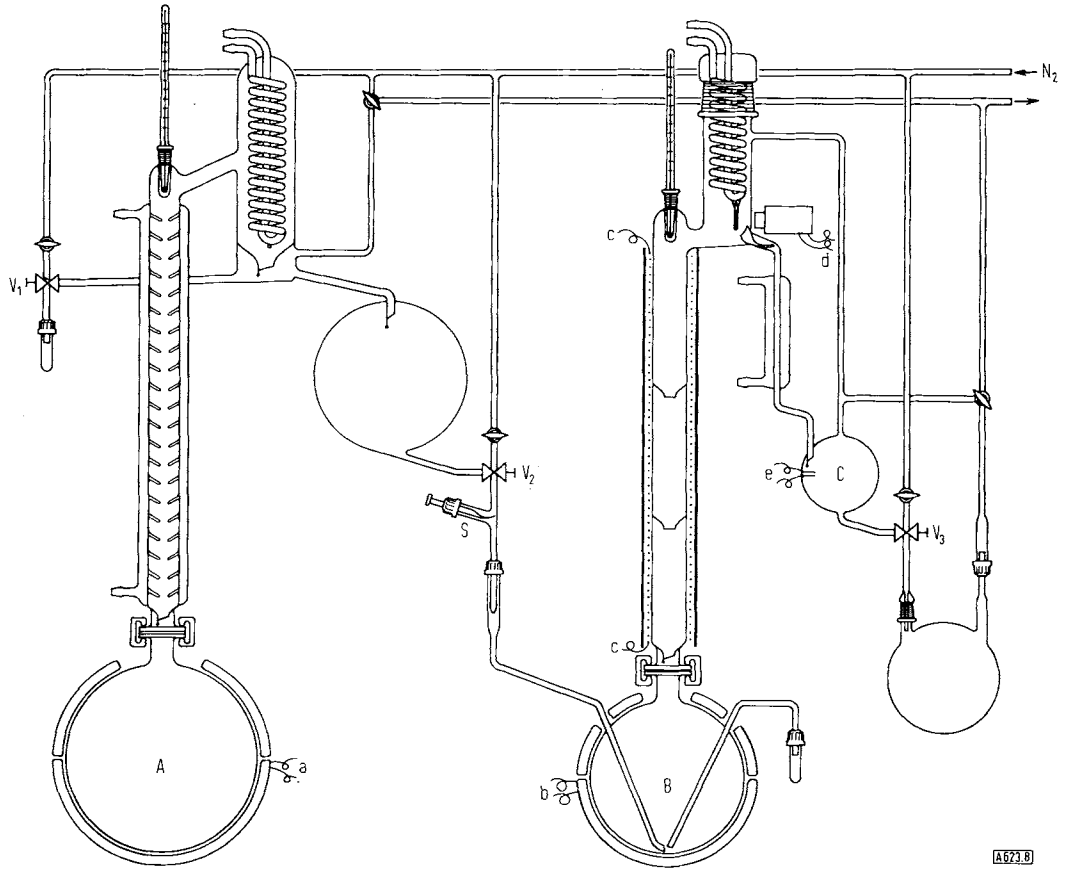

Fig. 8. Apparatus for the purification of solvents [216]. Dehydration of the solvent (isopropanol in this case) in A (approx. 5 l), distillation into B, addition of other reagents (in this case sulfanilic acid) for purification (in this case elimination of basic components) through S, final distillation from B (packed column, about 20 theoretical plates), C fraction collector, a,b,c, controlled heaters, d electromagnetically controlled take-off (adjustable reflux ratio [217]), e conductance measuring cell (A = 0.02 cm^{-1}) for examination of the distillate. V_1, V_2, V_3 nitrogen-purged, grease-free through-flow valves in the distillate line (description [218]). The entire apparatus operates under carefully purified protective gas.

Mention should also be made in this section of an interaction that is generally disregarded, and which is due to insufficient purification of the solvent. It can be seen from the results discussed above that effects due to impurities frequently cannot be eliminated by correction of the conductance values. Figure 8 shows a purification arrangement used by us. From chemical purification, *via* distillation, until its introduction into the measuring cell, the solvent remains under a protective gas. For example, iso-C_3H_7OH is purified in A over Al powder as described by *Walden, Ulich* and *Laun*[214]. After distillation into B, sulfanilic acid is added through S. The distillation product contains 5 ppm of H_2O, CO_2 is undetectable, and $\sigma_L = 10^{-9}$ ohm^{-1} cm^{-1}.

Figure 9 shows Λ-$\sqrt{c}$ curves for $KOCH_3$ in methanol, highly purified methanol being used in one case (A) and methanol distilled in air in the other (B). The interfering impurity is CO_2, which reacts with the electrolyte to form

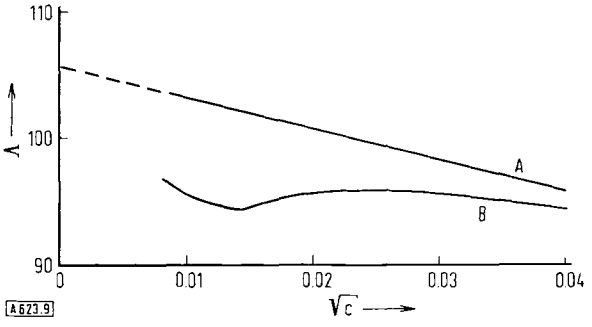

Fig. 9. Influence of the CO_2 content of methanol on the conductance of $KOCH_3$ in this solvent (25 °C) [71]. A: highly purified methanol; B: methanol distilled in air.

potassium methyl carbonate. Special investigations on the purity of the solvent are necessary in many cases (cf. *e.g.* [120, 215]).

The effect of the water content on the conductance is shown in Figure 10. The diagram shows a plot of $\vartheta = \Delta\Lambda$/wt-% of H_2O against the root of the electrolyte concentration for NaCl[215] (line) and for $NaOCH_3$ (circles) in methanol (25 °C).

Since these electrolytes form their ions by chemical reaction with the solvent, solutions of such electrolytes, by definition, exhibit a specific solvent-electrolyte interaction. No clear-cut distinction from the electrolyte properties discussed in the last section is possible, as is shown by the case of $AlCl_3$/acetonitrile.

For HCl in water/ethanol mixtures (0–100 %)[219] and in water/*n*-propanol mixtures (0–100 %)[220], the conductance data over the entire mixing range can be described by eq. (44); HCl is almost completely dissociated in solutions containing large quantities of water (up to 80 % of ethanol and up to 60 % of propanol, $K_A < 10$). The values of K_A in pure ethanol ($D = 24.3$) and in pure propanol ($D = 20.40$) are 48 and 171 respectively. This is not in conflict with earlier results of very accurate measurements on HCl in water by *Stokes*[221], since *Stokes*' work covered a wider concentration range.

Janz et al.[222–224] studied hydrogen halides HX mainly in acetonitrile and benzonitrile, and explained the conductance data and their time dependence on the basis of multi-step reactions leading to the overall reaction

$$HX + L \rightleftharpoons LH^+ + X_{solv.}$$

and which may be followed by triplet formation

$$HX + X_{solv.} \rightleftharpoons HX_{2,\,solv.}$$

(L = solvent).

The conductance of acetic acid in methanol-water[79] and ethanol-water mixtures[225] has been discussed on the basis of two cations H_3O^+ and ROH_2^+. $(CH_3)_2S$ and $(CH_3)_3N$ give ion triplets in liquid hydrogen halides[226]. (For other investigations in this medium and in ClF_3 and BrF_3, see[226–228] and[229].)

As was shown by *Kortüm* and *Koch*[230], the dissociation constants found from the conductance data for 2,6-dinitrophenol in water-methanol mixtures do not agree, at high methanol contents, with the constants found from optical measurements. Ions that cannot

contribute to charge transport in the associate, but still retain their identity as ions, give the same spectrum as free ions.

7.6. Dependence of Conductance on Pressure, Temperature, and Frequency

The dependence of the limiting conductance of tetraalkylammonium salts, potassium salts, and picric acid in dimethylformamide on temperature and pressure (25 to 65 °C, 1 to 1900 atm) was discussed by *Brummer* [231] on the basis of a kinetic model [232]. This discussion led to ΔH and ΔV values for the transport mechanism. The theoretical principles of a kinetic study are presented by *Hills* [233].

Horne, *Myers*, and *Frysinger* [234] compared the pressure dependence of the conductance of aqueous solutions (5 to 45 °C, 1 to 7000 atm). While the activation energy of the conductance of a KCl solution shows a variation parallel to that of the viscosity with rising pressure, the behavior of HCl is quite different. As *Horne* also suggested in a different context [235], the protonic conductance in aqueous solution contains components due to a Grotthus mechanism. At pressures below 1380 bar, the rotation of the water molecule is reported to be rate determining, at pressures above this value, the proton jump becomes rate determining. (For such pressure studies on solutions of several electrolytes, cf. [236].)

The conductance of tetraisopentylammonium picrate in diethyl ether and benzene decreases with increasing pressure (up to 5000 atm), owing to an increase in the viscosity of the solvent and a displacement of the ion pair and triplet formation equilibria as a result of an increase in the dielectric constant [237].

The temperature dependence of conductance in nonaqueous solvents is illustrated by the work of *Carvajal*, *Tölle*, *Smid*, and *Szwarc* [238] on various tetraphenylborates in dimethoxyethane (DME) and tetrahydrofuran (THF) (−70 to +25 °C). In both solvents, $(C_4H_9)(C_5H_{11})_3N^+$ forms contact pairs with $(C_6H_5)_4B^-$, and these contact pairs dissociate into unsolvated ions ($\Delta H_{diss.}$ = −1.3 kcal/mole in THF and −2.3 kcal/mole in DME). On the other hand, Na^+ and $(C_6H_5)_4B^-$, form ion pairs with inclusion of solvent molecules; the ion pairs dissociate into a solvated Na^+ and an unsolvated $(C_6H_5)_4B^-$ ($\Delta H_{diss.}$ = −1.3 kcal/mole in THF and −1.8 kcal/mole in DME).

The temperature coefficient of the conductance of copper perchlorate dihydrate as a function of concentration is negative in several solvents [239].

The pressure and temperature dependences of the conductance, as well as of the dissociation constant of ionogens and the association constant of ionophores, are the objects of further studies [157, 186, 240–245].

The decrease in conductance with increasing pressure is explained in the theoretical study by *Ebeling*, *Falkenhagen*, and *Kraeft* [213] as being due to the increase in the number of solvent molecules (which can be treated as neutral components) per unit volume as a result of the increase in pressure. The results of investigations by *Hensel* and *Franck* [246] on the pressure dependence of aqueous salt solutions are satisfactorily described in this way.

The frequency dependence of the conductance (1–100 kHz) of tetrabutylammonium picrate in dichlorobenzene-benzene mixtures was studied by *Nanney* and *Gilkerson* [247]. The results obtained at low salt concentrations are explained by the Debye-Falkenhagen theory, while the relaxation of the ion pair equilibrium is used to explain the variation of the conductance at higher salt concentrations.

The Wien effect was studied by *Spinnler* and *Patterson* [248] for aqueous solutions of uranyl salts (5 to 65 °C).

The numerical calculations for this work were carried out by kind permission of Professor J. Dörr, Computer Center of the Universität des Saarlandes, to whom I am very grateful. I thank Dr. G. Schwitzgebel for carrying out the calculations and for constructing the required programs. Thanks are also due to Fräulein K. Lenz and to Dipl.-Chem. G. Schmeer for their assistance with the preparation of the manuscript and of the drawings.

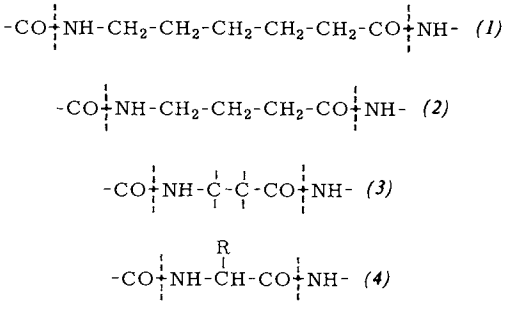
Poly-β-amides [**]

BY H. BESTIAN [*]

High molecular weight poly-β-amides with fiber-forming properties (repeating unit $-NH-CR_2-CR_2-CO-$) differ from the polyamides of the nylon series in that the amide groups are much more closely spaced. These polymers are thus the nearest of the synthetic polyamides to natural silk. The production of poly-β-amides was made possible by a recent synthesis of β-lactams from olefins and chlorosulfonyl isocyanate. The anionic polymerization of the β-lactams gives poly-β-amides containing up to 10000 monomer units in the chain. The molecular weight can be controlled as desired by means of initiators and chain terminators, and the properties can be varied within wide limits by the choice of the β-lactam or by copolymerization of several β-lactams. Remarkable differences are observed between polymers containing structural units in the threo form and those containing erythro structural units. The poly-β-amides can be spun into fibers having valuable textile properties.

1. Introduction

High molecular weight poly-β-amides with fiber-forming properties were still largely unknown a few years ago. These polyamides, in which the repeating unit is a β-amino acid skeleton, differ from polyamides of the nylon series in that the amide linkages are much more closely spaced, so that the polymers are therefore similar to the polypeptides, and to silk fibroin in particular. We have not adopted the term poly-β-peptides, which is also found in the literature, since the name polypeptides should be used only for polymeric α-amino acids. Some polyamides are shown in Scheme 1.



Scheme 1. Repeating units of some polyamides. *(1)* polycaprolactam (nylon 6), *(2)* polypyrrolidone (nylon 4), *(3)* poly-β-amides, *(4)* polypeptides such as fibroin.

While the polyamides containing six or more carbon atoms in the monomer unit became available from ω-amino acids or their lactams soon after their discovery by *W. H. Carothers*, considerable difficulties were encountered in the synthesis of high molecular weight polyamides with short structural units, since the close spacing of the amide linkages leads to lower solubility and raises the melting point into the decomposition range. These polyamides are also less stable to heat, so that the simple but rather vigorous melt condensation cannot be used.

During the past 10 to 15 years, special methods have been developed for each group of polyamides. These methods all involve the use of alkaline catalysts, low polymerization temperatures, and suitable solvents or diluents. Thus the high molecular weight peptides could be obtained from α-amino acids *via* the Leuchs anhydride, and pyrrolidone could be polymerized into a polyamide (nylon 4) having a sufficiently high molecular weight for fiber production.

2. Existing Methods

At roughly the same time as efforts were being made to find a route to synthetic polypeptides, attempts were also being made to prepare poly-β-amides (Table 1).

The polycondensation of β-alanine and its derivatives always led to low molecular weight poly-β-amides [1–4]. *Birkhofer* and *Modic* [5] succeeded in preparing the *N*-carboxy-β-amino acid anhydrides corresponding to the Leuchs compound (*e.g.* *N*-carboxy-β-alanine anhydride) and in synthesizing poly-β-amides containing up to 100 amino acid units. The α,α-disubstituted β-amino acids occupy a special place, since β-elimination, which can lead to loss of ammonia or to cleavage of the polymer chain, is suppressed in these cases. Thus,

Table 1. Preparation of poly-β-amides.

Starting material	Reaction conditions	Molecular weight	Ref.
$H_2N-CH_2-CH_2-COOH$	Condensation at 200 °C		[1]
$H_2N-CH_2-CH_2-COOC_2H_5$	Self condensation at 20 °C		[2]
$H_2N-CH_2-CH_2-COCl$	Thermal condensation under vacuum	< 5000	[3]
$HN-CH_2-CH_2-COOH$ $CO-SC_6H_5$	In dioxane at 60–80 °C catalyst: pyridine		[4]
N-Carboxy-β-alanine anhydride	Thermal decomposition at 150 °C	≈ 7000	[5]
$H_2N-CH_2-C(CH_3)_2-COOH$	In cresol at 190 °C	≈ 10000	[6]
$CH_2=CH-CO-NH_2$	In pyridine at 100 °C, alkaline catalyst	76000	[7]

Linkoln[6] was able to convert aminopivalic acid (in cresol at 190 °C) into polyamides whose viscosities correspond to molecular weights of 5000 to 10000.

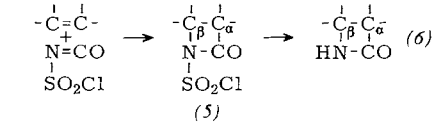
An unconventional method was successfully used by *Breslow*, *Hulse*, and *Matlack*[7] for the synthesis of poly-β-amides. These authors converted acrylamide into poly-β-alanine by alkali-catalyzed polyaddition, and isolated a small yield of a high molecular weight substance from the nonuniform crude product; the molecular weight of this substance as calculated from light-scattering measurements was 76000. The relatively low specific viscosity of 0.639 (measured in formic acid) indicates that the molecular weight of this poly-β-alanine is too low for the production of fibers.

3. β-Lactams as Starting Materials

Graf observed in 1952 that sulfur trioxide and cyanogen chloride combine to form a new isocyanate, *i.e.* *N*-carbonylsulfamoyl chloride[8].

$$SO_3 + ClCN \rightarrow ClO_2S-N=CO$$

This readily available compound is a stable liquid boiling at 108 °C. The reactivity of its isocyanate group is very greatly increased by the sulfonyl chloride group attached to the nitrogen. While investigating the reaction of this isocyanate with olefins, *Graf* discovered a new synthesis of β-lactams[9].



(5) *(6)*

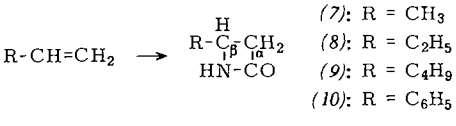
The isocyanate adds on to the olefinic double bond to give *N*-chlorosulfonyl-β-lactams *(5)*, from which free lactams *(6)* can be obtained by removal of the sulfonyl chloride group.

The addition proceeds under mild conditions, and no catalyst is required. Complete conversion of the isocyanate is obtained with even a small excess of olefin. Polar solvents increase the reaction rate and make the reaction easier to control.

The hydrolytic removal of the sulfonyl chloride group without opening the lactam ring initially presented difficulties. The attraction of electrons by the SO_2Cl group weakens the NC bonds. In the alkaline pH range, the ring is opened between N and CO, while in the strongly acidic range it is opened between N and C_β. Moreover, it was also necessary to consider the stability of the β-lactams formed on hydrolysis. *Graf* was able to remove the sulfonyl chloride group with high selectivity by pH-controlled hydrolysis in the weakly acidic range[9].

Many new β-lactams of simple structure have become readily obtainable, even on the industrial scale, by procedures developed on the above basis. The following discussions will be restricted to β-lactams that have been prepared from industrially available olefins and that can be used as starting materials for the preparation of poly-β-amides.

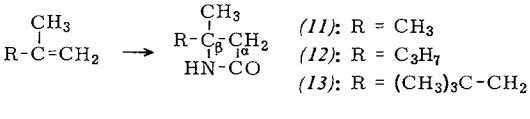
The α-olefins propylene, 1-butene, 1-hexene, and styrene give the β-lactams 4-methyl- *(7)*, 4-ethyl- *(8)*, 4-butyl- *(9)*, and 4-phenyl-2-azetidinone *(10)*.



(7): R = CH_3
(8): R = C_2H_5
(9): R = C_4H_9
(10): R = C_6H_5

As in conventional electrophilic additions, the carbonyl group of the isocyanate becomes attached to the doubly-bonded carbon atom having the higher electron density. Thus the synthesis yields the lactams of the unbranched β-amino acids. β-Butyrolactam *(7)*, which has recently become available from propylene, has particularly attracted our attention for the synthesis of poly-β-amides.

Olefins of the vinylidene type, *e.g.* isobutylene, 2-methyl-1-pentene, and diisobutylene (2,4,4-trimethyl-1-pentene), are much more reactive. The addition of the isocyanate to isobutylene proceeds rapidly even below 0 °C. The direction of addition is the same as that observed with the α-olefins. The vinylidene olefins give lactams of β-methyl-β-amino acids. [*(11)*, *(12)*, and *(13)*]. These lactams are very stable to oxygen, and this property is retained on conversion into poly-β-amides.



(11): R = CH_3
(12): R = C_3H_7
(13): R = $(CH_3)_3C-CH_2$

β-Lactams can also be obtained from olefins containing a double bond in the chain or in a ring[10]. The addition of the isocyanate to 2-butene proceeds as a *cis*

[6] *J. Linkoln*, U.S.-Pat. 2500317 (1946), American Celanese Corp.; Chem. Abstr. *44*, 5382b (1950).

[7] *D. S. Breslow*, *G. E. Hulse*, and *A. S. Matlack*, J. Amer. chem. Soc. *79*, 3760 (1957).

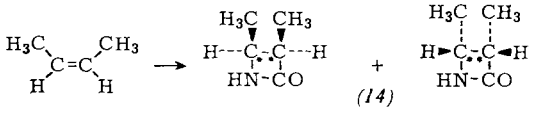
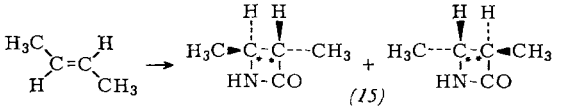
[9] *R. Graf*, Liebigs Ann. Chem. *661*, 111 (1963).

[10] *H. Biener*, Belg. Pat. 662258 (1965), Farbwerke Hoechst AG.; Chem. Abstr. *64*, 8134 (1966).

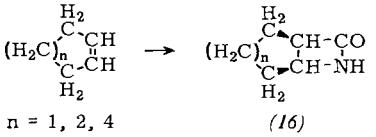
addition with high stereoselectivity. *cis*-2-Butene gives 98–99 % pure *cis*-α-methyl-β-butyrolactam *(14)*. The *trans*-lactam *(15)* having a similar degree of purity can be obtained from trans-2-butene. The α and β carbon atoms in these lactams are centers of unlike asymmetry. Consequently both lactams are formed as racemates. It should be possible to synthesize isotactic poly-β-amides having two centers of chirality in the structural unit from the antipodes (see Section 5).



(14)



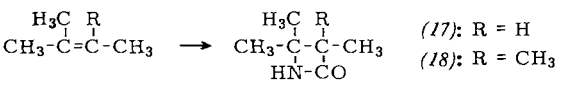
(15)



n = 1, 2, 4 *(16)*

When cyclic olefins of medium ring size are used in this synthesis, bicyclic β-lactams *(16)* with *cis* ring fusion are obtained. These compounds are interesting models for the synthesis of poly-β-amides, in which the mobility of the chain unit is restricted by bridging at the α and β carbon atoms.

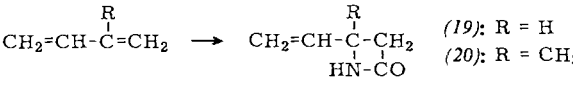
β-Lactams with three and four methyl groups [*(17)*, *(18)*] can be obtained readily and in excellent yields by the Graf method from 2-methyl- and 2,3-dimethyl-2-butene.



(17): R = H
(18): R = CH_3

In the methyl-substituted butenes, the π electrons are more readily available for nucleophilic attack on the isocyanate than in butene. In spite of the steric hindrance due to the methyl groups, the addition of the isocyanate proceeds rapidly and in high yield at room temperature.

The last β-lactams examined for the synthesis of poly-β-amides are the vinyl-β-lactams *(19)* and *(20)*.



(19): R = H
(20): R = CH_3

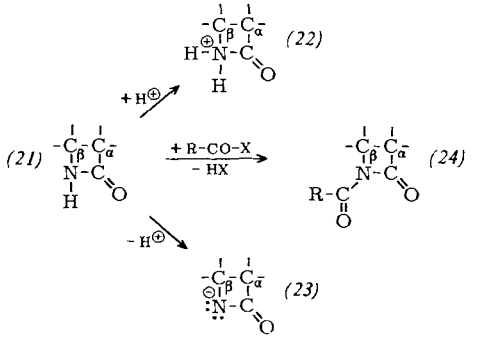
All the β-lactams mentioned here are quite stable, in spite of the strained ring. They can be purified by distillation or crystallization to the degree required for the synthesis of high molecular weight compounds. The IR spectrum shows a strong carbonyl band at 5.7 μm. γ- and δ-Lactams absorb at 5.9 μm.

The new β-lactams mentioned do not include the unsubstituted ring, β-propiolactam. This compound has not so far been obtained by the Graf method owing to the low reactivity of ethylene. β-Propiolactam, which was first obtained by *Holley*[11] from esters of β-alanine in a yield of 0.7 %, was prepared by a new method in sufficient quantities for the study of poly-β-alanine synthesized by the lactam route. The new synthesis begins with the ester of *N*-benzyl-β-alanine, which is readily obtainable from acrylic esters and benzylamine. Cyclization of this ester with ethylmagnesium bromide gives *N*-benzyl-β-propiolactam, which is converted into the unsubstituted β-propiolactam by reductive removal of the benzyl residue with sodium in liquid ammonia. The overall yield is 50 %.

4. Polymerization of the β-Lactams

With the synthesis of β-lactams having no substituents on the nitrogen, it became possible to prepare high molecular weight poly-β-amides[12]. The ring strain in the β-lactams facilitated the opening of the ring at the amide linkage. The head-to-tail linkage of these four-membered structural units leads exclusively to open-chain products and not to cyclic oligomers, which would hinder the formation of the high molecular weight compounds. It follows as a necessary consequence of the high ring strain in the β-lactams that the monomer ⇌ polymer equilibrium for β-lactams can be disregarded, in contrast to the corresponding equilibrium for the homologous lactams having five-, six-, and seven-membered rings. No reformation of the β-lactam ring by depolymerization of the poly-β-amides has been observed.

Since the ring opening has a decisive effect on the course of the polymerization, the β-lactam ring structures involved in the polymerization will now be discussed (Scheme 2).



Scheme 2. β-Lactam ring structures involved in the polymerization.

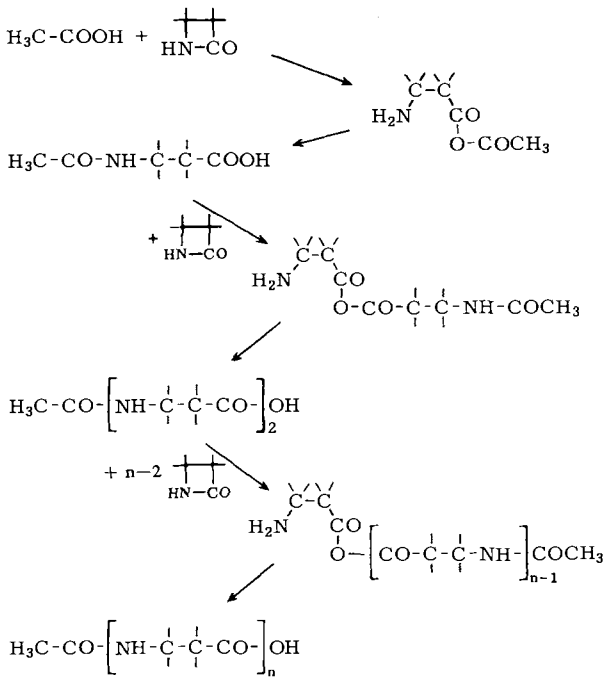
The ring opening in acid polymerization can be best interpreted by protonation on the nitrogen. Cleavage then takes place in the onium form *(22)* of the amide linkage. To initiate the alkaline polymerization, the lactamate anion *(23)* must be formed. The β-lactam ring in the lactamate structure, in contrast to that in the onium structure, is stable. The lactams *(21)*, and especially *(24)*, are opened on nucleophilic attack of the lactamate anion *(23)* at the amide bond (see Section 4.1.).

The acid induced polymerization proceeds as a stepwise polyaddition, as can be shown for the case of

[11] *R. W. Holley* and *A. D. Holley*, J. Amer. chem. Soc. *71*, 2129 (1949).

[12] *R. Graf*, *G. Lohaus*, *K. Börner*, *E. Schmidt*, and *H. Bestian*, Angew. Chem. *74*, 523 (1962); Angew. Chem. internat. Edit. *1*, 481 (1962).

acetic acid (Scheme 3). When stoichiometric quantities of acid and lactam are used, the resulting mixture contains the acetylamino acid together with large quantities of the oligomeric compounds containing two, three, and four monomer units.



Scheme 3. Polyaddition of β-lactams to acetic acid.

To explain the course of the reaction, it may be assumed that the addition of acetic acid leads to the formation of the mixed amino acid anhydride, which immediately changes into the acetylamino acid. Further reaction with unreacted lactam leads, again *via* the anhydride, to the stepwise formation of the oligomeric β-amino acids. The mixture of the oligomeric β-amides can be separated by esterification followed by vacuum distillation. This provides a convenient method for the preparation of the dimeric and trimeric compounds in reasonable quantities, and can be used with a wide variety of starting materials.

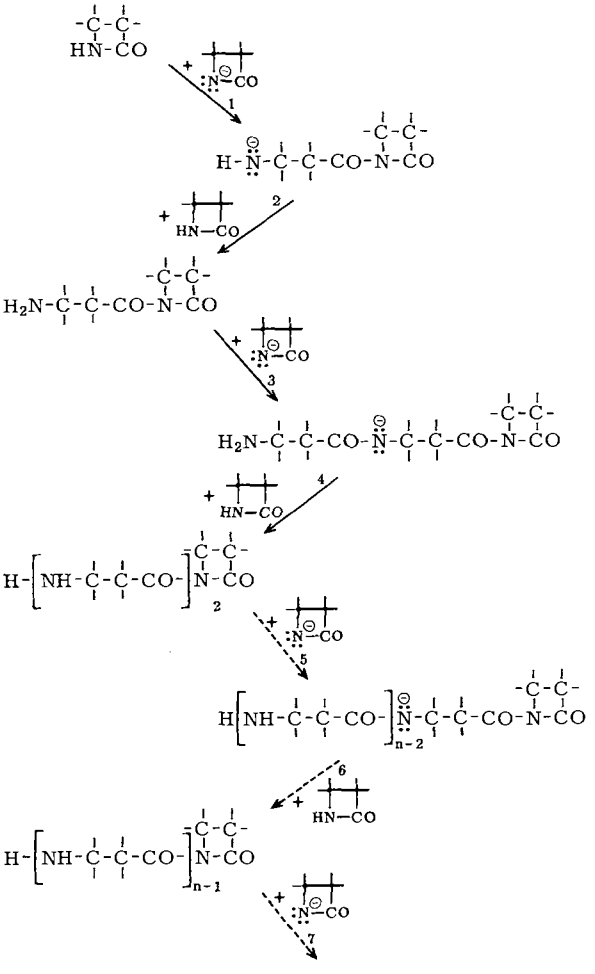
It was to be expected that when the β-lactams were allowed to react at 100 to 150 °C with less than the stoichiometric quantity of carboxylic acid, poly-β-amides having high degrees of polymerization would be formed in accordance with the polyaddition scheme presented for the stoichiometric reaction. This is also true of the formation of poly-β-amides having medium degrees of polymerization (up to about 50). The polyaddition of β-lactams to carboxylic acids is the best method known in this range. The average molecular weight is controlled by the quantity of carboxylic acid used.

High molecular weight poly-β-amides could not be obtained by this method. The stepwise growth of the polymer molecule by addition of lactam to the carboxyl group is a slow reaction, and at very low carboxyl group concentrations, it is necessary to raise the reaction temperature. This leads to side reactions (presumably ring opening between N and C_β) which stop the growth of the polymer chain.

4.1. Anionic Polymerization

The formation of poly-β-amides with high degrees of polymerization is much more strongly favored by the use of alkaline catalysts that also accelerate the polymerization of the lactams having larger rings. Thorough investigations have shown that β-lactams are the ideal structural units for the synthesis of the desired high molecular weight poly-β-amides. The polymer molecules are formed rapidly even at room temperature, with complete consumption of the lactam present. To facilitate the dissipation of the heat of reaction, the polymerization may be carried out in solvents or diluents.

To establish the optimal polymerization procedure, systematic studies were carried out on all parameters that influence the polymerization. Kinetic measurements and planned experiments were made possible by the favorable reaction conditions and by the use of selected model compounds[12]. On the basis of these investigations, it is possible to deduce a detailed picture of the course of the polymerization (Scheme 4).



Scheme 4. Anionic polyaddition of β-lactams.

The polymerization can be best interpreted by an anionic polyaddition mechanism. An essential condition for a smooth reaction is the constant presence of lactamate anions, which may be introduced directly as alkali metal lactamates or may be formed from the β-lactams at the beginning of the reaction. The β-lactam reacts with its anion to give ring opening. The anionic intermediate formed in this relatively slow initiation reaction is protonated by the lactam in the second, fast step. This step yields the dimeric lactam, with regeneration of the lactamate anion. The same

process is then repeated with the dimeric lactam, and the polymer chain is rapidly built up in this way.

Thus there are two steps involved in the incorporation of a lactam unit into the growing polymer chain:

a) Attachment of the lactam anion to the lactam ring with ring opening (arrows 1,3,5,7....).

b) Charge transfer from the chain to the monomeric lactam with regeneration of the lactamate anion (arrows 2,4,6,....).

The charge transfer, which is very fast, can be disregarded in the kinetic study of the course of the reaction. The rate of chain growth in the individual steps is determined by the attachment of the lactam anion. While the anion is attached to the original lactam in the initiation reaction, the chains subsequently grow by attachment of the anion to acylated lactam rings. These react several orders of magnitude faster than the free lactam. Consequently, the chains grow very rapidly, whereas their initiation is retarded.

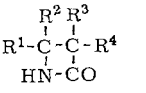
This inhibition of the initiation can be very easily eliminated by the addition of a small quantity of an acyllactam to the lactam used for the polymerization. The polymerization then proceeds almost ideally. The added acyllactam reacts very rapidly with the lactamate anions and the chains are initiated almost simultaneously. It is thus possible to obtain a relatively narrow molecular weight distribution. The number of chain initiations corresponds to the concentration of the acyllactam; thus the course of the polymerization is controlled by the chain initiation, and the molecular weight can be adjusted to the desired range.

The reaction course indicated also provides information about the end groups. If the polymer chain is initiated from the free lactam, the product contains amino end groups, which are detected with dinitrofluorobenzene in the manner described by *Zahn* and *Rathgeber*[13]. Similarly, acylamino end groups are formed if the polymerization is induced by acyllactams. The other end group is determined by the termination reactions. In the presence of small quantities of water, which is used to control the chain termination, the acyllactam group at the growing chain end is opened by a hydroxide ion, with formation of carboxyl groups.

Branching of the macromolecule could take place if an amide anion in the polymer chain reacted with the acyllactam group of a growing chain. However, our experimental findings showed no evidence of such branching processes.

As expected, the rate of chain growth depends on the number and nature of the substituents on the α and β carbon atoms of the lactam ring. According to *Hall*[14], polymerization of the five-membered ring lactam pyrrolidone is prevented even by the introduction of a single methyl group. However, the tendency toward ring opening is so strong in four-membered ring lactams that the anionic polyaddition with formation of high molecular weight poly-β-amides proceeds even when all the hydrogen atoms on the α and β carbon atoms are substituted, though the reaction rate decreases with increasing number of substituents (Table 2).

Table 2. Qualitative comparison of the polymerizabilities of substituted β-lactams as a function of the degree of substitution.
(1 = poor, 5 = good polymerizability).



R^1	R^2	R^3	R^4	Polymerizability
H	H	H	H	5
CH_3	H	H	H	4
CH_3	CH_3	H	H	3
CH_3	H	CH_3	H	*trans*: 4
				cis: 3
CH_3	CH_3	CH_3	H	2
CH_3	CH_3	CH_3	CH_3	1

Differences in the reactivities of the various β-lactams present no special difficulties in the preparation of poly-β-amides having uniform monomer units. The fast anionic polymerization offers sufficient latitude for adjustment of the parameters that influence the polymerization rate to suit the reactivity of the lactam. On the other hand, the differences in reactivity constitute a limitation in the preparation of poly-β-amides having different structural units since it is necessary to use components having comparable polymerization rates.

This condition is adequately satisfied by the very readily obtainable β-lactams having one or two substituents. Thus homogeneous copolymers having valuable properties can be prepared from β-butyrolactam and α-methyl-β-butyrolactam. Other combinations permit the preparation of readily soluble poly-β-amides. Despite the above-mentioned restriction, the wide range of β-lactams that can be obtained by the Graf synthesis offers great scope for variation in the preparation of polyamides containing β-amino acid structural units, as in the synthesis of polypeptides from α-amino acids *via* the Leuchs anhydride.

4.2. Molecular Weight

It has already been mentioned that the anionic polymerization permits the preparation of very high molecular weight poly-β-amides having linear structures and provides fairly accurate control of the degree of polymerization over a wide range. The range covered by the molecular weights can be illustrated by the case of the polyamide formed from β-methyl-β-butyrolactam (Fig. 1)[15].

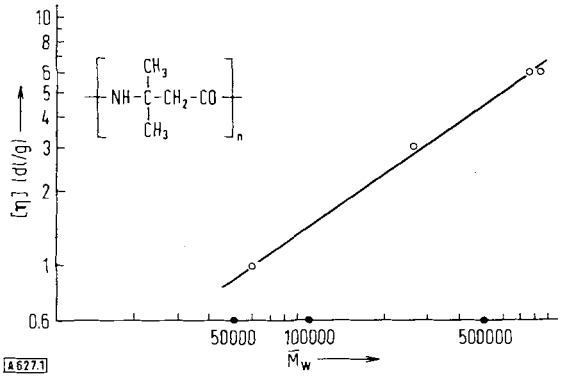


Fig. 1. Viscosity-molecular weight relationship from light-scattering measurements $[\eta] = 4.5 \times 10^{-4} \cdot \bar{M}_w^{0.7}$.

[13] *H. Zahn* and *P. Rathgeber*, Melliand Textilber. *34*, 749 (1953).
[14] *H. K. Hall*, J. Amer. chem. Soc. *80*, 6404 (1958).
[15] *E. Duch*, unpublished.

The measurements were carried out on polyamide samples whose intrinsic viscosities (dl/g in sulfuric acid) were 1 to 6. The molecular weights of these samples were found to be 60000 to about 750000. The high molecular weights are relatively easily obtainable. The lactams that recently became available from propylene, 2-butene, and butadiene gave poly-β-amides whose intrinsic viscosities of 8–10 dl/g indicate degrees of polymerization (P_w) of about 10000.

The parent substance β-propiolactam was also available for the first time for the synthesis of high molecular weight poly-β-alanine. The anionic polymerization of the propiolactam proceeds very rapidly, and conversion into poly-β-alanine is complete within a few minutes in dimethyl sulfoxide at room temperature. The intrinsic viscosity of the poly-β-alanine, which was obtained in a yield of 100 %, was 4–5, corresponding to molecular weights M_w of about 500000. This result confirmed our belief that the polymerization of lactams is also the best method for the preparation of high molecular weight poly-β-alanine.

5. Properties and Structure

The IR spectra of propiolactam and of the poly-β-alanine prepared from it (Fig. 2) show that the transition from the strained ring to the open-chain polymer results in a distinct displacement of the carbonyl stretching vibration toward longer wavelengths. The occurrence of the strong amide II band at 6.5 μm in poly-β-alanine indicates that the amide group changes from the *cis* to the *trans* configuration on opening of the ring and subsequent attachment to the macromolecule.

The properties of the poly-β-amides are mainly determined by the accumulation of the amide groups which form a tight crystal lattice as a result of hydrogen bonding. Some properties of a few of the poly-β-amides studied by us are shown in Table 3. The powder obtained from the polymerization and the films prepared from this powder give pronounced X-ray interferences, which indicate high crystallinity (see Fig. 3).

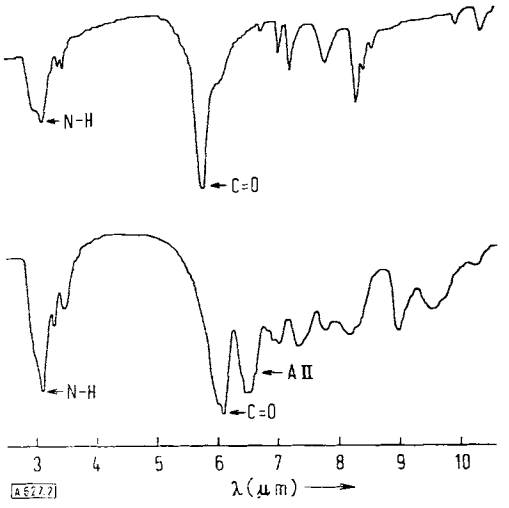

Fig. 2. IR spectra of propiolactam (top) and poly-β-alanine (bottom) in KBr. A II = amide II band.

A crystalline polyamide is obtained even from the tetramethylated monomer unit. On the other hand, bulky substituents such as a phenyl group or a propyl group together with a methyl group on the β-carbon atom lead to amorphous products.

It should be pointed out here that the melting points given are also decomposition points. They were determined by differential thermal analysis. The polymer chain is broken between the nitrogen and the β-carbon on melting of the crystal. The pyrolysis products are the amides and nitriles of the corresponding α,β-unsaturated carboxylic acids. The highly crystalline poly-β-amides are less soluble than the less crystalline polymers of this series. Hexamethylphosphoramide dissolves only a few poly-β-amides having methyl-substituted structural units. The polymers are completely dissolved by strong organic acids such as formic acid and dichloroacetic acid, and generally by sulfuric acid.

Two particularly interesting poly-β-amides have one methyl group on the α- and one on the β-carbon atom of the structural units. The carbon atoms are centers of unlike asymmetry, so that the structural unit occurs in two diastereoisomeric forms, and each of these as the racemate (see also Section 3). The poly-β-amides

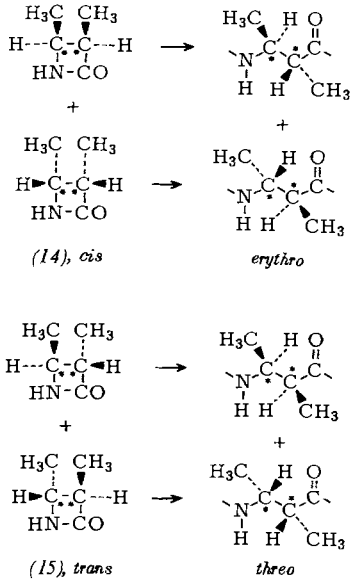
[b] Hexamethylphosphoramide.

built up from these *threo* and *erythro* units [16] have very different properties. The solubilities and decomposition points are given in Table 3, and the X-ray powder diagrams are shown in Figs. 3d and 3e.



The cyclic monomers were available in a very pure state both as the racemate of the *cis* form *(14)* and as the racemate of the *trans* form *(15)*. The configuration at the α- and β-carbon atoms is retained during ring opening and linking of the monomer units to form a chain. The zig-zag arrangement of the chain units is favored by the fact that the methyl groups can assume a staggered position instead of their former eclipsed position in the ring. In the *erythro* units, the methyl groups are in the *anti* position, while in the *threo* units they are in the *syn* position.

The polyamides consisting of these units differ considerably. *erythro*-Poly-β-amide is insoluble in all solvents suitable for polyamides (with the exception of concentrated sulfuric acid) whereas *threo*-poly-β-amide is readily soluble. Differential thermal analysis shows that the decomposition point of the *erythro* polymer is about 50 °C higher than that of the *threo* polymer. Since decomposition points determined by this method correspond roughly to the melting points of the crystallites, it may be concluded that the crystal lattice of the poly-β-amides formed from *erythro* units has a greater thermal stability.

The polyamides also differ in their X-ray powder diagrams (see Figs. 3d and 3e). The higher crystallinity of the *erythro*-polyamide (Fig. 3d) is shown by the sharpness of the reflections. Both polyamides give the strong outer reflection, which corresponds to a distance of 4.50 Å between the lattice planes. The difference in the crystal lattice is clear from the positions of the inner reflections. These correspond to interplane distances of 6.32 Å for the *erythro*-polyamide and 8.75 Å for the *threo*-polyamide.

[16] In agreement with the nomenclature report on steric arrangement in high polymers by *M. L. Huggins, G. Natta, M. Desreux*, and *H. Mark* [Makromolekulare Chem. *82*, 1 (1965)], we use the *threo-erythro* terminology for the two diastereoisomeric forms of the new fundamental structural unit.

The determination of the unit cell of the crystal lattice is not yet complete. Particularly in the case of *cis* lactams such as *(14)*, steric considerations point to selective linking of the units, and suggest the possibility of formation of diisotactic or disyndyotactic *erythro*-poly-β-amides. The elucidation of this problem will depend on the resolution of the *cis* lactams into their optical antipodes.

The crystal structure of the poly-β-amides is largely determined by the fundamental structural units used. The X-ray powder diagrams of the polymers are shown in Figure 3.

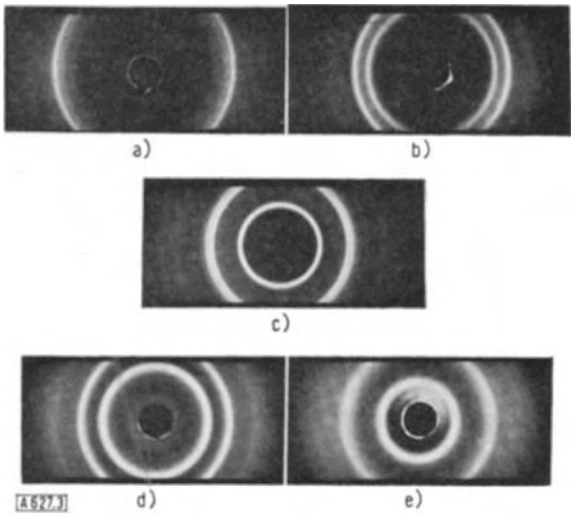


Fig. 3. X-ray powder diagrams of (a) poly-β-alanine, (b) poly-β-aminobutyric acid, (c) poly-β-valine, (d) poly-*erythro*-β-amino-α-methylbutyric acid, (e) poly-*threo*-β-amino-α-methylbutyric acid.

The polyamides having methyl-substituted structural units (Figs. 3b to 3e) are characterized by a strong outer reflection, the position of which varies only slightly. However, the inner reflection shows a wide variation of position. The polymer with the unsubstituted structural unit gives an entirely different diagram (Fig. 3a).

In the study of the lattice structure, we first considered poly-β-aminobutyric acid. Drawn films prepared from this polyamide could be used to determine the unit cell of the crystal lattice [17].

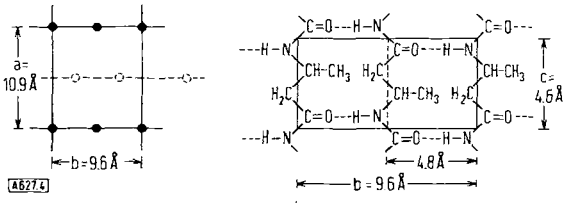

Fig. 4. Unit cell of poly-β-aminobutyric acid. The film was drawn parallel to the *c* axis.

The X-ray reflections of the drawn films lead to an orthorhombic unit cell having the dimensions given in Fig. 4. The identity period in the drawing direction, *i.e.* parallel to the *c* axis, was found to be 4.6 Å and so corresponds to the length of a β-amino acid structural unit in the almost extended polyamide chain. The IR spectrum of the film shows the perpendicular dichroism of the NH stretching vibration,

[17] *H. Scherer*, unpublished.

from which it must be concluded that the hydrogen bonds between adjacent chains are formed perpendicular to the drawing direction, *i.e.* parallel to the *b* axis in our model.

The interplane distances along the *a* and *b* axes of the lattice were determined from the equatorial reflections. The value of 4.8 Å is taken as the distance between chains linked by hydrogen bonds. This assignment is in complete agreement with the numerous investigations on polyamides and on fibroin. However, the distance between adjacent chains (4.8 Å) along the *b* axis cannot be the identity period in this direction. The orthorhombic lattice requires an antiparallel arrangement of adjacent chains, as shown in Figure 4. Thus the identity period is the distance from one chain to the next but one, and is equal to 9.6 Å.

The chains joined by hydrogen bonds form sheets. The arrangement of these sheets in the crystal lattice can be best illustrated by a section perpendicular to the drawing direction (see Fig. 4, left). In this diagram, the axes of the chain molecules appear as points. The hydrogen bonded sheets are arranged parallel to the *b* axis. The shortest distance between two identical sheets in the orthorhombic lattice was found from the X-ray reflections to be 10.9 Å.

As in fibroin, it must be assumed that a given sheet in poly-β-aminobutyric acid is identical only with the next but one, as indicated in the drawing. The unit cell then contains four β-amino acid units. The crystal density calculated on this basis agrees closely with the observed density of the film.

The unit cell of fibroin [18, 19] contains eight α-amino acid units. The main difference in the unit cells is that in fibroin identity along the polypeptide chain occurs only after a dipeptide unit 7.0 Å long, whereas in poly-β-aminobutyric acid identity occurs after one structural unit, *i.e.* after a distance of 4.6 Å.

6. Production of Filaments

The poly-β-amides are similar in structure to natural silk. The molecular weight can also be matched to that of fibroin (200000–300000) [20]. However, the problem of spinning filaments from the poly-β-amides, which are obtained in the form of powders, was not easy to solve. Melt spinning was impossible, since the melting points are high and lie in the decomposition range. The low solubility in suitable solvents makes dry spinning difficult. However, the observation that the poly-β-amides, with few exceptions, are readily soluble in formic acid or in a calcium isothiocyanate-methanol mixture led to the development of a spinning process similar to that used in industry for the production of rayon.

The spinning solutions contain 15–30 % of poly-β-amide. The precipitating bath consists of water, to which a salt is added in order to control the coagulation process. The filaments can be drawn by a factor of seven. Some of the poly-β-amides that are readily obtainable from the lactams were spun into filaments by this method and their suitability for the production of fibers was tested.

Table 4 shows the properties of filaments of two poly-β-amides, of natural silk, and of nylon 6. It is interesting to note that the filaments made from poly-β-aminobutyric acid, which are closest in structure to fibroin, are the nearest to natural silk in their properties.

Table 4. Comparison of filaments of poly-β-amides, natural silk, and nylon 6.

	Poly-β-valine	Poly-β-aminobutyric acid	Natural silk	Nylon 6
Crystallite m.p. (°C)	296	340	–	215
Density (g/cm³)	1.11	1.16	1.37	1.14
Breaking strength (g/den)	2–3	3.2–5.6	3.3–5.5	4.5–8.3
Elongation at break (%)	30–35	7–25	13–25	15–46
Moisture absorption (%)	4.5	8.6	9	4–4.5

Fibers and yarns are at present being prepared from poly-β-amides and made up into fabrics of a wide range of structures in order to test their practical application. Testing of these fabrics will show whether poly-β-amide fibers or yarns can compete successfully with conventional fibers.

I am grateful to Dr. H. Biener, Dr. E. Duch, Dr. E. Höroldt, Dr. H. Jensen, Dr. W. Rupp, Dr. H. Scherer, and Dr. E. Schmidt for their assistance and for valuable unpublished information.

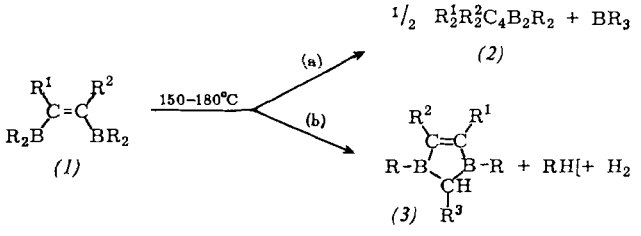
Formation of Boron Heterocycles from Vicinally Diborylated *cis*-Alkenes at High Temperatures

By *P. Binger* [*]

When vicinally diborylated *cis*-alkenes *(1)* [1] are heated, various boron heterocycles are formed, as in the pyrolysis of alkyl- and aralkylboranes [2].

Depending on the alkyl substituents on the carbon (R^1, R^2), *(1)* may disproportionate (path (a)) to give trialkylboranes

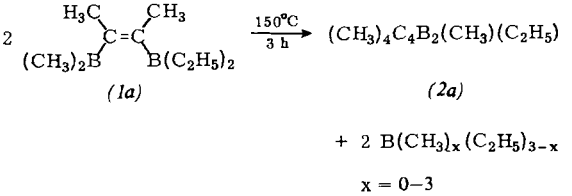


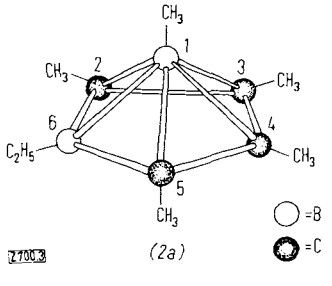
R	R^1	R^2	Temp. (°C)	Time (h)	Amount consumed (%)	(2) Yield (%)	(2) B.p. (°C/torr)	(3) Yield (%)	(3) B.p. (°C/torr)
CH_3	CH_3	CH_3	150	3	100	95	78/12	—	—
C_2H_5	C_2H_5	CH_3	160	5	80	55	123/12 [a]	35 ($R^3 = CH_3$)	92/12
C_3H_7	C_3H_7	CH_3	160	5	88	70	$59/10^{-3}$ [a]	15 ($R^3 = C_2H_5$)	$68/10^{-2}$
C_2H_5	C_2H_5	C_2H_5	160	5	60	1	$85/10^{-2}$	90 ($R^3 = CH_3$)	99/12

[a] Mixture of isomers.

and peralkylated 2,3,4,5-tetracarbahexaboranes(6) *(2)* [3], or it may react by path (b) to give peralkylated 1,3-diboracyclopent-4-enes *(3)* together with ethane ($R = C_2H_5$) or alkane, alkene, and hydrogen ($R > C_2H_5$, *e.g.* C_3H_7). Both reactions are irreversible.

Of the two possible isomeric tetracarbahexaboranes(6) that could be formed from the *B*-diethyl-*B'*-dimethyl-*C,C'*-dimethyl compound *(1a)* ($\nu_{C=C}$: 1555 cm^{-1}), the 1-methyl-6-ethyl compound *(2a)* (b.p. 93 °C/12 torr) is formed in 90% yield. Small quantities of the 1,6-dimethyl and 1,6-diethyl derivatives are also formed. No ring formation leading to *(3)* takes place.





In the skeleton of *(2)*, the four C atoms and the two B atoms form a pentagonal pyramid with a boron atom at the apex [3]. The protons of the *B*-alkyl groups give ^1H–NMR signals whose τ values are characteristic of the position of the substituents: B(1)–CH_3, $\tau = 10.69$ (s); B(1)–C_2H_5:$\tau = 9.88$ (q,$J = 6.5$ Hz), $\tau = 9.36$ (t,$J = 6.5$ Hz); (B6)–CH_3:$\tau = 9.70$ (s); B(6)–C_2H_5:$\tau = 8.90$ (methylene and methyl protons give one signal). The IR and Raman spectra contain no absorption bands for C=C bonds.

The structure of *(3)* is found from the ^1H–NMR and IR spectra in conjunction with mass-spectrometric analysis; *e.g.* for 1,3,4,5-tetraethyl-2-methyl-1,3-diboracyclopent-4-ene: ^1H–NMR signals of the group $\diagdown\!\!\diagup CH-R^3$:$\tau = 8.30$ ($\diagdown\!\!\diagup CH-$, q,$J = 6.5$ Hz), $R^3 = CH_3$: $\tau = 8.80$ (d,$J = 6.5$ Hz); IR spectrum : $\nu_{C=C}$:1525 cm^{-1}; mass spectrum : molecular weight 190, with two boron atoms.

The compounds *(2)* and *(3)* differ considerably in their chemical behavior. In contrast to *(2)* [3], *(3)* is readily solvolyzed by water, alcohols, or carboxylic acids. Complete alcoholysis results in cleavage of both $BC_{alkenyl}$ bonds and of one $BC_{alkylidene}$ bond with formation of alkoxyalkylboranes and the same *cis*-alkenes as are obtained from *(1)* [1], *e.g.*:

Chlorophyll-Water Interaction [1]

By *J. J. Katz* and *K. Ballschmiter* [*]

It has long been appreciated that chlorophyll and water have a special relationship [2–4], but the details of the interaction have remained unexplained. Recent IR [5] and NMR [6] investigations have shown that the central magnesium atom of chlorophyll has a coordination number that is always larger than 4, and is generally 5 [7]. In electron-donor solvents, chlorophyll occurs as a monomer with solvent molecules in an axial position. In nonpolar solvents, the coordination unsaturation of the magnesium is relieved either by interaction with nucleophiles [7] or by coordination of the ketone oxygen function of one molecule of chlorophyll with the

magnesium atom of another to form chlorophyll dimers. Water can act as a nucleophile and coordinate to the magnesium of chlorophyll, but the consequences of such an interaction depend on the concentration and on the type of nonpolar solvent used.

In the nonpolar solvents CCl_4, $CHCl_3$, or benzene, which are expected to be good solvation agents for the porphyrin ring, water acts as a nucleophile and disaggregates chlorophyll dimers (at concentrations of chlorophyll less than about 10^{-2} M) to Chl·H_2O or Chl·$2H_2O$. The extent to which disaggregation occurs is limited at higher chlorophyll concentrations because of the limited solubility of water in these solvents. In hydrocarbon solvents, such as cyclohexane, alkylcyclohexanes, dodecane, or hexadecane, which are generally poor solvating agents, but which could be expected to solvate strongly the phytyl chain of chlorophyll, the consequence of chlorophyll-water interaction below about 10^{-5} M is disaggregation; however, in more concentrated solutions chlorophyll-water micelles of colloidal dimensions, in which water coordinated to magnesium acts as the aggregating agent, are formed.

The IR spectra of chlorophyll *a* in the various nonpolar solvents are shown in Table 1. In all solvents the IR spectrum of dry chlorophyll characteristically shows an aggregation peak at 1650–1660 cm^{-1} as well as the free keto carbonyl at 1695 cm^{-1} [8]. Hydrated chlorophyll in CCl_4, $CHCl_3$, or benzene shows essentially the same spectrum with increased absorption at 1695 cm^{-1}, which is indicative of some disaggregation. In aliphatic solvents, however, a strong absorption peak at 1638 cm^{-1} is seen, whereas the absorption at 1695 cm^{-1} is very weak. We assign the peak at 1638 cm^{-1} to the Ring V ketone oxygen which is hydrogen-bonded to water coordinated to the central magnesium of another chlorophyll molecule: C=O···H–O(H)···Mg. Studies with models show that a water molecule coordinated to a magnesium atom can be so oriented as to form simultaneously a hydrogen bond to the ketone oxygen and to the methoxycarbonyl group of another chlorophyll molecule. The split ester peaks in the IR spectrum, as well as absorption maxima in the O–H stretching region, provide support for the feasibility of such an interaction. In pheophytin, the Mg-free chlorophyll derivative, only very slight changes in the IR spectrum are noted on the addition of water to a solution of the compound in an aliphatic hydrocarbon solvent. Obviously the H_2O-chlorophyll interactions discussed here require the presence of Mg.

Water interaction with chlorophyll in aliphatic solvents can thus, by repetition, build up aggregates in which the chlorophyll molecules are stacked parallel to one another with their phytyl chains immersed in the hydrocarbon solvent and with water molecules sandwiched between the rings. The formation of colloidal aggregates in hydrocarbon solvents is established by the results obtained from two independent lines of investigation: Neither dry chlorophyll in dry nonpolar solvents nor hydrated chlorophyll dissolved in CCl_4, or benzene, can be sedimented – even by continued ultracentrifugation. However, hydrated chlorophyll, dissolved in butylcyclohexane or hexadecane, is completely sedimented by ultracentrifugation at 130000 *g* for 30 minutes. In cyclohexane solution, sedimentation of hydrated chlorophyll at 130000 *g* occurs to only a limited extent – even after 14 hours of centrifugation – indicating smaller aggregate size in this solvent. X-ray diffraction of chlorophyll-water aggregates in hydrocarbon solvents reveals the presence of ordered arrays, whereas solutions of dry chlorophyll in hydrocarbon solvents show no X-ray reflections. A 5×10^{-3} M solution of hydrated chlorophyll in butylcyclohexane, dodecylcyclohexane, or hexadecane gives a sharp X-ray diffraction line corresponding to a 7.5 Å spacing. This distance is very close to that estimated from models for the Mg–Mg distance in two parallel chlorophyll molecules separated by a water molecule.

Earlier workers [3,4c] realized that there is a direct relationship between the visible absorption spectra and the extent of chlorophyll hydration. This can now be recognized explicitly as a correlation between λ_{max} (red) and the presence of (Chl–H_2O) aggregates. The red-shift exhibited by chlorophyll-water aggregates thus raises the question of possible relationships between (Chl–H_2O) micelles and the long-wavelength forms of chlorophyll known to occur in living plants.

Table 1. Infrared spectra in the region 1800–1600 cm^{-1} of dry and hydrated chlorophyll *a* in (A) CCl_4, $CHCl_3$, or benzene and (B) aliphatic or cycloaliphatic hydrocarbons. (Figures in cm^{-1}; vs = very strong; s = strong; m = medium; w = weak.)

State of Chlorophyll	Solvent Class	Propionic ester C=O	Methoxy-carbonyl C=O	H-bonded methoxy-carbonyl C=O [a]	Ketone C=O	Mg-coordinated ketone	H-bonded ketone [a]	Skeletal (C=C, C=N)
Dry	A	1735 (s)	1735 (s)		1698 (s)	1653 (s)		1608 (m)
	B	1737 (s)	1737 (s)		1700 (m)	1658 (s)		1608 (m)
Hydrated	A	1734 (s)	1734 (s)		1695 (s)	1652 (m)		1608 (m)
	B	1743 (s)[b]		1727 (m)	1695 (w)		1638 (vs)	1606 (m)
Dry	Film [c]	1735 (s)	1735 (s)		1690 (s)	1658 (s)		1608 (m)
Hydrated	Film [c]		1735 (s) [d]		1690 (w)		1638 (vs)	1604 (m)

[a] Three well defined peaks are seen in the O–H stretching region. A peak at 3590 cm^{-1} we assign to water coordinated to Mg: Mg···OH_2. A peak at 3460 cm^{-1}, to hydrogen-bonded methoxycarbonyl: $CH_3OC{=}O\cdots H{-}O(H)\cdots Mg$. A peak at 3280 cm^{-1}, to hydrogen-bonded ketone: C=O···H-O(H)···Mg. These assignments are entirely consistent with those made in the carbonyl region.

[b] The shift to higher frequency of the propionic ester C=O in chlorophyll-H_2O polymer suggest that this ester carbonyl function is subject to some small coordination interaction in chlorophyll dimer or chlorophyll dimer monohydrate.

[c] Dry film formed by evaporation from benzene; hydrated film formed by evaporation from cyclohexane.

[d] A broad band that includes all the ester contributions.

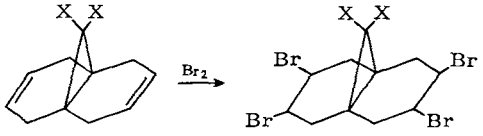
11,11-Dihalogeno-1,6-methano-[10]annulenes as Dihalogenocarbene Transfer Agents

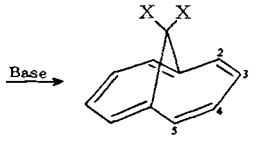
By *V. Rautenstrauch, H.-J. Scholl,* and *E. Vogel*[*]

Bridge-substituted 1,6-methano-[10]annulenes are of interest as potential generators of carbenes (thermal fragmentation to naphthalene and carbene) and as starting compounds for the preparation of benzocyclopropenes having substituents on the methylene carbon atom[1]. A carbene fragmentation of 1,6-methano-[10]annulenes[2] appears most likely to be possible when the carbene to be formed is stabilized by two halogen atoms. The present communication deals with the synthesis and thermal behavior of 11,11-difluoro-, 11,11-dichloro-, and 11,11-dibromo-1,6-methano-[10]annulene, *(3a)* to *(3c)*.



(1a), X = F
(1b), X = Cl
(1c), X = Br

(2a), X = F
(2b), X = Cl
(2c), X = Br



(3a), X = F
(3b), X = Cl
(3c), X = Br

These 11,11-dihalogeno-1,6-methano-[10]annulenes were obtained by bromination of the adducts *(1a)–(1c)* of dihalogenocarbenes[3] to the central double bond of 1,4,5,8-tetrahydronaphthalene and treatment of the resulting tetrabromides *(2a)–(2c)* (probably mixtures of stereoisomers) with bases.

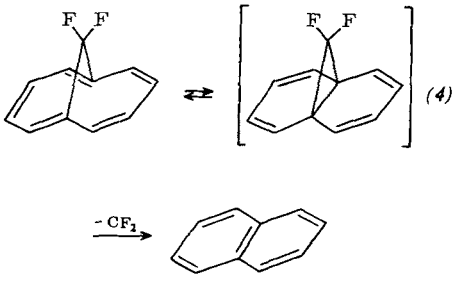
The tetrabromide *(2a)* could be smoothly dehydrobrominated by heating with methanolic potassium hydroxide; 11,11-difluoro-1,6-methano-[10]annulene *(3a)* was formed in 80% yield as a stable yellow compound having m.p. 122–123 °C. The structure of *(3a)* was established from the spectral data. The ^{1}H–NMR spectrum (CCl_4), as expected, contains an AA'BB' system at relatively low field strengths, centered at $\tau = 2.92$, ($\tau_{2,5} = 2.83$, $\tau_{3,4} = 3.02$; $J_{23} = 9.8$, $J_{34} = 8.9$, $J_{24} = -0.2$, and $J_{25} = 1.3$ Hz)[4], while the ^{19}F–NMR spectrum gives a signal at +126.2 ppm (CCl_3F as external reference)[5].

The UV spectrum [maxima at 253 ($\varepsilon = 64000$), 293 (5850), 380 (590), 389 (790), 398 (850), and 409 nm (535), in cyclohexane] is practically identical with the three-band spectrum of 1,6-methano-[10]annulene[6], except for the fine-structured longest-wavelength band, which has higher extinction coefficients for *(3a)*. Compound *(3a)* exhibits no tendency to enter into Diels-Alder reactions readily; this suggests that the energy threshold separating *(3a)* from the valence-isomeric norcaradiene form *(4)* is relatively high.

Dehydrobromination of *(2b)* gave 11,11-dichloro-1,6-methano-[10]annulene *(3b)* as yellow crystals having m.p. 104–107 °C (decomp.) in a yield of about 6% when 1,5-diazabicyclo[4.3.0]non-5-ene[7] (0 °C) was used as the base. The NMR spectrum ($CDCl_3$) of *(3b)* shows an only weakly resolved AA'BB' system at $\tau = 3.06$, which cannot be analyzed. The UV spectrum [maxima at 256 ($\varepsilon = 33900$), 280 (4720), and 388 nm (570), in cyclohexane] contains bands similar to those in the spectrum of *(3a)*, except that the extinction coefficients of the two short-wavelength bands are considerably lower. This decrease in the extinction coefficients may be due to a fast equilibrium of *(3b)* with an appreciable concentration of its norcaradiene form.

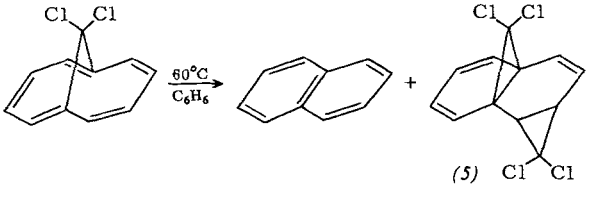
The dehydrobromination of *(2c)*, which was carried out in the same way as for *(2b)*, gave a low yield (2%) of an unstable yellow substance having m.p. 86–90 °C (decomp.), whose NMR spectrum (signal at $\tau = 3.25$ in $CDCl_3$) and UV spectrum [maxima at 259 ($\varepsilon = 23800$), 283 (5110), and 390 nm (450), in cyclohexane] indicates that it is *(3c)*.

On pyrolysis for a short time (450 °C/0.5 torr), 11,11-difluoro-1,6-methano-[10]annulene *(3a)* gave an almost quantitative yield of naphthalene, which was probably formed *via (4)*[8]. When *(3a)* was heated in an excess of cyclohexene at 250 °C (4 hours), 7,7-difluoronorcarane *(6)* was formed in 95% yield, based on reacted *(3a)*.



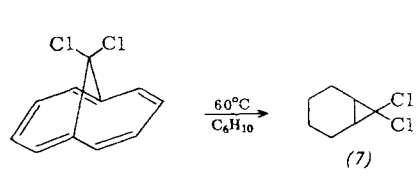
(4)

Owing to the unfavorable thermal behavior (partial decomposition and polymerization) of *(3b)*, the pyrolysis of this compound was carried out in dilute solution [approx. 0.1 M in *(3b)*] in benzene instead of in the gas phase. At 60 °C, the reaction was complete after 24 hours. The product consisted

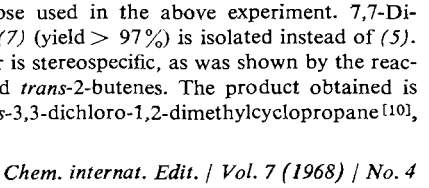


(5)

mainly of two substances (ratio 60:40), which were found to be naphthalene (main product) and an adduct of CCl_2 with *(3b)*. The product of the CCl_2 transfer, which is a colorless compound having m.p. 125–126 °C, probably has the norcaradiene structure *(5)*. The formation of *(5)* can be completely suppressed if the thermolysis of *(3b)* is carried out in benzene (again 0.1 M solution)[9] in the presence of a tenfold molar excess of cyclohexene and under otherwise identical



(6)



(7)

conditions to those used in the above experiment. 7,7-Dichloronorcarane *(7)* (yield > 97%) is isolated instead of *(5)*. The CCl_2 transfer is stereospecific, as was shown by the reaction with *cis-* and *trans*-2-butenes. The product obtained is pure *cis-* or *trans*-3,3-dichloro-1,2-dimethylcyclopropane[10],

respectively. Like *(3b)*, *(3c)* can transfer the bridge to cyclohexene in high yield (formation of 7,7-dibromonorcarane)[11].

[2] On pyrolysis for a short time (500 °C/0.5 torr), 1,6-methano-[10]annulene gives an almost quantitative yield of benzocyclohepta-1,3,5-triene, the formation of which is explained by a Berson-Willcott rearrangement [*J. A. Berson* and *M. R. Willcott III*, J. Amer. chem. Soc. *88*, 2494 (1966)].

[3] Compound *(1a)* (m.p. 62–63 °C), which has not been described before, was obtained by reaction of 1,4,5,8-tetrahydronaphthalene with sodium chlorodifluoroacetate.

[4] The spectrum was analyzed by *W. Bremser*.

[5] We are grateful to *P. Junkes* for recording the ^{19}F–NMR spectrum.

[8] For the formation of difluorocarbene by pyrolysis of *gem*-difluorocyclopropanes, see *B. Atkinson* and *D. McKeagan*, Chem. Commun. *1966*, 189; *J. M. Birchall, R. N. Haszeldine*, and *D. W. Roberts, ibid. 1967*, 287.

[9] Benzene had to be used as the reaction medium since *(3b)* is very sparingly soluble in cyclohexene.

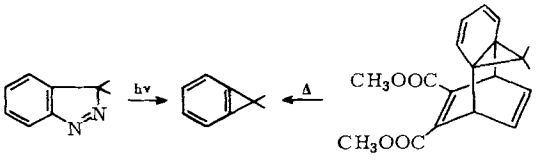
[10] It should be mentioned in this connection that the norcaradiene derivative 10,10-dichlorotricyclo[4.3.1.0]deca-2,4-diene can also transfer dichlorocarbene to olefins, though only at temperatures above 150 °C.

[11] The decomposition of a cycloheptatriene into benzene and a carbene has recently been reported by *A. P. Ter Borg, E. Razenberg*, and *H. Kloosterziel*, Recueil Trav. chim. Pays-Bas *85*, 774 (1966).

1,1-Difluorobenzocyclopropene

By *E. Vogel, S. Korte, W. Grimme*, and *H. Günther*[*]

Two methods are known at present for the preparation of benzocyclopropenes *(2)*. These are the photolysis of 3*H*-indazolines *(1)* and the pyrolysis of adducts of acetylenedicarboxylic ester with 1,6-methano-[10]annulenes *(3)*. While a number of 1,1-disubstituted benzocyclopropenes have been prepared by the first method[1], the parent compound itself has been synthesized by the second[2].

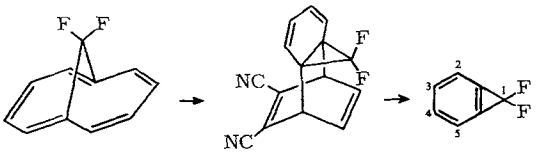


(1) *(2)* *(3)*

The availability of a large number of 1,6-methano-[10]-annulenes[2,3] with one or two substituents on the bridge led to a systematic study of the scope of the second process. Most of the bridge-substituted 1,6-methano-[10]annulenes examined so far (particularly 11-methyl-, 11-bromo-, and 11-cyano-1,6-methano-[10]annulene) gave Diels-Alder adducts of the type *(3)*, but the pyrolysis of these adducts did not lead to the desired benzocyclopropenes. The synthesis of 1,1-difluorobenzocyclopropene reported here shows that benzocyclopropenes substituted in the CH_2 group can also be obtained by this route.

11,11-Difluoro-1,6-methano-[10]annulene *(4)*[4] reacts with dicyanoacetylene at 100–110 °C (24 hours) to give a 1:1 adduct having m.p. 154 °C [yield 37%, based on reacted *(4)*]. On the basis of its spectral analogies with the 1,6-methano-[10]annulene-acetylenedicarboxylic ester adduct, the structure *(5)* is assigned to this product. The adduct *(5)* undergoes uniform and almost complete Alder-Rickert cleavage when passed through a pyrolysis tube heated at 380 °C in a high vacuum (approx. 10^{-4} torr). In addition to phthalodinitrile, there was produced a stable, colorless liquid having b.p. 33 °C/14 torr, $n_D^{20} = 1.4688$, which is the desired 1,1-difluorobenzocyclopropene *(6)*.

The main evidence for the structure *(6)* is provided by spectroscopic data. The UV spectrum [maxima at 242 (ε = 310), 246 (565), 252 (955), 258 (1230), and 264 nm (895) in cyclohexane] has the same shape as that of benzocyclopropene, but is displaced by about 13 nm toward shorter wavelengths. The ^1H–NMR spectrum (CCl_4) contains an AA'BB' system centered at $\tau = 2.46$, in which all the lines of the BB' part exhibit triplet splittings ($J_{H_2,F} = J_{H_5,F} = 3.4$ Hz) owing to long-range coupling with the fluorine atoms. In agreement with the ^1H–NMR spectrum, the ^{19}F–NMR spectrum[5] exhibits a triplet due to two magnetically equivalent F atoms at +80.4 ppm (CCl_3F as external reference), again with a splitting of 3.4 Hz. The equivalence of the fluorine atoms strongly suggests that the benzocyclopropene skeleton of *(6)* is planar. Analysis of the ^1H–NMR spectrum with the H,F coupling as a first order perturbation gave the values shown underneath formula *(6)* for chemical shifts and coupling constants[6]. The findings that the vicinal couplings differ appreciably in the sense $J_{23} > J_{34}$ and that J_{para}, contrary to the usual order, is greater than J_{meta} indicate that the Kekulé structure *(6)* is particularly important in the resonance hybrid of 1,1-difluorobenzocyclopropene[7]. The vicinal couplings in *(6)*, which are small compared with the *ortho* coupling in benzene (7.54 Hz)[8], evidently reflect a widening of the H–C–C angle[9], such as can be predicted for the fusion of a three-membered ring on a benzene ring. The formation of cycloheptane (85% of the hydrogenation product) on catalytic hydrogenation with platinum in glacial acetic acid (addition of sodium acetate) provides chemical evidence for the structure *(6)*.



(4) *(5)* *(6)*

$\tau_{2,5} = 2.52$, $\tau_{3,4} = 2.40$; $J_{23} = 6.7$ Hz, $J_{34} = 5.0$, $J_{24} = 0.9$, $J_{25} = 1.1$ Hz

The 1,6,7,7-tetrahalogenobicyclo[4.1.0]hept-3-enes, *e.g. (7)*, which according to *Tobey*[10] are relatively readily obtainable from dienes and tetrahalogenocyclopropenes, promise a simple route to 1,1-difluoro and possibly other 1,1-dihalogenobenzocyclopropenes. We found[11] in fact that the action of potassium hydroxide on *(7)* in triethylene glycol (at 80 °C and 14 torr) led to a liquid compound (yield approx. 40%), which was found to be identical with *(6)*.

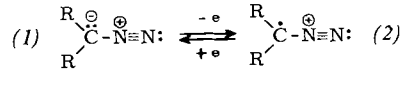
Electrochemical Oxidation of Diphenyldiazomethane[1]

By *W. Jugelt* and *F. Pragst*[*]

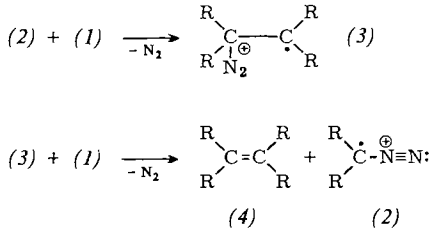
Few examples are at present known of free-radical reactions of aliphatic diazo compounds. The reaction of 9-diazofluorene with diaroyl peroxides is assumed to involve a free-radical intermediate *(2)*, R/R = fluorene residue[2]. The existence of such radical-cations *(2)*, R = C_6H_5, is demonstrated by the electrochemical oxidation of diphenyldiazomethane *(1)* which has been studied by the present authors. Diphenyldiazomethane is oxidized in a reversible diffusion-controlled one-electron process (20 °C, c = 0.05 to 0.5 mmole/l, ω = 34 to 118 sec^{-1}) at a rotating Pt disk electrode in 0.1 M $LiClO_4$/acetonitrile solution in the absence of oxygen at $E_{1/2}$ = +0.95 V (saturated calomel electrode)[3]. The reversibility of the redox process was demonstrated by means of a Kalousek switch[4] (switching frequency 12 Hz) at the rotating Pt electrode (ω = 63 sec^{-1}). The slope $dE/d[\log(i/i_d - i)]$ = 60 mV indicates a one-electron redox process. The cyclic current-voltage curve recorded at a stationary Pt electrode (rate of change of potential 400 mV/min) shows no current maximum in the cathodic branch corresponding to that in the anodic stage. It may therefore be assumed that the life of the radical-cations *(2)* formed as the primary oxidation products of *(1)* is relatively short, owing to subsequent irreversible reactions.

To study these secondary reactions, we followed the electrolysis of *(1)* under the same conditions at a constant potential (+0.95 V) at a rotating Pt electrode having a large area[5]. It was found that the quantitative decomposition of the diazo compound with liberation of N_2 requires only 15 to 4%, depending on concentration (c = 4 to 50 mmole/l), of the current required for a one-electron process. Tetraphenylethylene *(4)* is formed in 80% yield. The other electrolysis products were identified by thin layer chromatography as benzophenone *(6)*, benzopinacolone *(8)*, and benzohydrol *(9)*, R = C_6H_5 in each case. An electrochemically induced free-radical chain reaction of diphenyldiazomethane evidently takes place under these conditions.

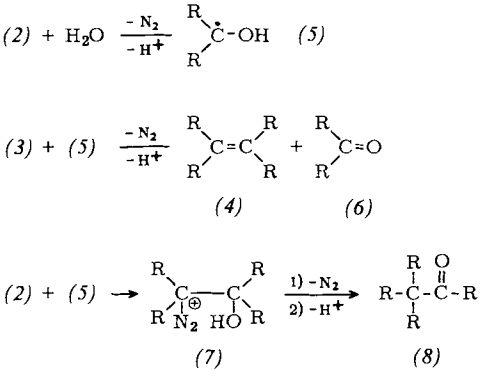
Initiation:



Propagation:

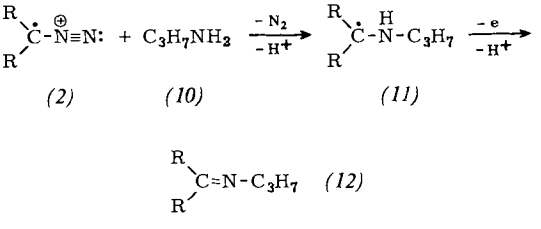


Termination:



Chain termination is caused by traces of water still present in the solution in spite of careful drying. Since the chain termination yields H^+ ions, the benzohydrol formed is probably the product of the acid-catalyzed hydrolysis of *(1)*.

The free-radical chain character of the electrochemically induced decomposition of diphenyldiazomethane is confirmed by the result of the electrolysis of this compound in the presence of an excess of *n*-propylamine *(10)*. A two-electron oxidation process can be detected coulometrically in this case. Benzophenone *n*-propylimide *(12)* was isolated as the reaction product.



The free-radical chain leading to *(4)* is obstructed under these conditions by the preferential reaction of the initially formed radical-cation *(2)* with *(10)*, which is the most nucleophilic reactant available, to give *(11)*. This free radical is then oxidized in a second step to *(12)*.

Derivatives with alkyl, cycloalkyl, or aryl residues on the C atoms or on the N atom of the 2-hydroxyethylamide group react in the same way. The yields are mostly very high, but the reaction time varies. Hydroxyalkylamides whose hydroxyl group is not in the β position or is sterically hindered do not react.

2-Hydroxyalkylamides of 3-nitrobenzenesulfonic acids also remain unchanged, whereas the derivatives of 2-nitrobenzenesulfonic acid react to form 2-hydroxyalkylamines. In this case, however, the yields are mostly considerably lower as a result of competing reactions. For example *N*-(2-hydroxyethyl)-*N*-methyl-2-nitrobenzenesulfonamide gives only a trace of amine when heated with an excess of dilute sodium hydroxide solution, whereas 2-methyl-3,4-dihydro-2*H*-5,1,2-benzooxathiazepine 1,1-dioxide (m.p. 118–119 °C) is formed in a yield of about 28 %.

N-(2-Hydroxyethyl)benzothiazole-2-sulfonamide and particularly *N*-(2-hydroxyethyl)-2,4-dinitrobenzenesulfonamide (m.p. 97 °C) are much more reactive. They rearrange under such mild conditions that the preparation of the pure sulfonamides with no rearrangement products requires great care.

The 2-hydroxyarylamides of 2- or 4-nitrobenzenesulfonic acid behave differently. Though they react in boiling dilute sodium hydroxide solution with elimination of the SO_2 group, the products formed are 2-aminoaryl ethers. For example, when *N*-(2-hydroxyphenyl)-4-nitrobenzenesulfonamide is heated for 2 hours in 6.5 % sodium hydroxide solution, 2-aminophenyl 4-nitrophenyl ether (m.p. 122 °C) is formed in 92 % yield.

It is only the more negatively substituted *N*-(2-hydroxyphenyl)-2,4-dinitrobenzenesulfonamide that reacts to give 2-hydroxyphenyl-2,4-dinitrophenylamine (m.p. 206 °C).

2-Aminoalkyl 4-nitrophenyl ethers cannot be obtained by the reaction of the corresponding starting compounds. They rearrange so readily into 2-hydroxyalkyl-4-nitrophenylamines that they cannot be prepared in the usual way [1].

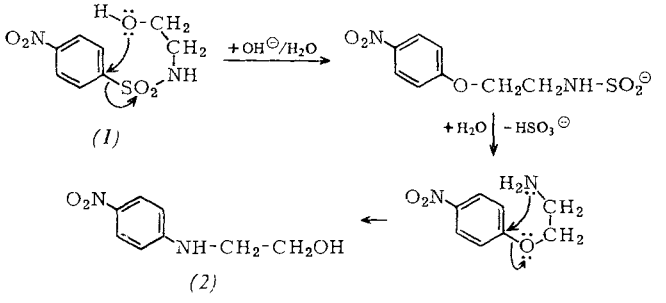
These findings show that the elimination of the SO_2 group takes place only if

1. the sulfonamide group is attached to an aromatic C atom having a strong partial positive charge and

2. there is a hydroxyl group in position 2 of an alkylamide or arylamide residue.

It may be concluded from the behavior of the 2-hydroxyphenylamides of 4- or 2-nitrobenzenesulfonic acids on the one hand and of the 2-aminoalkyl 4-nitrophenyl ethers on the other that the latter are intermediates in the reaction of the *N*-(2-hydroxyalkyl)-4-nitrobenzenesulfonamides, and that they cannot be detected only because their further reaction is faster than the rearrangement that leads to their formation.

We therefore believe that the SO_2 group is eliminated during a rearrangement in two intramolecular nucleophilic substitutions. The reaction therefore proceeds in the same manner as



(1)

(2)

the Smiles rearrangement [2] and the variants described by *Backer et al.* [3] and by *Caldwell* and *Schweiker* [4]. It is a special case, since the atoms are restored to their original order after the loss of one molecule of SO_2 by two rearrangements. The first step is also a new variant of the Smiles rearrangement.

This rearrangement may offer preparative advantages, since the starting materials are mostly readily obtainable and the operations simple to carry out. If the excess of alkali metal hydroxide is insufficient or if substances having a weakly alkaline reaction, such as sodium carbonate or ammonia, are used, side reactions take place on the nitro group as a result of the reducing action of the sulfite formed.

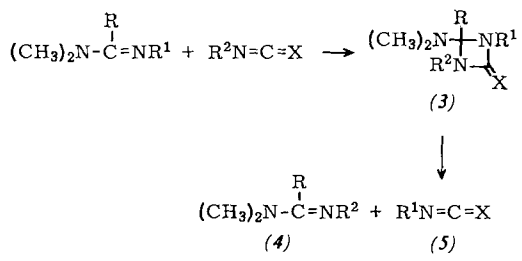
Cycloaddition of Isocyanates and Isothiocyanates to Amidines and Guanidines

By *H. Ulrich, B. Tucker*, and *A. A. R. Sayigh* [*]

The reactivity of olefins in cycloadditions with heterocumulenes decreases in the order ketene aminal > enamine > olefin. The same relationship is to be expected for C=N double bonds, and we have confirmed this for the cycloadditions of isocyanates and isothiocyanates to amidines and guanidines.

Whereas azomethines react with isocyanates only at high temperatures [1], amidines and guanidines react with *p*-toluenesulfonyl isocyanate and 4-nitrophenyl isothiocyanate at room temperature. The 1:1 cycloadducts *(3)* can be isolated in some cases, but they often disproportionate even at room temperature to form *(4)* and *(5)*. The structures of the new



1:1 adducts *(3)* were established by elemental analysis, by fragmentation, and from spectroscopic data.

(3)

R	R^1	R^2	X	M.p. (°C)	Yield (%)

[a] Detected by titration with di-n-butylamine.

The significance of the novel exchange reaction lies in the easy transfer of the substituents R^1 and R^2. The reaction may therefore be used for the preparation of C=N double bond systems or of heterocumulenes.

Procedure:

7.88 g (0.04 mole) of p-toluenesulfonyl isocyanate is added dropwise to a solution of 6.89 g (0.04 mole) of N,N,N',N'-tetramethyl-N''-n-butylguanidine in 70 ml of benzene. The ensuing exothermic reaction yields 12.55 g (85.3%) of the 1:1 adduct *(3)*, R = $(CH_3)_2N$, R^1 = n-C_4H_9, R^2 = p-toluenesulfonyl, X = O, m.p. 158–160 °C, ν(C=O) 1639 cm^{-1}, NMR data: aryl-CH_3 protons: τ = 7.63; N–CH_3 protons: τ = 6.93 and 7.04; n-C_4H_9 protons: τ = 6.6 and 8.5–9.2; aryl protons: τ = 2.08 and 2.80; intensity ratio 3:12:9:4.

A solution of 9.2 g (0.025 mole) of the 1:1 adduct in 90 ml of o-dichlorobenzene is slowly distilled. 2.0 g (84%) of n-butyl isocyanate can be detected in the distillate by titration with di-n-butylamine. 5.6 g (83.5%) of N,N,N',N'-tetramethyl-N''-p-toluenesulfonylguanidine, m.p. 142–143 °C (lit. m.p. 143–145 °C[2]) can be obtained from the residue by digestion with ether.

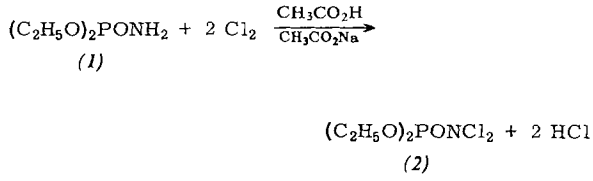
Synthesis of *O,O*-Diethyl *N,N*-Dichlorophosphoramidate and its Use for the Preparation of β-Chloro Amines from Olefins

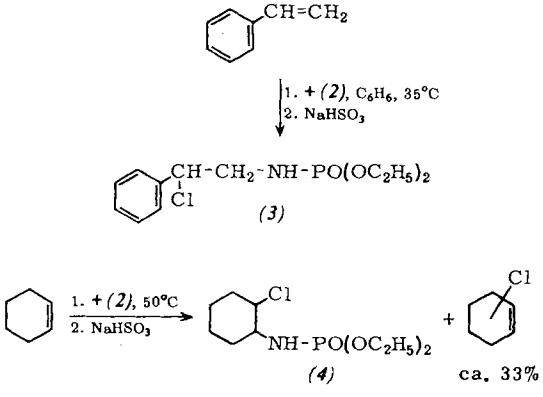
By *A. Zwierzak* and *A. Koziara*[*]

We have found that the chlorination of *O,O*-diethyl phosphoramidate *(1)* with gaseous chlorine at 15 to 20 °C in aqueous solution in the presence of acetate buffer (pH = 6.3) leads to the formation of *O,O*-diethyl *N,N*-dichlorophosphoramidate *(2)* in 85% yield. The reaction is strongly exothermic.



Compound *(2)* is a yellow, mobile liquid, which can be distilled without decomposition and is stable at room temperature, b.p. 56–57 °C/0.01 torr, n_D^{20} = 1.4620. The structure of the compound is deduced from elemental analysis, iodometric chlorine determination, and the IR spectrum [ν_{max} = 1288 cm^{-1} (P=O), 1268 cm^{-1} (P–O–C_2H_5)].

Like *N,N*-dichlorourethane[1], *(2)* readily adds to unsaturated hydrocarbons, such as styrene or cyclohexene, and forms *N*-chloro-*N*-(β-chloroalkyl)phosphoramidates, which can be readily reduced to the *N*-(β-chloroalkyl)phosphoramidates *(3)* and *(4)* by 20% aqueous sodium hydrogen sulfite

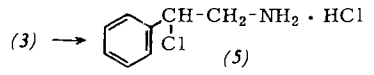


Compound *(3)* is a pale-yellow viscous oil, which was found by thin layer chromatography to be pure, b.p. = 135–136 °C/0.01 torr, n_D^{20} = 1.5097, yield 67%. IR (cm^{-1}): 3220 s (NH), 1245 s (P=O), 1170 m (P–O–C_2H_5), 1064 s, 1037 s (P–O–C as.)[2]. ^{1}H–NMR: broad singlet at τ = 2.66 (5H), triplet at τ = 5.03 (benzyl-H), J = 7.0 Hz, two quintets at τ = 6.01 and 6.05 (4H), two doublets at τ = 6.64 (2H), J_{H-CH} = 7.0 Hz, J_{H-NH} = 10.4 Hz, and a triplet at τ = 8.75 (6H), J = 6.8 Hz.

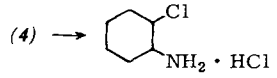
The compound *(4)* was purified by molecular distillation. It is a pale-orange viscous oil, which partly solidifies on cooling to give colorless crystals of *(4a)*; yield 7%. The yield of the noncrystallizing residue *(4b)* is 18%. *(4a)* has been identified as the pure *trans* isomer, and *(4b)* as a mixture of the *cis*- and *trans*-isomers. *(4a)*: m.p. 72–74 °C (from petroleum ether), IR (cm^{-1}): 3200 s (NH), 1250 s, 1237 s (P=O), 1168 w (P–O–C_2H_5), 1065 s, 1040 s (P–O–C as.), 739 m (C–Cl?). ^{1}H–NMR quintet at τ = 5.92 (4H), band complexes at τ = 6.6 to 7.6 (2H) and at τ = 7.5 to 8.8 (14H).

The structures of the addition products *(3)* and *(4)* were demonstrated by degradation reactions. Both compounds are

converted into the corresponding β-chloroamines *(5)* and *(6)* by the action of anhydrous hydrogen chloride in benzene at room temperature (24 hours)[3].



(5)



(6)

Compound *(5)* forms colorless crystals, m.p. 163–164 °C (from alcohol), yield 85 % (lit. m.p. 162–163 °C[4]).

The compound *(6a)* formed by degradation of *(4a)* is the hydrochloride of dl-*trans*-2-chlorocyclohexylamine. Colorless leaflets, m.p. 213 °C (from benzene/alcohol, 5:1), yield 50 %, IR (KBr): $\tilde{\nu}_{C-Cl}$ = 738 cm^{-1}, identical with a sample synthesized in accordance with[5].

The compound *(6b)* formed by degradation of *(4b)* is formulated as a mixture of *(6a)* and the hydrochloride of dl-*cis*-2-chlorocyclohexylamine. Colorless crystals, m.p. 183–189 °C (crude product), yield 59 %, IR(KBr): $\tilde{\nu}_{C-Cl}$ = 690 and 738 cm^{-1}. The corresponding values given in the literature are: m.p. (*cis*-isomer) 185–186 °C[6], IR (KBr): $\tilde{\nu}_{C-Cl}$ = 692 cm^{-1} (*cis*), 743 cm^{-1} (*trans*)[7].

Tris(dimethylamino)boranetricarbonyltungsten

By *G. Schmid*, *H. Nöth*, and *J. Deberitz*[*]

Aminoboranes are potential π-donor ligands, though they behave toward iodine as amines[1]. On the other hand, the synthesis of hexamethylborazoletricarbonylchromium *(1)*[2] and of bis-(3,4-dimethyl-2,5-diphenylcyclo-1,3,4-triazadiborolyl)iron(II) *(2)*[3] shows that cyclic aminoborane systems are π donors, though X-ray structural analyses have not yet been carried out. Acyclic aminoboranes should thus also have this property.

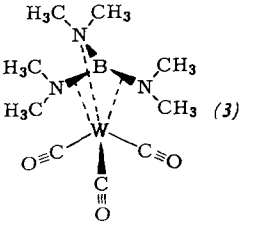
When tris(dimethylamino)borane, in analogy with[2], reacts with $(CH_3CN)_3W(CO)_3$ in dioxane for 8 hours at 80 °C or for 22 hours with frequent evacuation for short periods at 25 °C, yellow crystalline tris(dimethylamino)boranetricarbonyltungsten *(3)* is obtained in 5–10 % yield. The composition of *(3)* was verified by complete elemental analysis (with the exception of O). The crystals sublime at 30–40 °C/ 10^{-3}–10^{-4} torr; they are soluble in benzene and very sensitive to moisture. Decomposition takes place slowly at room temperature, and rapidly above 60 °C.

$$[(CH_3)_2N]_3B + (CH_3CN)_3W(CO)_3 \rightarrow [(CH_3)_2N]_3B{\cdot}W(CO)_3 + 3\ CH_3CN$$
(3)

The IR spectrum of *(3)* in *n*-pentane contains two sharp CO bands at 1930 (mw) and 1982 (s) cm^{-1}, showing that $B[N(CH_3)_2]_3$ is a stronger acceptor than hexamethylborazole. The UV spectrum in pentane consists of two broad strong bands at 28571 and 30581 cm^{-1}.

The ^1H–NMR spectrum in CCl_4 against $Si(CH_3)_4$ as the internal standard contains a single, sharp resonance line at −2.59 ppm, which is displaced by −0.09 ppm in relation to the signal of free $B[N(CH_3)_2]_3$. Thus the complex *(3)* contains magnetically equivalent N–CH_3 protons.

The ^{11}B–NMR signal of *(3)* against BF_3·ether as the external standard appears at −21.2 ppm and is displaced by +6.1 ppm in relation to the signal of $B[N(CH_3)_2]_3$. This change in the



(3)

chemical shift roughly corresponds to the difference between *(2)* and the free heterocycle[3], and is opposite in direction to the shifts of the ^{11}B–NMR signal in σ-donor complexes of aminoboranes. For example, the ^{11}B signal for $(CH_3)_2B$–N–$(CH_3)_2{\cdot}AlBr_3$ is found at −74 ppm[4], whereas that of the free aminoborane $(CH_3)_2BN(CH_3)_2$ lies at −44.6 ppm.

On the basis of these data, we postulate π-coordination of the tris(dimethylamino)borane in *(3)* with a relatively strong metal-boron interaction and $B[N(CH_3)_2]_3$ occupying three coordination sites (octahedral face).

Studies that are as yet incomplete indicate the existence of analogous complexes with other aminoboranes and other metals.

Formation of Phenylazomethyl Isocyanates on Oxidation of 2-Phenylsemicarbazones[1,2]

By *H. Schildknecht* and *G. Hatzmann*[*]

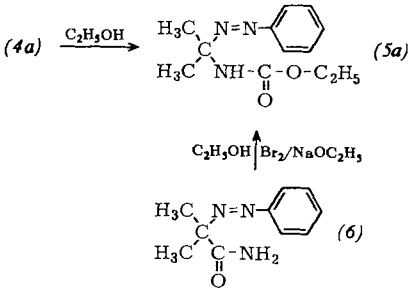
Chromyl acetate, $CrO_2(OAc)_2$[3], reacts with hydrazones of the type $R^1R^2C{=}N{-}NH{-}R^3$ with elimination of nitrogen and regeneration of the carbonyl compound from which the hydrazone is derived[4]. We found a different reaction in the oxidation of 2-phenylsemicarbazones *(1)*[5]. These are oxidized by chromyl acetate in chloroform to phenylazomethyl isocyanates *(4)*, the initially formed nitrene *(2)* presumably rearranging to the isocyanate *via* a five-membered ring *(3)*. Compound *(4)* is also formed on oxidation of *(1)* with lead tetraacetate.

The structure of *(4)* was established by elemental analysis, from the IR spectrum [ν_{as}(N=C=O) = 2220 cm^{-1}; no NH band], and from the UV spectrum [λ_{max} in cyclohexane for

	R	R^1	B.p. (°C/torr)	Yield (%)
(4a)	CH_3	CH_3	128–30/18	66
(4b)	CH_3	C_2H_5	80–81/0.2	71
(4c)	$(CH_2)_5$		134–135/2 (m.p. 49–51 °C)	30

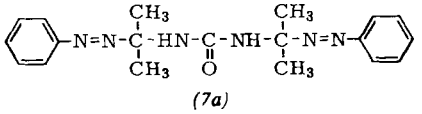
(4a): 268 nm (log ε = 4.05) and 385 nm (log ε = 2.18)], which agrees closely with the UV spectra of phenylazomethyl acetates[6] and of phenylazomethyl nitriles[7].

The reduction of *(4)* with lithium aluminum hydride again results in rearrangement, with formation of the original semicarbazone. The phenylazomethyl isocyanates react smoothly with amines to form the corresponding ureas. The addition of alcohols, on the other hand, proceeds only slowly and requires the presence of basic catalysts. *(4a)* reacts with ethanol in the presence of sodium ethoxide to give *(5a)*, b.p. 128–129 °C/0.4 torr, m.p. 53–54 °C, λ_{max} (cyclohexane): 268 nm (log ε = 3.95) and 387 nm (log ε = 2.19), IR: ν(NH) = 3350 cm^{-1} and ν(CO) = 1705 cm^{-1}.

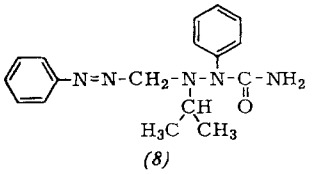


α-Phenylazoisobutyramide *(6)*[7] also gives *(5a)* on reaction with bromine and sodium ethoxide in ethanol, so that the structure of *(5a)* has also been verified by synthesis.

The reaction of *(4a)* in dioxane/water to form *(7a)*, m.p. 166–168 °C, IR: ν(NH) = 3340 cm^{-1} and ν(CO) = 1660 cm^{-1},



(7a)



(8)

also proceeds only very slowly in the absence of basic catalysts.

The analysis and the IR and UV spectra of *(7a)* indicate that it is identical with the compound obtained by *Whyburn* and *Bailey*[8] on oxidation of *(1a)* with permanganate, which these authors described as 1-isopropyl-1-phenylazomethyl-2-phenyl semicarbazide *(8)*. However, on the basis of the NMR spectrum, which contains only two singlets at τ = 3.70 (2H) and τ = 8.26 (12H) for two NH and four CH_3 groups, apart from a multiplet at τ = 2.20–2.80 (10H), the structure *(8)* must be abandoned in favor of *(7a)*. The UV spectrum in ethanol, λ_{max} = 263 nm (log ε = 4.35) and 396 nm (log ε = 2.52), in which the extinction values point to two phenylazo groups, is also in agreement with the structure *(7a)*.

Oxidation of (1):

A solution of 0.04 mole of chromyl acetate is prepared by reaction of equimolar quantities of chromium trioxide and acetic anhydride in 25 ml of anhydrous $CHCl_3$ while cooling with water (reaction time about 2 hours). The solution is added dropwise to an ice-cooled solution of 0.04 mole of the semicarbazone in 100 ml of anhydrous $CHCl_3$.The mixture is stirred for 30 min at room temperature and then hydrolyzed with 100 ml of 10 % Na_2SO_3 solution. The organic phase is washed with $NaHCO_3$ and the product is isolated by distillation.

The procedure for the oxidation of *(1)* with lead tetraacetate is similar to that described[6] for the oxidation of phenylhydrazones.

Preparation and Properties of Tungsten Oxide Bromide, $WOBr_3$

By *J. Tillack* and *R. Kaiser*[*]

In the course of investigations on the reactions that take place in halogen lamps, we synthesized $WOBr_3$ – a compound which has not been described before.

Tungsten, tungsten trioxide, and bromine (molar ratio 2:1:4.5) in an evacuated sealed tube were introduced into a temperature gradient of 400 to approx. 40 °C in such a way that the W/WO_3 mixture was in the hot half and the bromine in the cold half of the slightly inclined tube. After about an hour, practically all the bromine had reacted to give higher tungsten bromides and oxide bromides; the contents of the tube then reacted in a temperature gradient of 450/400 °C to give $WOBr_3$:

$$2\,W + WO_3 + 4.5\,Br_2 = 3\,WOBr_3$$

A small excess of bromine (about 1 mg of bromine per ml of tube volume after complete reaction to form $WOBr_3$) prevented the formation of lower, nonvolatile bromides or

oxide bromides of tungsten, and at the same time permitted the purification of the crude product by chemical transport[1] in the same tube in a temperature gradient of *e.g.* 400/350 °C:

$$WOBr_3\,(s) + WBr_6\,(g) = WOBr_4\,(g) + WBr_5\,(g)$$

$WOBr_3$ is transported from the hot zone into the cold zone. After the transport, the gas phase (mainly WO_2Br_2 and $WOBr_4$) can be condensed in what was formerly the hotter half of the tube, and so separated from the transported $WOBr_3$. The product is freed from volatile compounds of hexavalent tungsten by heating (250 °C) under vacuum.

Owing to the reversibility of the reaction, tungsten and oxygen, or WO_2, can also react with bromine to give $WOBr_3$.

The procedure described here gave analytically pure $WOBr_3$ in the form of shiny blue-black needles 10–20 mm long, or clusters of needles, which are stable in air.

In the analysis of the product, 50–120 mg of $WOBr_3$ was heated for about 16 hours at 140 °C in an H-tube[2] with 1 volume of concentrated HNO_3 + 1 volume of H_2O: the tungsten was determined as WO_3 and the bromide as AgBr. When dry $WOBr_3$ is heated in a test tube, marked formation of WO_2Br_2 and slight formation of Br_2 are observed.

$WOBr_3$ is not appreciably attacked by concentrated hydrochloric acid, dilute or concentrated acetic acid, sodium hydroxide solution, or ammonia solution, either at room temperature or when heated. It reacts with boiling water within a few seconds to give an intensely blue solution and a dark, bulky precipitate, which has not been studied in detail. $WOBr_3$ reacts in a similar manner with ethanol (96 and 100 %), ethylene glycol monomethyl ether, and some electrolytes, such as $ZnSO_4$.

Weakly oxidizing solutions (3 % H_2O_2 in 2 N H_2SO_4, 2 N NaOH, or 2 N NH_3) have little effect on $WOBr_3$. On addition of hydrogen peroxide, however, clear colorless solutions are obtained after a short time. $WOBr_3$ is insoluble in organic solvents, such as acetone, ether, petroleum ether, chloroform, or dioxane.

The X-ray characterization of $WOBr_3$ is based on the following *d* values and estimated intensities (in parentheses) of the first reflections up to an angle of $\vartheta = 39.7°$.

8.26 (10); 7.76 (10); 5.15 (5); 4.98 (5); 3.59 (10); 3.43 (3); 2.87 (2); 2.81 (7); 2.73 (7); 2.61 (3); 2.25 (7); 2.22 (7); 2.11 (5); 1.94 (7); 1.90 (2); 1.78 (3); 1.61 (7); 1.59 (2); 1.46 (3); 1.42 (2); 1.24 (2); 1.22 (1).

The density of $WOBr_3$ as determined pycnometrically in toluene at 25.0 ± 0.1 °C is $D_{pyc,\,25\,°C} = 5.87$; $D_{X\text{-ray}} = 5.84$.

Dirhenium Dihydratoheptoxide $Re_2O_7(OH_2)_2$ — New Type of Water Bonding in an Aquoxide[1]

By *H. Beyer*, *O. Glemser*, and *B. Krebs*[*]

Concentration of an aqueous solution of Re_2O_7 over P_2O_5 yields slightly yellow, hygroscopic crystals, which are referred to as "perrhenic acid" and formulated as $HReO_4$ (composition $Re_2O_7 \cdot H_2O$)[2,3]. Recrystallization from nitromethane gives single crystals[4], which are suitable for X-ray analysis. By such an analysis, we found that the compound corresponds to the composition $Re_2O_7 \cdot 2H_2O$, *i.e.* contains more water and exists as the molecule dirhenium dihydratoheptoxide $Re_2O_7(OH_2)_2$. It was shown in our first report[3] that, on the basis of its properties and a comparison of its simple IR spectrum with the complex spectrum of the polymeric Re_2O_7[5], "perrhenic acid" probably had a molecular structure.

$Re_2O_7(OH_2)_2$ crystallizes in the space group $P2_1/m\text{–}C_{2h}^2$. Lattice constants: $a = 8.82 \pm 0.02$ Å, $b = 8.89 \pm 0.02$ Å, $c = 5.03 \pm 0.01$ Å, $\beta = 112.0 \pm 0.3°$, $Z = 4$. The intensities were found from integrated Weissenberg and precession diagrams (measured photometrically, Weissenberg data corrected for absorption). Three-dimensional Patterson syntheses gave the positions of the rhenium atoms, and three-dimensional Fourier syntheses the positions of the oxygen atoms. Refinement by the method of least squares with isotropic temperature factors gave an *R* value of 4.6 % for the 1300 reflections observed. A final three-dimensional difference Fourier synthesis showed no maxima that could be considered as additional oxygen positions. The position parameters are given in the table. The figure shows a projection of the structure of $Re_2O_7(OH_2)_2$ parallel to [010].

Table 1. Position parameters of the atoms in $Re_2O_7(OH_2)_2$.

Atom	Multiplicity of equivalent positions	*x*	*y*	*z*
Re_1	2	0.8970	3/4	0.0356
Re_2	2	0.4454	3/4	−0.0146
O_1	2	0.654	3/4	0.011
O_2	2	0.303	3/4	−0.373
O_3	2	0.058	3/4	−0.091
O_4	4	0.934	0.903	0.266
O_5	4	0.418	0.908	0.164
$O_6(H_2O)$	4	0.778	0.905	−0.328

Since the positions of the protons could not be determined from the X-ray analysis, it was necessary to deduce the nature of the bonding of the water from the difference in the coordination of the oxygen atoms. Three formulations were considered: $Re_2O_5(OH)_4$, $Re_2O_6(OH)_2(OH_2)$, and $Re_2O_7(OH_2)_2$. The distance from rhenium to a terminal oxygen atom should be considerably smaller than the distance to an OH group or to an H_2O molecule. Only two terminal oxygen positions (O_6, O_6') per molecule had distances about 20 % greater from the octahedrally coordinated Re; it was therefore possible to decide conclusively in favor of the formulation $Re_2O_7(OH_2)_2$, which agrees with the IR spectrum and the ^1H–NMR broad-line spectrum[6].

Dirhenium dihydratoheptoxide $Re_2O_7(OH_2)_2$ is a remarkable compound. It is the first aquoxide in which coordinately bound water has been definitely detected, and the first metal aquoxide found to have a molecular structure in the solid state. The structure of the dinuclear hydratooxide is unusual. One rhenium atom is tetrahedrally surrounded by oxygen atoms, while the oxygens have a distorted octahedral arrangement around the second rhenium atom, the tetrahedral group being joined to the octahedral group by a common corner. The Re–O–Re angle is practically 180° — a rare situation. The ease of formation of the compound from Re_2O_7 is understandable from a comparison of the two structures. In Re_2O_7, one of the Re atoms is again surrounded by a tetrahedral arrangement of O atoms and the other is in a distorted octahedral environment, the two polyhedrons sharing a corner[7]. However, the resulting Re_2O_9 structural unit is linked to other units; consequently, Re_2O_7 is polymeric, in contrast to the molecular $Re_2O_7(OH_2)_2$. In the latter compound the molecules are joined to one another only by hydrogen bonds, the positions of which cannot yet be definitely established. One hydrogen bond could be

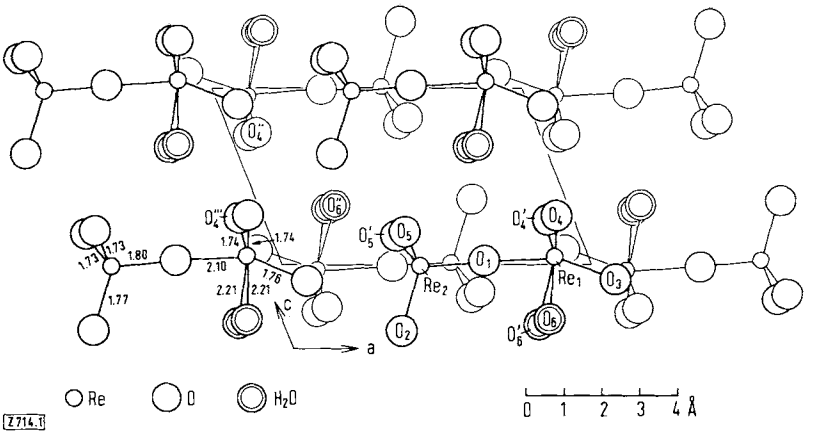

Fig. 1. Structure of $Re_2O_7(OH_2)_2$. Projection parallel to [010]. Atoms lying exactly in line are displaced slightly.

present between the atoms O_6'' and O_5' (cf. Fig. 1) and a second between O_6'' and O_4'', or between O_6'' and O_4'''. The hydrogen bonds are evidently retained in concentrated aqueous solutions of $Re_2O_7(OH_2)_2$, and this is the reason for the high viscosity of these solutions, as is the case with concentrated sulfuric and phosphoric acids. Tetrahedral ReO_4^- ions occur in dilute solution, and $ReO_3(OH)$ exists in the gaseous state [8].

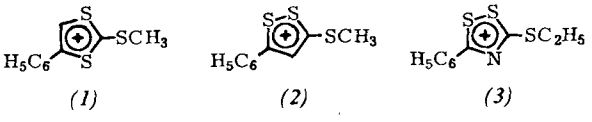
Heterofulvalenes and Azafulvenes

By *R. Gompper* and *R. Weiss* [*]

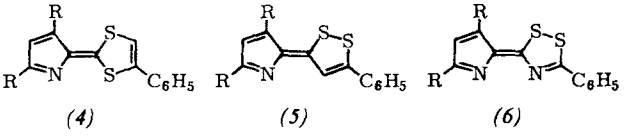
The synthesis of 3-(1,3-dithiolan-2-ylidene)indolium perchlorate from indole and 2-methylthio-1,3-dithiolanylium methyl sulfate [1] is the starting point for a simple route to the heterofulvalenes and azafulvenes [2], which have not yet been studied extensively.



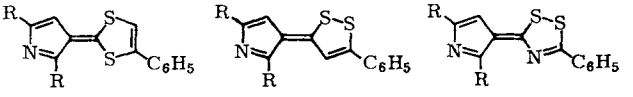
(1) *(2)* *(3)*

The reaction of dimethyl- or diphenylpyrroles with the methyl sulfates of *(1)* and *(2)* (which are prepared by heating the corresponding isotrithiones and trithiones with dimethyl sulfate) and with the fluoroborate of *(3)* (which is prepared from the corresponding azatrithione with triethyloxonium fluoroborate) proceeds at room temperature in glacial acetic acid within a few minutes (heating for 10 min is advisable in the case of the diphenylpyrroles) to give deeply colored solutions, from which crystalline perchlorates of the heterofulvalenes *(4)*–*(9)* are precipitated on addition of 70 % perchloric acid.

The free fulvalenes *(5)* and *(6)* crystallize from the solutions of the perchlorates in acetonitrile on addition of Hünig base. *(4a)* can be obtained from the perchlorate with Hünig base



(4) *(5)* *(6)*



(7) *(8)* *(9)*

(a), R = C_6H_5; *(b)*, R = CH_3

in ether. *(4b)*, *(7b)*, and *(8b)* can be stored for several hours in acetonitrile, whereas *(9b)* can be kept for only a few minutes.

Compound [a]	Yield (%)	M.p. (°C)	λ_{max} [b] (nm)	log ε	*p* [c]
(4a)		132	480	4.61

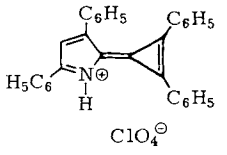
(9b⁺)	16	229 [d]	470	4.10	0.47

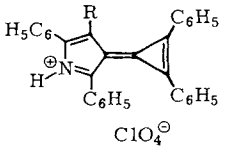
[a] (X^+) = perchlorates. [b] In acetonitrile. [c] = π-Bond order of the central C=C double bond. [d] = With decomposition.

When di- and triphenylpyrroles are heated with methylthiodiphenylcyclopropenylium perchlorate in glacial acetic acid or with dichlorodiphenylcyclopropene in acetonitrile, the

azatriafulvalenium salts *(10)*, m.p. 222 °C (dec.); $\lambda_{max}^{CH_3CN}$ = 390 nm, log ε = 4.70; $\nu_{C=C}$ = 1835 cm^{-1}, *(11a)*, m.p. 235 °C (dec.); $\lambda_{max}^{CH_3CN}$ = 372 nm, log ε = 4.18; $\nu_{C=C}$ = 1840 cm^{-1}, and *(11b)*, m.p. 205 °C (dec.); $\lambda_{max}^{CH_3CN}$ = 362 nm (shoulder), log ε = 4.09, $\nu_{C=C}$ = 1825 cm^{-1}, are obtained in yields of 79, 50, and 59% respectively. They are deprotonated to give the



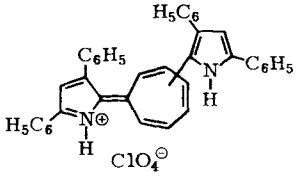
(10)



(11a), R = H
(11b), R = C_6H_5

azacalicenes *(10')* [$\lambda_{max}^{CH_3CN}$ = 384 nm, log ε = 4.63; $\nu_{C=C}$ = 1835 cm^{-1}], *(11a')* [unstable red oil], and *(11b')* [dark red solution]; *(10)* and *(11a)* by Hünig base in methylene chloride, *(11b)* by potassium *tert*-butoxide.

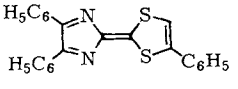
The action of tropylium perchlorate on 2,4-diphenylpyrrole under various conditions always gives a 1:2 adduct in a yield of about 15%. This adduct can be isolated as the perchlorate *(12)*, m.p. 282 °C (dec.); $\lambda_{max}^{CH_3CN}$ = 554 nm, log ε = 4.83. The free base is obtained from *(12)* with Hünig base (m.p. 279 °C; $\lambda_{max}^{CH_3CN}$ = 520 nm, log ε = 4.67). Compound *(12)* gives a red-violet anion with potassium *tert*-butoxide.



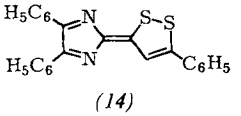
(12)

Benzoheterofulvalenes are obtained by reaction of pyrroles and indoles with the benzo-derivatives of the cations *(1)–(3)*.

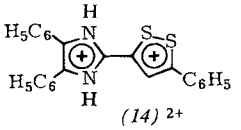
The Na salt of 4,5-diphenylimidazole, which is prepared by heating diphenylimidazole with NaH in benzene in the presence of a little diglyme, reacts surprisingly smoothly with *(1)* and *(2)* in boiling benzene to form the diazadithiafulvalenes *(13)* (red needles, m.p. 210 °C, yield 35%) and *(14)* (m.p. 205 °C; $\lambda_{max}^{CH_3CN}$ = 565 nm, log ε = 4.60; yield 49%). *(14)* forms a perchlorate [m.p. 280 °C (dec.); $\lambda_{max}^{CH_3CN}$ = 520 nm, log ε = 4.57]; reaction with an excess of perchloric



(13)



(14)



(14) $^{2+}$

acid gives the dication *(14)*$^{2+}$ ($\lambda_{max}^{CH_3CN-HClO_4}$ = 460 nm, log ε = 4.40). Compound *(13)* behaves in a similar manner.

Di- and triphenylpyrroles react with benzophenone dichloride in acetonitrile at room temperature to give the azafulvenes *(15)* and *(16)*, which are isolated as the perchlorates and are deprotonated with Hünig base. In the presence of two equivalents of NaH, 4,5-diphenylimidazole reacts with benzophenone dichloride in boiling benzene to give the tetraphenyldiazafulvene *(17)*, which has already been synthesized by another route[3], and with 2-methylthio-1,3-dithiolanylium methyl sulfate to form the 6,6-dithiodiazafulvene *(18)*.

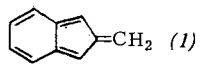
Isobenzofulvenes

By *K. Hafner* and *W. Bauer*[*]

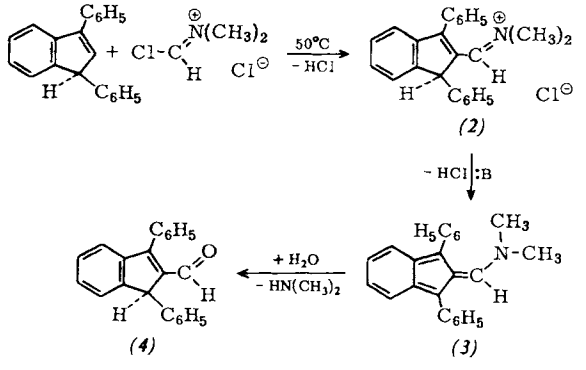
The hitherto unknown isobenzofulvenes (benzo[*c*]fulvenes) are of interest as being isosteric with isobenzofuran, isobenzothiophene, and isoindole, as well as with the still hypothetical nonafulvenes (cyclononatetraenefulvenes). Like fulvene, isobenzofulvene *(1)* should be stabilized by electron donors on the exocyclic C atom[1].



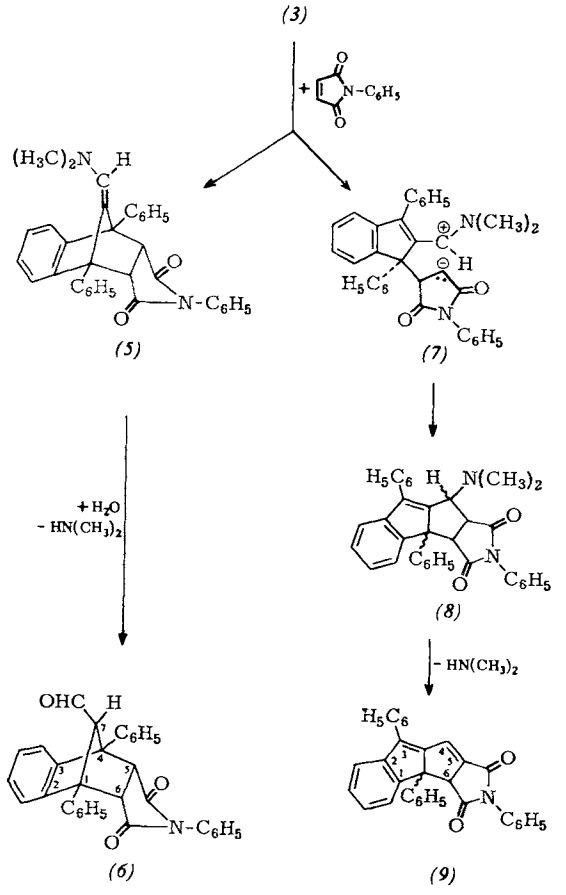
(1)

We have been able to confirm this assumption by the synthesis of *N,N*-dimethyl-*N*-(1,3-diphenyl-2-indenylidenemethyl)amine *(3)* [2].

1,3-Diphenylindene [3] reacts with chloromethylenedimethyliminium chloride in chloroform at 50 °C (about 8 days) to form *N,N*-dimethyl-*N*-(1,3-diphenyl-2-indenylmethylene)iminium chloride *(2)* in 83 % yield [light yellow crystals, dec. p. > 75 °C; UV spectrum in CH_2Cl_2: λ_{max} = 248 nm (ε = 9800), 270 (3200), 328 (11000), 379 (15400)]. The reaction of a suspension of *(2)* in ether/tetrahydrofuran (1:1) with diisopropylethylamine at −35 °C gives a deep blue solution. Removal of the solvent in a high vacuum gives *(3)* as dark blue, shiny prisms having m.p. 145–147 °C (from ether) [yield: 82 %; UV spectrum in tetrahydrofuran: λ_{max} = 250 nm (ε = 14900), 260 (14900), 339 (24800), 403 (26500), 593 (3540)]. The NMR spectrum (in $CDCl_3$ at 37 °C), which proves the structure of *(3)*, contains a singlet at τ = 2.01 (arising from the proton on the exocyclic C atom) and a multiplet centered at τ = 2.63 for the ten phenyl protons and the four protons of the fused benzene ring, as well as two singlets at τ = 6.89 and 7.36 for the two methyl groups of the tertiary amino group; in the NMR spectrum of *(3)* at 59 °C, the two signals combine to give one broad singlet at τ = 7.12.



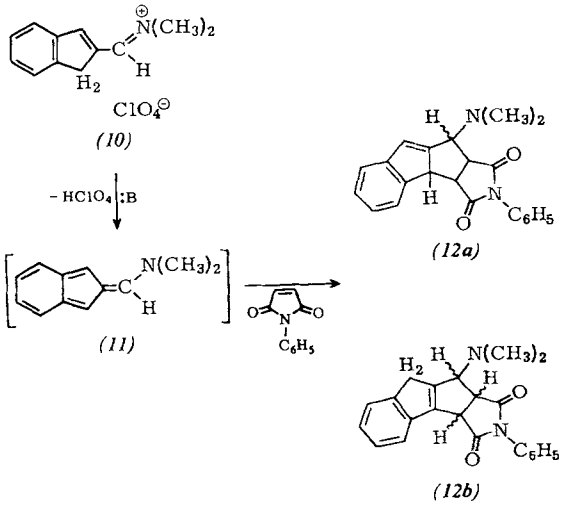
The mass spectrum of *(3)*, in addition to the molecular ion at *m/e* = 323, contains characteristic decomposition products at *m/e* = 246(M^+–C_6H_5),279(M^+–$N(CH_3)_2$), 308(M^+–CH_3) [4]. While *(3)* is stable by itself for a long time at room temperature in the absence of air, solutions of *(3)* in inert, aprotic solvents react rapidly with atmospheric oxygen to form a yellow resin; in the presence of water, *(3)* is hydrolyzed to 1,3-diphenylindene-2-carbaldehyde *(4)* [yield: 88 %; pale yellow prisms having m.p. 94–96 °C; UV spectrum in *n*-hexane: λ_{max} = 234 nm (ε = 18700), 239 (18500), 260 (8250), 265 (8100), 270 (7900), 307 (13500); NMR spectrum in $CDCl_3$: singlet at τ = 0.14 (CHO), multiplet centered at τ = 2.65 (aromatic protons), singlet at τ = 5.0 (H-1)]. Compound *(3)* combines with *N*-phenylmaleimide at 0 °C in ether/tetrahydrofuran (1:1) to form a green-yellow mixture, from which the products *(6)* [m.p. 238–240 °C; UV spectrum in dioxane: λ_{max} = 258 nm (ε = 1295), 264 (1015), 301 (75); NMR spectrum in $CDCl_3$: doublet at τ = 0.59 (*J* = 1.3 Hz) (CHO), multiplets centered at τ = 2.10 (four protons of the fused benzene ring) and at τ = 3.0 (15 aromatic protons of the three phenyl groups), singlet at τ = 5.39 (H-5, H-6), doublet at τ = 5.81 (*J* = 1.3 Hz) (H-7)] and *(9)* [m.p. 205–207 °C; UV spectrum in dioxane: λ_{max} = 222 nm (ε = 28400), 254 (22700), 375 (15800); NMR spectrum in $CDCl_3$: multiplet centered at τ = 2.47 (19 aromatic protons and H-4), doublet at τ = 6.0 (*J* = 2.6 Hz, allyl coupling, H-6)] formed by hydrolysis and by elimination of dimethylamine from the initially formed 1:1 adducts *(5)* and *(8)* could be separated by thin layer chromatography [silica gel PF_{254}, CCl_4-cyclohexane-isopropanol (30:30:1)].



The existing data are insufficient for a decision as to whether the compound *(6)* is the *exo* or the *endo* isomer. By analogy with the formation of corresponding Diels-Alder adducts of *N*-substituted isoindoles [5], the *endo* adduct *(5)* or its further reaction product *(6)* is probably formed first in the reaction of *(3)*.

The 1,3-cycloaddition to form *(8)* that accompanies the Diels-Alder reaction of *(3)* with *N*-phenylmaleimide probably proceeds by a two-step mechanism. A primary Michael addition with formation of the dipolar intermediate *(7)* is followed by the intramolecular cyclization of *(7)* to form the adduct *(8)*, which is stabilized by loss of dimethylamine to form *(9)*. A synchronous *cis* addition (1,3-dipolar cycloaddition) with formation of *(8)* [6] is incompatible with the Hoffmann-Woodward rules [7].

N,N-Dimethyl-*N*-(2-indenylmethylene)iminium perchlorate *(10)* [8] reacts with diisopropylethylamine in the same way as



the aldiminium salt *(2)*, with deprotonation. The expected *N,N*-dimethyl-*N*-(2-indenylidenemethyl)amine *(11)* has not yet been isolated as such, because of its low thermal stability.

Compound *(11)*, which is yellow-brown in solution (UV spectrum in CH_2Cl_2: λ_{max} = 364, 376 nm) reacts with *N*-phenylmaleimide at −40 °C to give a colorless 1:1 adduct having m.p. 215–216 °C. The UV spectrum (in *n*-hexane) [λ_{max} = 211 nm (ε = 28000), 217 (26000), 223 (23200), 258 (10100), 262 (9940), 267 (9000), 280 (3000), 286 (1100)] corresponds to that of an equimolar mixture of *N,N*-dimethyl-*N*-(2-indenylmethyl)amine and *N*-phenylsuccinimide, and so points to the formation of a 1,3 adduct having the constitution *(12a)* or *(12b)*; the NMR spectrum (in $CDCl_3$) of the adduct [multiplets centered at τ = 2.55 (9 H), 5.80 (3 H), 6.64 (2 H), and a singlet at τ = 7.68 (6 H)] is in agreement with a mixture of epimers of *(12b)*.

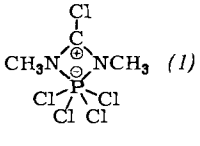
A Four-Membered Ring System Containing Hexacoordinated Phosphorus

By *H. P. Latscha* and *P. B. Hormuth*[*]

The reaction of *N,N'*-dimethylurea with phosphorus pentachloride (PCl_5)[1] in an inert solvent leads to the formation of a substance having the composition $C_3H_6Cl_5N_2P$. The compound is white, very sensitive to moisture, and melts at 129 °C after recrystallization from cyclohexane.

The ^1H–NMR spectrum in benzene against TMS as internal standard shows six equivalent methyl protons (δ = 2.67 ppm, J_{PH} = 20.8 Hz). The ^{31}P–NMR spectrum contains a signal at 202 ± 1 ppm (based on 85% H_3PO_4 as external standard), J_{PH} = 20 ± 1 Hz. This indicates a phosphorus atom having a coordination number of 6[2], and together with the elemental analysis, molecular weight, and IR spectrum, points to a 2,2,2,2,4-pentachloro-1,3-dimethyl-1,3-diaza-2-phosphonia^{VI}-cyclobutanide *(1)*.



(1)

Procedure:

1. For the preparation of *N,N'*-dimethylchloroformamidine hydrochloride see reference[1].

2. *N,N'*-Dimethylchloroformamidine hydrochloride is refluxed for five hours with PCl_5 (molar ratio 1:1) in CCl_4. The crude, slightly greenish product crystallizes out on concentration of the reaction solution. Recrystallization from anhydrous cyclohexane gives white crystals having m.p. 129 °C. The yield is almost quantitative.

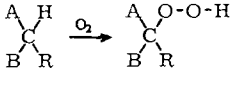
Autoxidation of Dimedone Derivatives

By *H. Bredereck, R. Franz,* and *G. Bauer*[*]

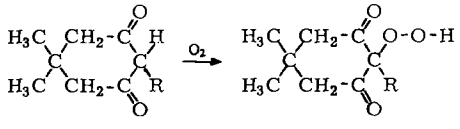
Hydroperoxides have until now been assumed to occur as intermediates in the initiation of the radical polymerization of vinyl monomers by means of CH-active compounds, atmospheric oxygen, Cu^{2+}, and Cl^-[1–3]. We have now



(1)

A and B = electron-withdrawing groups, R = H, alkyl

established their formation when dimedone derivatives are used as CH-active compounds. Dimedone hydroperoxides *(2)* were prepared for the first time by oxidation of dimedones with oxygen in benzene at room temperature.



(2)

(2), R =	Reaction time (h)	Crude yield (%)	M.p. (°C)
CH_3	12	40–50	55 (decomp.)
C_2H_5	12	35	81 (decomp.)
i-C_3H_7	12	40	116 (decomp.)
i-C_4H_9	15	30	90 (decomp.)
$C_6H_5CH_2$	2	70	119 (decomp.)

The hydroperoxides form colorless crystals that cannot be stored for long periods. They were identified by elemental analysis, iodometric titration, their reaction with lead tetraacetate, and their IR and NMR spectra.

The hydroperoxides that we have assumed to be formed during polymerization can decompose either thermally or on reaction with the cocatalysts Cu^{2+} and Cl^-[3,4]. For this reason we were able to isolate the hydroperoxides formed on autoxidation of dimedone derivatives only in the absence of these cocatalysts. In the case of benzyldimedone, however, we obtained the hydroperoxide also in the presence of Cu^{2+} and Cl^- because the extremely low solubility of the substance caused its immediate precipitation.

Procedure:

a) Reaction of the dimedone derivatives with R = CH_3, C_2H_5, i-C_3H_7, and i-C_4H_9: The dimedone derivatives (0.02 mole) are dissolved in benzene (50 ml) and shaken with oxygen at room temperature for 12–15 hours. The benzene is then distilled off in a rotary evaporator and the residue is purified by recrystallization from toluene or methanol.

b) Reaction of 2-benzyldimedone: 2-Benzyldimedone (0.03 mole) is suspended in benzene (50 ml) and, after addition of copper(II) acetylacetonate (1 mg) and lithium chloride (50mg), the solution is shaken with oxygen at room temperature for 2 hours. The starting material gradually dissolves and the hydroperoxide is obtained as a colorless flocculent precipitate that may be recrystallized from methanol.

Tris(organometalo)phosphine-pentacarbonylchromium and -dicarbonylnitrosylcobalt

By *H. Schumann* and *O. Stelzer* [*]

The properties and reactions of organometal-substituted phosphines suggested that the "lone" pair of electrons on the phosphorus atoms is involved in bonding by way of a (p → d)π interaction between phosphorus and germanium, tin, or lead [1]. Tris(organometalo)phosphines should therefore show little, if any, tendency to function as σ-donors in transition metal complexes.

After having prepared organometalophosphinetricarbonylnickel(0) [2], we have now succeeded in synthesizing further compounds containing coordinatively tetravalent phosphorus. The tris(organometalo)phosphinedicarbonylnitrosylcobalt complexes *(1)* are obtained almost quantitatively when tricarbonylnitrosylcobalt is allowed to react with tris(trimethylsilyl)-, tris(trimethylgermanyl)-, or tris(trimethylstannyl)-phosphine in tetrahydrofuran at room temperature, with stirring, for 24 hours. They are ruby-red substances that are moderately soluble in benzene, tetrahydrofuran, and cyclohexane; they are diamagnetic and may be isolated in a high state of purity by sublimation at 80–100 °C (10^{-5} torr). Like the isosteric organometalophosphinetricarbonylnickel(0) complexes, they are stable toward atmospheric oxygen but by way of contrast are found to have a higher thermal stability than the former.

$$(CO)_3Co(NO) + [(CH_3)_3M]_3P \longrightarrow \begin{matrix} OC \\ OC \\ ON \end{matrix}\!\!>\!Co\!-\!P\!<\!\begin{matrix} M(CH_3)_3 \\ M(CH_3)_3 \\ M(CH_3)_3 \end{matrix} + CO$$

(M= Si, Ge, Sn) *(1)*

(1), M =	Decomp.p. (°C)	J [^{1}HCM^{31}P] (Hz)	νCO (cm^{-1})	νNO (cm^{-1})	νPM_3 (cm^{-1})	νCoP (cm^{-1})
Si	100	5.5	2024 1965	1742	413 389	450
Ge	132	5.3	2016 1960	1739	392 376	440
Sn	190	3.6	2008 1938	1718	352 345	438

If a solution of hexacarbonylchromium and tris(trimethylsilyl)-, tris(trimethylgermanyl)-, or tris(trimethylstannyl)-phosphine in tetrahydrofuran at room temperature is irradiated for 5 hours with UV light [3], carbon monoxide is evolved and the tris(organometalo)phosphinepentacarbonylchromium(0) complexes *(2)* are formed.

$$Cr(CO)_6 + [(CH_3)_3M]_3P \longrightarrow (CO)_5Cr\!\leftarrow\!P[M(CH_3)_3]_3 + CO$$

(M = Si, Ge, Sn) *(2)*

(2), M =	Decomp. p. (°C)	J[^{1}HCM^{31}P] (Hz)	νCO (cm^{-1})	νPM_3 (cm^{-1})	νCrP (cm^{-1})
Si	100	4.85	2058 1934 1901	424	474
Ge	150	4.7	2057 1934 1904	389	461
Sn	190	3.3	2053 1927 1898	347	458

On removal of the solvent in vacuum, yellow crystals are obtained which sublime at 60–100 °C (10^{-5} torr). With the exception of the silicon compound, they are stable toward atmospheric oxygen, and, like the analogous cobalt complexes, they have a relatively high thermal stability.

The coupling constants J[^{1}HCM^{31}P] of the complexes are in some cases considerably greater than those of the free organometalophosphines (M = Si: 4.62 Hz, Ge: 4.00 Hz, Sn: 1.95 Hz). The IR spectrum of the chromium compounds contains the three CO stretching vibrations required by C_{4v} symmetry; the vibrations are shifted only slightly toward shorter wavelengths with increasing atomic weight of M because the influence of the ligands is distributed over five CO groups [4]. The IR spectrum of the cobalt complexes *(1)* shows two CO stretching vibrations and one NO stretching vibration. As the phosphine ligands increase in size, the CO and the NO stretching vibrations are also displaced toward lower wavenumbers. In addition to the internal vibrations of the trimethylmetal groups, three further bands between 4000 and 280 cm^{-1} are to be seen in the IR spectrum of the Co complexes; we assign these to the $\nu_s PM_3$, $\nu_{as} PM_3$, and the νP–Co vibrations. The IR spectrum of the chromium compound contains two bands in this region, which correspond to the νPM_3 and the νP–Cr vibrations.

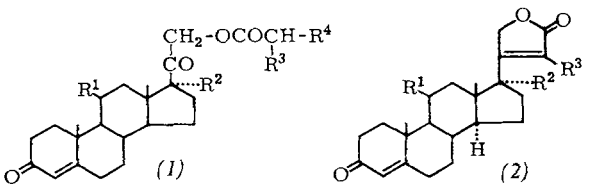
A New Cardenolide Synthesis

By *H.-G. Lehmann* and *R. Wiechert* [*]

When treated with alkali, 21-acyloxy-20-keto steroids *(1)* [1] undergo an intramolecular Wittig-Horner reaction to form cardenolides *(2)*.

Thus we were able to prepare 22-methyl-3-oxo-14α-carda-4,20(22)-dienolide *(2a)* (m.p. 243.5–245 °C, yield 51 %) by heating a mixture of 1-(3,20-dioxo-4-pregnen-21-yloxycarbonyl)ethyltriphenylphosphonium bromide *(1a)* with one equivalent of sodium hydride in dimethylsulfoxide, under



(a), $R^1 = R^2 = H$, $R^3 = CH_3$, $R^4 = P(C_6H_5)_3Br$
(b), $R^1 = R^2 = OH$, $R^3 = H$, $R^4 = P(C_6H_5)_3Br$
(c), $R^1 = R^3 = H$, $R^2 = OH$, $R^4 = PO(OC_2H_5)_2$

nitrogen, for four hours at 100 °C, pouring the mixture into acidified sodium chloride solution, filtration, chromatographic purification of the residue with hexane/acetone on silica gel, and recrystallization from ethyl acetate.

If a competing 17α-hydroxyl group is also present, it is advisable to use weaker bases. In such a case, we were able to isolate 11β,17-dihydroxy-3-oxo-14α-carda-4,20(22)-dienolide *(2b)* (m.p. 254–254.5 °C, yield 67 %) after refluxing (11β,17-dihydroxy-3,20-dioxo-4-pregnen-21-yloxycarbonylmethyl)triphenylphosphonium bromide *(1b)* with an excess of anhydrous potassium carbonate in *tert*-butanol for eight hours, working up, chromatographic purification, and recrystallization from ethanol.

On refluxing diethyl (17-hydroxy-3,20-dioxo-4-pregnen-21-yloxycarbonyl)methanephosphonate *(1c)* with an excess of potassium carbonate in *tert*-butanol for two hours, working up, and recrystallizing the product from ethyl acetate, we obtained 17-hydroxy-3-oxo-14α-carda-4,20(22)-dienolide *(2c)* (m.p. 267.5–270 °C, yield 51 %).

The UV spectrum of 17-hydroxy-3-oxo-5β,14α-card-20(22)-enolide, m.p. 240–242 °C, shows that the UV extinction coefficient $\varepsilon_{216} = 13\,300$ for the 17-hydroxy-20(22)-cardenolide system is lower than that for the corresponding 17-unsubstituted cardenolides [2]. The NMR signals for the 21-CH_2 group of the compound carrying no hydroxyl group on C-17 lie at 4.75 ppm (that of the olefinic proton on C-22 lies at 5.85 ppm), whereas the corresponding signals for 17-hydroxy-20(22)-cardenolides are to be found at 4.92 and 5.90 ppm (in $CDCl_3$ with $(CH_3)_4Si$ as internal standard).

The fact that this cyclization can also be applied to secondary ketol acylates was demonstrated by the reaction of *rac*-benzoin and 17β-hydroxy-3-methoxy-1,3,5(10)-estratrien-16-one.

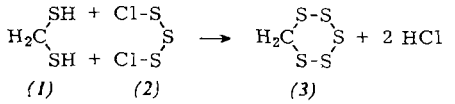
Synthesis of Pentathiane [1]

By *F. Fehér, B. Degen*, and *B. Söhngen* [*]

Tetrathiane (1,2,4,5-tetrathiacyclohexane) was first described a few years ago [2]; we have now succeeded in synthesizing pentathiane *(3)*. In contrast to cyclohexasulfur this compound is surprisingly stable and can be obtained relatively easily from methanedithiol *(1)* [3] and dichlorotrisulfane *(2)* [4] using the dilution technique.



(1) *(2)* *(3)*

When strongly heated *(3)* is converted mainly into cyclomethyleneheptasulfane [5]. The twelve-membered ring compound 1,7-dimethylenecyclododecasulfur, which ought to be formed by a four-center reaction, could not be isolated.

Procedure:

Methanedithiol (0.1 mole) and dichlorotrisulfane (0.1 mole) are each dissolved separately in 100 ml of water-free ether. The two solutions are added at the same rate from dropping funnels to 3.5 l of water-free ether; the reaction mixture is continuously stirred during the addition, which is carried out at room temperature and over a period of 12 hours. The hydrochloric acid and insoluble polymeric products formed in the reaction are then removed from the reaction mixture, the former by passage of a stream of dry nitrogen and the latter by filtration. The filtrate is concentrated in a rotary evaporator until the appearance of a slight turbidity. Cooling of the concentrated liquor for 24 hours at −10 °C results in the precipitation of *ca.* 5.1 g (29 % yield) of a coarse crystalline product (m.p. 90–93 °C). This crude product can be purified by dissolving it, with stirring, in 1 liter of water-free methylene chloride, and working up of the resulting solution after decantation from insolubles, *i.e.* by concentration in a rotary evaporator and subsequent cooling at −10 °C. 3.5 g of pure *(3)* is obtained (pale yellow crystals, m.p. 95–96 °C).

The composition and structure of *(3)* are proved by elemental analysis, cryoscopic molecular weight determination in carbon disulfide, and by the IR spectrum (KBr disk, ν_{CH} 2950 2890; ν_{CS} 692; ν_{SS} 456, 473, 488 cm^{-1}). The mass spectrum of *(3)* shows the presence of the molecular ion at $m/e = 174$ and fragmentation ions of low intensity at $m/e = 156$, 141, 123, 127, 112, 110, 78, 76, 64, 46, and 45. The UV spectrum of *(3)*, in cyclohexane [$\lambda_{max} = 285$ nm ($\log \varepsilon = 3.12$), 244 nm ($\log \varepsilon = 3.65$)] is similar to that of cyclohexasulfur [6]. The NMR spectrum of an approx. 10 % solution in carbon disulfide recorded at 23 °C shows two doublets centered at $\delta_1 = 3.584$ and $\delta_1 = 5.373$ (referred to TMS).

Treatment as an AB system yields a coupling constant $J = 14.0$ Hz and a shift of the two nuclei towards each other of $\nu_0\delta = 160.4$ Hz. Results of investigations of the temperature dependence of the NMR spectrum suggest that the six-membered ring inverts at high temperatures:

Preparation and Properties of Trifluorodithioacetic Acid

By *E. Lindner* and *H.-G. Karmann* [*]

Perfluorinated dithiocarboxylic acids were hitherto unknown. We have now succeeded in preparing trifluorodithioacetic acid *(3)* in fairly high yield by thiolysis of CF_3CN *(1)* with a mixture of liquid H_2S and HCl. The reaction proceeds in two stages and leads first, with evolution of a considerable

amount of heat, to trifluorothioacetamide *(2)*. On further thiolysis at 40 °C, compound *(2)* is converted into *(3)* within a period of two to three days.

$$\underset{(1)}{CF_3CN} + H_2S \xrightarrow[H_2S]{25\,^\circ C} \underset{(2)}{CF_3CSNH_2}$$

$$\underset{(2)}{CF_3CSNH_2} + H_2S + HCl \xrightarrow[H_2S]{40\,^\circ C} \underset{(3)}{CF_3CSSH} + NH_4Cl$$

The HCl present in the reaction mixture not only promotes the proton-catalyzed reaction but also serves to bind the NH_3 evolved as NH_4Cl, which being insoluble in liquid H_2S can then be readily removed.

Procedure:

CF_3CONH_2 (336 mmole) and P_4O_{10} (360 mmole) are mixed together and heated strongly. The reaction yields compound *(1)* which is collected in a cooled receiver (liquid nitrogen as coolant) and is subsequently distributed between three thick-walled tubes (each having a volume of *ca.* 75 ml). H_2S (four times the volume of *(1)*) is then condensed into the tubes, as well as 3–4 ml of HCl, and they are then sealed. In the course of the reaction that ensues when the tubes are allowed to warm to room temperature, compound *(2)* crystallizes out in the form of matted needles. Only when this stage has been reached are the tubes heated to a maximum of 40 °C, whereupon the vapor pressure of H_2S rises to 28.3 atm. Within 2–3 days, compound *(2)* is no longer visible and NH_4Cl precipitates out. The tubes are opened in an atmosphere of N_2. After evaporation of the unreacted H_2S and HCl and removal of the NH_4Cl by filtration, distillation in high vacuum (b.p. 25–30 °C/10^{-3} torr) yields the oxygen-sensitive acid *(3)* in 72 % yield (calculated with respect to CF_3CONH_2).

The composition and structure of *(3)* were established by elemental analysis and IR spectroscopic investigations (in CCl_4). The band at 2578 cm^{-1} (m) corresponds to the ν(S–H) stretching vibration, whereas the intense absorptions at 1299 (s), 1253 (vs), 1180 (vs), 1137 (s), 1115 (vs), and 1081 (m) cm^{-1} are to be attributed to the stretching vibrations of the CF_3 and the CS_2H groups. The spectrum of the deuterium compound CF_3CSSD, which is formed when *(3)* is shaken with D_2O, contains the ν(S–D) band at *ca.* 1870 cm^{-1}.

The highly viscous acid *(3)* is much more readily oxidized to the disulfide *(4)* by atmospheric oxygen than are non-fluorinated aliphatic dithio acids.

$$\underset{(3)}{2\,CF_3CSSH} + 1/2\,O_2 \rightarrow H_2O + \underset{(4)}{(CF_3CS)_2S_2}$$

The bis(trifluorothioacetyl) disulfide *(4)* is a light-yellow liquid that can be distilled in high vacuum at 80 °C/10^{-3} torr. The thermal instability of compound *(3)* is remarkable; decomposition of the acid with deposition of sulfur sets in at temperatures above 100 °C. It is readily soluble in the common organic solvents and also in alcohol when warmed (ester formation); however, it is completely insoluble in water.

If a solution of *(3)* in diethyl ether is slowly poured on to an aqueous solution of $Pb(NO_3)_2$, deep-yellow crystals of lead bis(trifluorodithioacetate) *(5)* are precipitated at the interface. When exposed to air, compound *(5)* decomposes within a few hours to a black substance (PbS).

$$\underset{(3)}{2\,CF_3CSSH} + Pb^{2+} \rightarrow \underset{(5)}{Pb(CF_3CSS)_2} + 2\,H^+$$

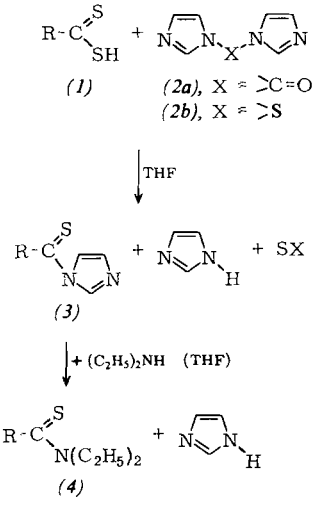
Synthesis of Thiocarboxamides by the Azolide Method

By *W. Walter* and *M. Radke* [*]

In connection with investigations on the preparative chemistry of azolides *Staab* synthesized various derivatives of thiocarbonic acids by way of *N,N'*-thiocarbonyldiimidazole [1]. The azolides have not hitherto been used for the synthesis of thioamides [2]. We have found that the reaction of dithiocarboxylic acids *(1)* with *N,N'*-carbonyldiimidazole *(2a)* or di-1-imidazolyl sulfide *(2b)* is suitable for the synthesis of the thioamides *(4)* of aromatic and aliphatic



carboxylic acids in one step without isolation of *(3)*. *N,N*-Diethylacetamide can, for example, be obtained in 28 % yield. In the reaction of *(2a)* with dithiobenzoic acid a number of by-products are formed which make the working up of the desired thioamide difficult; the reaction of *(2b)*, however, leads to the formation of pure *N,N*-diethylthiobenzamide in 49 % yield.

Birkhofer [3] prepared di-1-imidazolyl sulfide *(2b)* from *N*-trimethylsilylimidazole and SCl_2; we found that it could be prepared, in a state of purity satisfactory for the thioamide synthesis, by a method analogous to the Staab method [4].

Procedure:

a) Di-1-imidazolyl sulfide: A solution of 47.0 g (0.69 mole) imidazole in 500 ml anhydrous tetrahydrofuran (THF) is transferred to a 1-liter three-necked flask fitted with a KPG stirrer, a drying tube, and a 100 ml dropping funnel with pressure equalizer. 17.7 g (0.17 mole) of SCl_2, freshly distilled over phosphorus trichloride, is dissolved in 50 ml of anhydrous THF with vigorous stirring and then introduced dropwise into the flask over a period of 1/2 h. The mixture becomes slightly warm and turns yellow in color. After about 10 minutes a colorless precipitate separates out. After the addition of the SCl_2/THF solution is complete the mixture is stirred for a further 2 h. The precipitate is then filtered off by suction through a G4 sinter and the filtrate concentrated in a rotary evaporator at 50 °C (bath temperature) in the absence of moist air. The yellow crystalline di-1-imidazolyl sulfide which separates out is dried under oil-pump vacuum and stored under vacuum in a low-temperature cooling box. Yield 23.0 g (82 %), m.p. 80–85 °C (literature [3] m.p. 110–111 °C).

b) *N,N*-Diethylthiobenzamide: A solution of 5.4 g (35 mmole) of dithiobenzoic acid in 150 ml water-free ether and 100 ml anhydrous THF is transferred to a 500 ml three-necked flask fitted with a KPG stirrer, a drying tube, and a 50 ml dropping funnel with pressure equalizer. 6.6 g (40 mmole) of di-1-imidazolyl sulfide is added to the solution with stirring. The mixture becomes slightly warm and its

color changes from violet to light red. When all of the di-1-imidazolyl sulfide is in solution (after *ca.* 10 minutes), 45 ml anhydrous THF containing 4.3 ml (3.0 g; 41 mmole) of dry diethylamine is added dropwise to the mixture over a period of 30 minutes. The mixture is stirred for 1½ h and then concentrated in a rotary evaporator at 45 °C (bath temperature). The resulting red oil is dissolved in 100 ml $CHCl_3$, neutralized by washing twice with 100 ml 1 N H_2SO_4, and finally extracted with 100 ml portions of water until the aqueous extract is colorless. The organic phase is then concentrated in a rotary evaporator at 45 °C (bath temperature). A green oil is obtained which solidifies as greenish yellow crystals on cooling [crude yield 5.6 g (83 %)]. The crystals are dissolved in ethanol, insoluble sulfur is removed, and the solution is treated dropwise with water until a definite turbidity appears. On standing, diethylthiobenzamide crystallizes from the solution as greenish yellow needles [pure yield 1: 3.8 g (57 %)]. For further purification, an ethanolic solution of the product is boiled with activated charcoal for 15 minutes, filtered, and the filtrate treated with water. Chromatographically pure diethylthiobenzamide is obtained as pale yellow needles, m.p. 41–42 °C [pure yield 2: 3.3 g (49 %)].

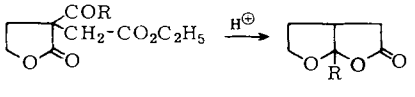
Synthesis of Hexahydrofuro[2,3-*b*]pyrrol-2-ones

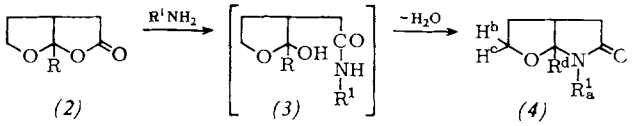
By *C. Lange*, *H. Wamhoff*, and *F. Korte* [*]

In a recent attempt to synthesize β-acyl-δ-lactones [1] from α-acyl-α-ethoxycarbonylmethyl-γ-lactones *(1)* we obtained, by a special type of acyllactone rearrangement [2], hexahydrofuro[2,3-*b*]furan-2-ones *(2)* [3].



(1) *(2)*

By virtue of their acetal-type structure these lactones can be converted into hexahydrofuro[2,3-*b*]pyrrol-2-ones *(4)* under comparatively mild conditions.

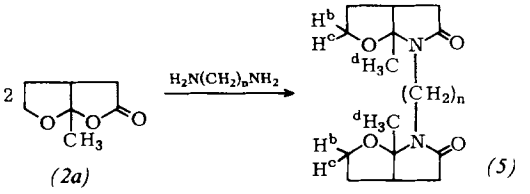


(2) *(3)* *(4)*

	R	R^1	Yield (%)	M.p. (°C) [B.p. (°C/0.01 torr)]
(4a)	CH_3	H	61	145–146
(4b)	C_5H_{11}	H	47	109
(4c)	CH_3	C_3H_7	63	[47–48]
(4d)	CH_3	C_4H_9	51	[59–60]
(4e)	CH_3	C_5H_{11}	67	[72–73]
(4f)	CH_3	C_8H_{17}	74	[92–93]
(4g)	CH_3	C_6H_5–CH_2	85	[100]

One must assume – similarly to the observations reported by *Barton* [4] in his investigation of the terpenoid bitter principle clerodin – the formation of the semiacetal amide *(3)* as an intermediate, which subsequently undergoes ring closure with loss of water.

Bifunctional amines react with two equivalents of lactone to form the 1,1′-alkylenebi(hexahydrofuro[2,3-*b*]pyrrol-2-ones) *(5a)* [*n* = 2, m.p. 160 °C, yield 46 %] and *(5b)* [*n* = 4, m.p. 155 °C, yield 41 %].



(2a) *(5)*

The following spectral data are found to be in agreement with the suggested structures: The IR spectrum (in $CHCl_3$) of *(4a)–(4g)* shows a carbonyl vibration at 1690–1700 cm^{-1}; the spectra of *(5a)* and *(5b)* show carbonyl bands at 1670 to 1675 cm^{-1}. In the NMR spectra (in $CDCl_3$; for TMS $\tau = 10$) most of the protons give rise to strongly coupled signals. In the spectra of *(4a)* and *(4b)* signals occur which can be ascribed to the lactam protons H^a at $\tau = 2.76$ and 3.23 resp. The signals assigned to the methyl protons H^d of *(4a)*, *(4c)–(4f)*, *(5a)*, and *(5b)* occur – similarly to the corresponding signals of *(2a)* [3,5] – between $\tau = 8.4$ and 8.5 whilst the methylene group H^b/H^c occurs as an AB part of an AB–MN spectrum, a complex group of signals between $\tau = 5.9$ and 6.5.

Synthesis of (4) and (5):

The lactone *(2)* is either boiled with a threefold excess of a primary amine in ethanol for 6 h or heated with liquid ammonia in an autoclave at 90–100 °C for 1 h. Bifunctional amines react with two equivalents of *(2a)*, at the temperature of boiling, within 20 h. Compounds *(4a)*, *(5a)*, and *(5b)* precipitate as solids whereas the other lactams are isolated as oils and are purified by distillation.

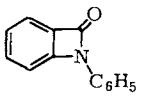
N-Phenylnaphtho[2,3-*b*]azetinone

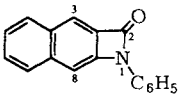
By *G. Ege* and *E. Beisiegel* [*]

The existence of *N*-phenylbenzoazetinone *(1)* in solution has been proved by trapping reactions [1] and by IR spectroscopy [2].

The formal similarity of the aceneazetinones *(1)* and *(2)* and the acenecyclobutadienes, of which the 1,2-diphenylnaphtho[*b*]cyclobutadiene has been prepared by *Cava et al.* [3], led



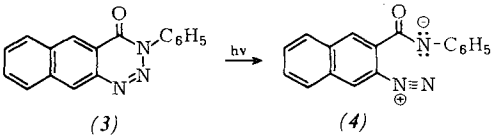
(1)



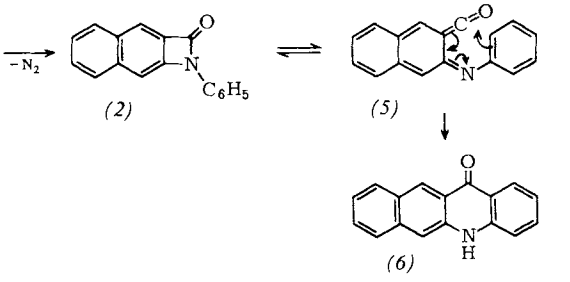
(2)

us to attempt the synthesis of *N*-phenylnaphtho[2,3-*b*]-azetinone *(2)*.

When a solution of 3-phenyl-3,4-dihydronaphtho[2,3-*d*]-1,2,3-triazin-4-one *(3)* [m.p. 226 °C, UV in CH_2Cl_2: 365 nm (ε = 6800); 348 nm (ε = 8500), 265 nm (ε = 44500), 246 nm (ε = 28300); IR (KBr): CO at 1700 cm^{-1}] in tetrahydrofuran is irradiated under a high-pressure mercury-vapor lamp (450 W, Hanovia) one equivalent of nitrogen is evolved with formation of *N*-phenylnaphtho[2,3-*b*]azetinone *(2)* and benzo[*d*]acridone *(6)*. After chromatographic working-up (silica gel, CH_2Cl_2) these compounds are isolated in yields of 92 % and 5 % respectively.



(3) (4)



(2) (5) (6)

Compound *(2)* is recrystallized from ether as golden-yellow rods, m.p. 155 °C, mol. wt. (osmometric) 245.8, (mass spectrometric) 245, UV (in CH_2Cl_2): 394 nm (ε = 2000), 276.5 nm (ε = 52000), 232 nm (ε = 36000). The β-lactam structure follows from the IR spectrum, in which a CO band appears at 1805 cm^{-1} in KBr (1815 cm^{-1} in CH_2Cl_2); it is remarkable that this band is shifted *ca.* 60 cm^{-1} to higher wavenumbers than is the corresponding CO band in the spectrum of 1,4-diphenyl-3-azetin-2-one[4]. The NMR spectrum of *(2)* shows a multiplet of aromatic protons between τ = 2.2 and 3.1 ($CDCl_3$); one proton, possibly the C-8 one, shows a greater upfield shift than the others and appears at τ = 3.07. In this region the spectrum of *(2)* resembles that of methyl 3-amino-2-naphthoate.

If compound *(2)* is boiled in methanol or heated in morpholine, the well known methyl 3-phenylamino-2-naphthoate or the morpholide, m.p. 155–156 °C, is obtained. The diazonium intermediate *(4)* probably occurs[5] during the formation of *(2)* from *(3)*; *(6)* is formed from *(2)* by valence isomerization to the non-isolable ketene *(5)*[6] and subsequent cyclization. We have obtained evidence for this reaction course by photolyzing compound *(2)*, from which we obtained *(6)*.

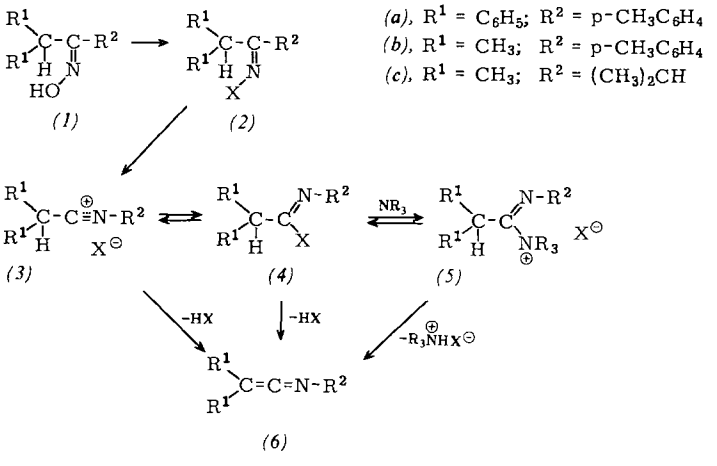
Preparation of Ketene Imines by a Beckmann Rearrangement

By *S. Hünig* and *W. Rehder*[*]

The Beckmann rearrangement of oximes *(1)* is initiated by conversion of the oximo hydroxyl function into a nucleofugal leaving group[1]. The intermediate *(2)* yields the nitrilium ion *(3)*[2], which was suspected some time ago[3] and which can exist in equilibrium with the imidic acid *(4)*. This imide *(4)* – and thus also compound *(3)* – can eliminate HX to form the ketene imine *(6)*, the existence of which is proved by its synthesis from the chloro imide *(4)*, X = Cl, with triethylamine in boiling toluene[4]. It is possible that compound *(5)* also plays a role[5].



Therefore all Beckmann rearrangements, which are carried out in aprotic solvents in the presence of a sufficiently strong, weakly nucleophilic base, should yield ketene imines *(6)*, which can be recognized by their intense IR absorption at *ca.* 2000 cm^{-1}[4].

These conditions apply, *e.g.*, for oxime sulfonates *(2)*, X = RSO_3[5,6]. Whereas esterification of the sterically hindered OH group in *(1a)–(1c)* proves difficult with benzenesulfonyl chloride, *(2a)–(2c)*, X = CH_3SO_2[8], are formed within 15 min when the reaction is carried out with methanesulfonyl chloride + triethylamine (even at −15 °C in toluene) owing to the formation of the intermediate sulfene[7]. On heating with an excess of triethylamine in toluene at 100 °C, the Beckmann rearrangement affords *(6)*. Thus *(1a)* yields a solution containing 95 % of *(6a)* within 20 min, *(1b)* gives a solution containing 83 % of *(6b)* after 90 min, and *(1c)* affords a solution containing 80–90 % of *(6c)* after 55 min. (The yields were determined by comparing the intensities of the IR bands of *(6a)* and *(6b)*[4] with standard solutions.) The hitherto unknown compound *(6c)* is one of the few completely aliphatic ketene imines[4b,9], Treatment of 3.3 mmoles of *(1a)* according to *Stevens*[10] affords *(6a)*, m.p. 79–80 °C, in 38 % yield.

As starting materials we used the pure R^1R^1CH-*syn*-oximes *(1)* whose constitutions were proved by Beckmann rearrangement to the corresponding toluidides and by the low frequency of the C–H signal in the NMR[11]. *(1a)*: m.p.

190–191 °C from methanol, δ = 6.25 ppm (singlet) in DMSO; *(1b)*: m.p. 96–97 °C from *n*-pentane[12], δ = 3.57 ppm (septet) in CCl_4.

These results are being published[13] because the reaction the sequence *(1)* → *(6)* has meanwhile been realized[15] by addition of triphenylphosphine dibromide, whose reaction with benzaldoxime was known[14].

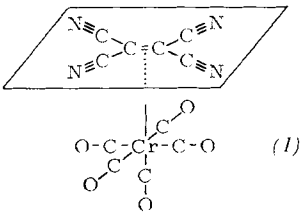
New Metal Complexes of Tetracyanoethylene

By *M. Herberhold*[*]

Treatment of $Ni(CO)_4$ with tetracyanoethylene (TCNE) leads, *via* a redox reaction[1,2], to the formation of the salt $Ni^{2+}(TCNE^-)_2$[1]. If the yellow solution of TCNE in benzene is irradiated in the presence of a hexacarbonylmetal $M(CO)_6$, replacement of a CO ligand takes place and the monosubstituted product $(TCNE)M(CO)_5$ (M = Cr, Mo, W) is formed. This photochemical substitution, by means of which the first TCNE complexes of the metals of the sixth sub-group could be synthesized, depends upon primary fission of CO from the metal carbonyl and stabilization of the light-sensitive TCNE complex by the aromatic solvent.

In the solid state, the intense blue-violet tetracyanoethylene-pentacarbonylchromium(0) *(1)* (decomp. at 102 °C with black coloration) is stable to air but somewhat sensitive to light. In solution it slowly decomposes, the decomposition being considerably accelerated on exposure to light; the intense green solutions in aromatic hydrocarbons are the most stable. Donor ligands [amines, CH_3CN, $P(C_6H_5)_3$] replace the TCNE of the complex.



(1)

The suggested structure *(1)*, with π-bonded TCNE as monoolefinic ligand, is based on the following findings:

1. The composition $(C_6N_4)Cr(CO)_5$ is established by elemental analysis and by mass spectrometry. The mass spectrum[3] shows the presence of the molecular ion (*m/e* = 320) and the fragment ions (*m/e* = 292, 264, 236, 208, and 180) which are expected to arise by stepwise loss of the CO ligands. The most abundant fragment ion is $Cr(C_6N_4)^+$ (*m/e* = 180). In the mass spectrometer, compound *(1)* decomposes to $Cr(CO)_6$ and TCNE.

2. The IR spectrum of *(1)* shows only one sharp C≡N stretching vibration at 2203 cm^{-1} (KBr), which is shifted toward lower wave numbers compared to the corresponding stretching vibration in the spectrum of TCNE[4] ($\nu C{\equiv}N$ = 2262 and 2222 cm^{-1}). This indicates the filling of antibonding orbitals in the cyano groups and is in accord with the occurrence of back-bonding from metal to ligand as has been established in other olefin-π-complexes. In the TCNE complexes $(PR_3)_2Pt(C_6N_4)$ ($\nu C{\equiv}N$ = 2222 cm^{-1})[5] and $[(P(C_6H_5)_3]_2Rh(CO)Cl(C_6N_4)$ ($\nu C{\equiv}N$ = 2230 cm^{-1})[6], once again only one strong $\nu C{\equiv}N$ absorption was observed. An unsymmetrical coordination of the ligand *via* the lone pair on the nitrogen atom or *via* the π system of a cyano group can therefore be ruled out.

3. The electronic spectrum of *(1)* is characterized by an intensive charge-transfer band ($\varepsilon \approx 1\times10^4$–$2\times10^4$ liter $mole^{-1}$ cm^{-1}), whose λ_{max} value depends strongly on the solvent. In the reflectance spectrum with LiF as standard white, a broad structureless maximum occurs at 760–820 nm; λ_{max} in the absorption spectrum occurs, depending upon the donor properties of the solvent, at 786 (mesitylene), 822 (toluene), 836 (benzene), 845 (nitrobenzene), 802 (acetonitrile), 878 (cyclohexane), or 900 nm (chloroform). The solvent molecules apparently envelope the π-bonded cyanoolefin, whose acceptor capacity for charge transfer from metal to the TCNE is thus varied.

A structure with π-bonded TCNE can also be assumed for the homologous blue-violet compounds $(TCNE)M(CO)_5$ (M = Mo, W). The analogous reaction of $C_5H_5Mn(CO)_3$ with TCNE leads to formation of a blue-green complex, whose ^1H-NMR spectrum (in [D_6]-acetone) contains a signal ascribable to the five-membered ring protons at about τ = 0.57 further downfield than the corresponding signal (at τ = 4.95) in the spectrum of $C_5H_5Mn(CO)_3$.

Procedure: $(TCNE)Cr(CO)_5$

0.550 g (0.0025 mole) of $Cr(CO)_6$ and 0.256 g (0.0020 mole) of TCNE are dissolved in 200 ml of benzene that is saturated with N_2 and irradiated with a high-pressure mercury-vapor lamp (Hanovia 450 W), which is housed in a water-cooled Jenaer glass jacket. When decomposition sets in and a darkening in the color of the green solution is observed (after *ca.* 4 hours), the mixture is fitered through a G3 sinter in a nitrogen atmosphere and the filtrate irradiated until the beginning of further decomposition (after *ca.* 2 hours). The clear green filtrate is then evaporated to dryness and the blue residue thus obtained is heated at 40–45 °C under vacuum until all the $Cr(CO)_6$ and TCNE has evaporated off (*ca.* 8 hours). The blue crude complex *(1)* (yield 0.08–0.10 g, 12.5–15.5 %) can be further purified by dissolution in

toulene at 50 °C followed by recrystallization with *n*-hexane at −95 °C. Small amounts of analytically pure complex, in the form of deep violet crystals, can be obtained by sublimation under vacuum at 45–50 °C; however, 95 % decomposition must be allowed for.

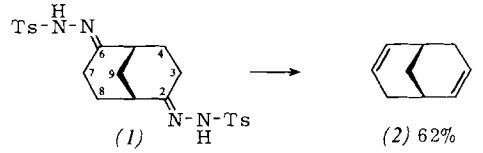
CONFERENCE REPORTS

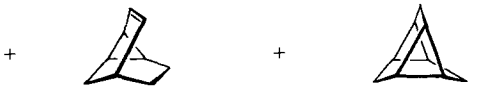
Asteranes

By *H. Musso* [*]

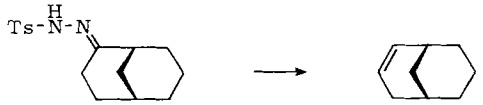
Decomposition of the bis(tosylhydrazone) *(1)* by sodium 2-hydroxyethoxide in ethylene glycol affords as main product the 2,6-diene *(2)*, as well as the tricyclic compound *(3)* and triasterane *(4)*; insertion to the 9-position or from the 2- to the 4-position in *(1)* was not observed [1]. However, in the analogous reaction of the monoketone derivative *(5)* *H. Klusacek* isolated tricyclo[4.3.0.0^{2,9}]nonane *(8)* as well as *(6)* and *(7)*; and *(8)* could be hydrogenated to bicyclo[3.3.1]-nonane and perhydroindane.



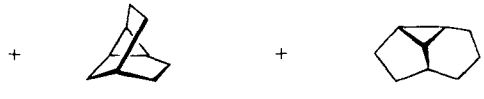
(1) *(2)* 62%



(3) 26% *(4)* 10%



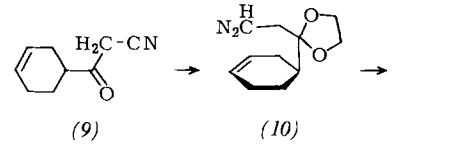
(5) *(6)* 81%



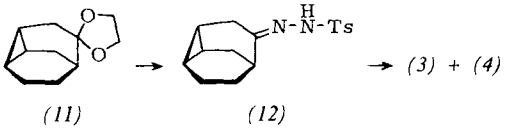
(7) 7.5% *(8)* 11.5%

A new synthesis of triasterane *(4)* starts with 3-cyclohexene-carboxylic ester, which is readily accessible by a diene reaction and condenses with acetonitrile to give *(9)*. Protection of the carbonyl group, hydride reduction of the nitrile to the amine, and cleavage of the alkylnitrosourea derived therefrom led to the diazo compound *(10)* which was decomposed by copper powder in cyclohexane to the protected tricyclic ketone *(11)* and two further products. The ketone obtainable from *(11)* afforded a tosylhydrazone *(12)* which with sodium 2-hydroxyethoxide in ethylene glycol again decomposed to a mixture (6:4) of *(3)* and *(4)* (*H. Klusacek*).

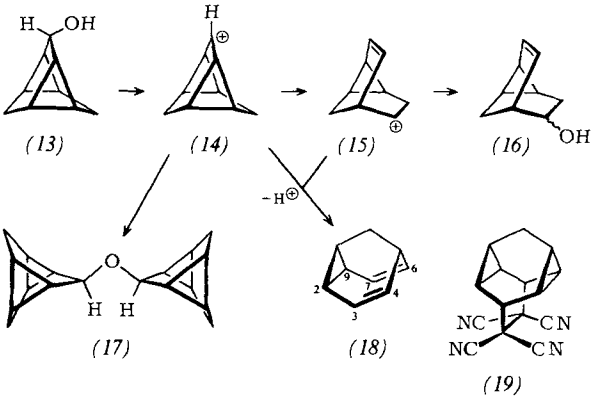
According to experiments by *U. Biethan* the alcohol *(13)* that is obtained from triasteranone on treatment with $LiAlH_4$ is rather unstable. In the crystalline state and in pentane over $Mg(ClO_4)_2$, *(13)* gives good yields of the ether *(17)*, and in water at 50 °C rearranges to the unsaturated alcohol *(16)*.



(9) *(10)*



(11) *(12)* → *(3)* + *(4)*



(13) *(14)* *(15)* *(16)*

(17) *(18)* *(19)*

In presence of strong bases the carbonium ion *(14)* → *(15)* loses a proton with formation of the diene *(18)* [2], which reacts with tetracyanoethylene in benzene at 20 °C to give the homo Diels-Alder adduct *(19)*. The NMR-spectrum indicates constitution *(19)* and unequivocally disproves structures which would be produced by addition at the 4,6- or 2,6-positions.

Kinetic Investigations with Solid Electrolytes

By *H. Rickert*[*]

Solid state galvanic cells have two properties that are important for kinetic studies: (1) reaction velocities can be measured in suitably constructed cells by means of the electric current and (2) the EMF of the cells provides thermodynamic information, particularly about chemical potentials or activities. The combination of velocity measurements with determination of thermodynamic parameters often permits analysis of kinetic processes. Four typical examples were discussed:

a) Diffusion of oxygen in solid and liquid metals.

b) Evaporation and condensation of sulfur, selenium, and iodine from and on to their solid metal compounds (including description of electrochemical Knudsen cells for study of the thermodynamics of vapors, *e.g.*, sulfur and selenium vapor).

c) Passage of Ag ions and electrons through the phase boundary Ag_{solid}/Ag_2S_{solid}.

d) The kinetics of formation of NiS_{solid} from Ni at 400 °C.

Lecture at Hannover (Germany), on November 23, 1967 [VB 125 IE]

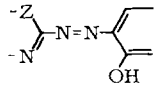
Heterocyclic Azo Dyes in Complex Chemistry and in Analytical Chemistry

By *L. Sommer*[*]

For many years azo dyes have been used as sensitive reagents in analytical chemistry (*e.g.*, for trace analysis and spectrophotometric determination of metals, also as indicators for metals in chelatometric titrations). N-Heterocyclic azo dyes



containing the characteristic donor grouping have won a special place. Dyes of the pyridine, thiazole, triazole, and tetrazole series normally form red or reddish-orange metal chelates, and derivatives of *p*-cresol, *p*-methoxyphenol, and chromotropic acid blue or green metal chelates which are more or less soluble in water. Metal ions with empty or with full or partly filled d-orbitals are particularly reactive. Analytically the most valuable reactions of heterocyclic dyes are those with ions of Cu^{II}, Zn, Cd, Sc, lanthanides, Ti^{IV}, V^{V}, Nb^{V}, Fe^{II}, Fe^{III}, Co^{II}, Ni^{II}, Pd^{II}, Ga, In, Tl^{III}, Pb^{II}, and UO_2^{2+}. No analytical importance attaches to the reactions of Be, Ca, Sr, Ba, Al, Sb^{III}, Cr^{III}, Mo^{VI}, or W^{VI} unless additional donor groups are present in the dye molecule.

Complex formation in solution has been studied for 4-(2-pyridylazo)resorcinol (PAR) and 4-(2-thiazolylazo)resorcinol (TAR) and compared with that of 1-(2-pyridylazo)-2-naphthol (PAN) and its thiazole analog (TAN).

PAR and TAR give protonated and "normal" 1:1 metal chelates over a broad pH range; at pH $\geqslant$ 5 in solutions containing an excess of reagent, 1:2 chelates are also formed, but only with difficulty and not always by Cu^{II} and not at all by uranyl.

Loss of the proton from the hydroxyl group on self-dissociation of the dye, and formation of a protonated metal chelate, must be taken into account when formulating the complex constants; so must the formation of hydroxychelates of In, Ga, and Tl^{III} in the hydrolysis range of these ions. The acidity of the *p*-hydroxyl proton is appreciably increased by formation of a stable protonated metal chelate as well as by presence in solution of an excess of metal ions of higher valence. PAN and TAN preferentially afford coordinately saturated metal chelates, which dissolve also in slightly polar solvents. Formation of 1:3 and 1:4 chelates of the lanthanides is an exception to the otherwise strictly maintained tridenticity.

The stability of metal chelates of N-heterocyclic azo dyes, as well as the tendency to complex formation of metal ions with this group of ligands, are with few exceptions directly proportional to the electronegativity of the metals (calculated with regard to their valence): $Pd^{II} > Cu^{II} > UO_2^{2+} > Fe^{II} > Ni^{II} \sim Co^{II} > Pb^{II} > Zn > Cd \sim Mn^{II}$; $Tl^{III} > Bi > Ga > Fe^{III} > In > Sc > Al >$ lanthanides $> Y > La$ The thiazole azo dyes are found to give chelates that are less stable than those obtained from pyridine azo dyes.

Coordination of the metals proceeds in two steps: the first involves bonding of the heterocyclic nitrogen, and the second is closure of the chelate ring by way of the *o*-hydroxyl oxygen and the azo nitrogen atom situated farthest from the heterocyclic nitrogen.

Chemisorption on Metal Films

By *G. Wedler*[*]

Changes in the physical properties of thin metal films on adsorption of gases can often be used for a study of the nature of the bonding between adsorbent and adsorbate. Since properties, such as the electrical conductivity and photoeffect, of evaporated films often differ markedly from those of the compact material, interpretation of adsorption effects requires a knowledge of the properties of films. We have studied Ni films of systematically varied thickness that were condensed at 77 °K in ultra-high vacuum at a rate of *ca.* 10 Å/min and then annealed at increasing temperatures. Electron-microscopical and X-ray-diffraction measurements show that the crystals are small plates and increase in size with increasing layer thickness and annealing temperature; the crystallites are arranged mostly with the {111}, and to a smaller extent with the {100}, faces parallel to the glass support[1]. The texture of the crystallites is dependent on the conditions of preparation. Because of the different coefficients of thermal expansion of the glass support and the metal film the annealed films are under a stress which leads to a decrease in the separation between the network planes that lie parallel to the support.

By applying Sondheimer theory to the dependence of electrical resistivity of the film on layer thickness the mean free path l_0 of the conduction electrons and the specific resistance ρ_0 can be determined for compact material that has the same volume density of impurity centers as the film. l_0, ρ_0, and analysis of the line profile of the X-ray reflections lead to the same conclusions about increase in the degree of order of the originally disordered films with increasing temperature.

Study of the dependence of the electron work function on layer thickness and temperature shows that for unannealed Ni films condensed at 77 °K the work function is the same, φ = 4.59 V, down to layer thicknesses of 40 Å. With rise in annealing temperature φ increases – more for thin than for thick films – so that films annealed at 373 °K give a constant work function of 4.95 V only at thicknesses of $>$ 200 Å.

When considering adsorption effects it is advisable either to study their dependence on the thickness of the metal films or

simultaneously to carry out other measurements that afford thermodynamic values.

Thus it is found, for instance, with the system Ni/CO that the increase in resistance observed as a consequence of adsorption cannot be explained by a change in the electron concentration or a decrease in the effective film thickness due to formation of a compound on the surface. However, if the fact is taken into consideration that a change in the number of free electrons must alter their mean free path, then the dependence of the increase in resistance on the film thickness, as measured, can be described correctly and quantitatively.

Information about the various species of an adsorbate occurring side by side in one system can be obtained by combining measurements of the electrical resistance, electron work function, and differential heats of adsorption and, if possible, studying their temperature dependence. Thus it can be shown that in the system Ni/H_2 at equilibrium pressures of $< 10^{-4}$ torr and 273 °K there is no molecularly adsorbed hydrogen (as there is at 77 °K) but that account must be taken of a second atomically sorbed species.

Rhenium(VII) Oxide and "Perrhenic Acid"

By *B. Krebs* [*]

The structure and coordination state of solid Re_2O_7 and of solid "perrhenic acid" have hitherto been unknown. Attempts to predict the constitution on the basis of spectral data and thermodynamic data did not lead to unambiguous results. The structure of both compounds has now been clarified in detail by X-ray structure analysis; this gave at the same time the composition of "perrhenic acid" that was not determined analytically in previous work. Both structures are characterized by unusual coordination relations. ReO_6 octahedrons and ReO_4 tetrahedrons, largely covalently bound, occur together.

Dirhenium heptoxide crystallizes in space group $P2_12_12_1$ (D_2^4) with $a = 12.508$, $b = 15.196$, $c = 5.448$ Å, $Z = 8$, and presents a new type of structure that has no direct relation to other oxide structures [1]. Chains of ReO_6 octahedrons, joined together at corners, are linked by corners to ReO_4 tetrahedrons in such a way that a polymeric double-layer lattice arises. The double layer can be described as an arrangement of rings comprising four polyhedrons linked at their corners (O–T–O–T) and in turn linked to one another by octahedrons. The separations in the tetrahedrons are between 1.68 and 1.81 Å, the terminal bonds being shorter than the bridge bonds in accord with their higher bonding order. The octahedrons are strongly distorted: Re is shifted from the center parallel to one of the three-fold octahedral axes (three Re–O distances between 2.06 and 2.16, the remaining three between 1.65 and 1.75 Å). Re_2O_7 thus constitutes a transition between the structure of the more strongly ionic oxides MoO_3 and WO_3 (distorted octahedral six-coordination) and the molecular structures of RuO_4 and OsO_4 (tetrahedral four-coordination). The mechanism of evaporation of the oxide with formation of Re_2O_7 molecules with tetrahedral coordination can be readily deduced from the structure.

Solid "perrhenic acid" (which can be recrystallized from organic solvents) has a molecular structure in which also distorted ReO_6 octahedrons occur alongside ReO_4 tetrahedrons (in the binuclear compound one octahedron is joined by a corner to one tetrahedron) [2]. The fact that two of the terminal Re–O bonds of the octahedron are very much longer (2.21 Å) than any of the others (octahedron, terminal 1.73–1.76 Å; bridge 2.10 and 1.80 Å; tetrahedron, terminal 1.73–1.77 Å) is in agreement with the broad-line ^1H–NMR spectrum and the IR spectrum in indicating that the compound is correctly formulated as dihydratoheptaoxidodirhenium $Re_2O_7(OH_2)_2$ with trebly linked oxygen in the H_2O.

Preparative Chemistry of Chalcogenides

By *A. Rabenau* (Lecturer) and *H. Rau* [*]

If hydrogen sulfide is passed into an aqueous solution of a lead salt in the presence of free hydrohalogen acid, the first, precipitate is not black PbS but materials whose color changes from yellow *via* orange to red and finally *via* brown to black. The nature of these precipitates is an old problem of preparative chemistry. As early as 1836 *Hünefeld* [1] ascribed the composition $3\ PbS \cdot 2\ PbCl_2$ to a red precipitate obtained in this way from a solution containing hydrochloric acid. *Parmentier* [2] isolated from solutions containing hydrochloric or hydrobromic acid red precipitates which, according to analyses, should have formulas $PbS \cdot PbCl_2$ or $PbS \cdot PbBr_2$, respectively. *Lenher* [3] found $PbS \cdot 4PbI_2$. Since the low stability of the precipitates makes it impossible to separate preparatively the several phases constituting the mixture and X-ray control was not available at that time, the question of the existence of lead sulfide halides remained open.

On hydrothermal synthesis of PbS in concentrated hydrohalogen acids [4] we have isolated deep red single crystals of the composition $Pb_5S_2I_6$ *(1)* and $Pb_7S_2Br_{10}$ *(2)* [5]. Thermoanalytical and X-ray studies show that these are stable ternary phases in the pseudobinary systems $PbS–PbI_2$ and $PbS–PbBr_2$; they decompose peritectically at 418 *(1)* and 381 °C *(2)*, respectively. Analysis of the *d*-values of a compound "$PbS \cdot PbBr_2$" [6] showed that the preparation consisted of *(2)* and $PbBr_2$.

Experiments carried out on precipitates obtained from solutions containing hydrobromic acid showed that the precipitates consisted of PbS, *(2)*, and a still unidentified further phase in proportions that varied with the concentration of HBr.

No crystals other than $PbCl_2$ or PbS were observed during hydrothermal synthesis in concentrated hydrochloric acid. However, a ternary phase, Pb_4SCl_6, was found on rapid cooling of melts of the system $PbS–PbCl_2$; it was obtained in pure crystalline form on quenching a melt of this composition from 600 °C. This compound is metastable and decomposes into the binary components when kept at temperatures between 200 and 450 °C (eutectic).

Biochemistry of Phosphatides Containing Vinyl Ethers (Plasmalogens)

By *Hildegard Debuch*[*]

Plasmalogens [2-acyl-1-(1-alkenyl)-*sn*-glycero-3-phosphoryl compounds[**]] occur, usually as choline or 2-aminoethyl esters, *in almost all animal cells and tissues*. By mild acid hydrolysis the aldehyde that is bound like a vinyl ether is liberated and a corresponding β-lysophosphatide is formed, whereas on mild alkaline hydrolysis a lysoplasmalogen is obtained. An "ether phosphatide" is obtained on catalytic hydrogenation. (Such compounds often occur in small amounts also in Nature.)

Plasmalogens are, specifically, components of the lipid mixtures that are obtained from myelin sheaths of nerve fibers (occurring there almost exclusively as 2-aminoethyl esters) and from the phosphatide fractions of heart muscle (here usually cholineplasmalogens). Correspondence in chain length and degree of hydrogenation can often be found when studying the α-groups of glycerophosphatides that are always derived from fatty acids, fatty aldehydes, or fatty alcohols. *In vitro* experiments with tissue homogenates or cell fractions from brain contributed little to the nature of biosynthesis of plasmalogens, so that *in vivo* experiments must be carried out to clarify such problems. Results to date do not provide unambiguous evidence whether the enol-ether-like linkage of the aldehyde in plasmalogens arises through oxidation of an ether group or through reduction of an ester linkage; in any case, ^{14}C-labeled aldehydes are not direct precursors of plasmalogens in the brain *in vivo*.

Fluorides and Perfluoroorgano-substituted Compounds of I^{1+} and I^{3+}

By *M. Schmeisser*[*]

Iodine monofluoride is accessible in good yields as a pale gray solid of decomposition point 0 °C by reaction of iodine with the stoichiometric amount of fluorine, by reduction of iodine trifluoride with iodine in presence of traces of pyridine, and by metathetical reaction of iodine chloride with nitrosyl fluoride, in all cases in CCl_3F at temperatures from −40 to −50 °C:

$$I_2 + F_2 \rightarrow 2\,IF$$

$$I_2 + IF_3 \xrightarrow{C_5H_5N} 3\,IF$$

$$ICl + NOF \rightarrow IF + NOCl$$

Compounds $C_5H_5N{\cdot}I(O_2CR)$, where R = CF_3 or C_6F_5, are obtained by the action of iodine on silver salts of the corresponding perfluorocarboxylic acids in pyridine/benzene and can be considered as further derivatives of I^{1+}.

Pale yellow, solid iodine trifluoride, decomposition point −28 °C, is formed on treatment of iodine with an excess of fluorine at −45 °C in presence of catalytic amounts of IF_3 or pyridine and can be stabilized as 1:1 adducts with organic nitrogen bases. The compounds IF_2Cl, CF_3IF_2, $C_6F_5IF_2$, and IF_2NO_3, which can be considered as derivatives of IF_3, are formed on low-temperature fluorination of ICl, CF_3I, and C_6F_5I, or in the case of IF_2NO_3 by reaction of IF_2Cl with chlorine nitrate.

The covalently constituted iodine tris(perfluoroacylates)[1] $I(O_2CR)_3$, where R = CF_3, C_2F_5, C_3F_7, or C_6F_5, can be obtained in almost quantitative yields (a) by oxidation of iodine with fuming nitric acid in presence of the corresponding perfluorocarboxylic anhydride, (b) by treatment of iodine trichloride with silver perfluoroacylates, or (c) in the case of iodine tris(trifluoroacetate) by the action of peroxotrifluoroacetic acid and trifluoroacetic anhydride on elemental iodine; they can be isolated in pure form by fractional vacuum sublimation:

(a) $I_2 + 6\,HNO_3 + 6\,(CF_3CO)_2O \rightarrow 2\,I(O_2CCF_3)_3 + 6\,NO_2 + 6\,CF_3CO_2H$

(b) $ICl_3 + 3\,AgO_2CCF_3 \xrightarrow{(CF_3CO)_2O} I(O_2CCF_3)_3 + 3\,AgCl$

(c) $I_2 + 3\,CF_3CO_3H + 3\,(CF_3CO)_2O \xrightarrow[-15\,°C]{CCl_3F} 2\,I(O_2CCF_3)_3 + 3\,CF_3CO_2H$

When method (c) is used an intermediate, iodyl trifluoroacetate $IO_2(O_2CCF_3)$, can be isolated in 95 % yield.

Analogously to the preparation of iodine tris(perfluoroacylates) methods (a) and (c) can be used for preparation, also in almost quantitative yield, of pentafluorophenyliodine bis(perfluoroacylates) $C_6F_5I(O_2CR)_2$, where R = CF_3, C_2F_5, C_3F_7, or C_6F_5. Treating these compounds with $NaHCO_3$, leads to formation of dimeric pentafluoroiodosobenzene $(C_6F_5IO)_2$, as does hydrolysis of $C_6F_5IF_2$. This dimer reacts with perfluorocarboxylic anhydrides in the reverse reaction, regenerating the corresponding pentafluorophenyliodine bis(perfluoroacylates).

Mechanism of Indirect Nuclear Spin Coupling

By *H. Dreeskamp*[*]

Scalar "indirect" spin coupling of nuclei of a molecule causes splitting of NMR signals owing to interaction of the magnetic field of the outer shell electrons and the magnetic dipole that is associated with the nuclear spin. The coupling constants J and their appropriate signs can be determined by analysis of the spectrum or by double resonance experiments and thus can be traced back to the coupling constant of directly bound C and H atoms. This constant is known to be positive (with the implication that a positive J denotes decrease in energy owing to antiparallel spin) from measurements on partially oriented molecules.

For tetramethyl derivatives and hydrides of elements of the fourth main group the normalized coupling constants J' (defined as the constants referred to a gyromagnetic ratio of + 1) of two nuclei linked by one bond have positive signs and are, within a good approximation, proportional to the product of the valence electron densities at the site of the coupling nuclei. It is thence concluded that the Fermi contact term makes a preponderant contribution to coupling of nucleus and electrons.

In a paper concerned with an MO approach to coupling constants calculated from peturbation energies and considering only the Fermi contact term, *Pople* and *Santry*[1] predict for J' a progression from positive values for the C–H and the C–C bond to negative values for the C–F and H–F bond. The analogous constants for Se and Te compounds confirm this theory, since J' for Se–C and Te–C is small

and negative but for Se–H is small and positive (each referred to data for compounds of the fourth main group). Finally, for hydrides of elements of the fourth main group, the geminal H–H coupling constant shows a progressive change from −12.4 Hz for CH_4 to +15.3 for SnH_4, which can be interpeted by a simple MO theory.

These examples can be used to show that values and absolute signs of coupling constants can, in principle, always be determined and that even relatively simple approximations yield useful interpretation of these data. Thus investigation of indirect nuclear spin coupling can enrich our conceptions of the electron shell of molecules.

Abnormal Reaction in Alkylation of Silicon and Germanium Tetrahalides

By *J. Valade* [*]

It is known that alkylation of silicon and germanium tetrahalides by Grignard compounds can be used for preparation of C–Si and C–Ge bonds. Abnormal reactions (formation of H–Si or H–Ge bonds) have been occasionally noted. We have shown that for $SiHal_4$ and $GeHal_4$ these can become the main reactions.

The Grignard compound decomposes at 160 °C first into the unstable magnesium hydride which forms compounds having H–Si or H–Ge bonds ; on silicon two, but on Ge only one halogen atom is replaced by hydrogen. At 4 °C halogen-hydrogen exchange also occurs, but this differs from exchange at higher temperatures.

In the case of silicon the reaction at 4 °C proceeds through Cl_3SiH to yield R_2SiHCl. Ge^{IV}, however, is first converted into Ge^{II}, which is reoxidized to a germylated Grignard compound containing Ge^{IV}. The presence of this intermediate can be demonstrated best by hydrolysis.

Adsorption Calorimetry

By *S. Černý* [*]

The bond dissociation energy is the measure of the strength of bonding of adsorbed particles to solid surfaces. Experimental determination of the bonding energy is, however, difficult and thus it is usually the adsorption energy, *i.e.*, the heat of adsorption, that is measured. Although the relation between bond energy and adsorption energy is close, it is not quite simple since the total energy effect consists, not only of the dissociation energies of the forming and breaking bonds, but also of the changes in degree of freedom of the system, and in particular, the final regrouping of the surface atoms of the adsorbent.

The value of the heat of adsorption and its dependence on occupation of the surface is extremely important for a study of chemisorption and heterogeneous catalysis. Nevertheless, there are few reliable data for heats of adsorption, on the one hand because the crystallographic state of the surface is usually inadequately defined and there is insufficient information about surface contamination, and on the other hand because of shortcomings in the measuring technique for the heat of adsorption itself.

Heats of adsorption can be measured indirectly or directly. Indirect methods utilize either equilibrium data (adsorption isosteres, retention times in gas chromatography) or kinetic data (thermal desorption, field emission microscopy). Direct, *i.e.*, calorimetric, determinations of heats of adsorption are carried out in calorimeters that operate adiabatically, isothermally, or diathermally; the first two of these types can be used only for powder adsorbents, but the diathermal calorimeter can be used also for films and threads.

For small temperature differences the heat transport (by conduction or radiation) between the calorimeter and the outer covering is described by Newton's law. The simple Tian formula is approximately valid for all diathermally operating calorimeters. If the explicit equation for the kinetics of the adsorption process is available, an expression can be set up for variation in the measured quantity with time. This expression affords the heat of adsorption and also provides a model of the calorimetric curves for use in an analog computer. Setting up the analog model provides valuable information about the role of individual parameters of the calorimeter and the kinetic parameters of the adsorption process.

SELECTED ABSTRACTS

Reactions of organocopper compounds with halogenoolefins have been studied by *J. Burdon, P. L. Coe, C. R. Marsh,* and *J. C. Tatlow.* Copper acetylides suspended in DMF or pyridine react readily with halogenoolefins at 40–100 °C to give ethynylolefins, *e.g.*

$$C_6H_5{-}C{\equiv}CCu + ICH{=}CHCl \longrightarrow C_6H_5{-}C{\equiv}C{-}CH{=}CHCl.$$

The yields are between 40 and 90%. The ease with which the halogens are replaced decreases in the order I > Br > Cl; fluorine is not replaced. Perfluoroalkyl iodides react when heated with halogenoolefins and copper bronze in pyridine or DMF to give perfluoroalkylolefins, *e.g.*

$$C_7F_{15}I + ICH{=}CHCl \xrightarrow[Cu]{} C_7F_{15}CH{=}CHCl.$$

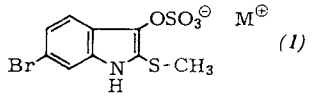
The reaction very probably proceeds *via* perfluoroalkylcopper compounds (yield 50–96%). / Chem. Commun. *1967*, 1259 / –Ma. [Rd 816 IE]

"Self assembly" of the fr-phage from the subunits of the coat protein and the phage RNA has been observed by *T. Hohn.* The isohedral protein coat of the fr-phage consists of more than 180 protein subunits having a sedimentation constant of 4 S. Since the shape of the coat can be achieved only with distortion of the surface arrangement of the subunits, the positions of the subunits are not equivalent. The subunits do not associate in 0.5 M tris-acetate buffer, even in the presence of the phage RNA. In 0.15 M tris-acetate buffer, on the other hand, about 80% of the material aggregates into particles

having a sedimentation constant of 70 S, which are practically indistinguishable from virulent phages under the electron microscope. (The sedimentation constants of the virulent phages is 79 S.) The subunits do not aggregate in the absence of the RNA, in contrast to the behavior of the tobacco mosaic virus, in which the coat protein subunits are arranged in equivalent positions. The yield of virulent phages in the self-assembly process is admittedly only 10^{-7} to 10^{-8}.

European J. Biochem. *2*, 152 (1967) / –Hö. [Rd 823 IE]

A precursor of antique purple, 6,6'-dibromoindigotin, has been isolated by *J. T. Baker* and *M. D. Sutherland* from a hypobranchial-gland extract from the Australian marine snail *Dicathais orbita* in the form of the Ag salt of a pale yellow-orange compound silver "tyrindoxyl" sulfate. The compound was identified as *(1)*, M = Ag. Enzymatic hydrolysis of the Na salt with aqueous gland extract followed by exposure to sunlight gave 6,6'-dibromoindigotin. When chromatograms of *(1)*, M = Na, were sprayed with 1N HCl and heated to 100 °C, the violet pigment was again formed.



(1)

Gland extracts from autolyzing snails gave a pale yellow-green precipitate of tyriverdin, $C_{36}H_{30}Br_4N_4O_5S_4$, which also gave 6,6'-dibromoindigotin, as well as dimethyl disulfide, on exposure to light. It is presumably a quinhydrone of *(1)* and a dehydro-*(1)*. / Tetrahedron Letters *1968*, 43 / –Ma. [Rd 815 IE]

Hydroxylammonium fluoride *(1)* has been prepared for the first time by *B. Frlec* and *H. H. Hyman*. Anhydrous HF was condensed on hydroxylammonium chloride in all Kel-F system, and the reaction was controlled by cooling with liquid nitrogen. When the reaction is complete, the system is slowly warmed to –78 °C. HCl vaporizes first, and the unreacted HF is then distilled off, the final stages being carried out under vacuum at room temperature. When the residual liquid $NH_2OH \cdot xHF$ (x = 1.6–2) is washed with anhydrous ethanol it forms crystalline, hygroscopic $(NH_3OH)F$ *(1)*. After drying under vacuum, *(1)* melts at 90 ± 3 °C (with decomposition; Kel-F capillary tubes). The thermal decomposition of *(1)* at 215 °C probably yields the following products.

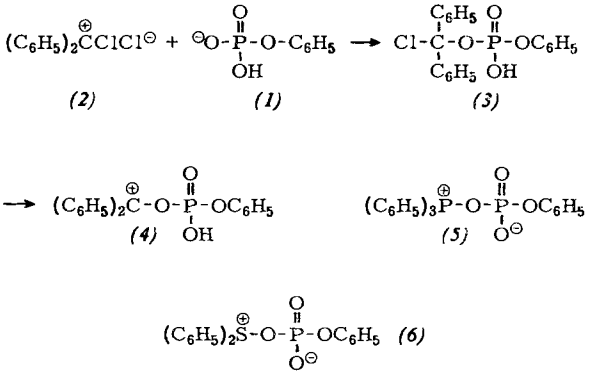
$$\underset{(1)}{3\,(NH_3OH)F} \xrightarrow{\Delta} NH_4F + 2\,HF + N_2 + 3\,H_2O$$

/ J. inorg. nuclear Chem. *29*, 2124 (1967) / –WG. [Rd 789 IE]

A new red modification of tin(II) oxide and the known red and black modifications were obtained in very pure states by *W. Kwestroo* and *P. H. G. M. Vromans*. The three modifications are prepared from 99.9999% tin, which is dissolved in pure hydrochloric acid. Concentrated ammonia is added to the freshly prepared $SnCl_2$ solutions. When the alkaline solution is heated 12–15 h at 70 °C, black tetragonal SnO is formed. In the preparation of the known red orthorhombic SnO, a little phosphorous acid is added to stabilize the product. To prepare the new red phosphorus-free tin oxide, sufficient NH_3 must first be added to raise the pH value to about 9. Concentrated hydrochloric acid is then added rapidly, in such a way that the temperature rises above 95 °C and the pH falls to a value of 4–5. The white precipitate changes within a few minutes into a red modification which is stable even in the absence of phosphite, and differs from the known red modification in its X-ray diagram as well as crystallographically. Its structure has not yet been established. / J. inorg. nuclear Chem. *29*, 2187 (1967) / –WG [Rd 790 IE]

The trimethylsilyl group can be used as a protective group for terminal alkynes in Grignard syntheses. *C. Eaborn*, *A. R. Thompson*, and *D. R. M. Walton* arrived at this conclusion while working with the phenylacetylene system, but believe that this method is also suitable for other alkynes. For example, *p*-bromophenylethynyltrimethylsilane can be readily prepared from *p*-bromophenylethynylmagnesium bromide and trimethylchlorosilane, and reacts with magnesium in THF to form the Grignard reagent $p\text{-}(CH_3)_3Si\text{–}C{\equiv}C\text{–}C_6H_4\text{–}MgBr$. Carboxylation yields the acid $p\text{-}(CH_3)_3Si\text{–}C{\equiv}C\text{–}C_6H_4\text{–}COOH$, and treatment with dilute alkali gives 4-ethynylbenzoic acid in an overall yield of 55%. / J. chem. Soc. (London) *C 1967*, 1364 / –DK. [Rd 791 IE]

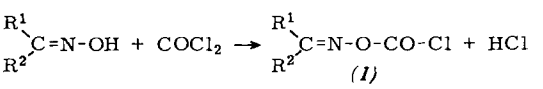
Phosphorylations involving carbonium, phosphonium, and sulfonium ions as intermediates have been described by *H. Kaye* and *Lord Todd*. Phenyl phosphate *(1)* reacts rapidly and quantitatively with dichlorodiphenylmethane *(2)* at 25 °C in a mixture of pyridine and a polar solvent such as nitrosomethane, DMF, or acetonitrile to form P^1,P^2-diphenyl pyrophosphate and benzophenone. In the presence of an excess of *n*-propanol and a very large excess of *(2)*, the reaction leads quantitatively to phenyl *n*-propyl phosphate. In the first step of the reaction, *(2)* probably reacts in the ionized form with *(1)* to form *(3)*, which is a phosphorylating agent of the P–X–Y–Z type. The carbonium ion *(4)* formed from *(3)* can then phosphorylate phenyl phosphate directly or after decomposition into monomeric phenyl metaphosphate, which is also a phosphorylating agent. The esterification of *n*-propanol probably proceeds *via* the pyrophosphate.



(2) *(1)* *(3)* *(4)* *(5)* *(6)*

Dichloromethylenetriphenylphosphorane (which can be prepared from triphenylphosphine and CCl_4) and diphenyl sulfide chloride react in a similar manner with phenyl phosphate to form the phosphorylating agents *(5)* and *(6)*. / J. chem. Soc. (London) *C 1967*, 1420 / –DK. [Rd 792 IE]

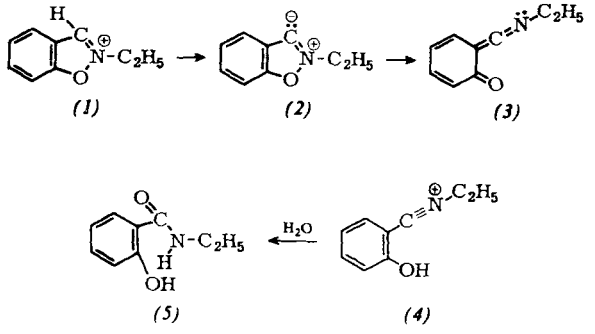
***O*-Chloroformyloximes,** a new and very reactive class of compounds, have been obtained by *A. Jumar*, *P. Held*, and *W. Schulze* by reaction of ketoximes with $COCl_2$. To avoid carbonate formation, the $COCl_2$ is preferably used in excess, and the reaction is carried out below 0 °C to obtain high yields. Examples: *(1)* $R^1 = R^2 = CH_3$, yield 88%, b.p. 50 to 53 °C/1.5 torr; $R^1 = CH_3$, $R^2 = C_6H_5$, yield 56% b.p. 58 °C/0.8 torr; $R^1 = CH_3$, $R^2 = C_6H_5$, yield 81%, m.p. 29–30 °C.



(1)

Chloroformyloximes are colorless, highly reactive substances. They react in the same way as carbonate ester chlorides with compounds containing reactive hydrogen (alcohols, thiols, amines). / Z. Chem. *7*, 344 (1967) / –DK. [Rd 793 IE]

The reaction of nucleophiles with *N*-ethylbenzoisoazolium cations *(1)* has been studied by *D. S. Kemp*. The first step is a base-catalyzed deprotonation to form *(2)*, and this is followed by a very fast *trans*-elimination:



(1) *(2)* *(3)*

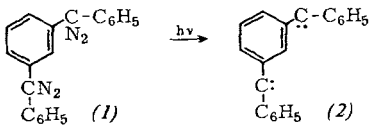
(5) *(4)*

The base finally adds to *(3)* or its conjugate acid *(4)* to form *N*-ethylsalicylamide *(5)*. Compounds *(3)* and *(4)* exhibit high selectivity toward bases. For example, high yields of *O*-acetyl-*N*-ethylsalicylamide are formed in aqueous acetate solution; this reaction thus provides a method for the *O*-acylation of salicylamides. / Tetrahedron *23*, 2001 (1967) / –Bu. [Rd 800 IE]

The stereochemistry of the electrolytic reduction of the C–Cl bond has been studied by *Barbara Czochralska*. In the reduction of optically active 2-chloro-2-phenylpropionic acid to α-phenylpropionic acid in 96% ethanol (mercury cathode, –1.4 V with respect to the Ag/AgCl electrode, 0.2 M CH_3COOH and 0.1 M $(C_2H_5)_4NCl$ as electrolytes), a product that had undergone inversion at the asymmetric C atom was obtained in 77–92% yield. The reaction may be assumed to proceed as follows: As in S_N2 substitution a carbanion with inverted configuration is formed in the rate-determining step *via* a complex involving five-coordinated carbon; the carbanion is then protonated by the solvent, with retention of configuration. / Chem. Physics Letters *1*, 239 (1967) / –Hz. [Rd 801 IE]

The molecular geometry of allyl alcohol has been studied by *A. Narasimha Murty* and *R. F. Curl jr.* on the basis of the microwave spectra of normal and of D- and ^{18}O-substituted allyl alcohol. Of the five conformations considered, that which best explains the spectra is one in which the ethylene group and the OH group are *gauche* with respect to each other, and the proton of the OH group is directed toward the ethylene bond. However, the postulated interaction between H and the π electrons is not strong enough to increase the O–H bond length appreciably (0.96 Å in alcohols, 0.97 Å in this compound). The dipole moment of allyl alcohol is 1.55± 0.04 D. / J. chem. Physics *46*, 4176 (1967) / –Hz. [Rd 802 IE]

A bis-carbene with a quintet ground state, according to *K. Itoh*, is formed by photolysis of 1,3-bis(α-diazobenzyl)benzene *(1)*. *(1)* can be incorporated into single crystals of benzophenone in a specific orientation. On photolysis of these crystals at 77 °K, one observes an ESR spectrum corresponding to a molecule having a spin quantum number S = 2 (quintet). This multiplicity had been predicted for the ground state of the expected photolysis product. Measurements at lower temperatures show that the observed ESR spectrum does in fact correspond to the ground state of *(2)*. *(2)* is very probably also formed on photolysis of *(1)* in liquids; however, the very complex ESR spectrum obtained in this case cannot yet be interpreted. / Chem. Physics Letters *1*, 235 (1967) / –Hz. [Rd 803 IE]



(1) *(2)*

Raman spectra of the tetraisothiocyanate complexes of the IIB metals in aqueous solution have been studied by *K. A. Taylor, T. V. Long II*, and *R. A. Plane*. The displacements of the C–S vibrational frequencies (700–800 cm^{-1}) in the complex in relation to those in the isothiocyanate ion show that the isothiocyanate ion is bound *via* nitrogen in the zinc complex and *via* sulfur in the mercury complex, while both types of linkage occur in the cadmium complex. This is also shown by the fact that cadmium complexes containing less than four isothiocyanate ligands give two C–S stretching frequencies, which merge into a single broad band in the case of the tetraisothiocyanate complex. The C–N frequencies (about 2100 cm^{-1}) are unaffected by *N*- or *S*-bonding of the isothiocyanate. / J. chem. Physics *47*, 138 (1967) / –Hz. [Rd 804 IE]

A free-radical flavoprotein containing flavin mononucleotide has been isolated and crystallized by *W. A. Bulen* from *Azobacter vinelandii*. The calculated molecular weight is 31200/mole of FMN; the protein contains one thiol group, but no iron or molybdenum. The free-radical nature of the anaerobically prepared flavoprotein was detected by paramagnetic resonance (EPR) measurements. The absorption maxima at 580 and 615 nm indicate a flavin semiquinone. This protein exhibits unusual behavior on oxidation and reduction. The anaerobically prepared protein, which is stable to atmospheric oxygen, is oxidized only in the presence of 50% saturated urea solution. The oxidized flavoprotein is reduced only very slowly and only to the semiquinone by dithionite; complete reduction is possible only in 75% saturated urea solution. This dependence of the stability of the free radical on the tertiary structure and the details of the EPR signal suggest the participation of a redox-active disulfide group. / J. biol. Chem. *242*, 3345 (1967) / –Scha. [Rd 805 IE]

A new reaction of nicotinamide adenine dinucleotide (NAD^+) has been discovered by *B. Zimmerman et al.* and by *B. M. Olivera* and *I. R. Lehman*. NAD^+ is required by an enzyme ("sealase") from *Escherichia coli* that converts hydrogen-bonded rings in the DNA of the λ-phage into covalently bonded rings. In this reaction, the ring closure takes place between a 5′-phosphoryl end and a 3′-hydroxyl end of the DNA by a 3′–5′-phosphodiester linkage. One NAD^+ is consumed per bond, the NAD^+ being broken down into adenosine 5′-monophosphate and nicotinamide mononucleotide. In the absence of DNA, the enzyme catalyzes an exchange between NAD^+ and NMN, but not between NAD^+ and 5′-AMP. The ring closure could therefore involve an adenylate enzyme as an intermediate (at the 5′ end of the DNA), which undergoes nucleophilic attack by the 3′-hydroxyl group of the opposite end. / Proc. nat. Acad. Sci. USA *57*, 1841, 1700 (1967) / –Scha. [Rd 806 IE]

Benzyl alcohol dehydrogenase, a new alcohol dehydrogenase (alcohol:NAD oxidoreductase; E.C. 1.1.1.1.), has been isolated by *M. Katagiri et al.* from a strain of *Pseudomonas* grown on toluene as the only source of carbon. The enzyme requires NAD^+ as an electron acceptor; $NADP^+$ cannot be used instead. The enzyme is stabilized by organic solvents. It is specific for primary, predominantly aromatic alcohols such as benzyl alcohol, saligenin, and furfuryl alcohol, but

not for aliphatic alcohols (methanol and ethanol are not affected). The enzyme is not inhibited by complexing agents or by monoiodoacetate and hydroxylamine, which are strong inhibitors of yeast and liver ADH respectively. It is inhibited by *p*-mercuribenzoate at a concentration of 1 μM. Since the benzyl alcohol dehydrogenase occurs only in bacteria grown on toluene or benzyl alcohol, it may be assumed that the occurrence of the enzyme is connected with the degradation of the toluene. / Biochim. biophysica Acta *139*, 173 (1967) / –Scha. [Rd 807 IE]

A simple ultramicro method for the quantitative determination of nitrogen in lipids and certain other compounds has been described by *G. H. Stone-Stanley*. It is possible to determine as little as 0.015 μg-atom of N. The samples are heated in 72% $HClO_4$, and after the addition of phenol, sodium pentacyanonitroferrate(II), alkaline phosphate buffer, and NaClO, the stable blue color at 635 nm is determined. No special purity requirements are imposed on the reagents apart from the water. / Biochem. J. *104*, 293, (1967) / –Scha. [Rd 808 IE]

A "Darwinian evolution experiment" has been carried out *in vitro* by *D. R. Mills, R. L. Peterson*, and *S. Spiegelman*. These authors used the enzyme "replicase" (RNA-dependent RNA polymerase), which is induced in *Escherichia coli* by the bacteriophages MS-2 and Qβ. This replicase requires the intact homologous RNA as a template and synthesizes identical RNA molecules, which can in turn be used as templates, and which are infectious. The system was subject to a selection pressure, *i.e.* the RNA was to be reproduced as rapidly as possible. The first molecules synthesized were accordingly removed soon after the start of the reaction and transferred to the next test tube to act as new templates. The rate of incorporation of ^{32}P–UTP into the RNA increased considerably in the course of the transfer, and after the 74th transfer, the molecules were being reproduced 15 times as rapidly as at the beginning. After only the 4th transfer the RNA had lost its infectious properties, and after the 74th transfer the molecule had been shortened by 83%. Since the replicase does not reproduce arbitrary fragments of the RNA, this process is a true "evolution" to an RNA that has a higher affinity for its enzyme, and which has lost all superfluous segments (which would have been necessary for the programming of an intact phage) in favor of those required for recognition and reproduction. / Proc. nat. Acad. Sci. USA *58*, 217 (1967) / –Scha. Rd 809 IE]

Three new α-amino acids of the type $R-O-CH_2-CH_2-CH(NH_2)-COOH$ (*O*-ethylhomoserine, *O*-propylhomoserine, and *O*-butylhomoserine) have been isolated by *T. Harada et al.* from culture media of *Corynebacterium ethanolaminophilum* when the media contained 1% of the corresponding alcohols (ethanol, *n*-propanol, and *n*-butanol). The amino acids were isolated by ion-exchange and paper chromatography and identified by elemental analysis and IR and NMR spectra. Comparison with synthetic material showed that the *O*-ethylhomoserine was the L isomer. The physiological role of these compounds is not yet known. / Biochem. biophysic. Res. Commun. *28*, 485 (1967) / –Scha. [Rd 810 IE]

The frequency-, temperature-, and concentration-dependent absorption of ultrasonic radiation by benzoic acid solutions was used by *L. Borucki* to determine the thermodynamic data given in the table for the association of benzoic acid (ν = 4 to 52 MHz; T = 15 to 55 °C). If it is assumed that the volume effect of the reaction can be disregarded, that the solutions behave ideally, that the dispersion of the speed of sound is negligible, that the absorption of sound is entirely due to the equilibrium $A+A \rightarrow A_2$, and that the monomers and dimers do not exist in isomeric forms, the reduced absorption coefficient is given by

$$\frac{\alpha}{\nu^2} = \frac{D\tau}{1+(2\pi\nu\tau)^2} + \left(\frac{\alpha}{\nu^2}\right)_S + bx$$

(x = mole fraction of sample; τ = relaxation time; b = -56×10^{-15} to 2.5×10^{-15} $cm^{-1} \cdot sec^2$; D = complicated expression involving the coefficient of cubic expansion and the static specific heat)

The diffusion of the molecules together ($A+A \rightarrow (A+A)$) is found to be rate-determining, rather than the subsequent dimerization ($(A+A) \rightarrow A_2$). In benzene the dimerization is disturbed by the formation of solvent complexes, or else several relaxation effects occur. The solvent dependence of the enthalpies and entropies of reaction is due to electrostatic effects. / Ber. Bunsenges. physik. Chem. *71*, 504 (1967) / –Jg. [Rd 811 IE]

A surface layer of Ag_2O_3 on silver catalysts used at 200 to 300 °C for the reaction ethylene + oxygen → ethylene oxide has been detected by electron optics (reflection and fine-range diffraction; replica method) and by X-ray analysis (Debye-Scherrer) by *M. Feller-Kniepmeier, H. G. Feller*, and *E. Titzenthaler*. Chemisorption models with formation of atomic oxygen and reactions *via* silver peroxide AgO_2 have been discussed. However, no AgO_2 or Ag_2O has been found. After removal from the carrier (Al_2O_3) by ultrasonic radiation, the fresh and the used catalysts exhibit characteristic differences, the former having caked, shapeless crystals, whereas the used catalyst frequently contains oriented, overgrown or pure Ag_2O_3 needles. The formation of Ag_2O_3 begins on the compact metal at 240 °C and can be detected up to 400 °C. An oriented arrangement of the crystallites in an oxidizing atmosphere is observed only in the presence of a component (*e.g.* ethylene) that makes transport reactions possible. Pure Ag_2O_3 without an Ag nucleus is catalytically inactive. / Ber. Bunsenges. physik. Chem. *71*, 606 (1967) / –Jg. [Rd 812 IE]

Crustacyanin, a chromoprotein from lobster shell, has been described by *H. Kühn* and the late *R. Kuhn*. The chromoprotein can be isolated from the shell with complexing agents on dissolution of the $CaCO_3$, and can be purified by precipitation with ammonium sulfate and ultracentrifugation. It is a blue (λ_{max} = 632 nm) protein having a molecular weight of 310000–320000 and containing 16 molecules of astaxanthin. The color depends on the quaternary structure of the protein, which can be (partially) reversibly resolved

into subunits. In neutral solutions of low ionic strength, β-crustacyanin (λ_{max} = 585 nm, molecular weight 38000, two molecules of astaxanthin) is formed. This can be split into two fragments (λ_{max} = 440, 482 nm, molecular weight 19000, each containing one molecule of astaxanthin) in 0.15% sodium dodecyl sulfate. It is only on further dissociation in 6–8 M urea in alkaline solution into fragments having a molecular weight of 7000–10000 that the pigment (λ_{max} = 400 nm) is separated in the form of aggregates containing protein. The intact crustacyanin molecule has an axial ratio of 1:10 (viscosity measurements). This together with the partial specific volume ($\bar{v}$ = 0.66 ml/g) leads to an estimated value of about 300 Å for the length of the molecule, which corresponds exactly to the length of eight astaxanthin molecules. / European J. Biochem. *2*, 349 (1967) / –Hö.

[Rd 827 IE]

A three-dimensional Fourier synthesis of human deoxyhemoglobin with 5.5 Å resolution has been completed by *H. Muirhead, J. M. Cox, L. Mazzarella,* and *M. F. Perutz.* The tertiary structure of the chains of human deoxyhemoglobin and of horse oxyhemoglobin is the same; however, there are appreciable differences in the quaternary structure. A preliminary structural analysis of horse deoxyhemoglobin showed that the differences between horse oxyhemoglobin and human deoxyhemoglobin are not species differences, but are the result of the incorporation of oxygen. The change in the quaternary structure on deoxygenation may be described as rotation of the subunits in the same direction through 9.4° (α chains) and 7.4° (β chains) about axes that converge outside the molecule in an acute angle above the two-fold axis of symmetry. This leads to loosening of the entire structure, and the distances between similar chains become greater. The interactions between the β chains are completely eliminated, since the distance between the β_1 amino group and the β_2 carboxyl group increases from 6 to 12 Å. The identity of the tertiary structures of horse oxyhemoglobin and human deoxyhemoglobin is shown by means of stereo pictures. / J. molecular Biol. *28*, 117 (1967) / –Hö. [Rd 824 IE]

An RNA synthesis in the direction 3′→5′ has been found by *D. H. L. Bishop, N. R. Pace,* and *S. Spiegelman* to occur alongside RNA synthesis in the known direction, *i.e.* from 5′ to 3′. The authors were able to elucidate the structure of the intermediates "HS" and "FS" (structures after *Hofschneider* and *Franklin* respectively) that can be detected during the reproduction of the RNA of the phage Qβ, and which can be separated by electrophoresis in polyacrylamide. The HS complex formed first consists of the RNA template and the attached incomplete ("negative") complementary chain. In the FS complex, the restarted positive chain is also bound to the negative chain. It was verified by the use of β,γ-labeled trinucleotides that the negative chain is synthesized in the "conventional" 5′→3′ direction, since all the newly incorporated nucleotides immediately lose their radioactivity because of the elimination of pyrophosphate. Only the nucleotide in the 5′ position (in this case GTP) retains its triphosphate. On the other hand, the last nucleotide incorporated into the new positive chain in the FS structure still has its triphosphate, *i.e.* the 3′-OH group of the entering nucleotide reacts with the 5′-triphosphate group of the existing chain. In this case, therefore, the synthesis takes place in the 3′→5′ direction. The synthesis of the new positive chain is started before the negative chain is complete. / Proc. nat. Acad. Aci. USA *58*, 1790 (1967) / –Hö. [Rd 828 IE]

Biologically active DNA has been synthesized *in vitro* by *A. Kornberg and M. Goulian.* The procedure used was as follows. DNA of the phage X 174 (annular) was incubated with φ X 174-induced *Escherichia coli* polymerase, polynucleotide ligase, and the four trinucleotides (TTP replaced by 5-bromo-UTP). The reaction product consists of double rings of the introduced ("positive") chain and the synthesized ("negative") chain containing bromine, these rings being wound round one another. They are treated with DNase until (statistical) opening of one ring per double ring had occurred. DNA containing bromine could then be separated from bromine-free DNA by density gradient centrifugation. The negative ring containing bromine, which was itself biologically active, was then used as a template for the synthesis of a new positive ring. The biological activity was detected by mixing the synthetic DNA with spheroblasts of *Escherichia coli,* in which the synthesis of new φ X 174 phages took place. The success of the experiment depended on the high purity of the polymerase (particularly removal of DNase) and the possibility of a reliable separation of the DNA introduced from that synthesized. This is the second case of an *in vitro* reproduction of biologically active hereditary matter (the other was the reproduction of phage RNA by *S. Spiegelman* two years ago), and the first case for DNA. / Proc. nat. Acad. Sci. USA *58*, 2321 (1967) / –Hö. [Rd 829 IE]

Methanol is oxidized in *Pseudomonas* by an unusual alcohol dehydrogenase. *C. Anthony* and *L. J. Zatman* have studied the C_1 metabolism of the bacterial strain that can grow on methanol as the only source of carbon and energy. The alcohol dehydrogenase was enriched by a factor of 10 (from *Pseudomonas sp.* M 27). It was found to behave homogeneously in the analytical centrifige ($S_{20,w}$ = 7.78 S) and on electrolysis on polyacrylamide. The molecular weight is 146000 (Archibald method). The spectrum of the enzyme shows maxima at 280 and 350 nm. The enzyme does not require nicotine adenine dinucleotide; nor is it a flavoprotein. *N*-Methylphenazonium methyl sulfate is used as the primary electron acceptor in the test. Denaturation results in the liberation of a low molecular weight substance exhibiting green fluorescence (fluorescence maximum 460 nm, excitation maxima 260 and 365 nm). On stepwise denaturation, the quantity of the material liberated is proportional to the loss of activity. It is assumed that a pteridine derivative acts as the prosthetic group. The enzyme molecule contains about 30 molecules of glucosamine. Ammonia or methylamine must be added for activation in the test. / Biochem. J. *140*, 953, 960 (1967) / –Hö. [Rd 825 IE]

The mode of action of the B_{12} coenzyme in the reduction of ribonucleotides has been studied by *R. H. Abeles* and *W. S. Beck.* 5,6-Dimethylbenzimidazolyl-5′-deoxyadenosylcobamide is required for the reduction of nucleoside triphosphates to deoxynucleoside triphosphates by thioredoxin or dihydrolipoic acid. When coenzyme B_{12} that is labeled with tritium in the 5′ position of the deoxyribose is used, one atom of tritium is given up to the water for each molecule of nucleotide reduced. If the reaction is allowed to take place with unlabeled coenzyme in water containing T_2O, tritium is incorporated into the coenzyme and is also attached to the 2′-deoxyribosyl carbon atom of the nucleotide. Thus coenzyme B_{12} acts as a hydrogen transfer agent in the synthesis of deoxyribonucleotides, as is also assumed for the methylmalonyl-CoA isomerization. / J. biol. Chemistry *242*, 3589 (1967) / –Hö. [Rd 826 IE]

Lehrbuch der Elektrochemie (Textbook of Electrochemistry). By *G. Kortüm*. Verlag Chemie GmbH, Weinheim/Bergstr. 1966. 4th Edit., xvi, 592 pp., illustrations and 72 tables, DM 52.–.

Originally written for science students in their later semesters, this book has acquired a very much wider circle of readers owing to the increasing importance of electrochemistry for many areas such as biochemistry, analysis, chemical kinetics, industrial processes, and new methods of generating electricity.

Basically, the book is devoted to the fundamental aspects. Only occasionally are indications of industrial use to be found in the text. The presentation of the principles covers much material. Thus the first 40 pages are reserved for the fundamental laws, and 45 pages are devoted to chemical thermodynamics. In the preliminary chapter on the preparation of pure substances the band model for the solid state is taken up anew, thereby laying the ground for the later treatment of electrode kinetics at semiconductor electrodes.

A third of the total number of pages is devoted solely to the theory of electrolytes. It contains a new section on concentrated solutions and molten salts (7 pages; the most recent papers cited there were published in 1962).

The phase boundary electrode/electrolyte occupies the main part of the book (five chapters). Analytical uses are here treated at reasonable length. The accounts of studies of the structure of the electrochemical double layer and of the types of polarization have been thoroughly revised. Numerous references to original papers make for easier access to the specialist literature in these fields.

The last of the 15 chapters has the title "Uses of electrochemical processes". Here are to be found very condensed but clear treatments of galvanic elements, of analysis, of the problems of electrodeposition, and of corrosion. Industrial electrochemical processes are not described, a fact that need not be deplored in this case, for an increased consideration of uses and industry in this book, which is directed to fundamental theories, would have destroyed the remarkable flexibility of the presentation and exceeded the limits of the treatment.

A chapter on photopotentials and electroluminescence in electrochemical systems could, however, have rounded off the picture of modern electrochemistry and should indeed find a place in this monograph.

It is not hard to prophecy that the fourth edition will confirm the view that *G. Kortüm*'s book is a standard work on electrochemistry, and is recognized as such beyond the boundaries of Germany. *F. v. Sturm* [NB 680 IE]

Physikalisch-chemisches Rechnen in Wissenschaft und Technik (Physicochemical Calculation in Science and Industry). By *H. Fromherz*. Verlag Chemie GmbH., Weinheim/Bergstr. 1966. 3rd Edit., xvi, 341 pp., 43 illustrations, DM 35.–.

On the assumption that the fundamental physicochemical laws can be learnt and mastered only by using them for relevant numerical examples, the author has collected 210 problems that are taken from actual practice or are met with daily by the physical chemist in his industrial work or in purely scientific work in the laboratory. In general, the present edition does not range beyond the limits of the second edition [*], but a number of formal details have been modified to meet recent international agreements.

Each of the 14 chapters is introduced by a preliminary statement of the important laws and the corresponding dimensions; but the main emphasis is always placed on setting and solving special problems. These exercises deal with problems of distillation technique, as well as others such as arise in connection with rocket propulsion, operation of a nuclear reactor, or medico-physiological work. Approximations are often used in solving the problems, since without approximations it is often impossible to make progress in practice. For example, the degree of dissociation is occasionally treated as identical with the conductivity coefficent, although these two concepts have somewhat different meanings; yet, in practice, treating the two numerical values as if they were equal often gives a better quantitative solution to an equilibrium problem than is obtained by the usual neglect or idealization of the degree of dissociation.

This book can certainly be recommended, not only to the beginner, but also to the expert, for it contains many hints on how to handle special problems more quickly.

Kl. Schäfer [NB 679 IE]

Landolt-Börnstein, Zahlenwerte und Funktionen aus Naturwissenschaften und Technik (Landolt-Börnstein, Numerical Values and Functions from Science and Technology). Edited by *K.-H. Hellwege*. Gruppe II: Atom- und Molekularphysik. Band II. Magnetische Eigenschaften der Koordinations- and metallorganischen Verbindungen der Übergangselemente (Group II: Atomic and Molecular Physics. Vol. II: Magnetic Properties of Coordination and Organometallic Compounds of the Transition Elements). By *E. König*. Springer Verlag, Berlin-Heidelberg-NewYork 1966. xii, 578 pp., DM 232.–.

The present volume fully justifies the concept behind the "New Series" of Landolt-Börnstein, according to which a loosely connected series of rather small volumes on special areas is separated from the rigid arrangement into a few volumes covering wide fields. Research on magnetic properties, which has developed so rapidly, would have been very difficult to include clearly within the framework of the "Old Series". Specialized information on the magnetic properties of coordination and organometallic compounds of transition elements is collected in the volume under review.

The first part contains the results of measurements of magnetic susceptibility together with the temperature of measurement, the data being arranged according to the transition element concerned. The methods of determination and, for paramagnetic substances, the resulting magnetic moments and Θ values are also given. The arrangement thus corresponds with the established form of the *Foëx* and *Gorter* publication of 1957; the arrangement of literature references also corresponds to theirs. The references extend to 1965 but are not complete for the end of that year.

The tables are preceded by a brief introduction in which the fundamental equations for determination of magnetic moments from susceptibility values are given, together with diamagnetic corrections and also the calculation of moments with consideration given to the influence of ligand fields and the orbital momentum components. Ferro- and antiferromagnetic interaction are also briefly mentioned but ferrimagnetic interaction is not.

The most important and fundamental facts are skilfully extracted. Moreover, a comprehensive review of the literature makes it possible for the reader to obtain further information from more detailed works (for which purpose *Figgis* and *Lewis*' reviews seem particularly suitable). The tabular section (379 pages), which is supplemented by graphical presentation of magnetic measurements (29 pages), contains a few misprints (*e.g.* the reference for NbF_4 is to be found under A 65 Gi, not under 65 Gi), but these should not escape the critical user.

In the second Part the supplementary results of EPR measurements are again presented in a clear table (95 pages), the arrangement being the same as in the first part. Here too there is a short introduction, with references arranged according to specialist fields.

All in all, this is a reference book that will soon become essential to the expert. *W. Bronger* [NB 658 IE]

Einführung in die Liganden-Feldtheorie (Introduction to Ligand Field Theory). By *H. L. Schläfer* and *G. Gliemann*. Akademische Verlagsgesellschaft, Frankfurt 1967. 1st Edit., xiv, 522 p., 147 figures, DM 59.–.

The book is divided into two practically independent parts A and B, which approach the subject-matter from two different points of view.

The first part (and many readers will not go beyond it) starts with the problem "color and constitution" in complexes. Ligand and central atom absorption bands are distinguished empirically, and the important findings of the ligand field theory are likewise explained by reproductions of spectra and diagrams rather than by mathematical formulas. The reader is informed why the hexammine complex of divalent copper is deep blue, and is also told the answer to a number of other problems from the field of complex chemistry. Magnetic properties are also clearly explained, and a discussion of the important problem of the "kinetic stability" of complexes is included. Unfortunately, no theory of metal carbonyls and metal aromatic complexes is given, though the fundamentals underlying their comprehension are fully stated. A few lines of small print are all that is offered about the f electrons of the rare earths, and the interesting d^0 complexes of the type of the MnO_4^- ions have been left out.

While the second part of the book presupposes that the reader has but little knowledge of quantum chemistry, it is clear that it is designed for those who enjoy mathematical formalism. Presentation is in a clear, careful, systematic, and to some extent a pedantically detailed form. Before proceeding to the ligand field theory proper, the authors present a detailed description of the theory of free ions and group theory. The principal results are clearly tabulated.

The authors interpret the ligand field theory as an extension of the electrostatic theory, based on a classical article by *Bethe* (1929) and the evidently not very well known work of *Ilse* and *Hartmann* (1951). Justifiably, the molecular orbital theory of complexes is regarded as merely an extension and not as a true alternative.

Recent publications in this currently very active field are not considered in the discussion. The authors confine themselves to what is generally accepted, but give useful references to relevant literature.

The book can be recommended to a wide circle of readers, but above all to those interested in complex chemistry. A better coordination of Parts A and B might, perhaps, be achieved in a subsequent edition; Part B could, for instance, provide an explicit description of the derivation of the Tanabe-Sugano diagrams which form such an important item in Part A. A few blemishes in presentation could also be eliminated. *W. Kutzelnigg* [NB 703 IE]

Die Organische Chemie des Zinns (The Organic Chemistry of Tin). By *W. P. Neumann*. Ferdinand Enke Verlag, Stuttgart 1967. 1st Edit., xii, 232 pp., 4 illustrations and numerous tables, DM 69.–.

The chemistry of organotin compounds is one of the most important divisions of modern organometallic chemistry, because intensified research in this field and increased practical importance are bringing it more and more into prominence. The appearance of a monograph on the subject is therefore to be welcomed. Research on organotin compounds has been carried out by both organic and inorganic chemists, so that progress has profited from the experience of both groups of workers. Nevertheless, in spite of the common subject, the original papers usually bear the stamp of their origin both in the problem chosen and in the approach to its solution. This book is no exception in that it was obviously conceived and worked out by a true organic chemist, as the title also shows; it is to be taken literally.

The properties, methods of synthesis, and reactions of many organotin compounds are described in detail, reaction routes are interpreted mechanistically when possible, and relations between structure and reactivity are studied critically; further, points of practical interest, such as the numerous possibilities of industrial use, are treated at adequate length. On the other hand, other aspects are given only summary treatment, for instance, physicochemical and spectroscopic data (UV, IR, Raman, NMR, and Mössbauer spectra occupy a total of 3 pages), the complex-chemical behavior of organotin compounds, and the organotin derivatives of the transition metals. However, the original literature of these areas is well covered (930 references) and thus is at least made accessible from this course. The book therefore supplements the previous, smaller reviews of organotin chemistry, and may even replace them. The reviewer nevertheless considers the price rather high. *H. Schmidbaur* [NB 673 IE]

Kollagen (Collagen). By *G. Reich*. Verlag Theodor Steinkopff, Dresden 1966. xii, 308 pp., 61 illustrations, 85 tables, DM 48.80.

This book carries the modest-sounding sub-title "An Introduction to Methods, Results, and Problems of Collagen Research", but that is only a partial description of it. In fact, the book provides a good introduction into the varied aspects of our knowledge of this fibrous protein for those who are not specialists in collagen chemistry and also contains a wealth of references for the specialist. The appearance of this collation is particularly welcome because there has been considerable development of research on collagen in the past 10 to 15 years and the numerous recent original papers on chemical, medicinal, and technical aspects of the collagen field no longer suffice without considerable preknowledge; such knowledge has until now been difficult to obtain.

After an introduction into the construction of connective tissue, the structure and the physical and chemical properties of collagen are treated in great detail. Sections on general methods of protein chemistry are scattered throughout the text to help the beginner. The biological, biochemical, and medical aspects of collagen are intentionally treated rather more summarily; the detailed treatment returns with the production of leather and gelatin. The text is characterized by very conscientious coverage of the literature (1260 references). This has the natural result that very often the conclusions reached in the literature are described rather than the methods used or the experimental data, but this is to be welcomed in the interests of clarity and readability. The book will be a valuable help in literature searches for those who wish to delve deeply into the problems of collagen chemistry. Because the reviews that have appeared in the English language are outdated or concern mainly specialized sectional problems, this book may well gain a very wide audience.

H. Hörmann [NB 657 IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz*. Vol. 22. Bioenergetics. Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st Edit., xi, 214 pp., 51 figures, Dfl. 35.–[1].

In intermediate metabolism, dissimilatory and synthetic energies are thermochemically coupled. The energy cycles

[1] Vol. 16, cf. Angew. Chem. *79*, 159 (1967); Angew. Chem. internat. Edit. *6*, 191 (1967).

and routes form the subject matter of volume 22 of this comprehensive handbook of biochemistry, which, so to speak, gives a chapter by chapter account of the foundations of a "submolecular biology". In the first chapter *A.* and *B. Pullman* describe the general ideas and methods of quantum biochemistry, which is concerned with the quantum mechanical investigation of the electronic structure of biologically important molecules. The achievements and predictions realizable by means of this theoretical treatment are illustrated by a number of examples. *B. Grabe*'s new interpretation of the "energy-rich bond" is, of course, not mentioned since only the literature up to the beginning of 1966 is referred to. Attempting to force such a rapidly developing science into a relatively slowly appearing compendium clearly has its limitations.

The mechanisms of energy transfer are dealt with by *Th. Förster* in a short section devoted to the problem of transfer of free energy between various cell components. A lucid account is given of the theoretical and the experimental approaches to the resolution of this problem which, of course, still rely largely on the use of models. Charge transfer complexes may be involved in conducting energy from one system to another in solution and in solids. The points touched on in the first chapter are discussed in more detail in the chapters written by *E. J. Bullock*. The latter also contain a tabular survey of the complex molecules of most biological substances, and in particular those of the flavins and the pyridine nucleotides. The excellently written and well thought out section by *P. Mitchell* is likely to prove of greatest interest to the biochemist. In 25 pages the principles of the chemo-osmotic ion translation through membranes are discussed. The four chapters blend well to give contemporary treatment of the subject. As the price might lead one to expect, printing and presentation are faultless.

L. Jaenicke [NB 721a IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz*. Vol. 28: Morphogenesis, Differentiation and Development. Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st Edit., xii, 276 pp., Dfl. 42.50.

This volume of "Florkin-Stotz" demonstrates that embryology has at last outgrown its descriptive biology stage and is beginning to be understood on a molecular level as the chemical and physical parameters of the growing embryo become accessible to measurement. The contributors to this volume do not conceal the fact that the analytical treatment of these problems is tedious, and that a chemical understanding of the phenomenon of "life" is still far off. As on every occasion in the past, the editors have succeeded in finding experienced and skilled specialists to write about the selected topics. *A. Monroy* deals with oogenesis, in which an inert mature egg is fertilized and made to grow into a living organism by making the genetic information fixed in it capable of being identified. The information is contained in nucleic acids, the behavior of which during cell differentiation is described by *J. Brachet* in analogy to the better understood processes in bacteria. *E. Scarano* and *G. Augusti-Tocco* deal with chemical embryology in a most carefully compiled section which contains 416 references.

The biochemical processes and the metabolic pathway regulators acting by interaction of macromolecules during embryogenesis are modeled largely on reactions known to take place in the adult organism. An article by *T. Yamada*, which resembles more a review than a critical evaluation, discusses how the embryonic induction factors effect the formation of specific cell populations from undifferentiated prospective material.

The biochemical processes occurring during hormone-induced metamorphosis of amphibia are described by *R. Weber*. This widely embracing work provides interesting interpretations of long known but still uncertain processes which must operate in conjuction with "an attuned organism".

The analogous chapter on insect metamorphosis by *L. J. Gilbert* is an indication of the potential of insect biochemistry rather than just a compilation of data. This volume is stimulating in many respects although some of the aspects are treated subjectively. The bibliography includes very recent work; unfortunately, however, references to previous volumes are somewhat sparse. The neat arrangement of the work needs no reiteration. Like its predecessors, this volume has been printed on soft rough paper. The readability is therefore spoilt, not by glare, but rather by unsharp contours.

L. Jaenicke [NB 721b IE]

Cross Electrophoresis, its Principles and Applications. By *S. Nakamura*. Elsevier Publishing Co., Amsterdam-London-New York 1966. 1st Edit., ix, 194 pp., numerous illustrations and tables, Dfl. 47.50.

In 1953 *Grassmann* and *Hübner* showed that paper electrophoresis by the curtain principle is suitable for detection of complex formation or association by dyestuffs if the two components are applied in such a way that the paths taken by them on electrophoresis cross each other. This principle was applied by *Nakamura* to horizontal paper electrophoresis, extended to a two-dimensional technique, and tested on a series of interacting systems. Thus arose what is called "cross electrophoresis". However, a special case, in which the substances are applied to the strips in parallel streaks so that the faster-moving component passes over the slower (which reacts with it), is described by *Lang* as "Überwanderungselektrophorese" (overrunning electrophoresis).

The first 36 pages of this book are devoted to principles and apparatus, the next 23 pages to immunochemical use of the method. It seems to the reviewer that, particularly in immunological reactions, the usual carrier material (paper) might be replaced with advantage by agarose plates or acetate foil; then, similar results are to be expected to those obtained by *Ressler*'s or *Laurell*'s method in which the antibodies are equally distributed in the medium. Later sections of the book treat the behavior of trypsin inhibitors and the possibilities of studying enzyme-substrate complexes. 400 citations from the literature are given in this book, including more than 30 to work of the author.

For those who can and wish to apply this comparatively little-used technique to their own problems, this book is a safe guide, being written in clear language and well set out. Unfortunately the pictures obtained by means of cross electrophoresis have no aesthetic appeal!

B. Kickhöfen [NB 675 IE]

The Structure of Inorganic Radicals. By *P. W. Atkins* and *M. C. R. Symons*. Elsevier Publishing Corp., Amsterdam-London-New York 1967. 1st Edit., x, 280 pp., numerous illustrations and tables, bound, Dfl. 60.–.

Our knowledge of free radicals, their electronic states and bonding, has been greatly extended by the use of electron paramagnetic resonance (EPR). In this work, inorganic radicals have a special place because their composition is generally simple. Their electronic states are important for clarification of the electronic structure of analogous diamagnetic molecules which arise from these radicals by addition or removal of an electron. In the book under review, an attempt is made to collect the EPR results on inorganic radicals in a uniform framework, to consider them critically, and thus to make them accessible to a wider circle of readers.

The book begins with an introduction to the technique of EPR investigations and to the methods of preparation and matrix-isolation of radicals. This forms the basis for a gradually developing treatment of the types of radical: electrons in matrices and in solution; ions and atoms in matrices; and radical molecules containing two, three, four, or five atoms. A chapter in which generally valid conclusions

are drawn from the results already discussed closes the text of the main part of the book. Each chapter is introduced by a short description of its contents. Interpretation of the experimental results is highly critical. The literature is almost completely taken into account up to and including 1964.

Since the most important object of the book is to clarify the electronic structure of radicals, the authors' attempt to banish theoretical treatment of the results to a brief mathematical appendix must be criticized. This division has the result that many concepts and quantities are used in the main part although their definition is to be found only in the appendix. The reader thus needs some basic knowledge of quantum chemistry.

The book doubtless fills a noticeable gap and should thus be recommended to all who are concerned with the electronic structure of simple molecules and/or ESR measurements, and to every inorganic chemist. Printing and style are good, but in spite of many good points the price seems to be too high.

E. König [NB 677 IE]

Nuclear Magnetic Resonance for Organic Chemists. Edited by *D. W. Mathieson*. Academic Press Inc., London-New York 1967. 1st Edit., ix, 287 pp., numerous illustrations, tables, and spectra, 65 s/$ 10.50.

This book is a collection of lectures and practical exercises (with solutions) that formed a summer course held for chemists by the Royal Institute of Chemistry, London, in 1964.

The chapters are written by several authors but coordinate well with one another, and they present a cross-section of high-resolution nuclear resonance spectroscopy in which applications of the methods and analysis of the spectra, rather than theory, are placed in the foreground.

After a short introduction into the general principles of nuclear resonance spectroscopy (*N. Sheppard*), chemical shifts and spin-spin coupling are treated in detail and very clearly (*J. A. Elvidge*).

The next three sections treat the analysis of three-, four-, and multi-spin systems (*E. O. Bishop*), and the ABX spectral type is dealt with in detail (*C. N. Banwell*).

The first part ends with chapters on the dependence of coupling constants on stereochemical factors (*R. J. Abraham*) and a short account of the magnetic resonance of nuclei other than hydrogen that are of interest to organic chemists (*J. Feeney*).

The examples of spectral analysis comprise 22 very well chosen and in part very difficult problems (with solutions), which are discussed in detail and approached from the most varied directions.

In sum, the book provides a good survey of the problems and possibilities of nuclear resonance spectroscopy and can be highly recommended to organic chemists interested in structure determination.

H. Friebolin [NB 664 IE]

Introduction to Mass Spectrometry. Volume 3 of the series "Spectroscopy in Education". By *H. C. Hill*. Heyden & Son Ltd., London 1966. 1st Edit., xi, 135 pp., many illustrations, board 30 s or $ 4.50.

H. C. Hill is an experienced worker in the English heavy chemicals industry. In 135 pages he gives a concise survey of the mass spectrometry of organic compounds. Experimental technique, methods of introducing the sample into the ion source of the apparatus, and methods of recording the spectra are discussed with exclusive reference to the AEI apparatus (apparatus from a few other firms have a bare mention). The mechanism of formation of fragments of organic molecules in the electron-impact ion source is treated in detail, and this lays the foundation for the next section which is concerned with interpreting mass spectra for elucidation of the structure of organic compounds. The important rules for their interpretation are derived and illustrated by means of examples. 18 spectra of "unknown substances" are left for the reader to handle; unfortunately they are rather one-sidedly chosen – only one benzene derivative, no heterocyclic compound, the remainder all aliphatic or cycloaliphatic compounds.

The book can be recommended as an introduction; but anyone wishing to concern himself more deeply with methods and apparatus of mass spectrometry will soon have to turn to more detailed monographs. The title does not indicate that this book concerns only an introduction to the mass spectrometry of organic compounds and to the interpretation of spectra for structural analysis of such compounds; the many other uses of mass spectrometry are not mentioned.

H. Kienitz [NB 670 IE]

Analysis of Copper and its Alloys. By *W. T. Elwell* and *I. R. Scholes*. Pergamon Press, Oxford 1967. 1st Edit., xiii, 183 pp., 11 illustrations and 4 tables, 50 s.

This book sets out the various chemical procedures used for analysis of copper and its alloys. Methods are described for determination of 29 elements – Cu, Al, Sb, As, Be, Bi, B, Cd, C, Cr, Co, H, Fe, Pb, Mn, Hg, Ni, N, O, P, Se, Si, Ag, S, Te, Sn, Ti, Zn, and Zr (Hf); these are preceded by general considerations on sampling.

Each chapter begins with a survey of the methods available, indicating those which are at present most generally used, always with references to the original papers; and each chapter is divided according to the methods used for determination of the elements under consideration in respect of the concentration ranges of interest. The analytical procedures are formulated precisely and are provided with data concerning their applicability and – what is extremely relevant – usually also their accuracy. Not only gravimetric and titrimetric methods, but also photometric techniques and some instrumental methods (polarographic and atomic absorption spectrometric) methods are described. The chapter on the determination of non-metals – H, C, O, N, and S – must be singled out as particularly valuable.

The book is written by distinguished experts in the field, from the laboratories of Imperial Metal Industries, England. Only a few wishes remain unfulfilled: for instance, for photometric determination of some elements reagents are preferred that can no longer be regarded as the most effective, *e.g.* hydrogen peroxide for determination of Ti, or iodide for determination of Bi; on the other hand, occasionally reagents are preferred that – at least in our experience – have not been generally adopted, *e.g.* zinc dibenzyldithiocarbamate for photometric determination of Cu and *p*-nitrophenylazo-orcinol for that of Be. Finally, the importance of temperature in direct iodometric titration of Sn should have been more strongly emphasized.

Elwell-Scholes can be most warmly recommended to all who are interested in the analysis of copper.

G. Kraft [NB 669 IE]

Bile Salts. By *G. A. D. Haslewood*. Methuen & Co. Ltd., London 1967, xi, 116 pp., several illustrations and tables, 27s 6d.

This little book gives a good summary of the chemistry, biochemistry, and physiology of bile acids and their conjugates, without pretention to being an exhaustive monograph. It builds on older collective books, and thus 71 % of the references are to literature published after 1960. In addition, very many unpublished observations from the author's laboratory are reported – and the author is among the most knowledgeable workers in this field.

The chemical structure, physical properties, separation, determination, and biosynthesis of gallic acids and their derivatives, as well as their possible role in the organism, are described, often too briefly but yet in suitable form. A special chapter is devoted to the distribution of the various bile acids; this is the only chapter where complete coverage is attempted and it forms a basis for a discussion of the importance of bile acids in evolution in the animal world. This part is without doubt the most valuable contribution and should ensure a wide readership for *Haslewood*'s little book, particularly among biologists and all others who are interested in the history of the development of animals.

G. Snatzke [NB 659 IE]

Gas Phase Reaction Rate Theory. By *H. S. Johnston.* From the series: Modern Concepts in Chemistry. The Ronald Press Company, New York 1966. 1st Edit., ix, 362 pp., numerous illustrations and tables, $ 10.–.

H. S. Johnston is the author of many papers on reaction kinetics. In the introductory chapter of this book he separates the concept of elementary chemical reactions from that of physical and physicochemical reactions. The principles of quantum mechanics and of classical and statistical mechanics that are important for gas-phase reactions are enunciated in six further chapters. In this part, particular attention is paid to the one-dimensional tunnel effect, the description of molecules by normal coordinates and of equilibria by the distribution functions of classical and wave-mechanical statistics. Then follows the main portion of the book, with chapters on impact velocities, bimolecular atom-transfer reactions, activation energies, preexponential factors of bimolecular atom transfer, the kinetic isotope effect, three-body collision reactions with particular attention to recombination of iodine atoms, the theory of complex reactions, and finally a summary.

The individual chapters are of a high standard and are written with the set purpose of demonstrating the theoretical principles underlying the rates of gas-phase reactions. Carefully selected experimental results obtained by modern methods are compared with the conclusions drawn from theory. As customary in books by American authors, the reader is presented with problems on which he can test his understanding of the subject. The excellent exposition is intended primarily for the physical chemist and is likely to rouse the enthusiasm of the reader for the old, but still very topical, field of gas-phase reaction kinetics. *H. Wolff* [NB 666 IE]

Treatise on Adhesion and Adhesives. Edited by *R. L. Patrick.* Vol. 1: Theory. Marcel Dekker Inc., New York 1967. 1st Edit., xi, 476 pp., numerous illustrations and tables, bound $ 21.75.

Following *De Bruyne* and *Houwink*'s monograph "Adhesion and Adhesives" of 1951, there now appears a three-volume "Treatise on Adhesion and Adhesives". The first volume, concerned with the theory of adhesion, has already been published.

Since intensive work in this field (particularly from a technological point of view) began only after 1950, a comprehensive treatment of recent views on problems of adhesion and their physicochemical basis was urgently needed.

The present volume contains contributions, some in excellent form, from nine authors who report mainly the results of work in their own special fields. It seems unavoidable that this should lead to some overlap of content and to overemphasis of some problems.

After a relatively short introduction by *R. L. Patrick, R. J. Good* gives a short summary of current knowledge of intermolecular interactions in the boundary region. Detail has intentionally been omitted, since it can be obtained from comprehensive monographs. *R. R. Stromberg* deals with adsorption of high polymers from solution on to solid surfaces. Because high polymers undergo marked changes in conformation during the adsorption process, there is as yet no satisfactory theoretical treatment for this subject, particularly as regards changes in entropy. For instance, the temperature-dependence of adsorption of polymers is not yet fully understood.

The relation between the structure of the adhesive and its adhesive behavior is reported by *I. R. Huntsberger.* The problem of wetting receives detailed discussion, the well-known papers by *Zisman* being reported. In contrast to some other researchers, the author is of the opinion that electrostatic interaction is of negligible importance for adhesives. Problems of adhesives that are of a mechanical or industrial nature (elongation, strain, fracture) are treated by *T. Alfrey Jr., D. H. Kaelble, G. R. Irwin,* and *J. L. Gardon.* Clear separation of theory from empiricism is not always achieved in these articles, as indeed is the case generally with problems that lead to formulas containing many parameters. The four contributions assume specialist knowledge of theoretical mechanics. It would be welcomed if in later editions some references were included in the article by *T. Alfrey Jr.*, so as to help the non-physicist with this field.

Finally there is an informative and comprehensive account of the chemistry of surfaces by *F. M. Fowkes*, who treats the most important problems from a thermodynamic and molecular-theoretical point of view.

To summarize, it may be said that this book will appeal equally to the chemist and to the technologist and engineer. It is to be hoped that the two further volumes of the "Treatise on Adhesion and Adhesives" will appear soon.

G. Peschel [NB 674 IE]

The Solid-Gas Interface. Edited by *E.A.Flood.* Marcel Dekker Inc., New York 1967. Vol. I, 1st Edit., 514 pp., numerous illustrations, bound $ 21.75.

The editor has set himself the task of providing, in cooperation with recognized experts, a two-volume work giving a survey of phenomena occurring at the gas/solid interface insofar as these are to be ascribed to physical adsorption and its consequences. Experimental results and theory are both considered.

In the first volume, which has now appeared, it is mainly the principles and their theoretical description that are treated. The second volume is to report recent experimental methods and results.

After an historical introduction by *H.Taylor, E. A. Flood* treats adsorption from the point of view of Gibbs and Polanyi thermodynamics. The Langmuir theory and the BET theory are described by *S. Brunauer, L. E. Copeland,* and *D. L. Kantro*; derivation of the adsorption isotherm and testing of its applicability form the main part of this section.

E. L. Pace is concerned with experimental investigations of thermodynamic values for the adsorption phase, such as heat of adsorption, heat capacity, and entropy of the adsorbent. A survey of the heats of adsorption measured by various schools is provided by *J. M. Holmes,* and *A. C. Zettlemoyer* and *K. S. Narayan* discuss heats of wetting and their relation to adsorption.

Van der Waals forces arising at the solid/gas interface, and chemical binding forces, are treated by *A. D. Crowell*; questions of surface energy and surface tension of crystalline solids are discussed by *G. C. Benson* and *K. S. Yun. W. J. Dunning* considers the structure of the surface and its importance for adsorption.

W. A. Steele studies mobile and localized monolayer adsorption, as well as multilayer adsorption, from the standpoint of statistical mechanics, and *J. M. Honig,* in a highly specialized article, places entropy at the focus of his considerations.

D. L. Kantro, *S. Brunauer*, and *L. E. Copeland* discuss determination of surface area by the BET method; *H. E. Farnsworth* reports on possible ways of preparing atomically "pure" solid surfaces and on tests of their "purity".

A section by *J. B. Hobson* is devoted to physical adsorption at extremely low pressures; a section by *S. Ross* is concerned with the influence of heterogeneity of the surface on adsorption. Finally, *G. D. Halsey* gives a summarizing, critical survey of the contributions in volume I of "The Solid-Gas Interface".

The particular advantage of this book over others lies in the facts that physical adsorption is discussed in it from such different standpoints and that, for once, the variety of factors that influence physical adsorption is recorded. The extensive references to the literature at the end of each chapter also deserve mention. It is to be hoped that the second volume will also contain such a wealth of information.

G. Wedler [NB 683 IE]

The Chemistry of Lignin. By *I. A. Pearl*. Edward Arnold (Publishers) Ltd., London 1967. Marcel Dekker, Inc., New York. 1st Edit., xi, 339 pp., 24 figures, $15.75.

Since the appearance of the last comprehensive review of lignin chemistry by *F. E. Brauns* and *D. A. Brauns* in 1960 our knowledge of the structure of lignin has become much more precise. The new book by *I. A. Pearl* offers a clear, concise, and readable survey of the present state of lignin chemistry, and is intended for chemists, biologists, and plant physiologists.

In the chapter on methods of isolation, the greatest amount of space is devoted to the lignin-sulfonic acids obtained from sulfite waste liquor. Today's most valuable lignin preparation — Björkman lignin — is discussed very briefly, in contrast to Klason and hydrochloric acid lignin, and no method of preparing it is given. In the chapter on structure, the presently postulated structure of lignin would be more soundly based if the classification were arranged in terms of structural units; moreover, it is superfluous to give eleven alternative proposed structures for spruce lignin. Considerable confusion is caused by the detailed and repeatedly cited formulation scheme of *Forss* and *Fremer* (pp. 124–127 and 162–169) which not only differs markedly from all other proposed structures, but also ignores the postulates of many groups of workers concerning the nature and number of the structural types present in lignin.

In two further chapters the biosynthesis of the monomeric lignin precursors (*p*-hydroxycinnamyl alcohols) and the chemical reactions of lignin during technical processing (sulfite and sulfate pulping and bleaching) are dealt with in detail. Chapter 6 deals with the chemical reactions of lignin and is restricted to a brief selection of the reactions that are most important in regard to the structure and use of the material. The following chapters give an account of the physical properties, the biological and thermal decomposition, and the bonding of lignin in the plant. A clearly written chapter displaying an impressive knowledge of the subject and describing the utilization of technical lignins in terms of their chemistry and economic aspects concludes the book. Some minor flaws are to be found: α-α linkages (γ-γ according to IUPAC) are retained (p. 71), though the evidence adduced would suggest 1,2-diarylpropane bonds. On p. 127 the fact that pinoresinol units have been clearly detected in natural lignin is ignored. A twelfth structural scheme (p. 157) for spruce lignin proposed by *F. E. Brauns* in 1962 was allegedly based on NMR evidence obtained by *McCarthy* in 1964. It would be desirable if more emphasis were placed on results and their evaluation concerning the structure of lignin (*e.g.* UV, Δε, IR and NMR spectra).

The bibliography includes all material published up to the end of 1965 with few exceptions; some of the literature cited is otherwise not readily accessible. All in all, the reader is offered a survey based on expert knowledge and a thorough approach to the subject. At the same time, the book deserves commendation for its clarity and concentration on the essentual features of lignin chemistry. *H. Nimz* [NB 714 IE]

BY R. HUISGEN[*]

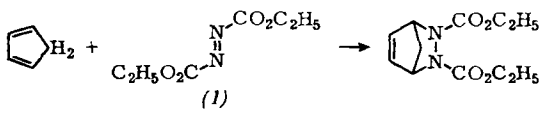
Dedicated to Professor A. Steinhofer on the occasion of his 60th birthday

The growing volume of publications on cycloadditions indicates that this general type of reaction merits a place beside the better-known substitutions, eliminations, and additions. The world of phenomena does not provide us with definition and classification principles. These are created by the scientist and are not free from arbitrariness. A terminology[1] is suggested for cycloadditions. These reactions do not all proceed by the same mechanism. Since ideas about reaction mechanism can change with the introduction of new criteria, it is shortsighted to base definitions and classifications on mechanism alone. Consequently, the definition of cycloadditions will not be restricted simply to multi-center processes with a cyclic electron shift.

1. Definition

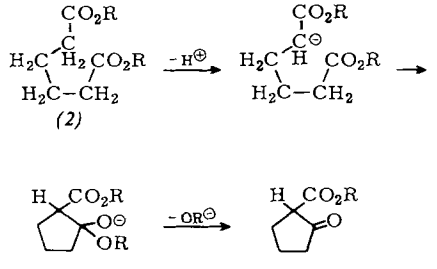
It is much easier to agree on which reactions are definitely cycloadditions than on the criteria to be applied in borderline cases. On the other hand, the term loses its value if the definition is too all-encompassing. In cases of doubt, usefulness should take precedence over absolute consistency.

The reaction of cyclopentadiene with diethyl azodicarboxylate *(1)*[3] led *Diels* and *Alder* to develop the reaction scheme which bears their names. In this cycloaddition, the total number of bonds remains unchanged, but the number of σ bonds increases at the expense of the number of π bonds.



(1)

Rule 1. Cycloadditions are ring closures in which the number of σ bonds increases.



(2)

The Dieckmann condensation[4] of adipates *(2)* constitutes a ring closure, with elimination of alcohol in the overall reaction. Though the cyclization step agrees with Rule 1, it should not be regarded as a cycloaddition. It is simply an intramolecular ester condensation.

The final product *(3)* in the next example again is not equivalent to the sum of the components. The synthesis of piperidines from amines and pentamethylene dibromide consists of two alkylation steps, the second of which is also a ring closure. The intramolecular S_N2 reaction is, however, not a cycloaddition.

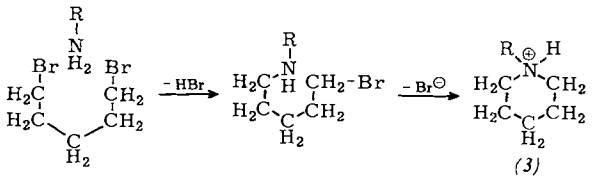
[1] The rules developed earlier in a handbook article [2] are expounded here and illustrated by examples.

[2] *R.Huisgen, R.Grashey,* and *J.Sauer* in *S. Patai*: The Chemistry of Alkenes. Interscience, New York 1964, p. 739.

[3] *O. Diels, J. H. Blom,* and *W. Koll,* Liebigs Ann. Chem. *443,* 242 (1925); *O. Diels* and *K. Alder, ibid. 450,* 237 (1926).

[4] *W. Dieckmann,* Ber. dtsch. chem. Ges. *27,* 102 (1894).

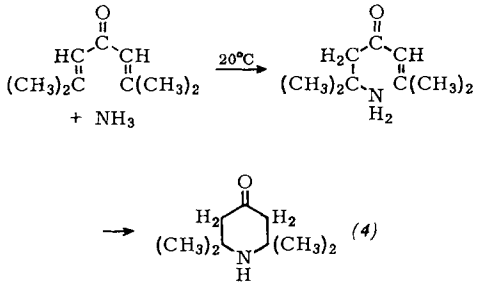


(3)

Rule 2. Cycloadditions are not associated with the elimination of small molecules or ions. The cycloadduct corresponds to the sum of the components.

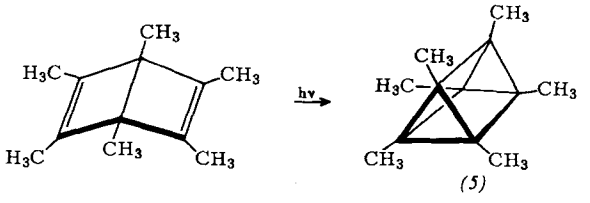
"Cycloadditions are chemical transformations giving at least one product having at least two new bonds as constituents of a new ring". This recent definition [5], which does not forbid the elimination of small molecules, is inadequate in our opinion [6], since the above reaction would then be a cycloaddition when the starting material was 1,5-dibromopentane, but not if the 5-bromopentylamine was isolated and then converted into *(3)*.

In the formation of tetramethyl-4-piperidone *(4)* from phorone and ammonia [7], though the final product corresponds to the sum of the components, the reaction is better classified as the addition of an amine to electrophilic double bonds. The reaction, which proceeds in several steps, involves the cleavage of NH bonds.



(4)

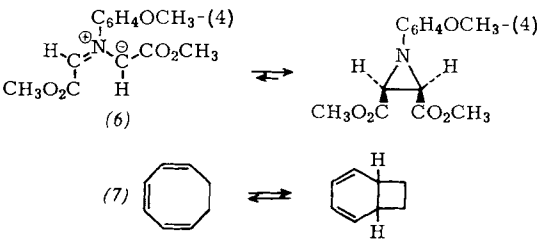
Rule 3. Cycloadditions do not involve the cleavage of σ bonds.



(5)

As in substitutions, the reacting groups in cycloadditions may be parts of the same molecule. A current example of this is the photochemical formation of hexamethylprismane *(5)* from the Dewar benzene derivative [8].

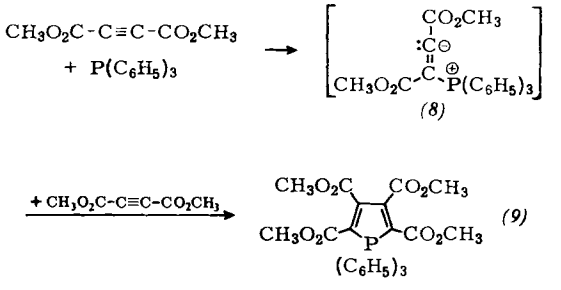
Electrocyclic reactions [9] cannot be denied recognition as cycloadditions, even when they are transannular. In this case one new σ bond is formed at the expense of



(6) *(7)*

a π bond. Examples of such reactions are the conrotatory closure of the aziridine ring from the azomethine ylide *(6)* [10] and the disrotatory valence isomerization of 1,3,5-cyclooctatriene *(7)* [11].

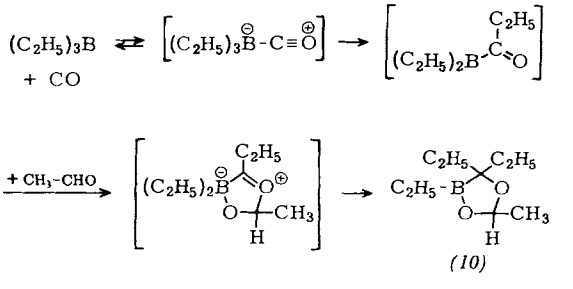
Rule 4. Cycloadditions can be intramolecular if one molecule contains the necessary functional groups.



(8) *(9)*

More than two components may also come together to form a ring.

Reactions of this type probably always involve several steps. Triphenylphosphine combines with two molecules of dimethyl acetylenedicarboxylate to form the unstable phosphole derivative *(9)* [12]. Though the 1:1 intermediate zwitterion *(8)* cannot be isolated, it can be intercepted with carbon dioxide [13].



(10)

The synthesis of a 1,4,2-dioxaborolane *(10)* from triethylborane, carbon monoxide, and acetaldehyde [14] actually involves three intermediates that cannot be isolated. From the existence of the boranecarbonyl, it is probable that the trialkylborane first reacts with the CO; the subsequent migration of an ethyl group again

[5] *J. E. Baldwin*, J. org. Chemistry *32*, 2438 (1967).

[6] The reason for this liberal definition was probably that in a series of small papers entitled "Cycloadditions", the American author dealt with a reaction that did not comply with Rule 2, which was already widely accepted at that time.

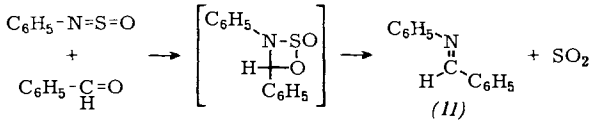
[14] *M. E. D. Hillman*, J. Amer. chem. Soc. *85*, 1626 (1963).

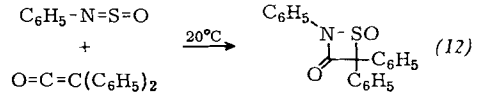
has nothing to do with the cycloaddition. The unstable primary product of the cycloaddition to acetaldehyde is stabilized by a further migration of an alkyl group.

Rule 5. When more than two components combine, only the reaction step leading to the ring is a cycloaddition.



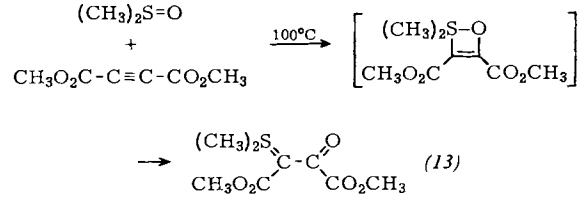
(11)

The ring of the primary cycloadduct may be rapidly opened or fragmented. When *N*-sulfinylaniline is heated with benzaldehyde, benzylideneaniline *(11)* and sulfur dioxide are formed [15]. Other four-membered cycloadducts of *N*-sulfinylaniline, *e.g.* the 1,2-thiazetidin-3-one derivative *(12)* obtained with diphenylketene [16], can be isolated.

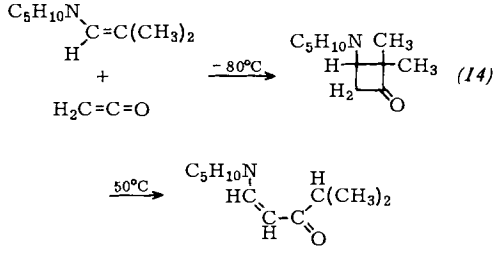


(12)

The addition of dimethyl sulfoxide to esters of acetylenedicarboxylic acid [17] can be plausibly explained by a 2 + 2 cycloaddition followed by ring opening to form *(13)*. Similar four-membered rings (1,2-oxaphosphetanes) could also occur as intermediates in the Wittig olefination of carbonyl compounds [18].



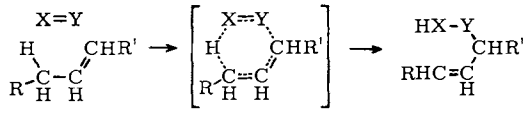
(13)



(14)

A better-established case is the intermediate cycloadduct in the β-acylation of enamines with ketenes. In the example given, *i.e.* the reaction of 1-piperidinoisobutene with ketene, the cyclobutanone derivative *(14)*, though thermally unstable, can be isolated [19]. The tendency toward ring opening is completely absent in 3-piperidino-2,2,4,4-tetramethylcyclobutanone, which is formed from the above-mentioned enamine and dimethylketene [20].

However, it is recommended that the term cycloaddition should be avoided when the reaction simply involves a cyclic transition state, as is the case in "ene reactions". These are allylic substitutions by a compound X=Y with an obligatory double bond shift; they are also contrary to Rule 3.



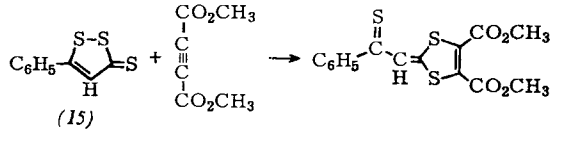
The reactant X=Y may be *e.g.* maleic anhydride [21], formaldehyde [22], or an ester of azodicarboxylic acid [23]. These ene reactions are undeniably related in mechanism to the Diels-Alder addition. However, cyclic activation configurations are postulated for so many reactions that though they might greatly enrich the range of cycloadditions, the enrichment would be uncontrolled and of doubtful value. The cycloadduct must have a finite life.

Rule 6. The products of the cycloaddition need not be stable or isolable, but the cycloadducts must occur at least as intermediates.

2. Classification

Cycloadditions are best classified on the basis of the number of new σ bonds. The resulting classes may be subdivided according to the size of the ring and the number of ring members contributed by each component.

Probably the only difficulty in the application of the first criterion is presented by simultaneous or subsequent ring opening.



(15)

In the reaction of 5-phenyl-3*H*-1,2-dithiole-3-thione *(15)* with dimethyl acetylenedicarboxylate [24], the net gain is one σ bond. The 1,3-dithiole ring formed obviously contains two new σ bonds, but the old ring is opened with the loss of one σ bond. The reaction is logically a cycloaddition with formation of two new σ bonds. The same situation arises in the cycloaddition

[15] *G. Kresze* and *R. Albrecht*, Angew. Chem. *74*, 781 (1962); Angew. Chem. internat. Edit. *1*, 595 (1962).

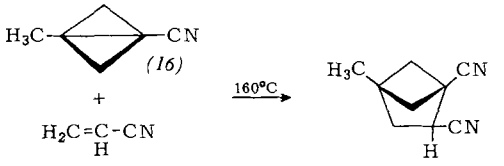
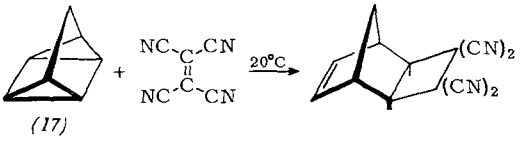
[24] *H. Behringer* and *R. Wiedenmann*, Tetrahedron Letters *1965*, 3705; *D. B. J. Easton* and *D. Leaver*, Chem. Commun. *1965*, 585.

of 1-cyano-3-methylbicyclo[1.1.0]butane *(16)* with acrylonitrile [25]. In this case there is no doubt about the simultaneity of the intra-annular loss of one σ bond (though not a "true" one) and the formation of two σ bonds to the unsaturated nitrile.



In the cycloaddition of quadricyclane *(17)* with tetracyanoethylene [26], the number of rings decreases from four to three. It is possible, however, to single out the cycloaddition step from the more complicated overall process. The ring to be considered is the new four-membered ring; thus two new σ bonds are formed.



(17)

Unification of the notation is desirable in the application of the ring-size criterion. The terminology "1,4-1′,2′ cycloaddition" is clumsy, as well as confusing, because *e.g.* hexa-2,4-diene adds in the 2,5 positions. A simpler and clearer name for this process, which yields a five-membered ring, is 3+2 cycloaddition. In this notation, the formation of a cyclic sulfone from butadiene and sulfur dioxide is a 4+1 cycloaddition.

Further subdivision may be based on method or on mechanism. Thus the photochemical 2+2 cycloadditions, which can in turn be grouped into singlet and triplet processes, can be distinguished in this way from *e.g.* the thermal dimerization of the polyfluoroalkenes or the cycloaddition of ketenes to olefins. Views on the mechanism of the "true" Diels-Alder reaction are so firmly established [27] that this name is not given to any 4+2 cycloaddition that deviates from this mechanism in any important criterion.

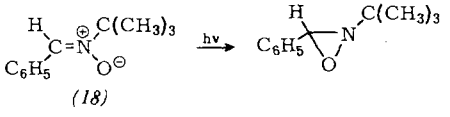
The distinction between one-step multi-center reactions and two-step processes, which relates to the energy profile of cycloadditions, is significant. This distinction is often the object of current investigations, but should not be used as a criterion, *e.g.* by regarding only one-step reactions as "true" cycloadditions. The Woodward-Hoffmann rules [28] predict the possibility of one-step processes on the basis of the conservation of orbital symmetry.

A few examples will now be given to illustrate the suggested classification system.

This group includes the wealth of electrocyclic reactions [9].

Three-membered Rings

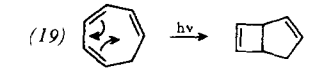
The equilibrium between azomethine ylides and aziridine derivatives was mentioned in Section 1 [compound *(6)*] [10]. A photochemical example is the conversion of the nitrone *(18)* into the oxaziridine [29].



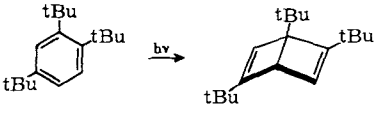
(18)

Four-membered Rings

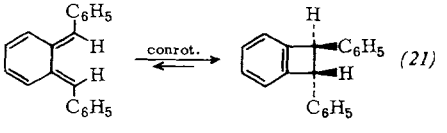
1,3-Dienes are converted into cyclobutenes on irradiation (for 1,3-butadiene, see [30]). Cycloheptatriene *(19)* [31], tropolone γ-methyl ether [32], and similar compounds react as 1,3-dienes, since this photocyclization in ring systems can only be disrotatory.



Even the benzene system behaves as a diene, as is shown by the photochemical formation of Dewar benzene derivatives *(20)* [33].



An example of the thermal conrotation is provided by the equilibrium established between *trans*-1,2-diphenyl 1,2-dihydrocyclobutabenzene *(21)* with *trans,trans*-5,6-bis(benzylidene)-1,3-cyclohexadiene [34].



(21)

Five-membered Rings

2-Acyl-5-phenyltetrazoles spontaneously lose nitrogen; the resulting *N*-acylnitrilimines are immediately transformed into 2,5-disubstituted 1,3,4-oxadiazoles *(22)* [35]. Many 1,5-cyclizations follow this scheme.

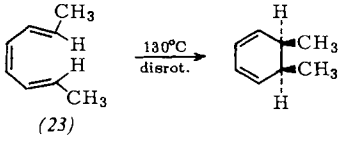
[35] *R. Huisgen*, *J. Sauer*, *H. J. Sturm*, and *J. H. Markgraf*, Chem. Ber. *93*, 2106 (1960).

(22)

Six-membered Rings

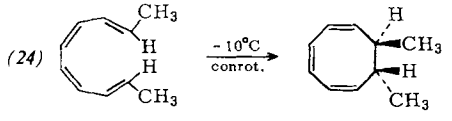
Compounds such as *(23)* containing the 1,3,5-hexatriene system give cyclohexadienes when heated (disrotatory)[36] or when exposed to light (conrotatory)[28]. The valence tautomerism of oxepin with benzene oxide[37] is an intracyclic example of such a change.



(23)

Eight-membered Rings

all-*cis*-Octatetraene changes spontaneously into 1,3,5-cyclooctatriene[38]. The cyclization of *trans,cis,cis, trans*-2,4,6,8-decatetraene *(24)* at −10 °C (this is a surprisingly ready formation of an eight-membered ring) reveals the steric course of this reaction[39].



(24)

2.2. Two New σ Bonds

The cycloadditions of the greatest preparative importance belong to this group, which is estimated to include 90 % of the known cycloadditions. Thus the small number of examples given is no reflection on the importance of this class.

2 + 1 → 3

The component that provides the single ring member must be both electrophilic and nucleophilic. This requirement is satisfied by carbenes, azenes, the oxygen atom, and halogen cations. The addition of dibromocarbene to *cis*- and *trans*-butene[40] illustrates the *cis*-stereospecificity of the reaction.

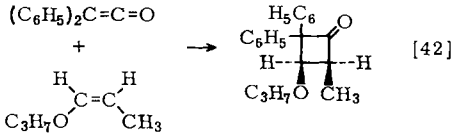
[40] *W. v. E. Doering* and *P. La Flamme,* J. Amer. chem. Soc. *78,* 5447 (1956).

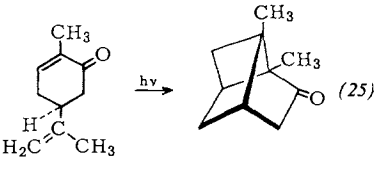
2 + 2 → 4

This group includes the thermal dimerizations of fluorinated olefins and of allenes and ketenes, as well as their additions to ordinary or conjugated olefins[41]. There is no uniformity of mechanism in this group.



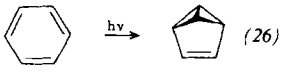
[42]

A reaction type of not minor importance is the photochemical dimerization of α,β-unsaturated carbonyl compounds or their addition to ordinary alkenes and alkynes or aromatic compounds[43]. An example of an intramolecular photoisomerization[44] is the formation of carvonecamphor *(25)*[45].



(25)

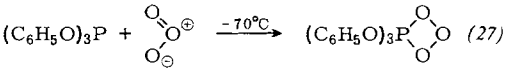
Irradiation of benzene yields benzvalene *(26)*[46]. In this interesting variant, the two new σ bonds are used for the formation of the bicyclo[1.1.0]butane system.



(26)

3 + 1 → 4

This scheme is very rarely encountered. A 1:1 adduct *(27)* of triphenyl phosphite and ozone exhibits the ^{31}P resonance of pentacovalent phosphorus[47].



(27)

3 + 2 → 5

The 1,3-dipolar cycloaddition is a one-step multi-center process[48]. According to work carried out in the past eight years, its versatility in the synthesis of heterocycles[49] is comparable to that of the Diels-Alder reaction in the formation of carbocyclic systems. The

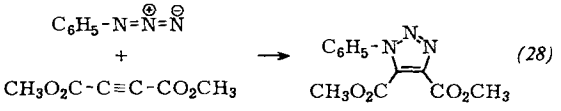
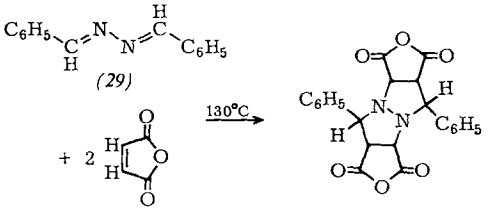
example of the formation of the triazole *(28)* [50] should serve to remind us that this type of reaction was known before the turn of the century.



(28)

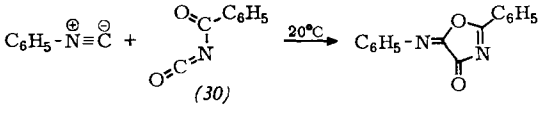
We encountered a reaction of a deviating charge type in Section 1 in the formation of *(10)* from trialkylborane, CO, and acetaldehyde [14]. Another example is the "criss-cross addition" of two molecules of maleic anhydride to benzalazine *(29)* [51].



(29)

4 + 1 → 5

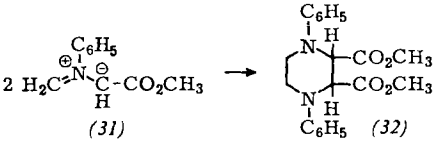
The best-known reaction of this type is the formation of cyclic sulfones from 1,3-dienes and sulfur dioxide [52]. The reaction of acyl isocyanates such as *(30)* with isonitriles [53] also belongs to this group.



(30)

3 + 3 → 6

Some 1,3-dipoles achieve stability by dimerization. The azomethine ylide *(31)* that exists in equilibrium with the ester of 1-phenylaziridine-2-carboxylic acid at 180 °C undergoes a head-to-head addition to form the piperazine derivative *(32)* [54].

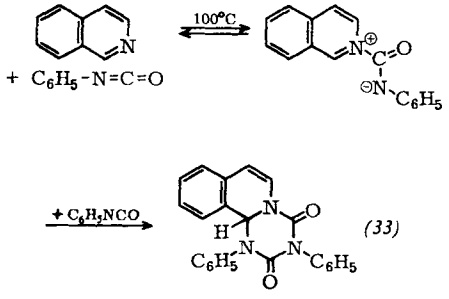


(31) *(32)*

4 + 2 → 6

The Diels-Alder reaction is the most extensively studied of all cycloadditions, and the literature has been summarized in numerous reviews and books [55]. Like many cycloadditions, the one-step multi-center process is particularly fast when one of the components is electron-rich and the other electron-deficient. The combination of electron-rich 1,3-dienes with electron-deficient dienophiles, the original type, has been supplemented recently by additions "with inverse electron requirements" [27].

A second principle of appreciable scope that leads to six-membered rings is the 1,4-dipolar cycloaddition, which, unlike the Diels-Alder addition, is a two-step process [56].

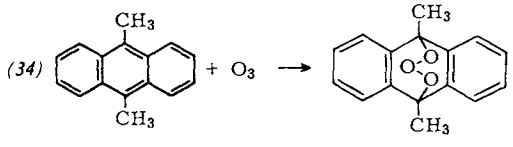


(33)

In the formation of the bisadduct *(33)* from phenyl isocyanate and isoquinoline, the isocyanate acts both as the electrophilic 1,4-dipole and as the dipolarophile [57].

4 + 3 → 7

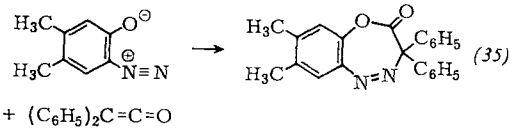
One of the few known examples of this type of reaction is the addition of ozone to the 9,10 positions of 9,10-dimethylanthracene *(34)* [58].



(34)

5 + 2 → 7

Ketenes react with aromatic *o*-diazo oxides to form 1:1 adducts, which are very probably 2,3-dihydro-1,4,5-oxadiazepin-2-ones *(35)* [59].



(35)

6 + 1 → 7

cis-1,3,5-Hexatriene adds sulfur dioxide across the ends of the conjugated system [60]. The formation of the seven-membered ring *(36)* is thus a vinylog of the 4 + 1 addition with formation of cyclic sulfones [52].

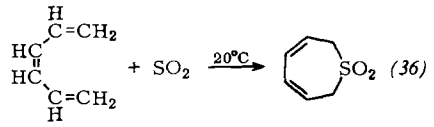
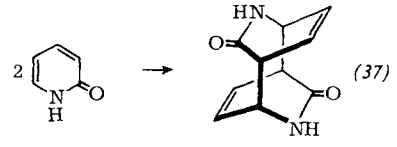
[60] *W. L. Mock*, J. Amer. chem. Soc. *89*, 1281 (1967).

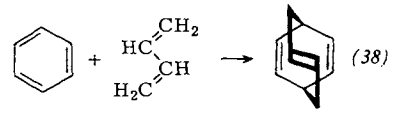


4 + 4 → 8

In the photodimerization of α-pyridone [61], two molecules combine in the 3,6-positions to give the *anti-trans* dimer *(37)*.

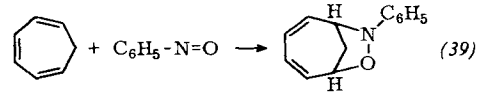


The *trans*-conformer of 1,3-butadiene adds to the 1,4-positions of benzene on UV irradiation to give the highly strained bicyclo[4.2.2]deca-3,7,9-triene *(38)*, which enters into a subsequent thermal reaction with butadiene [62].



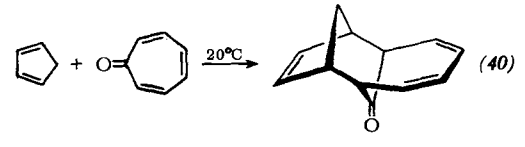
6 + 2 → 8

Whereas dienophiles normally add to the valence-tautomeric norcaradiene form of cycloheptatriene, nitrosobenzene apparently prefers a 1,6-addition to the monocyclic form to give the oxazolidine derivative *(39)* [63].



6 + 4 → 10

The 1,3,5-triene system in tropone also reacts as a unit with cyclopentadiene; the ease of formation of the ten-membered ring in *(40)* is remarkable [64].



6 + 6 → 12

The dimerization of *N*-ethoxycarbonylazepine *(41)* leads to a twelve-membered ring with two nitrogen bridges. However, there is some evidence that the 6π + 6π reaction, which is forbidden as a thermal multi-center addition, involves another dimer as an intermediate [65].

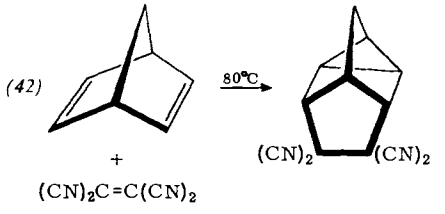
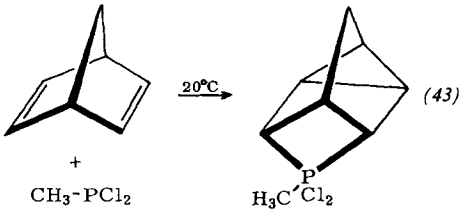
2.3. Three New σ Bonds

The reaction in this case leads in principle to more than one new ring. The homo-Diels-Alder reaction of norbornadiene *(42)* with tetracyanoethylene [66] may be regarded as a 5 + 2 cycloaddition; however, the reaction leads not to a seven-membered ring, but to a six-membered ring with a fused three-membered ring.



Similarly, the reaction of norbornadiene with dichloromethylphosphine leads in a 5 + 1 scheme to a polycyclic phospholane *(43)* with a new cyclopropane ring [67].



A 7 + 2 cycloaddition is found in the reaction of 1,3,5,7-tetramethylenecyclooctane *(44)* with tetracyanoethylene [68]. The new six-membered ring contains all three new σ bonds, but the eight-membered ring is simultaneously tied off into two five-membered rings.

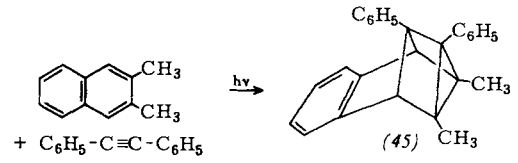
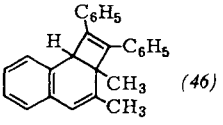
[67] *M. Green*, J. chem. Soc. (London) *1965*, 541.

[68] *J. K. Williams* and *R. E. Benson*, J. Amer. chem. Soc. *84*, 1257 (1962).

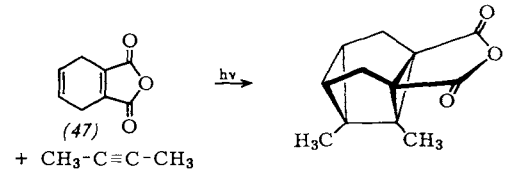
2.4. Four New σ Bonds



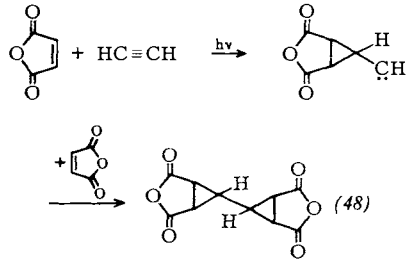
The triple bond of tolan undergoes a photoaddition to two quasi-double bonds of 2,3-dimethylnaphthalene[69]. However, it is questionable whether the polycyclic structure *(45)* is formed by a single photochemical act of addition. Two successive 2 + 2 cycloadditions could take place *via* the intermediate *(46)*.



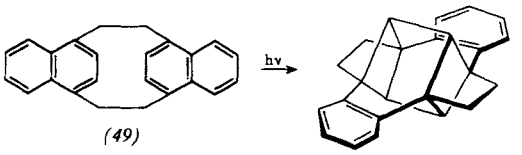
It is not so easy to break down the photoaddition of 2-butyne to 1,4-cyclohexadiene-1,2-dicarboxylic anhydride *(47)* into reaction steps[70], unless the intermediate resulting from the formation of the first cyclopropane ring is assumed to be a carbene.



This possibility cannot be ruled out, as is shown by the photosensitized cycloaddition of acetylene to two molecules of maleic anhydride to form the compound *(48)*[71]. The objections to a triple collision mechanism are so great that two successive 2 + 1 cycloadditions must again be considered. Thus it is not yet possible to prove the existence of cycloadditions



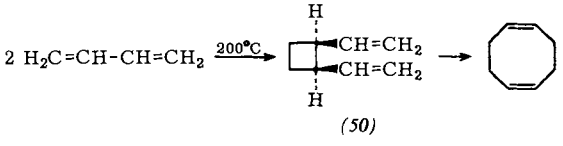
in which four new σ bonds are formed simultaneously. The situation is more favorable in intramolecular reactions, such as the photocyclization of [2,2]-paracyclonaphthane *(49)*[72].



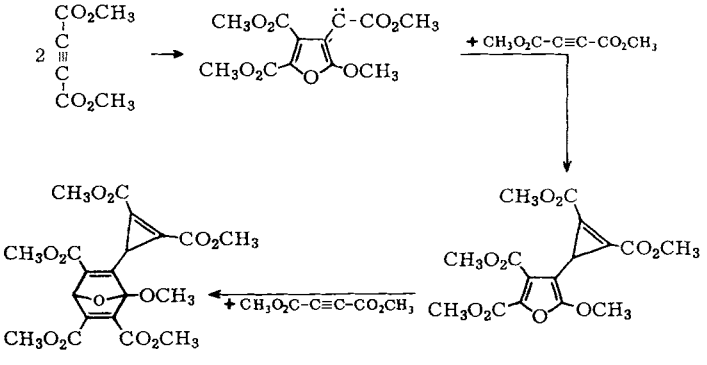
3. Concluding Remarks

The last few examples showed that even a heuristic classification principle is not always unambiguous. Mechanistic studies are sometimes necessary to determine whether several rings are formed simultaneously or consecutively.

Mention should also be made of the possibility that the ring compound isolated is not a primary cycloadduct, but the result of a cyclic rearrangement. In the thermal dimerization of butadiene to form 4-vinylcyclohexene, 10 % of *cis,cis*-1,5-cyclooctadiene was isolated as a by-product[73]. The formation of *trans*-1,2-divinylcyclobutane (5 %) as another by-product[74] suggests that the eight-membered ring was formed by a Cope rearrangement of the *cis*-1,2-divinylcyclobutane *(50)*; this has in fact been demonstrated[75]. Thus we are dealing not with a 4 + 4, but with a 2 + 2 cycloaddition.



There are also complex cases in which several cycloadditions take place consecutively. This is illustrated by the thermal tetramerization of dimethyl acetylenedicarboxylate (120 °C, 15 %)[76]. The sequence of



3 + 2, 2 + 1, and 4 + 2 cycloadditions is speculative; the first two steps may even take place in the reverse order.

Carbonylation of Olefins under Mild Temperature Conditions in the Presence of Palladium Complexes

BY K. BITTLER, N. v. KUTEPOW, D. NEUBAUER, AND H. REIS[*]

Dedicated to Professor A. Steinhofer on the occasion of his 60th birthday

During a search for catalysts that allow carbonylation reactions on olefins to proceed below 100 °C, complex palladium(II) compounds having the formula L_mPdX_n were found to be catalytically active. L denotes a ligand such as a phosphine, nitrile, amine, or olefin, X is an acid residue, and m+n is 3 or 4. The catalysts permit the carbonylation of heat-sensitive compounds, as well as selective carbonylation of polyunsaturated olefins. The new process can also be carried out on the industrial scale, as is shown by the carbonylation of cyclododecatriene.

1. Introduction

In the carbonylation method developed by *Reppe*, carbon monoxide is allowed to react with organic compounds such as acetylenes, olefins, alcohols, ethers, and esters under the catalytic influence of metal carbonyls and carbonylmetal hydrides [1]. The carbonylation of unsaturated compounds usually involves the participation of compounds having an acidic hydrogen such as water, alcohols, thiols, ammonia, amines, or carboxylic acids. The end products are carboxylic acids and their functional derivatives, unsaturated products being obtained from acetylenes and saturated products from olefins [1].

The reaction of olefins with carbon monoxide and water or alcohols to form acids or esters was already known when *Reppe* and his co-workers turned their attention to this field. The earlier processes proceeded only at high pressures (700–900 atm) and high temperatures (about 300 °C), in the presence of catalysts such as phosphoric acids, heteropolyacids, boron trifluoride, and metal halides. The metal carbonyls were often regarded as reaction inhibitors, and even as poisons for the catalysts, so that a great deal of work was devoted to the suppression of their formation in catalytic reactions such as the methanol synthesis. However, *Reppe*'s experiments with acetylene and carbon monoxide under pressure showed that metal carbonyls and carbonylmetal hydrides are excellent carbonylation catalysts, which are effective at lower temperatures. These catalysts make possible many important and interesting syntheses.

Reppe's first catalytic carbonylation was the reaction of acetylene with CO and H_2O under pressure to form acrylic acid; nickel carbonyl was used as the catalyst. In contrast to the earlier processes for olefin carbonylation, this reaction proceeds under relatively mild conditions (about 30 atm and 170 °C). Esters of acrylic acid are obtained under the same conditions from acetylene, CO, and alcohols in the presence of halides of metals that form carbonyls, for example, $NiBr_2$ and NiI_2, as well as complex Ni halides.

The next obvious step was to apply the experience gained in the carbonylation of acetylene to that of olefins. The attempt to prepare propionic acid and its esters by the catalytic reaction of ethylene with CO and water or alcohols in the presence of Ni salts or $Ni(CO)_4$ was an immediate success. Corresponding to the lower reactivity of the double bond as compared with the triple bond, however, much more vigorous reaction conditions, *e.g.* 250–320 °C and 200–300 atm, must be used for the carbonylation of olefins.

Operation in this temperature range has certain disadvantages. Thus the carbonylation of olefins, particularly above about 150 °C, is always accompanied by side reactions, such as the water-gas reaction. The hydrogen that is formed hydrogenates unreacted olefin, and reacts with CO and the olefin to form aldehydes, alcohols, and ketones, as well as other products. Another disadvantage is that isomerizations, polymerizations, resinifications, and cleavages proceed more readily at higher temperatures. There is also a danger of increased corrosion.

$$CO + H_2O = CO_2 + H_2$$

Some (mainly straight-chain) olefins can be carbonylated to form carboxylic acids at 120–190 °C if water is present in excess and if the reaction is carried out in solvents such as ketones, dioxane, amides, or alcohols with octacarbonyldicobalt as the catalyst [2]. In these cases the solvents must dissolve both the olefins and the carboxylic acids formed.

Olefins can be carbonylated at even lower temperatures to give esters in a process developed by du Pont [3].

The process is based on the reaction of the olefin with CO and a primary monofunctional alcohol in the presence of a catalyst system (an alcohol-soluble Sn or Ge salt and an alcohol-soluble salt of a rare metal of group VIII in a molar ratio of 1:1 to 20:1) at 100 to 3000 atm and 50–325 °C. Below 250 °C the reaction is successful only with platinum salts. The reaction temperature required for the cheaper palladium salts is above 250 °C and these compounds therefore offer no advantage over conventional catalysts.

This situation led to a search for new catalysts that would act at lower temperatures than the conventional catalysts, and would at the same time be relatively cheap and accessible. We chose the Pd compounds, which readily form complexes with olefins, since we believed that the olefin could be carbonylated at a lower temperature when activated *via* a Pd-olefin complex than when the carbon monoxide is activated *via* a metal carbonyl catalyst, as in the usual process. The investigations soon led to Pd complexes such as bis(triphenylphosphine)palladium dichloride that satisfied our requirements and permitted *e.g.* the synthesis of esters of carboxylic acids below 100 °C [4].

Tsuji et al. [5–8] discovered independently that the reaction of olefins with CO in an alcoholic solution of hydrogen chloride in the presence of $PdCl_2$ under conditions such as 80 °C and 100 atm leads to esters of saturated or unsaturated acids. However, this process is accompanied by side reactions, such as the addition of hydrogen chloride to the olefin. Moreover, $PdCl_2$ in aqueous or alcoholic solution is readily reduced to the metal by carbon monoxide.

2. Palladium Complexes and their Catalytic Activity

Palladium metal, palladium carbonyl halides [9,10], olefinpalladium halides [11], and complex palladium(0) compounds have been considered for use as catalysts for the carbonylation of olefins below 100 °C.

By analogy with the pure metal carbonyls used in Reppe syntheses, palladium(0) compounds were examined first. Since palladium does not form metal carbonyls, the complexes *(1)* and *(2)* were chosen.

$[(C_6H_5)_3P]_4Pd$ *(1)* $[(o\text{-}CH_3\text{-}C_6H_4O)_3P]_4Pd$ *(2)*

Complex *(1)* is the more readily obtainable of these. It can be prepared, for example, by reactions (a) [12] and (b) [14]

$$Pd(NO_3)_2 + 9\,(C_6H_5)_3P \rightarrow \underset{(1)}{Pd[P(C_6H_5)_3]_4} + N_2O + 5\,(C_6H_5)_3PO \quad (a)$$

$$[(C_6H_5)_3P]_2PdCl_2 + CO + 2\,P(C_6H_5)_3 \rightarrow \underset{(1)}{Pd[P(C_6H_5)_3]_4} + COCl_2 \quad (b)$$

A method (c) using cyclohexadiene [13, 13a] has also proved useful:

$$PdCl_2 + 2\,C_6H_8 \rightarrow C_6H_6 + HCl + 1/2\,[C_6H_9PdCl]_2 \xrightarrow{+NaC_5H_5} C_6H_9PdC_5H_5 \xrightarrow{P(C_6H_5)_3} \underset{(1)}{Pd[P(C_6H_5)_3]_4} \quad (c)$$

Synthesis (c) can be simplified by the use of allyl alcohol instead of cyclohexadiene, *via* the intermediates π-allylpalladium chloride [15] and π-allyl-π-cyclopentadienylpalladium [16]. This modified route is also the most suitable for the preparation of *(2)*.

The carbonylation of ethylene and propylene with alcohol as a reactant and 0.05–0.5% of tetrakis(triphenylphosphine)palladium as the catalyst does not proceed below 100 °C. On addition of catalytic quantities of hydrogen chloride to the reaction mixture, however, the desired esters are formed, even at temperatures between 40 and 80 °C.

After the reaction, a yellow crystalline precipitate containing Pd was always observed; this was identified as the known compound $[(C_6H_5)_3P]_2PdCl_2$ [17], which is readily obtainable and very stable. This complex is so active in the pure state that it can catalyze the carbonylation of olefins below 100 °C with or without the addition of HCl.

Since Pd(0) compounds are evidently inactive in the absence of HCl, whereas complex Pd(II) halides exhibit high activity, a number of Pd(II) complexes were prepared (some for the first time), and their activities as carbonylation catalysts at low temperatures were tested with many olefins. A selection of these Pd complexes is given in Table 1.

Bis(triphenylphosphine)palladium dichloride and palladium complexes [4] containing triphenylphosphine together with a more weakly bound ligand, such as triphenylphosphinepiperidinepalladium dichloride or triphenylphosphinebenzylaminepalladium dichloride, have the highest catalytic activities, whereas olefin-

Table 1. Relative activities of palladium catalysts in carbonylations.

Very good:

$[(C_6H_5)_3P]_2PdCl_2$; $(C_5H_{11}N)\cdot PdCl_2\cdot P(C_6H_5)_3$ [a];
$(C_6H_5CH_2NH_2)\cdot PdCl_2\cdot P(C_6H_5)_3$;
$C_3H_5\cdot PdCl\cdot P(C_6H_5)_3$ [b]

Good:

$[(C_6H_5)_3P]_2PdBr_2$; $(C_6H_5CN)_2PdCl_2$;
$(C_5H_{11}N)_2\cdot PdCl_2$ [a]; $[(C_6H_5)_3P\cdot PdCl\cdot SC_6H_5]_2$

Moderate:

$[(C_6H_5)_3P]_2PdI_2$; $[(C_6H_5)_3P]_2PdSO_4$;
$[(C_6H_5)_3P]_2Pd(CH_3COO)_2$; $[(C_6H_5)_3P]_2Pd(NO_3)_2$;
$[(n\text{-}C_4H_9)_3P]_2PdCl_2$; $[(n\text{-}C_4H_9)_3N]_2PdCl_2$

Poor:

$[(o\text{-}CH_3\text{—}C_6H_4O)_3P]_2PdCl_2$; $(NH_3)_2PdCl_2$;
$(CH_2=CH\text{—}CH_3)_2\cdot PdCl_2$; $C_{12}H_{18}\cdot PdCl_2$ [c]

Ineffective:

$[HCON(CH_3)_2]_2PdCl_2$

[a] $C_5H_{11}N$ = piperidine. [b] C_3H_5 = π-allyl. [c] $C_{12}H_{18}$ = 1,5,9-cyclododecatriene.

palladium chloride complexes and even $PdCl_2$ [5] itself are less active as catalysts. This can be explained by insufficient stabilization of bivalent palladium by olefins as ligands in the presence of carbon monoxide, so that it is reduced by CO to the metal, which is inactive in this reaction unless hydrogen halide is added. The activity of the olefinpalladium chlorides increases at higher hydrogen chloride concentrations. The activity is reduced by high temperatures and by high carbon monoxide pressures.

Apart from the complex ligands, the anion also plays an important part. Only chlorides and bromides exhibit pronounced activity; palladium complexes that contain a nitrate, iodide, acetate, or sulfate anion are only moderately active catalysts.

3. Carbonylation of Olefins in the Presence of Palladium Complexes

A wide range of esters can be prepared from olefins and alcohols by carbonylation at low temperatures in the presence of the palladium complexes listed in Table 2 [4].

These palladium catalysts can be used for the preparation not only of esters, but also of acids, by the use of water instead of alcohols [4]. However, temperatures about 50 °C higher are generally required for the preparation of acids, so that greater demands are made on the stability of the palladium catalyst toward reduction.

Table 2. Synthesis of esters by carbonylation of olefins in the presence of alcohols. Catalyst: *e.g.* $[(C_6H_5)_3P]_2PdCl_2$, reaction conditions 300—700 atm CO.

Olefin	Temp. (°C)	Reaction product	Yield based on reacted olefin (%)
$CH_2=CH_2$	60—100	$CH_3\text{—}CH_2\text{—}COOC_2H_5$	90
$CH_3\text{—}CH=CH\text{—}CH_3$	70	$CH_3\text{—}CH_2\text{—}CH(CH_3)\text{—}COOCH_3$	95
$CH_3\text{—}CH=CH_2$	50—70	$CH_3\text{—}CH_2\text{—}CH_2\text{—}COOC_2H_5$ + $(CH_3)_2CH\text{—}COOC_2H_5$	90
Diisobutylene	120	$(CH_3)_3C\text{—}CH_2\text{—}C(CH_3)_2\text{—}COOC_2H_5$ and isomers	92
$CH\text{—}COOC_2H_5$ ‖ $CH\text{—}COOC_2H_5$	140	$H_5C_2OOC\text{—}CH\text{—}COOC_2H_5$ | $CH_2\text{—}COOC_2H_5$	70
$CH_2=CH\text{—}CH_2OH$	100	$CH_2=CH\text{—}CH_2\text{—}COOCH_3$	65
$CH_2=CH\text{—}CH=CH_2$	70	$CH_3\text{—}CH=CH\text{—}CH_2\text{—}COOC_2H_5$	71.5
Styrene	90	$C_6H_5\text{—}CH(CH_3)\text{—}COOC_2H_5$	95
Diethyl-4-cyclohexene-1,2-dicarboxylate *(3)*	90	Triethyl 1,2,4-cyclohexanetricarboxylate *(4)*	88
4-Vinylcyclohexene *(5)*	60	Methyl 2-(3-cyclohexenyl)-propionate *(6)*	85
4-Vinylcyclohexene *(5)*	120	Methyl 2-(methoxycarbonylcyclohexyl)propionate *(7)*	80

1,5,9-Cyclododecatriene *(8)*	50—70 [a]	Diethyl 5-cyclododecene-dicarboxylate *(10)* [+*(9)* + *(11)*]	70—80 *(10)*
1,5,9-Cyclododecatriene *(8)*	> 70 [a]	Triethyl cyclododecanetricarboxylate *(11)* [+*(9)* + *(10)*]	70—80 *(11)*
Cyclooctatetraene	90	Ethyl bicyclo[4.2.0]octa-2,4-diene-7-carboxylate	33

[a] The temperature limits depend on the HCl concentration, the catalyst concentration, and in some cases the catalyst used; the temperature limits indicated are valid for 0.35% of $[(C_6H_5)_3P]_2PdCl_2$ and 10% of HCl in C_2H_5OH.

The palladium(II) complexes which are always added only in catalytic quantities, also catalyze the formation of acyl chlorides from olefins, CO, and hydrogen chloride [18], and of anhydrides from olefins, CO, and acid

[18] *N. v. Kutepow, K. Bittler, D. Neubauer*, and *H. Reis*, German Pat. 1237116 (1964), BASF.

Whereas carbonylation of olefins with isolated double bonds always results in the loss of the double bond, allyl alcohol and allyl chloride are carbonylated with retention of the double bond [4, 19].

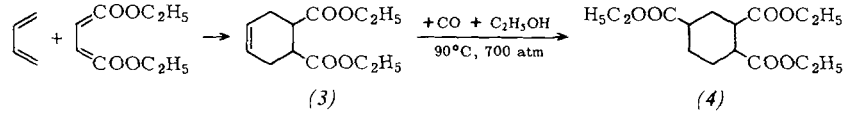
$$CH_2=CH-CH_2X + CO + ROH \rightarrow CH_2=CH-CH_2COOR + HX$$

X = halogen or OH
R = alkyl or aryl

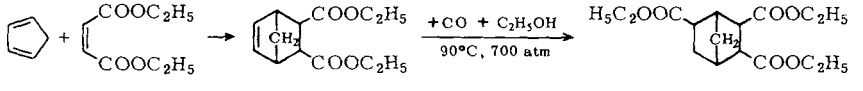
4. Advantages of the Complex Palladium Catalysts

The greatest advantage of the complex palladium catalysts, which catalyze the carbonylation even at concentrations of 0.05% and less, is their activity at low temperatures. Carbonylation with conventional catalysts, such as metal carbonyls of the iron group, takes place only at temperatures above 160 °C, *i.e.* temperatures at which the heat-sensitive olefins decompose, polymerize, isomerize, or in the presence of water and carbon monoxide, are hydrogenated by the hydrogen formed.

Thus Diels-Alder adducts such as the cyclohexene derivative *(3)* and the corresponding norbornene derivative, which readily dissociate into their components at high temperatures, were carbonylated for the first time with palladium complexes.



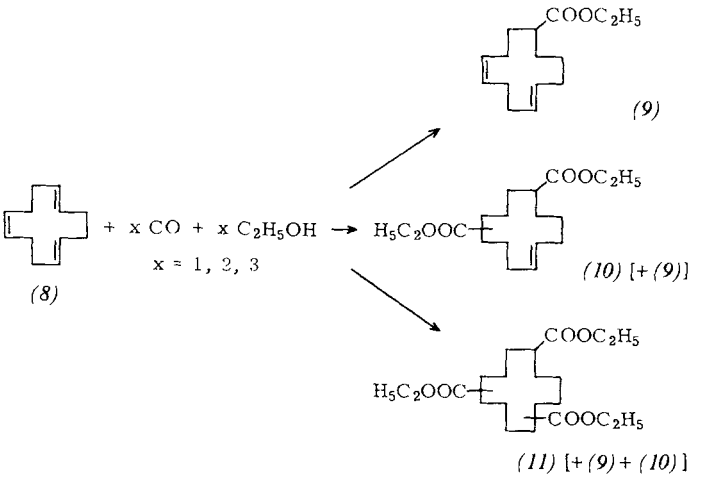
(3) *(4)*



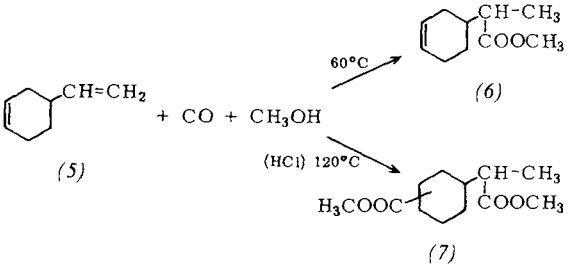
Another surprising advantage of the palladium complexes is that polyunsaturated olefins can be selectively carbonylated in their presence. For example, it was not previously possible to convert 1,5,9-cyclododecatriene *(8)* into 4,8-cyclododecadiene-1-carboxylic acid or its esters or to corresponding polycarbonylated compounds, since acenaphthene derivatives and polymerization products were formed instead. Although *Rüll* [19] recently obtained esters of cyclododecanecarboxylic acid by the reaction of *(8)* with CO and alcohol in the presence of $[Co(CO)_4]_2$ as catalyst, this process leads to many by-products. The complex palladium(II) catalysts, on the other hand, made it possible to cause one, two, or all three double bonds in cyclododecatriene to react, depending on the reaction conditions, to give mainly the mono- *(9)*, di- *(10)*, and triester *(11)*; the monoester can in fact be obtained without by-products.

When *trans,trans,cis*-1,5,9-cyclododecatriene is used, one of the two *trans* double bonds reacts first, and then the *cis* double bond.

[19] *Th. Rüll*, Bull. Soc. chim. France *10*, 2680 (1964).



Vinylcyclohexene *(5)* can also be converted either into the cyclohexenylpropionate *(6)* or into the diester *(7)* by variation of the conditions.



5. Mechanism of the Reaction

The catalyst could promote carbonylation by activation either of the carbon monoxide or of the olefin by addition to the central atom of the complex.

Activation of CO below 150 °C may be ruled out, since non-olefinic compounds, such as alcohols and alkyl halides, that can be satisfactorily carbonylated with conventional catalysts cannot be carbonylated with palladium(II) complexes.

Thus the catalyst must activate the double bond of the olefin. A feasible explanation for this process is that the olefin displaces a ligand from the palladium complex, and is itself bonded to the palladium by a π bond. This intermediate has not yet been isolated, but the above assumption is supported by the fact that complexes in which two ligands are bound unequally strongly to the central atom are particularly active. The carbonium ion of the polarization-activated

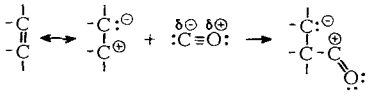
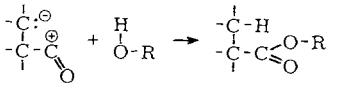
[a] The crude discharge is washed twice with a solution of $CaCl_2$, washed once with a solution of Na_2CO_3, and dried over solid $CaCl_2$ before vacuum distillation. [b] $C_5H_{11}N$ = piperidine. [c] Alcohol distilled off at atmospheric pressure.

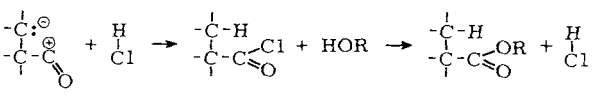
double bond then undergoes nucleophilic attack by carbon monoxide in its resonance form $:C^{\delta\ominus} \equiv O^{\delta\oplus}:$



In the absence of hydrogen chloride, the intermediate then reacts with alcohol, and the reaction product is simultaneously released from the catalyst.



Small quantities of hydrochloric acid very greatly increase the reaction rate. This effect is probably due to the higher acidity of the hydrogen in HCl as compared with alcohols; the synthesis of the esters probably proceeds *via* an intermediate acyl chloride.



Acyl chlorides are in fact obtained in the absence of alcohol or water[6, 18]. Moreover, hydrogen chloride may catalyze the addition of the olefin to the catalyst, since it forms quaternary salts with basic complex ligands, and these ligands can therefore be removed more readily.

In the carbonylation of olefins of the type $R^1R^2C{=}CH_2$, where R^1 and R^2 are first order substituents, carbon monoxide preferentially attacks the carbon atom carrying the smaller number of hydrogen atoms (Table 3). This behavior is reminiscent of the rules for the addition of hydrogen halides (Markovnikov rule).

6. Selective Carbonylation of 1,5,9-Cyclododecatriene

The carbonylation of the heat-sensitive 1,5,9-cyclododecatriene[4] was studied closely, since this is an ideal example of a selective carbonylation; moreover, there has been considerable interest for a long time in the preparation of 13-tridecanolactam[20] by conversion of 1,5,9-cyclododecatriene *via* 4,8-cyclododecadiene-1-carboxylate into cyclododecanecarboxylate, followed by reaction of the latter ester with nitrosylsulfuric acid.

Bis(triphenylphosphine)palladium dichloride was found to be the best catalyst because of its selective action, resistance to reduction, relative activity, and ready availability (see Table 4, Part a).

Table 4, Part b, illustrates the temperature-dependence of the reaction. Higher temperatures favor the formation of the

[20] *H. Metzger* and *H. Urbach*, German Pat. 1192649 (1961), BASF.

diester, and ultimately of the triester. At sufficiently low temperatures (about 50 °C), only the monoester *(9)* is formed. A very close relationship exists between the catalyst concentration and the temperature. It can be seen from Table 4, Part c, that if the catalyst concentration is decreased, the temperature must be raised in order to obtain roughly the same conversions and yields under otherwise identical conditions.

Cyclododecatriene can in principle be carbonylated even in the absence of hydrogen halide. However, higher reaction temperatures are required in neutral than in acidic media under otherwise identical conditions. The strong influence of hydrogen chloride on the reaction rate can be seen from the fact that no diester is formed in the absence of hydrogen chloride, despite the higher temperature (see Table 4, Part d). Cyclododecatriene and alcohol can be made to react in stoichiometric quantities. If necessary, alcohol can be used in excess. Carbon monoxide is sufficiently soluble in the reaction mixture at 300 atm to permit the reaction to be carried out in an industrially favorable pressure range.

The influence of the contact time and in particular its effect on the influence of the other parameters was studied in the apparatus shown in Figure 1 (see also Table 5).

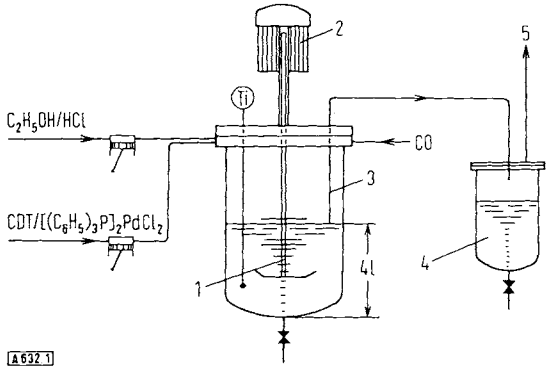


Fig. 1. Apparatus for the carbonylation of *trans,trans,cis*-1,5,9-cyclododecatriene (CDT). 10 l Hofer autoclave fitted with a magnetic lifter agitator and lined with Hastelloy B; continuous operation.
1 = stirrer, 2 = magnet, 3 = immersion tube, 4 = discharge vessel, 5 = waste gas outlet.

Alcoholic hydrochloric acid and bis(triphenylphosphine)-palladium dichloride in cyclododecatriene are pumped into the 10-l autoclave. Liquid and gas are continuously withdrawn into a pressureless glass vessel through an immersion tube fitted in such a way that 4 l of liquid are always present in the autoclave. The distance between the sieve plates on the magnetic lifter agitator and the frequency and stroke are determined beforehand in model experiments for optimum mixing of the gas and liquid phases.

Table 5 shows, *inter alia*, that diester formation can be suppressed by the use of a shorter contact time, since diethyl cyclododecenedicarboxylate is not formed directly from cyclododecatriene, but from the monoester.

7. Re-use of the Catalyst

The recovery and re-use of the catalyst is of the utmost importance in the industrial use of the synthesis. It was found preferable not to isolate the complex as such, but to return it to the synthesis in the form of the "catalyst residue" obtained when the alcohol, the cyclododecatriene, and the monoester are distilled off.

The first experiments were carried out in autoclaves with glass inserts to exclude any effects due to foreign ions from the wall of the autoclave. It is shown in Table 4, Part d, that higher temperatures are necessary in order to obtain the same conversion and yield in the absence of hydrogen chloride. However, to allow the catalyst tests with and without hydrogen chloride to be carried out at approximately the same temperatures, the catalyst concentration was increased by a factor of about ten for the experiments without HCl to ensure that the same conversions and yields would be obtained. When the catalyst is re-used, hydrogen halide must be added, since the catalyst is otherwise inactive, even at higher concentrations, after having been used once.

Figure 2 shows the behavior of the catalyst in the presence of and in the absence of HCl.

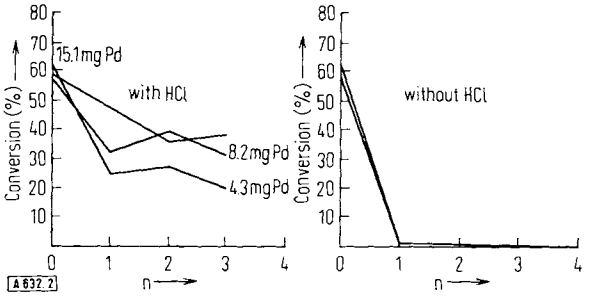

Fig. 2. Attempts to re-use the catalyst. Experiments with HCl (left): 75 °C, 300 atm CO, ≈ 0.055 wt.-% of $[(C_6H_5)_3P]_2PdCl_2$, molar ratio ethanol:cyclododecatriene = 1.2:1, 3.3 wt.-% of HCl in C_2H_5OH. Experiments without HCl (right): 80 °C, 300 atm CO, 0.45 wt.-% of $[(C_6H_5)_3P]_2PdCl_2$, molar ratio ethanol:cyclododecatriene 1.2:1.
Abscissa: n = frequency of re-use.

In the presence of HCl, the catalyst is sufficiently active even after being re-used three times. The decrease in activity after repeated use is due mainly to mechanical losses during the

preparation of the catalyst residue. Slight losses also occur, particularly at higher temperatures, as a result of the reduction of palladium(II) to metallic palladium; this reduction becomes even more pronounced when the "more water-like" methanol is used instead of ethanol.

It is advantageous to add one mole of triphenylphosphine per g-atom of palladium [21] to the catalyst residue.

8. Industrial Synthesis of Cyclododecadienecarboxylate

On the basis of the above results, a pilot plant (synthesis and isolation sections) was constructed for the continuous production of the monoester. Hastelloy alloys, particularly Hastelloy B, must be used for parts subjected to high pressures. Low-pressure parts were made of glass. A scheme of the pilot plant is shown in Figure 3.

Alcohol containing HCl was fed, together with dissolved catalyst residue, cyclododecatriene with fresh catalyst, and technical carbon monoxide (300 atm), into a 3-l reactor lined with Hastelloy B. Unreacted carbon monoxide is re-introduced into the reactor; inert gases are displaced from the reactor as waste gas. The product discharged from the reactor is freed from alcohol in the first thin-film evaporator. The alcohol is condensed and returned to the reaction after the addition of hydrogen chloride. The residue containing the catalyst is separated from unreacted cyclododecatriene and monoester in the second thin-film evaporator. Most of the catalyst

residue is also returned to the synthesis. The mixture of monoester and cyclododecatriene vapors from the second thin-film evaporator is passed into a separating column, unreacted cyclododecatriene being obtained as the head product. The pure ethyl cyclododecadienecarboxylate is obtained as a residue at the bottom of the column in a yield of 90%, based on reacted cyclododecatriene.

Sulfonyl Hydrazones of Cyclic Amides and Quaternary Azo Sulfones of Heterocycles as Reagents in Azo Chemistry [1]

BY S. HÜNIG [*]

IN COLLABORATION WITH W. BRENNINGER, H. GEIGER, G. KAUPP, W. KNIESE, W. LAMPE, H. QUAST, R. D. RAUSCHENBACH, AND A. SCHÜTZ

Dedicated to Professor A. Steinhofer on the occasion of his 60th birthday

Sulfonyl hydrazones of cyclic amides undergo oxidative coupling with phenols and reactive methylene components. The reaction proceeds via the azo sulfones, which may be used as such, and which, as ambident cations, enter into many reactions with nucleophiles and extend the scope of oxidative coupling. The reaction with phenols is a two-step process, in which the limiting cases $k_1 \ll k_2$, $k_1 \approx k_2$, and $k_1 \gg k_2$ can be realized by slight variation of the reactants.

1. Introduction

Some years ago, two articles [2] were published concerning a new principle for the introduction of the azo group into aromatic amines, phenols, and reactive methylene compounds. These nucleophilic reactants exhibit general coupling with amidrazone systems *(1)* or their vinylogs *(2)* under the action of oxidizing agents. Typical examples of these com-

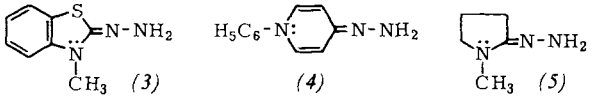
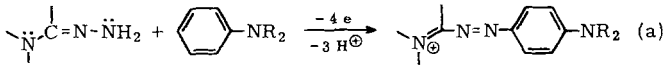
pounds, which will be referred to in the following discussion as "hydrazones" are shown in formulas *(3)* to *(5)*.



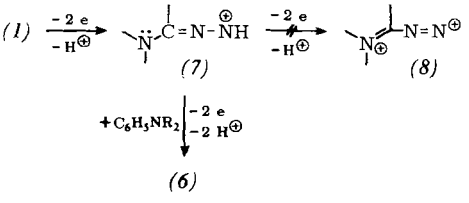
(3) *(4)* *(5)*

Equation (a) shows the stoichiometry for the oxidative coupling with an aromatic amine. It might have been concluded from the structure of the coupling product



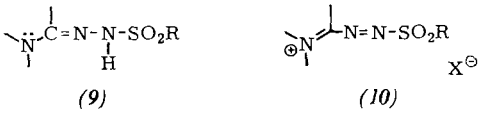
(1) *(6)* (a)

(6) that *(1)* is oxidized to *(8)*, an unusually electrophilic diazonium ion which would react immediately with the nucleophilic component. It is certain, however, that the quaternary diazonium ions *(8)*, which are unknown, do not occur even as unstable intermediates. The coupling actually proceeds *via* the resonance-stabilized form *(7)*, and is exactly analogous to



(7) *(8)* *(6)*

the oxidative coupling of *p*-phenylenediamines [2]. However, since aromatic azo sulfones Ar–N=N–SO_2R couple smoothly [3] it should be possible to use the hydrazones *(1)* and *(2)* at the oxidation level *(7)* or *(8)* if the β–N atom is attached to a sulfonyl group. This structural condition is met by the sulfonyl hydrazones *(9)* and the quaternary azo sulfones *(10)*. Both types of compounds do in fact couple smoothly



(9) *(10)*

[*(9)* oxidatively], and have even wider ranges of application than the hydrazones *(1)* and *(2)*. The following sections treat the synthesis and reactions of compounds of the types *(9)* and *(10)* and the coupling mechanism.

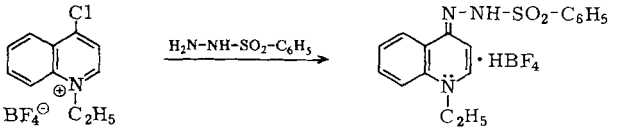
2. Sulfonyl Hydrazones *(9)*

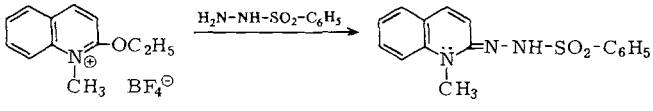
2.1. Synthesis [4-8]

Sulfonyl hydrazones *(9)* may be synthesized by one of the following routes, depending on the availability of the starting material:

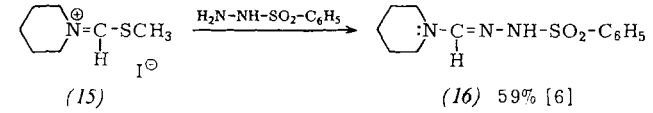
a) By analogy with the preparation of the hydrazones *(1)* and *(2)*, reactive quaternary salts such as *(11)*, *(13)*, or *(15)* are allowed to react with sulfonyl hydrazines.



(11) *(12)* 84% [7]



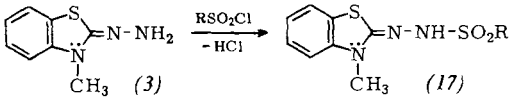
(13) *(14)* 72% [8]



(15) *(16)* 59% [6]

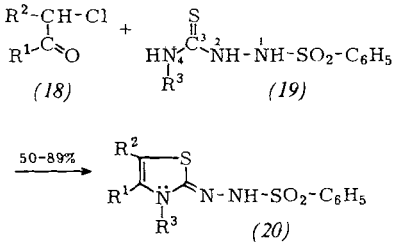
Halogen, SR, and OR have been found to be good leaving groups. Most of the sulfonyl hydrazones were obtained in this way.

b) If the hydrazone itself is readily obtainable [9], as in the case of *(3)*, it may be sulfonated with sulfonyl chlorides, *e.g.* to form *(17)* [4]. This is the most convenient way of varying the substituent R in the sulfonyl group.



(3) *(17)*

c) 2-Thiazolonesulfonyl hydrazones *(20)* are most easily synthesized from α-halogeno ketones *(18)* and benzenesulfonyl thiosemicarbazides *(19)* [5]. Independent of the nature of R^3, the ring closure always takes place at the N^4 atom [10].



(18) *(19)* *(20)*

R^1 = H, alkyl, aryl; R^2 = H, alkyl; R^3 = alkyl, aryl.

[9] *R. Riemschneider* and *S. Georgi,* Mh. Chem. *91*, 623 (1960).

[10] This is not self-evident. The corresponding benzoyl thiosemicarbazones undergo ring closure on the N^4 atom for R^3 = alkyl and on the N^3 atom for R^3 = aryl (cf. [5]).

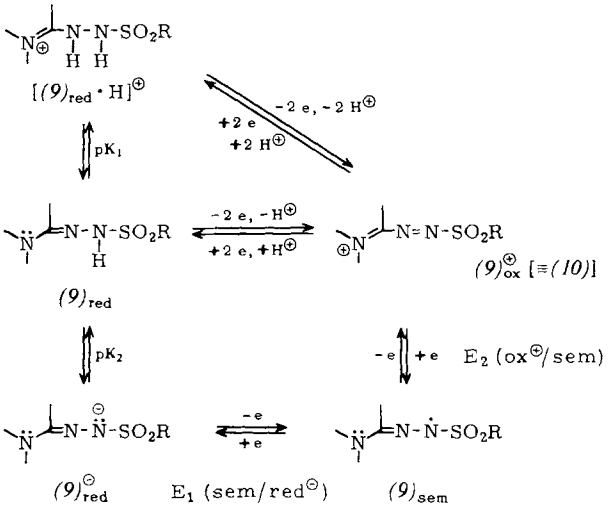
2.2. General Properties

In comparison with the hydrazones *(1)* and *(2)*, the sulfonyl derivatives are less soluble and are much more stable on standing. The acidity of the NH group is frequently sufficiently high to enable them to dissolve in sodium hydroxide (method of purification[4]) and their equivalent weights to be determined with tetrabutylammonium hydroxide in benzene/methanol[11]. Moreover, the basicity of the amidrazone grouping allows protonation, and hence titration with perchloric acid/glacial acetic acid[12].

2.3. Polarographic Behavior[8]

In reversible redox reactions, the underlying process can be positively deduced from the position and number of polarographically measured half-wave potentials and from the slope and pH-dependence of the curves[13]. It has been shown that both the free hydrazones *(1)* and the cations $[(1)\,H]^{\oplus}$ lose *two* electrons in *one* step during the oxidation, with formation of the oxidized stage *(7)*, which cannot be isolated[2,14].

The sulfonyl hydrazones *(9)* and the cations $[(9)\,H]^{\oplus}$ behave similarly. They may be regarded as the reduced stages (red) $(9)_{red}$ and $[(9)_{red}\cdot H]^{\oplus}$ of a reversible redox system, which lose $2e + H^{\oplus}$ and $2e + 2\,H^{\oplus}$ respectively to give the completely oxidized stage (ox), for which the only possible structure is the azo sulfone *(10)*. In contrast to the hydrazones *(1)*, the sulfonyl hydrazones *(9)* have a second pK value in the alkaline range, which links *(9)* with the corresponding anion $(9)^{\ominus}$. This anion has two pH-independent oxidation stages, which must be ascribed to the radical $(9)_{sem}$



and the oxidized stage $(9)_{ox}^{\oplus}$ [≡ *(10)*]. We thus have a reversible two-step redox system of the type

$$red^{\ominus} + ox^{\oplus} \underset{}{\overset{K}{\rightleftarrows}} 2\ sem$$

The formation constant K of the semiquinone, which is a measure of the thermodynamic stability of the radical, can assume surprisingly high values, as can be seen from Table 1.

It can also be deduced from Table 1 that the half-wave potentials decrease with increasing basicity of the sulfonyl hydrazones, as is the case with the free hydrazones[2,14]. The potentials also show that the quaternary azo sulfone stage *(10)* can be reached under the conditions of oxidative coupling, and that it must be possible to obtain *(10)* from *(9)*.

Table 1. Half-wave potential (against the saturated calomel electrode) of benzenesulfonyl hydrazones (as anions) at pH = 10.9 in *N*-methylpyrrolidone/water and semiquinone formation constants K.

Benzenesulfonyl hydrazone of	1st (mV)	2nd (mV)	K (± 10%)

1-Methyl-2-quinolone	−44	218	2.3×10^4
1-Methyl-4-quinolone	−67	141	2.9×10^3
10-Methyl-9-acridone	69	247	9.3×10^2

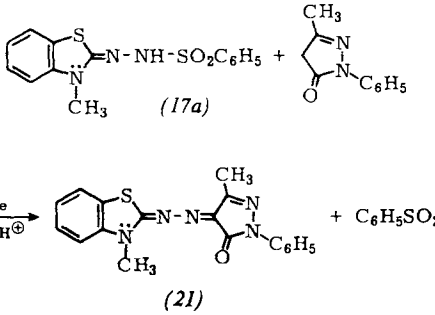
2.4. Oxidative Coupling

2.4.1. The Partners

Phenols and reactive methylene compounds in the widest sense are excellent partners for oxidative coupling (see below). On the other hand, pure coupling products can be obtained only with difficulty from aromatic amines, even under carefully controlled conditions[8].

2.4.2. Stoichiometry of Oxidative Coupling

The reaction proceeds by the path shown in the following example.



(17a) (b)

(21)

In contrast to the coupling of the hydrazones *(1)* and *(2)* (eq. (a)), evidently only two oxidation equivalents are consumed in the formation of *(21)*. The sulfonyl residue appears as sulfinate, which can be trapped with 1,4-naphthoquinone.

[14] *S. Hünig* and *H. Balli*, Liebigs Ann. Chem. *628*, 56 (1960).

2.4.3. pH-Dependence of the Coupling Yield

In the oxidative coupling of the sulfonyl hydrazone *(22)* with phenol (which is a medium-activity partner) between pH 6 and 12, the basicity of the medium is found to have a considerable influence on the yield of dye *(23)* (Fig. 1).

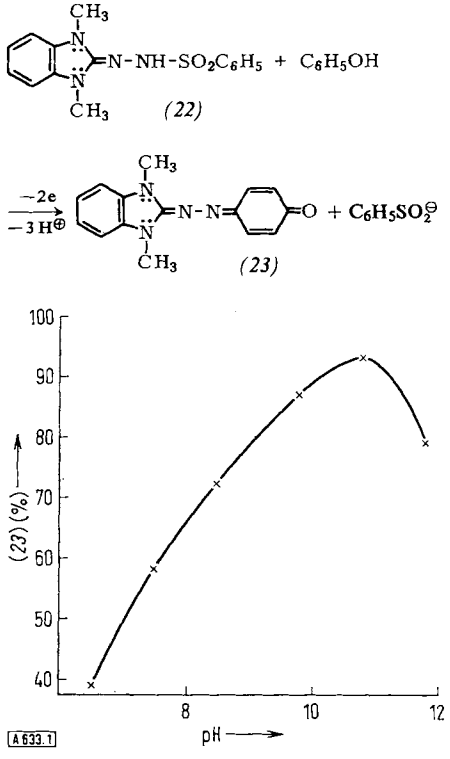

Fig. 1. Yield of *(23)* as a function of the pH value in the oxidative coupling of *(22)* with phenol in the ratio of 1:10.

The result can be generalized. The highest coupling yields are obtained between pH 10 and 12; the oxidative decomposition of sulfonyl hydrazones becomes predominant only in more strongly alkaline media. On the other hand, the coupling optimum for the free hydrazones *(1)* and *(2)* occurs at pH 8–10 and oxidative decomposition is practically the only reaction observed at pH 11.5 [14, 15]. For this reason weak C–H acids such as benzyl cyanide and phenylacetone, which cannot be oxidatively coupled with the hydrazone *(3)*, can be coupled with the sulfonyl hydrazone *(17a)* to form the azines *(24)* and *(25)* [4].

(24), R = CN (29%)
(25), R = CO-CH_3 (38%)

2.4.4. Influence of the Structure of the Sulfonylhydrazone on the Coupling Activity

Sulfonyl hydrazones with an amidrazone structure, *e.g. (16)*, generally give the lowest coupling yields (5–40% in the reaction with 1-hydroxy-2-naphthanilide [6]). Incorporation of the substituted amide N atom (N-4 of the amidrazone) into a ring [6] increases the coupling activity only if the sulfonyl hydrazone is derived from an aromatic heterocycle [*e.g. (12)*, *(14)*, *(17)*, *(20)*, and *(22)*]. It is observed [4] that the coupling yield increases with the basicity of the parent heterocycle; the opposite is true of the hydrazones *(1)* and *(2)* [2, 14]. Table 2 shows a quantitative comparison with phenol as the coupling component.

(26) *(27)* *(23)*

R = =O

Table 2. Maximum yields of dye in oxidative coupling under standard conditions. Path A — from free hydrazone/phenol 1:100, pH = 8–10, in methanol/water, oxidizing agent: $K_3Fe(CN)_6$. Path B — from benzenesulfonyl hydrazone/phenol 1:10, pH = 11 in *N*-methylpyrrolidone/water, oxidizing agent: $K_3Fe(CN)_6$.

Dye	Path A yield (%)	Path B yield (%)
(26)	90	55
(27)	21	66
(23)	7	94

The influence of the heterocycle is far less noticeable with the much more reactive α-naphthol.

2.4.5. Influence of the Sulfonyl Residue on the Coupling Yield

The nature of the sulfonyl residue also affects the coupling yield, as is shown by a quantitative study of the oxidative formation of *(26)* from *(17)* (Table 3).

Table 3. Yields of dye *(26)* from the hydrazones *(17)* and phenol (1:1) in sodium hydroxide/methanol; oxidation with $K_3Fe(CN)_6$. The free hydrazone *(3)* reacts to give a yield of 3%.

(17)

R (aliphatic)	Yield (%)	R (aromatic)	Yield (%)
		4-CH_3–C_6H_4	31
HO	4 [a]	C_6H_5	38
$(CH_3)_2N$	25	2-NO_2–C_6H_4	59
		3-NO_2–C_6H_2	61
Morpholino	28	2,5-Cl_2–C_6H_3	61
CH_3	31		
	23 [a]		
$ClCH_2$	58		
	30 [a]		

[a] With ethanolamine instead of sodium hydroxide solution.

Comparison with the hydrazone *(3)* again makes it clear that oxidative coupling of the free hydrazones does not take place in strongly alkaline media. The groups are arranged in Table 3 in order of their effect. Thus the coupling yield increases with the acidity of

[15] *S. Hünig* and *G. Köbrich*, Liebigs Ann. Chem. *617*, 203 (1958).

the sulfinic acid cleaved [16]. Benzene- or methylsulfonyl hydrazones are satisfactory for practical purposes.

3. Quaternary Azo Sulfones *(10)*[7]

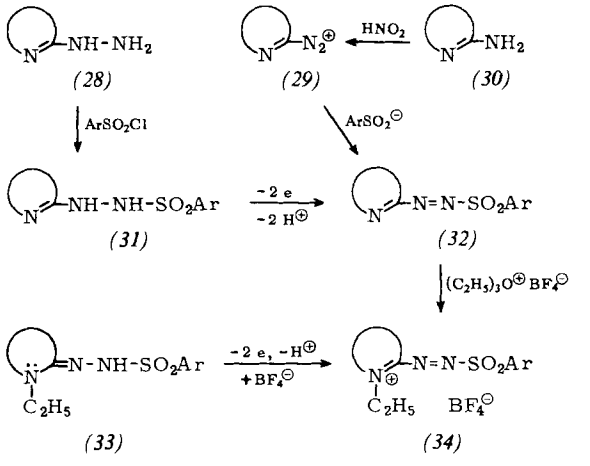
The only examples of this type of compound studied so far are derived from aromatic heterocycles. However, it should be possible in principle to prepare quaternary azo sulfones of the general type *(10)*.

3.1. Syntheses[7]

Heterocyclic quaternary azo sulfones can be prepared by three routes, which allow the use of different starting materials.

a) If the 2-amino heterocycle *(30)* can be diazotized (*e.g.* 2-aminobenzothiazole), the azo sulfone *(32)* is obtained smoothly from the diazonium salt *(29)* with sulfinate. Alkylation of *(32)* yields the desired quaternary azo sulfone *(34)*. The last step limits the application of this route, since diazonium salts can generally be obtained only from amines *(30)* of weakly basic heterocycles, the basicity of which is further weakened in the azo sulfone *(32)* to such a degree that *e.g.* the benzothiazole derivative can no longer be alkylated even with triethyloxonium fluoroborate [17].

b) This difficulty can be overcome if the hydrazine derivative *(28)* or *(31)* of a more strongly basic heterocycle (*e.g.* quinoline) is available. The azo sulfone *(32)*, which is readily obtainable by dehydrogenation of *(31)*, can then be smoothly alkylated to give *(34)*.



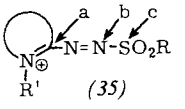
c) The starting materials having the widest applicability are the sulfonyl hydrazones *(33)*. These are converted by various oxidizing agents, particularly lead(IV) acetate in glacial acetic acid or strong nitric acid, into the quaternary azo sulfones *(34)* in 80 to 100% yield.

3.2. Properties

In contrast to the highly brisant perchlorates of the quaternary azo sulfones, the orange fluoroborates *(34)* are insensitive to shock and can be stored indefinitely. Their purity can be checked by reduction to the sulfonyl hydrazones *(33)* by titration with $Ti^{3\oplus}$ or $I^{\ominus}$ [7]. The susceptibility of quaternary azo sulfones *(34)* toward nucleophiles increases rapidly with decreasing basicity of the parent heterocycle, so that reactions are best carried out in non-basic, aprotic solvents such as acetonitrile or acetone. It is also possible in this way to extend the limits of application of oxidative coupling with sulfonyl hydrazones. Owing to their high coupling activity and the intense color of the products formed, the quaternary azo sulfones [particularly 6-methoxy-3-methyl-2-(tosylazo)benzothiazolium tetrafluoroborate *(44)*] are highly suitable for use as spray reagents in the chromatographic detection of the components discussed in Sections 3.3.3 to 3.3.6.

3.3. Reaction with Nucleophiles

The quaternary azo sulfones *(35)* are ambident cations [18] and the attack by nucleophiles is expected

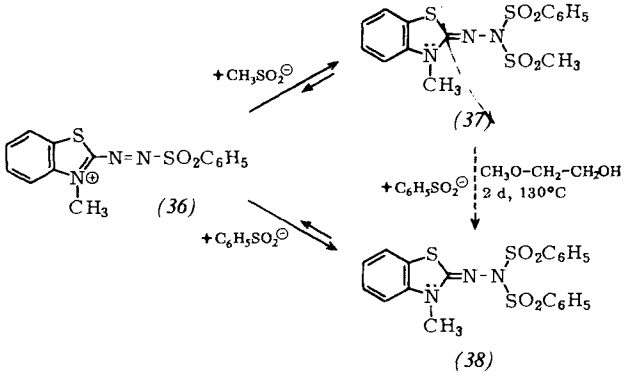


(35)

to take place mainly *via* path a or b. However, the strongly electron-attracting azo system could behave as a "pseudohalogen", so that the nucleophile should also be able to attack the sulfonyl group by path c.

3.3.1. Reaction with Sulfinate

The addition of sulfinate ions by path b is extremely rapid, yielding the sparingly soluble, very stable bis-sulfonyl compounds, *e.g.* *(36)* → *(37)*. The reaction is reversible, since prolonged heating of *(37)* with an excess of benzenesulfinate leads to *(38)* [7], a product that can only be formed *via* *(36)*. An important consequence of this reversibility is discussed in Section 3.4.



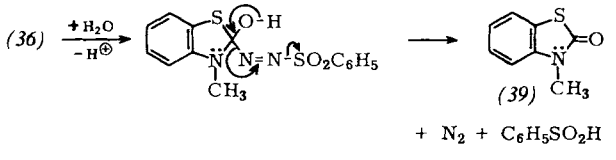
[16] *C. D. Ritchie, J. D. Saltiel,* and *E. S. Lewis,* J. Amer. chem. Soc. *83*, 4601 (1961).

[17] Stronger alkylating agents such as alkyl iodide and silver fluoroborate in nitromethane (*H. Meerwein* and *K. Wunderlich,* Angew. Chem. *69*, 481 (1957)) or dialkoxycarbonium salts (*K. Dimroth* and *P. Heinrich,* Angew. Chem. *78*, 714 (1966); Angew. Chem. internat. Edit. *5*, 676 (1966); *S. Kabuss,* Angew. Chem. *78*, 714 (1966); Angew. Chem. internat. Edit. *5*, 675 (1966)) might work.

[18] For the chemistry of ambident cations, cf. *S. Hünig,* Angew. Chem. *76*, 400 (1964); Angew. Chem. internat. Edit. *3*, 548 (1964); ambident behavior of other azo quaternary salts; *S. Hünig* and *W. Kniese,* Liebigs Ann. Chem. *708*, 170 (1967).

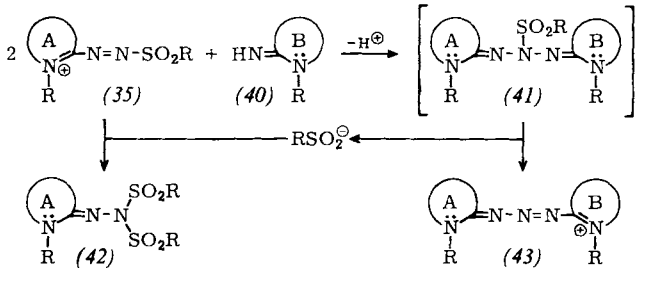
3.3.2. Reaction with Simple O- and N-Nucleophiles

Nucleophiles such as acetate, sulfite, secondary amines, and even cyanide decompose the quaternary azo sulfones, also in aprotic solvents, to give numerous products. Prominent among these are the bissulfonyl compounds *(42)*, an indication that sulfinate is liberated in the reaction. Furthermore, symmetrical azines (*e.g. (62)*, cf. Section 3.3.7) are always present. Reagents containing hydroxyl groups behave similarly. The reaction of *(36)* with steam gives 35% of *(39)*; this can be interpreted by the attack of the nucleophile by path a followed by fragmentation.

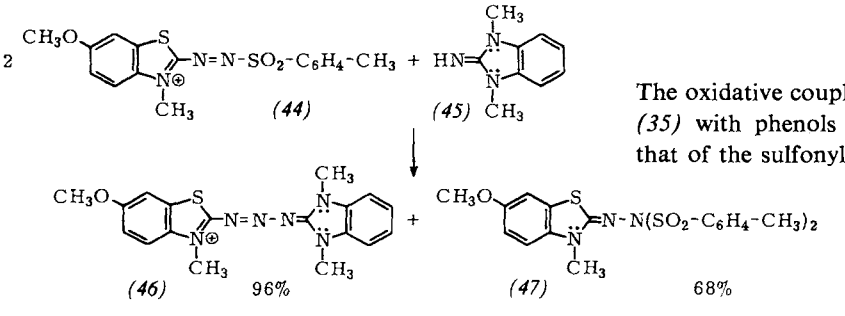


3.3.3. Reaction with Heterocyclic Imines

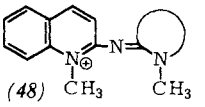
Imines of aromatic heterocycles of the type *(40)* attack the azo quaternary salts *(35)* in the β position by path b.



The adduct *(41)* immediately achieves stability by formation of the triazacyanine *(43)*, the sulfinate released being trapped by the excess of azo sulfone *(35)* to form the bissulfonyl compound *(42)* [7]. Asymmetric triazacyanines can also be obtained in this way, *e.g. (46)* from *(44)* and *(45)* [19]. This provides a

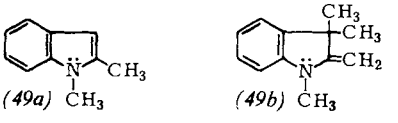


welcome addition to the known methods for the synthesis of triazacyanines [20, 21]. The imine *(40)* may be varied widely without affecting the reaction. On the other hand, attack by path a becomes more important when *(35)* is a 2-quinolinium derivative, so that the main products are asymmetric monoazacyanines of the type *(48)*.

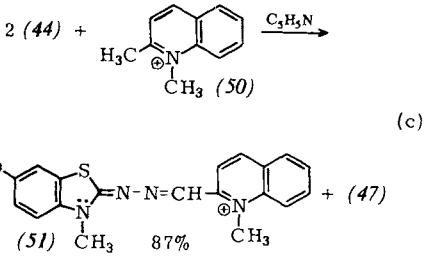


3.3.4. Reaction with C-Nucleophiles of the Enamine Type [22]

It was shown in 1957 that compounds containing the enamine grouping undergo oxidative coupling with the hydrazone *(3)* if their basicity is so low that they are at least partly unprotonated in the acidic medium required. This is true of the indole derivatives *(49a)* and *(49b)* (Fischer bases), which couple smoothly [2, 23]. However, oxidative coupling does not take place with most heterocyclic 2-methyl quaternary salts [*e.g. (50)*],



since they can be deprotonated to give the reactive enamine form only in basic media. By the use of azo sulfones *(35)*, the coupling reaction with 2-methyl quaternary salts can be carried out in an aprotic solvent in the presence of weak bases, as shown by the example in eq. (c). This provides a new approach to the diazatrimethinecyanines [21].



(c)

3.3.5. Reaction with Phenols

The oxidative coupling of the quaternary azo sulfones *(35)* with phenols proceeds even more readily than that of the sulfonyl hydrazones *(9)*. The resulting diazamerocyanines (*e.g. (54)*, $\lambda_{max}^{CH_3OH}$ = 484 nm (ε = 46000)) are obtained in a very pure state and in high yields, even when the reactants are used in a molar ratio of 1:1. Since the sulfinic acid formed does not

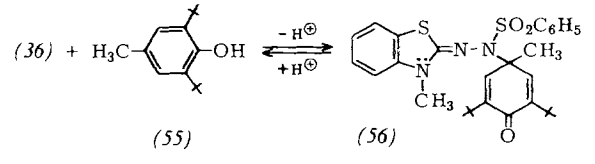
(52) (53a), X = H (53b), X = F

(54)

compete with the phenol for the azo quaternary salt, the reaction must proceed in two stages, the formation of an adduct [*e.g.* from *(52)* and *(53a)* or *(53b)*] being faster than the further reaction to form the end products. A colorless adduct having the structure *(56)* can in fact be isolated from the azo sulfone *(36)* and 2,6-di-*tert*-butyl-4-methylphenol[7]. Since the adduct *(56)* cannot proceed to the merocyanine, it couples with phenols [*e.g.* *(53a)*], probably after conversion back into *(36)* and *(55)* by protonation.

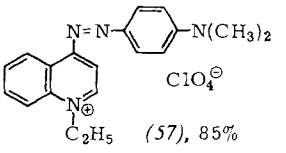


(55) (56)

As in the oxidative coupling of the hydrazones *(1)*, *p*-halogenophenols such as *(53b)*, are particularly suitable for coupling with quaternary azo sulfones. In the reaction *(52)* + *(53b)* → *(54)*, the sulfonyl residue is cleaved off at the sulfonic acid oxidation level, and so cannot compete with the phenol.

3.3.6. Reaction with Aromatic Amines[7]

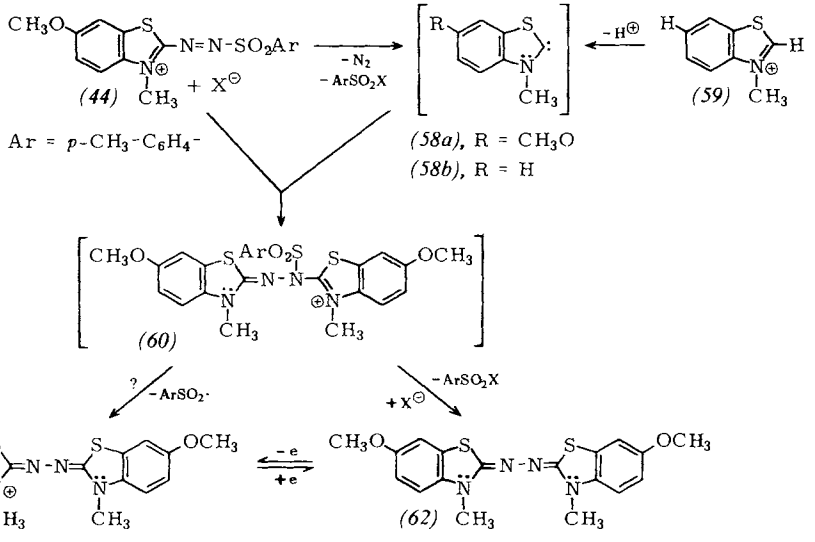
Quaternary azo sulfones couple smoothly with aromatic amines, even in cases in which oxidative coupling with the hydrazones *(3)* or sulfonyl hydrazones *(9)* does not take place. A typical example is the formation of the blue dye salt *(57)* ($\lambda_{max}^{CH_3OH}$ = 610 nm (ε = 62000)), which can be obtained only from the azo sulfone.



(57), 85%

3.3.7. Reaction with Nucleophilic Carbenes[7]

It was mentioned in Section 3.3.2. that azines [*e.g.* *(62)*] always occur among the products of the decomposition of azo sulfones [*e.g.* *(44)*] with nucleophiles. In this case the nucleophile evidently attacks the sulfonyl group by path c to give the nucleophilic carbene *(58a)*[24] as a reactive cleavage product, which decomposes *via* the adduct *(60)* by heterolysis to give the azine *(62)* or by homolysis to give the stable radical cation *(61)*, which is easily recognizable by its characteristic electronic spectrum[25]. This proposed reaction course is supported by the fact that the carbene *(58b)* formed from the quaternary salt *(59)* under the reaction conditions takes part in the reaction. Thus in the presence of compound *(59)*, both the symmetrical azine *(62)* and the azine having only one methoxyl group are formed.



(44) Ar = *p*-CH_3-C_6H_4- (58a), R = CH_3O (58b), R = H (59) (60) (61) (62)

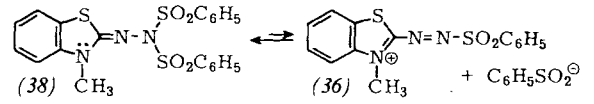
3.4. Coupling of Bissulfonyl Hydrazones

If the quaternary azo sulfones *(10)* [or *(35)*] are regarded as stabilized quaternary heterocyclic diazonium salts, the bissulfonyl compounds *(42)* must be described as extremely highly stabilized diazonium

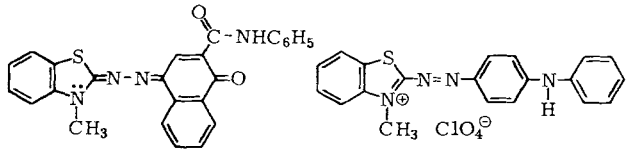
[24] For the chemistry of nucleophilic carbenes, cf. *H. Quast* and *S. Hünig*, Chem. Ber. *99*, 2017 (1966).

[25] *S. Hünig, H. Balli, H. Conrad*, and *A. Schott*, Liebigs Ann. Chem. *676*, 36, 52 (1964).

salts. Their solutions remain unchanged for several weeks, even in the presence of phenol or amine. However, when the components are heated in nitrobenzene, they rapidly couple to form the dye. As described



(38) *(36)* + $C_6H_5SO_2^{\ominus}$



(63), 62% *(64)*, 68%

earlier (Section 3.3.1.), the dissociation of *(38)* can be brought about by heating. In the presence of 1-hydroxy-2-naphthanilide or of diphenylamine, the azo quaternary salt *(36)* is rapidly removed from the equilibrium, and the dye *(63)* ($\lambda_{max}^{CH_3CN}$ = 540 nm (ε = 46000)) or *(64)* ($\lambda_{max}^{CH_3CN}$ = 604 nm (ε = 82000)) is formed within a few minutes. This unusual azo coupling could be important in some cases.

4. Mechanism of the Oxidative Coupling of Sulfonyl Hydrazones with Phenols[26]

4.1. Conclusions from Preparative Studies

The following conclusions regarding the mechanism may be drawn from the preparative experiments:

a) Oxidation of the sulfonyl hydrazones *(9)* yields azo sulfones *(10)* which couple smoothly with phenols. It is thus possible to eliminate the oxidation step and to study only the coupling of the quaternary sulfone with phenol.

b) The coupling proceeds *via* an adduct.

4.2. Kinetics of the Coupling of Quaternary Azo Sulfones with Phenols

4.2.1. Substances and Conditions

The reactants are the azo sulfone *(36)* and the phenols *(53a)* and *(53b)*, whose blocked *o*-positions guarantee exclusive *p*-coupling. The solvent is very pure acetonitrile with pyridine as the base. A 20-fold excess of pyridine and phenol, which reacts as a hydrogen-bonded complex *(65)* in acetonitrile, ensures a pseudo-first order reaction. The disappearance of azo sulfone and the formation of dye are followed optically as functions of time.

[26] *S. Hünig* and *G. Kaupp*, Tetrahedron *23*, 1411 (1967).

4.2.2. Coupling with 2,6-Diethylphenol *(53a)*

The kinetic experiment, in which 80–90% of dye *(70)* is ultimately formed, proceeds in a remarkable manner (Fig. 2). After a reaction time of about 10 min, the azo sulfone *(36)* is completely consumed (curve A) whereas only about 5% of dye has been formed (curve F). The main constituent of the reaction mixture at this point is a relatively stable intermediate, which slowly decomposes to form the dye *(70)* (curve 100-F-A).

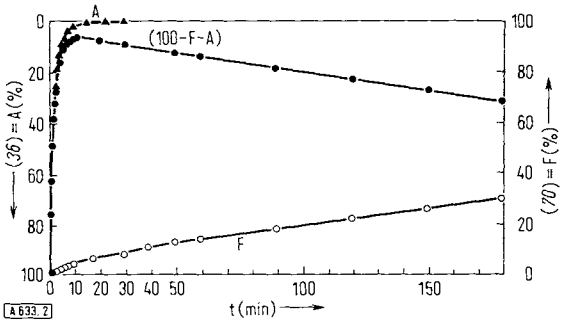


Fig. 2. Coupling of the azo sulfone *(36)* (2.36×10^{-5} mole/l) with 2,6-diethylphenol *(53a)* (5.6×10^{-4} mole/l) in the presence of pyridine (5.6×10^{-4} mole/l) in acetonitrile at 20 °C to form the dye *(70)*.

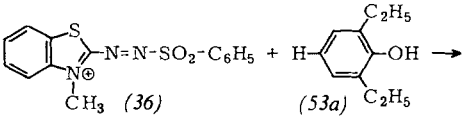
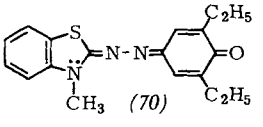


(36) *(53a)*



(70)

An adduct that is kinetically identical with the intermediate can in fact be obtained from *(36)* and *(53a)*. By analogy with *(56)*, this would be expected to have the structure *(66)*. However, IR data and results of H–D exchange experiments point conclusively to the constitution *(67)*. Thus the compound *(66)*, which is undoubtedly the initial product, very rapidly rearranges to *(67)*, from which the dye *(70)* is then formed.

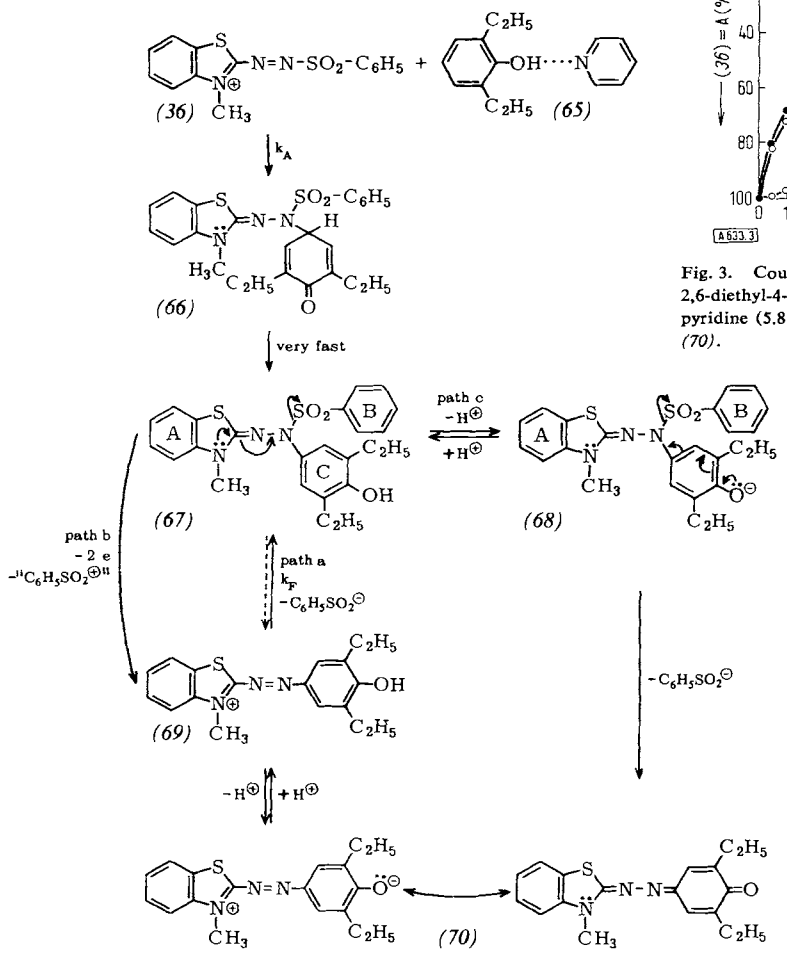
The behavior of *(67)* is very unusual, since this intermediate can liberate the dye *(70)* in three ways:

Path a: Under the conditions of the reaction, *(67)* dissociates almost exclusively into the benzenesulfinate anion and the dye cation *(69)*. Though the phenolic structure of *(67)* suggests the possibility of participation of pyridine as in *(65)*, this does not occur since only two of the three rings A, B, and C in *(67)* can lie in one plane, and decomposition with the assistance of ring A is favored. The cation *(69)* is immediately deprotonated in the presence of pyridine to form the weakly basic dye *(70)*. Compound *(70)* can be converted back into the adduct *(67)* by an excess of benzenesulfinic acid in the absence of pyridine.

Path b: More ($\approx$ 5%) dye *(70)* is formed during the first few minutes than is calculated from k_A and k_F. Comparative experiments show that this is due to the azo sulfone *(36)* that is still present during this period and which oxidizes the adduct *(67)* to the dye *(69)* or *(70)*.

Path c: This path is of no importance under the conditions of the reaction. The dye formation is accelerated by about two

orders of magnitude only in the presence of strong bases such as sodium methoxide or sodium phthalimide. The anion *(68)* is evidently involved in this reaction.



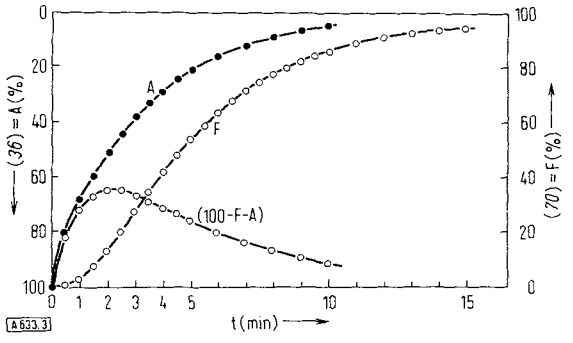


Fig. 3. Coupling of the azo sulfone *(36)* (2.75×10^{-5} mole/l) with 2,6-diethyl-4-fluorophenol *(53b)* (5.8×10^{-4} mole/l) in the presence of pyridine (5.8×10^{-4} mole/l) in acetonitrile at 20.0 °C to form the dye *(70)*.

Coupling may be summarized as follows:

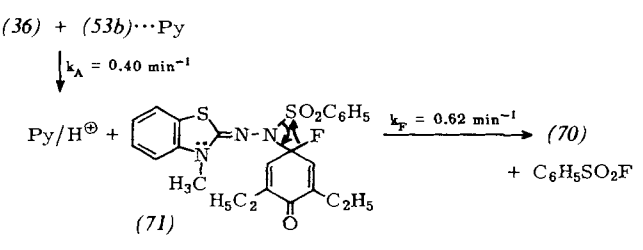
$$(36) + (65) \xrightarrow{k_A = 0.43\ \text{min}^{-1}} (66) \xrightarrow[\text{fast}]{\text{very}}$$

$$(67) \xrightarrow[\text{path a}]{k_F = 1.86 \times 10^{-3}\ \text{min}^{-1}} (69) \xrightarrow[\text{fast}]{\text{very}} (70)$$

Thus the reaction takes place in several stages, the ratio of the rates of the two slowest steps being $k_A : k_F \approx 200:1$.

4.2.3. Coupling with 2,6-Diethyl-4-fluorophenol *(53b)*

Under the same conditions as those described for *(53a)*, the coupling of *(36)* with *(53b)* proceeds differently. Whereas only 50% of dye is formed after 30 min with *(53a)*, coupling with *(53b)* is complete after only 12 min. The intermediate must therefore be shorter-lived in this case. Nevertheless, 34% of the intermediate (curve 100-F-A, Fig. 3) is present after an induction period of 1.85 min.

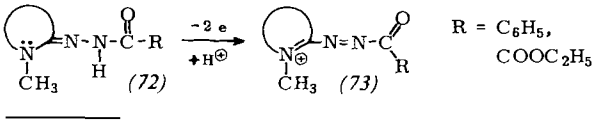


In this reaction the intermediate must have the structure *(71)*. Since its decomposition is practically unaffected by pyridine and *(53b)*, it must be assumed that an intramolecular reaction takes place with formation of the dye *(70)* and benzenesulfonyl fluoride. The ratio $k_A : k_F$ in this case is approximately 1:1.

4.3. Coupling of Carbonylazo Quaternary Salts with Phenols

4.3.1. General

Carbonylazo quaternary salts of the type *(73)* can be prepared by oxidation of the "carbonylhydrazones" *(72)* [27], the reaction being completely analogous to *(9)* → *(10)*.



[27] *S. Hünig* and *G. Kaupp*, Liebigs Ann. Chem. *700*, 65 (1966).

The carbonylazo quaternary salts, like the sulfonylazo quaternary salts, are reduced smoothly; they add sulfinate and 2,6-di-*tert*-butyl-4-methylphenol *(55)* to form adducts corresponding to the compounds *(42)* and *(56)*. In particular, they couple in high yields with *p*-halogenophenols to give the same dyes [*e.g. (54)*] as are formed from the corresponding quaternary azo sulfones [27]. This reaction can therefore be included in the kinetic investigation.

4.3.2. Mechanism of the Coupling of the Carbonylazo Quaternary Salt *(74)* with 2,6-Diethyl-4-fluorophenol *(53b)* [26]

Under the conditions described earlier (see Sections 4.2.2. and 4.2.3.), the coupling of *(74)* with *(53b)* takes roughly twice as long as the coupling of the azo

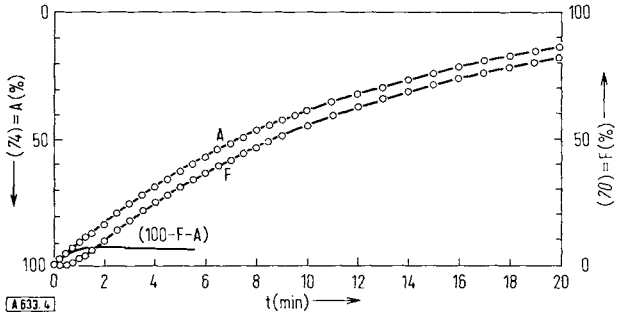


Fig. 4. Coupling of the carbonylazo quaternary salt *(74)* (2.49×10^{-5} mole/l) with 2,6-diethyl-4-fluorophenol *(53b)* (5.10×10^{-4} mole/l) in the presence of pyridine (5.0×10^{-4} mole/l) in acetonitrile at 20.0 °C to form the dye *(70)*.

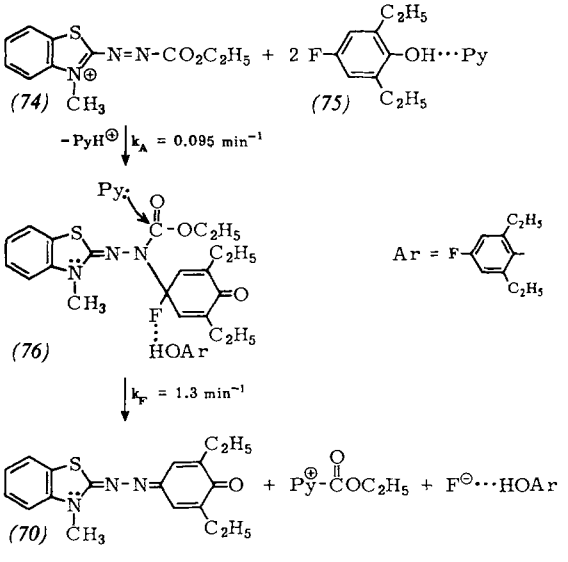
sulfone *(36)*, probably because of the weaker electrophilic character of *(74)* as compared with that of *(36)* (Fig. 4).



The consumption of *(74)* (curve A) is directly related to the formation of the dye (curve F), so that it may again be concluded that an intermediate accumulates in the reaction mixture (maximum 7%, curve 100-F-A). It can be deduced from the kinetic data that *(74)* and *(75)* first combine to form the adduct *(76)*, the decomposition of which is distinctly dependent upon the concentrations of pyridine and of *(53b)*. These reactants probably participate in the manner shown. The ratio of the rates for the two-step reactions is $k_A : k_F \approx 1:130$.

4.3.3. Coupling of the Carbonylazo Quaternary Salts *(73)* with Phenols Possessing No *p*-Substituent

The coupling mechanism deduced above for *p*-halogenophenols suggests that the carbonylazo quaternary salts *(73)* should not react with phenols possessing no *p*-substituent. The carbonyl residue would have to be cleaved from the intermediate (cf. *(76)*, with H instead of F) as C_6H_5CHO or C_2H_5OCHO and this reaction would have very unfavorable energy requirements in comparison with the formation of $Py^{\oplus}-COOC_2H_5 + F^{\ominus}\ldots HOAr$ and $C_6H_5SO_2^{\ominus}$ (cf. Section 4.2.2.). Nevertheless, approximately 30% dye formation is observed. This is due to the oxidation of the intermediate (cf. *(67)*, with COR instead of $SO_2C_6H_5$) by unreacted azo quaternary salt *(73)*, corresponding to the conversion *(67)* → *(70)* by path b (Section 4.2.2.).

4.3.4. Comparison of the Coupling Mechanisms

The three couplings studied [*(36)* + *(53a)*, Fig. 2; *(36)* + *(53b)*, Fig. 3; *(74)* + *(53b)*, Fig. 4] proceed as two-step reactions with an adduct intermediate. The situation is rare in that the three limiting cases

$$k_1 \ll k_2 \qquad k_1 \approx k_2 \qquad k_1 \gg k_2$$

are observed with closely related reactants whose overall reactions lead to very similar products.

These investigations have been supported for some time by various grants. We are grateful to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Badische Anilin- und Sodafabrik AG, Ludwigshafen/Rhein, for their generous assistance. We also thank the Adox Fotowerke Dr. C. Schleussner, Frankfurt/M., for their support at the beginning of this work.

"Bicarburet of Hydrogen". Reappraisal of the Discovery of Benzene in 1825 with the Analytical Methods of 1968

BY R. KAISER [*]

Dedicated to Professor A. Steinhofer on the occasion of his 60th birthday

The historical background and the admirable analytical procedure that led Michael Faraday to the discovery of benzene in 1825 are discussed. Using modern techniques of instrumental analysis, the author retraces the isolation and analysis of benzene, and shows that the starting material used by Faraday must have been a very complex mixture of hydrocarbons, which would make severe demands even on present-day preparative analytical techniques, since it contains more than 300 components at concentrations greater than 100 ppm. The magnitude of the changes in analytical techniques can be seen from the fact that it is no longer necessary to isolate individual compounds, and that a great deal of information can be obtained with a much smaller quantity of material and in a much shorter time. Nevertheless, Faraday's persistence, experimental skill, and accuracy of measurement remain an example to the analyst of today.

1. The Beginnings of Gas Lighting

On July 16, 1825, at the Royal Institution, London, *Michael Faraday* (1791–1867) reported on new compounds of carbon and hydrogen and on other products from the pyrolysis of (sperm) oil. Soon afterward, *Berzelius* described *Faraday*'s discovery of benzene as the most important chemical result of 1825, and at the "Benzene Festival" in Berlin in 1890, *A. W. Hofmann* was able to show his enthusiastic audience a small glass ampoule containing about 3 ml of benzene that had been enriched, isolated, purified, and accurately described by *Faraday* in 1825 in a beautifully consistent analytical investigation.

The significance of *Faraday*'s discovery has only recently been appreciated by chemists, and today 10000 tonnes of benzene is being produced anually by the industry [1]. Even more impressive than the discovery of benzene, however, is *Faraday*'s analytical achievement, in view of the enormous complexity of the starting material used, as we realized when we retraced this historic work with the aid of modern methods.

The first steps in artificial lighting by gas had been taken around the end of the 18th and the beginning of the 19th century. Flames that gushed out of the earth and lit up wide areas were reported by the earliest historians, but it was not until 1664 that *Clayton* observed that heating (dry distillation) of coals results in the liberation of a gas that burns with a luminous flame, and which can be collected. (From a letter written by *Clayton* to *Robert Boyle* [2].)

In 1667, *Shirley* wrote in the "Philosophical Transactions" about the presence of a burning spring at the Wigan collieries in Lancashire, and showed that the combustibility was a property, not of the water from the spring, but of the gas that was mixed with the water. In 1726, *Hales* ("Plant Statics") described an experiment in which the combustible gas formed on distillation of coal was quantitatively determined. In the second volume of his "Chemical Investigations" (1767), *Watson* reported that coal gas does not lose any of its illuminating power when passed through water; this observation proved to be particularly important in the subsequent development of the purification of gases. The problem of the lighting power was, at a later date, also of special interest to *Faraday* in his work.

It was in 1790 that gas lighting was first developed to a practical stage by *William Murdoch*. Two years later, *Murdoch* installed gas lighting in his house in Redruth. He distilled coal in iron retorts and led the resulting gas over distances of more than 20 m through tinned iron and copper pipes to the lighting points. In 1798 he lit part of *Boulton* and *Watt*'s large spinning mill in Soho (Birmingham), and in 1805 he presented accurate calculations to show that lighting is cheaper with gas than with candles. The first large gasworks, the "*Privileged Gas Lighting Company*", was founded in 1809 to light London and Westminster, and Westminster Bridge was lit for the first time in 1813. In 1815, *John Taylor* was granted a patent for the production of lighting gas by pyrolysis of fatty oils (at about 600 °C). This type of lighting was introduced in Liverpool, Bristol, and Hull, and in 1819, *David Gordon* patented the production of "portable gas" [3]; this portable gas was the source of *Faraday*'s starting material in which he discovered "three new hydrocarbons".

The ideas that led *Gordon* to use oil gas and "to make gaslight portable" may well have been as follows. Oil gas at that time gave a flame three times as bright as that of coal gas, so that only one third of the volume of gas was needed to obtain the same lighting power. Compression of the gas gives a further large reduction in volume, so that it was ultimately possible to obtain a gaslight flame that would burn for eight hours from gas compressed by a factor of 32 and stored in a space of $^1/_4$ cubic foot [4]. Portable gas could be connected to isolated street lights for which connection to the mains would be too expensive, and a further advantage was that it could be bought and used as required, without the need for any special structural arrangements.

[*] Dr. R. Kaiser
Badische Anilin- & Soda-Fabrik AG.,
Ammoniaklaboratorium

[1] *R. Sachtleben*, Die BASF *14*, No. 1, p. 22 (1964).

[2] *P. Bolley*: Das Beleuchtungswesen. Friedrich Vieweg und Sohn, Braunschweig 1862, p. 173.

[3] *Gordon*'s portable gas lamp. Dinglers polytechnisches Journal *12*, 249 (1823); *19*, 161 (1826).

[4] *E. L. Schubarth*: Elemente der technischen Chemie. In Commission bei August Rücker, Berlin 1835, p. 141.

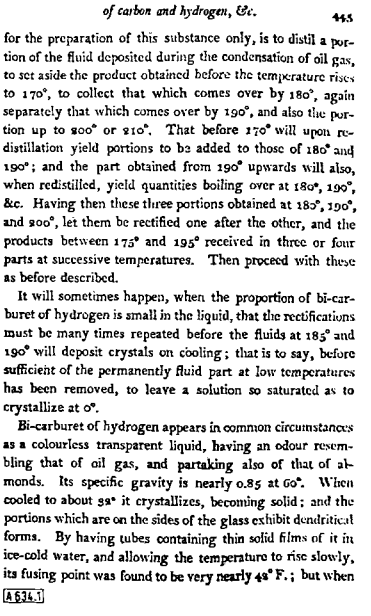
Gordon thus founded the Portable Gas Company in London and, after numerous technical difficulties had been overcome, started the production and sale of portable gas [4]. However, during the introduction and compression of the oil gas by means of a compression pump into a large copper container, from which the portable copper containers were filled with compressed gas, it was observed that an average of some 230 cubic inches of an unknown oily substance separated out from 1000 cubic feet of oil gas, possibly depriving the gas of a large part of its lighting power. Another great difficulty was to regulate the flow of gas from the containers of compressed gas so that it was not too fast initially and not too slow when the container was nearly empty – irregular flow gave rise to very non-uniform flames of varying brightness [4].

The separation of the liquid during the compression of the gas, the importance of this liquid to the lighting power of the gas, and the deposition of liquid on the valves of the gas containers, particularly in winter, led *Gordon* in 1820 to ask *Robert Faraday*, who worked for his Company, whether his brother *Michael* would examine this liquid.

The problem greatly interested *Michael Faraday*, since after his initial experiments with the liquid he thought that he had discovered liquid gas, which did not have to be compressed, and which had a high lighting power [5]. Two years later he isolated butene. The very same liquid that *Faraday* searched for and finally found is nowadays used in non-electric camping lights, which can in fact give a very bright light for many hours from a cartridge of the liquid gas. It was not until 1825 that he had collected sufficiently large quantities of the oil-gas condensate to allow a systematic analytical study of the product.

There is evidently a historical error associated with the discovery of benzene by *Faraday*. *A. W. Hofmann* started his official speech at Berlin (Benzene Festival 1890) with the sentence "The whole thing began with a piece of blocked gas pipe", meaning that benzene, which readily solidifies in winter because of its melting point of 5.5 °C, had separated out of the gas. However, the blockage was due not to benzene, but to condensation water that had frozen in the pipes, which were often badly laid. *Faraday*'s outstanding achievement was the purification of the benzene present in the oil-gas condensate by repeated fractional distillations and crystallizations until a product was obtained that gave the correct melting point of 5.5 °C. Benzene cannot separate out in gas pipes, since even highly enriched benzene deposits contain well over 300 other substances that lower the melting point of the benzene. The method used by *Faraday* for the enrichment of benzene from oil gas by distillation is reproduced in facsimile (Fig. 1).

[5] Entry in Faraday's laboratory journal dated April 17, 1823: "Now search among combustible gases for one becoming a liquid under 8 or 10 or even 20 atmospheres or at common temperature; examine oil-gas products *etc.*"



of carbon and hydrogen, &c. 445

for the preparation of this substance only, is to distil a portion of the fluid deposited during the condensation of oil gas, to set aside the product obtained before the temperature rises to 170°, to collect that which comes over by 180°, again separately that which comes over by 190°, and also the portion up to 200° or 210°. That before 170° will upon redistillation yield portions to be added to those of 180° and 190°; and the part obtained from 190° upwards will also, when redistilled, yield quantities boiling over at 180°, 190°, &c. Having then these three portions obtained at 180°, 190°, and 200°, let them be rectified one after the other, and the products between 175° and 195° received in three or four parts at successive temperatures. Then proceed with these as before described.

It will sometimes happen, when the proportion of bi-carburet of hydrogen is small in the liquid, that the rectifications must be many times repeated before the fluids at 185° and 190° will deposit crystals on cooling; that is to say, before sufficient of the permanently fluid part at low temperatures has been removed, to leave a solution so saturated as to crystallize at 0°.

Bi-carburet of hydrogen appears in common circumstances as a colourless transparent liquid, having an odour resembling that of oil gas, and partaking also of that of almonds. Its specific gravity is nearly 0.85 at 60°. When cooled to about 32° it crystallizes, becoming solid; and the portions which are on the sides of the glass exhibit dendritical forms. By having tubes containing thin solid films of it in ice-cold water, and allowing the temperature to rise slowly, its fusing point was found to be very nearly 48° F.; but when

A 634.1

Fig. 1. Method for the enrichment of benzene from oil gas condensate by distillation (facsimile of *Faraday*'s publication [6]).

The final outcome of *Faraday*'s investigations on the oil gas condensate was summarized by *Schubarth* [4]:

"...eine ölartige Substanz, welche theils farblos ist, theils grün beim reflektirten und gelb-braun beim durchgehenden Licht, specifisches Gewicht 0,821, wie Oelgas riecht, sehr flüchtig ist und sehr leicht kocht, beim Ausgießen wie Champagner braust, sich in Wasser nicht, aber in Alkohol, Aether, den Oelen auflöst, sich leicht mit Schwefelsäure verbindet. Sie ist ein Gemeng von mehreren flüchtigen Oelen, die einander rücksichtlich der Brennbarkeit und Leuchtkraft sehr ähnlich sind, aber durch verschiedne Flüchtigkeit sich unterscheiden. *Faraday* hat deren 3 beschrieben.

1. Bicarburet of hydrogen, (HC)
   Fp +5,5 °C spec. Gewicht bei 15 ° 0,85
   bei 0 ° 0,956
   Siedet bei über 85 °C über.
   Sie besteht aus 92,45 Kohlenstoff und
   7,55 Wasserstoff oder aus
   gleichem Volum Kstdampf und Wstgas.
2. (H_3C_2), die beim Erstarren der vorigen Materie übrig gebliebene Flüssigkeit, wird durch Erkälten nicht fest.
   Spec. Gewicht bei 15,6 °: 0,86
   Siedepunkt 85,5 °, von concentrierter Schwefelsäure stärker angegriffen, als die erstere und besteht aus 89,09 Kohlenstoff und 10,91 Wasserstoff; oder aus 2 Vol. Kstdampf und 3 Vol. Wstgas.
3. (H_4C_2), dritte Flüssigkeit
   Siedepunkt unter 0 °C
   spec. Gewicht bei 12 ° 0,627
   die leichteste aller bekannten Flüssigkeiten.

Die Zusammensetzung ist dieselbe wie die des ölbildenden Gases [*] nur in einem doppelt verdichteten Zustand."

Faraday did not give formulas in the original article, and the discrepancy in the evaluation of the equivalent weights (HC = bicarburet of hydrogen) will be discussed later.

The remarkable feature of *Faraday*'s work is the perseverance that he showed in the analysis of the oil gas concentrate. During the distillation of the crude

[6] *M. Faraday*, Philos. Trans. Roy. Soc. (London) *1825*, I, 440.

[*] Nowadays: ethylene.

product he found that the boiling behavior continuously changed with each repetition of the distillation.

When he isolated a narrow fraction and then redistilled it, he again found that it boiled over a wide range. By critical observation he found that repeated fractionation ultimately led to a fixed boiling point.

Figure 2 shows what was probably one of the first boiling curves, which were reported in digital form. A theoretical boiling curve as found on gas-chromatographic analysis of oil gas condensate with a thin film capillary 100 m long is also shown.

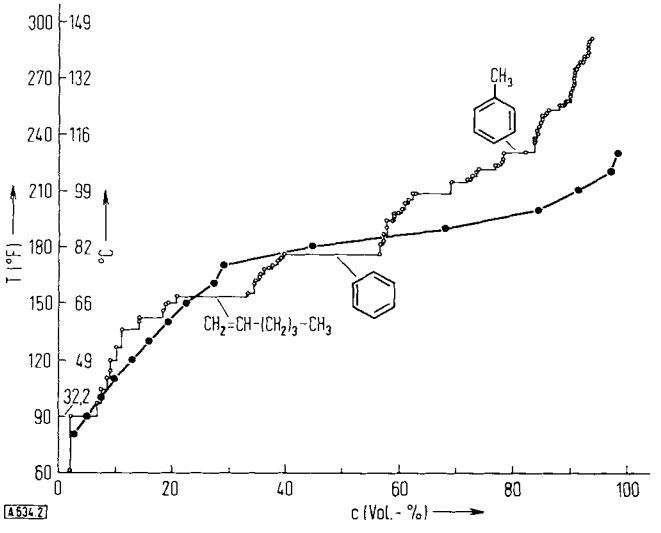


Fig. 2. Boiling curves from *Faraday*'s data (—•—•—) and from the gas-chromatographic analysis (—o—o—).

On repetition of this work on the micro scale, we found that the boiling point increases by 1 °C per drop of distillate in the first few distillations. After many fractionation steps, *Faraday*, isolated a distillate having a constant boiling point of 85 °C. He then used this distillate to determine the melting point and again found that in many cases liquid existed together with solid over a range of from −18 to −10 °C. This seemed too wide a range and by repeated isolation of the crystals at low temperature (pressing out on a press cooled to −18 °C between cooled layers of paper with exclusion of condensation water), he finally obtained constant melting-point benzene of a purity that would be the envy of any modern preparative chemist working under the same conditions.

Faraday also applied an exemplary degree of criticism in the evaluation of the results of his quantitative elemental analysis. His discussion of the error[6] should be read by all those who occasionally forget that measurements are always subject to errors.

Table 1 shows the results obtained by *Faraday* in 1825 together with modern results.

The name "bicarburet of hydrogen" can be explained on the basis of the "proportionals" used at that time. One proportional of C = 6 and one proportional of H_2 = 1, together with the results of the elemental analysis and the error discussion

C:H = 11.44:1 or C:H = 12:1

led to 2 proportionals of carbon and 1 proportional of hydrogen, *i.e.* "bicarburet of hydrogen".

Table 1. Results obtained by *Faraday* in 1825 and values from modern international sources for benzene.

	1825	1968
B.p. (760 torr)	85.3 °C (= 186 °F) [a]	80.10 ± 0.01 °C
M.p.	+ 5.5 °C (= 42 °F) [7] [b]	5.53 ± 0.01 °C [c]
d (15.6 °C)	0.86	d_4^{20} 0.8786 ± 0.0003
Molecular weight	39 (times 2)	78.1147 ± 5×10⁻⁵
Elemental analysis	92.45 C to 7.55 H	92.256 C to 7.744 H

[a] It is difficult even today to calibrate a thermometer in the region of 100 °C, since the barometric pressure is fully effective. Differences of opinion still exist concerning the differences between the temperature reference scales and the magnitude of systematic calibration errors. Moreover, the Fahrenheit scale was extended by linear extrapolation of the fundamental or calibration range of 0—32 ° Fahrenheit, so that systematic errors some distance away from the calibration range are quite understandable.

[b] It is much easier to avoid errors in calibration around 0 °C and around the zero of the Fahrenheit scale (temperature of common salt/ice). This explains the difference in the boiling point found in 1825.

[c] The melting point of benzene is difficult to determine accurately, since dry benzene is strongly hygroscopic. In international comparison experiments arranged recently by IUPAC, the determination of the melting point of benzene gave particularly poor results [7].

3. Re-examination of the Discovery of Benzene

We have tried to retrace *Faraday*'s work with modern analytical methods. The conditions of that period obviously cannot be simulated, since we are now familiar with "bicarburet of hydrogen" or "benzene" (as *Mitscherlich*, 1835, named the substance) or "benzol" (*Liebig*'s name for the mother-substance of what was later to become a large chemical industry). The analyst of today can recognize and characterize an individual substance in a mixture by the "dynamic" method. He no longer has to be a skilful preparative chemist in order to isolate the sample for analysis, as was the case in *Faraday*'s time. The repetition of this work again aroused our esteem for *Faraday*'s achievement when we saw the complexity of the mixture, since it took us days of effort on the micro scale to isolate the high-purity product that had been described so accurately about 140 years ago. (However, the preparative isolation was necessary in our case only because we wished to know what led *Faraday* to describe another substance, which must have overtaxed his measuring and analytical facilities. This will be commented on in detail in Tables 2–4.)

Using the simple apparatus shown in Figure 3, we pyrolyzed 3.3 g of sperm oil in 300 seconds and collected all the products quantitatively. The crude sperm oil, which had already been stored for some years, was continuously pumped into a steel tube at 600 ± 10 °C, and the pyrolysis products were carried into a cold trap by a very weak current of nitrogen. The steel tube was connected to a high current transformer and was subjected to direct electrical heating.

[7] *O. Riedel*, personal communication.

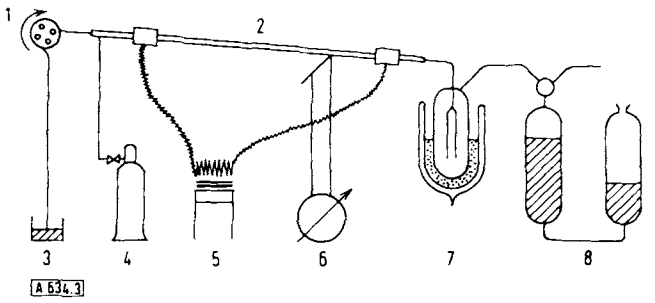

Fig. 3. Pyrolysis apparatus 1: Sleeve pump (0.65 g/min); 1: V2A steel tube (4×0.5 mm, 1 m long, 600 ± 10 °C); 3: sperm oil (3.3 g); 4: nitrogen (8 ml/min); 5: transformer; 6: voltmeter; 7: condensate (at 20 °C: 0.76 g); 8: pyrolysis gas (1654 Ncm³).

A total of 1654 Ncm³ of gas were evolved from 3.3 g of oil. The analysis of the gas is shown in Table 2.

The liquid pyrolysis products, which weighed 0.75 g after deaeration at 20 °C, were distilled in one stage in a microdistillation apparatus up to 121 °C = 250 °F. 1 µl of the yellowish distillate was used for the GC/MS analysis.

A GC/MS analysis is a gas-chromatographic analysis with mass-spectrometric evaluation or mass-spectrometric recordings immediately preceded by gas-chromatographic separation of the products. The gas-chromatographic signals are received by the mass spectrograph in a direct instrumental coupling. A high-efficiency thin film capillary was used for the separation.

In a period of about 20 minutes, a capillary GC/MS combination of this type provides sufficient information to keep several experts very busy for several weeks with its processing and evaluation unless an on-line computer is used. We confined ourselves therefore to the recognition of the main constituents of the liquid sperm-oil pyrolyzates vaporized at temperatures up to 120 °C.

The complete evaluation of the data without the use of a computer would have taken about three months.

Table 2. Analyses of the gaseous pyrolysis products of sperm oil.

	1835 [1] (Vol.-%)	1968 (Vol.-%)
Hydrogen	3—7.7	7.9
Hydrocarbon gas (= saturated flammable gases)	46—50	24
Chlorine absorbable gases (= unsaturated gases)	22.5—38	40
in Detail:		
Oxygen		1.9
Carbon monoxide		18.5

1,3-Butadiene		1.3
C_5 3-Methyl-1-butene		0.02
Other C_5 compounds		Traces

A rough calculation shows that for the direct use of a computer with programming for structure evaluation, which is still in the very early stages of its development, a computing time of a few minutes should have been enough to accomplish the same work, provided that all the analytical data were stored on magnetic tape and that the mass spectra were evaluated "on line", *i.e.* directly.

The results of the combination analysis (see Fig. 4, chromatogram 1) are summarized in Table 3. In addition to the mass-spectrometric evaluation, substantial gas-chromatographic evaluation was also necessary, since the mass-spectrometric data alone yields remarkably little information in the analysis of olefins.

The pyrolysis condensate having the composition given in Table 3 (see Fig. 4, chromatogram 1) was com-

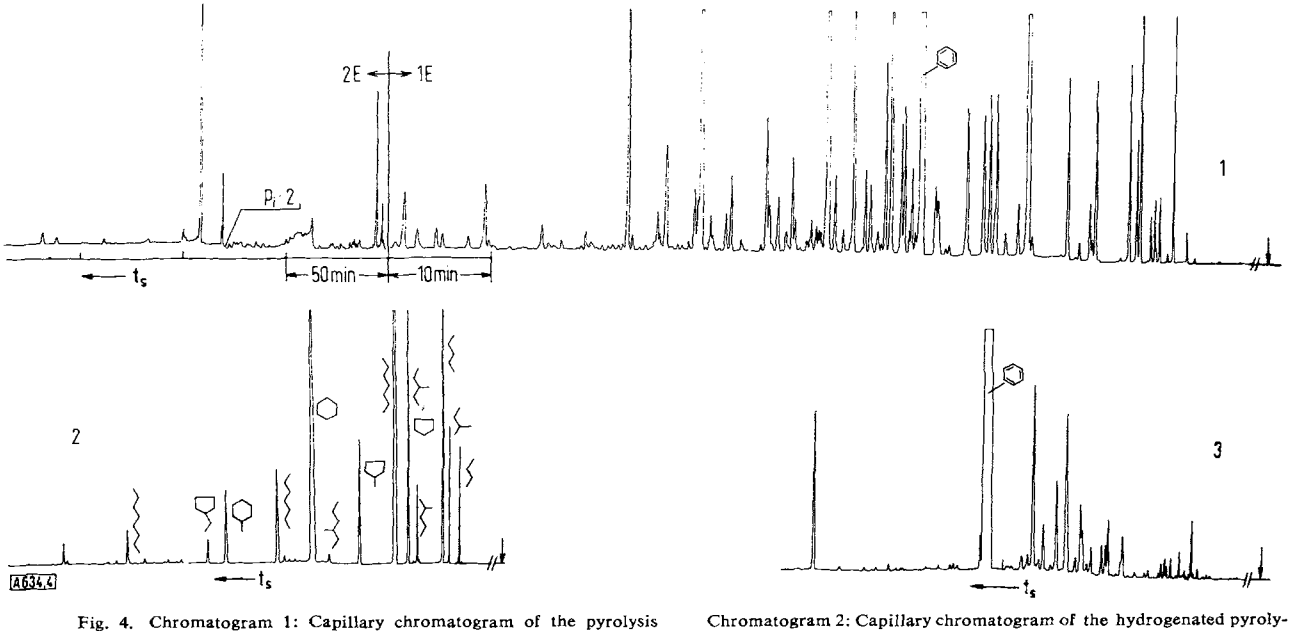

Fig. 4. Chromatogram 1: Capillary chromatogram of the pyrolysis condensate having b.p. 20—120 °C, temperature-programmed and partly pressure-programmed, shown with modified chart drive. Steel thin film capillary, p_i = 2.2 atm N_2.

Chromatogram 2: Capillary chromatogram of the hydrogenated pyrolysis condensate.
Chromatogram 3: Capillary chromatogram of the "hydrocarbon C_2H_3", which was found to be the mother liquor of the crystallizing benzene.

Table 3. Composition of the pyrolysis condensate, determined by gas-chromatographic analysis and GC/MS combination analysis (see Fig. 4, chromatogram 1). Conditions: 100 m thin film capillaries, medium-polarity, polar, nonpolar, are directly coupled to the Varian-Mat CH 4/5 mass spectrometer. A mass spectrum is recorded for each peak at the instant of entry into the ion source. Number of species on medium-polarity capillary in concentrations above 100 ppm: >250; >90 components with retention indices lower than 763 (benzene). Number of species on polar capillary appearing before benzene at a low temperature: > 130. Number of species on nonpolar capillary ≈ 340. Only the hydrocarbons in concentrations higher than 0.5 % were qualitatively identified.

	Conc. (wt.-%)

pletely hydrogenated, the aromatic compounds giving naphthenes. The number of species in concentrations above 100 ppm decreased from 340 to 42; thus the 340 detectable compounds have only about 40 carbon skeletons, by far the most abundant of which are the C_6 structures. This can be seen from Figure 4, chromatogram 2, and from Table 4.

The complexity of the pyrolysis condensate boiling between 20 and 120 °C is interesting. According to tables of CH compounds that have been analytically detected, some 700 components are found in this boiling range. Above a limiting concentration of 100 ppm, we found almost half of all possible compounds. This result is not in conflict with similar investigations, since all the hydrocarbons actually present are found only by carrying the investigations far into the trace range; with a minimum concentration of 1 ppm, it is possible to detect about 80 % of all the possible hydrocarbons and when the limiting concentration of a complete analysis is set even lower, more structures are found than are given in the modern tables. Thus it is evidently not true that *e.g.* gasoline does not contain all the possible saturated hydrocarbons; this is simply a matter of lowering the limiting concentration sufficiently far. The term "complete analysis" is meaningless unless the concentration limit is specified.

The hydrocarbons listed in Table 4 were found in concentrations above 1000 ppm after complete hydrogenation (the Table does not mention that traces of less than 1000 ppm were also detected in the range nonane to decane).

Faraday described two other new hydrocarbons, including the lightest of all liquids known up to 1825, *i.e.* butene ("specific gravity" 28, corresponding to a molecular weight of 56, with the formula 4 proportionals of H_2 and 4 proportionals of C, present-day notation C_4H_8); however, this product was still mixed with the

isomeric butenes. *Faraday* knew that the liquid he was dealing with had a boiling range of −18 to 0 °C, that it was not pure, and that the main component was not C_2H_4 (ethylene, known at that time as "olefiant gas"). This could be deduced from the properties of the chlorinated olefin.

However, the aids available at that time failed *Faraday* in the identification of the "third hydrocarbon". In 1835, this third hydrocarbon was described in *Schubarth*'s "Elemente der technischen Chemie" [4] as C_2H_3, b.p. = 85.5 °C, specific gravity at 15.6 °C = 0.86. It was in fact a solution of about 30 % of C_4 to C_8 hydrocarbons in 70 % of benzene, which remained stable above −18 °C as the mother liquor in the crystallization of benzene. It contains at least 110 components at individual concentrations of more than 100 ppm (see Fig. 4, chromatogram 3). The mother liquor also contains unstable compounds that decompose during the concentration of the solution, and which have not been identified even yet. There is thus good reason for the aim of modern analysis to be an elucidation of the structures of compounds of this type dynamically in concentrations down to the ppb range, and without first isolating the compounds.

It may be concluded from our analytical results and from a comparison with historical analytical values that our distillate and the oil gas condensate from *Gordon*'s portable gas are very similar. If we assume that this is correct, *Faraday* was faced with a mixture containing at least 320 hydrocarbons in concentrations of more than 100 ppm each. Some substances having properties very similar to those of benzene cannot be completely separated from benzene even with the aid of a thin film capillary having a separation number [8] of more than 60. We would have to use a number of separating capillaries connected both in series and in parallel in order to free benzene completely from accompanying substances. Isolation of products that are pure according to their melting points is well nigh

[8] The separation number is in our view the most useful assessment of the separating efficiency of a chromatographic system. In a chromatographic range for which the separation number is *e.g.* 60, a maximum of 60 other signals can be satisfactorily separated (in 4,6 σ separation) between a pair of homologs (*R. Kaiser*, Z. analyt. Chem. *189*, 1 (1962)).

impossible; however, the classical method of preparing the substance is no longer necessary, since, as mentioned previously, pure isolated products are no longer required for the recognition of structures.

The quantitative evaluation of the capillary-chromatographic analysis was carried out after storage of the chromatogram on a magnetic tape by play-back through an automatic electronic direct integrator, which has the properties of a simple minicomputer. Ten minutes after the beginning of the first capillary chromatogram, the directly coupled mass spectrometer recorded the unmistakable mass spectrum of benzene by means of a UV fast recorder. Twenty minutes after a repeated GC recording, the mass spectrum of the signal showed conclusively the presence of toluene. The other main components were identified in the third combination GC/MS run by combined evaluation, and the results were checked by quantitative determination of the hydrocarbons by complete catalytic hydrogenation of the pyrolysis distillate in the form of a structure balance analysis. It is not necessary here to go into details of the apparatus and procedure, which correspond to present-day practice [9].

An interesting historical connection should be mentioned. The production of portable gas was started by *Gordon*, who asked *Faraday* for his assistance. Compressed coal gas was later also sold in portable containers, in order to supply gas to consumers whose homes were not yet connected to gasworks. At the age of 27, the Mannheim goldsmith and jeweller *Friedrich Engelhorn* (1821–1902) founded the firm "Engelhorn und Comp." for the production and sale of portable gas. Three years later, in conjunction with two gas engineers, he founded the "Badische Gesellschaft für Gasbeleuchtung", which installed street lighting in Mannheim. In 1861, *Engelhorn* set up a new company, "Sonntag, Engelhorn und Clemm"; this was the first tar factory in Germany, which produced, not only coal-tar dyes, but also their precursors such as aniline *via* benzene from tar. This Mannheim aniline factory ultimately became the Badische Anilin- und Soda-Fabrik AG., to whose management the author is deeply indebted for their generous support of his analytical investigations.

I am grateful for the idea of this work to Dr. H. Wolter, Völklingen, who has taken a particularly profound interest in the history of Faraday's work. I am also grateful to Dr. W. Benz, who carried out the mass-spectrometric investigations and evaluations, to Dr. E. Frommer for the gas analysis, and to Fräulein L. Arnold, Herr H. Fiedler, Fräulein C. Schneider, and Herr W. Schäfer for the preparation, working-up, and chromatographic analysis of the sperm oil pyrolysis products.

The Biosynthesis of Aromatic Amino Acids and its Regulation

BY F. LINGENS [*]

Microorganisms synthesize the aromatic amino acids phenylalanine, tyrosine, and tryptophan, as well as the related compounds p-aminobenzoic acid, tetrahydrofolic acid, p-hydroxybenzoic acid, ubiquinone, vitamin K, and nicotinic acid, by a highly branched route passing through shikimic acid. The biosynthesis is not regulated in the same way in all the organisms studied. The regulation is strongly dependent on the ability of the enzymes involved to be resolved into isozymes, their ability to be inhibited, and their activation, repression, and induction.

1. Introduction

The synthesis of aromatic amino acids in nature starts with intermediates of the carbohydrate metabolism. The main pathway ("shikimic acid route") of this highly branched biosynthetic chain leads to phenylalanine, tyrosine, tryptophan, and *p*-aminobenzoic acid. In some microorganisms, in mammals, and even in humans, tryptophan is used *inter alia* as a starting material for the biosynthesis of nicotinic acid; *p*-aminobenzoic acid is used for the biosynthesis of tetrahydrofolic acid. It has very recently been discovered that vitamin K and ubiquinone are also derived from the main pathway for the biosynthesis of aromatic compounds (see Scheme 1). The single biosynthetic chain described here is subject to biochemical regulation.

The investigations described in this review were carried out mainly on the Enterobacteriaceae *Escherichia coli*, *Aerobacter aerogenes*, and *Salmonella typhimurium*, on yeasts (particularly *Saccharomyces cerevisiae*), and on

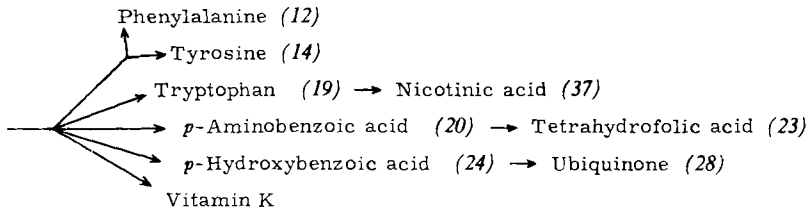

Scheme 1. General scheme of the biosynthetic pathways.

the mold *Neurospora crassa*. It must be pointed out that findings relating to a single organism, particularly in connection with the regulation of biosynthetic processes, cannot be generalized without further investigation. For example, nicotinic acid can be biosynthesized in microorganisms in several different ways; moreover, many microorganisms cannot produce either ubiquinone or vitamin K.

The regulation of biosynthetic chains is a means of ensuring that the end products are formed only as required. The end product of a chain may, for example, inhibit the first enzyme of the chain (negative feedback). The end product may also inhibit the biosynthesis of some or all of the enzymes of the chain (repression).
