The Defensive Chemistry of Land and Water Beetles[**]

By H. Schildknecht[*]

Wherever life forms have arisen, they have had to defend themselves, even on the lowest levels, against their own kind. Darwin called this the struggle for life. The following discussion shows that this struggle can be carried on chemically with compounds of widely differing classes. Examples of defensive substances found are hot quinones in bombardier beetles, and weak and strong carboxylic acids, phenols, terpenes, steroids, and alkaloids in other Adephaga.

1. Introduction

Beetles require extraordinary means for the acquisition and preservation of their *Lebensraum*, for wherever they live, under stones and in the ground, in soil and dung, or in a pool, there are always various kinds of microorganisms present. They must also defend themselves against other insects, as well as against larger enemies such as birds, mice, and frogs. The fact that beetles nevertheless exist, are practically free from attack by fungi, and always look clean is largely due to a defensive chemistry suited to their living habits.

2. Contents of the Pygidial Defensive Glands of Land Beetles

Like insects, many bacteria are attracted by warmth and humidity; however, the latter prefer neutral or weakly alkaline media. The simplest way for a beetle to protect itself against microbes is therefore to render its immediate surroundings either acid or strongly basic.

For example, those silphids that live in carrion secrete a 4.5% ammonia solution for their protection[1]. In this way the carrion beetles defend themselves not only against attack by putrefactive bacteria but also against larger enemies and against feeding rivals.

Only three species of beetles, *i.e. Oeceoptoma thorica* L., *Silpha obscura* L., and *Phosphuga atrata* L., have been found to use a base as a defensive substance. Carboxylic acids are more common[2]; isobutyric and isovaleric acids, for example, can be detected by electrophoresis and gas chromatography in six groups of carabids. These lower fatty acids are not very effective, and do not provide sure protection in a frequently changing environment, particularly since the action of any antiseptic is concentration-dependent[3]; it is also inconceivable that these carboxylic acids could ensure lasting repulsion of predatory insects. A better repellent is strong formic acid, which can be effective as a cytotoxin even when dilute, particularly if its penetration into the hostile organism is assisted by lipophilic aliphatic hydrocarbons[4]. In 25 species of beetles we found that, with only one exception (*Lebia chlorocephala*), formic acid was accompanied mainly by *n*-undecane, and in some cases by *n*-decane and *n*-tridecane. Beetles of the genus Pseudophonus (9–16 mm) can spray 70–75% formic acid over a distance of 20 cm in fine droplets from their 1.5–2 mm paired pygidial defensive glands (see Fig. 1)[5].

When a stone is turned by the wayside during a search for insects an aromatic odor often becomes percepti-

ble before any creature is observed. On closer examination, a shiny ground beetle, *e.g. Carabus auratus*, will be seen which emits clouds of aromatic vapor when touched, even in captivity. This vapor is almost pure methacrylic acid, which the beetle secretes, contaminated with about 5% of the homologous tiglic acid (*trans*-2-methylbutenoic acid) (see Table 1). These acids are also cytotoxins, and though they are more lipophilic than formic acid, the C_{10}, C_{11}, and C_{13} paraffins have also been detected in half of the 16 species examined.

As a hypothesis regarding the evolution of the compounds that occur in the defensive secretions, it may be assumed that in the origin of species of beetles, selection of a chemical characteristic can also be advantageous for a particular species [6]. In this light the saturated fatty acids may be regarded as original and the unsaturated acids as derived. The antibiotically active unsaturated carbonyl group can become effective only if adequate lipophilicity is assured, either by an aliphatic residue in the molecule itself or by admixture with an aliphatic solubilizing agent. We have observed both principles, and they will undoubtedly be encountered even more often during the elucidation of chemical defense mechanisms.

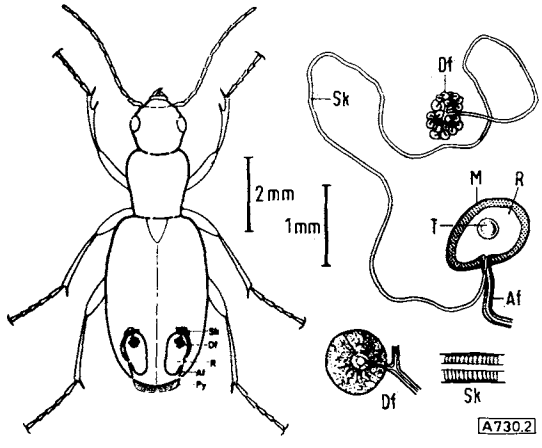

Fig. 2. *Idiochroma dorsalis* and its pygidial defensive gland system; Sk = collecting tube, Df = glandular follicle, Af = excretory tube, Py = pygidium, R = reservoir, M = musculature, T = "oily" droplet.

The pygidial defensive glands of *Asaphidion flavipes* and of *Bembidion quatriguttatum*, for example, contain *n*-valeric acid mixed with paraffins, as well as salicylaldehyde; from *Idiochroma dorsalis* (Fig. 2) we isolated not only the more lipophilic methyl salicylate but also *n*-undecane as the main component, together with 12% of formic acid and a little *n*-decane [8].

The phenolic active group, which is present in salicylaldehyde and in salicylic acid, occurs particularly widely in water beetles. Use of the particularly effective disinfectant *m*-cresol very probably also represented an advance for the three species of Chlaenius *Ch. tristis*, *Ch. crysocephalus*, and *Ch. bipunctatus* [2,9]. The hydroquinones are less effective than *m*-cresol, since they lack the alkyl group. We therefore find them only as precursors of the bactericidal and fungicidal *p*-benzoquinones [10], which are so characteristic as defensive substances in beetles that we referred to an entire group of these insects, in an earlier publication [11], as "quinone beetles".

Nevertheless, neither the tenebrionid family [12–14] nor the carabid genera Scaritini and Chlaeniini, with their defensive substances *p*-benzoquinone, toluquinone, ethylquinone, and 2-methyl-3-methoxy-*p*-benzoquinone (in *Clivina fossor*) can match the brachynids (bombardier beetles) in the effectiveness and elegance of their protection.

3. The Defensive Chemistry of the Bombardier Beetle

The brachynids have bladders weighing 1 mg in which they store, not the unstable quinones, which react with protein, but aromatically stabilized hydroquinones in a hydrogen peroxide solution whose concentration is frequently as high as 28% [15]. A hot toxic gas consisting of benzoquinone, toluquinone, and unreacted hydroquinone and hydrogen peroxide is emitted with an audible report by oxygen under pressure (Fig. 3).

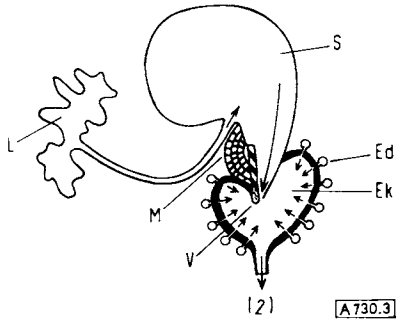

Fig. 3. Pygidial defensive gland system of the bombardier beetle; L = lobes, S = collecting bladder, M = sphincter muscle, V = valve, Ed = enzyme glands, Ek = explosion chamber. The collecting bladder S contains *(1)* and H_2O_2.

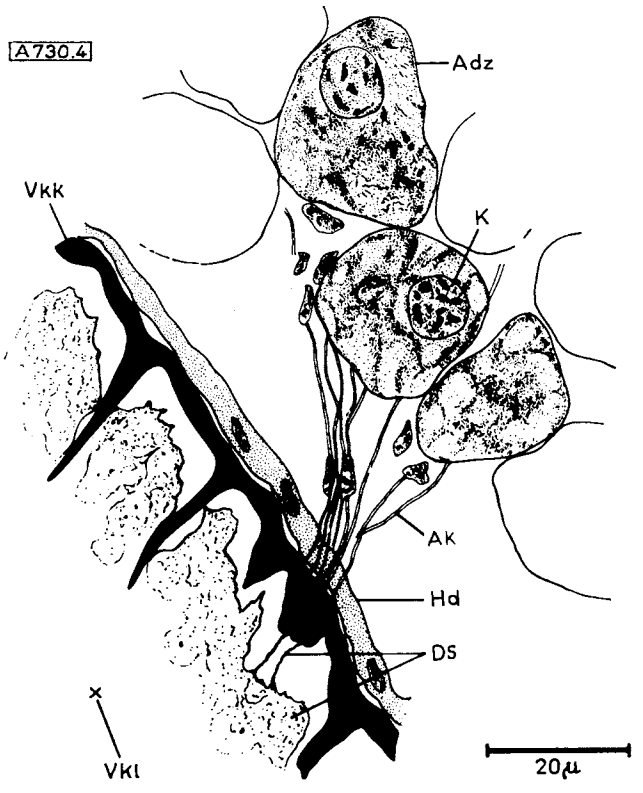
These were our first observations [15,16] on this defense mechanism, which is unique in the entire animal kingdom. The further results reported here arise from experiments on the nature of the catalysts that bring about the explosive reaction of the pygidial gland secretion in the combustion chambers [17]. These chambers are chitin capsules 200 to 300 μm long with very spiny interiors, into which emerge, from raised sieve plates, bundles of excretory tubes of numerous unicellular annex glands, whose enzyme secretion can be pipeted off with glass capillaries as a deep brown liquid. Indigenous bombardier beetles such as *Br. explodens* yield 0.01 to 0.03 μl, and the rather larger *Br. crepitans* yield 0.02 to 0.1 μl of a 40 to 60% protein solution that decomposes hydroquinone/hydrogen peroxide solution explosively, even in a test tube, to



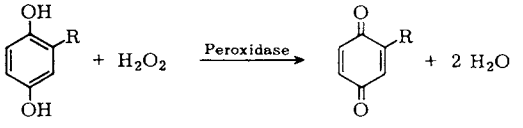


Fig. 4. Cross section through the pygidial defensive gland vestibule and the annex glands (Adz) of the bombardier beetle (portion). Ak = excretory tube, K = nucleus, Hd = hypodermis, Vkk = vestibular cuticle, Ds = glandular secretion, VkL = vestibular lumen.

give benzoquinone and oxygen. This double reaction of the pygidial gland secretion requires two enzymes, *i.e.* catalase for the decomposition of the hydrogen peroxide into water and oxygen, and peroxidase for the oxidation of hydroquinone, if one disregards the slight peroxidase activity of catalases.

$$2\ H_2O_2 \xrightarrow{\text{Catalase}} 2\ H_2O + O_2$$

(1) R = H, CH_3 *(2)*

After micro zone electrophoresis of the combustion chamber liquid, we detected both enzymes on the cellulose acetate film by spraying with a synthetic pygidial gland secretion. For seven species of Brachynus (*Br. crepitans, explodens, immaculicornis, plagiatus, sclopeta, ganglbaueri, exhalans*), we observed one spot giving strong liberation of gas and another that merely turned brown. Only for *Br. ganglbaueri* was the catalase transported farther than the peroxidase. The enzyme pattern obtained in this way is reproducible and characteristic of the species, both in the rates of migration of the proteins and in the intensity of the spots.

The micropreparative isolation and subsequent characterization [18] of these insect catalases and peroxidases was facili-

tated by the unusually high concentrations in which these enzymes are present in the brachynids, which are up to 10000 times the concentrations in the livers of mammals.

The annex gland secretion was separated into three fractions by gel filtration on Sephadex G-200 (see Fig. 5). The first fraction, which had a high molecular weight, exhibited peroxidase and catalase activity, the

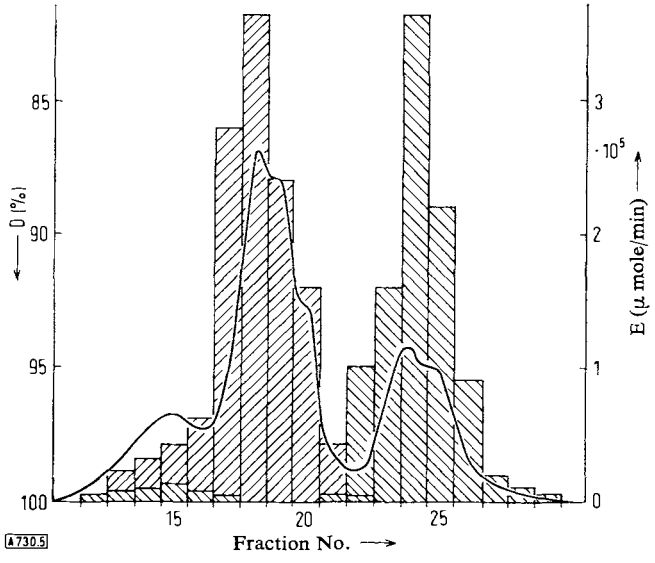

Fig. 5. Fractionation of the combustion chamber proteins from *B. crepitans* by gel filtration; D = transmission at 280 nm (%)[continuous curve], E = enzyme activity (µmole of H_2O_2 transformed/min). Hatching: /// = catalase; \\\ = peroxidase.

second exhibited only catalase activity, and the third only peroxidase activity. A combination of micro zone electrophoresis and gel filtration allowed the isolation, from the three beetle peroxidases, of one peroxidase that was uniform on disk electrophoresis. Of two catalase fractions, one was almost uniform, while the other consisted of three protein components exhibiting catalase activity. The molecular weight of the uniform crepitans catalase (225000) is very similar to that of plant and animal catalases; the molecular weight of the one beetle peroxidase corresponds to that of the ox thyroid, cytochrome c, and lacto-peroxidases. The typical prosthetic group of the known catalases and peroxidases, protohematin IX, was also found in the beetle enzymes.

An unusual feature of the Brachynus catalase, however, is the fact that it has its optimum activity between 70 and 80 °C, and even exhibits considerable activity after being boiled for a short time. The ox liver

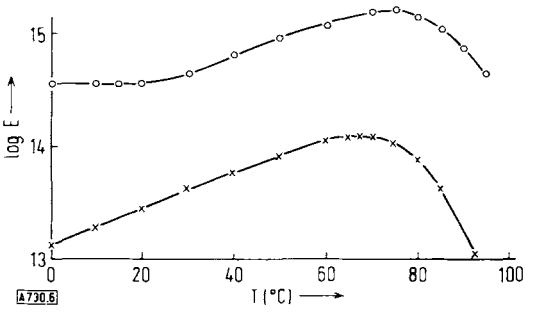

Fig. 6. Temperature-activity diagram of Branchynus catalase (-o-o-o-) and of Brachynus peroxidase (-x-x-x-); E = enzyme activity (µmole of H_2O_2 transformed/min · mole porphyrin).

catalase with which it was compared has its activity optimum at 52 °C and is completely inactivated at 62 °C. The optimum temperature range for the Brachynus peroxidase is between 65 and 75 °C; there is nothing unusual about this, since the peroxidases include some of the thermally most stable enzymes known. What is unusual is its substrate stability and donor specificity. It is appreciably more stable to hydrogen peroxide than other peroxidases, and, unlike most, it does not react with benzidine or *p*-phenylenediamine, but prefers hydroquinone or pyrocatechol as its hydrogen donor.

This is practically the only system that can be used by an organism to produce an explosive reaction using endogenous substances, since it is particularly characteristic of catalases that their activity increases without limit with the concentration of the substrate [19]. The nature of the enzyme, the high hydrogen peroxide concentration, and the reaction temperature in the chitin capsule, which is unusually high for a biochemical process, allow such rapid evolution of gas that an explosion occurs, and the denaturing action of hydrogen peroxide on the enzymes hardly becomes effective.

The secretion of the annex glands, which is retained in the explosion chamber by many chitin bristles (see Fig. 4), thus remains so active after each defensive reaction by a hot detonation [*] that it can still ignite the last of a dozen propellant charges.

4. Defensive Substances of Water Beetles (Dytiscidae)

4.1. Active Substances of the Pygidial Defensive Glands

The dytiscids are among the best swimmers of all fresh-water invertebrates. The boat-shaped beetles can slide through the water with the minimum of friction, unimpeded by spines or projections of any kind. Only when they are forced to remain in the water for a long time do their wing covers become coated with a microbial slime and the surface of the insect loses its water repellency. Since a hydrophilic body does not pass through the water so easily, the beetles remove these parasites from time to time by coating themselves with a disinfectant paste, which they force out of their pygidial defensive glands while sitting on a blade of grass. The principal components of the paste, apart from benzoic acid, are phenols, all of which have an antiseptic action [20]. It can be seen from Table 2 that

methyl *p*-hydroxybenzoate (PHB) is particularly common as an antiseptic in water beetles. This may be related to the observation, by *Beveridge* and *Hugo* [21], that none of the nine strains of bacteria that they examined could decompose methyl *p*-hydroxybenzoate, though they could decompose other aromatic compounds studied, and that despite the use of this ester by water beetles for millions of years, the microorganisms have evidently never built up a resistance to it.

The great diving beetle (*Dytiscus marginalis*) uses a disinfectant paste that is formed in its defensive glands from methyl *p*-hydroxybenzoate, benzoic acid, and a glycoprotein, which is pre-crosslinked by *p*-hydroxybenzaldehyde (also present in a high concentration) and the ε-amino groups of lysine. During the act of cleaning [22] in air, compact, often film-like deposits are formed on the wing covers, the antiseptics being embedded in the coating. Evidence concerning the nature of the coating is provided by an electron micrograph, by its extreme insolubility, and by the high cysteine/cystine content (17.25%) of the high molecular weight glycoprotein [23]. Owing to its hydrophilic sugar component the film is removed spontaneously when the insect returns to the water, the beetle thus regaining its hydrophobic surface. It is not yet known whether the marginalin [3-(*p*-hydroxyphenylmethylene)-5-hydroxybenzo[*b*]furan-2-one] *(3)* [24] that also occurs in the

(3)

pygidial defensive glands of *Dytiscus marginalis* also possesses properties that are of use to the beetle, since this lactone, like all other derivatives of benzylideneisocoumaranone, had not previously been found in nature and no relation is known between structure and antibacterial action in unsaturated lactones [25].

4.2. Active Substances of the Prothoracic Defensive Glands

If a great diving beetle is taken from the aquarium for the investigations described above, it may be found to spray the fetid contents of its rectal ampoule in a thick jet from its anus. At the same time it often emits, from the collecting bladders situated in its prothorax, a milky liquid, which is reported by *Frisch* [26] to poison fish and amphibians. *Blunck* [27] assumed that this is a specific means by which the beetle protects itself against large enemies among the vertebrates, *i.e.* a nerve poison that affects heart beat and breathing. The pure crystalline active substance was identified on the basis of spectroscopic data as 11-deoxycorticosterone (Cortexone) [28].

When administered per os to pike or trout, this steroid has the same stunning effect as the natural secretion. Cortexone (as a foreign hormone) has no effect on the beetle itself. It is also found in the prothoracic defensive glands of other water beetles (see Fig. 7) such as *Agabus bipustulatus* and *Acilius sulcatus* (19 μg/beetle)[29], which are in fact a treasure trove of α,β-unsaturated and α,β-γ,δ-diunsaturated C_{21} keto-steroids. 6,7-Dehydrocortexone, which is the principal component (56 μg) in the vesicles of Acilius, had not previously been known as a natural product; other components detected are 1 μg of 20α-hydroxy-4-pregnen-3-one, 6 μg of 4,6-pregnadiene-3,20-dione, and 7 μg of cybisterone (20α-hydroxy-4,6-pregnadien-3-one), which was first discovered in *Cybister*

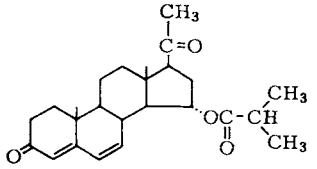
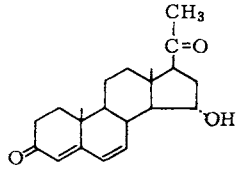
lateralimarginalis[30]. An interesting subsidiary steroid found in this Cybister species is 12β,20β-dihydroxy-4,6-pregnadien-3-one *(4)*, dehydration of which on C-20

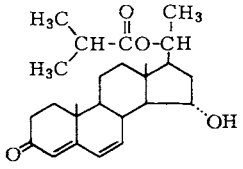


(4)

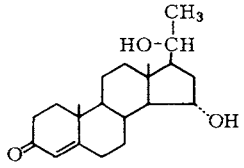


(5)

gives 12-hydroxy-4,6-pregnadiene-3,20-dione *(5)*, the principal steroid in a Mexican Cybister species (*C. tripunctatus?*). The Mexican Cybister, which I caught in an ideal biotope for water beetles, *i.e.* the ditches of the floating gardens at Xochimilco (Mexico City), keeps more than 1 mg of this steroid available for its protection[32].



The steroids *(6)*, *(7)*, and *(8)* of *Agabus sturmi* are further modified by a change in the position of the OH groups; these are hydroxylated pregnadienones (which



(6)

(7)

(8)

(9)

are typical of dytiscids) only one of which had previously been known[33], and which can also occur here as esters of isobutyric acid[31]. The steroid *(9)* of *Platambus maculatus* (7–8 mm long) is also hydroxylated on C-15; 0.7 mg of *(9)* have been isolated from the milky secretion of 100 beetles[34].

Of the insect steroids mentioned, some that can be prepared in good yields have been tested for their action on cold-blooded animals. At a concentration of 2 mg of steroid/1 l of water, for example, the test fish showed appreciable changes in behavior after 15 to 30 minutes. They could be turned on their side, and righted themselves only with difficulty. At a steroid concentration of 10 mg/l, the fish were lying motionless at the bottom of the tank after half an hour, but recovered completely when placed in fresh water. Experiments in which *Ilybius fenestratus* (Fig. 8) were fed to toads and frogs were particularly informative.

Fig. 8. *Ilybius fenestratus* (12 mm).

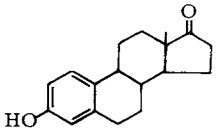
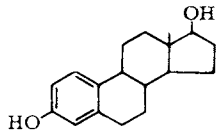
[34] *H. Schildknecht*, *H. Tacheci*, and *U. Maschwitz*, Naturwissenschaften *56*, 37 (1969).

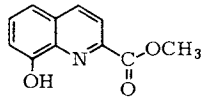
After only 20 minutes, one common toad vomited out the four beetles that it had eaten within five minutes. The beetles are often still alive when they are disgorged. If they are dead, they have sacrificed themselves for the continued existence of their entire race, since after they have been fed once or twice with *Ilybius*, the toads will no longer eat beetles, even when they are very hungry.



In addition to a very small quantity of a C_{21} steroid (cf. Table 3) the secretion contains the C_{19} and C_{18} steroids *(10)* (28 μg)[35], 1,2-dehydrotestosterone *(11)* (16 μg), estrone *(12)* (2 μg), and 17β-estradiol *(13)* (19 μg)[36], and, to our great surprise, methyl 8-hydroxyquinoline-2-carboxylate *(14)* as the principal component (350 μg)[37].



(10)



(11)

(12)

(13)

(14)

It is possible that the insect uses this strong antiseptic to prevent the penetration of microorganisms into its large defensive organs, which would result in total infection of its body, while it again has the pygidial defensive substances *p*-hydroxybenzaldehyde, *p*-hydroxybenzoic acid, and the methyl ester of the latter for external disinfection of its body.

The biosynthesis of insect steroids can be studied with ^{14}C-labeled precursors. Beetles are excellent subjects for such studies, since the steroids produced are not metabolized further, but collect as described in readily isolable glands. Moreover, the regenerating power, as in the case of *Acilius sulcatus*, is very high, even in insects kept in the laboratory.

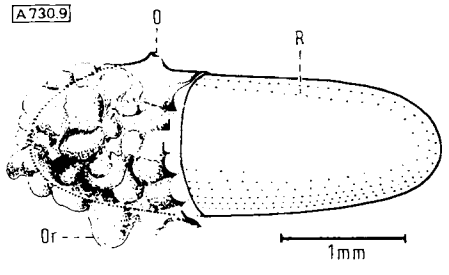


Fig. 9. Prothoracic defensive gland of *Dytiscus marginalis* with secretion cells above; R = reservoir, Dr = glands, and O = opening.

Insects require cholesterol, sitosterol, or similar starting materials for the formation of steroids[38]. The greater the similarity of a sterol to cholesterol, the more efficiently it can be used; cholesterol is often degraded by removal of the entire side chain at C-17 or of part of it at C-20, with formation of pregnenolone, from which progesterone is then formed.

In our experiments[39] we injected 25 to 30 water beetles with [2-^{14}C]-mevalonolactone, [4-^{14}C]-cholesterol, or [4-^{14}C]-progesterone; after a regeneration time of six weeks, the concentration and activities of the Acilius steroids were determined. The steroids of the insects treated with mevalonolactone, as expected, exhibited no activity; cholesterol and progesterone, on the other hand, were incorporated. The water beetles must therefore absorb cholesterol or steroids of similar structure with their food.

Table 5. Specific incorporation and specific activities after injection of [4-^{14}C]-cholesterol and [4-^{14}C]-progesterone.

	Cholesterol		Progesterone	
	(%)	(μCi/mmole)	(%)	(μCi/mmole)
6,7-Dehydrocortexone	0.73	[310]	0.01	[3.4]
Cortexone	0.51	[230]	0.14	[50]
Cybisterone	1.13	[480]	0.03	[10]
6,7-Dihydrocybisterone	1.20	[510]	2.46	[881]
6,7-Dehydroprogesterone	0.85	[360]	0.007	[2.4]

In our biosynthesis experiments, which are described only briefly here, we were able to show that after injection of [4-^{14}C]-cholesterol, the rates of incorporation for the enones and dienones are of the same order of magnitude, whereas after injection of [4-^{14}C]-progesterone the dienones were labeled to a much smaller extent than the enones (see Table 5).

We assume that the biosynthetic path for these groups of steroids branches before the progesterone stage. This hypothesis is supported, in our opinion, by the fact that with [^{14}C]-4,6-cholestadien-3-one as a precursor, the rates of incorporation were higher for the dienones than for the enones. No activity was found in the dehydroprogesterone, which thus appears to be formed by an entirely different path from the other dienones. It can be provisionally concluded that progesterone, which has not so far been found in the defensive glands of water beetles, is metabolized in the lobes into cortexone and dihydrocybisterone, but dehydroprogesterone is not converted into dehydrocortexone and cybisterone.

5. *Stenus bipunctatus*

Stenus bipunctatus is a small black staphylinid. As a land beetle, it lives in the region of river banks, but can also move well on the water. If the beetle, which on average weighs 1.5 mg and is about 5 mm long, is chased by a bird while on the water, it streaks toward the bank and safety with the speed of an arrow and without using its legs[40]. To produce this elegant

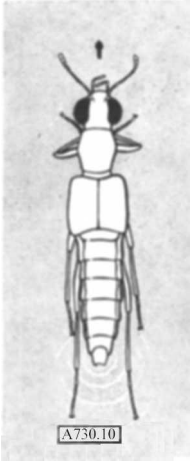
movement, the beetle immerses the tip of its abdomen into the water and emits, from two protruding sacs corresponding to the pygidial defensive glands of other land beetles, substances that propel it in the same way as a toy boat is propelled by camphor. The reaction necessary for driving the beetle forwards is most probably provided by the spreading pressure that is set up when the surface-active secretion is transferred to the surface of the water.



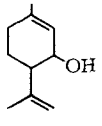


Fig. 10. *Stenus bipunctatus* in motion. Drawing by *T. Hölldobler*.

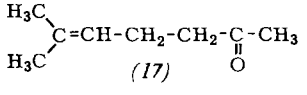

In agreement with preliminary tests, which pointed to a complex secretion [41], *Maschwitz* found two pairs of pygidial defensive glands on dissection of *Stenus bipunctatus*, the larger smelling of amine when crushed and the smaller having a peppermint-like odor. To isolate the pygidial gland secretion in large quantities, we heated 1000 insects under vacuum, extracted the distillate with benzene, and concentrated the extract by ice zone melting. The concentrate was divided into three fractions by gas chromatography. The principal component was 1,8-cineole [*] *(15)*, while isopiperitenol [**] *(16)* and methylheptenone [*] *(17)* were also

(15)

(16)

(17)

present. All these terpenes are surface active, and propel a "paper beetle" through water in the manner described. Whether the nitrogen heterocycles of the large glands reinforce this effect or have some other function cannot be decided until the compounds have been synthesized.

[**] It could not be established whether the compound was *cis*- or *trans*- isopiperitenol.

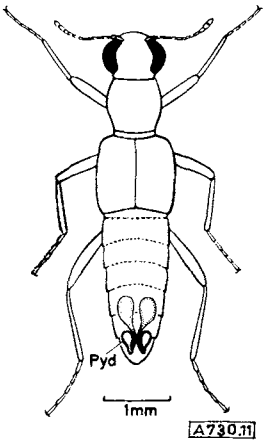

Fig. 11. *Stenus bipunctatus* with pygidial defensive glands.

6. Outlook

The functional assignment of the pygidial defensive glands of the Adephaga on the basis of the chemical findings is indisputable. However, one can think of enemies, other than microorganisms, that must also be fought with the substances mentioned. This is supported *e.g.* by the work of *Eisner* [42,43].

The antimicrobial activity must be regarded from the viewpoint of a homology between the epidermal glands and the complex defensive glands of the beetle. The toxins stored in the latter may originally have been intended for protection of the entire body against attack by microorganisms; *i.e.* the pygidial defensive glands formed by combination of the epidermal glands also secrete antiseptic substances, but the spectrum of action of these substances is extended. Could this not have been so even at the epidermal gland stage? It is through the skin that the principal contact with the hostile environment occurs. Primitive poison equipment intended for use against enemies of other species is found mainly in the skin and have developed from the skin.

The chemistry of the epidermal glands is important. The function of the pygidial glands of the true water beetles could not be correctly demonstrated until the contents of the appropriate storage organs had been identified. The substances in the epidermal glands of the dytiscids were then seen to be insufficient by themselves for the bodily hygiene of the insects.

The question of the action of the as yet unknown contents of the known pygidial defensive glands was thus reversed in the case of the water beetles. It was known that the water beetles periodically coat themselves with the secretion from their pygidial glands [44]. The question why was answered by chemistry. On the other hand, at least the toxic action was known for the prothoracic glands of some species of Dytiscinae [27],

whereas the elucidation of the natural products was not easy.

In the case of the Colymbetes species, neither the function of the prothoracic glands nor the nature and action of their chemical products has been fully explained, and this is also true of the pygidial glands of the whirligig beetles.

Colymbetes fuscus leads an amphibious existence. It requires no special protection in or on the water against predaceous fish and frogs, since it is nimble and readily takes to the air. On land, however, it finds great difficulty in moving around, and could easily be attacked by small mammals. It is therefore not surprising that the substances in its prothoracic glands are very toxic to rats. One fraction obtained on fractionation of the crude secretion on Sephadex caused a decrease of up to 30% in blood pressure [45]. A relationship can be seen here with the toxic action of the principal component of the toxin from the prothoracic defense glands of *Ilybius fenestratus*, which causes clonic spasms in mice [46]. The toxic substance is methyl 8-hydroxyquinoline-2-carboxylate *(14)*.

Organic Dyes in Laser Technology

By F. P. Schäfer [*]

Laser technology has been developed to a very high level since 1960. Significant advances have been made possible only by the use of organic dyes as optical shutters for the production of giant pulses. Ultrashort pulses in the picosecond range were first produced in 1966; their measurement was greatly facilitated by the use of organic dyes. Probably the most important recent advance in the laser field is the dye laser, which was first described in 1966, and in which the active medium is a solution of an organic dye.

1. Organic Dyes as Optical Shutters

To facilitate the explanation of the use of organic dyes as optical shutters, let us first consider the laser principle, taking a simple ruby laser as an example. A ruby rod situated between two mirrors is pumped [**] with a flash lamp. Photons starting out *e.g.* from the point X travel to the left along the optical axis of the resonator, are reflected at the mirror Sp_2, travel back along the ruby rod, are reflected again by the mirror Sp_1, and finally return to the point X; in the course of this journey, the photons are both amplified and attenuated by the resonator. Let the amplification resulting from one passage through the ruby rod be V; let the attenuations due to incomplete reflection by the mirrors Sp_1 and Sp_2 be given by the reflection factors R_1 and R_2 respectively, and other losses, due *e.g.* to scattering, diffraction, and absorption, by an attenuation factor A. The effective amplification for one cycle is therefore $V^2 \times R_1R_2 \times A^2$.

If the effective amplification is less than 1, the number of photons will decrease. If it is equal to 1, the photon flux will remain constant; if it is greater than 1, however, the number of quanta will increase, and the intensity of the light beam will steadily build up, *i.e.* a laser emission occurs. For high values of the loss factor A, this is possible only if the amplification V is sufficiently great, whereas with small losses even a small amplification is sufficient to start the oscillation if the reflection factors are close to unity as a result of complete silvering.

A particularly interesting case is that of time-dependent losses $A(t)$ [1]. This case can be produced *e.g.* by insertion of a Kerr cell and a polarizer in the laser re-

[**] The excitation of the laser material is generally referred to as "pumping".

[1] *R. W. Hellwarth*: Control of Fluorescent Pulsations. Advances in Quantum Electronics. Columbia University Press, New York 1961, p. 334.

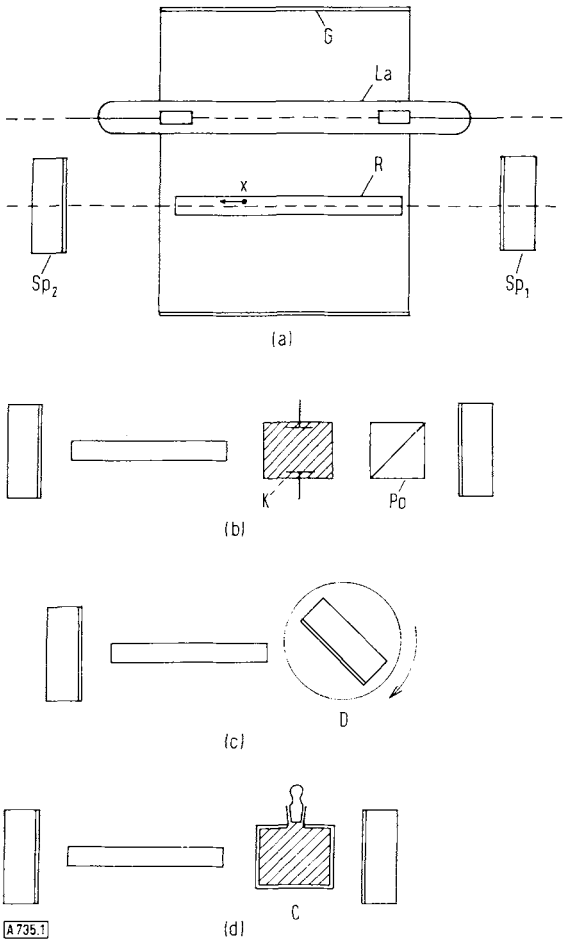

Fig. 1. Construction of normal-pulse and giant-pulse lasers. $Sp_{1,2}$: laser mirrors, R: ruby rod, La: flash lamp, G: reflector for the pumping light, K: Kerr cell, Po: polarizer, D: rotating mirror, C: cell containing dye. The flash lamp and the reflector for the pumping light have been omitted in Figs. 1b–1d.

sonator, as illustrated in Figure 1b [2]. The blocked Kerr cell corresponds to high losses in the resonator, and the open Kerr cell to low losses. In "giant-pulse operation", the ruby rod is first brought to a state of high amplification by a particularly powerful pumping flash, while the Kerr cell is blocked so that no laser oscillation can occur, since the losses in the resonator cannot be overcome even at very high amplification. The ruby rod reaches its highest amplification shortly after the pumping flash reaches its maximum intensity, and the Kerr cell is now opened by a sudden increase in voltage. The resulting sudden decrease in the losses allows the effective amplification to increase to far beyond unity, so that laser oscillation can occur. Because of the high effective amplification, this oscillation can build up to a high intensity within a few cycles in the resonator, so that a very intense, short laser flash, *i.e.* a "giant pulse", is emitted. The main difficulty of this process is the accurate synchronization of the pumping flash and the jump in the voltage across the Kerr cell.

Another method of producing giant pulses is to mount one of the mirrors of the laser resonator on the shaft of a high-speed motor (Fig. 1c) [3,4]. While the rotating mirror is not exactly parallel to the fixed mirror, the losses in the resonator are large, since part of the beam is cut out for each cycle. The pumping flash and the rotation of the mirror can be accurately synchronized so that the parallel position of the mirrors exactly coincides with the maximum amplification in the ruby. In addition to the synchronization difficulties in this case, the high motor speeds required present mechanical and optical problems, so that this method is now used only in special cases.

The synchronization dfficulties in both of these methods result from the fact that the losses in the resonator must be actively eliminated at the exact instant of maximum amplification in the ruby rod. A better method would be one in which the losses are eliminated automatically and passively at the correct instant. A passive optical shutter of this nature can be produced in the form of a cell containing a suitable dye in an appropriate concentration (Fig. 1d) [5–8].

The operation of this optical shutter can be qualitatively explained as follows. The laser emission begins when the amplification reaches a certain value fixed by the absorption in the cell. The initially weak laser beam passing through the cell at first raises only a small proportion of the dye molecules into the excited state. Since the absorption is proportional to the concentration of the molecules in the ground state, it is reduced slightly by the action of the laser light. The effective amplification and the light intensity in the laser beam are accordingly increased and this in turn leads to a further decrease in the absorption of the dye. The absorption of the dye is thus ultimately almost totally eliminated by the increasing intensity of the light in a fast feedback process, and so the optical shutter is opened. As in the cases described above, the effective amplification now has a value much greater than 1, and a giant pulse is produced.

Let us now estimate the order of magnitude of the radiation intensity required to eliminate the absorption for a simplified example. Let photons of frequency ν_L fall on a solution of m dye molecules per unit volume in a cell of length L at a rate of n per cm^2 per second. The molecules are assumed to be either in the ground state or in the first excited singlet state, which is separated from the ground state by an energy $h\,\nu_L$ (h = Planck's constant). Let the effective cross section of the molecules for absorption and stimulated emission be σ (with parallel orientation of the transition moment and the electric vector of the stimulating light). The relation between σ and the molar decadic extinction coefficient ε is given by

$$\sigma\ (\text{in cm}^2) = 0.385 \times 10^{-20}\ \varepsilon\ (\text{in cm}^2/\text{mmole})$$

Let the occupancies of the ground and excited states be m_0 and m_1, and let the average life of the excited state be τ. The change in the occupancy of the ground state due to absorption is

$$dm_0/dt = -n\,\sigma\,m_0$$

while the change in the occupancy of the excited state due to spontaneous emission is

$$dm_1/dt = -m_1/\tau$$

and that due to stimulated emission is

$$dm_1/dt = -n\,\sigma\,m_1$$

For the steady state, therefore, we have

$$-dm_1/dt = dm_0/dt = -n\,\sigma\,(m_0-m_1) + m_1/\tau = 0 \qquad (1)$$

Substitution of $m = m_0 + m_1$ in eq. (1) gives

$$m_0-m_1 = m/(2\,n\,\sigma\,\tau + 1) \qquad (2)$$

The photon flux n in a thin layer of thickness dl is reduced under these conditions by

$$dn = -(m_0-m_1)\,n\,\sigma\,dl \qquad (3)$$

Insertion of eq. (2) in eq. (3) and integration over the length of the cell gives the absorption law

$$\ln(n_0/n) = m\,\sigma\,L - 2\,\sigma\,\tau\,(n_0-n) \qquad (4)$$

In this equation, n_0 is the incident photon flux, and n is the photon flux emerging from a cell of length L. For small τ or small n_0, eq. (4) becomes the well known Beer-Lambert law.

If the molecules pass very rapidly from the state reached on absorption of a photon into another energy level from which they can fall back to the ground state after an average life τ (by spontaneous emission or radiationless deactivation), appreciable stimulated emission cannot occur at the same frequency ν_L. Thus

$$m_0 = m/(n\,\sigma\,\tau + 1) \qquad (2a)$$

Integration of

$$dn = -m_0\,n\,\sigma\,dl$$

gives the absorption law

$$\ln(n_0/n) = m\,\sigma\,L - \sigma\,\tau\,(n_0-n) \qquad (4a)$$

Figure 2 shows the absorption $1-n/n_0$ found from equations (4) and (4a) for a typical example[9] as a function of the irradiation intensity $S_0 = h\,\nu_L\,n_0$. In the example in question, the absorption is practically eliminated at an irradiation intensity of the order of 10 MW/cm².

[9] *W. Schmidt*, Dissertation, Universität Marburg 1966.

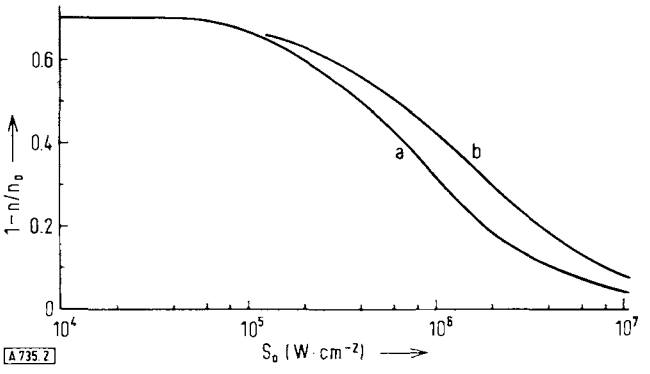

Fig. 2. Absorption $1-n/n_0$ as a function of the irradiation intensity S_0 in a dye solution of concentration $m = 3.2 \times 10^{15}$ cm^{-3} (corresponding to 5.3×10^{-6} mole/l), effective cross section of the molecules $\sigma = 0.39 \times 10^{-15}$ cm² (corresponding to $\varepsilon = 10^5$ lmole^{-1} cm^{-1}), life of the excited state $\tau = 1$ ns, cell length $L = 1$ cm. Curve a) calculated according to eq. (4), curve b) according to eq. (4a) (after [9]).

The quantitative treatment of the production of giant pulses with dye solutions as optical shutters is described by three coupled differential equations, of which one describes the time variation of the occupancies of the ground and excited states of the dye molecules, another gives the time variation of the occupancies of the ground and excited states of the chromium ions in the ruby rod, and the third gives the time

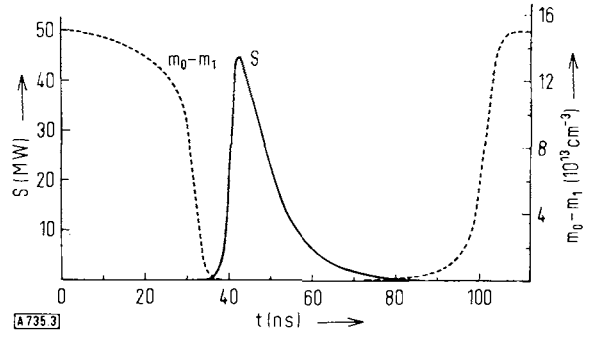

Fig. 3. Radiation output S and occupancy difference m_0-m_1 between the excited state and the ground state as functions of time for a typical example (after [9]).

variation of the photon flux in the laser resonator. The solution obtained for these three coupled differential equations by numerical integration is shown in Figure 3 for a typical example. The diagram shows the rapid increase in the photon flux in the resonator (the quantity plotted is the radiation output $S(t)$, which is proportional to the photon flux) and the simultaneous rapid decrease in the difference in occupancy between the excited and the ground states ($\Delta m(t) = m_0-m_1$) of the dye molecules during the giant pulse. Similar calculations can be found in[10–13].

Good agreement is found for the calculated and experimental values of the maximum intensity and half-width of the giant pulse emitted in the case of the cyanine dye *(1a)* (see Table 1). The quantitative treatment of the effect shows that the ratio of the effective cross sections of the dye molecules and active centers in the laser material at the laser wavelength should be as high as possible. This is satisfactorily fulfilled by the combination *(1a)*/ruby, since the effective cross

[10] *M. Hercher*, Appl. Optics *6*, 947 (1967).

[12] *V. V. Korobkin, A. M. Leontovich, M. N. Popova*, and *M. Ya. Shchelev*, JETP Letters *3*, 194 (1966).

[13] *B. L. Borovich, V. S. Znev*, and *V. A. Shcheglov*, Soviet Physics JETP *22*, 717 (1966).

section of the dye *(1a)* at the ruby wavelength, σ_F (694 nm), is 0.46×10^{-16} cm^2, while that of the chromium ions in ruby, σ_R (694 nm), is 1.8×10^{-20} cm^2, *i.e.* the ratio $\sigma_F/\sigma_R = 2.5 \times 10^3$.

This means that each photon absorbed in the dye solution, which decreases the absorption of this solution, was formed by stimulated emission in the laser material with passage of an active center into the ground state, *i.e.* its formation was associated with an increase in the absorption of the laser material. In the extreme case, if the effective cross sections in the dye solution and in the laser material are equal, the two effects balance each other, and no shutter effect occurs. It is also clearly advantageous to use dyes whose lives in the excited state are not too short.

This is also readily understandable if one considers that the radiation intensity required to keep a considerable proportion of the dye molecules in the excited state against the deactivation process is of the order of $h\,\nu_L n_{1/2} = h\,\nu_L/(\sigma\tau)$, and the fraction of the photons in the resonator that are consumed for this purpose is lost from the laser output. This is practically equivalent to saying that the fluorescence quantum yield η of these dyes should not be appreciably smaller than 10^{-3}, since η and the lifetime τ of the molecules in the excited state are related by $\tau = \eta\,\tau_0$; τ_0 is the natural lifetime, which can be found from the absorption spectrum of the dye by means of the relation

$$1/\tau_0 = 2.89 \times 10^{-9} \times n_B^2\,\tilde{\nu}_{max}^2 \int \varepsilon(\tilde{\nu})\,d\tilde{\nu}$$

(integral: longest-wave electronic absorption band)

$\tilde{\nu}_{max}$ is the wavenumber of the maximum of the band, and n_B is the refractive index of the dye solution. For the typical value of $\tau_0 = 5$ ns and a fluorescence quantum yield $\eta = 10^{-3}$, therefore, we obtain the very high value of about 10^9 W/cm^2 for the irradiation intensity required to bring half of the molecules into the excited state according to eq. (2a) (at the wavelength of the ruby laser, a photon flux 3.48×10^{18} photon/s corresponds to a power of 1 W). However, all solid laser materials are destroyed at these irradiation intensities, and new disturbance effects occur, such as the two-quantum absorption discussed later.

The number of suitable dyes is extremely large in the case of the ruby laser. The first dyes to be used as optical shutters were phthalocyanines[8] and cyanines[5–7]. The absorption and fluorescence spectra, together with a simplified term diagram, are given in Figure 4 for a phthalocyanine [dye *(5a)*] and in Figure 5 for a cyanine [dye *(1a)*].

The wavelength of the ruby laser practically coincides with the maximum of the long-wave absorption band of the phthalocyanine. The absorption occurs in this case into higher levels of the first excited singlet state, from which a fast relaxation to the ground level of the state occurs in about 10^{-12} s. Stimulated emission at the wavelength of the ruby laser is not possible from this level; the ground state is instead deactivated either

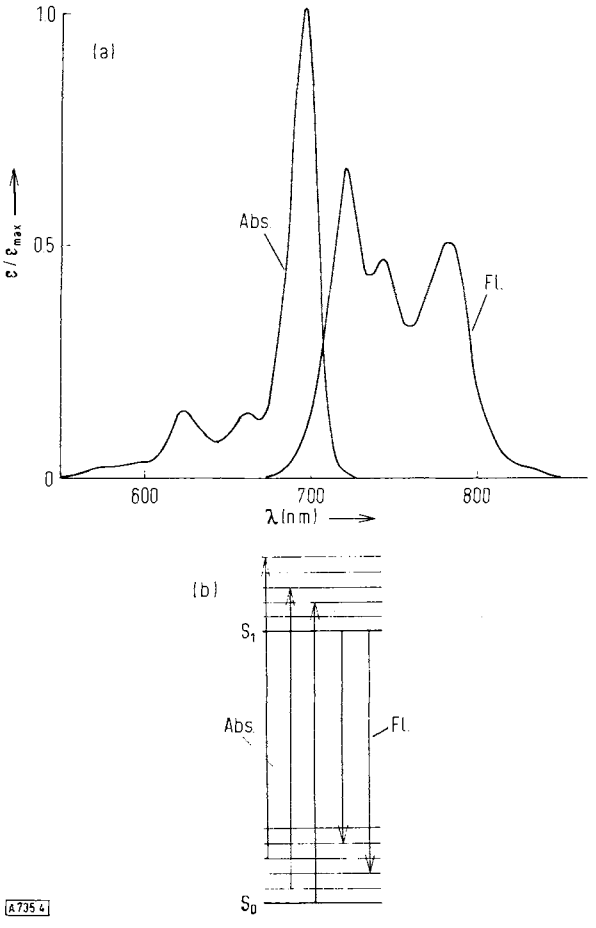

Fig. 4. a) Absorption and fluorescence spectra of the phthalocyanine derivative *(5a)* in α-chloronaphthalene (after [8, 50]).
b) Corresponding term diagram. The length of the absorption arrows corresponds to the energy of a ruby photon.

radiationlessly, by spontaneous emission of fluorescence, or by stimulated emission at a wavelength other than that of the ruby laser. This is therefore a case that fits well into the three-level diagram of Figure 4b.

For the dye *(1a)*, on the other hand, the wavelength of the ruby laser practically coincides with the maximum of the fluorescence band. The absorption takes place in the long-wave tail of the absorption band, mainly from thermally excited levels of the ground state to the ground level of the first excited singlet state, from which the molecule can return to the ground state by stimulated emission at the wavelength of the ruby laser as well as radiationlessly or by spontaneous emission of fluorescence. A suitable model in this case, therefore, is the two-level diagram of Figure 5b.

Under otherwise identical conditions, "two-level dyes" of this type are more effective optical shutters than the "three-level dyes", since a higher radiation intensity is required for the three-level diagram than for the two-level diagram to reduce the absorption to a given value, as can be seen from Figure 5b. The losses in the laser resonator are thus correspondingly reduced; this is particularly important for high-output lasers, in which the radiation intensity is increased to the destruction limit of the ruby crystal to obtain the highest possible outputs.

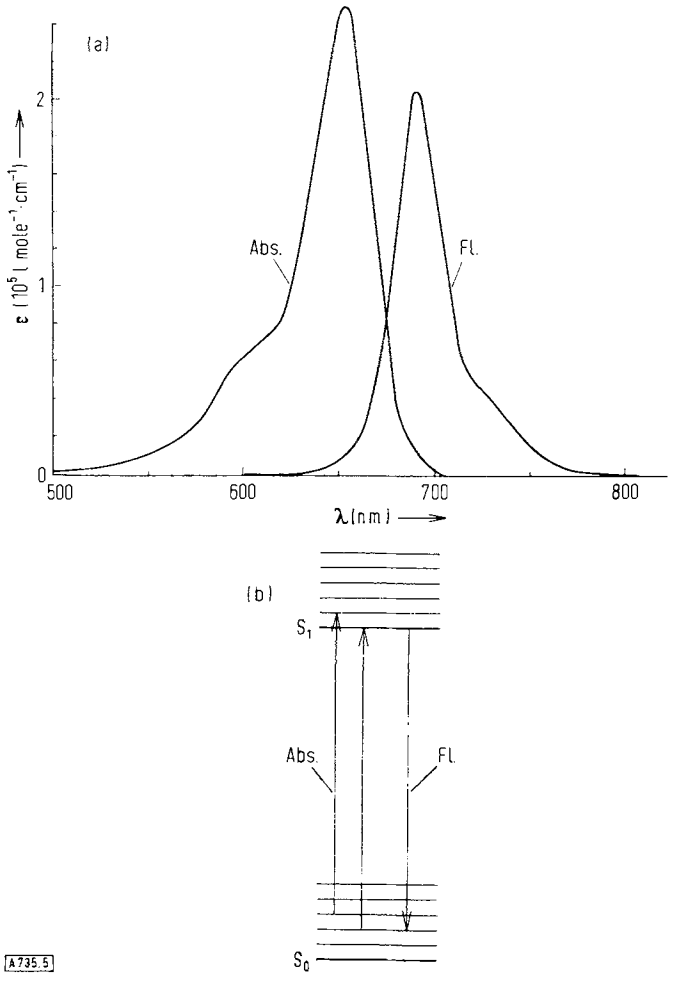

Fig. 5. a) Absorption and fluorescence spectra of cyanine dye *(1a)* in methanol.
b) Corresponding term diagram. The length of the absorption arrows corresponds to the energy of a ruby photon.

Pronounced deviations from the behavior expected on the basis of these models are found with some dyes, in which the absorption decreases only slightly, if at all, at high radiation intensities [9], or in some cases even increases [14], though a shutter effect is to be expected from their absorption spectra and lives. To explain these deviations, it must be remembered that absorption of light quanta at the laser wavelength is possible by transition from the first excited singlet state to higher singlet states, and that for many molecules, particularly with halogen substituents, the radiationless transition from the first excited singlet state to the lowest triplet state (intersystem crossing) is sufficiently fast to bring a considerable fraction of the dye molecules into the triplet state within a few nanoseconds. Additional absorption can also occur in this case by transitions to higher triplet levels.

The transitions from the first to the second excited singlet state that were deduced earlier from deviations of the shutter dyes from the theoretically expected behavior have now been detected directly. An anomalous fluorescence emission from the second excited singlet state to the ground state, such as had previously been found only for azulene, was observed [15]. Moreover, the absorption spectra of the first excited singlet states have recently been measured directly for several dyes [16, 17].

Some shutter dyes are listed in Table 1. As an indication of the effectiveness of the dye, the table contains the ratio (where known) of the intensity (S_R) of the giant pulse produced with this dye to the intensity (S_N) of the normal pulse produced under otherwise identical conditions. No investigations have been carried out as yet to determine which of the above factors is responsible for the difference in the individual activities as shutter dyes.

The effectiveness of the shutter dye is influenced by the solvent as a result of solvatochromism effects, this influence being strong *e.g.* for the dye *(3b)*, as well as by differences in the life of the excited state. The solvent also has a strong influence on the photochemical stability. Thus a 10^{-4} M solution of the dye *(1a)* in methanol can generally be used only for a few days if reproducible giant pulses are to be produced. A similar solution in dimethyl sulfoxide, on the other hand, can be kept for several weeks, provided that the cell containing the dye solution is protected from the UV light of the pumping flash lamp, so that only the laser radiation passes through it.

Figure 6 shows the results of transmission measurements on a cell containing dye solutions as a function of the irradiation intensity. The dyes *(6)* and *(7)* are

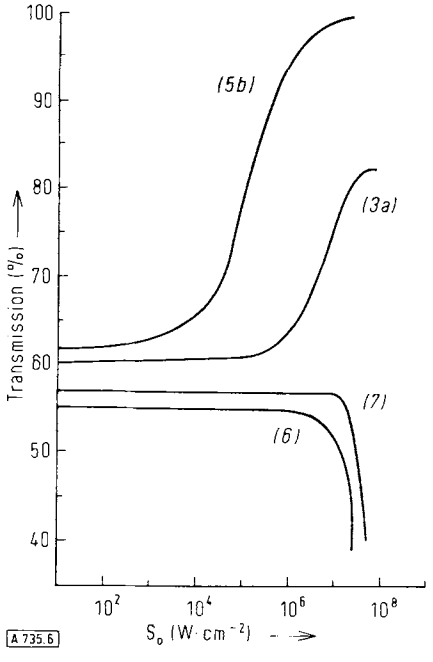

Fig. 6. Transmission of a cell containing dye as a function of the irradiation intensity. The figures by the curves are the numbers of the dyes in Table 1 (after [14]).

examples of dyes whose absorptions are greater in the excited state than in the ground state. These dyes are naturally unsuitable for use as shutter dyes.

for the wavelength of the ruby laser (694 nm), only a few suitable dyes are known for the wavelength of the neodymium glass laser (1064 nm), since only a few substances have electronic bands in this wavelength range. The dyes that do satisfy the requirements are again mainly cyanine dyes [9, 19, 20], as well as pyrylium salts [21].

The structure of the dye in the most widely used commercial shutter solutions (Kodak No. 9860 and Kodak No. 9740) is not revealed by the manufacturers. All these substances have a short storage life even in the dark, and are photochemically

very unstable. They give reproducible results for a few days only in cells made of red filter glass.

As a possible solution to the problem, it has been suggested that the triplet-triplet absorption of suitable dye solutions be used to produce the shutter effect by subjecting the dye solution to flash irradiation together with the neodymium glass rod in order to bring a large fraction of the molecules into the triplet state [22,23]. Apart from the technical difficulties, this method is not very effective because of the short lives of the higher triplet states and the low steady-state occupancy of the lowest triplet level in liquid solutions (due to the relatively short relaxation time of the lowest triplet level to the ground state). This is confirmed by the existing experimental results [22,23].

A certain improvement could possibly be obtained by the use of solid solutions, *e.g.* dyes polymerized into polymethyl methacrylate. A better solution, in principle, should be the use of stable radical-ions that exist in equilibrium with the oxidized and reduced forms [24,25]. If some of the radicals are destroyed photochemically, they are replaced, provided that sufficient of the reduced and oxidized forms is still available. If the radical-ion content of the solution is relatively low, the absorption can be kept practically constant for long periods in this way. This is illustrated by the case of the radical-ion of thianthrene [dye *(9)*], which is a good shutter for neodymium glasses as a solution in trifluoroacetic acid, and which remains practically unchanged over a period of several weeks [32]. Another well-established method of obtaining reproducible results is the use of a circulating system with a continuous flow cell, a pump, and a large reservoir containing dye solution; the cell may be thermostated to avoid schlieren.

2. Production of Ultrashort Laser Pulses

A particularly interesting development of the method described above leads to a method of producing ultrashort pulses, *i.e.* pulses with half-widths of the order of a few picoseconds, the peak powers of which may be several gigawatts. This method can be readily explained with the aid of an electric analog (Fig. 7) [26].

The signal at the input of a wide-band amplifier is amplified and passed through a delay line with a transit time T_L, through a nonlinear attenuator and a spectral filter, and back to the input of the wide-band amplifier. The spectral filter has a band-pass width of $\Delta\nu$, and the nonlinear attenuator attenuates strong signals to a smaller extent than weak signals.

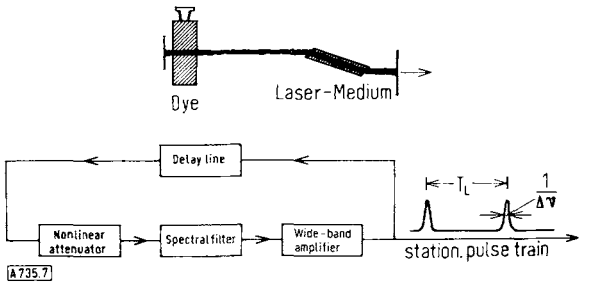

Fig. 7. Construction of a laser for the production of ultrashort pulses and block circuit diagram of an electrical analog. T_L is the transit time of the pulse, and $\Delta\nu$ is the spectral half-width of the spectral filter.

It is clear that this arrangement is a pulse generator, if one considers that even when no external signal is applied to the input of the wide-band amplifier, there is always noise present, and a randomly occurring high noise peak is more strongly amplified than a low noise peak. If the effective amplification of this high noise peak is greater than 1, it undergoes continuous further amplification. Pulses having a half-width $1/\Delta\nu$ in the steady state that depends on the half-width of the spectral filter appear at the output of the wide-band amplifier with a period equal to the transit time T_L.

All these elements can in effect be found in a giant-pulse laser. A dye solution acts as the nonlinear attenuator, the active laser material as the amplifier, the laser material also as the spectral filter (since it amplifies only in the region of its fluorescence band, with consequent restriction of the band width of the laser light), and the time taken by the light to make one round trip in the laser resonator as the delay line. To obtain a uniform train of pulses, the transit time must be uniform, *i.e.* apart from the laser resonator mirrors, there must be no other reflecting surfaces, such as glass-air interfaces of the cell wall. The laser material and the dye cell are therefore either arranged at the Brewster angle or provided with an antireflection coating. The cell containing the dye solution must also be placed as near as possible to one of the mirrors since several concurrent trains of pulses will otherwise be produced.

Pulses having a minimum half-width of 2 to 4 ps and a peak output of 5 GW have been produced in an arrangement of this type with the dye *(2e)* in ruby lasers [27]. To give some idea of what these quantities mean, let us recall that light travels a distance of only 0.3 mm in a picosecond, and that the world electricity production is about 700 GW. Somewhat lower outputs were obtained with dyes *(3a)* [27,28] and *(1a)* [29]. Pulses with half-widths of down to 0.4 ps [30] and outputs of several hundred MW [31] have been produced with the commercial shutter dye solutions Kodak 9740 and 9860 in neodymium glass lasers.

These low half-widths cannot be measured even with the fastest photoelectric cells and oscillographs available at present. Methods based on the use of nonlinear optical effects in certain crystals have therefore been suggested, and in some cases successfully tried out [33–36]. All these methods demand an advanced experimental technique. It was therefore an important step forward when it was found possible to convert the time information very easily into space information by means of the two-quantum absorption in organic dyes and so to make the time half-width of the pulses directly measurable as a space half-width [37]. A model will now be presented for the two-quantum absorption in organic dyes.

3. Two-Quantum Absorption in Organic Dyes

A general quantum-mechanical theory of multiquantum processes has existed since 1931 [38]. There seems however to be little prospect of applying this theory to organic dyes in the light of the present stage of development of quantum chemistry; at best, the order of magnitude of the absorption can be found by a rough estimation [39]. The absorption can however be calculated [40] with results that agree well with those obtained by experiment, if one starts with the postulate that two photons of wavelength λ_0 striking the molecule simultaneously are absorbed by it, as well as one photon of wavelength $\lambda_0/2$. It must be specified what is meant here by "simultaneously". The transit time of the photons (which are regarded as corpuscular) when they travel with the velocity of light c through the π-electron cloud of the molecule with thickness w and maximum cross section σ_{max} is $T = w/c$. If two photons fall within this time on the area covered by the π-electron cloud of the molecule, this may be described as simultaneous incidence. If n photons/cm^2 s (wavelength λ_0) fall on a thin layer of dye solution having thickness dl, the steady number of molecules m^* through whose π-electron clouds a photon is just passing is given by

$$m^* = (m/3)\,\sigma_{max}\,n\,w\,/\,c \qquad (5)$$

where the factor 1/3 arises from the averaging of the random orientation of the molecules. As was mentioned earlier, σ_{max} can be found from the absorption spectrum of the dye: $\sigma_{max} = 3\sigma$.

According to the postulate mentioned above, the effective cross section σ_1 of any one of these m^* molecules for a second photon of wavelength λ_0 is the same as the effective cross section of the molecule for the absorption of a single photon of wavelength $\lambda_0/2$. The attenuation of the laser light in this layer is therefore

$$-\mathrm{d}n = 2\,\sigma_1\,m^*\,n\,\mathrm{d}l$$

The factor of 2 takes into account the fact that two photons disappear in each act of absorption. Integration over the length L of the cell gives the absorption law for the two-quantum absorption:

$$\frac{1}{n_1} - \frac{1}{n} = \frac{2}{3}\,m\,\frac{w}{c}\,\sigma_{max}\,\sigma_1\,L$$

where n_1 is the photon flux at the rear end of the cell. Even at very high irradiation intensities, the absorption is so weak that we can write $nn_1 \approx n^2$. Introduction of the cross section F of the beam gives, to a good approximation, the number m_{abs} of molecules excited per unit time, and multiplication of m_{abs} by the fluorescence quantum yield η gives the number n_{fl} of fluorescence photons emitted per unit time:

$$n_{fl} = \eta\,m_{abs} = (2/3)\,\eta\,m\,(w/c)\,\sigma_{max}\,\sigma_1 FLn^2 \qquad (6)$$

As can be seen from eq. (6), n_{fl} is proportional to the square of the photon flux n. It should also be proportional to the product of the maximum absorption cross section σ_{max} and the cross section σ_1 at wavelength λ_0. This relation has been checked with the apparatus shown in Figure 8.

The giant pulses emerging from the rotating-prism neodymium glass laser were passed through a reversed Galilean telescope to reduce the cross section of the beam and so increase the intensity; the giant pulses then passed through a frequency doubler crystal, in which part of the neodymium laser light was converted into light of half the original wavelength (532 nm). Either the neodymium laser light or the light of half the original wavelength could be filtered out, as desired, in the succeeding filters. Part of the remaining light was reflected by a glass plate and directed to the monitor photoelectric cell, which recorded the pulse behavior of the light. The major part of the light was then focused by a lens on a cell containing a dye solution that absorbed at half the original wavelength. A photomultiplier recorded the emerging fluorescence light, which was excited either by the neodymium laser light at 1064 by two-quantum absorption or by normal absorption in excitation by light of wavelength 532 nm. This excitation with light of half the original wavelength can be accurately calculated from the intensity measured by the monitor photoelectric cell and the known absorption spectrum of the dye, and can thus be used for the calibration of the fluorescence excited by two-quantum absorption. Owing to the high excitation intensity and the low fluorescence intensity, care was necessary to avoid scattered light and dust.

The relation found between the fluorescence output n_{fl} and the excitation power n for an aqueous solution of Rhodamine B [dye *(10b)*] is shown in Figure 9. The slope of the straight line for two-quantum excitation is 2.05 ± 0.1, while that for one-quantum absorption is 0.98 ± 0.03 (double-logarithmic plot).

A check on the dependence of n_{fl} on $\sigma_{max}\sigma_1$ gives agreement in the order of magnitude, with a relatively

large scatter. Examination of these values suggested that fw/c should be used for the transit time instead of w/c, where f is the oscillator strength of the absorption band in question for one-quantum absorption. The oscillator strength of a band is generally a measure of the resonance of the electrons in the field of the stimulating light wave. Improvement of eq. (6) to eq. (6a)

$$n_{fl} = (2/3)\,\eta\, m f (w/c)\, \sigma_{max}\, \sigma_1\, FLn^2 \qquad (6a)$$

and comparison of the experimental results with those given by eq. (6a) shows not only the required linear dependence of fluorescence intensity n_{fl} on $f\sigma_{max}\sigma_1$ (Fig. 10), but also an excellent agreement with the absolute calculated values if the only remaining free

(21)

parameter w is taken to have a value of 1.5 Å. This value approximately corresponds to the thickness of the π-electron cloud normal to the molecular plane.

To use the fluorescence stimulated by two-quantum absorption for the measurement of the half-width of ultrashort pulses, the train of pulses is passed through a cell C, the far end of which is silvered (Sp), so that the beam is turned back on itself (Fig. 11). The fluorescence produced by each incoming pulse having a peak

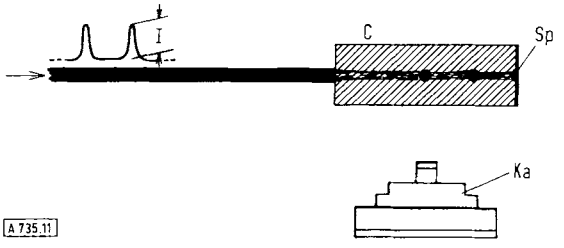

Fig. 11. Arrangement for the measurement of the time half-width of ultrashort pulses with the aid of the two-quantum absorption. Explanation in text.

intensity I (which is proportional to the photon flux n) is $F_{\rightarrow} = \text{const.}\ I^2$, and that of each returning pulse is $F_{\leftarrow} = \text{const.}\ I^2$, *i.e.* the total fluorescence recorded by the camera Ka is

$$F_{\rightarrow} + F_{\leftarrow} = 2 \times \text{const.}\ I^2$$

Only at the points where an incoming and returning pulse meet is the fluorescence intensity $F = \text{const.}\ (2I)^2$, *i.e.* it is twice as high here as at neighboring points. The width of these bright areas divided by the velocity of light then gives the time half-width of the pulses.

In the selection of the dye, it need only be remembered that it should, as far as possible, be free from absorption at the laser wavelength, have a strong absorption band at half the wavelength, and have the highest possible fluorescence quantum yield η. Thus a solution of Rhodamine 6G [dye (10c)] is generally used for neodymium glass laser pulses[41] and *e.g.* 9,10-diphenylanthracene in benzene[42] or 6-acetylaminopyrene-1,3,8-trisulfonic acid in water[29] for ruby lasers (for more detailed discussion, see[43]).

4. Dye Lasers

As was explained in Section 1, a considerable proportion of the molecules of a dye can be raised to the first excited singlet state by irradiation with a giant-pulse ruby laser. Spontaneous fluorescence occurs first from the vibrationless level of the first excited singlet state into higher levels of the electronic ground state, corresponding to a wavelength greater than that of the stimulating laser (cf. Fig. 4b). If one of these fluorescence photons strikes excited molecules on its way out of the cell, it will induce the emission of further fluorescence quanta from these molecules, and is correspondingly amplified when it leaves the cell. If the cell is placed in a laser resonator whose mirrors always reflect part of the light emerging from the cell back into the cell, where it is further amplified, this process can build up into laser emission provided that the effective amplification is greater than 1.

The "threshold condition" for this is found directly if one considers that the substantial attenuation due to incomplete reflection by the mirrors of the resonator (reflection coefficients R) and due to reabsorption of the fluorescence light of wavelength λ in the long-wave tail of the absorption band of the dye takes place by a factor $e^{-\sigma_{abs}(\lambda)m_0L}$, while the amplification factor is $e^{+\sigma_{fl}(\lambda)m_1L}$.

In these expressions L is the length of the cell and σ_{abs} is the effective cross section, which is obtained (see above) from the absorption spectrum at wavelength λ, while the effective cross section σ_{fl} of the stimulated fluorescence emission is obtained from the intensity of the spontaneous fluorescence by means of the relation

$$\sigma_{fl} = \text{const.}\ \lambda^5 \times dI_{fl}/d\lambda$$

with the subsidiary condition $\sigma_{fl,max} = \sigma_{abs,max}$. $dI_{fl}/d\lambda$ is the spectral intensity distribution of the spontaneous fluorescence, such as is usually recorded in fluorescence spectrophotometers. The threshold condition is thus

$$e^{-\sigma_{abs}m_0L}\ R\ e^{+\sigma_{fl}m_1L} \geqslant 1 \qquad (7)$$

Taking logarithms, rearranging, and inserting $m = m_0 + m_1$, we obtain the simpler expression[44]

$$(\sigma_{fl} + \sigma_{abs})\ (m_1/m) - \sigma_{abs} = S_L/m \qquad (8)$$

where

$$S_L = \frac{1}{L} \ln \frac{1}{R}$$

In this form, the left-hand side of the threshold condition contains only spectroscopic data for the dye, with the fraction m_1/m of excited molecules as a parameter, while the right-hand side contains the data for the laser resonator and the concentration of the dye solution. By insertion of the dye and resonator data for a particular case it is possible to calculate the fraction m_1/m of molecules that must be excited (and hence the pump power required) for each wavelength so that the laser emission can begin. The emission will then start first at the wavelength that requires the lowest value of m_1/m, and hence the lowest pumping power. This wavelength also depends on the concentration. Eq. (8) shows that an increase in the concentration has exactly the same effect as *e.g.* an increase in the length of the cell.

[44] *F. P. Schäfer,* invited paper International Quantum Electronics Conference, Miami 1968.

The concentration dependence of the emission wavelength has been calculated for the cyanine dye *(1d)* from its spectroscopic data and plotted in Figure 12

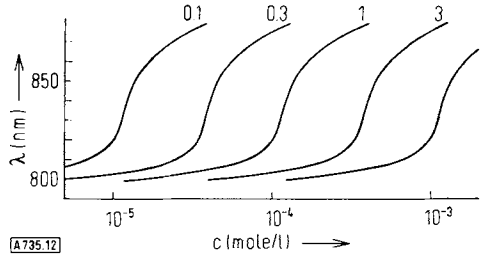

Fig. 12. Concentration dependence of the laser wavelength for *(1d)* according to eq. (8), calculated from the absorption and fluorescence spectra. The figures by the curves show the value of $S_L = \frac{1}{L} \ln \frac{1}{R}$.

with the parameter S_L (see above). It can be seen that *e.g.* 10^{-4} M solutions of this dye in a cell having length $L = 1$ cm and silvered by vapor deposition of silver (one of the deposits being so thin that a transmission of a few percent allows the output of the emission from the laser resonator) corresponding to a value of $S_L \approx 0.3$ cm^{-1} should emit at $\lambda = 875$ nm, whereas in an unsilvered cell corresponding to $S_L \approx 3$ cm^{-1} they should emit at $\lambda = 820$ nm.

The apparatus shown in Figure 13 was used to check this [45]. The solution in the cell is stimulated by the ruby laser. The excitation intensity can be reduced by a fixed factor by means of neutral density filters. Part of the stimulating ruby laser

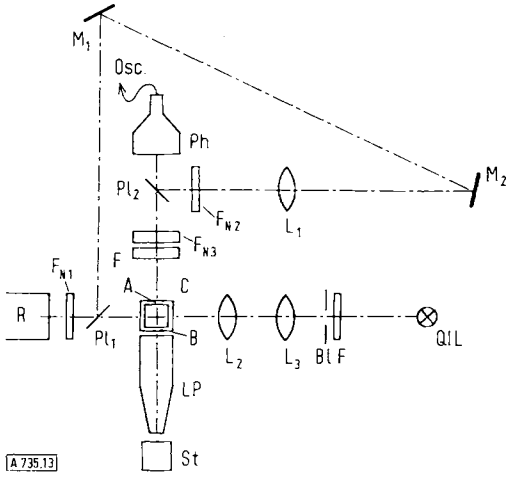

Fig. 13. Arrangement for the investigation of the stimulated fluorescence emission from dye solutions. R: ruby laser, C: cell containg dye solution, A,B: cell windows through which the stimulated fluorescence emerges, St: spectrograph, LP: light guide, Ph: photoelectric cell, $Pl_{1,2}$: glass plates, $M_{1,2}$:deflecting mirrors, F: spectral filter, $FN_{1,2,3}$: neutral density filters, $L_{1,2,3}$: lenses, Bl: aperture diaphragm, QIL: quartz-iodine lamp, Osc. = oscilloscope (after [45]).

light is split out as a reference signal and led by a separate path to the photoelectric cell. The spontaneously emitted or stimulated fluorescence light emerging from the cell, on the other hand, passes directly through a colored glass filter, which cuts out scattered light, and a neutral density filter (for specified intensity reduction) to the photoelectric cell. Part of the fluorescence light is introduced into the spectrograph through a light guide. Using the calibrated tungsten-iodine lamp and a system of lenses, apertures, and interference filters, the fluorescence of the cell can be excited continuously with the same geometry and spectral distribution as when pulse-stimulated by the ruby laser. In this case the cell C forms a resonator in which the plane-parallel windows A and B act as resonator mirrors, which reflect part of the emission back into the cell. The R value for the unsilvered cell due to reflection at the glass-air interface is 0.04, while the reflection for silvered cells can be varied over a wide range (maximum about $R = 0.95$) by varying the thickness of the vapor-deposited coating.

The dye emission output is found as a function of the excitation output by evaluation of the oscillogram; the results for the dye *(1d)* in 10^{-3} M methanol solution in an unsilvered cell are shown in Figure 14 [46]. It can be seen that the dye emission power suddenly increases by several powers of ten at an excitation power of about

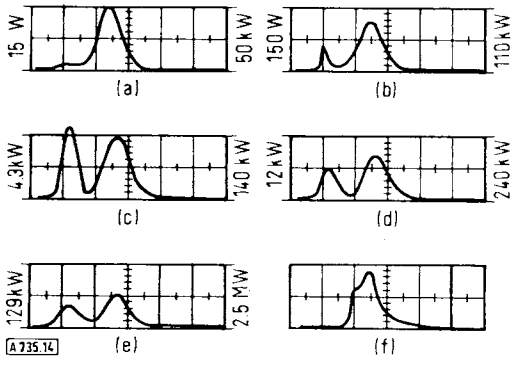

Fig. 14. Oscillograms (traced) recorded with the arrangement of Fig. 13. Deflection speed: a) to e): 10 ns/cm. b) to e): first pulse fluorescence, peak output indicated at left; second pulse pumping ruby laser; peak output at right; 10^{-3} M solution of *(1d)* in methanol; f: fluorescence pulse just above the laser threshold, as in b), but with a deflection speed of 2 ns/cm (after [46]).

100 kW, when the laser threshold is reached. The transition from spontaneous to stimulated emission can also be seen in the spectrum, as illustrated in Figure 15, which shows the absorption spectrum of the

Repetition of these experiments with solutions of different concentrations gives the concentration dependence shown in Figure 16, which agrees very well with the expected behavior.

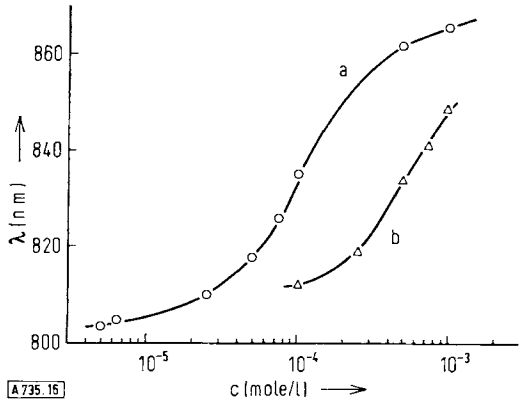

Fig. 16. Concentration dependence of the laser wavelength of *(1d)* in methanol solution. Measured wavelength of the emission maximum a) for a silvered and b) for an unsilvered cell (after [46]).

The diagram of Figure 12 can also be used to find the dependence of the laser wavelength on the length of the cell with the concentration as the parameter and with a reflection coefficient $R = 0.98$, which is readily obtainable by dielectric multilayer coating. It can be seen from Figure 17 that laser emission should be obtained even with layer thicknesses of only a few wavelengths.

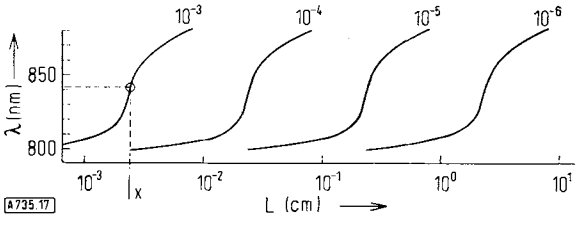

Fig. 17. Dependence of the laser wavelength λ on the layer thickness L for *(1d)* in methanol with laser mirrors having a reflection factor $R = 0.98$. The figures by the curves show the concentration (mole/l) of *(1d)*. X = 25 μm cell.

This has been confirmed (Fig. 18) experimentally by holding the dye solution between two reflecting plates separated by pieces of film.

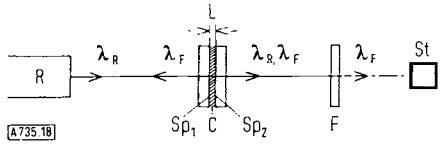

Fig. 18. Thin layer laser arrangement. $Sp_{1,2}$: reflective coatings, C: cell containing dye solution, F: colored filter (to absorb ruby laser light), St: spectrograph, R: ruby laser, λ_R, λ_F: wavelengths of ruby laser and dye laser emissions (after [45]).

The reflecting plates were coated with dielectric multilayers, which gave only a few percent reflection at the ruby wavelength but a reflection of more than 98% at wavelengths above 750 nm. The excitation with ruby laser pulses could thus be carried out through a reflective coating. The emission was recorded with a photoelectric cell and a spectrograph.

Densitometer curves for a number of layer thicknesses are shown in Figure 19. The curves show sharp equidistant maxima.

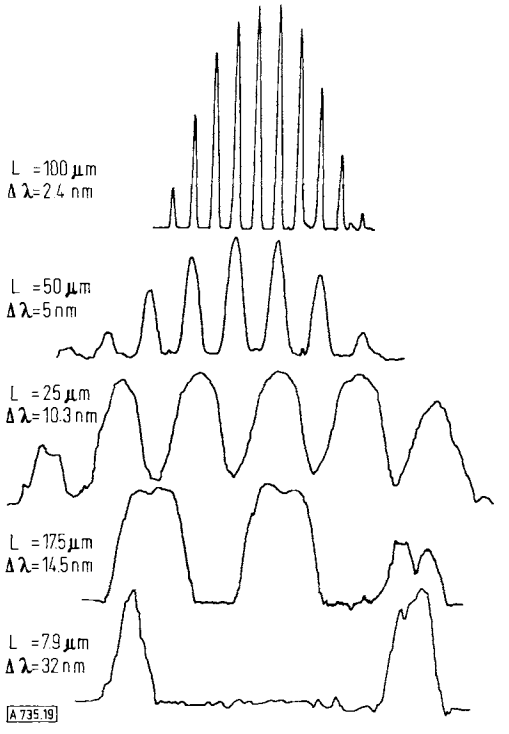

Fig. 19. Densitometer curves for the emission from the thin layer laser of Fig. 18 with the dye *(1d)*. L is the thickness of the layer of dye solution and Δλ is the distance between two adjacent maxima in the spectrum (after [45]).

The distance between the maxima can be easily calculated from the thickness of the pieces of film and the refractive index, bearing in mind that the forward and return light waves in the resonator can be superimposed to give stationary waves only if the length of the resonator is an integral multiple of half the wavelength. Thus $p\,\lambda/2 = n_B L$ where $p = 1,2,3,\ldots$, λ is the wavelength of the laser emission in air, and n_B is the refractive index of the solution at this wavelength. The distance Δλ between the maxima in the spectrum is then $\Delta\lambda = \lambda^2/2\,n_B L$.

For thicknesses of a few μm, there are only two maxima inside the fluorescence band width, and for a thickness of about 3 μm (not shown in Fig. 19) there is only one possible emission wavelength, whose position within the fluorescence band of the dye could be altered as desired by variation of the compression of the pieces of film. The above relations are valid for laser emission normal to the reflecting surface. Emission from other directions is discussed in [45].

Very many dyes (mostly cyanines [46,51,52]) can be stimulated with ruby lasers, and give laser emission between about 710 and 1300 nm. Nineteen cyanine dyes have been named with which this wavelength range could be covered without a gap [47]. Neodymium glass lasers can also stimulate laser emission in some cyanine dyes that still absorb sufficiently at 1.06 μm [48,49]. Other dyes that can be stimulated with the

[a] Excitation with a flash lamp.

ruby laser are the phthalocyanines, in which dye laser emission has been observed for the first time[50] and methylene blue (dissolved in sulfuric acid)[53]. The choice is however greatly limited by the fact that the direct stimulation of dyes with ruby lasers occurs only in the longwave red region.

The number of suitable dyes is greatly increased *e.g.* by converting part of the light emitted from ruby or neodymium glass lasers into light of half the original wavelength in an ammonium dihydrogen phosphate crystal and using this light for excitation[54]. This forms the basis of a simple method for the visual observation of laser emission. The pumping light is allowed to enter a partly silvered cell containing dye solution, and the collimated dye laser beam emerging normal to the silvered surfaces is caught on a screen. Part of the frequency doubled neodymium laser light can be converted in another crystal into light of wavelength 266 nm. This wavelength allows a considerable further increase in the number of dyes that can be stimulated to laser emission[55]. In particular, many of the scintillator dyes used in nuclear technology can be stimulated to dye laser emission in this way. This gives laser emission even in the ultraviolet region at wavelengths down to 341 nm (*p*-terphenyl in cyclohexane). A selection is given in Table 2.

It was found that some dyes with fluorescence quantum yields close to 1 do not exhibit dye laser emission even with high excitation outputs. Examples are perylene in benzene or cyclohexane and some cyanines having the general formula *(22)* dissolved in methanol or water[56]. This is understandable if it is assumed that an absorption from the first excited singlet state

into higher singlet states occurs in these dyes at the wavelength at which the laser emission of the dye would otherwise appear. The triplet-triplet absorption probably plays a minor role in these cases, since only

a very small fraction of the excited molecules can pass into the triplet state during the rise time of the stimulating light pulse, which lasts only a few nanoseconds, because of the high quantum yield of the dye.

The influence of the triplet-triplet absorption is very noticeable, on the other hand, when pumping light sources with slow rise-times are used. For example, if a ruby laser with normal-pulse operation (rise time about 150–500 ns) is used instead of a giant-pulse laser (rise time about 8 ns) for the excitation of a dye laser containing dye *(1d)*, no emission is obtained even when the excitation power is 30 times the threshold power found with giant pulses [57].

Since the life of the excited state of this dye is $\tau = 2$ ns [46] and its quantum yield is $\eta = 0.65$ [*], a very considerable fraction of the excited molecules pass into the triplet state during the rise time, which is long in relation to the lifetime, and they can remain in this state in liquid solution for periods of the order of a microsecond. The accompanying depopulation of the ground state and of the excited singlet state is sufficient under certain circumstances to make laser emission impossible because of the lower amplification. The increase in losses due to the triplet-triplet absorption probably has an even stronger effect for very many molecules.

Figure 20 shows the occupancies m_1 as a function of time for various fluorescence quantum yields and rise rates of the pumping pulse for a concentration of 10^{-4}

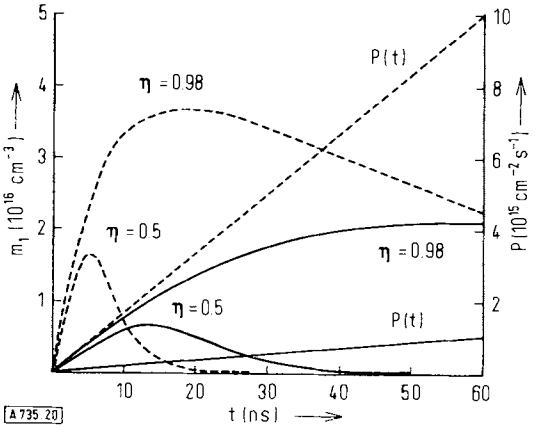

Fig. 20. Time variation of the occupancy of the first excited singlet state $m_1(t)$ (left-hand scale) for various pumping power curves $P(t)$ (right-hand scale) and various quantum yields η.
Broken: rapidly rising pumping power; continuous: slowly rising pumping power (after [57]).

mole/l and a life of 1 ns. It is assumed here for simplicity that the radiationless deactivation occurs exclusively *via* the lowest triplet level and that the life of this state is very long in relation to the life τ of the excited singlet state. It can be seen that the occupancy of the first excited singlet state passes through a maximum, the value of which for a given quantum yield η increases with the rate of rise of the pumping power P. To pump a dye laser with a flash lamp, the pulses of the latter must rise as rapidly as possible, and the fluorescence quantum yield of the dye must be as high as possible and its triplet-triplet absorption as low as possible in the region of the laser wavelength. Many dyes can be stimulated to laser emission with suitable flash lamps (see Table 2) [57–59].

It is to be expected from the calculated fluorescence emission curve in Fig. 20, which is based on simplifying assumptions, that the laser emission from most dyes will stop after only a short time, even if the pumping light output increases further.

Figure 21 shows this type of behavior for trisodium 6-triacetylaminopyrene-1,3,8-trisulfonate *(13a)* in 10^{-3} M aqueous solution [60]. The laser emission lasts only 100 ns, whereas the pumping lamp gives an output above the threshold value for more than 1 μs.

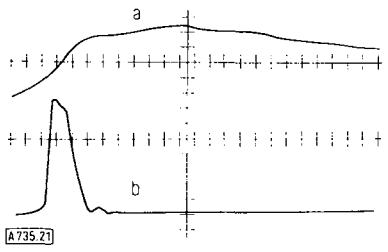

Fig. 21. Oscillogram (traced) of a) pumping light pulse and b) dye laser pulse for a 10^{-3} M aqueous solution of trisodium 6-acetylaminopyrene-1,3,8-trisulfonate *(13a)*. Deflection speed 100 ns/cm (after [60]).

Continuous dye laser emission thus seems impossible from Figure 21. It can however be obtained if the relaxation time of the molecules from the triplet state to the ground state can be reduced to such a degree that the depopulation of the ground state and the increase in the absorption at the laser wavelength due to the triplet-triplet absorption become insignificant. This has been achieved in solutions of Rhodamine 6G *(10c)* in methanol by saturation with atmospheric oxygen [61]. (It is well known that oxygen greatly shortens the life-times of triplet states.)

It has been estimated that the life τ_T of the triplet state of Rhodamine 6G in a solution saturated with oxygen should be at most about 0.2 μs. This gives a lower steady-state concentration of molecules in the triplet state and, as is shown by the oscillogram in Figure 22, makes it possible to obtain laser emission over a time

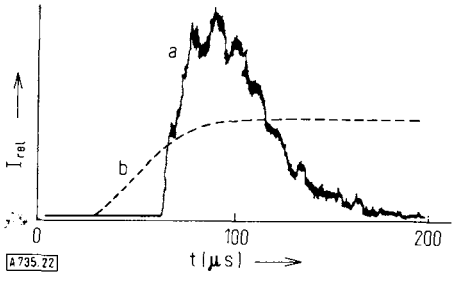

Fig. 22. Oscillogram (traced) a) of the dye laser emission of an air-saturated 5×10^{-5} M solution of Rhodamine 6G *(10c)* in methanol. The time variation b) of the pumping light pulse (recorded with higher sensitivity) is shown for comparison (after [61]).

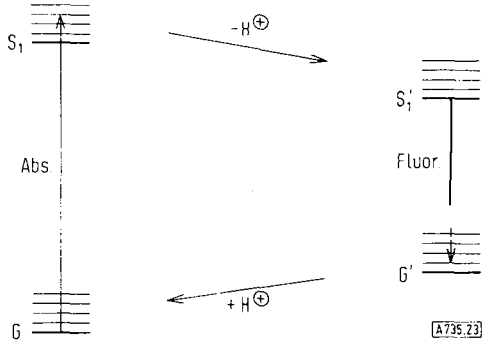
that is long in relation to τ_T in a suitable laser resonator, even with an excitation source having a long rise time.

No laser emission was observed when nitrogen was passed through methanol solution or when 96% ethanol (which dissolves only half as much oxygen as methanol) was used. This shows that, for Rhodamine 6G at least, the accumulation of molecules in the triplet state is not so high that it prevents continuous emission. The cessation of the laser emission in Figure 22 after about 150 μs despite the fact that the excitation output was still constant is probably due to thermal and acoustic disturbance of the laser resonator by the excitation light source; this should not be a fundamental problem, but should be capable of being overcome by improved technical solutions. It is to be hoped that continuous dye laser emission will be obtainable with suitable continuous excitation light sources.

The possibilities of the dye laser are considerably extended by the use of compounds that are formed only in the excited state [41]. Three examples of this are shown in Figure 23–26.



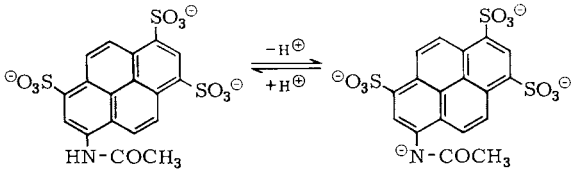


Fig. 23. Term diagram for absorption and fluorescence of 6-acetylaminopyrene-1,3,8-trisulfonate in alkaline solution.

It is well known that 6-acetylaminopyrene-1,3,8-trisulfonate is a much stronger acid in the excited than in the ground state [62]. In alkaline solution the trianion dissociates after transition to the excited state, and the fluorescence of the

tetra-anion predominates. A dye laser emission of longer wavelength is accordingly obtained, and the threshold output is greatly reduced, as can be seen from Figure 24, which was recorded under the same conditions as Figure 21 but in alkaline solution. The greater difference between the fluorescence and absorption spectra leads to smaller losses; moreover, the lower laser level is continuously being depopulated as a result of the rapid recombination of the anion in the ground state.

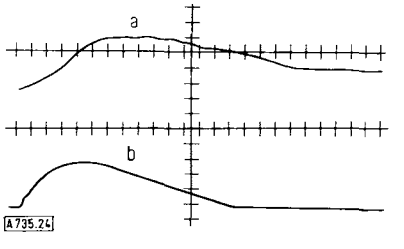

Fig. 24. Oscillogram as in Fig. 21, but in alkaline solution.

A significant lowering of the threshold output and displacement of the laser wavelength by about 10 nm has also been found for the pyrylium salt *(12c)* on addition of a small quantity of dimethylaniline, evidently as a result of the formation of a charge transfer complex in the excited state (Fig. 25), such as is known from other systems [63].

[61] *B. B. Snavely* and *F. P. Schäfer*, Physics Letters *28A*, 728 (1969).

[63] *H. Knibbe*, *D. Rehm*, and *A. Weller*, Ber. Bunsenges. physik. Chem. *72*, 257 (1968).

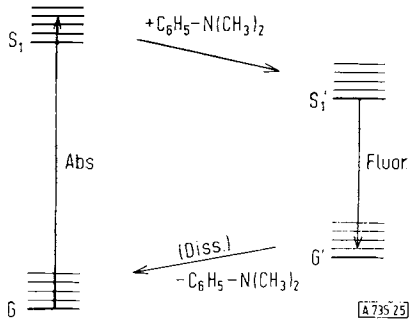

Fig. 25. Term diagram for absorption and fluorescence of a solution of 2,6-bis(*p*-methoxyphenyl)-4-phenylpyrylium tetrafluoroborate *(12c)* in methanol/dimethylaniline.

In the case of *p*-dimethylaminonitrostilbene we find, not a chemical reaction in the excited state, but a change in the solvation state of the molecule, whose dipole moment in the excited state is different from that in the ground state [64]. The threshold output in this case decreases when benzene/cyclohexane is replaced as the solvent by the more strongly polar ethyl acetate (Fig. 26).

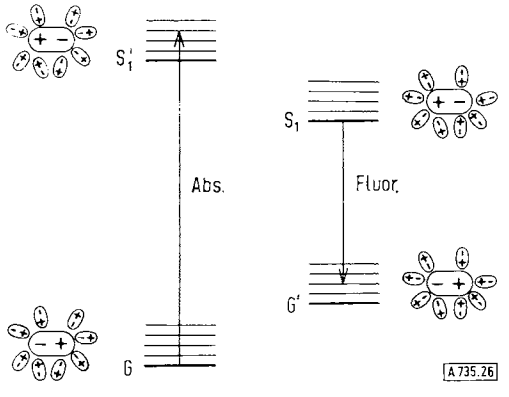

Fig. 26. Term diagram for absorption and fluorescence of *p*-dimethylaminonitrostilbene in a polar solvent.

As was mentioned earlier, the wavelength at which the dye laser emission begins for any dye can be adjusted as desired within the fluorescence band by variation of the concentration and cell length, as well as of reflection and other losses. If the losses change during excitation, as is the case particularly in dye lasers pumped with flash lamps, where *e.g.* the triplet-triplet absorption increases during the excitation, the laser wavelength also changes during the pulse [65–67]. It is essential for many applications that the laser wavelength should have a fixed, constant value, and that the spectral band width of the emission should be as small as possible. Both requirements can be satisfied if dispersing elements are introduced into the laser resonator.

The simplest solution is to replace one of the mirrors of the resonator with a reflection grating [68] (Fig. 27).

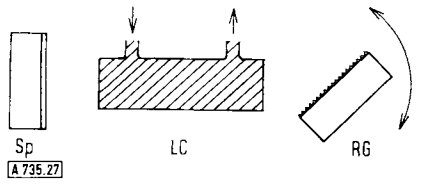

Fig. 27. Construction of a tunable laser. Sp: laser mirror, LC: laser cell, RG: reflection grating. The curved double-headed arrow shows the direction of rotation of the grating for adjustment of the wavelength.

A high reflection for a narrow range of wavelengths can then be obtained by rotating the grating about an axis parallel to the grating lines, and the reflection coefficient for adjacent ranges decreases to such an extent that the laser threshold is not reached.

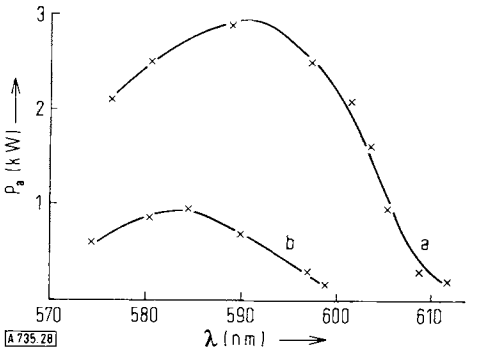

Fig. 28. Output P_a of a tunable laser in accordance with Fig. 27 with 10^{-4} M methanolic solution of Rhodamine 6G *(10c)* and a grating having 610 lines/mm.

a) First order,

b) second order (after [60]).

Figure 28 shows a plot of the laser output against the wavelength, which is adjusted by means of the grating angle for a grating having 610 lines per mm and a laser using Rhodamine 6G *(10c)*; the spectral band width for the first order was about 2 nm, and that for the second order was about 0.4 nm [60]. By insertion of one or more Fabry-Perot filters in the resonator, the width of this wavelength range can be reduced much further, without appreciable reduction of the laser output. The sodium concentration in the ionosphere up to an altitude of about 100 km has recenty been measured with a dye laser having a band width of 1.5 Å [*] and tuned exactly to the sodium resonance line (589.6 nm) [70].

The potochemical stability of dyes in dye lasers pumped with flash lamps has not been extensively studied. Some indication is provided by the fact that a laser of this type has been operated for several hours at a pulse frequency of 30 Hz with a few liters of a Rhodamine

The Coordination Number – an "Inorganic Chameleon"[1]

By R. Hoppe[*]

The purpose of the present article is to describe the changing ambiguous character of the term "coordination number" and its present-day definition in structural chemistry, particularly of typical solids (assemblies of particles with short-range and long-range order). An effort is made at the same time to describe the crystal structure of solids as simply as possible while also taking long-range order into account, i.e. by determining "effective" coordination numbers by the geometrical "polyhedron method" or from MAPLE (Madelung Part of Lattice Energy) values.

1. Introduction

The term "coordination number" comes from classical complex chemistry [2], and denotes the number of *ligands* arranged around a *central particle* "in the first coordination sphere". In this "naive" sense, the coordination number is always a whole number. Examples often given to illustrate a coordination number of 6 are compounds derived from the ions $[Cr(NH_3)_6]^{3+}$ and $[Co(NH_3)_6]^{3+}$, which have an octahedral structure.

Classical complex chemistry is essentially a chemistry of solutions, usually aqueous. It is now known that difficulties can be encountered in specifying "naive" coordination numbers even in the simple case of aquo complexes in solution.

Complicated equilibria occur in the fast exchange of the "aquo ligands" with "solution water molecules". One ionic species (*e.g.* $[Zn(OH_2)_6]^{2+}$) often predominates, but others (*e.g.* $[Zn(OH_2)_5]^{2+}$) are also present, though sometimes only in very small quantities. Owing to the rapidity of the exchange and the possibility of an associated change in the coordination number, the coordination number can only be specified as a space-time average, and is then not necessarily integral.

Pfeiffer [3] was probably the first to apply the term "coordination number" to solids, soon after the elucidation of the structure of NaCl [4]. In using this term, he was making reference to the analogy between $[PtCl_6]^{2-}$ in which Pt^{4+} has a coordination number of 6, and the NaCl structure, in which Na^+ is surrounded by six Cl^-.

Since then the coordination number, like the terms ionic or atomic radius and bond angle, have come into use for the description and interpretation of crystal structures. The pioneering work of the 1920's showed even then the limits within which this is possible in principle.

It is admittedly advisable nowadays to place a clear question mark after these classical (and in practice still useful) basic concepts of crystal chemistry when their application is not restricted to pure "molecular lattices".

For example, the "centralistic" concept of coordination number, which relates only to the central ion of a complex (no one has so far raised the question of the coordination number of a ligand), is not strictly applicable in the NaCl structure, since the relation between the Na^+ and the Cl^- ions is reciprocal; in other words, six Na^+ surround one Cl^-, just as one Na^+ is surrounded by six Cl^-. Instead of a coordination, therefore, we have an adjunction. So far, moreover, the role of the "complementing ions" in complexes (*e.g.* Cl^- in $[Co(NH_3)_6]Cl_3$ or K^+ in $K_2[PtCl_6]$) has not received the attention that it merits.

1.1. Subdivision of Chemistry

The following discussions are based not on the usual subdivision of chemistry but on one that distinguishes between molecular chemistry and solid state chemistry [5].

The chemical and physical behavior (even in the solid state) of many compounds, such as HCl, BF_3, CH_4, and C_6H_6 is determined by molecules. IR and Raman spectra provide detailed information about their structure and bond strengths within the discrete structural groups. In chemical reactions, *e.g.* in the oxidation of CH_4 to CO_2 and H_2O the reacting species is the individual molecule.

In the example mentioned, one molecule of CH_4 is the 'first' to be oxidized and another molecule is the 'last'. Some of the CH_4 molecules may even escape oxidation entirely. Thus, though subject to the laws of thermodynamics and of chemical kinetics, and hence to the law of large numbers, the individual particle in the assembly of molecules can, in a sense, have a fate of its own.

An entirely different state of affairs is found in typical solids (NaCl, Al_2O_3, *etc.*). The chemistry of these compounds and their crystal structure are largely determined by the existence of assemblies of particles [1]. The uniform (preferably so in the ideal case) behavior of the equivalent particles of an assembly is due to *long-range* as well as to *short-range* order.

Apart from transitions, reactions in the solid state occur mainly at the surface of the crystallites. Thus a given solid substance in the sense mentioned here can be prepared in forms that differ very markedly in their "reactivity", though their chemical compositions are the same.

It is interesting to observe how often thermodynamically unstable molecules can be reproducibly synthesized under mild conditions, often in high yields, whereas the preparation of definite unstable forms in the case of typical compounds is often problematic in solid state chemistry.

It was formerly difficult to obtain and interpret information from IR and Raman spectra for typical coordination lattices such as NaCl, since the vibrations cover comparatively large regions of the crystal at the same time and can react sensitively to imperfections of all kinds. Recent investigations (*e.g.* on NaCl, Nb_2O_5, *etc.*) have, however, shown that "sharp" spectral lines occur in this situation too.

The differences in these two subdivisions of chemistry are particularly noticeable in structural chemistry.

It is relatively easy to deduce the spatial arrangement of the atoms, often in detail, from the formulas of molecules (*e.g.* $SOCl_2$ or β-$C_{10}H_7SO_3H$) with the aid of certain fundamental concepts of chemical bonding. In the case of typical solids (*e.g.* NaCl or AgF_2), on the other hand, it is, as yet, still principally impossible to predict the arrangement of the particles in the "assembly". Thus no one can say with certainty what structure a still unknown but possibly obtainable modification of NaCl would possess that is thermodynamically unstable under normal conditions. Compounds that are chemically very similar, such as $BaMnF_6$ and $CaMnF_6$ ($=Ca_{0.5}Mn_{0.5}F_3$) can be structurally quite different [6]. For other compounds (*e.g.* $[-CH(CH_3)-CH_2-]_n$), the behavior of the assembly depends not only on the degree of polymerization n but also on the nature and variation of the arrangement (in the example, whether isotactic, syndiotactic, or atactic).

1.2. Preliminary Remarks

The result of conventional crystal structure determinations is a geometrical arrangement, *i.e.* the positions of centers of gravity of particles in space.

The following discussion is concerned not with attempts to interpret such results from the point of view of chemical bonding but only with geometrical arrangements in solids. The conventional discussion of crystal structures takes no account of the difference between the two fields of chemistry defined in Section 1.1:

1. The actual "Gordian knot" of the cluster of structural problems in solid state chemistry is severed by crystallography with one radical cut, separating spacing from symmetry. The unusually rapid progress made in the structural investigation of solids during the last few decades would not otherwise have been possible. Spacing and symmetry can usually be unambiguously described by but few figures (lattice constants, space group symbol, occupied point positions, and corresponding position parameters).

2. The basic information about the crystal structure is given by the unit cell (cf. Fig. 1); this is the "motto" of the ideal structure, which is built up by translation of the unit cell in the three lattice directions.

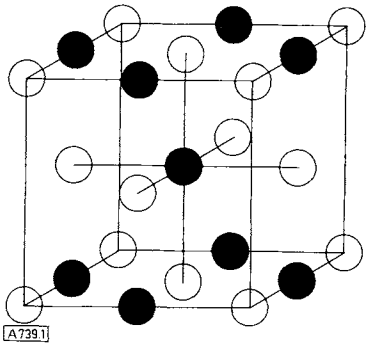

Fig. 1. Unit cell of the NaCl type (schematic).

The conventional description of a structure also includes the coordination numbers (*e.g.* coordination number = 6 for Na^+ with respect to Cl^- in NaCl) of the crystallographically different particles, the corresponding distances (*e.g.* d_{Na-Cl} = 2.81 Å), and possibly the bond angles (NaCl : 90 and 180 °).

3. However, these data characterize only the short-range order of the crystal structure, and are therefore sufficient in the case of solid molecular structures only.

[6] *R. Hoppe* and *K. Blinne*, Z. anorg. allg. Chem. *291*, 269 (1957).

For solid state structures such as the NaCl and CaF_2 types, the unit cell, like an ordinary molecule, is usually small, and this might easily blind one to the fact that the behavior of the solid compound in question is determined by an "assembly" possessing long-range order.

Our considerations, the aim of which is to show the changeable character of the term "coordination number" in the field of solid chemistry, arise from an attempt[5] to find the simplest possible way of describing the crystal structure of solids in such a manner that the long-range order is also accounted for.

2. An Excursion into Classical Complex Chemistry

For our first example we shall consider the hypothetical gaseous complex ions $[SnF_6]^{2-}$ and $[SnF_5I]^{2-}$ (Fig. 2).

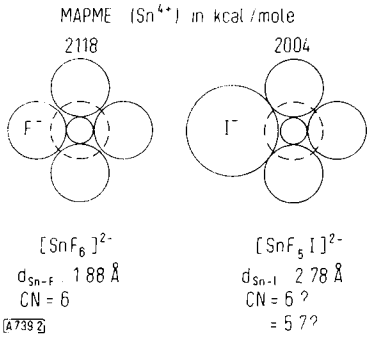

Fig. 2. Structure of "isolated" hexahalogenostannate(IV) ions.

Hexafluorostannates(IV) of the type $M_2SnF_6 \cdot aq$ have been known since *Marignac*[7], and have recently been the subject of numerous studies, particularly on the anhydrous compounds M_2SnF_6[8,9] (M = Li, Na, K, Rb, Cs). On the basis of these and further investigations on SnF_4[10], it may be assumed that the "isolated" complex $[SnF_6]^{2-}$ is octahedral; $d_{Sn-F} = 1.88$ Å.

No compounds containing the complex $[SnF_5I]^{2-}$ are known as yet. We shall assume that the six bond directions in this complex also possess octahedral symmetry, and that the interatomic distances are $d_{Sn-F} = 1.88$ Å and $d_{Sn-I} = 2.78$ Å.

There are then two possible answers to the question of the coordination number of Sn^{4+} in $[SnF_5I]^{2-}_{gas}$:

1. The greater Sn–I distance is merely due to the greater radius of I^-. If the ions are assumed to be spherical, Sn^{4+} and I^- would be in contact with each other as well as Sn^{4+} and F^-. On the basis that "anything in contact is to be taken as a neighbor" (a ligand in this case), the coordination number of Sn^{4+} is thus 6.
2. The Sn–I distance is much greater than the Sn–F distance. If it were very large (about 10 Å), it would be reasonable to ignore this ligand when counting neighbors. Conclusion: the effective coordination number of Sn^{4+} in $[SnF_5I]^{2-}$ is presumably smaller than 6 (about 5.7?).

This answer would also be supported by the fact that the "Madelung part of the molecular energy" (MAPME; see section 8) of $[SnF_5I]^{2-}_{gas}$ is 14 kcal/mole smaller than that of $[SnF_6]^{2-}_{gas}$ (cf. Fig. 2).

3. The *Wigner-Seitz* Polyhedron Method

We adopt the conventional answer[1] to the question of the coordination number of Sn^{4+} in $[SnF_5I]^{2-}$, *i.e.* the definition that anything in contact is a neighbor, and should accordingly be included in the determination of the coordination number.

3.1. The Coordination Number for the NaCl Type

It can be seen from Figure 3 that in KF, each K^+ particle and each F^- particle is in contact with six oppositely charged neighbors, *i.e.* K^+ and F^- both have a coordination number of 6.

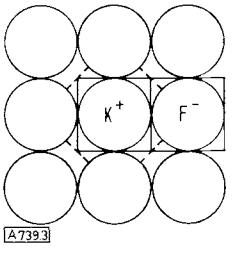

Fig. 3. Neighbors in KF.

In the case of LiI, as shown in Figure 4, application of the "contact definition" shows that Li^+ has the conventional coordination number 6, of the NaCl type, whereas I^- "is in contact" not only with the six Li^+ neighbors but also with twelve I^- neighbors. The coordination number of I^- in LiI is thus surprisingly found to be 18.

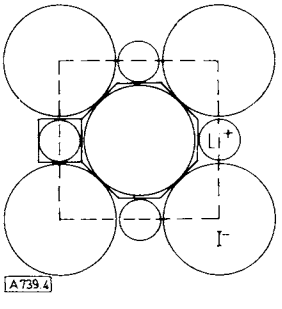

Fig. 4. Neighbors in LiI.

For compounds where there is some doubt as to whether ionic or atomic radii should be used for the construction of the touching "spherical" particles, the coordination number may be uncertain.

Quite apart from this practical difficulty, however, the "effective" coordination number defined by the number of touching neighbors can differ very considerably from the conventional values, and may not even be whole numbers.

[10] *R. Hoppe* and *W. Dähne*, Naturwissenschaften *49*, 254 (1962).

3.2. The Coordination Number for the CsCl Type

The CsCl type (cf. Fig. 5) can occur for AB compounds when the ratio of the atomic (or ionic) radius r_A/r_B is between 0.73 and 1.37. In the special case where $r_A/r_B = 1.0$, the structure corresponds metrically to the body-centered cubic structure found for many metals.

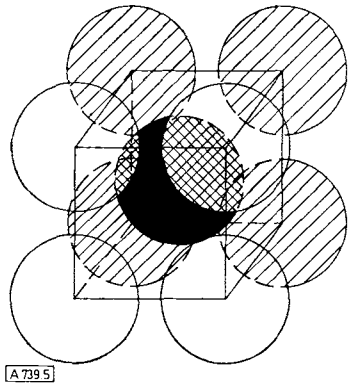

Fig. 5. Unit cell of the body-centered cubic structure. (The "atoms" are shaded differently for clarity.)

Figures 3 and 4 show schematic planes normal to the lines that join touching particles (*e.g.* from I^- to Li^+ and I^-) and that are situated at the point of contact of pairs of particles.

This type of polyhedron construction can be extended. If *e.g.*, in the CsCl type, an arbitrarily chosen ion Cs^+ is connected by straight lines to *all* of the other Cs^+ and Cl^- ions in the crystal and each connecting line divided by a perpendicular plane in the ratio of the ionic radii of the particles joined by the line, there emerges from the infinite number of these planes a "smallest" polyhedron around Cs^+ (cf. Fig. 6). The construction of the polyhedron corresponds to that described by *Wigner-Seitz* for metals.

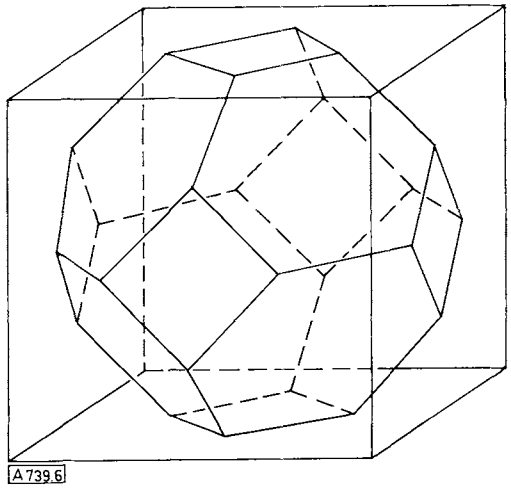

Fig. 6. Coordination polyhedron for CaCl (schematic).

In the case of the CsCl structure, and hence of the body-centered cubic structure, the polyhedron has 8 + 6 faces instead of only six; this polyhedron is a combination of an octahedron and a cube, the cube faces being smaller than the octahedron faces when $r_{A^+} = r_{B^-}$.

This points to an obvious "quantitative" refinement in the counting of "field neighbors"[11]. The areas of the individual faces of the "coordination polyhedron" are calculated and "normalized" to give the largest face a value of 1. The sum of the "normalized" areas of the faces of the polyhedron is then an "effective" coordination number. This gives a value of approximately 10 instead of the conventional 8 for the effective coordination number of a cubic body-centered metal (*e.g.* α-iron).

Table 1. The effective coordination number (ECN) of gallium metal (by the poly hedron method).

"Neighbors" No.	Area (normalized)	ECN
1	1.000	1.00
2	0.597	
3	0.585	
4	0.570	
5	0.517	
6	0.487	3.76
7	0.402	
8	0.255	4.42
9	0.123	
10	0.073	
11	0.073	
12	0.045	
13	0.030	
14	0.023	4.78

Table 1 shows the result of a polyhedron construction for gallium[12]. The effective coordination number is approximately 4.8.

In the very interesting Ga structure, which is difficult to explain theoretically, one neighbor is very close (d = 2.43 Å); others follow with d = 2.71 (2×), 2.74 (2×), 2.80 (2×), 3.72 (2×) Å, *etc.* No conventional coordination number can be given in this case.

The effective coordination number calculated by the polyhedron method fits satisfactorily into the sequence of coordination numbers for the series Cu (coordination number = 12), Zn (effective coordination number = 8–9[13]), Ga (effective coordination number ≈ 5), Ge (coordination number = 4). Table 1 shows that the effective coordination number of gallium is practically determined by the eight nearest of the fourteen neighbors considered here.

3.3. Close Packing of Spheres

Many metals crystallize with "close-packed" structures, of which there are an infinite number of variants. Those found most often in practice are cubic close packing (*every* metal atom occupies a center of symmetry) and hexagonal close packing (*no* metal atom occupies a center of symmetry), and simple (Pr, Nd) or fairly complicated (Sm) alternating structures are occasionally encountered. A 'pure' metal[14] only

[11] Cf. also *K. Schubert*: Kristallstrukturen zweikomponentiger Phasen. Springer, Berlin 1964, p. 18ff.

[12] *R. Hoppe*, unpublished; cf. *R. Hoppe*, 18. IUPAC-Congress, Montreal 1961, Abstr. sci. Papers, p. 73; *G. E. R. Schulze*, Kristall u. Techn. *1*, 375 (1966).

[13] Cf. ECN of Cd (Fig. 8).

[14] For example, hexagonal close packing occurs in Ca metal only when it is stabilized by impurities.

rarely (Co?, Ce) crystallizes in more than one close packing[15]; the reasons for this are unknown.

The coordination polyhedron of cubic close packing, for example, is a dodecahedron, and the effective coordination number is 12.0. The packing factor, *i.e.* in the case of wooden spheres, for example, the proportion of the volume that is occupied by wood, is 74.0% for any close packing of spheres in three-dimensional space. The effective coordination number for primitive cubic packing of spheres (cf. Fig. 7) is 6, and the packing factor is only 52.4% [four examples are known at present: α-Po, SbII (high pressure form: 20 °C, 70 kbar), metastable phases in the systems Ag/Te and Au/Te].

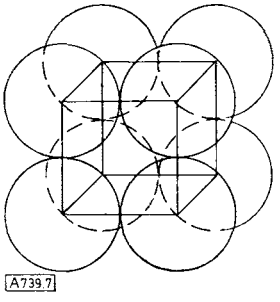

Fig. 7. Primitive cubic close packing (α-Po).

3.4. The Body-Centered Cubic Crystal Structure

There are however metals, such as the elements of the group Vb triad, that crystallize with a body-centered cubic instead of a close packed structure. One of the modifications of polymorphic metals often belongs to this type (Ba, Np, Pu, *etc.*). It is interesting to note that the body-centered cubic form of polymorphic metals is always the highest-temperature form "from which the metal melts"[15]. Even iron, which changes from the body-centered cubic form to the cubic close packing of γ-iron at 910 °C, changes back into the body-centered cubic δ-modification at 1390 °C.

The packing factor of 68.0% for the body-centered cubic structure is higher than one would expect for the conventional coordination number of this type of structure, which is 8. An empirical plot of the coordination number against the packing factor (Fig. 8) indicates that the packing factor for a coordination number of 8 should be only 60%, while a packing factor of 68% corresponds to an "effective coordination number" of 9.6 according to this curve.

This remarkable situation is connected with the fact that the ratio of the distances to nearest and to next-nearest neighbors in cubic close packing, as in primitive cubic packing, is $1 : \sqrt{2}$, whereas the corresponding ratio for the body-centered cubic structure is $1 : 2/\sqrt{3}$. In addition to the eight nearest neighbors, therefore, there are six others for which the distance is increased by a factor of $2/\sqrt{3}$ only (cf. Table 2). It is thus understandable to some extent why many metals change from close packing into this form before melting. Other metals (such as Mn or Pu) that exhibit unexpectedly low packing factors at

[15] *R. Hoppe*, lecture, Tagung der Gesellschaft für Metallkunde, Clausthal-Zellerfeld 1947; *Ch. Zener*, Physic. Rev. *71*, 846 (1947); *L. Kaufman*, Progr. Mater. Sci. *14*, 2 (1969). – With the exception of Co these are usually 4f and 5f elements only.

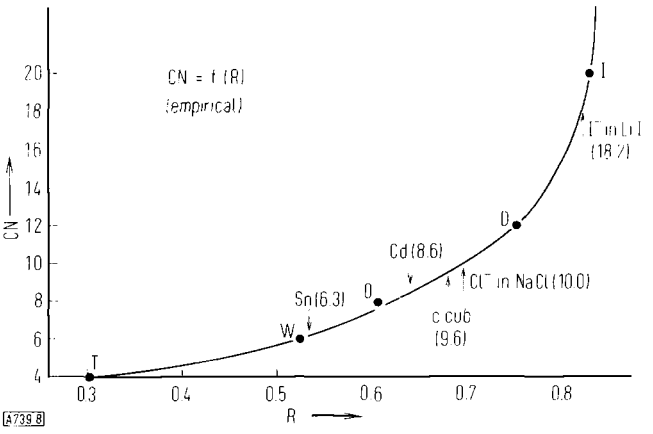

Fig. 8. Empirical relation between coordination number and packing factor. T = tetrahedron, W = cube, O = octahedron, D = dodecahedron I = icosahedron.

low temperatures (γ-Pu: 62.7%), possibly because of directed bonds, also change into the body-centered cubic structure after "breakdown" of the directed bonds when heated.

4. An Excursion into the Fourth Dimension

Let us consider an ionic compound of the type AB, *e.g.* Na^+Cl^-.

In the one-dimensional crystal space there is only one electrostatically favorable crystal structure for such a compound (Fig. 9), and there is again only one electrostatically favorable arrangement of the ions in a two-dimensional crystal (Fig. 10).

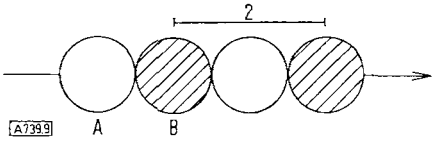

Fig. 9. Electrostatically most favorable structure of a one-dimensional AB ionic crystal.

In both cases we find a similarity to the known NaCl type of the three-dimensional crystal space in the "alternating" principle $Na^+Cl^-Na^+ \ldots$ along lattice lines. However, they both also show a similarity to the CsCl type (cf. Fig. 5) with respect to the "centering" principle, as shown in Figure 10. It is only in the three-

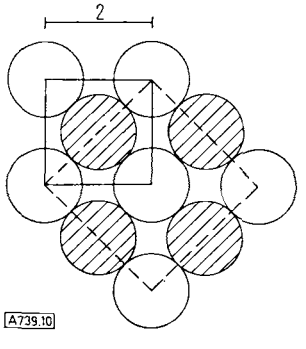

Fig. 10. Electrostatically most favorable structure of a two-dimensional AB ionic crystal.

dimensional crystal space that alternation and centering separate to give the NaCl and CsCl types; however, the two types are still energetically so similar that compounds such as CsCl and RbCl occur in both forms.

It can be seen from Figure 11 that the ratio of the shortest cation-cation/cation-anion distances for the CsCl type decreases rapidly as we pass from one-dimensional to three-dimensional space, and reaches a value of 1 in four-dimensional space. In a four-dimensional space, therefore, this type of structure would scarcely be possible for ionic compounds like Na^+Cl^-, but occur at best in the case of intermetallic compounds similar to NaTl and its structural relatives in three-dimensional space.

In this light the CsCl type is an oddity of structural chemistry in three-dimensional space.

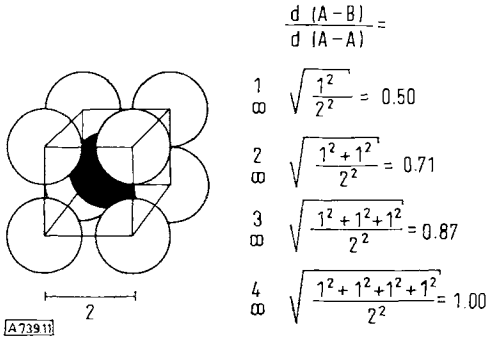

Fig. 11. Ratio of the shortest cation-anion/cation-cation distances for the CsCl type in one- to four-dimensional crystal space.

The same is true of the closely related body-centered cubic structure (cf. Table 2). It can be seen that a four-dimensional body-centered metal has 24 (*i.e.* 16 + 8) "exactly equally" distant neighbors, and the special position of the body-centered cubic structure in three-dimensional space becomes comprehensible.

It is astonishing, that not one of the known crystal structures has, as yet, been investigated and/or discussed with respect to the question of which observed facts are to be considered as "trivial for 3-dimensional space" and which of the known structural peculiarities is a singularity of this common space!

Table 2. Numbers (n_1 and n_2) and distances (d_1 and d_2) of "nearest" and "next-nearest" neighbors for centered packing of spheres in n-dimensional space.

Dimension,	n_1	n_2	d_1	d_2	d_2/d_1	CN
1	2	2	1	2	2.00	2
2	4	4	$\sqrt{2}$	2	1.41	4
3	8	6	$\sqrt{3}$	2	1.15	8 + 6
4	16	8	$\sqrt{4}$	2	1.00	24

5. Packing Factor and the Coordination Polyhedron

Let us now consider the diamond structure, the primitive cubic structure, and cubic close packing from among the crystal structures of elements. Each of these types is associated with a certain coordination number and a certain packing factor; in the order given, these are coordination number = 4 (34.0%) coordination number = 6 (52.4%), and coordination number = 12 (74.0%).

Application of the polyhedron method, on the other hand, shows that each type is associated with a certain coordination polyhedron, *i.e.* tetrahedron (coordination number = 4), cube (coordination number = 6), and dodecahedron (coordination number = 12).

It seems reasonable to extend the considerations to the other regular polyhedra, *i.e.* the octahedron and the icosahedron.

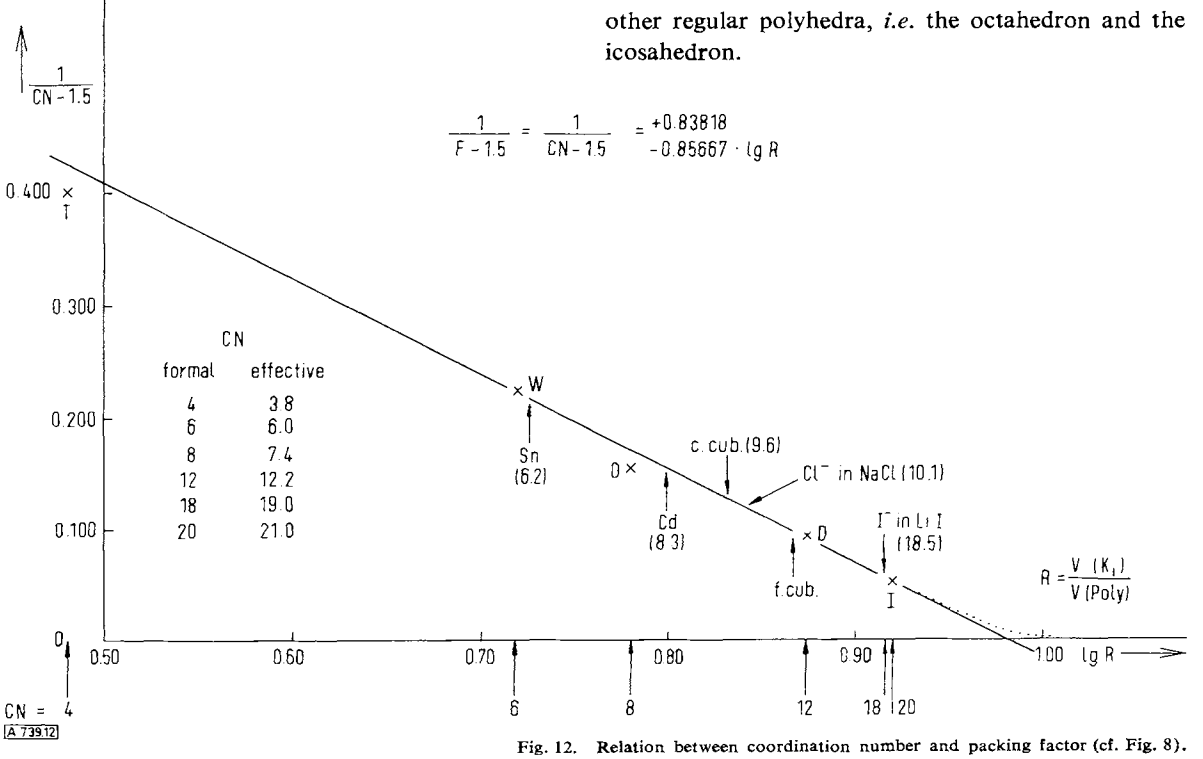

Fig. 12. Relation between coordination number and packing factor (cf. Fig. 8).

The packing fraction in every case is the ratio of the volume of the "inscribed sphere" to the volume of the regular polyhedron (Table 3).

Table 3. Regular polyhedra and the largest "inscribed" spheres.

Polyhedron	$R = \frac{\text{Volume (sphere)}}{\text{Volume (polyhedron)}}$	log R
Tetrahedron	0.3023	0.4804−1
Cube	0.5236	0.7190−1
Octahedron	0.6046	0.7815−1
Dodecahedron	0.7547	0.8778−1
Icosahedron	0.8288	0.9184−1

When the reciprocal of the number of faces of the regular polyhedron minus 1.5 is plotted against the logarithm of the packing factor (cf. Fig. 12), the values for cubes, dodecahedra, and icosahedra lie practically on a straight line. This line therefore gives "reasonable" values of the effective coordination number against the packing factor for the body-centered cubic structure (and *e.g.* also for the ion I^- in LiI, cf. Section 3.1).

The practically linear relation can be used to find the effective coordination number from the packing factor. The (small) deviation of the octahedron and its hemihedral form, the tetrahedron, from this very relation is presumably due to far-reaching geometrical causes.

6. Thermodynamic Cycles

Figure 13 shows the Born-Haber cycle for the formation of KF from the elements. Step I brings the reactants (K metal and F_2 gas) to the "same starting conditions". Step II is characterized by the very simplicity of physically definite processes.

Step III on the other hand, is complicated, and its mathematical treatment is difficult, since it leads to an ordered "solid state" collection of particles. The bonding will in reality rarely be purely ionic. Polarization, repulsion, covalency, *etc.* must be taken into account in order to obtain satisfactory values for the lattice energy in step III. This lattice energy can be expressed as the sum of a series of individual contributions, as follows:

$$E_L = E_M + E_{Pol} + E_{Rep} + E_{Cov} + \text{----------} + E_{Corr}$$

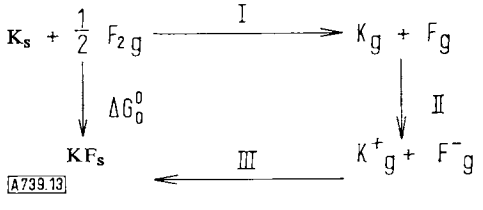

Fig. 13. Born-Haber cycle for KF (schematic).

For compounds consisting of ions, such as KF, the most important term is E_M, the "Madelung part of the lattice energy" (MAPLE). E_{Pol} takes polarization, including ion-dipole and dipole-dipole interactions *etc.*, into account, and can make a decisive contribution. E_{Rep} takes into account the Born repulsion, which is also important, and E_{Cov} allows for the covalent bonding component. The sum of all the terms generally still differs from the "experimental" lattice energy, and this difference can be allowed for by the additional term E_{Corr}.

This cycle, which is important in principle, involves difficulties in practice. This is because it is adapted to the formation of salts from their components, *i.e.* usually from a metal and a non-metal. The calculation of ΔG_0° (*e.g.* for the formation of KF_{solid} from K_{solid} and F_{2gas} at 0 °K) from steps I–III thus necessarily involves substances that represent the three principal limiting cases of chemical bonding, *i.e.* metallic, atomic, and ionic bonding.

Cycles of the type shown in Figure 14 are much simpler. In this case we consider the formation of a ternary fluoride from the binary components. If we assume for simplicity that the ions are "rigid" and take only E_M into account in the calculation of the lattice energies, remarkable differences may be found between this MAPLE value and the "true" lattice energy.

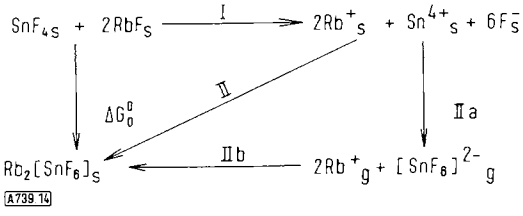

Fig. 14. Born-Haber cycle for $Rb_2[SnF_6]$ (schematic).

On the other hand, the Rb–F bond in RbF is undoubtedly very similar to that in $Rb_2[SnF_6]$, and the same is true of the Rb–F distances. The Sn–F bond in solid SnF_4 (with an octahedral environment according to $^2_\infty[SnF_{4/2+2}]$) will also be very similar to that in $Rb_2[SnF_6]$. Finally, the Sn–F distances in SnF_4 and in $Rb_2[SnF_6]$ are expected to be very similar. The errors resulting from the radical simplification of step I (Fig. 13) are therefore cancelled out by the "analogous" errors with opposite signs in step II. Such calculations on various examples have shown that MAPLE-data often provides a reasonable representation of the lattice energy in such cycles. However, the influence of E_{Pol} in particular must be taken into account in more detailed calculations.

The MAPLE values are still more definite and reliable in cycles of the type shown in Figure 15. Here, we

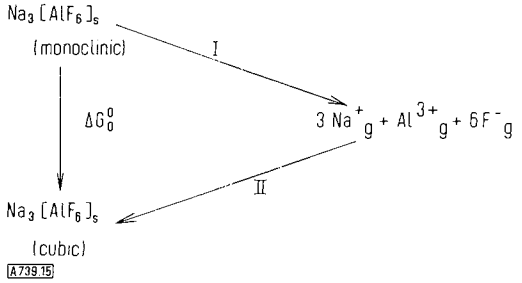

Fig. 15. Born-Haber cycle for $Na_3[AlF_6]$ (schematic).

discuss the transitions of compounds into structurally very similar (observed or hypothetical) modifications [16].

7. Madelung Constants and MAPLE Values [5]

In order to calculate the lattice energy, it is necessary to know the corresponding Madelung constant [17] which is a number characteristic of the structure. The Madelung Constant is the sum of Partial Madelung Constants. For example

$$MC(CaF_2) = PMC(Ca^{2+}) + 2 \cdot PMC(F^-) \quad (1)$$

The MAPLE values can be calculated from the Partial Madelung Constants *e.g.* in accordance with

$$MAPLE(Ca^{2+})_{CaF_2} = \frac{331.81 \cdot PMC(Ca^{2+})_{CaF_2}}{d_{Ca-F}} \quad (2)$$

d_{Ca-F} (in Å) is the shortest cation-anion distance, on which all Madelung Constants and Partial Madelung Constants are based as the unit distance (cf. Table 4). The factor of 331.81 $[e^2.10^8 N_L]$ effects the conversion into kcal/mole.

Table 4. Partial Madelung Constants and MAPLE values for CaF_2 ($d_{Ca-F} = 2.365_5$ Å).

Particle	PMC	MAPLE (kcal/mol)	$^*_i$MAPLE (kcal/mol)
Ca^{2+}	3.276116	459.5	272
F^-	0.881337	123.6	292
Σ (CaF_2)	5.03879	706.8	

The numerical value of the MAPLE depends on the geometry of the charge distribution in the crystal space, the magnitude of the charge assigned to the individual particles, and the magnitude of the reference distance *d*. To allow the comparison of MAPLE values for different structures and particles having different charges, the value must be reduced to unit charge and unit distance [18]:

$$^*_i MAPLE = \frac{MAPLE}{z_i^2} \cdot d_{ki} \quad (3)$$

Table 5. $^*_i$MAPLE as a function of Q_i.

Q_i	$^*_i$MAPLE (kcal/mol)	Q_i	$^*_i$MAPLE (kcal/mol)
8	292	3	254
7	291	2	230
6	290	1.5	204
5	282	1.0	166
4	272		

The values given are representative for binary compounds if the ratio of the shortest anion-anion distance, d_{AA}, and the shortest cation-anion distance, d_{KA}, is $d_{AA}/d_{KA} = \sqrt{2}$. Deviations occur for tertiary compounds when the d_{ki} values are very different from one another.

z_i is the charge on the particle in question, and d_{ki} is the shortest cation-anion distance (in Å) (cf. Table 4). The $^*_i$MAPLE values for typical coordination lattices are a function of Q_i (cf. Table 5).

For simple structures in which all the short cation-anion distances are exactly equal,

$$Q_i \approx \sum_{j=i}^{j=j} n_j \cdot z_j/z_i \quad (4)$$

where z_j is the charge of the neighbors, n_j is their number, and z_i is the charge of the particle in question. Thus *e.g.* for CaF_2:

$$Q(Ca^{2+}) = 8 \times 1/2 = 4; \quad Q(F^-) = 4 \times 2/1 = 8$$

In more complicated structures, the distances to the "nearest" neighbors are not necessarily all equal (cf. *e.g.* Table 6). In such cases the empirical equation

$$Q_i = \sum_{j=i}^{j=j} n_j \cdot z_j \left(\frac{d_{ki}}{d_j}\right)^6 \quad (5)$$

is often useful for the calculation of Q_i. The meanings of n_j, z_j, and z_i are the same as before. d_{ki} is the shortest of all the distances from the particle in question to others, and d_j denote all other distances.

Table 6. Na_{II}–F distances in $Na_3[AlF_6]$. The coordination of Na_{II} in $Na_3[AlF_6]$ is unusually complicated. The "spectrum" of the Na_{II}–F distances begins at 2.20_3 Å; no definite conventional coordination number can be given.

d_{kj} (Å)	Contribution to Q_i	ECN
$2.20_3 \equiv d_{ki}$	1.000	1.000
2.324	0.726	1.7
2.330	0.714	2.4
2.442	0.539	3.0
2.454	0.523	3.5
2.670	0.316	3.8
2.774	0.251	4.1
2.859	0.209	4.3
3.125	0.123	4.4
3.524	0.060	4.5
3.535	0.059	4.5
3.982	0.029	4.5

Thus $Q_i = 4.5$.
Expected $^*_i$MAPLE (Na^+) from Table 5: 270 kcal/mole; found: 277 kcal/mole.

Reduced MAPLE values are structure-specific (cf. the example of AuF_3 in Table 7); owing to the relatively slow decrease in the potential energy with $1/r$, they also take into account the long-range order of assemblies. The combined application and discussion of MAPLE and $^*_i$MAPLE values is a new and often valuable aid to the elucidation of crystal structures [19–21].

The specific short-range and long-range order of typical molecular lattices of essentially covalent compounds such as BrF_3 or XeF_2 can also be expressed in

[16] Cf. *e.g. R. Hoppe*, Z. anorg. allg. Chem. *364*, 263 (1969).

terms of structural geometry by $^{*}_{i}$MAPLE values of this type, if we assign charges to the particles corresponding to their oxidation states, *e.g.* $Br^{3+}(F^-)_3$ (cf. Table 8 and the supplementary example of ICl_3, Table 9). We are, of course, not concerned with the absolute calculation of lattice energies, but wish only to express structural-geometrical facts by a number such that the long-range order is also taken into account.

$^{*}_{i}$MAPLE calculations are very useful even in the case of compounds such as Hg_2Cl_2, B_2F_4, or C_2H_6 if the approach is suitably modified [22].

Particle	MAPLE (kcal/mole)	$^{*}_{i}$MAPLE (kcal/mole)
Br^{3+}	983	187
F^-_I	141	242
F^-_{II}	125	231
F^-_{III}	152	281 [a]

[a] It can be seen that F_{III} tends to form Br–F .... Br bridges, a tendency that is more pronounced in $ICl_3 = I_2Cl_6$ (cf. Table 9).

Table 9. Distances and MAPLE values for ICl_3(solid).

Particle	d_{kj} (Å)	
$I-Cl_I$	2.67_8; 2.72_0;	3.83_2
$I-Cl_{II}$	2.38_5;	3.86_7
$I-Cl_{III}$	2.37_6;	4.03_0

$\frac{d_{I-I}}{d_{I-Cl}} = 1.70$

Particle	MAPLE (kcal/mole)	$^{*}_{i}$MAPLE (kcal/mole)
I^{3+}	715	189
Cl_I	126	338 [a]
Cl_{II}	78 [b]	188
Cl_{III}	105	249

[a] The bridge position of Cl in I_2Cl_6(solid) is clear from the $^{*}_{i}$MAPLE value.

[b] The abnormally low MAPLE(Cl_{II}) value is surprising.

8. $^{*}_{i}$MAPLE Values, Q_i Values, and Coordination Numbers

Equations (4) and (5) relate Q_i to the number n_j of neighbors for typical "coordination lattices"; on the basis of Table 5, a Q_i value can be assigned to each $^{*}_{i}$MAPLE value, and can then be used to deduce n_j. Thus by a method that is quite different from the "geometrical polyhedron methods" one obtains data about "effective" coordination numbers, which must be treated differently because of their different source. Eq. (5) in particular leads to interesting information in comparisons of similar variants of the same structural type [23] (see the example of Na_{II} in $Na_3[AlF_6]$; Table 6).

Similarly, the "Madelung Part of the Molecular Energy" (MAPME) can also be plotted as a function of Q_i of the central particle in the case of discrete molecules or complex ions (Fig. 16).

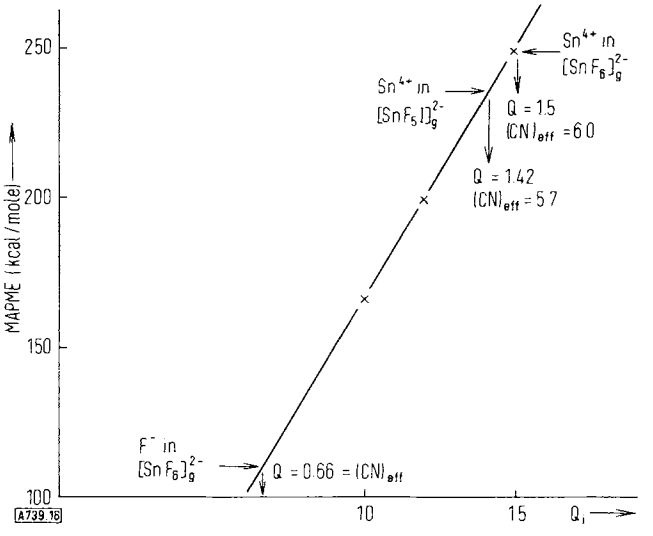

Fig. 16. Relation between MAPME and Q_i values and the "effective" coordination number.

A value of 5.7 is obtained in this way as the effective coordination number for Sn^{4+} in $[SnF_5I]^{2-}$, cf. Section 2. Finally, it is also possible to try to find the effective coordination numbers of ligands by this method. The value found for F^- in $[SnF_6]^{2-}$ is 0.7.

9. Closing Remarks

MAPLE calculations are of direct practical interest for the comparison of commensurable structures.

An example is *Holmberg*'s discussion on the structure of ScOF[24], where X-ray and structure-chemical methods failed to distinguish between three alternatives. The MAPLE values calculated by us (cf. Table 10) show clearly that in agreement with *Holmberg*'s suggestion, only alternative I can be seriously considered[25]. Many other examples have similarly shown the value of MAPLE calculations for detailed structural discussions.

The discrepancy between the accuracy of modern X-ray structure determinations and the possibility of understanding and critically interpreting their results, even only semiquantitatively, is amazing, and never since the "golden twenties", with their exceptionally fruitful symbiosis of physics, chemistry, mineralogy, and crystallography has it been so striking as it is today. Solid state chemistry in the true sense begins only with crystal chemistry, and is in fact a lot more in the eyes of the experimental chemist. But even the value of the advance in structural chemistry as a first step of solid state chemistry is, however, doubtful so long as structural facts cannot be critically and quantitatively evaluated and checked for internal consistency or inconsistency. We are conscious of the limitations of the very one-sided structure-geometrical view taken here, but we nevertheless hope to stimulate further discussion.

Table 10. Crystal structure of ScOF [24]: MAPLE values in kcal/mole.

MAPLE	Alternative I	Alternative II	Alternative III (statistical distribution of O^{2-} and F^-)
Sc^{3+}	1122.0	1043.5	1083.3
O^{2-}	543.1	393.1	365.2
F^-	138.9	215.2	251.7
Σ	1804.0	1651.8	1700.2

From Planck to Bohr

The First Fifteen Years in the Development of the Quantum Theory

By Armin Hermann[*]

The quantum theory, which is nowadays a fundamental basis of chemistry that is regarded as self-evident, initially presented immense difficulties to human thought. An insight into many particulars of its fascinating evolution is provided by the correspondence of those involved in the development of the theory between 1899 and 1913, which has now been thoroughly sifted for the first time by the author.

1. The Continuity Principle

The principle "*natura non facit saltus*", *i.e.* all natural processes take place continuously and not spasmodically, had played a very important part in the development of science during the 17th century. This is shown particularly clearly in the creation of differential and integral calculus, the spirit of which is also the spirit of physics. The entire philosophy of *Leibniz* in particular is permeated with the continuity principle in its widest sense.

[*] Prof. Dr. Armin Hermann
Lehrstuhl für Geschichte der Naturwissenschaften
und Technik der Universität
7 Stuttgart 1, Postfach 560 (Germany)

Leibniz clearly stated "that the present always conceals the future in its bosom, and that any given state can only be explained naturally by the state immediately preceding it. Unless we accept this, there will be many things in the universe that defy the principle of sufficient reason and force us to marvel or to have recourse to chance for the explanation of the phenomena". The principle of the continuity of all natural processes was expressed by many scientists and philosophers in the 18th and 19th centuries, though it was not usually formulated as self-evident.

"An act of despair" was how *Max Planck* later described his theoretical proof of the law of black body radiation: "The entire affair can in short be described as an act of despair. I am peaceful by nature, and averse to hazardous adventures. However, ...a theoretical interpretation had to be... found at all costs... The two principal laws of heat seemed to me

to be all that had to be retained in any circumstances. Apart from these, I was ready to make any sacrifice of my physical beliefs" [1].

2. The Birth of the Quantum Theory

December 14, 1900, the day on which *Planck* described the derivation of his radiation law to the Physical Society in Berlin, saw the birth of the quantum theory. As an unwilling revolutionary, *Planck* had smashed the principle of the continuity of natural processes by postulating discrete energy steps for the linear oscillator, expressed by the formula

$$\varepsilon = h\nu$$

Contrary to a widely held belief, however, *Planck* had no suspicion of this corollary at the turn of the century. If he had no impression in 1900 of having overthrown the continuity principle, what did he mean by "act of despair" and the "sacrifice of physical beliefs"?

The sacrifice that *Planck* had knowingly made was the surrender of the purely axiomatic thermodynamic view of the second law of heat and the acceptance of the atomistic-probabilistic interpretation, which he had until then vigorously rejected. Only a few years earlier, in 1896, he had carried on an argument on this topic in the Annalen der Physik, through his assistant *Ernst Zermelo*, with *Boltzmann*.

And *Planck* was now forced to adopt the detested "Boltzmann method" to derive the law of black body radiation! The need to divide the energy into discrete atomistic portions was then only a minor additional difficulty: "This was a purely formal assumption, and I did not really think too much about it, since my only concern was to obtain a positive result, whatever the cost."

Following *Planck*'s work, the theory of radiation was investigated in the first few years of the present century by *Rayleigh*, *Jeans*, and *Lorentz*. By various routes, but always adhering rigidly to the thought processes of classical physics, they all arrived at the Rayleigh-Jeans formula. It was felt that this had to be accepted; it had been shown that there is no true equilibrium of black body radiation, and the energy passes from the resonators into the radiation and to ever-decreasing wavelengths. This viewpoint was still defended by *Hendrik Antoon Lorentz* in April 1908 at the International Congress of Mathematicians in Rome.

Willy Wien commented on this in a letter to *Arnold Sommerfeld*: "I am very disappointed by the lecture given by *Lorentz* in Rome. I take a poor view of the fact that he merely presented the old Jeans theory without adding any new point of view ... In my opinion the theory is not worth considering, since observations show enormous deviations from the Jeans formula. It also seems rather odd to me to regard as the advantage of the Jeans theory the fact that the entire unlimited multiplicity of the electronic vibrations can be retained, despite its complete failure to represent the true facts. And the spectral lines? *Lorentz* has not shown himself to be a leader of science this time."

Lorentz's caution was in line with his personality, but it was undoubtedly also stamped with the prejudices of the turn of the century: Anyone who shook the foundations of science, whatever his motives, was suspected of being a revolutionary.

Rayleigh, *Jeans*, *Lorentz*, and *Planck* were all alike in this respect. In the early years the only difference between *Planck* and the others was that *Planck* had been familiar with the natural constant h at least since May 1899, and he knew that its value can be found very accurately from radiation measurements. In *Planck*'s eyes the constant h existed and had to be explained, however inconvenient this might often appear to be. As late as 1910 he addressed the following warning to the innovators, and above all to *Albert Einstein* and *Johannes Stark*: "In introducing the quantum of action h into the theory, one must proceed as conservatively as possible, *i.e.* changes in the existing theory should be restricted to those that have proved absolutely essential."

3. The Appearance of *Einstein*

In 1905 *Albert Einstein*, who was at that time 26 years of age and an "Expert, 3rd Class" at the Swiss Patent Office in Bern, published three papers of great importance in the celebrated Volume 17 of the Annalen der Physik: The Theory of Brownian Movement, The Special Theory of Relativity, and The Light Quantum Hypothesis.

With his later almost proverbial independence of thought and his intellectual lack of respect, unlike *Planck*, *Lorentz*, and *Rayleigh*, he did not look upon the electromagnetic theory of light and mechanics as venerable structures that had to be treated "as conservatively as possible". From the very beginning he considered the Maxwell equations to be valid only for average values in time and space. Thus matter could often be successfully dealt with on the basis of the continuum concept, as *e.g.* in the theory of elasticity, and it became necessary to consider the corpuscular structure only for finer effects.

According to *Einstein*, the same was true in electrodynamics. The Maxwell equations are valid for optical interferences, but the corpuscular structure of light must be taken into account for the "groups of phenomena concerned with the production and transformation of light". Also according to *Einstein* (in 1909), the electron is "an alien in electrodynamics", since it is still not understood how the finite electronic charge is stably concentrated in a small space despite the very large Coulomb repulsion forces between the various elements of charge.

Early in 1909, *Einstein* came to the conclusion that the two deficiencies of the Maxwell theory must be linked

[1] The sources of the quotations reproduced here are to be found in *A. Hermann*: Frühgeschichte der Quantentheorie (1899 to 1913). Physik-Verlag, Mosbach/Baden 1969. This book also includes a complete review of the published and unpublished literature.

with each other. He tried to explain both the quantum structure of radiation and the electron, *i.e.* he tried to derive a single theory embracing both the electron and the light quantum. Einstein believed in 1909 that the key to the solution of this problem was the fact that e^2/c and h have the same dimensions, those of an action. "It seems to me from the relation

$$h = e^2/c$$

that the same modification of the theory that contains the elementary quantum e as a consequence will also contain the quantum structure of radiation." It should be mentioned that *Max Planck* had put forward a similar (though more cautiously formulated) view in a letter to *Ehrenfest* as early as 1905. *Planck* thought it possible that from the elementary quantum of electricity, "there is a bridge to the existence of an elementary quantum of energy h".

The elementary quantum of electricity e and *Planck*'s quantum of action h are nowadays regarded as independent natural constants, and it is considered a prerequisite of any future theory of elementary particles that the value of the Sommerfeld fine structure constant

$$2\pi e^2/hc = 1/137$$

can be calculated from it.

Einstein's paper in the Physikalische Zeitschrift of March 1909 elicited a comment from *Willy Wien*. It was around that time that *Wien* was composing his article on radiation theory for the Mathematische Enzyklopädie, in which he wrote: "I cannot at present accept *Einstein*'s opinion ... that the magnitude of the element of energy is related to that of the elementary quantum of electricity... The element of energy, if indeed it has any physical significance, must derive from a universal property of the atom."

This was entirely different from *Planck*'s view. Faced with the need to find a derivation for the radiation law, *Planck* had overcome the positivistic objection of *Mach* and *Ostwald* to atomism, and even did atomism a considerable service by his interpretation of the Planck-Boltzmann constant k. However, *Planck*'s linear oscillator remained a physically anemic object; it did not occur to *Planck* at first to look for a way of bridging the gap between this and real atoms. *Planck* had always regarded the "search for the absolute as the highest aim of research", and the "absolute" was precisely what was independent of the special properties of matter.

Einstein and the majority of the German physicists and chemists had likewise scarcely thought about the question of the constitution of atoms. *Max Born* said about this: "Well, the atom was the central problem at that time, and the Germans didn't known it." It must however be added that the most important idea was the quantum concept, and the French and English didn't know that.

4. The First Model of the Atom Based on the Quantum Theory

Who then was the first to attempt a quantum-theoretical treatment of the atom? Well, it was not one of the leading physicists or chemists, but a historian of physics named *Arthur Erich Haas*: In 1909, *Haas* had submitted a paper on the history of physics as his thesis for habilitation at the University of Vienna. This paper was not appreciated by the physicists of the faculty, and they imposed upon *Haas* the additional condition that he prepare another purely physical paper. To satisfy this condition, *Haas* started to read the latest physical literature. This was firstly the book by *Joseph John Thomson* on "Electricity and Matter", which deals almost exclusively with the structure of atoms, and secondly the newly published Mathematische Ezyklopädie containing *Wien*'s article. *Haas* combined *Wien*'s suggestion of deriving the element of energy from a universal property of atoms with the Thomson model of the atom, and so produced an important forerunner of the Bohr theory of the atom.

In the Thomson model, which consisted of an extended positively charged atomic sphere with point electrons, *Haas* considered only the electron orbitals on the surface of the atomic sphere; his model is therefore mathematically equivalent to *Rutherford*'s. For the forces acting on the surface and in the external space of a spherically symmetrical charge distribution, one can think of the total charge as being united in the center.

To determine the two unknowns, *i.e.* the radius of the electron orbital and the frequency of revolution, *Haas* needed another equation as well as the classical expression that equates centrifugal force to the Coulomb attraction force. This second equation can be obtained only by a "quantum-theoretical" approach. *Haas* was very fortunate in that he equated potential energy to the Planck element of energy $h\nu$.

This agrees with the later Bohr condition for the ground state of the hydrogen atom, and *Haas* therefore correctly obtained the "Bohr" radius of the hydrogen atom, which we could thus historically call the "Haas" radius. It is significant, however, that he wrote

$$h = 2\pi e\sqrt{am}$$

and not the equation solved for a. *Haas*, like *Wien*, considered the property of the atom to be the fundamental quantity from which the quantum of action h was derived.

The Bohr radius a is not a measurable quantity, so that the Haas relation provides no basis for numerical calculations. Using a similar hypothesis, however, *Haas* also derived an expression for the Rydberg frequency, which was thus traced back, as it was later by *Bohr*, to the fundamental quantities of the electron theory and the quantum of action. *Haas*'s determination is wrong by a factor of only 8, which is due to the inaccuracy of the numerical values used for the elementary charge and the quantum of action.

The reaction to his ideas was described very vividly by *Haas* in his autobiography: "In Vienna I at first met only scorn, and even ridicule. When I lectured to the Wiener Physikalisch-Chemische Gesellschaft, *Lecher* thought he was being very funny when he called the whole thing a carnival joke ... *Hasenöhrl* explained that I could not be taken seriously, as I had naively mixed up two branches of science that could have absolutely nothing to do with each other, namely quantum theory (which was concerned with the theory of heat) and spectroscopy (which was optical)" [2].

Thus the attempt to produce a quantum theory of the atom had apparently come to nothing in February 1910. However, the ideas developed by *Haas* were soon re-examined and pursued further by *Schidlof*, by *Sommerfeld*, and by *Hasenöhrl*. At about the time of *Haas*'s "carnival joke", a decisive *volte-face* in favor of the quantum concept had occurred. Everyone that had supported a quantum theory had hitherto been treated as an outsider, whereas from 1910 onward the quantum concept became, so to speak, respectable. How did this change of opinion come about? To find the answer to this question, we must dig a little deeper.

5. *Einstein*'s Influence on *Stark*, *Sommerfeld*, and *Nernst*

Einstein's light quantum hypothesis was regarded by the experts as the most radical attempt to derive the law of black body radiation, and it was accordingly received with much skepticism. Using the corpuscular theory of light, *Einstein* was able to provide a simple model for the interaction of light with atoms, molecules, and solids. As is well known, the "Einstein equation" for the photoelectric effect, which was deduced in 1905, consists simply of the application of the energy theory. In this way *Einstein* was able to extend the range of validity of the quantum concept. This valuable extension remained only a theory at first, since the experimental verification of these effects dragged out over several years, *e.g.* up to 1915/16 in the case of the photoelectric effect.

In the search for new quantum phenomena, the first to follow *Einstein*, from about 1907 on, was *Johannes Stark*. He named a whole series of processes in which the quantum law should, in his opinion, be evident. In addition to many that were correct, such as the ultraviolet boundary of X-ray bremsstrahlung, these included many that were not.

Like *Einstein*, *Stark* thought nothing of opposing the prevailing opinion. Opposition to dogma seemed to him to be a necessity of life. When the many quantum approaches were united in the Bohr theory in 1913 (and this theory,more over, was confirmed by his own experiments), *Stark* suddenly turned against the quantum concept and continued to oppose it until his death. Up to 1913, however, he fought with the same vehemence in favor of the quantum idea, and for this reason *Stark*, who is still remembered as a conservative physicist of the older generation, had his merits at the time as an avantgardist.

In late 1909, *Johannes Stark* tried to wring an agreement with the quantum theory from *Sommerfeld*, virtually by brute force. However, *Sommerfeld* had no difficulty in demonstrating embarrassing physical errors to *Stark*. Thus *Sommerfeld* wrote: "Nothing could be further from my intention than to start a quarrel with you. This would be very unequal, since you are far above me *in* experimental ideas, and I above you in theoretical lucidity." *Sommerfeld* and *Stark* carried on a lively discussion of the quantum concept in X-ray bremsstrahlung in the Physikalische Zeitschrift and in their correspondence. They entered into an argument that was the start of a deadly enmity, which was to affect the subsequent lives of both men.

The outcome for *Sommerfeld*, *Planck*, and the experts was essentially a corroboration of the wave theory of light and of X-rays. *Sommerfeld* expressly demonstrated in 1910 that the quantum of action had nothing to do with X-ray bremsstrahlung.

In March 1910, however, *Arnold Sommerfeld* was subjected to pressure by his own assistant *Peter Debye*. The latter had developed what was perhaps the shortest and clearest derivation of the Planck radiation law. Like *Rayleigh* and *Jeans*, he considered the characteristic vibrations of the cavity, which, however, are now provided with the quantum-theoretical energy average. *Debye* told *Sommerfeld* that he had now reached a firm opinion in his considerations on radiation, and that he wished to publish his views. *Sommerfeld* felt responsible for all the work done by his co-workers. What should he do? It was recorded with surprise at *Sommerfeld*'s institute that he suddenly felt in need of a rest in the middle of the year and went off to spend a week in Switzerland. As his pupil *Paul S. Epstein* commented, *Sommerfeld*'s idea of recreation was to talk physics all day with *Einstein*.

Like the other experts, *Sommerfeld* had first met *Einstein* in 1909 at the Salzburg Naturforscherversammlung, where the two men had formed a friendship based on mutual respect. *Einstein* now wrote in a letter to *Johann Jacob Laub* that *Sommerfeld* had spent a whole week with him "to discuss the question of light and some matters concerning relativity. His presence was a real occasion to me. He has largely accepted my ideas ..."

For *Sommerfeld*, *Einstein*'s power of persuasion was based not only on the force of his personality but also on the proven success of the relativity theory. This had very rapidly gained acceptance among those that mattered up to about 1908. Though the two most important physical theories of the beginning of the 20th century, *i.e.* the quantum theory and the theory of relativity, have no direct logical connection, they are closely linked from a historical standpoint. The success of the theory of relativity now also accelerated the development of the quantum theory.

The quantum theory gained an important champion in the person of *Sommerfeld*. Unlike *Planck*, *Sommer-*

[2] *A. E. Haas*: Der erste Quantenansatz für das Atom (= Dokumente der Naturwissenschaft. Vol. 10). Battenberg, Stuttgart 1966, see p. 16.

feld had a large circle of pupils, with whom he was constantly exchanging ideas, and on whom he made a strong impression. Thus from about the beginning of 1911, enthusiastic efforts were being made even among the younger scientists to solve the quantum problem.

6. *Nernst* and the First Solvay Congress

Even before *Sommerfeld*, the quantum theory had won another important adherent, who also enjoyed absolute and authoritative rule over a large institute. This was *Walther Nernst*. *Nernst* was interested in thermodynamics. He had formulated the third law of thermodynamics in 1906, and had deduced from it that the specific heat of all substances must tend toward a constant limiting value as the temperature approaches absolute zero. *Nernst* had therefore already set out to measure specific heats at low temperatures over a wide front when the Einstein theory of specific heat came to his notice in late 1909 or early 1910.

When the term ended, in March 1910, *Nernst* hurried off to *Einstein* in Zürich with the results of his measurements. Both men were delighted. A letter written by *Einstein* reads: "There is no doubt in my mind about the correctness of the quantum theory. My predictions about specific heats appear to have been brilliantly confirmed."

In addition to thermal radiation, there was now a second field whose experimental results could be explained with the aid of the quantum concept, and only with its aid. The quantum concept now rested, in *Sommerfeld*'s words, on "two stout supporting pillars", and *Einstein* stated that *Nernst* had freed the problem from its "theoretical shadow existence" [3].

Nernst was filled with enthusiasm by this encounter with a problem of the utmost importance to the foundations of science, and he looked around for further work. He initiated moves to acquire *Albert Einstein* for the Preussische Akademie, and in June 1910 he began preparations for an international "Quantum Conference" to enable the leaders in the field to reconsider the foundations of their science. *Nernst* wanted this conference, like the Karlsruher Chemikertagung in 1860, to be a landmark, and this aim was achieved in full. The preparations for the congress, which attracted a great deal of attention, the Solvay Congress itself, which started on October 30, 1911, in Brussels, and the official and unofficial congress reports won over many who had previously been mere by-standers.

In this trail-blazing atmosphere, the Haas idea was also activated. *Sommerfeld* had adopted this idea, but in Brussels he switched to the opposite view, *i.e.* that "h is not explained by molecular dimensions; on the contrary, the existence of molecules may be regarded as a function and a consequence of the existence of an elementary quantum of action".

After the Solvay Congress, *Sommerfeld* expected *Einstein* to provide the fundamental clarification of the constitution of the atom with the aid of the quantum theory, as is shown by the correspondence that passed between *Einstein* and *Sommerfeld* [4]. On October 29, 1912, *Einstein* made the following reply to a question by *Sommerfeld*:

"Your letter perplexes me still further. I assure you, however, that I have nothing new of any interest to say about the quantum problem. I am in complete agreement with the Debye-Born view, and can find nothing in it to criticize. However, this achievement is of little help in the solution of the principal difficulties."

Sommerfeld subsequently wrote to *Hilbert*: "My writing to *Einstein* was in vain, as you can see from this. *Einstein* is evidently so steeped in gravitation that he is deaf to everything else."

7. The Bohr Model of the Atom

As everyone knows, it was *Bohr* that made the breakthrough in February and March 1913 with his quantum theory of the atom. This success was largely due to *Bohr*'s conviction that it was the quantum of action that was responsible for the stability of the planetary atom. This conviction was essentially the result of *Sommerfeld*'s lecture in Brussels.

The international congress in Brussels carried the quantum concept beyond the boundaries of the German-speaking world. It had a deep impression on the young *Léon Brillouin* and *Louis de Broglie* in France and on *William Nicholson* and *Niels Bohr* in England. The quantum concept found a fertile soil particularly in the traditions of English natural science. The positivistic objection to atomism had played no part in England, and unlike in Germany, the constitution of the atom had long been a center of interest here.

As a guest at *Rutherford's* Institute in Manchester, *Bohr* witnessed the new experiments on radioactivity and the scattering of α and β rays at the beginning of 1912, and like the rest of *Rutherford*'s coworkers he was convinced of the correctness of the planetary model of the atom. *Bohr* was interested by the questions that followed directly from the experiments, and he found the answer. In an interview of the Sources for History of Quantum Physics with *Georg von Hevesy* we find: "I asked *Rutherford*: ... 'Where do the beta particles come from?'. *Rutherford* answered: Ask *Bohr! Bohr* with no difficulty answered that electrons involved in radioactive transmutation process come from the nucleus, and all of the other electrons come from the exterior of the atom".

Bohr deduced information about many important properties of the atom on what was still, so to speak,

[3] Cf. *Einstein, Debye, Born, Kármán*: Die Quantentheorie der spezifischen Wärme (= Dokumente der Naturwissenschaft. Vol. 8). Battenberg, München 1967

[4] *A. Einstein, A. Sommerfeld*: Briefwechsel. Sechszig Briefe aus dem goldenen Zeitalter der modernen Physik. Schwabe Verlag, Basel/Stuttgart 1968, see p. 26.

a pre-quantum-theoretical basis. This was a frequently overlooked prerequisite for the successful treatment of the problem. Toward the end of 1912 *Bohr* was clear:

about the correctness of the planetary model of the atom,

about the concept of atomic number, *i.e.* about the assignment of the models with one, two *etc.* electrons to the actual atoms,

about the separation of the "nuclear" from the "atomic" phenomena,

about the possibility that one and the same atom can exist in various "states",

about the ability of the Planck quantum of action to ensure the stability of the atom,

and that no further "explanation" of such a quantum theory is necessary.

On *Rutherford*'s advice that he avoid unnecessary complications and calculations, *Bohr* concentrated on the simplest model, that of the hydrogen atom, with one electron. In a letter to *Rutherford*, *Bohr* wrote that he was considering only the ground state of the atom, the "natural permanent state", and had no intention of trying to apply his ideas to the line spectra. That was on January 31, 1913. On March 6, 1913, however, he submitted the finished article on the theory of the spectrum of hydrogen to *Rutherford* for publication in the Philosophical Magazine.

The decisive step must therefore have been made in February 1913. Who or what persuaded *Niels Bohr* to embark on a theory of spectral lines? And how did he achieve such speedy success?

On October 31, 1962 less than three weeks before his death, *Bohr* himself was asked about this by *Léon Rosenfeld* and *Thomas S. Kuhn* on behalf of the Sources for History of Quantum Physics [5]. The record reads: "*Rosenfeld*: 'How did you come to examine the spectra?' *Bohr*: 'The spectra was a very difficult problem... And I discovered it, you see ... And I found the hydrogen spectrum. I was just reading the book of *Stark*, and at that moment I felt now we'll just see how the spectrum comes.' *Kuhn*: 'Was this at Manchester that you were reading *Stark?*' *Bohr*: 'No, no, that was later in Copenhagen ... it was in January, I think of 1913."

The author must confess that he was quite bewildered by this information. Having been in possession of the major part of *Stark*'s scientific legacy for a number of years [6], he had repeatedly referred to the importance of *Stark*'s contribution to the development of the early quantum theory. He had never dared, however, to assume that it had had such a direct influence on the emergence of the Bohr theory. We know from *Rutherford*'s letter of January 31, 1913, that the date of this decisive stimulus was February 1913, and not January.

What, then, were the ideas of *Stark*'s that had such an unusual outcome? According to *Stark*, even a single electron can emit an entire spectrum of lines. The electron returns from the almost completely separated state to a very eccentric elliptic orbital near the center of the atom. The orbital is strongly curved at the perihelion, and the acceleration of the electron is accordingly high. At this point electromagnetic energy is emitted in the form of a light quantum.

Stark wrote: "The electron's residual kinetic energy carries it away from the center Z again; because of the loss of energy, however, it can no longer move away to its original distance, but curves back again at a shorter distance." According to *Stark*, this repeated return of the electron to the atom is accompanied by emission of a light quantum at the aphelion and at the perihelion of the movement.

Stark developed these ideas in 1908, and reproduced them in 1911 in his book "Prinzipien der Atomdynamik. II. Die elementare Strahlung" (Principles of Atomic Dynamics. II. Elementary Radiation). *Bohr* obtained this book in February 1913.

When one accepts, as *Bohr* did, the planetary model of the atom with Coulomb forces between the nucleus and the electron, the application of *Stark*'s ideas follows automatically:

The path of the electron is an ellipse before the emission of radiation.

The path is again an ellipse after the emission, but this ellipse is situated closer to the nucleus. The energy of the electron is now lower.

The question how the electron moves from one ellipse to another need not be answered immediately.

Application of *Stark*'s concept to the basis of the Rutherford model of the atom thus gives families of ellipses, which must be classified according to their electronic energy.

"As soon as I saw *Balmer*'s formula the whole thing was immediately clear to me", *Bohr* told *Rosenfeld* more than once. Compare this with *Bohr*'s other statement: "I was just reading the book of *Stark*, and at that moment I felt now we'll just see how the spectrum comes." Thus *Niels Bohr* must have read *Stark*'s book and seen the Balmer formula at roughly the same time, *i.e.* in February 1913.

Bohr's copy of *Stark*'s "Prinzipien der Atomdynamik II" was found among his books at the Niels Bohr Institute in Copenhagen. This book contained a scrap of paper on which *Bohr* had noted two references to articles published in 1912. It appears, therefore, that *Bohr* procured these articles in direct connection with the reading of *Stark*'s book. One of the two deals with the theory of spectral lines, and contains the formula

$$\nu = N\left(\frac{1}{n^2} - \frac{1}{m^2}\right)$$

"As soon as I saw *Balmer*'s formula the whole thing was immediately clear to me": taken together with the idea of various elliptic orbitals, this formula gave the

[5] The American-financed "Sources for History of Quantum Physics" has been recording the relevant source material for some years, and has also arranged interviews with the workers involved. The Director for Europe is Prof. *F. Hund* (Göttingen).

[6] *Stark*'s legacy is now in the possession of the Staatsbibliothek der Stiftung Preussischer Kulturbesitz in Berlin-Dahlem.

"transitions" between pairs of elliptic orbitals m and n. Since there was evidently no suggestion of classifying the elliptic orbitals on the basis of energy, *Bohr* could apparently write the following formula directly for the energy emitted in a spectral line:

$$h\nu = h \cdot N \left(\frac{1}{n^2} - \frac{1}{m^2} \right)$$

All that remained now was to classify the various elliptic orbitals according to their energy; in other words, to complete the work, *Bohr* merely had to derive the formula

$$E_n = h \cdot N \cdot \frac{1}{n^2}$$

Without knowing about *Haas*, *Bohr* had tried in the middle of 1912 to relate the kinetic energy to the frequency of revolution. In an unpublished manuscript by *Bohr* dated July 1912, which was edited by *Léon Rosenfeld* to celebrate the 50th anniversary of the Bohr model in 1963, we find the formula

$$E_{kin} = K \cdot \nu$$

which at that time referred only to the ground state. The K in this formula should be closely related to the Planck constant.

It was now a simple matter for *Bohr* to find the correct expression by trial and error. Thus the "mechanism" of spectral lines, which had been sought since the discovery of spectral analysis by *Kirchhoff* and *Bunsen*, was found.

It is well known that the Bohr model of the hydrogen atom was then developed, by the addition of *Sommerfeld*'s quantum conditions, into a system of formulas that really deserved to be called a quantum theory. "Your spectral investigations", wrote *Einstein* to *Sommerfeld*, "are among my finest physical experiences. It is only through them that *Bohr*'s idea becomes totally convincing" [7].

Since the majority of physicists had accepted the quantum concept since 1912 and a corresponding theory had now been produced, developments entered a new phase. The early history of the quantum theory was closed.

Polyurethane Ionomers, a New Class of Block Polymers

By D. Dieterich, W. Keberle, and H. Witt[*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

Linear polyurethanes containing ionic centers at wide intervals are heteropolymers having a pronounced segment structure, i.e. ionomers. As a result of interactions between chains (Coulomb forces and hydrogen bonds), their properties are similar to those of crosslinked elastomers. They are strongly associated both in organic and in aqueous solutions. Polyurethane ionomers in polar organic solvents spontaneously form stable aqueous dispersions on addition of water, with the ionomer as the disperse phase. The particle size can be varied between 20 nm and 1 mm.

1. Polyelectrolytes by the Diisocyanate Polyaddition Process[1–3]

By reaction of diisocyanates *(1)* with diols containing tertiary amino groups *(2)*, *Schlack* obtained basic, linear polyurethanes, which dissolve in aqueous acids to form polyurethane polyammonium salts *(3)* [4].

Diisocyanates react with diaminobenzenesulfonates, or diaminobenzoates to form water-soluble polyurea polysulfonates or polycarboxylates *(4)* [5].

•• = $-NH-CO-NH-$

Polyelectrolytes such as *(5)*, *(6)*, and *(7)* have also been prepared by polymer-analogous reaction of polyureas containing secondary amino groups with sultones or acid anhydrides in the presence of bases [6], by quaternization of basic polyester urethanes [7], and by ternization of polythioether urethanes [8].

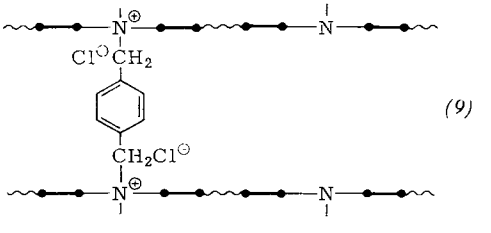
~~~ = Polyester residue

A feature common to the isocyanate-based polyelectrolytes is the more or less random distribution of numerous (250 to 800 milliequivalents/100 g of polymer) of ionic centers over the macromolecule; the

www = Ether residue

products are accordingly soluble in water, but not in organic solvents. These polyelectrolytes are of no importance in the field of plastics.

2. Segment Polyurethanes



The diisocyanate polyaddition process also permits the production of nonrandom distributions of the ionic center. Thus reaction of a high molecular weight polyester diol that is free from (potentially) ionic centers with excess diisocyanate yields a polyester diisocyanate (NCO prepolymer), which reacts with *N*-methylimino-2,2'-diethanol (*N*-methyl-*N*,*N*-bis(2-hydroxyethyl)-amine) to give a segment polymer having the structure *(8)*.

In this structure, organophilic, apolar polyester segments (molecular weight about 2000; this corresponds to a length of about 120–210 Å) alternate with shorter basic polar urethane segments (length about 40–70 Å) formed from the diisocyanate and the basic chain-lengthening agent. These reactions can also be carried out with polyether diols.

2.1. Difunctional Quaternization – Crosslinked Elastomers

The thermoplastic rubber-like material can be "vulcanized" with bifunctional quaternizing agents such as 1,4-bis(chloromethyl)benzene [9]; chemical linkage of the chains occurs to give a three-dimensional network *(9)* of the type found in elastomers.

~~~

2.2. Monofunctional Quaternization – Linear Elastomers

If the quaternization is carried out instead with a monofunctional agent such as dimethyl sulfate or methyl chloride, chemical crosslinking is impossible. Nevertheless, this again gives an elastomer, which, at $N^{\oplus}$ contents of more than 0.4%, differs characteristically from the basic starting material (Table 1) [10].

Table 1. Change in the properties of basic uncrosslinked segment polyurethanes on quaternization (salt formation) (measurements on films 0.3 mm thick).

	1% N	1% $N^{\oplus}$
Tensile strength	<10 kg/cm² plastic, soft	200–300 kg/cm² highly elastic
Elongation at break	–	600–800%
Modulus (100% elongation)	<1 kg/cm²	40 kg/cm²
Tear propagation	<5 kg/cm¹	30–40 kg/cm²
Elastic range	nonexistent	−40 to 120 °C
Thermoplasticity	from −40 °C	from 120 °C
Swelling in water at room temperature after 24 hours	<10%	50–100%
Solubility in benzene	+	–
in acetone	+	–
in water	–	–
in 70% aqueous acetone	–	+

The tensile strength of the elastomer depends on the $N^{\oplus}$ content (Table 2). 0.2% of $N^{\oplus}$ has little effect on the properties; the material remains plastic.

The dependence of the elastomeric range on the content of quaternary ammonium groups is illustrated by the shear modulus curves obtained by free torsional oscillation (Fig. 1).

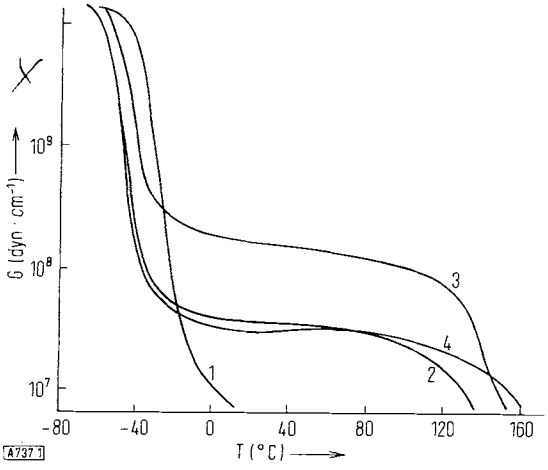

Fig. 1. Shear modulus G as a function of temperature for polyurethanes with various degrees of quaternization.

G > 10^9: glass state; G = 10^7–10^9: elastic range; G < 10^7: plastic range. 1: 0.12% $N^{\oplus}$; 2: 0.86 $N^{\oplus}$; 3: 1.06% $N^{\oplus}$; 4: 1.06% $N^{\oplus}$ and chemical crosslinking with hexakis(methoxymethyl)melamine.

Whereas the polyurethane 1 passes directly from the glass state into the thermoplastic range, the polyurethanes 2 and 3 exhibit pronounced elastomeric character between −40 and +130 °C. The additional chemical crosslinking in polymer 4 gives only a slight increase in the elastic range, extending it to 150 °C.

In the last five examples of Table 2, the content of quaternary ammonium groups was varied while the content of urethane groups was kept constant. Comparison with the earlier examples shows the influence of the urethane group content on the tensile strength. Both the quaternary ammonium groups and the urethane groups are evidently essential to the elastomer character.

It had been observed earlier that the reaction of polyester urethane dibromides with diazabicyclooctane, which is a polyquaternization addition, leads not to plastic but to elastic products with high tensile strengths, such as *(10)* [10a], though no chemical crosslinking has evidently taken place, since these products dissolve in 80% aqueous tetrahydrofuran.

(10)

2.2.1. Solvent Effects

Alkylation of the basic segment polyurethane in benzene (20%) leads to a marked increase in viscosity and formation of a solid elastic gel, which does not exhibit thermoreversible liquefaction and does not dissolve in benzene or acetone. In sufficiently dilute benzene solution (*e.g.* 5%), considerable turbidity appears with formation of microgel dispersions, which settle in time and undergo syneresis to form an elastomer. In polar media, (tetrahydrofuran, acetone), on the other hand, no gel is formed at concentrations below 10%. The solutions exhibit an anomalous dependence of the viscosity on concentration, so that the apparent molecular weight found from viscosity measurements increases rapidly with increasing concentration (Table 3).

Table 3. Viscometrically determined apparent molecular weight of a polyurethane polyammonium ionomer as a function of concentration.

Conc. (g/100 ml acetone)	Mol.-wt.
0	10000
0.5	11500
1.0	13000
2.0	20000
4.0	200000
6.5	400000
8.0	$>10^6$

In a solution of 6.5 g of the quaternized product in 100 ml of acetone, the viscosity is reduced to about 1/10th of the original value by 3% of water. The apparent molecular weight decreases from 400000 to 100000.

quaternization [10]. Neutralization of the basic polyurethane dissolved in polar organic solvents with *e.g.* hydrochloric acid gives a polyurethane polyhydrochloride that forms colloidal solutions in water and yields films having the same properties as the quaternized products.

Weaker acids (pK value >4, *e.g.* acetic acid and aspartic acid) readily give the hydrophilic polyurethane salts, which can be transferred into the aqueous phase, but these dry to give soft to tacky coatings. Thus elastomer formation no longer occurs. Polyurethane polyacetates are so strongly hydrolyzed in water that the acetic acid evaporates with the water on drying, to leave the rubbery, hydrophobic, basic starting polyurethane.

By subsequent treatment in baths containing 1–10% of acid, basic groups still present in a thin surface region of the polyurethane can be converted into salts. The reaction can be detected from the change in the mechanical properties (Table 4 and Fig. 2). (The bifunctionality of oxalic acid is of practically no importance.)

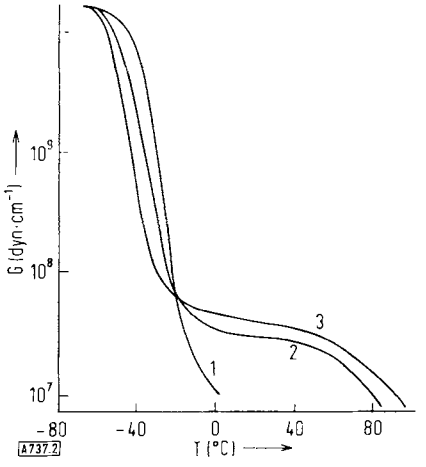

Fig. 2. Shear modulus G of an incompletely quaternized polyurethane film before and after storage in aqueous oxalic acid.
1: Partly quaternized with CH_3Cl, approx. 0.2% $N^{\oplus}$; 2: subsequently treated for 16 h in 1% oxalic acid; 3: subsequently treated for 16 h in 5% oxalic acid.

Table 4. Change in the properties of an incompletely quaternized polyurethane film on subsequent treatment with aqueous oxalic acid.

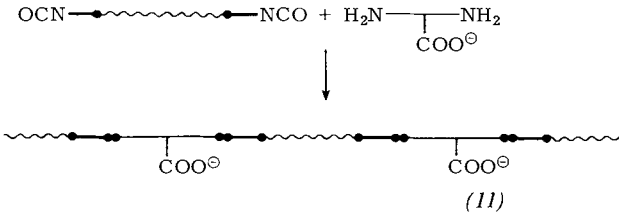
CH_3Cl 4 h 80 °C	31	1176	5	13	25	3	0	62
+16 h in 1% oxalic acid	83	738	19	48	33	12	9	69
+16 h in 5% oxalic acid	138	715	26	76	40	40	9	85

[a] DIN 53504. [b] Elongation after the indicated times at an elongation of 500%. [c] DIN 53379.

The ionomer is not precipitated even by large quantities of water, but forms an opaque sol. The product obtained when this sol is dried is insoluble in water.

2.3. Action of Acids

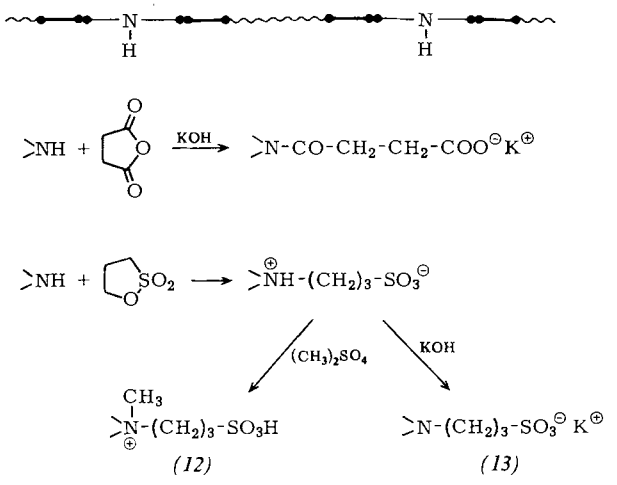
Polyurethane polyammonium ionomers are obtained even more readily by the action of acids [11] than by



[11] *D. Dieterich, E. Müller,* and *O. Bayer,* DBP 1178586 (Dec. 5, 1962); DBP 1179363 (Feb. 28, 1963); Chem. Abstr. *62,* 6633f, 2900g (1965); *D. Dieterich* and *H. Meier,* Netherlands Publ. Pat. Appl. 67/03743 (German Priority, March 12, 1966), all Farbenfabriken Bayer.

2,2′-diethanol (bis(2-hydroxyethyl) sulfide) into the polysulfonium ionomers[12] and into anionic polyurethane ionomers.

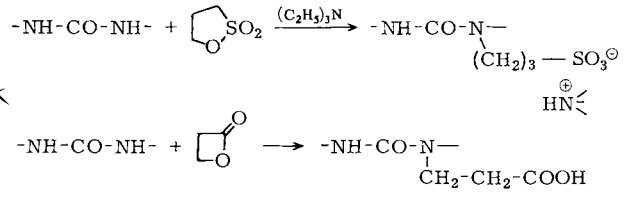
2.4. Anionic Ionomers



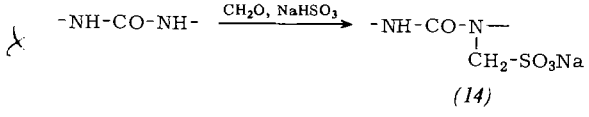
Quaternary ammonium groups can be readily introduced into the polyurethane macromolecule to form cationic ionomers by means of tertiary amines containing hydroxyl or amino groups. The preparation of anionic segmented polyurethane ionomers by reaction with bifunctional anionic "chain lengtheners"[12a,13] such as dihydroxy- and diaminocarboxylic acids, on the other hand, is more difficult, since the free carboxyl groups can react with the isocyanates and insoluble inner salts can be formed. The anionic component is therefore preferably introduced as the sodium or potassium salt.

Salts of aliphatic diamino acids such as *N*-(2-aminoethyl)-3-aminopropanesulfonate, *N*-(2-aminoethyl)-β-aminopropionate, and lysinate give the best results in the chain lengthening of NCO prepolymers formed from polyester or polyether diols and excess diisocyanate.

(11)



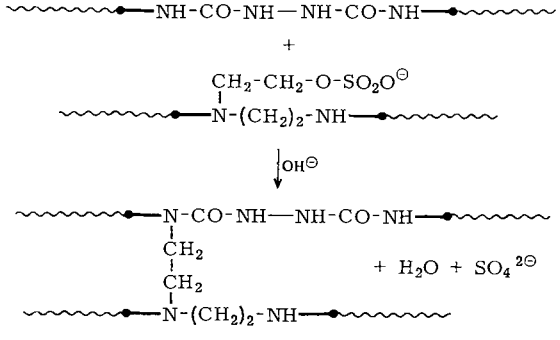
The polyaddition to give the macromolecule, *e.g. (11)*, takes place within a few minutes. Owing to hydration of the anionic groups, no abnormal viscosity increase is observed. The resulting polyurethane urea ionomers have a particularly high tensile strength and solvent resistance. Soft products are obtained *e.g.* by incorporation of tartaric acid, the carboxyl groups of which are neutralized by triethylamine immediately upon addition.



(12) *(13)*

Special methods for the introduction of ionic centers are the reaction of high molecular weight segmented polyurethanes or polyureas with cyclic compounds such as sultones, lactones, or anhydrides in the presence of strong bases[14]. The reaction can take place on secondary amino groups, and the products obtained with sultones are zwitterion ammoniosulfonates, which can be converted into cationic ionomers *(12)* by quaternization and into anionic ionomers *(13)* by reaction with bases.

A procedure of greater practical interest is the modification of existing polyurethanes containing urea groups[14].



Ionomers such as *(14)* can also be prepared by sulfomethylation or aminomethylation[15].

(14)

If a salt of a sulfuric acid half ester is introduced as the anionic group, the ionomers can be crosslinked by heating with alkalis, with elimination of sulfate[16].

The segmented polyurethane ionomers containing carboxylate or sulfonate groups also have high tensile strength and elasticity with predominantly linear structures.

Plastic ionomers such as *(15)* on the other hand are obtained when low molecular weight diisocyanates are allowed to react with high molecular weight polyesters containing sulfonate groups[16a].

3. Interaction Between Chains

The most suitable subjects for the investigation of the characteristic physical behavior of linear polyurethane ionomers are polyurethane polyammonium salts, since these can be obtained simply and specifically from the basic starting polyurethanes in a polymer-analogous reaction, and can be compared with these.

3.1. Coulomb Forces

The character of a segment polymer is greatly intensified by the formation of the ammonium ion from the tertiary nitrogen atom. Apolar polyether segments are separated by salt-like segments, which are held in the unraveled state by repulsion between neighboring positively charged nitrogen atoms.

In nonaqueous media, the unsolvated "salt segments" are brought together by Coulomb forces to form a sort of microionic lattice (Fig. 3), as a result of which the viscosity can increase by a factor of 1000 within a few seconds.

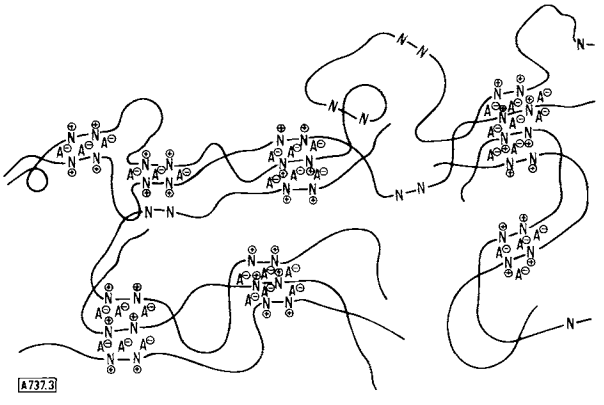

Fig. 3. Interchain association of the ionic segments of polyurethane ionomers in non-aqueous organic solution. $A^{\ominus}$ = anion.

When the association of the ionic centers (an intermolecular or intramolecular salt precipitation, so to speak) occurs at least twice (intermolecularly) in each macromolecule, it leads to the formation of aggregates ("micelles") whose length is many times that of the original molecules, and which are responsible for the observed enormous increase in viscosity. As in the case of soaps, the association is strongly dependent on concentration.

The morphology of the associates depends *inter alia* on the length of their structural units. Whereas high molecular weight polyurethane ionomers form a clear elastic gel in anhydrous acetone (uniform network), similar ionomers with lower molecular weights (approx. 10000) can form milky dispersions that exhibit the Tyndall effect and remain very fluid. Discrete sphereocolloid associates appear to be present in this case.

Interchain or, at high dilution, intrachain association due to Coulomb forces is indicated by the following observations:

The association decreases with increasing size of the organic residue on the quaternary nitrogen atom. A butyl group has a greater association-reducing effect than a methyl group, because of its bulk and better solvation by the organic solvent. Polarizable anions have the same effect.

The association also decreases with increasing dielectric constant, and also with the polarizability of the solvent (dioxane).

3.2. The Influence of Water

The association is very greatly reduced or eliminated by the addition of small quantities of water. Formamide and formic acid have the same effect, though to a smaller degree (Fig. 4). Similar associate formation and its disturbance by traces of water have been observed for solutions of soap in *e.g.* paraffin oil [17].

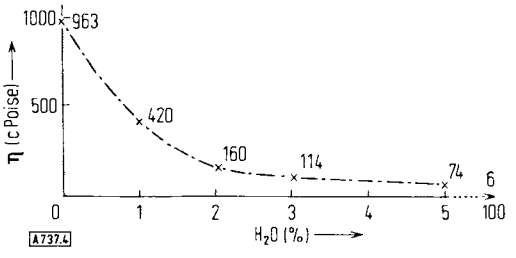

Fig. 4. Decrease in the viscosity of a 6.5% solution of polyurethane in acetone on addition of water.

Polyurethane ionomers are evidently completely solvated only in aqueous organic media (*e.g.* 80% acetone) (Fig. 5).

Fig. 5. Solvation of polyurethane ionomers in approx. 80% acetone +20% water (schematic). / / / = acetone, v v v = water.

3.3. Hydrophobic Interaction

A further increase in the water content of the water-acetone ratio leads again to an increase in viscosity, until finally the viscosity decreases again and the solution simultaneously becomes opaque.

As a result of the decrease in the acetone content, the polyether segments lose their solvation sheath, and they come together to form hydrophobic associates (Fig. 6), the viscosity again increasing at first. With decreasing acetone concentration, the associates rearrange into spherocolloids with the result that the solution becomes cloudy and its viscosity decreases considerably. The result is an aqueous colloidal sol having a low viscosity (Fig. 7).

[17] *J. G. Honig* and *C. R. Singleterry*, J. physic. Chem. *58*, 201 (1954); cf. *J. Stauff*: Kolloidchemie. Springer, Berlin 1960.

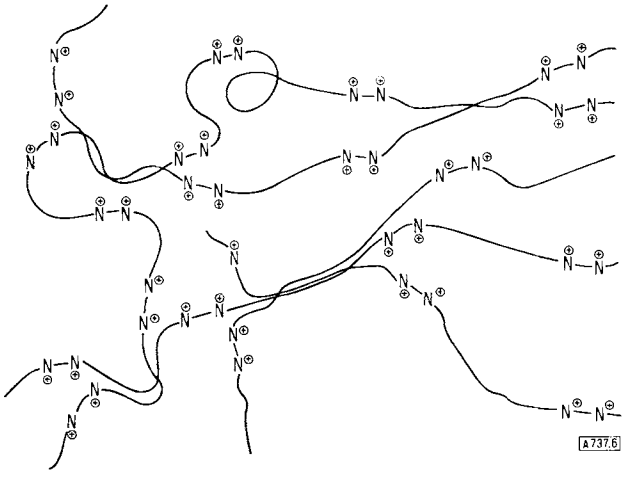

Fig. 6. Interchain association of the hydrophobic segments of polyurethane ionomers in approx. 60% acetone +40% water (schematic).

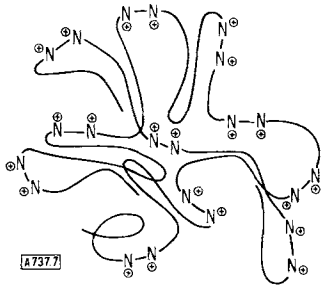

Fig. 7. Interchain association of the hydrophobic segments of polyurethane ionomers after rearrangement into the spherocolloid in approx. 40% acetone +60% water (schematic).

The increase in viscosity on addition of water is particularly pronounced when the tetracoordinate nitrogen carries a butyl group instead of a methyl, with the result that the hydrophobic bonding is strengthened.

The dissolved particles in the purely aqueous polyurethane sols are thus again associates, the size of which varies according to their hydrophilicity.

The polyurethane ionomers, like soaps, inverse soaps, and many dye salts thus belong to the group of association colloids. However, whereas the other substances mentioned are low molecular weight compounds that assume pseudo-high molecular weight character only on association to form micelles, the polyurethane ionomers are already high molecular weight segment polymers, which associate to form super macromolecules (according to *Staudinger*: "macromolecular associations"), giving particle weights (micelle weights) of more than 500000 and, in particular, "crosslinking" occurs by association.

3.4. Hydrogen Bonds

The polymer chains should also be oriented in the solvent-free state, polar segments tending to associate with polar segments, and apolar with apolar.

Thus the two types of association that are observed in succession on transition from the organic to the aqueous phase are now present together, so that we have an alternation of hydrophobic and hydrophilic heteropolar micelle segments. The X-ray diagram of stretched films shows two types of short-range order, which is in agreement with the above views.

On quaternization, the band due to the urethane NH group in basic segment polyurethanes, which is normally situated at 3340 cm^{-1}, shows a bathochromic shift of 30 to 80 cm^{-1}, depending on the degree of quaternization, with simultaneous broadening.

This observation can be interpreted as follows: The urethane groups, whose probability of encountering a urethane group of a neighboring chain was low before quaternization, are now arranged opposite one another (Fig. 8). Hydrogen bonds can therefore be formed, and these are responsible for the surprisingly high mechanical strength and the pronounced elastomeric character of the materials. Thus crosslinking has occurred as a result of molecular orientation, the forces responsible for this crosslinking being Coulomb forces and hydrogen bonds, and its strength being equivalent to that of chemical crosslinking.

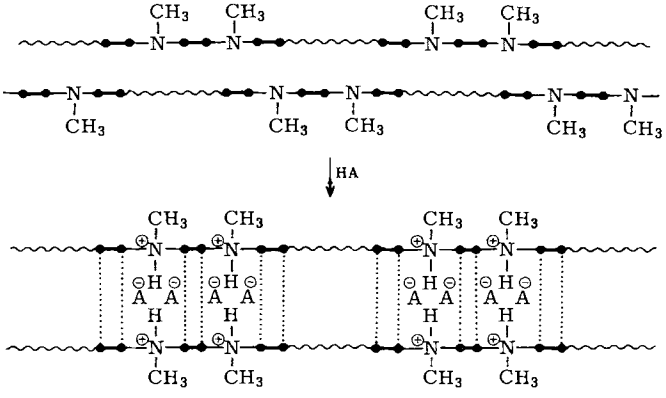

Fig. 8. Alignment of the polymer chains.

This view provides a plausible explanation for the influence of the position and number of the polyurethane groups on the "physical crosslinking". The anomalous increase in the permanent elongation with increasing degree of crosslinking, which is never found with covalently crosslinked elastomers, is now also understandable. Under tensile loads, strong forces are exerted on the hydrogen bonds, so that bonds are broken and reformed where the energy conditions are more favorable. The result is reorientation with partial slipping. The forces leading to reorientation are greater for the more strongly "crosslinked", less yielding materials, as are the possibilities for "engaging" during the slipping process; these materials accordingly exhibit higher permanent elongations.

If the ionomers are prepared from 4,4'-diisocyanatodiphenylmethane, NH-π-electron interaction cannot be ruled out.

However, bonding *via* protonated basic nitrogen, such as is assumed to occur in "HCl-crosslinked" butadiene/2-methyl-5-vinylpyridine copolymers [17a], is unlikely, since there is no great difference between polyurethane ionomers prepared with HCl and those prepared with CH_3Cl.

3.5. Tertiary and Quaternary Structure

Linear polyurethane ionomers are thus very stable "secondary-valence gels" as a result of the combined

[17a] *I. S. Ochrimenko, A. A. Petrov,* and *V. V. Vercholanzev,* Vysokomolekuljarnye Soedinenija *3*, 724 (1961); *4*, 1463 (1962).

action of electrostatic forces and hydrogen bonds. Chemical modification of the primary macromolecule, *i.e.* salt formation, leads to a tertiary structure, which has a greater influence on the properties of the polymer than might be expected from the small chemical change. This phenomenon is extremely important in natural polymers, such as collagen, pectins, and nucleic acids.

It must be assumed that "hydrophobic bonds", and hence quaternary structure [18], are also formed, since the properties are also influenced by the nature and length of the hydrophobic residues. This is true in particular of the polyether or polyester segments, but also applies to isocyanates and to the alkylating group of the quaternizing agent.

The presence of hydrophobic bonds would explain the facts that films and coatings deposited from aqueous polyurethane sols are insoluble in water and that such sols are in fact formed.

It would also explain the surprising aging resistance of aqueous polyester urethane sols. Whereas unstabilized polyester urethane elastomers suffer hydrolytic degradation by water, even finely divided sols of polyester urethane ionomers show practically no decomposition after three years.

The unsolvated hydrophobic polyester segments are tightly packed into the interior of the sol particles, while the strongly hydrated urethane segments with the mutually repelling ammonium groups are situated on the outside. The polyester groups are thus protected against hydrolysis as effectively as in the dry solid [19].

If on the other hand the ester groups are situated close to the ammonium nitrogen atom, as is the case in polyurethanes made from basic polyester after quaternization, sols prepared from these substances undergo hydrolytic degradation within a short time.

3.6. Comparison with Polypeptides

Polyurethanes are characterized by three types of interchain and intrachain interactions: 1. electrostatic forces, 2. hydrogen bonds, and 3. hydrophobic interactions. A comparison with proteins thus seems appropriate.

It is assumed [20] that the primary structure (chemical composition and sequence of the covalently bonded chains) of the polypeptides determines the total structure (*i.e.* secondary, tertiary, and quaternary structures) even of complicated proteins with very high molecular weights. The structures of higher order follow from the primary structure as a result of the three types of interactions mentioned.

Model substances for proteins must consist of covalent chains, and must satisfy the requirements for these interactions. Thus, by allowing salts to diffuse into solutions of degraded native polypeptides ("ionotropy"), *Thiele* was able to form anisometric associates that largely corresponded to the initial natural products [21].

Preliminary experiments showed that sols of polyurethane ionomers can also be solidified by electrolytes to give ionotropic gels. Hence it is to be expected that polyurethane ionomers can also form anisometric, complex structures, and they have the advantage of great versatility. In particular, the hydrophilic character can be decreased and the "plastic character" increased by variation of the structure and length of the hydrophobic segment.

The physico-chemically protein-like character of the polyurethane polyelectrolytes and of the ionomers is indicated *e.g.* by their excellent compatibility with gelatin [4, 22]. The use of polyurethane ionomers in medicine thus appears possible [23].

4. Aqueous Dispersions of Polyurethane Ionomers

The most remarkable and technically the most important property of all polyurethane ionomers is their ability to form stable dispersions with water spontaneously under certain conditions [10–16]. The products are binary colloidal systems in which a discontinuous polyurethane phase is dispersed in a continuous aqueous phase. The diameter of the disperse polyurethane particles can be varied between about 20 and 5000 nm.

Solutions of polyurethane ionomers in polar solvents such as acetone, methyl ethyl ketone, and tetrahydrofuran spontaneously form dispersions when water is stirred in. The organic solvent can then be distilled off to give solvent-free sols and latices of the ionomers. There is no need for the usual emulsification [24–28].

4.1. Precipitation Dispersion

If 100 g of the polymer contains more than about 70 milliequivalents of cationic or anionic groups, the transition from the organic solution to the aqueous sol is perfectly continuous, and involves the stages described above (ion association, molecular solution hydrophobic association). The process can be referred to as "precipitation dispersion", since the addition of water leads first to precipitation of the hydrophobic polymer components, which are however stabilized by the ionic segments.

4.2. Dispersion by Phase Inversion

Polyurethane solutions with lower contents of ionic groups (even 5 milliequivalents/100 g of polymer can be sufficient for the formation of stable dispersions without emulsifiers) can also take up water with initial formation of a water-in-polymer emulsion (W/O type), which becomes more viscous with increasing water content until it undergoes phase inversion to give a nonviscous O/W emulsion. The water penetrates from the ionic groups into the body of the polymer, with the result that the structure changes and the polymer finally divides into spherical globules surrounded by water. The hydrophobic polyether or polyester segments are contained in the interior of these globules, while the urethane, or urea and salt groups are situated outside in the hydrated region.

4.3. The Boundary Layer

Whereas a polystyrene latex stabilized with soaps forms a clearly defined two-phase system (anhydrous disperse polystyrene phase and polymer-free continuous aqueous phase with a unimolecular layer of soap at the interface), the polyurethane ionomer dispersions have a more or less extensive boundary layer, where the water content increases in the outward direction. This effect becomes more pronounced as the concentration of ionic groups is increased; the turbidity decreases, and almost clear sols are ultimately obtained. The degree of swelling as found from light scattering and its angular variation is between 1.2 and about 5, depending on the content of ionic groups; this corresponds to effective concentrations of swollen particles of 60–85%. The pronounced structure viscosity points to a strong interaction between the dispersed particles, and together with other characteristics, such as the chemical crosslinking of concentrated sols as a whole, indicates that the state is similar to that of a solution.

For this reason and because of the hydration of the particles, care is necessary in the determination of particle sizes, since the particle diameter is a definite quantity only for the dried and unswollen material, which can be determined *e.g.* by electron microscopy. However, this method fails for soft ionomers with small particles (<200 nm), owing to the tendency of the particles to coalesce and form films.

The particle size distribution is generally narrow in dispersions prepared by "precipitation dispersion", and much broader in the coarser dispersions obtained by phase inversion (Fig. 9, curves 1 and 2, 3 and 4).

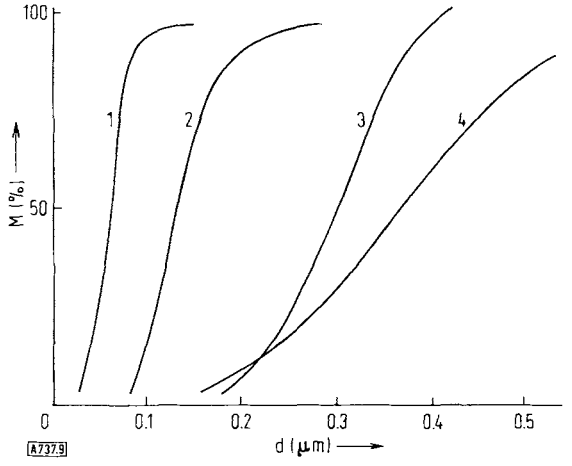

Fig. 9. Particle size distribution of some polyurethane dispersions, calculated from the change in light transmission, *i.e.* of the concentration, with time in the ultracentrifuge. Correction according to *Mie*, taking into account the degree of swelling (determination Dr. *Scholtan* and Dr. *Lie*).
M = weight fraction; d = diameter; 1–4: see text.

Dispersions containing *e.g.* 2–5 milliequivalents of ionic groups/100 g of polymer exhibit only slight swelling and give particle sizes of around 1 μm. Dispersions of this nature can thus be prepared with solids contents of 45–60% and with low viscosities, even when their molecular weights are very high.

Rheopexy, *i.e.* a sudden increase in viscosity under mechanical stress, is often observed with particle diameters of between 2 and 5 μm and with concentrations greater than 45%. In the extreme case, sampling is impossible, since *e.g.* insertion of a spoon leads to reversible solidification of the surrounding dispersion. The interaction between the particles must be particularly strong in this case because of the absence of a film of emulsifier.

4.4. Redispersible Suspensions

If the content of ionic groups is reduced still further, dispersion yields polyurethane suspensions with particle diameters greater than 5 μm and up to about 1–2 mm. Such suspensions are generally uninteresting; they sediment rapidly, with the result that the particles stick together and coalesce. If however chemical crosslinking is carried out during or after dispersion, the result is a suspension of elastomer particles, and though these particles sediment, they can be suspended at any time by simple stirring. Polyurethane powders can also be prepared in this way [29].

Polyurethanes can also be obtained in the form of fine, short fibers suspended in water (Fig. 10). Depending on the structure and the method of preparation, therefore, polyurethane ionomer particles ranging in size

[29] *H. Witt* and *D. Dieterich*, DBP 1282962 (April 28, 1966); *D. Dieterich* and *H. Witt*, Brit. Pat. 1158088 (German Priority, Feb. 1, 1967), both Farbenfabriken Bayer.

from a few macromolecules (Fig. 11) to the mm range can be obtained (Fig. 12). The unswollen dispersion particles in Figure 13 are typical of ionomers.

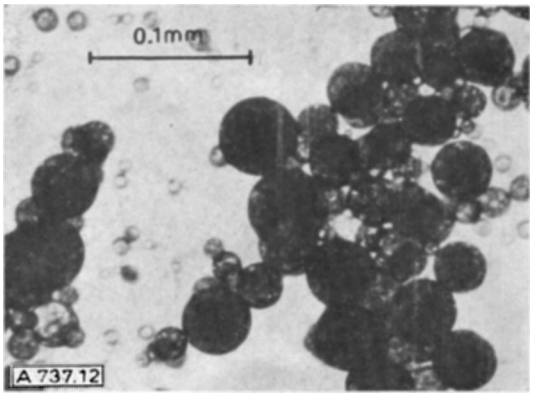

Fig. 12. Polyurethane suspension spherical, optical microscope 220×.

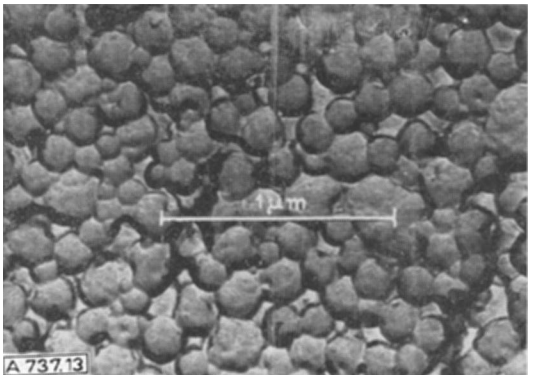

Fig. 13. Polyurethane latex, freeze-dried (carbon replica), 31 000× (recorded by Dr. *Menold*). The rough surface of the particles indicates shrinkage of the particles during freeze-drying.

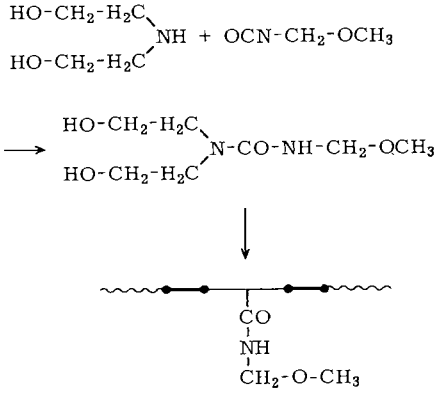
5. Use

Polyurethane ionomers allow the controlled modification of the flexibility, dimensional stability, and swellability of photogelatin [22]. The two components evidently form a sort of simplex by interaction of the cationic or anionic centers of the polyurethane with the amphoteric zwitterionic centers of the gelatin and by hydrogen bonding between urethane and amide groups.



Polyurethane dispersions, as aqueous one-component systems that have reacted to completion, can be used wherever reactive polyurethane systems from organic solvents have been used in the past, or where the application of such systems has been impossible because of the solvent content, despite the desirability of the valuable properties of the polyurethane (elasticity, tensile strength, abrasion resistance, good low-temperature behavior, and high solvent resistance).

The most interesting characteristic of these dispersions is their outstanding film-forming ability which is practically equal to that of organic solutions. Even dispersions of very hard polyurethanes, such as are required for paints, dry even at room temperature or below to give high-gloss coatings.

Soft polyurethane ionomers are suitable for the coating and impregnation of textiles, where their good resistance to perchloroethylene is valuable.

To improve their water-resistance, polyurethane ionomers can also be chemically crosslinked *e.g.* by polyisocyanates or polyfunctional alkylating agents. Formaldehyde and its derivatives have proved particularly useful for this purpose [30]. They react even at room temperature in the presence of aliphatic urethane or urea groups.

Methoxymethyl isocyanate may be used for the synthesis of one-component systems containing reactive groups [31].

[30] *D. Dieterich* and *E. Müller*, DBP 1187012 (March 13, 1963); *E. Müller* and *D. Dieterich*, DAS 1284963 (May 3, 1965); both Farbenfabriken Bayer.

[31] *G. Oertel*, *H. Holtschmidt*, *K. Wagner*, and *K. E. Zenner*, DBP 1244410 (Feb. 3, 1965); *D. Dieterich*, *W. Keberle*, and *E. Müller*, DBP 1241104 (June 5, 1965); *W. Keberle* and *D. Dieterich*, Belg. Pat. 682689 (German Priority, June 18, 1965); all Farbenfabriken Bayer.

Anionic polyurethane dispersions are more stable than their cationic counterparts toward electrolytes (particularly in the presence of sulfonate groups), and hence have a better pigment tolerance, and they have the additional advantage that they can be combined with commercial polymer dispersions and additives. Cationic products exhibit particularly good adhesion, *e.g.* even to glass.

There are possibilities for the use of crosslinked redispersible polyurethane ionomer suspensions in the production of microporous sheet materials (synthetic leather).

Our own work in this field has been supported by a number of colleagues from the applications, analytical, engineering, and technological departments. Special contributions were made by Dr. M. Hoffmann (Polymer Analysis) and Dr. Erwin Müller, who directed this development. We are grateful to all those mentioned. Special thanks are due to the former head of the Scientific Laboratories, Prof. Dr. O. Bayer, who initiated this work in 1962 and furthered its progress by numerous discussions.

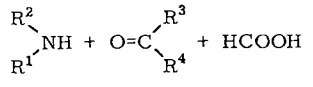
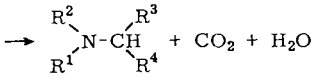
Reactions with Addition Compounds Containing Activated Formic Acid



By K. Wagner[*]



Dedicated to Professor K. Hansen on the occasion of his 60th birthday

Addition compounds of formic acid with tertiary organic bases in ratios higher than that required for salt formation (3 : 1 and 2 : 1 adducts) contain formic acid in a highly activated form. In particular, the 3 : 1 adducts of formic acid with trimethylamine and triethylamine are liquid reducing agents that are convenient to handle and are suitable for use in many selective reductions. These addition compounds have a surprisingly strong reducing action on sulfur dioxide, which is rapidly converted, even at low concentrations, into crystalline rhombic sulfur. Sulfones and polysulfones can be prepared in good yields by three-component reactions from activated formic acid, sulfur dioxide, and polarized vinyl compounds.

1. Introduction

In the Leuckart-Wallach reaction, formic acid acts as a strong reducing agent in the presence of carbonyl compounds.

R^1 - R^4 = H, Alkyl, Aryl

This method of aminoalkylation was greatly extended by *Wietzel*[1] and *Clarke*[2] with the use of formaldehyde as the carbonyl component in the reduction. The reaction is widely used as an elegant method of permethylation.

In studies on cleavage reactions of hexamethylenetetramine with acetic anhydride[3] and phosgene[4], anhydrous formic acid[5] was also used. Liquid, distillable cleavage products, whose compositions were unknown at first, but which possessed reducing properties, were isolated. The reducing power of these compounds was much greater than the well-known reducing action of formic acid.

2. Methods for the Preparation of Addition Compounds Containing Activated Formic Acid and their Thermal Behavior

2.1. Preparation and Constitution of the Addition Compounds

The reaction of concentrated formic acid with hexamethylenetetramine yields a liquid, distillable reaction product having the analytical composition $C_6H_{15}NO_6$

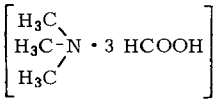
(b.p. 87 °C/14 torr), together with small quantities of dimethylformamide and methylformamide. When this reaction is followed with the aid of gas analysis, it is found that the compound $C_6H_{15}NO_6$ can be obtained in practically quantitative yield and without by-products only if formaldehyde is also present, the proportions being at least 6 moles of formaldehyde and 24 moles of formic acid per mole of hexamethylenetetramine.

$$+ 6\ CH_2O + 24\ HCOOH \qquad (1)$$

$$\longrightarrow 4\ C_6H_{15}NO_6 + 12\ CO_2 + 6\ H_2O$$

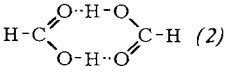


The CO_2 balance found under these conditions clearly points to a permethylation corresponding to the Leuckart-Wallach reaction. The unknown compound should therefore contain bound trimethylamine and this is in fact the case as is shown by equations (2) to (4).

$$C_6H_{15}NO_6 + 3\ NaOH \rightarrow (CH_3)_3N + 3\ HCOONa + 3\ H_2O \quad (2)$$

$$C_6H_{15}NO_6 + 3\ C_6H_5{-}N{=}C{=}O \rightarrow (CH_3)_3N + 3\ C_6H_5{-}NH{-}CHO + 3\ CO_2 \quad (3)$$

$$C_6H_{15}NO_6 + HCl \rightarrow [(CH_3)_3NH]^{\oplus}Cl^{\ominus} + 3\ HCOOH \quad (4)$$



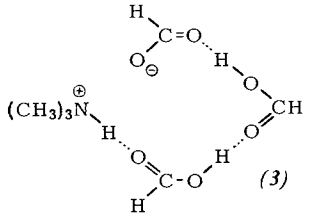
The liquid addition compound $C_6H_{15}NO_6$ [6] has the constitution *(1)*. An identical adduct can be obtained

(1)

in quantitative yield by passing one mole of gaseous trimethylamine into three moles of anhydrous formic acid.

The IR spectrum of *(1)* contains characteristic bands for both the carboxyl and the carboxylate groups. The very pronounced broadening of the OH bands indicates that extremely strong hydrogen bonds must be present. This agrees with the molecular structure found for formic acid, for which an eight-membered cyclic chelate *(2)* [7,8] with hydrogen bonds has been detected both in the liquid phase and in the vapor within a certain temperature range.

(2)



Comparison of the ^{1}H-NMR spectra of the addition product and of the corresponding 1 : 1 salt of trimethylamine and formic acid shows that the electron density in the position of the alkyl protons is lower in the addition compound than in the salt.

[6] *K. Wagner* and *H. Holtschmidt*, German Pat. 1233398 (March 14, 1964), Farbenfabriken Bayer

[7] *J. Karle* and *L. O. Brockway*, J. Amer. chem. Soc. *66*, 574 (1944).

[8] *R. Hofstadter*, J. chem. Physics *6*, 540 (1938).

On the basis of IR-spectroscopic observations, elementary analysis, and osmotic molecular weight determinations in halogenated hydrocarbons such as chloroform, the constitution *(3)* has been proposed for the addition product of three moles of formic acid with one mole of trimethylamine [9].

(3)

2.2. Thermal Properties of the 3 : 1 and 2 : 1 Addition Compounds

The formation of these adducts is not restricted to trimethylamine as the organic base. Many tertiary aliphatic, cycloaliphatic, and heterocyclic amines react with formic acid beyond the salt formation stage, often with formation of liquid 1 : 2 or 1 : 3 adducts. The 1 : 3 adducts are the more stable, and are also the more interesting from the chemical point of view. They are stable up to about 140 °C, and can be distilled under reduced pressure (see Table 1); they decompose above 140 °C in the absence of catalysts [eq. (5)] or below 140 °C in the presence of cuprous chloride and noble metals [eq. (6)] [10].

$$[R_3N \cdot 3\ HCOOH] \xrightarrow{> 140°\ C} R_3N + 3\ CO + 3\ H_2O \quad (5)$$

$$[R_3N \cdot 3\ HCOOH] \xrightarrow[\substack{Cu_2Cl_2\\ \text{noble metal}}]{90\text{–}120°C} R_3N + 3\ H_2 + 3\ CO_2 \quad (6)$$

Table 1. Distillable adducts of formic acid and tertiary bases.

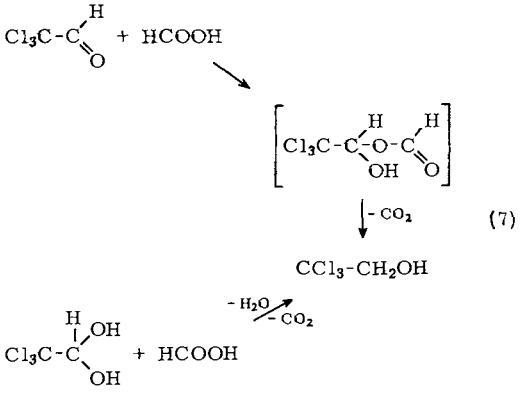
	B.p. (°C/14 torr)
$(H_3C)_3N + 3\ HCOOH$	87
$(C_2H_5)_3N + 3\ HCOOH$	94
$(C_4H_9)_3N + 3\ HCOOH$	102
$(C_2H_5)_3N + 2\ HCOOH$	84

The addition compounds with *N*-methylpiperidine, *N*-methylmorpholine, and *N,N*-dimethylbenzylamine readily decompose in accordance with eq. (5) on distillation. Adducts of imidazole and substituted imidazoles and of 1,4-diazabicyclo[2.2.2]octane cannot be distilled.

3. Reductions with Addition Compounds containing Activated Formic Acid

The study of the decomposition of the adducts containing activated formic acid by traces of Cu_2Cl_2 and palladium in accordance with eq. (6) led to two reduction methods based on different reactions.

[9] *M. Pestemer*, *N. Joop*, and *K. Wagner*, unpublished.



[10] *K. Wagner*, unpublished.

One of these reductions (cf. Section 3.2) is a true hydrogenation, in which the actual reducing agent is hydrogen formed from the adducts in accordance with eq (6) and then catalytically activated by copper(I) chloride and noble metals. The other method, in which no free hydrogen occurs (see Section 3.1), allows the selective reduction of α-halogenated carbonyl compounds in good yields.

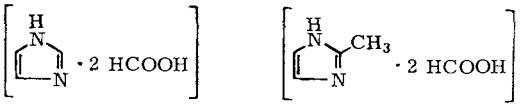
3.1. Selective Reduction of Polarized Carbonyl Compounds with Activated Formic Acid

The selective reduction of α-halogeno aldehydes and ketones to the alcohols does not proceed by hydrogenation following reaction (6); there is consequently no need to add copper(I) chloride, noble metals, or hydrogenation catalysts such as Raney nickel. On the contrary, these additives greatly reduce the yield, since they make the reduction less selective, and reductive dehalogenation occurs.

A simple laboratory method will be described for the selective reduction of chloral hydrate to trichloroethanol [11] [*].

(7)

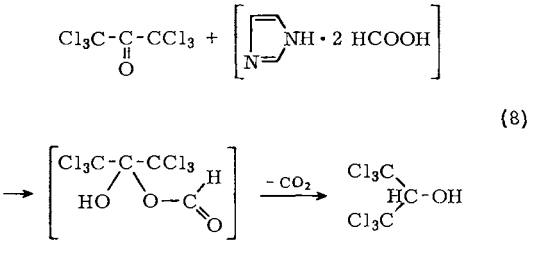
The driving force for this reaction is probably the tendency of formic acid to add to polarized double bonds; in the case of carbonyl compounds this yields hemiacylals of aldehydes, which are then decarboxylated by nucleophilic attack by the tertiary base.



Application of this reduction to chloral, chloral hydrate, or chloral-ethanol adduct yields trichloroethanol in yields of more than 87%. This reduction is simpler and much faster than the classical method for the preparation of trichloroethanol, *i.e.* the *Meerwein-Ponndorf* reduction of anhydrous chloral.

The preferred reducing agents are the liquid 3 : 1 adducts of formic acid with trimethylamine, triethylamine, dimethylethylamine, or diethylmethylamine, since these can be purified by distillation. The compound to be reduced is largely dissolved in the liquid addition compound, and fresh formic acid is continuously added to the system at a rate corresponding to the rate of liberation of CO_2 at 95 to 100 °C, so that the 3 : 1 adduct is still present in the reaction mixture at the end of the reaction.

[11] *K. Wagner*, US-Pat. 3397963 (April 1, 1965), Farbenfabriken Bayer.



[*] The abbreviation $HCOOH_a$ is used for $[(CH_3)_3N \cdot 3\,HCOOH]$ and $[(C_2H_5)_3N \cdot 3\,HCOOH]$.

Even unstable ketones such as hexachloroacetone and fluorinated ketones can be reduced to the secondary alcohols in good yields and under mild conditions by activation of formic acid with imidazole or 2-methylimidazole. The resulting adducts *(4)* and *(5)* are remarkably fluid, and have a viscosity of about 34 cp at room temperature.

(4) *(5)*

Hexachloro-2-propanol has only recently been described [12]. It was prepared, not by reduction of hexachloroacetone, but by reaction of anhydrous chloral with alkali metal trichloroacetates; the yields are low (35–36%) and the purity of the compound (m.p. 85–86 °C) is only moderate. The selective reduction in accordance with eq. (8) [13], on the other hand, can be carried out very simply.

(8)

Hexachloroacetone is added dropwise over about 2 hours to the imidazole-formic acid adduct at 55 to 65 °C. Concentrated formic acid is added continuously at a rate of about 2.1 g of formic acid per liter of carbon dioxide liberated. After the reduction the water-soluble imidazole adduct is removed by extraction with water, and hexachloro-2-propanol crystallizes out immediately (m.p. 89 °C); the yield is about 89%.

3.2. Hydrogenations by Catalytic Decomposition of the Addition Compounds

Under the influence of catalysts such as platinum, rhodium, and iridium, formic acid slowly decomposes even at room temperature into hydrogen and carbon dioxide [14]. This decomposition of formic acid can be greatly accelerated in the addition compounds by the use of copper(I) chloride and palladium on active charcoal as the catalyst.

The hydrogen formed in this case is activated by the noble metal catalyst, so that many aldehydes, ketones, and functional groups such as $-NO_2$, $-NO$, $-NHOH$, $-N(\rightarrow O)=N-$, $-N=N-$, $-NH-NH-$, $-NH-NH_2$, $=NOH$, $=NH$, and $=N-R$ can be hydrogenated in good yields, or $>N-N<$ bonds can be reductively broken. This reduction method practically corre-

[12] *R. Haszeldine, R. Farmer*, and *H. Goldwhite*, Brit. Pat. 1019891 (Feb. 9, 1966); Chem. Abstr. *64*, 12549 (1966).

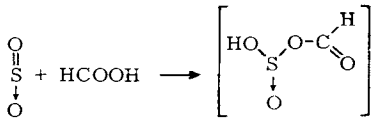
[13] *K. Wagner*, German Pat. Appl. P 1793243.3 (April 21, 1968), Farbenfabriken Bayer.

[14] *I. E. Adadurow*, Ž. fiz. Chim. *2*, 142 (1931); Chem. Zbl. *1933*, I 1240.

sponds to the conventional hydrogenation methods, but proceeds at atmospheric pressure. It is recommended in the laboratory for the reduction of sparingly soluble compounds or for cases where it is desirable to obtain the *N*- or *O*-formylated derivatives of the hydrogenation products in a single operation. Nitriles, dinitriles, and polyacrylonitrile cannot be hydrogenated, since addition of the activated formic acid to the nitrile group predominates over hydrogenation.

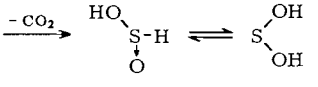
4. Reactions of Addition Compounds Containing Activated Formic Acid with Sulfur Dioxide

4.1. Reduction of Sulfur Dioxide to Crystalline Sulfur

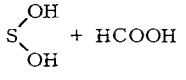


Probably the most striking example of the high activity of the formic acid in the addition compounds is the fast and practically quantitative reduction of sulfur dioxide to crystalline rhombic sulfur[15]. Sulfur dioxide itself is well known to be a relatively strong reducing agent; however, it behaves as a strong oxidizing agent toward these addition compounds. Since even very dilute sulfur dioxide can be readily reduced and the resulting crystalline sulfur can always be filtered out extremely easily, this reaction has been investigated in connection with the cleaning of industrial waste gases.

Overall reaction:

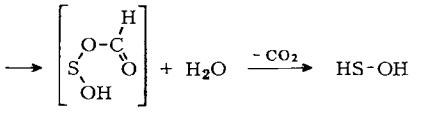


$$8\,SO_2 + 16\,HCOOH \rightarrow S_8 + 16\,CO_2 + 16\,H_2O \qquad (9)$$

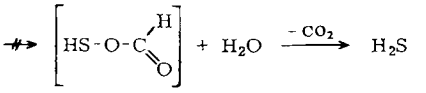


Under normal conditions, 44.8 liters of CO_2 are liberated per g-atom of sulfur.

Reaction steps:



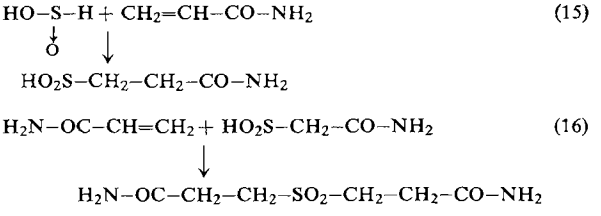
(10)



(11)

HS-OH + HCOOH

(12)



$$2\,H_2S + SO_2 \longrightarrow 3\,S + 2\,H_2O \qquad (13)$$

$$8\,HS\text{-}OH \longrightarrow S_8 + 8\,H_2O \qquad (14)$$

It can be concluded from the investigation of the reaction by gas analysis that sulfur dioxide is not reduced to hydrogen sulfide, and therefore that the sulfur formation cannot be explained by the well known reduction in accordance with eq. (13). When the reduction is carried out at various temperatures and with simultaneous checking of the CO_2 balance, it is found that the reduction leads first in accordance with eq. (10) to sulfoxylic acid (H_2SO_2), which it in turn reduced to the very unstable hydroxysulfane (H_2SO) [eq. (11)]. The hydroxysulfane is so unstable that instead of undergoing further reduction in accordance with eq. (12) it decomposes readily, as a sulfur homolog of hydrogen peroxide, into water and probably free-radical sulfur, which achieves stability by formation of S_8 and is obtained as rhombic sulfur eq. (14).

4.2. Interception of Short-Lived Intermediates of the Reduction of Sulfur Dioxide by Three-Component Reactions

The intermediates involved in the reduction, such as sulfoxylic acid and hydroxysulfane, can be used for a simple preparation of organic sulfinic acids, sulfenic acids, and sulfoxides, and particularly of monosulfones and polysulfones (see Table 2)[16]. These preparations can be carried out very readily and in excellent yields by dissolving vinyl compounds in the adducts containing activated formic acid before the introduction of sulfur dioxide, adding small quantities of polymerization inhibitors, and introducing SO_2 into the reaction mixture at 90 °C.

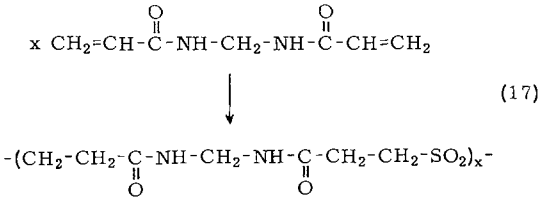
(15)

(16)

Table 2. Monosulfones prepared by three-component reactions.

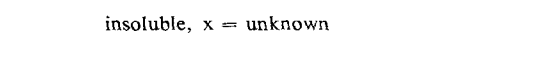
Vinyl compound	Monosulfone	M.p. (°C)
$CH_2=CH-COOH$	$(HOOC-CH_2-CH_2)_2SO_2$	220
$CH_2=CH-CO-NH_2$	$(H_2N-OC-CH_2-CH_2)_2SO_2$	228
$CH_2=C(CH_3)-CO-NH_2$	$(H_2N-OC-CH(CH_3)-CH_2)_2SO_2$	178
$CH_2=CH-COOC_2H_5$	$(C_2H_5OOC-(CH_2)_2SO_2$	86
$CH_2=CH-CN$	$(NC-CH_2-CH_2)_2SO_2$	86–87
$CH_2=CH-SO_2-CH_3$	$(CH_3-SO_2-(CH_2)_2)_2SO_2$	268

The sulfones listed can in most cases be very readily isolated, whereas the primary products, *i.e.* the organic sulfuric acids, can be obtained only with difficulty because of their instability.



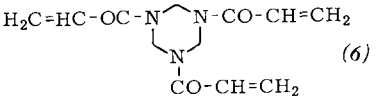
4.3. Interception of Short-Lived Intermediates of the Reduction of Sulfur Dioxide for the Synthesis of High Molecular Weight Polysulfones

As is shown by equations (15) and (16), sulfoxylic acid (H_2SO_2) reacts as a bifunctional compound. It reacts



[15] *K. Wagner*, German Pat. Appl. P 1442692.7 (April 4, 1964); US-Pat. 3397963 (April 1, 1965).

[16] *K. Wagner*, DBP 1222048 (Dec. 8, 1964), Farbenfabriken Bayer.



with suitable vinyl compounds to form sulfinic acids, and if the reaction mixture still contains activated vinyl compounds, sulfones are very rapidly formed. High molecular weight polysulfones can thus be readily prepared by polyaddition reactions with sulfoxylic acid if suitable divinyl compounds are used as acceptors.

(17)

insoluble, x = unknown

(6)

insoluble, three dimensionally crosslinked polysulfone

With introduction of sulfur dioxide at a suitable rate during the preparation of polysulfones, water-soluble polysulfones with sulfinic acid end groups can also be prepared by this method.

The results obtained in the reduction of sulfur dioxide have led to the investigation of the action of activated formic acid on nitrous gases, dinitrogen trioxide, and nitrous acid. It is difficult to isolate intermediates of the reduction. The utmost care is necessary in the treatment of even small reaction mixtures from the reduction of potassium and sodium nitrites, since violent decompositions have sometimes been observed.

5. Addition Compounds Containing Activated Formic Acid as Formylating Agents and as Solvents

Many of the liquid adducts, particularly those of one mole of trimethylamine or triethylamine with three moles of formic acid can be used as formylating agents for *N*- and *O*-formylations, since the addition compounds are generally good solvents for high molecular weight polyols and polyamines, and the formylations are accelerated in these solvents. Reductive degradations of natural polymers such as cellulose and polypeptides proceed particularly readily.

I am grateful to Professor Dr. Holtschmidt for the use of his unpublished experimental results on the hexamethylenetetramine-formic acid cleavage reaction, to Professor Dr. Pestemer for spectroscopic studies, to Dr. Joop for NMR measurements, to Dr. Fauss for osmotic molecular weight determinations, and to Dr. Klauke for the preparation of partly fluorinated ketones.

Chlorosulfenylated Carbonic Acid Derivatives

By G. Zumach and E. Kühle[*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

The present article deals first with the synthesis of chlorocarbonylsulfenyl chloride and its imino analogs. The chemical behavior of these bifunctional compounds is illustrated for selected examples. Special attention is given to the syntheses of five-membered heterocycles containing sulfur, oxygen, and/or nitrogen.

1. Introduction

The present article deals with compounds that can be regarded both as carbonic acid derivatives and as sulfenic acid derivatives. Two compounds of this series, *i.e.* trichloromethanesulfenyl chloride *(1)* and *N*-dichloromethylenesulfenylamide chloride *(2)*, have been known for a long time.

Trichloromethanesulfenyl chloride *(1)* consists formally of an orthocarbonyl trichloride group and a sulfenyl chloride group. It was first synthesized more than 100 years ago by *Rathke*[1] by chlorination of carbon disulfide in the presence of iodine, and is still produced on the large scale by the same method.

$$S{=}C{=}S + 3\,Cl_2 \xrightarrow[I_2]{} Cl_3C{-}SCl + SCl_2 \qquad (1)$$

In 1924, *Kaufmann* and *Liepe*[2] obtained "thiocyanogen trichloride" by chlorination of thiocyanogen; this product was later found to be *(2)*[3].

Wissenschaftliches Hauptlaboratorium
der Farbenfabriken Bayer AG
509 Leverkusen-Bayerwerk (Germany)

[1] *B. Rathke*, Ber. dtsch. chem. Ges. *3*, 858 (1870).

[2] *H. P. Kaufmann* and *J. Liepe*, Ber. dtsch. chem. Ges. *57*, 923 (1924).

[3] *E. Kühle*, *B. Anders*, and *G. Zumach*, Angew. Chem. *79*, 663 1967; Angew. Chem. internat. Edit. *6*, 649 (1969).

$$NCS{-}SCN + 3\,Cl_2 \rightarrow 2\,ClSN{=}CCl_2$$
(2)

Whereas *(2)* behaves in most reactions as a masked sulfur dichloride, with elimination of cyanogen chloride, the chlorosulfenylated carbonic acid derivatives to be described here are derived from trichloromethanesulfenyl chloride *(1)*:

$$Cl{-}\overset{\overset{X}{\|}}{C}{-}S{-}Cl$$

(1), X = Cl, Cl
(7), X = O
(3), X = S
(9), X = N–R
(4), X = Cl, SCl

We shall now consider chlorocarbonylsulfenyl chloride *(7)*, the iminochloromethanesulfenyl chloride *(9)* [4], chlorothiocarbonylsulfenyl chloride *(3)*, and dichloromethanebis(sulfenyl chloride) *(4)*. Chlorothiocarbonylsulfenyl chloride *(3)*, which should occur as an intermediate in the chlorination of carbon disulfide, has not yet been prepared so far as we know, but was described by *Klason* [5] as the product of the thionation of thiophosgene.

$$Cl{-}\overset{\overset{S}{\|}}{C}{-}Cl + S \xrightarrow[130-150\,^\circ C]{} Cl{-}\overset{\overset{S}{\|}}{C}{-}SCl$$
(3)

The very high boiling point of 140 °C at about 15 torr given by *Klason* cannot be correct for this compound, since thiophosgene boils at 73–74 °C under normal pressure.

Dichloromethanebis(sulfenyl chloride) *(4)*, which is also an intermediate of the chlorination of carbon disulfide, has however been obtained in this way in the presence of UV light as a compound that can be isolated only in the cold, and that has an extrapolated boiling point of 183 °C [6]:

$$S{=}C{=}S \xrightarrow[UV]{Cl_2} Cl_2C(SCl)_2$$
(4)

2. Syntheses

2.1. Syntheses of Chlorocarbonylsulfenyl Chloride

Chlorocarbonylsulfenyl chloride *(7)* (b.p. = 98 °C, n_D^{20} = 1.5165) was first obtained by thermolysis of alkoxydichloromethanesulfenyl chlorides *(6)* at 60 to 70 °C [7]. Since the required starting compounds are obtainable only from alkyl *S*-methyl dithiocarbonates *(5)* [8], this synthesis is of little preparative value.

$$\text{Alkyl-O}{-}\overset{\overset{S}{\|}}{C}{-}SCH_3 \xrightarrow{Cl_2} \text{Alkyl-O}{-}CCl_2{-}SCl + CH_3S{-}CCl_3$$
(5) *(6)*

$$(6) \xrightarrow{60-70\,^\circ C} O{=}C{-}SCl + \text{Alkyl-Cl}$$
Cl
(7)

Chlorocarbonylsulfenyl chloride *(7)* is now obtainable on the industrial scale by a simple process that proceeds smoothly. This process makes use of trichloromethanesulfenyl chloride *(1)*, which is subjected to partial hydrolysis with sulfuric acid [9]. Concentrated sulfuric acid is used with the quantity of water required for the hydrolysis, and the components are heated at 45 to 50 °C. Chlorocarbonylsulfenyl chloride *(7)* separates out as an oil that is immiscible with sulfuric acid.

$$Cl_3C{-}SCl \xrightarrow[H_2SO_4]{H_2O} ClC(=O){-}SCl + 2\,HCl$$
(1) *(7)*

2.2. Syntheses of Iminochloromethanesulfenyl Chlorides

Iminochloromethanesulfenyl chlorides *(9)* always occur as intermediates in the chlorination of isothiocyanates *(8)* to form isocyanide dichlorides *(10)* [3].

Whereas aliphatic compounds *(9)* are mostly unstable and can be handled only with special precautions (dis-

$$R{-}N{=}C{=}S \xrightarrow{Cl_2} R{-}N{=}C(Cl)(SCl) \xrightarrow[-SCl_2]{Cl_2} R{-}N{=}CCl_2$$
(8) *(9)* *(10)*

tillation under nitrogen), the aromatic and acylated compounds are fairly stable (Table 1).

Proof of the structure of the compounds *(9)* is provided by their synthesis from sulfur dichloride and from isocyanides, *e.g.* from cyclohexyl isocyanide.

3. Reactions of Chlorocarbonylsulfenyl Chloride

3.1. Open-Chain Reaction Products

Both the chlorosulfenyl and the chlorocarbonyl grouping of chlorocarbonylsulfenyl chloride *(7)* are available for nucleophilic substitutions *e.g.* with alcohols, thiols, and amines. These reactions can also be carried out selectively in some cases. The action of alcohols on chlorocarbonylsulfenyl chloride *(7)* in a molar ratio of 1 : 1 leads to alkoxycarbonylsulfenyl chlorides *(11)* [15] (Table 2).

$$\underset{}{ROH} + \underset{\underset{O}{\|}}{ClC-SCl} \xrightarrow{30-60\,^{\circ}C} \underset{\underset{O}{\|}}{RO-C-SCl} + HCl$$

(7) *(11)*

Very good yields are obtained in this reaction if the alcohol is added to the chlorocarbonylsulfenyl chloride at 30–60 °C, care being taken to ensure that a little chlorocarbonylsulfenyl chloride is still present at the end of the reaction.

Table 2. Alkoxycarbonylsulfenyl chlorides *(11)*.

R	B.p. (°C/torr)	Yield (%) [a]	R	B.p. (°C/torr)	Yield (%) [a]
CH_3	73–74/100	74	$ClCH_2CH_2$	99–104/19	69
C_2H_5	45–47/15–16	78	$C_6H_5-CH_2CH_2$	155–159/14	63
n-C_3H_7	99/100	95.5	$CH_3OCH_2CH_2$	93–96/20	56
n-C_8H_{17}	89–93/0.3	78			

[a] Yields not optimized.

In contrast with the alcohols, aliphatic thiols react with chlorocarbonylsulfenyl chloride in equimolar quantities on the chlorosulfenyl residue with formation of the alkyl chlorocarbonyl disulfides *(12)* [16]. This

$$\underset{}{RSH} + \underset{(7)\ \underset{O}{\|}}{ClS-CCl} \xrightarrow{0-30\,^{\circ}C} \underset{(12)\ \underset{O}{\|}}{R-S-S-CCl} + HCl$$

reaction is so selective that it stops at the disulfide stage *(12)* even when the thiol is used in excess (Table 3).

C_2H_5	59–60/11	92
n-C_4H_9	54–55/0.2	76

[a] Yields not optimized.

The structure of the compounds *(12)* is shown by the carbonyl band, which occurs at a relatively low wavelength (5.6 μm), and from the reaction with an amine *e.g.*

$$\underset{(12a)\ \underset{O}{\|}}{C_4H_9-S-S-CCl} + HN(C_2H_5)_2 \rightarrow \underset{(13)\ \underset{O}{\|}}{C_4H_9-S-S-C-N(C_2H_5)_2}$$

Butyl *N,N*-diethylcarbamoyl disulfide *(13)* gives a carbonyl band (at 6.0 μm) and yields tetraethylurea, dibutyl disulfide and dibutyl trisulfide in the mass spectrometer [17].

Some other reactions of the alkoxycarbonylsulfenyl chlorides *(11)* and alkyl chlorocarbonyl disulfides *(12)* are shown in Scheme 1.

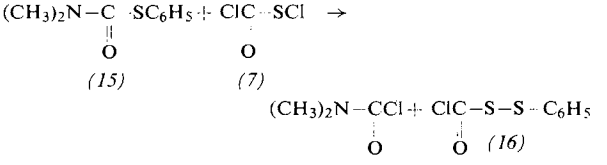
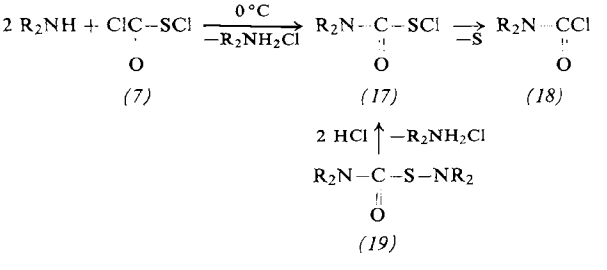
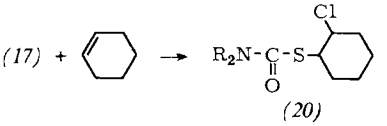


Scheme 1.

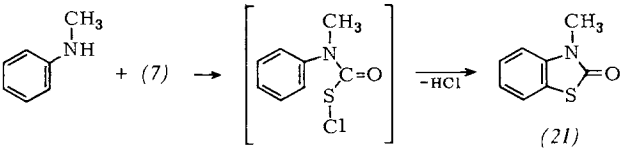


Thiophenols are oxidized by chlorocarbonylsulfenyl chloride *(7)* to diaryl disulfides *(14)*.

Aryl chlorocarbonyl disulfides can also be prepared by another route. The action of chlorocarbonylsulfenyl chloride *(7)* on an *S*-aryl ester of thiocarbamic acid, *e.g. (15)*, leads to elimination of carbamoyl chloride and formation of an aryl chlorocarbonyl disulfide *e.g. (16)* [18], b.p. = 86–88 °C/0.7 torr.



Chlorocarbonylsulfenyl chloride *(7)* reacts in the cold with aliphatic amines, as with alcohols, on the chlorocarbonyl residue at first, but the resulting carbamoylsulfenyl chlorides *(17)* readily decompose with elimination of sulfur to form the carbamoyl chlorides *(18)*. Even the mild cleavage of the carbamoylsulfenylamides *(19)* with hydrogen chloride yields the same products [19].



The unstable carbamoylsulfenyl chloride *(17)* can however be intercepted with cyclohexene *e.g.* to form the compound *(20)* (R = CH_3, n_D^{20} = 1.5329).

With aromatic amines, this "interception reaction" takes place intramolecularly with cyclization. Thus

chlorocarbonylsulfenyl chloride *(7)* reacts practically quantitatively with *N*-methylaniline to give *N*-methylbenzothiazolone *(21)* [20], b.p. = 140 °C/2 torr.

Primary and secondary amines react smoothly with chlorocarbonylsulfenyl chloride *(7)* in a molar ratio of 2 : 1 to give the stable carbamoylsulfenylamides *(19)* (Table 4).

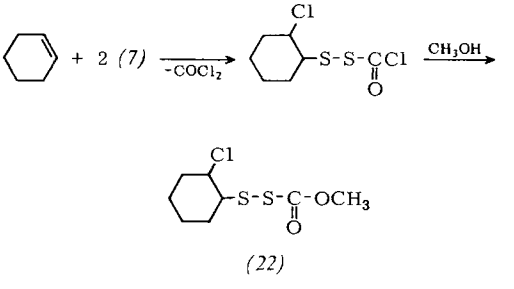


Table 4. Carbamoylsulfenylamides R–C(=O)–SR *(19)*.

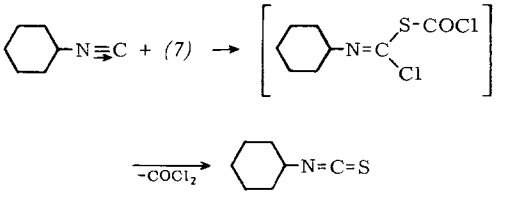
morpholino	(119)	70	anilino	(133–134)	86



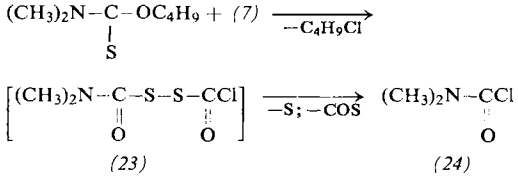
[a] Yields not optimized.

As well as substitutions, chlorocarbonylsulfenyl chloride *(7)* can also undergo additions, of which two types will be described.

The addition of compound *(7)* to olefins in a molar ratio of 2 : 1 leads to elimination of phosgene and formation of 2-chloroalkyl chlorocarbonyl disulfides. Chlorocarbonyl 2-chlorocyclohexyl disulfide reacts with methanol to form the compound *(22)*, b.p. = 143 to 145 °C/1.8 torr.

Isothiocyanates are formed by addition of chlorocarbonylsulfenyl chloride *(7)* to isocyanides, again with elimination of phosgene.

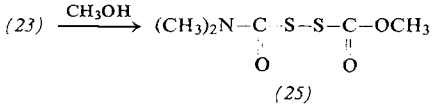
In the reaction of chlorocarbonylsulfenyl chloride *(7)* with an *O*-alkyl *N*,*N*-dialkylthiocarbamate, chloroalkane is eliminated as in a reaction described by *Harris* [21]. The expected chlorocarbonyl *N*,*N*-dialkylcarbamoyl disulfide, *e.g. (23)*, decomposes even at 0 °C



[18] *G. Zumach* and *E. Kühle*, German Pat. Appl. P 1947952.8 (Sept. 23, 1969), Farbenfabriken Bayer AG.

[19] The dimethylthiocarbamidosulfenyl chloride formed as an intermediate in the chlorolysis of tetramethylthiuram disulfide also immediately loses sulfur to form dimethylthiocarbamoyl chloride; cf. *E. J. Ritter*, US-Pat. 2466276 (Feb. 2, 1946), Sharples Chem. Inc.

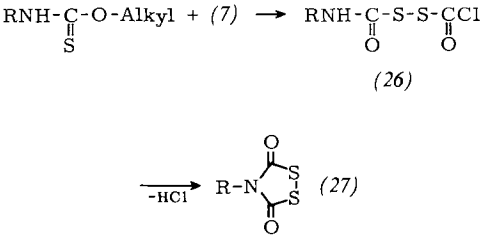
[20] *E. Mühlbauer*, Leverkusen, unpublished.



[21] *J. F. Harris*, J. Amer. chem. Soc. *82*, 155 (1960).

with liberation of sulfur and carbon oxide sulfide to give the *N,N*-dialkylcarbamoyl chloride, in this case *(24)*.

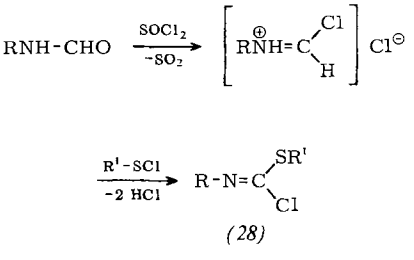
(23) *(24)*



It is sometimes possible to intercept the unstable intermediate *(23)* as an ester or amide, *e.g.* as the ester *(25)* (b.p. = 120–122 °C/0.3 torr).

(25)

3.2. Ring Closure Reactions



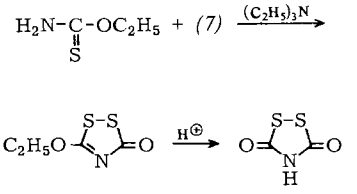
In contrast with the reaction of chlorocarbonylsulfenyl chloride *(7)* with *O*-esters of *N,N*-dialkylthiocarbamic acids, in which the unstable intermediate *(23)* changes into dialkylcarbamoyl chloride *(24)*, the carbamoyl chlorocarbonyl disulfides *(26)* formed in the reaction of compound *(7)* with *O*-alkyl esters of *N*-monosubstituted thiocarbamic acids can achieve stability by cyclization to form 1,2,4-dithiazolidine-3,5-diones *(27)* (method a in Table 5)[22].

(26) *(27)*

This reaction proceeds particularly smoothly with *O*-alkyl esters of *N*-arylthiocarbamic acids in the presence of a tertiary amine as a hydrogen chloride acceptor.

N-monosubstituted formamides react with sulfenyl chlorides in the presence of thionyl chloride to give the iminocarbonic acid derivatives *(28)*[23].

(28)

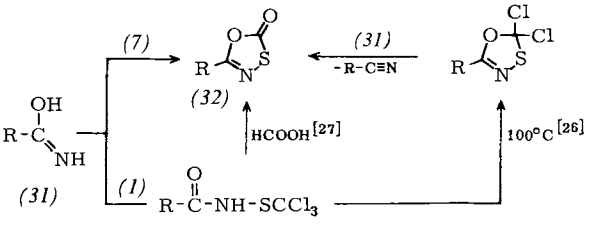


Chlorocarbonylsulfenyl chloride *(7)*, however, does not give *(28)* with R′ = COCl; two moles of *(7)* react instead with one mole of the monosubstituted formamide to give the heterocycle *(27)* (method b in Table 5)[24].

Table 5. 1,2,4-dithiazolidine-3,5-diones *(27)*. For methods a and b see text.

R	M.p. (°C) (B.p. (°C/torr))	Yield (%) [a] Method a	Method b
CH_3	38–39 (80/0.2)	67	40
n-C_4H_9	(90–92/0.15)	83	—
C_6H_{11}	87–88	41	42
C_6H_5–CH_2	93–94	35	—
C_6H_5	168	75.5	28
p-Br–C_6H_4	109–110	41	—
3,4-Cl_2–C_6H_3	166–168	79	35
3-Cl-4-CH_3O–C_6H_3	183–184	70	39

[a] Yields not optimized.



The unsubstituted 1,2,4-dithiazolidine-3,5-dione *(30)*, m.p. = 142–144 °C cannot be obtained by the two methods described. It is obtained by reaction of *O*-ethyl thiocarbamate with *(7)* in the presence of triethylamine followed by hydrolysis of the intermediate *(29)* with concentrated hydrochloric acid.

(29) *(30)*

As a bifunctional compound, chlorocarbonylsulfenyl chloride *(7)* can be used with other bifunctional reactants for the synthesis of heterocycles containing sulfur. Thus primary carbonamides *(31)* undergo *N*-sulfenylation and simultaneous ring closure with *(7)* to form 5-substituted 2-oxo-1,3,4-oxathiazoles *(32)*[25]. These can also be obtained from the amides *(31)* with trichloromethanesulfenyl chloride *(1)*[26,27].

When primary thioamides are used, the sulfenylation with *(7)* takes place not on the nitrogen but on the

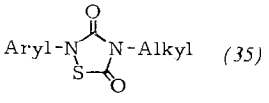
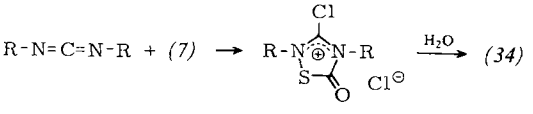
sulfur, with formation of 5-substituted 3-oxo-1,2,4-dithiazoles *(33)* [10,28].



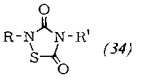
(33)

N,N'-Disubstituted ureas react with compound *(7)* not in the enol form but in the keto form with "*N,N'*-bridging" to form 2,4-disubstituted 1,2,4-thiadiazolidine-3,5-diones *(34)* [29].

(34)



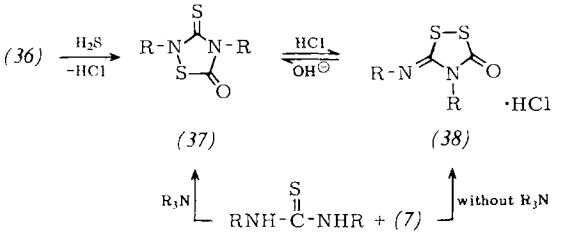
As is shown by NMR spectroscopic studies and independent synthesis (see Section 4.2.3), the reaction of *N*-alkyl-*N'*-arylureas with compound *(7)* leads exclusively to 4-alkyl-2-aryl-1,2,4-thiadiazolidine-3,5-diones *(35)*. No isomers are formed.



(35)

Another synthesis for (preferably symmetrically substituted) compounds *(34)* is the addition of *(7)* to carbodiimides followed by hydrolysis of the intermediate 3-chloro-5-oxothiadiazolinium chlorides *(36)* [30]. A number of 1,2,4-thiadiazolidine-3,5-diones *(34)* are listed in Table 6.

The IR spectra of the compounds *(36)* contain a split absorption band between 1650 and 1750 cm^{-1}, the stronger component, situated around 1730 cm^{-1}, being due to the CO group, and the weaker component, situated around 1680 cm^{-1}, to a C=N double bond.



(36)

Table 6. 1,2,4-Thiadiazolidine-3,5-diones  *(34)*

R	R'	M.p. (°C)	Yield (%) [a]
CH_3	CH_3	65	44
CH_3OCH_2	CH_3	52–54	47

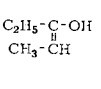
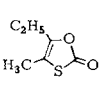
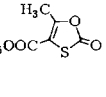
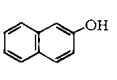
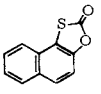
[a] Yield not optimized.

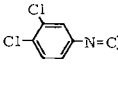


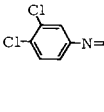












The reaction of *(36)* with hydrogen sulfide in aprotic solvents leads to 3-imino-5-oxo-1,2,4-dithiazolidine hydrochlorides *(38)* and the thiadiazolidines *(37)*. The reaction probably proceeds *via* the 5-oxo-3-thioxo-1,2,4-thiadiazolidines *(37)*, which rearrange in the presence of hydrogen chloride into *(38)*. The salts *(38)* can also be obtained by the reaction of *N,N'*-disubstituted thioureas with chlorocarbonylsulfenyl chloride *(7)* in the absence of a hydrogen chloride acceptor, whereas compound *(37)* is formed in the presence of a tertiary amine. The bases of the salts *(38)* are unstable and change back into *(37)* [31].

The reversible rearrangement *(37)*⇌*(38)* can be followed IR-spectroscopically by observation of the appearance and disappearance of an absorption band at 1620 cm^{-1}, which must be assigned to the C=N double bond in *(38)* [32].

In contrast with the reaction of *N*-alkyl-*N'*-alkylureas with the compound *(7)*, the reaction of *N*-alkyl-*N'*-arylthioureas with *(7)* leads to isomer mixtures in which the component *(39)* generally predominates strongly. Other examples of ring closure reactions with *(7)* are listed in Table 7.

Table 7. Cyclizations with chlorocarbonylsulfenyl chloride *(7)*

Reaction partner	Reaction product	B.p. (°C/torr) (m.p. (°C))	Yield (%) [a]

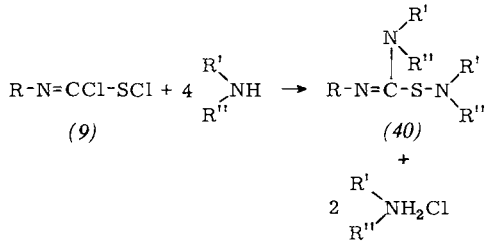
4. Reactions of Iminochloromethanesulfenyl Chlorides

4.1. Open-Chain Reaction Products

The principal reactants for reactions of iminochloromethanesulfenyl chlorides *(9)* to give open-chain products are primary and secondary aliphatic and aromatic amines. The reaction with two moles of amine yields *S*-aminoisothioureas *(40)*, the stability of which depends on the substituents (Table 8).



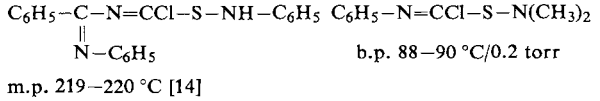


Table 8. *S*-Aminoisothioureas *(40)* [35].

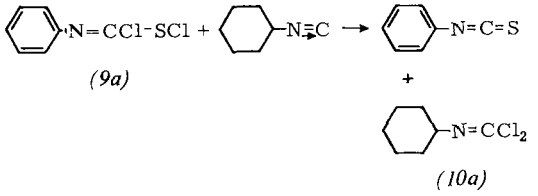
R	R′	R″	M.p. (°C) (B.p. (°C/torr))	Ref.	Yield [a] (%)
C_6H_5	H	C_6H_5	150–150.5	[34]	71
C_6H_5	CH_3	CH_3	(88/0.015)	[10]	45
C_6H_5–CO	H	C_6H_5	102–103	[12]	63
p-Cl–C_6H_4–CO	H	*p*-CH_3–C_6H_4	215–216	[13]	90

[a] Yields optimized.

Delocalization of the double bond in *(40)* can be detected in certain cases by NMR spectroscopy [34].

Selective reaction of iminochloromethanesulfenyl chlorides *(9)* with only one mole of amine is also possible; the products are sulfenylamide derivatives.

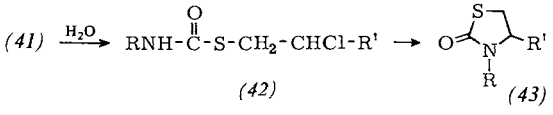


m.p. 219–220 °C [14]

b.p. 88–90 °C/0.2 torr

The reaction of the compounds *(9)* with alkoxides leads to elimination of sulfur [14], whereas with sodium thiolates they give isothiocyanates and diaryl disulfides [34].

In the presence of isocyanides, the iminochloromethanesulfenyl chlorides, *e.g. (9a)*, lose chlorine with regeneration of the isothiocyanates from which they are derived, while the isocyanides are converted into isocyanide dichlorides *e.g. (10a)*.

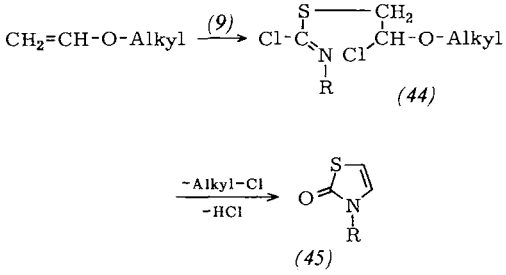


(9a) *(10a)*

As sulfenyl chlorides, the compounds *(9)* also add to olefinic double bonds [3,36].

(41)

Hydrolysis of the adducts *(41)* leads to the *S*-esters of thiocarbamic acids *(42)*, which, when R′ is an electronegative residue (*e.g.* phenyl), can sometimes cyclize to give 2-oxo-1,3-thiazolidines *(43)* [36].



(42) *(43)*

4.2. Ring Closure Reactions

4.2.1. Reaction with Vinyl Ethers

A special case of the reaction of iminochloromethanesulfenyl chlorides *(9)* with olefins is the addition of *(9)* to vinyl alkyl ethers. The resulting adducts *(44)* lose chloroalkane and hydrogen chloride even at room temperature to give 2-oxo-1,3-thiazolines *(45)* (Table 9) [10, 37].

(44) *(45)*

Table 9. 2-Oxo-1,3-thiazolines *(45)*.

4.2.2. Reaction with Ketones and Aldehydes

The first step in the reaction of compounds *(9)* with ketones is probably the addition of the SCl grouping to the enolized form of the ketone[38]. The hypothetical intermediate *(46)* is stabilized by ring closure and intramolecular neutralization of the hydrogen chloride to form the salt *(47)*, from which the base *(49)* can be liberated with tertiary amines even below 0 °C. With another mole of tertiary amine, *(49)* can be converted into the oxathiole *(50)* (Table 10). The compounds *(47)* and *(49)* rearrange instantaneously on contact with water or alcohol into the 4,5-disubstituted 2-oxo-1,3-thiazolines *(48)* (Table 11).

[a] Yields not optimized.

4.2.3. Reaction with Compounds Containing C–N Multiple Bonds

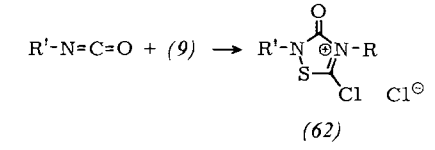
Possibly the most interesting property of the iminochloromethanesulfenyl chlorides *(9)* is their ability to react with certain compounds containing C–N multiple bonds. With isothiocyanates, for example, they form sparingly soluble unstable products that

have been known for a long time as "mustard oil monochlorides", and for which we[3] have proposed the polar structures *(53)* and *(54)*[38a].

Reaction of *(9)* with aliphatic primary aldehydes yields 2-oxo-1,3-thiazolines *(51)* [≡ *(48)*, R'' = H] that are monosubstituted in position 5 (Table 11). The isomeric iminooxathioles *(52)* are not formed[37].

Scheme 2.

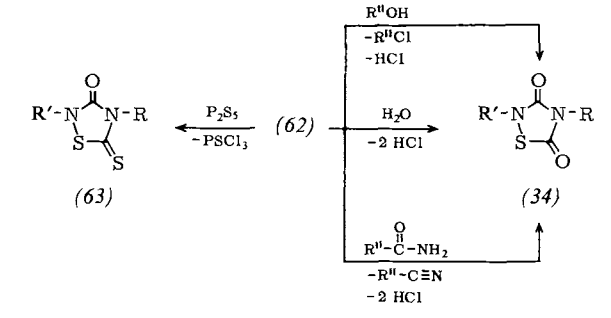
[38] *G. Ottmann, G. D. Vickers*, and *H. Hooks jr.*, J. heterocyclic Chem. *4*, 527 (1967).



[38a] In view of the differences in the nucleophilic strengths of N, O, and S, we favor type *(54)* in the case of the isothiocyanate adducts and type *(53)* for the isocyanate adducts.

The salt character of the compounds explains their sparing solubility in organic solvents. The hydrolysis of the "mustard oil monochlorides", *e.g. (55)*, to give the "mustard oil oxides" *e.g. (57)*, can be similarly explained [39].

The structure of *(57)* can be proved by degradation with amines to form *N,N',N''*-trisubstituted monothiobiurets [40,41] as well as by independent synthesis (see Scheme 2).

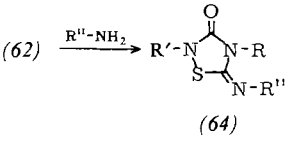


We have obtained similar results in the hydrolysis of *(55)*, with CH_3 instead of C_6H_5. In principle, mixed aromatic-aliphatic compounds *(57)* can also be prepared by the methods described, but the products are usually mixtures of isomers that are difficult to separate.

Isocyanates, like isothiocyanates, can also react with the compounds *(9)* [42], and the products are again sparingly soluble, salt-like substances, which we believe to be 3-oxothiadiazolinium chlorides *(62)* [38a]. The synthesis described proceeds particularly easily and in high yields when the chlorination of isothiocyanates is carried out in the presence of isocyanates [43].

(62)

Hydrolysis of the very reactive compounds *(62)* with water [42,44] yields 1,2,4-thiadiazolidine-3,5-diones *(34)*, which are also obtained from *N,N'*-disubstituted ureas with chlorocarbonylsulfenyl chloride *(7)* or from carbodiimides with *(7)* (see Table 6). *(34)* is also obtained in the reaction of *(62)* with alcohols, which is accompanied by elimination of chloroalkane, or with primary amides, which is accompanied by the formation of the nitriles. *(62)* reacts with hydrogen sulfide, or preferably with phosphorus pentasulfide, to give 3-oxo-5-thioxo-1,2,4-thiadiazolidines *(63)* (Table 12).



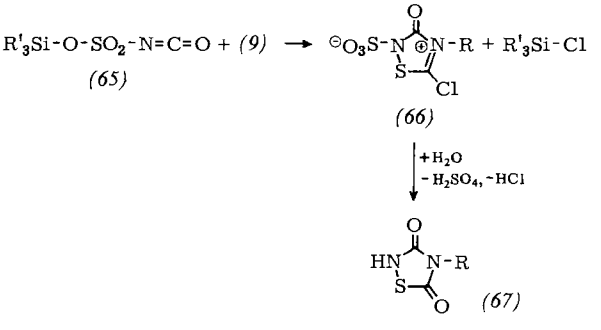
(63) *(34)*

Table 12. 3-Oxo-5-thioxo-1,2,4-thiadiazolidines *(63)*.

R'	R	M.p. (°C)	Yield (%) [a]
CH_3	CH_3	60	60
C_6H_5	CH_3	142–143	56
3,4-Cl_2–C_6H_3	CH_3	170	63

[a] Yields not optimized.

The aminolysis of *(62)* with primary aliphatic and aromatic amines leads to 5-imino-3-oxo-1,2,4-thiadiazolidines *(64)* (Table 13) [45,46].



(64)

Table 13. 5-Imino-3-oxo-1,2,4-thiadiazolidines *(64)*.

R'	R	R''	M.p. (°C) (B.p. (°C/torr))	Yield (%) [a]
C_4H_9	CH_3	C_4H_9	(110/0.05)	76.5
i-C_3H_7	C_6H_5	C_6H_{11}	101–102	81
C_6H_5	C_2H_5	C_6H_5	55–56	51
p-Cl–C_6H_4	C_6H_5	C_6H_5	134–135	6

[a] Yields not optimized.

A special case of the addition of iminochloromethanesulfenyl chlorides *(9)* to isocyanates is the addition to silyloxysulfonyl isocyanates *(65)* or the corresponding chlorination of isothiocyanates in the presence of *(65)*. These reactions lead to elimination of the chlorosilanes, again with formation of sparingly soluble products, for which we propose the structure of inner salts *(66)*. Their hydrolysis yields 1,2,4-thiadiazolidine-3,5-diones *(67)* with no substituent in position 2 (Table 14) [47].

(65) *(66)* *(67)*

Table 14. 1,2,4-Thiadiazolidine-3,5-diones *(67)*.

R	M.p. (°C)	Yield (%) [a]	R	M.p. (°C)	Yield (%) [a]

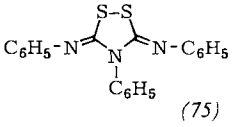
(73b)	CH_3	Cl_3C–CH_2	*p*-Cl–C_6H_4–N	95	37

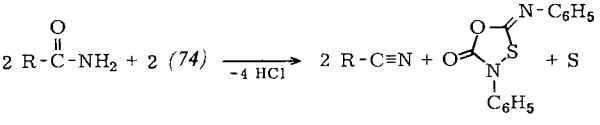
[a] Yields not optimized.



C-3. On aminolysis of *(71)* with primary aliphatic or aromatic amines, imino derivatives *(73)* are formed (Table 16).

4.2.4. Other Reactions

Thioureas react smoothly with the compounds *(9)* in the presence of a tertiary amine to form diiminodithiazolidines. For example, *N,N'*-diphenylthiourea reacts with *N*-phenyliminochloromethanesulfenyl chloride *(74)* to form 3,5-bis(phenylimino)-4-phenyl-1,2,4-dithiazolidine *(75)*.



(74)

(75)

The reaction of chlorocarbonylsulfenyl chloride *(7)* with primary amides (Section 3.2) cannot be applied to the compounds *(9)*. Whereas aliphatic compounds *(9)* give compounds such as *(58)* with primary amides (cf. Section 4.2.3), the aromatic compounds, *e.g. (74)*, give the 2-imino-5-oxo-1,3,4-oxothiazolidines, *e.g. (76)*, m.p. = 112 °C.

(76)

We are grateful to Prof. Dr. Holtschmidt for his valuable suggestions. Dr. Heitzer kindly recorded a large number of IR and NMR spectra and contributed to the progress of the investigations by discussion, while we are indebted to Dr. Weiss, Inorganic Section of Farbenfabriken Bayer AG, for providing the chlorocarbonylsulfenyl chloride.

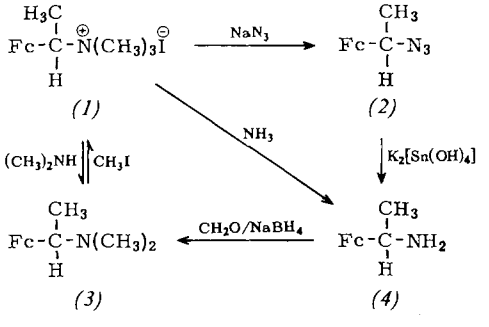
The Stereochemistry of the α-Ferrocenylethyl Carbonium Ion



By *G. Gokel, P. Hoffmann, H. Klusacek, D. Marquarding, E. Ruch*, and *I. Ugi* [*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

Recent investigations of the solvolytic reactions of α-ferrocenylalkyl compounds have demonstrated a pronounced stability of ferrocenylalkyl cations [1–8]. This is explained by assuming metal participation [1–3,6] or iron hyperconjugation [4,7,8].

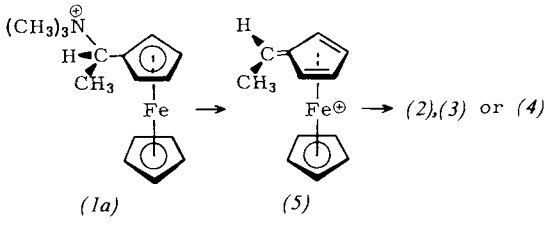
Both interpretations imply stereoselective nucleophilic substitutions of α-ferrocenylalkyl compounds. There is some evidence for the stereoselectivity of the above reactions [2,4,6,7] but to our knowledge no studies on the retention of optical activity during nucleophilic substitutions on non-cyclic centers of chirality having a ferrocenyl ligand have been performed.

With regard to the use of optically active 1-ferrocenylaminoalkanes as regenerable amine components in four-component peptide syntheses [9,10], we were interested in investigating the reactions depicted in Scheme 1, which involves several nucleophilic substitutions at a center of chirality bearing a ferrocenyl ligand.

Scheme 1. Fc = Ferrocenyl.

We observed complete retention of the configuration of the chiral center during the nucleophilic substitutions in this cycle. This is further relevant evidence for the unique influence of an α-ferrocenyl group upon the mechanism of nucleophilic substitution.

Reaction of (*R*)-α-ferrocenylethylamine *(4)* [10,11], ($[\alpha]_D^{20}$ = −20.8 °, *c* = 4.0 in ethanol) with formaldehyde (5 moles) and $NaBH_4$ (3 moles) in methanol at 0 °C yields 90% of *(3)* [b.p. 81 °C/0.035 torr; $[\alpha]_D^{20}$ = +14.0 °, *c* = 1.0 in ethanol; NMR in CCl_4 (rel. to TMS as internal std.): τ = 8.65 (d), *J* = 6.9 Hz, $-CH(CH_3)-N$, I_{rel} = 3; τ = 8.01 (s), $-N(CH_3)_2$, I_{rel} = 6; τ = 6.48 (q), *J* = 6.9 Hz, $-CH(CH_3)-$, I_{rel} = 1; τ = 6.00 (s), ferrocene protons, I_{rel} = 9; IR, film on KBr: 3092 cm^{-1}, 1108 cm^{-1}, 1000 cm^{-1}].



Methyl iodide (4.5 moles) in acetone alkylates *(3)* at 0 °C to form 95% of *(1)* [m.p. 126–127 °C; $[\alpha]_D^{20}$ = +41.6, *c* = 0.64 in methyl cellosolve].

In ethylene glycol-water (1 : 1) or diglyme-water (3 : 2) at 50 °C *(1)* (0.1 moles/kg) and sodium azide (0.6 moles/kg) react to form 88% of *(2)* [3] (b.p. 80 °C/0.02 torr; $[\alpha]_D^{20}$ = −66.1 °, *c* = 1.36 in benzene; NMR (CCl_4): τ = 8.52 (d), *J* = 6.8 Hz, $-CH(CH_3)-N$, I_{rel} = 3; τ = 5.90 (s), ferrocene protons; and τ = 5.72 (q), *J* = 6.8 Hz, $-CH(CH_3)$, I_{rel} (for ferrocene protons $+CH(CH_3)$) = 10. IR (film on KBr): 3090, 2095, 1105, 998 cm^{-1}.

The conversions of *(1)* into *(4)* (by conc. aqueous ammonia) and *(3)* (by dimethylamine in water or acetonitrile) at 20 °C also occur with retention.

The reduction of *(2)* with $K_2[Sn(OH)_4]$ [12] at 25 °C in methyl cellosolve-water (1 : 1) leads back to 90% of *(4)* [$[\alpha]_D^{20}$ = −20.8 °, *c* = 4.0 in ethanol; all data identical with those of an authentic sample].

We interpret the observed facts by assuming that *(1)* reacts from the conformation *(1a)* with concerted cleavage of the anti-periplanar Fe—C and C—N bonds, forming the cation *(5)* as an intermediate, which subsequently reacts with the nucleophilic azide anion; this is analogous to olefin-forming β-eliminations [13]. During the latter step, an N—C bond is formed by a process which resembles, sterically and electronically, a reversal of the elimination *(1a)* → *(5)*.

Nucleophilic substitutions of analogous α-ferrocenylalkyl systems bearing substituents on C-2 of the ferrocene also occur with retention with nucleophilic anions. Partial epimerization occurs with weaker nucleophiles. Recently, we found that (1*S*)-(*R*)-1-(2-trimethylsilylferrocenyl)-1-ethyltrimethylammonium iodide reacts with sodium methoxide in methanol to form (1*S*)-(*R*)-1-(2-trimethylsilylferrocenyl)-1-methoxyethane; with methanol alone a mixture of the latter and a minor amount of its (1*S*)-(*S*)-diastereomer results [14].

The steric peculiarities of α-ferrocenyl carbonium ions such as *(5)* are easily understood from the qualitative results of theoretical analyses of the bond systems of sandwich complexes [15].

This treatment indicates that the complex is stabilized by six bonding pairs of electrons which occupy hybrid orbitals of the rings and the central atom. These ring orbitals are the occupied π-orbitals of the isolated quasi-aromatic rings, and the central atom orbitals are of the d^2sp^3 configuration.

The relevant point for our problem is that the occupied bonding orbitals are linear combinations in which the ring orbitals participate with large coefficients and the central atom orbitals participate with small coefficients. This leads to the following qualitative description:

The essential difference between the π-electron distribution of the isolated rings carrying unit negative charge and that of the two complexed rings is a slight deformation of π-electron density toward the central atom in the latter case. The electron polarizability parallel to the plane of the rings is not appreciably affected. We can therefore draw conclusions about the present system from the electron distribution in fulvene and thus arrive at formula *(5)*.

Since there is an appreciable rotational barrier around the ferrocenyl-C_α bond (with a slightly weakened ring-metal bond), stereoisomeric α-ferrocenyl alkyl ions, such as *(5)* and its optical antipode, behave differently in chemical reactions (see also ref. [14]).

Thermal Cyclization of *o*-Chloroaryl Isothiocyanates

By *E. Degener, G. Beck*, and *H. Holtschmidt*[*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

The observation that numerous polychloro amine derivatives undergo stabilization by ring closure when heated, induced us to study the thermal behavior of polychloroaryl isothiocyanates. We found that *o*-chloroaryl isothiocyanates *(1)* cyclize to 2-chlorobenzothiazoles *(2)* in preparatively satisfactory yields at 330–380 °C, which are unusually high temperatures for organic reactions.

(1) *(2)*

	R¹	R²	R³	R⁴	(2) Yield (%)	M.p. (°C)
(a)	Cl	Cl	Cl	Cl	90	162–164
(b)	Cl	H	Cl	H	50	105–107
(c)	Cl	Cl	H	Cl	50	108–109
(d)	Cl	H	Cl	Cl	50	115–116
(e)	Cl	Cl	CN	Cl	50	185–189
(f)	—CCl=CCl—CCl=CCl—		Cl	Cl	90	260

Ring closure is particularly smooth and uniform for the polychlorinated isothiocyanates *(1a)* and *(1f)*; the less highly chlorinated isothiocyanates *(1b)–(1d)* give nitriles as well as *(2)*.

This cyclization is related to the isomerization of cyano-*N*-(pentachlorophenyl)formimidoyl chloride to hexachloroquinoxaline previously observed by us[1]; this also occurs only at high temperatures (*ca.* 400 °C) and similarly involves migration of an *o*-chlorine atom.

Direct Synthesis of Chlorinated Pyrimidines

By *R. Braden, K. Findeisen*, and *H. Holtschmidt*[*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

In recent years isocyanide dichlorides have become a readily accessible class of compounds[1]; their high chemical reactivity has led to a wide variety of new compounds[2]. On reaction with bifunctional nucleophiles, various kinds of ring closures can be accomplished[2,3]. α-Chlorinated aliphatic isocyanide dichlorides, whose α-chlorine atoms generally react first on nucleophilic substitution[4], occupy a special position. Compounds having mobile halogen atoms add readily to nitriles[5,6].

We have found that in the presence of Lewis acids at elevated temperatures α-dihalogenated isocyanide dichlorides *(1)* react with nitriles *(2)* bearing two hydrogen atoms in the α-position to give chlorinated pyrimidines *(4)*. The reaction takes place in two stages, the rate-determining step being the elimination of hydrogen chloride. In a number of cases, however, it was possible to stop the reaction at the first stage and to detect the primary product *(3)*.

R	(4) R¹	Yield (%)	M.p. (°C)
Cl	H	88	89–93

Cl	2,3,4-$Cl_3C_6H_2$	65	200
Cl	$NC-CH_2$	14	125
Cl	2-(2,4,6-trichloro-5-pyrimidinyl)ethyl	32	200
CCl_3	H	5	[a]
C_6H_5	H	58	88

[a] B.p. 140–155 °C/0.5 torr.

If the α-chlorine atoms of the isocyanide dichloride are replaced by hydrogen and the α-hydrogen atoms of the nitrile by chlorine the reaction proceeds in an analogous fashion. Of particular interest is the reaction of trichloroacetonitrile *(2')*, R^1 = Cl, with trichloromethyl isocyanide dichloride *(1)*, R = Cl; chlorine is evolved leaving a 30% yield of tetrachloropyrimidine (m.p. 67 °C).

$$R{-}CH_2{-}N{=}CCl_2 + R^1{-}CCl_2{-}CN \rightarrow (3) \rightarrow (4)$$
(1') *(2')*

R	R^1	*(4)* yield (%)	m.p. (°C)	b.p. (°C/torr)
Cl	Cl	46	67	
$ClCH_2$	Cl	5		130–145/0.5

The reaction is carried out in the following manner: The starting materials are mixed together, then mixed with about 0.1% of a Lewis acid (preferably iron(III) chloride) and heated to 200 °C. The process may be performed in low-boiling polar solvents in an autoclave or in high-boiling solvents under normal pressure.

Synthesis of Disulfonimides, *N*-Sulfonyl Carboxamides, and α-Oxo *N*-Sulfonyl Carboxamides

By *F. Bentz* and *G.-E. Nischk* [*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

Starting from *N*-sulfinyl sulfonamides *(1)* and sulfonic acids *(2)* we have prepared disulfonimides *(3)* in excellent yield [1] (see Table for examples).

The *N*-sulfinyl sulfonamides *(1)* can usually be obtained by boiling the sulfonamides with an excess of thionyl chloride,

$$R^1{-}SO_2{-}NSO + R^2{-}SO_3H \xrightarrow{40-150\,^\circ C} R^1{-}SO_2{-}NH{-}SO_2{-}R^2 + SO_2$$
(1) *(2)* *(3)*

R^1	R^2	*(3)* Yield (%)	M.p. (°C)
m-NO_2–C_6H_4	*p*-CH_3–C_6H_4	85	Isolated as K salt
C_6H_5	*p*-CH_3–C_6H_4	82	160
CH_3	*p*-CH_3–C_6H_4	92	116

usually without a solvent. Aliphatic or aromatic sulfonic acids may be used in the reaction, *e.g.*, methane-, chloroethane-, or benzene-sulfonic acid or their substitution products such as toluene- or chlorobenzene-sulfonic acid.

The components *(1)* and *(2)* are usually allowed to react in the molar ratio 1 : 1 in a melt or in the presence of a solvent. Solvents used were inert organic solvents such as toluene, chlorobenzene, and dichlorobenzene. Aliphatic and aromatic *N*-sulfinyl sulfonamides *(1)* also react with aromatic or aliphatic monocarboxylic acids, giving *N*-sulfonyl carboxamides [2].

$$R^1{-}SO_2{-}NSO + R^3{-}COOH \rightarrow R^1{-}SO_2{-}NH{-}COR^3 + SO_2$$
(1) *(4)*

R^1	R^3	*(4)* Yield (%)	M.p. (°C)
m-NO_2–C_6H_4	C_6H_5	73	173 (glacial acetic acid)
m-NO_2–C_6H_4	C_2H_5	84	115 (benzene)
C_6H_5	$ClCH_2$	67	104 (benzene)
m-NO_2–C_6H_4	Cl_2CH	63	137 (benzene)
C_6H_5	Cl_3C	61	92 (benzene)

The reactions, which are sometimes violent, are carried out in a melt or in an inert solvent (for examples see the Table).

N-Sulfinyl sulfonamides react with dicarboxylic acids, giving bis(substituted amides), *e.g.* *m*-nitrobenzene-*N*-sulfinylsulfonamide and adipic acid give an 82% yield of a product having m.p. 252 °C.

With oxamic esters or oxalic esters, sulfonamides give α-oxo *N*-sulfonyl carboxamides *(5)* in very high yield [3,4].

$$R^4{-}SO_2{-}NH_2 + \underset{\displaystyle COR^5}{\overset{\displaystyle |}{COOC_2H_5}} \xrightarrow{60-140\,^\circ C} R^4{-}SO_2{-}NH{-}COCOR^5 + C_2H_5OH$$
(5)

R^4	R^5	*(5)* Yield (%)	M.p. (°C)
m-NO_2–C_6H_4	$NHCH_3$	100	245
m-NO_2–C_6H_4	OC_2H_5	100	195
p-CH_3–C_6H_4	$NHCH_3$	100	156
m-NO_2–C_6H_4	NH_2	96	247
m-NO_2–C_6H_4	$N(CH_3)_2$	100	230
CH_3	$CH_2{=}C(CH_3){-}CONHCH_2NH$	100	208 (water)
C_6H_5	$(CH_2{=}CHCH_2)_2N$	87	95
m-NO_2–C_6H_4	$CH_2{=}CHCH_2NH$	100	178
C_6H_5	$CH_2{=}C(CH_3){-}CONHCH_2NH$	100	217

The sulfonamide is caused to react with an alkali hydroxide in an alcohol, preferably methanol, with addition of an aromatic hydrocarbon that boils higher than the alcohol. The alcohol and part of the aromatic hydrocarbon are distilled off at atmospheric pressure, then the oxamic ester or oxalic ester is added and the mixture is warmed (for examples see the Table).

The strongly acidic properties of these products *(3)*, *(4)*, and *(5)* give compounds of high molecular weight having very good dyeing properties towards basic dyestuffs.

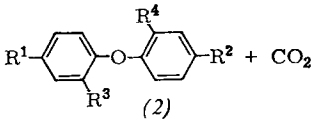
A New Synthesis of Substituted Diphenyl Ethers



By *H. Witt*, *H. Holtschmidt*, and *E. Müller*[*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday

It has already been reported[1] that phenyl *o*-phenoxybenzoate can be prepared in high yields by heating a melt of diphenyl carbonate in the presence of small amounts of K_2CO_3 at 230—270 °C. We have now found that the diphenyl ethers *(2)* can be prepared from *o*- and/or *p*-substituted diphenyl carbonates *(1)* when subjected to similar reaction conditions.

(1)

(2)

R¹	R²	R³	R⁴	Catalyst wt.-% calc. w. r. t. *(1)*	Temp. (°C)	Yield of *(2)* (%)[a]
NO_2	H	H	H	1 K_2CO_3	210—250	17
NO_2	NO_2	H	H	0.5 $KOCOCH_3$	180—205	>90
H	H	NO_2	NO_2	1 $KOCOCH_3$	190—220	41
NO_2	NO_2	NO_2	NO_2	1 $KOCOCH_3$	156—186	89
NO_2	NO_2	Cl	Cl	1 K_2CO_3	186—226	31
CN	CN	H	H	1 K_2CO_3	200—242	65
$SO_2C_6H_5$	$SO_2C_6H_5$	H	H	1 K_2CO_3	240—260	66
$COOCH_3$	$COOCH_3$	H	H	1 K_2CO_3	200—214	22

[a] Not optimized.

A prerequisite for this reaction is that at least one of the groups R¹—R⁴ is a second order substituent; preparatively useful yields, however, are obtainable only from symmetrically substituted, particularly *p,p'*-disubstituted, diphenyl carbonates. Numerous other alkali metal compounds may be used as catalysts (in amounts of 0.5—2 wt.-%) instead of potassium carbonate.

4,4'-Dinitrodiphenyl ether (2), $R^1=R^2=NO_2$, $R^3=R^4=H$[2]

4,4'-Dinitrodiphenyl carbonate (1000 g) (crude phosgenation product, m.p. 140 °C)[3] is melted (silicone oil bath) in a 2 l three-necked flask fitted with stirrer, internal thermometer, and a delivery tube connected *via* a bubble counter. Potassium acetate (5 g) is added slowly, with stirring, to the melt at a temperature of 150 °C. Decarboxylation (180—205 °C, bath temperature 190—215 °C) is complete after 4—5 hours. The temperature of the mixture is then allowed to drop to 150 °C, and, after the apparatus has been fitted with a reflux condenser, toluene (580 g) is added slowly. The solution is filtered hot from insoluble residue (*ca.* 8 g). The filtrate is then cooled and the 4,4'-dinitrodiphenyl ether which crystallizes out is recovered by filtration, washed with a little methanol, and finally dried in a vacuum (yield 749 g (88 %), m.p. 144 °C). A further 28 g can be recovered by concentration of the mother liquor, m.p. 142 °C, total yield 91 %. If recrystallized starting material is used, yields of more than 93 % of the ether can be obtained.

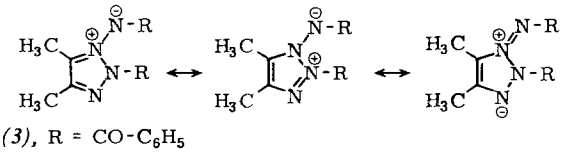
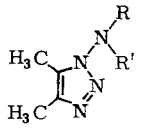
Mesoionic 2-Benzoyl-1-benzoylimino-4,5-dimethyl-1,2,3-triazole

By *S. Petersen* and *H. Heitzer*[*]



Dedicated to Professor K. Hansen on the occasion of his 60th birthday

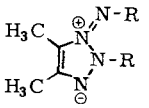
The oxidation product first prepared by *H. v. Pechmann* and *W. Bauer* by reaction of 2,3-butanedione bis(benzoylhydrazone) *(1)*[1] with potassium hexacyanoferrate(III) was formulated[2] as 2,3-dibenzoyl-5,6-dimethyl-2,3-dihydrotetraazine *(2)*.



(1) *(2)*

The ^{1}H-NMR spectra (in $CDCl_3$) of the oxidation product at 60 and 220 MHz[3] show that the compound does not have a symmetrical structure. Two methyl-group signals appear in the 60 MHz spectrum at 2.23 ppm and 2.36 ppm in addition to a multiplet (signal width *ca.* 20 Hz) centered at 8.1 ppm which is due to the protons of both aromatic rings that are *ortho* to the carbonyl groups. In the 220 MHz spectrum the multiplet is resolved into two pseudo doublets at 8.116 ppm and 8.236 ppm (J = 7.8 to 8.0 Hz). The remaining six aromatic protons absorb between 7.4 and 7.8 ppm. On the basis of these findings, therefore, we suggest that the oxidation product has the structure of a mesoionic triazole *(3)*,

(3), R = $CO-C_6H_5$



which is in agreement with the chemical properties of this compound. The ready hydrolytic and thermal loss of a benzoyl group is now understandable since the compound is being considered as an azolide[4]. As is already known, compound *(3)* affords 1-(dibenzoylamino)-4,5-dimethyl-1,2,3-triazole *(4)*[5] when heated and 1-benzoylamino-1,2,3-triazole *(5)* when treated with hydrochloric acid. Hydrolysis of *(3)* with concentrated hydrochloric acid at higher temperatures leads to formation of the free 1-amino-4,5-dimethyl-1,2,3-triazole *(6)*[2]. We have obtained 4-chlorobenzoic anhydride as reaction product by recrystallizing compound *(7)*

(4), R = R' = COC_6H_5

(5), R = COC_6H_5, R' = H

(6), R = R' = H

(7), R = $COC_6H_4Cl(p)$

from aqueous dimethylformamide. All these secondary reactions can now be adequately explained without recourse, as previously, to complicated assumptions of rearrangement and ring contraction.

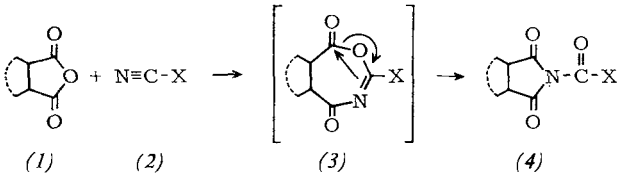
Direct Conversion of Cyclic Carboxylic Acid Anhydrides into Carboximide Derivatives



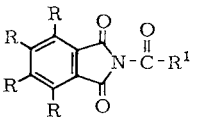
By *E. Grigat* [*]

Dedicated to Professor K. Hansen on the occasion of his 60th birthday.

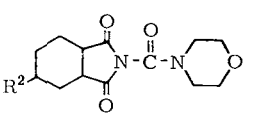
Although cyanates *(2)*, X = OR, react with carbonyl halides to give *N*-acyliminocarbonic halides [1], attempted reactions with carboxylic anhydrides have so far been unsuccessful [2, 3].

Cyclic anhydrides of aromatic and cycloaliphatic dicarboxylic acids *(1)* are exceptions. They react exothermally with cyanates *(2)*, X = OR, at 150 °C in the presence of catalytic amounts of triethylamine to give *N*-acylated cyclic dicarboximides *(4)*, X = OR. Cyanamides react analogously, even without addition of triethylamine, to give *(4)*, X = NR_2 (see Table). The reaction probably proceeds, like reaction of *(2)* with acid halides, *via* a primary *N*-acylation of the CN group. The non-isolable primary addition product *(3)* is stabilized by intramolecular transacylation to *(4)*.

The compounds *(4)*, X = OR, can be converted into compounds *(4)*, X = NR_2, by reaction with amines.



(1) *(2)* *(3)* *(4)*



N-(2,4-Dimethylphenoxycarbonyl)phthalimide (4a)

A mixture of phthalic anhydride (29.6 g, 0.20 mole) and 2,4-dimethylphenyl cyanate (32.5 g, 0.22 mole) is heated and stirred at 180 °C. On adding a few drops of triethylamine the temperature of the mixture rises to 230 °C. After 15 minutes' stirring, the reaction mixture is cooled, mixed with about 50–80 ml alcohol, and the compound *(4a)* which separates is recovered by filtration (48 g = 81% yield).

Table. Representative carboximide derivatives.

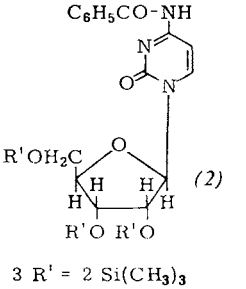
Separation of Nucleosides on Polymer Gels Containing Thymine or Cytidine

By *G. Greber* and *H. Schott* [*]



By using Amberlite ion exchangers, which contained covalent built-in nucleoside species, *Tuppy* and *Küchler* [1] were able to separate *via* the base-pairing reaction of *Watson* and *Crick* [2] the corresponding nucleoside from an aqueous solution of two nucleosides. These experiments were carried out with extremely small amounts of substance (0.04 mg/0.04 ml).

In the meantime it has been established [3,4] that measurable base pairing of nucleosides takes place only in chloroform or

(1)

R = $Si(CH_3)_3$

(2)

3 R' = 2 $Si(CH_3)_3$

dimethyl sulfoxide (DMSO) and not in water. Separation of nucleosides on a preparative scale ought to be possible, therefore, on organic polymer gels which swell in these solvents and which contain covalent nucleoside residues.

We have prepared such gels and tested their separation efficiency regarding the nucleosides thymidine (T), adenosine (A), cytidine (C), and guanosine (G). 1-[2,3,4-*O*-tris(trimethylsilyl)-6-methacryloyl-β-D-glucopyranosyl]thymine *(1)* and N^4-benzoyl-$O^{x'}$,$O^{y'}$-bis(trimethylsilyl)-$O^{z'}$-methacryloylcytidine *(2)* [5] were copolymerized radically with tetramethylene dimethacrylate to give insoluble thymine- and cytidine-containing polymer gels that swell in organic solvents. Cleavage of the trimethylsilyl groups with HCl/acetone and of the trimethylsilyl- and benzoyl groups with NH_3/methanol afforded T gels and G gels, which swell in DMSO or DMSO/$CHCl_3$ and exhibit very good flow rates.

With T gels it was not possible to separate the 1 : 1 complex of the two corresponding nucleosides formed from equimolar amounts of T and A in DMSO. On the other hand it was possible to separate the excess amounts of A from the 1 : 1 complex formed from a mixture of T and an excess of A. In experiments with an analogous sample gel that did not contain T species, no interactions took place and consequently there was no separation effect.

In separation experiments carried out with CG mixtures on C gels similar results were obtained as with TA mixtures on T gels. With C gels, however, it was found that not only good separation of the 1 : 1 TA complex could be accomplished but also that the separation could be improved by lengthening the column. The two non-classical 1 : 1 complexes between A and G and between T and G can be completely separated on C gels. These results confirm indirectly the interaction energies [6] calculated for vacuum for the classical and non-classical base pairs. Accordingly, the value for the base pair CG (—19.2 kcal/mole) is almost three times higher than that for the other combinations (AT = —7.0, AC = —7.8, AG = —7.5, TG = —7.4, and TC = —6.5 kcal/mole).

Chromatographic procedure:

Glass columns, 48 cm in length and 1 cm in diameter, were filled with 18 g of swollen T- or C-gel — a mixture of DMSO/$CHCl_3$ (2 : 3) being used as swelling agent. For separation, up to 100 mg of mixed nucleosides was dissolved in DMSO (*ca.* 20 mg/ml), transferred to the column, and then developed at room temperature with a mixture of DMSO/$CHCl_3$ (2 : 3), the flow rate being about 38 ml/h. The separation process was monitored in a measuring cell using a Uvicord-Ultraviolet absorptiometer and recorded in the form of a UV absorption diagram by an LKB pen recorder. Samples of the eluate were collected at regular intervals and the separation of the nucleosides examined by UV absorption measurements using a Zeiss spectrophotometer PMQ 11 at E_{280}/E_{260} nm.

The Color of Trimethylsilyl Derivatives of Diimine [1]

By *H. Seidl*, *H. Bock* [*], *N. Wiberg*, and *M. Veith* [**]

The n→π* excitation energies of hetero atom chromophores are lowered drastically by trimethylsilyl substituents (Table 1); for instance bis(triphenylsilyl) ketone [2,3] is violet in contrast to the colorless dialkyl ketones, and bis(trimethylsilyl)diimine [5] is blue in contrast to the colorless dialkyldiimines [6].

Table 1. n→π* excitation energies (cm^{-1}) of silyl- and alkyl-substituted hetero atom chromophores [R = C_6H_5 in $(R_3Si)_2CO$, otherwise CH_3].

X	 [3]	 [4]	X—N=N—X [5, 6]
CR_3	35800	40200	27200
CR_3/SiR_3	26800		20000
SiR_3	18500	33400	12750

On the basis of experimental data [7] the color of the silyl ketones has to be ascribed to the strong inductive rise of the highest occupied n-orbital of the oxygen atom due to the R_3Si group in the β-position and to the lowering of the π*-orbital by $Si \leftarrow C_\pi$ interaction with unoccupied atomic orbitals of silicon in α-position to the C=O π-system. The long-wavelength shift of the n→π* absorption band of bis(trimethylsilyl)diimine whose R_3Si groups are in α-position to both the N=N π-system and to the nitrogen lone pairs n_N is, however, still unexplained.

For a study of the substituent effects on the azo chromophore [8] we selected the more stable phenyl derivatives *(1)* [9] and *(2)* [10], for which additional experimental data can be obtained. Their ionization energies (determined by mass spectroscopy [11]), electron-spectroscopic excitation energies, and half-wave reduction potentials [12] are collected in Table 2.

Table 2. Experimental data for *tert*-butyl- *(1)* and (trimethylsilyl)-phenyldiimine *(2)*.

	C_6H_5—N=N—$C(CH_3)_3$ *(1)*	C_6H_5—N=N—$Si(CH_3)_3$ *(2)*
$IE(n_N)$ (eV)	7.75	7.05
$\tilde{\nu}_m^{n\to\pi^*}$ (cm^{-1}) [13]	24400	17250
$\tilde{\nu}_m^{\pi\to\pi^*}$ (cm^{-1}) [13]	38400	37500
$E_{1/2}^{Red}$ (V)	—1.35	—1.13

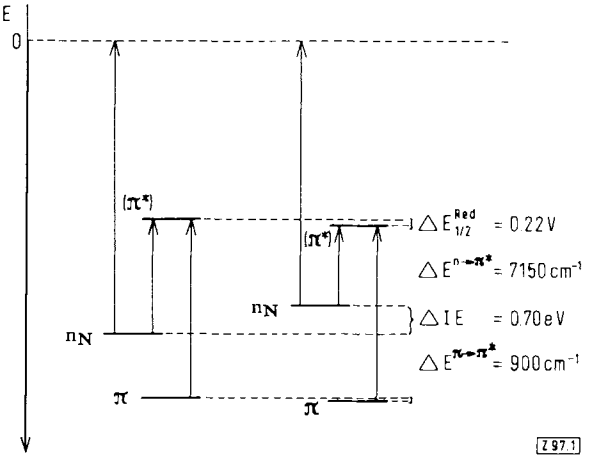

Fig. 1. Experimental energy level schemes for *tert*-butyl- *(1)* and trimethylsilyl-phenyldiimine *(2)*.

Comparison of the energy level schemes for the inner molecular orbitals of *(1)* and *(2)* drawn up from the data in Table 2 shows that the R_3Si substituent in phenyldiimine derivatives also increases the energy of the nitrogen lone pair n_N whilst lowering the π-molecular orbitals. The decreased $n\rightarrow\pi^*$ excitation energy of *(2)*, and thence also of bis(trimethylsilyl) diimine, is then to be explained as in the case of the silyl ketones[7]. However, as the rise in the n_O level of the oxygen due to silicon in the β-position amounts to 0.9 eV relative to the standard *tert*-butyl phenyl ketone[7], a difference in the ionization potential $\Delta IE > 1$ eV would be expected between the alkyl- and the silyl-substituted phenyldiimine derivatives, because the inductive effect of substituents in the α-position should be enhanced by a factor $I_\alpha/I_\beta \approx 1.6$[14].

The observed difference of only 0.7 eV can be accounted for by an additional $Si\leftarrow n_N$ interaction (in the direction opposite to the inductive increase) of the n_N lone pair with unoccupied atomic orbitals of the silicon in α-position to the nitrogen[15]. The interaction should lead to an increase in the NNSi angle since a wider angle favors the overlap[16].

Neither the NNSi angles[13] in the trimethylsilyldiimine derivatives nor the interaction between the two n_N electron pairs discussed for azo compounds[6,8] is known. Since, however, the whole visible and ultraviolet region of the electronic spectrum of bis(trimethylsilyl)diimine shows only the $n\rightarrow\pi^*$ absorption at 12750 cm^{-1}, the n_a/n_s splitting must exceed 4.7 eV[17].

[12] Measured in a 0.1 M *N,N*-dimethylformamide solution of tetrabutylammonium iodide against the mercury pool at 25 °C.

[13] The corresponding extinction values $\varepsilon_m^{n\rightarrow\pi^*}$ and $\varepsilon_m^{\pi\rightarrow\pi^*}$ ($l \cdot mole^{-1} \cdot cm^{-1}$) are for *(1)* 100 and 7100, respectively, and for *(2)* 29 and 16350, respectively. As for the (trimethylsilyl)styrenes, the differences in the $\pi\rightarrow\pi^*$ transitions are explained by expansion of the π-system in *(2)*; for the $n\rightarrow\pi^*$ transitions they possibly can be interpreted on the basis of increased p hybridization of the lone pair due to widening of the angle and the thus more strongly overlap-forbidden transition in the case of the silicon compound.

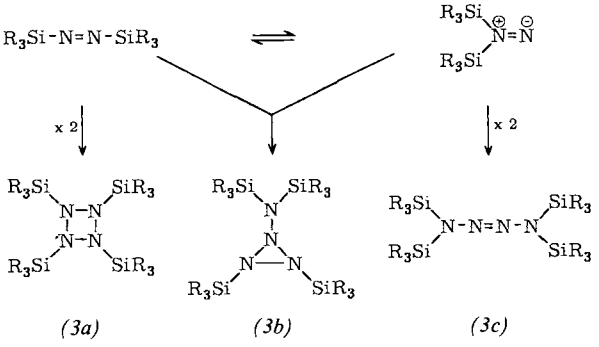
[17] *Note added in proof*: The n_a/n_s splitting in azomethane has been found by photoelectron spectroscopy to amount to 3.3 ± 0.2 eV [*E. Haselbach, J. A. Hashmall, E. Heilbronner*, and *V. Hornung*, Angew. Chem. *81*, 897 (1969); Angew. Chem. internat. Edit. *8*, 878 (1969)].

1,1,4,4-Tetrakis(trimethylsilyl)tetrazene[1]



By *N. Wiberg* and *W. Uhlenbrock*[*]

Thermal decomposition of bis(trimethylsilyl)diimine *(1)* below 0 °C affords almost exclusively tetrakis(trimethylsilyl)-hydrazine *(2)* and nitrogen[2]. We have now found that an increase in thermolysis temperature reduces the yield of these two products; instead, other thermolysis products are formed, and in particular a compound having the composition $(R_3Si)_4N_4$ *(3)* (R = CH_3; elemental analysis, mass spectrum) as well as tris(trimethylsilyl)hydrazine *(4)*.

The hydrogen required for formation of *(4)* comes from methyl groups; those molecules affected by hydrogen abstraction react further to give various products that have not yet been examined in detail.

The ^1H—NMR spectrum of compound *(3)* contains only one signal in the $(CH_3)_3Si$ region [δ = —16.7 Hz, measured against TMS as internal standard in benzene[3]]. Thus, of the isomers *(3a)*, *(3b)*, and *(3c)* that are *formally* possible according to

(3a) *(3b)* *(3c)*

(3b) can be ruled out (the same applies to the compound $(R_3Si)_2N{-}N(SiR_3){-}N{=}N(SiR_3)$). The IR and Raman spectra indicate the presence of *(3c)* rather than *(3a)*; unequivocal evidence for an atomic skeleton containing an N=N bond comes, in particular, from the position, intensity, and polarization of a band at 1444 cm^{-1} that is absent from the Raman spectrum of *(2)*[4]. The electronic spectrum of the compound also lends support to the 2-tetrazene structure: as in the case of organic tetrazenes[5] an $n\rightarrow\pi^*$ transition of medium intensity is observed at about 280 nm, λ_{max} = 293 nm, (ε = 5820).

The exclusion rule apparent from the vibrational spectra and the small dipole moment of $\mu = 0.45$ D[3] also indicate that *(3c)* is present in the *trans* configuration (C_{2h}).

The colorless, crystalline tetrakis(trimethylsilyl)tetrazene, which melts at 38—39 °C[3] and sublimes at about 70 °C[3], is the first silyl-nitrogen compound known to contain a four-membered nitrogen chain. It decomposes very slowly above about 160 °C, yielding mainly hexamethyldisilazane and nitrogen

$$(3c) \xrightarrow[+\,2H]{>160\,^\circ C} 2\,(R_3Si)_2NH + N_2$$

As in the case of thermolysis of *(1)*, hydrogen transfer leads to by-products that have not been investigated further. Under normal conditions *(3c)* does not react with oxygen and is not attacked by water below 130 °C. Acids catalyze the hydrolysis of *(3c)* to ammonium azide and hexamethyldisiloxane

$$(3c) \xrightarrow[-\,2R_3SiOSiR_3]{+\,2\,HOH} (H_2N{-}N{=}N{-}NH_2) \longrightarrow [NH_4]N_3$$

Procedure:

A pure sample of *(1)*[2] (36.17 g, 207.5 mmoles) in benzene (200 g) is heated to 150—160 °C for 1 h in an extremely dry, sealed bomb tube; 32.3 % of the nitrogen in the compound is liberated during thermolysis. Fractional distillation of the reaction mixture at 65—75 °C/*ca.* 10^{-3} torr yields a colorless mixture of *(2)* and *(3)*, from which pure *(3)* (5.10 g, 14.63 mmoles; yield 14.1 %) can be isolated by repeated recrystallization from pentane at —78 °C.

Structure of the Anion in Solid $K_4[Ni_2(CN)_6]$

By *O. Jarchow*[*], *H. Schulz*, and *R. Nast*[**]

"Bellucci's salt" $K_4[Ni_2(CN)_6]$ has already been subjected to preliminary X-ray structure analysis[1,2] and been investigated in a series of IR and Raman studies[3–6], the results of which, however, have so far failed to provide an unequivocal answer to the long-discussed question of the structure of the $[Ni_2(CN)_6]^{4-}$ ion. A recent X-ray study of the compound[7] has now yielded the structure shown in the Figure for the hexacyanodiniccolate(I) ion. The dinuclear anion is seen to contain two almost planar tricyanoniccolate(I) units that are linked *via* an Ni—Ni bond about which they are twisted by 82 ° with respect to each other. The mean deviation of the cyano ligands from the respective $Ni(CN)_3$ planes is 0.04 Å and thus approaches the limits of experimental accuracy. The somewhat greater deviation of the Ni atoms from these planes — 0.18 Å for Ni-1 and 0.16 Å for Ni-2 — is interpreted as a steric effect of the potassium ions (not shown in the Figure).

[Z 111 3]

The Ni—Ni bond of 2.32 Å is remarkably short; the Ni^I radius (1.16 Å) calculated from this figure is of the same order of magnitude as the value given by *Pauling* for the Ni radius in purely metallic bonding. The mean length of the Ni—C bond is 1.91 ± 0.02 Å, that of the C—N bond 1.13 ± 0.02 Å. The angles Ni-2—Ni-1—C-3 and Ni-1—Ni-2—C-6 not shown in the Figure are each equal to 169 ° and thus deviate considerably from 180 °.

The possibility of additional linkage of the Ni atoms *via* cyano bridges[1,3,5] can now be ruled out since the distances Ni-2—C-1 (2.90 Å) and Ni-1—C-4 (2.96 Å) are far too great for such bonding.

The symmetry of the complex anion in the solid approaches 2 (C_2); the slight deviations observed are attributed to the low overall symmetry $P\bar{1}$ of the structure. The twofold axis is vertical in the plane of the Figure and passes through the center of gravity of the Ni—Ni dumbell.

3-Isopropylidene-2,2-dimethyloxirane (Tetramethylallene Oxide)[1,2]

By *H. M. R. Hoffmann* and *R. H. Smithers*[*]

Allene oxides show promise as versatile intermediates in numerous reactions, for instance as precursors of allylic cations in (4 + 3) cycloadditions[3]. We have obtained 3-isopropylidene-2,2-dimethyloxirane (tetramethylallene oxide) *(3)* in two simple stages starting from readily available diisopropyl ketone *(1)*, which on PBr_3-catalyzed bromination gives the known 1,3-dibromoketone *(2)*[4]. Debromination of *(2)* with a zinc-copper couple in dimethylformamide affords a *ca.* 5 % solution of compound *(3)*[5]. To our surprise tetramethylcyclopropanone[7] was *not* formed under these conditions. Solutions of *(3)* in dimethylformamide are stable at —78 °C and also for one hour at 35 °C, provided that $ZnBr_2$ is absent.

(4a), X = Cl
(4b), X = Br
(4c), X = OAc
(4d), X = OCH_3
(4e), X = OH

(3) reacts with a variety of compounds containing acidic hydrogen to form the ring-opened keto derivatives *(4)*. For instance, passage of gaseous hydrogen chloride into a solution of *(3)* immediately gives rise to *(4a)* [8], while gaseous hydrogen bromide affords *(4b)* [9]. A solution of *(3)* and acetic acid form the acetate *(4c)* [6a]. *(3)* and methanol react to *(4d)* [9], which interestingly can also be prepared from *(2)* by debromination with a zinc-copper couple in methanol. *(3)* and water form *(4e)* [9], also obtainable in high yield directly from *(2)* by treatment with a zinc-copper couple in tetrahydrofuran-water (4 : 1 v/v) at room temperature. *(3)* and D_2O give rise to *(4f)*; ^{1}H-NMR in dimethylformamide: τ = 8.95 (6H/br. s), τ = 8.7 (6H/s). Generally, ring-opening of *(3)* is markedly accelerated by $ZnBr_2$. The compounds *(4)* were identified by NMR spectroscopy and, when known, by comparison with authentic material.

3-Isopropylidene-2,2-dimethyloxirane (3)

A solution of 2,4-dimethyl-2,4-dibromo-3-pentanone *(2)* [4] (5 g) in dimethylformamide (DMF) (7 ml) is added dropwise to a stirred suspension of a zinc-copper couple (3.6 g) in DMF at −10 °C under nitrogen. Debromination ensues immediately as shown by the rise in temperature to *ca.* −5 °C. After completed addition of *(2)* the reaction mixture is stirred for a further 30 min and the excess of the metal removed by rapid filtration under nitrogen. In order to remove the $ZnBr_2$ the mother liquor (*ca.* 25 ml) is diluted with formamide (25 ml) and distilled at −10 °C/0.002 torr into a trap kept at −78 °C. A *ca.* 5% solution of *(3)* in DMF results, the formamide remaining behind together with $ZnBr_2$. ^{1}H-NMR in DMF: τ = 8.44 (6H/s), τ = 8.55 (3H/s), τ = 8.65 (3H/s). IR (in DMF): 1145 cm^{-1}; other region obscured by bands of DMF. Mass spectrum: *m/e* = 112 and fragmentation peaks consistent with a partial rearrangement into tetramethylcyclopropanone (cf. also [6b,9]).

Transfer of Methoxyphenylcarbene Ligands from Molybdenum to Iron and Nickel [1]

By *E. O. Fischer* and *H.-J. Beck* [*]

Earlier experiments had shown that in the thermal decomposition of methoxyphenylcarbenepentacarbonylchromium(0) [2] the ligand $:C(OCH_3)C_6H_5$ undergoes dimerization with formation of *cis*- and *trans*-α,α′-dimethoxystilbene [3]. Meanwhile we have succeeded for the first time in transferring a carbene ligand from one metal to another. When subjected to UV irradiation methoxyphenylcarbenecarbonylcyclopentadienylnitrosylmolybdenum(I) *(1)* [4] reacts with pentacarbonyliron in benzene to give methoxyphenylcarbenetetracarbonyliron(0) *(2)*, which could not be prepared [6] by conventional methods [2, 5].

$$C_6H_5Mo(NO)(CO)C(OCH_3)C_6H_5 + Fe(CO)_5 \xrightarrow[C_6H_6]{h\nu}$$
(1)

$$(CO)_4FeC(OCH_3)C_6H_5 + C_5H_5Mo(NO)(CO)_2 + \ldots$$
(2)

Characterization of the iron complex *(2)*, which is red-brown, sensitive to air, readily volatile, and diamagnetic, follows from the mode of preparation, total analysis, and spectroscopic findings.

The ^{1}H-NMR spectrum of *(2)* in deuterioacetone contains two singlets of relative intensities 5 : 3 at $\tau_{C_6H_5}$ = 2.54 and τ_{OCH_3} = 5.15. Four ν_{CO} bands occur in the IR spectrum (*n*-hexane; LiF optics) at 2055 m (A_1), 1990 m (A_1), 1964 s, and 1947 cm^{-1} s (both resulting from E), which are to be expected for a molecule of symmetry C_{3v} containing an asymmetric ligand such as $:C(OCH_3)C_6H_5$ in an axial position [7,8].

The mass spectrum [9] (50 eV), which provides independent confirmation of the composition of *(2)*, shows the molecular ion at *m/e* = 288, the fragmentation pattern $[(CO)_nFeL]^+$, *n* = 4, 3 . . . 0, expected for the $(CO)_4Fe$ residue, and the typical mass line *m/e* = 240 for the dimerized carbene ligand. A dipole moment measurement in cyclohexane at 20 °C yielded a value of μ = 3.19 ± 0.1 D.

At present the question whether the transfer reaction proceeds *via* a phenylmethoxycarbene formed as intermediate or whether *(2)* occurs by direct reaction of molecules *(1)* with $Fe(CO)_4$ fragments cannot be answered. A further similar transfer reaction should also be mentioned in which tetracarbonylnickel reacts with *(1)* immediately on stirring in tetrahydrofuran without UV irradiation to give a violet diamagnetic product that is very sensitive to air. On the basis of current spectroscopic findings (IR, ^{1}H-NMR), partial analysis, and a mass spectroscopically determined

molecular weight $m/e = 620$, we would expect a trimeric structure with empirical formula $[Ni(CO)C(OCH_3)C_6H_5]_3$ having terminal CO ligands and $C(OCH_3)C_6H_5$ groups.

Experimental:

All operations must be carried out in an inert gas and in a fume cupboard since metalcarbonyls are extremely poisonous. A solution of *(1)* (1.65 g, 4.8 mmole) and $Fe(CO)_5$ (6.47 ml, 48 mmole) in benzene (100 ml) is vigorously stirred and subjected to UV irradiation (water-cooled, high-pressure lamp Q 81, Quarzlampen GmbH, Hanau) for a period of 5 hours. The reaction mixture is filtered through a G4 frit and the solvent removed at reduced pressure. The brown-yellow residue is taken up in 5 ml of an hexane/benzene mixture and then purified by column chromatography (silica gel, Merck) with hexane and benzene.

The first dark-red zone contains *(2)* as a red-brown, analytically pure oil (yield *ca.* 20% w.r.t. *(1)*), which is readily soluble in organic solvents.

Tetraphenyl Orthosulfite

By *J. I. Darragh* and *D. W. A. Sharp* [*]

Previously the only known orthosulfite was the perfluoropinacol derivative *(1)*, which can be prepared [1] by the action of disodium perfluoropinacolate on sulfur tetrachloride. We have now found, however, that phenyl orthosulfite *(2)* can be prepared by reaction of more than 3 moles

(1)

(2)

of phenoxytrimethylsilane with one mole of sulfur tetrafluoride. The action of smaller ratios of phenoxytrimethylsilane on sulfur tetrafluoride leads to formation of phenoxytrifluorosulfur *(3)* and diphenoxydifluorosulfur *(4)*, along with traces of triphenoxyfluorosulfur *(5)*. Full analytical data are available for compounds *(2)*, *(3)*, and *(4)*; compound *(5)* has been characterized by spectroscopic data only. The ester *(2)* is a white hygroscopic solid which is hydrolyzed to phenol and diphenyl sulfite.

The coordination arrangement about the S^{IV} atom in *(2)* when it is surrounded by four oxygens is of interest since the lone pair of electrons on the sulfur should be stereochemically active and the structure derived either from a trigonal bipyramid or a square pyramid. The ^{1}H-NMR spectrum of *(2)* is complex and cannot be used to obtain definitive information on the stereochemistry of the molecule; the ^{19}F-NMR spectra (see Table) of compounds *(3)*, *(4)*, and *(5)*, on the other hand, are closely analogous to that of SF_4 [2], which has been shown by microwave spectroscopy to have a structure derived from a trigonal bipyramid [3]. It is noteworthy that the ^{19}F-NMR spectrum of *(3)* shows non-equivalence of the fluorine atoms at room temperature; previous studies of mono-substituted derivatives of SF_4 have shown equivalence of the fluorine atoms at room temperature [4]. The spectra of *(4)* and *(5)* are consistent with fluorine atoms in the apical positions of the trigonal bipyramid. All of this evidence strongly favors a coordination arrangement in *(2)* in which the oxygens are arranged at four apices of a trigonal bipyramid with the lone pair of the sulfur occupying an equatorial position.

Table: ^{19}F-NMR data of sulfur tetrafluoride and its phenoxy-substituted derivatives (measured in CD_3CN; external standard CCl_3F).

Compound	F_{axial} (ppm)	$F_{equatorial}$ (ppm)	J_{F-F} (Hz)
SF_4	−116.4 [2]	−69.4 [2]	78 [2]

A Reinterpretation of the ESR Spectrum Ascribed to a Non-degenerate State of the Benzene Radical Anion [***]

By *J. Kelm* and *K. Möbius* [*]

Köhnlein, Böddeker, and *Schindewolf* [1] observed a 15-line ESR spectrum for solutions of benzene(−) at 0 °C produced by reduction of benzene by a Na—K alloy in dimethoxyethane/tetrahydrofuran (DME/THF); they interpreted this finding on the basis of the assumption that the unpaired electron occupies the symmetrical benzene orbital. This observation is of particular interest because it indicates that counter ions can remove the orbital degeneracy and stabilize the symmetrical MO.

In our attempts to reproduce the 15-line spectrum we found that it occurs only when the solvent DME/THF is dried with $LiAlH_4$; the spectrum is not obtained when the solvent is dried only with Na—K alloy under high vacuum (cf. ref. [1b, 2]).

Like *Wormington* and *Bolton* [3], we succeeded in resolving each of the 15 lines into more than 13 components. Attempts to simulate this substructure by hyperfine structure (HFS) splitting of four equivalent alkali metal ions failed to reproduce the gradual decrease in intensity of the outermost lines. *Wormington* and *Bolton* [3] simulated the substructure on the

assumption of an additional HFS splitting with at least seven further protons.

We therefore agree with these authors that the radical in question, hereafter designated X, is not benzene(—) whose degeneracy has been lifted but a product of its reaction with the solvent. In order to substantiate this hypothesis, we have measured the g factors of benzene(—) and of X (relative error ±2.5 ppm) at various temperatures (see ref. [4] for measuring technique): The values show a weak but significant temperature dependence (Table); comparison of the two radicals was on the basis of the values recorded at −30 °C (Fig. 1).

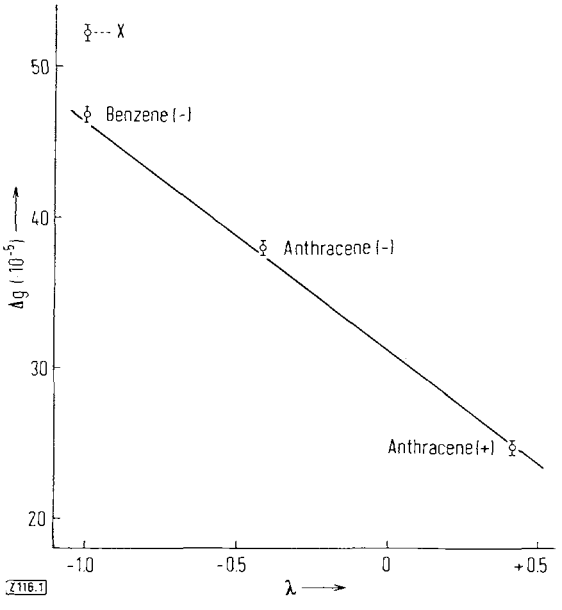

Fig. 1. Stone plot, $\Delta g = f(\lambda)$.

Table 1. Variation of g factors (not corrected for second-order effects) of benzene(—) and in X with temperature.

T (°C)	Benzene(—)	T (°C)	X
−32	2.002787	+25	2.002829
−64	2.002810	−30	2.002841
−84	2.002828	−70	2.002838

According to *Stone* [5], the deviation of the g factor from the value for the free electron $g_0 = 2.002319$ is a linear function of the Hückel energy coefficient λ of the lowest half-filled π orbital. With our instrumentation, the Stone line has the analytical form $\Delta g = [(31.2 \pm 0.4) - (15.1 \pm 0.7)\ \lambda] \times 10^{-5}$ [6], which we were able to verify by subsequent measurements of the g factors of anthracene(—) (2.002699) and anthracene(+) (2.002566).

If the X spectrum is assigned to a nondegenerate state of benzene(—), then $|\lambda|$ should decrease by about 0.07 (this estimate is based on an energy drop of 500 cm^{-1} for the symmetrical MO [7] and a resonance integral of −20 kcal/mole [8]). Accordingly, the g factor of the X spectrum should be about 5 ppm *smaller* than the g factor of benzene(—). The opposite effect is observed (Table and Fig. 1). If an alkali metal ion pair is present the g factor should be even smaller [9]. Not only the experimental findings (cf. ref. [3]) but also the fact that addition of LiCl to solvents that have been treated with with K—Na fails to give the X spectrum (although the HFS then observed suggests "contact") [10] appear to refute the assumption that X is an isolated benzene(—)/counter ion whose degeneracy has been lifted. Like the unsuccessful simulation attempts, the large g factor of X contradicts the assumption of an ion pair but rather suggests a reaction product. If the radical X were a pure hydrocarbon then $|\lambda|$ should also be smaller than 1; according to *Stone*'s theory a product of this kind should have a smaller g factor than benzene(—).

We therefore believe that the X spectrum arises from an unknown product of benzene(—) with the solvent, whose formation is favored by the presence of $LiAlH_4$, and in which the unpaired electron can delocalize to a fractional extent into the p orbitals of the oxygen. It is conceivable that the Al nuclei ($I = 5/2$, $\mu = 3.64\ \mu_N$) also contribute to the HFS interaction in this product since, according to *Paddock* [11], the equilibrium

$$[AlH_4]^- \rightleftarrows H^- + AlH_3$$

is set up in ethereal solvents, the ether coordinating with AlH_3 and thus shifting the equilibrium to the right; on distillation AlH_3 is found in the distillate [10, 11].

Synthesis of *p*-Quinones with Thallium(III) Trifluoroacetate[1]

By *A. McKillop, B. P. Swann, M. J. Zelesko*, and *E. C. Taylor* [*]

Much of the present interest in the chemistry of 4-*tert*-butylphenols has been centered upon the ease with which they may be converted, by treatment with nucleophiles in the presence of one-electron oxidizing agents [2], into 4,4-disubstituted cyclohexadienones which then, by acid-catalyzed loss of isobutylene [3], yield 4-substituted phenols. We describe a useful extension of this general principle which permits the direct conversion of 2,6-disubstituted 4-*tert*-butylphenols into the corresponding 2,6-disubstituted *p*-quinones.

We have found that thallium(III) trifluoroacetate [4] is an extremely effective oxidizing agent for *p*-quinone synthesis. Thus, a 2,6-disubstituted 4-*tert*-butylphenol (0.05 mole) is stirred for 1—2 h with a standard solution of thallium(III) trifluoroacetate (0.11 mole) in trifluoroacetic acid (TFA), excess TFA evaporated under reduced pressure, the residue poured into 50 ml of ice-water, and the *p*-quinone *(5)* isolated by extraction with chloroform and evaporation of the dried extracts. Typical *p*-quinones prepared in this manner are given in the Table.

We suggest that these oxidations proceed as shown in the above Scheme [for the formation of intermediates analogous to *(2)* and *(3)* see [5] and [6]].

In principle, such oxidations of 2,4,6-trisubstituted phenols should also be possible in those cases where the substituent on C-4 is capable of departing with its bonding electron pair. The reactions take place at room temperature and require 6—10 hours. Representative conversions are given in the following Table:

Table. Examples of the oxidation of phenols *(1)* to *p*-quinones *(5)* by thallium(III) trifluoroacetate.

R	R^1	R^2	R^3	R^4	Yield (%)
$(CH_3)_3C$	$(CH_3)_3C$	H	H	$(CH_3)_3C$	73
$(CH_3)_3C$	Br	H	H	Br	57
$(CH_3)_3C$	Br	H	H	CH_3	89
$(CH_3)_3C$	Br	CH_3	H	$(CH_3)_3C$	70
$(CH_3)_3C$	CH_3	H	H	CH_3	88
$(CH_3)_3C$	$(CH_3)_3C$	H	H	C_6H_5	62
Br	Br	H	H	Br	77
Br	Br	H	H	$(CH_3)_3C$	81
Cl	Cl	H	H	CH_3	82
I	I	H	H	I	62
CH_3COO	$(CH_3)_3C$	H	H	$(CH_3)_3C$	97
OH	$(CH_3)_3C$	H	H	H	91
OH	CH_3	H	H	H	77
OH	CH_3	CH_3	H	CH_3	82
OH	Cl	Cl	Cl	Cl	73

Hydroquinones can also be oxidized to *p*-quinones by this method (see Table); in this instance reaction is complete within a few minutes at room temperature.

The Preparation of Solutions of Anhydrous Perchloric Acid in Methylene Chloride: A Cautionary Note

By *H. Musso* and *B. Bock* [*]

During an attempt to prepare a solution of anhydrous perchloric acid in methylene chloride according to a published procedure [1] a violent explosion occurred which completely destroyed a fume hood. A mixture of 25% oleum and 70% perchloric acid was prepared exactly according to the instructions given, allowed to stand overnight, and then extracted with dry methylene chloride. After the extraction apparatus had been working for about one hour and the methylene chloride was boiling gently the mixture in the non-heated part of the apparatus at the methylene chloride interface suddenly began to boil vigorously and immediately exploded. The methylene chloride had been freshly-distilled over P_4O_{10} and did not contain any impurities that could be detected by gas chromatography.

It is strongly recommended that this procedure be carried out with extreme care and that only small amounts of reagents be used; furthermore, the extraction flask should be kept adequately cooled.

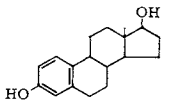
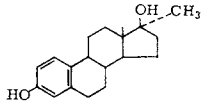
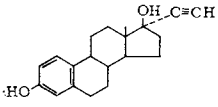
A New Method for Structure Determination of Hydroxy Steroids [**]







By *E. Breitmaier, W. Voelter, G. Jung*, and *E. Bayer* [*]

Determination of the position and conformation of the OH group in steroids by common chemical and molecular-spectroscopic techniques often runs into considerable difficulties. Since ^{19}F-NMR spectroscopy of *O*-trifluoroacetylated steroids only detects the OH group, the ^{19}F-NMR spectra of these compounds are readily interpretable singlet systems; moreover, the amount of sample required for recording the 56.4-MHz ^{19}F-NMR spectra is reduced to about 10 μmoles, which is much smaller than that required for ^{1}H-NMR spectra and is a realistic amount for a natural product. Recent measurements on a 94.1-MHz instrument have shown that the amounts required can be reduced by a further factor of ten, and even by several orders of magnitude if the CAT technique and Fourier transformation are applied [1].

Comparison of the CF_3 signals of the *O*-trifluoroacetyl group (abbreviation: *O*-TFA) attached to C-17 in 5α- and 5β-dihydrotestosterone (see Table) shows that the linkage of rings A and B, which are relatively far removed from C-17, gives rise to a distinct signal shift in the ^{19}F-NMR spectrum. The ^{19}F-NMR spectra of 17β-estradiol and 17α-methyl- and 17α-ethynylestradiol, on the other hand, reflect the effect of the substituents attached to C-17 in ring D on the position of the CF_3 signal of the *O*-TFA group on C-3 in ring A.

[a] δ (C-6) = 0.453 ppm; [b] δ (C-6) = 0.343 ppm; [c] δ (C-6) = −0.11 ppm; δ (C-7) = −0.03 ppm.

Further relationships between the chemical shift and the position of the *O*-TFA groups may be summarized as follows:

1. The CF_3 signal of the *O*-TFA group on C-3 in androstane derivatives is between 0.33 and 0.38 ppm.

2. In the case of estrane derivatives, the CF_3 signal of the phenolic *O*-TFA group is shifted downfield owing to the ring current effect, occurring between −0.11 and −0.17 ppm.

3. The CF_3 signal of the secondary *O*-TFA group on C-17 is between 0.14 and 0.18 ppm.

4. If C-17 is a tertiary carbon atom bearing only saturated alkyl groups, the CF_3 signal of the *O*-TFA group attached to this atom is shifted downfield.

5. Neighboring electron-withdrawing substituents such as *O*-TFA or carbonyl groups shift the CF_3 signals of an *O*-TFA group downfield.

6. The ethynyl group on C-17 in 17α-ethynylestradiol shifts the CF_3 signal of the 17β-*O*-TFA group upfield.

The *O*-TFA derivatives can be prepared by reacting the steroids with trifluoroacetic anhydride[1]. Prior to the ^{19}F-NMR measurements the reaction products only have to be kept for 10 h at 25 °C and 0.5 torr over potassium hydroxide in order to remove moisture and trifluoroacetic acid. The 56.4-MHz ^{19}F-NMR spectra were recorded at 25 °C on a Varian HA-60 instrument using 0.1 M solutions of *O*-TFA steroids in carbon tetrachloride containing 2 % of methyl trifluoroacetate as internal standard. The chemical shifts of the CF_3 signals can be measured with an accuracy of ± 1 %, and do not depend on concentration within these limits.

Nonaphenylcyclotrisilaphosphanetricarbonylmolybdenum(0)[**][1]

By *H. Schumann* and *H. Benda*[*]

Hexamethylcyclotrisilazanetrichlorotitanium(III) and -vanadium(III) are well known[2]. Attempts to couple cyclotrisilazanes or analogous cyclic compounds containing elements

of Groups IVb and Vb as tridentate ligands to transition metal carbonyls have hitherto failed. We have now been able to prepare the first representative of this class of compounds, nonaphenylcyclotrisilaphosphanetricarbonylmolybdenum(0) *(1)*, by reaction of nonaphenylcyclotrisilaphosphane[3] with cycloheptatrienetricarbonylmolybdenum.

R = C_6H_5 *(1)*

Compound *(1)* can be prepared in yields of up to 52% as brilliant yellow crystals which are readily soluble in tetrahydrofuran and hot benzene, are sensitive to air, and decompose slowly with charring at temperatures above 165 °C. The IR spectrum[4] shows two sharp νCO bands at 1931 and 1838 cm^{-1} and three νSiP bands at 393, 333, and 305 cm^{-1}, corresponding to a molybdenum complex having an octahedral structure (C_{3v}) with silylphosphine in the chair configuration as tridentate ligand. A complete elemental analysis and cryoscopically determined molecular weight were also in agreement with such a structure.

Attempts to prepare analogous germyl- and stannyl-tricarbonylmolybdenum complexes as well as the corresponding chromium and tungsten compounds resulted in the formation of complex mixtures only.

Experimental:

A solution of nonaphenylcyclotrisilaphosphane[**] (3 mmole) in tetrahydrofuran (20 ml) is added to a solution of cycloheptatrienetricarbonylmolybdenum (3 mmole) in methylcyclohexane (30 ml) with exclusion of oxygen. The initially dark red reaction mixture turns pale in color on stirring for 25 hours at 50 °C and a yellow precipitate of *(1)* is formed which can be purified by recrystallization from warm benzene.

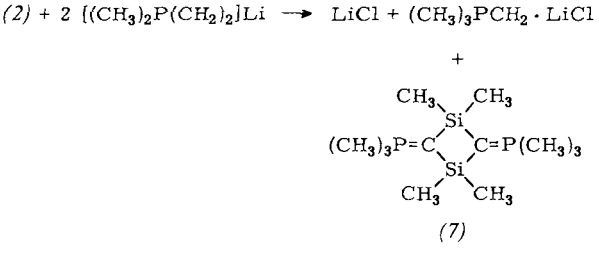
Trans-Silylation – A New Method for the Synthesis of Silylated Phosphorus Ylides[1]

By *H. Schmidbaur* and *W. Malisch*[*]

The possibility of synthesizing cyclic silylalkylenephosphoranes[1] has hitherto been seriously limited because of the inavailability of silylated phosphorus ylides with reactive substituents on the Si atom. We have now found that trialkylsilyl groups on an ylide C-atom can be exchanged smoothly for halogenosilyl groups. As a rule this "trans-silylation" proceeds sufficiently rapidly even at room temperature to give pure products in high yields; the only by-product formed in the reaction is the readily separable trialkylchlorosilane.

Bis(trimethylsilyl)methylenetrimethylphosphorane *(1)*[2,3] can be readily converted into bis(dimethylchlorosilyl)methylenetrimethylphosphorane *(2)* by reaction with an excess of dimethyldichlorosilane:



(1) *(2)*

Correspondingly, reaction of *(1)* with methyltrichlorosilane leads to formation of bis(methyldichlorosilyl)methylenetrimethylphosphorane *(3)*, and with silicon tetrachloride to bis(trichlorosilyl)methylenetrimethylphosphorane *(4)*.

Even mixed halogen- and halogenoalkyl-substituted silyl groups can be readily introduced on the ylide C-atom in this way; reaction of *(1)* with $ClCH_2(CH_3)SiCl_2$ yields $(CH_3)_3P{=}C[Si(CH_3)(CH_2Cl)Cl]_2$ *(5)*.

Sometimes, intermediates are formed in these trans-silylation reactions; thus, in the reaction of *(1)* with $SiCl_4$ in equimolar quantities the unsymmetrically silylated ylide *(6)* is obtained as the main product.

The ylides *(2)*–*(5)* open a new route to cyclic silylalkylenephosphoranes[1]; compound *(2)* reacts with metalated methylenetrimethylphosphorane[4] leading directly to the four-membered heterocycle *(7)*, which was recently prepared for the first time by another route[1].

(7)

(2) + $[CH_3P(CH_2)_3]Li_2$ → 2 LiCl + *(7)*

These reactions clearly illustrate the mobility of the substituents on the methylene C-atom situated in an α-position to the phosphorus atom[5,6].

Compound *(8)* (see Table) was prepared as the first siloxane having an ylide function by reaction of *(2)* with $LiOSi(CH_3)_3$ in the molar ratio 1 : 2.

Table. Properties of the ylides *(2)*–*(8)* [a].

	M.p. (°C)	B.p. (°C/torr)
(2) $(CH_3)_3P{=}C[Si(CH_3)_2Cl]_2$	30–31	80–81/0.1
(3) $(CH_3)_3P{=}C(SiCH_3Cl_2)_2$	47–48	90–92/0.1
(4) $(CH_3)_3P{=}C(SiCl_3)_2$	122	113/0.1 [b]
(5) $(CH_3)_3P{=}C[Si(CH_3)(CH_2Cl)Cl]_2$	–3–0	[c]
(6) $(CH_3)_3P{=}C(SiCl_3)Si(CH_3)_3$ [d]	–	–
(7) $[(CH_3)_3P{=}CSi(CH_3)_2]_2$	70–71	68/0.01 [b]
(8) $(CH_3)_3P{=}C[Si(CH_3)_2OSi(CH_3)_3]_2$	–6 to –4	75.5/0.1
$(CH_3)_3P{=}C[SiH(CH_3)Cl]_2$	–	88/0.1

[a] The composition and structure of the new compounds were established by elemental analysis, molecular weight determination, and NMR and IR spectroscopy. [b] Sublimes. [c] Non-distillable.
[d] Detected NMR-spectroscopically in admixture with *(4)*.

The ylides *(1)*–*(8)* do not react with trimethylchlorosilane. Trimethyliodosilane, on the other hand, reacts with *(1)* to give tris(trimethylsilyl)methyltrimethylphosphonium iodide

as a stable, colorless adduct. The cation of this salt is of particular interest on account of its isosteric relation to tetrakis(trimethylsilyl)methane[7].

On the Conformational Isomerism of the Eight-membered P–N Ring in Octaoxocyclotetraphosphazanates

By *Dietrich Mootz* and *Bernhard Berking*[*]

The conformational isomerism of the P–N skeleton of alkali-metal octaoxocyclotetraphosphazanates (salts of tetrametaphosphimic acid), deduced from the vibration spectra, was described by *Steger* and *Lunkwitz*[1] and less completely by *Griffith* and *Rutt*[2]. We have investigated this by X-ray analysis of the selected examples $K_4[PO_2NH]_4 \cdot 4H_2O$ *(1)* and $Cs_4[PO_2NH]_4 \cdot 6H_2O$ *(2)*. The conformations and symmetries of the structures thus determined for the anion are shown in the Figure.

Steger and *Lunkwitz*[1] determined the point group of the anion in crystals of *(1)* as C_{2h}-2/m with the mirror plane through two opposing phosphorus atoms. The chair conformation resulting from this was confirmed by the crystal structure analysis (see left and right upper Figs.), in which minor deviations of the atomic positions from C_{2h} (exact symmetry only C_i-$\bar{1}$) have no significance.

Steger and *Lunkwitz*[1] assigned S_4-$\bar{4}$ as the point group of the anion from the crystal spectra of *(2)*. However, our crystal structure analysis results in the higher precise symmetry (required by the space group) of D_{2d}-$\bar{4}$2m with the mirror planes through opposing nitrogen atoms (see lower left and right Figs.). This particular saddle conformation was ascribed by *Griffith* and *Rutt*[2] to the anion in aqueous solution, whereas *Steger* and *Lunkwitz*[1] found only symmetry S_4 in this case also.

Mean values of the bond lengths and angles found by us for the anions are given in the Table, which includes for comparison the corresponding values from an X-ray structure analysis[3] of the crystalline dihydrate of free tetrametaphosphimic acid, $H_4[PO_2NH]_4 \cdot 2H_2O$ (molecular symmetry S_4, tub conformation):

		(1)	*(2)*	*(3)*
d (Å)	P–O	1.500	1.498	1.501
	P–N	1.673	1.676	1.661
∢(°)	O–P–O	117.8	117.7	116.1
	O–P–N	107.9	107.5	108.3
	N–P–N	108.1	106.9	107.4
	P–N–P	131.9	128.9	125.6

Both the salts studied contain a complex system of hydrogen bonds: whereas in *(1)* both anion-water bridges (NH · · · O and O · · · HO) and anion-anion bridges (NH · · · O) contribute to bonding of the structure, there are no bridges of the latter type in *(2)* owing to its greater water content. Coordination of the cations by oxygen is six-fold in *(1)* (an octahedron and a trigonal prism, both distorted), but *(2)* with its eleven Cs–O distances between 3.0 and 4.5 Å cannot by given a simple description in terms of a characteristic polyhedron.

(1) forms monoclinic crystals in space group $P2_1/c$ with two formula units in the unit cell; *(2)* forms tetragonal crystals in $P4_2/nmc$ also with $Z = 2$. An automatic diffractometer (AED from *W. Hoppe* of Siemens AG) was used for collection of the data. Determination and refinement of the structures was by the usual methods. Final *R*-factors were 0.039 for *(1)* with 1579 reflections and 0.055 for *(2)* with 569 reflections.

Crystal Growth from the Vapor Phase

By *R. Nitsche* [*]

Successful solid-state research requires the production of single crystals of high purity with defined doping and few structural imperfections. Most crystal growth methods are based on the solid-liquid phase transition, *i.e.* they involve the use of melts or solutions. These methods cannot be used for substances whose melting points are difficult to reach experimentally, that decompose or sublime prior to melting, or for which no suitable solvents exist.

To close these gaps, increasing use has recently been made of vapor-phase methods. Whereas sublimation is confined to a relatively small number of volatile substances, gas reaction methods are very widely applicable. In these methods a gaseous mixture yielding the solid phase reacts under controlled conditions in a growth chamber in the presence of seeds. The gas mixture is transported to the seed by:

a) Blowing separate gas streams into the growth chamber (flow transport).

b) Reaction of the polycrystalline feed material from which crystals are to be grown with a gas at temperature T_1 to give one (or several) volatile compound(s), transport of the gas mixture, whose composition corresponds to the heterogeneous equilibrium at T_1, to the seed (at T_2) by diffusion, convection, or flow, and reversal of the reaction with deposition of the solid phase according to the equilibrium conditions at T_2 (chemical transport).

c) Combination of a and b.

With skilful control (low supersaturation, good temperature stability), gas reactions can yield crystals of considerable size having high purity and structural perfection. Crystals of elements and binary compounds (oxides, sulfides, phosphides, *etc.*), as well as of many ternary and quaternary compounds have been grown.

Two types of apparatus are used:

1) Closed systems (mostly sealed quartz tubes) for automatic chemical transport in the temperature gradient between the solution chamber (T_1) and the growth chamber (T_2).

2) Open systems for chemical transport in flowing gases between T_1 and T_2 or for direct combination of separate gas streams.

(1) Is particularly suitable for the growth of large crystals over long periods, and (2) for the growth of monocrystalline layers on oriented substrates (epitaxy), for which less time is required. Continuous or abrupt modification of the crystal composition (*i.e.* formation of solid solutions or doping) is possible during growth.

Structure and Function of Cell Receptors

By *R. Drzeniek* [*]

Cell receptors play a decisive role in many interesting biological phenomena, *e.g.* in the action of drugs, toxins, hormones, antibodies, and viruses on living cells. Although the best-known receptor theory, that proposed by *Paul Ehrlich* who regarded cell receptors as having defined chemical structures, dates back to about 1900, first attempts to isolate these receptors and to characterize them chemically were not made until comparatively recently.

There has been no lack of experiments designed to modify the mode of action of biologically active substances by chemical changes. However, such an approach becomes all the more difficult to justify the more complicated the mode of action of a substance is.It would therefore appear advisable to limit primary studies on the reactions between substances and their cell receptors to *in-vitro* systems that are as simple and comprehensible as possible. Such systems are currently being developed.

In this way the action of digitalis glycosides on cell membrane components that are designated transport adenosine triphosphatase can be tested [1]. Studies in which the action of receptors on artificial lipid membranes can be measured appear particularly promising. The effect of transport adenosine triphosphatase and digitalis compounds on the permeability of black lipid membranes may be cited as a model [2].

Considerable interest attaches to the analysis of cell receptors in virology too. It is a known fact that a virus infection can only occur when the infectious agent becomes bound to a corresponding cell surface. Virus-binding cell receptors have been isolated and some of them characterized for a number of different viruses. The best-known receptors include those for certain phages and for myxoviruses.

The components isolated primarily by *Weidel et al.* [3] from cell walls of *E. coli* are lipoproteins and/or lipopolysaccharides that react specifically with certain T-phages. Cell receptors for myxoviruses (influenza and parainfluenza viruses) contain acylated neuraminic acid [4], whose structure has been completely elucidated [5], as receptor-dominant sugar. The component of the myxoviruses which reacts specifically with the neuraminic acid of the cell, *i.e.* the enzyme neuraminidase, has been isolated in highly pure form [6] and rendered visible under an electron microscope [7]. The substrate specificity [8] and the function of neuraminidase [9] are particularly interesting. Studies on the *in-vitro* interactions between cell receptor and virus neuraminidase represent the starting point for the elucidation of the mechanism of infection by myxoviruses.

Organometal Pseudohalides [1]

By *K. Dehnicke* [*]

Lewis acids and alkyl- and arylmetal compounds react with gaseous ClN_3 to form organometal azides in accordance with equation (1).

$$R_nM + ClN_3 \rightarrow R_{n-1}M{-}N_3 + RCl \qquad (1)$$

New azides of the type $RHgN_3$, with R = cyclopentadienyl, cyclopropyl, and cyclopentyl, can be synthesized in this way, as can also the compound $(CH_3)_2BiN_3$. $As(CH_3)_3$, on the other hand, like the tetraalkyl compounds of the elements of Group IV A, is inert towards ClN_3; $(CH_3)_2AsN_3$, however, can be obtained by reaction (2).

$$(CH_3)_2AsI + AgN_3 \rightarrow (CH_3)_2As{-}N_3 + AgI \quad (2)$$

All the above mentioned organometal azides are monomeric and nonexplosive. IR and laser-Raman spectra afford information concerning their structures; thus, it is found that the N_3 group is covalently bound and distorted at the α—N atom. Cyclopropylmercury azide occurs as a mixture of the *cis*- and *trans* isomers, whereas the cyclopropyl ring in liquid dicyclopropylmercury rotates freely (pseudosymmetry $D_{\infty h}$). In many cases, organometal thiocyanates are accessible from alkyl- or arylmetal compounds and dithiocyanogen in accordance with eq. (3).

$$R_nM + (SCN)_2 \rightarrow R_{n-1}M{-}SCN + RSCN \quad (3)$$

They differ considerably in their physical and chemical properties from the corresponding well-known isothiocyanates. We have prepared the previously unknown compounds $(C_6H_5)_2BSCN$ (monomer), $(CH_3CdSCN)_\infty$, $(C_2H_5CdSCN)_\infty$, $(C_2H_5OCdSCN)_\infty$, and $(CH_3)_2BiSCN$ (degree of association unknown) by the method shown in reaction (3). In contrast to the substitution reaction (3), addition of $(SCN)_2$ in accordance with eq. (4) leads exclusively to organometal isothiocyanates.

$$R_3M + (SCN)_2 \rightarrow R_3M(NCS)_2 \quad (4)$$

$As(CH_3)_3$, $As(C_6H_5)_3$, $Sb(CH_3)_3$, and $Sb(C_6H_5)_3$ react with $(SCN)_2$ in this manner (4). In a few cases organometal azides can be converted into thiocyanates as shown in eq. (5).

$$2\ CH_3Hg{-}N_3 + (SCN)_2 \rightarrow 2\ CH_3Hg{-}SCN + 3\ N_2 \quad (5)$$

Stereo- and Polymerization Chemistry of Tellurites and Tellurates in the Solid State

By *J. Zemann* [*]

The following common features for the coordination and polymerization chemistry of tellurium can be inferred from the previously reported crystal structures of tellurites and tellurates:

With oxygen, tetravalent tellurium forms either a trigonal pyramid with dTe—O ≈ 1.95 Å and $\sphericalangle$ OTeO $\approx 95°$ (*e.g.* $CuTeO_3 \cdot 2\,H_2O$ and $ZnTeO_3$) or a trigonal bipyramid in which an equatorial corner is unoccupied; the deformation can be explained, therefore, as being due to occupation of this "free" corner by a lone pair of electrons having large spatial demands (*e.g.* tetragonal TeO_2). Coupling of TeO_3 pyramids, to Te_2O_5 units in $(Ca,Mn,Zn)[Te_2O_5]$ and $Fe(OH)[Te_2O_5]$, to Te_6O_{12} rings in the mineral cliffordite (whose chemical composition corresponds approximately to $U_2O_4[Te_6O_{12}]$), and to a two-dimensional infinite layer in $Te_2O_3[SO_4]$, is well known. In $Zn_2[Te_3O_8]$ one TeO_4 group is bonded to two TeO_3 groups *via* oxygen atoms. In tetragonal TeO_2, TeO_4 groups are coupled *via* Te—O—Te bonds to form a three-dimensional framework and in rhombic TeO_2 to form a layer structure; in the latter case the four Te—O bond lengths vary from 1.88 to 2.19 Å.

That the following coordination occurs rather often in the oxygen compounds of tetravalent tellurium appears to be important: a fourth oxygen atom coordinates to a TeO_3 pyramid having three short Te—O bonds to form a bond whose length is about 20% longer than those in the pyramid. This results in a coordination very close to that which has been described for the TeO_4 group. These "long" Te—O bonds, which are obviously much weaker than the short ones, vary greatly in length and it is difficult to give an upper limit. Examples are $(Ca,Mn,Zn)[Te_2O_5]$, $Fe(OH)[Te_2O_5]$, and cliffordite.

Compounds of oxygen and hexavalent tellurium exhibit predominantly octahedral coordination and can undergo polymerization to double octahedra (in $K_4[Te_2O_6(OH_4)] \cdot 7.3\,H_2O$) or to infinite chains (as in $K[TeO_3OH]$). A coupling *via* corners to form infinite chains has been detected in $K[TeO_2(OH)_3]$.

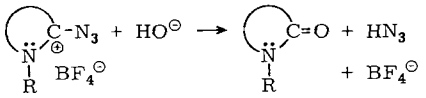
Heterocyclic Azidinium Salts in Preparative Chemistry

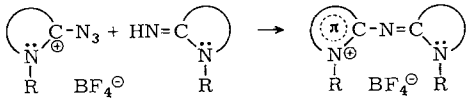
By *H. Balli* [*]

Heterocyclic azidinium salts *(4)* [1] have previously been prepared *via* the routes (a), (b), and (c) [1,2]. The N-heteroaromatic compounds pyridine, thiazole, 1,2,4-triazole,



quinoline, isoquinoline, benzimidazole, benzothiazole, benzoxazole, benzoselenazole, and their substitution products could be used in the syntheses.

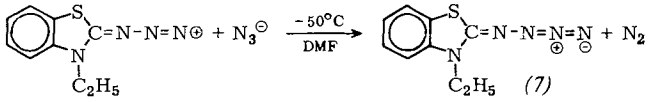
The salts *(4)* react as electrophiles having ambidentate reactivity in the routes (d) or (e).



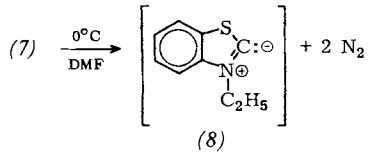
Hard bases, X, react according to route (d) with substitution of the azido group on the hard carbonium ion of *(4b)*.

1. Hydrolysis of azidinium salts.

(4b)



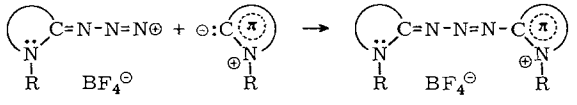
2. Synthesis of azamonomethinecyanines *(6)* with the bases *(5)*.



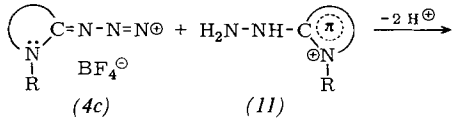
(4b) *(5)* *(6)*

Soft bases, X, react according to route (e) with addition at the terminal nitrogen atom of the azido group of *(4c)*, secondary reactions often occurring at the same time.

1. Addition of azide ions.

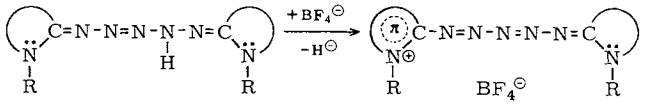


(7)



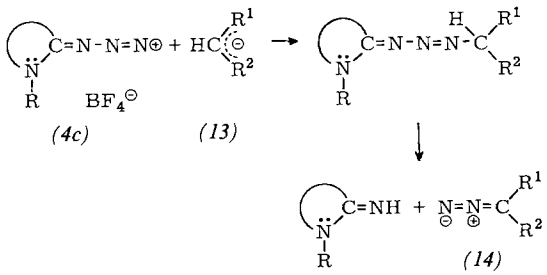
(8)

2. Addition of heterocyclic ylides such as *(8)* or *(9)*; synthesis of triazatrimethinecyanines *(10)* [3].

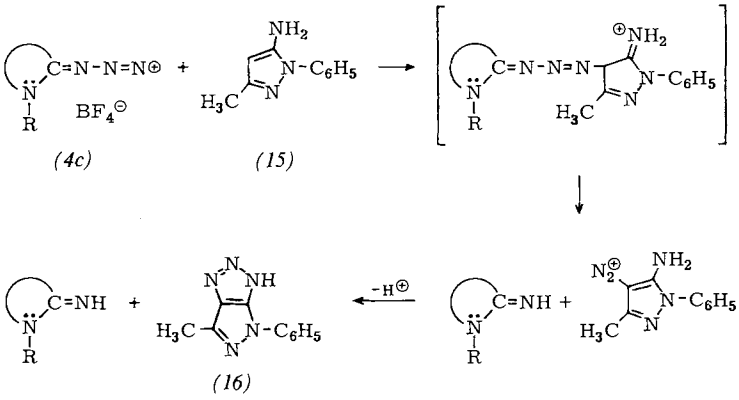


(4c) *(9)* *(10)*

3. Addition of heterocyclic hydrazines *(11)* with subsequent oxidation to pentaazapentamethinecyanines *(12)* [4].



(4c) *(11)*



(12)

4. Addition of anions of reactive methylene compounds *(13)* or hydroxyaromatic compounds involving diazo group or azo group transfer (synthesis of diazo compounds and azo dyes) [5]. Examples for *(14)* are diazomeldrum acid (yield 46 %), 4-diazo-3-methyl-1-phenyl-5-pyrazolone (96 %), 2,4,6-tris(diazo)-1,3,5-cyclohexanetrione (95 %).

(4c) *(13)* *(14)*

Dissolution of Bituminous Coals at Temperatures below 200 °C

By *G. Kölling* [*]

Bituminous coals are scarcely soluble in most solvents at temperatures below 200 °C; however, in "specific" solvents such as phenols, pyridine bases, and a few amines, their solubility can be as high as 40 %.

After alkylation with alkyl chlorides and $AlCl_3$ at 50 °C, or with olefins, HF, and BF_3 at 80 °C the solubility increases still further. Even more efficient is acylation with higher fatty acids and $AlCl_3$ at 50 °C, a treatment which makes medium-rank coals soluble but for their inert constituents.

The carbon matter pretreated in this way can easily be further investigated. The average molecular weight is found to be about 3000 after deduction of the alkyl groups introduced. Similar values have been reported by *van Krevelen* [1] and his co-workers as a result of an extrapolation of the average molecular weights which they had found by studies on partial extracts.

Lecture at Mülheim/Ruhr, November 27, 1969 [VB 219 IE]

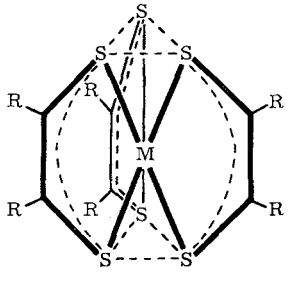
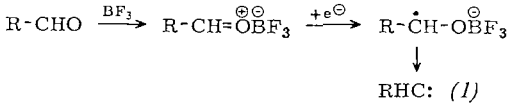
The kinetics of the oxidation of plutonium have been studied by *D. T. Larson* and *D. L. Cash*. The plutonium was stabilized by alloying with 1 wt.-% of Ga in the Δ-phase; the surface to be oxidized was cleaned by bombardment with argon ions in a high vacuum. Oxidation was then carried out at 28–90 °C under 5×10^{-2} torr of oxygen. The growth of the oxide layer was followed by optical methods: linearly polarized, monochromatic light appears elliptically polarized after reflection at the surface. Analysis of the ellipticity affords the complex refractive index of the system (metal + oxide layer). If the complex refractive indices of the metal and oxide are known it is possible to calculate the thickness of the oxide layer. The results obtained after a short induction period can be represented by the equation



$$d^2 = kt + C$$

where d is the thickness of the oxide layer, k is the rate constant, and t is the reaction time. This form of rate equation would indicate a diffusion-controlled process. The activation energy is 30 kcal/mole. X-ray diffraction studies have shown that PuO_2 is the main product. / J. physic. Chem. *73*, 2814 (1969) / —Hz. [Rd 118 IE]

Semiconductor properties of transition metal chelates that are derived from α-dithiones have been described by *E. J. Rosa* and *G. N. Schrauzer*. The specific resistances (at 25 °C) of the compounds investigated lie between 10^3 and 10^{15} Ω cm (organic substances with extended aromatic bonding systems and charge-transfer complexes have conductivities in the same range). In the case of the square-planar complexes $M(S_2C_2R_2)_2$ *(1)* with M = Ni, Pd, Pt; R = *e.g.* CH_3, C_6H_5, a linear relationship was found between the logarithm of the specific resistance and the first polarographic half-wave potential, indicating that charge transport takes place in the lowest unoccupied π MO's of the complexes. The charge carrier was characterized as predominantly negatively charged by measurements of the Hall effect. In the series of trigonal-prismatic complexes $M(S_2C_2R_2)_3$ *(2)*, R = *e.g.* CH_3, C_6H_5, the Re complexes have a conductivity six orders of magnitude better than the complexes of V, Cr, Mo, and W.



(1)

(2)

This suggests that the single electron of the Re complex is to be found in an orbital that is delocalized over the whole molecule. / J. physic. Chem. *73*, 3132 (1969) / —Hz. [Rd 116 IE]

A new route to phenylcyclopropanes has been described by *I. Elphimoff-Felkin* and *P. Sarda*. On reduction of benzaldehyde with amalgamated zinc powder in ether and in the presence of BF_3, phenylcarbene *(1a)* or possibly a carbenoid of type *(1)* is formed as intermediate. In the presence of olefins or enol acetates, phenylcyclopropanes or phenylcyclopropyl

(1a) *(2)* *(3)*

R = C_6H_5

acetates are formed respectively. Examples: Cyclohexene → 7-phenylnorcarane, 35% yield (calculated with respect to benzaldehyde); 1-cyclopentenyl acetate → *(2)*, 24% (*endo* : *exo* = 3 : 2); 1-methylvinyl acetate → *(3)*, 26% (*cis* : *trans* = 1 : 2); allyl methyl ether → 1-methoxy-2-phenylcyclopropane, 25% (*cis* : *trans* = 1 : 1). / Chem. Commun. *1969*, 1065 / —Ma. [Rd 110 IE]

Phosphorus oxide fluorides of high molecular weight occur in the products formed on reacting P_4O_{10} with PtF_4, according to mass spectrometric investigations carried out by *D. W. Muenow*, *O. M. Uy*, and *J. L. Margrave*. The components react rapidly at room temperature with considerable evolution of heat. Mass lines having *m/e* values up to *ca.* 1000, which can be ascribed to the molecular ions $P_nO_{2n-1}F_{n+2}^+$ (n = 1—13), $P_nO_{2n}F_{n+2}^+$ (n = 2—11), and $P_nO_{2n+1}F_{n+2}^+$ (n = 2—10), occur in the spectra produced by 15 V electrons on the products vaporized from a Knudsen cell. It is assumed that the ions of the first type originate from linear polymeric molecules having the structure $F_2P(O)—O[—PF(O)—O]_m—P(O)F_2$; the oxide fluorides POF_3 and $P_2O_3F_4$ are the first members of this homologous series. No suggestions are made regarding the structures of the parent molecules of the other two types of ions. / J. inorg. nuclear Chem. *31*, 3417 (1969) / —Bl. [Rd 124 IE]

A simple method for the preparation of methylphosphines, $H_nP(CH_3)_{3-n}$ (n = 0—2), is described by *K. D. Crosbie* and *G. M. Sheldrick*. Reduction of dimethyl methylphosphonate, $CH_3PO(OCH_3)_2$, with $LiAlH_4$ in monoglyme leads to methylphosphine in 87% yield. Methylphosphine is quaternized within 24 hours by methyl iodide in methanolic solution, the following equilibria being established:

$$\begin{aligned}
CH_3PH_2 + CH_3I &\rightleftharpoons (CH_3)_2PH_2^+ + I^- \\
(CH_3)_2PH_2^+ + CH_3OH &\rightleftharpoons (CH_3)_2PH + CH_3OH_2^+ \\
CH_3PH_2 + CH_3OH_2^+ &\rightleftharpoons CH_3PH_3^+ + CH_3OH \\
CH_3OH_2^+ + I^- &\rightleftharpoons H_2O + CH_3I \\
(CH_3)_2PH + CH_3I &\rightleftharpoons (CH_3)_3PH^+ + I^- \quad \textit{etc.}
\end{aligned}$$

Under suitable reaction conditions these systems prove useful for the preparation of dimethyl- and trimethyl-phosphine in 70% yield. / J. inorg. nuclear Chem. *31*, 3684 (1969) / —Bl. [Rd 125 IE]

α-Ag_3NSeO_3 is not salt-like but built up of Ag_3NSeO_3 molecular units, which possess a three-fold symmetry axis and are arranged as a double helix in the rhombohedral space group R3c (a_r = 6.184 ± 0.003 Å, α = 86.35 ± 0.01 °; $d_{exp.}$ = 6.63, $d_{calc.}$ = 6.56 g cm^{-3}). NAg_3 and SeO_3 groups having an approximately tetrahedral configuration are arranged in an eclipsed conformation with a dihedral angle of 11.1 °; the

interatomic distances are: AgN 2.178 ± 0.018, SeN 1.667 ± 0.050, and SeO 1.670 ± 0.015 Å. The double helix structure of the Ag_3NSeO_3, which has been determined with an automatic diffractometer by *J. K. Fawcett, V. Kocman, S. C. Nyburg*, and *R. J. O'Brien*, results from the short intermolecular AgO distance of 2.217 ± 0.015 Å and an NAgO angle of 173.8 ± 1.5 °. / Chem. Commun. *1969*, 1198 / —HB.

[Rd 126 IE]

Compounds containing the sulfur cations S_8^{2+} and S_{16}^{2+} have been obtained by *R. J. Gillespie* and *J. Passmore*. The substances were prepared as crystalline hexafluoroarsenates according to

$$S_8 + 3\,AsF_5 \rightarrow \underset{(1)}{S_8[AsF_6]_2} + AsF_3$$

and

$$2\,S_8 + 3\,AsF_5 \rightarrow \underset{(2)}{S_{16}[AsF_6]_2} + AsF_3$$

in HF at 0 °C. Both salts show the IR and ^{19}F-NMR spectra of $[AsF_6]^-$. *(1)* is blue (λ_{max} at 599 nm) and crystallizes in the space group $P2_1/c$ with $Z = 16$ S_4AsF_6; since the asymmetric unit contains 4 S_4AsF_6 and the substance is diamagnetic at room temperature, only S_8^{2+} and S_{16}^{4+} come into question as possible cations: by analogy with Se_8^{2+}, preference is given to S_8^{2+}. *(1)* and *(2)* (red) become reversibly paramagnetic on heating to *ca.* 100 °C, probably owing to the dissociation $S_{2n}^{2+} \rightleftarrows 2\,S_n^+$. / Chem. Commun. *1969*, 1333 / —HB.

[Rd 134 IE]

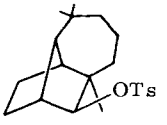
Compounds having the 1,2,4,3,5-trithiadiborolane skeleton, a new 6π system has been prepared by *Max Schmidt* and *W. Siebert* in a variety of ways. Thus, 2,3-dibromo-1,2,4,3,5-trithiaborolane *(1)* is formed according to

$$2\,BBr_3 + 2\,H_2S_{n>1} \rightarrow \underset{(1)}{Br\text{-}B\langle S\text{-}S\rangle B\text{-}Br} + 4\,HBr + (2n\text{-}3)/8\,S_8$$

in 90% yield as a water-clear, extremely hygroscopic liquid instead of the expected perhydro-1,2,4,5,3,6-tetrathiadiborin derivative. Compound *(1)* remains undecomposed even after six hours' heating at 200 °C. It can also be prepared in 50 to 60% yield according to

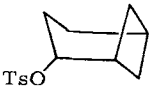
$$H_2S + H_2S_2 + 2\,BBr_3 \rightarrow (1) + 4\,HBr$$

The bromine atoms in *(1)* can be replaced, *inter alia*, by diethylamino, diphenylamino, alkyl, phenyl, and alkylthio groups. The ring in *(1)* is cleaved on treatment with alcohols and thiols. / Chem. Ber. *102*, 2752 (1969) / —Kr. [Rd 113 IE]



The electrochemical reduction of rhodium(I)- to rhodium(0) compounds has been accomplished by *D. C. Olson* and *W. Keim*. For the reaction $[(C_6H_5)_3P]_3RhCl$ in acetonitrile/toluene was treated with a large excess of $(C_6H_5)_3P$ as well as with $(C_2H_5)_4ClO_4$ and electrolyzed at −2.3 V to a conversion of 98%. $[(C_6H_5)_3P]_4Rh$, light-green crystals that decompose at 175—179 °C, was formed in 70% yield. Under similar conditions in acetonitrile $[(C_6H_5)_2PCH_3]_3RhCl$ affords the solid black compound $[(C_6H_5)_2PCH_3]_4Rh$ (74% yield). Having a d^9 electron configuration, Rh^0 should form paramagnetic complexes. However, $[(C_6H_5)_3P]_4Rh$ is diamagnetic, and the magnetic moment of the paramagnetic compound $[(C_6H_5)_2PCH_3]_4Rh$ (1.16 BM) is much lower than expected. The authors assume that a metal-metal interaction takes place

$$\underset{\text{diamagnetic}}{L_4Rh\text{–}RhL_4} \rightleftarrows \underset{\text{paramagnetic}}{2\,L_4Rh}$$



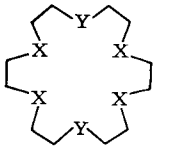
similar to that in $[Co(CO)_4]_2$. / Inorg. Chem. *8*, 2028 (1969) / —Kr.

[Rd 114 IE]

Tosylates of low stability have been prepared by *R. M. Coates* and *J. P. Chen*, who have developed a simple method entailing conversion of the alcohols into the sulfinates by treatment with *p*-toluenesulfinyl chloride as first step[1]. Subsequent mild oxidation with *m*-chloroperbenzoic acid at

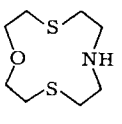
(1)

(2)



0 °C still yields tosylates in those cases where the oxidizing agents used previously (*e.g.* $KMnO_4$ in aqueous acetone and H_2O_2 in protonic solvents) are too strong. Examples: *(1)*, yield 84% (calculated with respect to the *p*-toluenesulfinate); *(2)*, 82%; cyclohexyl tosylate, 88%. / Tetrahedron Letters *1969*, 2705 / —Kr.

[Rd 115 IE]



Syntheses involving perfluoroalkyl radicals from perfluoroalkyl iodides are reported by *N. O. Brace*. Alkenecarboxylic acids afford adducts of the type $RCH_2\text{—}CHI\text{—}(CH_2)_n\text{-}COOH$ (n = 1—16) (R = perfluoroalkyl) in high yields. Dehydrohalogenation of $CF_3\text{—}(CF_2)_3\text{—}CH_2\text{—}CHI\text{—}CH_2\text{—}COOH$ *(1)* with 2 mol. equiv. of base gives $CF_3\text{—}(CF_2)_2\text{—}CF\text{=}CH\text{—}CH\text{=}CH\text{—}COOH$ *(2)*, and with 1 mol. equiv. a mixture of $CF_3\text{—}(CF_2)_3\text{—}CH_2\text{—}CH\text{=}CH\text{—}COOH$ and *(1)* is formed. On hydrolysis of $RCH_2\text{—}CHI\text{—}CH_2\text{—}CH_2\text{—}COOH$, however, only $RCH\text{=}CH\text{—}CH_2\text{—}CH_2\text{—}COOH$ is formed, as is typical for such compounds. / 158th ACS Meeting 1969, Abstracts of Papers, FLUO 42 / —Ma.

[Rd 119 IE]

The synthesis of macrocyclic polythioethers has been reported on by *D. St. C. Black* and *I. A. McLean*. The hexathioether *(1)* and the tetrathioetherdiether *(2)* were prepared by reaction of 1,2-dibromoethane with the disodium salts of 3-thiapentane-1,5-dithiol and 3-oxapentane-1,5-dithiol, respectively, in ethanol in high dilution (yields 31% and 7% resp.). *(1)* behaves as a sexidentate ligand and yields complexes of the type [M (ligand)] (picrate)$_2$, M = Ni, Co. Compound *(2)* does not form complexes. The twelve-membered macrocyclic compound *(3)*, which can be prepared from the disodium salt of 3-oxapentane-1,5-dithiol and bis(2-bromoethyl)amine (yield 18%), readily forms the metal complexes Ni(ligand)Cl_2 and Co(ligand)X_2, X = Br, Cl.

[Rd 123 IE]

The structures of IF_6^+ and IF_6^- have been investigated by *S. Bukshpan*, *J. Soriano*, and *J. Shamir* by means of the Mössbauer effect of ^{129}I. $IF_6^+AsF_6^-$ was prepared from AsF_5 and IF_7, and $Cs^+IF_6^-$ from CsF and IF_5; IF_5 and IF_7 were 85% enriched with ^{129}I. IF_6AsF_6 shows a single line in the Mössbauer spectrum which indicates an octahedral arrangement of the F atoms about the iodine. The complex spectrum of $CsIF_6$ can best be interpreted as being indicative of a structure in which six fluorine atoms and one lone pair are arranged about iodine in the form of a pentagonal bipyramid, the lone pair occupying an equatorial position. From the chemical shifts it can be concluded that iodine donates an average of 0.93 electrons to each atom of fluorine in the formation of IF_6^+ and 0.88 electrons in the formation of IF_6^-; these values hardly differ from those found in IF_7 and IF_5. / Chem. Physics Letters *4*, 241 (1969) / —Hz. [Rd 136 IE]

The dipole moment of tris(2,4-pentanedionato)aluminum has been determined by *R. D. Nelson jr.* and *C. E. White*. The molar refraction of benzene solutions of this compound has been measured both in the far infrared with the aid of an HCN laser (wavelength 337 μm) and in the microwave region. The component due to reorientation of dipoles is given by the difference between these two polarization values. The dipole moment is 1.1 D; this arises from the fact established earlier by X-ray diffraction that the O-metal-O plane in many pentanedionates is inclined by about 20° to the plane through the CO skeleton of the ligand. Unusually short dielectric relaxation times can be interpreted as being due to a flipping of the ligand plane about the O—O axis. / J. physic. Chem. *73*, 3439 (1969) / —Hz. [Rd 137 IE]

The evaporation of graphite has been investigated by *J. T. Clarke* and *B. R. Fox*. Graphite fibers (cross-section 0.4 × 1 mm) were heated to a temperature of 2500 to 3400 °K in a vacuum or in helium by strong current pulses. At 3400 °K the rate of evaporation was sufficiently great (*ca.* 6 mg cm^{-2} s^{-1}) for a direct determination of the heat of evaporation to be carried out; at 3400 °K this is 102 kcal $mole^{-1}$. It can be concluded from the experimental results, in combination with thermodynamic data about graphite and its evaporation products measured at lower temperatures, that graphite evaporates as C_2 at temperatures above 3000 °K. / J. chem. Physics *51*, 3231 (1969) / —Hz. [Rd 138 IE]

The fractionation of hydrogen isotopes during dehydration of $CuSO_4 \cdot 5H_2O$ has been investigated by *K. Heinzinger*. In this hydrate four hydrogen molecules are known to be coordinated to copper and the fifth to be fixed in the crystal *via* hydrogen bonds. The D/H ratios in these two types of water molecules differ by about 5.7%; the copper-coordinated water is richer in H. Within the period of several days required for the dehydration of the hydrate at room temperature no isotope exchange takes place in the solid. At temperatures below 50 °C the copper-coordinated water is liberated first. / Z. Naturforsch. *24a*, 1502 (1969) / —Hz. [Rd 139 IE]

The equilibrium of the system nitrosyl bromide/bromine/nitrogen monoxide has been investigated by *H. Feilchenfeld*, *J. Kenat*, and *S. Manor* by spectrometric analysis of the vapor phase. In the presence of an excess of Br_2, $NOBr_3$ preponderates in the liquid phase at temperatures below 25 °C and NOBr at temperatures above 40 °C. The boiling point of NOBr is found to be 14—15 °C when an excess of NO is present (2.8 atm); the vapor pressure equation

$$\log p\,(\text{torr}) = 8.368 - 1577.64T\ (°K)$$

derived from measured values yields a figure of 14.5 °C. Previous values given for this boiling point lie between —2

and +30 °C. The heat of evaporation of NOBr at the boiling point and under atmospheric pressure is 7.2 kcal/mole. / Trans. Faraday Soc. *65*, 2350 (1969) / —Hz. [Rd 141 IE]

The reaction of N_2O with copper surfaces has been studied by *J. J. F. Scholten* and *J. A. Konvalinka*; a surface oxide is formed and nitrogen is desorbed. The activation energy of this reaction increases with the degree of covering of the surface. The transition from surface oxidation to internal oxidation involves an incubation time at not too high a temperature. At 90 °C and 200 torr N_2O a coverage degree of 1 (one atom of O per two atoms of Cu) is found. Since further uptake of oxygen is strongly hindered (activation energy *ca.* 20 kcal/mole) this reaction is suitable for the reproducible determination of the areas of free copper surfaces in catalysts./ Trans. Faraday Soc. *65*, 2465 (1969) / —Hz. [Rd 142 IE]

BOOK REVIEWS

Handbook of Chemistry and Physics. Edited by *R. C. Weast.* 49th Edit., The Chemical Rubber Co., Cleveland, Ohio, 1968. 2096 pp., bound, DM 89.80.

It is no simple matter to revise a handbook that has appeared in 48 editions[*] since 1913. Apart from minor corrections, most of the data and numerical tables retain their validity for years on end. At the same time increasing space has to be found for new material as science progesses and new methods are developed. The crucial problem therefore becomes the size of such a work, notwithstanding the use of lightweight paper. The present 49th edition of the "Rubber Handbook", with its total of nearly 2100 pages, is certainly as large as it could be without becoming unwieldy, and it is gratifying to learn from the Foreword that the publishers are thinking in terms of an appreciable reduction in size. Among the measures taken with this in mind is a table, published for the first time, giving the names of all publishers, institutions, laboratories, *etc.* having compilations of physical, physicochemical, or chemical data that are not of sufficiently general interest to be included in the handbook itself. The present edition does in fact again contain some 200 pages of new tables, in particular in the following fields: X-ray data for minerals, wavelengths of characteristic X-rays of elements, properties of semiconductors, heat capacity of organic compounds, physical properties of pigments and commercial plastics, density of heavy water, and viscosity of water between 0 and 100 °C. A number of tables have been brought up to date by the inclusion of new data.

The usefulness and reliability of the work have been established beyond doubt over numerous editions. At the same time one continues to hope for a complete revision of the largest table in the book (500 pages), *i.e.* the table giving the physical properties of organic compounds. In its present form this is below the standard of the rest of the book with regard to the presentation of the formulas and the utterly impractical arrangement of the compounds (even after 20 pages of instructions it is difficult to find a substance, or even to establish whether it is in fact listed somewhere in the table). Perhaps the imminent 50th edition may be seen by the publishers as a suitable occasion for rearranging the whole table, a step which is in any case desirable from the point of view of saving space. In all other aspects the handbook is, as always, highly commendable. *H. Grünewald* [NB 841 IE]

Handbuch der analytischen Chemie (Handbook of Analytical Chemistry). Edited by *W. Fresenius* and *G. Jander*. Part III: Quantitative Bestimmungs- und Trennungsmethoden. (Quantitative Methods of Determination and Separation). Vol. IV aα: Elemente der vierten Hauptgruppe I: Kohlenstoff, Silicium (Elements of the Fourth Main Group I: Carbon, Silicon). Compiled by *H. Grassmann* and *W. Prodinger*. Springer-Verlag, Berlin-Heidelberg-New York 1967. 1st ed., viii + 563 pp., 110 figs., paperback, DM 153.—; bound DM 158.—.

In the section on carbon the author had to face the difficulty of deciding where to draw the line, for the book would have been extended indefinitely if it had covered all methods of organic elemental analysis for all organic compounds. The choice made was to treat combustion methods relatively shortly and methods of determining CO_2 in greater detail. In addition, special methods (spectral analysis, activation analysis, X-ray scattering, β-back-scattering) and determination of carbon in many materials (metals, carbides, ores, soils, *etc.*) are also discussed. Finally there follow chapters on the analysis of some simple compounds (hydrocarbons, ethylene oxide, CO, COS, $COCl_2$, HCN, HCNO, HCNS, HCOOH, CH_3COOH, and oxalic acid).

The material on CO and CO_2 and the chapters on combustion methods and on the determination of HCN, HCNO, HCNS, COS, and $COCl_2$ can be seen as particularly valuable reviews and one is very grateful to have these facts collected from the scattered literature of these compounds. However, it could be maintained that the "purely organic" compounds should have been omitted; at the least their selection is arbitrary and their discussion in this book is unexpected.

The section on silicon deals in detail with the determination of SiO_2 in silicates and fluorspars and of silicon in metals, SiC, and organosilicon compounds; gravimetric, titrimetric, and photometric methods are discussed. It is welcome that the numerous variants of these procedures have been put together clearly. It should also be emphasized that many experimental details are given, which greatly increases the value of this section to the practising chemist.

However, several important methods are missing. That determination of silicon by atomic absorption or gas chromatography is not mentioned may be because these methods were perfected after the manuscript was complete; but that cannot explain the absence of determination by spectrography, X-ray spectral analysis, and activation analysis — processes that are not wholly unimportant.

R. Bock [NB 853 IE]

Kristallisation. Grundlagen und Technik. (Fundamentals and Techniques of Crystallization). By *G. Matz.* Springer-Verlag, Berlin-Heidelberg-New York 1969. 2nd Edit., vii + 418 pp., 174 figs., 55 tables, bound DM 72.—.

The theory and the techniques of crystallization have received much attention in the past twenty years. As a result, a wide variety of better single crystals can now be grown, and many crystalline substances with the required particle size and particle-size distribution can be obtained on a large scale by mass crystallization.

While several good books exist on the art of growing single crystals, this is the first comprehensive and up-to-date book on mass crystallization. In fact, the book deals mainly with the designing and the operation of mass crystallizers, and gives only a sketchy account of the theory and techniques of growing single crystals.

[*] Cf. Angew. Chem. *81*, 90 (1969); Angew. Chem. internat. Edit. *8*, 86 (1969).

Though this is the second edition, the book is completely new in scope and subject matter. It is a successful book, which gives the first comprehensive account of industrial mass crystallization and its theory, and which thus fills a gap in German and other literature.

The first chapter, giving the basic definitions, covers only five pages and is not very satisfactory. This is followed by another short chapter (4 pages) on the methods of crystallization. The bulk is made up of Chapter III on the fundamentals of crystallization (170 pages) and Chapter IV on the techniques of crystallization (200 pages), both of which are successful.

The third chapter deals first with nucleation, growth, and crop-formation, involved in any crystallization whether the product is a crystalline mass or a single crystal. The author surveys all the important theories, namely the Volmer-Becker-Stranski equations for nucleation, the Gibbs-Wulff minimum requirement for crop-formation, Frank's theory of spiral growth, the Kossel-Stranski molecular theory, with its far-reaching deductions for nucleation and growth, and the Nernst-Berthoud diffusion theory (*Berthoud*'s name should be retained here, and Berthoud's diffusion layer should be more clearly distinguished from the two-dimensional Volmer diffusion). This chapter also covers the basic forms of crystallization, *i.e.* crystallization from solution (thermal precipitation, salting-out, freezing-out, and fractional precipitation), from melts (*e.g.* by cooling and zone crystallization), by sublimation (under vacuum, with a carrier, in a fluid bed, and fractional sublimation), and crystallization of adducts.

All the forms of crystallization are illustrated by examples and clear diagrams. Their theories are developed mathematically, with special reference to mass crystallization. As a result, the latter is given a broad and firm theoretical basis.

Besides some general technological problems concerning *e.g.* heat transfer, particle size, particle-size distribution, and crust-formation, Chapter IV is mainly concerned with the industrial apparatus and methods of mass crystallization. The author describes in 160 pages 74 typical examples of industrial crystallizers for *e.g.* solution, fusion, and sublimation crystallization, and gives clear diagrams for various modes of operation, unit processes, and overall schemes. — In fact, this chapter determines the character of the whole book.

This is a good book, despite minor flaws in composition, uniformity, and information, which can always be found in the first comprehensive book on any wide field. It has been written for experienced industrial chemists and technologists dealing mainly with mass crystallization, and is likely to provide a good guide in this field for a long time. It is thoroughly recommended to all who are involved or interested in industrial crystallization processes.

A. Neuhaus [NB 848 IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz*. Vol. 17: Carbohydrate Metabolism. Elsevier Publishing Corp., Amsterdam 1969. 1st Edit., xiii + 292 pp., 59 figs., 30 tables. bound Dfl. 47.50; subscr. price Dfl. 38.—.

Cleavage and oxidation of sugars have been regarded as contrasting metabolic reactions — especially since *Pasteur* established the antagonism between aerobiosis and fermentation. It remained for modern biochemistry to show that there is here no fundamental difference but that we have a regulation phenomenon. Oxidative degradations are repressed in the absence of oxygen, and the electrons are removed by internal oxido-reduction.

As is well known, the fundamental reactions have been laid bare largely among microorganisms. The metabolism of carbohydrates has been treated in very great detail in several recent collective works, but in almost all these cases the main emphasis has been on synthesis and degradation of carbohydrates in mammals. The same limitation applies to this volume of "Comprehensive Biochemistry"[1]. It begins with a short chapter on absorption, digestion, resorption, and transport of mono- and di-saccharides and the control of these processes; here *R. K. Crane* describes in a few pages the most important facts that prove a carrier mechanism.

Then *E. Helmreich* gives an excellent and critical review of the control of synthesis and degradation of the polysaccharides glycogen, starch, and cellulose. A large but deserved space is naturally devoted to phosphorylase and its regulation by the reactants; the literature is covered up to 1968 in this section. — In a further 70 pages *I. A.* and *Z. B. Rose* describe the different steps of glycolysis; the enzymes are characterized by their kinetic data, which are important for the overall reaction. — The oxidation of glucose 6-phosphate and the relevant pentose cycle are reported by *S. Pontremoli* and *E. Grazi*; in this short section particular attention is paid to differentiating the forms of glucose 6-phosphate dehydrogenase that have genetic importance. The "shunt" proper is only briefly mentioned.

The central nervous system obtains almost all its energy from a rapid degradation of glucose. The distinguishing feature of metabolism in the brain is control of these processes; they are clearly explained by *H. S. Bachelard* and *H. McIlwain*. — Conversion into aldonic and uronic acids is a further special area of carbohydrate metabolism; this has been given an exhaustive chapter in which *O. Touster* shows how the sugar acids are formed from metabolic carbohydrates and which special reactions are effective for the purpose. — Amino sugars are present as glucosaminoglycanes in the cell membranes of lower and higher organisms. *A. S. Stoolmiller* and *A. Dorfman* present a good review of this complex area.

In comparison with other reports of carbohydrate metabolism, greater stress is laid in this book on additions to and subtractions from the system, as well as its ramifications, so that the value of the volume is increased — it can also be regarded as an extension of other presentations. The various sections are well chosen and are written by experts in the particular fields. The literature is covered mostly up to the end of 1967. A missing chapter on oxidative degradation of carbohydrates has had to be postponed to the next volume, which, it is hoped, will appear as supplement with the minimum of further delay. *L. Jaenicke* [NB 851 IE]

Distortions of the π-Electron System in Substituted Benzenes

By A. R. Katritzky and R. D. Topsom[*]

The factors leading to substituent effects on the electron distribution in aromatic molecules are discussed, particular attention being paid to the π-electron system. IR spectroscopy has proved an extremely useful probe in this field of study. Substituent d-orbital participation and the relevance of the π-inductive effects are also considered.

1. Introduction

The determination of electronic interactions in aromatic molecules has long been the aim of many chemists. Sure knowledge of the mechanisms and magnitudes of such interactions would allow the prediction of many physical properties, reaction rates, and equilibrium constants, and also assist in the correlation of the mass of existing data. This review is particularly concerned with effects of substituents on the π-electron system in aromatic compounds and makes only passing reference to field and σ-bond inductive effects. No attempt has been made to ensure an exhaustive coverage of the literature, while particular emphasis is placed on the use of the infrared methods that we have recently developed [1–3].

We start below by discussing the overall effect of placing a substituent on a benzene ring. [We generally consider a substituent group as a whole but it must be appreciated that, where this contains more than one atom, much of the charge disturbance may be located in bonds other than that connecting it to the ring.]

2. Effect of Substituents on the Benzene Ring

Aromatic and, in particular, benzene derivatives have provided the majority of the series of compounds used by physical organic chemists to examine correlations between structure and reactivity. The benzene nucleus contains both of the usually distinguished types of bond; the σ bond has cylindrical electronic symmetry about the bond direction while the π bond has a node in the bond axis. The π electrons in benzene can also be regarded as delocalized and we thus have a relatively simple and symmetrical system of fixed geometry allowing investigations of features of the major bonding concepts. [Additional advantages of benzene derivatives for such studies are the relative ease of preparation of series of variously substituted derivatives and the availability of several positions at which tests can be made for changes in electric character.]

Many physical organic chemists and theoreticians have recently treated σ and π systems discretely and the accord obtained between predictions and experimental results suggests that the approach is both useful and, at least to some extent, meaningful. The assumption that we can, to a large extent, discuss effects in the π system of benzene independently of its σ framework is thus gradually becoming accepted and we present additional confirmatory evidence in the later part of this review. [At the same time, recent calculations [4–6] including both σ and π electrons

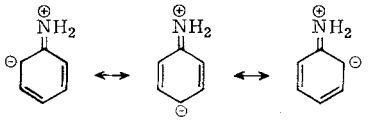
have provided measures of the total electrical effect of substituents on aromatic rings.]



The separate treatment of changes in σ and π electron densities and discussions of the effect of one on the other assumes that we know something of their individual effects. It is relatively easy to observe the former in isolation by considering systems containing saturated linkages. Thus the effect of adding a substituent to an alkyl group has been well explored. The two most likely forms of charge transmission have become known as the σ inductive effect (I_σ) and the field effect (F). The former describes the transmission of charge by the successive and diminishing polarization of a series of adjacent σ bonds:

$$\delta^{\ominus}\ \delta^{\oplus}\quad \delta\delta^{\ominus}\quad \delta\delta\delta^{\ominus}$$
$$Y{-}CH_2{-}CH_2{-}CH_2{-}$$

Earlier workers assumed that this effect would still be appreciable at the second carbon atom and factors such as $^1/_3$ have been suggested [7,120] for the proportion of charge disturbance relayed from one carbon atom to the next. It is now considered by many workers [8–12,121,122], however, that the σ inductive effect is of minor magnitude compared to the direct, through space, electrostatic effect of the polarity of the substituent bonds on the system although this is still subject to argument [123]. Thus the fact that monofluoroacetic acid is stronger than acetic acid is considered to be mainly a result of the increased stabilization of the carboxylate anion brought about by interaction with the C–F dipole. [Recent calculations [13,14] have also suggested that any small I_σ effect might show alternation along a chain of carbon atoms in an aliphatic system but this apparently does not occur [124] in the σ framework of a benzene ring.]

A substituent attached to a benzene ring can still give rise to field and I_σ effects. Recent work on aromatic systems [9,15–17] supports the view that field effects predominate over σ inductive ones. It is not always necessary to distinguish these effects and they are frequently referred to by physical organic chemists under the general term "inductive effects", a practice that can lead to confusion.

Additional effects exist in substituted aromatic systems. Physical organic chemists until recently considered "mesomeric effects" as being the only important contribution to charge disturbance apart from inductive effects. Thus in aniline it was considered that the lone pair of electrons on the nitrogen could interact with the π-electron system of the ring leading to their delocalization and a somewhat enhanced electron density in the ring. In valence-bond language, it was considered that canonical forms of type *(1)* made some contribution to the ground state.

(1)

The amino substituent thus transfers charge to the ring in opposition to its inductive effect. The dipole moment of aniline can be shown to be directed towards the ring and this can be explained if the mesomeric effect is stronger than any inductive effect. In a similar manner, it was suggested that some delocalization of the π electrons of the benzene ring could occur into a substituent such as a nitro or carbonyl group where free orbitals were available.

More recently, the question has arisen as to whether the inductive effect of a substituent could in turn influence the π-electron system. This has been called [9] the inductoelectromeric [18] or π-inductive effect (I_π) [19]. This type of effect had already, however, been considered by spectroscopists and theoretical chemists.

Quantum mechanical calculations need more exact mathematical definitions of the inductive and mesomeric effects than those used by organic chemists. Since the absorption spectra and theory of aromatic systems make no predictions concerning the σ electrons, the inductive effect of a substituent was taken as the effect of the potential field of the substituent *on the π electrons* of the unsubstituted molecule. Thus the inductive effect of a substituent as used by most theoretical chemists does not include the I_σ or F effects above, but consists rather of the I_π effect together with any disturbance of the π system caused by electron repulsion between it and electrons on the substituent group. Some workers [20] include this last effect under the general heading of an I_π effect. [In fact, *Jaffe* [19] originally proposed the term I_π to cover only this perturbation to the π system of the benzene ring effected by the assignment of realistic Coulomb integrals to attached substituent atoms.]

Some doubt has been expressed recently as to whether a single electron-withdrawing substituent attached to a benzene ring does show a mesomeric effect. It has been suggested [21] that the effect of a nitro group and

other similar electron-withdrawing substituents on the π-electron system of the benzene ring is solely due to the π-inductive effect in the ground state. This result is based on the acidity of *p*-substituted benzoic acids.

Since both the carboxy and the carboxylate groups are electron-withdrawing in their own right, it is quite possible that the nitro group shows no particular change in mesomeric effect in this ionization. This result is therefore not necessarily relevant to the ground state of nitrobenzene itself. Further, these mesomeric effects are small and in the same direction as inductive effects, which makes them difficult to investigate by the method used. Evidence has been offered [22] for an appreciable amount of mesomeric interaction in the ground state of nitrobenzene, which will be discussed further below.

It has also recently been suggested [20] that the major part of π-electron disturbances caused by substituents having free electrons on the atom attached to the ring is caused by non-bonded repulsions rather than mesomeric interaction. There are some measurable differences to be expected depending as to whether the π disturbance in a molecule such as aniline arises from a mesomeric effect or from electron repulsion. In the former case the amino group should be approximately coplanar with the benzene ring to allow for maximum mesomeric interaction, which should result in the most stable molecule. The ring-nitrogen bond should be slightly shorter as a consequence. On the other hand, π-electron repulsion is greatest when the amino group is coplanar with the benzene ring. Electron diffraction work [23] does suggest substantial bending of the amino group in aniline with respect to the ring and this has been interpreted [20] as evidence for the dominance of repulsion terms. There is some X-ray and neutron diffraction evidence for $C_{Ar}-N$ bond shortening in some *p*-substituted aniline derivatives, but this may be related to the possibility of "through conjugation" between the two substituents (see Section 4).

It seems clear from an analysis [24] of the second order inductive shifts of the benzene 2600 Å band in substituted benzenes and the first order inductive shift of the azulene visible band that some mesomeric contribution certainly exists in the excited state and we consider that present evidence suggests that this also occurs in the ground state.

The effect of the potential of the substituent atoms on the π-system of the ring has recently been discussed in several semi-theoretical papers. The lack of marked change in the ultraviolet spectrum of the anilinium ion compared to benzene posed a problem [25] since a considerable disturbance of the π electrons would be anticipated if the I_π effect were of any significance.

It has been suggested [26,27] that inductive effects on the π system can be subdivided into two classes. *Craig* and *Doggett* [26] have proposed that inductive effects of the I_π type be differentiated from repulsive orbital terms arising from electron exchange between overlapping π orbitals. They suggest that the latter be known as "orbital penetration effects". Our own work [3] provides evidence for the importance of such effects; for example the $[N(CH_3)_3]^+$ substituent is a slightly stronger resonance donor than a tertiary butyl group. These orbital penetration effects are claimed, however, to be considerably smaller in magnitude than mesomeric effects in compounds like aniline and phenol although they act in the same direction.

Murrell and *Williams* [27] and *Godfrey* [28] subdivide the inductive effect of a substituent on the π system into short- and long-range forces. They show that exchange terms can be treated empirically as though they arose from short-range effects. Coulomb terms must be considered both as short- and long-range effects. The I_π effect is considered to arise mainly from the short-range contributions. The fact that the overall effect of the chlorine atom in chlorobenzene is to distort the π system of the nucleus away from the substituent is therefore interpreted as showing the predominance of the exchange terms over the coulombic ones, since the mesomeric contribution is considered to be low in this case.

This explanation has come in for some criticism as a result of work [29] on vertical ionization potentials which suggests a slight overall π-electron withdrawal by chlorine. The suggestion that this would indicate a similar effect in the ground state conflicts with results [3,30,31] showing that the chloro substituent repels the π-electron system. *Murrell* and *Williams* suggest that for a methyl group the inductive perturbation is almost entirely of the short-range type and is probably dominated by the exchange terms. They also advocate including both field and exchange terms within the "inductive effect" since it is hard to differentiate them.

Thus, from a semi-theoretical point of view, π-electron disturbances in the ground state of substituted benzenes can be caused by:

1. Mesomeric effects
2. Coulombic effects
3. Exchange or orbital repulsion effects.

3. Hammett Relationships

We now wish to go back and consider the development of various physical organic concepts in the light of the discussion above. It is very important to understand that some properties discussed are ground state ones (dipole moments, NMR, IR), some are transition state ones (reactions), while others represent differences between various ground state energies (equilibria) or between ground and excited states (UV). There are numerous examples in the literature where authors have, either knowingly or otherwise, correlated properties of two different classes.

Early studies of electron disturbances in benzene derivatives were mainly limited to the interpretation of dipole moment measurements and ultraviolet spectra. The former is a ground state property which depends on the charge separation in the molecule with respect to both the amount of charge and the effective distance apart. So-called "mesomeric moments" for benzene derivatives have been obtained [32] by subtracting the dipole moment found for alkyl derivatives from that for the corresponding benzene derivative. These have been further modified by some workers [33] to allow for a distance term. Mesomeric moments do show a general relationship with some indices of charge disturbance in the benzene ring but fail to correlate well with the disturbance of the π system. They are therefore best used, until better understood, as providing a general guide to the direction and order of magnitude of the effect of a substituent on the π-electron density in substituted benzenes.

Changes in frequency and intensity of ultraviolet absorptions caused by the $\pi \rightarrow \pi^*$ exaltation in substituted benzenes also provide some information about electronic movements. The absorptions, however, depend on the difference in π-electron distribution between the ground and excited state and thus do not necessarily mirror the effect in the ground state itself. The results of UV studies can prove useful [125,126] in an analysis of the factors leading to the π-electron disturbances as indicated above. Optical exaltations have also been used [34] as a measure of π-electron movement.

Most of the work in this field from 1940 to 1960 was concentrated on the linear free energy relationships pioneered by *Hammett* [35]. In this work the effect of a substituent on a standard equilibrium, rate of reaction, or physical property was observed. The Hammett equation

$$\log k/k_0 = \rho\sigma$$

was used to correlate the results. The value of ρ varies according to the electronic demands of the reaction or property measured but is a constant for a fixed set of conditions. The σ constant for a substituent Y in the *meta* or *para* position (*ortho* positions are complicated by steric interactions which are beyond the scope of this review) gives a measure of its electronic effect on the reaction or measurement center X.

(2) *(3)*

The σ constant is thus rather a measure of the transmission of the substituent's electronic effect to the reaction site than a measure of its effect on the benzene ring in isolation. The acidity of *m*- and *p*-substituted benzoic acids was originally taken as a standard reaction and ρ arbitrarily taken as unity. The σ values derived were found to be broadly applicable to some other equilibria and physical properties. However, *Hammett* [35] had pointed out that σ constants might vary for certain substituents depending on the electronic requirements of X in cases where X and Y could interact. Thus in the aniline-anilinium ion equilibrium, it is possible for an electron-withdrawing substituent such as a nitro group to interact more in the neutral molecule than in the charged one when situated in the *para* position.

This "through conjugation" *(3)* leads to a different σ value here compared to the value obtained from the benzoic acid-benzoate anion equilibrium. The value obtained for the *m*-nitro substituent is similar in both cases since no low energy conjugated forms are possible. Obviously substituents having a free electron pair on the α atom can show enhanced electron donation if the reaction center places a demand on it. New substituent constants, σ^+ and σ^-, were obtained [36] for cases where the property measured placed a demand on electrons or had a surplus of them, respectively. The σ values thus depend on the reaction studied and some authors [36,37] have pointed out that a whole range of values, between σ^+ and σ^- as extremes, may be required. Attempts have been made, notably by *Yukawa* and *Tsuno* [38], to relate the σ value for a substituent to a second constant typical of the particular reaction being studied (cf. [7,36,39–41]). Other workers [42] have tried to define new sets of constants allowing for exalted substituent values and variable

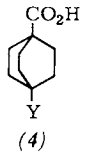
reaction conditions, but this appears to offer no advantage over extra-parameter equations using σ values.



Physical properties such as IR and NMR spectra have also been correlated with σ constants. For example, the frequency of the carbonyl stretching vibration in *m*- and *p*-substituted acetophenones correlates reasonably with normal σ constants [43,44]. The frequency of an infrared absorption depends on the environment of the vibrating atoms in the molecule, but includes mass effects and usually has contributions from vibrations of neighboring bonds. The intensity is related to the way the dipole moment alters with the normal coordinate during the vibration being considered. The intensity should thus be extremely useful for correlation purposes, but difficulties in obtaining reliable values have until recently limited such work. The intensities of the C≡N stretching vibrations in substituted benzonitriles have recently been shown [45] to correlate with σ^+ values. However, infrared properties may also fail to correlate [46] well with any particular set of σ constants.

The realization that a large part of the variation in σ values could be ascribed to direct conjugation between the substituent and the reaction site led to an attempt to estimate σ^0 values for systems where such interactions were precluded or minimized. The σ^0 values should thus be a measure only of the interaction of the substituent with the benzene ring as felt at the reaction site. The usual approach has been to measure properties such as the acidity of substituted phenylacetic acids where the reaction site is one atom removed from the ring.

Fair agreement is found for σ^0 values from various sources; as with normal σ values, different values are required for *meta* and *para* substitution. [Both σ and σ^0 values can be affected [47] by the solvent where specific interactions such as hydrogen bonding exist.]

A rather more detailed knowledge of the way in which a single substituent interacts with a benzene ring would be very valuable as a foundation to the understanding of the types of reactions and equilibria mentioned above which effectively involve the transmission of electronic effects in disubstituted benzenes. *Taft* and his co-workers [48] pioneered attempts to split σ values into inductive and "resonance" contributions. The inductive part was considered as the electrical disturbance in the σ bonds and through space arising from the charge distribution in the substituent, while the resonance part consisted of all disturbances observed in the π system of the ring. It is important to note the difference between this division and terminology and those used by the theoretical chemists (Section 2).

A measure of the inductive effects of substituents was obtained from 1) a comparison [49] of the rates of acid and alkaline hydrolysis of aliphatic ester (σ^*), 2) the acidities of a series of 4-substituted bicyclo[2.2.2]-octane-1-carboxylic acids [50] *(4)* which show a geometrical similarity to *p*-substituted benzoic acids, and

(4)

3) a comparison [48] of σ_m and σ_p values assuming an identical inductive component for each and that a constant proportion of the resonance effect of a substituent was relayed from the *ortho* or *para* positions to the *meta* one.

$$\sigma_m = \sigma_I + \alpha\sigma_{R(p)}$$

$$\sigma_p = \sigma_I + \sigma_{R(p)}$$

Values of 0.33 or 0.5 have been suggested [48] for α.

After scaling to a common basis these σ_I values were remarkably constant [36,39] and suggested that they have a real meaning. Further confirmation was found in the accurate correlation of ^{19}F–NMR shifts of *m*-substituted fluorobenzenes with σ_I values, although the reason why these shifts fail to correlate with σ_M has presented a difficulty [15,51]. Nevertheless, it is unlikely that σ_I values should be the same for *meta* and *para* positions whether they are mainly caused by field or I_σ effects. *Schmid* [52] has recently shown however, that the intensity of C–H stretching modes in the *ortho*, *meta*, and *para* positions of monosubstituted benzenes are functions of σ_I. It may thus be that $\sigma_{I(m)}$ is linearly related to $\sigma_{I(p)}$ as recently suggested in empirical equations [41,53].

If σ_I can be obtained, then the resonance contribution can be found:

$$\sigma_R = \sigma - \sigma_I$$

$$\sigma_R^0 = \sigma^0 - \sigma_I$$

The second value, σ_R^0, represents the disturbance of the π system in a monosubstituted benzene. It is thus a constant value, unlike σ_R which varies with the method of measurement since the possibility of conjugation with the reaction site is present. The value of σ_R^0 may vary with temperature and solvent, but provided these are fixed, affords a quantity of physical

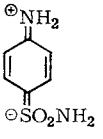
meaning and a basis for calculations [7]. Thus the calculated total charge transfer between a substituent and the ring in a series of monosubstituted benzenes has been shown [54] to be proportional to σ_R^0.



4. π-Electron Disturbances

The value of σ_R^0 determined in the *para* position of a substituted benzene should provide a measure of the π-electron disturbance along the major axis of the corresponding monosubstituted benzene. Various techniques have been used which provide qualitative or quantitative measures of such disturbances. The solvent and temperature conditions are not always the same.

X-Ray results: π-Electron disturbances should affect the bond lengths in the benzene nucleus. In practice such changes are very small and only accurate neutron diffraction work allows even a qualitative result in favorable cases. Thus the bond lengths in β-sulfanilimide *(5)* [55] indicate the contribution of structure *(6)*.

(5)

(6)

Dipole moment results: Mesomeric moments do not show a reasonable correlation with σ_R^0 values as indicated in the previous section. Some correlation is found between the corrected values of *Exner* and σ^+ or σ^- values but it is difficult to see why enhanced σ values are required.

NMR results, chemical shifts: The chemical shifts of the hydrogen or substituent atoms attached to a benzene ring or of the carbon atoms themselves (^{13}C) should in principle give a measure of the electron density at the position in question, provided anisotropic and ring current effects are not important. It has been recently suggested [56] that after allowing for ring current variation, *p*-hydrogen chemical shifts in a series of monosubstituted benzene derivatives depend linearly on the π-electron density variations on the adjacent carbon atom as calculated by a non-empirical Hückel LCAO method. It has been shown that *p*-hydrogen shifts are linear with *p*-^{13}C shifts [57] and ^{19}F shifts [127] in the corresponding compounds suggesting that the shifts are mainly caused [58] by changes in the π-electron density. Other calculations (HMO) for both *o*-H and *p*-H chemical shifts have indicated [128] dependence on π-electron densities on the corresponding carbon atom and it was further suggested that *m*-H shifts [59] are affected by the π-charge on the carbon atoms next to the *m*-C atom.

Thus the evidence for the small effect of inductive or field effects on proton shifts in benzene derivatives has been adduced [129] but this conflicts with an analysis [130] of the results.

m-^{13}C shifts [60] in monosubstituted benzenes are small, rather random, and do not correlate with *m*-H values. A very good correlation with σ_R^0 is obtained [30], nevertheless, when the *p*-^{13}C shift is corrected by the corresponding *meta* value. Some theoretical justification has also been produced [61] for a correlation of ^{13}C shifts with π-electron density. However, *Bloor* [6] has suggested that ^{13}C shifts in *all* ring positions of monosubstituted benzenes are well correlated by the total electron density as calculated by a CNDO method. He suggests that there may be a fortuitous and close relationship between the π-electron and total electron density in the case of *p*-carbons.

Taft and his co-workers [62] have made quite an extensive study of ^{19}F chemical shifts of *m*- and *p*-substituted fluorobenzenes. The *meta* shifts relative to fluorobenzene are shown [67] to accurately follow a linear correlation with σ_I values while the *para* shifts, when corrected by the corresponding *meta* values, correlate well [63] with σ_R^0.

$$\sigma_R^0 = -0.339\left(\int_H^{p-X} - \int_H^{m-X}\right)$$

where $\int_H^{p-X}$ is the ^{19}F chemical shift difference between *p*-X-fluorobenzene and fluorobenzene, and $\int_H^{m-X}$ is the analogous quantity for the *meta* derivative. These σ_R^0 values are almost solvent independent except where specific solute-solvent interaction occurs. They could, however, be somewhat in error for cases where the fluorine atom can conjugate with an electron-withdrawing *para* substituent, for example in *p*-nitrofluorobenzene or donate into d-orbitals, for example in *p*-iodofluorobenzene (see Section 9).

The corrected shifts here thus correlate well with the corresponding corrected C-13 shifts as well as with σ_R^0 values obtained from chemical experiments involving the determination of σ^0 and σ_I. *p*-F shifts have been shown [131,132] to follow the calculated π den-

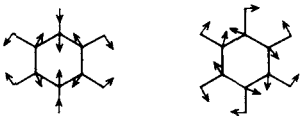
sity at the fluorine or attached carbon atom and to be insensitive to σ electron effects. Allowance must be made [132] for the effect of *ortho* substituents in such correlations.

Some work on nitrogen shifts of substituted nitrobenzenes and pyridines has also been reported [64–67] some of which show broad correlations with electron densities.

NMR results, coupling constants: Proton-proton coupling constants have been used frequently [60,68] to gain information about the electronic structure of olefinic and aromatic compounds. The values are relatively insensitive and this makes it hard to interpret the reasons for the variations noticed. Some limited correlations of J_{H-H} values with electronegativity values [60,69] or proton chemical shifts [70,71] have been reported, but there is disagreement [59,72–74, 133] as to whether inductive effects or changes in π-electron density are the more important. Both could well contribute in approximately equal amounts [134]. Two recent papers [75,76] report that the geminal coupling constants between the nonequivalent protons of a benzylic methylene group in 2-benzyloxytetrahydropyrans vary as the Hammett value of a substituent in the *meta* or *para* position.

$^{13}C-H$ coupling constants may show similar effects but only limited results are available [60,77,135] and the changes are rather small. Some work has also been reported on fluorine-fluorine [78], fluorine-hydrogen [72,79,136], and nitrogen-hydrogen coupling constants [137].



Nuclear quadrupole and electron spin resonance: NQR frequencies of some monosubstituted [^{35}Cl]-chlorobenzenes vary [80] almost linearly with inductive effects presumably because the measurements are not very sensitive to changes in the double bond character of the C–Cl bond. Nevertheless, they may be somewhat sensitive to π-electron densities [81]. Some related ESR results reported include a correlation [82] with σ values for *m*- and *p*-substituted diaryl nitroxides.

IR spectra: We have recently shown [1,2] that the intensities of the ν_{16} ring-stretching bands of monosubstituted benzenes give a quantitative measure of the distortion of the π system of the ring along the main axis. This integrated area A of the bands near 1600 and 1585 cm^{-1} is related to σ_R^0 for the substituent.

$$A = 17600\,(\sigma_R^0)^2 + 100 \qquad (1)$$

The small constant term in the equation is required since an overtone band also occurs in this frequency range. This was the first correlation between aromatic ring vibrations and substituent constants for substituted benzenes, although it had earlier been recognized [83] that the intensities of certain ring vibrations were qualitatively related to the electron donating or withdrawing power. Some Raman absorptions [84] and optical exaltations [34] have been shown to follow a similar pattern.

The 1600 cm^{-1} (ν_{16a}) and 1585 cm^{-1} (ν_{16b}) bands in monosubstituted benzenes arise from the IR forbidden, in-plane ν_{16} benzene vibration at 1585 cm^{-1}. The direction of the atomic displacements in the degenerate pair in benzene itself is shown below.

Such diagrams of the forms of the normal modes are the result of force-field calculations on benzene, and a comparison of the calculated and observed frequencies in its halogenation and deuterated analogs [85,138].

The degeneracy is lifted when the symmetry is reduced from D_{6h} to C_{2v} by attaching one symmetrical substituent to the ring and two infrared active vibrations are obtained. Calculations [85] show that the forms of the normal coordinates are very similar to benzene itself.

A considerable amount of the potential energy of the vibration of these modes is involved in C–H bending. *Scherer* [86] has calculated the actual potential energy distribution and showed that the contribution from C–H bending is about 30 %. Most of the intensity

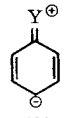
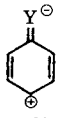
arises from the ν_{16a} vibration, however, and it can be seen that the C–H bending modes are symmetrical and any contributions they may make to the dipole moment will cancel out. The intensity thus derives from C–C stretching modes. The contribution to the potential energy from the C–H and C–X stretching modes has been shown [86] to be negligible.

If the substituent is not symmetrical the ν_{16a} and ν_{16b} vibrations have A symmetry and thus intensity can be shared. Because of this mixing and the closeness of the two absorption frequencies, the combined intensities are always used for correlations.



Some insight into the nature of the substituent-ring interaction may be obtained by a valence bond treatment. In a monosubstituted benzene, during the vibration ν_{16a} there is a distortion of the molecule in the sense of *(7)* ⇌ *(8)* (where the effect is much exaggerated).



(7)

(8)

(9)

(10)

The shorter bonds will have greater double-bond character and the longer bonds greater single-bond character. If the substituent Y is capable of resonance interaction with the ring, then canonical forms of types *(9)* or *(10)* (whether *(9)* or *(10)* will depend on whether Y is an electron donor or acceptor) will be of greater importance for *(7)* than for *(8)*. This will lead to an oscillating dipole during the vibration and hence to an increased intensity in the infrared spectrum. The π-dipole moment change with respect to the normal coordinate of the vibration is evidently directly proportional to σ_R^0, for together with equation (2) this leads to the relationship observed in equation (1).

$$A = \frac{N\pi}{3c^2}\left(\frac{\partial\mu}{\partial Q}\right)^2 \qquad (2)$$

We have calculated [139] $\partial\mu/\partial Q$ for these vibrations from a knowledge of normal coordinates. Values based on π-electron densities (HMO) show very reasonable agreement with those observed experimentally while more elaborate calculations [140] (CNDO) allow discussion of the effects of π- and σ-electron densities. A molecular orbital model involving vibronic formalism has also been used [141] to explain the relationship between these intensities and σ_R^0.

A similar relationship between A and σ_R^0 has been found [87] for the ν_{13} vibrations of monosubstituted benzenes but the analysis is somewhat more complex here since C–H bending modes contribute to the overall intensity.

5. Disubstituted Benzenes

In a disubstituted benzene *(11)*, clearly both Y and Z can exert their normal mesomeric, π-inductive, and orbital-repulsion effects. There is the additional possibility of through conjugation *(12)*, which would lead

(11)

(12)

to further π distortions. Some direct evidence for this comes from X-ray or neutron diffraction work with *p*-sulfanilimide [55] (Section 4) and *o*- [88] and *p*-aminobenzoic acids [88, 142]. In addition it is possible that the effects of one substituent can alter those of the other [89]. Thus it is feasible that a substituent Z with a strong inductive effect might alter the mesomeric contribution of a second substituent Y. Some substituents may also accept electrons into d-orbitals if opposed by a second, strongly electron-donating substituent (Section 9) and this may account for the X-ray observed [90] C_{Ar}–N bond shortening in *p*-chloroaniline. Careful investigation of π-electron disturbances should provide evidence about these additional interactions and this is obviously best carried out on the ground state.

Dipole moment measurements can provide some evidence of π-electron disturbances but their limitations have already been discussed. Proton, carbon-13, or fluorine chemical shifts are of limited value, since the positions involved in disubstituted benzenes are nearly all in close proximity to the substituent and thus likely to be subject to anisotropic effects. Some evidence can be adduced, however, from the observation that proton shifts are frequently approximately additive based on the corresponding monosubstituted benzenes. Deviations from additivity are found [91] where the two substituents can conjugate with each other through the aromatic ring. Proton-proton coupling constants can similarly suggest [92] quinonoid contributions, although they are usually approximately additive [93, 135] as are C–H [135] and H–F coupling constants [136]. However, the most general method at

present is the infrared one, since this provides a measurement of the disturbance in the benzene nucleus itself.

A quantitative correlation might be expected between the summed band intensity ($A\nu_{16a} + A\nu_{16b}$) of *p*-disubstituted benzenes and the intensities of the corresponding monosubstituted benzenes, provided no interaction occurs between the substituents. Thus, calculations on *p*-dichlorobenzene[85,86] suggest that ν_{16} for *p*-disubstituted benzenes has normal coordinates similar to those for the monosubstituted analogs. If the two substituents in a *p*-disubstituted benzene act independently then by using the valence bond approach it follows that the stabilization of the dipolar character of the form *(13)* of the vibrational transition *(13)* ⇌ *(14)* will be the difference (both substituents donors or acceptors) or sum (one donor, one acceptor) of the charge stabilization for the

(13)

(14)

corresponding monosubstituted benzenes. If the dipole contributions by the two substituents are added vectorially, then this relation becomes equation 3 for all combinations of substituent types.

$$\partial\mu/\partial Q_p = (\partial\mu/\partial Q_1) - (\partial\mu/\partial Q_2) \quad (3)$$

$$A_p = b\,(\sigma_R{}^01 \cdot \sigma_R{}^02)^2 + c \quad (4)$$

The intensity of the ν_{16} band for *p*-disubstituted benzenes should therefore be given by (4) where *c* represents the contribution from overtone and combination bands and *b* is a constant. The constant *b* would be expected to be near that of 17600 found for monosubstituted benzenes; however, the exact form of the normal vibration is likely to vary somewhat.

Non-interacting substituents were indeed found to follow this relationship as described later. More complex formulas were necessary[3] for substituents of low symmetry. Similar relationships were found to describe the intensity of the ν_{13a} vibration of *p*-disubstituted benzenes[87] and the ν_{16} vibrations of *o*- and *m*-disubstituted benzenes[94], substituted pyridines[95], and substituted durenes[2]. These relationships allow one to study the steric and electronic effects on the π-electron distribution in the aromatic ring brought about by a second or further substituent.

6. Monosubstituted Benzenes

Table 1 lists the $\sigma_R{}^0$ values for some 140 monosubstituted benzenes calculated from the intensities of their ν_{16} vibrations using eq. (1). The intensities of the vibrations are almost independent of solvent[1,2] unless specific interaction such as hydrogen bonding occurs. Thus, while the intensity of the ν_{16} bands of anisole is almost identical in carbon tetrachloride and isopropanol, the value for phenol increases quite markedly in the latter solvent. We are currently using this technique to investigate[96] various aspects of hydrogen bonding and complex formation.

In equation (1) the constant term (100 units, l/mole^{-1} cm^{-1}) allows for the f plus g combination[97] of the C–H in-phase wagging modes which occur in the vicinity of 1600 cm^{-1}. This is probably of variable intensity and we estimate a resulting error of ±50 units. Values of $\sigma_R{}^0$ below 0.1 units are therefore better determined from the intensities of polysubstituted benzenes and, in particular, from those found for *m*-disubstituted benzenes where the two substituents are not likely to interact, or from the intensities of olefins.

The measurement of the ν_{16} intensities gives a measure of the π-electron disturbance but does not determine whether this is towards or away from the substituent. This is obvious for many substituents from other work such as NMR spectroscopy but the ν_{13} inten-

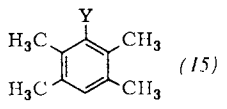
sities are also useful in this respect. This band is allowed in benzene itself and the intensity is found [87] to be increased by electron-donating substituents and reduced by electron-withdrawing ones. There may be some confusion with substituents showing only weak effects but results from polysubstituted compounds usually allow a definite decision to be made. The direction of the π-electron disturbance is shown in the Table where this is well established; electron donating substituents have negative σ_R^0 values. Signs for substituents having little effect, for example derivatives of Group IV and V elements [98], were generally assigned using *meta* derivatives.

The results obtained generally show very good agreement with σ_R^0 values obtained by NMR or reactivity methods where these values are available (Fig. 1). The results for individual substituents have been fully discussed elsewhere [2] and we limit ourselves in this review to just a few examples.



We earlier concluded [2] that σ_R^0 values derived from infrared intensities are indeed a measure of mesomeric interaction and recent theoretical calculations [54,99] support this view.

7. Steric Effects. Results of Studies on Durenes

The concept of the reduction of mesomeric interaction between ring and substituent by twisting is fundamental to present theories on conjugation. For example, from the ^{19}F-NMR spectrum of 4-fluoro-*N*,*N*,2-trimethylaniline, *Taft et al.* [63] found the value $\sigma_R^0 = -0.24$ for the twisted $N(CH_3)_2$ group, a reduction of 56 % by the steric effects of one *o*-methyl group. We utilized substituted durenes *(15)* to test the effect of steric hindrance on infrared intensities. The IR spectrum of durene [*(15)*, Y = H] shows no band near 1600 cm^{-1}; the ν_{16} mode is forbidden because of the

[98] *J. M. Angelleli, R. T. C. Brownlee, A. R. Katritzky, R. D. Topsom*, and *L. Yakhontov*, J. Amer. chem. Soc. *91*, 4500 (1969).

[99] *A. K. Chandra*, Molecular Physics *14*, 577 (1968).

(15)

D_{2h} symmetry of the molecule. Although a normal coordinate analysis has apparently not been carried out for durene, the form of the modes for 1,2,4,5-tetrachlorobenzene[85] suggests that the ν_{16a} mode will not be very different from that in benzene. Steric hindrance in durenes has been the subject of considerable work, and a decrease in conjugation of substituents compared with that in phenyl derivatives has been demonstrated by UV spectra[100], dipole moments[101], NMR shielding[102], and chemical reactivity[103].

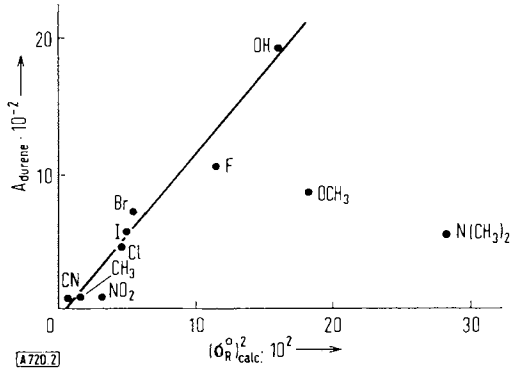


Fig. 2. Correlation of A_{durene} (1 mole^{-1} cm^{-2}) with $(\sigma_R^0)^2$ according to eq. (5).

In Figure 2 the A values for the durenes are plotted against $(\sigma_R^0)^2$ for the corresponding substituent. Substituents with cylindrical symmetry (CN, CH_3, halogens, and possibly OH) show a linear relation found by the least-squares procedure to be as in eq. (5); the small non-zero intercept is probably not significant. The lower overall values for the durenes for the symmetrical substituents may be a result of a decreased contribution of CH wagging mode to the ν_{16} for durene as compared with benzene[86].

$$A_{durene} = 11300\ (\sigma_R^0)^2 - 30 \qquad (5)$$

Equation (5) indicates that in the durene system, the substituents of low symmetry, $N(CH_3)_2$, OCH_3, NO_2, exhibit effective σ_R^0 values of 0.23, 0.28, and 0.10 respectively. This suggests steric inhibition of respectively 58, 35, and 41 % of the resonance interaction. If the angle of twist is related to the resonance interaction by an equation of the type

$$\sigma_R t = \sigma_R^0 \cos \Phi$$

where σ_R^t indicates the value for the twisted substituent, then this corresponds to angles of twisting as follows: $N(CH_3)_2$, 65 °; OCH_3, 49 °; NO_2, 54 °. (Such treatment assumes implicitly that π-inductive effects are completely absent; see below.) These results agree[2] fairly well with those reported in the literature. Other work[38,104] also suggests that the OH group in hydroxydurene is still substantially coplanar with the ring.

8. *p*-Disubstituted Benzenes

Equation (4) gives the expected intensity of IR bands in *p*-disubstituted benzenes with non-interacting substituents, where c is the contribution from overtone and combination bands. *p*-Disubstituted benzenes show overtone bands near 1900 cm^{-1} and near 1630 cm^{-1}. The species of these bands[97] are A_1 for compounds of C_{2v} symmetry and B_{3u} for symmetrically substituted (V_h) compounds. Hence for compounds of C_{2v} symmetry, mixing is to be expected between the 1630 cm^{-1} band and the bands under discussion.

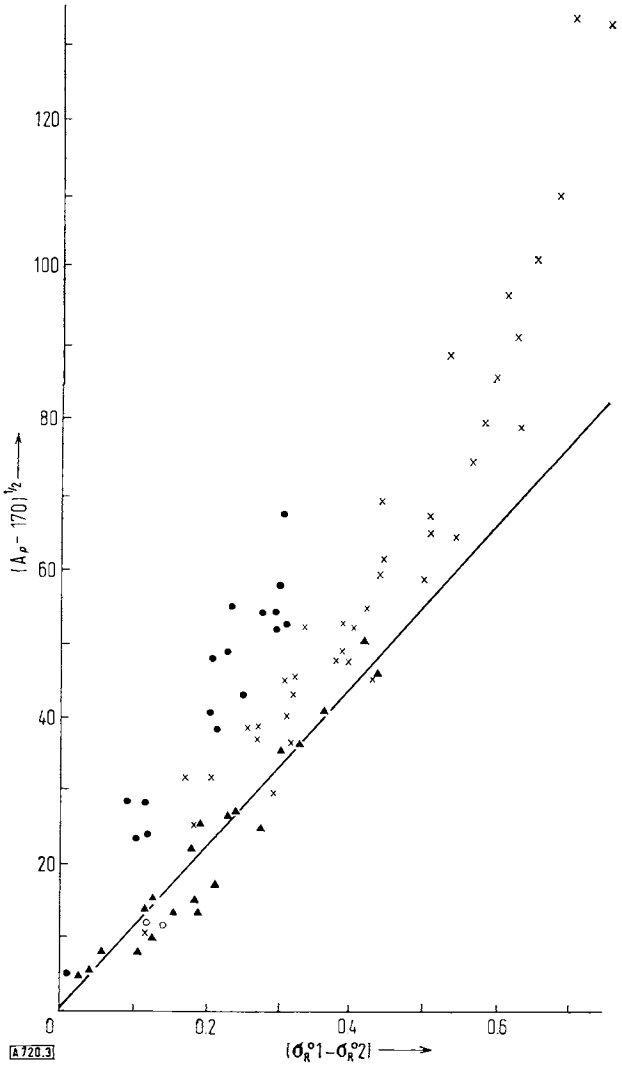

Fig. 3. Plot of equation (6) with correction for asymmetry effect; ●, strong donor paired with d-orbital acceptor; ▲, other donor-donor compounds; ×, donor-acceptor compounds. The line shown is that found by a least-squares plot of the points of type ▲.

[104] *C. E. Ingham* and *G. C. Hampson*, J. chem. Soc. (London) *1939*, 981; *N. A. Puttnam*, *ibid. 1960*, 5100.

Measurement of the 1630 cm^{-1} band intensity is possible [3] for symmetrically *p*-disubstituted compounds, since the ν_{16} vibration is forbidden here, and also approximately for some of the less symmetrical compounds. The average value found is 170 units and this value was therefore taken for *c*. A plot of $(A_p - 170)^{1/2}$ against $\sigma_R{}^01 - \sigma_R{}^02$ is shown in Figure 3. This plot omits nitrobenzenes substituted with another electron-withdrawing group in the *p*-position since these compounds give [3] very anomalous results. This may be caused by the relatively low ionization potential of the nitro group leading to a reversal of its normal π-electron-withdrawing properties and a series of benzenes with *p*-nitroso- and *p*-azo substituents is currently being investigated [105] since these substituents have even lower ionization potentials.

Figure 3 shows that most compounds with donor-donor and acceptor-acceptor substituents follow our expectation and the line is drawn to fit these by a least-square plot leading to the equation

$$A_p = 11\,800\,(\sigma_R{}^01 - \sigma_R{}^02) + 170 \qquad (6)$$

It was necessary to use a somewhat more complex formula [3] where the compounds contained asymmetric substituents since $\sigma_R{}^0$ is a vector quantity. The points in Figure 3 are corrected for this.

The two classes of compounds that do not fit this line are those with donor-acceptor substituents and those where a strong donor, $\sigma_R{}^0 < -0.3$ (*e.g.* $N(CH_3)_2$, OCH_3, F), is paired with a substituent possessing a vacant d-orbital next to the ring (*e.g.* Cl, Br, I, SMe).

The positive discrepancies observed for the compounds containing donor-acceptor substituents can be ascribed [3] to resonance interaction between the substituents leading to some contribution of the *p*-quinonoid form *(12)*. All these points can be fitted to the line if a correction term is introduced in eq. (6) leading to eq. (7).

$$A_{p-A/D} = 11\,800\,[\sigma_R{}^0D - \sigma_R{}^0A + K_A\,(\sigma^+D - \sigma D)] + 170 \qquad (7)$$

The power of the donor to increase its interaction here is well represented by $(\sigma^+ - \sigma)$ but empirically found factors for the acceptor (K_A) are roughly proportional to $\sigma_R{}^0$ not $(\sigma^- - \sigma)$. The important thing to note, however, is that one value of K_A fits an acceptor substituent for interaction with any donor in the *para* position. The results for *p*-disubstituted benzenes containing donor-acceptor substituents plotted according to eq. (7) are shown in Figure 4. Values of K_A for important substituents are 0.36 (CO_2CH_3 and $CO_2C_2H_5$), 0.57 (CHO), 0.45 ($COCH_3$), 0.55 (NO_2), and 0.29 (CN).

The results above do suggest some additional interaction in fluorobenzenes containing an electron-accepting substituent and thus the ^{19}F–NMR results will not give accurate $\sigma_R{}^0$ values for these substituents.

[105] *A. R. Katritzky, S. Ohlenrott,* and *R. D. Topsom,* unpublished results.

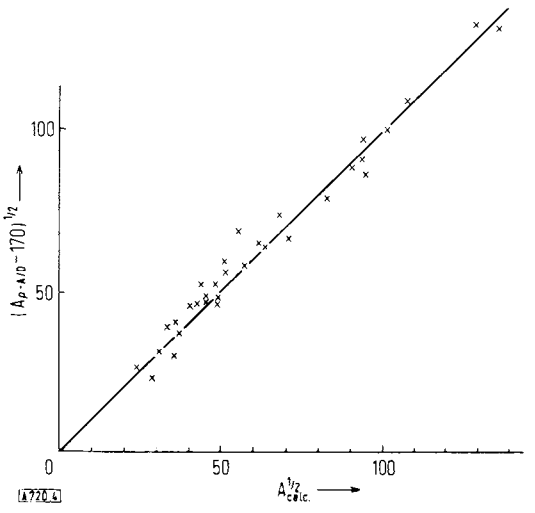

Fig. 4. Comparison of calculated and observed *A* values for donor-acceptor compounds [cf. eq. (7)]. The line shown has unit slope.

However, the $\sigma^+ - \sigma$ value for F is small (– 0.11) and such resonance interaction would not be expected to increase the observed $\sigma_R{}^0$ value by more than 0.03 unit.

9. d-Orbital Interactions

The halogens normally behave as resonance donor groups with negative $\sigma_R{}^0$ values. However, for compounds where Cl, Br, or I (but not F) is placed *para* to a strong donor substituent, the observed intensity is significantly greater than expected from eq. (6). Similar results are found for other substituents which have vacant d-orbitals on the atom next to the ring and we have therefore suggested [3,98] that this arises from direct resonance interaction between the *para* substituents.

The effect is greater in the series I > Br > Cl for the halogens d-orbital acceptors and $N(CH_3)_2 > NHCH_3 > ND_2 > OCH_3 > F$ for the donor group. The discrepancies are fitted [3] by introducing a correction term in eq. (6) leading to eq. (8)

$$A_{p\,X-D} = 11\,800\,(\sigma_R{}^0D - \sigma_R{}^0X + K_X\,\sigma_R{}^0D)^2 + 170 \qquad (8)$$

where X refers to the d-orbital acceptor. Some values [3,98] of K_X are listed in Table 2.

Table 2. Values of K_X for d-orbital acceptors.

Substituent	K_X	Substituent	K_X
Cl	0.32	$SiMe_3$	0.48
Br	0.42	$GeMe_3$	0.50
I	0.55	$SnMe_3$	0.65
SMe	0.44		
SMe_2^+	0.67		

A plot of observed *A* values against those calculated by eq. (8) is shown for some halobenzenes containing *p*-electron-donating substituents in Figure 5. It is evident that the one K_X value per substituent fits all cases. It should be noted that eq. (8) is of different

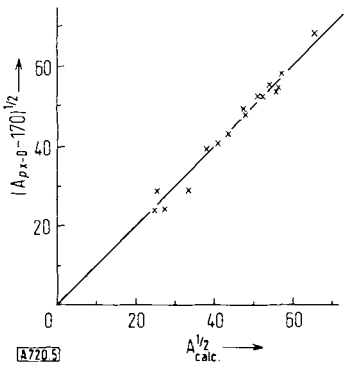

Fig. 5. Comparison of calculated and observed A values for strong donor-d-orbital acceptor compounds [cf. eq. (8)]. The line shown has unit slope.

form from eq. (7) for normal donor-acceptor compounds.

We have discussed elsewhere[3,98] the considerable previous evidence for the participation of d orbitals in π bonding. The IR results, which include the charged $[S(CH_3)_2]^+$ substituent, cannot be reasonably explained on alternative theories such as the polarizability of the bond connecting the d-orbital substituent to the ring. Additional evidence comes from our results[87] on the 1500 cm^{-1} band since the form of this vibration for *p*-substituted benzenes allows one to determine that *both* of the substituents are showing an increased resonance interaction with the ring in these compounds.

Interaction of this type between fluorine (as donor) and d-orbital acceptors would be expected to effect the σ_R^0 values obtained for such substituents by the ^{19}F–NMR methods. The direct exaltation is $K_X \sigma_R^0(F)$ and we can correct σ_R^0 values if we assume that half of the change is due to the fluorine atom behaving as a stronger donor and half is due to the d-orbital interaction. Thus the reported σ_R^0 value for iodine determined by the ^{19}F–NMR method is 0.17 but the addition of 0.08 units $[1/2 K_X \sigma_R^0(F)]$ gives a value of 0.25 in agreement with our work on mono-substituted benzenes (Table 1).

10. The π-Inductive Effects of Charged Substituents

The results for eight *p*-substituted compounds containing the groups $[N(CH_3)_3]^+$ or $[ND_3]^+$ show[3] clearly that these groups are resonance donors with σ_R^0 values of −0.15 and −0.18 respectively. The $[S(CH_3)_2]^+$ substituent[98] is also apparently a weak donor (−0.09) while the $[P(C_6H_5)_3]^+$ substituent[98] has only a small resonance effect of indeterminate sign. These disturbances of the π system away from the charged substituent are in accord with other evidence: pK_a measurements indicate[106] σ_R of −0.11 for $[N(CH_3)_3]^+$; ^{19}F–NMR data[107] from *p*-fluorotrimethylanilinium chloride indicate a σ_R^0 of −0.08 for $[N(CH_3)_3]^+$; pK values of substituted phenols[108] and the equation $\sigma_R = 1.5\,(\sigma_p - \sigma_m)$ give $\sigma_R = -0.12$ for $[N(CH_3)_3]^+$ (but +0.25 for $[S(CH_3)_2]^+$). The effect of $[N(CH_3)_3]^+$ groups on benzenoid chemical shifts has been shown[109] to indicate a somewhat higher electron density at the *para*, rather than the *meta* position to $[N(CH_3)_3]^+$, but this was ascribed to the weakening of the inductive effect with distance. Resonance interactions between the ring and substituents were not considered.

The reactivity of charged substituents has attracted much recent attention[110–112,143] since kinetic and product studies have shown that a considerable amount of *para* substitution occurs with electrophilic reagents. The oxonium group has been reported[113] to be 100 % *para* directing. Some, at least, of these authors[111,143] have recognized that the substituent may increase the electron density at the *para* position by interaction of the filled p orbitals of the substituent with the ring. Our work affords strong evidence for this and may have an effect on theoretical calculations[25,114,144] which have considered effects on the π system of ammonium or trimethylammonium substituents as arising mainly from π-inductive effects acting in the opposite direction.

The idea that a substituent may have any substantial I_π effect, that is disturb the π-electron system of an aromatic ring either as a secondary result of changing the σ charge distribution on the aromatic carbon to which it is attached or by a through-space field effect, is made untenable by these results since it would act in the opposite direction to that observed. Other strong evidence comes from the absence of any significant effect on the π system shown by substituents such as $[CH_2NR_3]^+$[115], $C(CN)_3$[16,116], and CCl_3[2,116], which all presumably have strong primary inductive effects, and the marked reduction in σ_R^0 value of unsymmetrical substituents when these are twisted[2,117] out of the aromatic plane. The CF_3 substituent remains somewhat of an anomaly[2,118,119].

Our results do not allow detailed conclusions to be drawn about the extent of repulsive interaction between filled orbitals on the substituent and the π system of the ring. The occurrence of this for $[N(CH_3)_3]^+$ suggests that similar effects do exist for CR_3 and presumably also in substituents such as NR_2 which contain lone pairs. However we feel that most of the π disturbance in NR_2 is caused by conjugative electron donation. It was noted earlier that repulsive interactions are included in the "I_π effect" by some authors. Even though we consider I_π effects induced by polarity of substituent bonds to be negligible, this repulsive interaction is in the opposite direction and we strongly suggest that it should be made clear which effect is referred to in each instance. There has been some suggestion[119] that repulsive interactions directly affect positions other than the one to which the substituent is connected in certain cases and further work on model compounds in which various atoms of a substituent are held close to the *ortho* and *meta* positions is highly desirable.

11. Conclusions

To summarize, our own and recent other work leads us to conclude that in non-crowded systems there are only three important effects of a substituent on a benzene ring.

1. Conjugative or mesomeric interactions. This effect is felt mainly at the *ortho* and *para* positions and results in transfer of electron density from ring to substituent or *vice versa*.

2. Repulsion of the π electrons of the ring by p electrons of the substituent. This is felt mainly at the *ortho* and *para* positions but the nett result is a redistribution of the existing π density of the ring.

3. A direct field effect of the substituent potential on a reaction or measurement site elsewhere in the ring. This factor will only be obvious if the method of measurement is susceptible to a field effect. A recent example of this[17,145,146] is found in the observation that unless highly polar solvents are used alicyclic fluorides do not show ^{19}F–NMR shifts caused by field effects from remote substituents while aryl fluorides do. This apparently occurs because in the latter case the unshared p electrons on the fluorine atom can be induced by the field effect to conjugate further with the π system of the aromatic ring; this is not possible with the alicyclic compounds.

In addition there is probably a small σ-inductive effect but this will diminish rapidly, albeit alternatively, with the length of the carbon chain.

In disubstituted benzenes, there is the additional possibility of interaction between the substituents which will mainly be shown in the form of conjugative effects which require them to be placed *ortho* or *para* to one another.

Organogold Chemistry

By Brunhilde Armer[*] and Hubert Schmidbaur[**]

Organogold compounds having at least one Au–C σ or π bond and gold-carborane complexes have recently received rapidly increasing attention, from the point of view of valence theory and structure as well as on practical grounds. Interesting possibilities are offered particularly in connection with the use of gold and its derivatives as heterogeneous or homogeneous catalysts for organic reactions, and new problems also arise.

1. Introduction

In the chemistry of the noble metals[1], the organo derivatives of these elements have been growing in importance for a number of years. This growth has reached a very advanced stage *e.g.* in the cases of iridium and platinum[2,3]. Increasing interest has recently also been shown in organogold compounds, largely because of their potential applications. Well-known examples are the catalytic activity of metallic gold in many syntheses and the use of thermally unstable organogold compounds for the production of very pure, firmly adhering gold coatings on suitable support materials.

In the 30 or so years that have elapsed since the publication of the classical work by *Krause* and *v. Grosse*[4], which covers the literature on organometallic chemistry up to 1936, no further comprehensive reviews of this field have appeared. Even in more recent monographs it has been either omitted altogether[2] or discussed only briefly[3]. In the present article we present a critical review of articles on organogold compounds published up to 1969. In accordance with a generally accepted definition[2], we shall consider only compounds that contain at least one gold-carbon bond, excluding simple and complex gold cyanides.

2. Organogold Compounds Containing Gold-Carbon σ Bonds

2.1. Trialkylgold(III) Compounds and their Derivatives

Though the first efforts to prepare organogold compounds were made[5,6] more than 100 years ago, *i.e.* in the very early stages of organometallic chemistry, it was only at the beginning of the present century that their existence was conclusively demonstrated[7]. Even then, however, it was not yet possible to isolate the parent compounds. This achievement was reserved for the experiments of *Gilman*[8,9] and *Coates*[10] in the 1940's and 1960's respectively. The first information about the functional compounds of the types R_2AuX and $RAuX_2$, which had been obtainable even earlier, nearly all came from the laboratory of *Gibson*, who practically single-handed laid the foundations for later and more extensive investigations (see Sections 2.2 and 2.3).

2.1.1. Trimethylgold

Trimethylgold[8,9] is formed on reaction of a suspension of gold tribromide or dimethylgold bromide in ether with methyllithium at −65 °C:

$$[AuBr_3]_2 + 6\,LiCH_3 \xrightarrow{(C_2H_5)_2O} 2\,(CH_3)_3Au \cdot O(C_2H_5)_2 + 6\,LiBr$$

$$[(CH_3)_2AuBr]_2 + 2\,LiCH_3 \xrightarrow{(C_2H_5)_2O} 2\,(CH_3)_3Au \cdot O(C_2H_5)_2 + 2\,LiBr$$

The ether solutions, which contain the reaction product as the ether adduct, show signs of decomposition even at −40 to −35 °C, with formation of a gold mirror and a mixture of methane and ethane. $(CH_3)_3Au$ cannot be freed from solvent even at low temperatures, and its physical properties are accordingly still unknown.

An interesting parallel is found in the cases of platinum and iridium, where the pure alkylmetal compounds have similarly defied isolation so far[11]. $(CH_3)_4Pt$ and $(CH_3)_3Ir$ appear to be capable of existing only as components of complexes. The same is true of $(CH_3)_3Au$.

2.1.2. Complexes of Trimethylgold with n-Donors

The influence of the coordinately bound ether is evidently not sufficient to stabilize $(CH_3)_3Au$ under normal conditions; trimethylgold can however be stabilized with nitrogen donors and above all with phosphorus donors, and the resulting coordination

compounds can be handled without difficulty at or above room temperature [9,10].

These adducts can all be prepared by reaction of the ether solution of trimethylgold with the bases [9,10]. Trimethylgold-trimethylphosphine can also be obtained from the ethylenediamine adduct by a displacement reaction. Trimethylgold-diethyl ether does not however react with aniline, dimethylaniline, *p*-phenylenediamine, piperidine, ethylamine, dimethylamine, or glycosine. The IR bands of the phosphine complexes of $(CH_3)_3Au$ have been substantially assigned, and the dipole moments of the compounds have also been determined [10]. Characteristic temperatures for trimethylgold adducts are given in Table 1.

Table 1. Trimethylgold addition compounds.

	M.p. (°C)	Dec. (°C)	Ref.
$(CH_3)_3Au \cdot O(C_2H_5)_2$	–	−40 to −35	[8, 9]
$(CH_3)_3Au \cdot NH_2CH_2CH_2NH_2 \cdot Au(CH_3)_3$	–	94–98	[9]
$(CH_3)_3Au \cdot$ 2-Aminopyridine	–	–	[9]
$(CH_3)_3Au \cdot NH_2CH_2{-}C_6H_5$	51.5–53	–	[9]
$(CH_3)_3Au \cdot P(C_6H_5)_3$	120 (dec.)	–	[10]
	119	–	[10a]
$(CH_3)_3Au \cdot P(CH_3)_3$	23 (Subl.-pt. 25/0.004 torr)	–	[10]

These compounds are very probably approximately square-planar complexes of Au^{III} (dsp^2); however, this assumption has not yet been experimentally checked.

The thermal decomposition of trimethyl(triphenylphosphine)gold(III) proceeds in steps [10]:

$$(C_6H_5)_3P{\rightarrow}Au(CH_3)_3 \xrightarrow{\Delta} C_2H_6 + (C_6H_5)_3P{\rightarrow}AuCH_3$$
$$\xrightarrow{\Delta} {}^1/_2\,C_2H_6 + (C_6H_5)_3P + Au$$

This decomposition leads only to ethane (no methane).

2.1.3. Reactions of Trimethylgold with Acids

Reaction of trimethylgold with acids HX leads to cleavage of a gold-carbon bond and formation of methane:

$$(CH_3)_3Au + HX \rightarrow (CH_3)_2AuX + CH_4$$
$$X = Cl, SC_6H_5, SCH_2COOH$$

In the presence of bromide, cleavage with hydrogen chloride yields dimethylgold *bromide* instead of dimethylgold chloride. It has surprisingly been found that trimethylgold is stable to phenol and trichloroacetic acid. The course of the commutation reaction

$$2\,(CH_3)_3Au + AuBr_3 \rightarrow 3\,(CH_3)_2AuBr$$

with the Lewis acid $AuBr_3$ [9] is as expected from the behavior of the alkylmetal compounds of aluminum, gallium, indium, or thallium [3].

Very little information is available at present on higher homologs of trimethylgold. The almost complete lack of information about the possible range of existence of tri*aryl*gold compounds is particularly striking. We seem to have here a completely unexplored, and possibly unfriendly, new territory.

2.2. Dialkylgold(III) Halides and Related Compounds

There are numerous known examples of organogold compounds having the general formula R_2AuX, where X may be either a monodentate (*e.g.* halide or cyanide) or a polydentate ligand (*e.g.* 2,4-pentanedionate, 8-quinolinolate, sulfate); Some of the earliest known organogold compounds belong to this group.

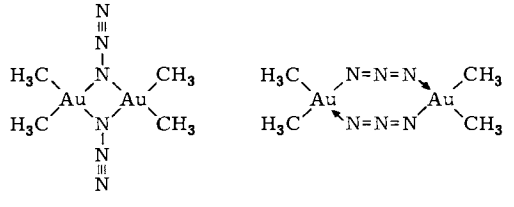
2.2.1. Dialkylgold Halides and Pseudohalides

2.2.1.1. Preparation

Dialkylgold halides (see Table 2) are generally formed in the reaction of gold(III) halides [7,12] with alkylmagnesium halides in ether:

$$AuX_3 + 2\,RMgY \rightarrow R_2AuY + MgX_2 + MgXY$$

Tetrabromoauric acid [13] and the pyridine complexes of gold tribromide and trichloride [14,15] can also be used as the gold halide component. $AuCl_3 \cdot py$ and the Grignard reagent from 1,5-dibromopentane and magnesium [16,17] give mainly decamethylenegold bromide and (in small quantities) pentamethylenegold bromide, which can be isolated as ethylenediamine complexes. The action of hydrobromic acid on the complex of the latter compound yields colorless crystals whose analytical data point to a dimer having a composition $(C_5H_{10}AuBr)_2$:

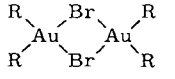


Dialkylgold cyanides can be obtained from the bromides by reaction with silver cyanide [12].

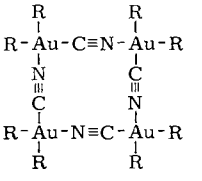
$$R_2AuBr + AgCN \rightarrow R_2AuCN + AgBr$$

Recently the explosive dimethylgold azide has also been prepared and characterized using analytical and spectroscopic methods [12a].

$$[(CH_3)_2Au \cdot en]I + AgN_3 \rightarrow [(CH_3)_2Au \cdot en]N_3 + AgI$$
$$[(CH_3)_2Au \cdot en]N_3 + 2\,HCl \rightarrow {}^1/_2[(CH_3)_2AuN_3]_2 + en \cdot 2\,HCl$$



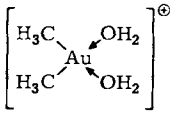
Two possible structures are suggested from the results of molecular weight determinations and from IR- and NMR-spectra (both D_{2h}!):



No dialkylgold fluorides have been described as yet. Extensive efforts to prepare dimethylgold fluoride, whose structure is particularly interesting in view of the peculiar situation in gold trifluoride [18], have had little success [19]. This compound has not been isolated in the pure crystalline state, though its existence is beyound doubt, as is adequately demonstrated by IR and NMR spectra. The hope of discovering a molecular structure corresponding on the one hand to that of AuF_3 and on the other to that of the (isosteric) $(CH_3)_2AuOH$ (see Section 2.2.2) has not yet been fulfilled.

2.2.1.2. Properties

The characteristics of the known dialkylgold halides and cyanides are listed in Table 2. All the compounds are sensitive to light. Molecular weight determinations on some of the halides in benzene or $CHBr_3$ [14,15,20] point to a dimeric molecular structure. The small dipole moment of diethylgold bromide (1.37 D) [21,22] and results of its X-ray structural analysis [22] confirm the four-membered ring structure with an approximately square-planar arrangement of the ligands around the gold atoms, as expected for the dialkylgold(III) halides:



A square-planar arrangement of the ligands has also been found for diethylgold and dipropylgold cyanides. The compounds are tetrameric [23]. Dipropylgold cyanide has a dipole moment of only 1.47 D [22]. X-ray studies [24] have shown that four monomer units combine to form a square having an edge length of 5.18 Å, with twelve atoms on the edges and corners of the square.

Only a few dialkylgold halides have been examined spectroscopically. The ^{1}H-NMR spectra of diethylgold bromide [25] and dimethylgold iodide [25,26] in $CCl_4/CHCl_3$ and of aqueous solutions of dimethylgold nitrate and dimethylgold perchlorate [26] each show only one signal, and so confirm the symmetrical arrangement of the ligands in the oligomers.

The Raman spectra of aqueous solutions of dimethylgold nitrate or dimethylgold perchlorate and of sodium dimethyldihydroxoaurate [26] show that the structural unit $(CH_3)_2Au$ is not linear, but angular. Thus the methyl groups in the solvated dimethylgold ion are in the *cis* position:

Neopentyl	–	–	–	121–123	–	[9]	–	–	–	–	–	–

The equilibria of hydrolysis for this cation have been studied in detail [26a].

The IR spectra of dimethylgold bromide and dimethylgold iodide have also been recorded [25–27]. The energy threshold for internal rotation was determined from the dependence of the shape of the antisymmetric CH_3 deformation band in $(CH_3)_2AuI$ on temperature (90 to 298 °K), and was found to be approximately 770 cal/mole [27].

On the basis of UV spectroscopic studies on alkylgold compounds, *Chakravorty* [28] concludes that the alkyl groups produce a stronger ligand field than halide. Diethylgold bromide, unlike the tetrabromoaurate, is colorless. The energy of the $d_{x^2-y^2}$ orbital can therefore be assumed to be higher in the alkylgold compound than in the tetrabromoaurate.

An unknown volatile gold compound is formed when methyl chloride is blown through a molten euctectic gold-silicon alloy (380 °C) [29]; the crystals, which are colorless at −196 °C, decompose above −70 °C with deposition of gold.

≡$[R_2AuCN \cdot AuCN]_4$

Organogold compounds are also postulated as intermediates in the reactions of alkyllead compounds with gold trichloride [30], though they have not yet been isolated.

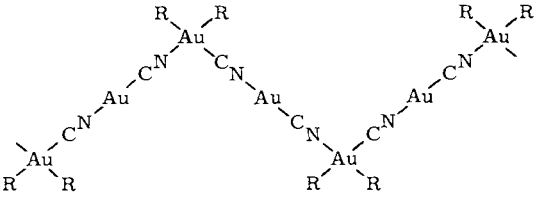
2.2.1.3. Thermal Behavior

Dialkylgold halides and cyanides are thermally unstable. Thus dimethylgold bromide decomposes when heated in boiling ether for 48 hours [8, 31], with formation of ethane, metallic gold, traces of methylgold dibromide, and gold tribromide.



Diethylgold and dipropylgold cyanides decompose in a similar manner [23], the former slowly at room temperature, and the latter only in boiling benzene. The alkyl groups are removed stepwise.

$$[R_2AuCN]_4 \xrightarrow{\Delta} 2\,R_2Au_2(CN)_2 + 2\,R\text{–}R$$

$$2\,R_2Au_2(CN)_2 \xrightarrow{\Delta} 4\,AuCN + 2\,R\text{–}R$$

$$R = C_2H_5 \text{ or } n\text{-}C_3H_7$$

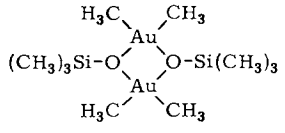
The dialkyldigold dicyanide formulated as an intermediate can be isolated. The following structures are particularly feasible for these compounds, which are insoluble in non-destructive solvents [32].

≡$[R_2AuCN \cdot AuCN]_n$

They correspond to coordination compounds of dialkylgold(III) cyanides and gold(I) cyanide.

2.2.2. Dialkylgold(III) Compounds Containing Gold-Oxygen Bonds

The structurally simplest of the known dialkylgold compounds containing the Au–O bond (see Table 3) is trimethylsiloxodimethylgold, which is formed from



[31] *L. W. Woods*, Iowa State Coll. J. Sci. *19*, 61 (1944); Chem. Abstr. *39*, 693 (1949).

[32] *C. S. Gibson*, Proc. Roy. Soc. (London), Ser. A *173*, 160 (1939); Chem. Abstr. *34*, 1578 (1940).

dimethylgold bromide and sodium trimethylsilanolate [25].

$$[(CH_3)_2AuBr]_2 + 2\ NaOSi(CH_3)_3 \rightarrow [(CH_3)_2Au{-}OSi(CH_3)_3]_2 + 2\ NaBr$$

It can be concluded from the results of molecular weight determinations and from the NMR and IR spectroscopic data that trimethylsiloxodimethylgold exists in the dimeric state as a four-membered ring, and this again allows a square-planar arrangement of the ligands around the gold atoms. This assumption is confirmed by the diamagnetic behavior of the compound. The colorless crystals can be sublimed in a

high vacuum without decomposing. They decompose explosively at 120 °C, with deposition of a gold mirror on the walls of the vessel.

Dimethylgold hydroxide is particularly interesting. It is obtained from dimethylgold iodide and sodium hydroxide [26].

$$2\ [(CH_3)_2AuI]_2 + 4\ NaOH \rightarrow [(CH_3)_2AuOH]_4 + 4\ NaI$$

This compound is not dimeric, but *tetrameric* [33]. The ^{1}H-NMR spectrum shows two signals of equal intensity instead of the expected CH_3 singlet. A three-dimensional X-ray structural analysis [33] showed a puckered eight-membered Au–O ring system. The gold atoms in this ring nevertheless have the expected square arrangement of the ligands. In this structure (Fig. 1), the two methyl groups on each gold atom have structurally different environments, and are therefore magnetically nonequivalent. The isosteric $(CH_3)_2AuF$ should have a similar structure (see Section 2.2.1.1).

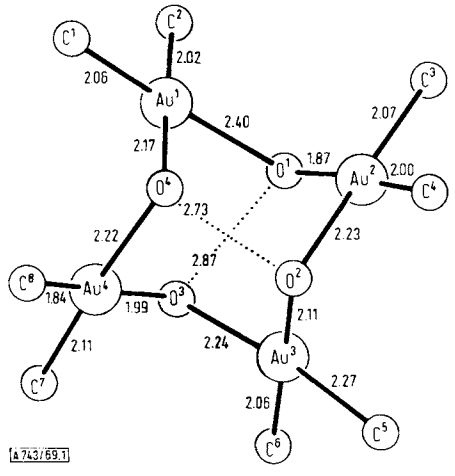


Fig. 1. Structure of cyclo-tetrakis(hydroxodimethylgold). (Bond lengths in Å.)

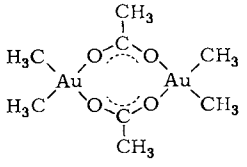
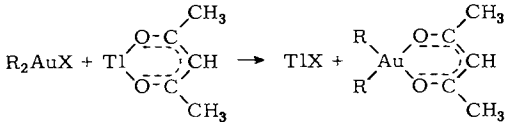


[33] *G. E. Glass, J. H. Konnert, M. G. Miles, D. Britton*, and *R. S. Tobias*, J. Amer. chem. Soc. *90*, 1131 (1968).

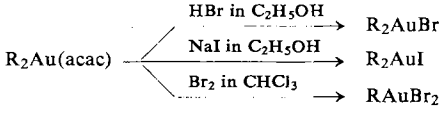
Trimethylplatinum hydroxide is also oligomeric; however, this compound forms tetramers having a cubane-like skeleton [34].



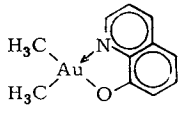
Colorless, crystalline dimethylgold acetate [35], which was only recently prepared from dimethylgold bromide and silver acetate in tetrahydrofuran, is again dimeric according to molecular weight determinations.

$$[(CH_3)_2AuBr]_2 + 2\ CH_3COOAg \rightarrow [(CH_3)_2Au{-}O(O)CCH_3]_2 + 2\ AgBr$$

The IR and NMR spectra confirm the assumption that the acetate groups act as bidentate ligands in the dimeric molecules. This leads to a structure with a planar eight-membered ring system and a coplanar arrangement (point group D_{2h}) of all the heavy atoms (Au, O, C). The extremely thin, plate-like appearance of the crystals and their diamagnetism agree well with this view.



Dialkyl(2,4-pentanedionato)gold complexes (acetylacetonates) had been prepared much earlier from dialkylgold halides and 2,4-pentanedionatothallium [15,22].



R = C_2H_5, CH_3; X = Br, I

The compounds are colorless, crystalline, and soluble in most organic solvents. They exhibit characteristic cleavage reactions:

According to IR studies [26], these complexes are typical chelates. Dimethylgold-2,4-pentanedionate has been the subject of studies of ligand exchange processes [26b]. The temperature dependence of NMR-spectra of its solution in 2,4-pentanedione provided the parameters of activation for a process in which ligands and solvent molecules compete for the central atoms.

8-Quinolinol also behaves as a bidentate, chelating ligand in corresponding compounds [36]:

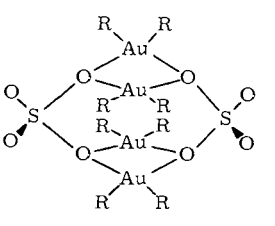
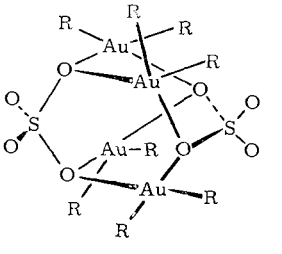
Dialkylgold compounds of dicarboxylic acids have been known for some time [37]. They are prepared by reaction of aqueous solutions of bis(dialkylgold) sulfates with the sodium salts of the corresponding dicarboxylic acids, *e.g.*:

$$[(C_2H_5)_2Au]_2SO_4 + \begin{matrix}COONa\\COONa\end{matrix} \rightarrow Na_2SO_4 + \text{  }$$

Bis(diethylgold) oxalate crystallizes in long, colorless needles. The results of molecular weight determinations are compatible with the indicated structure involving two five-membered rings. With malonic acid instead of oxalic acid, a fundamental change in structure is observed. Bis(diethylgold) malonate evidently contains not two, but four gold atoms per molecule; the compound is dimeric. The following structure is postulated:

The higher homologs also appear to be dimeric. Bis(diethylgold) oxalate dissolves in an aqueous solution of sodium oxalate, and a salt having the composition



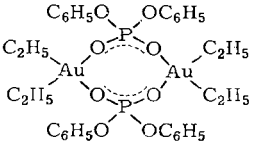


can then be isolated from the solution.

Bis(diethylgold) phthalate [37] probably has a structure similar to that of the oxalate. The isophthalic acid derivative is trimeric, while the terephthalic acid derivative is polymeric and insoluble. The reaction of dialkylgold bromides with silver sulfate in acetone yields bis(dialkylgold) sulfates [12].

$$2\,[R_2AuBr]_2 + 2\,Ag_2SO_4 \rightarrow [(R_2Au)_2SO_4]_2 + 4\,AgBr$$
$$R = C_2H_5 \text{ or } n\text{-}C_3H_7$$

The structure of the dimeric compounds is unknown; two suggested structures [38] are:



The first of these is less likely on steric grounds [38].

Bis(diethylgold) sulfate and 2,2'-bipyridyl react to form the complex salt $[(C_2H_5)_2Au \cdot bipy]_2^{\oplus}[(C_2H_5)_2Au(SO_4)_2Au(C_2H_5)_2]^{2\ominus}$, in which the anion presumably has a structure similar to that of diethylgold diphenyl phosphate (see below).

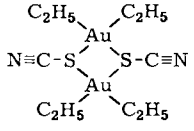
Related compounds have also been synthesized from the disilver salts of monophenyl phosphates and monophenyl arsenates [39]. These compounds are dimeric, like the sulfates, and probably have a similar constitution. Mention should also be made in this connection of the dimeric diethylgold diphenyl phosphate, which undoubtedly again has a structure involving an eight-membered ring system.

[37] *C. S. Gibson* and *W. P. Weller*, J. chem. Soc. (London) *1941*, 102.

[38] *R. V. G. Ewens* and *C. S. Gibson*, J. chem. Soc. (London) *1941*, 109.

[39] *M. E. Foss* and *C. S. Gibson*, J. chem. Soc. (London) *1949*, 3075.

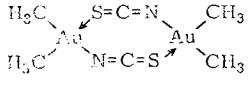
Reactions of diethylgold and di-*n*-butylgold bromides with silver phosphate yield polymers having the composition $(R_2Au)_3PO_4$ that are sparingly soluble in all tested solvents [33].



2.2.3. Dialkylgold(III) Compounds Containing Gold-Sulfur Bonds

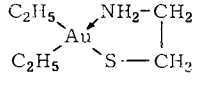
Dimethylgold thiolates were mentioned earlier in connection with the reactions of trimethylgold (Section 2.1.3).

They can also be prepared from dialkylgold halides and thiols in the presence of bases [12]. Dimeric diethylgold thiocyanate is formed in the reaction of diethylgold bromide with silver thiocyanate [40].



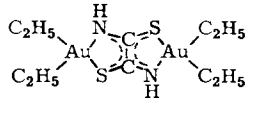
$$[(C_2H_5)_2AuBr]_2 + 2\ AgSCN \rightarrow [(C_2H_5)_2AuSCN]_2 + 2\ AgBr$$

Initially the evidence seemed to indicate that this molecule does not contain gold-nitrogen bonds; it was therefore thought to have the following structure:



The compound decomposes above 80 °C with formation of gold(I) thiocyanate.

Recently di*methyl*gold thiocyanate has also been prepared and investigated [40a]. This compound is a dimer as well, but is said to have a double bridge structure of the following type:



Only this formulation can explain the NMR-nonequivalence of methylgroups observed.

The reaction of diethylgold bromide with 2-aminoethanethiol yields a compound in which the nitrogen also has a donor function [41].

Bis(diethylgold) dithiooxamide [41] is formed on reaction of diethylgold bromide with dithiooxamide. This complex is isosteric with bis(diethylgold) oxalate, and probably has the structure:

[40] *W. L. G. Gent* and *C. S. Gibson*, J. chem. Soc. (London) *1949*, 1835.

[40a] *R. S. Tobias et al.*, unpublished; cited in [12a].

[41] *R. V. G. Ewens* and *C. S. Gibson*, J. chem. Soc. (London) *1949*, 431.

Dialkylgold compounds containing Au–S bonds (cf. Table 4) also include derivatives of monothiocarbonic and dithiocarbonic acids and of thioacetic acid:

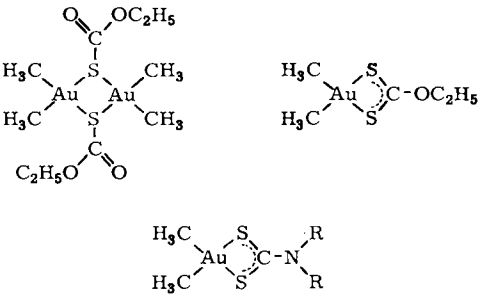


Table 4. Dialkylgold(III) compounds containing Au–S bonds.

	M.p. (°C)	Dec. (°C)	Ref.
$[(CH_3)_2AuSCN]_2$	—	—	[40a]
$[(C_2H_5)_2AuSCN]_2$	62–64	—	[40]

The *N*,*N*-dialkyldithiocarbamates are also obtainable from gold(I) *N*,*N*-dialkyldithiocarbamates [42].

$$Au(S_2CNR'_2) \xrightarrow{Br_2} Br_2Au(S_2CNR'_2) \xrightarrow{RMgX} R_2Au(S_2CNR'_2)$$

Thioacetic acid and trimethylgold react to give polymeric dimethylgold monothioacetate [35].

$$(CH_3)_3Au + HS(O)CCH_3 \rightarrow CH_4 + [(CH_3)_2AuS(O)CCH_3]_n$$

2.3. Alkylgold(III) and Arylgold(III) Dihalides and Related Compounds

2.3.1. Alkylgold Dihalides

The alkylgold derivatives of the type $RAuX_2$ are remarkably unstable, and only alkylgold *dibromides* (see Table 5) are known at present. These are formed in the reaction of dialkylgold bromides with bromine in chloroform or carbon tetrachloride [7, 12, 14, 15, 21],

$$R_2AuBr + Br_2 \rightarrow RAuBr_2 + RBr$$

[42] *H. J. A. Blaauw*, *R. J. F. Nivard*, and *G. J. M. van der Kerk*, J. organometallic Chem. *2*, 236 (1964).

and also in small yields in the commutation reaction [14]

$$R_2AuBr + AuBr_3 \rightarrow 2\ RAuBr_2$$

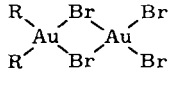

Table 5. Alkylgold and arylgold dihalides $RAuX_2$.

	Dec. (°C)	Ref.
$[CH_3AuBr_2]_2$	–	[15, 31]
$[C_2H_5AuBr_2]_2$	80–85	[7, 12, 14, 31]
$[C_6H_5CH_2AuBr_2]_2$	140	[12]
$[C_6H_5CH_2CH_2AuBr_2]_2$	150–160	[12]
$[n\text{-}C_3H_7AuBr_2]_2$	54 (m.p.)	[21]
$[n\text{-}C_6H_{13}AuBr_2]_2$	150	[12]
$C_6H_5AuCl_2$	73–75	[43]
$CH_3C_6H_4AuCl_2$	–	[43]
$C_6H_5C_6H_4AuCl_2$	65	[43]
$NCC_6H_4AuCl_2$	–	[44]

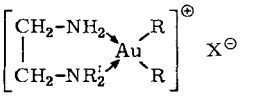
The compounds dissolve only very sparingly in organic solvents. Their high reactivity toward compounds containing olefinic double bonds and to benzene is particularly characteristic. Thus the reaction of ethylgold dibromide with benzene leads to bromobenzene, diethylgold bromide, and gold(I) bromide [14]. Ethylgold dibromide decomposes at 80–85 °C according to the equation

$$[C_2H_5AuBr_2]_2 \rightarrow 2\ AuBr + 2\ C_2H_5Br$$

Alkylgold dibromides, like dialkylgold halides, are *dimeric* [14, 21]. Their dipole moments are unusually high in comparison with those of the dialkyl compounds [21], the following unsymmetrical structure is therefore assumed.

The reaction behavior also points to a structure of this kind. For example, ethylgold dibromide reacts with an aqueous solution of KBr to give $K[AuBr_4]$ and $(C_2H_5)_2AuBr$ [14]. *n*-Donors such as ethylenediamine [14] and pyridine [21] react with alkylgold dibromides to form complexes of gold(III) bromide and of dialkylgold bromide.

2.3.2. Arylgold Dihalides



Benzene reacts vigorously with aqueous gold(III) chloride to form 1,2,4,5-tetrachlorobenzene; with a large excess of benzene, chlorobenzene and gold(I) chloride are formed. If this halogenation is stopped by addition of ether, acetic acid, ethyl acetate, or alcohol, phenylgold dichloride can be isolated in small yields [43]. This product is also thought to be formed as a preliminary stage in the reaction that has long been known as the "auration" of benzene [43].

Phenylgold dichloride is sparingly soluble in water and ether, and readily soluble in salt solutions and alcohol. Dihalogenogold derivatives have also been obtained with substituted benzenes [43,44]. However, these compounds have not yet been sufficiently studied. For this reason, Table 5 does not contain all the known examples.

Gold(III) chloride and pyrrole react to form a sparingly soluble black dye containing gold, the constitution of which is unknown [45].

2.4. Complex Organogold(III) Compounds with *n*-Donors

The pronounced tendency of trivalent gold atoms to form complexes is obvious even from the molecular structures of the functional organogold compounds. If a suitable strong donor is lacking, oligomerization or polymerization occurs. The constitution of the addition compounds formed in the presence of complexing agents was unknown for a long time, or was even given incorrectly; the necessary clarification was then provided by later investigations [46]. Contrary to the earlier views, many of the compounds have an ionic structure, particularly in the case of polydentate ligands. Typical examples are the ethylenediamine complexes of the dialkylgold halides:

R	R′	X	M.p. (°C)	Dec. (°C)	Ref.

C_2H_5	$^1/_2$ $[(C_2H_5)_2AuO_3AsOC_6H_5]_2$ [a]	138	[39]

[a] For structure see text.

The bipyridyl may also be replaced by phenanthroline [46]. The evidence of the ionic character is based mainly on the results of conductivity measurements and of metathetical reactions in which the counterions are exchangeable.

Interesting organogold complex ions with sulfate, phenyl phosphate, and phenyl arsenate groups as bidentate ligands have been found in some cases as counterions:

The structural principles presumably correspond to that of the uncharged organogold sulfates, phosphates, *etc.* The large bond angles that are possible with a planar arrangement of the ring atoms appear to be preferred to those resulting from formation of four-membered rings. The eight-membered ring also avoids tricoordination of the oxygen atoms. Many parallels are to be found in the chemistry of inorganic heterocycles [47–52].

Table 6. Adducts of dialkylgold halides with monofunctional donors.

	M.p. (°C)	Ref.

$(CH_3)_2AuBr \cdot P(C_6H_5)_3$	151	[10a]
$(CH_3)_2AuI \cdot S(CH_2C_6H_5)_2$	77–78 (dec.)	[15]
$[(CH_3)_2Au(OH_2)_2]NO_3$, ClO_4	–	[26, 54, 55]
$(C_6F_5)_2AuCl \cdot P(C_6H_5)_3$	150	[55a, 55d]
$C_6H_5AuBr_2 \cdot P(C_6H_5)_3$	199–201 (dec.)	[55c]

Diethylgold bromide also forms adducts with ammonia [7, 20], pyridine [20], and dibenzyl sulfide [15, 53]. The compositions of some of these complexes are given in Table 6. Their structure is unknown.

A triphenylphosphine complex of dimethylgold bromide is formed from $(CH_3)_3Au \cdot P(C_6H_5)_3$ and bromine or mercuric bromide [10a]. The complex $C_6F_5AuBr_2 \cdot P(C_6H_5)_3$ was obtained from $C_6F_5Au \cdot P(C_6H_5)_3$ and bromine [55c].

Triphenylphosphine also forms a 1 : 1 complex with bis-pentafluorophenylgold chloride, as described by *Nyholm* and *Royo* [55a]. "Oxidation" of $AuCl \cdot P(C_6H_5)_3$ by $(C_6F_5)_2TlCl$ according to

$$(C_6F_5)_2TlCl + AuCl \cdot P(C_6H_5)_3 \rightarrow (C_6F_5)_2AuCl \cdot P(C_6H_5)_3 + TlCl$$

yielded this first perfluoroarylgold(III) compound. Its reduction with hydrazine leads to $C_6F_5Au \cdot P(C_6H_5)_3$ – a compound which can also be obtained from $AuCl \cdot P(C_6H_5)_3$ and C_6F_5MgBr [55c].

The crystal structure of $(C_6F_5)_2AuCl \cdot P(C_6H_5)_3$ has been determined [55d]. The configuration of the gold atom is square planar with the phenyl rings in a *cis*-position. The Au–C distances of 2.12 and 2.18 Å are relatively short.

Dialkylgold halides are hydrated in water. A dihydrate $[(C_2H_5)_2Au(OH_2)_2]Br$ was postulated some time ago for diethylgold bromide [20]; these views have been confirmed by more recent investigations [25, 26, 26a, 54, 55]. The vibration-spectroscopic behavior, which was mentioned in Section 2.2.1.2, verifies the *cis* position of the ligands. Extensive experiments have now been carried out in an attempt to obtain information about the equilibrium constants of the solvation of dimethylgold cations and about the rate of exchange of the water molecules in the first coordination sphere of the gold atom on the basis of ^{17}O-NMR spectra [55]. The activation energy for the H_2O exchange is 8.4 ± 1.8 kcal/mole. This gives a mean residence time ("preexchange lifetime") of 2.2×10^{-5} s at 25 °C for the water molecules bound to gold. Both

quantities have distinctly higher values for the analogous trimethylplatinum cation, the activation energy being 9.4 ± 1.0 kcal/mole and the preexchange lifetime 8.0×10^{-5} s, again at 25 °C. This difference is probably due to steric factors.

2.5. σ-Organogold(I) Compounds

2.5.1. Phosphine-Stabilized Alkylgold(I) and Arylgold(I) Compounds

σ-Alkyl and σ-aryl derivatives of Au^I, like those of Au^{III} appear to be capable of existing only in the presence of stabilizing complexing agents. In any case, all the known compounds of this type contain such ligands, particularly tertiary phosphines. Complexes of this nature were first prepared by *Coates et al.* [56] by reaction of organolithium compounds with the phosphine complexes of the gold(I) halides.

$$R'_3P{\rightarrow}AuX + LiR \rightarrow R'_3P{\rightarrow}Au{-}R + LiX$$

R = CH_3, C_2H_5, mesityl; X = Cl, Br; R′ = C_2H_5, C_6H_5

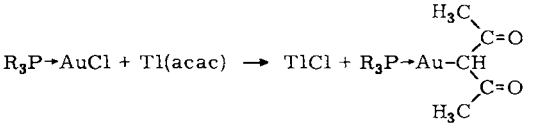
Some of the compounds that have been synthesized by this method are listed in Table 7. Some exhibit considerable thermal and chemical stability; they are soluble as the monomers in organic solvents, and are diamagnetic. Their dipole moments in the region of 5.4 to 5.6 D [57] indicate a relatively low polarity. IR spectroscopy met with difficulties because of the low intensity of some important bands, but nevertheless yielded some fundamental information [10].

These $RAu \cdot PR_3'$ compounds have recently gained new interest through mechanistic studies by *Ingold* and *Gregory* [10a]. As prototypes of compounds undergoing mono- and bimolecular electrophilic substitutions at carbon (S_E1 and S_E2, resp.) they have been shown to supplement the classical examples for this class of reaction mechanisms, the organomercurials. Kinetic studies of the reactions

$$RAu \cdot PR'_3 + HgX_2 \rightarrow RHgX + XAu \cdot PR'_3$$

R′ = C_6H_5; X = Cl, Br, I, CH_3COO, NO_3

have shown an S_E2 process for R = CH_3 and C_2H_5, but an S_E1 mechanism for
R = $C(CN)(C_4H_9)(OCOC_2H_5)$, in agreement with expectation.



Substitutions in trialkylgold complexes $R_3Au \cdot PR_3'$ also occur with an S_E2 type mechanism [10a].

The structure of the compounds is assumed to be linear, corresponding to an sp-hybridized gold atom. Appreciable (d→d)π back-bonding components are probable for the Au–P bond [10, 57]. This approach or the SHAB [61, 62] principle offers possibilities of explaining the stabilizing effect of the phosphine ligands.

An interesting variant is found in the work of *Lewis et al.* [59]. The reaction of chlorotriphenylphosphinegold(I) with 2,4-pentanedionatothallium(I) yields a corresponding Au^I complex, in which, however, the heavy metal is bound to carbon and not to chelating oxygen atoms!

$R_3 = (C_6H_5)_3$, $(C_6H_5)_2C_2H_5$, or $(C_2H_5)_3$

NMR and IR spectra verify the composition and constitution. This preference for the C rather than for the O ligand is almost unique in the chemistry of metal acetylacetonates [63]. Significantly, parallels are found only with platinum [64] and rhodium [65].

2.5.2. Alkenylgold and Alkynylgold(I) Compounds

2.5.2.1. Cyclopentadienylgold(I) Derivatives

Hüttel et al. have described a compound having the composition C_5H_5Au [60], and so filled one of the last gaps in the field of cyclopentadienylmetal derivatives [66]. The reaction of certain olefin complexes of

AuCl with NaC_5H_5 in tetrahydrofuran at −60 °C yields the desired compound as a very unstable yellow powder. A π-bonded structure of the ferrocene type and an ionic structure can be ruled out on the basis of spectroscopic studies; a constitution involving an Au–C σ-bond is therefore probable (monohapto). This view is strongly supported by the observations on the corresponding phosphine complexes, which are formed on reaction of $(C_6H_5)_3P \cdot AuCl$ with NaC_5H_5 or with C_5H_6 in the presence of bases, as well as from C_5H_5Au and $(C_6H_5)_3P$. It is soluble in organic solvents, and NMR spectroscopic measurements are therefore possible[60]. Only one signal was recorded for the C_6H_5 protons, as is typical of cyclopentadienylmetal compounds having a "non-stationary" M–C bond[67–73]. C_5H_5Au compounds thus appear to belong to the class of stereochemically dynamic organometallic compounds[67,68]. This is not contradicted by the NMR spectrum of the methylcyclopentadienyl derivative[60], which gives three groups of signals having the relative areas 2:2:3[71]. However, the very low temperature measurements required for final proof have not yet been carried out in either case.

2.5.2.2. Unsaturated Heterocycles Containing Gold

In the investigation of the reaction behavior of 1,2,3,4-tetraphenylbutadienylene-1,4-dilithium, *Braye et al.*[74] allowed this compound to react with gold trichloride. By a reaction course that is not entirely clear they obtained a yellow crystalline compound, m.p. = 190–195 °C (dec.), to which they assigned the structure of a 1-auracyclopentadiene:

Since there is no evidence for this structure, it is offered only with reservations.

2.5.2.3. Alkynylgold(I) Compounds

The general interest in metal acetylides[2,3] is evident even for gold in a number of extensive articles[75–78].

Ethynylenedigold(I) (gold(I) acetylide, carbide) has been known for a long time and feared for its high brisance[76,77]. According to *Nast*[76] a relatively stable ammonia adduct of Au_2C_2 is obtained from AuI and KC_2H in liquid NH_3. With an excess of KC_2H, complex potassium gold acetylides are formed, *e.g.* $K[Au(C{\equiv}CH)_2]$ and $K_2[HC{\equiv}CAuC{\equiv}CAuC{\equiv}CH]$, the latter being when acetylene is introduced at the same time (Table 8).

These compounds are formed on reaction of freshly reduced $AuCl_3$ with suitable alkali metal alkynides; the products are sparingly soluble yellow polymers. In the presence of donors (amines, phosphines, or arsines), however, low molecular weight complexes, which are mostly soluble as monomers in organic solvents, are formed. The *amine* complexes are not monomeric in organic solvents, presumably as a result of oligomerization due to hydrogen bonds, as is also shown by an X-ray structure analysis on isopropylaminephenylethynylgold(I)[78a]; even in the solid state, there is no π interaction of the gold atom with the electron system of the C≡C bond in this case, such as occurs in the corresponding compounds of copper and silver[78b,c]. This provides important evidence of the relatively lower tendency of gold to form metal-olefin π bonds (see Section 4).

The oligomerization observed in the case of the uncomplexed *tert*-butylethynyl compound cannot how-

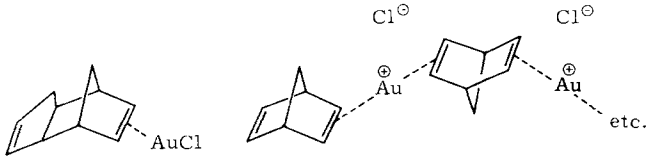
ever be explained without the assumption of such bonds.

On the other hand, the fact that the IR absorption of the C≡C bonds are only slightly altered indicates that the interaction is weak [75, 76].

3. Isocyanide Complexes of Gold

Isocyanide complexes of gold(I) and gold(III) have been described by *Sacco* and *Freni* [55b]. In these compounds we meet again the gold-carbon σ-bond: R–N≡C→AuX.



Reviving interest in this class of compounds is evident from a recent paper by *Vaughan* and *Sheppard* [55c], on organogold(I) complexes of isocyanides (Table 10). Information on the back-donation of electrons in the arylgold and isocyanidegold moieties was derived from ^{19}F-NMR-investigations of these compounds. ^{19}F chemical shifts are quite sensitive to all alterations in the state of bonding of the phenyl ring and are thus an excellent probe for this purpose.

4. Organogold Compounds Containing Gold-Carbon π Bonds

It is remarkable how recently the existence of simple olefin-gold complexes was verified when one thinks that the corresponding compounds of platinum (Zeise salt) are among the classical representatives of this class of compounds. Though compounds of this type were postulated as reaction intermediates a long time ago, they could not be isolated [79]. It was *Hüttel et al.* [80,82–85] and *Chalk* [81] who showed that gold is probably also capable of forming relatively stable π complexes. This is true in particular of Au^{I}, though less so of Au^{III}. The result is in agreement with the stability relations of the π complexes of Pt^{II} and Pt^{IV}. However, the stability even of Au^{I} complexes is still very low so that reversible addition or removal of olefin ligands is often possible. This in fact makes complexes of this type particularly interesting as intermediates in reactions of olefins in the presence of gold and its compounds as homogeneous or heterogeneous catalysts [86].

The known olefin-gold complexes have mostly been prepared by reaction of gold trichloride or tetrachloroauric acid or its salts with an olefin [80,81] (the first step being reduction to Au^{I}), or from AuCl and olefin [80,81]. The reaction is carried out at the lowest possible temperature (−60 to +20 °C). In the reduction of $AuCl_3$ it is possible under mild conditions or on addition of complexing agents to intercept intermediates in which both AuCl and $AuCl_3$ are coordinately bound [83–85]. Their overall composition is olefin·Au_2Cl_4; their diamagnetism (NMR), however, shows that these are not Au^{II} compounds but Au^{I}/Au^{III} compounds.

The bonding of the olefin ligands to gold is so weak in some cases that the dissociation of the hydrocarbon can be followed gravimetrically at room temperature [82], as *e.g.* in the case of cyclopentenechlorogold(I). The IR spectra show a characteristic shift of the C=C stretching vibration to lower wave numbers ($\Delta\tilde{\nu} \approx 120$–$140\ cm^{-1}$) as a result of complex formation; the NMR spectra of the olefins also change. However, all the structural details have not been verified in every case. X-ray studies in particular are still lacking. Consequently, Table 11 contains no structural information; the formulas given indicate the views that are held at present [80–85].

5. Gold-Carborane Compounds

It has been known for some years that anionic fragments of the carborane icosahedron can form stable complexes with transition metal ions that are completely novel from the standpoints of structure and of valence theory [87–92]. The development of this line of research has not even been halted by the noble metals gold and platinum [93,94]. The "gold dicarbollides" synthesized so far contain gold-carbon bonds of an entirely new type, and should therefore be mentioned before we conclude this article.

On the basis of X-ray structural investigations [94] on the isomorphous copper compound $(C_6H_5)_3PCH_3[Cu(C_2B_9H_{11})_2]$, the anion of the analogous gold compound must be assumed to have the constitution *(1)* (M = Au; $n = 1$).

(1)

This structure appears to be characteristic of d^8 and d^9 complexes in that the two carbollide caps in the structure are considerably displaced with respect to each other (a symmetrical arrangement is preferred in d^3 to d^7 complexes). *Wing* interprets this arrangement as a consequence of a π-allyl type interaction [94]. Other explanations are however possible [93].

The red $[Au(C_2B_9H_{11})_2]^{\ominus}$ ion containing Au^{III} can be reduced electrolytically to the corresponding deep blue paramagnetic Au^{II} complex, $[Au(C_2B_9H_{11})_2]^{2\ominus}$, which, *cum grano salis*, is the only "organometallic" gold(II) compound known at present.

The Behavior of Acid Halides Toward Lewis Acids and Lewis Bases

By Ekkehard Lindner[*]

Reactions of some typical acid halides of carbonic and trithiocarbonic acids and of orthophosphoric and sulfuric acids with Lewis acids and Lewis bases are compared. Acylium, perfluoroacylium, thioacylium, and even sulfonylium ions are obtainable with Lewis acids. It is possible by conductivity measurements and by electronic and above all IR spectroscopic investigations to determine whether the 1:1 adducts of acid halides and Lewis compounds are acylium or sulfonylium salts or donor-acceptor complexes. In the reaction with Lewis bases, the halogen atom in the acid halide is replaced by the electron donor, generally with formation of nonpolar molecular compounds or complexes.

1. Introduction

This article presents a comparative report on the reactions of some typical acid halides that are formally derived from carbonic and trithiocarbonic acids and from orthophosphoric and sulfuric acids (RCOX, RCSX, OPX_3, R_2POX, and RSO_2X; R = organic or inorganic residue; X = halogen or acid residue) with Lewis acids and Lewis bases.

Particularly significant results were obtained from studies on the dependence of the C–O, C–S, P–O, or S–O bond on the acceptor or donor strength of the Lewis acid or base and on the electronegativity of the organic or inorganic residue bonded to the carbon, phosphorus, or sulfur. The ability of Lewis acids such as BF_3, PF_5, AsF_5, or SbF_5, whose central atoms have no free electron pairs, to accept the halogen atom of an acid halide depends on their acceptor strength. The coordination number of the Lewis acid rises to its maximum value, the Lewis acid being converted into an anion, while the acid halide forms an "electron-deficient" cationic system such as

$$R-\overset{\oplus}{C}=\ddot{O}: \leftrightarrow R-C\equiv\overset{\oplus}{O}:$$

The originally nonbonding electrons on the oxygen or on the sulfur make a considerable contribution to the resulting positive charge on the elements carbon, phosphorus, or sulfur, leading to additional π components in the C–O, C–S, P–O, and S–O bonds. The residue R also has an important influence on these bonds because of its inductive effect.

If, on the other hand, Lewis bases are allowed to act on acid halides, the halogen may also be split off as an anion. In this case, however, it is replaced by the electron donor, generally with formation of non-polar compounds. In contrast with the reactions with Lewis acids, the π components of the C–O, C–S, P–O, and S–O bonds are now decreased; the bond strength again depends on the donor strength of the Lewis base and on the electronegativity of the residue R.

[*] Priv.-Doz. Dr. E. Lindner
Institut für Anorganische Chemie der Universität
8520 Erlangen, Fahrstrasse 17 (Germany)

The phenomena just described can be followed particularly readily by methods based on vibration spectroscopy. In the IR spectra of the cationic systems formed from Lewis acids and acid halides, the frequencies of the element-oxygen or element-sulfur stretching vibrations increase considerably, pointing to correspondingly high force constants. In the reaction products of Lewis bases with acid halides, these stretching frequencies often show an extremely pronounced decrease; the force constants have therefore become extremely small.

2. Acyl Halides and Perfluorinated Acyl Halides

2.1. Reactions with Lewis Acids

Though acylium salts have been known for a long time[1], it was *Seel*[2] that first recognized them as "carboxonium" compounds and detected them. They are obtained *e.g.* by reaction of CH_3COF and BF_3 or CH_3COCl and $SbCl_5$ below 0 °C.

Their salt-like character has been confirmed by conductivity measurements in liquid SO_2

$$CH_3COF + BF_3 \underset{> 20\,°C}{\overset{< 20\,°C}{\rightleftharpoons}} [CH_3CO][BF_4]$$

Above the boiling point of CH_3COF (20.8 °C), the salt is largely dissociated into the two starting components.

Stable acylium salts were first reported by *Olah et al.*[3], who described them as "oxocarbonium" derivatives because of the positive charge on the carbonyl carbon atom. Two methods have become particularly widely used for the preparation of acylium salts[2,3]; these are the reaction of acyl fluorides with Lewis acids such as BF_3 or ElF_5 (El = P, As, Sb) and the reaction of acyl chlorides or bromides with the anhydrous silver complexes $Ag[BF_4]$ or $Ag[ElF_6]$ ("silver salt method")

[2] *F. Seel*, Z. anorg. allg. Chem. *250*, 331 (1943); *252*, 24 (1944).

[3] *G. A. Olah, S. J. Kuhn W. S. Tolgyesi*, and *E. B. Baker*, J. Amer. chem. Soc. *84*, 2733 (1962).

in strongly polar solvents such as nitromethane or liquid SO_2:

$$RCOF + ElF_{n-1} \rightarrow [RCO][ElF_n]$$

or

$$RCOX + Ag[ElF_n] \rightarrow [RCO][ElF_n] + AgX$$

El = B, $n = 4$; El = P, As, Sb, $n = 6$; X = Cl, Br

The second method is often more favorable for preparative reasons. *Olah et al.*[3] isolated the thermally surprisingly stable, but extremely hygroscopic, acetylium, propionylium, and benzoylium cations as the salts $[RCO][ElF_n]$. The arsenic and antimony compounds, which are among the most stable of these, are almost completely in the form of the acylium salts *(1)* even at room temperature, whereas the PF_6^- derivative contains considerable quantities of a polarized donor-acceptor complex *(2)* under the same conditions.

$[R-C\equiv O:]\ [ElF_n]$ $\qquad$ $R-C(=O^{\delta\oplus}\cdots ElF_{n-1}^{\delta\ominus})-F$

(1) $\qquad$ *(2)*

The question whether a 1:1 adduct of the type $RCOF \cdot ElF_{n-1}$ is in the form of the acylium salt *(1)* or of a donor-acceptor complex *(2)* can be answered by conductivity measurements or by IR spectroscopic investigations[3,4]. Whereas the CO stretching absorption of *(1)* appears above 2290 cm^{-1}, *i.e.* in the CO triple bond region, the corresponding band for the compounds *(2)* lies below 1620 cm^{-1}; in other words, it has been shifted toward longer wavelengths relative to that of the free acid fluoride.

By X-ray studies on $[CH_3CO][SbF_6]$, *Boer*[5] was able to show the existence, in the solid state, of isolated linear $[CH_3CO]^+$ cations (symmetry C_{3v}), in which the C–H, C–C, and C–O distances are considerably shorter (d C–C = 1.378 Å, d C–O = 1.116 Å) than in aldehydes and ketones, owing to the positive charge on the carbonyl C atom. MO calculations gave the following charge distributions: –0.11 for the methyl carbon atom, 1.18 for the carbonyl carbon atom, –0.35 for the oxygen, and 0.09 for each hydrogen atom[5].

Acylium salts can also be detected chemically[3]. They react with benzene by a Friedel-Crafts mechanism to form the ketones. Only the salt form *(1)* has an acylating action, whereas *(2)* has not.

Electronegative ligands, such as perfluoroalkyl groups, have a considerable influence on the C–O bond. 1:1 complexes of perfluoroacyl fluoride with phosphorus, arsenic, or antimony pentafluoride can be prepared by the "silver salt method"[3] if liquid SO_2 is used as the solvent:

$$RCOBr + Ag[ElF_6] \rightarrow RCOF \cdot ElF_5 + AgBr$$

R = CF_3, C_2F_5; El = P, As, Sb

The advantage of acid bromides is obvious, since AgBr has a lower solubility product than AgCl. It has been found possible to prepare trifluoroacetylium hexafluoroantimonate(v) below –25 °C[6]. The conductivity diagram[7] (from measurements in liquid SO_2) shows a marked change of direction at the boiling point of CF_3COF (–57 °C). Below this temperature the specific conductivity increases very rapidly; $CF_3COF \cdot SbF_5$ is therefore best formulated as a 1:1 electrolyte $[CF_3CO][SbF_6]$ at these temperatures (equivalent conductivity at –60 °C: Λ_c = 83.6 Ω^{-1} $cm^2 mole^{-1}$).

Low-temperature IR studies revealed a band of medium intensity at 2371 cm^{-1}, which practically disappears at room temperature, and which is characteristic of a C≡O stretching vibration. From the occurrence of two other absorptions at 1780 and 1631 cm^{-1} (*i.e.* shifted to longer wavelengths in relation to CF_3COF) in the IR spectrum of $CF_3COF \cdot SbF_5$, which can be assigned to a keto (⟩C=O) stretching vibration, it is concluded that a considerable amount of the compound exists as a polarized donor-acceptor complex above –57 °C[6,7]. Whereas $CF_3COF \cdot AsF_5$ decomposes into CF_3COF and AsF_5 above –57 °C, and $CF_3COF \cdot PF_5$ cannot be isolated at all, the thermally more stable $CF_3COF \cdot SbF_5$ reacts with benzene at 6 °C to form $CF_3COC_6H_5$, which could be detected in small quantities when precipitated as the 2,4-dinitrophenylhydrazone.

The homologous 1:1 adduct $C_2F_5COF \cdot SbF_5$ exhibits no conductivity (in nitromethane) at room temperature and, as its IR spectrum shows, it is only partly in the form of the 1:1 electrolyte even below –30 °C. The action of C_6H_6 on $C_2F_5COF \cdot SbF_5$ does not yield the ketone[7].

2.2. Reactions with Lewis Bases

The behavior of aliphatic and aromatic acyl halides toward organometallic Lewis bases, particularly carbonylmetalates, was studied in detail several years ago[8–11].

$$RCOCl + Na[M(CO)_n] \xrightarrow{(C_2H_5)_2O} R-C(=O)-M(CO)_n + NaCl$$

e.g. R = CH_3, C_2H_5, C_6H_5, *etc.*; M = Mn, Re; $n = 5$; M = Co; $n = 4$, *etc.*

This reaction yields extremely reactive acylcarbonylmetal compounds, some of which are of industrial interest[10]. Derivatives are also known in which CO groups are replaced by other ligands, as in $CH_3COCo(CO)_3PR_3$[12] and π-$C_5H_5Fe(CO)_2COCH_3$[13], with the result that the stability is generally greatly

[13] *J. P. Bibler* and *A. Wojcicki*, Inorg. Chem. *5*, 889 (1966).

increased [14]. It is interesting to note that only the *trans* complexes are obtained in the case of $RCO\text{-}Co(CO)_3PR_3$; the acyl residue and the phosphine ligand are arranged axially around the Co atom, and the three CO groups equatorially (pseudo-C_{3v}) [15]. On the other hand both *cis* and *trans* forms of the pseudo-octahedral Mn complexes of the type $RCOMn(CO)_4PR_3$ [16–18] have been isolated [17–19].

A characteristic of all acylmetal compounds is that owing to the strong donor properties of the metal, the keto (⟩C=O) stretching bands, in the sense of the polar limiting form *(b)* are strongly shifted toward longer wavelengths, pointing to a weakened C=O

(a) *(b)*

bond [11]. Carbonylacylmetal compounds eliminate CO when heated in the absence of air [8,9,11]. This reaction has been followed for acetylpentacarbonylmanganese with the aid of the isotopes ^{14}C [20] and ^{13}C [21]:

$$CH_3\overset{*}{C}OMn(CO)_5 \rightarrow CH_3Mn(CO)_4\overset{*}{C}O + CO$$

The CO removed was originally terminal, *i.e.* it did not come from the acetyl group. Conversely, no activity of the acetyl group can be detected in a reaction of $\overset{*}{C}O$ on $CH_3Mn(CO)_5$ under pressure [22]:

$$CH_3Mn(CO)_5 + \overset{*}{C}O \rightarrow CH_3COMn(CO)_4\overset{*}{C}O$$

Similar experiments with organocobalt derivatives led to the same results [15]. When partly halogenated acyl chlorides, such as CH_2XCOCl (X = F, Cl), are used, rotational isomers of the type $CH_2XCOMn(CO)_5$ are observed in the reaction with $[Mn(CO)_5]^-$, as is shown by NMR and IR data [23].

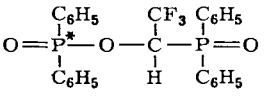
Perfluorinated acyl halides [24–27] or anhydrides of carboxylic acids [11,28,29] react with organometallic Lewis bases to give the carbonylperfluoroacylmetal compounds.

$$RCOX + Na[M(CO)_n] \rightarrow NaX + RCOM(CO)_n$$

R = CF_3, C_2F_5, C_3F_7 *etc.*; X = Cl, OCOR; M = transition metal

The stability of the metal complexes is considerably increased by the introduction of perfluoroalkyl groups, which relieve the metals of their negative charge. This is particularly noticeable in the case of cobalt; whereas $CH_3COCo(CO)_4$ [10,14] decomposes rapidly above −30 °C, $CF_3COCo(CO)_4$ [28] is stable up to 55 °C. Carbonylperfluoroacylmetal complexes can also be decarbonylated [26–29]; the products are the carbonylperfluoroalkylmetal complexes, which are thermally stable and resistant to atmospheric oxygen. The higher homologs $C_2F_5COCo(CO)_4$ and $C_3F_7COCo(CO)_4$ characteristically eliminate CO at much lower temperatures (>30 and >0 °C respectively) [29]. The carbonyl group between the metal and the perfluoroalkyl residue is thus evidently increasingly eliminated as the number of F atoms increases.

As expected, the electron-attracting perfluoroalkyl residues shift the keto (⟩C=O) stretching bands to higher frequencies in relation to those of the unfluorinated acylmetal compounds (cf. Table 1).



The behavior of acyl halides toward organophosphorus and organoarsenic compounds has also been studied. *Issleib* and *Priebe* [30] were the first to obtain $CH_3COP(C_6H_5)_2$ [from CH_3COCl and $LiP(C_6H_5)_2$], which can be readily oxidized with oxygen to $CH_3COPO(C_6H_5)_2$. Since Lewis basicity decreases in the order amines (though these occupy a special place because of the absence of energetically favorable d orbitals in nitrogen), phosphines, arsines, and stibines, it is particularly interesting to compare the properties of perfluoroacyldiphenylphosphines and perfluoroacyldiphenylarsines [31].

$$RCOX + MEl(C_6H_5)_2 \xrightarrow[THF]{-78\,^\circ C} RCOEl(C_6H_5)_2 + MX$$

R = CF_3, C_2F_5; X = Cl, Br, OCOR; M = Na, K; El = P, As

The colorless to orange-red liquids are extremely sensitive to air and moisture.

Contrary to expectations, oxidation of $CF_3COP(C_6H_5)_2$ with molecular oxygen leads, not to $CF_3COPO(C_6H_5)_2$, but by a complicated path that depends on the solvent (toluene or hexane) to 1-diphenylphosphoryl-2,2,2-trifluoroethyl diphenylphosphinate [31a] and CO_2. The

structure was demonstrated by alkaline decomposition to diphenylphosphinic acid and trifluoroethanol, and by mass spectroscopic (molecular mass line: 500), NMR (two ^{31}P signals), and IR studies. The proton on the asymmetric C atom gives the splitting scheme of first order coupling in the high-resolution ^1H-NMR spectrum, *i.e.* a doublet of quartets of doublets (coupling constants: $^2J_{HP} = 12.5$ Hz; $^3J_{HP^*} = 4.7$ Hz; $^3J_{HF} = 7.8$ Hz). The IR spectrum is characterized in particular by $\nu(C-H_{aliphat.})$ (2924 cm^{-1}) and ν_{as} $(P-O-C_{aliphat.})$ (1092 cm^{-1}) apart from the intense P–O and CF_3 stretching vibrations. The peculiar oxidation behavior of $CF_3COP(C_6H_5)_2$ is due to the electron-attracting CF_3 group and the lone pair of electrons on the phosphorus.

Whereas $CH_3COP(C_6H_5)_2$ and the perfluoroacyldiphenylarsines decompose when heated in the absence of air, perfluoroacyldiphenylphosphines, like the acylcarbonylmetal and carbonylperfluoroacylmetal compounds, quantitatively eliminate CO to form perfluoroalkyldiphenylphosphines. The removal of CO is evidently facilitated when the keto group is directly

$$RCOP(C_6H_5)_2 \xrightarrow{175\,^\circ C/190\,^\circ C} RP(C_6H_5)_2 + CO$$
$$R = CF_3,\ C_2F_5$$

flanked by a strong electron donor and an electronegative alkyl residue. $CF_3P(C_6H_5)_2$ can also be prepared from $(C_6H_5)_2PP(C_6H_5)_2$ and CF_3I [32].

An insight into the molecular structure and the difference in the chemical behavior of perfluoroacylphosphines and perfluoroacylarsines is provided above all by the IR spectra. The phosphines are characterized by the very low frequency (1702 cm^{-1}) of the keto (>C=O) stretching vibrations, whereas the corresponding band for the homologous arsines, in agreement with their weaker donor properties, is situated at a wave number about 55 cm^{-1} higher [31]. This is probably due to stronger participation of the limiting form *(6)* in the phosphorus compounds than in the arsenic compounds.

(a) *(b)*

The other IR data support this view, the CF_3 and P–C_{acyl} stretching vibrations being particularly characteristic.

Moreover, the behavior of $CF_3COSn(CH_3)_3$, which was recently isolated in the reaction of $LiSn(CH_3)_3$ with CF_3COCl, is quite comparable with that of $CF_3COAs(C_6H_5)_2$. Owing to tin's lack of donor properties, the colorless liquid does not eliminate CO when heated, and is even stable to dry oxygen. In agreement with this, the keto (>C=O) stretching vibration occurs at a very short wavelength [32a].

Table 1 shows a comparison of the C–O stretching frequencies and force constants of (trifluoro)acetyl fluoride and some derivatives.

Table 1. C–O stretching vibrations and estimated force constants of (trifluoro)acetyl fluoride and some derivatives.

3. Thioacyl Halides

A particularly interesting aspect in systematic studies is the behavior of thioacyl halides toward Lewis acids and Lewis bases. The only thioacyl halide that has been verified in every respect so far is thiobenzoyl chloride. *Staudinger* and *Siegwart* [35] obtained this compound as early as 1920 from dithiobenzoic acid and thionyl chloride. The preparation of CF_3CSCl [36] was also described for the first time in a patent a few years ago.

3.1. Reactions with Lewis Acids

As was seen in Section 2.1, the "silver salt method" is particularly suitable for the preparation of acylium salts. Stoichiometric quantities of C_6H_5CSCl and $Ag[SbF_6]$ react in liquid SO_2 at −40 °C to give an extremely hygroscopic, light brown complex, which is found even at room temperature to be the surprisingly stable thiobenzoylium hexafluoroantimonate(v) [37]:

$$C_6H_5CSCl + Ag[SbF_6] \xrightarrow[\text{liq. } SO_2]{-40\,^\circ C} [C_6H_5CS]\,[SbF_6] + AgCl$$

The ionic structure is shown by conductivity measurements (equivalent conductivity at −50 °C: Λ_c = 80.9 Ω^{-1} cm^2mole^{-1}), by IR studies [$\nu(C-S) = 1332$ cm^{-1}; $\nu(SbF_6^-) = 673$ cm^{-1} (T_{1u})], and by reaction with benzene:

$$[C_6H_5CS]\,[SbF_6] + C_6H_6 \rightarrow (C_6H_5)_2CS + H[SbF_6]$$

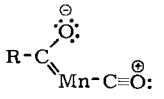
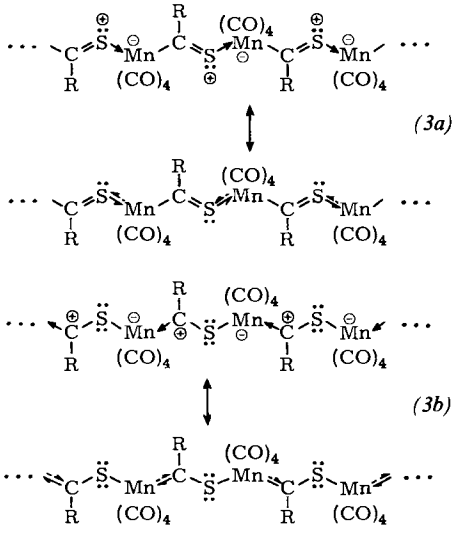
Thiobenzophenone is formed in a yield of about 40 %. This was the first reaction to yield a thioacylium ion, and it was shown that thioacyl halides also react by the Friedel-Crafts mechanism. *Mayer* and *Scheithauer* [38] had previously obtained thiobenzophenone from thiobenzoyl chloride, benzene, and anhydrous Al_2Cl_6, and these authors also explained the reaction by a Friedel-Crafts mechanism.

According to the IR spectrum, the $[C_6H_5CS]^+$ cation can be essentially described by the limiting formulas *(1a)–(1c)*.



(1a) *(1b)* *(1c)*

3.2. Reactions with Lewis Bases



The reactions of thioacyl halides with organometallic Lewis bases are much more complicated than those of acyl halides, and are by no means uniform. Thus C_6H_5CSCl and $Na[Mn(CO)_5]$ react quantitatively at −78 °C in THF to give $C_6H_5CSMn(CO)_5$ [39]; however, this product eliminates one CO per Mn atom above −70 °C. In contrast with the reactions of the $[Mn(CO)_5]^-$ anion with acyl halides [11], carboxylic acid anhydrides [28,29], or even sulfonyl halides, in which the reaction product still contains an intact $Mn(CO)_5$ residue, no such product can be obtained in this case. The product isolated is instead a non-polar, chromatographically uniform brown compound that is inert to atmospheric oxygen, and which has the formula $[C_6H_5CSMn(CO)_4]_n$ (n is 3 or 4, depending on whether the reaction mixture is warmed rapidly or slowly to room temperature). It must be assumed from the solubility behavior of the "tetrameric" Mn compound that it is polymeric in the solid state, and breaks down into smaller fragments only on dissolution. It is interesting to note that the molecular weight of the "tetramer" falls to that of the "trimer" within a few days.

The coordination vacancy created on the manganese by the loss of CO is filled by the sulfur, as is shown in particular by IR data. The long wavelength of the ν(⟩C=O) band for the acylpentacarbonylmanganese compounds (cf. Section 2.2) points to appreciable participation of the polar limiting form *(2)*. Formal

(2)

replacement of the oxygen in the acyl residues by sulfur should lead to a decrease in the C–S bond order. Finally, the nucleophilic strength of the sulfur is understandable if one considers that sulfur is more readily polarizable than oxygen because of its greater atomic radius, and the nucleophilic strength is further increased by the negative charge carried by the sulfur in the polar limiting form. Intramolecular elimination of CO seems to be ruled out for steric reasons, so that only polymeric products are to be expected. One does in fact obtain a compound consisting of ···-$Mn(CO)_4$-C(R)–S–$Mn(CO)_4$–C(R)–S–··· units. The compound may be regarded either as a thioketone complex *(3a)* or as a carbene complex *(3b)* [40]; no distinction can be made on the basis of the IR spectrum.

(3a)

(3b)

It is interesting to note that there is no absorption between 700 and 1500 cm^{-1} that can be assigned to a C–S stretching vibration. However, a new band of medium to low intensity, which suggests a C–S vibration, appears at 630 cm^{-1} (cf. Table 2). In agreement with the proposed structures *(3a)* and *(3b)*, the spectrum also shows four C–O absorptions having very high wave numbers (*cis* position of the CO groups), *i.e.* 2100, 2020, 2011, and 1955 cm^{-1} for $n = 3$ and 2090, 2032, 2008, and 1956 cm^{-1} for $n = 4$. Only X-ray structural analysis can show whether structure *(3a)* or *(3b)* is present, since the Mn–C distance should be greater than 2 Å in a carbene complex [41].

The reaction of C_6H_5CSCl with the Lewis base $[Re(CO)_5]^-$ is fundamentally different from the reaction with $[Mn(CO)_5]^-$. All the results with $[Re(CO)_5]^-$ point to the formation of a dithiolate complex [42].

Table 2. C—S stretching vibrations and estimated force constants of C_6H_5CSCl and some derivatives.

Compound	ν(C—S) (cm^{-1})	f_{CS} (mdyn/Å)
C_6H_5CSCl	1250	8.03
$[C_6H_5CS][SbF_6]$	1332	9.12
$[C_6H_5CSMn(CO)_4]_n$	630	≈2.0

4. Phosphoryl Halides and Diorganophosphinyl Halides

4.1. Reactions with Lewis Acids

On reaction of phosphoryl halides (OPX_3; X = Cl, Br) with $Ag[SbF_6]$[39] in a polar solvent such as acetonitrile, though AgX separates out of the solution, no salt $[OPX_2]^+ [SbF_6]^-$ is formed. $Ag[SbF_6]$ evidently acts as a fluorinating agent in this case; OPF_3 ($\nu(P-O)$ = 1415 cm^{-1}) is formed quantitatively, irrespective of the stoichiometric ratio of the starting compounds

$$OPX_3 + 3\ Ag[SbF_6] \xrightarrow{20\,^\circ C} OPF_3 + 3\ AgX + 3\ SbF_5$$

The instability of phosphorylium ions is so severe that even organosubstituted derivatives $[R_2PO]^+$ cannot be stabilized. On reaction of bis(dimethylamino)phosphinyl chlorides or diphenylphosphinyl chloride on $Ag[SbF_6]$ in liquid SO_2 or acetonitrile in accordance with

$$R_2POCl + Ag[SbF_6] \xrightarrow[\text{liq. } SO_2/CH_3CN]{T > 0\,^\circ C} R_2POF{\cdot}SbF_5 + AgCl$$

R = $(CH_3)_2N$, C_6H_5

only donor-acceptor complexes of the form $R_2P(F)O^{\delta\oplus}\ldots SbF_5^{\delta\ominus}$ could be detected[42a].

4.2. Reactions with Lewis Bases

Hieber and *Duchatsch*[43] have shown that the phosphoryl halides $OPCl_3$ and $OPBr_3$ halogenate organometallic Lewis bases. Reaction with $[Co(CO)_3P(C_6H_5)_3]^-$ leads primarily to the halogen derivatives, which are

$$OPX_3 + Na[Co(CO)_3P(C_6H_5)_3] \xrightarrow{-70\,^\circ C} XCo(CO)_3P(C_6H_5)_3 + NaX + \{OPX\}$$

X = Cl, Br

thermally unstable and immediately change into the dicarbonyl compounds $XCo(CO)_2[P(C_6H_5)_3]_2$.

Toward neutral Lewis bases, such as triphenylphosphine or triphenylarsine, phosphoryl halides and thiophosphoryl halides act as excellent chalcogen transfer agents[44].

$$El'PX_3 + El(C_6H_5)_3 \rightarrow PX_3 + El'El(C_6H_5)_3$$

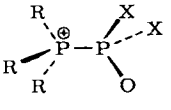
El' = O, S; X = Cl, Br; El = P, As

This reaction can be applied to any monodentate or polydentate organophosphine or organoarsine.

For phosphoryl halides (X = Cl, Br) in particular, the transfer of chalcogen to phosphines takes place *via* an extremely hygroscopic, thermally stable, isolable intermediate. This was found from concentration-dependent molecular weight determinations, conductivity measurements, IR studies, and its hydrolysis properties to be an ionic dihalogenophosphoryltriphenylphosphonium halide containing a P–P bond[45]:

$$OPX_3 + P(C_6H_5)_3 \xrightarrow{OPX_3} [(C_6H_5)_3PP(X_2)O]X$$

The observed chalcogen transfer occurs only in the presence of small quantities of moisture:



$$[(C_6H_5)_3PP(X_2)O]X \rightarrow OP(C_6H_5)_3 + PX_3$$

The salts may be regarded as substitution compounds of phosphoryl halides. Some time ago, *Gutmann*[46] described a crystalline adduct having the composition $OPCl_3{\cdot}2C_5H_5N$, which dissociates in $OPCl_3$ into the ions $[C_5H_5NP(Cl_2)O]^+$ and Cl^-. *Baaz* and *Gutmann*[47,48] later showed that tertiary aliphatic amines, as Lewis bases, also have a substituting action in $OPCl_3$ solution:

$$(C_2H_5)_3N + OPCl_3 + FeCl_3 \xrightarrow{OPCl_3} [(C_2H_5)_3NP(Cl_2)O][FeCl_4]$$

$As(C_6H_5)_3$, which is very readily soluble in $OPCl_3$, also reacts with the solvent[45]. However, the colorless $[(C_6H_5)_3AsP(Cl_2)O]Cl$ slowly loses $OPCl_3$ above room temperature, owing to the weaker donor properties of $As(C_6H_5)_3$.

The number of IR absorptions in the spectra of the compounds $[(C_6H_5)_3PP(X_2)O]X$ points to low symmetry [point group C_s, with $P(C_6H_5)_3$ as a point mass]. This leads to a pseudotetrahedral arrangement of the four ligands [2 X^-, $P(C_6H_5)_3$, and O] about the central phosphorus atom (Fig. 1).

R = C_6H_5

Fig. 1. Structural model of the cations $[(C_6H_5)_3PP(X_2)O]^+$.

As can be seen from Table 3, the P–O and P–Cl stretching vibrations in the phosphonium salts occur at higher frequencies than in the parent compounds

Table 3. P–O and P–Cl stretching vibrations of phosphoryl halides and their substitution products $[(C_6H_5)_3PP(X_2)O]X$.

Compound	Structure	ν(P–O) (cm^{-1})	ν(P–X) (cm^{-1})
$OPCl_3$	C_{3v}	1290 (A_1)	577 (E) 486 (A_1)
$OPBr_3$	C_{3v}	1261 (A_1)	488 (E) 340 (A_1)
$[(C_6H_5)_3PP(Cl_2)O]Cl$	C_s	1320 (A′)	587 (A′) 564 (A″)
$[(C_6H_5)_3PP(Br_2)O]Br$	C_s	1305 (A′)	492 (A′) 479 (A″)

OPX_3 corresponding to greater double-bond components in the P–O and P–Cl bonds, owing to the positive charge on the phosphorus of the PR_3 group. Dihalogenophosphoryltriphenylphosphonium halides can be converted specifically into 1:1 triphenylphosphine oxide-metal halide complexes containing a metal-oxygen-phosphorus bridge by reaction with metal halides. This reaction, which is of preparative interest, proceeds particularly well when the metal halides are soluble in an inert solvent (ether).

$$[(C_6H_5)_3PP(Cl_2)O]Cl + MCl_n \rightarrow (C_6H_5)_3POMCl_n + PCl_3$$

Many new 1:1 complexes have been obtained in this way [MCl_n = $TiCl_4$ (complex: yellow), $ZrCl_4$ (pale yellow), VCl_3 (pink), $FeCl_3$ (light yellow), and $CoCl_2$ (deep blue)]. The $AlCl_3$-[50] and $NbCl_5$ adducts[51] prepared by these reactions are already known.

The triorganophosphine oxide-metal halide complexes described many years ago by *Pickard* and *Kenyon*[52] have recently been subjected by numerous authors[51,53–56] to IR-[57] and UV spectroscopic studies[58].

While *Tyree et al.*[59], *Cotton et al.*[60], and *Merijanian* and *Zingaro*[61] also extended these studies to triorganoarsine oxides, *Tyree et al.*[58,62], *Gans et al.*[63], *Kohl*, *Lewis*, and *Whyman*[64], and *Hart* and *Newbery*[65] also reported on triphenylphosphine oxide-metal oxide halide complexes. The compounds can be prepared in general by direct action of triphenylphosphine oxide on the metal halide, and contain more $OP(C_6H_5)_3$ than they should for a ratio of 1:1. On the other hand, the formation of the few hitherto known 1:1 triarylphosphine oxide-metal halide adducts[50,51,66] was fortuitous.

The intense ν_{as}(P–O–M) bands[49] lie between 1160 and 950 cm^{-1} depending on the acceptor strength of the metal, and are shifted (considerably in some cases) toward longer wavelengths in relation to that of $OP(C_6H_5)_3$ (1191 cm^{-1}). Since each metal atom is bonded to only one phosphine oxide residue, the $(p\rightarrow d)_\pi$ back-bonding component of the O–P bond is greatly decreased. This can be illustrated by two titanium compounds; $2(C_6H_5)_3PO \cdot TiCl_4$[53]: ν(P–O) = 1130 cm^{-1}; $(C_6H_5)_3POTiCl_4$[49]: ν(P–O) = 1060 cm^{-1}.

The ν_s(P–O–M) stretching vibrations are more difficult to assign; this has been achieved with certainty for $(C_6H_5)_3POAlCl_3$[49,67] and $(C_6H_5)_3POCoCl_2$[49] (cf. Table 4). The simplified calculation of the force constants for the P–O and Al–O bonds on the basis of the three-particle model gives f_{PO} = 7.5 mdyn/Å and f_{AlO} = 1.7 mdyn/Å; the two P–O and Al–O oscillators are therefore strongly coupled with each other. By application of the Siebert approximation[68], bond orders of 1.7 and 0.3 are estimated for the P–O and Al–O bonds respectively. The relatively small force constant of the weak Al–O bond, which is characteristic of this addition complex, can be confirmed by experimental observations[49]. With the stronger acceptors $TiCl_4$, $ZrCl_4$, and particularly $NbCl_5$, the ν_{as}(P–O–M) stretching vibrations absorb at unusually low frequencies, corresponding to a stronger metal-oxygen bond. Finally, with $MoCl_5$ or WCl_6, the oxygen is actually displaced from the phosphorus to the metal[49,62,69,70].

Table 4. Some P–O–M stretching vibrations of 1:1-triphenylphosphine oxide-metal halide complexes.

Compound	ν_s(P–O–M) (cm^{-1})	ν_{as}(P–O–M) (cm^{-1})	Ref.
$(C_6H_5)_3POAlCl_3$	388	1156	[49, 50]

halogen exchange is observed at room temperature [72]. CF_3SO_2Cl and FSO_2Cl do not react with $Ag[SbF_6]$ [73]. Organosulfonylium ions cannot be stabilized even by strong Lewis acids unless the sulfur can transfer its positive charge to the organic residue, with participation of quinonoid limiting forms in the case of aromatic systems [72].

Thus the *p*-dimethylaminobenzenesulfonylium ions *(4)*, which (for El = Sb) are stable up to room tem-

(4a) *(4b)*

perature, but are very hygroscopic, can be prepared in accordance with

$$RSO_2Cl + Ag[ElF_6] \xrightarrow[\text{liq. } SO_2]{-25\,^\circ C} [RSO_2][ElF_6] + AgCl$$

$R = p\text{-}(CH_3)_2NC_6H_4$; El = Sb, As, P

from $p\text{-}(CH_3)_2NC_6H_4SO_2Cl$ [containing the $(CH_3)_2N$ residue, which acts as a strong electron donor] and the complexes $Ag[ElF_6]$ in liquid SO_2.

The participation of the quinonoid limiting form *(4b)* deepens the color of the complexes. This effect is particularly noticeable in *p*-dimethylaminobenzenesulfonylium hexafluoroantimonate(v), which is readily soluble in liquid SO_2, and whose deep orange color [$p\text{-}(CH_3)_2NC_6H_4SO_2Cl$ is lemon yellow] is a definite indication of the quinonoid form *(4b)*. Further evidence is provided by the electronic spectra. Whereas $p\text{-}(CH_3)_2NC_6H_4SO_2Cl$ has an intense maximum in the visible region at 24509 cm^{-1}, the band characteristic of the cation shows a bathochromic shift to 21 413 cm^{-1}. The ionic structure of the antimony complex is also shown by conductivity measurements in nitromethane (cf. Table 5).

Owing to the conjugation effect [limiting form *(4b)*], the symmetric and asymmetric SO_2 vibrations of $[p\text{-}(CH_3)_2NC_6H_4SO_2][SbF_6]$ absorb at higher frequencies than the corresponding vibrations in $p\text{-}(CH_3)_2NC_6H_4SO_2F$ (cf. Table 7). The stronger O–S double bond character [$(p\rightarrow d)_\pi$] and the intense absorption band at 662 cm^{-1} [$\nu(SbF_6^-)$ (T_{1u})] also point to the ionic structure. The stability of the $[p\text{-}(CH_3)_2NC_6H_4SO_2]^+$ cation decreases with decreasing acceptor strength of the Lewis acids AsF_5, PF_5, and BF_3. Table 5 shows a comparison of the properties of some *p*-dimethylaminobenzenesulfonyl and *p*-dimethylaminobenzenesulfonylium compounds.

Table 5. Properties of compounds of the type $p\text{-}(CH_3)_2NC_6H_4SO_2X$ and $[p\text{-}(CH_3)_2NC_6H_4SO_2]X$.

X	Color	Stability	Conductivity (Ω^{-1} cm^2 mole^{-1})
Cl	yellow	stable	–
F	beige	stable	–
SbF_6	orange	up to 30 °C	74.64
AsF	olive green	up to −20 °C	8.26
PF_6	light green	up to −25 °C	10.58
BF_4	–	not isolable	–

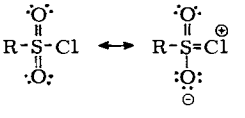
5.2. Reactions with Lewis Bases



Organometallic sulfonyl or "*S*-sulfinato" complexes have been known only since 1964 [74]. They can be prepared by two basic methods:

a) by the action of sulfonyl halides or sulfonic acid anhydrides on organometallic Lewis bases, and

b) by insertion of SO_2 between the metal and the organic residue ("SO_2 insertion").

Neither process is generally applicable, but each complements the other.

Method a): The action of $p\text{-}CH_3C_6H_4SO_2Cl$ on the Lewis base $[Mn(CO)_5]^-$ leads not only to the expected pentacarbonyl-*p*-toluenesulfonylmanganese and $ClMn(CO)_5$, but also to a series of by-products, some of which are polymeric [75], and which prevent the preparation of pure $p\text{-}CH_3C_6H_4SO_2Mn(CO)_5$. The formation of $ClMn(CO)_5$ is based on the strongly electron-attracting effect of the *p*-toluenesulfonyl residue on the Cl atom; the halogen atom acquires a positive charge because of the inductive effect, with the result that the S–Cl bond assumes double bond character [76]. The instability of the $[p\text{-}CH_3C_6H_4SO_2]^+$ cation confirms these views.

If, however, $p\text{-}CH_3C_6H_4SO_2Cl$ is replaced by the anhydride $(p\text{-}CH_3C_6H_4SO_2)_2O$, heterolysis occurs in the presence of the carbonylmetalates of manganese, iron, and cobalt, which act as Lewis bases.

$$RSO_2\text{–}O\text{–}SO_2R \rightleftharpoons [RSO_2]^+ [RSO_3]^-$$

$R = p\text{-}CH_3C_6H_4$

The extremely unstable $[RSO_2]^+$ cation immediately reacts further with the anions mentioned [76], as follows:

$$[RSO_2]^+ + [\text{Lewis base}]^- \xrightarrow[THF]{-80\,^\circ C} RSO_2\text{Lewis base}$$

$[\text{Lewis base}]^- = [Mn(CO)_5]^-$, $[\pi\text{-}C_5H_5Fe(CO)_2]^-$, and $[Co(CO)_3P(C_6H_5)_3]^-$

Like the reaction of perfluorinated carboxylic acid anhydrides with carbonylmetalates, this reaction proceeds almost quantitatively [28,29]. The diamagnetic compounds [RSO_2Lewis base] are thermally very stable. The method is not applicable to other systems (*e.g.* $[Re(CO)_5]^-$ or $[\pi\text{-}C_5H_5Mo(CO)_3]^-$).

Unlike *p*-toluenesulfonic acid anhydride, $(CF_3SO_2)_2O$ is totally unsuitable for the introduction of a CF_3SO_2

[74] *J. P. Bibler* and *A. Wojcicki*, J. Amer. chem. Soc. *86*, 5051 (1964).

[75] *W. Beck*, private communication.

[76] *E. Lindner* and *H. Weber*, Z. Naturforsch. *22b*, 1243 (1967).

group; it oxidizes the carbonylmetalates to the neutral carbonylmetal compounds in every case[77]. The CF_3SO_2 derivatives were first isolated in yields of about 20 % on condensation of equimolar quantities of CF_3SO_2Cl with $[M(CO)_5]^-$ (M = Mn, Re), $[\pi\text{-}C_5H_5Fe(CO)_2]^-$, and $[Co(CO)_3P(C_6H_5)_3]^-$ in THF solution at −60 to −80 °C[77,78]:

$$CF_3SO_2Cl + [\text{Lewis base}]^- \rightarrow CF_3SO_2\text{Lewis base} + Cl^-$$

The perfluorinated compounds are thermally much less stable than the *p*-toluenesulfonyl derivatives (Table 6).

Table 6. Melting points and decomposition points of *p*-toluenesulfonyl and trifluoromethanesulfonyl complexes.

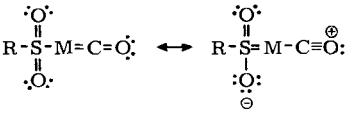
Compound	M.p. (°C)	Decomposition (°C)
$p\text{-}CH_3C_6H_4SO_2Mn(CO)_5$		150
$CF_3SO_2Mn(CO)_5$	83	120
$CF_3SO_2Re(CO)_5$	65	65
$p\text{-}CH_3C_6H_4SO_2(\pi\text{-}C_5H_5)Fe(CO)_2$		200
$CF_3SO_2(\pi\text{-}C_5H_5)Fe(CO)_2$		150
$p\text{-}CH_3C_6H_4SO_2Co(CO)_3P(C_6H_5)_3$		90
$CF_3SO_2Co(CO)_3P(C_6H_5)_3$		20
$CF_3SO_2(\pi\text{-}C_5H_5)NiCO$		−30

The principal products of the action of sulfonyl halides, and particularly of CF_3SO_2Cl, on carbonylmetalates are the carbonylchlorometal compounds, the yield of which largely depends on the electronegativity of the residue attached to the sulfonyl sulfur atom. It is significant that FSO_2Cl in which the CF_3 group has been replaced by the still more electronegative fluorine, reacts quantitatively with $Na[Mn(CO)_5]$ to give $ClMn(CO)_5$[78]

$$FSO_2Cl + Na[Mn(CO)_5] \xrightarrow[THF]{-80\,^\circ C} ClMn(CO)_5 + NaF + SO_2$$

and is therefore suitable for use as a mild halogenating agent. It would seem reasonable to prevent this undesirable reaction by the use of the sulfonyl fluorides instead of the chlorides, but this procedure has not acquired much importance, owing to the low yields[79]. The reaction of alkali metal organosulfinates with halogenated carbonylmetal compounds or halogenocarbonylmetalates has been used for the preparation of the Cr and W complexes $Na[M(CO)_5SO_2C_6H_5]$ (M = Cr, W)[80].

Finally, mention should also be made of the behavior of CF_3SO_2Cl toward carbonylmetal complexes with aromatic ligands ($[\pi\text{-}C_5H_5Fe(CO)_2]_2$[79] and $[\pi\text{-}C_5H_5NiCO]_2$[81]); the CF_3SO_2-iron and CF_3SO_2-nickel compounds listed in Table 6 are formed in yields of about 10%.



Method b): "SO_2 insertion" is particularly suitable for the preparation of carbonylalkanesulfonylmetal, carbonylbenzenesulfonylmetal, carbonyl-α-toluenesulfonylmetal, and carbonyl-*p*-toluenesulfonylmetal derivatives, which are formed in high yields and mostly without by-products[74,79,80,82], *e.g.*

$$RM(CO)_5 + SO_2 \rightarrow RSO_2M(CO)_5$$

Many sulfinato complexes derived from manganese[82], rhenium[80], and iron[79] have been obtained in this way: the compounds $RSO_2M(CO)_5$ (M = Mn, Re) and $\pi\text{-}C_5H_5Fe(CO)_2SO_2R$ (R = CH_3, C_2H_5, C_6H_5, $CH_2C_6H_5$, $p\text{-}CH_3C_6H_4$). Depending on the strength of the metal-carbon bond, liquid SO_2 is allowed to act on the organometallic compound (for example $\pi\text{-}C_5H_5Fe(CO)_2CH_3$[79]) either below the boiling point of SO_2 or under pressure at higher temperatures (about 40 °C) (*e.g.* $C_6H_5Mn(CO)_5$[80]). It is interesting to note that the SO_2 insertion cannot be applied to perfluorinated carbonylorganometallic compounds[80]. $CF_3Mn(CO)_5$ does not take up SO_2 even under extreme conditions; the metal-carbon bond is too strong, owing to the π-components.

The thermal behavior of the sulfonyl complexes described is quite different from that of the acyl compounds. No elimination of SO_2 was observed in any case[80]. The decomposition reactions are uncontrolled, and generally proceed with initial loss of CO.

The positions of the symmetric and asymmetric SO_2 stretching vibrations are strongly dependent on the nature of the residue X bound to the organosulfonyl group[76]. As can be seen from Table 7, their frequencies are highest for $p\text{-}CH_3C_6H_4SO_2F$, and, for the same organosulfonyl residue, they decrease with increasing donor strength of X; for the organometallic residues X = $Mn(CO)_5$, $\pi\text{-}C_5H_5Fe(CO)_2$, and $Co(CO)_3P(C_6H_5)_3$ in particular they fall by up to 200 cm^{-1}. This is also found in the trifluoromethanesulfonyl derivatives. The large decrease in the frequencies of the SO_2 bands is characteristic of organometallic sulfonyl compounds, and indicates the presence of strong bonds between the metal and the sulfur:

The electron-attracting CF_3 group causes a considerable increase in the frequencies of the SO_2 stretching vibrations. The low frequency $\nu_s(SO_2)$ and $\nu_{as}(SO_2)$ vibrations naturally mean that the C–O absorptions must occur at very short wavelengths, as was in fact found in every case. The spectra of the manganese and rhenium complexes are characterized by the presence of five absorptions in the terminal CO group region. The C_{4v} symmetry is so strongly perturbed because of the angular RSO_2 ligands that the B_1 vibration, which is forbidden in the IR, is in fact observed, and the band of the E vibration is also split.

6. Summary and Outlook

It was shown in Sections 2 to 5 that acylium, perfluoroacylium, thioacylium, and even sulfonylium ions are obtainable though only under extreme conditions in some cases. All the described reactions of acyl, perfluoroacyl, thioacyl, or sulfonyl halides and carboxylic acid or sulfonic acid anhydrides with organometallic, organophosphorus, or organoarsenic Lewis bases thus have fundamentally the same course. When a nucleophile dissolved in a polar medium approaches the acid halide or anhydride, the reaction proceeds uniformly *via* a transition state *(5)* or *(5a)* toward the limiting arrangement, the ions *(6)* or *(6a)* (heterolysis).

The intermediate cations *(6)* and *(6a)* can now react with the nucleophile, *i.e.* the Lewis base, to give the derivatives *(7)* and *(7a)* respectively. The rate-determining step is the heterolysis.

El = O; X = Cl, Br, OCOR; R = (perfluoro)organo group;
El = S; X = Cl; R = C_6H_5;
R^1 = p-$CH_3C_6H_4$, p-$(CH_3)_2NC_6H_4$; X = Cl, p-$OSO_2C_6H_4CH_3$

The surprising stability of the thiobenzoylium ion and the entirely novel polymeric tetracarbonylthiobenzoylmanganese compounds are of preparative interest. Thioacyl halides appear to be more reactive than other acid halides, as is shown by their behavior toward organometallic Lewis bases.

I am very grateful to my co-workers Dr. H. Kranz, Dr. H. Weber, Dr. G. Vitzthum, Dipl.-Chem. H.-G. Karmann, Dipl.-Chem. U. Kunze, Dipl.-Chem. H.-D. Ebert, and Dipl.-Chem. K.-M. Matejcek, who have played a vital part in these investigations, and to H. Schless, R. Lehner, and H. Scheer, who also made valuable contributions. Sincere thanks are due to Professor Dr.-Ing. H. Behrens for his interest in this work and for his generous support. I also thank the Verband der Chemischen Industrie, Fonds der Chemischen Industrie, and the Deutsche Forschungsgemeinschaft for their financial support.

Structure of the Solvation Shell of Dissolved Particles

By H. G. Hertz[*]

The first part of the article deals with the structure of the solvation shell of simple ions, particularly those with the inert gas structure, in aqueous and non-aqueous solution. It is nowadays possible in favorable cases, to determine the solvation number or the coordination number in the first sphere. The solvation shells appear to be "more liquid" than was formerly believed. The hydration of neutral inert particles in aqueous solution is discussed in the second part. Caution is advised in the postulation of particular structural arrangements in the solution.

1. Introduction

An attempt is made to present some of the existing knowledge about the structure of the solvation shells of dissolved particles. It is not surprising that different views exist on a subject as complicated as this. Nevertheless, there should be no doubt about the experimental facts and their interpretation in the first part of the article. Toward the end of the article, on the other hand, it will be necessary to cover ground about which there is less certainty.

The results to be described here will be discussed from the points of view of the "molecular structures" of the liquids, the discussion being confined to liquid solutions in the narrowest sense. The essential nature of a liquid is best understood by considering it as a very large "heap" of molecules [1]. Figure 1 shows part of a

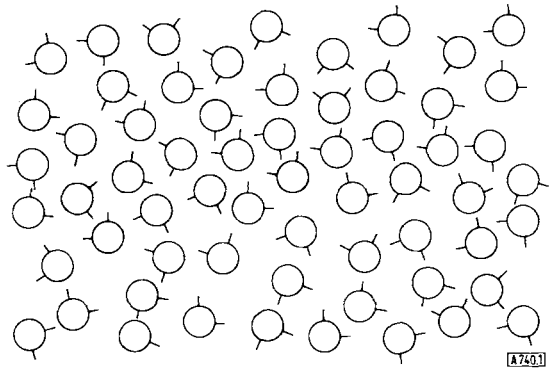

Fig. 1. Two-dimensional molecular model of a liquid.

two-dimensional analog of such an "heap". The molecules bear a certain resemblance to water molecules, but this is of no importance to the following discussion. The structure of this liquid can be described by the probability of finding certain intermolecular distances and orientations relative to an arbitrarily chosen molecule. This is described quantitatively by the molecular *distribution functions*, which generally contain several maxima and minima as a characteristic property of the *structure of the liquid* [2].

Figure 1 should be regarded as a "snapshot" showing the situation at one particular instant. For a low molecular weight liquid at room temperature, the picture of the liquid will have changed to such an extent after 10^{-11} to 10^{-10} sec, as a result of molecular motion, that any correlations in the arrangement of neighboring individual particles are no longer recognizable.

Introduction of foreign particles into the liquid leads to a change in its structure, and new molecular motions appear. The structural peculiarities that exist in the neighborhood of the dissolved particles and the nature of the molecular motions of solvent molecules, which are related to the dissolved particles form the subject of the present article.

Let us consider a few examples that illustrate the problem. Figures 2, 3, and 4 show possible effects of the dissolved particles on the structure of the solvent.

The classical positive solvation or hydration of ions (Fig. 2) needs no explanation. Figure 3 shows a slight change in the solvent in addition to pure replacement of particles. Accurate analysis of the distribution of the particles and of their orientation in relation to the ions and to themselves, *i.e.* the study of the molecular

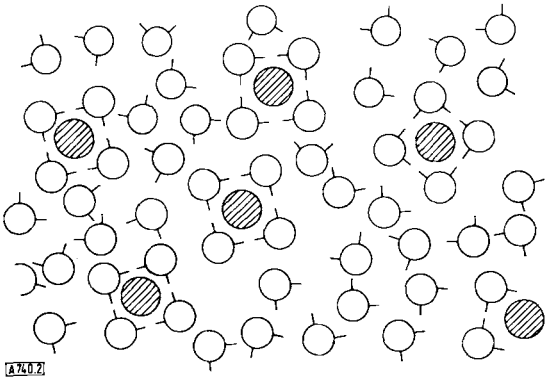

Fig. 2. Two-dimensional molecular model for strong solvation of dissolved particles in a liquid. In aqueous solution, the lines attached to the circles denote OH bonds for dissolved anions, and lone pairs of electrons for dissolved cations.

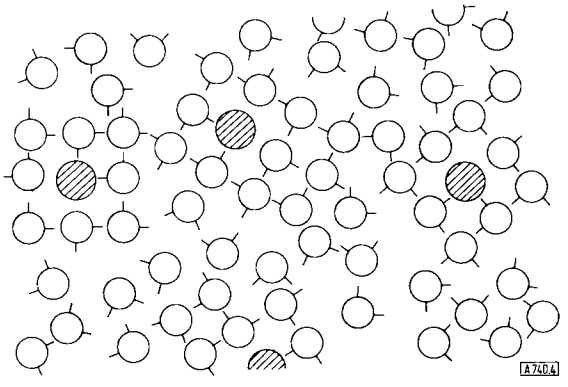

Fig. 4. Two-dimensional molecular model for solvation of "inert" dissolved particles with no fixed orientation between the molecules of the liquid and the dissolved particles.

distribution functions[2], would reveal that the ions act as centers of orientation, so that solvation of the ions is in fact present. In Figure 4 we see no orientation of a fixed molecular axis toward the center of the dissolved particle, but only orientation of the solvent molecules with respect to one another. It is to be expected that the linkage of two individual water molecules in the solvation shell of an ion in accordance with Figure 2 persists much longer than in pure water. The reorientation time of a molecule in the solvation shell will also be much longer than in pure water.

Figures 2, 3, and 4 provide some idea of what would be involved in a complete knowledge of the structural peculiarities of solvation. A precise analytical description would require a set of multi-dimensional molecular distribution functions[2], a requirement that is still far beyond our present capabilities. The gaps that remain will be pointed out in the following discussion. It will be seen that in addition to structural questions proper, molecular motions also play a part. The concept of solvation structure is accordingly extended to include molecular motions.

The discussion will however be confined to solvation phenomena connected with changes in the structure of the solvent around the *whole particle*. This excludes the wide field of specific interactions between molecules (or molecule-ions) in organic liquids. The following pages will thus be devoted to simple ions in aqueous and non-aqueous solvents and neutral particles in aqueous solution.

2. Solvation of Ions

2.1. True Solvation Structure

2.1.1. Aqueous Solutions

Let us first consider the old problem of hydration numbers. What are hydration numbers?

From the point of view of the structure, the question would have to be answered by considering Figure 2 or 3. As the situation passes from that of Figure 2 to that of Figure 3, however, it becomes increasingly difficult to specify a hydration number. It is generally necessary to decide arbitrarily which and how many water molecules are to be regarded as belonging to the hydration sphere. A reasonable procedure is to take the area under the first maximum or under the first two maxima of the radial probability distribution function for the pair ion-water molecule as a measure of the hydration number. For several reasons, hydration numbers defined in this manner will depend on the concentration.

Alternatively, we can try to define the hydration numbers from the point of view of the molecular motions. To do this, we follow the decay of the spatial correlation between the ion in question and the water molecules in its environment. If it is found, for example, that such a correlation exists for $n_h^{\pm}$ molecules, but not for any of the other molecules in the environment, then $n_h^{\pm}$ can be taken as the hydration number of the system. The result in this case will naturally depend on the time limit selected and the limit allowed for the breakdown of the correlations.

The conventional way to obtain the hydration number is as follows. One measures some physical quantity X, which is expressed in the form

$$X = X_0(1-x^+-x^-) + x^+X^+(n_h^+) + x^-X^-(n_h^-) \qquad (1)$$

x^+ and x^- are the mole fractions showing how many particles there are in the environment that is to be regarded as the hydration complex of the cation and of the anion respectively. $X^+(n_h^+)$, $X^-(n_h^-)$, and X_0 are the physical property in question for the hydration complexes of the cation and of the anion and for the unbound state. Both $x^{\pm}$ and $X^{\pm}$ can contain information about the hydration numbers $n_h^{\pm}$. This method is thus characterized by two points: The complicated molecular system of the solution is divided into discrete microscopic regions, and physical properties that are often rigorously defined only in macroscopic terms are assigned to these regions.

Comparison with Figure 3 in particular shows how rough this method can be. The hydration number obtained does not depend on our definition of the hydration sphere (first or second coordination sphere, residence time of the water molecules in the hydration sphere, *etc.*), but depends on the numerical values of the physical property that are assigned to the hydration complex. Thus different determination methods

often give qualitatively the same overall behavior for the hydration numbers, whereas distinct quantitative differences are obtained (see *e.g.* [3]). Hydration numbers of less than 4 for spherical ions are difficult to understand. The number of regions (first hydration sheath, second hydration sheath) in eq. (1) could naturally be increased, but the number of unknowns would then also increase.

The determination of the radial distribution function for ion/water systems by measurement of the areas of X-ray diffraction patterns of electrolyte solutions is in principle a satisfactory method of determining the hydration numbers (see *e.g.* [4]). Thus *Brady* [5] found a value of 6.3–6.5 for the hydration number of Er^{3+} in the first sphere (first coordination number) on this basis. This value must be treated as indicating six-fold coordination. Information about the second coordination sphere of Er^{3+} was also obtainable [5]; in the case of the erbium halides, however, this also contains two halide ions. Er^{3+} is a relatively small ion with a high charge, so that the situation corresponds to that of Figure 2. Difficulties arise with ions having larger radii or lower charges. Firstly, ions having low atomic numbers have low scattering powers for X rays, and so make only a small contribution to the overall diffraction picture. Secondly, all the pair distribution functions in the solution are superimposed in the primary result, so that the water-water distributions in the hydration shell and in the free water are involved as well as the cation-water and anion-water distributions. The corresponding distances are often similar. Several methods have been described [6–8] for the derivation of the desired hydration numbers (first coordination numbers) (see Table 1). The X-ray diffraction experiments were carried out at moderate concentrations (2–5 mole/kg of H_2O), so that the values for K^+ are probably not valid for infinite dilution. In the case of the Cs^+ ion, perturbation of the intact hydration shell by halide ions has been observed at moderate concentrations [8].

Table 1. Hydration numbers $n_h^{\pm}$ (coordination numbers in the first sphere) for some ions in water; concentration ranges 2–5 mole/kg.

Ion	Salt	$n_h^{\pm}$	Method	Ref.
K^+	KOH	4 (to 5?)	X-ray [a]	[6]
Er^{3+}	$ErCl_3$, ErI_3	6	X-ray	[5]
Cl^-	LiCl	6.2–7.3	X-ray	[8]
Br^-	LiBr	7.2–8.9	X-ray	[8]
I^-	LiI	8–9	X-ray	[8]
Al^{3+}	$AlCl_3$, $AlBr_3$, $Al(ClO_4)_3$	6	NMR	[11, 12, 19, 22]
Be^{2+}	$BeCl_2$, $Be(ClO_4)_2$	4	NMR	[12, 19, 22]
Ga^{3+}	$Ga(ClO_4)_3$	6	NMR	[12, 20, 21]
In^{3+}	$InCl_3$	4.7 [b]	NMR	[12]
Mg^{2+}	$Mg(NO_3)_2$, $Mg(ClO_4)_2$	6	NMR	[12, 15–17]
Cr^{3+}	$Cr(ClO_4)_3$	7 (6?) [c]	NMR	[22]
Ni^{2+}	$Ni(ClO_4)_2$	4 or 6	NMR	[25]
Co^{2+}	$Cr(ClO_4)_2$	6	NMR	[26]

[a] X-ray diffraction. [b] In water/acetone (1 : 3 v/v), $n_h^+ = 6$. [c] The difference from the expected value of 6 can be explained by the relaxation mechanism in the second coordination sphere of the (paramagnetic) Cr^{3+} ion.

X-ray diffraction experiments yield information on hydration numbers in the sense of the definition of the actual structure. We shall now discuss investigations that are closely related to the residence time of the water molecules in the hydration shell. These studies are based on NMR measurements. The condition for the occurrence of separate NMR lines in different chemical (*i.e.* different electronic) environments (see *e.g.* [9, 10]) is

$$\tau \gg (\Delta\omega)^{-1} \qquad (2)$$

τ is the average time spent by the nucleus in question in the particular electronic environment, and $\Delta\omega$ is the absolute value of the difference in the chemical shifts (in Hz) between the different environments through which the nucleus passes in the exchange process.

A typical case of the application of the inequality (2) is the exchange of the proton or water molecule between the hydration shells and the free water in electrolyte solutions. In diamagnetic electrolyte solutions at and above room temperature, the particle exchange between the various regions of the solution is always so fast that the inequality (2) is not satisfied. On the contrary, the relation

$$\tau \ll (\Delta\omega)^{-1}$$

is always valid, so that the solution water gives only one NMR signal. The position of this signal corresponds to the average of the shifts of all the environments through which the proton or the ^{17}O nucleus passes. By lowering the temperature, however, the residence time τ can be prolonged to such an extent, in suitable cases, that the inequality (2) is satisfied. Thus *Fratiello et al.* observed a separate NMR signal for the water of hydration in addition to the signal for free water in aqueous solutions of Al, Ga, Be, and In salts at about −50 °C [11, 12].

Two examples are shown in Figure 5. Measurement of the areas below the two absorption lines shows that for each dissolved Al^{3+} ion there are six water molecules (or more precisely their protons) in an environment in which the chemical shift in relation to the residual water is −272 Hz and in which the residence time is very much longer than $(272 \times 2\pi)^{-1}$ s $\approx 6 \times 10^{-4}$ s. A negative chemical shift of this order of magnitude is expected, according to the theory of

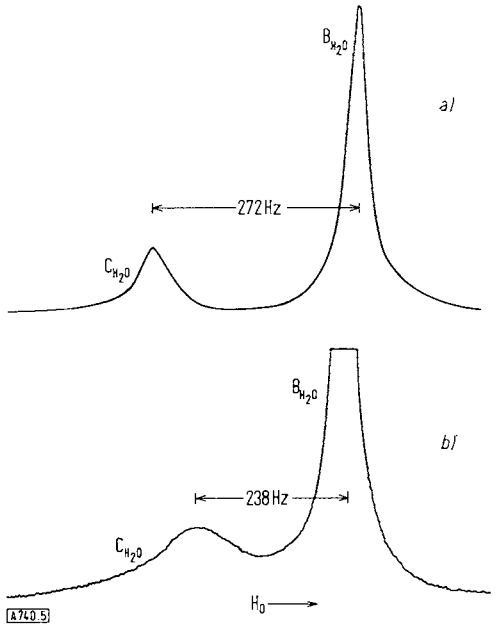

Fig. 5. Proton resonance spectra of aqueous solutions of Al and Ga salts. C_{H_2O} is due to the water in the hydration shell, and B_{H_2O} to that in the unbound state. (a) 1.59 mole of $Al(ClO_4)_3$ per kg of H_2O at −50 °C; (b) 2.42 mole of $GaCl_3$ per kg of H_2O at −58 °C. We thank Dr. *A. Fratiello* for these diagrams.

chemical shift [13,14], for the water protons in the electrostatic field of the cation. Since a strong electric field can exist only in the immediate vicinity of the ion, and since it is extremely unlikely that the same shift is produced by different field strengths, it is concluded that the six water molecules characterized by a long exchange time and a strong interaction are those of the first coordination sphere of *one* type of ion. The method thus leads directly to the hydration numbers in the first sphere. The results obtained so far are also collected in Table 1.

It can be seen in Figure 5b that the signal for the water of hydration in $GaCl_3$ solution is broader than that in $Al(ClO_4)_3$ solution. The coordination number for $GaCl_3$ is given by *Fratiello et al.* as only 5.7; a relatively fast exchange of the water protons, and possibly also of Cl^- ions, is already taking place. The figures given in Table 1 for the NMR results again refer to solutions of medium to high concentration (1.5–4.0 mole/kg of H_2O). In the case of In^{3+}, it is clear that the anions (Cl^-) have already occupied some sites in the hydration shell. The value given in parentheses for In^{3+} refers to a solution in a water-acetone mixture. The resolution of the lines is often much better in systems of this type [12]. Separate signals were originally obtained for the solvation shell in the case of Mg^{2+} only when an organic component (methanol [15,16], acetone [12,17]) was added to the aqueous solution. Later, however, separate (though broad) lines were obtained for the two residence ranges of water for concentrated solutions of $Mg(ClO_4)_2$ and $Mg(NO_3)_2$ (c = 3–4 mole/kg of H_2O) in water with no added organic component at −70 to −80 °C [17].

By means of a trick, separate NMR signals have even been observed for the water of hydration at room temperature with pure water as the solvent for the cations Al^{3+}, Ga^{3+}, and Be^{2+}. The trick consists in the addition of a paramagnetic ion, such as Co^{2+} or Dy^{3+}, in whose hydration shell very rapid water exchange takes place, to the solution of the ion under examination. This leads to a strong chemical shift of the water that is not contained in the hydration shell of Al^{3+}, with the result that the condition of the inequality (2) can be satisfied. Investigations of this type have been carried out for the ^{17}O resonance [18–21].

Similar experiments, again with the addition of paramagnetic ions, but which do not lead to the appearance of separate lines, also yield information about the hydration numbers in the first sphere [18–22]. No details can be given here. On the other hand, the measurements reported by *Swift* and *Sayre* [23] provide no reliable information about hydration numbers (see also [24]). A separate NMR signal has been found for the hydration shells of two paramagnetic ions (Ni^{2+}, ^{17}O resonance, room temperature [25]; Co^{2+}, proton resonance, about −60 °C [26]). The hydration number of Ni^{2+} may be either 4 or 6; the area measurement is very uncertain, but *Connick* and *Fiat* [25] favor a value of 4 on grounds of consistency with other NMR data. The coordination number in the first sphere of Co^{2+} is found to be 6 [26].

As was mentioned earlier, the hydration numbers provide information about the area under the first maximum of the (radial) pair distribution function for the particle pair ion-water. The next question is that of the shape of this distribution function in the region of the first maximum. A very sharp, steep maximum would correspond to a hydration shell in which, as in the case of a rigid molecule, the distances of the particles lie within a very narrow range. A flat, broad maximum, on the other hand, would indicate a relatively wide range of values for the distance between the ion and the water molecules, and would correspond roughly to the distribution of the intermolecular distances of pairs of particles in pure liquids. Pertinent

information should again be obtainable by X-ray diffraction measurements. So far as we know, however, this problem does not appear to have been raised in the literature, and no investigations of the type required appear to have been carried out on electrolyte solutions. Owing to the overlap of distributions, as well as for other reasons, definite clarification of this structure problem will be possible only in a few favorable cases. However, the X-ray diffraction studies reported so far show that the maxima in the distribution functions, as expected, are very much sharper for the strongly hydrated Er^{3+} [5] than for solutions of KOH [6], KCl [6], LiCl [7], NaCl [8], and CsCl [8]. The sharpness for these last-named solutions is roughly the same as that for pure water. Because of the low scattering power of Li^+, however, no contribution can be expected for this ion.

Let us now turn to the question of the orientation of the water molecules in the hydration shell. The hydration energy of the ions is based mainly on ion-dipole interaction. It has always been regarded as obvious that at least one of the protons of the water molecule points toward the anion, whereas in the case of a cation, the water protons are directed away from the ion. Experimental evidence has been presented only in very rare cases, since it was accepted that none was necessary. There is in fact no doubt that such an arrangement of the water molecules exists in cases of strong hydration (cf. Fig. 2). The nuclear magnetic relaxation rate, which describes how quickly the (macroscopic) nuclear magnetization reaches its equilibrium value, depends in electrolyte solutions on how quickly the hydration complex reorients itself in the course of thermal motion, and is determined by the interaction of the water protons with their environment [9, 10, 27–29].

These two contributions can be observed separately with some paramagnetic ions. The interaction part here involves the distance of the protons in the first hydration shell from the center of the ion. Evaluation of the measurements gives roughly the distance expected for the proton directed away from the ion in the cases of Mn^{2+} [28, 30, 31], Cu^{2+}, and Cr^{3+} [31]. For the diamagnetic ions F^- [32, 33] and Li^+ [34, 35], only the product of the reorientation time of the hydration complex and the interaction factor can be determined experimentally from the relaxation rate of the ionic nucleus. Since the reorientation time is roughly known (see below), however, it can again be shown that the interaction term corresponds, on the whole, to the expected arrangement of the water protons in relation to the ion in question.

A question frequently discussed in the literature is whether the water molecule in the hydration shell of the anion is arranged symmetrically (center of the ion on the dipole axis, *i.e.* the bisector of the angle HOH) or unsymmetrically (center of the ion on the projection of one of the two O–H directions) [33, 36–40]. We cannot yet give a definite answer to this question [*].

While there is no doubt about the substantial nature of the orientation of the water molecules with strongly hydrated ions, the situation is not so clear with weakly hydrated ions, the behavior of which is illustrated diagrammatically in Figure 3. This is because of a special effect that occurs with large inorganic ions in aqueous solution, and which has been referred to as the structure breaking effect [42] and as negative hydration [43] (see also Section 2.2.3). The water in these solutions behaves spectroscopically and in its mobility as water whose temperature is higher than the true value. For example, the fluidity and the self-diffusion coefficient as well as the reorientation rate of the water molecule in a concentrated aqueous solution of potassium iodide are higher than in pure water at the same temperature. Because of this and other properties, the fairly large class of salts that exhibit this behavior are referred to as *structure breakers* [44], though nothing is known about the true change of structure in the solution. Conversely, salts with strongly hydrated ions are called structure formers. It is naturally questionable whether phenomena as complicated as changes in the structure of a solution can be adequately described by such simple terms [2]. Nevertheless, this terminology has become accepted as useful.

[*] An attempt has recently been made to determine the orientation of the water molecules in the system $F^-(H_2O)_4$ directly by a quantum mechanical *ab initio* calculation [41]. According to this calculation the unsymmetrical arrangement of the water molecules has the lower energy. However, the behavior at large ion-water molecule distances does not agree with that expected on the basis of the ion-dipole interaction. Moreover, the value found for the H_2O–H_2O interaction between two isolated water molecules with the same set of functions is much too high. This state of affairs greatly reduces the value of these calculations.

The hydration energy is naturally negative even for the structure-breaking ions, and depends on the ion-dipole interaction. The hydration energy is determined mainly by the difference in the amounts of work required to charge the ion in water and *in vacuo*. This is a consequence of the fact that the water dipoles in the environment of a dissolved particle assume a more favorable orientation when the particle is charged (ion-dipole interaction; for the orientation of the water molecules around a neutral particle, see Section 3). It should be mentioned now that a specific hydration of neutral apolar particles is nowadays assumed for water. *Frank* and *Evans*[42] called this effect "iceberg formation"; in the present article we shall use the somewhat neutral expression "hydration of the second kind". In the hydration of the second kind, there is a certain molecular orientation of water with respect to a neutral particle, *e.g.* a Xe atom. This orientation very probably becomes unfavorable when the Xe atom is replaced by an I^- ion. The electric field due to the charge calls for a more favorable orientation of the water dipoles. However, the field strength, which depends on the size of the particle and the magnitude of the charge, is not enough to bring the dipoles fully into the ideal orientation, *e.g.* as shown in Figure 2. Many of the dipoles thus remain in the "half-way" position and a relatively isotropic orientation of the water molecules occurs around a structure-breaking ion. It can be shown from thermodynamic data that the entropy[42] and the energy[44] increase when structure-breaking particles (large ions having the inert gas structure) become charged; the disorder in the solution, extending into the first coordination sphere of the ion[45] (see later), thus increases.

There are thus physical arguments that suggest the possibility of a relatively isotropic orientation distribution of the water molecules in the first coordination sphere of structure-breaking ions. Definite information is not yet available. However, there is a clue that could lead to further knowledge on this subject. The chemical shifts of the ionic nuclei ^7Li, ^{23}Na, and ^{27}Al (structure formers) in solutions in D_2O are extremely small in comparison with those in H_2O[46,47]. On the other hand, replacement of H_2O by D_2O leads to appreciable chemical shifts for the anionic nuclei ^{19}F, ^{35}Cl, $^{79,81}Br$, and ^{127}I[46,48,49], while replacement of $H_2{}^{16}O$ by $H_2{}^{18}O$ leads to practically no shift in the ^{19}F resonance (structure former). This shows qualitatively that the hydrogen nuclei are evidently nearer to the anion than to the cation. Measurements for the structure-breaking anions Cl^-, Br^-, and I^- in $H_2{}^{18}O$ have unfortunately not been reported, but the ^{133}Cs resonance (structure breaker) is displaced only slightly (if at all) more in D_2O than in $H_2{}^{18}O$[46].

The following rough calculation also points to incomplete orientation in the hydration shell. The average residence time of a water molecule in the hydration shell of the I^- ion is approximately $2 \times 10^{-12} - 4 \times 10^{-12}$ s (see below). Let us assume for simplicity that the molecule reaches a site in the hydration shell by a brief free "flight". The mean "flight velocity" can be taken from the kinetic gas theory to be approximately 6×10^4 cm/s. The "flight distance" to the site and back is of the order of magnitude of the diameter of a water molecule, *i.e.* about 3×10^{-8} cm, and the "time of flight" in the first coordination sphere is thus about 0.5×10^{-13} s. About 12–25% of the time spent by the water molecule in the hydration shell is therefore spent in free flight, *i.e.* the molecule is disoriented during this time. The orientation distribution of the water molecules thus has a broadening of at least this order of magnitude.

2.1.2. Non-aqueous Solutions

According to the above discussion, the solvation structure of an aqueous electrolyte solution lies between the two limiting situations indicated in Figures 2 and 3. Particularly for aqueous solutions of structure-breaking salts, there is a possibility that the true structure will be very close to the situation illustrated in Figure 3. Solutions of electrolytes in non-aqueous solvents very probably approximate to the structure model shown in Figure 2, *i.e.* they should have a more highly structured solvation shell than we expect in aqueous solutions. This can be seen from thermodynamic data. The thermodynamic transfer quantities are the changes in the free enthalpy of solvation (ΔG_t^0), the enthalpy of solvation (ΔH_t^0), and the entropy of solvation (ΔS_t^0) on transfer of a salt (or ion) from water into the non-aqueous solvent. The final state to which the operator Δ refers is thus the solution in the non-aqueous solvent. The experimental values found for the standard enthalpies of transfer ΔH_t^0 of some simple electrolytes such as alkali metal halides, nitrates, and perchlorates in solvents such as methanol, ethanol, formamide, *N*-methylformamide, *N*,*N*-dimethylformamide, acetone, and dimethyl sulfoxide are predominantly *negative*[50–58]. The free enthalpies

of transfer of these simple salts are all positive [59–63], though negative values are assumed for certain cations after separation into ionic components [59,60]. In solvents such as ethanol and acetone, for which no experimental ΔG_t^0 values are available, it can again be concluded that $\Delta G_t^0 > 0$ from the decrease in solubility as compared with that in H_2O. From $\Delta G_t^0 > 0$ and $\Delta H_t^0 < 0$, since

$$T\Delta S_t^0 = \Delta H_t^0 - \Delta G_t^0$$

we find $\Delta S_t^0 < 0$. This is a particularly clear result: The (standard) entropy of solvation is more negative, *i.e.* the degree of order in the solvation structure is higher, in non-aqueous solvents than in water. Figure 6 shows the ionic standard entropies for a number of

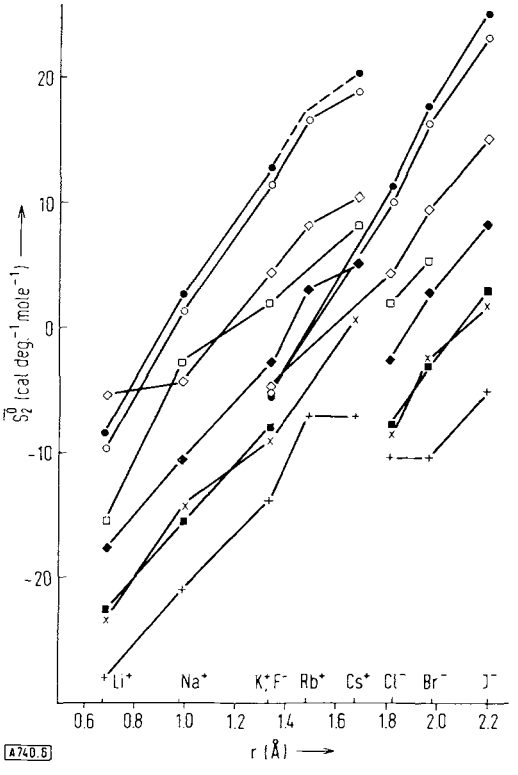

Fig. 6. Partial ionic entropies of some ions in various solvents (◇ = formamide, □ = *N*-methylformamide, × = *N,N*-dimethylformamide, ◆ = methanol ■ = ethanol ○ = H_2O, ● = D_2O, ÷ = NH_3) according to *C. M. Criss, R. P. Held,* and *E. Luksha* [64].

ions in various solvents (after *Criss, Held,* and *Luksha* [64]; the standard state is mole fraction x = 1). The standard entropy of transfer of a given ion is the difference between one of the numerical values of Figure 6 and that for the solvent H_2O. The entropies of transfer for a solvent become increasingly negative with decreasing characteristic structure of the solvent in the pure state [64].

The stronger solvation of ions in non-aqueous solvents is particularly clear from the fact that the ionic electric conductivities at infinite dilution are lower than in water, particularly when they are adjusted to take the viscosity of the solvent into account [65]. The hindrance of the movement of the ions by the adhering solvent molecules is thus greater in non-aqueous solvents.

So far as we know, however, no X-ray diffraction studies that directly show the sharper solvation structure have been reported as yet. Any diffraction diagrams that have been made for such systems appear more complicated than those of aqueous electrolyte solutions, owing to the greater number of intramolecular and intermolecular interatomic distances. An example is the investigation [66] of potassium iodide in formamide, which gave a value of 4.6 for the first coordination number of K^+ at a relatively low concentration (0.714 mole/kg of solvent); the coordination number decreases at higher concentration as a result of the increased ion association.

Since ions in non-aqueous solvents are generally more strongly solvated than in water, it is to be expected that the average residence time of a solvent molecule in the solvation shell will be longer. It should therefore be easier to observe separate NMR signals for the molecules in the solvation shell. Experience has shown that, even in non-aqueous solvents, the solvation complex is sufficiently long-lived only in exceptional cases. These exceptions are naturally again the small, highly charged ions. Thus a coordination number of 6 was found at room temperature for Al^{3+} in dimethyl sulfoxide [67], *N,N*-dimethylformamide [68–71], and acetonitrile [72], as well as for Ga^{3+} in *N,N*-dimethylformamide [69]. The chemical shift between the protons in molecules of the solvation shell and the free solvent molecules is about 20–50 Hz, depending on the nature of the system. Complications result from the fact that involved complexing equilibria can now occur with the anions [68,69,72]. At lower temperatures (<0 °C), Be^{2+} in dimethylformamide [73], $n_h^+ = 6$, Mg^{2+} in methanol [16], $n_h^+ = 6$, and ammonia [74], $n_h^+ = 5$ (?),

and the paramagnetic ions Co^{2+}, $n_h^+ = 6$, and Ni^{2+} (n_h^+ not determinable) in methanol [75] and dimethylformamide [76] also give separate lines for bound and free solvent. The chemical shift in the sites of the solvation shell is about two orders of magnitude greater for paramagnetic than for diamagnetic ions. No separate signal was observed for the solvation shell in methanolic solutions of $LiClO_4$, $Ca(ClO_4)_2$, and $Ba(ClO_4)_2$, even at −110 °C; the exchange with the free solvent must therefore still be too fast in these cases [15, 16].

If the molecules of an organic solvent contain protons in non-equivalent positions, the signals of these protons will be displaced to different extents by the ion in relation to the signals of the free solvent [17, 68, 76]. This yields information about the arrangement of the molecules in the solvation shell. Thus it has been shown that coordination of dimethylformamide to the cation very probably occurs *via* O, and not *via* N [71, 73]. It can be seen from Figure 7 that in the case of Mg^{2+} in methanol [17], the cation has a relatively large influence on the OH proton, but only a small influence on the methyl protons [16] (for Mn^{2+} in methanol and in formic acid, see [77] and [78] respectively). Figure 7

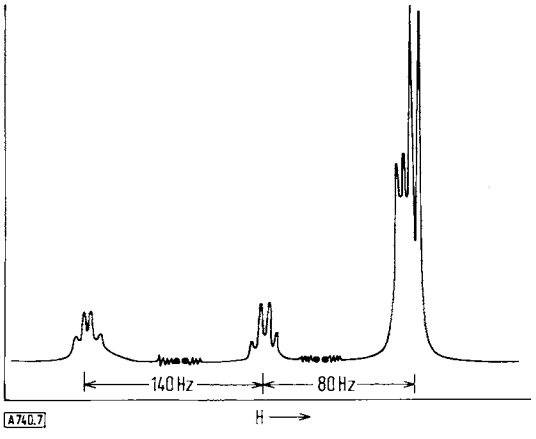

Fig. 7. Proton resonance spectrum of methanol in a solution of $Mg(ClO_4)_2$ in methanol and acetone at −60 °C. The applied magnetic field strength increases from left to right. The OH or methyl signal at lower field strengths corresponds to the methanol molecule in the solvation shell. The composition of the solution (in moles) is: $Mg(ClO_4)_2$ 0.55; CH_3OH 6.72; $(CH_3)_2CO$ 11.65; after *N. A. Matwiyoff* and *H. Taube* [17].

relates to a ternary mixture; in this case acetone is also added to the solution. The attainability of low temperatures, the magnitude of the chemical shift, and the solubility are often appreciably influenced by mixed solvents [17, 78–81].

2.2.1. Aqueous Solutions, General

We now ask what conclusions can be drawn from the molecular motions concerning the structure of the hydration shell. Figures 1–4 all show the situation at one particular constant, and the positions of all the points shown will change with time. For reasons that will appear shortly, the time range in which we are interested lies between 10^{-14} and 10^{-10} s, *i.e.* it extends over four orders of magnitude. The fast motions are intramolecular and intermolecular periodic motions. However, the periodicity of these motions is no longer rigorous, since the potentials that determine the intramolecular and intermolecular vibrations have changed relative to a coordinate system fixed in space after about 10–1000 periods. This is a consequence of the (in contrast with the periodic motions) disordered thermal motion of the molecules and ions, *i.e.* Brownian motion. This "disordered" motion includes both the translational motion of the particles, which leads to normal diffusion, and the rotational diffusion motion, *i.e.* the reorientation of the (non spherically symmetrical) particles. These disordered thermal motions are slow in the time range chosen. Still slower motions ($t > 10^{-10}$ s for certain exchange processes) need not be considered.

2.2.2. "Fast" Motions in Aqueous Solution

Let us consider in more detail the fast periodic motions, the *intramolecular* vibrations of the water molecule with vibration periods in the range 1×10^{-14}–2×10^{-14} (wave numbers $\tilde{\nu}$ between 3500 and 1500 cm^{-1}) (Fig. 8). One might imagine that these vibrations

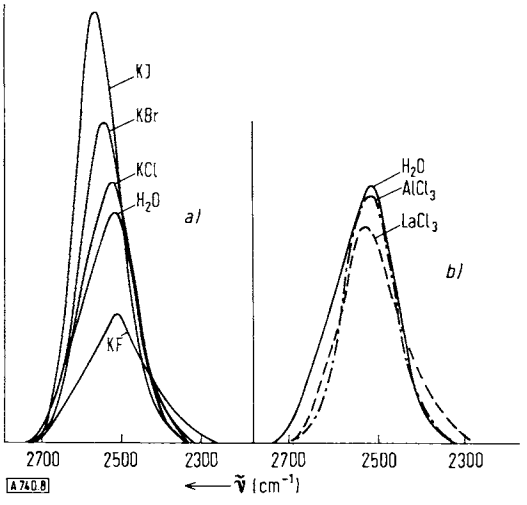

Fig. 8. The OD stretching vibration of HOD in the Raman spectra of some electrolyte solutions in water containing 5 mole-% of D at 27 °C, after *T. T. Wall* and *D. F. Hornig* [82].

would have different frequencies in the hydration shells of the ions and in the unbound water, and that separate intramolecular IR or Raman lines would

[82] *T. T. Wall* and *D. F. Hornig*, J. chem. Physics *47*, 784 (1967).

therefore be observed for the corresponding regions in electrolyte solutions. Surprisingly, however, no such line splitting has yet been observed, even with strongly hydrated ions such as Al^{3+} and La^{3+} [82] (see Fig. 8b). Other ions also generally fail to exhibit splitting; the only exception known at present is the splitting of the (symmetrical) OH stretching vibration in the IR spectrum of a solution of $NaClO_4$ in heavy water (containing HOD) [83,83a], for which no satisfactory interpretation has yet been found. In general, therefore, the difference in the frequencies of the intramolecular vibrations in the water of hydration and in the unbound water is small in relation to the bandwidth of these vibrations. Only a small frequency shift is observed for the symmetrical stretching vibration and the bending vibration of the overall solution [82–91]. With alkali metal halides, hydration has the same effect as a temperature rise (see Fig. 8a), *i.e.* the stretching vibration moves to higher frequencies and the bending vibration to lower frequencies. KF, however, exhibits the reverse behavior [82,83,88]. Anions have a stronger influence than cations, so that even the more highly charged strongly hydrated cations cause only a rather small overall displacement of the bands, corresponding in direction to a temperature decrease [82] (Fig. 8b). The effects are often on the very limit of the attainable accuracy of measurement, and the number of systems that have been studied is still relatively small. The chemical shifts of the proton resonance of the solution water show a similar behavior, though the tendency to negative shifts with strongly hydrated ions, again corresponding to a temperature decrease, is greater [14]. The frequency shift of the intramolecular vibrations is evidently connected with the breakdown of the structure of the water on the one hand and with the hydration of the ions on the other.

The Raman intensities of the stretching and bending vibrations do not exhibit the behavior expected from the parallelism with rising temperature. The halide anions exhibit a considerable increase in intensity in the order $F^- < Cl^- < Br^- < I^-$ [86–88], which is attributed to a decrease in the polarity of the O–H bond [80] and to a specific interaction with these ions as a result of their low electronic excitation states [82,92].

Intermolecular vibrations of pure water are the torsional or librational vibrations, which are due to the restricted rotation of the water molecule in relation to its neighbors. The periods of the vibrations are around 4.3×10^{-14} and 7.4×10^{-14} ($\tilde{\nu}$ = 780 and 450 cm^{-1}). Translational vibrations of the water molecule in the potential of its nearest neighbors are found at still lower frequencies ($\tilde{\nu}$ = 175 and 60 cm^{-1}; all the bands are very broad); the periods are 1.9×10^{-13} and 5.6×10^{-13} s. A rigid hydration complex as shown in Figure 2, which is a true "new molecule", should naturally exhibit new vibrations. In the limiting case of weak hydration (Fig. 3), the intermolecular vibrations of the water are also expected to change; owing to the greater disorder, these vibrations should be less well developed than in pure water, and the corresponding absorption bands should be broadened and displaced to lower frequencies. The existing experimental data are not very extensive. New absorptions corresponding to the case of Figure 2 for strongly hydrated cations have occasionally been observed in the Raman spectrum as broad, weak bands, *e.g.* for Zn^{2+} [93–95] and In^{3+} [96]. The frequencies roughly agree with those of the corresponding solid crystal hydrates [93–95].

The far IR spectra of alkali metal halides in aqueous solution [97] show, on the whole, the expected behavior with regard to the effects of structure formation or structure breaking (see Fig. 9).

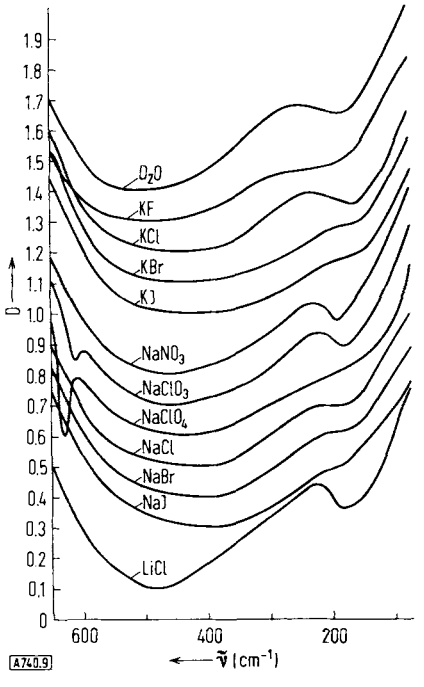

Fig. 9. Normalized IR transmittance D of D_2O solutions of some electrolytes in the low wave number range. The concentration is 4 mole/l in every case. Of the salts in Figure 9, KF and LiCl contain structure-forming ions. In the presence of these salts, the frequencies of the torsional and translational bands of the D_2O used as the solvent change only slightly; KF causes broadening of the bands, while LiCl makes them sharper. The other salts, apart from NaCl, are typical structure breakers. These always displace the torsional bands to lower frequencies, with simultaneous broadening. The translational band is displaced only slightly and in both possible directions, and is almost completely absent in the case of iodides. No further details can be given here.

A particularly strong influence of the anions, especially of the halide ions, is seen in the Raman spectra [98,99]. In the presence of Cl^- and the structure breaker Br^-, the torsional band at 780 cm^{-1} is strongly displaced, and that at 450 cm^{-1} less strongly, to lower frequencies, again in agreement with the above predictions. The change in the purely dynamic vibration picture is masked, however, by the strong increase in the Raman scattering intensity, which is again due to a decrease in the polarity of the bond or the specific interactions with Cl^- and Br^- (and also I^-). This effect, which exhibits a remarkably small temperature dependence [98,99], is not yet understood in detail. *Walrafen* believes that strong hydration of these anions can be deduced, particularly since the displaced frequencies agree with those in crystal hydrates of chlorides and bromides [98–100]. This would be contrary to our view that *e.g.* Br^- is a pronounced structure breaker.

The translational intermolecular bands disappear from the Raman spectrum in the electrolyte solutions studied so far. Finally, mention should also be made of the translational intermolecular bands in the Raman spectra of acetate and formate solutions, which must be assigned to the hydration shells of these ions [101].

More definite information about the intermolecular vibration spectrum is obtainable in principle from neutron scattering measurements which are based on the fact that inelastically scattered neutrons take up quanta of the lattice vibrations as kinetic energy. Since there are no complex effects of the electronic structure of the molecules, the contributions of the cations and of the anions are perfectly equivalent. With the strongly hydrated cations, one generally finds [102] new vibrations due to the hydration complex as well as the vibrations of pure water. Comparison with the vibration spectra of the corresponding crystal hydrates shows identity with the frequencies of the solution for certain vibrations, whereas other details may differ in the solid state and in the solution. Large, singly charged ions, on the other hand, produce only small deviations from the vibrations of pure water; their effect appears to consist essentially in broadening and weakening of the water bands [102]. To sum up, we can say that investigations on the vibration picture of electrolyte solutions have led to certain conclusions regarding the structure problem, but the information obtained is often very limited.

2.2.3. "Slow" Motions in Aqueous Solution

Having discussed the "fast" motions, we must now consider the "slow" motions. Let us start with the rotational diffusion motion of a rigid cationic hydration complex having the hydration number $n_h^+ = 6$ and with an octahedral arrangement of the six water molecules around the central ion. The reorientation time of this hydration complex in water is approximately 10^{-10} s at 25 °C. This time is known from proton relaxation measurements on aqueous solutions of doubly and triply charged paramagnetic ions (*e.g.* Mn^{2+}, Cu^{2+}, V^{2+}, Gd^{3+} [27–29, 103]).

The concept of the reorientation time can be grasped intuitively, but let us be more precise here. The reorientation time, whose order of magnitude is as given above, is the time in which the correlation of the vector R in Figure 10 relative to a given initial direction is lost. For the isotropic rotational motion of a

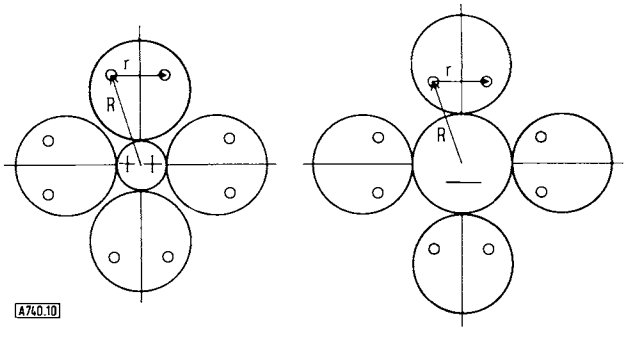

Fig. 10. Schematic section through the hydration complex of a cation and anion to illustrate the vectors R and r in the complex.

rigid hydration complex, this is also the reorientation time found for any vector in the complex, *e.g.* for the vector r joining the two protons of a water molecule (Fig. 10). Thus if measurement of the proton relaxation rate leads to the same reorientation time as above for this vector, the hydration complex is a rigid system; if on the other hand the values obtained are distinctly smaller, it must be concluded that the hydration complex is not rigid. In the latter case, *e.g.* rotation of the water molecules occurs about the axis shown, with the result that the directional correlation for the vector r decays more rapidly.

Knowledge of the orientation time of the vector r thus enables us to decide whether or not the hydration complex is rigid. It is now clear why 10^{-10} s was chosen as the upper limit of the time range to be considered. It can also be concluded qualitatively that the shorter the reorientation time of the intramolecular vector r, and hence of the water molecule in the hydration shell, the more closely will the structure of the hydration resemble that in Figure 3. It must again be said, however, that there is as yet no definite proof of this conclusion. Table 2 shows some reorientation times of water molecules (vector r) in the hydration shell, $\tau_r^{\pm}$, which were obtained from proton relaxation times

[103] *E. Wicke*, Angew. Chem. *78*, 1 (1966); Angew. Chem. internat. Edit. *5*, 106 (1966).

in diamagnetic electrolyte solutions [32]. The hydration numbers that were not known from Table 1 were estimated. The orientation time of the H_2O molecule in pure water at 25 °C is $\tau_r^0 = 0.4 \times 10^{-11}$–$0.8 \times 10^{-11}$ s [29]; this may be taken as a reference value.

Table 2. Reorientation times $\tau_r^{\pm}$ of water molecules in the hydration shells of some ions (25 °C) [a, b] [32, 34].

Ion	Hydration number n_h^+	τ_r^+ (10^{-11} s)	Ion	Hydration number n_h^-	τ_r^- (10^{-11} s)
Li^+	4	2.3	F^-	6	1.8
Na^+	4	1.4	Cl^-	8	0.7
K^+	5	0.7	Br^-	8	0.6
Rb^+	6	0.5	I^-	9	0.4
Cs^+	6	0.4	NO_4^-	10	0.6
Mg^{2+}	6	4.2	ClO_4^-	10	0.4
Ca^{2+}	6	2.8	CO_3^{2-}	10	1.9
Sr^{2+}	6	2.5	SO_4^{2-}	10	1.4
Ba^{2+}	6	2.2	HgI_4^{2-}	14	0.6

[a] These values are based on a value of $\tau_r^0 = 0.8 \times 10^{-11}$ s for pure water.

[b] As a consequence of the NMR method used to obtain these data, all the times may be smaller by a factor of up to 3. If the hydration numbers implied in the reorientational motion are greater than those given here, the values of $\tau_r^{\pm}$ tend toward the reorientation time of pure water.

Let us first consider the ions for which $\tau_r^{\pm} > \tau_r^0$, *i.e.* the structure forming ions. The values given here are maximum values (they may be smaller by a factor of 3 [32]). If the number of water molecules per ion that execute slower motions than the molecules of pure water is greater than the number $n_h^{\pm}$ given in Table 2, the times $\tau_r^{\pm}$ decrease still further and approach τ_r^0. We can now make the following important observation from Table 2: None of the reorientation times is as great as the value $\tau_r^{\pm} \approx 10^{-10}$ s proposed above for the rigid complex. Even for Mg^{2+}, τ_r^+ is smaller than this limiting value by a factor of 2. It is probable, therefore, that even the hydration shell of Mg^{2+} is not rigid, and the water molecules rotate about the axes in Figure 10.

It is also very unlikely, from nuclear magnetic relaxation measurements on the F^- ion, that the fluoride ion is surrounded by a rigid, long-lived hydration shell. The term "long-lived" here means that the residence time of a water molecule in the hydration shell is longer than 10^{-10} s. Taking into account the possible configurations of the hydration shell, the nuclear magnetic relaxation time of ^{19}F in aqueous KF solution gives a value of at most about 5×10^{-11} s for the reorientation time of the vector R [33]; this is smaller than the value expected for the rigid complex. If the hydration shell were rigid and long-lived despite this deviation, the reorientation time of the complex (vector R) and its concentration dependence should also be found in the reorientation time of the molecules of the water of hydration (vector r) and its concentration dependence; however, this is not so. The reorientation time of the water molecules is always found to be shorter [33].

The self-diffusion coefficient of water in a KF solution having a concentration of about 9 mole/kg of H_2O is about 30% greater than that of the F^- ion [33]. The motion of the water molecules can thus no longer be strongly correlated with that of the F^- ions. A concerted translational diffusion of the ion and the surrounding water is however feasible at low concentrations $c_{F^-} \to 0$. It seems reasonable to conclude that the residence time of the water molecules in the hydration shell of F^-, even at low concentrations is not much greater than the mean jumping time of a water molecule in the solution ($\approx 10^{-11}$ s) [33]. Similar situations are found with the Li^+ and Ca^{2+} ions [104, 105]. It has been shown that as in the case of F^-, internal rotational motions also occur in the hydration shell of Li^+ [35, 106, 107].

Thus the study of the slow motions in electrolyte solutions with structure-forming ions appears to lead to a structural model that tends toward weak ("liquid") structuring extending over a large area rather than to rigid, compact hydration complexes.

It can also be seen from Table 2 that the reorientation times of the H_2O molecule are shorter in the hydration shells of many ions than in pure water. These are the structure-breaking ions. The description "structure-breaking" is partly based on this increase in the mobility of water, which also includes the translational diffusion motion [32, 104, 105, 108–110].

A comparatively fast isotropic reorientation of the H_2O molecule in the hydration shell should make the residence time of the molecule in the hydration shell shorter than the residence time in an "equilibrium position" of pure water [111]. It is interesting to note that the structure breakers even include a few doubly charged ions such as HgI_4^{2-}, $Hg(CN)_4^{2-}$, and CdI_4^{2-} [44]. Smaller values are also found for the activation energies for the reorientation of water in the neighborhood of structure-breaking ions than in pure water [32].

Frank and *Wen* [112] proposed the following model for the hydration of a structure-breaking ion. Each ion is always surrounded by a rigid hydration shell (zone A), and outside this is a region (B) in which the mobility is higher than in water. For structure-breaking ions, the influence of zone B on the observed mean mobility is greater than that of zone A. Against this picture is the model in which the region of increased fluidity extends right to the surface of the structure-breaking ion [43, 45]. There is no direct experimental evidence of the correctness of the multi-zone model. The orientation time of the water molecules in the environment *e.g.* of the I^- ion at $c = 6$ mole/kg of H_2O is shorter than in pure water. It has not, however, been found that this reorientation time becomes longer as $c \to 0$, as would be required for the multi-zone model; if anything it becomes shorter.

On the other hand, it is not absolutely certain that the increase in the reorientation time with decreasing concentration as required by the multi-zone model is not masked by the disappearance of phenomena due to the ion-ion interaction [113–117]. In our opinion, the probability of this is extremely small, and we therefore favor the view that the zone of increased fluidity extends all the way to the surface of the structure-breaking ion.

The hydration energy, which has appreciable values even for structure-breaking ions, is mainly based on ion-dipole interaction. How then can the mobility of the water be increased, in view of the orientation of the dipoles in the field of the ion? It was this very question that forced *Frank* and *Wen* [112] to postulate their model. The hydration energy is determined by the energy required for complete removal of the water molecule from the ion or for its complete disorientation. If, however, the hydration shell always contains a few disoriented water molecules, the reorientation of any molecule of water of hydration must require only a relatively small quantity of energy, since one of the disoriented molecules can simultaneously change into the energetically favorable orientation [44]. The presence of disoriented molecules is shown very clearly by the increase in entropy and in energy that accompanies the formation of the solvation shell of a charged particle from that of an uncharged particle (Section 2.1.1). It can be shown that the fluidity, which is lower at very weak electric field strengths than that of pure water, increases at first (with few exceptions) with increasing field strength of the ion (*i.e.* with decreasing radius for a given charge), passes through a maximum and decreases until it finally again falls below that of pure water [44]. *Samoilov* [43] has also given an explanation of negative hydration (but see [44]).

2.2.4. Non-Aqueous Solutions

No spectroscopic studies that might contribute information about the structure of the solvation shell appear to have been reported for the "fast" motions in non-aqueous electrolyte solutions. The slow motions of the solvent molecules in the solvation shell have been investigated for several electrolytes in methanol, ethanol, acetone, dimethyl sulfoxide, formamide, *N*-methylformamide, ethylene glycol, and glycerol. In the first six solvents no structural breaking effect, *i.e.* no increase in fluidity, occurs. The reorientation of the molecules thus takes longer in the solvation shell than in the pure solvent. This is in agreement with the view that the solvation in this case is structurally more strongly developed than in water. It is interesting to note that the fluidity of ethylene glycol and of glycerol is increased by large ions such as Cs^+, I^-, and Br^-, though to a smaller extent than in the case of water [44].

3. Hydration of Neutral Particles and Ions with Inert Groups

3.1. General

Let us confine our discussion initially to non-polar, inert particles such as inert gases, saturated aliphatic hydrocarbons (methane, ethane, *etc.*), and inert inorganic compounds (CF_4, NF_3, SF_6). These substances exhibit a striking anomaly in aqueous solution. The (standard) entropy difference

$$\Delta S^0 = \bar{S}_2^0 - S_{2g}^0$$

for the transfer of one mole of the inert gas from the gaseous state (S_{2g}^0) into the aqueous solution ($\bar{S}_2^0$) at room temperature is approximately 10 cal deg^{-1} · mole^{-1} more negative than that expected from experiments on non-aqueous solvents (Barclay-Butler rule) [42]. The entropy of transfer $\Delta\bar{S}_t^0$ from water into an organic solvent is therefore positive, and thus has the opposite sign to that for ions. According to our definition, therefore, solvation of the entire particle does not occur in non-aqueous solvents. At sufficiently low temperatures, the dissolution process is always exothermic [42,118]. The low solubility of these substances in water, *i.e.* the marked increase in the (standard) free enthalpy for the dissolution process, ΔG^0, is therefore an entropy effect according to

$$0 < \Delta G^0 = \Delta H^0 - T\Delta S^0$$

As was indicated earlier, the anomalous negative entropy effect disappears as the temperature approaches the boiling point of water. Thus ΔS^0 increases rapidly with rising temperature at or below room temperature, *i.e.* $d\bar{S}_2^0/dT$ has large positive values. The same is therefore also true of the partial molal specific heat $C_{p2}^0 = T(d\bar{S}_2^0/dT)$ [119].

Frank and *Evans* [42] interpreted this characteristic entropy effect as resulting from an "increase in structure" in the water due to the dissolved inert particles: Owing to the bond deficit in the vicinity of the dissolved particle, the bonds between the water molecules are strengthened. This would imply a special orientation of the water molecules that is not based on a strong interaction with the dissolved particle, and which evidently results from the peculiarity of the water molecules ("iceberg-formation" [42] or "hydration of the second kind" [2]).

An increase in structure according to *Frank* and *Evans* can only mean that the number of hydrogen bonds in

[119] See *e.g. D. M. Himmelblau*, J. physic. Chem. *63*, 1803 (1962).

these solutions is greater than in pure water. In this view, this is also the cause of the negative ΔH^0 values. Since only van der Waals interaction exists between the dissolved particles and the water molecules, the structure could be pictured *e.g.* as shown in Figure 4. *Frank et al.* did not tie themselves to any special geometrical form for the hydration structure.

The hypothesis of *Frank* and *Evans* for the hydration of inert particles has now become a fixed part of present-day ideas on aqueous solution systems. Nothing is known, however, about the true mutual arrangement of the water molecules in the nearer or more distant environment of the dissolved particles. The increase in structure due to apolar dissolved particles or groups, which is often accepted as a fact, cannot yet be conclusively verified. As was mentioned earlier, the concepts of an increase and a decrease in structure are too simple. What is certain is that changes in structure occur [2].

The energy and entropy effect in the dissolution of apolar particles in water has also been interpreted (though not entirely satisfactorily) without the use of the concepts of hydration and increase in structure. Since water has a very open structure, comparatively little energy and entropy are required, according to *Eley* [120], to incorporate the dissolved particles in the only slightly enlarged cavities. According to *Powell* and *Latimer* [121], the anomalous entropies of solution can be explained by a decrease in the free volume in the solution and consequent hindrance or stiffening of the intermolecular vibrations. A similar picture follows from *Everett*'s model [122], according to which making a hole in the network of H-bonded water molecules to accommodate a solute molecule leads to contraction of the network in the vicinity of the hole owing to the resulting disequilibrium, and this leads in turn to denser packing and a decrease in entropy. No quantitative treatments of these views have yet been carried out.

3.2. Other Experimental Observations

The discussion will now be extended to the solution behavior of molecules having polar groups or an electric charge in addition to the inert alkyl groups (alcohols, ketones, tetraalkylammonium salts, *etc.*). These are the systems used in many investigations, since the solubility is greater. Many of the typical phenomena of hydration of the second kind are undoubtedly retained with these dissolved particles, but it is necessary to consider overlap of the contributions of the polar and of the apolar groups [123].

Probably the most impressive evidence in favor of the formation of definite structures is the existence of solid gas hydrates [124, 125] and clathrates [126]. It seems reasonable to regard the increase in structure in the aqueous solution as preformation of the solid hydrated structure [127–131].

It is not known, however, to what extent structures that are stable in the solid state are retained in the liquid state. Caution is necessary in view of the fact that the solution effects in question occur with very many substances, whereas only a few examples are known of hydrate formation in the solid state (see also [2]).

The disappearance of the negative entropy effect with rising temperature, as was mentioned earlier, requires a large positive value for the partial molal specific heat of the solute. Positive (partial) molal specific heats have in fact been found for several organic molecules and ions with polar groups or an electric charge in addition to alkyl groups [112, 132–138]. C_{p2}^0 usually increases with the number of CH_2 groups. The partial molal volume of the solutes with alkyl groups is smaller at low concentration in aqueous solution than the corresponding molal volume in the pure liquid or in apolar solvents [118, 138, 139–142]. It can probably be concluded that the filling of holes in the water structure by dissolved particles is not accompanied by formation of an equivalent quantity of new holes by additional iceberg structures. The water molecules may be more densely packed in the solution than in pure water. The compressibilities of solutions of alcohols, acetone, and a

few other organic liquids with high water contents are lower than that of water [143–145].

For aqueous solutions containing alcohols, lower fatty acids, salts of fatty acids, ketones, nitriles, and tetraalkylammonium salts at low concentrations, the viscosity [124, 146–148], the reciprocal self-diffusion coefficient of the water molecule [149–152], the dielectric relaxation time [153, 154], and the reorientation time of the water molecule as found from nuclear magnetic relaxation times [142, 155, 156] are greater than for pure water. It can be concluded in particular from the behavior of the last three quantities that a state with a closer resemblance to the solid occurs in the solutions than in pure water. The motion in the latter case is evidently opposed by larger forces and torques associated with definite solvation structures.

However, the postulated decrease in the rate of molecular reorientation appears to be relatively small; at best, the reorientation time in the hydration shell is 1.5 to 2 times the value in pure water [142]. It has also been shown experimentally that in the translational motion, the hydration shell *e.g.* of the tetraalkylammonium ions is not firmly linked to the ion [152]. One would also expect much lower values for the equivalent conductivities than those actually observed if these ions and their hydration shells were in fact joined to form a rigid complex [157]. From another point of view, however, *Kay* interpreted his conductivity measurements on tetraalkylammonium ions with long alkyl chains in terms of a "structure forming effect" [158, 159].

Results of X-ray diffraction experiments on aqueous alcohol solutions have occasionally been used as evidence of the true increase in structure in these systems [43, 138]. In our opinion, however, these results are not sufficient to clarify the question under discussion.

The chemical shift of the proton resonance of water in solutions of some organic substances containing non-polar (alkyl) groups at room temperature generally becomes more positive as the number of CH_2 groups in the dissolved particle increases [160–162]. Taken in conjunction with the other observations for H bonds [9, 10, 160], this means that the non-polar groups decrease the number of hydrogen bonds in the water, instead of increasing it as postulated by *Frank* and *Evans*. At least a type of H bond different from that occurring in the free water must be formed in solutions of this type (see also [103]). *Glew et al.* recently observed a negative chemical shift of the protons of the solution water relative to pure water for *tert*-butanol, tetrahydrofuran, and acetone (in decreasing order) at low concentrations [130]. These authors believe that they have found the reinforcement predicted by *Frank* and *Evans* for the H bond formation between the water molecules. No negative shift is found with propylene oxide or dioxane at the same temperature. The only possibility of explaining this apparent contradiction is by a careful check of which part of the total effect is due to the polar group and which to the inert molecular residue. This will require further measurements on homologous series at 0 °C.

The literature contains conflicting evidence on the question of the influence of alkyl groups on the intramolecular vibrations of water. The frequency of the OH stretching vibration in the IR spectrum has been found to increase with the length of the alkyl chain for tetraalkylammonium ions in D_2O [83]. The frequency of the same vibration in the Raman spectra of alkyl sulfates in H_2O is reported to decrease as the number of C atoms increases [163]. The first of these observations would indicate breakage of H bonds, while the second would indicate formation of new H bonds (cf. also [90]). The interpretation of the Raman measurements on the solutions of alkyl sulfates [163] is subject to the general uncertainty that even today hinders our understanding of Raman scattering intensities. (For further solution properties, see [2].)

Efforts have also been made to explain the increase in structure in aqueous solutions of non-polar particles on a purely theoretical basis [118, 164, 165]. One of these attempts was based on a one-dimensional model, for which rigorous calculation is possible. According to this calculation, it should in fact be possible, in agreement with the hypothesis of *Frank* and *Evans*, for

additional structure aggregates ("clusters") to be formed by the water molecules. The problem is merely to what extent the models assumed correspond to the real systems.

4. Conclusions

An understanding of the solvation structure of dissolved particles depends mainly on the interpretation of the anomalous entropy and energy effects. The difficulty of this problem is shown by the pressure dependence of the entropy of pure water in the region of 20 °C. As the pressure is increased, the entropy (and initially also the viscosity) decreases, though the general view is that H bonds are broken.

The observations associated with the motion of the water molecules and the existence of solid hydrates appear to lend partial support to the hypothesis of the increase in structure, but the properties based directly on the electronic structure of the water molecule do not readily fit this hypothesis. If an increase in the structure of the water is in fact associated with the dissolution process, it is of a different type from the increase in structure that occurs when pure water is cooled. The packing of the water molecules in the solution is evidently different from that in pure water.

Energy Production in Anaerobic Organisms[**]

By K. Decker, K. Jungermann, and R. K. Thauer[*]

Biological redox processes are required for the synthesis of "energy-rich" compounds which are in an enzyme-controlled equilibrium with the general energy carrier adenosine triphosphate (ATP). The basic mechanisms of biological energy transformation are substrate level (SLP) and electron transport phosphorylations (ETP). In anaerobic catabolism the numerous nutrients are channelled into only a few substrate level phosphorylations; the occurrence in chemotrophic anaerobes of energy conservation coupled to electron transport has not yet been demonstrated unequivocally. At present, the determination of the ATP turnover (Y_{ATP}) in growing cells appears to be a promising method of approaching this problem. The existing knowledge of oxygen dependent enzyme reactions and their molecular evolution provides the basis for a biochemical definition of aerobic and anaerobic organisms.

1. Introduction

Biological energy production was believed by *Lavoisier* to depend upon oxidations with atmospheric oxygen; this view was held for more than a century [1]. It is now known that about 3×10^9 years ago, when life first appeared on earth [2], energy could not have been produced by combustion reactions, since our planet was still surrounded by a reducing, oxygen-free atmosphere [2, 3]. It is therefore probable that the first living organisms were anaerobes.

"Life without oxygen" still occurs on earth; it is found wherever putrefactive processes or excessive oxygen consumption by aerobic cells gives rise to niches of oxygen deficiency. This anaerobic life is sustained either by the radiant energy of the sun (phototrophy) or by the chemical energy (chemotrophy) of oxygen-independent reactions. It is reasonable to assume that the photosynthetic apparatus is a relatively late acquisition of anaerobes, and that the energy was originally provided by a chemotrophic metabolism. Thus, the study of strict anaerobes has gained interest also in connection with the evolution of cellular chemistry.

In this paper the principles of biological energy transformation will be discussed first. In view of the very large number of potential nutrients, it will not be attempted to discuss all the known pathways of substrate utilization in anaerobes. Instead, some recently elucidated examples will be presented to show how the numerous substrates (carbohydrates, amino acids) are transformed and directed to a few substrate level phosphorylations. Since electron transport phosphorylations have so far been definitely detected only

in chemotrophic aerobes (respiratory chain [6]) or in phototrophic cells [9], the question whether they can also occur in chemotrophic anaerobic metabolism is of great interest at the moment, and is therefore also an important aspect of the following discussions.

The importance of growth yield measurements for the determination of the *in vivo* ATP turnover and hence for an understanding of the relations between overall metabolism and cell growth will also be discussed. Finally, the molecular evolution of biological energy transformations, and thus the position of the anaerobes in phylogeny, will be considered. An attempt will be made to provide a biochemical basis for the physiological definition of anaerobic organisms and their distinction from facultative and obligate aerobes.

2. Biological Energy Transformation

The metabolism of living cells is an open system characterized by the constant input and output of matter and energy, and whose chemical reaction chains are in a steady state. It can be subdivided into catabolism ("Energiestoffwechsel"), which provides the molecular energy carrier adenosine triphosphate (ATP), and anabolism ("Baustoffwechsel"), which uses the energy of ATP for the synthesis of monomers, for polymerizations, and for active transport (Fig. 1).

The energy metabolism is an exergonic system of electron donating and accepting reactions or reaction

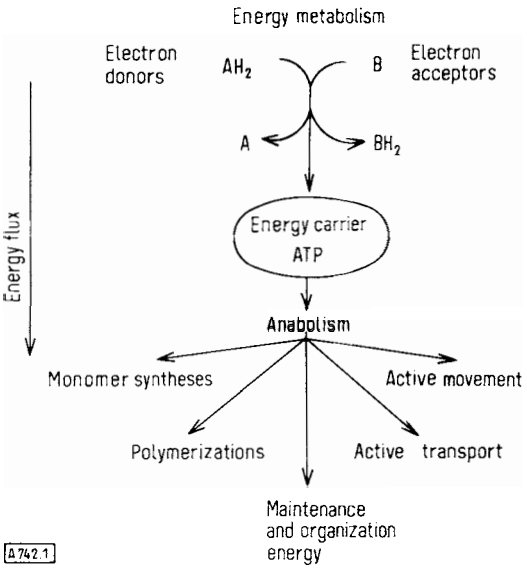

Fig. 1. The energy flux in metabolism.

conserved in the form of "energy-rich" compounds [4], which are in an enzyme-controlled equilibrium with the ATP system [eq. (a)]

$$ATP^{4\ominus} + H_2O \rightleftharpoons ADP^{3\ominus} + HPO_4^{2\ominus} + H^{\oplus}$$
$$(\Delta G_0' = -8.2 \text{ kcal/mole})[5, 5a][*] \quad \text{(a)}$$

Energy is transformed *via* the ATP* system [**] in two ways. *Substrate level phosphorylations (SLP)* convert the free energy of hydrolysis (the "group potential") [4]

		Electron donation (dehydrogenation)	Electron acceptance (hydrogenation)	$\Delta G_0'$ (kcal/reaction) [b] overall process
Chemotrophy [c]	Fermentation	glucose $\rightarrow$ (ATP) 2 pyruvate$^{\ominus}$ + 2 $H^{\oplus}$ + 4 [H]	4 [H] + 2 pyruvate$^{\ominus}$ $\rightarrow$ 2 lactate$^{\ominus}$	− 47.5
	Respiration	glucose + 12 H_2O $\rightarrow$ (ATP *(SLP)*) 6 $HCO_3^{\ominus}$ + 6 $H^{\oplus}$ + 24 [H]	24 [H] + 6 O_2 $\rightarrow$ (ATP *(ETP)*) 12 H_2O	−680.2
Photosynthesis [c]	Photosynthesis	H_2O $\xrightarrow{h\nu}$ 1/2 O_2 + 2 $H^{\oplus}$ + 2 $e^{\ominus}$	2 $e^{\ominus}$ + 2 $H^{\oplus}$ $\rightarrow$ (ATP *(ETP)*) 2 [H] *(NCPP)*	+ 56.7
		Chl $\xrightarrow{h\nu}$ Chl$^{\oplus}$ + $e^{\ominus}$	$e^{\ominus}$ + Chl$^{\oplus}$ $\rightarrow$ (ATP *(ETP)*) Chl *(CPP)*	0

[a] *SLP* = substrate level phosphorylation. *ETP* = electron transport phosphorylation. *NCPP*, *CPP* = noncyclic and cyclic photophosphorylation.
[b] Without ATP* formation and without radiant energy, see Tables 2 and 3.
[c] Chemosynthesis and chemotrophy are frequently used as synonyms in the English literature [8] and denote the biological production of energy from chemical reactions alone. The term chemosynthesis is therefore a more comprehensive term than fermentation and respiration. In the German literature, on the other hand, chemosynthesis refers only to the production of energy from redox processes between inorganic electron donors and electron acceptors, particularly oxygen. Chl = chlorophyll.

chains which are coupled by electron carriers. The donating part of the process comprises the flow of **electrons** from the donor substrate to the first **electron** carrier (usually NAD); the accepting part is the flow from the first electron carrier to the final acceptor.

The fraction of the total energy released by the redox processes that can be utilized by the cell is initially

[f] ΔG_0(f) of acrylate = −68.4 kcal/mole, calculated from eq. (92) and ΔG_0(f) of propionate [10]. [g] Calculated by analogy with glyceraldehyde-3-P/3-P-glycerate [12]. [h] Calculated from the ΔG_0(f) values (kcal/mole) of the following groups: $-COO^{\ominus}$, −86.5; −CHO, −31.0; >CHOH, −37.0; $-CH_2OH$, −40.5; $>CH_2$, +1.2; $-CH_3$, −2.9. [i] Analogous to eq. (51).

of an "energy-rich" bond into a pyrophosphate bond of ATP; they occur in the electron-donating part of the overall redox process. *Electron transport phosphorylations (ETP)* [6, 7, 7a] convert the electrochemical potential between two redox partners in the electron-accepting part of the energy metabolism into an "energy-rich" (pyrophosphate) bond (see Table 1).

Only the complete elucidation of electron transport phosphorylation will show whether it is justified mechanistically to distinguish it from substrate level phosphorylation. Current views [6] suggest that electron transport phosphorylation is closely linked to physical processes (ion gradients, membrane potentials) at particulate cell elements, whereas substrate level phosphorylations are chemical processes catalyzed by soluble enzymes.

2.1. Biological Redox Processes

The metabolic processes that occur in nature are characterized by the diversity of the substrates that can be used for the production of energy. This is particularly true of the electron donors, but also to a considerable degree of the acceptors; they can be either organic or inorganic. The formal division of the energy metabolism into electron donating (Table 2) and electron-accepting (Table 3) reactions allows assembly of the many types of metabolism by combination of the much smaller number of partial processes.

Donor and acceptor processes differ in the mechanism of energy conservation. Donor processes are associated only with substrate level phosphorylations (Table 1); they are essentially the same for aerobic and for anaerobic organisms. In electron acceptor processes, aerobic organisms use oxygen as the terminal oxidant, while anaerobes use both organic (*e.g.* pyruvate, crotonate, acetaldehyde) and inorganic (*e.g.* $H^{\oplus}$, $HCO_3^{\ominus}$, $SO_4^{2\ominus}$) [*] electron acceptors.

The hydrogenation of oxygen in the respiratory chain is associated with a very efficient type of ATP* synthesis (*ETP*). The reduction of the anaerobic electron acceptors, on the other hand, does not appear to allow ATP* synthesis by ETP, since only a few electron acceptors have a sufficiently positive redox potential (Table 5).

Protons can also act as electron acceptors [eq. (113), Table 3] yielding molecular hydrogen. This increases the number of anaerobically possible electron donor processes, since the electrons can be removed *via* the hydrogenase system in any dehydrogenation. However, there is a thermodynamic price to pay for this advantage. The endergonic formation of hydrogen [eq. (113)] requires 4.6 kcal/mole, and this must also be supplied by the exergonic dehydrogenation step. Hydrogen formation has never been observed as the sole electron-accepting reaction of any energy metabolism.

Anaerobiosis also imposes restrictions on the electron-donating process. Thermodynamic considerations

[a] Cf. [a], Table 2. [b] Analogous to eq. (69). [c] Cf. [h], Table 2. [d] Cf. [f], Table 2. [e] Analogous to eq. (81). [f] Analogous to eq. (93). [g] Cf. [e], Table 2. [h] 2 ATP* are required for the activation of sulfate, whereas no ATP* appears to be necessary for the reduction of sulfite [14].

practically rule out saturated carboxylic acids as donor substrates, since their dehydrogenation [Table 2, eq. (8) and (9)] is so endergonic that any coupling with anaerobic acceptor processes with simultaneous ATP* synthesis seems hardly possible (but see [16,17]). Similarly, the dehydrogenating cycles [see Table 2, eq. (1), (2), and (13)] cannot serve as sources of energy under anaerobic conditions. Furthermore, the endergonic tricarboxylic acid cycle does not allow a net ATP* synthesis from C_2 units (acetate) by substrate level phosphorylation. Degradation of a substrate beyond acetate is therefore feasible for energy production only if the oxidation of the reduced coenzymes formed in the cycle can be linked to electron transport phosphorylation. This is not possible with the known anaerobic acceptor systems.

If no hydrogen is liberated in the energy metabolism of an anaerobic organism, the hydrogen balance must be compensated internally resulting in further restrictions on the possible metabolic pathways. Whereas aerobic metabolic processes are always intermolecular, the anaerobic energy metabolism must often also be intramolecular. In intermolecular redox processes the electron-donating and the electron-accepting steps (Table 1) are coupled only *via* the electron carrier, whereas in the intramolecular redox processes both the electron carrier and the electron acceptor act as coupling links (Fig. 2). Intramolecular redox processes consequently lose one "degree of freedom": the extent of possible dehydrogenations of the donor substrate and hence also the economic efficiency (Section 2.3) are limited by the need for compensation of the hydrogen balance *via* an intermediate formed from the donor (product coupling).

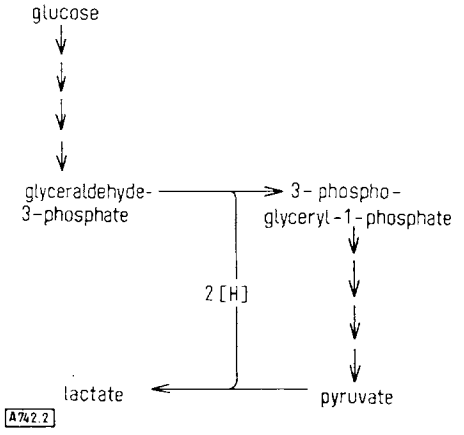

Fig. 2. Product coupling in glycolysis; pyruvate as product.

2.2. Energy-Rich Compounds

The "energy-rich" compounds formed in the redox processes of the cellular metabolism are characterized by their free energies of hydrolysis ("group potentials"), which lie in the range 6–15 kcal/mole. However, compounds leading to the formation of an "energy-rich" pyrophosphate bond but utilizing an electrochemical (with respect to a suitable electron acceptor) rather than a hydrolysis potential must also be regarded as "energy-rich" in the biochemical sense; these include substances such as NAD(P)H, $FADH_2$, $FMNH_2$, certain hydroquinones, and reduced cytochromes. In any case, the decisive factor is the ability of these compounds to serve for ATP* formation under the given conditions, *i.e.* that they exist in an enzymatic equilibrium with the ATP* system.

Compounds important for substrate level phosphorylations in anaerobic metabolism are listed in Table 4, while possible donors for electron transport phosphorylations are given in Table 5. It can be seen (particularly from Figure 3) that despite the large number of nutrients available to anaerobic organisms, there are only six to eight substrate level phosphorylation steps for energy conservation. Many anaerobic microorganisms must accomplish the entire ATP* formation by a single substrate level phosphorylation, whereas most aerobic cells have in addition to several substrate level phosphorylations also the very effective electron transport phosphorylation system of the respiratory chain.

2.3. Efficiencies

The production of "energy-rich" compounds, and hence the possibility of energy transfer to the master carrier ATP*, requires an overall metabolism that

Table 4. The "energy-rich" substrates of the ATP-synthesizing enzymes (substrate level phosphorylation).
ADP + substrate ~ P ⇌ ATP + substrate (137)
ADP + P_i + substrate ~ X ⇌ ATP + substrate + X (138)
P_i = inorganic phosphate.

Type of compound	Substrate ~ P or substrate ~ X in eq. (137) and (138)	$\Delta G_0'$ (kcal/mole)	Enzyme	Eq.

[b] Analogous to acetyl phosphate.

Table 5. Possible "energy-rich" compounds for electron transport phosphorylation.

The redox potential of "energy-rich" compounds must be so much more negative than that of the respective electron acceptor at pH = 7 that the synthesis of one mole of ATP* becomes energetically possible. This means that in a two-electron transport $\Delta E_0'$ must be at least 200 mV ($\Delta G_0'$ = −9.2 kcal/mole) between two adjacent redox partners in an electron transport chain.

[a] $E_0' \equiv E_0$ (standard conditions) against the H electrode at pH = 7 and 25 °C. Calculated from the $\Delta G_0'$ values of Tables 2 and 3.

[b] The redox potentials of flavin enzymes may differ by as much as 200 mV from the values for the free coenzymes.

(formulated with the concentration of the exogenous substrates and of the products[*]) is sufficiently exergonic[**] [eq. (b)]:

$$\Delta G' = \Delta G_0' + 1.4 \log ([\text{products}]/[\text{exogenous substrates}]) \quad \text{(b)}$$

In order to synthesize an ATP* a free energy of −8.2 kcal/mole is needed for a reaction when carried out reversibly. The *thermodynamic efficiency* η [eq. (c)] of such an idealized *in-vitro* process is 100%.

$$\eta = \frac{n \times \Delta G_0' \text{ (ATP hydrolysis)}}{\Delta G_0' \text{ (overall process)}} \times 100\ (\%) \quad \text{(c)}$$

n = moles of ATP* formed per overall process

So high an efficiency cannot be reached in living cells, which are open systems with steady state equilibria, since not all the individual processes are reversible or even quasi-reversible. Moreover, the stoichiometric coupling of energy-supplying reactions and ATP* formation leads to a "quantization" of the energy transfer, with the result that only packets of 7–9 kcal/mole can be utilized for energy conservation. Exergonic processes yielding substantially smaller amounts of free energy in fact reduce the efficiency of the overall process; this is also true of the part of the energy of strongly exergonic reactions that exceeds 7–9 kcal/mole (Fig. 4).

A theoretical derivation of the upper efficiency limit for metabolic processes in living organisms has not yet been provided.

Experience has shown, however, that η values of more than 50% for overall processes are very unlikely. The

[*] They include the synthesized cell material which, in the case of anaerobes, can usually be disregarded as a product with little loss of accuracy (see Table 7)

[**] In microbiological cultures, the concentration ratio of products to exogenous substrates is generally $\geq 10^{-2}$ at the beginning of a growth phase and $\leq 10^2$ towards the end. The effectively utilizable energy of a metabolic process $\Delta G'$ thus deviates by at most ±2.8 kcal/mole from its standard free energy $\Delta G_0'$. It is therefore permissible to use $\Delta G_0'$ as the mean of $\Delta G'_{\text{initial}}$ and $\Delta G'_{\text{final}}$ for the assessment of the thermodynamics of an overall metabolism.

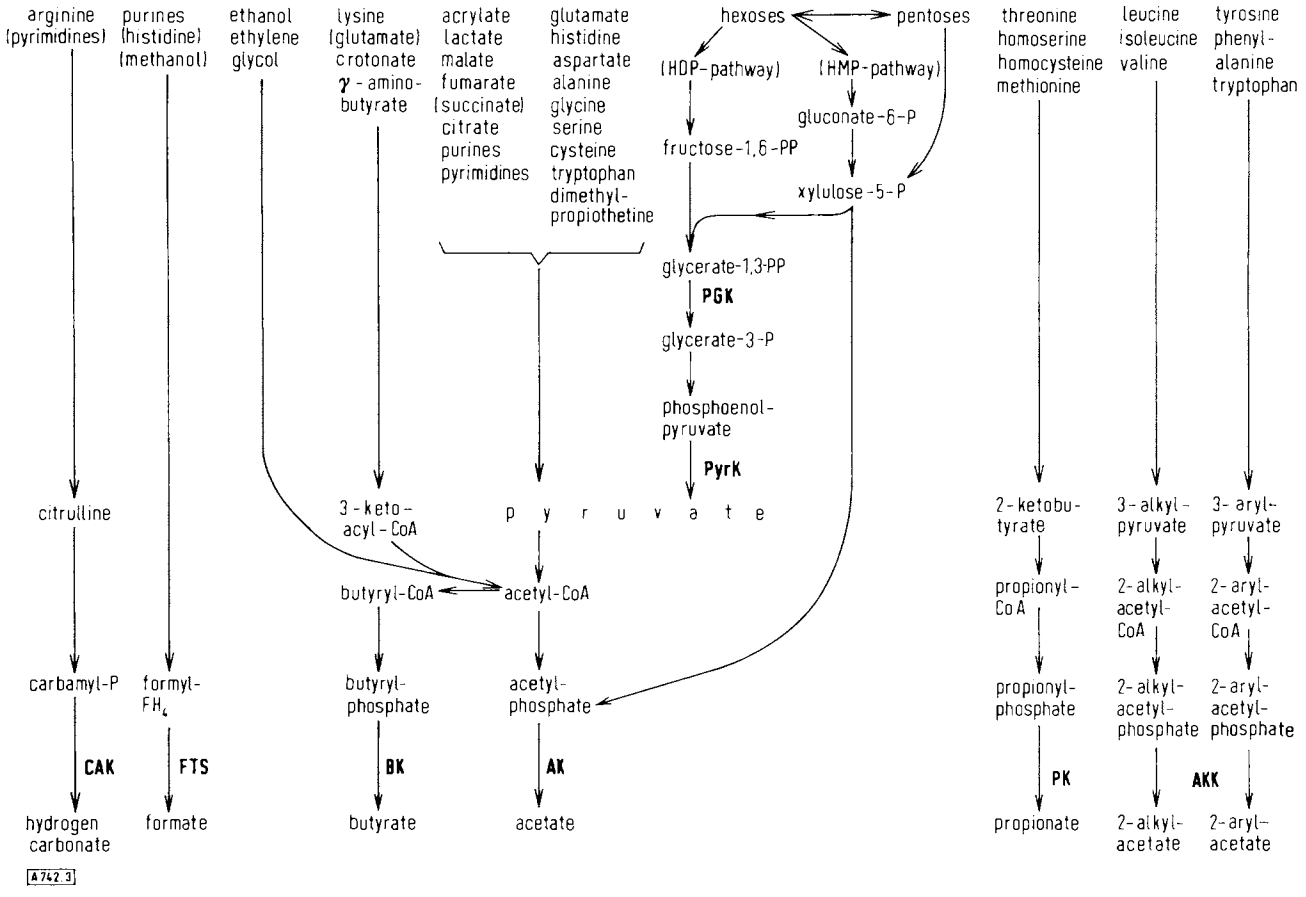

Fig. 3. Participation of the ATP*-synthesizing reactions in the catabolism (energy metabolism) of carbohydrates, amino acids, carboxylic acids, alcohols, and purine bases in anaerobes. HDP (hexose diphosphate) pathway; HMP (hexose monophosphate) pathway; CAK = carbamate kinase; FTS = formyltetrahydrofolate synthetase; AK = acetate kinase; PK = propionate kinase; BK = butyrate kinase; AAK = alkyl (aryl) acetate kinase; PGK = phosphoglycerate kinase; PyrK = pyruvate kinase.

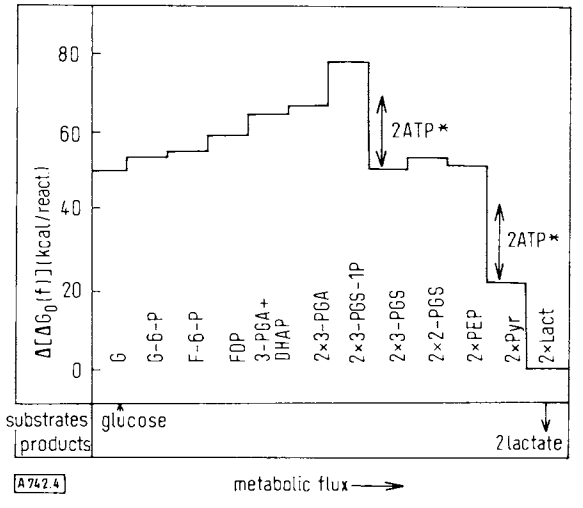

Fig. 4. Energy profiles of the metabolites of glycolysis. The free energies of formation ΔG_0 (f) of inorganic phosphate and of water are accounted for in the calculation of the differences. G = glucose; F = fructose; 3-PGA = 3-phosphoglyceraldehyde; DHAP = dihydroxyacetone phosphate; PGS = phosphoglycerate; PEP = phosphoenol pyruvate; Pyr = pyruvate; Lact = lactate.

majority of anaerobes work at efficiencies of 15 to 30%. With oxygen as an electron acceptor and a functional electron transport phosphorylation, the thermodynamic efficiency η is only slightly, the *economic efficiency* γ [eq. (d)]

$$\gamma = \frac{\text{moles of ATP* formed}}{\text{mole of substrate transformed}} \qquad \text{(d)}$$

of a cell considerably, improved (*e.g.* fermentation of glucose $\gamma = 2$, $\eta = 34\%$; respiration of glucose $\gamma \leqslant 38$, $\eta \leqslant 46\%$).

If the pathway of an energy metabolism is known, the η values can be calculated from eq. (c). For anaerobic lactic acid fermentation (Tables 2 and 3; eq. (34) + 2 × eq. (78)] they are found to be 34.5% (Embden-Meyerhof pathway, $\gamma = 2$) and 17.3% (Entner-Doudoroff pathway, $\gamma = 1$); the corresponding η values for the anaerobic alcohol fermentation [eq. (34) + 2 × eq. (79)] are 30.4% and 15.2% respectively. The relations between $\Delta G'_0$ of the catabolism, ATP* yield (γ), and cell synthesis, which are closely interrelated, will be discussed in detail in Section 2.4.

Certain predictions concerning the course of *in vivo* ATP* syntheses seem possible on the basis of thermodynamic data. The following rules are useful for the formulation and evaluation of the energy metabolism:

1. The effectiveness of the cell metabolism depends on its economic [γ in eq. (d)], rather than its thermodynamic efficiency [η in eq. (c)].

2. The thermodynamic efficiency of the metabolism of chemotrophic anaerobes does not exceed 50%, and is usually between 15 and 35%.

3. The transfer of energy by the ATP* system (substrate level and electron transport phosphorylations) is stoichiometrically related to the substrate turnover ("quantization" of energy).

4. If $\Delta G_0'$ of a catabolism allows the formation of only one "energy-rich" compound and if a substrate level phosphorylation is mechanistically feasible, it is more likely than a conceivable electron transport phosphorylation.

The application of these rules will be discussed in Section 3 in connection with some examples of anaerobic energy metabolism.

2.4. ATP* Turnover in Growing Cells

2.4.1. Limitation of Growth by Energy Metabolism

The central position of ATP* in metabolism relates the formation and consumption of this compound closely to the total free energy turnover in the cell. Since the intracellular concentration of ATP is of the order of 1–5 mmoles/l, and so represents a stationary ATP* energy of less than 0.04 kcal/g of fresh cells, the adenylic acid system obviously has a catalytic role. It can be calculated that ATP* must be consumed and resynthesized at least 4000 times[*] during the doubling of the cell mass in a growing bacterial culture. The function of ATP* as a switchboard for the energy turnover necessitates a kinetic equilibrium between ATP* producing and consuming reactions:

$$v_{\text{ATP* formation}} = v_{\text{ATP* consumption}} = v_{\text{growth}}$$

v = reaction rate

The process with the smaller capacity thus becomes the limiting factor for cell growth.

In aerobic organisms anabolism is generally rate-limiting. The energy-supplying processes can then be matched if (a) the increased ATP concentration or the decreased ADP (AMP) concentration have regulatory functions; (b) ATP* energy is diverted to the syntheses of storage material (polysaccharides, fats, poly-β-hydroxybutyric acid, *etc.*); (c) the energy-supplying processes are uncoupled or short-circuited: either less ATP* is formed or excess ATP* is split ("ATPases") with liberation of heat. In cases (b) and (c), which are found in aerobic bacteria, there is no proportionality between ATP* formation and cell synthesis.

In anaerobes the growth-limiting factor appears to be mainly the generation of ATP* in catabolism. This can be understood in view of the relation of the catabolic to the anabolic substrate supply in aerobic and anaerobic organisms.

This may be illustrated by the following example.

Consider an aerobic and an anaerobic cell that have the same enzymatic capacity and the same mechanisms (where relevant) of anabolism and of catabolism (*e.g.* formation from glucose of lactate or of CO_2); let the maximum anabolic capacity per cell be arbitrarily 30 C_3 units (*e.g.* pyruvate)/min, and the maximum catabolic capacity 100 C_6 units (*e.g.* glucose)/min.

An average of 8 ATP* are required for the conversion of one C_3 unit into cell material.

An aerobic organism can make use of its full anabolic capacity by complete degradation [eq. (37) and (136)] of $(8 \times 30)/38 = 6.3$ C_6 units for the supply of energy and $30/2 = 15$ C_6 units for the supply of anabolic precursors, *i.e.* using a total of only about 20% of its catabolic capacity.

The anaerobe on the other hand would have to use [eqs. (34) and (79)] $(8 \times 30)/2 = 120$ C_6 units for the production of energy alone, and a further 15 for the anabolic substrate, *i.e.* 135% of its actual catabolic capacity.

2.4.2. Growth yields (Y_S, Y_P, Y_{ATP})

The ATP* turnover in a living cell can be measured, if at all, only with great difficulty (*e.g.* by incorporation of ^{18}O from water into phosphate)[22a]. This important quantity must therefore be determined by measurement of the growth yields.

The growth yield Y_S or Y_P is defined as the number of grams Z of cell material (dry mass) formed on consumption of S moles of the energy substrate or with formation of P moles of product.

$$Y_S = \frac{Z\ [\text{g}]}{S\ [\text{moles}]} \qquad \text{(e)}$$

$$Y_P = \frac{Z\ [\text{g}]}{P\ [\text{moles}]} \qquad \text{(e')}$$

If the metabolism of the substrate, and particularly the phosphorylation reactions involved, is known, the net gain γ of ATP* (economic efficiency) can also be expressed in relation to the amount of substrate consumed S or product formed P.

$$\gamma_S = \frac{\text{moles of ATP* formed}}{\text{mole of substrate consumed}} \qquad \text{(d')}$$

$$\gamma_P = \frac{\text{moles of ATP* formed}}{\text{mole of product formed}} \qquad \text{(d'')}$$

The ATP growth yield (Y_{ATP}) is thus found to be

$$Y_{ATP} = \frac{Y_{S(P)}}{\gamma} \frac{[\text{g cells}]}{[\text{mole ATP}]} \qquad \text{(f)}$$

This quantity indicates how many grams of cell material are synthesized at the cost of one mole of ATP*. Y_{ATP} is thus the coupling factor between the ATP* turnover and the cell growth. If it were found to be a biological constant, conclusions about unknown metabolic pathways and in particular about the number of ATP*-forming steps (substrate level and electron transport phosphorylation) could be drawn from yield measurements.

Significant results can be obtained from yields methods only if very strictly defined experimental conditions are observed[23–26]. In particular, it is necessary to

[*] Assuming that 5 μmoles of ATP are present per g of wet cells and that the average growth yield (Y_{ATP}) is 10 g of dry cells (corresponding to 50 g of wet cells) per mole of ATP*, 20000 μmoles of ATP* are required for the synthesis of 1 g of wet cells. The ATP* pool must therefore have been turned over at least 4000 times during the doubling of the cell mass.

ensure that the growth is energy-limited (limited by the energy-substrate), that the measurements are carried out only during the active (logarithmic) growth phase, that the metabolic balance of the energy substrate is quantitatively obtained by measurement of Y_S and Y_P, and that additives to the nutrient medium, *e.g.* yeast extracts, are used for the anabolism rather than for the catabolism. The individual differences of various organisms as to nature, structure, and composition of the proteins, nucleic acids, and polysaccharides are compensated by the approximately equal ATP* requirements for their syntheses (Table 6).

Y_{ATP} values of about 10.5 are obtained when monomers (this refers mainly to the amino acids) are supplied for cellular synthesis in the form of protein hydrolyzates (complex medium). If no monomers are added (minimal medium), additional energy is required for their synthesis from the energy substrate; the Y_{ATP} values found under these conditions are consequently smaller (Table 7). The fact that the difference in the Y_{ATP} values obtained on minimal media is small as compared to complex media suggests that ATP* is necessary for the production of monomers even with supplemented media.

Whereas the ATP* requirement for monomer syntheses and polymerization can be calculated (Table 6), this is not possible at present for the other ATP*-consuming processes (Fig. 1), such as movement energy (particularly in ciliated cells), transport energy (active uptake of molecules or ions from the medium, active transport within the cell), "maintenance energy" [47–49] (resynthesis of cell components in connection with their "dynamic state") [50], and "organization energy" (negative entropy of cellular organization) [23, 26, 51].

It is assumed that the movement energy and in most cases (particularly in non-active uptake of the energy substrate) also the osmotic energy accounts for only a small part of the total energy expenditure; similarly, the turnover of the cell components in actively growing cells appears to be unimportant. The question how much energy a growing cell has to expend in the form of negative entropy of organization has been treated theoretically with varying results [23, 26]; little relevant experimental material appears to be available.

Though the above-mentioned experimental conditions were only partly observed in most cases (Table 7), the data obtained lead to the conclusion that a Y_{ATP} value of about 10.5 is generally valid for anaerobes under energy-limited conditions and for growth on

Table 6. ATP* requirement of the anabolism of *C. kluyveri* [27, 28].

complex media. A Y_{ATP} of about 15 has been calculated on the basis of a component analysis of *C. kluyveri* (Table 6) and of the known biosynthetic mechanisms [28]; this value may be taken as the upper yield limit when minimal media are used.

2.4.3. Measurement of Y_{ATP} in the Crotonate Metabolism of *Clostridium kluyveri*

The simplicity of the energy metabolism of *C. kluyveri* with crotonate and hydrogen carbonate as the sole carbon substrates [52] made this strict anaerobe [42] a good subject for the determination of Y_{ATP}. The experimental conditions mentioned in Section 2.4.2 could be maintained.

The anaerobic disproportionation of crotonate follows eq. (g) [sum of eqs. (22) and (93) in Tables 2 and 3]:

$$2\ \text{crotonate}^{\ominus} + 2\ H_2O \rightarrow \text{butyrate}^{\ominus} + 2\ \text{acetate}^{\ominus} + H^{\oplus} \quad (\Delta G_0' = -26.3\ \text{kcal/reaction}) \qquad (g)$$

It is clear from the scheme of the energy metabolism (Fig. 5) that this process is stoichiometrically coupled with a substrate level phosphorylation, and that one ATP* is formed by the acetate kinase reaction [eq. (h)] per proton produced.

$$\text{acetyl phosphate} + \text{ADP} \rightleftharpoons \text{acetate} + \text{ATP} \qquad (h)$$

[52] *R. K. Thauer, K. Jungermann, J. Wenning*, and *K. Decker*, Arch. Mikrobiol. *64*, 125 (1968).

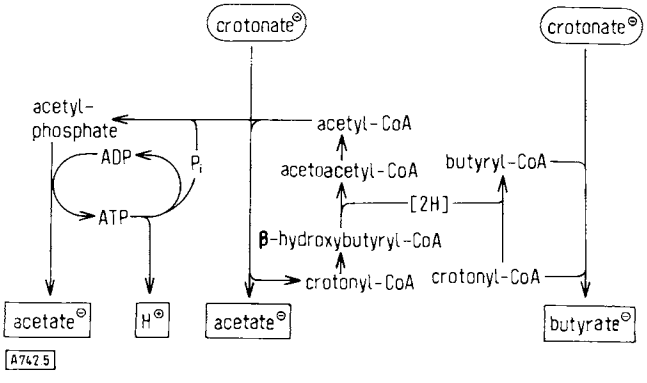

Fig. 5. Scheme of the crotonate fermentation in *Clostridium kluyveri*. P_i = inorganic phosphate.

γ is thus 0.5 with respect to crotonate and 1.0 with respect to $H^{\oplus}$. Identical Y_{ATP} values were calculated from measurements of the cell yield (Table 8) related

Table 8. Y_{ATP} values of the crotonate metabolism of *Clostridium kluyveri* [a].

Substrate or product [b]	$Y_{S(P)}$	γ	Y_{ATP}
crotonate	4.8	0.5	9.6
butyrate	9.6	1.0	9.6
acetate	4.8	0.5	9.6
$H^{\oplus}$	9.1	1.0	9.1

[a] One $H^{\oplus}$ is consumed during the reduction of acetate and CO_2 *via* pyruvate to the average oxidation state of the cell material. By measuring the growth yield per mole of $H^{\oplus}$, therefore, one obtains only the quantity of ATP* that is consumed in the synthesis of the cell material starting from pyruvate. Owing to the low incorporation (3.1%, see Table 7), the deviation lies within the limits of the experimental error. [b] See eq. (g).

to substrate consumption (Y_S) and to product formation (Y_P). The same result was obtained in corresponding experiments with ethanol + acetate + hydrogen carbonate as the growth substrates (Table 7).

3. The Energy Metabolism of Obligate Anaerobes

The most important growth substrates of anaerobic organisms are listed in Figure 3. Some classes of substances (*e.g.* saturated fatty acids, alkanes, and isocyclic aromatic compounds, see Section 2.1) cannot be utilized for the production of energy in the absence of oxygen for thermodynamic and mechanistic reasons. The nutrients of anaerobes are mainly alcohols or acids with additional functional groups which permit further dehydrogenation and hydrogenation reactions. Substrate level (and possibly electron transport) phosphorylations are inserted into the metabolism of these substrates in order to conserve their potential energy. In this section typical energy conserving processes in strict anaerobes are discussed (see Fig. 3 and Tables 2 and 3).

3.1. Substrate Level Phosphorylations

The number of enzymatic processes associated with substrate level phosphorylation has been found to be surprisingly small (Table 5). From the various different substrates[53,54], a few "energy-rich" intermediates (acyl-CoA, formyl-FH_4, carbamyl phosphate) are formed. In anaerobes the necessity to direct the growth substrates to one of these "energy-rich" metabolites with compensation of the H balance (product coupling) requires pathways of substrate conversion quite different from those found in aerobic organisms. Examples are the anaerobic degradation of glutamic acid[39,55,56], glycine[57–59], lysine[60–63], and the purines[64–67].

3.1.1. Acylate Kinases

The process catalyzed by the acylate kinases[39,65,68–70] [eq. (i)] is the most important reaction for the production of energy in anaerobes. It occurs in all Clostridia that utilize amino acids, purine bases, carbohydrates, and alcohols, as well as in sulfate-reducing bacteria. Its occurrence in methanobacteria has not been verified. The acylate kinases can therefore be regarded as typical enzymes of anaerobic life; their central function, as well as that of the associated α-keto acids (pyruvate), can be seen from Figure 3.

Acylate kinases are also found in facultative aerobes[71] (*e.g. E. coli*); they have never been definitely detected in strictly aerobic cells (plants, animals)[69,72].

$$\text{acyl phosphate} + \text{ADP} \rightleftharpoons \text{acylate} + \text{ATP} \qquad (\Delta G'_0 = -2.5 \text{ kcal/mole}) \qquad \text{(i)}$$

Acyl phosphates are formed mainly from acyl-CoA by phosphotransacylation [eq. (j); P_i = inorganic phosphate].

$$\text{acyl-CoA} + P_i \rightleftharpoons \text{acyl phosphate} + \text{CoASH} \qquad (\Delta G'_0 = +2.5 \text{ kcal/mole}) \qquad \text{(j)}$$

In systems whose purpose is the activation of an acid (acylate thiokinases, aminoacyl-t-RNA synthetases), the direction of the acyl~P (*e.g.* acyl adenylate) synthesis is thermodynamically favored since two pyrophosphate bonds [eq. (m)] of the ATP are involved.

$$\text{acylate} + \text{ATP} \rightleftharpoons \text{acyl adenylate} + \text{PP} \qquad \text{(k)}$$
$$\text{PP} + H_2O \rightarrow 2\,P_i \qquad \text{(l)}$$
$$\text{acylate} + \text{ATP} + H_2O \rightarrow \text{acyl adenylate} + 2\,P_i \qquad \text{(m)}$$

3.1.2. Formyltetrahydrofolate Synthetase

The formyltetrahydrofolate synthetase reaction[19,67,73–75] converts the bond energy of the N^{10}-formyl-FH_4 into a pyrophosphate bond of ATP [eq. (n)].

$$\text{formyl-}FH_4 + \text{ADP} + P_i \rightleftharpoons \text{formate} + \text{ATP} + FH_4 \qquad (\Delta G'_0 = +2.0 \text{ kcal/mole}) \qquad \text{(n)}$$

[75] *H. R. Whiteley* and *F. M. Huennekens*, J. biol. Chemistry *237*, 1290 (1962).

The ATP* formation according to eq. (n) is an extremely specialized process confined to a few anaerobes (*e.g. C. acidi urici, C. cylindrosporum*)[66,67]. The "energy-rich" formyl or formimino group is formed on degradation of purines, and possibly also from methanol (*via* methyl-FH_4) [Section 3.2.4] and from histidine[54].

Formyltetrahydrofolate synthetase activity is however found not only in anaerobes but also in aerobic cells including the liver of animals[76], where it fulfills an anabolic function.

3.1.3. Carbamate Kinase

ATP* formation from carbamyl phosphate[18,77,78] [eq. (o)] is associated with the degradation of arginine (*S. faecalis*)[24,29] and possibly of pyrimidines (*Zymobacterium oroticum*)[54]. However, this reaction has not been found to be the sole ATP* source in any organism.

carbamyl phosphate + ADP $\rightleftharpoons$ ATP + carbamate ($\Delta G'_0 = -2.0$ kcal/mole) (o)

As in the case of acylate kinases [eq. (i)] and of the acyl thiokinases, a different pathway has also been provided in nature for the anabolic formation of carbamyl phosphate [eq. (p)].

The enzyme carbamyl phosphate synthetase requires *N*-acetyl glutamate and possibly biotin[79,79a] as cofactors, uses glutamine instead of NH_3, consumes two moles of ATP*, and so leads to the practically irreversible formation of carbamyl phosphate[79].

2 ATP + CO_2 + glutamine + 2 H_2O $\rightarrow$ carbamyl phosphate + glutamate + 2 ADP + P_i (p)

3.1.4. Phosphoglycerate Kinase and Pyruvate Kinase

In carbohydrate fermentations[53] the enzymes phosphoglycerate kinase (PGK) and pyruvate kinase (PyrK) participate in ATP* synthesis by substrate level phosphorylations [eq. (q) and (r)]. Pyruvate kinase does not lead to a "*de novo*" synthesis of ATP*; rather, the phosphate needed for carbohydrate activation (*e.g.* hexokinase reaction) and derived from ATP* is transferred back to ADP.

1,3-phosphoenolpyruvate + ADP $\rightleftharpoons$ 3-phosphoglycerate + ATP ($\Delta G'_0 = -6.7$ kcal/mole) (q)

Phosphoenolpyruvate + ADP $\rightleftharpoons$ pyruvate + ATP ($\Delta G'_0 = -5.7$ kcal/mole) (r)

Only these two enzymes of anaerobic carbohydrate catabolism still have an important role in aerobic energy metabolism.

3.2. Does Electron Transport Phosphorylation Occur in Chemotrophic Anaerobes

Though electron transport phosphorylation in chemotrophic anaerobes is theoretically feasible, its existence has not yet been convincingly demonstrated. Possible candidates are 1. *C. kluyveri, C. sticklandii*; 2. *Methanobacillus omelianskii* and *Methanosarcina barkeri*; 3. *Desulfovibrio* species. An attempt will be made to answer this question on the basis of the existing experimental data.

3.2.1. The Ethanol-Acetate Metabolism of *Clostridium kluyveri*. Reduction of Crotonyl-CoA to Butyryl-CoA

C. kluyveri grows on ethanol, acetate, and CO_2 with formation of butyrate, caproate, and hydrogen[80]. The condensation of ethanol and acetic acid to form butyric acid (and caproic acid) [eq. (45) + eq. (69) = eq. (s), and 2 × eq. (45) + eq. (69) + eq. (71) = eq. (t)] was long regarded as a process that should involve electron transport phosphorylation, in view of the absence of any recognizable substrate level phosphorylation[10,81,82].

ethanol + acetate $\rightarrow$ butyrate + H_2O ($\Delta G'_0 = -8.6$ kcal/reaction) (s)

2 ethanol + acetate $\rightarrow$ caproate + 2 H_2O ($\Delta G'_0 = -17.2$ kcal/reaction) (t)

Electron transport phosphorylation was thought to be coupled to the reductive formation of butyryl-CoA [eq. (u)].

crotonyl-CoA + H_2 $\rightarrow$ butyryl-CoA ($\Delta G'_0 = -18.6$ kcal/reaction) (u)

The electrons could be transferred to a flavoprotein *via* a pyridine nucleotide. Electron transport phosphorylation is theoretically conceivable in such a sequence, since the reduction of flavoproteins by pyridine nucleotides in the respiratory chain is also associated with phosphorylation. The detection of such a process would thus be of fundamental importance, particularly since the reduction of crotonyl-CoA has been found in a *soluble* enzyme system[82].

However, the discovery that the energy metabolism is associated with the formation of $H^{\oplus}$, H_2 gas, and ATP* in stoichiometric amounts [eq. (i) and (j)] and that this ATP* synthesis is sufficient for growth (see section 2.2) ruled out *C. kluyveri* as a candidate for electron transport phosphorylation[42].

The quantitative data on the ethanol-acetate fermentation, together with the results of the dispropor-

[80] *B. T. Bornstein* and *H. A. Barker*, J. biol. Chemistry *172*, 659 (1948).

[82] *C. W. Shuster* and *I. C. Gunsalus*, Federation Proc. *17*, 310 (1958).

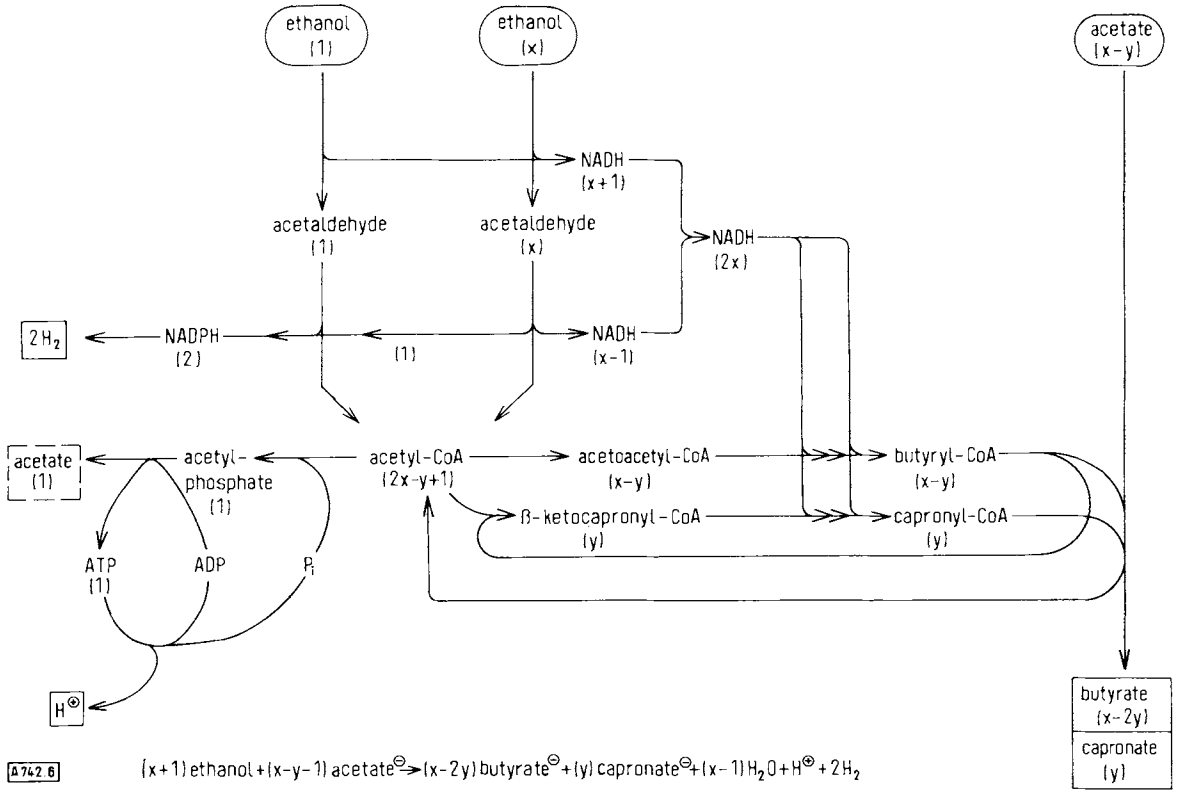

Fig. 6. Scheme of the ethanol-acetate fermentation in *Clostridium kluyveri*. The factors x and y take into account the non-stoichiometric coupling of fatty acid and ATP* synthesis and the growth phase dependent relation of butyrate and caproate formation [42]. At the beginning of the growth phase $x \approx 5$ and $y \approx 1$.

tionation of crotonate [eq. (g)], also allow an interpretation of the coupling mechanism between the energy-supplying and the ATP*-synthesizing processes, as well as an explanation of the acetate requirement of *C. kluyveri* [42,82a] (Fig. 6).

The dehydrogenation of acetaldehyde to acetyl-CoA is the only individual reaction of the catabolism that is linked to a *de novo* formation of an "energy-rich" bond. The right-hand part of Figure 6 shows, however, that the greater part of the "active acetate" is consumed in the butyrate synthesis.

The ATP* synthesis by substrate level phosphorylation can only be associated with the process shown in the left-hand part of Figure 6. However, there is no organic hydrogen acceptor available in this reaction sequence. The free energy of the dehydrogenation of acetaldehyde can therefore be converted into ATP* energy only if electrons react with protons to form hydrogen. Formation of H_2 from NADPH has been demonstrated in a soluble system of *C. kluyveri* (Fig. 8) [83,84].

It is not immediately obvious from Figure 6 why *C. kluyveri* cannot grow with the reactions in the left-hand half of the diagram alone, without the need for the extensive fatty acid formation. However, the formation of acetate and hydrogen from ethanol [eq. (45)] is endergonic, and alone cannot be associated with a net ATP* synthesis. The synthesis of butyrate (or caproate) from ethanol and acetate [eq. (s) and (t)], on the other hand, is exergonic, though not sufficiently so, when the η values are taken into account (see Section 2.3), for the stoichiometric formation of one ATP* per butyrate formed. The fatty acid synthesis must therefore be repeated several times, like a "pump mechanism", to provide sufficient free energy for an ATP* synthesis that is physiologically possible ($\eta \leqslant 35\,\%$). The CoA transferase system [eq. (v)] is responsible for this non-stoichiometric energy coupling.

$$\text{butyryl-CoA} + \text{acetate} \rightleftharpoons \text{butyrate} + \text{acetyl-CoA} \qquad (\Delta G_0' \approx 0) \qquad \text{(v)}$$

The higher group potential of the butyryl-CoA resulting from its exergonic formation is transferred to the acetyl-CoA pool by reaction (v) and so allows a thermodynamically feasible ATP* synthesis [eq. (w); cf eqs. (i) and (j)].

$$\text{acetyl-CoA} + \text{ADP} + P_i \rightleftharpoons \text{ATP} + \text{acetate} + \text{CoA} \qquad (\Delta G_0' \approx 0) \qquad \text{(w)}$$

Since the different group potentials of the CoA-thioesters are reflected in their steady state concentrations (Fig. 7), the non-stoichiometric relation of butyrate, caproate, and ATP* syntheses can also be explained by eq. (v). Under growth conditions, the "pump mechanism" is repeated approximately five times per mole of ATP*, leading to a thermodynamic efficiency of about 20 %.

[83] *K. Jungermann, R. K. Thauer, E. Rupprecht, C. Ohrloff*, and *K. Decker*, FEBS Letters *3*, 144 (1969).

[84] *R. K. Thauer, K. Jungermann, E. Rupprecht*, and *K. Decker*, FEBS Letters *4*, 108 (1969).

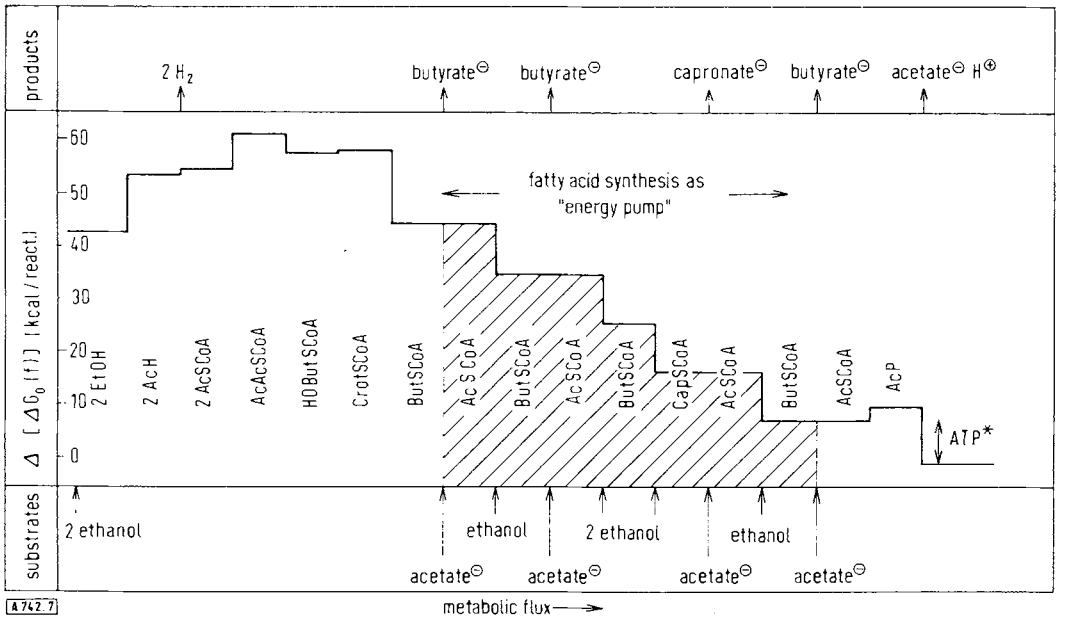

Fig. 7. Energy profile of the metabolites of the ethanol-acetate fermentation of *Clostridium kluyveri*. Note the increase in the group potential $\Delta G'_0$ of acetyl-CoA with each "cycle" of the fatty acid synthesis as result of the increase in the potential difference Δ [ΔG_0(f)] with respect to ethanol.
The free energies of formation ΔG_0(f) of coenzyme A, P_i, and H_2O are accounted for in the calculation of the differences.
EtOH = ethanol; AcH = acetaldehyde; Ac = acetyl; AcAc = acetoacetyl; HOBut = β-hydroxybutyryl; Crot = crotonyl; But = butyryl; Cap = caproyl. Overall metabolism:
6 ethanol + 3 acetate$^{\ominus}$ → 3 butyrate$^{\ominus}$ + 1 caproate$^{\ominus}$ + 4 H_2O + $H^{\oplus}$ + 2 H_2.

The necessity of synthesizing C_4 and C_6 fatty acids also explains why *C. kluyveri* requires acetate as a substrate and cannot grow on ethanol alone.

The main assimilatory reaction of *C. kluyveri* [52,85] is the ferredoxin (Fd)-dependent pyruvate synthesis [86,87] [eq. (x)] (see also Fig. 8).

$$\text{acetyl-CoA} + Fd^{2\ominus}_{red} + 2H^{\oplus} + HCO_3^{\ominus} \rightarrow \text{pyruvate}^{\ominus} + \text{CoA} + Fd_{ox} + H_2O \qquad (x)$$

This acetate and CO_2 assimilation has no effect on the total carbon balance (Table 7).

It is interesting to note that in *C. kluyveri*, the reduction of ferredoxin ($E'_0 = -420$ mV) is effected not by electron donors with a more negative redox potential but by pyridine nucleotides ($E'_0 = -320$ mV) (Fig. 8).

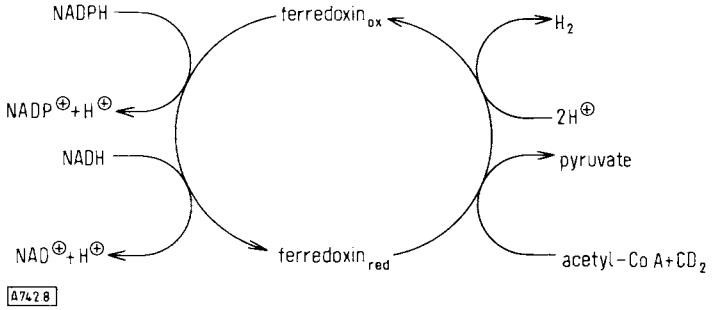

Fig. 8. Ferredoxin-dependent reactions in *C. kluyveri*. The reduction of Fd by NADPH is activated by NAD$^{\oplus}$ and inhibited by NADH, while the reduction of Fd by NADH is activated by acetyl-CoA.

3.2.2. The Alanine-Glycine Metabolism in *C. sticklandii*. Reduction of Glycine to Acetate and NH_3

Some clostridia can obtain their energy from a redox process in which one mole of an amino acid is dehydrogenated and 2 moles of another are reduced (Fig. 9) [54].

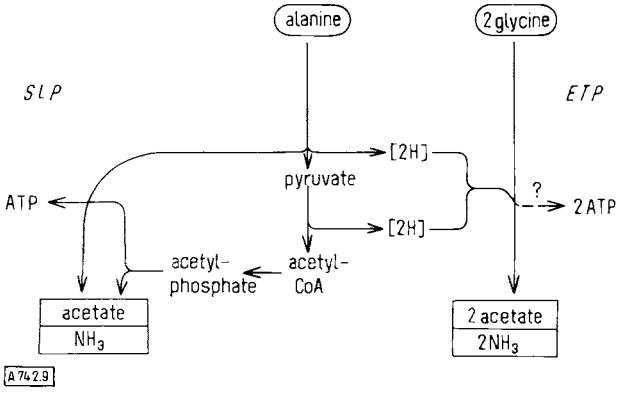

Fig. 9. Scheme of a Stickland reaction (alanine-glycine metabolism of *Clostridium sticklandii*).
SLP = substrate level phosphorylation: *ETP* = electron transport phosphorylation.

The dehydrogenation is associated with a substrate level phosphorylation. In *Clostridium sticklandii* and *Clostridium lentoputrescens*

$$\text{glycine} + \text{NADH} + H^{\oplus} \rightarrow \text{acetate}^{\ominus} + NH_4^{\oplus} + NAD^{\oplus} \quad (\Delta G'_0 = -14.4 \text{ kcal/mole}) \qquad (y)$$

the reducing system [eq. (y)] also appears to be coupled with an ATP* formation [88,89].

[88] *T. C. Stadtman*, Biochem. Z. *331*, 46 (1959).

[89] *T. C. Stadtman*, Arch. Biochem. biophysics *113*, 9 (1966).

The details of this process, which involves several protein fractions and cofactors, are not yet known. Since this phosphorylation is sensitive to uncoupling agents, the presence of electron transport phosphorylation was postulated. If the reductive process were coupled to an electron transport phosphorylation, which should proceed stoichiometrically, the thermodynamic efficiency (η) of the catabolism would be about 65%. Yields as high as this make such a reaction unlikely. Y values have not yet been determined owing to the complicated nutrient requirements of these organisms. It is not yet possible to decide whether electron transport phosphorylation is involved in the reduction of glycine.

3.2.3. The Ethanol-CO_2 Metabolism in *Methanobacillus omelianskii*. Reduction of CO_2 to CH_4

The metabolism of the methane-forming organisms presents some mechanistically and thermodynamically interesting problems. The formation of methane from CO_2 and ethanol is, as a whole, an exergonic process [2 × eq. (45) + eq. (117) = eq. (z)].

$$2\,\text{ethanol} + HCO_3^{\ominus} \rightarrow 2\,\text{acetate}^{\ominus} + H^{\oplus} + CH_4 + H_2O \quad (\Delta G'_0 = -29.3\ \text{kcal/reaction}) \qquad (z)$$

Since the available results [90] indicate that acetate in eq. (45) is not formed *via* acetyl-CoA, the course of the ATP* synthesis in this organism is unknown. Moreover, it has recently been reported that the cultures described as *M. omelianskii* are a symbiotic association of two species of bacteria, one of which has a metabolism according to eq. (45), and the other a metabolism according to eq. (117) [91]. It is thermodynamically impossible, however, for an organism to maintain its energy metabolism by means of the endergonic reaction eq. (45) alone. Certain observations indicate that the organism growing on CO_2 and H_2 also requires acetate for growth [91]. It is not possible at present to give an interpretation of the metabolism of "*M. omelianskii*", and hence of the problem of electron transport phosphorylation.

3.2.4. The Methanol Metabolism in *Methanosarcina barkeri*. Reduction of CH_3OH to CH_4

Methanosarcina barkeri forms methane and CO_2 by a disproportionation of methanol [3 × eq. (104) + eq. (44) = eq. (aa)] [43].

$$4\,CH_3OH \rightarrow 3\,CH_4 + HCO_3^{\ominus} + H^{\oplus} + H_2O \quad (\Delta G'_0 = -75.5\ \text{kcal/reaction}) \qquad (aa)$$

On the basis of an experimental Y_S value of about 3.3, corresponding to $\gamma = 0.3$, one mole of ATP* would be formed per 3–4 moles of methanol consumed; ATP* synthesis could most likely occur in the dehydrogenation of methanol *via* the formyltetrahydrofolate synthetase reaction [eq. (n)]. Since an additional electron transport phosphorylation in the reduction of CH_3OH to CH_4 should give a γ value of 1.0, there is no reason to postulate an electron transport phosphorylation in this fermentation.

[91] *M. P. Bryant, E. A. Wolin, M. J. Wolin*, and *R. S. Wolfe*, Arch. Mikrobiol. *59*, 20 (1967).

3.2.5. The Lactate-Sulfate Metabolism in Desulfovibrio Organisms. Reductions of Sulfate to Sulfide

In these organisms [26,92], the dehydrogenation of lactate (or pyruvate) to acetate is coupled with the reduction of inorganic sulfate [2 × eq. (17) + eq. (125) = eq. (bb) or 4 × eq. (10) + eq. (125) = eq. (cc)].

$$2\,\text{lactate}^{\ominus} + SO_4^{2\ominus} \rightarrow 2\,\text{acetate}^{\ominus} + 2\,HCO_3^{\ominus} + H_2S \quad (\Delta G'_0 = -40.6\ \text{kcal/reaction}) \qquad (bb)$$

or

$$4\,\text{pyruvate}^{\ominus} + SO_4^{2\ominus}\ 4\,H_2O \rightarrow 4\,\text{acetate}^{\ominus} + 4\,HCO_3^{\ominus} + H_2S + 2\,H^{\oplus} \quad (\Delta G'_0 = -85.2\ \text{kcal/reaction}) \qquad (cc)$$

The eight electrons for the reduction of $SO_4^{2\ominus}$ to $S^{2\ominus}$ are provided by the dehydrogenation of lactate (2 moles) or pyruvate (4 moles). The formation of acetate is accompanied by a substrate level phosphorylation, so that 2 ATP*/mole of reduced $SO_4^{2\ominus}$ are formed with lactate as the electron donor, and 4 ATP*/mole of reduced $SO_4^{2\ominus}$ with pyruvate. The reduction of the sulfate is preceded by its activation [eq. (dd)] [14].

$$\text{ATP} + \text{sulfate} \rightarrow \text{adenosine 5'-phosphosulfate} + \text{pyrophosphate} \qquad (dd)$$

Pyrophosphate is presumably hydrolyzed [eq. (l)] also in these bacteria, so that the activation of $SO_4^{2\ominus}$ is associated with a net consumption of 2 ATP*. ATP* synthesized by substrate level phosphorylation would be available for the anabolic requirements of the organism only in the presence of pyruvate, and not of lactate. However, determination of Y_{ATP} with lactate and pyruvate as substrates gave similar values between 9 and 10 [26]. Since *Desulfovibrio* has a cytochrome c_3, which takes up the electrons from the dehydrogenation of pyruvate, and since autotrophic growth has been reported [93], electron transport phosphorylation has been postulated to occur. This hypothesis is supported by reports [94,95] of a phosphorylation coupled to the reduction of sulfate in cell-free extracts of *D. gigas* and its uncoupling by substances such as 2,4-dinitrophenol, which also inhibit oxidative phosphorylation.

Autotrophy, however, has been questioned [96–98]; moreover, all the substrates and products involved in the energy metabolism have not been determined simultaneously. The stoichiometry of eqs. (bb) and (cc)

has thus not been experimentally verified. Though the prevailing evidence points to electron transport phosphorylation in *Desulfovibrio*, conclusive proof has not yet been presented.

4. Position of Anaerobes in Phylogeny

Considering important catabolic and anabolic mechanisms an attempt will be made to provide a biochemical basis for the classification of anaerobes and aerobes and for the definition of the principal types of metabolism.

4.1. Molecular Evolution

The first life forms must have arisen at a time when the earth was still surrounded by a reducing atmosphere[2,3]. The nutrients available to these primordial anaerobes were simple abiogenic organic compounds such as amino acids, alcohols, short-chain substituted fatty acids, purine bases, and carbohydrates[99]. These chemoheterotrophic organisms probably obtained their energy by substrate level phosphorylations (fermentations, see below). The ability to utilize the light energy of the sun (photosynthesis, see below) *via* electron transport phosphorylation is believed to have developed later, though still in the anaerobic phase. The first photoautotrophic (still anaerobic) organisms then evolved from these photoheterotrophic organisms.

The change to the oxygen atmosphere of today is generally explained by the biological photolysis of water (of the plant photosynthesis type[*]). The most recent mechanisms of biological energy transformation may therefore be considered to be the chemoheterotrophic and chemoautotrophic redox processes with oxygen as the terminal electron acceptor (respiration, see below), and the aerobic organisms are therefore the most recent organisms.

Remarkable similarity exists between the energy-converting systems in respiration and in photosynthesis; both have particulate electron transporting cytochrome systems, which are coupled to ATP* synthesis. It may therefore be assumed that they did not develop independently, but that one arose from the other. The evolution of the respiratory from the photosynthetic apparatus can easily be pictured since the photosynthetic electron transport effected by cytochrome could in principle have been diverted to oxygen by acquisition of a single autoxidizable enzyme, *i.e.* cytochrome oxidase (Fig. 10). Cytochrome oxidase, *Warburg*'s "Atmungsferment", must therefore be regarded as the specific enzyme of the aerobic energy metabolism.

The enzyme class of oxygenases may be regarded as an even more recent acquisition in the phylogenetic scheme (Fig. 10). They are typical enzymes of aerobic anabolism, but are also involved in catabolism (*e.g.* aromatic compounds) in a few cases[99a].

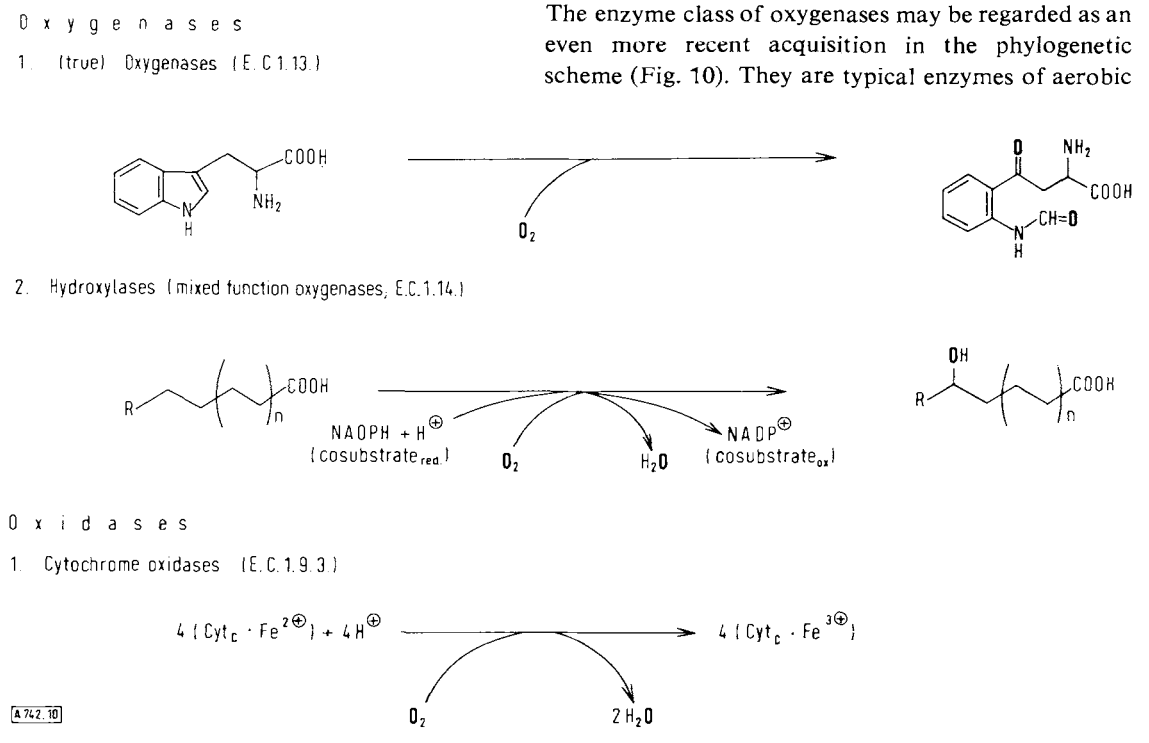

Fig. 10. Reactions of oxygenases, hydroxylases, and oxidases. Oxygenases introduce *both* atoms, and hydroxylases only *one* atom of molecular oxygen into a substrate. Oxidases require molecular oxygen as an electron acceptor; oxygen is *not* introduced into the substrate.

4.2. Anaerobes-Aerobes

The usual physiological classification of organisms into anaerobes and facultative and obligate aerobes was based on the ability to grow in the absence and/or in the presence of oxygen [100]. Current knowledge of oxygen-dependent enzyme processes and their molecular evolution now provides a means of substantiating these definitions on the basis of the metabolic chemistry.

Anaerobes are defined as organisms that do not possess cytochrome oxidase and oxygenases. *Facultative aerobes* have an oxygenase-independent metabolism, and obtain their energy both by oxygen-dependent (cytochrome oxidase) and by oxygen-independent (pyridine nucleotide regenerating dehydrogenases or reductases) redox processes. *Obligate aerobes* are organisms that depend in their energy metabolism always upon cytochrome oxidase, and usually in their anabolism also upon oxygenases. This group includes organisms whose anabolism is only indirectly oxygen dependent. These organisms grow only when supplied with substances that are biosynthesized in oxygenase-catalyzed reactions [100a]. Examples of such compounds are polyenoic acids [101], steroids [102, 103], and phycobilins [*] [104], and for most organisms also monoenoic acids and pyridine nucleotides.

According to this definition, brewers yeasts (*e.g. Saccharomyces cerevisiae*) are obligate aerobes, enterobacteria (*e.g. Escherichia coli*) are facultative aerobes, and the lactobacilli (*e.g. Lactobacillus plantarum*) are anaerobes. *Saccharomyces* can grow in the absence of oxygen; under anaerobic conditions, however, it requires the addition of steroids and unsaturated fatty acids [101, 105]. "No life without oxygen" is valid for these organisms, though *Pasteur*'s experiments on anaerobiosis with yeasts had helped to cast doubt on this thesis. *E. coli* has no oxygenases [101], and can be grown in the absence of oxygen. In the presence of oxygen, a cytochrome oxidase dependent metabolism is induced [106], which allows higher growth yields and a shorter generation time; *E. coli* must therefore be regarded as a facultative aerobe. Lactobacilli have neither cytochrome oxidase nor oxygenases [107], and must be regarded as anaerobes; the same is true of the few strains that are capable to some extent of a cytochrome-independent "flavoprotein respiration" catalyzed by constitutive or oxygen-inducible NADH oxidases and NADH peroxidases [108].

The anaerobic lactobacilli and propionibacteria occupy an exceptional position. Some of the lactobacilli form nonheme catalases (pseudocatalases) or, in the presence of exogenous porphyrins, heme catalases [107, 109]. In propionibacteria, in addition to cytochromes and catalases [110], one also finds all the enzymes of the tricarboxylic acid cycle [111], which is responsible for the terminal oxidation of the carbon substrate in aerobes. These properties, which are unusual for anaerobes, suggest that the lactobacilli and the propionibacteria have arisen from facultative aerobes by losses of different extent in the cytochrome system, *i.e.* by reversion to an earlier stage of development [107].

Animals, higher plants, algae, protozoa, and fungi require steroids and polyenoic acids for cell synthesis, and the blue-green algae require polyenoic acids and phycobilins. All eucaryonts and the blue-green algae of the class of procaryonts are therefore obligate aerobes.

Bacteria require neither steroids [112] (but see also [113]) nor polyenoic acids [101] or phycobilins [104], and form pyridine nucleotides and monoenoic acids in oxygenase-independent reactions. Anaerobes and facultative aerobes can therefore occur only among the bacteria. Even here, however, some obligate aerobes are found which synthesize pyridine nucleotides (*Xanthomonas pruni*) [114] and monoenoic acids (*Bacillus megaterium, Micrococcus lysodeikticus, Mycobacterium phlei*, and *Corynebacteria*) [115] only with oxygenases (Table 9).

If lactobacilli and propionibacteria are considered to be revertants, then the clostridia, the methane-forming, and sulfate-reducing bacteria, as well as the purple and green sulfur bacteria, are the true anaerobes. Since autotrophy developed from heterotrophy in evolution, the metabolism of the autotrophic sulfur bacteria is hardly akin to that of the primordial anaerobes. The sulfate-reducing bacteria represent a higher stage of development in view of their cytochrome content. There remain therefore the clostridia and the methane-forming bacteria, whose metabolism most closely resembles that of the primordial anaerobes.

Table 9. Occurrence of cytochrome oxidases and oxygenases in living organisms.

			Catabolism	Anabolism	
			cytochrome oxidases [a]	oxygenases [b]	
Procaryonts	lower protista	bacteria	−	−	anaerobes
			±	−	falcultative aerobes
			+	±	
		cyanophyta	+	+	
Eucaryonts	higher protista	algae protozoa fungi	+	±	obligate aerobes
	plants		+	+	
	animals		+	+	

[a] Cytochrome oxidases (E.C. 1.9.3.). [b] Oxygenases (E.C. 1.13. and 1.14), *e.g.* tryptophan pyrrolase for NAD(P) synthesis, fatty acid hydroxylase for the synthesis of unsaturated fatty acids, squalene epoxidase for steroid synthesis.

This view is supported by the observation that the ability to metabolize all types of nutrients has been retained only in this group of anaerobes, whereas even the facultative aerobes can utilize only carbohydrates and closely related compounds in the absence of oxygen. This may be regarded as a consequence of a change in the nutrient supply that paralleled the change from a reducing to an oxidizing environment. Whereas a large number of classes of substances were still available to the primordial anaerobes, a large stock of carbohydrates was produced together with the oxygen by photosynthesis. The aerobes that developed were therefore probably selected in the direction of carbohydrate utilization.

The corrin ring can be synthesized by all bacteria, whereas not all can synthesize the porphin ring, and even fewer the phorbin ring. Moreover, the side chains of the pyrrole rings are most completely retained in the corrin system in comparison with the other tetrapyrroles. It may therefore be deduced that the corrin ring system is phylogenetically the earliest (Fig. 11). From this point of view the methane-forming bacteria and the clostridia described in this article are closest to the primordial anaerobes.

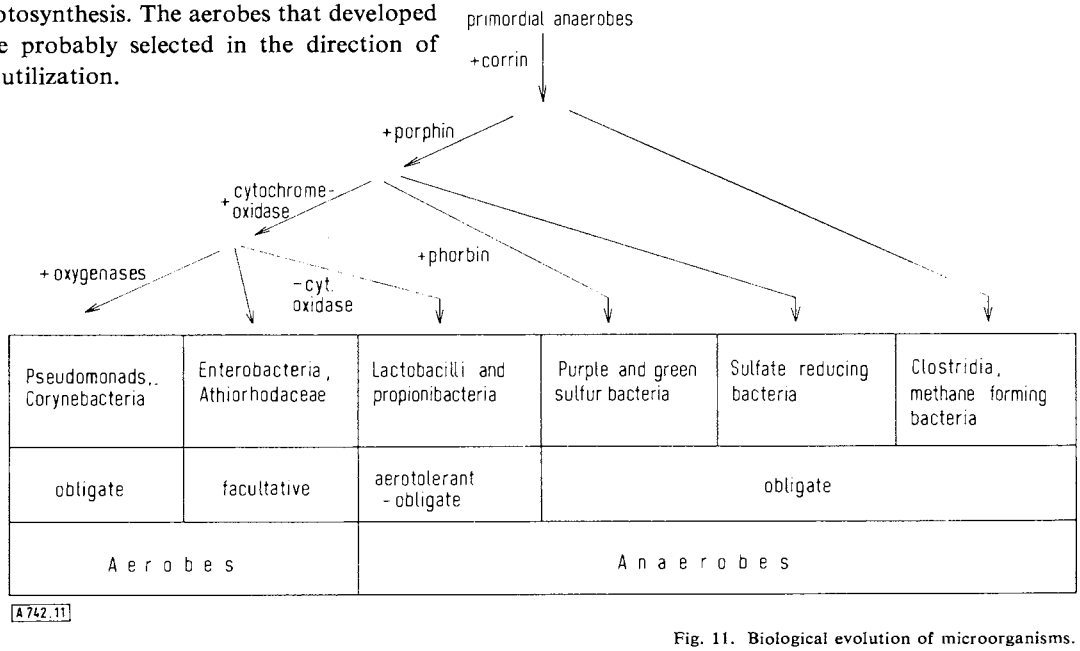

Fig. 11. Biological evolution of microorganisms.

Consideration of the molecular evolution of the tetrapyrrole compounds (Fig. 11) leads to the same result. Corrin, porphin, and phorbin rings are synthesized in the cells from porphobilinogen *via* common intermediates[116]. Since the biosynthesis of the phorbin ring proceeds *via* the porphin system, the porphin ring probably preceded the phorbin ring in the evolution.

4.3. Fermentation, Photosynthesis, and Respiration

Closely related to the concepts of aerobiosis and anaerobiosis are the terms fermentation and respiration which were mostly derived from physiological observations. These terms are frequently used inconsistently in the literature. Redox processes with organic electron acceptors are usually referred to as fermen-

tations, while those with inorganic electron acceptors (except O_2) are described as anaerobic respiration. Respiration occurs when oxygen acts as the terminal oxidant. Terms such as "fumarate respiration" and "inorganic fermentation" are incompatible with this view.

A self-consistent definition of the basic metabolic types, *i.e.* fermentation, respiration, and photosynthesis, is provided by the relation of electron donor and acceptor systems on the one hand and the ATP* synthesizing pathways on the other (Table 1). In *fermentations*, ATP* is formed by substrate level phosphorylation only, whereas *cell respiration* is a redox process in which ATP* is synthesized mainly by electron transport phosphorylation. Photosynthesis is dominated by light-driven electron transport phosphorylations. *Inorganic fermentation* would thus be a redox process with an inorganic electron acceptor, in which ATP* is formed exclusively by substrate level phosphorylation. *Anaerobic respiration* is an oxygen-free energy metabolism with an ATP* synthesis coupled to electron transport.

A consistent and functionally logical definition is obtained by assigning respiration to electron transport phosphorylation and fermentation to substrate level phosphorylation. The terms organic and inorganic fermentation and aerobic and anaerobic respiration then become unambiguous.

α-Platinum(II) Chloride and Platinum(III) Chloride

By *U. Wiese, H. Schäfer, H. G. v. Schnering, C. Brendel,* and *K. Rinke* [*]

Platinum(II) chloride is usually prepared by the route $H_2PtCl_6 \cdot 6H_2O \rightarrow PtCl_4 \rightarrow PtCl_2$ at about 500 °C in a stream of Cl_2. The resulting "β-$PtCl_2$" has a molecular lattice: Pt_6Cl_{12} molecules contain a regular Pt_6 octahedron, the Cl atoms being arranged in front of its edges [1]. This structural type is encountered, in particular, in niobium-tantalum chemistry.

We have now discovered a new modification, "α-$PtCl_2$", which is formed when Pt_6Cl_{12} is heated in a small ampoule for 1—2 days at 500 °C, or on reaction of the elements in quartz ampoules in a temperature gradient [Pt at 650 °C; α-$PtCl_2$ deposition at 550 °C; $p(Cl_2$, end) ≈ 3 atm].

Like those of the β modification, crystals of α-$PtCl_2$ are almost black and exhibit a reddish luster; when powdered both forms are yellowish brown.

α-$PtCl_2$ is characterized by the following interplanar spacings (Å), the intensities being given in parentheses; Guinier photograph:

6.48 (10); 6.31 (10); 5.43 (5); 3.322 (1); 3.255 (1); 3.242 (1); 3.156 (3); 3.104 (8); 2.885 (3); 2.713 (3); 2.581 (1); 2.544 (3); 2.236 (5); 2.224 (3); 2.106 (3); 1.909 (1); 1.845 (5); 1.781 (3); 1.700 (1); 1.674 (1); 1.656 (5); 1.622 (3); 1.601 (5).

α-$PtCl_2$ is not isotypic with the well known α-$PdCl_2$, which is built up of planar $PdCl_{4/2}$ chains.

Whereas β-$PtCl_2$ dissolves in benzene to form a definite Pt_6Cl_{12}-benzene adduct, α-$PtCl_2$ is insoluble in this solvent. The rate of conversion of β- into α-$PtCl_2$ is so slow that both modifications can be independently studied by thermal analysis (thermobalance, 4 °C/min; 1 atm of argon): quantitative decomposition of α-$PtCl_2$ to the elements is complete at 570 °C, that of β-$PtCl_2$ at 550 °C. In a vacuum (thermobalance, 4 °C/min), extensive volatilization in addition to decomposition is observed only with β-$PtCl_2$. Correspondingly, gaseous platinum chloride is recorded only in the mass spectrum of β-$PtCl_2$. Since the $Pt_6Cl_{12}^+$ ion has the lowest appearance potential, Pt_6Cl_{12} clearly vaporizes.

We have obtained crystals of the known [2] compound platinum(III) chloride (greenish black needles) on chlorination of the metal in a temperature gradient [quartz ampoule; Pt at 600 °C; other end of ampoule at 400 °C; deposition of $PtCl_3$ at intermediate temperatures; $p(Cl_2$, end) = 10 atm].

$PtCl_3$ forms trigonal rhombohedral crystals having a = 21.235 (9), c = 8.550 (10) Å; c/a = 0.403; space group $R\bar{3}$—C_{3i}^2; $d_{X\text{-ray}}$ = 5.39, d_{pyk} = 5.27 g/cm³. The compound has the same structure as the recently described $PtBr_3$ [3]; thus it contains $[Pt_6Cl_{12}]$ and $^1_\infty[PtCl_2^aCl_{4/2}^b]$ units. The average bond lengths are: Pt^{II}—Cl (4×) = 2.32; Pt^{IV}—Cl^a (2×) = 2.37; Pt^{IV}—Cl^b (4×) = 2.29 Å.

Thermal degradation of $PtCl_3$ (thermobalance, 1 atm argon) proceeds quantitatively, *via* a poorly defined β-$PtCl_2$ stage, to the elements. In a vacuum, considerable volatilization of Pt_6Cl_{12} accompanies decomposition, as is also apparent from the mass spectrum.

Oxidative Addition of the Azide Ion to Olefins. A Simple Route to Diamines [1] [**]

By *H. Schäfer* [*]

Organic anions can be oxidatively added to non-activated double bonds [2]. We have now found that this type of reaction can also be extended to inorganic anions, *e.g.* to the azide ion. In the electrolysis of a 1.2 M solution of sodium azide in glacial acetic acid vigorous evolution of gas is observed at the anode thus indicating formation of azide radicals and their decomposition to nitrogen [3,4]. On addition of olefin to the electrolyte (olefin: glacial acetic acid 1 : 3 v/v) the anodic gas evolution is suppressed and azidoalkanes can be isolated (see Table). The azidoalkanes thus formed were characterized by C, H, N analysis, IR- and NMR spectroscopy, or by reductive elimination of nitrogen with Raney-Ni/hydrogen or $LiAlH_4$ to give amines which were then compared gas chromatographically with authentic substances.

The oxidative addition of the azide ion to olefins affords a one-step synthesis of 1,2- and 1,4-diazidoalkanes, which can be converted into 1,2- and 1,4-diamines respectively by reductive elimination of nitrogen [5].

Olefin	Azidoalkane	Yield (%) [a]	[b]	[c]
Styrene	1,4-Diazido-2,3-diphenylbutane	57		55
α-Methylstyrene	1,4-Diazido-2,3-dimethyl-2,3-diphenylbutane	45		43
Cyclooctene	1,2-Diazidocyclooctane	24

[b] Yield of azide referred to starting amount of olefin.
[c] Yield of amine, referred to current consumption, after reductive elimination of nitrogen.

1,4-Diazido- and 1,4-Diamino-2,3-dimethyl-2,3-diphenylbutane

A solution of sodium azide (12 g) and α-methylstyrene (50 ml, 43 g) in glacial acetic acid is electrolyzed at 40 °C using an anode potential of +1.6 V (against Ag/AgCl) controlled by a potentiostat and a current density of 30 mA/cm^{-2} at platinum electrodes in a cell without diaphragm until consumption of 0.150 Faraday. The solution is then poured into water (200 ml), extracted with ether, and the ethereal phase is washed with dilute sodium hydroxide until neutral and then dried over sodium sulfate. After distilling off the ether and excess α-methylstyrene there remains 21.0 g of crude product. 0.41 g of the diazide can be separated from 0.8 g of the crude product by preparative thin layer chromatography using benzene/petroleum ether (40—60 °C) (1 : 1 v/v) as eluent. 5.6 g of the crude product is hydrogenated in methanol with Raney-Ni/hydrogen to give 2.3 g of the diamine (b.p. 160—165 °C/0.01 torr). The structures are confirmed by C, H, N-analysis, molecular weight, IR-, NMR-, and mass spectra.

[a] TMS as internal standard.

cinic anhydride and with tetracyanoethylene to yield 1-tricyanovinylazulene[1].

In contrast, the 5-azaazulene system[2] is able to enter into cycloadditions with alkynes, the heterocycle undergoing simple conversion into previously inaccessible derivatives of carbocyclic azulene. 6-Phenyl-5-azaazulene *(1)*[3] reacts with an excess of tolan at 350 °C to give 30% of 5,6-diphenylazulene *(3a)*[4] and benzonitrile, as well as 5% of 4,5,6-triphenylazulene *(5a)* and hydrocyanic acid. Formation of *(3a)* and *(5a)* would suggest the intermediacy of the 1,4 adducts *(2a)* and *(4a)* and their Alder-Rickert cleavage to the carbocyclic azulene. Disrotatory thermal valence isomerization of *(1)* to *(7)* and *(8)*, which is forbidden by the Woodward-Hoffmann rules[5], and subsequent elimination of benzonitrile or hydrocyanic acid to give the pentalenes *(9)* and *(10)*, respectively, which could also react with tolan to give *(3a)* and *(5a)*[6], was ruled out by experimental findings[3]:

1-Methyl-6-phenyl-5-azaazulene and 4-methyl-6-phenyl-5-azaazulene give different azulenes with tolan. If the reaction sequence *(1)*→*(7)*→*(9)* were to apply, then both azaazulenes would give 1-methylpentalene and thus either the same methyldiphenylazulene or an identical mixture of isomers.

Evidence for 1,4-adduct formation during reaction of *(1)* with acetylenes comes from the reaction of *(1)* with cyclooctyne[7] in the molar ratio 1 : 4 at 170 °C (reaction time: 15 s). From the reaction mixture a 25% yield of the 1,4 adduct *(2b)* can be isolated, whose Alder-Rickert cleavage (250 °C; 30 s) affords 5,6,7,8,9,10-hexahydrocycloocta[*f*]azulene *(3b)* (60%) and a minor amount of 3-phenyl-5,6,7,8,9,-10-hexahydrocycloocta[*c*]pyridine *(6b)*. The strained adduct *(4b)* was also expected but, unlike *(2b)*, decomposes to 6-phenyl-7,8,9,10,11,12-hexahydrocycloocta[*e*]azulene *(5b)* (30%) under the reaction conditions.

The hetero atom in the seven-membered ring of the 5-azaazulene system alters the electron distribution and reduces the π-electron delocalization compared with the azulene system[8]. This effect is probably responsible for the 1,4 addition of the α,β-unsaturated azomethine partial structure in *(1)* to the alkynes. The reaction may proceed *via* a Diels-Alder reaction "with inverse electron demands"[9] or as a two-step cycloaddition. Decomposition of the 1,4 adducts *(2)* and *(4)* to carbocyclic azulene derivatives and pyridine profits from the energy gain involved in formation of the cyclic conjugated systems.

Metal-Ligand Bonding in Sulfinato Complexes of Transition Metals

By *E. Lindner*, *G. Vitzthum*, *D. Langner*, and *I.-P. Lorenz*[*]

Bis- and tris(sulfinato) complexes are formed in the reaction of sodium sulfinates with soluble compounds of divalent and trivalent transitions metals in water or alcohol:

$$n\ RSO_2Na + MX_n \rightarrow \underset{(1)-(5)}{M(SO_2R)_n} + n\ NaX \qquad (1)$$

(X = halogen, acetate)

M \ R		p-$CH_3C_6H_4$	C_6H_5	CH_3
(n = 2)	Zn	*(1a)*	*(1b)*	*(1c)*
	Cd	*(2a)*	*(2b)*	
	Hg	*(3a)*	*(3b)*	*(3c)*
(n = 3)	Cr	*(4a)*	*(4b)*	*(4c)*
	Fe	*(5a)*	*(5b)*	*(5c)*

The toluene- and benzenesulfinato complexes of zinc, cadmium[1], and mercury[2] *(1a)*–*(3b)* have already been described. We have now succeeded in preparing bis(methanesulfinato)mercury *(3c)* and -zinc *(1c)* as the *S*-type.

Apart from the anhydrous mercury compounds *(3a)* and *(3b)*[3], little has been known about the structure of the complexes *(1a)*–*(2b)* except that the RSO_2^- ligands are linked to M^{2+} *via* oxygen.

We have now found that the type of bonding of the ligands to the metal ion in *(1a)*–*(3b)* is *particularly dependent on the water content* of the compounds.

The benzene- and methanesulfinato complexes *(1b)*, *(2b)*, *(3b)*, and *(3c)* prepared in water at room temperature are

obtained as dehydrated salts after drying over P_4O_{10} in a vacuum at 25 °C for 12 h. Under the same conditions, the *p*-toluenesulfinato complexes *(1a)*–*(3a)* crystallize as 1 : 2 adducts with water; the "crystal water" can be removed from *(1a)*–*(3a)* by drying for a period of 60 h, in the case of *(1a)* at temperatures above 120 °C and in the case of *(2a)* and *(3a)* — contrary to previous reports [1] — at a temperature as low as 25 °C.

If KBr pellets are prepared in a moist atmosphere, the IR spectra of *(1b)*–*(3b)* are surprisingly similar to those of *(1a)* to *(3a)*; all the compounds (except *(3c)*) then contain water and in accordance with the slight difference in frequency between $\nu_s(SO_2)$ and $\nu_{as}(SO_2)$ (cf. Table 1) are to be formulated as distorted octahedrally configurated bis(sulfinato-*O*,*O'*) diaqua complexes. Inter- or intramolecular arrangement of the RSO_2^- groups cannot be differentiated.

The large frequency difference and the shortwave position of $\nu_s(SO_2)$ and $\nu_{as}(SO_2)$ indicate that the anhydrous mercury complexes *(3a)*–*(3c)* are *S*-bonded.

During the conversion of hydrated into the anhydrous cadmium compounds *(2a)* and *(2b)* a reversible re-orientation of the bonding of the RSO_2^- ligands to the Cd^{2+} takes place; the IR spectra of the anhydrous complexes points to a sulfinato-*O* bonding (large frequency difference, longwave $\nu_{as}(SOM)$ bands [3]).

Three SO bands having the irreducible representation $A_2 + 2E$ are found in all cases. Accordingly we assume the complexes *(4a)*–*(5c)* to have an octahedral configuration with D_3 symmetry as is also indicated by the electronic spectrum. The RSO_2^- ligands are linked *via* both oxygen atoms to the central ions (small frequency difference: sulfinato-*O*,*O'* type). The solubilities — *(4c)* and *(5c)* are very readily soluble in ethanol — also indicate that these compounds are monomeric.

Table 1. SO_2 stretching vibrations (cm^{-1}) of sulfinato complexes of zinc, cadmium, and mercury.

		(a)	*(b)*	*(c)*	Assignment	Bond type
(1)	with H_2O	992 s; 966 sh 943 vs	989 vs; 958 sh 942 vs		$\nu_{as}(SO_2)$; $\nu_s(SO_2)$	Sulfinato-*O O'*
	without H_2O	1050 m, 1020 sh 971 vs, 963 vs	1051 m, 1024 w 1003 m, 985 vs 962 vs	1025 sh, m; 960 s 930 s [4]	$\nu(SO_2)$	Sulfinato-*O*, mainly sulfinato-*O*,*O'*
(2)	without H_2O	1031 s; 924 m 1015 s; 904 m	1030 s; 919 m 1024 s; 903 m		$\nu(SO)$; $\nu_{as}(SOM)$	Sulfinato-*O*
	with H_2O	990 vs; 965 sh 947 vs	988 vs; 965 sh 946 vs		$\nu_{as}(SO_2)$; $\nu_s(SO_2)$	Sulfinato-*O*,*O'*
(3)	with H_2O	1037 vs; 980 s	1022 vs; 980 s			
	without H_2O	1229 m; 1040 vs 1203 vs	1194 vs; 1037 vs	1177 vs, 1061 vs		Sulfinato-*S*

Interpretation of the spectra of anhydrous *(1a)* and *(1b)* is difficult since in addition to the bands of medium intensity (indicative of sulfinato-*O* complex) very intense absorptions also occur, which, on account of their position and frequency-difference, are characteristic of a sulfinato-*O*,*O'* complex: very probably the *O*,*O'* type bond preponderates in this particular case. In contrast to *Carey* and *Clark* [4] we have found that $(CH_3SO_2)_2Zn$ formed by an "SO_2 insertion" reaction, like *(1a)* and *(1b)*, is a sulfinato-*O*,*O'* complex (cf. Table 1). We were able to prepare for the first time the sulfinato-*S* isomer $[H_3C(O_2)S]_2Zn$ ($\nu_{as}(SO_2)$ = 1190 vs, $\nu_s(SO_2)$ = 1060 cm^{-1} s) according to eq. (1).

The green and the yellow tris(*p*-toluene-, benzene-, and methanesulfinato) derivatives, respectively, of chromium *(4a)*–*(4c)* and of iron *(5a)*–*(5c)* are characterized by intense SO stretching vibrations in the region 900–1000 cm^{-1} (cf. Table 2).

Unusual Cleavage of *Sn,Sn*-Disubstituted Oxastannadihydroanthracene by Electron Impact

By *I. Lengyel* and *M. J. Aaronson* [*]

The two most abundant ions in the mass spectra of 10,10-dialkyl-9-oxo-10-stanna-9,10-dihydroanthracenes *(1)* (R = nC_mH_{2m+1}, $m \geq 2$) are *(2)* and *(3)*, resulting from initial Sn—C_{alkyl} bond cleavage followed by elimination of a neutral alkene from the second 10-alkyl group with concomitant shift of a hydrogen atom to the metal in *(3)* [1] [*e.g.* in compounds *(1a)* and *(1b)*].

In this connection, it was of eminent interest to investigate related compounds constructed in such a way that no easily-transferable hydrogen is available from the substituents in position ten. Suitable models to meet this condition appeared to be the derivatives *(1c)*–*(1e)* [2]. Their mass spectra [3] still exhibit predominant peaks for the ions *(2c)*–*(2e)* but no peaks for *(3c)*–*(3e)*.

Subsequent fragmentation takes a different course, involving competitive expulsion of different neutral particles. The most favored path of further decomposition is ejection of the elements of dibenzofuran, to give ions *(4c)*–*(4e)*, confirmed by the presence of the appropriate metastable peaks for compounds *(1d)* and *(1e)*. Alternatively, elimination of particle C_6H_4O leads to ions *(5c)*–*(5d)*. Finally, for *(1d)*, there is the interesting loss of C_6H_4 (dehydrobenzene), again confirmed by a metastable peak at *m/e* 228.8 (this value applies to the ^{120}Sn isotope [4]), to give *(6)*, *m/e* 289. The elimination of C_6H_4

(a), R = n-C_4H_9; *(b)*, R = C_2H_5; *(c)*, R = CH_3; *(d)*, R = C_6H_5; *(e)*, R = Cl

rom other even-electron ions has been observed in electron-mpact experiments with dialkyl derivatives *(1)*, R = alkyl[5].

One factor that apparently renders the overall energy balance of fragmentation *(2d)* →*(6)* favorable, despite the low stability of the neutral particle expelled, is the resonance-stabilization of the ion *(6d)*.

It is important to note that the ejection of dehydrobenzene — a neutral particle — is still a process of lower energy requirement than ejection of a second phenyl radical [*(2d)* →*(7)*]. It has been pointed out[6] that even-electron to odd-electron decompositions, if not forbidden, are at least rare in organic mass spectrometry. Ion *(7)* is absent in the spectra of all compounds discussed in this paper.

It should be noted that the major decomposition path (as judged by relative peak intensities) of the molecular ion of the dichloro compound *(1e)* is expulsion of neutral $SnCl_2$ rather than $Cl^{\bullet}$, to give metal- and chlorine-free ion *(8)*, *m/e* 168 (the base peak at 12 eV). This observation is consistent with the known[7,8] bond strength differences: the Sn—R bond strength increases in the order Sn-alkyl < Sn-phenyl < Sn—Cl.

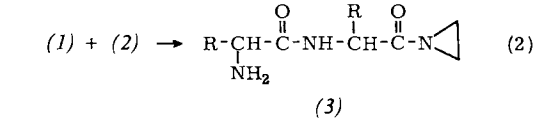
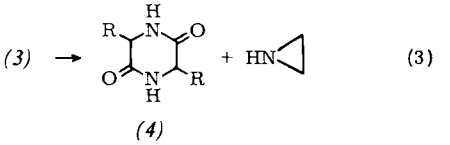
Diketopiperazines from Leuchs Anhydrides[1][**]



By *P. Rosenmund* and *K. Kaiser*[*]

Leuchs anhydrides (1,3-oxazolidine-2,5-diones) *(1)* prepared from DL-amino acids react instantaneously with aziridines with liberation of CO_2 at room temperature to give pure diketopiperazines (piperazine-2,5-diones) *(4)* in high yield. THF and anhydrous and 95% ethanol are suitable solvents. Highest yields of *(4)* are obtained when the Leuchs anhydride is added in small portions to an excess of aziridine. Diketopiperazines are not formed if amines other than aziridine, *e.g.* triethylamine or diethylamine, are used.



In view of the facts that the reaction is independent of solvent and that aziridines obviously act catalytically we consider that reaction probably proceeds as follows:

(1) *(2)* (1)

(1) + *(2)* → *(3)* (2)

(3) → *(4)* + HN (3)

	R	*(4)*, yield	*(4)*, m.p. (°C)
(a)	$C_6H_5CH_2$	80	297–300
(b)	C_6H_5	75	260
(c)	CH_3	78	270
(d)	$C_6H_5CH_2OCONH(CH_2)_4$	73	205

Because of the relatively low nucleophilicity of aziridine, reaction (1) is slow and consequently the concentration of *(2)* always remains small. Reaction of *(2)* with *(1)* yields the di-

peptide aziridide *(3)* which undergoes rapid cyclization to give *(4)* with simultaneous liberation of aziridine, which thus becomes available for further reaction. This cyclization greatly hinders polymerization which otherwise would readily occur — particularly in the presence of small amounts of base. That reaction (3) proceeds rapidly can be ascribed to the fact that compound *(3)* has the character of an activated carboxylic acid derivative.

We have been able to support this view by the following observations: If *N*-trifluoroacetylphenylalaninaziridide (prepared in 72% yield, m.p. 107—108 °C, by reaction of trifluoroacetylphenylalanine and aziridine by the anhydride method) is treated with 0.2 N NaOH at room temperature in order to remove the trifluoroacetyl residue[2], phenylalanine is formed exclusively; the aziridino residue, therefore, is just as labile as the trifluoroacetyl group. Hydrolysis with semiconcentrated aqueous ammonia affords phenylalaninamide (87%). Moreover, sodium ethoxide in ethanol liberates aziridine from N-trifluoroacetylphenylalaninaziridide.

General method of preparation:

The Leuchs anhydride *(1)* is added in small portions (10 mg) with vigorous stirring at room temperature to a solution of aziridine (0.3 ml) in ethanol (or THF) (3 ml). The mixture is allowed to stand after each addition until evolution of CO_2 is complete and all anhydride has dissolved to give a clear solution; addition of anhydride is discontinued as soon as the solution becomes turbid. After 1—5 min almost analytically pure diketopiperazine *(4)* crystallizes out in 70—80% yield. The mother liquor contains a further 10—15% of *(4)*.

Ionization and Rearrangement of Diphenylphenoxymethylmagnesium Chloride[**]

By *H. F. Ebel*, *V. Dörr*, and *B. O. Wagner*[*]

In earlier investigations[1] of metalated ethers and their rearrangement (Wittig rearrangement) the change of properties when going from the magnesium and zinc derivatives of diphenylphenoxymethane, *(1a)* and *(1b)* respectively, to the alkali metal derivatives *(1c)* was emphasized. Whereas *(1a)* and *(1b)* are colorless and do not rearrange to the triphenylmethoxides *(2a)* and *(2b)*, the alkali metal compounds *(1c)* are deep red and undergo slow conversion into *(2c)*.

(1) *(2)*

(a), R = MgHal; *(b)*, R = ZnHal;
(c), R = Alkali metal; *(d)*, R = H

Spectral properties and the tendency to rearrange depend on the nature (not specified in the formulas) of the bonds involving the metal atoms; only derivatives *(1)*, in which the C—R bond is ionic, are deeply colored and capable of rearrangement.

We have now found that hexamethylphosphoric acid triamide (HMPT), which has repeatedly been shown to have superior solvation properties for organomagnesium[2,3] and other organometallic compounds[3] and which recently has been called a "super-solvent" in carbanion chemistry[4], changes the properties of *(1a)* profoundly.

On adding a solution of isopropylmagnesium chloride [at least 2 equiv., relative to *(1d)*] in THF to diphenylphenoxymethane *(1d)* at 65 °C, a colorless solution results. If HMPT (30 equiv.) is now added, the mixture starts boiling and gradually assumes a deep red color. After 96 hours there is no *(1d)* present in the hydrolysis product (gas chromatography: 10m SE-30 column, 5% on Chromosorb W, 24 ml N_2/min, 250 °C), and after one crystallization the melting point is that of triphenylmethanol *(2d)* (m.p. 161—161.4 °C). Using only HMPT as solvent, the rearrangement is complete after 30 min at 110 °C (see *Experimental*).

A 0.13 N solution of *(1d)* in ether was refluxed with an excess of isopropylmagnesium chloride in presence of HMPT for several hours, and then diluted with THF in a closed apparatus, the ratio of dilution varying from 1 : 1000 to 1 : 125. The resulting solutions exhibited a well developed absorption band, λ_{max} = 461 nm, which obeyed the Beer-Lambert law. The band differs from the absorption measured earlier[1] for *(1c)* only in a shift to longer wavelengths by 12 nm. We suggest that *(1a)*, Hal = Cl, forms solvent-separated ion pairs in presence of HMPT. Our measurements on magnesium derivatives of diphenylmethane, triphenylmethane, and fluorene led to similar results[5].

Thus we have demonstrated by chemical and spectroscopic means, and using a simple model, that organomagnesium compounds may assume pronounced carbanionoid[6] properties.

Experimental:

HMPT (0.60 mole) is added dropwise under argon to an ethereal solution (100 ml) of isopropylmagnesium chloride (0.097 mole). The ether is then removed by distillation and *(1d)* (0.04 mole) is added at 110 °C to the pale yellow, viscous solution. A clear red solution is formed with evolution of gas (propane). After 30 min the mixture is cooled in an ice bath and treated with twice its volume of 5 N HCl. The colorless crystals of *(2d)* (yield 95% after filtration, washing with water, and drying) are recrystallized from ethanol (yield 83%; m.p. 161—161.5 °C).

Nucleophilic Imino- and Aminomethylation of Ketones[1] [**]

By *Thomas Kauffmann*, *Edgar Köppelmann*, and *Heike Berg*[*]

Electrophilic aminomethylation (Mannich reaction) is a well known important reaction step in organic synthesis. We have now found that an aminomethyl group can be introduced

into compounds *nucleophilically* by way of diphenylmethyleneaminomethyllithium *(2)*, the $=C(C_6H_5)_2$ group acting as a "synthesis mask". Here, we report on the reactions of *(2)* with ketones.

N-(Diphenylmethylene)methylamine *(1)* is metalated to *(2)* when treated with an equimolar amount of lithium diisopropylamide in THF/ether (10 : 1) at −45 °C (*ca.* 75% *N*-(diphenylmethylene)deuteriomethylamine on addition of D_2O). The solution containing *(2)* reacts with benzophenone at −45 °C to give an adduct that yields the iminomethyl compound 2-(diphenylmethyleneamino)-1,1-diphenylethanol *(3)* (see Table) on hydrolysis with water. At 65 °C the isomeric 2-(diphenylmethylamino)-1,1-diphenylethanol *(5)* is formed (yield 12%, m.p. 186 °C) and not compound *(3)*. Hydrolysis of *(3)* with 2 N HCl (90–100 °C) affords the previously described aminomethyl compound *(4)* (see Table). Analogous reactions can be carried out with all the other ketones mentioned in the Table.

$$(C_6H_5)_2C{=}N{-}CH_3 \xrightarrow{LiN(C_3H_7)_2} (C_6H_5)_2C{=}N{-}CH_2Li$$
(1) *(2)*

$$(2) \xrightarrow[2.\ H_2O]{1.\ O{=}C(C_6H_5)_2} (C_6H_5)_2C{=}N{-}CH_2{-}C(OH)(C_6H_5)_2 \xrightarrow{2N\ HCl}$$
(3)

$H_2N{-}CH_2{-}C(OH)(C_6H_5)_2$ *(4)*

$(C_6H_5)_2CH{-}N{=}CH{-}C(OH)(C_6H_5)_2$ *(5)*

Used	Obtained		Yield [3] (%)
$R{-}C(R^1){=}O$	$R{-}C(R^1)(OH){-}CH_2{-}N{=}C(C_6H_5)_2$	$R{-}C(R^1)(OH){-}CH_2{-}NH_2$	
$R = R^1 = C_6H_5$	m.p. 136–137 °C	m.p. 110 °C (110–111 °C [2])	42 and 76
$R = C_6H_5$, $R^1 = C_6H_4{-}CH_3(p)$	m.p. 105 °C	m.p. 104 °C (108–109 °C [4])	32 and 78
$R + R^1$ = 2,2'-Biphenylylene	m.p. 181 °C	m.p. 140–142 °C	52 and 80
$R = CH_3$, $R^1 = C_6H_5$	b.p. 215–225 °C 10.05 torr	b.p. 150–155 °C/16 torr (97 °C/0.45 torr [5])	32 and 48

Correspondingly, *N*-benzylideneaminobenzylsodium *(6)*, which can be prepared by reaction of *N*-benzylidenebenzylamine with $NaNH_2$ in absolute ether at −35 °C [6], is suitable for imino- and aminobenzylation. Reaction of *(6)* with benzophenone in ether at −35 °C leads to the formation of 2-benzylideneamino-1,1,2-triphenylethanol *(7)* (72% yield), which, on hydrolysis with 2 N HCl (80 °C), affords almost quantitative yields of the previously described aminobenzyl compound *(8)* [7].

$$HC(C_6H_5){=}N{-}CHNa(C_6H_5) \xrightarrow[2.\ H_2O]{1.\ O{=}C(C_6H_5)_2} HC(C_6H_5){=}N{-}CH(C_6H_5){-}C(OH)(C_6H_5)_2 \xrightarrow{2N\ HCl}$$
(6) *(7)*

$H_2N{-}CH(C_6H_5){-}C(OH)(C_6H_5)_2$ *(8)*

If reaction of *(2)* is carried out in pure diethyl ether at 0 °C [addition of benzophenone at −50 °C] instead of in THF/diethyl ether [*(1)* can also be metalated to *(2)* in diethyl ether], *N*-(diphenylmethylene)-2,2-diphenylvinylamine *(9)* is formed (yield 28%, m.p. 183 °C) instead of *(3)*. This reaction (2-azadienation of a carbonyl group) is of interest because 2-azadienes were hitherto relatively difficult to prepare.

$$(2) \xrightarrow[2.\ H_2O]{1.\ O{=}C(C_6H_5)_2/O(C_2H_5)_2} (C_6H_5)_2C{=}N{-}CH{=}C(C_6H_5)_2$$

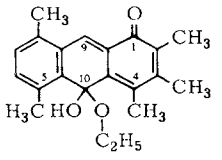
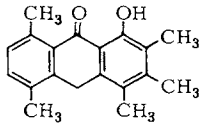
Synthesis of an *ana*-Anthraquinone[1]

By *Peter Boldt* and *Alwin Topp* [*]

We have attempted to prepare 2,3,4,5,8-pentamethyl-1,10-anthraquinone *(3)* and thus, for the first time, a compound containing the long-sought [2] *ana*-anthraquinone system [3] by oxidation of the conjugated hydroquinone *(2)* or its tautomer 4-hydroxy-1,2,3,5,8-pentamethylanthrone *(1)*.



(1) *(2)*



(3)

Compound *(3)* was found to decompose so readily that it could be obtained in pure form only in very dilute solution but not in the solid state. It is formed as a red, amorphous compound in about 50% yield, alongside decomposition products, on dehydrogenation of *(1)* with 2,3-dichloro-5,6-dicyanobenzoquinone at 0 °C[4] in solvents such as anhydrous ether, in which the resulting *(3)* is only moderately soluble. After reaction (about 5 min) the mixture must be immediately cooled to −20 °C. When chromatographed with chloroform (containing 0.3–0.5% ethanol) at −50 °C, the eluate subsequently being concentrated at temperatures below −20 °C, the crude product afforded a red crystalline compound that must be 10-ethoxy-10-hydroxy-2,3,4,5,8-pentamethyl-1(10*H*)-anthracenone *(4)*.

(4)

(5)

This assignment is indicated by the NMR spectrum[5] [2.25, 2.29, 2.49, 2.53, 2.64 (15 H (5 aromatic CH_3)/s); 6.04 (H-9/s); 7.19, 7.27 (H-7/d, H-6/d) ($J_{6,7}$ = 7.8 Hz); 1.0 (3 H (1 aliphatic CH_3/t) (J = 7.0 Hz); 3.0 (2 H (O—CH_2)/m); 7.52 (1 H (OH)/s)], the mass spectrum [essentially only peaks at *m/e* 278, 46 and 45, $M^{\oplus}$ of *(3)*, $M^{\oplus}$ and $[M-1]^{\oplus}$ of ethanol], and the UV and visual spectrum [λ_{max} = 496 nm ($CHCl_3$)]. Moreover, compound *(4)* could be reduced to *(1)*, albeit in only low yield (20%), by zinc or toluhydroquinone.

The presence of a molecular associate of *(3)* and ethanol (1 : 1), as suggested by the mass spectrum, can be ruled out: On repeated chromatography of pure *(4)* with $CHCl_3$/CH_3CD_2OH on silica gel at −50 °C no ethanol exchange was observed. — Since the longest-wave maximum of *(3)*, which was prepared in the absence of water or ethanol, lies at the same position [λ_{max} = 496 nm (ether)] as that of *(4)*, it may be assumed that hemiketal formation has taken place at C-10. Hemiketal formation at C-1 would radically change the chromophore system of *(3)*.

In the solid state and in the absence of moisture and light, compound *(4)* can be stored at 20 °C for several days; in solution, however, it decomposes very rapidly in a second order reaction with respect to *(4)*: $k_2 \approx 50$ l mole^{-1} s^{-1} at 20 °C, $CHCl_3$.

Compound *(1)* could be prepared by Friedel-Crafts reaction of 3,6-dimethylphthalic anhydride with 2,3,4-trimethylphenol, cyclization of the resulting (46% yield) benzoylbenzoic acid with sulfuric acid to 1-hydroxy-2,3,4,5,8-pentamethyl-9,10-anthraquinone (87%), reductive acetylation to 4-acetoxy-1,2,3,5,8-pentamethylanthrone (30%), and hydrolysis (93%).

The position of the carbonyl group in *(1)* was established by comparison of the IR spectrum with that of 1-hydroxy-2,3,4,5,8-pentamethylanthrone *(5)*, which can be obtained from 1-hydroxy-2,3,4,5,8-pentamethyl-9,10-anthraquinone by reduction with tin/hydrochloric acid [*(1)*, OH: sharp, strong band 3350, CO 1635 cm^{-1}; *(5)*, OH: broad, very weak band 3420, CO 1614 cm^{-1}, in KBr]. The structures of all intermediates are in accord with the results of elemental analyses and with the NMR spectra.

As shown by the firm bonding of the ethanol in the hemiketal *(4)*, the slight change in the absorption maximum on hemiketal formation [*(3)* → *(4)*], and the ease with which *(3)* and *(4)* decompose, compound *(3)* is best described as a substituted *o*-benzoquinone methide.

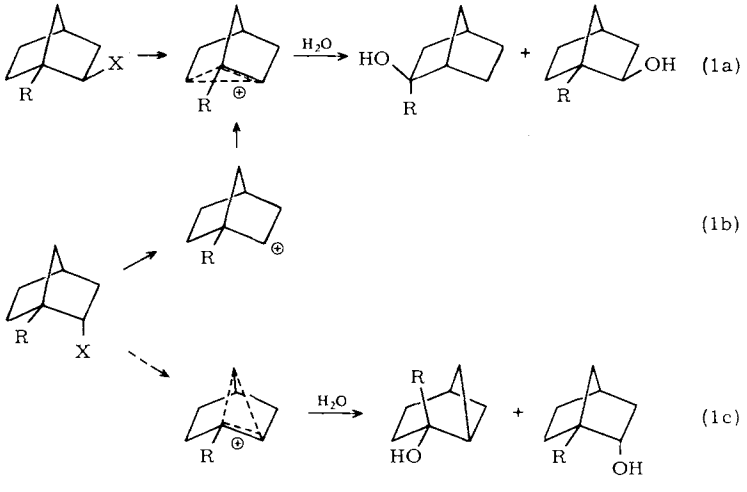
[4] Below 0 °C dehydrogenation proceeds too slowly, possibly owing to the reaction *(1)* → *(2)*.

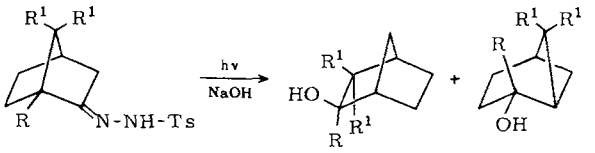


[5] δ-values, measured in deuteriochloroform at −25 °C, TMS internal standard. The fact that the aliphatic CH_3 and OCH_2 groups are adjacent was established by double resonance, the assignment of the OH band by deuteration

Rearrangement of Norbornanes to Norpinanes

By *Wolfgang Kirmse*, *Günter Arend*, and *Rainer Siegfried*[*]

Wagner-Meerwein rearrangements of *exo*-norbornyl derivatives proceed *via* routes involving the C-1—C-6 bond [eq. (1a)][1]. In contrast, reactions of *endo*-norbornyl derivatives involving the C-1—C-7 bond [eq. (1c)] are hardly known[2,3] because of the increased ring strain of the bicyclo[3.1.1]-heptane skeleton (or the bridged ions leading to this system). As a rule *endo*-norbornyl derivatives solvolyze to the same products as the *exo*-isomers, although a classical norbornyl cation must be invoked as intermediate [eq. (1b)].

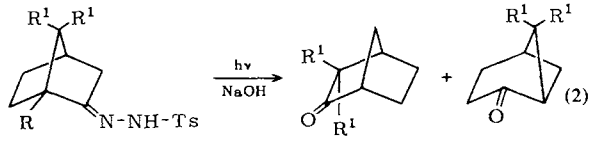


We have found that the reaction can follow the route shown in eq. (1c) when the leaving group is X is $-N_2^+$ and R is an electron-donating substituent. On irradiation of 1-substituted norcamphor- and apocamphor-tosylhydrazones *(1a)*—*(1c)*

(1a)

(1b)

(1c)

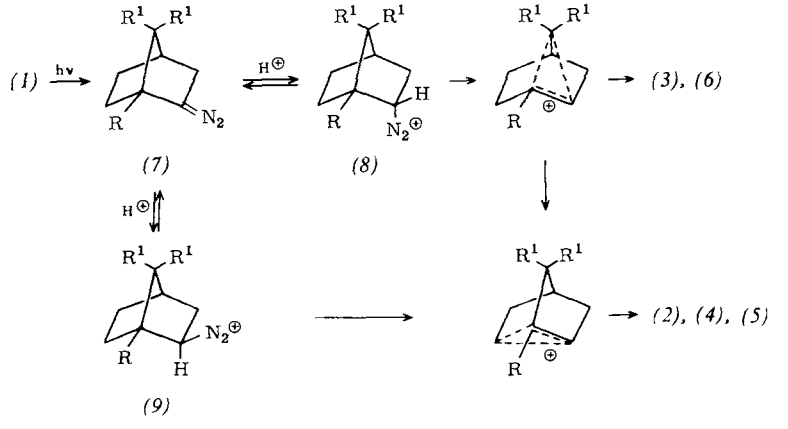


(1a)-(1c) (2) (3) (4)

(1a)–(1c)	(2)	(3)	(4)
(a), R^1 = H, R = CH_3	79.5 [4]	7.5	*exo* 1.6; *endo* 5.9
(b), R^1 = H, R = C_6H_5	69.3	1.9	*exo* 0.3; *endo* 0.2
(c), R^1 = CH_3, R = CH_3	31.4	3.1	*exo* 0.9; *endo* 0.4

in alkaline solution we observed rearrangement to bicyclo-[3.1.1]heptane derivatives *(3)*.

(1a)–(1c) were found to yield not only *(2)–(4)* but also olefins derived from the cationic intermediates of the rearrangement by elimination of a proton. Compound *(1c)* also afforded ring-cleavage products (limonene, terpinolene, α-terpineol). The reaction proceeds more cleanly with oxygen and nitrogen functions on C-1; the ketones *(5)* and *(6)* are then obtained as end products [eq. (2)]. Moreover, compounds bearing substituents with nonbonding electron pairs give higher yields of bicyclo[3.1.1]heptane derivatives than do *(1a)–(1c)*. This substituent effect increases in the order HO < NH—COR < NH_2. Replacement of H on C-7 by methyl also favors formation of bicyclo[3.1.1]heptane derivatives [cf. *(1f)* and *(1k)*, *(1g)* and *(1m)*].



(1d)-(1m) (5) (6)

(1d)–(1m)	(5)	(6)

(i), R^1 = CH_3, R = OH	86	14
(k), R^1 = CH_3, R = NH—CO_2CH_3	60	40 [6]
(l), R^1 = CH_3, R = NH—$COCH_3$	15	85 [6]
(m), R^1 = CH_3, R = NH_2	3	90

Wilt and *Wagner*[7] obtained only norcamphor *(5)*, R^1 = H, on solvolysis of 1-amino- and 1-acetoxy-2-*exo*-bromonorbornane.

We explain our results as being due to predominating *exo*-protonation of the diazo compound *(7)* initially formed from *(1)*. In the *endo*-diazonium ion *(8)* the steric situation is favorable for decomposition to *(3)* or *(6)* with anchimeric participation of the C-1—C-7 bond. If this process receives insufficient support from electron-donating substituents on C-1 and C-7, the more stable product *(2)*, *(4)*, or *(5)* is formed *via* the isomeric diazonium ion *(9)*.

μ-Carbonyldi-μ-difluoromethylenebis(tricarbonyliron)(Fe–Fe) and Di-μ-difluoromethylenebis(tricarbonylcobalt)(Co–Co)

By *Fritz Seel* and *Gerd-Volker Röschenthaler*[*]

We have been able to prove that the CO bridges in polynuclear carbonylmetal complexes can be replaced by CF_2 groups. Irradiation of a mixture of pentacarbonyliron and dibromodifluoromethane vapors with a high-pressure mercury vapor lamp[1] leads to the formation of μ-carbonyldi-μ-difluoromethylenebis(tricarbonyliron) (Fe–Fe) *(1)* along with $Fe(CO)_4Br_2$ and $FeBr_2$. Irradiation of a solution of tricarbonylnitrosylcobalt in CF_2Br_2 affords di-μ-fluoromethylenebis(tricarbonylcobalt) (Co—Co) *(2)*, $Co(NO)_2Br$, and $CoBr_2$.

(1)

(2)

Detailed information about the composition and structure of compounds *(1)* and *(2)*, which readily sublime at room temperature, was provided by their 70 eV mass spectra. The signals of highest intensity are due to the fragments $M(CF_2)_2M^+$ (M = Fe, Co); other signals occurring are those due to the molecular ions and the dissociation products resulting from CO cleavage as well as those of the fission fragments of $M(CF_2)_2^+$. The IR spectra of the complexes (see Table) are also in accord with the proposed structures; the spectra show that compound *(1)* contains a bridging CO group whereas compound *(2)* does not. The compounds are diamagnetic and therefore must contain metal-metal bonds. *(1)* and *(2)* are readily soluble in organic solvents such as ether, petroleum ether, benzene, or methanol and crystallize therefrom in the form of yellow needles. Just as $Fe_2(CO)_9$ is more stable than $Co_2(CO)_8$, compound *(1)* is more stable than *(2)* in air; however, it melts at 104 °C with decomposition. *(2)* sublimes at 45 °C under atmospheric pressure.

If a *solution* of $Fe(CO)_5$ in CF_2Br_2 is subjected to irradiation, orange-yellow, volatile tetracarbonylbis(bromodifluoromethyl)iron $(CF_2Br)_2Fe(CO)_4$ *(3)* is formed. This compound, which is probably a precursor of *(1)*, was also characterized by its IR (cf. Table) and mass spectra. Since *(3)* exhibits more than one IR-active CO absorption band it must be present in the *cis*-form. The signals of the molecular ion and fragment ions in the mass spectrum of *(3)* exhibit triplet and doublet structure as a result of the isotopy of bromine.

Table. CO bands (cm^{-1}) of the IR spectra of *(1)*, *(2)* and *(3)* in *n*-hexane solution, of $Fe_2(CO)_9$ in the solid state, of $Co_2(CO)_8$ (bridge form) in *n*-hexane, and of *cis*-$Fe(CO)_4Br_2$ in chloroform.

Experimental:

For the preparation of *(1)* equimolar amounts of $Fe(CO)_5$ and CF_2Br_2 are introduced into an evacuated quartz glass reaction flask at 0 °C ($p \approx 80$ torr) and the resultant gas mixture is irradiated; for the preparation of *(2)* and *(3)*, 0.03 M solutions of $Co(CO)_3NO$ and $Fe(CO)_5$ in CF_2Br_2 resp. are subjected to irradiation.

Reaction is complete in about 3 hours, when dark colored reaction products are deposited on the walls of the reaction vessel. Termination of the gas reaction can be recognized by a cessation of the pressure increase that accompanies evolution of carbon monoxide and tetrafluoroethylene. After pumping off the gases and excess starting materials compound *(1)* can be sublimed into a cold-trap (liquid nitrogen) and recrystallized from petroleum ether. The suspensions containing *(2)* and *(3)* must be filtered under nitrogen before evaporation in vacuum. The pure compounds can be sublimed onto a cold finger (Dry ice) in high vacuum. As is frequently the case in photochemical reactions, the yields are low: 15 to 20 mg from a 100 ml volume of gas (or solution).

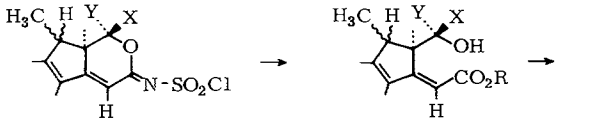
Cycloaddition to Homofulvenes

By *Rainer Askani*[*]



Whereas [6 + 2]-cycloadditions with fulvenes as 6π-electron components are still unknown, the homofulvene derivatives *exo*- and *endo* - 1,2,3,5,6 - pentamethyl - 4 - methylenebicyclo-[3.1.0]hex-2-ene *(1a)* and *(1b)*[1] have been found to undergo homo-[6 + 2]-cycloaddition with *N*-chlorosulfonyl isocyanate to give the adducts *(3a)* and *(3b)*, respectively, the reaction involving inversion at C-6. This finding is in accord with the requirements for a symmetry-allowed concerted reaction of the kind $[(\sigma 2_a + \pi 4_s) + \pi 2_s]$, while a corresponding reaction of fulvenes, being a $[\pi 6_s + \pi 2_s]$ process, is symmetry-forbidden[2]. A further possibility in the case of *N*-chlorosulfonyl isocyanate, *i.e.* that the reaction proceeds stepwise, would require stereospecific opening of the three-membered ring since no products exhibiting retention could be detected alongside those that had undergone inversion at C-6.

Reaction of *(1a)* and *(1b)* with *N*-chlorosulfonyl isocyanate is assumed to give initially *(2a)* and *(2b)*, respectively, which are converted into the conjugated isomers *(3a)* and *(3b)* by an allylic hydrogen shift under the reaction conditions[**]. Since only one product can be isolated in each case, this shift must be stereospecific; however, the available spectral data provide no definite information about the steric course. The conversion of both *(3a)* and *(3b)*, *via* the acids *(4a)* and *(4b)* and the esters *(5a)* and *(5b)*, into the same ketone *(6)* shows

[a] Satisfactory analytical results were obtained for all compounds.
[b] TMS as internal standard, τ scale.

that the adducts *(3a)* and *(3b)* differ only in the configuration of the carbon atom bound to the oxygen[3]. The ^1H—NMR signals of the group X—C—Y in *(3a)* and *(3b)* and of the lactones *(7a)* and *(7b)* accessible from *(4a)* and *(4b)*, respectively, (benzene, *p*-toluenesulfonic acid, water separator) suggest that inversion at C-6 takes place during the addition to *(1)*.

Methyl 2-(2-acetyl-2,3,4,5-tetramethyl-4-cyclopenten-1-ylidene)acetate (6)

A solution of *N*-chlorosulfonyl isocyanate (2.0 g) in ether (30 ml) is added dropwise to a solution of *(1a)* or *(1b)* (2.0 g) in ether (50 ml), to which a small amount of anhydrous potassium carbonate has been added, at −60 °C. The reaction mixture is kept at −60 °C for another hour, permitted to warm up to room temperature overnight, and then filtered. The filtrate is evaporated down to a volume of about 10 ml and placed in a refrigerator; pale yellow crystals of *(3a)* (2.2 g, 59 %) or *(3b)* (1.2 g, 32 %) are precipitated.

A solution of *(3a)* or *(3b)* (1.5 g) in dioxane (40 ml) is permitted to react for 24 h, with stirring, at 60 °C with a solution of potassium hydroxide (4 g) in water (30 ml). The aqueous phase remaining when the dioxane is distilled off is extracted with ether and acidified with hydrochloric acid. *(4a)* or *(4b)* (0.8—0.9 g, 70—80 %) is obtained.

A solution of 1.0 g of the ester *(5a)* or *(5b)*, obtained in 85 to 90 % yield from *(4a)* or *(4b)* on reaction with diazomethane, in acetone (5 ml) is treated with a solution of chromium trioxide (1.0 g) in water (5 ml) and conc. sulfuric acid (1 ml). After 10 min, water (100 ml) is added to the reaction mixture and the product *(6)* (0.9 g, 90 %) is extracted with ether.

[**] *Note added in proof* (January 31, 1970): If acetylenedicarboxylic esters, azodicarboxylic esters, maleic anhydride, or tetracyanoethylene is used as reactant instead of *N*-chlorosulfonyl isocyanate the adducts corresponding to *(2)* are isolated.

[3] According to the NMR spectra the configuration of the second H–C–CH_3 is identical in *(3a)* and *(3b)*; the same also applies to *(5a)* and *(5b)*.

Catalytic Cleavage of Aldehydes to Olefins, Carbon Monoxide, and Hydrogen

By *Jürgen Falbe*, *Hans Tummes*, and *Heinz-Dieter Hahn*[*]

The hydroformylation of olefins (oxo synthesis) according to *O. Roelen*[1] usually affords isomeric mixtures of aldehydes. All attempts to improve the selectivity in favor of straight-chain products have hitherto met with only limited success. Thus in the present-day industrial (10^6 t/a) hydroformylation of propene to butyraldehydes most processes produce at least one part of isobutyraldehyde for every four parts of *n*-butyraldehyde[2,3]. Only a small proportion of the large amount of isobutyraldehyde produced finds any application in the chemical industry, the rest being burnt for heating purposes.

Our experiments designed to alleviate this unsatisfactory state of affairs have now led to a highly selective cleavage of the isobutyraldehyde into the reactants of the oxo synthesis, propene, carbon monoxide, and hydrogen[4]:

$$\begin{array}{l} CH_3\text{-}CH\text{-}CHO \\ \quad\quad | \\ \quad CH_3 \end{array} \xrightarrow{\text{catalyst}} CH_3\text{-}CH{=}CH_2 + CO + H_2$$

The reaction takes place at 250–350 °C on a fixed-bed catalyst containing a metal of the platinum group in the gas phase at conversions of 80–100 %[4]. Only a small amount of the propene is hydrogenated to propane.

Experiments in a continuously operated pilot plant showed the catalysts to have adequate lifetimes; moreover, they can be regenerated a considerable number of times. Deposits of carbon or other decomposition products on the catalyst can be removed in the reactor by combustion in air.

By returning the above cleavage products to the oxo synthesis it is therefore possible to convert propene almost completely into the desired *n*-butyraldehyde.

The cleavage reaction can also be carried out with other aldehydes (see Table). Benzaldehyde yields the decarbonylation product benzene.

Examples (T = 280–300 °C; residence time [a] 3–4s).

Aldehyde	Conversion (%)	Yield in moles/100 moles of reacted aldehyde (selectivity)		
		Olefin	CO	H_2

Dichlorocarbene from Trichloromethyllithium[**]

By *Gert Köbrich*, *Horst Büttner*, and *Ernst Wagner*[*]

Despite numerous investigations[1–9] the question as to whether free dichlorocarbene is involved in the electrophilic reactions of trichloromethyllithium (TML) still remains unanswered. The thermolytic behavior of TML – compared with that of other carbenoids[8] – indicates a highly electrophilic species (thermally less stable than dichloromethyllithium[7,9], CCl_2 insertion into the α-CH bond of the solvent THF[7], high yields of cyclopropanes with olefins[1,3,4,7,9]), which could *a priori* be TML itself, a carbene complex having an ionized CCl bond, or free dichlorocarbene. Competition reactions, such as are used for the detection of unstable intermediates, suggest themselves as a possible means of distinguishing between these alternatives, particularly since numerical values are already available[13] for dichlorocarbene transfers to olefin mixtures from other substrates (chloroform/K *tert*-butoxide[10], Na trichloroacetate[11], phenyl trihalogenomethylmercury[12]).

Table 1. Dichlorocyclopropanes from trichloromethyllithium (competition experiments using 5 olefin + 5 cyclohexene + 1 TML; two experiments in each case).

$$\begin{array}{l} Li{-}CCl_3 \rightarrow LiCl + :CCl_2 \\ (-110\,^\circ C) \qquad (-73\,^\circ C) \end{array} \quad \begin{array}{l} \xrightarrow[k_a]{\text{olefin}} \text{dichlorocyclopropane ("A")} \\ \xrightarrow[k_b]{\text{cyclohexene}} \text{dichloronorcarane ("B")} \end{array}$$

Olefin	Product yields (%) (w.r.t. Li–CCl_3)				k_a/k_b	k_a/k_b – Comparative values from other substrates

We have investigated the decomposition of TML (−73 °C in THF) in the presence of six different mixtures of cyclohexene and a second olefin. The resulting compounds, dichloronorcarane ("B") and dichlorocyclopropane ("A"), were identified by comparison with authentic samples and analyzed by gas chromatography; the decomposition of TML was determined by $Cl^{\ominus}$ titration[4,7] (Table 1). Despite the fact that total yields in duplicate experiments often differ, the yield ratios corresponding to the rate ratios k_a/k_b are very accurately reproducible. The good agreement of our ratios with those in the literature (Table 1) leaves no doubt of a common intermediate in all cyclopropanations: dichlorocarbene. The small deviations can be ascribed to different excess energies[14] and to solvation effects. The carbene transfers from TML show no increased selectivity, as would be feasible for a "moderated" carbene (also on account of the mild conditions) and recognizable by a more pronounced tendency for the ratios to deviate from unity.

The ratios given in Table 1 reflect, above all, the electrophilicity of the intermediate. Competition experiments carried out according to *Moss* with vinylalkanes[15] reveal the steric factors involved in dichlorocarbene transfer. The rate ratio for 1-butene + 3-methyl-1-butene in the system chloroform/K *tert*-butoxide is 2.34[15]; in the case of TML we have obtained a value of 2.44 (total yield 34%). The good agreement of these data supports the conclusion that free dichlorocarbene is a common intermediate.

We have also reinvestigated the question of whether olefins accelerate the decomposition of TML. This investigation presented, as previously[3,4,5,7], a number of experimental difficulties since TML is quantitatively obtainable in a stable form only at −110 °C (in THF)[2,4,7] but is very sparingly soluble at this temperature and only slowly dissolves when warmed to the decomposition temperature (−73 °C); unavoidable variations in amount and quality of the solid phase lead to considerable deviations in the results (cf. the absolute yields of cyclopropanes, Table 1). The values given in Table 2 are average values obtained from four to eight independent experiments [constant solvent polarity ensured by keeping the total number of moles (cyclohexene + methylcyclohexane) the same] and serve much better than previous results[3,4,5,7] to illustrate beyond doubt the strong acceleration of TML decomposition by cyclohexene. These results — which are *per se* also consistent with a direct reaction between TML and the olefin — together with the previously mentioned results, are proof of the carbene transfer to cyclohexene as the rate-determining reaction step.

Table 2. Acceleration of Li—CCl_3 decomposition by cyclohexene (90 min at −73 °C).

20 mmoles of Li—CCl_3 +	Decomposition (LiCl)	Dichloronorcarane	No. of experiments
200 mmoles methylcyclohexane	36%	—	8
50 mmoles cyclohexene + 150 mmoles methylcyclohexane	86%	56%	6
190 mmoles cyclohexene + 10 mmoles methylcyclohexane	91%	72%	4

As indicated by the LiCl determination there is no enrichment of dichlorocarbene in the solution. It follows that at −73 °C a fast equilibrium is set up between TML, dichlorocarbene, and lithium chloride, from which dichlorocarbene is trapped in slower but irreversible consecutive reactions (the little known thermolysis reactions[7] and the addition to olefins to give cyclopropane).

$$LiCCl_3 \underset{\text{fast}}{\overset{\text{fast}}{\rightleftharpoons}} LiCl + :CCl_2 \xrightarrow{\text{slow}} \begin{cases} \rightarrow \text{cyclopropane} \\ \rightarrow \text{"normal" products of thermolysis} \end{cases}$$

Carbenoid/carbene equilibria are *mutatis mutandis* also known for the trichloromethyl anion in aqueous medium[16] and for tris(phenylthio)methyllithium[17,18].

Procedure:

Trichloromethyllithium, prepared by treating a solution of chloroform (2.40 g, 20.0 mmoles) in THF (70 ml), ether (5 ml), and petroleum ether (5 ml) with *n*-butyllithium (1.0—1.5 M in petroleum ether) at −115 to −110 °C[7] (dropwise addition over 40 minutes followed by 10 minutes' stirring) was allowed to warm to −100 °C within 15 minutes and 100 mmoles of each olefin was then added dropwise over a period of 10 minutes. The mixture was stirred for about 35 minutes and allowed to warm to −73 °C (± 2 °C) (internal temperature). After 90 minutes at this temperature the reaction flask was transferred to another cooled bath (−117 °C) and the reaction mixture was treated with a solution of methanol (1.0 g) and glacial acetic acid (2.0 g) in ether (5 ml). The usual working-up procedure was followed by potentiometric $Cl^{\ominus}$ titration of aliquots of the aqueous layer. The dichlorocyclopropanes present in the organic residue remaining after removal of the solvent by fractional distillation were then determined gas-chomatographically by comparison with authentic samples[10] and the aid of calibration curves using alkanes as internal standards (4 m columns, C-wax, SE30 or APL).

The Problem of an Intermolecular Charge-Transfer Triplet Excited State

By *Günther Briegleb* and *Dieter Wolf*[*]

Iwata, Tanaka, and *Nagakura*[1] have observed a structureless, long-wave (lw), long-lived (ll) emission band on excitation in the charge-transfer (CT) absorption band of relatively weak electron donor-acceptor (EDA) complexes of the electron acceptors (A) 1,2,4,5-tetracyanobenzene *(1)*, tetrachlorophthalic anhydride *(2)*, and pyromellitic dianhydride *(3)* with the electron donors (D) mesitylene *(6)*, durene *(7)*, hexamethylbenzene *(8)*, and phenanthrene *(9)*, *etc.*, in solution in diethyl ether-isopentane glass at $T = 77\,^{\circ}K$; they interpret this emission as CT phosphorescence of a complex triplet excited state $|\overset{\uparrow}{D}\overset{\uparrow}{A}^{-}|^{*}_{T}$. This would be the first detection of a CT triplet excited state, a finding of considerable theoretical interest[3] and of great significance, *e.g.* for the interpretation of photochemical processes, the photoconductivity of organic compounds, *etc.*

In this communication we report on the results of studies on complexes of *(1)* with the donors toluene *(4)*, *p*-xylene *(5)*, *(6)*, *(7)*, and *(8)* which lead us to a different interpretation of the green lw,ll emission under discussion.

a) 1,2,4,5-Tetracyanobenzene (1). After excitation in the 31600 cm^{-1} peak of the long-wave $S_0 \rightarrow S_1$ absorption band of *(1)* in solution in dipropyl ether glass at $T = 100\,^{\circ}K$ for a few minutes a gradual change may be observed in the primarily emitted, structured, blue phosphorescence of *(1)* (Fig. 1: 3a; 0,0 band: 22600 cm^{-1}, mean lifetime $\tau_0 = 2.7$ s): the maximum is shifted towards longer wavelengths and the mean lifetime is shortened. A plot of the difference between the phosphorescence spectra measured at different times results in a lw,ll emission band $\tilde{\nu}^{llEm} = 19600\ cm^{-1}$ in the green region of the spectrum (Table 1: 5). At the same time, irradiation in the region of the 31600 cm^{-1} absorption of *(1)* produces a new absorption spectrum with two characteristic absorption regions at ≈ 22000 and $\approx 26000\ cm^{-1}$ (Fig. 1: 2), due to a new molecular species hereafter designated as X[4,10]. It can be shown that X is formed *via* the triplet excited state of *(1)*[10]. The formation of X can be detected not only in glass solutions but also in crystals at $T = 77\,^{\circ}K$.

Irradiation in the long-wave absorption peak of X, $\tilde{\nu}_X^{Abs} \approx 21000\ cm^{-1}$, gives rise to a fluorescence $\tilde{\nu}_X^F$ (Table 1: 4) in the green spectral range having a maximum corresponding to that of the lw,ll emission band $\tilde{\nu}^{llEm}$ (Table 1: 5). We therefore interpret the green lw,ll emission band as delayed fluorescence $\tilde{\nu}_X^{llEm}$ of X as a result of energy transfer from triplet excited *(1)* to X in a frequency range in which the phosphorescence band of *(1)* and the long-wave absorption band of X (Table 1: 3) are superposed.

b) EDA complexes with A = (1); high donor concentration: $q = c_D/c_A = 2.8 \times 10^2$—$10^4$, $c_{(1)} \approx 1 \cdot 10^{-4}$ M (Table 1: 7).

Excitation of complexes of *(1)* with *(4)*, *(5)*, *(6)*, *(7)*, or *(8)* in dipropyl ether at $T = 100\,^{\circ}K$ within the CT absorption band $\tilde{\nu}_{CT}^{Abs}$ (Table 1: 2) produces the normal CT fluorescence. In addition, a green, structureless, lw,ll emission band $\tilde{\nu}^{llEm}$ very similar to the long-wave, long-lived emission of uncomplexed *(1)* may be observed (Table 1: 5 and Fig. 1: 5). As in the case of *(1)*, a new absorption band also appears which is characteristic of a molecular species X′. In this case, X′ is an aggregation of X with D, *i.e.* X′ ≡ X · D.

Accordingly, a shift towards longer wavelengths exhibited by both $\tilde{\nu}_X^F$ and $\tilde{\nu}^{llEm}$ and by the long wave absorption peak of X′ may be observed in the order (λ): *(7)* · *(1)* > *(6)* · *(1)* > *(5)* · *(1)* > *(4)* · *(1)*. This order runs parallel to decreasing donor strength or increasing ionization potential. X′ is formed *via* triplet excited *(1)*, which is excited *via* the singlet excited CT complex[9].

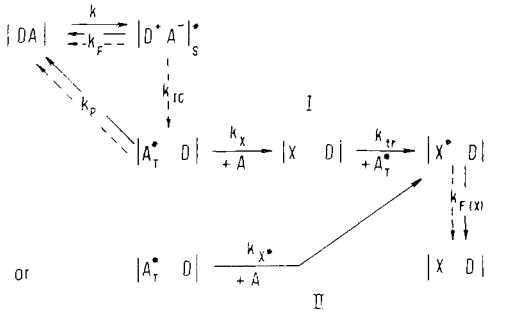
On excitation in the longest-wave peak of the X′ absorption band $\tilde{\nu}_{X'}^{Abs}$ (Table 1: 3) the fluorescence $\tilde{\nu}_{X'}^F$ of X′ (Table 1: 4 and Fig. 1: 4) occurs at a frequency corresponding to the lw,ll emission $\tilde{\nu}^{llEm}$ (Table 1: 5; Fig. 1: 5); as in the case of *(1)*, we therefore regard $\tilde{\nu}^{llEm}$ as delayed fluorescence of X′ due to energy transfer from triplet-excited *(1)* to X′[6].

Table 1. Band maxima of the absorption and emission spectra of 1,2,4,5-tetracyanobenzene *(1)* and the EDA complexes $|D \cdot (1)|$ (cf. Fig. 1).

	$\tilde{\nu}_{CT}^{Abs}$ ($10^3\ cm^{-1}$)	$\tilde{\nu}_X^{Abs}$ ($10^3\ cm^{-1}$)	$\tilde{\nu}_X^F$ ($10^3\ cm^{-1}$)	$\tilde{\nu}^{llEm}$ ($10^3\ cm^{-1}$)		$q = c_D/c_A$ [$c_{(1)} = 1 \times 10^{-4}$ M]
1	2	3	4	5	6	7
(1)	—	21.6	19.6	19.6	—	—
D = Toluene *(4)*	[a]	21.7	19.7	19.8	—	1×10^4
p-Xylene *(5)*	28—30 [b]	21.6	19.3	19.5	—	3.5×10^3
Mesitylene *(6)*	28.3 [c]	21.4	18.9	18.9	19.8 [f]	3.7×10^3
Durene *(7)*	25 [d]	21.2	18.7	18.8	19.5 [f]	2.9×10^2
Hexamethylbenzene *(8)*	24.6 [e]	21.3	19.1	18.3	18.3 [f]	1.1×10^{-1}
		21.1	19.0	17.8	—	1.1×10^2

[a] In the case of the complex $|(4) \cdot (1)|$ irradiation was carried out in the long-wave flank of the CT band (at 28500 cm^{-1}) since the maximum lies in the region of the 31600 cm^{-1} peak of *(1)*. [b] No separable maximum. [c] In the crystal [2]. [d] In CH_2Cl_2, $T = 293\,^{\circ}K$ [2]. [e] In dipropyl ether at $T = 293$ and $100\,^{\circ}K$. [f] $\tilde{\nu}^{llEm}$ band maxima measured by *Iwata*, *Tanaka*, and *Nagakura* [1, 5b] and interpreted as CT phosphorescence (in diethyl ether/isopentane (1 : 1), $T = 77\,^{\circ}K$).

The intensity decay of the long-lived emission is initially non-exponential ($\tau < 2.7$ s); but after about 5 s the intensity decreases exponentially with $\tau_0 = 2.7$ s.



c) EDA complexes with A = (1); low donor concentration: $q = c_D/c_A = 4$—77, $c_{(1)} = 1.1 \times 10^{-4}$ M.

On low-intensity excitation at low D concentration and low constant concentration of *(1)* formation of X is suppressed to such an extent that all the complexes of *(1)* with *(4)*, *(5)*, *(6)*, or *(7)* yield primarily the structured phosphorescence of *(1)*[7] (Fig. 1: 3). The fine-structure bands of this phosphorescence, which is excited *via* the CT singlet $|\dot{D}^{+}\dot{A}^{-}|^{*}_{S}$, are inevitably broadened by superposition[8] with the delayed fluorescence of X′. Consequently the intensity maximum shows a shift towards longer wavelengths.

d) The following reaction scheme (p. 172) is in accord with all observed phenomena, including the results of kinetic investigations[10].

No decision could be made in favor of either I or II, but it was possible to rule out other conceivable reaction mechanisms.

As is demonstrated by the occurrence of the phosphorescence spectrum of *(1)* on irradiation in the CT band at low

donor concentration under conditions which give rise to only low concentrations of X, the relation $E|\dot{D}+\dot{A}^-|_S^* > E|DA_T^*|$ applies to the complexes of *(1)* with *(4)*, *(5)*, *(6)*, or *(7)*. Consequently, in this case the species X′ which can only be formed *via* the triplet excited state of *(1)* may be observed after irradiation in the complex CT band [9].

e) Hexamethylbenzene-tetracyanobenzene. Irradiation in the CT band (24600 cm^{-1}) of the complex $|(8)\cdot(1)|$ at 100 °K does not give rise to the structured phosphorescence of *(1)*, even at low acceptor and donor concentrations; however, the delayed fluorescence of X′, $\tilde{\nu}_{X'}^{IIEm}$ (Table 1: 5) is observed in the green region of the spectrum. It is shifted towards relatively long wavelengths because of superposition by the phosphorescence of a mixed excimer $|(8)\cdot(1)_T^*|$ of a triplet excited $(1)_T^*$ and *(8)* which lies in the red region of the spectrum. The decrease in the $\tilde{\nu}_{X'}^{IIEm}$ intensity is not exponential (τ = 0.4 to 1.1 s). At increasing concentration of *(8)*, and accordingly increasing excimer concentration, the maximum $\tilde{\nu}_{X'}^{IIEm}$ shifts towards longer wavelengths. At higher temperatures (T = 112 °K), when the dipropyl ether glass starts to become viscous, the concentration of X, which may be enriched only in the glass (or crystal) matrix, is reduced to such an extent that only the red excimer-phosphorescence band ($\tilde{\nu}_{max}^{PE}$ = 16.5 × 10^3 cm^{-1}; Fig. 1: 6) may still be observed.

f) The results of our studies show that the II,Iw emission bands which have been discussed in connection with the question of a CT triplet excited state [1] have to be interpreted as delayed fluorescence of a molecular species X [4, 10]. In the case of the EDA complex $|(8)\cdot(1)|$, an additional mixed excimer phosphorescence of $|(8)\cdot(1)_T^*|$ is observed at longer wavelengths.

[4] X seems to be a radical ion pair $|\dot{A}^+\dot{A}^-|$ formed by electron transfer $A_T^* + A \rightarrow |\dot{A}^+\dot{A}^-| \rightleftarrows \dot{A}^+ + \dot{A}^-$ due to the increase in the electron affinity of *(1)* by an amount equal to the triplet excitation energy. The concentration of X may be increased to such an extent that it becomes detectable by absorption spectroscopy in a glass matrix or a crystal lattice both at 100 °K and at 77 °K: incorporation of the radical ions into the glass matrix hinders the reverse process $\dot{A}^+ + \dot{A}^- \rightarrow A + A$ so long as the matrix does not become viscous or fluid. Then the absorption spectrum of X disappears, but small concentrations of X [10] still remain detectable only by its green fluorescence. *Hayashi, Iwata*, and *Nagakura* [5] deduce the presence of $(1)^-$ from the ESR spectra of irradiated solid solutions of *(1)* and of complexes of *(1)* with *(4)*, *(5)*, *(6)*, *(7)*, or *(8)* in ethanol, as well as of *(1)* in *(6)*, *(4)*, or in *(4)*-ether at T = 77 °K. The interpretation of the Δm = 2-triplet ESR resonance at 1440–1610 gauss as an ESR signal of a CT triplet excited state should be reconsidered.

[5] a) *H. Hayashi* and *S. Nagakura*, Molecular Physics *13*, 489 (1967); b) *H. Hayashi, S. Iwata*, and *S. Nagakura*, J. chem. Physics *50*, 993 (1969).

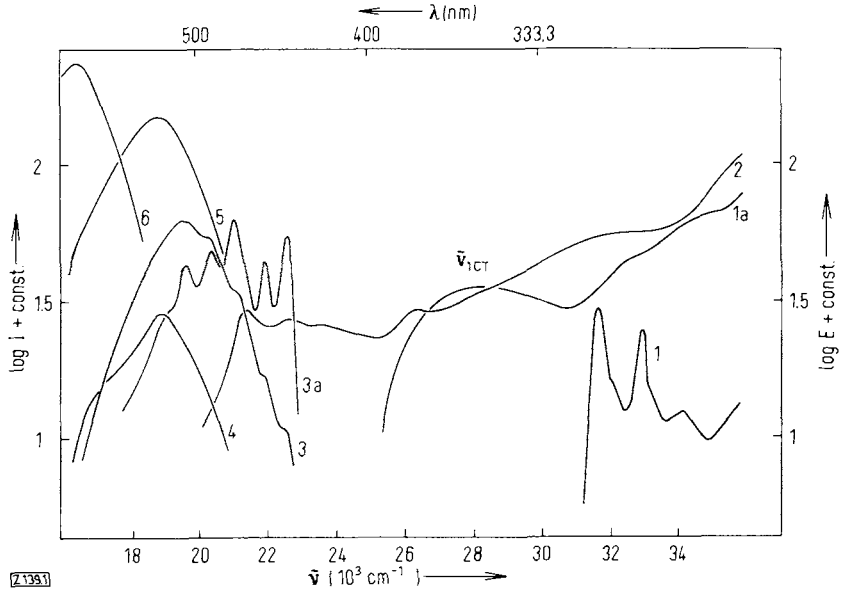

Fig. 1. Absorption and emission spectra of 1,2,4,5-tetracyanobenzene *(1)* and of EDA complexes $|D\cdot(1)|$ (cf. Table 1 and text).
1: Absorption spectrum of *(1)* (c = 1.1 × 10^{-4} M). 1a: Absorption spectrum of *(1)* with *(6)*. $\tilde{\nu}_{1CT}$: First charge-transfer absorption band; a second CT band lies in the absorption region of *(1)*. 2: Absorption spectrum of X′. 3a: Phosphorescence spectrum of *(1)* (c = 1.1 × 10^{-4} M). 3 and 5: Emission spectra of *(1)* with *(6)* in dipropyl ether glass at T = 100 °K. 3: $c(1)$ = 1.1 × 10^{-4}, $c(6)$ = 8.5 × 10^{-3} M; 5: $c(1)$ = 1.37 × 10^{-4}, $c(6)$ = 5.1 × 10^{-1} M. 4: Fluorescence spectrum of X. 6: Mixed excimer phosphorescence of $(1)_T^*$ with *(8)* ($c(1)$ = 1.1 × 10^{-4} $c(8)$ = 6.2 × 10^{-4} M; T = 112 °K).

[6] *Iwata, Tanaka*, and *Nagakura* [1] observed the green lw,ll emission which they interpret as CT triplet phosphorescence only in complexes with D = *(6)*, *(7)*, or *(8)*, but not for complexes with D = *(4)* or *(5)*. In contrast, we find the green, structureless lw,ll emission band also for the complexes with *(4)* and *(5)* but at high D concentrations.

[7] *Iwata, Tanaka*, and *Nagakura* [1] found the structured phosphorescence of *(1)* on excitation in the CT band only with complexes of *(1)* with benzene and with *(4)* and *(5)* and in accordance with their interpretation they assumed CT phosphorescence to make only a very slight contribution.

[8] This superposition effect is considerably stronger at medium and high D concentration; the fine structure disappears and the shifts of the maxima of the lw,ll emission increase with the donor concentration.

[9] In cases where $E|\dot{D}^{+}\dot{A}^{-}|_{S}^{*} < E|DA_{T}^{*}|$ formation of X' could not be detected (*e.g.* when A = *(1)*, D = tetramethyl-*p*-phenylenediamine).

[10] Further details, also regarding complexes with A = *(2)* or *(3)*, see *G. Briegleb* and *D. Wolf*, to be published.

Plant Bioregulators in the Metathoracic Glands of Myrmicine Ants[**]

By *Hermann Schildknecht* and *Knut Koob*[*]

Atta sexdens, the leaf-cutting ant, is a highly developed evolutionary form of the colony-building ants. Its behavior has been the subject of many investigations — the chemistry of its glands, on the other hand, has been studied in part only[1], despite the fact that both these topics are closely interrelated. We were surprised to learn that the metathoracic glands contain phenylacetic acid[2] and even more surprised by the results of a recent analysis of the contents of these glands that are very sparingly soluble in water.

Pure secretion from 60 glands could be separated by thin-layer chromatography on silica gel GF (Merck) in petroleum ether/ether/acetic acid (67 : 30 : 3) into two fluorescence-quenching zones, that nearer the front (R_f = 0.5) being due to phenylacetic acid and the other (R_f = 0.3) to an unknown substance. Since this unknown substance rapidly decomposed with discoloration from pink to brown we isolated it from a metathoracic extract obtained from a 40 g quantity of ants by column chromatography on Sephadex (LH20). According to its UV spectrum and its reaction with van Urk's reagent[3] the unknown substance had to be an indole derivative. Polarity of the molecule suggested the presence of a carboxyl group; since the acid itself readily decomposed, the methyl ester was isolated, purified, and identified.

Of the many substances used for comparison with the gel-chromatographically isolated unknown component only 3-indolylacetic acid had the same R_f value and exhibited the same color reaction and UV absorption. Furthermore, we were able to identify the corresponding fraction, obtained by column chromatography in the esterified secretion as methyl 3-indolylacetate, mass spectrometrically. Quantitative UV spectrometry showed that each gland contained 10^{-7} to 5×10^{-7} g or 5.7×10^{-10} to 2.8×10^{-9} mole of 3-indolylacetic acid; this corresponds to a 1–6% solution of 3-indolylacetic acid in the glands.

We have also detected 3-indolylacetic acid in the ant *Myrmica laevinodis*. This finding is very interesting because the myrmicine ants gather their food for winter[4] as did primitive men earlier. The leaf-cutting ants go one step further — they cultivate fungi[5]. The "collectors and growers", therefore, very probably learned much earlier than man to breed growing things and then store them as food. The heteroauxin 3-indolylacetic acid not only influences growth but also hinders seed germination[6]. We now wish to ascertain whether the phenylacetic acid and 3-indolylacetic acid act synergistically[7].

CONFERENCE REPORTS

Structural Chemistry of Refractory Metallic Compounds

By *H. Nowotny*[*]

The compounds having the highest melting points known so far, HfC and TaC, belong to the structurally simple transition metal (T) monocarbides. Although many of these compounds are nonstoichiometric, due to a carbon deficiency, the vacancies (and the carbon atoms) nevertheless exhibit some degree of order[1]. This order is even more pronounced in the subcarbides T_2C, which were previously generally regarded as hexagonally close-packed metal host lattices having a random distribution of carbon atoms. In fact a series of ordered structures is now known, *e.g.* the anti-CdI_2, ζ-Fe_2N, or ξ-Nb_2C types, which all exhibit an unequal T—C—T and T-vacancy-T distance. This emphasizes the significance of the octahedral structural unit $[T_6C]$. It is remarkable that similar structural principles are encountered in transition metal carbide hydrides. Thus, Zr_2CH can be regarded as an interstitial compound of hydrogen with a Zr_2C host lattice (anti-CdI_2 type).

A large number of carbides, which are formed, *e.g.*, by the action of a further transition metal or of a meta-metal on TC or T_2C, yield a uniform class, in which the octahedral unit dominates; inclusion of other small nonmetal atoms and the trigonal-prismatic structural unit extends this class considerably. This classification naturally also permits inclusion of long-known complex carbides and related compounds such as the η_1-carbides in high-speed tool steels and the η_1-oxide in ferrotitanium. Linkage of the $[T_6X]$ octahedra *via* corners leads to the perovskite carbides, *e.g.* Ti_3AlC, or to the filled U_3Si type, *e.g.* Cr_3AsN, or to the filled β-Mn type, *e.g.* Mo_3Al_2C, *etc.* Linkage of the $[T_6X]$ octahedra *via* edges produces the H phase, *e.g.* Cr_2AlC, or the Ti_3SiC_2 type, *etc.* Common features become apparent regarding the components and the composition in agreement with the structural units: *e.g.* the H phase V_2PC can be considered as the sum of the two kinds of building units [VC]-octahedra + [VP]-trigonal-prisms, which are already present in the binary compounds; similarly, Mo_2BC is built up from the structural elements occurring in the cubic form MoC_{1-x} and MoB.

There are good reasons for assuming that the metallic host lattice is mainly responsible for the high stability of carbides,

complex carbides, and their analogs; electron transfer to the host lattice strengthens the T—T bonds. Band calculations on the basis of OPW and APW methods, and ESCA measurements suggest strong T—X bonds.

Solid State Reactions with and without Gas Phase at High Temperatures with Special Consideration of High-Frequency Plasma

By *Hk. Müller-Buschbaum* [*]

In recent years high-frequency plasma torches have found increasing use besides the usual laboratory heat supplies suitable for solid-state reactions. The high frequency energy is transferred to plasmas inductively or *via* a peak discharge at very high frequencies. Principally, there are two types of plasma torch.

1. High-pressure plasma torch (pressure range: 760 torr)
2. Low-pressure plasma torch (pressure range: 10^{-3} to 10^{-1} torr)

The use of torches opened at one end (high-pressure plasma torches) for the production of large single crystals by a modified Verneuil process has been described by several authors. The main advantage of such torches is that a defined gaseous atmosphere can be set up at a low plasma speed. However, they have disadvantages; for example, the uncontrollable stay period of the sample in the hot zone at unknown reaction temperatures, and a separation of the starting material components by mechanical and electromagnetic forces. A low-pressure plasma inside a closed system developed by our group makes the heating of small amounts of a substance possible and is particularly suitable for the preparation of small single crystals. Compared with high pressure plasma torches there is one disadvantage of this closed type of torch, *i.e.* the reduced pressure in the plasma which results in poorer reactions as far as thermally moderately decomposing or volatilizing substances are concerned. In a reaction between plasma and solid effects occur that are due to ionization of the gases: highly positively charged atoms of heavy gases (at extremely high temperatures) no longer exhibit the chemical characteristics of the corresponding molecular or atomic gas. This is also the case for ionized hydrogen, which does not have reducing properties. True "Plasma chemistry" (in the plasma state only!) therefore appears to be a difficult and questionable experimental field.

Internal and External Contributions to the Biogenesis of Mitochondrial Proteins

By *W. Sebald* (lecturer), *W. Neupert*, and *G. D. Birkmayer* [*]

The biogenesis of mitochondria involves cooperation of the extramitochondrial protein synthesis with the protein-synthesis system localized within the mitochondria. The capacity of this system for protein synthesis is illustrated *inter alia* by the finding that growing peptide chains can be detected on the mitochondrial ribosomes after incubation of isolated mitochondria with ^{14}C-amino acids. The ^{14}C-amino acids that are incorporated *in vitro* are also found in the inner mitochondrial membrane. After separation of the membrane proteins by gel electrophoresis, four to five of the protein bands contain tracer. The highest content of tracer is found in the fourth band from the starting point; this band contains 4% of the total membrane protein and it is found to migrate at about the same rate in the gel electrophoresis of mitochondrial membranes of rat liver, locust flight muscles, and *Neurospora crassa*. In the corresponding band of cytoplasmic *mi*-1-mutants of *Neurospora crassa*, in which only traces of cytochrome aa_3 and b are spectrally detectable, less protein and no radioactivity are found.

(1)

The *in vitro* results can be confirmed *in vivo* by an independent method. If the hyphae of *Neurospora crassa* are preincubated in 3-[2-(3,5-dimethyl-2-oxocyclohexyl)-2-hydroxyethyl]glutarimide [cycloheximide *(1)*] (0.1 mg/ml), incorporation of ^{14}C-amino acids into the extramitochondrial and soluble mitrochondrial proteins is inhibited to an extent of more than 99%. About 15% of the membrane proteins are formed by cycloheximide-resistant mitochondrial protein synthesis. These membranes, when labeled *in vivo*, exhibit the same distribution of radioactivity after gel electrophoresis as do those that are labeled *in vitro*.

Incorporation of ^{14}C-amino acids into the proteins of gradient-purified mitochondrial ribosomes *in vivo* is completely inhibited by *(1)*. Consequently this part of the mitochondrial protein synthesis apparatus is afforded by the extramitochondrial system. On isolation of enzymically active, spectrally pure cytochrome oxidase from mitochondria labeled *in vivo* in the presence of *(1)* by treatment with Triton X-100 followed by fractional ammonium sulfate precipitation and chromatography on DEAE cellulose, the specific activity decreases substantially compared to that of the total membrane proteins. In the chromatographic separation on DEAE cellulose, the protein from band 4, and consequently the activity, accumulates in one fraction which does not contain cytochrome oxidase. This protein can be further purified on CM cellulose, the specific activity being increased to an amount 10 times greater than that of the membranes. It thus serves as a possible means of integrating cytochrome oxidase into the inner mitochondrial membrane (*i.e.* as an "integrator protein").

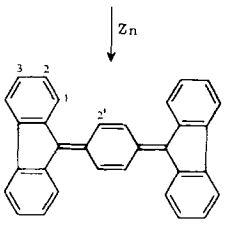
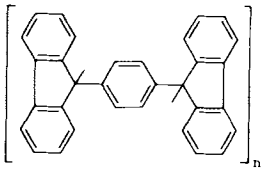
Color by the Action of Mechanical Forces on Organic Molecules

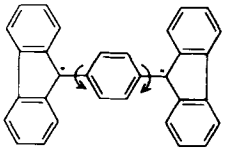


By *Hans Weidinger* and *Reinhard Steinmetz* (lecturer) [*]

Dehalogenation of 1,4-bis(9-bromo-9-fluorenyl)benzene *(1)* leads to the formation of the saturated solvent-containing oligomer *(3)* and not the expected quinonoid *p*-xylylene *(2)* [1]. Osmometric molecular weight determinations in benzene at 37 °C, in tetrahydrofuran at 45 °C, and in pyridine at 60 °C, yield values of about 1600 (n = 4) for the molecular weight of *(3)*.

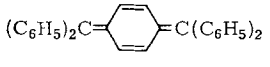


A slight amount of cleavage and blue-violet coloration takes place when compound *(3)* is subjected to heat or mechanical pressure, both in the solid state and in solution. Although the monomeric fragments occur mainly as quinonoid *p*-

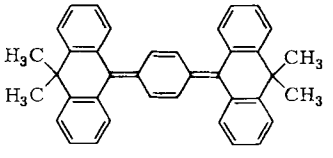


(1)

(2)

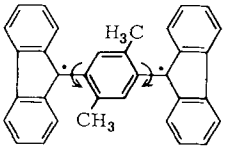


(3)

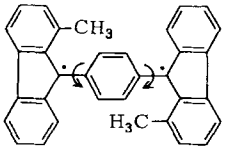


(4)

xylylene *(2)* in solution, the paramagnetism of the blue-violet crystals indicates the presence of radicals (and possibly twisted biradicals *(4)*). By suitable substitution of the dibromide *(1)*, it can be shown that the difference in behavior of the Thiele hydrocarbon *(5)* from that of the *p*-xylylene *(2)* is due to interaction of the mutual hindrance of the H atoms on C-1 and C-2′ with the aromatization tendency of the quinonoid system.



(5)



(6)

Thus the properties of the *p*-xylylene system *(2)* remain essentially unchanged by substitution at C-2 and C-3, whereas radicals very sensitive to oxygen are obtained, *e.g.* *(7)* and *(8)*, when methyl groups are introduced in positions 1 or 2′.

(7)

(8)

In hydrocarbon *(6)*, on the other hand, the mutual hindrance of the H atoms in positions 1 and 2′ is removed as a result of the angular structure. Hence compound *(6)*, like the Thiele hydrocarbon *(5)*, is stable as the *p*-xylylene and in contrast to *(2)* shows no tendency to oligomerize.

Cryptates, a New Class of Cation Complexes

By *J. M. Lehn*[*]

Formation of complexes between cations of alkali metals or alkaline earth metals and organic ligands is of importance in:

1. The activation of inorganic anions in organic solvents;
2. The transport of cations.

We have synthesized diazapolyoxa macrobicyclic compounds of the following type[1]:

(1), m = n = p = 1
(2), m = n = 1; p = 2
(3), m = 1; n = p = 2
(4), m = n = p = 2

The substances react with a variety of cations to form stable complexes which may be regarded as inclusion compounds. Since the cation is "hidden" in the center of the molecule, the name "cryptates" is proposed for these compounds.

The stability constants of complexes of *(1)* with alkali metals and alkaline earth metals decrease in the following order: $Ba^{2+} > Sr^{2+} > K^{+} > Ca^{2+} > Rb^{+} > Na^{+} > Li^{+} > Cs^{+}$ (in water). Both the bicyclic compounds and the complexes can occur in several conformations.

Compound *(1)* can be used as a means for dissolving inorganic salts in organic solutions, *e.g.* KSCN, KF, and $Ba(SCN)_2$ can be dissolved in chloroform.

In a few cases the rate of cation exchange (in D_2O) could be measured by NMR spectroscopy. At 30 °C alkali metal cations exchange much more rapidly than alkaline earth metals.

If potassium hydroxide is dissolved in tetrahydrofuran together with *(1)*, the hydroxide ion becomes a very strong base which, among other things, cleaves a proton from the methylene group in fluorene.

Radioactive Drugs

By *Martin Wenzel*[*]

Radioactive drugs, *e.g.* compounds containing ^{131}I or ^{32}P, are widely used in nuclear medicine as radiopharmaceuticals for localization of different organs and functional diagnosis. Moreover, the term "radioactive drugs" can also refer to drugs that are, in themselves, not radioactive but have been labeled with radioisotopes. Such labeled compounds are used in the elucidation of questions involving the resorption, distribution, and excretion, as well as for the study of the metabolism, of these drugs in the organism.

The development and testing of new drugs by the pharmaceutical industry would nowadays be almost unthinkable without using radioisotopes. In contrast, these methods have found almost no application in pharmaceutical education at universities.

Radioactive drugs can be synthesized by the standard methods of preparative chemistry. Since only the weak β-emitters ^{14}C and ^{3}H are generally used for labeling, the experimental operator has to take precautions against incorporation, and consequent internal irradiation, but not against external irradiation.

Control of the radiochemical purity is important, and this is best accomplished by chromatographic methods. Radioactive drugs can be located in organs and in cell organelles by autoradiography. Metabolic routes can be established by chromatographic separation of radioactive excretion products.

It is even possible, after injection of "metabolically labile" substances labeled with tritium, to recognize specific reactions *in vivo* in the overall organism when the tritiated water content of the respiratory water is determined; this technique is illustrated by studies on the *in vivo* oxidation of testosterone[1] and estradiol.

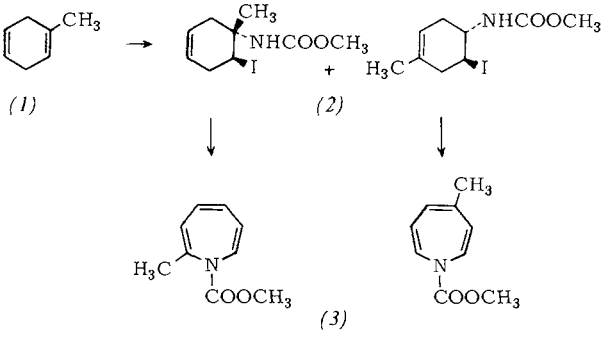
SELECTED ABSTRACTS

Bishomoquinone, tricyclo[5.1.0.0^{3,5}]octane-2,6-dione, has been synthesized in the *anti- (2a)* and *syn* form *(2b)* by *A. Yogev, J. Heller,* and *A. S. Dreiding* from 1,5-cyclooctanedione by treatment with 4 mol. equiv. of phenyltrimethylammonium tribromide and heating of the resulting isomers of 2,4,6,8-tetrabromo-1,5-cyclooctanedione *(1a)* and *(1b)* (m.p. 225 to 226 and 196–198 °C, resp.; joint yield 53%) with copper powder in a high vacuum to 150 °C. *(1a)* affords 70% of *(2a)* (m.p. 179–180 °C) and 5% of *(2b)* (m.p. 100–101 °C), the corresponding yields from *(1b)* being 25% and 13%. The *syn*

(1) *(2a)* *(2b)*

and *anti* forms were assigned by reduction to the diols, which were examined by NMR spectroscopy. / Chimia *23*, 411 (1969) / —Ma. [Rd 127 IE]



The catalytic cyclodimerization of allene, the first known example of a metal-catalyzed cyclodimerization in the vapor phase, has been described by *F. W. Hoover* and *R. V. Lindsey jr.* A phosphine-modified carbonyl-Ni catalyst having the empirical formula $(C_6H_5)_2PC_6H_4P(C_6H_5)_2 \cdot Ni(CO)_2$, which was prepared from an equimolar mixture of 1,4-bis(diphenylphosphino)benzene and $Ni(CO)_4$, converts a stream of allene diluted with helium at 200 °C into 1,3- and 1,2-dimethylenecyclobutane (60 and 13%, resp.), and 27% of trimer, predominantly 1,2,4-trimethylenecyclohexane. Attempted thermal dimerization in the liquid phase (THF) with the same catalyst effected cyclomerization to a tetramer, a pentamer, and higher oligomers, without formation of any dimers. The pentamer is 1,2,4,6,8- or 1,2,4,6,9-pentamethylenecyclodecane. / J. org. Chemistry *34*, 3051 (1969) / —Ma. [Rd 128 IE]

μ-Oxodifluorophosphoryldifluorophosphine *(1)*, a phosphorus oxide fluoride whose P atoms are in different oxidation states (+3 and +5), has been obtained by *D. D. DesMarteau* by photolysis (λ = 2537 Å) of $P(O)F_2Br$ in the presence of Hg at 23 °C

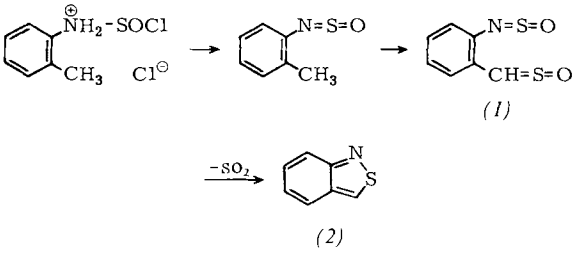
$$2\,P(O)F_2Br + Hg\,(excess) \xrightarrow{h\nu} \underset{(1)}{F_2POP(O)F_2} + Hg_2Br_2$$

in 40% yield, alongside POF_3, F_2POPF_2, $P_2O_3F_4$, PF_3, *etc.* Compound *(1)* is a colorless liquid, b.p. 48 °C, m.p. —31 °C, which slowly decomposes at 23 °C. It is extremely sensitive to moisture. Reaction with stoichiometric amounts of HCl at 23 °C proceeds almost quantitatively to give $HOP(O)F_2$ and PF_2Cl. / J. Amer. chem. Soc. *91*, 6211 (1969) / —Ma. [Rd 129 IE]

A general synthesis of 1*H*-azepine derivatives *(3)* is described by *L. A. Paquette, D. E. Kuhla, J. H. Barrett,* and *R. J. Haluska.* Electrophilic addition of iodine isocyanate to readily accessible 1,4-cyclohexadiene derivatives such as *(1)*, followed by cyclization of the resulting carbamates *(2)* with

(1) *(2)* *(3)*

bases to give unsaturated aziridines and subsequent bromination-debromination, affords the 1*H*-azepines *(3)*. They form tricarbonyl-Fe complexes. / J. org. Chemistry *34*, 2866 (1969) / —Ma. [Rd 130 IE]



Two cyclic thiocarbonates, 1,3-dioxolane-2-thione *(1)* **and 1,3-oxathiolane-2-thione** *(2)* have now been unambiguously synthesized for the first time by *F. N. Jones* and *S. Andreades. (1)* was obtained directly from thiophosgene and ethylene glycol in boiling THF—CH_2Cl_2 in the presence of K_2CO_3 (yield 33%), and *(2)* from the lead salt of 2-mercaptoethanol and thiophosgene in CH_2Cl_2. *(1)* is a colorless oil, m.p. 55 to 55.5 °C, and *(2)* a pale yellow oil, m.p. *ca.* —20 °C; both are

(1) *(2)*

thermally unstable and sensitive towards acids, bases, and moisture. Halide ions isomerize *(1)* and *(2)* to thio- and dithiocarbonates. Alkylation with alkyl halides affords unstable compounds that rearrange to β-halogenoethylthio- and -dithiocarbonates. On treatment with acids the compounds polymerize to polythio- and polydithiocarbonates. *(1)* and *(2)* react with triphenylphosphine to give ethylene. / J. org. Chemistry *34*, 3011 (1969) / —Ma. [Rd 131 IE]

A new synthesis of benz[c]isothiazole and its derivatives has been accomplished by *M. Davis* and *A. W. White* by reaction of *o*-toluidine and substituted *o*-toluidines with thionyl chloride in boiling xylene, mesitylene, or bromobenzene.

(1)

(2)

Yields of up to 80% are obtained. It is assumed that the unsubstituted compound *(2)* is formed *via* the benzylidenesulfinyl compound *(1)*. 2-Amino-5-nitrotoluene does not give any benzisothiazole. / J. org. Chemistry *34*, 2985 (1969) / —Ma. [Rd 132 IE]

The isomerization of perfluoropyridazines *(2)* has been studied by *C. G. Allison*, *R. D. Chambers*, *Yu. A. Cheburkov*, *J. A. H. MacBride*, and *W. K. R. Musgrave*. Pyrolysis of tetrafluoropyridazine *(2a)* at 820 °C and of bis(heptafluoroisopropyl)pyridazine *(2b)* at 560 °C gave tetrafluoropyrimidine *(3a)* (60% yield) and 4,6-difluoro-2,5-bis(heptafluoroisopropyl)pyrimidine *(3b)* (*ca.* 50%), respectively. This thermal isomerization probably proceeds *via* a fluorinated 1,5-diazabenzvalene that undergoes aromatization. Irradiation of *(2a)* and *(2b)* under a quartz lamp, on the other hand, leads almost

(1) *(2)* *(3)*

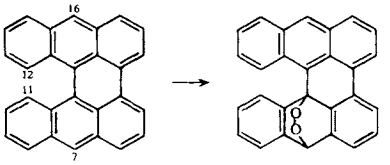
(a), R = F
(b), R = iso-C_3H_7

quantitatively to the pyrazine derivatives *(1a)* and *(1b)*, respectively. The photochemical conversion of *(2a)* probably occurs by way of tetrafluorodiazaprismane (formed *via* the Dewar-benzene analog?), scission of the N—N bond, and rearomatization. / Chem. Commun. *1969*, 1200 / —Ma. [Rd 133 IE]

Dinitrogen tetrafluoride occurs below room temperature as a mixture of the centrosymmetric *trans*-form and the *gauche* form in the ratio 53 : 47 according to electron diffraction investigations carried out by *M. C. Cardillo* and *S. H. Bauer*; the *trans* conformation is about 300—500 cal/mole more stable and the rotation barrier has a value of 3—7 kcal/mole. Both rotamers have equal bond lengths: dNN = 1.489 ± 0.007, dNF = 1.375 ± 0.004 Å; the bond angles in the *trans* form are ∢ FNF = 102.9 ± 0.75 and ∢ FNN = 100.6 ± 0.6 °, and in the *gauche* form (dihedral angle 67.1 ± 0.8 °) ∢ FNF = 105.1 ± 1.5, ∢ FNN = 100.1 ± 1.5, and ∢ F′NN = 104.3 ± 1.0 °. / Inorg. Chem. *8*, 2086 (1969) / —HB. [Rd 135 IE]

Formation and decomposition of carbonic acid in aqueous solution has been investigated by *M. J. Welch*, *J. F. Lifton*, and *J. A. Seck* using a method involving determination of the exchange of ^{15}O between water and carbon dioxide. ^{15}O, which has a half-life of 2 min, is suitable as tracer when very small amounts of CO_2 are being investigated; the reaction can therefore be investigated over a wide pH range without addition of buffers which change the rate of reaction. A value of $\ln(10^3 k_1) = 34.69 - 9252/T$ was found for the constant k_1 in the reaction

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$



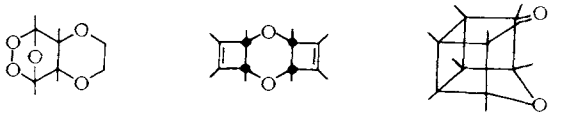
and $\ln(10^6 k_{-2}) = 48.08 - 12720/T$ for k_{-2} in the reaction

$$HCO_3^{\ominus} \rightleftharpoons OH^{\ominus} + CO_2$$

/ J. physic. Chem. *73*, 3351 (1969) / —Hz. [Rd 140 IE]

The structure of the Se_8^{2+} ion in $Se_8(AlCl_4)_2$ is similar to that of bicyclo[3.3.0]octane and is derived from the Se_8 ring in the crown form by linkage of a 1,5 bond and flipping of the Se-3 atom into a *syn-cis-anti* conformation. Se_8^{2+} can be regarded as intermediate between the 48-electron systems Se_8 and S_8 and the 44-electron system S_4N_4, in which two S atoms are situated above and two below the N_4 plane and are linked transannularly by 1,5 and 3,7 bridges. The Se—Se distances of 2.32 ± 0.03 Å are the same as those in Se_8; the Se—Se—Se angles are about 98 °, except at atoms 3 and 7 where they are about 90 °. The single crystals of $Se_8(AlCl_4)_2$ studied by *R. K. McMullan*, *D. J. Prince*, and *J. D. Corbett* were prepared by transport in the gas phase; they are orthorhombic, having space group $Pca2_1$ with a = 14.92 ± 0.02, b = 10.67 ± 0.01, and c = 13.22 ± 0.01 Å; Z = 4. / Chem. Commun. *1969*, 1438 / —HB. [Rd 143 IE]

The structure of the photo-oxide of dibenzo[*a*,*o*]perylene has been established by *H. Brockmann* and *F. Dicke*. Dibenzo[*a*,*o*]perylene *(1)*, prepared by dehydrogenation of its 7,16-dihydro derivative in the gas phase at 300 °C (red prisms containing 1.13% of CS_2, 50% yield), is converted on irradiation of its red solution in carbon disulfide into a yellow



(1) *(2)*

solution of the photo-oxide *(2)* (yellow prisms containing 1.43% of CS_2, 70% yield). The structure was derived from the electronic spectra and the NMR spectrum. Neither *(1)* nor *(2)* is planar. / Chem. Ber. *103*, 7 (1970) / —Kr. [Rd 146 IE]

Dioxabicyclo[*n*.2.0]alkenes *(1)*—*(4)* have been prepared by *R. Criegee* and *R. Rucktäschel* for studies on valence isomerism and ozonization. Conrotatory opening of the 4-membered ring must give a *trans* double bond which is possible

BOOK REVIEWS

Chemische Thermodynamik (Chemical Thermodynamics). By *A. Münster*. Verlag Chemie GmbH, Weinheim Bergstr. 1969. 1st Edit., x, 261 pp., 34 figs., paper, DM 29.—.

A new book on thermodynamics is assessed by how much it is better than the others. The principles of thermodynamics should be explained with impeccable logic, and the applications should be real ones.

That the good points of the present book outweigh its failings is due to the pedagogic experience of the author, who follows Gibbs' method consistently, introduces the main laws as (experimentally validated) axioms, and derives all further relations by relatively simple mathematics.

To find a successful description of Carathéodoric axiomatics in such a small booklet is surely sensational. On a second reading of the relevant chapter the reader recognizes the pedagogic value of *Carathéodory*'s work, which is presented in a considerably more readable form by *Münster* than in the original. It is shown that *Carathéodory*'s first law (anywhere near a given state of a system is a neighbor state that is not accessible from it by an adiabatic route) becomes equivalent to the second law only after addition to it of a further law (one of experience).

Description of the general conditions for equilibrium and stability is followed by the customary applications of thermodynamics to phase equilibria, chemical equilibria, critical phases, electrochemical equilibria, matter in a gravitational and in a centrifugal field.

The paragraph on the Nernst heat law in the chapter on chemical equilibria deserves special mention. *Münster* has here not only explained the various formulations of this law critically, but he has also consistently avoided the usual recourse to statistical considerations.

The book's weaknesses perhaps result from its advantages. Thus in the classical formulation of the main laws, *Münster* avoids the classical introduction of heat and temperature, possible though this is, and reserves it for the later section on Carathéodoric axiomatics. This applies also to the clear definitions of the concepts "adiabatic" and "quasistatic". The tendency to express physical connections in mathematical terms has adverse effects on the readability, particularly for the beginner who has not acquired perspective; unusual symbolisms (rot $\vec{R}$ = grad × $\vec{R}$) are partly to blame for this. The more experienced reader will turn gladly to this book for advice on presenting the axiomatics of thermodynamics.

Kl. Schäfer [NB 850 IE]

Differentialthermoanalyse (Differential Thermal Analysis). By *D. Schultze*. Verlag Chemie GmbH, Weinheim Bergstr. 1969. 1st Edit., 335 pp., 196 figs., 42 tables, plastic cover, DM 58.—.

Chemical changes of materials usually go hand in hand with thermal effects. Since thermal effects can be measured with a considerable degree of accuracy by modern electronic meth-

ods, the field of differential thermal analysis (DTA) has developed rapidly during the last 10 years, particularly in Anglo-Saxon countries and in the Soviet Union.

There has unfortunately not previously been any review in the German language that does justice to the importance of this method. The possible uses and the results had to be looked for tediously in the original papers in the most varied journals and in manufacturers' literature.

This gap is now closed by the monograph to be discussed here. After a concise historical introduction and an accurate explanation of the fundamental principles, the author describes the measuring equipment and the influence of the experimental parameters. He then considers the applications and so comes to the quantitative evaluation of DTA diagrams, where there is some unavoidable overlap with a similar discussion in the chapter on experimental conditions.

It is to be welcomed wholeheartedly that the author has compared the various theories and their fields of application clearly and critically. The last remnants of a previous prejudice that differential thermal analysis is a too empirical and somewhat inaccurate and uncritical method (this being due to its involving relatively complicated heat-conductivity relations as well as thermodynamics and reaction kinetics) have only been dispersed by the provision of a firm theoretical basis. It must, however, be emphasized that these objections do not apply to the liquid system studied by *Borchardt* and *Daniels*, and that, *e.g.*, contrary to the assumption on p. 74, the signal height can often be used for approximate calculation of the heat of reaction. In view of the sensitivity of modern methods of temperature measurement the possibility of working in solution is very attractive for the organic chemist.

The last part of the book gives a good impression of the varied applications of DTA and related methods, *e.g.*, to problems of metallurgy, mineralogy, semiconductor physics, the chemistry of complexes, organic chemistry (in particular that of high polymers and fuels), and the study of explosives and catalysis.

With its many instructive illustrations and tables and a comprehensive list of references, this book will offer much new information to the expert, and it is to be hoped that it will convince many non-expert readers that thermoanalytical methods are more generally applicable than might be assumed from glances at individual papers in the field.

E. *Koch* [NB 849 IE]

Chemie der Heterocyclen (Chemistry of Heterocycles). By *A. R. Katritzky* and *J. M. Lagowski*. Springer-Verlag, Berlin-Heidelberg-New York 1968, 1st Edit., xii + 183 pp., bound DM 48.—.

This book is intended as a textbook for the chemistry of heterocycles. It is divided into seven chapters. An introduction (chapter 1) is followed by an account of the chemistry of six-membered heterocycles (chapters 2 and 3). Chapter 4 deals with five-membered heterocycles. In chapter 6 the heterocyclic three- and four-membered rings are dealt with (5 pages) and in chapter 7 the physical properties of heterocyclic compounds (7 pages).

Each chapter is divided into a general part (nomenclature, occurrence, important individual compounds, schematic synthetic principle), and a special part (syntheses, reactivity, reactions). The production is careful; printing errors and errors of fact are rare. The extensive material is clearly and sensibly arranged, aided in particular by the many formulas and the fact that they can be easily traced by their consecutive numbering. Cross-references to other parts of the book are, however, not easy to trace; for example, page 25 would have been preferable to 2.II.C.2.c.2.

The authors have attempted to give a complete, logical survey of heterocyclic chemistry, and they have succeeded. But who will use the book? The student will be discouraged by the large number of isolated facts that are not essential for him. On the other hand, most reaction sequences are too briefly described (*e.g.* the azulene synthesis, p. 46). Also, there is often no mention of reaction conditions, even for important syntheses; and the chemist working in the field of heterocycles will feel the lack of references to original literature. For these reasons this book can be given only limited recommendation. *H. Ahlbrecht* [NB 852 IE]

Problems in Organic Reaction Mechanism. By *F. M. Menger*. From the "Appleton-Century-Crofts Series in Chemistry". Edited by *W. C. Agosta*. Appleton-Century-Crofts, New York 1969. 1st Edit., vii + 121 pp., numerous formulas, bound $ 2.95.

One often has to admire the ease with which Americans write books. The present work by *F. M. Menger*, however, has been compiled with such a light hand as to give the impression of being a set of lecture notes rather than a serious book.

The first part (19 pp.) contains formulas representing 55 organic reactions for which the student is required to state a reaction mechanism. Twenty-one examples are taken from the period 1956–1960, and 26 from 1961–1967.

The solutions to the problems are given in the second part. The examples are also intended to acquaint the student with some of the basic concepts of organic chemistry, such as resonance, tautomerism, electronegativity, acidity, reactive intermediates (carbonium ions, carbanions, free radicals, carbenes, arynes, *etc.*). Certain fundamental problems are discussed in greater detail in connection with the answers to the first 20 examples. Only formulas are given by way of solutions to examples 21—55.

Such an attempt to deal with the principles of organic chemistry in a few pages can scarcely hope to convey even a partial understanding of the many complex reactions involved. In other words, this "introduction" to organic chemistry, which takes up almost half of the book, could well have been left out altogether.

The presentation of the material lacks the diligence required in a book intended for the beginner. Apart from a whole series of misleading printing errors, one is annoyed by, for example, equations being written out in full for some reactions, while in other cases ions, atoms, or molecules that are added or split off have simply been omitted. Teachers will find the book useful for the references cited on pages 120 and 121. The shortcomings mentioned render it unsuitable for students. *F. Effenberger* [NB 844 IE]

Noble-Gas Chemistry. By *J. H. Holloway*. Methuen & Co. Ltd., London 1968. 1st Edit., xiii + 211 pp., numerous illustrations, bound 40s.

J. H. Holloway has written an excellent survey of the chemistry of noble gases.

Part I (29 pages) is devoted to the elements, and Part II (35 pages) to species (such as He_2^+) that are only known spectroscopically, clathrates, and biological effects (*e.g.* solubility of xenon in the blood).

Part III (101 pages) is divided into nine chapters concerned with the chemistry of noble gases proper, beginning with the history of their compounds. We then have chapters on binary fluorides (36 pages), oxides and oxide fluorides (28 pages), complex compounds, xenon chlorides, and compounds of krypton and radon. A separate chapter is devoted to the xenon compounds such as XeO_3 and XeF_6 which are dangerous from the point of view of explosion hazards: Chapter 8 deals with the chemical bonding in noble-gas compounds, and Chapter 9 with their use.

The very full bibliography, with but few gaps, merits special mention.

The numerous illustrations and tables enhance the value of this book, which combines experiment, theory, and individual results (including crystal structure and crystal chemistry). The reviewer has read it with considerable interest, and has formed the opinion that it will be found very useful by student and teacher alike.

R. Hoppe [NB 845 IE]

The Molecular Orbital Theory of Organic Chemistry. By *M. J. S. Dewar*. From the "McGraw-Hill Series in Advanced Chemistry". McGraw-Hill Book Corp., New York 1969. 1st Edit., xiv + 484 pp., numerous figures and tables, bound, approx. DM 74.—.

The book is highly ambitious right from the word go. It represents an attempt to derive organic chemistry from the principles of quantum mechanics. By bringing in such heavy artillery as *Dirac*'s Bra-Ket formalism in the very first chapter the author risks frightening away readers who would be quite capable of following the rest of the book. Quantum-chemical approximation methods are discussed in Chapter 2, semi-empirical methods of quantum chemistry in Chapter 3, and an outline of the theory of atoms and small molecules is presented in Chapter 4. Two-thirds of the book deals with the properties of organic molecules, *e.g.* their bond energies and their stability, as well as the problem of aromatic character (Chapter 5), and the mechanisms of chemical reactions (Chapter 8). The theory of UV spectra is deliberately omitted, but on the other hand we find something on the MO theory of electron spin resonance (Chapter 7). A separate chapter (9) is reserved for aromatic systems with heteroatoms, and finally, in Chapter 10, we are told something of the topical field of the quantum chemistry of σ-bonds.

As regards methods, the central position in the book is occupied by *Dewar*'s version (*i.e.* the one parametrized for properties of the ground states) of the semi-empirical Pariser-Parr-Pople method for π-electrons, abbreviated by the author to "Pople method", for the usefulness of which he adduces convincing comparisons from experiment and theory. However, the justification for the Pople method (in particular for the neglect of differential overlapping) is not entirely convincing. The Hückel MO (HMO) method is very elegantly derived from that of Pople, the derivation clearly revealing both the limitations and the possibilities of the HMO method (provided, of course, that one has previously allowed oneself to be persuaded of the admissibility of *Pople*'s approximations).

As an alternative to the Pople method the author offers a perturbation-theory simplification of the HMO method (called PMO), which makes use in particular of the properties of alternant hydrocarbons. This method is very neat and no doubt quite useful since it yields important results without computation, but it is not so straightforward as one might think after reading Chapter 6.

The book disposes of a number of traditional misconceptions, although the discussions sometimes tend to get out of hand.

One will not begrudge the author his tendency to highlight his own work, in many cases to excess, but he would have done better to resist the temptation to include the "SPO method", which can claim no more than historical interest either in its first or in its second formulation.

Despite any reservations that one may have on points of detail, one must in fairness admit that there exists no other textbook of theoretical organic chemistry on a comparable level.

Werner Kutzelnigg [NB 859 IE]

The Chemistry of the Nitro and Nitroso Groups. Part 1. Edited by *H. Feuer*. From the series "The Chemistry of Functional Groups". John Wiley and Sons Ltd., London-New York 1969. 1st Edit., xii + 771 pp., numerous formulas and tables, 281 s.

This book, the first of two volumes to be devoted to the nitro and nitroso groups, forms part of the series "The Chemistry of Functional Groups" edited by *S. Patai*. It contains nine chapters, written by a total of ten authors, on theoretical aspects of C—NO and C—NO_2 bonding, the spectroscopy and photochemistry of the two groups, the formation and the reactions of the nitroso group, the formation of aliphatic and alicyclic nitro compounds, of nitronic acids and esters, and of nitroamino groups. There is also a chapter on the activation of nucleophilic aromatic substitution by nitro groups. The introduction includes a summary of the chapters and authors of the still awaited second volume. Among other things, it indicates that the formation of aromatic nitro compounds, the effect of nitro groups on electrophilic and radical aromatic substitutions, and the Meisenheimer complexes of nitro compounds will be discussed only in this future volume. It can be seen that the final topic of the first volume fits more properly within the overall framework of the second. From remarks in the preface it may be gathered that this faulty arrangement of chapters is due to the late arrival of some of the manuscripts. In our opinion the publisher should have found a way of avoiding this fundamental weakness of multi-author publications. Since a critical discussion of the first (fragmentary) volume without a knowledge of the contents of the second volume would not be altogether fair to the authors whose contributions have already appeared, the review of the entire work will be held over until the publication of the second volume.

The Chemical Behavior of Active Nitrogen

By R. Brown and C. A. Winkler[*]

Active nitrogen, which is formed on passage of an electric discharge through a stream of nitrogen, is detected by a characteristic yellow afterglow. It can be determined quantitatively, e.g. by gas phase "titration" with nitric oxide. Active nitrogen reacts with many chemical elements, as well as with organic and inorganic compounds. Although nitrogen atoms are responsibe for many of the reactions of active nitrogen, electronically excited molecules also play a role.

1. Introduction

Morren, in 1865, first reported the now well-known yellow nitrogen afterglow that results when an electrical discharge is passed through molecular nitrogen [1]. Subsequently, *Lewis* confirmed its relatively long lifetime, and identified the banded spectrum of the emission with that of molecular nitrogen [2–4]. From 1911 to 1913, *Strutt* published several papers in which he showed that the glowing gas possesses a marked chemical reactivity, as a consequence of which he referred to it as active nitrogen [5–8]. He recognized that many of its properties could be attributed to nitrogen atoms. Since that time, however, the chemical activity has been ascribed also to such species as molecular nitrogen ions, and various electronically or vibrationally excited nitrogen molecules. Progress in resolving the resulting controversies was hindered for many years by uncertainties in the experimental values for the dissociation energy of ground state molecular nitrogen, and probably continues to be hindered by a greater sensitivity of active nitrogen systems to experimental conditions than has generally been recognized.

Mitra made a comprehensive review of the work on active nitrogen prior to 1945 [9]. The available information led him to suggest that the chemical activity of active nitrogen was due to N_2^+, but he later recognized that this was inconsistent with experimental evidence [10]. *Evans*, *Freeman*, and *Winkler* proposed a "unified" mechanism to account for the more significant experimental observations [11]. Data available at that time suggested that the lifetimes of *electronically* excited molecular species were too short for them to be important participants in the reactions. Consequently, it was concluded that, while nitrogen atoms are the predominant chemically active species in the yellow (Lewis-Rayleigh) afterglow, *vibrationally* excited ground state $N_2(X\,^1\Sigma_g^+)$ molecules might be responsible for certain reactions in which nitrogen atoms seemingly do not participate [12]. However, recent data on the lifetimes of electronically excited nitrogen molecules suggest that their participation could be significant [12a, 12b].

Subsequent reviews have examined the main spectroscopic and chemical features of active nitrogen [13–17]. The present discussion will, therefore, be directed largely to the information that has become available during the past few years. The discussion will be further limited to reactions involving uncharged nitrogen species in the region of the Lewis-Rayleigh afterglow. No attempt will be made to discuss more transient nitrogen afterglows and reactions of atomic and molecular nitrogen ions.

2. Experimental Methods

Most studies of the reactions of active nitrogen have been made in conventional, fast flow, low pressure (< 10 torr) systems of the type shown schematically in Figure 1. Comprehensive surveys of the methods applicable to such systems, and their limitations, have been made [18–20]. Generally, the active nitrogen is produced by either a microwave or a condensed DC discharge, although other methods, such as shock tube and vacuum ultraviolet photolysis [17a], have been tried with varying degrees of success [17]. It has been suggested that the reactions of N atoms can also be studied by γ-irradiation of dilute solutions of reactant in liquid nitrogen [20a, 20b].

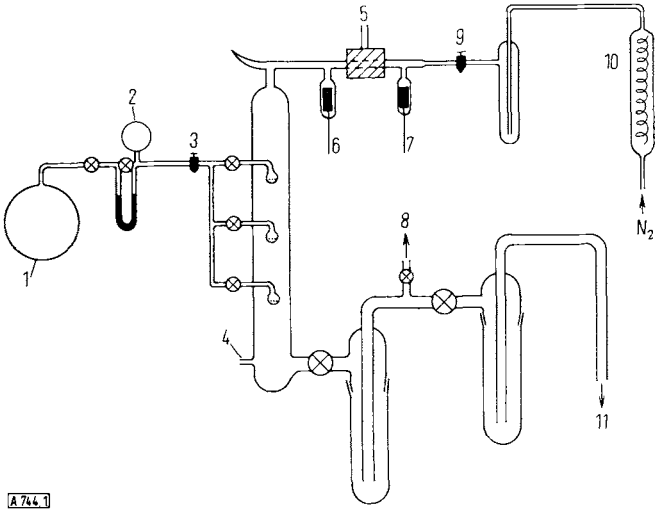

Fig. 1. Apparatus for production and investigation of active nitrogen. 1, storage. 2, calibrated volume. 3, flow control. 4, pressure gauge. 5, microwave source. 6 and 7, condensed discharge. 8, analysis. 9, flow control. 10, copper furnace. 11, vacuum.

The active nitrogen concentration is generally assumed to be given by the concentration of atomic nitrogen, and may be estimated by either physical or chemical methods. Such methods as ESR, mass spectrometry, and photometric measurements have the advantage of minimum interference with the actual system, but they generally do not give an absolute measurement of [N]. The measuring equipment is usually calibrated with reference to some chemical reaction, such as the gas phase "titration" with NO (see Section 4.2.1.) [15–17]. The method depends upon the very high rate of reaction of NO with N and certain well-defined color changes that occur essentially at the equivalence point.

It has also been proposed that the N atom concentration may be given by the maximum yield of HCN from the reaction of active nitrogen with C_2H_4 and some other hydrocarbons [21–28]. However, the value of [N] measured by the NO "titration" is usually considerably greater than that by the maximum HCN production from the hydrocarbons, *i.e.* a ratio NO/HCN >1 [29–31]. This discrepancy is probably due to complications in the hydrocarbon reactions [15, 32, 33].

A recent report that maximal HCN production might, under certain conditions, be greater than the amount of NO destroyed (NO/HCN <1) has now been shown to be due to back diffusion [17, 34]. It has been found that, with a system presumed to be "unpoisoned", back diffusion of reactants or products into the discharge zone, in amounts as little as one part in 5 million of N_2, may treble the production of N atoms. The problems associated with the estimation of the active nitrogen concentration have been discussed in detail elsewhere [15, 17].

3. The Nitrogen Afterglow

The Lewis-Rayleigh afterglow consists predominantly of certain bands of the first positive [*] system ($B\,^3\Pi_g \rightarrow A\,^3\Sigma_u^+$), together with some of the "Y" bands ($B'\,^3\Sigma_u^- \rightarrow B\,^3\Pi_g$). Despite many investigations, the

[*] The sign + or − as superscript describes the symmetry behavior on reflection in a plane through the symmetry axis of the molecule.

mechanism by which the afterglow is produced is not fully understood (c.f. earlier theories[14,17]). This is due, in part, to conflicting experimental evidence.

There seems to be general agreement that the intensity of the first positive bands is second order in [N], but the effect of total pressure is not as well understood[35–38]. "Pressure jump" experiments have shown that, at about 0.04 torr, the intensity is pressure dependent[39,39a,39b]. Recent evidence seems to indicate, however, that the intensity is independent of pressure at higher pressures, at least in the range 1 to 10 torr[35,36,38]. As the pressure is increased, there appears also to be a change from first to zero order dependence of the intensity on [M], the third body concentration[39]. *Gross* used a glow discharge shock tube to study the dependence of the intensity (I) on pressure (0.25–1.5 torr) and on temperature in the range 300 ° to 2400 °K[36]. He found

$$I = 0.60 \times 10^{-17} \left(\frac{T}{300}\right)^{-0.90} [\mathrm{N}]^2 \text{ photons cm}^{-3} \text{ sec}^{-1}$$

Berkowitz, Chupka, and *Kistiakowsky*[40] proposed that the afterglow is produced by

$$\mathrm{N}(^4\mathrm{S}) + \mathrm{N}(^4\mathrm{S}) + \mathrm{M} \rightleftarrows \mathrm{N}_2(^5\Sigma_g^+) + \mathrm{M} \quad (1)$$

$$\mathrm{N}_2(^5\Sigma_g^+) + \mathrm{M} \rightarrow \mathrm{N}_2(\mathrm{B}\,^3\Pi_g,\ v = 12) + \mathrm{M} \quad (2)$$

$$\mathrm{N}_2(\mathrm{B}\,^3\Pi_g) \rightarrow \mathrm{N}_2(\mathrm{A}\,^3\Sigma_u^+) + h\nu \quad (3)$$

The $\mathrm{N}_2(\mathrm{B}\,^3\Pi_g)$ state is assumed to be populated by predissociation from the $(^5\Sigma_u^+)$ state in a collision-induced radiationless transition.

Benson[41] has suggested that the production of the first positive emission depends upon the primary reaction

$$\mathrm{N}(^4\mathrm{S}) + \mathrm{N}(^4\mathrm{S}) \rightleftarrows \mathrm{N}_2^*(^5\Sigma_g^+) \rightleftarrows \mathrm{N}_2^*(\mathrm{B}\,^3\Pi_g,\ v = 12) \quad (4)$$

Assuming that the curve-crossing transition has a probability between 10^{-1} and 10^{-2}, this reaction represents an equilibrium between free N(4S) atoms and rotationally "hot" molecules in the twelfth vibrational level of the B state. No third body is required. The vibrationally "hot" B state molecules can decay to the $\mathrm{A}^3\Sigma_u^+$ state by radiation, or undergo some form of relaxation – rotational, vibrational, or electronic. *Benson* showed that, for the intensity to be independent of pressure, it is kinetically required that the relaxation processes be much faster than the radiation process. It seems reasonable that rotational relaxation should be rapid, especially at pressures $\geqslant$ 1 torr[42]. Vibrational relaxation would occur by a stepwise process, and might be relatively inefficient[43–45]. On the other hand, recent studies seem to indicate rapid electronic quenching of the B state molecules by ground state N_2 molecules ($k = 6.2 \times 10^{-11}$ cm^3 molec^{-1} s^{-1})[39,46–48]. *Young* and co-workers have determined the quenching efficiencies of various gases for $\mathrm{N}_2(\mathrm{A}\,^3\Sigma_u^+)$ and $\mathrm{N}_2(\mathrm{B}\,^3\Pi_g)$[48a]. The Stern-Volmer type quenching of the B state by added gases can also be explained by this mechanism[35,38,49–52].

A somewhat similar mechanism for the production of the nitrogen after-glow, based on a collision induced population of the $\mathrm{B}\,^3\Pi_g$ state from the $\mathrm{A}\,^3\Sigma_u^+$ state, was proposed by *Campbell* and *Thrush*[38]. *Benson* pointed out, however, that the proposed population of $\mathrm{B}\,^3\Pi_g$ levels by collision from the $\mathrm{A}\,^3\Sigma_u^+$ level is inconsistent with the kinetic aspects of afterglow production[41]. This conclusion has been disputed by *Jonathon* and *Petty*[39b] in their study of the pressure dependence of the nitrogen afterglow. It has also been suggested that oxygen interacts with vibrationally excited $\mathrm{N}_2(\mathrm{A}\,^3\Sigma_u^+)$ to produce $\mathrm{N}_2(\mathrm{B}\,^3\Pi_g)$[52a].

The absence of the Vegard-Kaplan bands (*i.e.* $\mathrm{A}\,^3\Sigma_u^+ \rightarrow \mathrm{X}\,^1\Sigma_g^+$) in the nitrogen afterglow has been of considerable interest, since the $\mathrm{A}\,^3\Sigma_u^+$ state is continually populated by the first positive system. The Vegard-Kaplan bands have recently been detected in systems containing a large concentration of $\mathrm{A}\,^3\Sigma_u^+$ molecules in the absence of significant quantities of nitrogen atoms[53,54]. They have also been detected in the absorption spectrum of N_2[54a]. The emission was

destroyed by addition of nitrogen atoms [53]. This is consistent with a rapid reaction

$$N_2(A\,^3\Sigma_u^+) + N(^4S) \rightarrow N_2(X\,^1\Sigma_g^+) + N(^4S) \quad (5)$$

The rate constant at room temperature was estimated to be $k_5 = 5 \times 10^{-11}$ cm^3 particle^{-1} s^{-1}. Indirect proof for the occurrence of this reaction has been obtained from beam studies [55] and from mercury emission in an active nitrogen stream [56].

It has been pointed out that the reverse reaction can also occur [57], with a rate constant estimated from shock tube studies to be $k_{-5} = 1.9 \times 10^{-6}\ T^{-3/2}$ exp $(-142\ \text{kcal}/RT)$ cm^3 particle^{-1} s^{-1} [57a]. By combining these results with data from an earlier study by *Noxon* [58], a value has been calculated for k_5 that is in excellent agreement with the experimentally determined value [59].

4. Chemical Reactions of Active Nitrogen

Since studies of the reactions of active nitrogen prior to 1967 have already been extensively reviewed [17], the present discussion will be concerned primarily with progress since that time.

4.1. Recombination of Nitrogen Atoms

Of the reactions that may involve atoms produced by the gas phase dissociation of a stable diatomic molecule, the simplest is their recombination, either heterogeneously or by a three-body homogeneous process.

4.1.1. Heterogeneous Recombination

At low pressures (< 1 torr) in glass vessels, the heterogeneous recombination of nitrogen atoms becomes a significant factor in active nitrogen reactions [15, 60]. Its extent may be largely reduced by a strong "poisoning" by trace impurities in the nitrogen stream, or by coating the walls with a suitable "poison", such as phosphoric acid.

Early studies indicated that the heterogeneous recombination process was probably first order in [N] [61–63]. The values obtained for the first order rate constant varied from 4.0 s^{-1} to 4.2×10^{-2} s^{-1} for an unheated, clean glass surface [30, 64]. The corresponding value of γ, the recombination coefficient, varied between 10^{-4} and 10^{-5} for glass surfaces.

More recently, *Campbell* and *Thrush* have applied photometric methods to a flow system and found that the heterogeneous recombination is a second order process, with $k = 7.3 \times 10^{-16}$ cm^3 molec^{-1} s^{-1} [38]. Their observations have been confirmed by *Clyne* and *Stedman*, who found that two heterogeneous recombination processes may occur [65]. One of these is first order and predominates for low [N]. The other is second order in [N], and predominates in an unheated, clean pyrex vessel. Under such conditions, however, the first order process was appreciable at 90 °K and 611 °K, and the second order wall reaction could be virtually eliminated in an unheated vessel by coating the wall with phosphoric acid.

It is found, in general, that metal surfaces are more efficient than glass in promoting heterogeneous recombination [17]. The value of γ for metals can be fitted to the expression $\gamma = a/(bP + c)$, where P is the pressure and b and c depend on the surface [66]. Thus, for clean Mo sputtered on a glass surface, γ decreases from 0.22 at 0.09 torr to 0.04 at 1.35 torr [60]. The high efficiency of metals or their oxides, especially "spongy" cobalt and copper oxide, in causing heterogeneous N atom recombination has made them useful in the preparation of surfaces to terminate gas phase reactions [67].

4.1.2. Homogeneous Recombination

It is generally accepted that the homogeneous recombination of nitrogen atoms is a termolecular process

$$N + N + M \rightarrow N_2 + M \quad (6)$$

Homogeneous recombination has special importance as a major source of electronically excited nitrogen molecules, the precursors of the nitrogen afterglow. At pressures greater than about 3 torr, the rate of homogeneous recombination largely determines the rate of nitrogen atom disappearance.

Clyne and *Stedman* have recently followed the disappearance of N atoms by gas phase "titration" with NO, making an appropriate correction for the heterogeneous recombination [65]. They estimated a termolecular rate constant of $k_6 = 0.96 \times 10^{-32}$ cm^6 molec^{-2} s^{-1}. By combining their results with earlier data, they showed that the temperature variation of k_6 was given by the simple Arrhenius expression, with $A = 10^{-32.81}$ cm^6 molec^{-2} s^{-1} and $E = 1000$ cal mole^{-1} [38, 68, 69].

[69] *B. Cary*, Physics of Fluids *8*, 26 (1965).

It is interesting that the mechanism proposed by *Benson* for the first positive emission is not consistent with the third order kinetics observed for the homogeneous recombination of N atoms. This seems to suggest that reactions leading to first positive emission are of minor importance relative to the total extent of homogeneous recombination. This observation is supported by calculation of the relative rates of photon emission [36] and termolecular recombination [65] which show only one photon emitted as a consequence of 51 recombinations at 1 torr and 300 °K.

The variation in rate of recombination with change in M, the third body, has not yet been reliably determined. This is partly due to the fact that in such studies the intensity of afterglow emission has been used as a measure of N atom concentration. This is probably not a reliable method because a change in M can cause a change in intensity due to a shift in relative importance of the relaxation processes and the radiation process in afterglow production. It is well known that NH_3 and CH_4, for example, strongly quench first positive emission, presumably by rapid electronic quenching of one of the precursors of the afterglow [35, 38, 51, 70]. On the other hand, Ar and He increase the emission from the vibrational levels ($v < 12$) in the B state because of fast vibrational quenching [35, 43]. With Ar as a third body, the recombination rate appears to be unchanged [38], although a recent shock tube study of the reverse reaction [71]

$$N_2 + M \rightarrow 2\,N + M \qquad (7)$$

showed that the relative efficiencies of N, N_2, and Ar as third bodies are in the ratio 1 : 4.4 : 12. The rate of N atom production was obtained from vacuum UV absorption.

4.2. Inorganic Reactants

4.2.1. Nitric Oxide

Of all the reactions of active nitrogen with either inorganic or organic reactants, that with NO is perhaps best understood. The primary reaction of active nitrogen with NO almost certainly involves N atoms:

$$N + NO \rightarrow N_2 + O; \quad \Delta H^0 = -75 \text{ kcal mole}^{-1} \qquad (8)$$

This reaction probably occurs on an attractive potential energy surface since the heat of reaction seems to appear mainly as vibrational energy in the nitrogen produced [72–75]. It has been suggested that the infrared chemiluminescence that accompanies this reaction comes from NO excited by vibrationally excited N_2 [75a]. Reaction (8) has little or no activation energy, and proceeds at close to collision rates ($k_8 = 2 \times 10^{-11}$ cm^3 molec^{-1} s^{-1}) [76–79]. Because of its simplicity, this reaction has been used as a source of O atoms, especially when the presence of excess O_2 may cause undesirable complications [80].

When [NO] < [N], there is complete reaction of the available NO. Unreacted N atoms then react with O atoms produced in reaction (8), with emission of the β and γ bands of NO:

$$N + O + M \rightarrow NO^* + M \qquad (9)$$

$$NO^* \rightarrow NO + h\nu \qquad (10)$$

The emission may range in color from purple to blue as the concentration of N atoms decreases relative to that of O atoms.

The rate constant of reaction (9) at room temperature has been estimated to be $k_9 = 1.1 \times 10^{-32}$ cm^6 molec^{-2} s^{-1} [81, 82]. It has been reported that a sensitive measure of the N atom concentration can be obtained from the intensity of the β bands [38, 81]. Direct estimates of [N] have recently been made possible from a determination of the variation of the absolute intensity of the β, γ, and δ bands with temperature and pressure [83].

When [NO] is greater than [N], the N atoms are rapidly and completely consumed. The resulting O atoms then react with the excess NO:

$$NO + O + M \rightarrow NO_2^* + M \qquad (11)$$

The greenish-yellow NO_2 bands of the "air afterglow" are then emitted by a mechanism which is not yet fully understood [84].

At the equivalence point, *i.e.* [NO] = [N], reactions (9) and (11) are not possible, and there is no emission. Accordingly, a gas phase "titration" to this dark endpoint makes is possible to estimate [N] by visual or photometric methods. The results agree well with those obtained from maximum destruction of NO [29].

Fontijn and *Vree* have observed that chemi-ionization and formation of electronically excited species (such as NO(A $^2\Sigma$, B $^2\Pi$) and O(^{1}S)) is catalyzed by addition of certain carbon-containing compounds to systems containing N and O atoms [85]. As a result, the intensity of certain bands in the NO system is increased,

and the authors warn that "caution should be exercised in the use of the NO afterglow intensity for atom concentration measurements in the presence of a third reactant" [86].

4.2.2. Nitrogen Dioxide

To explain the experimental features of the fast reaction of active nitrogen with NO_2, it has been postulated that four primary reactions occur simultaneously [87]:

$$N + NO_2 \rightarrow N_2O + O \quad (43\%) \qquad (12)$$

$$N + NO_2 \rightarrow 2\,NO \quad (33\%) \qquad (13)$$

$$N + NO_2 \rightarrow N_2 + 2\,O \quad (13\%) \qquad (14)$$

$$N + NO_2 \rightarrow N_2 + O_2 \quad (10\%) \qquad (15)$$

The rate constant for removal of NO_2 by N atoms at room temperature was estimated to be $k = 1.85 \times 10^{-11}$ $cm^3\ molec^{-1}\ s^{-1}$. A study of the emission from the N_2O formed by reaction (12) showed that the bending mode ν_2 is not excited but the stretching modes ν_1 and ν_3 are vibrationally excited [88]. This seems to suggest that the reaction occurs on a repulsive potential energy surface.

4.2.3. Other Oxides of Nitrogen

Unlike the reactions of active nitrogen with NO and NO_2, the corresponding reactions with N_2O and with N_2O_5 are extremely slow. Mass spectrometric studies indicate that the rate constant for the reaction of N_2O_5 is $\leqslant 10^{-15}$ cm^3 $particle^{-1}$ s^{-1} [89].

The reaction of active nitrogen with N_2O does not appear to involve N atoms. The slight reaction that is observed has been attributed to reaction with electronically excited N_2 molecules, either in the $B\ ^3\Pi_g$ or the $A\ ^3\Sigma_u$ state [90, 91]. N_2O seems to be particularly effective as a third body for relaxation of vibrationally excited N_2 molecules [72, 73, 92, 92a]. It has been pointed out by *Rubin* that the cross-section for vibrational deexcitation of N_2 by N_2O, measured by *Morgan* and *Schiff*, was actually a cross-section for two processes [73, 93]

$$N_2(v = 1) + M \rightarrow N_2 + M + \text{kinetic energy} \qquad (16)$$

$$N_2(v = 1) + M \rightarrow N_2 + M^* \qquad (17)$$

followed by

$$M^* + N_2 \rightarrow M + N_2 + \text{kinetic energy} \qquad (18)$$

A rapid reaction of N atoms with NOCl has been reported recently [93a].

4.2.4. Hydrogen

Campbell and *Thrush* have studied the reaction of H_2 in a system containing both N and O atoms, produced by a partial "titration" of active nitrogen with NO [94]. Since no primary reaction is observed when H_2 is added to active nitrogen, the initial reaction in this system can be attributed to the reaction of O atoms with H_2 [95]:

$$O + H_2 \rightarrow OH + H \qquad (19)$$

From photometric measurements of the rate of consumption of O and N atoms, they were able to show that the rate of

$$N + OH \rightarrow NO + H \qquad (20)$$

is 1.4 times the rate of the corresponding reaction of O atoms.

4.2.5. Oxygen and Ozone

N atoms react with O_2 by [97, 98]

$$N + O_2 \rightarrow NO + O \qquad (21)$$

NO_2 and N_2O were also obtained as products [96]. The rate of reaction (21) at room temperature has been estimated to be $k_{21} \approx 1 \times 10^{-16}$ $cm^3\ molec^{-1}$ s^{-1} and has an activation energy of about 7 kcal $mole^{-1}$ [97–101, 101a]. It is interesting to note that N atoms react much more rapidly with $O(^1\Delta_g)$ than with ground state O_2 [101b].

The overall reaction of N atoms with O_3 has been postulated to be [78]

$$2\,N(^4S) + O_3 \rightarrow N_2 + O_2 + O(^3P) \qquad (22)$$

The rate of this reaction at room temperature has been estimated as $k_{22} = 5.7 \times 10^{-13}$ cm^3 molec^{-1} s^{-1} [78]. Although upstream addition of N_2O does not affect the O_3 reaction, about 75% of the N_2^* formed by reacting N atoms with NO are capable of destroying O_3 [74, 78].

4.2.6. Phosphorus

The reaction of active nitrogen with white phosphorus is fast ($k \simeq 2 \times 10^{-13}$ cm^3 molec^{-1} s^{-1}) and produces nitrogen-phosphorus polymers [102]. The P/N ratio of the polymeric product was found to vary with the relative concentrations of reactants. The N atom flow rate inferred from the amount of nitrogen incorporated into the polymer agreed well with that estimated by the NO "titration".

4.2.7. Ammonia and Hydrazine

The high activation energy ($\geqslant 17$ kcal mole^{-1}) thermodynamically required for hydrogen abstraction from NH_3 by N atoms makes its occurrence highly improbable. This is supported by mass spectrometric studies, which indicate that N atoms are not consumed in the presence of NH_3 [103]. It has been suggested, therefore, that the observed decomposition of NH_3 by active nitrogen [15, 17] is due to energy transfer from electronically excited nitrogen molecules.

Because of its relatively long lifetime, $N_2(A\,^3\Sigma_u^+)$ has frequently been postulated as the species responsible for the destruction of ammonia [104–106]. However, since the nitrogen afterglow may be quenched by NH_3, it is possible that a precursor of the afterglow, $N_2(^5\Sigma_g^+)$ or $N_2(B\,^3\Pi_g)$, might be involved [15], and that destruction of NH_3 might be represented as

$$N_2^* + NH_3 \rightarrow NH + 2\,H + N_2 \qquad (23)$$

followed perhaps by

$$NH + H \rightarrow H_2 + N \qquad (24)$$

$$NH + N \rightarrow N_2 + H \qquad (25)$$

Apparently, the reaction

$$NH + NH \rightarrow N_2 + 2\,H \qquad (26)$$

does not occur since $^{14}N^{15}N$ is produced exclusively during the reaction of ^{14}N active nitrogen with $^{15}NH_3$ [105]. Reaction (26) has been postulated to account for the rapid disappearance of NH radicals during gas phase radiolysis of NH_3, but the possible contribution of reaction (24) was not considered [107].

The fact that the N atom concentration remains virtually unchanged when NH_3 is added to active nitrogen might imply that reactions (24) and (25) occur to approximately the same extent. Since [H] < [N], it would follow that $k_{24} > k_{25}$.

When H atoms are added to excess active nitrogen, NH_3 is produced in amounts directly proportional to [H] [108]. Moreover, $NH(A\,^3\Pi \rightarrow X\,^3\Sigma^-)$ emission occurs during this reaction, which shows that NH radicals are present as an intermediate [109, 110]. Hence, the reaction

$$N + H \xrightarrow{M} NH \qquad (27)$$

must compete favorably with reactions (24) and (25). Further evidence for the importance of such a reaction is provided by the production of NH_3 during the reaction of active nitrogen with C_2H_4, where it is appreciable only when $[C_2H_4] < [N]$ [32].

Kinetic studies of the active nitrogen-NH_3 reaction indicate that it is not truly first order in $[NH_3]$ and tends to zero order as $[NH_3]$ is increased [104, 111]. This might be a "pseudo" zero order behavior with NH_3 in large excess if N atoms are continually regenerated as in reaction (24). It is also possible, however, that the reaction is partially heterogeneous, comparable with that observed at −196 °C [112].

The rate constant for the reaction of N atoms with N_2H_4, to produce NH_3 and H_2 [112a], has been estimated as 1.2×10^{-13} cm^3 molec^{-1} s^{-1} at 298 °K [34, 112b].

4.2.8. Phosphine

The reaction of active nitrogen with the phosphorus analog of NH_3, *i.e.* PH_3, is probably a reaction of N atoms [113]. The strength of the H_2P-H bond is such that H atom abstraction is thermodynamically possible, *i.e.*,

$$N + PH_3 \rightarrow NH + PH_2 \qquad (28)$$

The main products of the reaction are H_2 and the α-form of $(PN)_n$. No red phosphorus is formed.

4.2.9. Sulfur and Compounds of Sulfur

Although the reactions of active nitrogen with sulfur and with the various compounds of sulfur have been rather extensively studied, the formation of solid, polymeric products has tended to make interpretation of the results difficult. A great deal of spectroscopic work has been done on the reactions of active nitrogen with sulfur [5, 6, 114–124], CS_2 [6, 114, 125–128], H_2S [6, 123, 127, 129–132], SCl_2 [133–135, 135a], and S_2Cl_2 [8, 132, 135a, 136] (and also on $SeCl_4$ [134, 135, 137, 138]).

Spectroscopic studies clearly show that the NS radical is formed as an intermediate during the reaction of active nitrogen with sulfur. Various nitrides of sulfur, including $(NS)_x$ polymer, have also been identified as reaction products [136, 139].

Since S_8 is one of the products of the reaction of active nitrogen with H_2S it is not surprising that $(NS)_x$ polymer is also found as a product of this reaction [127, 136]. Other products identified were NH_3, S_7NH [136], and H_2.

Polymeric $(NS)_x$ is the only nitrogen-containing product that has been identified among the products of the reaction of active nitrogen with CS_2 and with COS [136]. A black polymer, resembling paracyanogen, was also formed during the CS_2 reaction [127], in accord with the spectroscopic observation of certain emissions of the CN system [126].

It has been found that N atoms react rapidly with SO, ($k = 0.8 \times 10^{-12}$ cm^3 molec^{-1} s^{-1} at room temperature), to form NO and S [140, 140a]. A similar, but slower O atom abstraction, ($k = 5.4 \times 10^{-16}$ cm^3 molec^{-1} s^{-1} at room temperature), occurs when N atoms react with SO_3 to form SO_2 and NO [140]. The SO_2 molecule appears to be too stable to be directly attacked by N atoms. However, a limited decomposition of SO_2, somewhat analogous to the NH_3 reaction, has been observed under appropriate conditions [140, 141]. It has been suggested that this is due to energy transfer from an electronically excited nitrogen molecule, since ESR measurements have indicated no decrease in [N] when SO_2 is added to active nitrogen [142, 143].

The reaction of active nitrogen with $SOCl_2$ was found to yield NOCl, N_2O, SO_2Cl_2, Cl_2, and small amounts of sulfur [136]. No sulfur nitrides could be detected. The main products of the reaction with the chlorides of sulfur, SCl_2 and S_2Cl_2, were NSCl and Cl_2 [136].

4.2.10. Oxides of Carbon

The interaction of active nitrogen with CO and CO_2 has received special attention recently because of the observed laser action in these systems. (The exchange of energy from vibrationally excited $N_2(X\,^1\Sigma_g^+)$ molecules to CO, CO_2, N_2O and similar molecules has been considered in detail elsewhere [92, 93, 144–150]).

Avramenko and *Krasnen'kov* have reported a rate constant, $k_{29} = 3.2 \times 10^{-13} \exp(-3.4\ \text{kcal}/RT)$ cm^3 molec^{-1} s^{-1}, for the reaction [151]

$$N + CO_2 \rightarrow NO + CO \qquad (29)$$

The production of NO, as well as $^{13}N-N$ and N_2O, was also reported to occur as a result of the reaction of recoil ^{13}N with CO_2 [152]. However, this is in disagreement with the observed laser action, which is not accompanied by CO_2 decomposition. Moreover, earlier studies reported only slight decomposition of CO_2 that appeared to be a result of a reaction with electronically excited nitrogen molecules [90, 91]. In an attempt to resolve this discrepancy, *Herron* and *Huie* have reinvestigated this reaction, using a mass spectrometer to follow reactant concentrations [153]. They were unable to detect any reaction at room temperature and concluded that $k_{29} \leqslant 1.7 \times 10^{-16}$ cm^3 molec^{-1} s^{-1}.

It has been suggested that the disagreement might be due to considerable heterogeneous reaction under the conditions used by the Russian workers [18]. This is perhaps also indicated by their report that the rate of the reaction of active nitrogen with H_2 to produce NH_3 is independent of temperature [154]. As mentioned earlier, other workers have been unable to detect any reaction with H_2 [94, 108].

A mass spectrometric study indicated only relatively small decomposition of C_3O_2 by active nitrogen (at room temperature $k = 2.3 \times 10^{-15}$ cm^3 molec^{-1} s^{-1}) to produce "dicyanogen" as the only detected gas phase product [155]. Intense emissions from the CN red and violet systems accompanied the reaction.

4.2.11. Halogens and Halogen Acids

Much of the present knowledge of the reactions of active nitrogen with halogens can be attributed to studies by *Phillips* and co-workers. In general, no stable products are formed, although N atoms do disappear, possibly by the sequence [57, 156–160]

$$N + X_2 \rightarrow NX + X \quad (30)$$

$$NX + N \rightarrow N_2^* + X \quad (31)$$

It might be expected, and spectroscopic data suggest, that the efficiency of the halogens in promoting recombination of N atoms follows the order $I_2 > Br_2 > Cl_2$.

A kinetic analysis has been made of the vacuum ultraviolet emissions observed during the reaction of active nitrogen with IX compounds (X = I, Br, Cl, or CN). The results indicate that, in certain cases at least, the N_2^* produced in reaction (31) was $N_2(^3\Delta_u)$ [57]. An analysis of energy requirements suggested that this state has an energy of 185 ± 3.5 kcal mole^{-1}. This value is considerably greater than that (171 kcal mole^{-1}) derived from a direct spectroscopic measurement of $^3\Delta_u \rightarrow B\,^3\Pi_g$ transition [161].

From a study of infrared emission, *Phillips* has shown that the intensity of the first positive bands increases markedly with addition of trace amounts of I_2 [162]. This effect has also been observed when other reactants, such as O_2, CH_4, and C_2H_4, are added to an active nitrogen stream [51].

A mass spectrometric study of the reaction of active nitrogen with Cl_2O indicated a rapid reaction of N atoms [163]. For long reaction times and $[Cl_2O] = 5[N]$ the ratio of Cl_2O consumed to N consumed was 0.93 ± 0.10. A rate constant at room temperature, $k_{32} = 9.1 \times 10^{-12}$ cm^3 molec^{-1} s^{-1}, was estimated for the postulated primary attack by N atoms:

$$N + Cl_2O \rightarrow NCl + ClO \quad (32)$$

The final products contained N_2, O_2, and Cl_2, but not NO. Similarly, a spectroscopic study of the reaction of active nitrogen with ClO_2 gave no evidence for the reaction [164]

$$N + ClO_2 \rightarrow NO + ClO \quad (33)$$

The reactions of active nitrogen with the halogen acids HI, HBr, and HCl clearly show the importance of bond energy in determining the course of a reaction. Both HI and HBr react quite readily, probably according to [165–168]

$$N + HX \rightarrow NH + X \quad (34)$$

to give free halogen and the ammonium salts, NH_4I and NH_4Br, respectively. Addition of Br_2 or H_2 during the HBr reaction causes a decrease in the rate of HBr destruction.

However, for HCl, reaction (34) would be highly endothermic and direct attack by N atoms is not likely [25]. Only slight decomposition of HCl to produce H_2 and Cl_2 is observed. It is possible that this is due to energy transfer from excited N_2, or, alternatively, to the catalyzed recombination of N atoms

$$HCl + N \rightarrow [HCl \cdot N] \xrightarrow{N} N_2 + H + Cl \quad (35)$$

The addition of small amounts of HCl to reactions of active nitrogen with hydrocarbons, *e.g.*, CH_4 or C_2H_6, has been found to increase markedly the HCN production from such reactions [32,169]. There is no net consumption of HCl. The probable mechanism is

$$Cl + RH \rightarrow R + HCl \quad (36)$$

followed by a rapid reaction

$$R + N \rightarrow HCN + R' \quad (36a)$$

4.2.12. Hydrogen Cyanide and Cyanogen

Both HCN and $(CN)_2$ are too strongly bonded to be attacked directly by N atoms. Thus, any apparent reaction is probably the result of a reaction with excited N_2 molecules.

Only slight decomposition of HCN by active nitrogen appears to occur, to produce H_2 and $(CN)_2$ [142,170]. Although it has been reported that the addition of HCN to active nitrogen does not significantly decrease the N atom concentration [142], it has been found that upstream addition of HCN greatly decreases the ability of active nitrogen to react with CH_3Cl [171].

The decomposition of $(CN)_2$ by active nitrogen produced large quantities of a black polymer on the walls of the reaction vessel [172]. A substance with $m/e = 76$, corresponding to $C_2(CN)_2$, was also formed [142]. Addition of H_2 or CH_4 to the reaction mixture was found to yield HCN [172].

The $(CN)_2$ reaction is probably initiated by $N_2(A\,^3\Sigma_u^+)$ [143] and might involve C atoms in its overall mechanism [170]:

$$(CN)_2 + N_2^* \rightarrow N_2 + 2\,CN \quad (37)$$

$$CN + N \rightarrow N_2 + C \quad (38)$$

$$C + (CN)_2 \rightarrow C_2N + CN \quad (39)$$

$$C_2N + N \rightarrow 2\,CN \quad (40)$$

The reaction is inhibited by certain additives [173], the relative efficiencies of which ($O_2 \gg CH_4 > N_2O > CO > CO_2 > SF_6$) might reflect their competitive reactions with either CN or C, *e.g.*,

$$CH_4 + CN \rightarrow CH_3CN + H \quad (41)$$

$$CH_4 + CN \rightarrow HCN + CH_3 \quad (42)$$

$$C + O_2 \rightarrow CO + O \quad (43)$$

The addition of O atoms favors the reaction and intensifies CN emission.

4.2.13. Metals and Metallic Compounds

The effects of adding metals to an active nitrogen stream in the region of the Lewis-Rayleigh afterglow have been studied in considerable detail [17]. Nitride formation has been observed with some metals, *e.g.*, Hg, K, or Ca [174,175]. However, emission from excited metal atoms is a much more general result. From studies of these emission, early workers made estimates of the energy content of active nitrogen. Active nitrogen has also been used for many years as a low energy source for excitation of line and band spectra of many molecules [5,176]. The production of Ba^+ when Ba is added to active nitrogen at 1125 °K suggests that N_2^+ is responsible for this reaction [176a].

Reactions of the more volatile metal halides with active nitrogen are usually accompanied by emissions from excited metal atoms [17], probably as a result of a collision with an electronically excited nitrogen molecule, perhaps in the $(^5\Sigma_g^+)$ state [176,177].

The enhancement of the first negative system of N_2, and Na line emission, have been observed during the reaction of active nitrogen with anhydrous Na_2SO_4 [178] The enhancement of the first negative system of N_2 and Na line emission, have been observed during the reaction of active nitrogen with anhydrous Na_2SO_4 [178]. These observations suggest simultaneous production of a neutral Na atom and a N_2^+ ion.

The reactions of active nitrogen with metal carbonyls result in a rapid, stepwise degradation of the carbonyls by the reaction [49]

$$M(CO)_n + N \rightarrow M(CO)_{n-1} + NCO \quad (44)$$

These reactions are accompanied by intense metal atom emission.

The reactions of active nitrogen with organometallic compounds have received only limited attention. In the temperature range 130 to 330 °C, a rapid, temperature-independent production of HCN was observed during the reaction of active nitrogen with $Hg(C_2H_5)_2$ [179]. It was suggested that the HCN resulted from a reaction of N atoms with C_2H_5 radicals, the presence of which was indicated by the production of small amounts of saturated hydrocarbons.

Both HCN and NH_3 (more HCN than NH_3) were obtained as products of the reaction of active nitrogen with methyl silanes [180,181]. Maximum HCN production increased with increase in temperature. Similarly,

the main product of the reaction of active nitrogen with $[(CH_3)_2SiO]_7$ was also HCN [182].

Spectroscopic studies of the reactions of active nitrogen with certain organometallic compounds suggest that transfer of energy from an electronically excited nitrogen molecule causes dissociation of the organometallic compound, and excitation of the products [183, 184]. The observed emissions from the excited metal atoms and from vibrationally excited CN suggest that the species concerned might be $N_2(^5\Sigma_g^+)$.

4.3. Organic Reactants

The reactions of active nitrogen with organic compounds have been reviewed in some detail a number of times [11, 15–17]. In general, the qualitative features of these reactions are fairly well understood, but relevant kinetic data are limited and the mechanisms that have been proposed are still dubious.

4.3.1. Alkenes

The reactions of active nitrogen with alkenes have been studied in considerable detail. They are of particular interest as a basis for much of our present knowledge of the reactions of active nitrogen with organic compounds. Until quite recently, the olefins, especially ethylene, were used as a chemical titrant for N atoms and have, therefore, been of special interest.

When alkenes are allowed to react with active nitrogen, HCN is rapidly formed as a major product. The amounts of alkene reacted and HCN produced increase linearly at first, then reach a constant ("plateau") value as the flow of alkene is increased [23, 185, 186]. For alkenes, this "plateau" value is generally independent of temperature. Similar behavior is observed for the active nitrogen reactions with many organic compounds. The attainment of such a temperature-independent "plateau" for HCN production from the olefins prompted the suggestion that it represented a measure of the N atom concentration in the system.

Although HCN generally constitutes more than 95% of the N-containing products from reactions of active nitrogen with alkenes, appreciable quantities of CH_3CN and $(CN)_2$ are also formed [187–190]. When [N] > [alkene], NH_3 production may also be significant [32]. Small quantities of CH_4, C_2H_6, C_2H_2, and possibly a C_3 hydrocarbon, are also found as products of the reaction of active nitrogen with C_2H_4 [23, 187].

The reaction with propene produces significant quantities of C_2H_4 as well as smaller amounts of C_2H_6 and C_3H_8 [187, 188, 190, 191]. Experiments with labeled C_3H_6 showed that some of the C_3H_6 recovered is resynthesized from hydrocarbon fragments produced during the reaction with active nitrogen [189].

In the reactions of active nitrogen with the butenes, the same "plateau" value for HCN was observed, but whereas butane is the main hydrocarbon product of the reaction with isobutene, both 1-butene and *cis*-2-butene produce mainly C_2 and C_3 hydrocarbons [*] [192].

The reactions of active nitrogen with alkenes are moderately fast ($k \geqslant 10^{-14}$ cm^3 molec^{-1} s^{-1} at room temperature) and have low activation energies ($E < 2$ kcal mole^{-1}) [187, 193, 194].

Rate constants for the reaction of active nitrogen with C_2H_4 have recently been calculated from photometric measurements of the intensities of the first positive and second positive systems of the nitrogen afterglow [195]. The value found from the second positive emission was about six times that estimated from the first positive emission. Although the significance of these results was not discussed the difference might be due to different rates of reaction of $N(^4S)$ and $N(^2D)$ with ethylene, as reported earlier [196].

A "unified" mechanism of the type

$$N + C_2H_4 \rightarrow [C_2H_4N] \quad (45)$$

$$N + [NC_2H_4] \rightarrow N_2 + C_2H_4 \quad (46)$$

$$[NC_2H_4] \rightarrow HCN + CH_3 \quad (47)$$

$$N + CH_3 \rightarrow HCN + 2\,H \quad (48)$$

was first proposed to explain the main features of these reactions [11]. More recently, *Herron* has suggested that the discrepancy between the N atom concentration measured by the NO "titration", and that inferred from the C_2H_4 reaction, may be explained by a mechanism that involves H atoms as an essential component [33], *e.g.*,

$$H + C_2H_4 \rightarrow C_2H_5 \quad (49)$$

$$N + C_2H_5 \rightarrow NH + C_2H_4 \quad (50)$$

$$H + C_2H_5 \rightarrow 2\,CH_3 \quad (51)$$

$$N + NH \rightarrow N_2 + H \quad (25)$$

$$N + CH_3 \rightarrow HCN + 2\,H \quad (52)$$

A loss of N atoms might be expected from reaction (50) followed by reaction (25).

Safrany and *Jaster* studied the effect of adding H atoms from a second discharge to the active nitrogen-ethylene reaction [32]. They found that the maximum HCN produced under these conditions is in essential agreement with the NO "titration" made in the presence of the added H atoms, which probably catalyze N atom recombination (see below). This would be in qualitative agreement with *Herron*'s mechanism since the addition of H atoms would favor reaction (51) and thus increase HCN production. They also found that, assuming CH_4 to be produced from CH_3 radicals and C_2H_6 from C_2H_5 radicals, HCN was produced mainly from the C_2H_6 precursor. They suggested that this is due to a rapid "cracking" reaction

$$N + C_2H_5 \rightarrow HCN + CH_3 + H \quad (53)$$

which would be faster than reaction (51). This does not imply that HCN production from the reaction of N atoms with CH_3 radicals is slow. These reactions were studied under conditions of an excess of hydrocarbon, which would favor reaction (53). There is experimental evidence that the corresponding reaction with CH_3 radicals is also fast [197]. This is supported by the rapid production of HCN from the HCl-catalyzed reaction of active nitrogen with CH_4, which must result from reaction of N atoms with CH_3 radicals (32).

Safrany and *Jaster* suggested that, under ordinary conditions, the disappearance of N atoms could proceed *via* NH radicals according to

$$NH + NH \rightarrow N_2 + 2\,H \quad (26)$$

The effect of adding H atoms could then be explained if the reaction

$$NH + H \rightarrow H_2 + N \quad (24)$$

could regenerate N atoms at a rate appreciably faster than the rate of N_2 formation by reaction (26).

Safrany has suggested that the reactions of H, O, and N atoms proceed by similar mechanisms, and that the difference in the final products obtained is simply a result of the different valences of the atoms [198]. He reinterpreted his earlier results on this basis, and concluded that H_2CN must be an important reaction intermediate in the reactions of active nitrogen with hydrocarbons. The possibility that this species might be involved in the mechanism of the reaction with ethylene had been suggested earlier [23]. Important steps of the overall mechanism might then be

$$N + C_2H_5 \rightarrow H_2CN + CH_3 \quad (54)$$

$$N + CH_3 \rightarrow H_2CN + H \quad (55)$$

$$N + H_2CN \rightarrow NH + HCN \quad (56)$$

$$H + H_2CN \rightarrow HCN + H_2 \quad (57)$$

When $[N] \gg [H]$, the formation of NH by reaction (56) would lead to loss of N atoms by reaction (25), while addition of H atoms, so that $[N] \approx [H]$, would suppress formation of N_2 by increasing the importance of reaction (57).

The reactions of active nitrogen with higher alkenes are assumed to be reduced essentially to reactions of N atoms with either CH_3 or C_2H_5 radicals by the intervention of "cracking" reactions.

Several features of the reactions of active nitrogen with alkenes cannot be explained adequately by this mechanism. Perhaps the most striking discrepancy lies in the formation of NH_3 as a product when $[C_2H_4] < [N]$. If the loss of N atoms were caused entirely by reaction (25), the loss of NH, with formation of N_2, should become more pronounced when N atoms are in excess. Furthermore, spin considerations suggest that reaction (24) should be at least four times as important as reaction (25) [12].

Reaction (25) should not be dismissed as of no significance. It has been shown that, when H atoms from a second discharge are added to active nitrogen, the concentration of N atoms (NO "titration") is decreased by about 17% [32, 193]. Since no known reaction of NO with H atoms could possibly compete with its very fast reaction with N atoms, it seems likely that the NO "titration" remains valid under these conditions, hence that H atoms may catalyze N atom recombination.

These mechanisms are also not adequate to explain the observed pressure dependence of the NO/HCN ratio [29, 139, 199]. This might, in part, be explained by a reaction of the type

$$N + H + M \rightarrow NH + M \quad (58)$$

It has been reported that HCN can be produced when mixtures of C_2H_4, or other hydrocarbons, with N_2 are allowed to react in a shock tube [200]. The temperature was too low (1400–6000 °K) to produce a significant number of N atoms. It was postulated, therefore, that HCN is produced by the reaction of a vibrationally excited nitrogen molecule with hydrocarbon radicals. The measured activation energies for the process involved are in the range 23 to 54 kcal $mole^{-1}$, much higher than those for corresponding N(^{4}S) reactions.

HCN has also been obtained from the radiolysis, with ^{60}Co γ-rays, of a gas phase mixture of nitrogen and C_2H_4 [201]. It is interesting to note that HCN production is insignificant when *trans*-2-butene is used instead

of C_2H_4. Furthermore, the presence of butene inhibits production of HCN from C_2H_4 in such systems. It has also been shown that HCN is not necessarily the major product when alkene-liquid nitrogen solutions are irradiated with γ-rays [20a, 20b].

4.3.2. Alkanes

The reactions of active nitrogen with the saturated hydrocarbons are similar in many respects to those with alkenes. However, the initiation reactions are probably different, especially for the lower members of the series, such as CH_4, C_2H_6, and cyclopropane.

At room temperature, the production of HCN from the reactions with the lower alkanes is appreciably decreased when NH_3 or SO_2 is added to the active nitrogen stream between the discharge and the point of hydrocarbon addition [140, 202]. It has also been found that the Arrhenius plots for the reactions of active nitrogen with certain alkanes have a definite change of slope [22]. These observations indicate that the alkane reactions are initiated by excited N_2 molecule reactions such as

$$N_2^* + RH \rightarrow N_2 + R + H \qquad (59)$$

To conserve spin, the N_2^* would have to be in either a singlet or a triplet state. The alkyl radical formed in such an initial step should react rapidly with N atoms.

As with the alkenes, the main product of the reactions of active nitrogen with alkanes is HCN. Other N-containing products that have been identified are NH_3, $(CN)_2$, and CH_3CN [30, 196, 198, 202, 203]. These are generally accompanied by various hydrocarbons [17].

At room temperature, the reactions with CH_4 or C_2H_6 showed an "induction" effect in the yield of HCN with hydrocarbon flow rate, which was overcome, however, by the addition of H atoms. Temperatures above, 200 °C were required to obtain "plateau" values for HCN production from C_2H_6 and C_3H_8 [30, 32, 204]. The "plateau" value was then identical with that obtained from the reactions with alkenes [30]. It should, perhaps, be noted that the rate of H atom attack on CH_4, or C_2H_6, is quite slow at temperatures below about 200 °C [205, 206]. Thus, the behavior of the active nitrogen reactions may be based on the change in rates of H atom attack on the alkanes with increase in temperature.

The presence of secondary C atoms in the butanes or higher alkanes increases the rate of reaction with active nitrogen, and "plateau" values for HCN production are observed even at room temperature [130, 207].

The rate constants for the reactions of active nitrogen with alkanes are lower than those for the reactions with alkenes ($k \simeq 10^{-15}$ cm^3 molec^{-1} s^{-1} at room temperature), and activation energies are higher [22, 203].

4.3.3. Alkynes

Recent studies indicate that the reactions of active nitrogen with alkynes should be divided into two groups: (a) the reaction with acetylene; (b) the reactions with other alkynes.

Unlike the reactions with most other hydrocarbons, the reaction of active nitrogen with C_2H_2 produces considerable amounts of $(CN)_2$ as well as the usual product, HCN [208, 209]. The reaction is also accompanied by deposition of a brown polymer (C = 65%, N = 27%, H = 7%) on the walls of the reaction vessel [170, 208]. Other N-containing products obtained are NH_3 and cyanoacetylene (C_2HCN) [186, 203].

It has been reported that the initial attack of C_2H_2 by N atoms is a slow process (for $[C_2H_2]/[N]$ 0.05, $k \approx 5 \times 10^{-15}$ cm^3 molec^{-1} s^{-1} at 300 °K) [170, 194, 211, 211a]. It was found, however, that the rate of reaction increased rapidly with increase in $[C_2H_2]$ ($0.05 < [C_2H_2]/[N] < 1$). When $[C_2H_2]/[N] > 1$, a comparatively slow reaction is observed [211a].

The mechanism of this reaction is probably quite complex [186]. The formation of C_2HCN, identified mass-spectrometrically, indicated that displacement reactions might be important, *e.g.*,

$$CN + C_2H_2 \rightarrow C_2HCN + H \qquad (60)$$

Safrany and *Jaster* have suggested that the overall behavior of the reaction is greatly influenced by the presence of $(CN)_2$ as a product [170]. Although the production of HCN is increased by about 50% by the upstream addition of NH_3 [210] it has little effect on the rate of the slow reaction ($[C_2H_2]/[N] > 1$) but decreases the rate of the fast reaction [211a]. In their study of the kinetics of this reaction, *Kistiakowsky* and co-workers [211a] suggest that the slow reaction ($[C_2H_2]/[N] > 1$) proceeds by a mechanism similar to the "unified" mechanism of *Evans*, *Freeman*, and *Winkler*. They also suggest that $N_2(A^3\Sigma_u^+)$ may initiate the fast reaction.

The reaction of active nitrogen with propyne and 2-butyne resemble the analogous reactions with alkenes. Both compounds produce significant quantities of $(CN)_2$ (about 50% of total HCN), but relatively little polymer. The Arrhenius parameters for the reactions of active nitrogen with alkynes other than acetylene are comparable with those for the corresponding reactions with alkenes [194].

The reactions of active nitrogen with isomeric allene and propyne were found to be remarkably similar [212]. Both reactions produce significant quantities of C_2H_2. Addition of H atoms to these reactions increased the yields of both HCN and C_2H_2, and it was suggested that production of C_2H_2 in the active nitrogen systems results from H-atom reactions, *e.g.*,

$$CH_2{=}C{=}CH_2 + H \rightarrow CH_3{-}C{\equiv}CH + H \quad (61)$$

$$CH_3{-}C{\equiv}CH + H \rightarrow CH_3 + C_2H_2 \quad (62)$$

4.3.4. Aromatic Hydrocarbons

The reactions of active nitrogen with aromatic compounds have not been studied in detail. The production of tars and solids, which deposit on the walls of the reaction vessel, seem to be characteristic of these reactions [181, 213–215]. Small yields of phenyl isocyanide, benzonitrile, and pyridine (but no aniline) were obtained from the reaction of active nitrogen with C_6H_6 [181, 215].

The emission spectrum recorded during the reaction of active nitrogen with solid benzene shows the vibrational structure of the phosphorescence spectrum of C_6H_6 shifted to higher wavelengths [216]. This was attributed to reaction with $N_2(A\,^3\Sigma_u^+)$.

4.3.5. Other Organic Compounds

The reactions of active nitrogen with several alkyl halides have been studied in considerable detail. The perfluorinated alkenes C_2F_4, C_3F_6, and perfluoro-2-butene yield a polymer (C = 26%, F = 65%, N = 9%) as the major N-containing product [217]. Fluorocarbons are also obtained, together with small quantities of FCN. It was suggested that the yield of FCN might be reduced by its reaction with the parent alkene to form a polymer, *e.g.*,

$$C_2F_4 + FCN \rightarrow (C_3F_5N)\ \text{polymer} \quad (63)$$

The main features of these reactions were explained by a mechanism similar to the "unified" mechanism for the reaction of active nitrogen with ethylene, proposed earlier by *Evans, Freeman,* and *Winkler* [11].

The kinetics of the reaction of active nitrogen with perfluoro-2-butene were studied by the diffusion flame technique [218]. The rate constant was estimated to be 7×10^{-14} cm^3 molec^{-1} s^{-1} at 313 °K, which does not agree with the value suggested by a mass-spectrometric study, *i.e.*, $k \leqslant 6 \times 10^{-15}$ cm^3 molec^{-1} s^{-1} at 500 °K [194].

The reactions of active nitrogen with the chlorinated methanes, except CCl_4, produce HCl and HCN as the main products [27, 219]. These reactions are unusual in that the maximum HCN yield seems to be temperature-dependent. It is possible that the HCl produced acts as a "catalyst" in a manner similar to that observed when HCl is added to the reactions of active nitrogen with certain hydrocarbons [32, 169].

The reaction of active nitrogen with CCl_4 is accompanied by an intense reaction flame and produces CNCl and Cl_2 [219]. The rate constant has been estimated as $k = 2 \times 10^{-12} \exp(-2.1\ \text{kcal}/RT)$ cm^3 molec^{-1} s^{-1} from an analysis of the product distributions [220].

The reactions of active nitrogen with CH_3OH and C_2H_5OH produced HCN and H_2O as the main products [221, 222]. The activation energies for these reactions were estimated to be 3.1 and 3.4 kcal mole^{-1}, and the steric factors to be 1.7×10^{-3} and 3.6×10^{-3}, respectively.

The reaction of active nitrogen with CH_3CHO showed no evidence for hydrogen abstraction by N atoms [223]. The main products of the reaction are HCN, H_2, and CO, with small amounts of glyoxal and substances with $m/e = 43$ and $m/e = 86$. The reaction with CH_3CDO does not seem to produce any DCN, and the H_2:HD:D_2 ratios are 1:0.88:0.33. The proposed mechanism was

$$N + CH_3CHO \rightarrow HCN + H_2 + CHO \quad (64)$$

$$CHO + CH_3CHO \rightarrow CO + H_2 + R \quad (65)$$

To account for the $m/e = 43$ peak, it was suggested that R might be CH_2CHO. The rate constant for reaction (65) was estimated to be $k_{65} = 2.0 \times 10^{-14}$ cm^3 molec^{-1} s^{-1} at 296 °K.

A qualitative study of the corresponding reaction with C_2H_5CHO suggested that it probably reacts by a similar mechanism [223].

The reactions of active nitrogen with CH_3NH_2 and CH_3CN typically produce HCN as the main product [28,181,224]. For both reactions, the "plateau" value for HCN production apparently increases with temperature.

5. CN Emission

The reactions of active nitrogen with C-containing compounds are generally accompanied by a characteristic CN emission. Both the red ($A\,^2\Pi \rightarrow X\,^2\Sigma$) and violet ($B\,^2\Sigma \rightarrow X\,^2\Sigma$) bands of CN have been observed in the flames that accompany such reactions [70], and they have been studied in considerable detail in an attempt to elucidate the mechanism by which these electronically excited states of CN may be populated.

It was noted earlier that $(CN)_2$ production from most of the active nitrogen-hydrocarbon reactions is small and, as *Strutt* pointed out, the intensity of the reaction flames need give no indication of the extent to which the main reactions occur to yield HCN as the final product [5,8]. This observation has recently been confirmed by *Avramenko* and *Krasnen'kov*, who showed that the rates of $(CN)_2$ or HCN formation are not related to the intensity of the emission spectra of CN, CH, and C_2 from the reactions of active nitrogen with CH_4, C_2H_2, C_2H_6, CH_3OH, and CCl_4 [225].

The mechanism for the population of electronically excited CN radicals in active nitrogen reactions is complex. Intensity measurements of the CN emissions, from reactions with cyanogen derivatives or halogenated hydrocarbons, showed three distinct vibrational energy population distributions in both the $A\,^2\Pi$ and the $B\,^2\Sigma$ states [226]. Three distinct mechanisms were proposed to account for these distributions. The first population distribution was observed mainly during reactions with cyanogen derivatives, YCN, at pressures < 0.1 torr and was attributed to either

$$N + N + YCN \rightarrow CN^*(A\,^2\Pi \text{ or } B\,^2\Sigma) + N_2(X\,^1\Sigma_g^+) + Y \quad (66)$$

or

$$N_2^* + YCN \rightarrow CN^* + N_2(X\,^1\Sigma_g^+) + Y \quad (67)$$

A second distinct population distribution was observed with halogenated hydrocarbons at higher pressures and fairly high reactant concentration. Excitation of CN was attributed to

$$N + CX \rightarrow CN^* + X \quad (68)$$

A third population distribution was observed in the reactions of cyanogen derivatives and halogenated hydrocarbons under "blue" flame conditions, *i.e.*, low reactant concentrations, when the first positive system of active nitrogen is still visible and emission results from excitation of previously formed CN according to

$$N + N + CN \rightarrow CN^* + N_2(X\,^1\Sigma_g^+) \quad (69)$$

or

$$N_2^* + CN \rightarrow CN^* + N_2(X\,^1\Sigma_g^+) \quad (70)$$

Absolute intensity measurements and the overall kinetics suggest that the N_2^* species of reaction (70) is $N_2(A\,^3\Sigma_u^+)$, or possibly $N_2(X\,^1\Sigma_g^+)$ in a high vibrational level (with energy > 149 kcal mole^{-1}) [227].

This mechanism has been confirmed by results of optical absorption measurements of ground state CN in active nitrogen flames [228].

6. The $N_2(A^3\Sigma_u^+)$ State

In the past, reactions of active nitrogen which could not be adequately explained in terms of N atom reactions have often been attributed to reaction with $N_2(A\,^3\Sigma_u^+)$ molecules. Because decay to the ground state $N_2(X\,^1\Sigma_g^+)$ by light emission is spin forbidden, $N_2(A\,^3\Sigma_u^+)$ molecules are relatively long-lived, and afford a particularly attractive choice as a second reactant [12a,17]. Several workers have recently obtained significant concentrations of the $N_2(A\,^3\Sigma_u^+)$ species in systems which contain a relatively small number of N atoms [53,54,143].

As mentioned previously [Section 3, eq. (5)], perhaps the most important reaction of $N_2(A\,^3\Sigma_u^+)$ molecules is the rapid reaction with N(^{4}S) atoms to produce vibrationally excited ground state molecules [53]. The rate of this reaction may be very sensitive to the vibrational energy of the A state molecules [228a]. Energy pooling by

$$N_2(A\,^3\Sigma_u^+) + N_2(A\,^3\Sigma_u^+) \rightarrow N_2(X\,^1\Sigma_g^+) + N_2(C\,^3\Pi_u) \quad (71)$$

has also been observed [228b]. The initial production of H atoms in reactions of active nitrogen with organic compounds might well be due to energy transfer from $N_2(A\,^3\Sigma_u^+)$. This species, with energy of 142–146 kcal/mole, may also serve as a triplet sensitizer [143]. With reactants having low-lying triplet levels, such as $(CN)_2$, SO_2, or CS_2, reaction of $N_2(A\,^3\Sigma_u^+)$ generally leads to emission from the reactant due to a rapid triplet-triplet transition. Other reactants, such as N_2O

or O_2, are partially dissociated by $N_2(A\,^3\Sigma_u^+)$ molecules [104, 143]

Excitation of NO by $N_2(A\,^3\Sigma_u^+)$ has been shown to occur efficiently by

$$N_2(A\,^3\Sigma_u^+) + NO(X\,^2\Pi) \rightarrow N_2(X\,^1\Sigma_g^+) + NO(A\,^2\Sigma^+) \quad (72)$$

Excitation of NO results in approximately one-half of the de-exciting collisions of $N_2(A\,^3\Sigma_u^+)$ with NO [229].

It has been suggested that the mercury 2537 Å emission might be used as a test for $N_2(A\,^3\Sigma_u^+)$ [56, 230–232].

The importance of $N_2(A\,^3\Sigma_u^+)$ molecules in active nitrogen is, however, somewhat limited by their relatively low concentration, which is estimated to be $\approx 10^{-3}$ [N] [204].

Magnetic Resonance of Paramagnetic Complexes

By Heimo J. Keller and Karl E. Schwarzhans[*]

The line width of the ESR and NMR signals of paramagnetic transition metal complexes is determined mainly by the electron spin-lattice relaxation time τ_e. Values of τ_e greater than 10^{-9} lead to ESR spectra that are readily resolved, while values smaller than 10^{-11} give NMR spectra having small line widths. Since fast relaxation processes are effective in nearly all transition metal complexes with several unpaired electrons and in all complexes having an orbitally degenerate ground state, the NMR method has a wider scope. The sign and magnitude of the electron-nucleus coupling can be determined with great sensitivity from the NMR spectra, whereas only the magnitude of this interaction can be determined from the ESR spectra. Free spin densities can be found very accurately from the NMR shifts, and the method can therefore be advantageously applied to kinetic measurements, e.g. on short-lived contact complexes.

1. Introduction

The use of both the electron spin resonance (ESR) and the nuclear magnetic resonance (NMR) effects can lead to the solution of a number of chemical problems in connection with paramagnetic transition metal complexes. Several reviews of both methods have been published in recent years, and results for transition metal complexes have also been discussed [1–8], but their *combined* application to paramagnetic complexes has been largely ignored. A question of prime interest to chemists is when to use NMR measurements in practice, and when ESR.

2. Theoretical Principles

2.1. Resonance Conditions

The problems will be considered on the basis of the simplest possible system, *i.e.* hydrogen atoms, assuming at first that these atoms are not influenced by their neighbors, so that it is possible to discuss the resonance properties of a single hydrogen atom.

It is well known that the hydrogen atom consists of one proton and one electron. Each of these elementary particles has a characteristic angular momentum (spin), which, according to the quantum theory, can only assume certain specific values. The angular momentum J, which differs in magnitude for the two particles in question, is therefore, figuratively speaking,

restricted to two definite directions in space. Thus there are only two possible (±) spin states for the proton and for the electron ($J = 1/2$).

Owing to the electric charge carried by the elementary particles, the angular momentum is associated with a magnetic moment, which can be calculated from

$$\beta = e_0 \hbar/2 m c \qquad (1)$$

where e_0 is the charge on the elementary particle, m is its mass, c is the velocity of light, and $\hbar$ is the Planck constant divided by 2π. However, the moments calculated from this equation, which are known as the nuclear magneton and the Bohr magneton ($\beta = \mu_N$ and μ_B) respectively, do not coincide with the magnetic moments found for the proton and for the electron in resonance experiments. These are given by the product of the magneton (β) with a purely empirical correction factor, the g factor.

$$\mu = g\beta \qquad (2)$$

Like the angular momentum vectors, the magnetic moments of the proton and the electron are also restricted to two directions. These two states, which are represented by antiparallel arrows, have the same energy provided that no external magnetic field is acting, *i.e.* the energy levels of the oppositely oriented magnetic vectors are degenerate (Fig. 1, a). In a strong external magnetic field H_0, the energy of the state in which the magnetic moment is parallel to the external field is reduced by a certain amount, while the energy of the state with the antiparallel orientation of the magnetic moment is increased by the same amount, *i.e.* the degeneracy is lost (Zeeman effect).

The splitting (ΔE_1 or ΔE_2) is proportional to the magnetic moment and to the strength of the external field (Fig. 1, b):

$$\Delta E \sim \mu H_0 \qquad (3)$$

Since the magnetic moment of the electron, according to eq. (1), is greater by a factor of $\approx 10^3$ than the moment of the proton, the splitting of the degenerate energy levels for electrons in accordance with eq. (3) is $\approx 10^3$ times as large as the corresponding splitting for nuclei. Figure 1 thus gives only a hint of the true state of affairs.

2.2. Resonance Spectrum of a Hydrogen Atom

Absorption or emission spectroscopy can now be carried out on the system chosen as our example. If electromagnetic energy corresponding to the difference between the magnetic electronic or nuclear levels (ΔE_1 and ΔE_2 respectively) is supplied to the system from a suitable source, the elementary particles with the parallel spin can be raised to the higher levels, with reversal of their magnetic moment into the antiparallel state. Two discrete frequencies are absorbed from a broad frequency spectrum in accordance with

$$\Delta E = h\nu = g\beta H_0 \qquad (4)$$

Since the transitions between the magnetic electronic levels have a much higher energy than those between the magnetic nuclear levels, ESR absorptions occur in the microwave region ($\nu \approx 10^9$–10^{10} Hz; $H_0 \approx 10^3$ gauss), while NMR absorptions, even at higher field strengths, occur in the radio wave region ($\nu \approx 10^6$ Hz; $H_0 \approx 10^4$ gauss). According to eq. (3), the magnitude

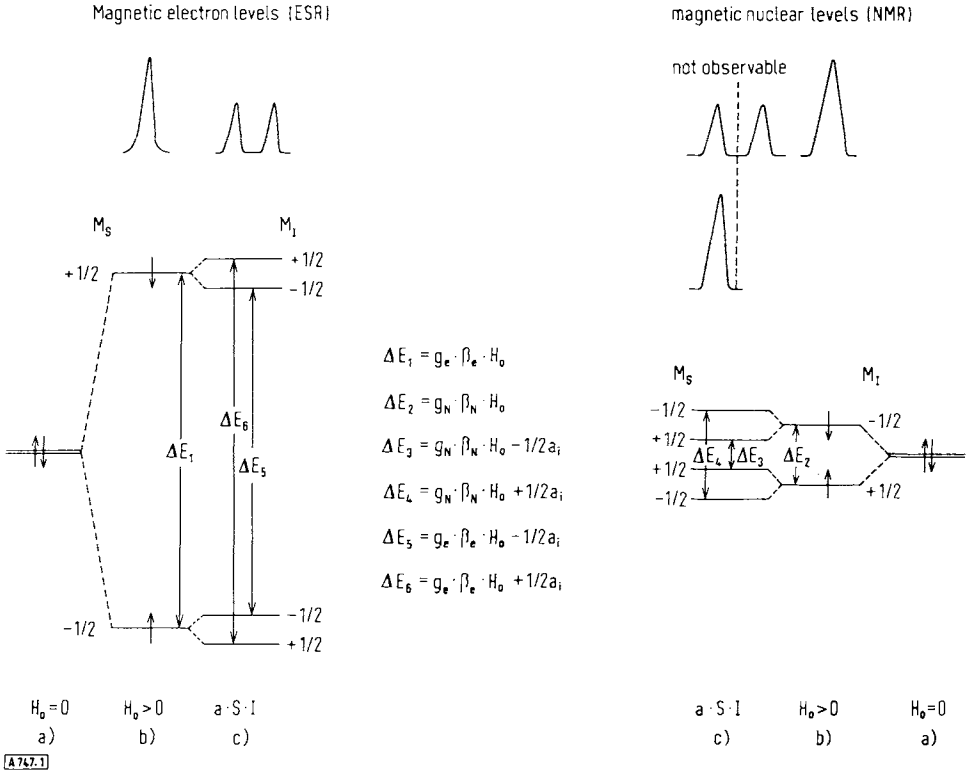

Fig. 1. Zeeman levels of a hydrogen atom in a strong external field H_0.

of the splitting of the levels is determined purely by the magnetic moments of the particles; this leads to differences in the methods used in ESR and NMR experiments. Nevertheless, the usual distinction between ESR and NMR spectroscopy does not seem to be justified merely on the basis of experimental peculiarities. The rules applicable to the two methods are qualitatively the same. The chemist is interested only in the parameters of the spectra that contain essentially chemical information; these are above all the shifts of the resonance signals in NMR, which correspond in practice to the g factor measured in ESR.

It has been assumed so far that the magnetic moments of the electron and of the proton do not influence each other. However, this is not so. There is in fact a strong "contact interaction" between these magnetic dipoles, which was first postulated by *Fermi* for the interpretation of optical spectra [9]. This interaction has a finite value only if the unpaired electron can be described by an orbital function with a finite probability for the position of the nucleus, as *e.g.* for unpaired electrons in s orbitals. The strength of the interaction depends on the spin quantum operators of the electron $\vec{S}$ and of the interacting nucleus $\vec{I}$, as well as on the absolute probability of finding the unpaired electron in the position of the nucleus ($|\psi(0)|^2$):

$$\mathscr{H} = a\,\vec{I}\,\vec{S};\quad a = \frac{8\pi}{3}\, g_e\beta_e g_N\beta_N|\psi(0)|^2 \qquad (5)$$

This results in further splitting of the electronic and nuclear levels. The electronic moments are now exposed to two different magnetic fields, *i.e.* the external field H_0 plus the magnetic moment of the nucleus with the nuclear moment parallel to the field direction on the one hand, and H_0 minus the nuclear moment with antiparallel orientation on the other. On insertion of the electron-nucleus interaction, therefore, we obtain the diagram shown in Figure 1, c, with the result that further transitions become possible. The orientation of the nuclear moment parallel to H_0 corresponds to $M_I = +1/2$, while the parallel orientation of the electronic moment, because of the opposite charge, corresponds to $M_S = -1/2$. Thus a large number of independent hydrogen atoms would give a resonance spectrum of four "allowed" lines. (Selection rules: $\Delta M_I = \pm 1$, $\Delta M_S = 0$ for nuclear transitions; $\Delta M_S = \pm 1$, $\Delta M_I = 0$ for electronic transitions.) The absorption line of the nuclear transition and the absorption line of the electronic transition exhibit splitting corresponding to equal energy differences. Two ESR lines should be observed in the microwave region and two NMR lines in the radio wave region (Fig. 1, c).

2.3. Relaxation

Unfortunately, this last view is still not sufficiently close to reality, since the hydrogen atoms are also appreciably influenced by time-dependent fields of their environment. Each atom executes thermal motions with a speed that varies with the temperature. Since the atom has magnetic dipoles, this motion produces an alternating electromagnetic field. If the frequency ν_w of this alternating field satisfies the resonance condition (4), a resonance transition is induced by this radiation in neighboring atoms. In the spectral region considered, induced emission and absorption are equally probable, so that both emission and absorption are stimulated by the electromagnetic "stray field". Thermal lattice energy can thus be converted into spin energy and *vice versa*. Fast transitions between the levels thus become possible, since a particle that has been transferred to a higher level by absorption of energy can return to the ground state by radiationless loss of energy to the "lattice". The lifetime of a given state is consequently shortened, sometimes to such an extent that according to the Heisenberg uncertainty relation

$$\Delta E \cdot \Delta t \geqslant \hbar \qquad (6)$$

its energy becomes uncertain. The line width of the resonance signal increases considerably. With very short lifetimes, this may have the result that the transitions can no longer be observed. Since the magnetic moments of electrons are very large, a very strong electromagnetic stray field prevails in paramagnetic systems, as in our example of hydrogen atoms or in dilute solutions of organic radicals, and causes extremely short nuclear lifetimes and hence broadening of the NMR lines. The two absorptions expected in the radio wave region cannot be detected. This led to the assumption that NMR spectra could not be recorded for paramagnetic compounds. However, this is incorrect above all for inorganic complexes [1–8]; on the contrary, NMR lines of adequate sharpness are the rule in this case.

The fact that the resonance signals of such compounds can be detected experimentally is the result of fast transitions between the *electronic* levels. If, for example, many such transitions occur during a specific thermal motion of a hydrogen atom, *i.e.* if the electron spin of this hydrogen atom changes its direction several times during the motion, the influence of the stray field produced by the thermal oscillation of the magnetic dipoles on nuclear relaxation decreases. Only a time average of all possible spin directions acts during a translation or rotation.

For a quantitative treatment of this intuitive model, it is necessary to define the relaxation time, *i.e.* the time after which 1/e of the excited spins have returned radiationlessly to the ground state. If the spins are very strongly coupled to the "lattice", *i.e.* if a fast exchange takes place between the energy of the spin system and degrees of freedom of the environment, the spin-lattice relaxation times are short. According to the relation (6), resonance absorptions should then be absent or extremely broad, as has been indicated for the NMR absorption of the hydrogen atom.

If, however, unpaired electrons have extremely short *electron* spin-lattice relaxation times, as in many

[9] *E. Fermi*, Z. Physik *60*, 320 (1930).

transition metal complexes, *i.e.* if the direction of their spin is reversed rapidly in comparison with the correlation time of the particles in the solution, the coupling of the nuclear spin with the lattice is largely eliminated; the *nuclear* spin-lattice relaxation times again become longer, and the line width of the NMR signals accordingly decreases. No ESR spectra are observed in such cases. Thus in solutions of paramagnetic compounds, the question when NMR and when ESR studies are possible is determined by the *electron* spin-lattice relaxation time [10–14]. With relatively long electron spin relaxation times (down to about 10^{-9} s), usable ESR spectra can be recorded, but only very broad-lined NMR spectra. With relaxation times shorter than 10^{-11} s, on the other hand, *i.e.* with extremely short electron spin relaxation times, only NMR spectra (usually with small line width) can be recorded. The two methods thus complement each other excellently [15].

In addition to the intramolecular transitions, fast intermolecular processes also have a similar averaging effect on the time-dependent internal fields. If, for example, the unpaired electrons in a molecule are strongly delocalized, the orbitals, which have a broad probability distribution, may overlap slightly in concentrated solution; an exchange interaction, in which the spin can also reverse rapidly, becomes possible. The requirements for this are often satisfied by organic radicals [16–18], but less often by complex compounds.

3. Electron Spin-Lattice Relaxation Times

We are thus faced with the question of the parameters that govern the electron spin-lattice relaxation times of metal complexes, in order to clarify whether to carry out NMR and/or ESR studies. The interpretation of the electron spin relaxation times of paramagnetic transition metal complexes has been discussed only quite recently [19], so we will confine ourselves here to just the essential aspects. Since the mechanisms are more complicated for an effective relaxation in complexes containing several unpaired electrons (zero-field splitting), it seems reasonable to confine the discussion to compounds with $S = 1/2$, *i.e.* with only one free electron spin. As a rough simplification, we can say that NMR absorptions with small line widths should be obtained for most complexes containing several unpaired electrons (the only exceptions are ions with an S ground state, such as Mn^{2+} and Fe^{3+}). These complexes are therefore particularly suitable for NMR studies [20–26].

On the other hand, in complexes having only one unpaired electron, the electron spin-lattice relaxation time is largely dependent on the symmetry and strength of the ligand field. According to an empirical relation [27]

$$\tau_e = \frac{\Delta^6 \cdot 10^4}{\lambda^2 H^2 T^7} \qquad (7)$$

the electron spin-lattice relaxation time τ_e is determined mainly by the energy difference between the highest occupied and the lowest unoccupied electron levels (Δ) and by the temperature. Reference was made earlier to the dependence of the line width on the spin-orbital coupling constant λ in complexes with varying λ values [28]; its effect on the relaxation time need not be considered further here.

At the same temperature and at comparable magnetic field strengths, τ_e for various metal complexes depends mainly on Δ. In paramagnetic complexes with orbitally degenerate ground states, the highest occupied and the lowest unoccupied levels have the same energy, so that Δ should be zero. Though thermal motion and fields of neighboring molecules cause slight splitting, all metal complexes with *orbitally degenerate* ground states, according to eq. (7), have extremely short electron spin-lattice relaxation times. ESR spectra should therefore be expected only at extremely low temperatures (a few °K), whereas NMR spectra should be very easy to record for compounds of this type.

To clarify this point further a short discussion of the splitting of d orbitals in transition metal complexes having different ligand field symmetries is given. According to a simple (electrostatic) ligand field scheme [29], the five d states (Fig. 2) split up into an undistorted or tetragonally distorted octahedral ligand field, as shown in Figure 3.

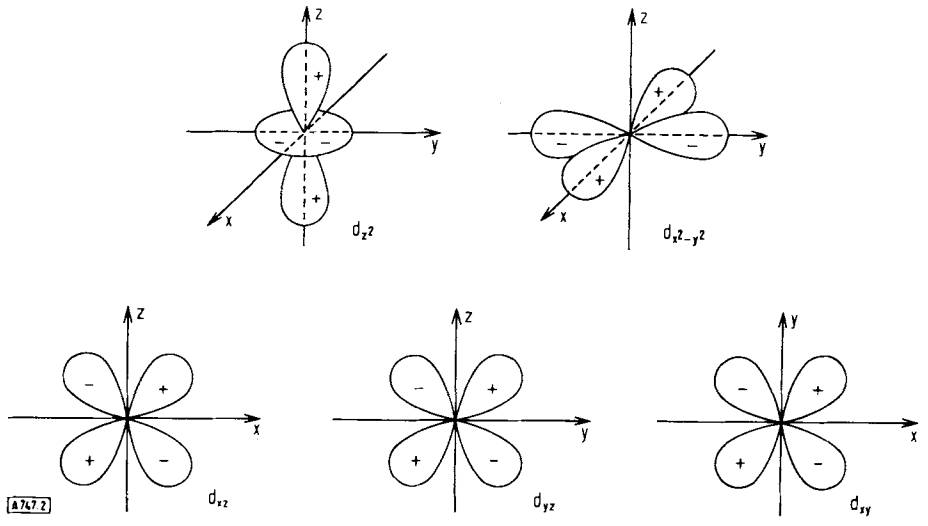

Fig. 2. d orbitals (schematic).

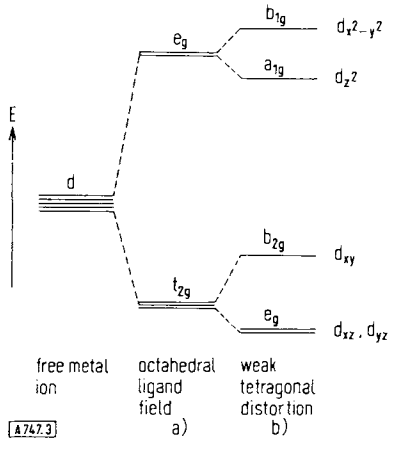

Fig. 3. Splitting of the five d orbital functions in an octahedral field (a) and with tetragonal distortion (b).

If the lower T_{2g} states contain 1,2,4, or 5 electrons and the higher E_g states 1 or 3 electrons, the result is an orbitally degenerate ground state with $\Delta \approx 0$. This situation is found *e.g.* in regular octahedral complexes of Ti^{III}, V^{IV}, or Cr^{II} and in regular tetrahedral complexes of Cu^{II}, Ti^{III}, and V^{II}, to give only a few examples.

If the regular arrangement of the ligands is disturbed, *e.g.* by a Jahn-Teller effect, the degenerate orbital functions fan out farther, the distance Δ between them increasing with increasing distortion. The electron spin-lattice relaxation time is thus a function of the degree of distortion. The line width in the NMR and/or ESR spectra can accordingly be used indirectly to deduce the arrangement of the ligands. For example, on transition from an octahedral to a planar arrangement in d^1 or d^2 complexes, the ESR lines are expected to become narrower while the NMR lines should become broader.

This expectation can be confirmed for $Cu^{II}(d^9)$ complexes with various ligand field symmetries. Cu^{2+} in regular tetrahedral coordination, similarly to the octahedrally coordinated Ti^{3+} ion, is in a triply degenerate $^2T_2$ state [29] (Fig. 4, a); ESR spectra of such complexes are extremely difficult to obtain [30–33]. On distortion of the ligands toward a planar arrangement, the levels split into an E and a B_2 state (Fig. 4, b). The ground state is not further orbitally degenerate, so the width of the ESR lines must decrease with increasing distortion, while that of the NMR lines increases, since τ_e increases with Δ [eq. (7)]. The field of the ligands can be varied in the bis(2-alkyliminomethylphenolato)copper(II) compounds *(1)* (Fig. 5) by varying the *N*-substituent [34].

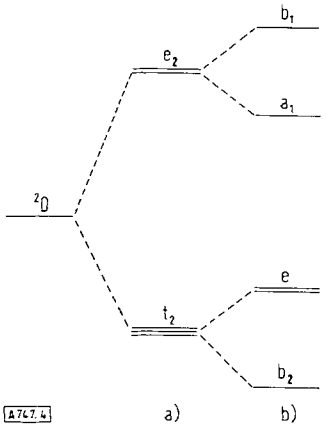

Fig. 4. Energy of the one-electron orbital functions of a tetracoordinate d^9 ion in the regular tetrahedral (a) and distorted tetragonal (b) ligand fields.

In the comparison of the *N-tert*-butyl *(1a)* with the isopropyl derivative *(1b)* (Fig. 5), the former was expected, on steric grounds, to exhibit a greater angle of twist between the planes of the practically planar ligands [35], and hence also to give a greater ESR line width.

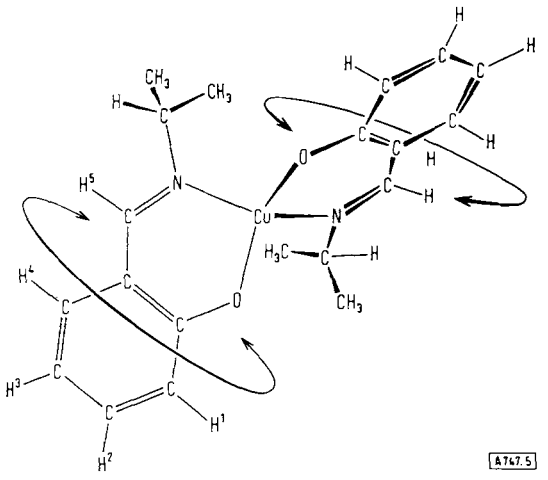

Fig. 5. Structure of bis(2-isopropyliminomethylphenolato)copper(II) *(1b)*.

As is shown in Figure 6, the two complexes give very different line widths at the same temperature (77 °K), *i.e.* 1.5 and 40 gauss respectively. Contrary to expectation, therefore, *(1a)* appears to have a more coplanar arrangement of the ligands, despite the expected

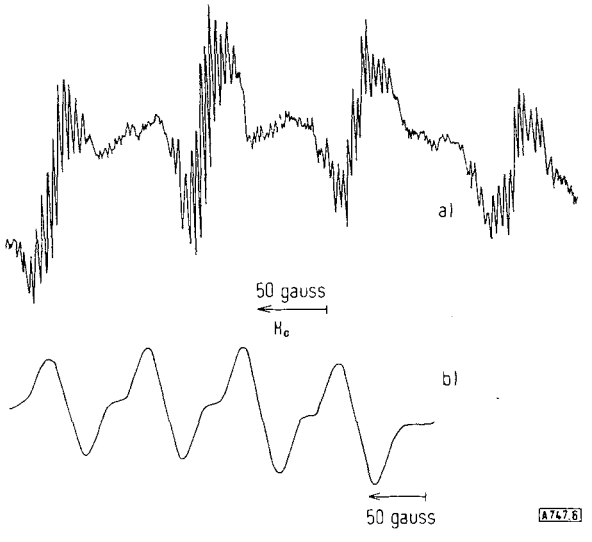

Fig. 6. ESR spectra of (a) bis(2-*tert*-butyliminomethylphenolato)-copper(II) *(1a)* and (b) bis(2-isopropyliminomethylphenolato)copper(II) *(1b)* incorporated into the corresponding Zn^{II} complexes in the direction $H_0 \parallel c$ at 77 °K.

enhanced steric hindrance. This surprising result was confirmed by X-ray studies, which show that the twist angle is 45° in *(1a)* [36], as compared with 60° in *(1b)* [37]. The line width of the ESR absorptions thus provides important information about the symmetry of the ligand field.

The observed large ESR line widths at room temperature suggest, on the other hand, that the compounds *(1)* with an approximately tetrahedral ligand field should give NMR spectra with reasonable line widths. ^{1}H-NMR absorptions of these complexes are in fact

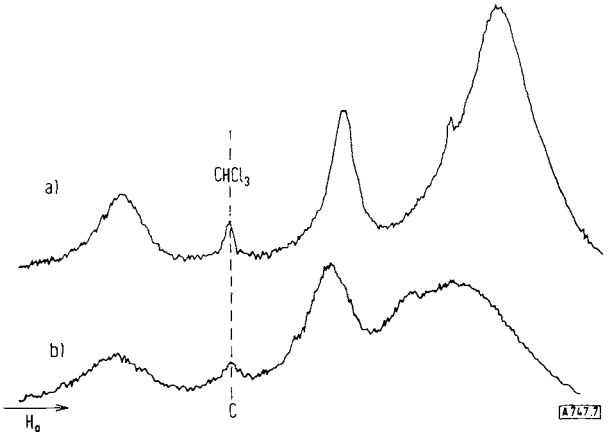

Fig. 7. ^{1}H-NMR spectra of bis(2-isopropyliminomethylphenolato)-copper(II) *(1b)* in $CDCl_3$ at 70 (a) and 20 °C (b).

readily observed having a line width of about 100 Hz (20 °C) [38] (Fig. 7, b).

These observations confirm the conclusion that the NMR and ESR line widths of the spectra of paramagnetic complexes in solutions of equal concentration are roughly inversely proportional to one another [15]. This can be said of complexes which are accessible by only one method as well as of species for which both methods can be used [38–41].

The dependence of the line width on the temperature can be seen from what has been said already. According to eq. (7), a temperature rise considerably shortens the electron spin-lattice relaxation time. Complexes *(1)* with an approximately tetrahedral ligand field give a very broad ($\approx$ 1000 gauss) structureless signal in the ESR spectrum at room temperature, while the NMR absorptions have line widths of about 100 Hz, which become narrower with rising temperature (Fig. 7, a). Well resolved NMR spectra are obtained at higher temperatures, and well resolved ESR spectra at lower temperatures, since the unstructured ESR line observed at room temperature has a distinct hyperfine structure at 77 °K. Both NMR and ESR studies can therefore be carried out on complexes of this type by varying the temperature.

It should be noted that τ_e is large for complexes with "strong" ligands; in these complexes, the orbital moment, and hence the cause of effective relaxation, is eliminated by substantially covalent metal-ligand bonds. Thus most of the paramagnetic organometallic complexes have long electron spin relaxation times and behave in resonance experiments as free organic radicals [42,43].

Attempts to compare the line width of NMR absorptions of different nuclei in a given paramagnetic complex show that the line width is influenced above all by the magnitude of the nucleus-electron coupling, *i.e.* the interaction measured by the value of a_i. Results of NMR experiments on organic radicals suggest that the line width increases with the value of a_i^2 [1,11,13,18,44]. This is obviously also true of the paramagnetic transition metal complexes. Owing to a "direct" interaction (cf. Section 2.6), the protons nearest to the metal ion often have the largest spin density, and hence also the greatest value of a_i. Fig. 8 shows the ^{1}H-NMR spectrum of bis(salicylaldehydato)bis(pyridine)nickel(II) (Fig. 9).

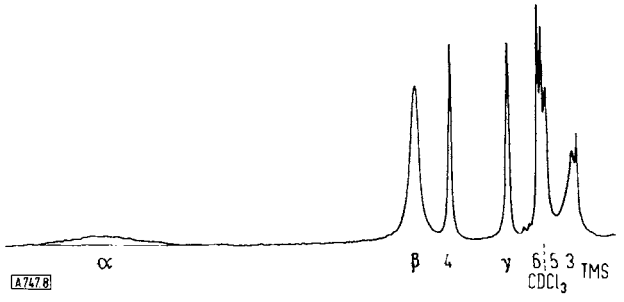

Fig. 8. ^{1}H-NMR spectrum of bis(salicylaldehydato)bis(pyridine)-nickel(II).

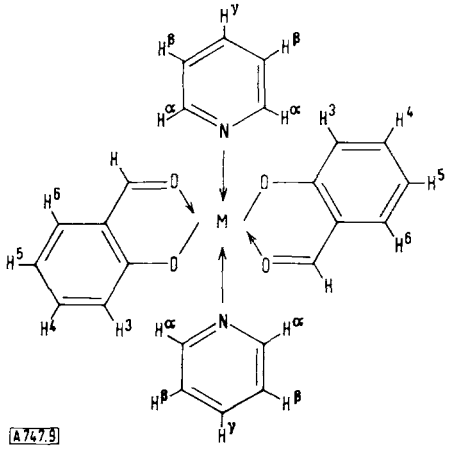

Fig. 9. Structure of bis(salicylaldehydato)bis(pyridine)nickel(II).

The signals of the high spin density protons close to the metal ion exhibit more pronounced broadening; this is true in particular of the signals of the pyridine protons in the α position, which almost dive into the electron cloud of the Ni^{II}. The line width can be used for identification of the protons if the structure of the complex is approximately known [45–47].

4. Number and Position of the ESR and NMR Absorptions

It can be seen from the above discussion that though the magnetic levels of the nuclei are greatly influenced by the strong magnetic electronic dipoles, the nuclear dipoles have only a small effect on the electron levels. They have an effect of second order on the position of the ESR absorptions, but the number of lines observed is determined by the number and nature of the nuclei that interact with the unpaired electron. "Hyperfine splitting" (measured as a_i in the units gauss or Hz) appears (Fig. 6), the magnitude of this splitting increasing with the probability of finding the unpaired electron in the position of the nucleus with which it is in interaction [1,7,8].

As was mentioned earlier, narrow NMR lines can be recorded only if the *electron* spin relaxation times are extremely short, *i.e.* if the transitions between the electron levels are extremely fast. This leads to the observation that a nucleus situated in the neighborhood of such a rapidly relaxing electron spin experiences only an averaged magnetic field due to the unpaired electron, and includes also the hyperfine fields if the electron spin relaxation time is very short in relation to that of the reciprocal nucleus-electron interaction (a_i).

$$\tau_e \ll 1/a_i \qquad (8)$$

For example, a proton cannot then distinguish between the various electron spin orientations. The NMR splitting (Fig. 1, c) disappears. Only one absorption signal is then observed, situated at the center of gravity of the intensities of the two original lines, which had unequal intensity [48]. This stems from the fact that according to

$$N_-/N_+ = \exp(-g\beta H_0 M/kT_s) \qquad (9)$$

the population of the lower levels is significantly greater at room temperature than that of the higher levels. The transition with the higher energy (ΔE_4 in Fig. 1, c) thus gives a higher absorption intensity than that with the lower energy (ΔE_3), which joins levels with smaller differences in population. The center of gravity of the intensities of the two lines is thus not given by the arithmetic mean, but is situated at somewhat lower field strengths. Pictorially speaking, there are more electrons with orientation parallel to the external field than with the antiparallel orientation in the neighborhood of the nuclei. The external field is reinforced, and the process corresponds to shielding, which results in a displacement to lower field strengths. The displacements increase with falling temperature [eq. (9)], and increase with the number of unpaired electrons per molecule. They show the same trend as the susceptibility of paramagnetic compounds [49].

$$\frac{\Delta H_i}{H} = -a_i \frac{\gamma_E g \beta S(S+1)}{\gamma_H 3kT} \qquad (10)$$

For comparison with the order of magnitude of ESR splitting, one can define a paramagnetic shift δ_p [18], which at room temperature is

$$\frac{\delta_p}{a_i}(RT) = \frac{75 \text{ ppm}}{\text{gauss}} \quad (11)$$

Free spin densities can thus be measured much more accurately by the NMR method, since shifts of up to 0.01 ppm are readily detectable, whereas an ESR splitting of less than 0.05 gauss cannot be detected. Moreover the direction of the shift gives the sign of the constant a_i, and hence of the coupling, which is not given by ESR spectra. The use of the NMR method for paramagnetic complexes thus offers two important advantages over ESR studies.

5. NMR Results

The first successful experiments were carried out on various paramagnetic bis(π-cyclopentadienyl)metal complexes [49].

Of the many examples reported so far [2,4,50-56], only a few typical measurements on bis(aminotropinoiminato)nickel(II) complexes will be discussed at first. The metal ions have a $^3T_2$ ground state (Fig. 4, a) in the tetrahedral ligand field, but a diamagnetic $1\,A_{1g}$ ground state with a square-planar arrangement of the ligands. The NMR line widths are a few hertz [26]. The activation energy of the change from the paramagnetic to the diamagnetic conformation and back can be determined from the shifts found at various temperatures [2].

The spin density at various points in the molecule can be calculated from the paramagnetic shifts of the protons, so that it has been possible to clarify the nature of the transfer of free spin density [*] to the ligands. Both σ and π bonds between the central metal and the ligand may be involved.

Whereas the spin densities on the aromatic ligands in the tetrahedral nickel(II) complexes mentioned, which have alternating signs, clearly point to transfer by π-orbital functions [2], predominant σ delocalization was postulated in particular for the hexacoordinate nickel(II) and cobalt(II) complexes [25].

However, the argument used to distinguish between σ and π delocalization seems questionable at first. In addition to spin transfer *via* metal-ligand bonds, strong direct metal-hydrogen interactions are also possible. By overlap of suitable metal orbitals with hydrogen orbitals of adjacent ligand protons, spin density can be transferred "directly" to these protons. The relationships are particularly clear in the bis(π-cyclopentadienyl)metal complexes [57-59].

According to the usual rules, which are based either on MO or on VB models, some of the unpaired electrons of the central metal ions should be distributed, *via* the metal-ligand bond, over the molecular orbitals involving the carbon p_z functions of the rings. These orbital functions would then have a considerable "positive" spin density, which should lead to strong deshielding of the carbon nuclei, and hence to displacements to lower fields for any ^{13}C absorption observed. Neighboring protons are not affected by this interaction.

Differentiation between "positive" and "negative" spin densities is found to be necessary when the interaction between protons and free electrons in carbon orbitals is also taken into account. As is shown in particular by the ESR spectra of organic radicals [1], the magnetic electron levels are split by the moments of adjacent protons (as shown in Figure 1, c for the hydrogen atom). According to eq. (5), this is possible only if the orbital function by which the unpaired electron can be described has a non-zero value at the position of the proton.

The problem is solved mathematically by admixture of electronically excited states with the ground state (configuration interaction) with the result that free

spin density is transferred *via* the C–H σ bond into suitable hydrogen orbitals. However, the positive spin density in the p_z orbital of carbon is so strongly polarized by the paired electrons involved in the C–H bond that the sign of the spin density at the proton is reversed. The *negative* spin density shields the proton from the field, with consequent signal displacement to *higher* fields. It is clear from the ^{1}H-NMR shifts given in Table 1 for bis(π-cyclopentadienyl)metal complexes that this model is unsatisfactory. Since these results also cannot be explained by a "pseudo-contact interaction" [58] or by polarization of the bonding electrons [60], a novel mechanism was postulated.

According to a simple term diagram (Fig. 10), the resonance properties depend solely on the number of electrons in the degenerate non-bonding metal orbitals σ_g' and δ_g and in the antibonding molecular orbital of π_g^* type.

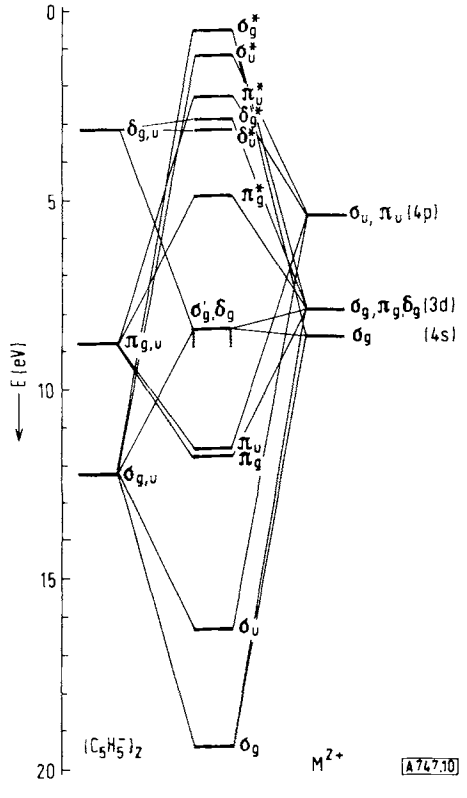

Fig. 10. Term diagram for $[M(C_5H_5)_2]$ (M = 3d metal).

In $V(\pi\text{-}C_5H_5)_2$, three electrons are distributed over the three orbitals of symmetry σ_g' and δ_g; these projecting vanadium orbitals, which are situated between the cyclic ligands, can overlap with the sterically favorable hydrogen orbitals of the ligand protons. The hydrogen-metal combination is occupied by an unpaired electron. Unlike in the above-mentioned transition *via* the carbon atoms, *positive* spin density can be transferred "directly" to the hydrogen atom in this way. The protons of the ligand thus experience strong deshielding, and the resonance signal appears at a *lower* field strength. This is true of all complexes with unfilled metal orbitals of σ_g and δ_g type. "Direct" spin transfer is no longer possible if these metal orbitals, which can interact favorably with the ring protons, are fully occupied by electron pairs (ferrocene). According to the term diagram given, further electrons (in the complexes $Co(\pi\text{-}C_5H_5)_2$ and $Ni(\pi\text{-}C_5H_5)_2$) are packed into the antibonding molecular orbitals of the type π_g^*. The free spin density in these orbitals which involves the ligand p_z carbon functions and metal functions comes from the central metal ion without spin reversal, so that, as in the model described earlier, the ring C atoms have a positive spin density, which is then transferred to the H atoms with sign reversal. The protons are thus strongly shielded, and signal displacements to higher field strengths result. The data in Table 1 are as expected. The shifts of protons of substituted cyclopentadienyl ligands and paramagnetic bis(π-benzene)-metal complexes also agree with this model [59].

It seems worth mentioning the result of an electron diffraction study on bis(π-cyclopentadienyl)metal complexes [61], according to which the H atoms are bent out of the plane of the ring and toward the central metal atom. This could be explained by weak hydrogen bonding between M and C.

On the basis of considerations such as this, it is at least questionable whether it is possible to distinguish between σ delocalization *via* metal-ligand bonds and the direct metal-hydrogen interaction corresponding to "through-space" electron-nucleus coupling [45]. The decay of positive spin densities with increasing distance from the central metal ion has until now been regarded as a typical characteristic of σ delocalization. However, the same is to be expected for direct M–H interaction, which is probably often the main cause of shifts of the ^{1}H-NMR signals. The direct interaction can be averaged out, for example, in the rapidly rearranging "tetrahedral" nickel(II) complexes, and pure π delocalization has in fact been found for these compounds [2]. Thus though very small spin densities can be detected experimentally, it is possible only in a few cases to determine definitely how the unpaired electrons are transferred to ligand atoms. From the chemist's point of view, however, it is usually most interesting to know how many unpaired electrons are present and how they are distributed, whilst the mechanism of transfer is of less importance. Altogether, the small contact shifts (a few ppm), though important in structure analysis, are not suitable as a source of information on the reactivity of a part of a molecule.

5.1. Pseudo-Contact Shifts

The NMR spectra of paramagnetic complexes are influenced additionally by possible pseudo-contact interactions [14], whose magnitude in accordance with

$$\frac{\Delta H}{H} = \frac{\beta^2 S(S+1)\,(3\cos^2 a_i - 1)}{27\, r_i^3\, kT}\,(g_\parallel + 2\,g_\perp)\,(g_\parallel - g_\perp) \qquad (12)$$

[60] *D. A. Levy* and *L. E. Orgel*, J.molecular Physics *3*, 583 (1961).

[61] *I. A. Ronova* and *N. V. Alekseew*, Ž. strukturnoj Chim. *7*, 886 (1966).

depends mainly on the steric relation of the nuclei to the central metal ion and on the anisotropy of the g factor. However, appreciable signal shifts occur only for compounds in which the unpaired electrons are largely localized on the central ion. These include complexes of the lanthanides [22,23] and of the actinides [62,63], in which the unpaired electrons remain in "inner" orbitals that are only slightly affected by the ligands, and complexes of 3d metals with "weak" ligands. It seems unlikely [67] from recent ^{14}N-NMR investigations on some ion associates [55] that the ^{1}H-NMR shifts observed for these substances are really due to pseudo-contact interactions [64–66].

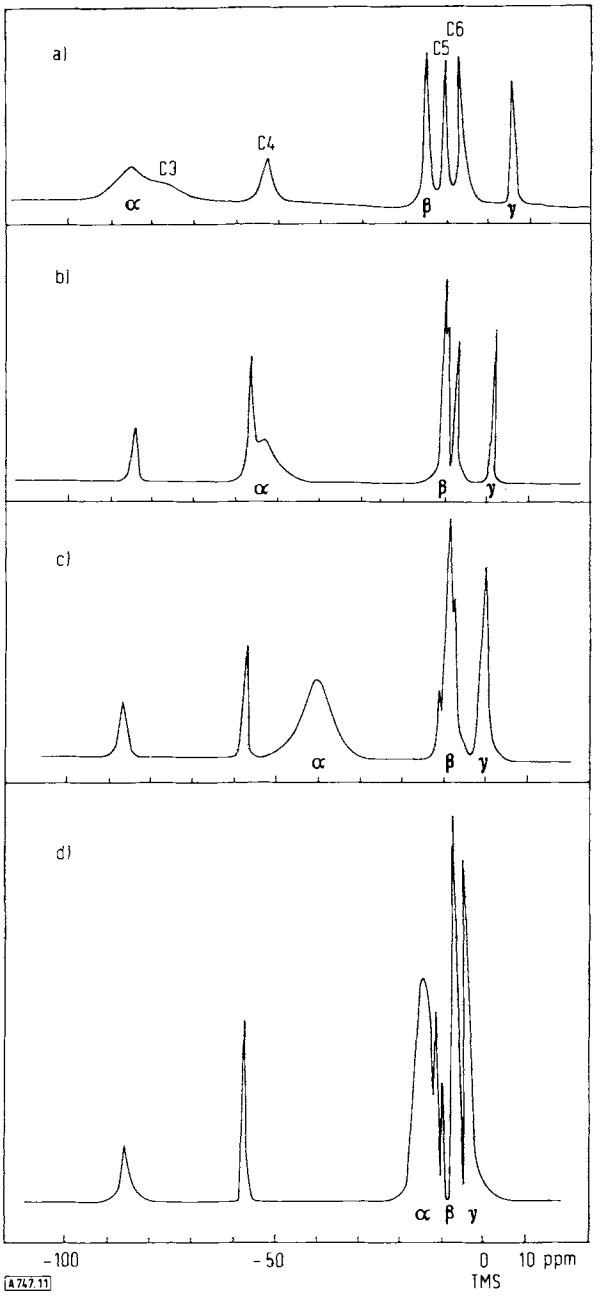

Fig. 11. ^{1}H-NMR spectra of bis(salicylaldehydato)bis(pyridine)-cobalt(II) with excess pyridine.

5.2. Time-Dependent Systems

Since even small changes in spin density cause relatively large NMR shifts, it is possible to detect even very short-lived complexes between a paramagnetic and a diamagnetic molecule [2,4,54,55]. It is particularly advantageous here that under the conditions of a fast exchange, *i.e.* when the diamagnetic partner is present in a large excess, the line widths found are relatively small. If, for example, excess pyridine is added to the cobalt(II) complex shown in Figure 9, the absorption signals of the pyridine protons become sharper (Fig. 11).

In the presence of small quantities of paramagnetic metal ions, it is possible in this way to determine the positions in the diamagnetic molecule where the metal ion is particularly readily attached from the line widths and shifts [2,4].

We are grateful to Professor H. P. Fritz, without whose suggestions and constant encouragement our own work would have been impossible. We also thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their generous financial support. B. M. Golla, P. B. Burkert, and W. Gretner have contributed to the success of the investigations by discussion and experiment.

Structure and Immunogenicity of Synthetic Antigens

By Erwin Rüde [*]

Synthetic antigens are often valuable tools in immunological research. They are usually linear or branched polypeptides, prepared by polymerization of N-carboxy-α-amino acid anhydrides or by polymerization of defined oligopeptides. Owing to their great variability, these simple antigens allow a systematic study of the chemical and physical parameters involved in immunogenicity, i.e. the ability of a substance to initiate an immune response in higher animals. The study of very simple synthetic antigens made possible the first detailed analysis of genetic factors controlling the immunogenicity of a substance. The results have led to a better understanding of many immunological phenomena, and have helped to explain the complex processes initiated by antigens that lead to a specific immune response.

1. Introduction

Many microorganisms (bacteria and viruses) are known to induce specific immunity in higher animals. In 1890, *von Behring* and *Kitasato* [1] demonstrated that immunity to diphtheria was associated with the presence of protective substances in the serum. These substances were called *antitoxins* since they were able to specifically neutralize diphtheria toxin. Subsequently, many additional antitoxins (*antibodies*), which are highly specific in their ability to react with the original invading organisms or their toxins, have been described.

Antibodies are serum proteins which, on the basis of their electrophoretic migration were classified in 1938 by *Tiselius* and *Kabat* [2] as γ-globulins. However, immunity and antibody formation can be induced not only by infection with living bacteria or viruses but also by injection of killed microorganisms, by macromolecular constituents of these microorganisms, and in general by many exogenous substances (usually macromolecular) of natural or synthetic origin. Those substances responsible for the induction of antibodies are known as *antigens*, or more recently also as *immunogens* (see below). Antigens not only induce the formation of antibodies, which circulate in the serum, but may also initiate defensive reactions that are mediated directly by certain cells. Like antibodies, these cells are specifically directed against the antigen in question, presumably with the aid of antibody-like receptors on the cell surface. This cellular immunity is of great importance in many immunological reactions, such as the rejection of transplanted foreign tissues or delayed hypersensitivity reactions.

In general, a substance must be foreign to the host in order to induce an immune response. Thus, the host is *immunologically tolerant* to its own constituents. Rare exceptions are seen in certain diseases known as autoimmune diseases. Tolerance toward exogenous substances that normally act as antigens can, however, also be produced experimentally. In the tolerant state the host is unable, for a limited period or for life, to form antibodies against the exogenous substance in question. The formation of antibodies to other foreign substances, on the other hand, is not affected. Thus, tolerance, like immunity, is very specific.

It is of great theoretical and practical interest to clarify the cellular and biochemical mechanisms of these processes. One of the most intriguing facets of this topic is the high specificity of all immunological reactions, which must ultimately depend upon the structure of the antigens and antibodies (or of the postulated antibody-like cell receptors).

When *Karl Landsteiner* [3] started his investigations on immunological specificity and its chemical foundations at the beginning of the present century, it was impossible to establish the structure of antibodies or of natural antigens, most of which are macromolecular substances. *Landsteiner* was, therefore, the first to use artificial antigens which were prepared by linking low molecular weight compounds (*e.g.* by azo coupling) to natural antigens, mostly proteins (cf. *e.g.* [4, 5]). After injection of proteins modified in this way, experimental animals formed antibodies that reacted specifically with the low molecular weight group introduced, as well as antibodies against the protein carrier itself. It was thus possible to vary the structure of the groups introduced into an antigen and to study the variation of the antibodies formed. Experiments of this nature led to the important discovery that antibodies are directed, not against the macromolecular antigen as a whole, but against specific structural subunits known as determinant groups. recent investigations, the active sites of antibody molecules are complementary to structures or determinant groups having a maximum size of about a hexasaccharide or of a tetra- to hexapeptide [6,8].

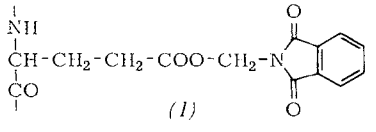
Extensive studies with artificial antigens have led to the view that antigens consist of two functionally different parts. *The high molecular weight carrier* is responsible for the antigenicity, *i.e.* for the stimulation of antibody formation, while *the determinant groups* determine the specificity of the antibody. Low molecular weight compounds that can function as determinant groups in the intact macromolecular antigen are themselves usually incapable of inducing antibody formation. These low molecular weight compounds can, however, be specifically bound by homologous antibodies. The same is true of many larger fragments of antigens. Serologically active substances of this type that are not themselves antigenic are known as *haptens*.

The structures of the determinant groups of natural antigens have been widely investigated during the past few decades. This approach has been particularly successful in establishing the determinants of polysaccharide antigens such as bacterial polysaccharides [4–7] and blood group substances [9]. The task has been more complicated in the case of proteins, since the structure of the determinant groups is determined in many cases by the secondary and tertiary structure of the protein [10].



During these investigations, which were almost exclusively concerned with the serological specificity of antigens, the term "antigen" was occasionally used as a general term for substances that react specifically with antibodies, *e.g.* that precipitate them. The primary property of an antigen, *i.e.* its ability to stimulate the formation of antibodies or cellular immunity *in vivo*, was often ignored. It is only recently that growing interest has been shown in the question of the chemical and physical properties that a substance must have in order to be antigenic in the sense of the original definition. The term "immunogenicity" was introduced to allow a clear distinction between this property and "antigenicity" in the sense of serological specificity.

It has been known for a long time from experience with natural antigens that the immunogenicity of a substance can depend in a characteristic manner on its composition and molecular weight [11]. Thus whereas foreign proteins have generally been found to be very effective immunogens, many highly purified polysaccharides are not immunogenic, particularly in rabbits. In addition to chemically modified and partly degraded antigens of natural origin, increasing use has been made since 1960 of completely synthetic polypeptide antigens for the systematic study of immunogenicity [12]. Synthetic polypeptides have a known, relatively simple, and modifiable structure, and so facilitate the interpretation of immunological results.

2. Synthesis of Model Antigens

Synthetic model antigens have, so far, been built up almost exclusively from amino acids. In most cases, these polypeptide antigens have not been synthesized by stepwise methods and, therefore, have no defined amino acid sequence, but are homopolymers or copolymers which can be prepared relatively easily even with high molecular weights. The synthesis of poly-α-amino acids of this type has been reviewed by *Katchalski* and *Sela* [13], and is therefore merely illustrated here with the aid of a few examples.

The monomeric starting materials are *N*-carboxy-α-amino acid anhydrides (Leuchs anhydrides) *(2)*, which are usually prepared by reaction of amino acids with phosgene in inert anhydrous solvents (Fuchs-Farthing method). Functional groups in the side chains of the amino acids are generally blocked by protective groups. Only tyrosine is usually used in unsubstituted form. Benzyl (benzyl esters, benzyl ethers) and benzyloxycarbonyl groups, which can be removed after the polymerization by treatment with hydrogen bromide in glacial acetic acid, are adequate as protective groups in the majority of cases. In the synthesis of polypeptide derivatives of proteins (see Section 2.3), on the other hand, it is necessary to use protective groups

(1)

that can be removed under milder conditions. The trifluoroacetyl group [14] and the phthalimidomethyl group [15] [cf. *(1)*] have been used to protect, respectively, the ε-amino group of lysine and the γ-carboxyl group of glutamic acid; these two protective groups can be removed above pH = 10, *e.g.* by treatment with piperidine in aqueous solution at 0 °C.

2.1. Linear Poly-α-amino Acids

N-Carboxy-α-amino acid anhydrides *(2)* can polymerize in inert solvents in the presence of basic cata-

lysts with loss of carbon dioxide. The products are linear poly-α-amino acids *(3)* [13].

(2)

(3)

Racemization does not occur either in the preparation of the anhydrides or during the polymerization. The average degree of polymerization can be widely varied by variation of the quantity and nature of the basic initiator. Tertiary amines and sodium methoxide generally give high molecular weights 2×10^4—10^6), while secondary and primary amines give lower molecular weights (10^3—2×10^4). Primary and secondary amines are incorporated into the peptide chain as amides at the C-terminal end.

Copolymerization of different *N*-carboxy-amino acid anhydrides yields polymers with an approximately random distribution of the various types of amino acid residues over the polypeptide chain. The solubility of linear polymers and copolymers in water, which is of particular interest for model antigens, is largely dependent on the amino acid composition (hydrophilic or hydrophobic side chains), the secondary structure (random coil, α-helix, or β form "crosslinked" by intermolecular hydrogen bonds), and the molecular weight [13,22]. Highly ordered homopolymers are generally less soluble than copolymers. For example, poly-L-alanine and poly-D-alanine are insoluble in water, whereas the "copolymer" poly-D,L-alanine dissolves very readily.

2.2. Branched Poly-α-amino Acids

The synthesis of branched (multichain) poly-α-amino acids for immunological studies was developed mainly by *Sela et al.* [16]. Usually, poly-L-lysine [*(4)* in Fig. 1] or a linear copolymer containing lysine residues was used as a backbone for such polymers. The ε-amino groups of the lysine residues act as initiators for the polymerization of *N*-carboxy-amino acid anhydrides. Peptide side chains, whose lengths can be varied within wide limits, are polymerized onto the linear backbone.

This reaction can be carried out in aqueous media, since the polymerization proceeds more rapidly than the hydrolysis of the anhydrides. Linear polymers of about the same length as the side chains are formed as by-products; these are separated from the branched high molecular weight polymer by dialysis or gel filtration.

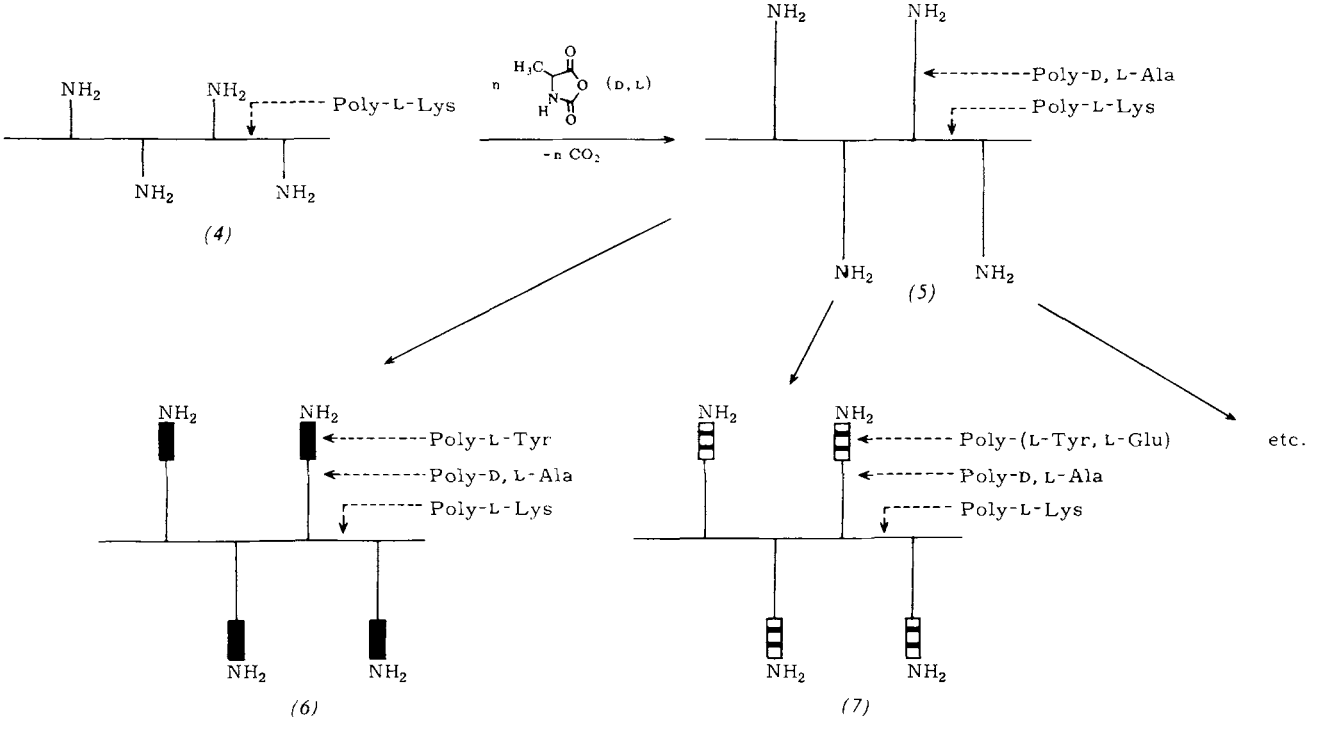

Fig. 1. Preparation of branched poly-α-amino acids according to *Sela* [12], schematic.

A branched polymer frequently used for the synthesis of model antigens is one having a poly-L-lysine backbone and poly-D,L-alanine side chains (on average 15 to 20 alanine residues) [17]. This polymer *(5)* is usually referred to as multichain poly-D,L-alanine. Poly-D,L-alanine side chains, unlike poly-L-alanine or poly-D-alanine side chains, make the polymer water-soluble. Similar polymers with polyproline side chains have recently been synthesized; like linear poly-L-proline or poly-D-proline, these polymers are water-soluble even when composed of amino acids of one optical configuration [18].

[17] *M. Sela, S. Fuchs*, and *R. Arnon*, Biochem. J. *85*, 223 (1962).

[18] *J. Jaton* and *M. Sela*, J. biol. Chemistry *243*, 5616 (1968).

Each side chain of these branched poly-α-amino acids again ends with an amino group, which can be used as the starting point for the polymerization of any other amino acid, such as tyrosine or short copolymers of tyrosine and glutamic acid [cf. *(6)* and *(7)* in Fig. 1][17–19]. The total number of possible variations is immense.

2.3. Polypeptide Derivatives of Proteins

The ε-amino groups of the lysine residues and the N-terminal amino groups of proteins [*(8)* in Fig. 2] can also act as initiators for the polymerization of *N*-carboxy-amino acid anhydrides. Polypeptide chains are

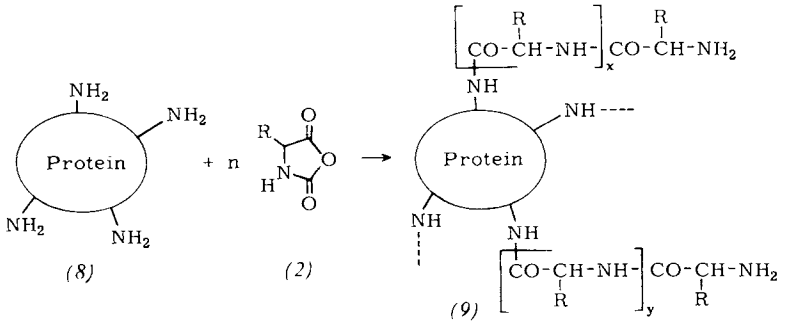

Fig. 2. Preparation of polypeptidyl proteins, schematic.

polymerized onto these amino groups under very mild conditions in aqueous solution at pH = 7[20]. However, all the amino groups of native proteins do not necessarily react with the anhydride, since the reactivities of individual amino groups are dependent on the secondary or tertiary structure of the protein[21]. The properties and the biological activity of polypeptide derivatives of the type *(9)* of enzymes, hormones[22,23], and antibodies[24] are naturally of great interest. Modified proteins of this type may in some cases be more valuable for immunological studies than proteins that contain only relatively small artificial determinants such as dinitrophenyl or arsanilic acid residues[25,26].

2.4. Polypeptides of Defined Sequence

The poly-α-amino acids described here are simple in structure but, owing to the method of synthesis, they have a random sequence of the amino acid residues. In many investigations, however, it is necessary to know the precise sequence of the amino acids. The stepwise synthesis of high molecular weight antigens having a specific amino acid sequence is laborious. *Prefabricated oligopeptides of known structure* are, therefore, used as the starting materials and are either converted into branched macromolecules by condensation with a linear backbone polymer, or are polymerized to form linear polymers with periodically repeating amino acid sequences.

E. Haber et al. have condensed the oligopeptide hormones angiotensin (octapeptide) and bradykinin (nonapeptide) onto a poly-L-lysine backbone according to the first method[27]. On average, one oligopeptide side chain was bound to every 33rd or every 5th lysine residue respectively *via* the C-terminal carboxyl group of angiotensin with carbodiimide, and *via* the N-terminal amino group of bradykinin with 1,2-diisocyanato-4-methylbenzene.

Boc = *tert*-butyloxycarbonyl; Bzl = benzyl; OSu = succinimidoxy.

An example of the synthesis of a model antigen *(13)* by the second method employed an oligopeptide whose N-terminal amino group was blocked by the *tert*-butyloxycarbonyl (Boc) residue and whose C-terminal end was activated as the *N*-hydroxysuccinimide ester (OSu) *(10)*. After removal of the Boc group with

hydrochloric acid, polymerization of the oligopeptide *(11)* (which was still protected as the hydrochloride) to *(12)* was started by liberation of the N-terminal amino group with triethylamine[28]; *(13)* was obtained from *(12)* by treatment with hydrogen bromide.

3. Immunological Methods

3.1. Immunization

The immunogenicity of a substance is nearly always determined by *in vivo* experiments. Only recently has it been possible to stimulate antibody formation *in vitro* using cultures of lymphoid cells or small fragments of spleen tissue[29]. To determine whether a substance is immunogenic, one naturally uses the immunization method that is thought, from existing knowledge and experience, to be most effective[30]. Synthetic model antigens are, therefore, nearly always injected together with an adjuvant, usually complete Freund's adjuvant.

Adjuvants increase the immunogenicity of antigens in a non-specific manner; nothing definite is known about their mode of action. Experience has shown that there is no generally applicable optimum immunization method. Antigens may be injected once or repeatedly, at various intervals, and in various doses. The success of a given course of immunization is decisively affected, *inter alia* by the nature of the antigen and the species of animal used. Consequently, statements about the immunogenicity of a substance are valid only for the conditions used in the tests. In particular, the observation that a substance is not immunogenic should not be generalized, since it is quite possible that a different immunization method or simply a different dose of the antigen could lead to antibody formation in another species of animal or in another strain of the same species.

Branched poly-D,L-alanine *(5)*, for example, was long thought to have no immunogenicity. However, antibody formation was detected in about 80% of the test animals (rabbits) when the polymer was injected into many intradermal sites instead of intramuscularly[31].

3.2. Detection of Antibodies

In addition to the immunization method, another important factor in the assessment of the immunogenicity of a substance is the sensitivity of the method for the detection of the antibodies. In investigations with synthetic antigens, generally applicable methods have been used both *in vitro* and *in vivo*[11,32]. The *in-vitro* methods include the precipitin test, passive hemagglutination, the complement fixation reaction, and binding assays with radioactively labeled antigens. Methods used for the detection of antibodies *in vivo* and for the detection of cellular immunity include skin tests. The treated animal is injected intradermally with small quantities of antigen, and if circulating antibodies are present, an allergic skin reaction appears after 15–20 min, possibly giving the typical appearance of the "Arthus' reaction" after about 5–6 hours. If, on the other hand, a skin reaction appears only after 1–2 days it is a delayed-type hypersensitivity (example: tuberculin reaction), which is not due to the presence of circulating antibodies but is mediated directly by specifically reactive cells.

The passive cutaneous anaphylaxis test (PCA test), on the other hand, is not carried out on the immunized animal itself. The serum sample to be tested for antibodies is transferred instead to a normal animal by intradermal injection. The antigen is then injected intravenously, together with a dye that makes the local antigen-antibody reaction visible.

4. Immunological Studies with Synthetic Antigens

4.1. Structural Aspects

Poly-α-amino acids were originally used mainly in physicochemical studies as simple models of the polypeptide chains of proteins[22]. The first observations that completely synthetic macromolecules of this type can also act as immunogens were due to *Stahmann et al.* (1955)[33]. In 1960, *Sela* and *Arnon*[34] synthesized a branched polymer and *Gill* and *Doty*[35] prepared a linear copolymer of amino acids; both of these products were found to be immunogenic. Many similar substances have been examined for immunogenicity in further investigations by various groups of workers (*Gill*, *Sela*, *Maurer*, *Benacerraf*, and others[12]).

4.1.1. Amino Acid Composition

The first question to arise was how the immunogenicity of synthetic polypeptides depended on their amino acid composition. The first systematic studies on this point, however, were carried out not with synthetic polypeptides but with polypeptide derivatives of gelatin, *i.e.* artificial antigens[19,36]. Gelatin itself is

only very weakly immunogenic, *i.e.* test animals on immunization produce only very small quantities of specific antibodies. By grafting peptide chains of various compositions onto the gelatin (Fig. 2) it was possible to determine which amino acids increased the immunogenicity of the gelatin (increased production of antibodies). Increased immunogenicity was observed primarily with some aromatic amino acids (tyrosine, phenylalanine), and also with cyclohexylalanine, the non-aromatic analog of phenylalanine. Amino acids such as serine, glutamic acid, and lysine had no effect. It is interesting to note that combinations of these inactive amino acids in the form of copolymers, *e.g.* of glutamic acid and lysine, lead to a pronounced increase in immunogenicity.

The simplest poly-α-amino acids, *i.e.* linear homopolymers *(3)* made from only one type of amino acid residue, appear, with few exceptions, to be non-immunogenic. Polyproline [37], polylysine [38,81], and polyglutamic acid [81], were weakly immunogenic in rabbits or guinea pigs, as demonstrated by the detection of antibodies or by delayed skin reactions (see Section 3.2). The non-immunogenicity of many homopolymers is not, however, due to inability of the animals to synthesize antibodies of suitable specificity. If amino acids in the form of short homopolymer chains were attached to a protein carrier (Fig. 2), antibodies that were directed against the homopolymers could be detected after injection of these artificial antigens, *i.e.* the homopolymers acted as determinant groups [25]. Homopolymers thus usually behave as haptens; they can initiate antibody formation only when combined with an immunogenic carrier.

The binding of linear homopolymers (haptens) to a protein carrier need not be covalent. The essentially non-immunogenic, negatively charged polyglutamic acid forms an insoluble complex with the positively charged methyl ester of serum albumin. Injection of this complex produces antibodies that are specifically directed against polyglutamic acid. Polylysine behaves similarly after complex formation with negatively charged carrier proteins [39]. It is even possible, in this way, to obtain antibodies against nucleic acids and against acidic polysaccharides that are non-immunogenic by themselves [40].

Unlike homopolymers, linear copolymers of two amino acids were found to be immunogenic in certain cases (depending on the amino acid composition and the species of animal examined), but usually not far all individuals of a species (genetic control, see Section 4.2). Finally copolymers of three, and particularly of four, different amino acids were generally effective immunogens [12,41].

Multichain poly-α-amino acids have been used mainly by *Sela et al.* for immunological studies. The starting polymer was usually multichain poly-D,L-alanine *(5)*, which, as mentioned earlier, was not immunogenic under the experimental conditions originally used by these authors. The influence of a variety of amino acids on the immunogenicity of this polymer was investigated by polymerizing them onto the ends of the D,L-alanine side chains (Fig. 1) [12,17,19,42]. Thus an average of 1.7 tyrosine residues bound per side chain was sufficient to convert multichain poly-D,L-alanine into an immunogen [cf. *(6)*]. Particularly effective immunogens were obtained by extension of the D,L-alanine side chains with short copolymers (about 6–7 amino acid residues) of glutamic acid combined with either tyrosine, histidine, or phenylalanine [cf. *(7)* in Fig. 1]. As in the case of gelatin, a combination of glutamic acid with lysine led also to an immunogenic polymer, whereas extension of the side chains with short homopolymers of glutamic acid or lysine alone had no effect.

However, no strict rules for the relation between amino acid composition and the immunogenicity of synthetic polypeptides can be derived from all these experiments. This may be due to the many factors that influence antibody formation *in vivo*. The following empirical rules can however be formulated:

1. Aromatic amino acids appear to be particularly effective in enhancing immunogenicity; however, they are not essential to the immunogenicity of a polymer, since polypeptides that do not contain aromatic amino acids can be effective immunogens.

2. A certain structural complexity appears to be important for immunogenicity. As is shown by the examples mentioned, the probability that a synthetic polypeptide will be immunogenic increases with the number of different amino acid residues present, and hence, in the case of copolymers, with the number of statistically possible amino acid sequences.

Several studies have shown that the induction of an immune response may be stimulated considerably by the cooperation of two types of lymphoid cells in antigen recognition. It has been suggested that these cells, with the aid of antibody-like cell receptors, possibly recognize different determinants of an antigen molecule [43,44]. One might expect, therefore, that substances having a complex structure with several different determinants will be more effective immunogens than very simple molecules such as homopolymers of amino acids.

Substantial agreement has been found between the results and the empirical rules derived from them for polypeptide derivatives of gelatin and for linear and highly branched synthetic poly-α-amino acids. The shape of a macromolecule is thus of no great importance to immunogenicity.

4.1.2. Steric Accessibility of Determinant Groups

Branched polypeptide antigens can be varied not only in their amino acid composition but also in the arrangement of the amino acid residues, so that it is relatively easy to study the influence of the steric accessibility of determinant groups on immunogenicity.

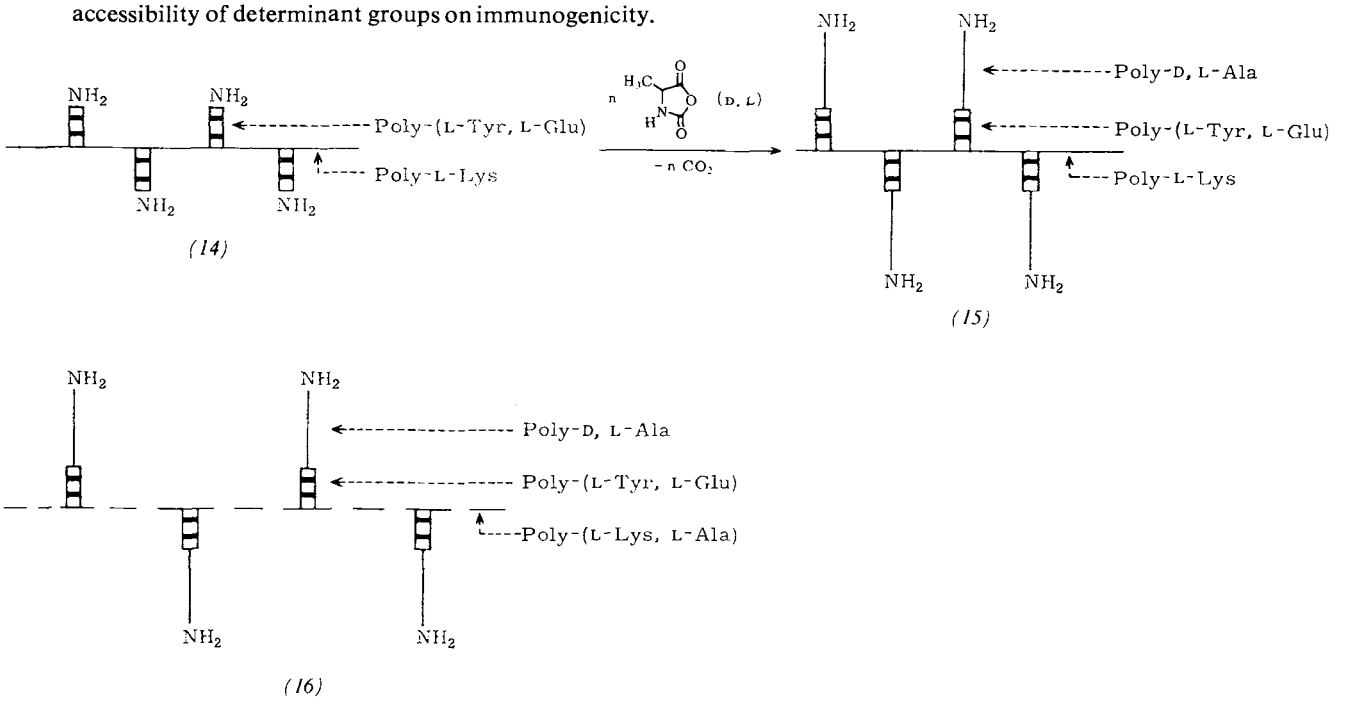

Fig. 3. Synthesis of branched poly-α-amino acids according to *Sela* [12], schematic.

Polymers were synthesized as follows and examined for their ability to initiate antibody formation [17]. Short copolymers of tyrosine and glutamic acid were polymerized directly onto a poly-L-lysine backbone. The resulting branched polymer *(14)* was found to be immunogenic. Extension of the side chains by about 20 D,L-alanine residues then gave a product *(15)* corresponding in molecular weight and in composition to the substance *(7)* described above. The tyrosine-glutamic acid sequences, however, were now in the interior of the molecule instead of on the outside. This polypeptide *(15)* was not immunogenic, though a related polymer with greater average distances between the side chains was. Such a polymer *(16)* was obtained by using a copolymer of lysine and alanine instead of pure poly-L-lysine as the backbone.

It follows from these investigations that those structures that are important to the immunogenicity of a macromolecule must be sterically accessible in order to initiate antibody formation. If this condition is satisfied, it does not appear to be essential that these structures (*e.g.* the Tyr-Glu sequences) are located at the end of, or within, the polypeptide side chains.

4.1.3. Chemical Substitution

In addition to amino acid residues a great variety of other groupings can be introduced into synthetic polypeptides [12]. Thus, the coupling products of poly-α-amino acids with simple aromatic haptens such as 2,4-dinitrophenyl groups [45,46], arsanilic acid [47,48], with penicillin [49], coenzymes [50], nucleosides [51], sugars [52], and glycolipids [52a] have been used as model antigens. Depending on the aim of the investigations, the focal point was either the immunogenicity of the substitution products or the specificity of the antibodies formed.

As was mentioned earlier, linear homopolymers such as poly-L-tyrosine and poly-L-lysine are usually very weakly or non-immunogenic. Immunogenic conjugates were obtained from both homopolymers by introduction of arsanilic acid residues or of dinitrophenyl, *p*-toluenesulfonyl (tosyl), or 5-dimethylamino-1-naphthalenesulfonyl (dansyl) groups respectively. Products containing about one hapten residue to about 20 amino acid residues were more immunogenic than more highly substituted derivatives, some of which were non-immunogenic [45,48].

Sugars are of great importance in determining the serological specificity of many natural antigens [4,5,7,9], and can also function as determinant groups in artificial antigens [52–56]. Pure polysaccharides, however, very often exhibit an immunological behavior which in several respects differs from that of protein and polypeptide antigens. For example, they are usually non-immunogenic in rabbits [11], but function as haptens, which can stimulate the synthesis of polysaccharide-specific antibodies only when combined with an immunogenic carrier (*e.g.* a protein) (see Section 4.1.1). In contrast to protein antigens immunization of mice with capsular polysaccharides of pneumococci, leads to antibody formation only at very low antigen doses, while no antibodies are detectable, at least in the serum of the animals, when the usual higher doses are used.

Higher doses of polysaccharides very readily produce immunological "paralysis" in the animals. As in the state of experimentally induced tolerance, the immunologically paralyzed mice are apparently incapable of forming antibodies against the polysaccharide in question for some time. Recent studies indicate that the state of immunological paralysis may not necessarily be identical with that of tolerance (see Section 4.1.5) [57,58].

In view of these immunological properties of polysaccharides, it appeared to be of interest to examine the influence of sugars on the immunogenicity of synthetic polypeptides. For example, is it possible to convert multichain poly-D,L-alanine *(5)*, which is only slightly immunogenic, into a good immunogen by the attachment of sugars in the same way as by grafting tyrosine peptides?

Since aromatic rings may be sufficient by themselves to confer immunogenicity, it was necessary to develop a method of linking sugars to synthetic polypeptides without the usual aromatic connecting links [53,55]. The sugars were bound to polypeptides *via* *O*-glycosides of serine, which also link the carbohydrate moiety to the peptide chain in many glycoproteins. The *O*-acetylated serine glycosides *(17)* of several mono- and disaccharides were prepared, as illustrated for the case of glucose, and converted into the *N*-carboxy amino acid anhydrides *(18)* by treatment with phosgene [59]. Using these anhydrides, serine glycosides could be polymerized onto the side chains of multichain poly-D,L-alanine *(5)* (an average of 1.5–2.5 glycosyl-serine residues per side chain) in the same way as other amino acids [52].

(18) *(17)*

The resulting sugar-polypeptide conjugates [*(19)* in Fig. 4] were tested for their immunogenicity in rabbits. Under the conditions used, multichain poly-D,L-alanine *(5)* itself was found to be weakly immunogenic for about 50% of the animals, whereas practically no antibody formation was observed on injection of the polymers containing glucose, *N*-acetylglucosamine, or lactose. With polymers containing galactose, rhamnose, or cellobiose, the antibody titer was approximately the same as or slightly higher than that found with multichain poly-D,L-alanine *(5)* [60]. In agreement with the behavior of polysaccharides, therefore, the sugars studied, unlike aromatic amino acids or nucleosides [51], appear to be incapable of significantly increasing the immunogenicity of the carrier polypeptide.

Further experiments were carried out to establish whether the immunogenicity of sugar-polypeptide conjugates could be enhanced by the additional incorporation of long-chain fatty acids as "internal adjuvants". Fatty acids in the form of glycolipids are important constituents of natural adjuvants, such as

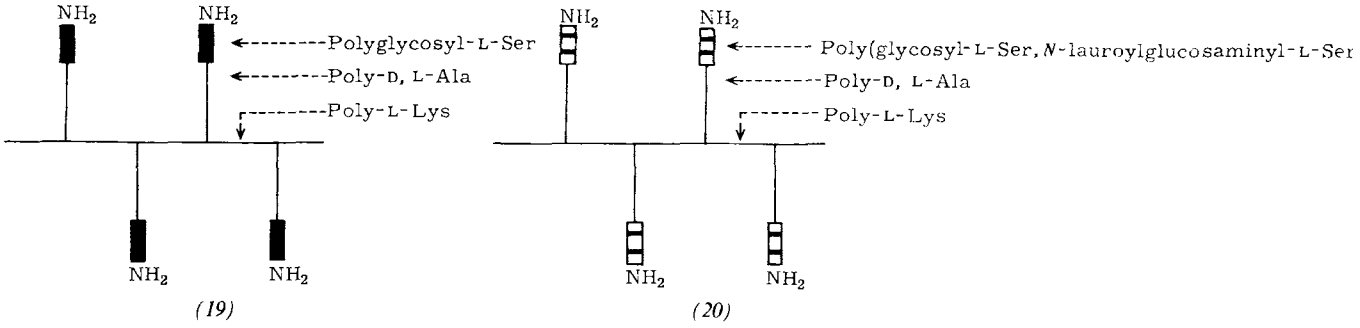

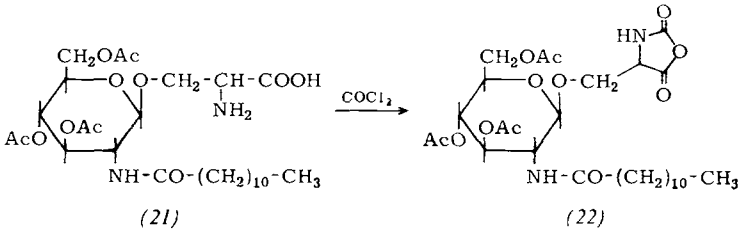

Fig. 4. Synthesis of branched sugar-polypeptide conjugates, schematic; Glycosyl = β-D-glucosyl, β-D-galactosyl, α-L-rhamnosyl, β-D-*N*-acetylglucosaminyl, β-D-lactosyl, or β-D-cellobiosyl.

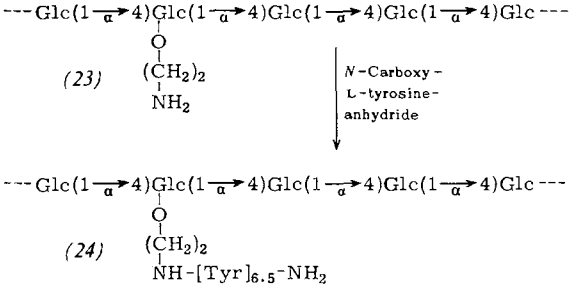
certain wax fractions from tubercle bacilli [61] or the endotoxins of gram-negative bacteria [62]. By analogy with these natural glycolipids, lauric acid bound to the amino group of glucosamine was linked to synthetic antigens [*(20)* in Fig. 4]. *O*-Peracetylated *N*-lauroyl-glucosaminyl-serine *(21)* was synthesized and polymerized onto the side chains of multichain poly-D,L-alanine [*via* its *N*-carboxy amino acid anhydride *(22)*], together with one of the above-mentioned serine glycosides, in the form of short copolymers (*e.g.* 0.6 *N*-lauroyl-glucosaminyl-serine and 2.0 glucosyl-serine residues per side chain).



(21) *(22)*

In most cases the resulting conjugates *(20)* containing fatty acids were more effective immunogens than the corresponding ones *(19)* containing simple serine glycosides only [60]. Due to the presence of fatty acid residues these polymers *(20)* were highly aggregated and at a content of about 0.7 *N*-lauroyl-glucosamine residues per side chain were insoluble in water. This property may contribute to the increased immunogenicity of such conjugates. (The influence of the state of aggregation on the immunogenicity of a substance is discussed in Section 4.1.4.) As shown by inhibition experiments, the antibodies formed were directed against both the glycosyl-serine and the *N*-lauroyl-glucosaminyl-serine residues. In the latter case the fatty acid residue appeared to be an essential part of the determinant group.

Model antigens containing polysaccharides as "backbones" instead of linear poly-α-amino acids have been synthesized for further investigations. In particular, simple peptide side chains were to be introduced into polysaccharides to determine the minimum conditions under which a non-immunogenic polysaccharide becomes immunogenic. With this in mind, dextran and amylose, both of which are non-immunogenic for rabbits, have been aminoethylated with ethyleneimine (every 7th to 40th glucose residue was substituted) [see *(23)*]. As in the synthesis of branched polypeptides, side chains of 6–7 tyrosine residues each were polymerized onto the primary amine groups by means of *N*-carboxy-L-tyrosine anhydride to form *(24)* [63].

Following the immunization of rabbits with poly-L-tyrosyl-polysaccharides *(24)* having both low and high degrees of substitution, specific antibodies were detected in the serum. Thus even relatively few tyrosine chains are sufficient to confer immunogenicity. Aggregation and low solubility of these polymers containing tyrosine peptides may also contribute to their immunogenicity. The antibodies formed in the

case of the dextran derivative are directed *both against the tyrosine side chains and against dextran itself*, whereas those formed in the case of the amylose derivative are directed *only against the tyrosine side chains*. This may be due to a natural tolerance of the animals to glycogen, which in its basic structure of (1→4)-α-linked glucose units is closely related to amylose. Finally, treatment of rabbits with polymers in which tyrosine side chains were attached to a polyvinyl alcohol backbone also led to a very weak

antibody response directed against the tyrosine chains[64]. According to *Gill* and *Kunz*[86], several other vinyl polymers were also immunogenic when injected in doses of 1 to at most 100 μg (see Section 4.1.5).

4.1.4. Molecular Weight and State of Aggregation of the Immunogen

It has long been accepted that a high molecular weight is a necessity if a substance is to be immunogenic. No general values can be given for the minimum molecular weight, which can evidently differ considerably from substance to substance. In the case of dextran, *Kabat* and *Bezer* found a sharp decrease in immunogenicity (in humans) when the average molecular weight was decreased from 90000 to 50000[65]. On the other hand, in studies with polypeptide antigens it was found that the molecular weight is frequently of surprisingly little importance to immunogenicity. Linear copolymers of alanine, tyrosine, and glutamic acid having an average molecular weight of 4000, for example, were similar in immunogenicity to polymers of higher molecular weight[17,66]. Among the oligotyrosine peptides the hexapeptide and the tripeptide, and even *N*-acetyltyrosine, were found to be immunogenic when coupled with, on average, one arsanilic acid residue[67].

Oligolysines whose terminal α-amino groups were substituted with 2,4-dinitrophenyl residues showed a very remarkable dependence of immunogenicity on the number of lysine residues[68,69]. All the substituted oligomers up to the hexapeptide were non-immunogenic, whereas α-dinitrophenyl-heptalysine and all higher homologs could induce both antibody formation and delayed hypersensitivity in guinea pigs.

Another surprising observation was that α-dinitrophenyl-nonalysine lost its immunogenicity when an L-lysine residue in the middle of the peptide chain was replaced by a D-lysine residue[70]. It has also been shown particularly clearly by these experiments that delayed type skin reactions could be caused only by substances that were themselves immunogenic, and not by haptens[69].

In experiments with low molecular weight substances one cannot rule out the possibility that the immunogenicity of these compounds arises only through fixation to body proteins or cells, particularly since it is known (see Section 4.1.1) that the binding of a hapten to a carrier need not be covalent. Even if such complex formation does occur, however, it does not explain the very marked dependence of immunogenicity on the chain length in the case of the oligolysine peptides.

As was mentioned in connection with synthetic sugar-polypeptide conjugates containing fatty acids, the association of molecules to form large aggregates may also have a considerable influence on immunogenicity. This was demonstrated particularly well in studies on the immunogenicity of immune globulin G (IgG)[71]. Normal preparations of bovine IgG usually contain small quantities of aggregated material in addition to IgG monomers, and when injected into mice without an adjuvant, induce antibody formation. After separation of the aggregated fraction by centrifugation, the aggregate-free material is no longer immunogenic, but leads to partial tolerance to bovine IgG after injection.

These and other experiments corfirm the long-established empirical rule that particles such as viruses, bacterial flagellae, *etc.* are much more potent immunogens than soluble proteins[72,73]. Since particles are more readily taken up by phagocytic cells (macrophages) than soluble materials, these observations are often regarded as an argument in favor of the participation of macrophages in induction of an immune response[74].

4.1.5. Optical Configuration of the Amino Acid Residues

As was first shown by *Landsteiner* and *van der Scheer* with tartaric acid, antibodies are capable of differentiating between the enantiomeric forms of determinant groups[75]. For example, antisera directed against a peptide consisting of L-amino acids do not cross-react with the corresponding peptide from D-amino acids, and *vice versa*. In the present discussion, however, we are not so much interested in the serological specificity of a polypeptide synthesized from L- or D-amino acids as in its immunogenicity and the following results are important in this connection.

As described above, the immunogenicity of gelatin or of multichain poly-D,L-alanine *(5)* could be considerably enhanced by the attachment of short peptide chains composed of L-tyrosine. The same effect is found with the corresponding peptides from D-tyro-

sine when polymerized onto these weakly immunogenic carriers, which themselves consist mainly of L-amino acids [76].

On the other hand, several authors found that polypeptides composed *exclusively* of D-amino acids were not immunogenic under the usual immunization conditions (about 1–10 mg of polypeptide per injection in the case of rabbits) [76–78]. However, the incorporation of 3% of L-amino acids into pure D-polymers was sufficient to convert the latter into weak immunogens, and the immunogenicity was further increased by a higher content of L-amino acids [79]. *Gill et al.* [80] then found – and this has since been confirmed [79,81] – that even polymers consisting entirely of D-amino acids are immunogenic when injected in very small quantities. Investigations on mice with D- and L-polymers of analogous composition gave the relation shown in Figure 5 for the antibody titer and the immunization dose [82].

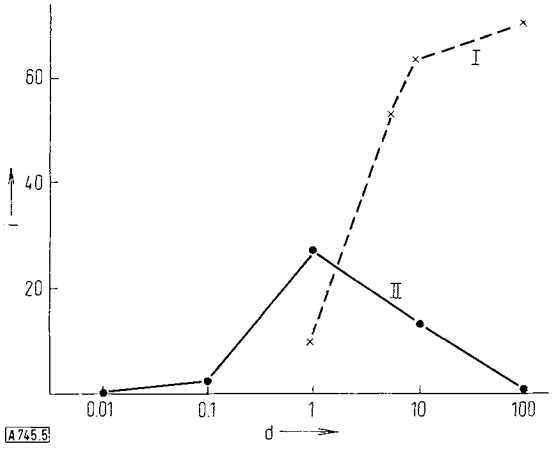

Fig. 5. Immunogenicity of copolymers of D- and L-amino acids having analogous composition, as a function of the dose used for immunization, according to *Janeway* and *Sela* [82]. I: L-polymer; II: D-polymer; *d*: dose in μg of polymer per mouse; i: antibody titer in % of 5 μg of radioactively labeled antigen bound to antibody per ml of serum.

Whereas the antibody titers increase with increasing dose for the L-polymer, reaching a plateau at 10 μg per mouse, the antibody titer obtained after immunization with the D-polymer passes through a maximum at about 1 μg per mouse, and falls off rapidly with larger doses. When injected without an adjuvant, the D-polymer, unlike the L-polymer, leads to immunological paralysis or tolerance even in very small doses. Similar experiments with rabbits also showed that polymers of D-amino acids produced no appreciable booster reaction [*] following secondary injection [81]. Polymers of D-amino acids thus behave in nearly all respects like certain polysaccharides (see Section 4.1.3). It seems reasonable to correlate this with the *very slow enzymatic degradation* observed for polymers of D-amino acids and for some polysaccharides [83–85].

Branched polymers having a linear poly-L-lysine backbone, poly-L-proline side chains, and short copolymers of D-tyrosine and D-glutamic acid attached to these side chains [cf. *(7)*] behaved like polymers that consist entirely of D-amino acids, despite their high content of L-amino acids (about 90%). Since no endopeptidases capable of cleaving the peptide linkage between L-proline residues have been yet detected, this becomes comprehensible because polymers of this type would behave as D-polymers insofar as their enzymatic degradation is concerned [18].

Even pure vinyl polymers such as polyvinylamine, polymethacrylic acid, and polyvinylpyrrolidone, which certainly show practically no susceptibility to enzymatic degradation, are, like polymers of D-amino acids, weakly immunogenic in rabbits when injected in very small quantities [86].

The possibility of enzymatic degradation thus appears to be of great importance for the immunological properties of a substance. Antigens that suffer little or no degradation and are eliminated from the organism only very slowly readily cause immunological paralysis, particularly when injected in fairly large doses. Paralyzed animals, like tolerant animals (see Section 1), appear to be incapable of producing circulating antibodies against the antigen in question, even after further injections of antigen with adjuvant.

Recent studies with polysaccharide antigens have shown that contrary to earlier observations, paralyzed mice have roughly the same number of cells forming antibody as do immunized animals, though no antibodies are detectable in their serum [58]. The antibody formation thus does not appear to be blocked as such. It is therefore proposed that the antibodies synthesized are immediately intercepted by the antigen and are then broken down enzymatically, while the antigen returns unchanged to the circulation. It is not yet certain whether this interpretation of the phenomenon of immunological paralysis is also generally valid for other antigens such as polymers of D-amino acids, or whether true blockage of antibody formation, and hence a state of tolerance, predominates.

4.1.6. Secondary Structure and Serological Specificity

In addition to model antigens prepared by polymerization or copolymerization of various amino acids, increasing use has recently been made of polypeptide antigens having a specific amino acid sequence, which allow a more precise interpretation of the immunological results, particularly with regard to the specificity of the antibodies formed.

The structure of the determinant groups of native proteins, as was mentioned earlier, is often determined, not directly by the linear sequence of amino acids, but by the three-dimensional configuration of the peptide chains. Using a synthetic antigen *(13)* consisting of repeating tripeptide units (Tyr-Ala-Glu-)$_n$ (see Section 2.4), *Sela et al.* were able to demonstrate clearly the influence of the secondary structure on the serological specificity of a polypeptide chain [28]. The linear polymer *(13)* is in the form of an α helix under physiological conditions, and is immunogenic for rabbits. The precipitation of the resulting antibodies with the helical polymer is not inhibited by the tripeptide Tyr-Ala-Glu or by the hexapeptide (Tyr-Ala-Glu-)$_2$. Moreover, these antisera do not cross-react with a branched polymer *(25)* having the same sequence Tyr-Ala-Glu at the ends of the side chains.

Conversely, antibodies obtained by immunization with this branched polymer exhibited practically no reaction with the linear helical polymer *(13)*. The

(25)

specificity of the antibodies is thus determined by the conformation of the peptide chain (α helix) in the first case (conformational determinant), and not simply by the linear sequence of the amino acids (sequential determinant), as with the branched polymer.

A polymer having the repeating sequence (Pro-Gly-Pro-)$_n$, which was synthesized as a model for collagen, probably exists in solution, like collagen, as a three-stranded helix [28]. This similarity of secondary structure is probably the reason for the positive cross reaction of the antibodies formed in response to this polymer with collagen from various sources.

It follows as a necessary conclusion from these observations that the frequently discussed "processing" of an antigen [87,90] in the induction of antibody formation cannot consist in extensive enzymatic degradation into small fragments, or at least not before recognition of the specificity of the determinant groups. Degradation of this nature would lead to loss of the tertiary and secondary structures of proteins or polypeptides, *i.e.* destruction of those features against which the antibodies are directed in many cases [10]. The immunogenicity exhibited by vinyl polymers under certain conditions also leads to the conclusion that degradation of the antigen is not necessary for the specific stimulation of antibody formation itself. On the other hand, the results described in Section 4.1.5 appear to indicate that enzymatic degradation is very important for the removal of antigen that has been circulating in the organism for a long time, since this can otherwise lead to immunological paralysis or tolerance.

[87] *B. Benacerraf, A. Ojeda*, and *P. H. Maurer*, J. exp. Medicine *118*, 945 (1963).

4.2. Genetic Aspects

It is well known that individuals of the same species often exhibit considerable differences in antibody formation against certain substances. Studies with protein antigens showed that this characteristic can be transmitted from one generation to the next [88]. It was not possible at first to clarify the relations, since the proteins used contained a large number of determinant groups (mostly unknown), and the formation of antibodies against such complex molecules is presumably controlled by several genes. The situation was greatly simplified, however, by the use of synthetic antigens that have proved particularly useful for investigations of this type.

The studies on the genetic control of antibody formation against synthetic antigens were stimulated by the observation that only about 40% of Hartley strain guinea pigs formed antibodies against a linear copolymer of L-lysine and L-glutamic acid [66], and also against derivatives of poly-L-lysine, such as 2,4-dinitrophenyl-, *p*-toluenesulfonyl-, and benzylpenicilloyl-polylysines [45,89]. It was then shown that for individual animals, either all or none of these hapten-polylysine conjugates were immunogenic, and that the ability to recognize this group of macromolecules as immunogens is determined by a dominant autosomal gene [46].

The failure of the immune response to occur in the group of animals that lack this "polylysine gene" (nonresponders) is not, however, due to the inability of these animals to synthesize antibodies of appropriate specificity, since anti-hapten antibodies were readily formed if the haptenic groups were coupled to another carrier or if *e.g.* dinitrophenylpolylysine was injected in the form of an insoluble complex with egg albumin [38]. In this case, the egg albumin functioned as carrier for the macromolecular hapten (see Section 4.1.1), and the animals produced antibodies of the same specificity as those formed by

[88] *E. Carlinfanti*, J. Immunology *59*, 1 (1948); *J. H. Sang* and *W. R. Sobey*, J. Immunology *72*, 52 (1954).

[89] *B. B. Levine, A. Ojeda*, and *B. Benacerraf*, Nature (London) *200*, 544 (1963).

animals for which dinitrophenyl-polylysine was itself immunogenic (responders). It is thus fairly certain that the "polylysine gene" is not directly involved in the synthesis of the antibody combining site. The two groups of animals also do not appear to differ significantly in their ability to degrade polylysine derivatives enzymatically [90].

The delayed hypersensitivity reaction, which is not due to circulating antibodies but is directly mediated by cells, could be produced in sensitized animals by intradermal injection of dinitrophenyl-polylysine only if the animals belonged to the group for which dinitrophenyl-polylysine was immunogenic. It did not appear in animals that lacked the "polylysine gene" and in which dinitrophenyl-polylysine functioned only as a hapten [38]. Recently it could be shown that the ability to respond to dinitrophenyl-polylysine can be transferred with bone marrow, spleen, or lymph node cells from normal responder guinea pigs into lethally irradiated nonresponder animals [91a]. Upon immunization about 15 days after cell transfer the recipients were able to form specific antibodies and to give delayed hypersensitivity reactions towards dinitrophenyl-polylysine. For reasons not yet understood it was not possible, however, to elicit a delayed skin reaction in nonresponder animals which had received one hour before lymphoid cells from responders previously immunized with dinitrophenyl-polylysine, though a passive sensitization by transferred cells was successful with other antigens [91].

Genetic differences have also been observed on immunization of mice of various inbred strains with linear and branched polypeptides [92,93]. In the latter case there were differences in the quantities of antibodies formed (Table 1) [94]. The antigens used were synthesized from multichain poly-D,L-alanine *(5)*, the side chains of which were elongated either with short polymers of L-glutamic acid or with short copolymers of L-phenylalanine and L-glutamic acid, L-tyrosine, and L-glutamic acid [cf. *(7)*], or L-histidine and L-glutamic acid.

When the first two polymers were tested, mice of strain CBA and C 57 showed no difference in antibody response, *i.e.* the first polymer was non-immunogenic and the second was strongly immunogenic in both strains. However, the two strains showed a very different antibody response to the polymer *(7)* containing tyrosine. The antibody titers for mice of strain CBA were only about 10% of those found for animals of strain C 57. The results were reversed on injection of the polymer containing histidine; it was now the C 57 mice that produced only very small quantities of antibodies.

Table 1. Immunogenicity of branched poly-α-amino acids for two inbred strains of mice, according to *McDevitt* and *Sela* [94].

Synthetic polypeptide	Immunogenicity [a] for mice of strain	
	CBA	C 57
Poly-L-Glu-*(5)*	−	−
Poly-(L-Phe, L-Glu)-*(5)*	+	+
Poly-(L-Tyr, L-Glu)-*(5)* ≡ *(7)*	+	++
Poly-(L-His, L-Glu)-*(5)*	+	+

[a] − Non-immunogenic; + weakly immunogenic; ++ strongly immunogenic.

Thus, the genetic control of the immune response to this group of polypeptides is – similar to antibodies – highly specific for the amino acid composition of the antigenic determinants. Crossover experiments indicated, that the ability to form high levels of antibody is controlled in each case to a large extent by an autosomal dominant gene. When such immunization experiments were extended to other strains of mice similar results were obtained and it was discovered that the ability to respond to these multichain polypeptides is genetically linked to the H2-locus which in mice controls the formation of certain histocompatibility antigens [95].

The influence of genetic factors on the immunogenicity of natural antigens such as insulin [96], bovine serum albumin [97], and lactate dehydrogenase has recently been studied in some detail. The immunological properties of lactate dehydrogenase were in certain respects analogous to those of the complexes of dinitrophenyl-polylysine with egg albumin [98]. The enzyme exists in the form of isozymes which consist of combinations of four of the subunits A or B (A_4, A_3B, A_2B_2, AB_3, B_4). The subunit B corresponds in its action to dinitrophenyl-polylysine in the experiments with guinea pigs; it is itself (as the isozyme B_4) immunogenic only for some of the animals (rabbits), but not for others. In the latter group, B behaves as a hapten, and only when combined with A as a carrier (isozyme A_2B_2) does it induce the formation of B-specific antibodies in these animals.

Very little is known yet about the mechanism of the genetic control of the immune response. Experimental results suggest that the recognition of the antigen is involved, whereas the information required for the synthesis of the corresponding antibodies appears to be potentially available.

5. Conclusion

The type of immune response induced in higher animals by an antigenic stimulus depends primarily on biological factors, of which only the genetic factors have been mentioned here. However, the chemical and physical nature of the antigen, as well as the dose and the method of administration, also play an important part. These factors, the combined effects of which are not yet clear, lead either to preferential formation of circulating antibodies and stimulation of cellular immunity or to specific tolerance. Selected examples have been presented to show that not only the investigation of the biological principles but also the study of the antigens themselves, particularly with the aid of synthetic antigens, can contribute to a better understanding of these processes. This discussion was restricted mainly to the aspect of antibody formation. However, mention should at least be made of the use of synthetic polypeptide antigens, and polypeptide derivatives of proteins for the study of immunological tolerance [99], the competition of determinant groups [26], and the localization of radioactively labeled antigens in lymphatic tissue [84, 100].

The wide use of *synthetic antigens* in the study of immunological problems is based primarily on their suitability as model substances. Our interest, however, is ultimately in the function of *natural antigens*. Only in rare cases have serological cross-reactions so far been observed between synthetic polypeptide antigens and natural antigens (see Section 4.1.6). With a more precise knowledge of the structure of natural antigens, however, it will become increasingly possible to synthesize antigens in such a way that they have certain determinants in common with the natural products. Whereas this aim was achieved by *Goebel* [54] as early as 1939 for polysaccharides, attempts to do the same with protein antigens have only recently been successful. Thus antigens containing the serologically important C-terminal hexapeptide sequence of the coat protein of tobacco mosaic virus [101] and a large polypeptide loop of lysozyme [102] have been prepared. Antigens of this type allow specific immunization against certain sub-units of natural antigens, and, consequently hold out hopes of useful practical applications.

I am grateful to Prof. Dr. D. Rowley and to Prof. Dr. W. Volk for critical perusal of the translated manuscript.

Detection of Hindered Rotation and Inversion by NMR Spectroscopy [1]

By Horst Kessler [*]

Rotations and inversions in organic molecules are readily recognizable from the temperature dependence of the NMR spectra. The study of the effects of substituents on the activation barriers of such processes permits the elucidation of reaction mechanisms, and the stability limits of isomers can also be determined. The knowledge of the stability limits is necessary for the specific synthesis of stable rotamers and invertomers.

1. Introduction

Modern organic stereochemistry has two aspects, one static and the other dynamic. The reactivity of a molecule is not determined purely by the predominant steric arrangement; the possibility of assuming other conformations that are more favorable to the reaction is often an important factor.

NMR spectroscopy provides the chemist with a means of studying intramolecular movements with activation energies of 5 to 25 kcal/mole [2–4]. Processes of this type are so fast that the resulting isomers cannot be separated at room temperature. On the other hand,

they are too slow for investigation by IR and Raman spectroscopy or by dielectric constant measurements [5].

The present article describes the application of NMR spectroscopic methods to the study of rotations. In view of their close relationship with rotations, inversions are also briefly discussed. Processes in which parts of a molecule (*e.g.* in cycloolefins [6]) rotate by simultaneous rotation about two or more bonds are not considered, and rotation in σ [7] and π metal complexes [8] is also excluded.

2. Theory

2.1. General

In the rotation about a bond in a molecule, there are certain energetically favored positions of the substituents. For example, a *planar* arrangement is most favorable for the substituents on two carbon atoms joined by a (p-p)π double bond. The dependence of the energy on the angle of rotation about the double bond is shown in Figure 1.

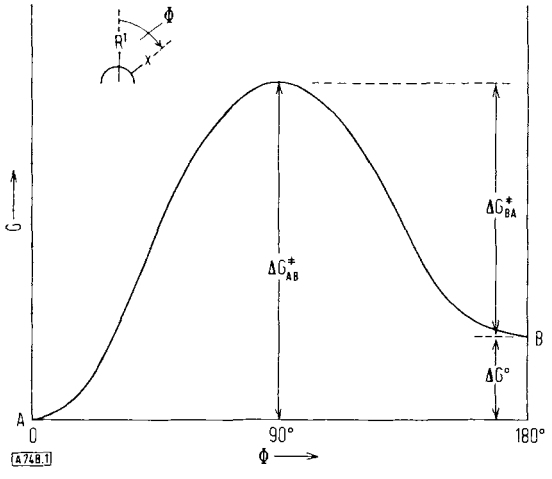

Fig. 1. Energy profile for rotation about a double bond. For A and B cf. *(1)*.

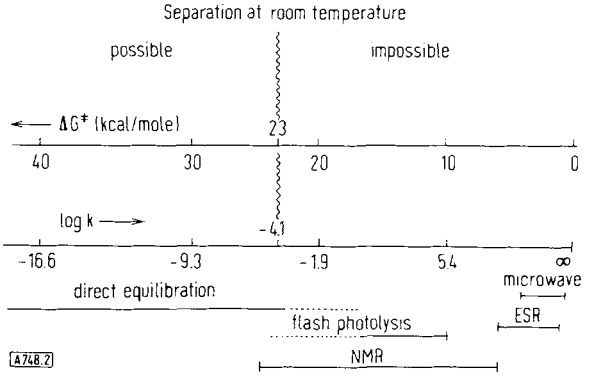
To convert the isomer A into the isomer B, it is necessary to supply the free enthalpy of activation $\Delta G^{\ddagger}_{AB}$. The energy $\Delta G^{\ddagger}_{BA}$ that must be supplied for the reverse isomerization differs by ΔG^0 from $\Delta G^{\ddagger}_{AB}$. The magnitude of the free enthalpy of activation determines the rate of the thermal isomerization. If $\Delta G^{\ddagger} \gtrapprox 23$ kcal/mole, the isomers are stable at room temperature; smaller $\Delta G^{\ddagger}$ values lead to more or less rapid thermal isomerization, the rate constant k_r of which is related to $\Delta G^{\ddagger}$ in accordance with the Eyring equation [eq. (1)] [9].

$$k_r = \frac{k_B T}{h} \exp\left(-\frac{\Delta G^{\ddagger}}{RT}\right) \qquad (1)$$

(k_B = Boltzmann's constant, h = Planck's constant, R = gas constant, T = absolute temperature).

$$\Delta G^{\ddagger} = 4.57\, T\,(10.32 + \log T/k_r \qquad (1a)$$

This situation is again illustrated in Figure 2, in which the rate constant k_r of an isomerization increases from left to right. The free enthalpies of activation $\Delta G^{\ddagger}$ at room temperature as calculated from eq. (1) are also shown. Separation of isomers is possible if the mean lifetime is of the order of a few hours or more. This corresponds to k_r values of less than 10^{-4} sec^{-1} or $\Delta G^{\ddagger}$ values greater than 23 kcal/mole (at 25 °C). The NMR method (see Section 2) covers a range extending downward from the vicinity of the separation limit, which is difficult to study by other methods.



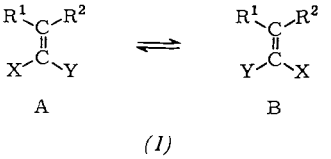


Fig. 2. Possibilities for the detection of intramolecular mobility.

Isomerization of this nature can be followed particularly readily by NMR spectroscopy when ΔG^0 is small, *i.e.* according to

$$\Delta G^0 = -RT \ln([A]/[B]) \qquad (2)$$

when the concentrations of the isomers are comparable.

The conditions for NMR spectroscopy are particularly favorable when $R^1 = R^2$ in *(1)*. A and B are then chemically identical [*]. In the NMR spectrum, how-

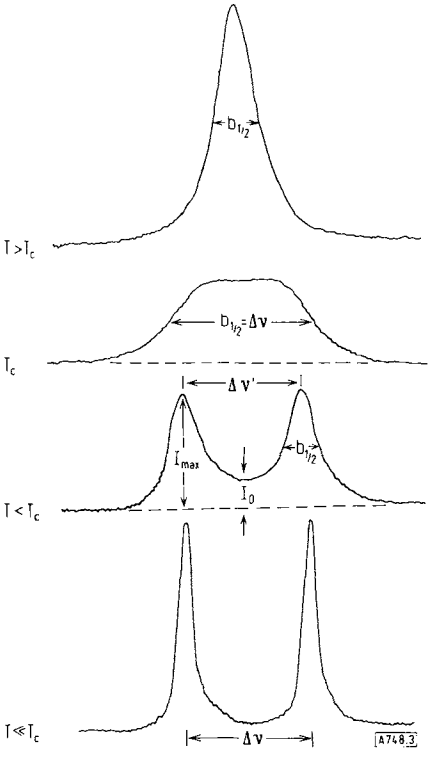
[*] A and B are "degenerate isomers", for which we propose the term "topomers". A and B differ by the exchange of diastereotopic [11d] groups, and are therefore diastereotopomers. The process of interconversion would then be called topomerization (diastereotopomerization). The exchange of prochiral [11d] groups then corresponds to an enantiotopomerization, which can be followed NMR spectroscopically because of the nonequivalence of the two X groups in CX_2Y substituents as prochiral groups. (*G. Binsch, E. L. Eliel*, and *H. Kessler*, unpublished).

ever, R^1 and R^2 are not equivalent if X and Y are different, and rotation about the double bond accordingly leads to "exchange" of the groups R^1 and R^2.

"Slow"[*] isomerization leads to two separate signals for R^1 and R^2 in the NMR spectrum, while "fast" rotation gives only one signal with an intermediate chemical shift (cf. Fig. 3).



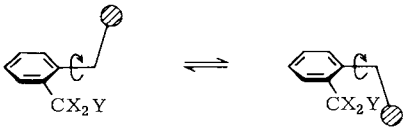


Fig. 3. Temperature dependence of the NMR spectrum as a result of chemical exchange (uncoupled AB case). For explanations see text.

For thermally induced rotations, the NMR spectra are temperature dependent in the transition region between "slow" and "fast" rotation, and can be used to determine the rate constants k_r. The activation parameters ($\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, E_a) can be found from k_r (see Section 2.2).

A different situation arises when rotation leads to racemization. The two X groups in CX_2Y substituents may be magnetically non-equivalent when the remainder of the molecule (viewed from the direction of the CX_2Y group) is chiral[10,11]. The intramolecular rotation can be detected with the aid of the temperature dependence of the magnetic non-equivalence. This is so *e.g.* in compounds of the type *(2)*[11c].

(2)

2.2. Kinetic Evaluation of NMR Spectra

As was mentioned above, the shape of the signal in the transition region can be used to determine the rate constants. The theory of line broadening is well developed and has been presented clearly[12], particularly for simple cases. Several methods of evaluation are available in practice:

1. By approximation equations.
2. By graphical evaluation of certain spectral parameters.
3. By computer matching of measured and calculated spectra.

A particularly simple situation occurs when two atoms (or groups) with initially sharp signals of equal intensity undergo chemical exchange (uncoupled AB case, see Fig. 3). For evaluation by approximation equations, parameters such as the line separation $\Delta\nu$[13], the line broadening $b_{1/2}$[14,21], and the intensity ratio I_0/I_{max}[15] in the low-temperature case, the line width $b_{1/2}$ in the high-temperature case[16], and the coalescence temperature[18] are found from the spectrum. The coalescence temperature is the temperature at which two signals just coincide (see Fig. 3). The validity of the equations is limited in most cases[17]. It is relatively easy to obtain the rate constant k_c of the chemical exchange at the coalescence temperature T_c. Ignoring the intrinsic width, we then have:

$$k_c = \pi\Delta\nu/\sqrt{2} \qquad (3)$$

($\Delta\nu$ = line separation without exchange)

for the uncoupled AB case[18][**].

---

[*] "Slow" on the NMR timescale means that the reaction rate constant $k_r \ll \pi\Delta\nu/\sqrt{2}$ ($\Delta\nu$ = signal splitting without exchange) [see eq. (3)]. "Slow" is to be regarded as a statistical-kinetic description in this context. A slow rotation is one in which only a small fraction of the molecules can overcome the energy barrier in unit time. The actual rotation of the individual molecule, however, is very fast owing to the small moment of inertia. "Infrequent" would therefore be a better term than "slow" and "frequent" would then have to be used instead of "fast".

[**] The uncoupled AB case refers to the spectrum of two types of nuclei (A and B) that are not coupled to each other. In the normal AB case, on the other hand, four lines are observed because of coupling of A with B and *vice versa.*

For the coalescence of an AB-type spectrum (to A_2), we have [19] (disregarding the intrinsic width):

$$k_c = \pi (\Delta\nu^2 + 6 J^2)^{1/2} / \sqrt{2} \quad (4)$$

where J is the constant for the coupling between the nuclei A and B.

Graphical methods [20] are particularly suitable for the evaluation, since the intrinsic widths of the lines and the temperature dependence of the splitting without chemical exchange [17,21] can be taken into account more satisfactorily.

If the contributions of two rotamers to the equilibrium are no longer equal ($\Delta G^0 \neq 0$), the ratio of the intensities of the bands is not equal to unity (evaluation *e.g.* according to [14]). Computers are necessary for the evaluation in more complicated cases; the shapes of the curves can then be simulated and compared with the experimental spectra.

The free enthalpy of activation $\Delta G_T^{\neq}$ can be calculated from the rate constants k_r by means of the Eyring equation (1). The temperature-dependent $\Delta G^{\neq}$ value contains the activation entropy $\Delta S^{\neq}$. To find the Arrhenius activation energy E_a, log k_r is plotted against the reciprocal of the temperature (A = frequency factor):

$$k_r = A \exp(-E_a/RT) \quad (5)$$

$$\log k_r = \text{const} - E_a/4.56\,T \quad (5a)$$

The E_a values (or $\Delta H^{\neq} = E_a - RT$) should be used for the comparison of compounds, since it does not contain the temperature-dependent entropy term $T\Delta S^{\neq}$. It has been shown, however, that the E_a values are mostly very uncertain. Thus for dimethylformamide [*], which has probably been studied more often by NMR spectroscopy than any other compound, the literature contains E_a values ranging from 7 to 28 kcal/mole and log A values of from 7 to 17 [2,23]. On the other hand, the values found for the free enthalpy of activation $\Delta G_c^{\neq}$ from the coalescence temperature with the aid of equations (1) and (3) all differ by less than 1 kcal/mole from the average (21.5 kcal/mole) [13, 15, 23, 24].

The reason for this is to be found in the k_r values, the errors in which increase with increasing distance from the coalescence temperature. However, only a relatively small temperature range of from about 20 to at most 60 °C is available for the evaluation. The gradient of the Arrhenius line, which is a measure of the activation energy E_a, and hence also its intercept on the ordinate (log A) are very strongly influenced by small deviations of the k_r values; high E_a values go with high log A values and *vice versa*. In a plot of the E_a values for dimethylformamide from the literature against the corresponding log A values, all but one of the points lie on a straight line passing through the origin (Fig. 4).

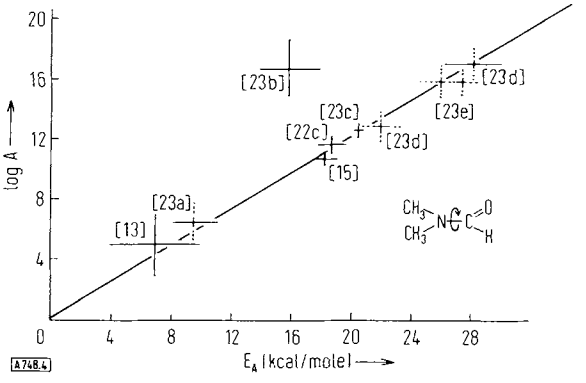

Fig. 4. Experimental kinetic data for the rotation about the C—N bond in solvent-free dimethylformamide. The numbers are literature references, and the lengths of the lines indicate the error limits. —E_a = Arrhenius activation energy, A = frequency factor [eq. (5)].

Where accurate measurements (such as *e.g.* in [21]) covering a fairly wide temperature range are not available, it is better to avoid a discussion of the physically accurate but numerically doubtful E_a values (or $\Delta H^{\neq} = E_a - RT$), and to use the $\Delta G_c^{\neq}$ values instead [17]. The temperature dependence of $\Delta G^{\neq}$ is then deliberately ignored, and normal frequency factors are postulated (low reaction entropies $\Delta S^{\neq}$). This procedure is not problematic above all in the comparison of similar types of substances. The stability of isomers at a given temperature is determined in any case by $\Delta G^{\neq}$.

If it is still desired to determine E_a and $\Delta H^{\neq}$, several methods should be used if possible in order to extend the temperature range. This can be done in suitable cases both by the measurement of k_r values by the spin echo method [25] and the double resonance method described by *Forsen* and *Hoffmann* [26] and by direct equilibration [24,27]. Since very few investigations of this nature and reliable line shape analyses have been carried out so far, the free enthalpies of activation at the coalescence temperature T_c are used for discussion in this article. The error in T_c (usually about ±2 to 5 °C) largely determines the error in the $\Delta G_c^{\neq}$ values (±0.5 to 4%). Owing to the temperature dependence of $\Delta G^{\neq}$, the coalescence temperature, which

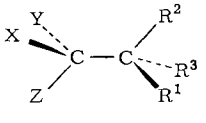
can be varied within certain limits by the choice of the measuring frequency, is given whenever possible.

The rate of intramolecular rotations and inversions, like that of other reactions, also depends on the solvent and on the concentration of the solute. In series of measurements on various substances, therefore, only one solvent should be used if possible[*]. Comparative discussions become increasingly problematic with increasing dissimilarity of the structures of the compounds and solvents investigated and of the concentrations and coalescence temperatures.

Other methods besides NMR spectroscopy can be used for the detection of intramolecular rotations[5].

3. Applications

3.1. General



Free rotation about a bond in the molecule may be sterically and electronically hindered. Thus the stability of *cis-trans* isomers about the CC double bond is so great because of electronic effects that their rotamers are described as configurational isomers, though they are really mostly very stable conformers. Rotation about a CC single bond (the σ bond is rotationally symmetrical) may be sterically hindered, as in the well-known example of atropisomerism in biphenyl derivatives, but can also be restricted by resonance effects, which give the single bond partial double bond character.

3.2. Rotations about Single Bonds

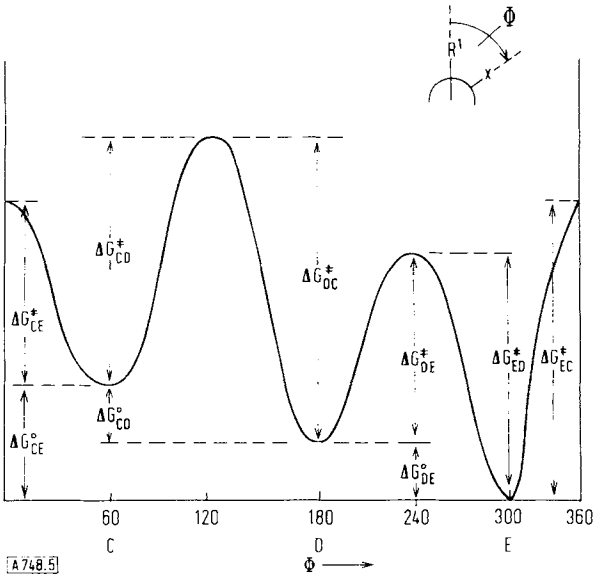
3.2.1. Carbon-Carbon Single Bonds

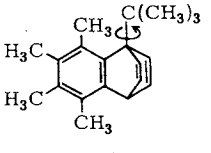
3.2.1.1. sp^3-sp^3 Hybridization

In the rotation about single bonds between sp^3-hybridized carbon atoms as in *(3)*[28], the heights of the energy barriers are determined mainly by the steric hindrance in the eclipsed transition state. The types of spectrum to be expected for fast and slow rotation have been discussed by *Pople*[29].

(3)

With identical substituents R^1, R^2, and R^3, the conformations C, D, and E in Figure 5 have equal energy contents and there is only *one* activation energy. For methyl groups ($R^1 = R^2 = R^3 = H$), this has a value of $E_a \lesssim 3$ kcal/mole[30], and can no longer be detected





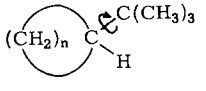


Fig. 5. Energy profile for rotation in an unsymmetrical ethane. C, D, and E are the stable staggered conformations at the indicated angles of rotation.

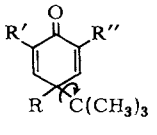
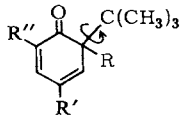
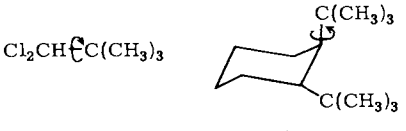
by NMR spectroscopy. Splitting due to hindered rotation about the CC single bond is however found for the *tert*-butyl group ($R^1 = R^2 = R^3 = CH_3$) (Table 1).



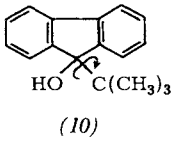
In the compounds *(7)* and *(9)*, one should expect splitting of the *tert*-butyl signal into three singlets having relative intensities of 1 : 1 : 1, and in the other compounds into two singlets having an intensity ratio of 2 : 1. The fundamental correctness of these considerations is shown by the low temperature spectrum of *(7a)*, in which all three methyl groups of the *tert*-butyl group are separated (Fig. 6)[33b].



(4)



(5)



(6)

(7)

(8) *(9)*

(10)

[*] This is unfortunately not always possible, owing to the general properties of the solvents (b.p., m.p., solvent power) and possible absorptions in the measurement region.

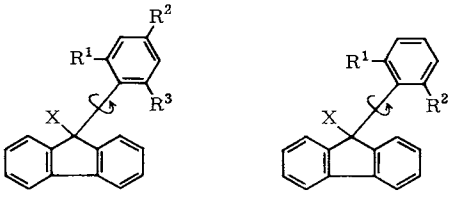
[37] *F. J. Weigert* and *J. D. Roberts*, J. Amer. chem. Soc. *90*, 3577 (1968).

3.2.1.2. sp^2-sp^3 Hybridization



Rotation about the single bond between sp^2- and sp^3-hybridized carbon atoms can be hindered by bulky substituents. Hindered rotation attracted particular interest in two *tert*-butyl derivatives *(12)* [38] and *(13)* [39] of benzene, triarylmethanes *(14)* [40], *o*-disubstituted alkylbenzenes *(15)* [34,41], and 9-arylfluorenyl compounds *(16)* [34,42] and *(17)* [34].

(12) *(13)*

(14) *(15)*

(16), $R^1 = R^3 = CH_3$ *(17)*, $R^1 = R^2 = OCH_3$

The "chemical exchange" of the methyl and methoxy groups in *(16)* and *(17)* also proceeds in principle by dissociation of the group X. However, this is not possible in the derivatives with X=H (except in the presence of basic catalysts). The decrease in $\Delta G_c^{\neq}$ in the order H > OH > Cl appears to be connected with the bulk of X. The larger X is, the greater is the hindrance in the ground state, and the smaller the energy difference between the ground state and the transition state [34].

3.2.1.3. sp^2-sp^2 Hybridization

Rotation barriers in biphenyl derivatives have so far been measured in only a few cases (Table 2).

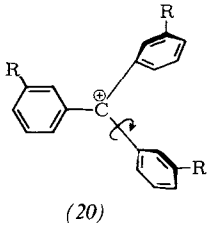
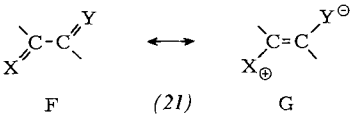
Table 2. Rotation in biphenyl derivatives.



Cpd.	R	$\Delta G_c^{\neq}$ (kcal/mole)	T_c (°C)	Ref.
(18a)	CH_3	17.4	−35	[43] [a]
(18b)	CH_2OCOCH_3	20.2	127	[44] [b]
(18c)	$CH(CH_3)_2$	>26.1	>200	[45]
(18d)	$C(OH)(CH_3)_2$	>24.5	>190	[45]
(19a)	OCH_3	13.7	−25	[46]
(19b)	$OCOCH_3$	18.5	+46	[46]

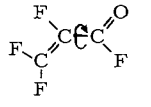
[a] Measured by direct equilibration.
[b] Calculated from the literature data.

$\Delta G_c^{\neq}$ increases very rapidly with the size of the residue R, and can ultimately no longer be determined by NMR spectroscopy.



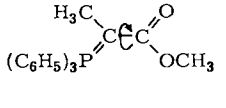
Steric hindrance of the rotation about the aryl-CO bond has been found in benzamides [47], benzophenones [48], and benzils [48]. It is so great in *tert*-butyl aryl ketones that the optical antipodes can be separated [49].

Rotation about C-aryl bonds is also sterically hindered in the propeller conformations of triarylmethyl cations *(20)* [50]. The geometry of the propeller (right-hand or left-hand screw) and the position of the substituents R lead to interesting isomerism phenomena.

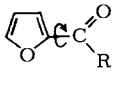


(20)

Steric hindrance of rotation is less common than "electronic hindrance". Owing to the participation of ionic limiting structures such as G in *(21)*, formal



F (21) G



single bonds often possess partial double-bond character. In such cases, the energy is lowest in the planar conformations *s-cis* (cisoid) and *s-trans* (transoid) [50a]; however, the activation energy required for rotation about the central bond is generally not very high. Some examples are given in Table 3.

[a] "Frozen in" at −105 °C. No barrier data.
[b] No barrier data.

$\Delta G_c^{\neq}$ increases with increasing difference between the electron donor and acceptor properties of X and Y. In compounds of the type *(25)*, therefore, rotation becomes increasingly difficult in the order X=H < OCH_3 < $N(CH_3)_2$. Hindrance of rotation about the aryl-C bond as a result of opposite polarization (aryl ring negative, substituent positive) has been found in ketene aminals [82, 112d].

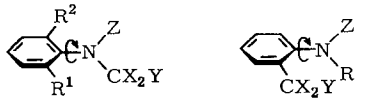
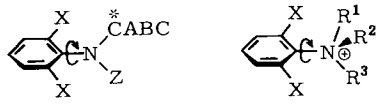
σ-π rearrangements or CC rotation are discussed for the isomerizations in π-allyl complexes [57].



(28) *(29)*

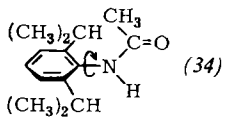
In connection with rotations in anions *(28)* [58] and cations *(29)* [59] of the allyl type, the reader is referred to the literature.



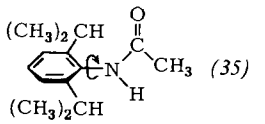
3.2.2. Carbon-Nitrogen Single Bonds

3.2.2.1. Steric Hindrance of Rotation

Steric hindrance of rotation about the aryl-N bond is the reason for the magnetic non-equivalence of the X atoms in substances of the types *(30)* to *(33)*. The rotation is less hindered in amines (Z = alkyl) [60,61] than in amides (Z = COR) [11c,60,62,63] and nitrosamines (Z = NO) [61,63]. The ammonium salts *(33)* are com-

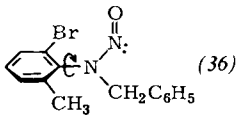


(30) *(31)*



(32) *(33)*

parable to the alkylated benzenes *(15)*; the energy threshold is higher because of the shorter bond (C–N as compared with C–C) [41a]. Examples from the amides [11c] and nitrosamines [61] are *(34)/(35)* and *(36)/(37)* respectively (the figures give $\Delta G_c^{\ddagger}$ in kcal/mole).



The degree of steric hindrance in the transition state of the rotation [*(34)* > *(35)*; *(36)* > *(37)*] determines the free enthalpy of activation $\Delta G_c^{\ddagger}$, which increases with the bulk of the substituents; the same is true of ring substitution [61].

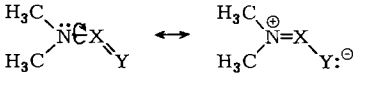
(35) 11.8



(36) 21.8

(37) 17.9

3.2.2.2. Hindered Rotation About Partial Double Bonds

C–N bonds with partial double-bond character occur in compounds of the type *(38)*.

(38)

X = CR, N

Y = CRR^1, NR, O, S, Se, $^{\oplus}$O-R, $^{\oplus}$S-R

The hindrance of rotation about the N–X bond is often used as proof of the planarity of the nitrogen atom. This is not evident because a partial double bond character can also result from overlap of the filled sp^3 orbitals on nitrogen with the empty p orbital on X. The nitrogen pyramid is flattened and the inversion rate on nitrogen increases by conjugation (see section 3.4.1).

The temperature dependence of the nuclear resonance has very often been used for the investigation of rotation about the partial double bond in amides. Since the discovery of the hindrance of rotation in dimethylformamide *(39a)* by *Phillips* [64], the first application of the NMR method to the study of kinetic processes, numerous articles dealing with the improvement of the measuring method and evaluation [2,13,15,23] as well as with the solvent and concentration dependence [2,22,65] of *(39a)* have been published. The substituents on the nitrogen and on the carbon have also been varied and their effects on the rate of rotation checked.

Let us first consider some examples that show the influence of the acyl component (substituent R) on the rotation barrier of *N,N*-dimethylamides *(39)* (Table 4). The $\Delta G_c^{\ddagger}$ values give a reliable indication at least of the direction (accelerating or retarding) in which the substituents affect the rotation rate.

The rotation about the amide bond (C–N) is hindered by the participation of the limiting structure I in the ground state. *Pauling* predicted an energy barrier of

about 21 kcal/mole, corresponding to a double bond component of about 40% [74]; this is surprisingly close to the value found experimentally for dimethylformamide. Substituents influence the activation energy

H I J

(39)

both electronically and sterically [*]. A strong contribution of the limiting structure J to the resonance reduces the double-bond character of the amide bond, and hence also the rotation threshold. This effect is clearly recognizable in the low $\Delta G_c^{\ddagger}$ value of the urethane *(39g)* as compared with those of the amides *(39a)* and *(39b)*.

Table 4. Hindered rotation in amides *(39)*.

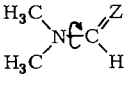
The bulkiness of the substituents can have various effects:

1. Large substituents on the nitrogen and in the acyl residue increase the energy content of the almost planar ground state because of their steric interaction (see also Section 3.4), with the result that the energy difference for the transition state ($\Delta G^{\ddagger}$) becomes smaller. This probably explains why the rotation barrier is lower for *N,N*-dimethyltrichloroacetamide [*(39d)*, $\Delta G_c^{\ddagger} \approx 15$ kcal/mole] than for *N,N*-dimethyltrifluoroacetamide [*(39e)*, $\Delta G_c^{\ddagger} \approx 18$ kcal/mole]. A similar effect is observed when the size of the residues on the nitrogen is increased [75].



2. Large substituents on the phenyl ring of benzamides *(39k)*, *(39l)* lock the dialkylamino group, *i.e.* they destabilize the transition state of the rotation, and so give stable separable rotamers.

Replacement of the oxygen of the amide grouping by other elements yields the compounds listed in Table 5.

The height of the rotation barrier, and hence the double-bond character, decreases with variation of the substituent Z in the order

Electron-attracting substituents increase $\Delta G^{\ddagger}$ (cf. [82]). A similar picture is found for *N,N*-dimethylbenzamide

(40)

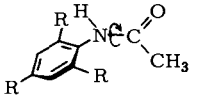
and its derivatives[84]. In enamines (C⟨) and *N*-aryl amidines (*N*-Aryl), the relationships are very strongly dependent on the substituents on the double bond and on the aromatic ring. Thus a very much smaller $\Delta G^{\neq}$ value is to be expected for Z = CH_2 than for $CHNO_2$.

The rotation barriers are particularly high in thioamides [cf. *(40)*, Z = S], so that some of these compounds can be resolved into rotational isomers[85]. This is due to the small tendency of sulfur to form double bonds, which leads to a particularly large contribution from the polar limiting structure [cf. I in *(39)*]. The energy thresholds for rotation in thioamides, so far as this can still be detected by NMR measurement, correlate well with the calculated π-bond orders[83].

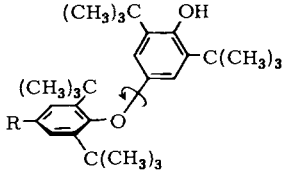


(a) *(b)*

(41)

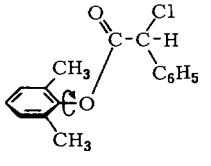
In *N*-monosubstituted amides *(41)*, the rotamers have different energy contents and participate unequally in the thermal equilibrium. Numerous studies have been carried out on compounds of this type, since they are of particular interest in biochemistry (peptide linkage)[86]. Both rotamers can always be detected in formamides (R = H)[86,87], whereas in higher amides (R = Alkyl) only the form *(41a)*, in which the residues R^1 and R are *trans* to each other, are found[88]. ΔG^0 is usually greater than 2–3 kcal/mole; the concentration of the form *(41b)* is thus <5%, and can no longer be measured (but cf.[89]).

In the ring-substituted acetanilides *(42)*, on the other hand, the Z form and the E form[89a] have very similar energies, and both can be detected[90]. As in the (substituted) benzamides *(39i)–(39l)* (Table 4), the energy barrier for rotation increases with the bulk of R. The



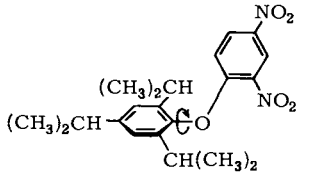
(42)

tert-butylated compound [R = *tert*-C_4H_9 in *(42)*] is the first *N*-monosubstituted amide for which both rotamers have been isolated as such[90].



Of the many articles on hindered rotation about partial CN double bonds, we should like to draw the reader's attention to a few from the natural products field[91].

3.2.3. Carbon-Oxygen and Carbon-Sulfur Single Bonds



Sterically hindered rotations about the C–O bond have been detected in aromatic ethers and esters *(43)* to *(45)* (see Table 6).

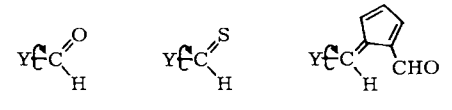
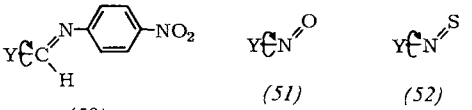
The temperature dependence of the NMR spectra of aromatic sulfides *(46)* and disulfides *(47)* must be interpreted similarly. The hindered rotation about the aryl-hetero atom bond decreases with increasing size of the hetero atom (O→S), as is shown by a comparison of the compounds *(45)* and *(46)*.

This also gave a lower limit for the barrier for inversion at a dicoordinate oxygen atom. From the results of measurements on *(45)*, this barrier must be higher than 17.8 kcal/mole in diaryl ethers [94]. If we generalize the findings for the inversion at nitrogen (Sections 3.3.2 and 3.4.1), the inversion barriers at the oxygen in dialkyl ethers, alcohols, and water should be much higher. This agrees with SCF calculations, which gave a barrier of >34 kcal/mole for these compounds [95b].

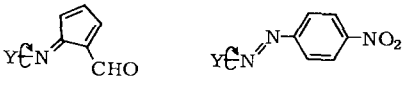


3.2.4. Nitrogen-Nitrogen and Nitrogen-Oxygen Single Bonds

The hindrance of rotation in nitrosamines *(48)* has been known for some time [2,96]. The high energy threshold (>20 kcal/mole) separating the preferred "planar" (cf. Section 3.2.2.2) conformations can be explained by the strong contribution of the polar limiting structure to the resonance. With suitable substitution on the amino nitrogen, the rotamers are so stable that they can be isolated as such [14,97].



(48)



Examples of other classes of compounds with hindered rotation about the N–N bond are shown in Table 7. The rotation barriers of similar NN and CN compounds are comparable in their order of magnitude. Besides *rotation*, *inversion* consisting of folding in the plane of the double bond is also conceivable at the doubly bonded nitrogen atom in nitrogen compounds of the types *(51)–(54)*.

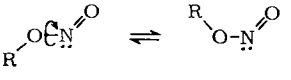
(54)	15.7	35	[99]



However, an inversion of this nature is hindered by the dialkylamino group (hetero effect, see Section 3.4) and is therefore less likely.

The barrier for rotation about the dimethylamino group in the substituted triazenes *(55)* has been correlated with the Hammett constant of X in the aryl residue (ρ = –2.0 to –2.1) [99]. The difficulty of rotation of the dimethylamino groups in the ketene aminals *(56)* also increases with the σ_p constant (ρ = –1.3) [82, 112d].

(55) *(56)*

Like the types of compounds mentioned so far, the alkyl nitrites *(57)* also exist as mixtures of cisoid and transoid rotamers [2]. The rotation barriers (approx. 10–14 kcal/mole) are lower than in the comparable nitrosamines.

(57)

Suitable hydrazine derivatives give complex temperature-dependent NMR spectra [100], which can only be explained by assuming hindered rotation about the NN single bond with simultaneous "slow" inversion at the nitrogen [101]. Calculations indicate that the energy required for rotation about NN single

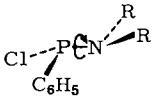
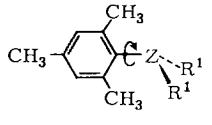
bonds (*ca.* 12 kcal/mole[102]) is significantly greater than for rotation about CC single bonds (approx. 3 kcal/mole).

3.2.5. Rotation About Other Single Bonds



Hindrance of rotation about S–S and Se–Se bonds has been found in sterically hindered aromatic disulfides and diselenides *(58)*[95].

The rotation about the P–N bond in *(59)* can be "frozen in"[103]. The rotation barriers are lower in these compounds than in the hydrazine derivatives, since the greater distance between P and N leads to a decrease in hindrance. The repulsion of the lone pairs of electrons is undoubtedly partly responsible for the magnitude of the hindrance of rotation about N–O[103b], N–N, N–S[104], and N–P bonds.



The trimesityl compounds of the elements of Group V [*(60a)–(60d)*; the values in parentheses are $\Delta G_c^{\neq}$ (kcal/mole) and T_c (°C)] are comparable to the triarylmethane derivatives *(14)*. The hindrance of rotation about the aryl-Z bond decreases as the size of the atom Z increases[34]. The observed temperature dependence of the NMR spectra is therefore not due to inversion at the Z atom (see Section 3.4).

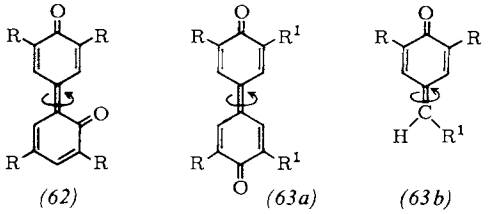
3.3. Isomerizations at Double Bonds



3.3.1. Carbon-Carbon Double Bond

The CC double bond has a very high configurational stability[*]. The rotation becomes detectable in the NMR spectrum only when the double-bond character is weakened, as in compounds of the types *(61)*[106] and *(62)*[107].

In the calicene derivatives *(61)*, strong participation of the polar limiting structure is to be expected. This greatly reduces the double-bond character and lowers the rotation barrier (cf.[108]). A polar limiting structure is also conceivable in *(62)*, though less likely. The

investigation of suitable *p*-diphenoquinones *(63a)*[109] and quinonemethides *(63b)*[110] shows in fact that the symmetry plays an important part. Neither electron-attracting nor electron-repelling residues R^1 in quinonemethides *(63b)* are sufficient to lower the rotation barrier to such a degree that it can be determined by NMR spectroscopy. The rotation is sufficiently fast only in the symmetrical quinonemethide *(64b)*, whereas the barrier in the electronically comparable but unsymmetrical quinonemethide *(64a)* is considerably higher[110] (the figures indicate $\Delta G^{\neq}$ in kcal/mole).

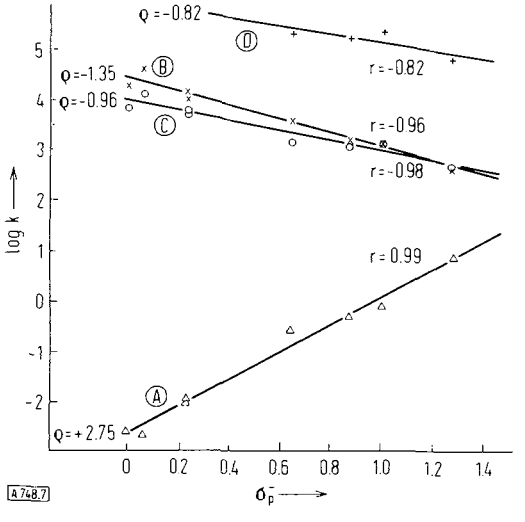
quency factor A in the Arrhenius equation. The normal log A value (11.4) found for *(63a)* [109] gives evidence for the singlet biradical transition state of the rotation in these cases. The ease of rotation in hexapentaene can probably by explained in a similar manner [111].

(66) *(67)*

Substituents X and Z in *(66)* and *(67)* with strongly electron-repelling or electron-attracting effects [112] weaken the double bond sufficiently for the rotation to be measured by NMR spectroscopy. SR, OR, and NR_2 have been investigated as electron-repelling substituents, and NO_2, CN, COR, COOR, and aryl as electron-attracting substituents [82,112]. Up to four rotations can be detected simultaneously in 2-aryl-2-cyano-1,1-bis(dimethylamino)ethylenes *(68)* [82,112d]. A different coalescence temperature is found for each rotation.

(68)

The kinetic data found from the spectra for all four rotations can be correlated with the Hammett σ constants of the residues R in the benzene ring (Fig. 7).



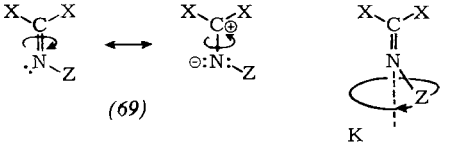


Fig. 7. Hammett correlation of the rotations in ketene aminals *(68)*.

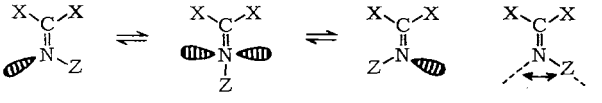
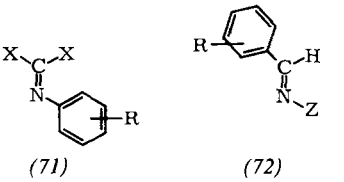
It can be seen from the gradient of the log k/σ correlation lines that the rotations about both CN single bonds and about the C-aryl bond are hindered by electron-attracting substituents, while the rotation about the central CC double bond is greatly facilitated.

3.3.2. Carbon-Nitrogen Double Bond Rotation and Inversion



There are in principle two possibilities for the *syn-anti* isomerization in imines *(69)* (cf. Section 3.2.4).

a) Rotation. The substituent Z describes a circle about the axis of the C–N bond ("out of plane" isomerization, K). The process is favored by polarization of the CN double bond. The sp^2 hybridization of the nitrogen atom, and hence the bond angle (C–N–Z), is retained.



(69) K

b) Inversion. The N–Z bond swings in the bond plane of the imine system from the *syn* into the (identical) *anti* position ("in plane" isomerization, L). The bond angle (C–N–Z) increases to 180° in the transition state. The CN double bond is, to a first approximation, unaffected.

(70) L

The influence of *p* substituents R in the aryl residue of *N*-arylimines of the type *(71)* on the free enthalpy of activation of the *syn-anti* isomerization follows the Hammett relation [113–116]. Contrary to previous reports in the literature [123] we were also able to show such a correlation in imino esters [*]. Irrespective of the substituent X, the reaction constant is $\rho = 1.7$ [116]. A substituent R in benzylideneamines *(72)*, on the other hand, has a much smaller influence ($\rho = -0.4$) [117]. The difference in the effects of variation of substituents on the N and on the C atom has been taken as evidence of inversion [113].

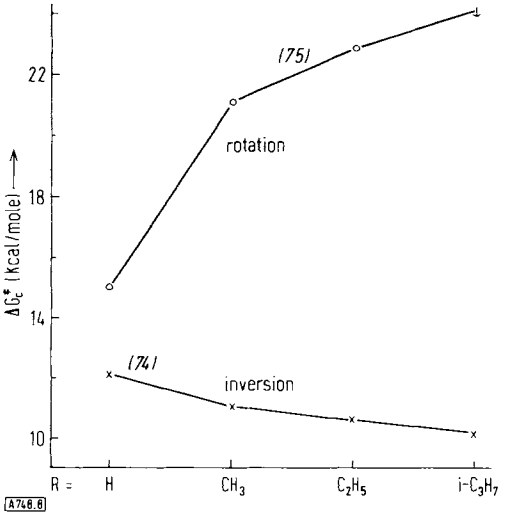
[117] *G. Wettermark, J. Weinstein, J. Sousa*, and *L. Dogliotti*, J. physic. Chem. *69*, 1584 (1965).

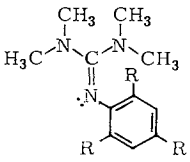
The small influence of the polarity of the solvent on the rate of isomerization of tetramethylphenylguanidine points to a similar conclusion[115,116b]. A polar solvent should facilitate isomerization by rotation, as has been found *e.g.* for ketene aminals[112d].

The influence of residues R in the *o*-position in arylimines *(73)* is particularly impressive. The activation threshold is lowered as the size of R increases[116, 118–120]. This can only be explained by inversion, in

(73)

which the steric hindrance is less in the extended transition state than in the ground state. Rotation would be hindered by the substituents R. Figure 8 shows a comparison of the $\Delta G_c^{\ddagger}$ values for the *inversion in guanidines (74)*[116] with those for *rotation* about the CN double bond *in the guanidinium salts (75)*[121][*], in which the lone pair of electrons is fixed and inversion is consequently impossible.





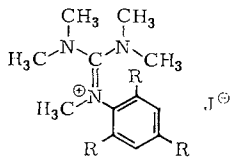


Fig. 8. Free enthalpies of activation for inversion [guanidines *(74)*] and rotation [guanidinium salts *(75)*] at doubly bonded nitrogen atoms.

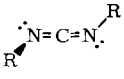
The contrary substituent effects in the two series and the low energy barriers for the *syn-anti* isomerization of the guanidines *(74)* also indicate that the process involved is an inversion.

Another argument in favor of inversion is the similarity of the effect of the substituent Z on the *syn-anti* isomerization in imines ($X_2C{=}NZ$) and on the in-

(74)

(75)

version at tricoordinate nitrogen (*e.g.* in aziridines, see Section 3.4.1.1)[116]. The isomerization rate increases very rapidly as the substituent Z is varied in the order:



$$RO \approx R_2N < \text{halogen} < \text{alkyl} < \text{aryl} < \text{acyl}$$

Substituents X on the imino carbon atom also increase the inversion rate, the order being[115,116a]:

quinone ring < alkyl < acetyl < alkoxycarbonyl < aryl < methoxy [123, 124] < alkylthio [124] < dialkylamino

With the aid of these sequences, it is possible to predict the rate constants within wide limits.

The fast inversion at nitrogen also explains why carbodiimides *(76)*, unlike allenes, do not form stable isomers. As predicted from calculations[125], the diastereotopic geminal H and CH_3 groups in the residues R have been found to be NMR-spectroscopically equivalent even at −100 °C. The activation energy of the inversion is presumably smaller than ≈9 kcal/mole in these compounds[45].

(76)

R = C_2H_5, i-C_3H_7, $CH_2C_6H_5$

3.3.3. Isomerization at Other Double Bonds

Isomerizations of oxonium and sulfonium salts containing CO and CS double bonds, *e.g. (77)*, are closely related to the isomerizations just described.

In the protonated carbonyl compounds [*(77)*, Z = H] that have been the subjects of most of the investigations[**], isomerization by deprotonation/reprotonation is possible as well as the rotations and inversions discussed for the CN double bonds[126b]. Experiments with systematic variation of the substituents, which should make it possible to decide which course is in fact followed, have not yet been carried out.

In the series of sulfur compounds, investigations have been carried out on the thiuronium salts *(78)*[121].

The influence of the substituent Z on the isomerization rate in these compounds is comparable to that in

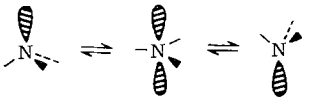
(78)

guanidinium salts *(75)* [45]. Thus large residues in the *o*-positions of *S*-arylthiuronium salts hinder the process, indicating that rotation is involved.

The inversion seems to have been conclusively verified in the imines. Some sulfonium salts appear to isomerize by rotation, but it is still too early to generalize.

Inversion is more likely in oxonium salts than in the sulfur analogs. However, no investigations on this point have been carried out as yet.

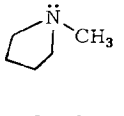


Rotation is the only possibility for *cis/trans* isomerization in olefins and immonium salts, apart from the protonated imines, in which inversion by deprotonation/reprotonation is also conceivable.

3.4. Inversions

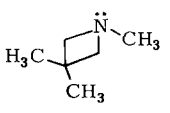
3.4.1. Inversion at the Nitrogen Atom

The inversion of the nitrogen pyramid in amines has been known for a long time. It proceeds *via* a planar state by a change in the hybridization of the nitrogen atom from sp^3 to sp^2 [*].



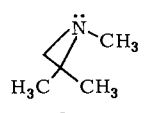
(79)

The barrier in ammonia and in many amines is so low ($\lesssim$6 kcal/mole) that it is difficult to detect by NMR spectroscopy, though the inversion rates can still be determined in such cases from the pH dependence of the spectra [135]. With suitable substituents, however, the pyramidal arrangement can be stabilized sufficiently to allow even the separation of invertomers ($\Delta G^{\neq} > 23$ kcal/mole).



3.4.1.1. Influence of Ring Strain

The inversion barrier is much higher in the azetidines *(81)* and aziridines *(82)–(84)* than in the unstrained pyrrolidines *(80)*. ($\Delta G^{\neq}$ is given in kcal/mole under the formulas).



7 [136a]

(82)

19.1 [138]

(83)

17.1 [139]

(84)

An intuitive explanation of this phenomenon can be obtained by considering the transition state. In the planar state, the nitrogen is sp^2-hybridized, so that the bond angle must increase to 120 °C during the inversion. When the nitrogen is incorporated in a small ring, however, the necessary spreading is hindered, *i.e.* the activation energy increases.

On the other hand, the s-character of the lone electron pair on nitrogen is much higher in the three-membered ring than in acyclic amines. This is indicative of a ground state stabilization with respect to the inversion transition state.

[*] With H atoms on the nitrogen, inversion is also possible by the tunnel effect [134]. This process becomes increasingly unlikely as the mass of the substituents on the nitrogen increases.

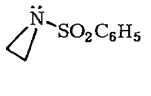
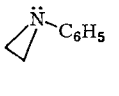
3.4.1.2. Steric Effect

The $\Delta G^{\neq}$ value decreases with increasing size of the residues on the nitrogen [cf. the series *(82)*–*(83)*→*(84)*]. This effect, which is not very large, is due to the fact that the steric hindrance is less in the planar transition state than in the pyramidal ground state.



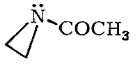
3.4.1.3. Electronic Effects

Electron-attracting substituents strongly depress the inversion barrier [cf. the series *(82)*→*(85)*→*(86)*→*(87)*, with indicated $\Delta G^{\neq}$ values].



20.5[136, 137]

(82)

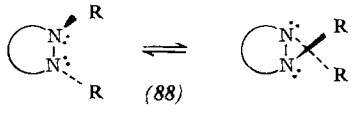


12.4[140]

(85)

11.7[141]

(86)



<6[141]

(87)

This effect, which stabilizes the planar transition state, is also the reason for the very fast nitrogen inversion in amides, which cannot be detected by NMR spectroscopy.

Electronegative substituents Z (halogen, oxygen, nitrogen) stabilize the pyramidal ground state of the nitrogen atom ("hetero effect"). Thus the inversion barrier has been measured in hydroxylamines[103, 142b] and hydrazine derivatives[100, 143] by NMR spectroscopy, though the inversion is to fast for measurement in this way in other acyclic amines.

Many articles have appeared on compounds *(88)*, in which two nitrogen atoms are built into adjacent positions in ring systems[144, 145].

(88)

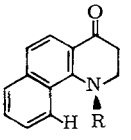
R = Alkyl, Acyl, Carboxyl, $(CH_2)_n$ *etc.*

The inversion in systems of this type is easy to follow by NMR spectroscopy. The inversions of the two N atoms do not occur simultaneously[145].

The hetero effect, which is also found in imines (cf. Section 3.3.2), could have two causes. 1. As the electronegativity of the substituents increases, so also does the s character of the lone pair of electrons on the nitrogen[146], with the result that the energy difference for the transition state (p character of the lone pair of electrons) increases. 2. The transition state is destabilized by the mutual repulsion of the lone pairs of electrons on the nitrogen and on the hetero atom. It is not yet possible to say which of these two effects predominates.

The configuration-stabilizing effect of halogen atoms shows that (p-d)π interaction cannot play any decisive part in the transition state. Sulfur substituents, on the other hand, appear to accelerate the inversion[104]. This is contrary to findings in some earlier investigations, in which a "slow" inversion is assumed for sulfenamines[147]. However, the temperature effect observed in these investigations can be better explained by hindered rotation about the SN bond.

Appreciable stabilities of the nitrogen pyramid are achieved by combination of the effects of ring strain and of hetero substitution.



(89a), Z = Halogen[148]

(89b), Z = NR_2[149]

(90a), Z = O[150]

(90b), Z = NR[151]

(91)

Stable nitrogen invertomers were first separated by *Felix* and *Eschenmoser* and by *Brois* in the halogenoaziridine series *(89a)*[148]. Invertomeric oxaziridines [*(90a)*, Z = O][150a] and diaziridines [*(90b)*, Z = NR][150b] are also stable at room temperature.

If the nitrogen atom is substituted with two hetero atoms, the pyramid is stable to inversion even in rings with more than three members. This was recently demonstrated in the case of an *N*-methoxy-1,2-oxazolidine[151].

Hindrance of the inversion by steric effects has been observed in dihydroquinolone systems *(91)*[152].

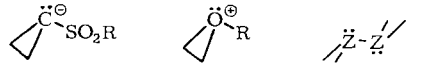
3.4.2. Other Inversions

Inversions can also occur at other atoms [152, 153].



(92) *(93)* *(94)*

(95) *(96)* *(97)*

The pyramids of carbanions *(92)* and oxonium salts *(94)* are isosteric with those of amines *(93)*. The inverting central atoms can also be replaced by other elements from the same group of the periodic system. The number of possible inversions is considerably increased by the inversion processes in the systems *(95)* to *(97)* containing doubly bonded atoms. NMR studies have so far been carried out on only a few inversions at atoms other than nitrogen [*].

Thus *Anet et al.* studied the inversion in cyclic carbanions *(98)* [155], and *Lambert et al.* analysed the same process in the oxonium salts *(99)* [156] (the figures are the $\Delta G^{\ddagger}$ values for inversion in kcal/mole).

17-18 *(98)* ≈10 *(99)* *(100)*

Z = P, As

Surprisingly low values of 26 kcal/mole were found for the inversion barriers for phosphorus and arsenic in compounds *(100)* [157]. The inversion of Grignard compounds has also been investigated [158]. Organometallic compounds of the type *(92)* usually exhibit complete racemization in chemical reactions [28]. Stereospecific reactions are possible only when the inversion barrier is increased by ring strain, as in the aziridines [28]. The inversion therefore becomes increasingly easy in the order *(92)*→*(93)*→*(94)*. If this observation is generalized, one should expect very small inversion barriers (<5 kcal/mole) in acyclic oxonium salts of the type *(94)*.

Similar results can be deduced for the species *(95)*→*(96)*→*(97)*. Whereas vinyllithium compounds of the type *(95)* react stereospecifically (or stereoselectively) [28], the inversion rates for imines lie in the NMR measurement range, and the ketonium salts *(97)* appear from preliminary results [45] to invert faster than comparable imines.

In species with the same central atom [*e.g. (92)* and *(95)* or *(93)* and *(96)*], types *(95)* and *(96)* have a distinctly higher barrier than types *(92)* and *(93)*. These cautious generalizations require further experimental confirmation.

The inversions of comparable pyramidal compounds should also become increasingly difficult with decreasing electronegativity of the central atom, *i.e.* in the order *e.g.* N→P→As, since the s character of the lone pair of electrons increases in this order [146], and the stronger the s character in the ground state, the more difficult is the inversion *via* a state in which the lone pair of electrons has pure p character.

Care is necessary in the interpretation of inversion barriers, since the mirror-image invertomer can be formed not only by direct intramolecular inversion but also by dissociation and recombination of the fragments. Isomerization by rotation must also be considered in the case of doubly bonded atoms (see Section 3.3.2).

NMR spectroscopy is a good method for the study of the substituent effects and the influence of the central atom on the inversion rates. The current interest in this topic is obvious from the number of publications that have appeared in recent years.

The investigations by our research group that are mentioned here were carried out with the support of the Deutsche Forschungsgemeinschaft, for which I am grateful. I also thank Prof. Dr. Eugen Müller for his interest in the work. Thanks are also due to Doz. Dr. A. Rieker for perusal of the manuscript and for numerous discussions, as well as to Dipl.-Chem. D. Leibfritz and Fräulein C. Burk for their assistance.

[*] In this connection, mention should be made of the pseudorotation at pentacoordinate phosphorus [154]. This process involves a rearrangement of the ligands that requires a change in the hybridization of the central atom in the transition state. Inversions at bivalent atoms (*e.g.* at oxygen in ethers, alcohols, and water) with linear transition states are briefly discussed in Section 3.2.3 for interconversions of C—O bond rotamers.

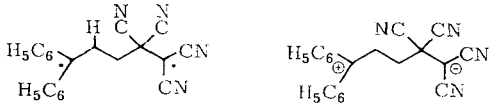
Reaction of 1,1-Diphenylcyclopropane with Tetracyanoethylene[**]

By *Th. Martini* and *J. A. Kampmeier*[*]

Thermal reactions between electron-deficient π-systems and C—C σ bonds have previously been encountered only with highly strained cyclopropane compounds[1] such as bicyclo-[2.1.0]pentanes, bicyclo[1.1.0]butanes, and quadricyclene[2,3]. A 1 : 1 cycloadduct of dispiro[2.4.2.0]decane and tetracyanoethylene was recently reported[4], but the structure was not clearly elucidated. We now report on the reaction of 1,1-diphenylcyclopropane *(1)*[5] with tetracyanoethylene *(2)*.

When compound *(1)* (4.4 g, 0.023 mole) and compound *(2)* (6.0 g, 0.047 mole) are heated together in benzene (100 ml) in an ampoule at 125 °C for 5 days, the color of the solution changes from blood-red to brown. After removal of the solvent, the residue is heated to boiling in CCl_4 (150 ml) and the hot solution filtered to remove undissolved *(2)*. The filtrate is kept at 0 °C for several hours and then reheated and refiltered to remove a final portion of *(2)*.

A 10 ml portion of $CHCl_3$ is added to the filtrate which is then allowed to stand at 0 °C for 2 days to give a brown crystalline product (4.5 g, 65 % calculated for a 1 : 1 adduct). The NMR spectrum of the product shows it to consist of *(3)* and *(4)* in the ratio 1 : 1.3. Careful NMR examination of all work-up fractions failed to give evidence for other products.



(1) *(2)* *(3)* *(4)*

The mixture could be separated by crystallization from absolute alcohol. The initial precipitate from alcohol is recrystallized from alcohol to give *(3)*, m.p. 202—203 °C. The alcoholic mother liquor from the original separation is evaporated to dryness and the residue taken up in cyclohexane. The crystalline product, obtained after the solution has been allowed to stand for a day, is recrystallized from cyclohexane to give *(4)*, m.p. 123—125 °C. Separation of 1.0 g of crude reaction product gives 0.35 g of *(3)* and 0.3 g of *(4)*. Both compounds give the expected C, H, N analyses and molecular weight (mass spectrometry).

The NMR spectrum of *(3)* [in $CDCl_3$ at 60 and 100 MHz: τ = 2.70 (10 aromatic H/s); 6.88 (4 aliphatic H/s)] and the UV spectrum [in CH_3OH (λ_{max} = 259 nm, ε = 665)] support structure *(3)*. The symmetrical structure, 1,1,2,2-tetracyano-4,4-diphenylcyclopentane, is ruled out by the NMR spectrum [in C_6D_6 (60 MHz); τ = 3.15 (10 aromatic H/m); 7.97 (4 aliphatic H/m[6])].

The NMR spectrum of *(4)* [in $CDCl_3$ (60 MHz): τ = 2.80 (10 aromatic H/m); 4.02 (1 olefinic H/t), J = 7.1 Hz; 5.80 (1 aliphatic H/s)[7]; 6.92 (2 allylic H/d), J = 7.1 Hz] shows an unusually large solvent shift[8] [in C_6D_6 (60 MHz): τ = 8.17 (1 aliphatic H/s) and 7.65 (2 allylic H/d)]. The UV spectrum [in cyclohexane (λ_{max} = 234 nm (sh), 259 nm, ε = 13600, 15500)][9] further supports structure *(4)*. Reaction of 1,1-diphenyl-3-propene[10] with *(2)* in an ene reaction[7,11], under the conditions described above, gave an independent synthesis of *(4)* in 9 % yield (pure product, based on reacted olefin). Neither the cycloadduct *(3)* nor rearrangement of the olefin to 1,1-diphenyl-1-propene is observed.

Cyclopropane does not react with *(2)* under the conditions described above. Heating compound *(1)* in benzene solution for four days with maleic anhydride (at 140 °C), fumaronitrile (at 175 °C), or 1,1-dichloro-2,2-difluoroethylene (at 130 °C) gave only unreacted starting materials. *(2)* is thermally stable at 130 °C. The formation of *(3)* and *(4)* is most simply explained in terms of a common, open-chain intermediate[2,11,12] *(5)* or *(6)*: cyclization leads to *(3)* and a 1,4 shift gives *(4)*.

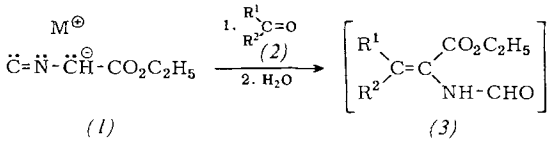
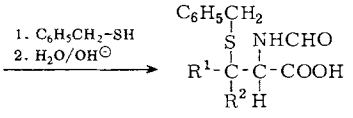
β-Substituted *N*-Formyl-*S*-benzylcysteines[11]



By *Ulrich Schöllkopf* and *Dieter Hoppe*[*]

β-Substituted *N*-formyl-*S*-benzylcysteines *(4)* warrant attention as cysteine precursors on account of the ease with which benzyl and formyl groups can be removed[2,3] and because they appear amenable to optical resolution[3].



We have now found that these compounds can be prepared in a "single-vessel" process by treating metalated ethyl isocyanoacetate *(1)* (prepared from ethyl isocyanoacetate and *e.g.* butyllithium, potassium *tert*-butoxide, or sodium hydride in tetrahydrofuran) with carbonyl compounds *(2)*, then adding phenylmethanethiol, evaporating off the solvent, adding water and potassium hydroxide to the residue, and finally warming for a short period.

The synthesis probably proceeds *via* β-substituted ethyl α-formylaminoacrylates *(3)*[4] which add the thiol after the

manner of a Michael reaction to give ethyl *N*-formyl-*S*-benzylcysteinates. Support for this reaction course comes from the fact that *N*-formyl-*S*-benzyl-β-phenylcysteine is formed in 85% yield on reaction of ethyl α-formylaminocinnamate[4] with phenylmethanethiol in ethanol containing sodium ethoxide and subsequent hydrolysis.

[a] In tetrahydrofuran. KOtBu = K *tert*-butoxide; BuLi = butyllithium. [b] The ester is only partially hydrolyzed.

N-Formyl-S-benzylpenicillamine (4b)

Butyllithium (0.04 mole as a 2.0 N solution in pentane) is added dropwise to a vigorously stirred solution of ethyl isocyanoacetate[5] (4.53 g, 0.04 mole) in tetrahydrofuran (30 ml) at −70 °C in such a way that the drops fall directly into the reaction mixture. A solution of acetone (2.35 g, 0.04 mole) in tetrahydrofuran (10 ml) is then also added dropwise, the mixture allowed to warm up to room temperature, and phenylmethanethiol added (5.0 g, 0.04 mole). After removal of solvent under vacuum, water (25 ml) is added to the residue and the mixture is stirred for 5 min before addition of potassium hydroxide (2.5 g, 0.045 mole). Stirring is continued until a homogeneous solution is obtained (*ca.* 15 min) which is then cooled to room temperature before addition of concentrated hydrochloric acid and subsequent ice-cooling. When crystallization starts, ether is added and the mixture is stirred for a short time. After 12 h (*ca.* −5 °C), 6.56 g (61%) of *(4b)* precipitated, m.p. 157 °C (from ethanol/water, 1 : 2).

N-Formyl-S-benzyl-β-phenylcysteine (4e)

A solution of ethyl isocyanoacetate (4.52 g, 0.04 mole) and benzaldehyde (4.26 g, 0.04 mole) in tetrahydrofuran (10 ml) is added dropwise to a vigorously stirred suspension of 80% potassium *tert*-butoxide (*tert*-butanol as crystal solvent) in tetrahydrofuran (30 ml) at 150 °C. After 15 min, phenylmethanethiol (5.0 g, 0.04 mole) is added and the mixture is treated as described above. *(4e)* (8.9 g, 70%) is obtained as a mixture of diastereomers. Recrystallization from ethanol affords a diastereomer having m.p. 170 °C.

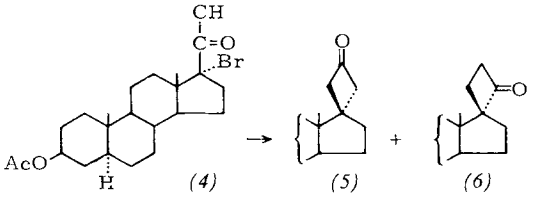
A New Spirocyclobutanone Synthesis in the Steroid Series[**]

By *Rudolf Wiechert*[*]

Reaction of 17-halogeno-16α-methyl-20-oxasteroids *(1a)*, *(1b)*, and *(3)*[1] with a 2.4-fold excess of dimethyloxosulfonium methylide[2] over a period of 90 minutes at 40 °C leads to formation of a product, which, after working-up, acetylation, and separation by column chromatography, affords the symmetrical spirocyclobutanone *(2)* [m.p. 190 to 192 °C (isopropyl ether), $[\alpha]_D^{24} = -126°$ ($CHCl_3$, $c = 0.5$)] in yields of 35–55%.

(1a), X = Cl
(1b), X = Br

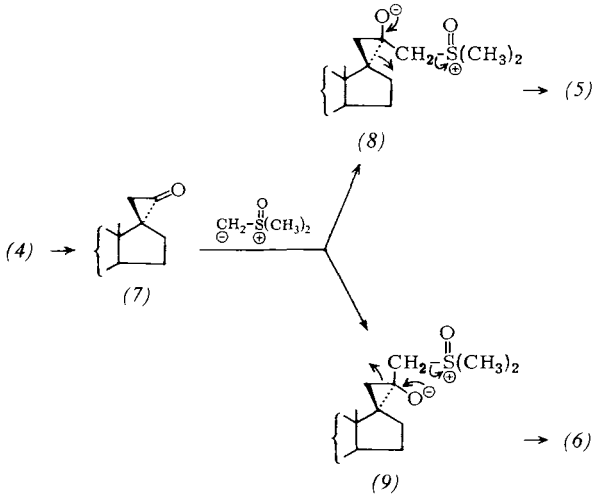


(2)

(3)

The νC=O band of the four-ring ketone *(2)* appears at 1790 cm^{-1}. A multiplet occurring at δ = 2.75 ppm in the NMR spectrum ($CDCl_3$, Varian A 60) can be assigned to the two CH_2 groups of the four-membered ring. On measuring the circular dichroism in dioxane a weak, negative Cotton effect can be detected (λ_{max} = 297 nm, $\Delta\varepsilon = -0.43$). The molecular weight (measured mass spectrometrically) is 384.

The analogous reaction of ketone *(4)*[3] (without methyl group on C-16) leads to formation of the symmetrical cyclobutanone *(5)* [yield 8%, m.p. 200.5–201.5 °C (isopropyl ether); IR: νCO = 1790 cm^{-1}; NMR: δ = 2.2–3.25 ppm (4H); CD: λ_{max} = 296 nm, $\Delta\varepsilon = -0.41$] and the ketone *(6)* (yield 17%, m.p. 162–164 °C).



Signals due to the two protons adjacent to the keto group give rise to a triplet in the NMR spectrum of *(6)* [A_2 part of

(4) *(5)* *(6)*

an A_2B_2 system, J = 8 Hz at δ = 2.78 ppm]. It can be concluded from the negative Cotton effect obtained in the CD curve (λ_{max} = 308 nm, $\Delta\varepsilon$ = −0.43) that the keto group lies on the backside of the molecule.

The formation of *(5)* and *(6)* [as well as *(2)*] under strongly basic reaction conditions can be assumed to proceed *via* an intermediate, a spirocyclopropanone *(7)*, as has been discussed in the case of the Faworskii rearrangement[4]. The adducts *(8)* and *(9)* expected from *(7)* can, for example, be stabilized by elimination of dimethyl sulfoxide and ring expansion in a concerted process to give *(5)* and *(6)*.

3β-Acetoxy-16α-methylspiro[androst-5-ene-17,1′-cyclobutan]-3′-one (2)

A mixture of trimethyloxosulfonium iodide (21.05 g, 96 mmole) in dimethyl sulfoxide (363 ml) and sodium hydroxide (3.83 g, 96 mmoles) is stirred at room temperature for 45 minutes. Compound *(1a)* (14.55 g, 40 mmole) is then added to the mixture, which is stirred for a further 1 1/2 hours at 40 °C and finally transferred with stirring to an acetic acid/ice-water mixture. The precipitate that forms is filtered off under suction, dried, and acetylated in pyridine/acetic anhydride for 16 hours at room temperature. The acetylated product is purified by chromatographic separation on silica gel [yield 8.45 g (55%)].

Photoacid Derivatives of an Achiral and a Chiral 2,4-Cyclohexadienone[1]

By *Gerhard Quinkert, Manfred Hintzmann, Peter Michaelis*, and *Peter Jürges*[*]

Light-induced cyclo/seco-isomerization of 2,4-cyclohexadienones affords dienylketenes that are converted into substituted hexadienoic acid derivatives by addition of protonic nucleophiles[2]. For instance, irradiation of 6,6-dimethyl-2,4-cyclohexadienone *(1a)*[3] by 365- or 313-nm light in the presence of water gives (3*Z*)-6-methyl-3,5-heptadienoic acid *(2a)*[2], whereas the cyclohexylamide *(2b)* thereof is formed in the presence of cyclohexylamine.

(1a), R = CH_3
(1b), R = C_6H_5 (rac.)

(2) *(3)*

(a), R = R^1 = CH_3; X = OH
(b), R = R^1 = CH_3; X = NH–C_6H_{11}
(c), R = C_6H_5; R^1 = CH_3; X = NH–C_6H_{11}
(d), R = CH_3; R^1 = C_6H_5; X = NH–C_6H_{11}

Cpd.	M.p. (°C)	UV (nm) (ε) [a]	IR (cm^{-1}) [b]	NMR (τ) [c]
(2b)	85	240 (24500)	3240, 1640	8.23 8.19
(3b)	100.5–101.5	240 (25300)	3280, 1640, 960	8.26 (ψ s)
(2c)	120–122	279 (23000)	3320, 1640	7.82
(2d)	100–100.5	255 (17000)	3320, 1640	7.89
(3c)	137–138	279 (27000)	3320, 1640 960	7.87

[a] In ether. [b] In KBr; all bands very strong. [c] Singlets of allylic methyl protons; HA 100; in $CDCl_3$; ψ s = pseudosinglet.

Monitoring the reaction UV-spectroscopically proves the transformation to occur in a *simple reaction* (*a series of straight lines* passes through the origin of the coordinates of an extinction difference diagram[4]). The 5,6-position of one double bond follows for *(2a)* from the results of ozonolysis[2], and for *(2a)* and *(2b)* from the NMR singlets of allylic methyl protons. Conjugation of the two CC double bonds can be deduced from the wavelength region of the electronic absorption spectrum, and absence of an IR band at 960 cm^{-1} requires the *Z*-configuration[5] for the 3,4-double bond[6]; the configurational isomer *(3b)* obtained by isomerization of *(2b)* with iodine, on the other hand, shows the CH wagging vibration characteristic of a doubly substituted ethylenic linkage with *E*-configuration[5].

The constitution of the photoproduct obtained from racemic 6-methyl-6-phenyl-2,4-cyclohexadienone *(1b)*[3] depends on the wavelength of the exciting light. In the presence of cyclohexylamine, 313-nm light *does not cause a simple reaction* (*a series of curves*, representing two linearly independent partial reactions, intersects the origin of the coordinates of an extinction difference diagram[4]); the amide *(2d)* is formed together with traces of *(2c)* and *(3c)*. Experiments with the individual amides *(2c)*, *(2d)*, and *(3c)* show that *(2c)* and *(3c)* are practically completely photoisomerized to *(2d)* under the irradiation conditions.

Under otherwise identical conditions, 365-nm light converts *(1b)* into a mixture of the (3*Z*, 5*Z*)- *(2d)* and the (3*Z*, 5*E*)-isomer *(2c)*. According to the extinction difference diagram this transformation occurs in a simple reaction. *(2c)* and *(2d)* are not isomerized either by direct irradiation with 365-nm light or by sensitization caused by electronically excited *(1b)*[8]. The constitution and configuration of *(2c)*, *(2d)*, and *(3c)* follow from the spectroscopic properties of the isomers and can be derived unambiguously from the straightforward relations to their synthetic precursors and derived products[9].

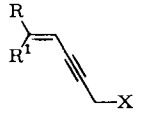
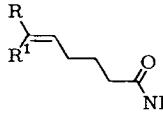
Synthesis and Determination of Configuration of (3*Z*, 5*E*)-, (3*Z*, 5*Z*)-, and (3*E*, 5*E*)-*N*-Cyclohexyl-6-phenyl-3,5-heptadienamide[1]



By *Gerhard Quinkert*, *Manfred Hintzmann*, *Peter Michaelis*, *Peter Jürges*, and *Uwe Krüger*[*]

Under conditions that exclude subsequent isomerization of the amide constituting the primary product, irradiation of 6,6-dimethyl-2,4-cyclohexadienone[2] by 365-nm light in the presence of cyclohexylamine leads to formation of *N*-cyclohexyl-6-methyl-3,5-heptadienamide, whereas under the same conditions racemic 6-methyl-6-phenyl-2,4-cyclohexadienone is converted into the (3*Z*, 5*E*)- and (3*Z*, 5*Z*)-configurations of *N*-cyclohexyl-6-phenyl-3,5-heptadienamide *(1a)* and *(1b)*[2]. Conversion of the enynes *(2a)* and *(2b)* into *(1a)* and *(1b)*, respectively, by partial hydrogenation on a Lindlar catalyst in methanol has shifted the problem of determination of the constitution and configuration from the dienes to the enynes. The pair of isomers *(2a)* and *(2b)* is readily accessible by synthesis (see below) and can be assigned structures with certainty by means of the nuclear Overhauser effect[3].



The amide *(3a)* is furnished by selective hydrogenation (Pt in glacial acetic acid) of the (3*Z*, 5*E*)-isomer *(1a)* or of the (3*E*, 5*E*)-isomer *(1b)* obtained from *(1a)* by isomerization with iodine; *(3b)* results from the (3*Z*, 5*Z*)-isomer *(1b)* under the same conditions.

Evidence of Two Configurational Isomers of Dienylketenes from 6-Methyl-6-phenyl-2,4-cyclohexadienone by Low Temperature Spectroscopy[1]

By *Gerhard Quinkert, Bernd Bronstert, Peter Michaelis,* and *Uwe Krüger*[*]

Stereochemical statements about the light-induced cyclo/seco-isomerization (originally postulated by intuition[2]) of racemic 2,4-cyclohexadienones containing a chiral center at C-6 to yield dienylketenes have hitherto been based on the number[3] and configuration[4] of the 6,6-disubstituted 3,5-hexadienoic acid derivatives that were considered to be derived from the ketenes. Low-temperature UV[5,6] and IR[5–7] spectroscopy permit unambiguous demonstration of the existence of the seco-isomers which are kinetically unstable at room temperature. We have found that irradiation of 6-methyl-6-phenyl-2,4-cyclohexadienone *(1)* with 365-nm light in the presence of cyclohexylamine affords the (3*Z*, 5*E*)-*(3a)* and the (3*Z*, 5*Z*)-configuration *(3b)*[9] of *N*-cyclohexyl-6-phenyl-3,5-heptadienamide[8] in the ratio 1 : 1.8. This raises the question whether two configurations of the dienyl-

Scheme 1

Scheme 2

ketenes are the primary products which pass by addition of the protonic nucleophile present into the acid derivatives actually isolated.

As reported previously[5a] for another case, measuring the UV spectrum of a solution of *(1)* in methylcyclohexane/isopentane (1 : 4) after its irradiation at —185 °C by 365-nm light (Fig. 1) allows formation of a photoproduct to be detected that regenerates *(1)* in a dark reaction when the temperature is raised [$t_{1/2}$ = 48 (—8.5), 95 (—15.4), 135 (—18.8), and 345 min (—26.3 °C)]. IR spectra (Fig. 2) measured in

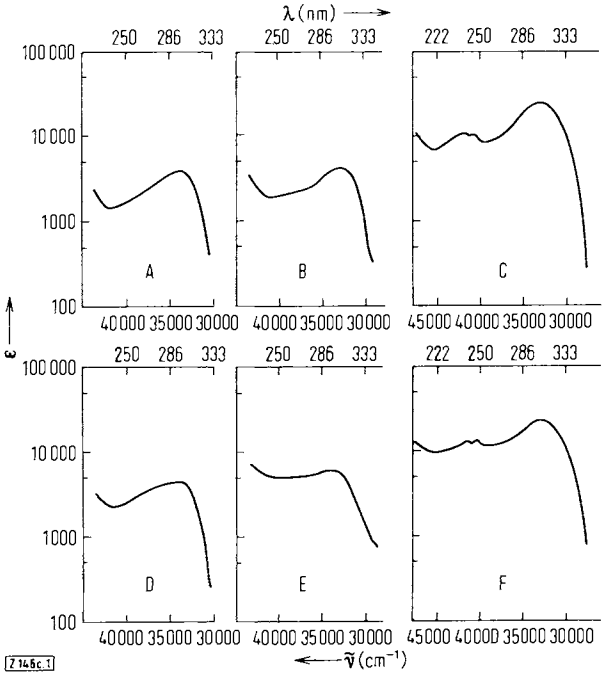

Fig. 1. UV spectra at various stages of cyclo/seco-isomerization. A, *(1)* in methylcyclohexane/isopentane (1 : 4) at room temperature; B, at —185 °C; C, after complete reaction with 365-nm light; D, after re-warming to room temperature; E, at —185 °C; F, after renewed irradiation with 365-nm light (94% reconversion of the photoproduct).

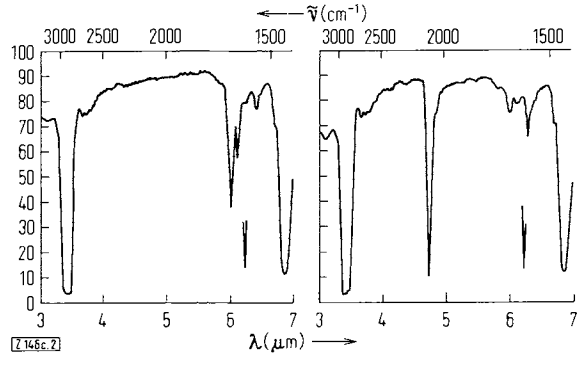

Fig. 2. Part of the IR spectra before (left) and after (right) irradiation of *(1)* in paraffin at —155 °C by 365-nm light.

paraffin before and after irradiation at —155 °C demonstrate the ketenic nature of the photoproduct and establish the ring opening that was previously assumed[2]. NMR spectra of the photoproduct (see Table) measured at —70 °C under various conditions[9] show that in this case the two ketenes *(2a)* and *(2b)* occur side by side. Rapid increase in temperature re-

NMR spectra of the photoproduct.

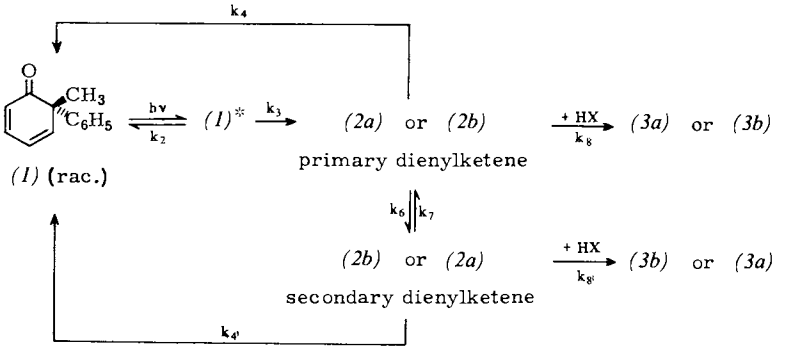
The Two Configurational Isomers of Dienylketenes Obtained as Primary Photoproducts from n,π*-Excited 6-Methyl-6-phenyl-2,4-cyclohexadienone[1]

By *Heinz-Helmuth Perkampus, Günter Prescher, Bernd Bronstert*, and *Gerhard Quinkert*[*]



The light-induced reaction of 6-methyl-6-phenyl-2,4-cyclohexadienone *(1)* in presence of cyclohexylamine (HX) leads to the configurational isomers *(3a)* and *(3b)* of *N*-cyclohexyl-6-phenyl-3,5-heptadienamide. Two configurational isomers *(2a)* and *(2b)* of the dienylketene formed as intermediates can be detected by low-temperature spectroscopy. The reaction may be construed as occurring by Scheme 1 or Scheme 2[2].

Schemes 1 and 2 differ in the nature and/or number of linearly independent reactions; and in such cases extinction difference diagrams afford a ready means for their differentiation[3]. These diagrams may relate, in the present instance, to the complete process of photochemical formation of the acid derivatives[4] or may be restricted to the light-induced cyclo/seco-isomerization[2] studied at low temperatures.

Linear extinction difference diagrams are obtained for ring fission of *(1)*, caused by light of wavelength 365 nm, in ether/isopentane/ethanol (5 : 5 : 2) at −185 °C or in methylcyclohexane/isopentane (1 : 4) at −70 °C. This finding accords with Scheme 1, but can be reconciled with Scheme 2 only if, in accord with the conditions of Bodenstein's hypothesis, the

Scheme 1

Scheme 2

concentration of either the primary or the secondary dienylketene is very small. However, NMR spectroscopy at −70 °C proves that the two ketenes are produced in comparable concentrations[2], so that Scheme 2 is excluded. 365-nm light converts *(1)* at room temperature or at −70 °C in the presence of protonic nucleophiles into derivatives of the two 6-phenyl-3,5-heptadienoic acids with configurations (3*Z*, 5*E*) *(3a)* and (3*Z*, 5*Z*) *(3b)*, *i.e.* under conditions where the products prove kinetically stable[4].

Photochemical formation of the acid derivatives is also characterized by linear extinction difference diagrams if carried out under these conditions in ether/isopentane (1 : 1)[4]. When the nucleophile concentration is about 0.1 mole/l, the slope of the line for the case of ethanol depends on its momentary concentration, but the slope is independent of concentration of the stronger nucleophile cyclohexylamine. These findings are to be expected from the relation[5] valid for Scheme 1:

$$\frac{\Delta E_1}{\Delta E_2} = \frac{(\varepsilon_{(3a)}-\varepsilon_{(1)})_1 + b\,(\varepsilon_{(3b)}-\varepsilon_{(1)})_1}{(\varepsilon_{(3a)}-\varepsilon_{(1)})_2 + b\,(\varepsilon_{(3b)}-\varepsilon_{(1)})_2};\quad b = \frac{k_3'}{k_3}\cdot\frac{(1+k_4/k_5\cdot c(\mathrm{HX}))}{(1+k_4'/k_5'\cdot c(\mathrm{HX}))}$$

which defines the slope of the straight lines in the extinction difference diagrams for wavelengths 1 and 2. For ethanol the quotients $k_4/k_5 \cdot c(\mathrm{HX})$ and $k_4'/k_5' \cdot c(\mathrm{HX})$ are not negligible in comparison with unity in the concentration region used, but for cyclohexylamine the limiting condition $b = k_3'/k_3$ has already been reached[6,7].

Since the primary ketene photoproducts recyclize and/or add nucleophiles, the quantum yield for disappearance of *(1)* depends on the strength and concentration of the protonic nucleophile. Under limiting conditions[5], which are reached at much lower concentration of cyclohexylamine than of ethanol, the numerical value ($\varphi = 0.55$) of the quantum yield is independent of the wavelength used (365 or 313 nm[8]) and of the addition of piperylene and presence of oxygen. These observations are immediately reconcilable with a n,π*-excited cyclohexadienone[9] of singlet character, from which the two dienylketenes *(2a)* and *(2b)* are formed side by side.

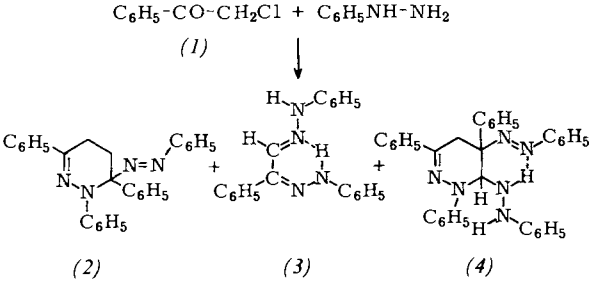
[5] *G. Prescher,* Dissertation, Technische Universität Braunschweig 1970.

[6] *b* applies and is constant during an addition reaction; 1, Bodenstein's hypothesis being applicable for *(1)*, (2a),* and *(2b)*; 2, for *c*(HX) (≈ 0.1 mol/l) ≪ *c*(1) (≈ 10^{-4} mole/l).

[7] Concentration invariance at sufficiently high *c*(HX) could occur with scheme 2 only if $k_8 \cdot c(\mathrm{HX}) \gg k_6$, *i.e.* on formation of an addition product.



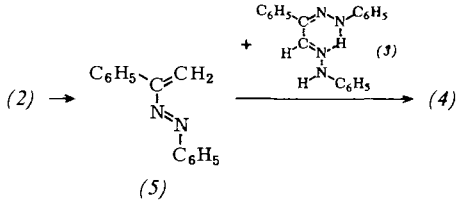
[8] 313-nm light subsequently converts the first portions of *(3a)* into *(3b)*. The quantum yield of this isomerization can, however, be separately determined as $\varphi = 0.47$.

[9] Independently of whether irradiation is undertaken in the π,π* or n,π* absorption region, the lower-energy n,π* state is obtained. Extreme external conditions may reverse the order of the two singlets [see *J. Griffiths* and *H. Hart,* J. Amer. chem. Soc. *90*, 5296 (1968)].

Osazone Formation from α-Haloketones. A Novel 1,4-Cycloaddition

By *William C. Stickler* and *William C. Hoffman*[*]

α-Haloketones are expected to give bis-phenylhydrazones (osazones) upon reaction with phenylhydrazine[1]. The reaction of the latter with phenacyl chloride *(1)* in cold alcoholic solution was first described by *Hess*[2]; neither the phenylhydrazone nor the osazone but the yellow crystalline 6-benzeneazo-1,3,6-triphenyl-1,4,5,6-tetrahydropyridazine *(2)* was isolated[3]. Our research group[4] was able to isolate from *(1)* in glacial acetic acid the long sought after osazone *(3)*, and also an unidentified pale-yellow crystalline product.



(1) *(2)* *(3)* *(4)*

Reinvestigation with the powerful aid of thin-layer chromatography revealed that in the reaction between phenacyl chloride *(1)* (0.01 mole) and phenylhydrazine (0.03 mole) in glacial acetic acid solution (40 ml), *(2)* is formed rapidly, reaching its maximum concentration in about 30 minutes and thereafter decreasing to a constant, very low concentration in about one hour. The osazone *(3)* gradually forms, reaching its maximum concentration after about 24 hours. After about 30 minutes from the start of the reaction, a third yellow substance *(4)*, m.p. 194—196 °C, makes its appearance, slowly increasing in concentration during several days; it proved to be identical with the above mentioned pale yellow compound.

NMR data[5], which we were able to confirm, and our own IR data[6] support the geometry given for the osazone *(3)*.

The structure *(4)* was derived from molecular weight determinations (*e.g.*, 522 from a mass spectrum), elemental analysis values, the IR spectrum [which resembles that of the osazone *(3)*: 3350 (N—H); a broad, low-intensity band centered at 3200 (N—H · · · N); 2930 and 2860 cm^{-1} (CH_2)], the NMR spectrum [in $CDCl_3$ δ = 13.03 (one N—H · · · N); 8.32 (C—H); 7.31 (25 aromatic C—H protons and one N—H proton (at δ = 7.53 ppm/m); 5.14 ppm (CH_2); the two N—H protons are readily "washed out" by D_2O], and the UV spectrum [in cyclohexane, λ_{max} = 405 nm (log ε = 2.158), which is considered characteristic of alkyl azo compounds[7]].

(2) *(5)* *(3)* *(4)*

Curtin and *Tristram*[3] rationalize formation of *(2)* as involving phenylhydrazone formation, followed by 1,4-elimination of HCl and subsequent dimerization of the resulting ene-azo intermediate *(5)*. They describe this dimerization as "suggestive of the Diels-Alder reaction".

We propose to extend their line of reasoning to explain the formation of *(4)*. The pyridazine *(2)* undergoes a retro-Diels-Alder type reaction to yield fragment *(5)*, which serves as the diene to the osazone *(3)*, acting here as the dienophile[8] in a novel 1,4-cycloaddition.

The phenacyl bromide behaves in an analogous fashion, but the iodide yields *(2)* in low concentration and leads to acetophenone phenylhydrazone as the main product.

α-Olefins from Ethylene[1]

By *Gisela Henrici-Olivé* and *Salvador Olivé*[*]

Ethylene is rapidly converted into solid polyethylene by the two-component catalyst $Cp_2TiRCl/RAlCl_2$ (Cp = cyclopentadienyl, R = alkyl) in toluene at 0 °C[2, 3]. *Bestian et al.*, however, have shown that the major products are liquid oligoethylenes — mainly 2-ethyl-1-olefins *(1)* having vinylidene terminal groups — when $Cl_2TiRCl/RAlCl_2$ is used as catalyst in CH_2Cl_2 as solvent at −70 °C[4, 5].

By systematically changing the reaction conditions and the ligands on titanium we have now been able to prepare C_6—C_{40} olefins *(2)* having predominantly vinylic end groups. The best results were obtained by using the following procedure:

$(C_2H_5O)_3TiCl$ (2 mmoles) is dissolved in toluene (100 ml) and treated with $C_2H_5AlCl_2$ (10 mmoles) under an atmosphere of argon. The homogeneous solution is then transferred to an autoclave and cooled to −20 °C. Ethylene is introduced into the autoclave at 12 atm and both pressure and temperature are kept constant during the time of reaction (1 hour). After withdrawal of the ethylene at the reaction temperature the conversion can be determined by weighing (increase in weight minus the solubility of the ethylene in the reaction solution): 34.6 g, corresponding to a conversion of 13.0 moles of ethylene per liter of reaction solution per hour.

The reaction solution was washed with water to remove catalyst; some solid polymer (0.9%) was precipitated. The organic phase was fractionated by vacuum distillation (see Table 1).

$H_2C=C(-H)-R$ (*1*) $H_2C=C(-H)-R$ (*2*)

Dicyclopropylacetylene by Fritsch-Buttenberg-Wiechell Rearrangement

By *Gert Köbrich* and *Dieter Merkel*[*][**]

Reaction of 1-chloro-2,2-dicyclopropylethylene *(2)*, prepared from dicyclopropyl ketone *(1)* by chloroolefination[1], with *n*-butyllithium in THF between −110 and +20 °C afforded the hitherto unknown dicyclopropylacetylene *(5)* as a stable, colorless liquid, beside 1,1-dicyclopropyl-1-hexene *(4)*. Hydrogenation of the acetylene *(5)* over a Lindlar catalyst proceeded almost quantitatively and stereospecifically to give *cis*-1,2-dicyclopropylethylene *(6)*[2].

The supposed carbenoid intermediate *(3)* has not been detected so far probably because the electron-repelling and bulky cyclopropyl groups slow down metalation of *(2)*, on the one hand, and accelerate decomposition of *(3)*[3] on the other.

Cpd.	Yield (%)	B.p. (°C/torr)	n_D^{20}	IR (cm^{-1}) [a]	NMR [b]
(2)	71	70/13	1.5028	3080 and 3005 (C—H); 1620 (C=C)	4.24 (1 =C—H/s); 7.7–8.3 (1 *cis*-allyl-H/m); 8.8–9.7 (9 H/m)
(4)	10 [c]	95/13	1.4725	3075, 3000, and 2955 to 2855 (C—H); 1650 (C=C)	4.95 (1 =C—H/t); 7.7–9.8 (19 H/m)
(5)	83 [c]	151/760	1.4900	3080 and 3000 (C—H); 2200 (C≡C), Raman band	8.6–9.3 (2 H/m); 9.3–9.6 (8 H/m)
(6)	97 [d]	140/760	1.4803	3070 and 3000 (C—H); 1690 and 1660 (C=C); 1043, 1015, 949, and 886	5.38 (2 =C—H) and 8.41 (2 allyl—H) as A_2B_2 system; 9.05 to 9.9 (8 H/m)

[a] Measured on capillary film. [b] τ scale; measured in CCl_4 with TMS as internal standard. [c] Based on *(2)*. [d] Based on *(5)*.

Interestingly, *(3)* does not undergo a dimerizing α-elimination to give butatriene *(7)*, as has been observed for analogous β,β-dialkyl derivatives under similar conditions[3a], but owing to the "olefinic behavior" of the three-membered rings[4] enters into a Fritsch-Buttenberg-Wiechell rearrangement that is characteristic of unsaturated β substituents (aryl[5], alkenyl, and alkynyl groups[3b]).

Experimental:

A solution of *(2)* (100 mmoles), prepared according to the general procedure given in ref.[6] and purified by distillation (spinning band column), in THF (200 ml) or THF/ether/light petroleum (50–70 °C) (4 : 1 : 1) (Trapp mixture[3a]) (200 ml) is treated with a solution of butyllithium (120 mmoles) in light petroleum at 20 °C under an inert gas and the reaction mixture stirred overnight. The crude product obtained after hydrolysis and the usual working up procedure contained *(5)* and *(4)* in 83 and 10% yield, respectively, (based on *(2)*, determined by gas chromatography) which were obtained about 97% pure on fractional distillation over a spinning band column, and free from impurities by preparative gas chromatography (6 m column, SE 30). Hydrogenation of *(5)* (10 mmoles) with Lindlar catalyst (0.5 g) and quinoline[7] (0.2 g) in a shaking apparatus (70 min at 20 °C) gave a 97% yield of *(6)* along with 3% of lower boiling products which were removed by preparative gas chromatography.

N,N'-Sulfonylbis(sulfur difluoride diimide)[1]

By *Herbert W. Roesky* and *Horst H. Giere* [*]

Sulfamide reacts with sulfur tetrafluoride at room temperature in the presence of sodium fluoride as HF acceptor to give *N,N'*-sulfonylbis(sulfur difluoride diimide) *(1)* in 22% yield.

$$H_2NSO_2NH_2 + 2\ SF_4 \rightarrow F_2S{=}NSO_2N{=}SF_2 + 4\ HF$$
(1)

At higher temperatures, however, this reaction leads exclusively to formation of *N*-fluorosulfonylsulfur difluoride imide $FSO_2N{=}SF_2$[2].

Compound *(1)* is a yellow evil-smelling liquid which loses HF on reaction with water. Its composition follow sfrom the results of elemental analysis and from the mass spectrum, which shows, in addition to the molecular ion *m/e* 232 (8.7%), the following characteristic fragments: *m/e* = 167 (FSO_2NSF_2; 12.3%), 148 (SO_2NSF_2; 61.8%), 84 (NSF_2; 19.7%), 83 (SO_2F; 18.5%), 70 (SF_2; 39.4%), 67 (SOF; 17.0%), 65 (NSF; 16.5%), 64 (SO_2; 13.4%), 51 (SF; 10.7%), 48 (SO; 25.7%), 46 (NS; 100.0%), 32 (S; 6.8%).

The bands in the IR spectrum (capillary) have not, as yet, been completely identified because of the difficulties due to coupling and superpositions. In the region of the (S=O) and (N=S) stretching vibrations, bands occur at 1430 w, 1385 s, 1270 m, 1215 vs, and 1180 vs (cm^{-1}). The absorptions at 820 s, 790 s, and 660 s (cm^{-1}) have been tentatively assigned to the (SN) and/or (SF) vibrations. The symmetry of the molecule is confirmed by the ^{19}F-NMR spectrum: a singlet is observed with δ_F = −41.5 ppm (CCl_3F, external) which compares with δ_F = −40.0 ppm for FSO_2NSF_2.

Experimental:

Sulfur tetrafluoride (108 g, 1 mole) is condensed into a 300 ml monel cylinder cooled with liquid nitrogen and containing a mixture of sulfamide (48 g, 0.5 mole) and sodium fluoride (84 g, 2 moles). The cylinder is then allowed to warm to room temperature and shaken for 20 hours. After removal of gaseous components — a little SF_4 and SOF_2 — the reaction products are washed portionwise from the cylinder with 300 ml CCl_4 and separated from NaF · HF by filtration under dry nitrogen. Concentration of the filtrate followed by distillation under vacuum affords compound *(1)* [b.p. 49 to 51 °C/0.01 torr; yield 26 g (22.4%)].

Method for Preparation of Compounds of the Type $R{-}(N{=}PX_2)_x{-}N{=}PCl_3$[1]

By *Herbert W. Roesky* and *Ludwig F. Grimm* [*]

N-Trimethylsilylaminodifluorophosphoranylidenedihalothiophosphorylamines *(1)*, prepared from the corresponding *N*-trifluorophosphoranylidenedihalothiophosphorylamine and hexamethyldisilazane[2], react with phosphorus penta-

chloride to give the linear phosphazene compounds *(2)*, hydrogen chloride and trimethyl chlorosilane being eliminated in the process.

(a), X = F; *(b)*, X = Cl

This method of forming P—N=P linkages can be extended: thus compound *(2)* has also been found to undergo a corresponding reaction with hexamethyldisilazane and PCl_5. The products are colorless and react vigorously with water; they can be vacuum distilled without decomposition. Their composition is established by elemental analysis and by mass spectrometry. The mass spectrum of *(2a)* contains characteristic fragments in addition to the molecular ion at *m/e* 334; in the case of *(2b)*, the molecular ion at *m/e* 350 (28.9%) is accompanied by the fragment ions observed at *m/e* = 315 ($SPFClNPF_2NPCl_2$; 97.2%), 283 ($PFClNPF_2NPCl_2$; 33.9), 245 ($SPFNPF_2NPCl$; 13.3), 213 ($PFNPF_2NPCl$; 17.2), 200 ($SPFClNPF_2$; 8.3), 184 (PF_2NPCl_2; 3.3), 168 ($PFClNPF_2$; 8.9), 133 ($PFNPF_2$; 7.2), 114 ($PFNPF$; 9.4), 101 (PCl_2; 3.3), 85 (PFCl; 8.9), 69 (PF_2; 27.2), 66 (PCl; 2.8), 63 (SP; 4.4), 50 (PF; 5.6), 45 (PN; 2.8), 36 (HCl; 17.8), 35 (Cl; 5.0), 32 (S; 2.2), 31 (P; 1.7).

The IR spectra exhibit characteristic absorption bands, which, however, cannot be assigned unequivocally owing to superposition. — *(2a)*: ν(P=N) 1400—1300 vs; ν(PF), ν(P—N), ν(P=S) 960—940 vs, 900—860 vs, 780 s, 735 vs; ν(PCl) 650 vs, 615 vs, and 560 m, 500 vs cm^{-1}. — *(2b)*: ν(P=N) 1340—1300 vs; ν(PF), ν(P—N), ν(P=S) 960—940 vs, 865 vs, 730 vs; ν(PCl) 645 vs, 610 vs, and 495 vs cm^{-1}.

The ^{19}F-NMR spectra are of higher order owing to ^{31}P coupling. *(2a)* : SPF_2 part, $\delta_F = +35.1$; PF_2 part, $\delta_F = +67.3$ ppm. *(2b)*: SPFCl part, $\delta_F = +3.7$; PF_2 part, $\delta_F = +66.9$ ppm (CCl_3F as external reference). In comparison, $SPF_2NPF_2NHSi(CH_3)_3$ [2] gives $\delta_F = +36.4$ ppm for the SPF_2 part, and $\delta_F = +66.5$ ppm for the PF_2 part.

Procedure:

Compound *(1a)* (0.2 mole) or *(1b)* [2] (0.2 mole) is added dropwise to PCl_5 (41.6 g, 0.2 mole). The reaction mixture is stirred and heated to 60—80 °C during the addition and then refluxed until all solids have dissolved. The residue remaining on removal of trimethylchlorosilane under vacuum is subjected to fractional distillation. *(2a)*, b.p. 65 °C/≈ 0.01 torr, yield 16.7 g (25%); *(2b)*, b.p. 96 °C/≈ 0.01 torr, yield 31.7 g (45%).

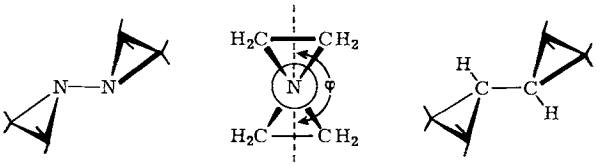
Conformational Analysis of 1,1'-Bisaziridyl by Vibrational Spectroscopy



By *Paul Rademacher* and *Wolfgang Lüttke* [*]

Dedicated to Professor Walter Hückel on the occasion of his 75th birthday

An unbiased consideration of the internal rotation of hydrazine and its derivatives initially suggests that the torsional potential curve is mainly determined by the repulsion of the lone pair electrons at the nitrogen atom; accordingly, the s-*trans* conformation should be the most stable form.

In contrast to this assumption, and in agreement with *ab initio* LCAO-MO-SCF calculations for hydrazine [5], it is found that in the case of hydrazine [1] and its simple derivatives so far investigated (*e.g.* tetramethylhydrazine [2], tetrafluorohydrazine [3], and tetrakistrifluoromethylhydrazine [4]) the most stable and sole existing conformation is a *gauche* form having a dihedral angle of ≈ 90 °. Consequently, hydrazines behave in a manner fundamentally different from their isoelectronic hydrocarbons in which an s-*trans*/*gauche* equilibrium is always observed in the gaseous and liquid states and generally only the s-*trans* form in the crystalline state [6].

Since aziridine differs in many respects from amines having an open C—N—C chain, it appeared to be of interest to us, in our investigations of the structure and conformation of compounds having two small rings coupled by a central single bond [7,8], to examine the internal rotation of 1,1'-bisaziridyl [9] *(1)* and to determine whether it undergoes inversion like other amines.

(1) *(1a)* *(2)*

With this aim in mind we recorded the IR spectra of *(1)* in the gaseous liquid, and crystalline states and its Raman spectrum in the liquid state. The following observations were made:

1. Although 36 normal vibrations are to be expected for compound *(1)* as a 14-atom molecule, its IR spectrum and Raman spectrum show relatively few bands.

2. The rule of mutual exclusion applies to the IR and Raman spectra of liquid *(1)*: apart from three bands no frequency coincidences occur.

3. There is no change in the number of IR bands of *(1)* during transition from the crystalline to the liquid and the gaseous states.

These observations can only be explained on the basis of a centrosymmetric C_{2h} structure; therefore, of all the possible conformers *only* the s-*trans* form is present, within the limits of experimental error, in *each of the three* different states. Thus compound *(1)* differs significantly not only from all the previously investigated hydrazines [1–4] but also from the isoelectronic hydrocarbon, bicyclopropyl *(2)*, which occurs as the pure s-*trans* conformer in the crystalline state only but as a mixture of the *gauche* and s-*trans* forms in the liquid and gaseous states [7].

The s-*trans* form of *(1)* can give rise to non-centrosymmetric conformers either by internal rotation about the N—N bond or by inversion at one of the nitrogen atoms. Since we observed only the s-*trans* form spectroscopically and since the inversion barrier is particularly high in aziridines [10–13] (*e.g.* > 22 kcal/mole for *N*-aminoaziridine [13,14]), the internal rotation must also be strongly hindered in this case; both factors are probably due to the particular electronic arrangement in the aziridine [15].

In order to determine the structural parameters of *(1)* accurately we are at present carrying out an electron diffraction investigation, a complete analysis of the vibrational spectrum, and NMR measurements.

Bis(trimethylstannyl) Selenide and Bis(trimethylstannyl) Telluride as Ligands in Carbonyl Complexes of Transition Metals[**]

By *Herbert Schumann* and *Robert Weis*[*]

We recently reported the first synthesis of pentacarbonylchromium(0), -molybdenum(0), and -tungsten(0) complexes with organo-silyl, -germyl, -stannyl, and -plumbyl sulfides as the sixth ligand[1]. The sulfur atom of these organometal sulfides is therefore sufficiently basic to act as σ donor and π acceptor toward the transition metal carbonyls which are to be regarded as Lewis acids.

Extension of these studies to organometal selenides and tellurides has shown that bis(trimethylstannyl) selenide[2] and bis(trimethylstannyl) telluride[3] react with hexacarbonylchromium, hexacarbonylmolybdenum, or hexacarbonyltungsten in tetrahydrofuran (THF) at room temperature and under UV irradiation[4] with displacement of one CO group.

The products *(1)*, *(2)*, and *(3)* are obtained almost quantitatively on irradiation of a mixture of the reactants; in the synthesis of *(4)* and *(5)*, however, owing to the high light-sensitivity of bis(trimethylstannyl) telluride complete formation of the highly reactive pentacarbonylmetal-THF complex must first be attained by UV irradiation of $Cr(CO)_6$ or $W(CO)_6$ in THF; in the dark, the complex exchanges THF for the new ligand bis(trimethylstannyl) telluride.

$$[(CH_3)_3Sn]_2X + M(CO)_6 \xrightarrow{h\nu} \begin{matrix}(CH_3)_3Sn\\ \\ (CH_3)_3Sn\end{matrix}\!\!>\!X\!-\!M(CO)_5 + CO$$

(1), X = Se, M = Cr; *(4)*, X = Te, M = Cr
(2), X = Se, M = Mo;
(3), X = Se, M = W; *(5)*, X = Te, M = W

Cpd.	X	M	Decomp. (°C)	νCO (cm^{-1})	$\nu_{as}Sn_2X$ [a] (cm^{-1})	$\nu_{s}Sn_2X$ [a] (cm^{-1})	δCH_3 [b] (Hz)

[a] Raman spectrum; we are grateful to Dr. *E. Lindner*, Erlangen, for recording the spectra.

[b] 5% solution in benzene; TMS as external reference.

All the compounds prepared are brilliant yellow and sensitive to atmospheric oxygen and water; their thermal stability is similar to that of the analogous organometal sulfide complexes. The IR spectra of the compounds in solution in cyclohexane show four CO stretching vibrations. This finding agrees neither with local C_{4v} symmetry for the $(CO)_5MX$ group (3νCO), nor with overall C_s symmetry for the $(CO)_5MXSn_2$ system (5νCO). On the other hand an sp^2 hybridization at X can certainly be ruled out. As illustrated by the frequencies of the CO stretching vibrations, the influence of the chalcogenide ligands on the band positions of these vibrations is so very slight that it is perfectly reasonable to assume C_{4v} symmetry for the group $(CO)_5MX$; in the presence of symmetry-lowering ligands the degeneracy of the E_1 vibration will, however, be lifted[5].

The remarkable stability of compounds *(1)* to *(5)* demonstrates that, in spite of their low basicity, organotin selenides and organotin tellurides can form σ-donor-π-acceptor complexes in the same way as diorganyl selenides or tellurides. Blocking one of the two lone pairs of the chalcogen atom by no means causes bond weakening such as would lead to cleavage of the tin-chalcogen bond.

Procedure:

Hexacarbonylchromium, hexacarbonylmolybdenum, or hexacarbonyltungsten (10 mmoles) and bis(trimethylstannyl) selenide (10 mmoles) are dissolved in THF (50 ml), which has been dried over CaH_2, in an irradiation apparatus (quartz immersion tube, argon countercurrent). The mixture is stirred and irradiated with a high-pressure mercury vapor lamp[4]. A pressure slightly lower than atmospheric in a gasometer that was fitted to check the evolution of CO is found to favor the reaction, which is complete after irradiation for 3 h when the solution has become orange yellow. In the synthesis of *(4)* and *(5)*, addition of bis(trimethylstannyl) telluride (10 mmoles) is carried out *after* irradiation of hexacarbonylchromium or hexacarbonyltungsten (10 mmoles) in the manner described above, and the reaction mixture is then stirred in the dark at room temperature for another two hours. After removal of the solvent under reduced pressure,

the products (light yellow powder in each case; yield 80 to 90%) can be recrystallized from pentane at −40 °C.

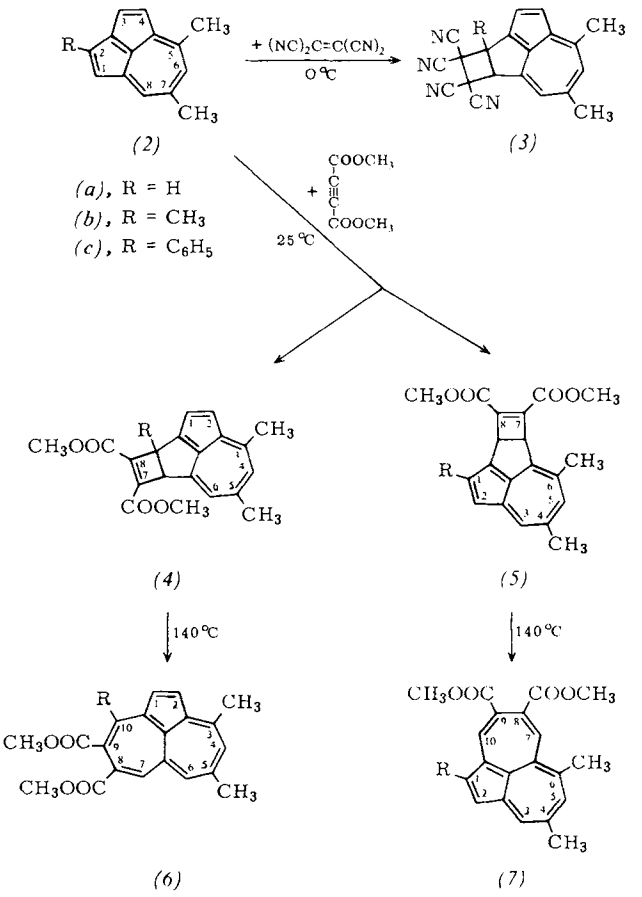
New Synthesis of Aceheptylene

By *Klaus Hafner* and *Rolf Fleischer* [*]

Like acenaphthylene *(1)*, the isomeric compound cyclopent[*cd*]azulene *(2)* can also undergo 1,2-cycloadditions at the double bond of the five-membered ring. In contrast to *(1)*,

(1) *(2)* A B



however, *(2)* — like other derivatives of pentalene [1] — combines with multiple-bond systems at 0 °C or at room temperature. The thermally labile 12π-electron system *(2)* is thus converted into stable azulene derivatives.

Reaction of *(2a)* with tetracyanoethylene at 0 °C affords the cyclobutane derivative *(3)* in 60% yield as the sole adduct [2]. Dimethyl acetylenedicarboxylate, however, adds to *(2a)* at 25 °C in methylene chloride (+1% of triethylamine, 15 h) both in the 1,2- and in the 3,4-position to form dimethyl 3,5-dimethyl-6b,8a-dihydrocyclobuta[*a*]cyclopent[*cd*]azulene-7,8-dicarboxylate *(4a)* (m.p. 112 °C, yield 40%) and the corresponding 4,6-dimethyl derivative *(5a)* (m.p. 143—144 °C, yield 10%) [3].

(2b) and *(2c)* [4] combine with dimethyl acetylenedicarboxylate only in the 1,2-position to give *(4b)* (m.p. 141 °C, yield 71%) and a mixture of *(4c)* (m.p. 103—104 °C, yield 53%) and the aceheptylene derivative *(6c)* (m.p. 152 °C, yield 8%), respectively.

X-ray structure analysis [5] and SCF calculations [5,6] indicate a high bond order for the 1,2- and 3,4-linkage in *(2)* and polarization consistent with participation of the resonance structures (2A) and (2B). These findings suggest that reactions of *(2)* with electron-deficient alkenes and alkynes are two-step cycloadditions proceeding *via* resonance-stabilized dipolar intermediates.

Thermal valence isomerization of the adducts *(4a)*, *(4b)*, *(4c)*, and *(5a)* in boiling xylene (1 h) leads to the aceheptylenes *(6a)* (m.p. 150 °C), *(6b)* (m.p. 147 °C), *(6c)* (152 °C), and *(7a)* (m.p. 119—120 °C), respectively, in yields of about 90%. The preparation of *(6)* and *(7)* from the readily accessible cyclopent[*cd*]azulenes supplements the previous syntheses [2,7] of the tricyclic 14π-electron system. The structures

of compounds *(4)*—*(7)* were established by elemental analysis, molecular-weight determination, and UV and NMR spectra.

[1] 1,3-Bis(dimethylamino)pentalene [*K. Hafner, K. F. Bangert*, and *V. Orfanos*, Angew. Chem. *79*, 414 (1967); Angew. Chem. internat. Edit. *6*, 451 (1967)] reacts with dimethyl acetylenedicarboxylate at 0 °C to give dimethyl 4,8-bis(dimethylamino)azulene-5,6-dicarboxylate [*V. Orfanos*, Dissertation, Technische Hochschule Darmstadt 1968]. In this case, two-step cycloaddition of the enamine system to alkyne giving a cyclobutene derivative is probably followed by valence isomerization of the product to the substituted azulene. A concerted [2 + 8] cycloaddition has been suggested by *R. B. Woodward* [Special Publication No. 21, Chem. Soc. (London) *1967*, 217] as initial step in the formation of diethyl 1,2,3,4,5,8-hexaphenylazulene-6,7-dicarboxylate from hexaphenylpentalene and diethyl acetylenedicarboxylate at 160 °C [*E. LeGoff*, J. Amer. chem. Soc. *84*, 3975 (1962)].

[2] *K. Hafner* and *J. Schneider*, Liebigs Ann. Chem. *624*, 37 (1959).

[3] In addition to *(4a)* and *(5a)*, a 4% yield of dimethyl dimethylaceheptylenedicarboxylate is formed, presumably by addition of the acetylene ester to *(2a)* in the 2,2a- or 2a,3-position.

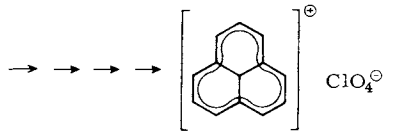
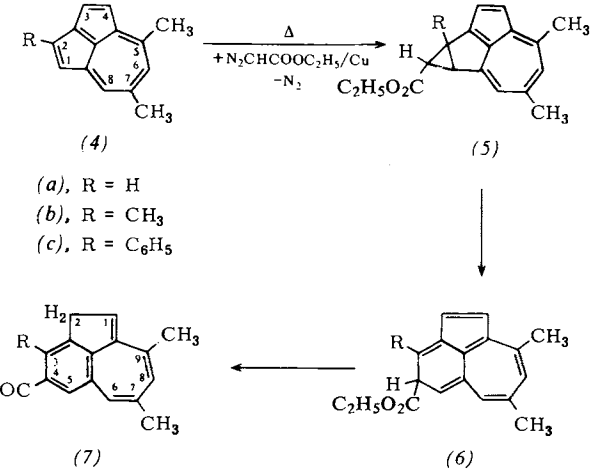
[7] *K. Hafner, H. Pelster*, and *H. Patzelt*, Liebigs Ann. Chem. *650*, 80 (1961); *K. Hafner* and *G. Schneider*, *ibid. 672*, 194 (1964).



New Synthesis of 2*H*-Benzazulenes

By *Klaus Hafner* and *Wolfgang Rieper*[*]

Acenaphthylene *(1)* combines with ethoxycarbonylcarbene, generated by thermolysis of ethyl diazoacetate, to give the stable cyclopropane derivative *(2)*, which can be converted into phenalenium perchlorate *(3)* *via* a multi-step synthesis[1].

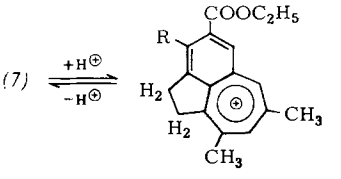


(1) *(2)*

(3)

The derivatives *(4a)*—*(4c)* of cyclopent[*cd*]azulene, an isomer of *(1)*, react similarly with carbenes (carbenoids) to yield 1,2-cycloaddition products. Unlike *(2)*, however, these products isomerize under the reaction conditions to the hitherto rather inaccessible 2*H*-benz[*cd*]azulene system *(7)*[2] which warrants interest as an isomer of phenalene.

The copper-catalyzed decomposition of ethyl diazoacetate in the presence of *(4a)*[3] in methyl cyclohexane at 90—100 °C leads directly to ethyl 7,9-dimethyl-2*H*-benz[*cd*]azulene-4-carboxylate *(7a)* (m.p. 93—94 °C) in 55—60% yield. Cycloaddition to the 1,2 bond of *(4a)* giving *(5a)* is probably followed by valence isomerization of the latter to the cross-conjugated tricyclic compound *(6a)*, which undergoes a hydrogen shift to give the stable molecules *(7a)*.



(4) *(5)*

(a), R = H
(b), R = CH_3
(c), R = C_6H_5

(7) *(6)*

Cycloaddition to the 3,4-bond of *(4a)*, which is also characterized by a high bond order, was not observed. In the case of *(4b)* and also *(4c)*[4], cycloaddition occurs exclusively at the 1,2-bond to give *(7b)* (m.p. 79—81 °C, 64%) and *(7c)* (m.p. 106—108 °C, 59%) (cf. ref.[5]).

In contrast to 2*H*-benz[*cd*]azulene[2b] and its 7,9-dimethyl derivative[6], compounds *(7a)*, *(7b)*, and *(7c)* can be isolated at room temperature and can be stored below 0 °C in the absence of atmospheric oxygen. Like 3,4,7,9-tetramethyl-2*H*-benz[*cd*]azulene[2a] they form trinitrobenzene adducts, and the heptafulvene system is reversibly protonated in position 1 to the bridged benzotropylium cation *(8)* by 70% perchloric acid. The structures of compounds *(7)* were established by elemental analysis, molecular-weight determination, and UV and NMR spectra.

CONFERENCE REPORTS

Biochemical and Genetic Aspects of Ribosome Specificity in Protein Synthesis

By *Orio Ciferri*[*]

70 S type of ribosomes, prepared from prokaryotic organisms or cell organelles (mitochondria and chloroplasts) of eukaryotic organisms, catalyze the reactions for protein synthesis *in vitro* only in the presence of polymerizing enzymes obtained from prokaryotes or organelles. No activity is evident when such ribosomes are tested in the presence of preparations of polymerizing enzymes extracted from the cytoplasm of the eukaryotic organisms. Ribosomes of the 80 S type, like those present in the cytoplasm of eukaryotes, are active *in vitro* only in the presence of preparations of polymerizing enzymes from the cytoplasm of such organisms.

Transfer factors T and G, which may be separated from the preparations of polymerizing enzymes, appear to be strictly ribosome specific. Indeed only one transfer factor T and one transfer factor G, specific for 70 S ribosomes, are present in the extract from cells of *E. coli*. In contrast, two transfer factors G and two transfer factors T, each specific for just one type of ribosome, may be detected in the non-photosynthetic eukaryotic alga *Prototheca zopfii*. Two ribosome specific transfer factors G have been demonstrated also in the case of the yeast *Saccharomyces cerevisiae*.

Extracts prepared from dark-grown cells of the photosynthetic flagellate *Euglena gracilis* display polymerizing activity only

on ribosomes of the 80 S type. On exposure to light, which induces the synthesis of the photosynthetic apparatus, a polymerizing activity specific for 70 S ribosomes becomes evident.

Ribosome specificity is not limited to the factors responsible for peptide chain elongation. Indeed the initiation factors, prepared from *E. coli*, catalyze the reactions for peptide chain initiation also on *Bacillus subtilis* ribosomes and on the ribosomes prepared from the mitochondria of the fungus *Neurospora crassa*.

The development of such studies at the genetic and biochemical levels may provide some interesting clues on the evolutionary relations that may exist between prokaryotic and eukaryotic organisms. In addition, within the latter group of organisms such studies may give some information on the genetic and metabolic autonomy of cellular organelles.

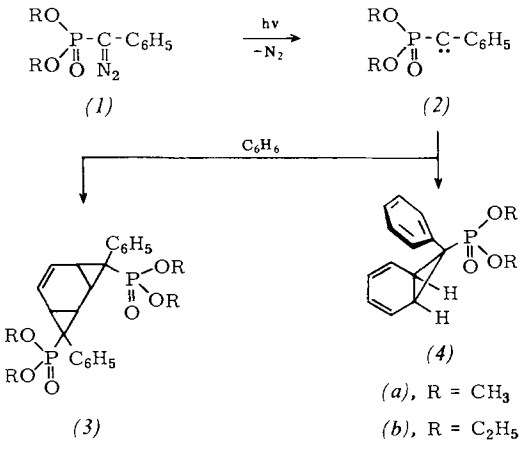
Recent Investigations on the Synthesis and Reactivity of Diazo Compounds

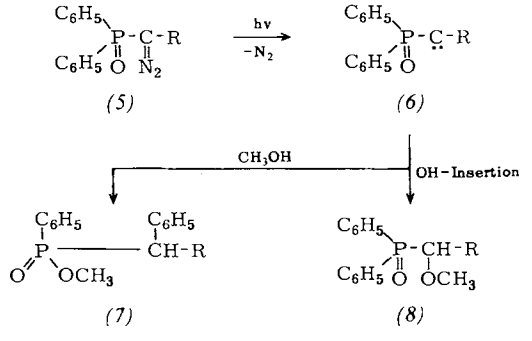
By *Manfred Regitz* [*]



Aliphatic diazo compounds can be prepared *via* three different but complementary routes by diazo group transfer with tosyl azide. Diacylmethanes react directly with the diazo-transfer agent (Route A)[1], whereas monoacylmethanes react only after previous formylation[1] (Route B). Diazomethane and non-acylated derivatives are accessible only *via* enamines of suitable structure (Route C).

Route A: R^1 and R^2 = acyl
Route B: R^1 or R^2 = acyl
Route C: R^1 and R^2 = H or alkyl

The synthesis of phenyldiethylphosphonodiazomethane *(1b)*[2] and diphenylphosphinyldiazomethanes *(5)*[3] and of 2-oxo-1-diazocycloalkanes[4] serve as model examples for routes A and B respectively. The carbenes *(2)* obtained photolytically from *(1)* add to benzene to give the 2 : 1 adducts *(3)* and the stable norcaradienes *(4)*; the NMR spectrum largely rules out an isomeric cycloheptatriene structure for *(4)* ($CDCl_3$, δ = 5.7—6.3 ppm, 4 olefinic protons; δ = 3.5—4.0 ppm, 2 cyclopropane protons).



Diphenylphosphinylcarbenes *(6)* have been investigated, particularly with regard to their rearrangeability. Thus photolysis of *(5a)* and *(5b)* in methanol leads *via* a Wolff

(1) *(2)* *(3)* *(4)*

(a), R = CH_3
(b), R = C_2H_5

rearrangement to the formation of the phosphinic esters *(7a)* and *(7b)* [61 and 71% resp.; NMR ($CDCl_3$): δ (OCH_3) = 3.6—3.7 ppm, doublet, $J_{POCH} \approx 11$ Hz].

(5) *(6)* *(7)* *(8)*

(a), R = H; *(b)*, R = COC_6H_5; *(c)*, R = $CO_2C_2H_5$;
(d), R = C_6H_5; *(e)*, R = $CONH_2$

The analogously generated carbenes *(6d)* and *(6e)*, on the other hand, undergo OH insertion to give the phosphine oxides *(8d)* and *(8e)* [100 and 81% resp.; NMR ($CDCl_3$): δ (OCH_3) = 3.4—3.5 ppm, singlet], while *(6c)* follows both routes [61% *(7c)* and 22% *(8c)*].

Depending on the size of the ring the photolysis and thermolysis of 2-oxo-1-diazocycloalkanes proceed either *via* ring contraction and hydride shift (2-cycloalken-1-ones) or transannular carbene insertion (bicyclic ketones)[5].

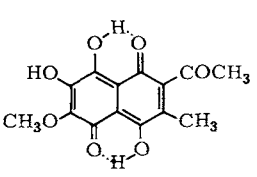
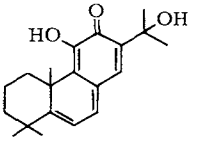
Recent Investigations of Plant Pigments

By *Conrad H. Eugster* [*]

1. *Carotenoids.* Most of the almost 180 carotenoids known to date have chiralic character. Until quite recently nothing was known about their absolute configuration (with the exception of capsanthin). Chemical correlation of the enantio-

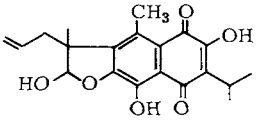


mers of α-cyclogeranic acids with α- and γ-ionones and with α- and ε-carotenes has now been achieved. Thus natural α-carotene was found to have the following structure *(1)* [1]:

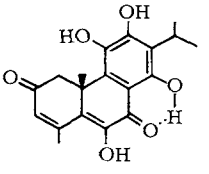


(1)

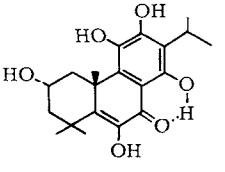
Xanthophyll (lutein), which is one of the main carotenoids found in green leaves, has the same configuration at C-6 [2].



2. *Pigments from leaf glands.* Several East African Labiatae and Leguminosae possess colored leaf glands from which new quinonoid pigments have been isolated, *e.g.*: cordeauxione *(2)* from *Cordeauxia edulis*; fuerstione *(3)* from *Fuerstia africana*; coleone A *(4)* and coleone B *(5)* from *Coleus igniarius*; coleone *(6)* from *C. aquaticus*.



(2)



(3)

(4)

(5)

(6)

Compound *(2)* is probably built up from seven acetate residues; the compounds *(3)*—*(6)* are obviously derived from mevalonic acid (proved by tracer analysis in the case of coleon A [3]).

3. *Russupteridines.* The genus *Russula* (*Basidiomycetes*) is multicolored. The plants of this genus contain yellow, red, and blue pigments, along with colorless compounds that exhibit a very strong fluorescence in UV light (the green pigments appear to be a mixture). Isoelectric focusing in a pH-saccharose gradient proved to be suitable for the analytical separation of the water-soluble pigments; a preparative separation was accomplished by combined Sephadex and cellulose chromatography. Spectroscopic and chemical investigations have shown that the main red pigment in *R. sardonia* is a novel derivative of a dimeric pteridine riboside [4]. We also assume that the orange-red pigments from the peel of the fly agaric (*Amanita muscaria*) are probably pteridine derivatives.

SELECTED ABSTRACTS

The reaction between oxygen atoms and acetylene at room temperature has been investigated by *J. N. Bradley* and *R. S. Tse*. The oxygen atoms were produced from molecular oxygen by a microwave discharge. The concentration of O, H, and OH were determined from the ESR spectra of the reacting gas mixture. The results can be described essentially in terms of the following reaction sequence:

$$O + C_2H_2 \rightarrow CH_2 + CO \quad (1)$$

$$O + CH_2 \rightarrow CO + 2\,H \quad (2)$$

$$CH_2 + C_2H_2 \rightarrow C_3H_4 \quad (3)$$

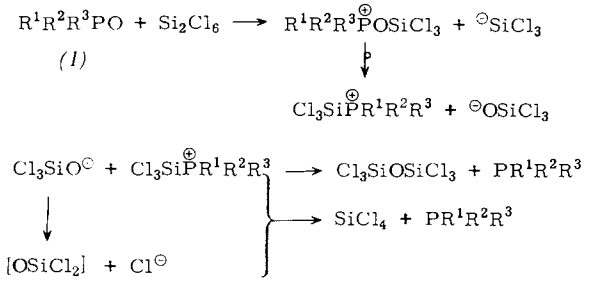
$$H + C_2H_2 \rightarrow C_2H_2 + {}^1/_2\,H_2 \quad (4)$$

The values $k_1 = (1.1 \pm 0.1) \times 10^8$ l mole^{-1} s^{-1} and $k_2/k_3 = 2.6 \pm 0.3$ were derived for the (relative) rate constants. The side reaction

$$O + CH_2 \rightarrow CH + OH \quad (2a)$$

with $k_{2a}/k_2 = 0.06 \pm 0.02$ also occurs; the resulting OH radicals are consumed according to

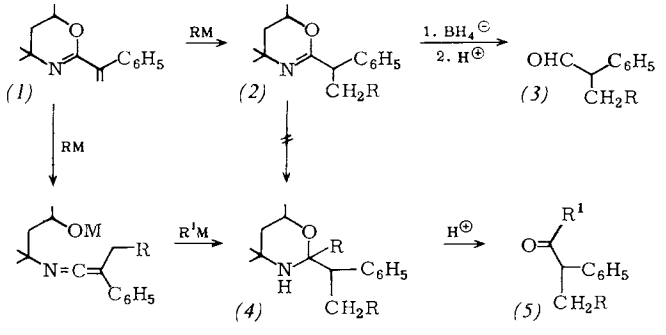
$$OH + C_2H_2 \rightarrow H_2O + C_2H \quad (5)$$



/ Trans. Faraday Soc. *65*, 2685 (1969) / —Hz. [Rd 145 IE]

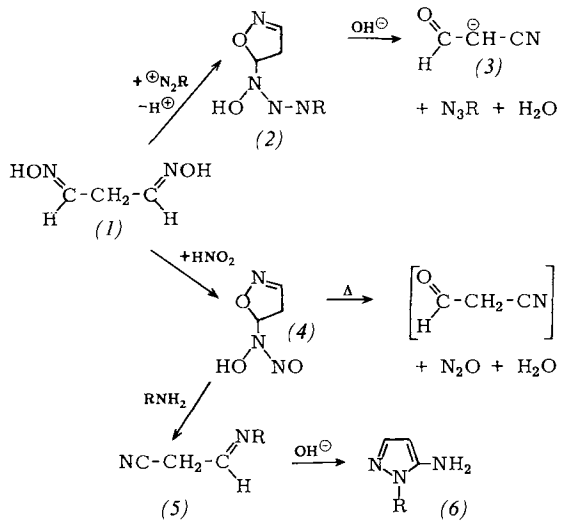
The phase diagram of the niobium-hydrogen system has been studied by *J. H. Pryde* and *C. G. Titcomb* by measurement of pressure and electrical resistance at —78 to +300 °C, an atomic ratio of H : Nb = 0 : 1—0.65 : 1, and a hydrogen partial pressure of 10^{-7}—10^1 torr. Gaseous H_2 was rapidly taken up by the metal at all temperatures. The boundary of the two-phase region (solid solution + hydride) is symmetrical about the atomic ratio H : Nb = 0.256 : 1; the critical point lies at 211 °C, H : Nb = 0.256 : 1, 1×10^{-1} torr. At about 86 °C hysteresis phenomena become apparent in the two-phase region in the resistance-temperature diagram which indicate changes in the lattice structure of the hydride. / Trans. Faraday Soc. *65*, 2758 (1969) / —Hz. [Rd 144 IE]

A novel effect of CO_2 on catalyst properties in the dimerization of butadiene has been observed by *J. F. Kohnle, L. H. Slaugh*, and *K. L. Nakamaye*. In the absence of catalyst, butadiene slowly dimerizes to 4-vinyl-1-cyclohexene *(1)*; in the presence of $[(C_6H_5)_3P]_3Pt$ the product ist still compound *(1)* along with a small amount of *trans*-1,3,7-octatriene *(2)*, provided reaction is allowed to take place in an atmosphere of nitrogen or argon. However, if CO_2 is present and oxygen carefully excluded, $[(C_6H_5)_3P]_3Pt$ converts butadiene mainly into compound *(2)*. Similar results are obtained if $[(C_6H_5)_3P]_4Pd$ is used as catalyst. The $[(C_6H_5)_3P]_4Ni$- and $[(C_6H_5O)_3P]_4Ni$-catalyzed dimerizations of butadiene in the absence of CO_2



lead mainly to 1,5-cyclooctadiene; in the presence of CO_2 the major product is *(1)*. The above observations are of interest to those studying metal catalysis since CO_2 is frequently present in reaction systems. / J. Amer. chem. Soc. *91*, 5904 (1969) / --Ma. [Rd 151 IE]

The use of hexachlorodisilane as a reducing agent has been reported by *K. Naumann, G. Zon*, and *K. Mislow*. Optically active acyclic phosphine oxides *(1)* can be converted to phosphines with a high degree of stereospecificity and with inversion of configuration. Hexachlorodisilazane likewise reduces amine oxides to amines and sulfoxides to sulfides. The authors propose the following reaction scheme for the reaction of *(1)*:



When carried out in refluxing benzene reduction is complete within about 5 minutes; if the contact time is extended beyond this period the optical purity of the product decreases. / J. Amer. chem. Soc. *91*, 7012 (1969) / —Kr. [Rd 148 IE]

A simple synthesis of α-phenylaldehydes and ketones is described by *A. I. Meyers* and *A. C. Kovelesky*. The readily accessible α-styryldihydro-1,3-oxazine *(1)* is treated with organometallic compounds, *e.g. n*-butylmagnesium bromide, to give *(4)* (R = R^1 = n-C_4H_9, 73% yield), which reacts with oxalic acid to give ketone *(5)* (overall yield 68%). Use of the

voluminous cyclohexylmagnesium bromide leads to the monoalkyl compound *(2)* only, which can be reduced with $NaBH_4$ to give the aldehyde *(3)* (R = cyclo-C_6H_{11}, total yield 98%). / Tetrahedron Letters *1969*, 4809 / —Kr. [Rd 150 IE]

Cyanoacetaldehyde derivatives and secondary products, *e.g.* 5-amino-pyrazoles, have been prepared by *H.-J. Sturm* and *H. Armbrust*. Dialkylaminoacroleins react with hydroxylamine to give malonoaldehyde dioxime *(1)*, which can occur in several isomeric forms and which, on treatment with aryldiazonium salts and HNO_2, yields the colorless coupling product *(2)* or *(4)*. In aqueous bases at room temperatures compound *(2)* decomposes exothermally to aryl azide and cyanoacetaldehyde *(3)*. Reaction of *(4)* with amines leads to

formation of the derivatives *(5)*, the hydrazones and thiosemicarbazones of which can be cyclized to the 5-aminopyrazoles *(6)* in good yields. / Liebigs Ann. Chem. *729*, 139 (1969) / —Kr. [Rd 153 IE]

***N,N*-Diethylaminooxysilanes** have been synthesized by *K. C. Pande* and *R. E. Ridenour* from chlorosilanes and an excess of *N,N*-diethylhydroxylamine in an inert solvent:

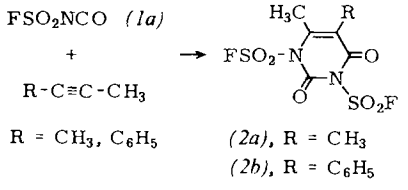
$$R_nSiCl_{4-n} + 2\,(4-n)\,(C_2H_5)_2NOH \rightarrow R_nSi[ON(C_2H_5)_2]_{4-n} + (4-n)\,(C_2H_5)_2NOH \cdot HCl$$

$n = 0$–3 *(1)*

Examples: *(1a)*, $n = 0$, R = CH_3, b.p. 95 °C/0.05 torr, yield 40%; *(1d)*, $n = 3$, R = CH_3, b.p. 44 °C/23 torr, yield 80%. $CH_3SiH[ON(C_2H_5)_2]_2$ *(2)* (b.p. 36 °C/0.2 torr, yield 45%), for example, was prepared in this way. Aminooxysilanes can be decomposed hydrolytically — *(1d)*, *e.g.*, decomposes to trimethylsilanol. Compound *(2)* reacts with *N,N*-diethylhydroxylamine to give *(1b)*:

$$CH_3SiH[ON(C_2H_5)_2]_2 + (C_2H_5)_2NOH \rightarrow CH_3Si[ON(C_2H_5)_2]_3 + H_2$$

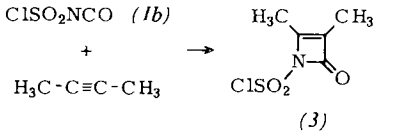
(2) *(1b)*



Tetrakis(diethylaminooxy)tetramethylcyclotetrasiloxane can also be prepared in this way. / Chem. and Ind. *1970*, 56 / —Kr. [Rd 155 IE]

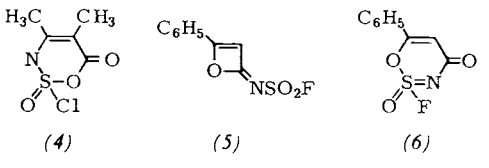
Reactions of silicon fluorides with methanol have been investigated by *J. L. Margrave, K. G. Sharp*, and *P. W. Wilson*. A mixture of gaseous SiF_2, SiF_4, and methanol was condensed at —196 °C. On warming the mixture to room temperature, SiF_3H and CH_3OSiF_3 were formed as major products and $(CH_3O)_2SiF_2$ as secondary product:

$$CH_3OH + SiF_4 \rightarrow CH_3OSiF_3 + HF$$
$$SiF_2 + HF \rightarrow SiF_3H$$
$$CH_3OH + SiF_2 \rightarrow CH_3OSiF_2H$$
$$CH_3OSiF_2H + CH_3OH \rightarrow (CH_3O)_2SiF_2 + H_2$$



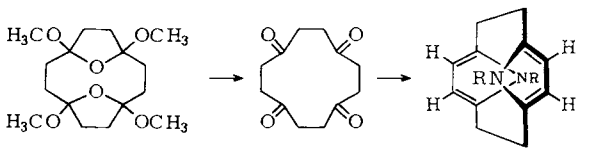
Formation of a secondary product by reaction of methanol with CH_3OSiF_3 does not take place. In the reactions described, a mechanism involving diradicals seems doubtful since products of the type $CH_3O(SiF_2)_nOCH_3$ were not observed. The two new methoxysilanes were identified, *inter alia*, by IR spectroscopy. / Inorg. nuclear Chem. Letters *5*, 995 (1969) / —Kr. [Rd 156 IE]

Cycloadditions of halogenosulfonyl isocyanates to alkynes is the subject of reports by *K. Clauss* and *H. Jensen*, and *K. D. Kampe*. Fluorosulfonyl isocyanate *(1a)* combines with 2-butyne in the molar ratio 2 : 1 at room temperature in chlorinated hydrocarbons to give dimethyluracil bis(sulfonyl fluoride) *(2a)* (m.p. 108.5 °C, 83% yield) while reaction of chlorosulfonyl isocyanate with 2-butyne leads to formation of a product (in 50% yield) having a m.p. of 57 °C and the structure of an azetinone derivative *(3)* (the valence isomer *(4)*, however, cannot altogether be ruled out). Phenylacetylene reacts with *(1a)* in the molar ratio 1 : 1 at temperatures



FSO_2NCO *(1a)* + $R-C\equiv C-CH_3$ → FSO_2-substituted azetinone

$R = CH_3, C_6H_5$ *(2a)*, R = CH_3; *(2b)*, R = C_6H_5



$ClSO_2NCO$ *(1b)* + $H_3C-C\equiv C-CH_3$ → *(3)*

(4) *(5)* *(6)*

below 35 °C to give the oxete derivative *(5)* [or the valence isomeric oxathiazinone derivative *(6)*], m.p. 100 °C, yield 36%. Reaction with methyl(phenyl)acetylene, on the other hand, leads to the uracil derivative *(2b)*, decomp. 145—149 °C. No crystalline products are obtained on reaction with *(1b)*. / Tetrahedron Letters *1970*, 119, 123 / —Kr. [Rd 157 IE]

***N,N*-Dimethyl[2.2](2,5)pyrrolophane** *(3)* has been prepared by *H. H. Wasserman* and *D. T. Bailey* from the tetramethoxy compound *(1)*, which can be obtained from [2.2](2,5)furanophane. Compound *(1)* can readily be converted into the tetraone *(2)* (m.p. 129—130 °C, 95% yield) by treatment with hydrochloric acid at room temperature. A solution of *(2)* in glacial acid is treated at 80 °C with anhydrous methylamine, adjusted to pH 10 by addition of ammonia, and then extracted with chloroform. The pyrrolophane *(3)* can be purified by chromatography (m.p. 144—145 °C, yield 42%). The signals

(1) *(2)* *(3)*

R = CH_3

due to the β-protons of the pyrrole ring appear at their normal positions ($\tau \approx 3.90$) in the NMR spectrum of *(3)*. The *anti*-configuration of *(3)* is thus confirmed. / Chem. Commun. *1970*, 107 / —Kr. [Rd 158 IE]

The yellow adduct (thiourea)$_2 \cdot I_2$, first described in 1912, has been shown to be a salt $[(H_2N)_2CS]_2I^+I^-$ *(1)* in an X-ray structure analysis carried out by *H. Hope* and *G. Hung-Yin Lin*. Compound *(1)* forms monoclinic crystals, space group C2/c, having $a = 22.27 \pm 0.02$, $b = 5.290 \pm 0.005$, $c = 9.808 \pm 0.005$ Å, $\beta = 115.31 \pm 0.03°$, and $Z = 4$. The I^I atom lies at the center of symmetry of the cation (∢ SIS 180.0 °); the interatomic distances are IS 2.629, SC 1.723, CN 1.298 and 1.318 Å; ∢ ISC 106.2 °. The ion is not perfectly planar, the $C(NH_2)_2$ groups being twisted 17 ° about the CS bond out of the CSISC plane. / Chem. Commun. *1970*, 169 / —HB. [Rd 161 IE]

The acidity of surface OH groups has been evaluated by *M. L. Hair* and *W. Hertl*. Hydroxyl band frequency shifts in the IR spectra of hydroxy compounds are known to be related to the acidity of the OH compound and to the basicity of the solvent. Comparison of the OH frequency shifts of methanol, phenol, and trichlorophenol in solutions and the OH frequency shifts of surface hydroxyl groups on adsorption of the corresponding solvents allowed the pK_a values of the surface OH groups to be correlated with the known pK_a values of alcohols and phenols. The pK_a values found were:

Mg—OH	15.5 ± 0.4
B—OH	8.8 ± 0.6
Si—OH	7.1 ± 0.5
P—OH	−0.4

For silica and a silica-alumina cracking catalyst, the same values were obtained which are in good agreement with an earlier value (≈ 7.0) obtained by titration. The surface groups have lower pK_a values than the first dissociation steps of the corresponding "molecular" acids. There is no obvious relationship between the two values. / J. physic. Chemistry *74*, 91 (1970) / —Hz. [Rd 163 IE]

BOOK REVIEWS

Messgrößenverarbeitung. Eine Einführung in die elektrische Messgrössenerfassung und -verarbeitung nichtelektrischer Grössen. (Treatment of measurements. An introduction to the electrical measurement and treatment of non-electrical quantities). By *E.-G. Woschni*. Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., xii, 156 pp., 105 figures, 1 table, cloth, DM 24.—.

The book deals essentially with two topics: 1. the electrical measurement of non-electrical quantities, including the discussion of the principal types of recording instruments, and 2. the processing and output of the electrical analog quantities produced.

The value of the book lies mainly in the first part. This not only discusses the advantages and disadvantages of electrical measurements but also explains briefly, though precisely, the measurement principles of a series of detecting elements, and presents a sufficiently extensive mathematical discussion to show the limiting conditions for the measurement.

A particularly welcome feature is the abundance of hints about dynamic properties, since errors are repeatedly made here in practical measurements.

The subsequent discussion of the further treatment of analog values is also welcome. The list of types of bridges and their compensation criteria, for example, is very useful.

In the final third of the book, however, an attempt is made to cover too much ground in too little space, with the result that some chapters (*e.g.* on spectral analysis and on correlation computers) do not contain much more information than the

headings. To make up for this deficiency it would have been necessary to provide a much more comprehensive bibliography than that given.

The chapter on the execution of computations would have been better omitted, since it is too short to give adequate explanations (*e.g.* of the digital computer) and since it is not directly connected with the main subject.

Gerhard Quietzsch [NB 854 IE]

Einführung in die Kernchemie Introduction to Nuclear Chemistry). By *K. H. Lieser*. Volume I of the series "Kernchemie in Einzeldarstellungen" (Nuclear Chemistry Monographs). Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., xvi + 720 pp., 230 figures, 103 tables, bound, DM 78.—.

The author, who lectures in nuclear chemistry at the Technische Hochschule Darmstadt, is to be congratulated on filling a long-standing gap in the German-language literature. Students or scientists wishing to acquaint themselves with nuclear and radiochemistry had in the past no alternative but to turn to American or British textbooks. Apart from the obvious language problem, there was the additional difficulty that "Nuclear Chemistry" in the USA leans far more heavily toward nuclear physics than does "Radio- und Kernchemie" as understood in Germany. Consequently, chemical aspects and methods tend to get somewhat neglected in these textbooks.

Lieser's book is oriented entirely toward the requirements of chemists wanting to learn about nuclear and radiochemistry. However, every interested reader will find in the book a thorough but readily digestible introduction to the theoretical principles, techniques, and applications of this domain.

In line with the "chemical" approach, the author begins with the periodic system of elements and the concept of isotopes. He continues with several chapters devoted to the physical principles of nuclear and radiochemistry, followed by discussions of the properties of atomic nuclei and radioactive radiation, decay processes, and nuclear reactions. The specialized techniques and equipment used are described in the chapters on radioactive radiation, major installations, separation and chemistry of radionuclides, and applications.

It is especially gratifying to find detailed sections on precisely those nuclear and radiochemical problems which are particularly interesting for the modern chemist and which are totally absent from other textbooks, *e.g.* isotopic effects and the chemical effects of nuclear reactions. They may not, strictly speaking, belong to the subject-matter of the book, but since these side effects are constantly encountered in nuclear and radiochemical experiments, it is right to mention them.

In addition to the physical principles and the most interesting chemical problems, the third main topic of the book consists of applications of radiochemistry and nuclear chemistry in science and industry. This is yet another pleasing feature, for many of the other textbooks only give these matters peripheral treatment. Individual chapters are devoted to nuclear fuels and reactor chemistry, isolation of radionuclides, synthetic elements, and isotope separation. Finally, the chapter dealing with applications includes radiochemical methods for analysis, biology, medicine, and cosmochemistry.

In conclusion, a few critical remarks are justified. At the same time, it is only fitting to point out that their brevity, and the fact that they concern in the main trivialities, bear witness to the excellence of the work. The reviewer would have preferred the sections on dating and activation analysis, which after all are among the most important subjects in nuclear and radiochemistry, and also that on nuclear models, to have been given more detailed treatment. The same may be said about the measurement of radioactive radiation, particularly as regards modern scintillation and semiconductor measuring techniques. These matters will of course be given due attention in a later volume in the monograph series. Nevertheless, since many readers, especially students, will buy only the "Introduction", it was wrong to curtail the chapter on measuring techniques in this way. Finally, the table of radionuclides in the Appendix does not seem to be very enlightening, whereas the inclusion of a nuclide chart is thoroughly commendable.

The table of nuclides, which finds its way into practically every textbook on nuclear and radiochemistry, contains scarcely any more information than the nuclide chart and is far less easy to refer to than the latter. For anyone seeking detailed information on a nuclide it will never replace a detailed table of isotopes. *G. K. Wolf* [NB 856 IE]

Synthetic Procedures in Nucleic Acid Chemistry. Vol. 1. Preparations of Purines, Pyrimidines, Nucleosides, and Nucleotides. Edited by *W. W. Zorbach* and *R. St. Tipson*. Interscience Publishers, John Wiley & Sons Ltd., London-New York 1968, 1st Edit., v + 570 pp., numerous figures, bound, approx. DM 75.—.

There can be no doubt that this book, the first volume in the series "Synthetic Procedures in Nucleic Acid Chemistry", is extremely useful and meets a definite need. More and more organic chemists and biochemists are submitting to the lure of the chemistry of the nucleic acids and nucleic-acid components, and they will find it a great advantage to have their first steps in this field guided by a collection of typical synthetic methods and tried and tested preparations of the main starting materials. For this reason, no library should be without this book.

On the other hand, some of the claims which the editors make in their preface are not justified. In its descriptions of synthetic techniques, analytical methods, and the preparation of the main compounds this book is not, with all due respect to its editors, completely up-to-date. Indeed, how could it be, when the literature from 1967 on could only be treated incompletely, if at all? One of many examples must suffice: the phosphorylation of nucleosides and nucleoside analogs, a very important reaction, is represented solely by the 2-cyanoethyl phosphate method, although more elegant and effective phosphorylation methods have become available since 1967.

The editors may well have intended to help the reader find his way through the very extensive literature of nucleoside and nucleotide chemistry by representative examples of the various syntheses, but unfortunately some of the authors are so sparing in their use of literature references that this opportunity has been missed.

Perhaps these comments will be taken into account in the subsequent volumes of this series.

Karl-Heinz Scheit [NB 860 IE]

Solute-Solvent Interactions. Edited by *J. F. Coetzee* and *C. D. Ritchie*. Marcel Dekker, Inc., New York-London 1969. 1st Edit., xiv + 653 pp., 53 figures, 138 tables, bound $ 29.50.

While brief summaries have been published on the influence of solvents on the rate and equilibrium position of organic reactions[1,2], there has been no comprehensive work on the solute-solvent interactions underlying this solvent effect. This gap has now been filled in exemplary fashion by the present book.

The first chapter (Heats and Entropies of Ionization) written by *J. W. Larson* and *L. G. Hepler* contains 44 pages giving a critical summary of thermodynamic data on the ionization of Brønsted acids in aqueous solutions. The second chapter (Medium Effects and pH in Nonaqueous Solvents, 51 pp.) by *R. G. Bates* deals with acidity scales in nonaqueous solvents

[1] Cf. Angew. Chem. internat. Edit. *7*, 158 (1968).

[2] Cf. Angew. Chem. internat. Edit. *8*, 465 (1969).

and the methods of determining them. In the third chapter (Acidity Functions, 121 pp.) *R. H. Boyd* discusses important aspects of the effect of the solvent on the acid-base equilibrium, also listing numerous tables of Hammett's H_0 and H_- functions for a large number of acids. The fourth chapter (Interactions in Dipolar Aprotic Solvents, 81 pp.) by *C. D. Ritchie* is concerned with the acidities of organic acids and the rates of proton-transfer reactions, but especially also with the effect of dipolar aprotic solvents on the rate of S_N1 and S_N2 reactions. The solvent polarity scale given in Table 4—13 on p. 281 requires some additions. In the fifth chapter (The Selective Solvation of Ions in Mixed Solvents, 41 pp.) *H. Schneider* describes the selective solvation of ions in binary solvent mixtures and their determination. While *E. M. Arnett* and *D. R. McKelvey* discuss the effect of changing over from H_2O to D_2O on the thermodynamic parameters of the solute in the sixth chapter (Solvent Isotope Effect on Thermodynamics of Nonreacting Solutes, 41 pp.), *P. M. Laughton* and *R. E. Robertson* in the seventh chapter (Solvent Isotope Effects for Equilibria and Reactions, 139 pp.) deal in detail with the effect of this solvent change on the equilibrium position and the rate of chemical reactions. The final chapter (Organoalkali Compounds in Ethers, 66 pp.) by *J. F. Garst* deals with the structure of the ethereal solutions of organometallic alkali metal compounds, with a detailed discussion of the effect of solvent polarity and cation and anion solvation on the formation and dissociation of ion pairs and their influence on equilibria and reaction rate. The book closes with a brief and rather fragmentary appendix dealing with purification methods for certain selected solvents.

There is no discussion of solvophobic interactions. Even the interactions between suitable acceptors (*e.g.* metal ions) and donor solvents ("coordinating solvents") are scarcely mentioned, despite their importance in coordination chemistry. In view of the scope of the subject matter some overlapping was seemingly unavoidable (*e.g.* Tables 2-2 on p. 52 and A II-9 on p. 199 are practically identical).

The book is interspersed with numerous examples, 53 figures and 138 tables. The bibliography lists nearly 1600 publications, and this, together with author and subject indexes, makes the book a useful reference work.

All in all, the present book gives an outstanding synopsis of all aspects of solvent-solute interactions, and no library should be without it. *Christian Reichardt* [NB 862 IE]

Oxidation: Techniques and Applications in Organic Synthesis. Vol. 1. Edited by *R. L. Augustine*. Marcel Dekker, Inc., New-York-London 1969. 1st Edit., x + 368 pp., numerous figures, $ 18.75.

The contents of this book are as follows: Chapter 1: Oxidation of hydrocarbons with transition metal compounds (*D. G. Lee*); Chapter 2: Oxidation of functional groups containing oxygen and nitrogen with transition metal compounds (*D. G. Lee*); Chapter 3: Oxidation reactions with selenium dioxide (*E. N. Trachtenberg*); Chapter 4: Glycol fission and related oxidation reactions (*A. S. Perlin*); Chapter 5: Oxidation reactions with peracids and peroxides (*S. N. Lewis*); Chapter 6: Ozonization (*J. S. Belew*).

This is the fourth book on oxidation reactions that I have had to review over the past five years[1]. In addition to this, the first volume of *K. Wiberg*'s "Oxidations in Organic Chemistry"[2] appeared during the same period, so that we may well ask ourselves whether a fifth book on the same subject is justified or necessary. In principle, this question can be answered in the affirmative. While the previous books for the most part considered oxidations from the mechanistic viewpoint, the present work is chiefly concerned with the methods used. Examples of tested operating procedures are thus given in heavy print. The preparation, purification, and analytical determination of the oxidants are mostly described in detail, as are the mode of action on the substrates and the reaction selectivity Mechanisms are invoked only to the extent that they are necessary for the comprehension of the mode of action.

It might appear that the editor intended to produce a sort of Houben-Weyl on oxidations. If this was the intention, however, the organization of the book is not very suitable, for the various chapters are arranged on the basis of oxidizing agent and not (with the sole exception of glycol fission) on the basis of the reaction to be performed. Thus, if we want to oxidize an unsaturated alcohol to an unsaturated aldehyde, we have to search through a number of chapters to find a suitable oxidizing agent, which means that we are still left with the consideration of the various alternatives and the choice of the best one.

Apart from this fundamental error in organization, the six chapters offer a wealth of valuable information. The literature is considered selectively up to 1968. Since all the authors have actually worked with the reactions they are describing, the subject material and the examples are based on personal experience. In many cases valuable tips which are not generally known have been given for the use (*e.g.* in Chapter 3 and 5) or for the preparation (*e.g.* in Capter 6) of oxidizing agents. The fact that someone with different experience (like the reviewer) might in many cases have chosen other examples or have given further tips, is no reflection on the authors' merit.

In addition to one or two easily recognizable printing errors, there are a few factual mistakes. For example, the statement on page 11 that the osmic ester obtained from OsO_4 gives metallic osmium (instead of Os^{IV} or Os^{II}) on reduction is as incorrect as the assertion that it would be reduced by alkaline mannitol solution (in actual fact, a transesterification occurs).

All in all this is a valuable book, particularly for chemists working with synthetic reactions. Its purchase is unhesitatingly recommended. *Rudolf Criegee* [NB 864 IE]

Inelastic Interactions of Slow Electrons with Adsorbed Particles

By Dietrich Menzel[*]

When slow electrons impinge on metal surfaces which are covered with an adsorbed layer, desorption of neutral particles as well as of positive ions, partly accompanied by fragmentation of the adparticles, is observed. The mechanism of these processes is of interest in connection with existing concepts of the surface bond. The effect can also be used as a probe for the investigation of complex adsorption layers.

Transfer of much smaller energies to the adsorbate can lead to vibrational excitation. This process may find application in the vibrational spectroscopic study of adsorbates.

If the energy transferred in the inelastic collision is high enough to ionize low-lying levels of the surface atoms, radiationless re-ordering of the electron configuration (Auger-effect) can occur subsequently. The secondary electrons of characteristic energy emitted in these processes can be used for qualitative analysis of the surface.

1. Introduction

When slow electrons (electrons with kinetic energies up to about a thousand electron volts) interact with matter, two basic kinds of interaction can be distinguished, which are normally designated as *elastic* and *inelastic*. We refer to *elastic* interactions when the collision leads to essentially zero energy transfer and the electrons are only deflected in the field of the atoms. As electrons possess wave properties, a phase relationship exists between incident and scattered beams, and interference may occur between the scattered electrons. When the scattering centers are arranged periodically, for instance in a defined crystal face, periodic extinction and re-inforcement of the scattered intensity are observed.

The method which uses this effect of electron diffraction for the investigation of crystal surfaces, is known under the acronym LEED (Low Energy Electron Diffraction) and has found wide application in recent years[1]. The small penetration depth of slow electrons in solids and the fact that their wavelengths are in the Ångstrom range, *i.e.* in the order of lattice parameters, are especially favorable for this use.

Such processes are relatively rare, however: above 50 eV, typically only a few percent of the impinging electrons are scattered elastically. The majority of the electrons interact *inelastically* and transfer part of their kinetic energy to the collision partner. In the case of isolated molecules this leads to rotational, vibrational[2], and electronic excitation or ionization[3]. The latter two processes are often followed by dissociation. These excitations and their coupling are investigated by "electron impact spectroscopy"[4]. The ionization processes are of importance for mass spectroscopy. When electrons collide with surfaces, all these processes can still occur. In addition others caused by interactions of the incident electrons with the electrons of the solid are possible: excitation of plasmons[5] and emission of secondary electrons[6]. These processes which are essentially caused by the

properties of the solid will not be treated in the following. We shall confine the discussion to inelastic interactions with surface complexes (adsorbates) consisting of metal surface atoms (adsorbens) and adsorbed particles (adsorpt).

Three processes can be distinguished. The excitation and ionization of adsorbates followed by dissociation of the surface complex, *i.e.* by desorption of neutrals and ions, has been investigated for a number of systems. This "electron impact desorption", which necessitates the transfer of 5 to 25 eV, is interesting in itself and can be used as a probe for the investigation of complex adsorption layers. Recently two other processes have created some interest. In analogy to the electron spectroscopy of free molecules, higher vibrational states can also be excited in surface complexes by transfer of some tenths of an eV. If much more energy is transferred (50 to 1000 eV), low-lying electronic levels can be ionized. A rearrangement of the electron system, coupled with the emission of another electron (Auger effect), can follow. The energy of the emitted electron is characteristic for the atom excited. The latter method particularly is in a state of rapid development and will certainly be used increasingly in the near future.

In all the examples of surface investigations discussed below the exact definition of the experimental conditions is a very important prerequisite. The investigated surface must be cleaned first, then covered with an adsorbed layer in a defined way and kept free of contamination for the duration of the experiment. This is only possible with the use of modern ultrahigh-vacuum techniques [7] which will not be discussed here.

2. Electron Impact Desorption

(Excitation, ionization, desorption, and dissociation of adsorbed particles by slow electrons.)

2.1. Experimental Methods

Plumlee and *Smith* [8] and *Young* [9] were the first to show mass spectrometrically that the collision of slow electrons on metal surfaces can lead to the emission of positive ions from adsorbed layers of residual gases. In a similar way *Moore* [10] investigated adsorbates of CO and O_2 on molybdenum and observed O^+ ions. The formation of positive ions was subsequently used repeatedly for the explanation of anomalies observed in ionization gauges and mass spectrometer ion sources [11]. Using a partial pressure analyzer, *Pétermann* [12] found that electron impact on CO/Ni adsorbates liberates neutral CO molecules.

This work showed that slow electrons can lead to the emission of neutrals as well as ions from adsorbed layers. The later more detailed investigations can be subdivided into two groups according to the experimental method used: either the change caused by electron impact of a parameter coupled to the adsorption is followed, or the desorbed particles are detected directly.

The first group includes the work of *Menzel* and *Gomer* [13] who used the work function Φ of the metal and its change with adsorption, $\Delta\Phi$, measured with the field emission microscope (FEM; [14]) as the particular parameter (concerning the use of the FEM for adsorption measurements see also [15]).

The advantages of this method are:

1. The FEM tip which consists of a hemispherical single crystal (radius of curvature about 1000 Å) has a well characterized surface and can be cleaned and covered in a defined way.

2. A relatively large number of adsorption systems have already been investigated with this instrument [14, 15], making the interpretation easier.

3. The work function change $\Delta\Phi$ caused by an adsorbed layer can be easily measured by recording the current-voltage characteristics of the field emitter: according to *Fowler* and *Nordheim* the following equation describes this characteristic approximately [14, 15]

$$\log (i\,V^{-2}) = A - b\,\Phi^{3/2} V^{-1} \qquad (1)$$

where i and V are emission current and applied voltage, resp., and A and b are constants (b depends on the geometry of the tip only and is not changed by adsorption). A plot of $\log (i\,V^{-2})$ versus V^{-1} yields a straight line with the slope $m = -b\,\Phi^{3/2}$. If the characteristics are recorded before and after covering the surface with an adsorbed layer, the result is

$$\Phi_2 = (m_2/m_1)^{2/3} \cdot \Phi_1. \qquad (2)$$

If Φ_1 (of the clean surface) is known, Φ_2 and $\Delta\Phi = \Phi_2 - \Phi_1$ can thus be found.

4. If the pressure in the system is kept low enough such that re-adsorption is negligible, very small desorption effects can be detected by integrating over a long time.

An example of the FEM tube used for the investigation of the system CO/W is shown in Fig. 1 [13].

In order to enable one to utilize the integrating method of measurement as far as possible, the tube is baked and sealed

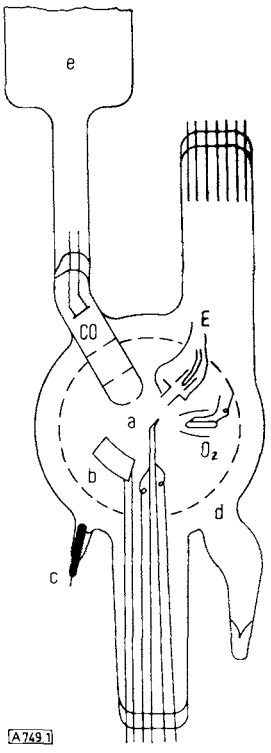

Fig. 1. FEM tube for electron impact desorption experiments (after [13], schematically).

a: Tungsten loop with field emission tip and potential leads; E: electron source; O_2: oxygen source; CO: source of carbon monoxide, with collimator; b: electron collector; c: anode contact; d: fluorescent screen; e: funnel for liquid hydrogen (for precooling of CO).

off from the vacuum line and immersed in liquid hydrogen or helium. Thus a residual pressure of below 10^{-15} torr is reached. The tip is cleaned and characterized by the recording of a F(owler)-N(ordheim) plot and then covered by a molecular beam liberated by heating one of the sources. The oxygen source consists of a heatable supply of CuO, the CO source of a platinum foil, onto which a small amount of CO, which has been introduced into the tube before seal-off, is condensed by cooling it with liquid hydrogen, while the tube is still warm; at the low temperature all molecules stick at the first collision. From a second F—N plot the work function change, $\Delta\Phi$, caused by this layer is measured. With the field emission voltage switched off, the tip is bombarded with electrons for a certain time; the change of the work function caused thereby is determined by recording another F–N characteristic. This procedure can be repeated as often as necessary. Thus the change of the work function as a function of the total number of impinged electrons is obtained. Besides the adsorption system CO/W the systems H_2/W, O_2/W, and Ba/W were investigated with similar tubes (see chapter 2.2.).

In a similar manner *Ermrich*[16] studied the system N_2/W, and *Bennette* and *Swanson*[17] the systems Cs/W and (Cs + O)/W. *Zingerman* and *Ishchuk*[18] used electron impact desorption, followed by the measurement of the change of $\Delta\Phi$ (with the retarding potential method), of oxygen on tungsten to distinguish O atoms above and below the metal surface.

Besides these indirect methods of recording electron impact desorption, the direct detection of the desorbed particles is possible. The above-mentioned work of *Plumlee* and *Smith*, *Young*, *Moore*, and *Pétermann* was of this type. In order to determine the effectiveness of the desorption of ions, *Redhead*[19] investigated the total ion emission (without mass analysis) from O_2 and CO on molybdenum with an apparatus, which allowed the kinetic energy of the desorbing ions to be measured at the same time (Fig. 2).

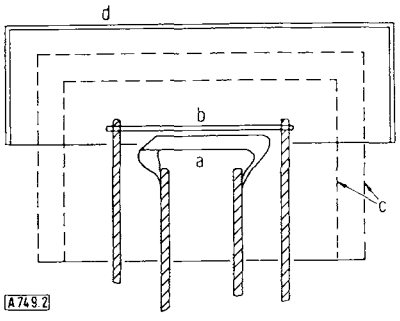

Fig. 2. Apparatus for the measurement of the intensity and the energy distribution of ions desorbed by electron impact (after [19], schematically).

a: anode (Mo); b: filament; c: grids; d: collector.

The anode (see Fig. 2) is a molybdenum ribbon, which is cleaned by flashing in ultrahigh vacuum and then covered with the gas to be investigated. It can be bombarded with electrons emitted from the filament; the potential difference between anode and filament determines their energy. The positive ions emitted from the anode are accelerated by the potentials at the grids and are intercepted by the collector, which is connected to an electrometer. The total ion current leaving the anode is thus measured, and the effectiveness of the ionic desorption is determined directly. If a retarding potential is established at one of the grids, only those ions with sufficient energy to surmount this barrier can reach the collector; thus by varying the retarding potential, the energy distribution of the ions can be recorded. Using a somewhat modified apparatus *Redhead* also investigated the system CO/W[20]. Similar experiments were done by *Yates et al.*[21] using CO, NO, O_2, and N_2 on W.

The mass spectrometric analysis of the electron induced ion emission introduced by *Moore* was extended by *Lichtman et al.*[22], *Degras* and *Lecante*[23], *Coburn*[24], and *Leck et al.*[25], who used the effect as a probe for the investigation of adsorption. The desorption of neutral particles, *e.g.* of CO from Mo, was observed by *Degras* and *Lecante*[23]. *Klopfer*[26] followed the processes caused by electron impact on adsorbed H_2O molecules by mass spectrometric analysis of the gas phase.

The analysis of the desorbing ions and neutrals in the same system – although with different sensitivity – was possible using a small, sensitive mass spectrometer, which could be baked out to attain ultrahigh vacuum [27] (see Fig. 3).

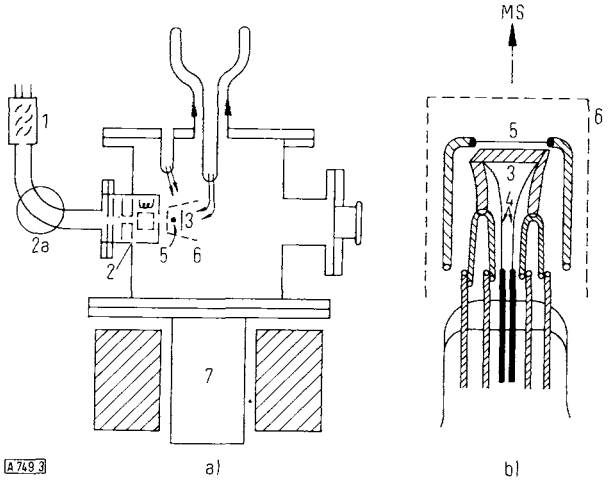

Fig. 3. a) Apparatus for the measurement of desorbed ions and neutrals (after [27], schematically). b) Target structure of a).

MS: mass spectrometer; 1: secondary electron multiplier; 2: ion source, 2a: magnet of MS; 3: target (tungsten ribbon); 4: potential leads; 5: cathode filament; 6: grid; 7: ion pump.

The anode structure corresponds essentially to that of *Redhead*, but is situated in front of the open ion source of the mass spectrometer. The target can be cooled by liquid nitrogen and heated to temperatures between 100 and 3000 K (measurement and regulation by the potential difference between the potential leads). After cleaning it is covered with the adsorbate by introducing the appropriate gas into the system. Electron bombardment of the adsorbate from the filament leads to desorption. If the desorbed *ions* are to be recorded, the ion source of the mass spectrometer is switched off, and the potentials are adjusted such that the ions originating on the surface are drawn into the mass spectrometer and analyzed. The secondary electron multiplier allows the measurement of very small ion currents. For the measurement of desorbed *neutrals*, the potentials are changed such that the surface ions cannot enter the mass spectrometer, and the ion source is switched on. A mass spectrum of the residual gas is then recorded. Desorbed neutrals are found by an increase of certain gas phase peaks upon turning on the electron beam to the surface, and a respective decrease when turning it off again. For the quantitative evaluation of these signals the pumping speed of the system has to be known. This cannot be determined accurately; for many purposes, however, a knowledge of the desorption signals in relative units suffices.

2.2. Results

As mentioned before, the earliest investigations [8 to 10, 12] had already shown that electron impact on adsorbates of electronegative gases such as oxygen, carbon monoxide *etc.* on metals liberates positive ions as well as neutral particles. *Moore* [10] was the first to notice that the number of desorbed particles of any kind (the other conditions remaining equal) is strictly proportional to the number of impinging electrons (see Fig. 4).

[27] a) *D. Menzel*, Z. Naturforsch. *23a*, 330 (1968); b) Ber. Bunsenges. physik. Chem. *72*, 591 (1968).

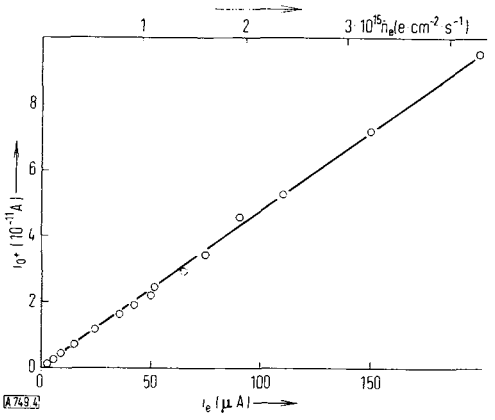

Fig. 4. Dependence of the O^+ desorption signal from CO/W on the electron current density (after [27]).

This linearity is only valid for electron currents which are not so high that the coverage of the surface is noticeably diminished by the bombardment. If the current is higher, the desorption signal decreases with bombardment time (this decrease can be used for the determination of the parameters of the interaction, as will be shown below). From the slope of the measured line the *probability* w of desorption of the particle concerned, *e.g.* the number of particles desorbed per impinging electron, can be derived for the measuring conditions:

$$w_{O^+} = \dot{n}_{O^+}/\dot{n}_e = i_{O^+}/i_e \qquad (3)$$

For electrons of 80 to 100 eV, which result in the maximum w values, numbers of $w_+ = 10^{-4}$ to 10^{-8} (ions) and $w_n \leq 10^{-2}$ (neutrals) were found.

The interaction is thus seen to be of first order in the number of electrons; *i.e.* the collision process between electrons and adsorbate is an isolated event. This suggests that the dependence of the number of desorbing particles on the number of adsorption complexes of a certain kind present on the surface is also linear. In this case the kinetics of electron induced desorption would be given by

$$-\frac{dN}{dt} = q \cdot \dot{n}_e \cdot N \qquad (4)$$

where N is the number of adsorbed particles of a certain kind per unit area, $\dot{n}_e$ is the number of electrons impinging per unit time and area, and q is a constant.

The term adsorbate *of a certain kind* has the following meaning in this context: It is well known from a number of investigations that at least the simple electronegative gases (hydrogen, oxygen, nitrogen, carbon monoxide *etc.*) on surfaces of simple geometry (single crystal faces, FEM tips, tempered ribbons and filaments; *not* powders and porous substances) are adsorbed in a few discrete *adsorption states*. These are characterized by the fact that parameters such as heat of adsorption, desorption rate, contact potential, geometrical structure, infrared spectrum *etc.* are virtually independent of the coverage N within such a state, and change abruptly from one state to the other [28]. The reason for this behavior must be that

[28] See *e.g. R. Gomer*, Discuss. Faraday Soc. *41*, 14 (1966).

the particle concerned can exist on the surface in different *binding states* (different electron configuration; possibly different geometrical orientation to the substrate as well). Applied to the work function change $\Delta\Phi$ used as the relevant parameter in [13], this means that within a certain adsorption state i

$$\Delta\Phi_i \sim N_i \tag{5}$$

i.e. all particles adsorbed in the state i have the same dipole moment (for CO on W this was confirmed experimentally by *Bell* and *Gomer* [29]).

The conjecture formulated in eq. (4) has been proven by *Menzel* and *Gomer* [13] in the following way:

As pointed out above, it was a characteristic of the experiments [13] to use such high electron currents i_e that the coverage N of the surface is decreased markedly by bombardment. By integration of eq. (4) and use of eq. (5) one then obtains for the time dependence of the coverage of an adsorption state i

$$N_i/N_i^0 = \exp(-q \cdot \dot{n}_e \cdot t) = \Delta\Phi_i/\Delta\Phi_i^0 \tag{6}$$

Here $\Delta\Phi_i$ is the change of work function caused by the state i (= difference between the momentary Φ and the Φ after total desorption of state i); N_i^0 and $\Delta\Phi_i^0$ are the values before electron bombardment.

As shown in Figs. 5 and 6, this equation is indeed valid.

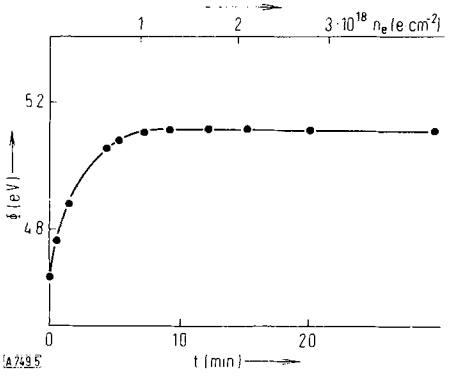

Fig. 5. Change of the work function of a tungsten tip covered with CO, by bombardment with 80 eV electrons (after [13]).

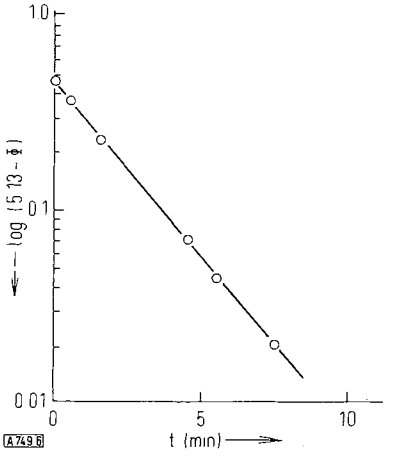

Fig. 6. Semilogarithmic plot of the change of Φ of Fig. 5.

[29] *A. E. Bell* and *R. Gomer*, J. chem. Physics *44*, 1065 (1966).

It was always found that the slopes of plots like that depicted in Fig. 6 were proportional to the electron current; by division through $\dot{n}_e$ a constant value of q was obtained. This result proves equations (5) and (6). The constant q is the interaction cross section used in collision experiments (dimension: area, *e.g.* cm^2), which describes the effectiveness of the interaction. The q value found in this way is obviously connected to the total desorption of state i, irrespective of desorption products, and is therefore called total desorption cross section. It can be found from the change occurring under bombardment of any parameter coupled linearly with the coverage N_i. For instance, it can also be found from the decrease of a desorption signal with bombardment time; according to eq. (4) every desorption signal is proportional to N_i (with the appropriate proportionality factor q_+ or q_n), and for its decrease under bombardment a relation similar to eq. (6) is obtained. In this way *Redhead* [19] used the decay of ion signals for the determination of q values; the same can be done with neutral signals [27]. As can easily be seen, for each desorption signal a relation holds

$$q_+ = w_+/N_i \quad \text{or} \quad q_n = w_n/N_i. \tag{7}$$

The total desorption cross section is of course

$$q = \Sigma q_+ + \Sigma q_n.$$

Using eq. (7) and assuming a plausible value of N, *Redhead* calculated from the directly determined values of w_+ and q that for the systems O_2/Mo and CO/Mo only a few percent of the desorbed particles are ions, and the predominant part consists of neutrals. The same was found for CO/W and H_2/W [27].

A further very important result was found by FEM measurements such as that shown in Fig. 5. *Different adsorption states of the same particle on the same surface have very different desorption cross sections q and can thus be easily distinguished.* The curve of Fig. 5 is so simple only because under the conditions used only one adsorption state of CO on W, the weakly bound "α-state", is desorbed with a measurable rate. The dipole of this state on the surface has its positive end outward, thus decreasing the work function. When it is desorbed Φ increases. The strongly bound "β-state" with a dipole moment in the opposite direction is present on the surface under the same conditions. However, its desorption cross section is smaller by about three orders of magnitude, as was found by measurements with much higher electron current, and therefore the decrease of Φ caused by its desorption is barely noticeable in Fig. 5. The change of Φ under bombardment of a surface which – by suitable pretreatment – contains a third adsorption state besides these two (weakly bound as α-CO, but with negative dipole as β-CO) is shown in Fig. 7.

Obviously the desorption cross section of α-CO is largest, as shown by the initial increase of Φ. After some time a decrease of Φ caused by desorption of the third state competes (the effect of desorption of β-CO

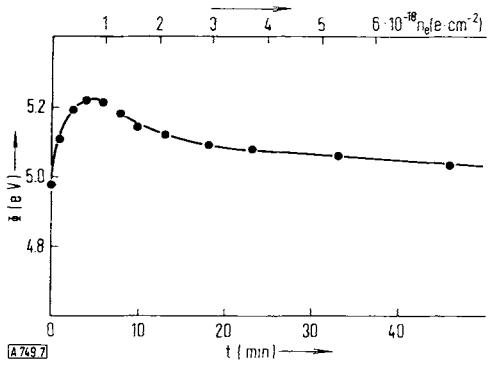

Fig. 7. Change of the work function of a tungsten tip containing three adsorption states of CO, by electron bombardment (after [13]).

is completely masked here). By extrapolation of the curve branches and semilogarithmic plotting, straight lines according to eq. (6) are again obtained (see Fig. 8). From the slopes the q values for the adsorption states can be found.

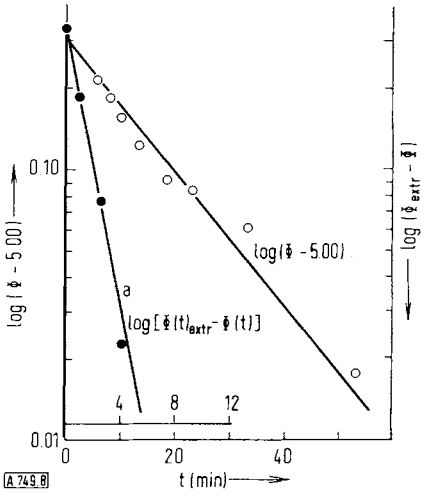

Fig. 8. Semilogarithmic plot of the extrapolated branches of the Φ(t) curve of Fig. 7 (after [13]).

In this way, one finds that $q = 3 \times 10^{-18}$ cm² for α-CO, $5-8 \times 10^{-21}$ cm² for β-CO and about 3×10^{-19} cm² for the third state (for electrons of 80–100 eV). As the total changes of Φ caused by electron desorption are proportional to the amount of the respective state present at the beginning of the experiment, such measurements can be used to study the coverages of the different states under different conditions and their changes and conversions by heating or by electron impact itself. Such measurements were performed extensively on the system CO/W [13c]. We shall come back to the conversion processes below.

It is seen that electron impact desorption is well suited to differentiate between adsorption states. Using the FEM method the above-mentioned three states, which had been characterized before with different methods, were identified. It was also shown that the α-state should be further subdivided [27]. Two states were found in each of the systems H_2/W and O_2/W. From the work of various authors one can make the generalization that for identical particles q is smaller the stronger the surface bond. In addition it was found [27] that different states can be characterized by different desorption products as well as by different q values. When tungsten is covered with CO at 100 K, electron impact causes emission of CO^+ and O^+ ions in a relation of about 10 : 1, in addition to the desorption of neutral CO. (A similar result was found for CO/Mo by *Degras* and *Lecante* [23].) When the target is heated stepwise in ultrahigh vacuum, so that no re-adsorption can occur, the CO^+ signal diminishes above 200 K (see Fig. 9).

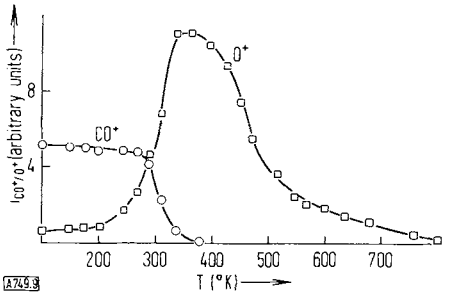

Fig. 9. Change of the CO^+ and O^+ signals from CO/W upon stepwise heating of the target ($\dot{n}_e = 2 \times 10^{13}$ e/cm² · s, 100 eV; after [27]).

This could simply be due to thermal desorption of the relevant state; that this takes place is shown by a transient increase of the CO pressure in the gas phase after each heating step. However, this thermal desorption is not the only cause of the decay of the CO^+ signal: the O^+ signal increases during the same interval and decays only after the CO^+ signal has virtually vanished. In these measurements the electron current density is kept so low that the change of surface coverage caused by electron impact desorption can be neglected; the electron beam is thus seen to serve only as a probe for the investigation of surface coverage and the processes observed are purely thermal. The explanation suggested for the reported observations is therefore as follows. The two ionic signals stem from two different adsorption states. The increase of the O^+ current, which implies an increase in the concentration of the corresponding state, must then be due to a conversion from the first state (characterized by CO^+ emission) caused by the temperature increase, besides desorption. Interestingly both *Redhead* [20] and *Yates et al.* [21] found that these two ionic signals also differ in the kinetic energy of the ions. Different adsorption states of the same particle on the same surface can thus be characterized by different q values, different desorption products and different kinetic energies of the desorbing ions.

The experiments discussed in this section demonstrate two different applications of eq. (4). Firstly, the surface can be bombarded with such high electron current densities that the coverage of adsorbed particles is diminished considerably; from such experiments the total cross section q can be evaluated according to eq. (6). Secondly, such small electron densities can be used that the change of surface coverage by electron impact desorption is negligible; then the desorption signals can be used as a perturbation free probe for coverage. This method was used for instance by

Lichtman et al. [22] to follow the kinetics of adsorption. A combination of both methods is found in the determination of q by *Redhead* [19] which has been mentioned above. A further example also serves to illustrate this application. As already mentioned, electron impact can lead to the conversion of one state into another; the coverage of each state can be followed by its desorption signal. For instance, if one starts with the same initial coverage as in the experiment of Fig. 9, but bombards the surface with a much higher electron density (*e.g.* by a factor 100), the curves of Fig. 10 result for the ionic signals as a function of bombardment time.

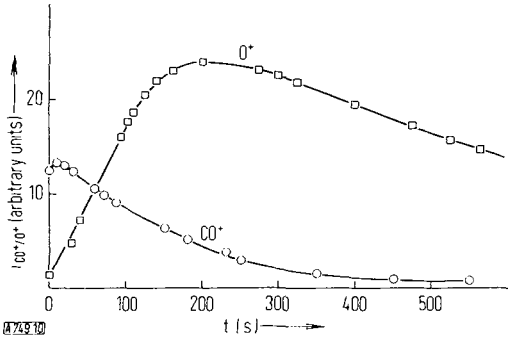

Fig. 10. Change of the CO^+ and O^+ signals from CO/W at 100 K caused by electron bombardment ($\dot{n}_e = 2 \times 10^{15}$ e/cm² · s, 100 eV (after [27]).

Again the CO^+ signal decreases; the O^+ signal at first increases, then goes through a maximum and finally decays also. The conversion of the state characterized by CO^+ emission, which can be induced thermally, is thus seen also to be obtained by electron impact. After removal of the first state by desorption and conversion, the second state is also diminished by further electron impact. Although other explanations of the observations cannot be excluded (see [27b] for further discussion), the ability of the electrons to cause conversions among adsorption states seems to be certain. *Menzel* and *Gomer* [13] observed such processes with the FEM; *Ermrich* and *van Oostrom* [30] found an electron induced state in the system N_2/W, which is not formed normally, *e.g.* thermally, and which possesses interesting characteristics.

All measurements discussed so far were done using electrons of 80 to 100 eV. In this energy range a maximum of the interaction cross sections is usually found for electron impact on free molecules. Usually the cross section decreases slightly towards higher energies and drops sharply towards lower energies. At the threshold energy it reaches the value 0. The value of the threshold energy is an interesting quantity, as it is the minimum energy required for the corresponding process. A similar behavior was usually found for the electron induced desorption processes, *e.g.* by *Moore* for O^+ desorption from CO/Mo [10]. An example of the energy dependence of a desorption signal is shown in Fig. 11.

[30] *W. Ermrich* and *A. van Oostrom*, Solid State Commun. *5*, 471 (1967).

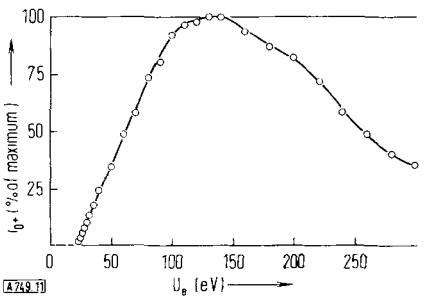

Fig. 11. Energy dependence of the O^+ desorption from CO/W (after [27]).

In some cases a further increase of the cross section was observed above 100 eV [20,27]; most probably this behavior was due to secondary effects. An interesting deviation from the usual energy dependence was reported recently by *Zingerman* and *Ishchuk* [18]. They found that the desorption cross section of oxygen from tungsten single crystal faces shows a periodic variation with energy, which they explain in terms of elastic scattering of the impinging electrons by the periodic surface structure. This effect needs further investigation.

Fig. 12 shows the range above the threshold for the desorption of CO^+ and O^+, and Fig. 13 the same range for the desorption of CO from the same state of CO/W [27]. The difference between the thresholds for CO^+ and O^+ is caused by the energy necessary for the rupture of the C–O bond and by the different

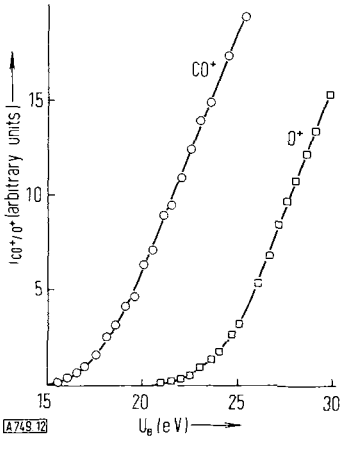

Fig. 12. Energy dependence of the desorption signals of CO^+ and O^+ from CO/W in the threshold region (after [27]).

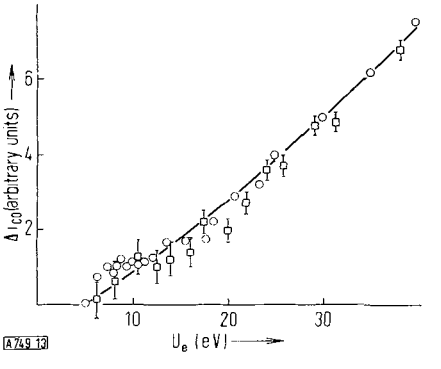

Fig. 13. Energy dependence of the desorption signal of CO from CO/W in the threshold region (after [27]).

heats of adsorption of CO and C. For a quantitative analysis the knowledge of the kinetic energies of the ions is necessary (*e.g.* see [21]). The large difference between the thresholds of CO^+ and CO shows that these two particles are formed in different ways. The q values quoted above (some 10^{-18} to 10^{-21} cm^2 for CO/W; the values for other systems lie in the same range for 100 eV electrons) are thus seen to be the maximum values. For similar electron induced processes in free molecules (excitation, ionization, dissociation), however, much higher maximum q values are found. Even for small molecules they amount to between 10^{-16} and 10^{-15} cm^2 and above. A mechanism which is to explain the experimental results must be able to account for this decreased "reactivity" of adsorbed particles with electrons. Metallic adsorbates are extreme cases in this respect: *Menzel* and *Gomer* [13] and *Bennette* and *Swanson* [17] found immeasurably small desorption cross sections for such layers.

2.3. Mechanism of the Electron Impact Desorption of Particles Adsorbed on Metal Surfaces

Because of the qualitative similarity of the processes it appears reasonable to assume that the interactions of electrons with adsorbed particles are, in principle, analogous to the processes with free particles, and that all special characteristics must be due to the bond with the metal surface. In free particles electron impact causes Franck-Condon transitions into excited or ionized states which can dissociate when the potential curves are suitably situated. As mentioned above, the maximum cross sections measured for such processes are at least in the range of 10^{-16} to 10^{-15} cm^2. Before the mechanism of the interaction with adsorbed particles is discussed, the most important findings will be summarized.

1. The impact of slow electrons on adsorbed layers of electronegative particles on metals causes desorption of neutral and positively charged particles, which can be accompanied by fragmentation. Normally the desorbed neutrals are in the majority and from threshold measurements, they appear to be formed in a different way from ions.

2. The maximum cross sections of these processes, which are found at electron energies of around 100 eV, just as with free particles, are smaller than those of comparable processes in free particles by several powers of ten.

3. Different binding states of the same adsorpt differ – in some cases appreciably – in their desorption cross sections. Sometimes the desorption products and the kinetic energy of desorbed ions are also different for different states.

4. Besides desorption, electron impact can lead to conversion of one binding state into another.

5. In the case of metallic, *i.e.* electropositive adsorpts, no electron impact desorption is found.

To explain these findings a mechanism has been proposed by *Menzel* and *Gomer* [13] which will now be covered briefly. A mechanism which is similar in many respects has been published independently by *Redhead* [19]. The starting point is the assumption that the binding of electronegative particles at a metal surface is caused by localized bonds which qualitatively are similar to the bonds in normal molecules. Electron impact should then lead to Franck-Condon transitions to excited or ionized surface complexes. In a one-electron approximation this means that an electron is lifted into a higher level within the surface complex or is taken into the metal or to infinity. In any case an electron vacancy is created in the adsorbate. If this view is correct and the respective levels are situated as shown in Fig. 14, the surface complex can dissociate subsequently, and a neutral or ionic particle can leave the surface.

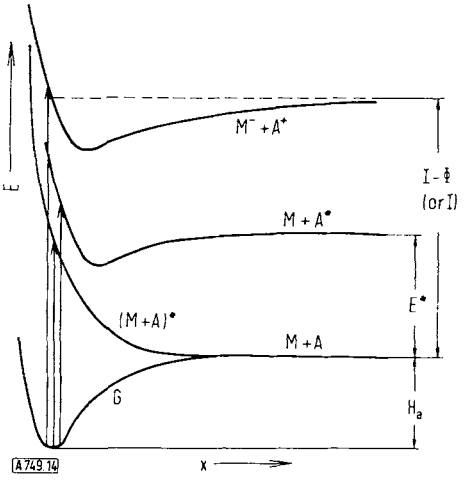

Fig. 14. Potential curves for the system metal–adsorbed particle, and possible transitions caused by electron impact.

M: metal; A: adsorbed particle; G: ground state of the adsorbate; $M^- + A^+$: ionic state of the adsorbate; $(M + A)^*$: antibonding state of the adsorbate; A^*: electronically excited state of the adsorpt; I: ionization potential of A; Φ: work function of M; H_a: heat of adsorption; E^*: excitation energy of A^*. The arrows indicate possible Franck-Condon transitions caused by electron impact.

As the bonds were assumed to be "normal", the interaction cross sections should be normal as well, *i.e.* in the order of 10^{-16} to 10^{-15} cm^2 at 100 eV. The much lower cross sections found in practice are then attributed to the closeness of the metal to the surface complex; the proximity of this practically infinite electron reservoir can lead to secondary processes. *Gomer* and *Swanson* [31] have shown in a different connection that the potential barrier between metal and adsorbate is easily penetrated by electrons, *i.e.* that the frequency of electrons tunneling through the barrier is high. By such a process the electron vacancy caused in the adsorbate by the excitation can be filled and the system returns to the ground state, desorption having been avoided. If these secondary processes are fast in terms of the lifetime of the excited states on the surface, then only a very small percentage of the initially excited particles are desorbed. The total desorption cross section will then be very small – as is observed. The number of the desorbed particles thus depends on

[31] *R. Gomer* and *L. W. Swanson*, J. chem. Physics *38*, 1613 (1963).

the tunneling rate through the surface barrier, which in turn will depend strongly (approximately exponentially) on the thickness of the barrier. This thickness is given by the binding state: for identical partners the bond length is known to be longer, the weaker the bond. The same should be true for surface bonds. This explains the large difference in the cross sections for different adsorption states: the weaker the bond, the greater the bond length, the smaller the tunneling rate, the smaller the proportion of the initially excited particles which can leave the surface before the bond is re-formed. Thus the weaker the bond, the larger the total desorption cross section – as found experimentally. This contains the assumption that the excited or ionized states for different adsorption states are identical. A quantitative estimate resulted in the correct order of magnitude for the observed effects [13b]. Depending on the position of the binding level of the adsorbate relative to the conduction band of the metal, the tunneling processes referred to above consist of resonance tunneling or two-electron transitions of the Auger type [40]. Even the latter seem to be fast enough to make the postulated mechanism possible.

Finally, the mechanism explains the likelyhood of conversions by electron impact. If several ground states exist, it is possible that the re-formation of the bond does not bring the particle back into the state it had occupied before the excitation, but to another: this is equivalent to a conversion. In reality these processes seem to be somewhat more complicated, however (see [13] and [27]).

The length of the arrows of Fig. 14 is determined by the minimum energy necessary for the transitions, *i.e.* the threshold energies. In the formation of an ion the electron set free in the ionization could enter the metal in a coupled process, so that only $(I - \Phi)$ eV would be necessary for its removal, or it could be lifted to the vacuum level, which would require the full ionization energy I. The experiment decided in favor of the latter possibility [27]. *Redhead* [19] assumed that desorbed neutral particles are formed *via* neutralization of ions by tunneling, while they are leaving the surface; *Menzel* and *Gomer* [13] envisaged the direct excitation of antibonding ((M + A)*) or excited (A*) states leading to neutral desorption. The difference in the threshold of ions and neutrals (see Figs. 12 and 13 above) showed the correctness of the latter assumption [27]. In the case of CO/W the desorption of electronically excited neutrals seems to occur, as suggested by observations of *Redhead* [20], *Baker* and *Pétermann* [32] and *Menzel* [27] (the threshold energy of Fig. 13 for desorption of neutral CO is compatible with this interpretation).

The discussed mechanism also explains why metallic adsorbates are not desorbed by electron impact. In metallic adsorption the bond is mainly formed by delocalized electrons: as the bonding levels of the adsorpt atoms are situated around the Fermi level of the metal substrate, they are broadened and a surface band is formed [31, 33]. It would thus make sense to speak of a surface alloy. The bonding electrons are thus included in the collective behavior of the metal electrons and alternate so fast between the adsorpt atoms and the interior of the metal that any excitation is transported into the bulk metal immediately and the surface remains free of excitation. This is seen to be an extreme case of the tunneling mechanism sketched above. Interestingly *Bennette* and *Swanson* [17] were able to show that cesium on tungsten *is* desorbed by electron impact when oxygen is also adsorbed. The presence of oxygen seems to modify the binding of the Cs atoms sufficiently to invalidate this concept of the electropositive bond.

The proposed mechanism thus appears to be plausible. It is further confirmed by the results of measurements of the temperature dependence of the cross sections [34], which seems to be determined by the vibrational structure of the adsorbate. It should be noted, however, that our treatment can only be a crude approximation. The use of a one-dimensional model (Fig. 14) is far from correct, especially as the two neglected coordinates, those parallel to the surface, are certainly important for defining the uniqueness of the different adsorption states – not to speak of the use of one-electron transitions in the place of many-body interactions. A better approximation will be very difficult, however. The good qualitative agreement with the experimental results shows, nevertheless, that the basic concepts used (excited and ionized adsorbate states and their potential curves, fast tunneling through the surface barrier) are appropriate.

2.4. Electron Impact Desorption as a Method and as a Disturbing Effect

Some examples of the use of electron stimulated desorption for the investigation of adsorbed layers have already been cited. These mainly rely on the difference of desorption cross sections and desorption products. So far only very simple systems have been investigated in such a way, and these turned out to be complicated enough. There is hope that the method can also be used for more complex layers. As the interaction between electron and adsorbate is an isolated process (see chapter 2.3. above), it is improbable that larger particles than those existing in the undisturbed adsorbed layer would be formed by secondary processes. The products of electron desorption should therefore allow conclusions about the composition and possibly the orientation of the adsorbates. An example of such conclusions can be given for CO/W. From the strongly bound states only desorption of O^+ ions, never of C^+ ions, was observed, although the dissociation of the free CO molecule by electron impact results in appreciably more C^+ than O^+. This suggests that the states concerned are bound to the metal *via* the C-end, which

[32] *F. A. Baker* and *L. A. Pétermann*, J. Vacuum Sci. Techn. *3*, 285 (1966).

[33] *R. W. Gurney*, Physic. Rev. *47*, 479 (1935); *T. B. Grimley*, Advances Catalysis and Related Subjects *12*, 1 (1960).

[34] *D. Menzel*, Surface Sci. *14*, 340 (1969).

has been concluded earlier from other investigations. Experiments on the investigation of complex adsorption layers (co-adsorption of several adsorpts, precursors of catalytic reactions) are under way.

It was remarked above that the effect of electron impact desorption can lead to disturbances in some instruments (see section 2.1). Another possibility of disturbance exists in LEED measurements. This method assumes that the surface structures shown by electron diffraction are identical with the structures existing without electron impact; the probe "electron beam" is assumed to create no changes. The electron current densities used in LEED are, however, in the order of magnitude of those used in the experiment of Fig. 10. Consequently the LEED electron beam can in fact change the adsorbed layer, especially if weak adsorption is being investigated. Besides mere diminution of coverage this change can consist of conversion processes and therefore result in qualitative changes in the adsorbate. In these circumstances the structure shown by LEED no longer corresponds to the undisturbed structure. This danger was pointed out by *Menzel*[35] some years ago; other authors actually demonstrated such effects during LEED investigations[36]. While the cross sections may be too small for such effects in cases of strong adsorption, care must be taken in LEED investigations of weak adsorption. In general, severe disturbances should be avoidable by decrease of the beam intensity or possibly by intermittent or pulsed operation; the value of the LEED method is therefore not seriously impaired.

3. Electron Impact Excitation of Vibrations of Adsorbed Particles

As electron impact can lead to vibrational excitation in free molecules, it should be expected that the same possibility exists for adsorbed particles. In principle the detection is possible, as in electron impact spectroscopy[4], by measuring the energy losses of the primary electrons. The experimental difficulties are appreciable here: the energy losses are of the order of 0.1 eV. The primary beam must therefore be very well monochromatized so as not to impair the resolution of the instrument (the electrons formed by thermionic emission from a cathode have a much broader distribution). The monochromator decreases the intensity considerably, and the subsequent energy analysis again selects only a very small part of the secondary electrons. The final intensities are therefore minute. *Probst* and *Piper*[37] succeeded in overcoming these difficulties; they found energy losses of very slow electrons occurring in the impact on adsorbed layers, which can be interpreted as vibrational excitation of the adsorbates. In at least one other laboratory work is in progress on the development of this method[38]. Fig. 15 shows the apparatus used by *Probst* and *Piper*.

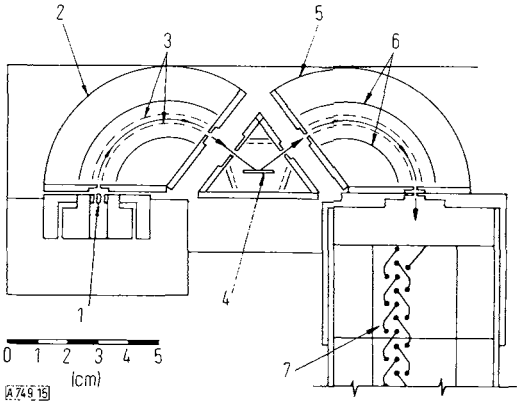

Fig. 15. Electron spectrometer for the measurement of vibrational excitation of adsorbates (after [37], with permission).
1: cathode; 2: monochromator; 3: deflection plates (grids); 4: target; 5: analyzer; 6: collection plates; 7: secondary electron multiplier.

A beam of very slow electrons (< 10 eV) is monochromatized in an electrostatic sector field (resulting half width < 50 meV) and hits the surface to be investigated. A fraction of the secondaries leaving the surface are analyzed in a second sector field according to their energy. The transmitted beam which corresponds to a particular energy loss is amplified by the secondary electron multiplier and recorded. By variation of the transmission condition of the second monochromator (analyzer) the distribution of the relative number of the secondaries as a function of their energy loss is obtained. As an example Fig. 16 shows this distribution for an adsorbed layer of hydrogen on a (100) face of tungsten.

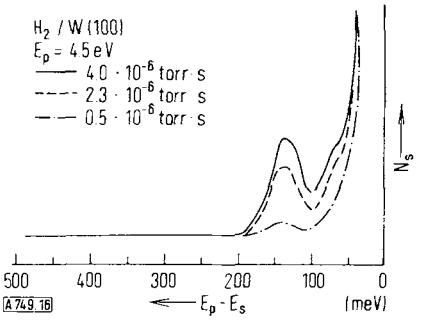

Fig. 16. Energy loss spectrum of very slow electrons from an adsorbed layer of hydrogen on (100) tungsten (from [37], with permission).

The maxima at energy losses of 135 and 69 meV are attributed to the vibrational excitation of atomically adsorbed hydrogen[37]. It can be expected that this new method will become of some importance, particularly as the recording of infrared spectra for adsorbates on well defined surfaces is not possible to date because of intensity limitations[*].

4. Auger Electron Emission

(Ionization of "inner" levels of adsorbed particles by electron impact.)

Another new method for the investigation of adsorbed particles by electron impact is the spectroscopy based on the emission of Auger electrons. It was introduced to surface studies by *Lander*[39] in 1953, but has only found broader application in the last four years. This method is particularly well suited for the qualitative analysis of surfaces and adsorbed layers, as it can characterize the kinds of atoms present in the surface. If an "inner" electron (*e.g.* from a K or L shell) of an atom is removed by the action of electrons or energetic photons, then an electronic re-ordering can occur as a secondary process instead of the emission of an x-ray photon (see Fig. 17).

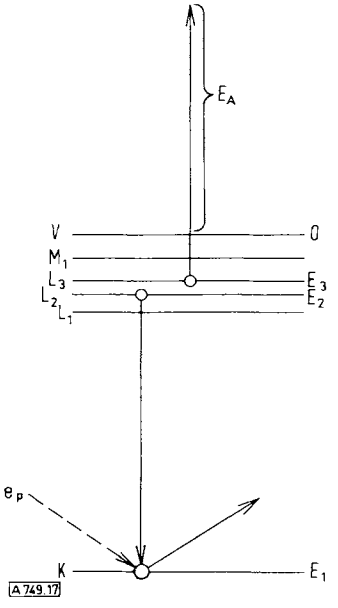

Fig. 17. Energy level diagram of a sulfur atom and schematic representation of the emission of a KL_2L_3 Auger electron.

An electron from a higher level falls into the low-lying vacancy; simultaneously a second electron is expelled from another (or the same) higher shell to balance the energy. The kinetic energy E_A of the emitted secondary (called Auger electron after the discoverer of the process[40]) is given by the energy balance as

$$E_A = E_1 - E_2 - E_3 \qquad (8)$$

where E_1 is the energy (relative to the vacuum level) of the primarily ionized level, E_2 is that of the level from which the electron filling the primary vacancy originates, and E_3 is that of the level from which the Auger electron stems. In the case shown the transition is called a KL_2L_3 Auger transition. As can be seen from eq. (8), E_A is independent of the energy of the incident primary electron (provided this energy is larger than E_1), and is given by the various possibilities of combination of the levels of the atom concerned.

Thus, if the energies of the Auger electrons emitted from a surface are measured, a qualitative analysis of the surface atoms is possible. The sensitivity to surface composition results from the small penetration depth of the slow primary electrons and the even smaller range of the secondaries in the solid. The combination of these two effects results in the majority of the Auger electrons originating from the first two to three atomic layers. As the Auger electrons stem from transitions between inner shells of the atoms, their energies are little influenced by the environment. Calibration spectra for different elements obtained from surfaces of known composition can therefore normally be used under other conditions.

The detection of Auger electrons is achieved by energy analysis of the secondary electrons emitted from the surface under electron bombardment. This can be done using different analyzer systems, *e.g.* with an electrostatic sector field[41] as in Section 3. or with a retarding potential method as in the energy analysis of electron impact desorbed ions (see Fig. 2). In the latter case the retarding field plot has to be differentiated for the energy distribution to be obtained. Particularly useful is the fact that the grid optics of a LEED system can also be employed efficiently as a retarding potential analyzer[42]. As most of the relevant Auger energies lie in the range between 50 and 1000 eV, primary energies of 1000 eV and higher must be used. Because of these high energies and the lack of a dependence of the Auger energies on the primary energies no monochromatization of the primary beam is necessary. The main problem lies in the fact that the number of the normal secondaries (*i.e.* those formed by interaction of the primaries with the collective electrons and the phonons of the solid) is far greater than that of the Auger electrons, which impedes their detection. However, the energy distribution of the normal secondaries is monotonic, so that the additional weak structure superimposed by the Auger electrons can be extracted by electronic means. This is done by modulation of the analyzer potential, which determines the energy loss of the electrons to be measured, with a small a.c. voltage; the a.c. component of the collector current is then detected selectively by a lock-in amplifier. With a suitable circuit the first derivative of the energy distribution of the secondaries (*i.e.* the second derivative of the retarding field plot, when LEED optics are used as analyzer) can be recorded directly. The structure caused by Auger electrons is then shown quite clearly. Fig. 18 shows the circuitry of *Palmberg* and *Rhodin*[43] which utilizes this principle in combination with a conventional display-type LEED optics.

The sensitivity of the analysis of surface atoms which, in the case of cesium on silicon has been reported as being 1/10 of a monolayer[44], can be further increased

by near-grazing incidence of the primary beam [45]. Sensitivity and speed of analysis can be further enhanced by the use of another type of analyzer [46].

Because of the ease of combination with a LEED system the method has already been used frequently for the examination of the cleanliness of surfaces for LEED investigations [47]. Fig. 19 shows an example of Auger spectra from a stainless steel surface which had been heated to various temperatures in ultrahigh vacuum for cleaning purposes [47a]. For some peaks the source atoms are given.

Segregation processes [41] on surfaces and grain boundaries and the surface composition of alloys [43] have also been investigated. It seems certain that the method can fruitfully be applied to other surface problems such as the investigation of the composition of metallic fracture planes, of active and poisoned catalysts, or of passive layers, to name only a few. A wider application of the method can therefore be safely predicted. This development will be further promoted by a refinement of the understanding of the underlying processes. In particular the investigation of the relationship between number of atoms present

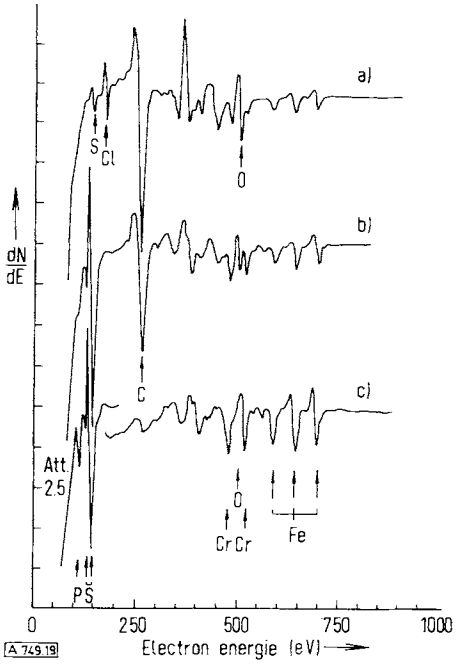

Fig. 19. Auger electron spectra of a stainless steel surface in ultrahigh vacuum (from [47a], with permission).

a: after bake-out; b: after 1 min at 600 °C; c: after 1 min at 820 °C.

and intensity of the peaks would allow an extension to quantitative analysis, and measurements of chemical shifts would give some information on environmental influences.

5. Conclusion

It was the aim of this survey to show that the specific processes brought about by energy transfer from slow electrons to adsorbed particles are well suited for the investigation of adsorbates. The three effects described differ in the amount of energy transferred ($\approx 10^{-1}$ eV for vibrational excitation, $\approx 10^{1}$ eV for electron impact desorption, $\approx 10^{2}$ eV for Auger emission) and in the kind of information obtained by them: spectroscopic data of the surface bond, elucidation of the kind and configuration of adsorbates and their binding states, and finally qualitative analysis of the surface atoms. As in all three cases the characteristics of the interaction depend on the parameters of the adsorbates, it may be expected that a better understanding of these processes will improve our theoretical concepts of the physical entities "surface" and "adsorbate".

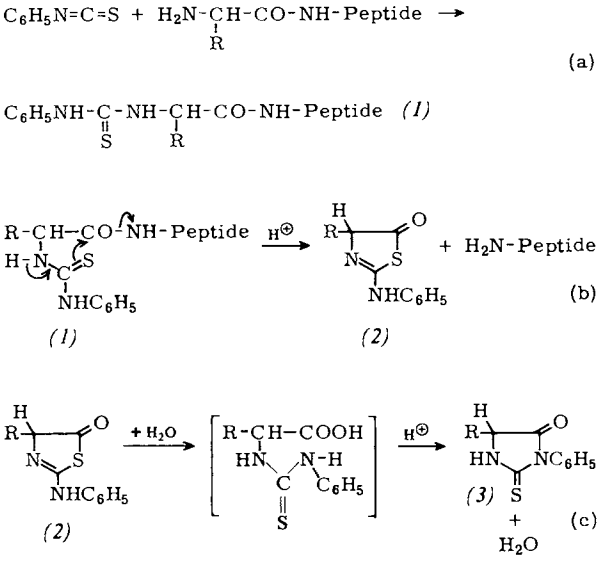
Automatic Analysis of Amino-Acid Sequences in Proteins and Peptides[1]

By M. von Wilm[*]

The development of the widely used automatic method from Edman's manual sequence analysis of proteins and peptides has resulted from modification of the procedure and from the use of a physically novel principle. All reaction, centrifugation, extraction, and drying operations are carried out in a rotating vessel. At a minimal cost in time and material, for example, sixty amino acids have been split off consecutively from a single sample of myoglobin.

1. Introduction

In 1950, the Swedish physician and biochemist *Edman* published his first article on the method of sequence analysis that is nowadays generally known as Edman degradation[2,3]. This involves the elucidation of the primary structure of a protein or peptide by successive controlled chemical degradation of the peptide chain from the amino end, followed by identification of the amino acids split off.



In 1967, *Edman* and *Begg*[4,5] described a protein sequenator, *i.e.* a device that allows the largely automatic analysis of the amino-acid sequences in proteins and peptides. This automatic method was first tested on myoglobin from the humpback whale; this substance, which is the oxygen-transferring protein of skeletal muscle, has a molecular weight of 17200. The sequence of the first sixty N-terminal amino acids of this protein was established in a single operation. Comparison with the known amino-acid sequence of sperm whale myoglobin[6] showed good agreement in all but six positions, in which different amino acids appeared.

Fifteen degradation steps could be carried out automatically with the sequenator in 24 hours. The quantity of substance required was about 5.0 mg; this corresponds to about 0.30 μmole of protein. The maximum number of degradation steps that was possible by the manual method was about 15, and each step took about two days. *Edman* reached the described perfection and automation of the method (1) by the use of a new principle in the reaction of the amino end group of the protein with the degrading reagent, and (2) by optimization of the reaction conditions on the basis of kinetic studies.

Edman recently reported the automatic degradation of a sequence of 22 amino acids of an antibody[7].

2. The Manual Edman Degradation

The reaction underlying the manual degradation involves the coupling of the peptides with phenyl isothiocyanate to give the phenylthiocarbamyl (PTC) derivative *(1)*, cyclizing cleavage to give the 2-anilino-5-thiazolinone derivative *(2)*, and rearrangement of *(2)* to give the 3-phenyl-2-thioxoimidazolidin-4-one (3-phenyl-2-thiohydantoin, PTH) derivative *(3)*.

The reaction of phenyl isothiocyanate with the α-amino end group of the peptide proceeds in accordance with equation (a) in pyridine/water, the pH value being adjusted to 8.5–9.0 with dilute sodium hydroxide solution. Pyridine and excess isothiocyanate are then extracted with benzene. Lyophilization of the aqueous phase containing the phenylthiocarbamyl derivative *(1)* of the peptide is followed by cleavage and rearrangement in a single step. The removal of the residual peptide and the rearrangement of the unstable *(2)* into *(3)* correspond to cyclizing transamidation.

The reactions (b) and (c) are carried out in glacial acetic acid HCl at 40 °C, or preferably in an anhydrous medium such as nitromethane HCl[2,3] to avoid hydrolysis of the peptide chain, at about 25 °C. Anhydrous trifluoroacetic acid has been in use for some time as the cleaving reagent[8,9]. The dissolved PTH-amino acid *(3)* is separated from the precipi-

tated residual peptide by centrifugation, and identified by thin layer chromatography after distillation of the solvent. The peptide, which has been shortened by one amino acid, can now be allowed to react again with phenyl isothiocyanate (see Fig. 1). (For improvements of this method, see [10, 11].)

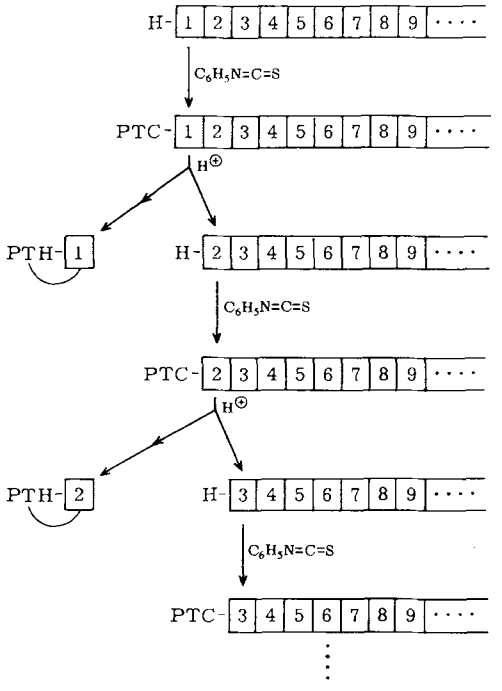

Fig. 1. Scheme of the Edman degradation.

The liquid phase procedure described is suitable only for proteins whose PTC derivatives are soluble in the acidic medium required for the cleavage. This condition is unfortunately not satisfied by most proteins. According to *Fraenkel-Conrat* [12], however, proteins that do not dissolve can be degraded by working on paper strips. Fourteen degradation steps were carried out on 1–2 mg of insulin by this method. The detection sensitivity is about 0.01 μmole per PTH-amino acid.

3. Methods for the Elucidation of the Primary Structure of Proteins and Peptides

3.1. Methods of End-Group Determination

The first efforts to elucidate the structure of peptides were based on the use of a reagent to label the α-amino or the α-carboxyl group of an amino acid situated at the end of a peptide chain, so that it could be qualitatively (and if possible quantitatively) detected after total hydrolysis of the peptide.

This requires reaction of the protein or peptide under the mildest possible conditions, to avoid hydrolysis of the peptide chain, which would lead to the formation of new end groups. Furthermore, the bond between the reagent and the amino end group must be resistant to vigorous hydrolysis.

Numerous reagents have been suggested for this end-group determination, which still plays an important part in the determination of the primary structure, particularly for the determination of the chain length and the number of chains with different sequences. A selection of the principal methods is presented in Table 1.

Table 1. Methods of end-group determination.

(6)	thin-layer chromatography	[15]
C-terminal:		
H_2N-NH_2	amino acid analysis	[16]

Dinitrophenylation (DNP method), which was used by *Sanger* [13] with great success in the determination of the structure of insulin, has become very important, and has been perfected by combination with paper chromatography and more recently with thin layer chromatography.

The most recent method is the dansyl method, which was introduced in 1952 by *Weber* [14] and later modified by *Gray* and *Hartley* [17, 18], and which permits the qualitative determination of 0.5 nmole of amino end groups. This method is thus about 100 times as sensitive as the DNP method. It has found steadily growing use since the introduction of special polyamide plates for the fast thin layer chromatography [19] of these compounds.

The *Akabori* method [16], in which only the C-terminal amino acid is not in the form of the hydrazide after hydrazinolysis of all the peptide linkages, has proved suitable for the detection of the C-terminal amino acids. The hydrazides are precipitated as Schiff bases by reaction with benzaldehyde, while the C-terminal amino acid, which remains in solution, is identified chromatographically.

3.2 Methods of Sequence Analysis

Investigators did not remain satisfied for long with the ability to determine only the N- or C-terminal amino acid. A search was therefore started for reactions by which the degradation process could be repeated many times. To be suitable for this purpose, a reagent must satisfy the following conditions:

1. The coupling reaction must proceed under very mild conditions, since hydrolysis of the peptide chain would also allow non-terminal amino acids to react.

2. The reagent used for substitution of the terminal amino acid must weaken the first peptide linkage in the chain, to enable the remainder of the peptide to be split off under mild conditions.

3. The derivative of the amino acid must allow easy chromatographic identification.

4. The detection sensitivity for this derivative should be as high as possible.

The first compound to be suggested for this purpose [20] was phenyl isocyanate, but this did not satisfy the requirements. The degradation with this reagent, which was considerably improved by *Brockmann* and *Abderhalden* [21] by finding much milder reaction conditions for the cyclizing cleavage, and which was first tested on a tripeptide, may be regarded as a precursor of the Edman reaction. Instead of phenyl isocyanate, *Edman* used phenyl isothiocyanate, which reacts more rapidly. He was able to show that the cyclizing cleavage was then possible under much milder conditions.

The most important of the compounds proposed for sequence analysis are listed in Table 2. Apart from the Edman degradation, however, these methods have not become generally accepted.

Table 2. Methods of sequence analysis.

Reagent	Detection	Ref.
N-terminal:		
$C_6H_5N=C=O$	m.p.	[20, 21]
$C_6H_5N=C=S$	paper, thin-layer, column chromatography	[2,3]
$S=C=S$	paper chromatography	[22]
$N=C=O^{\ominus}$	amino acid analysis after retrodegradation	[23]
leucine-aminopeptidase	amino acid analysis	[24]
C-terminal:		
$N=C=S^{\ominus} + (CH_3CO)_2O$	subtraction method	[25, 26]
carboxypeptidase A and B	amino acid analysis	[27]

The only method suitable for stepwise degradation from the C-terminus was first introduced in 1926 by *Schlack* and *Kumpf* [25] and was recently considerably improved by *Stark* [26].

In many cases, use is made of the possibility of obtaining information about the N- or C-terminal sequences of peptides by the action of peptidases. The enzymes most commonly used in this method are leucine aminopeptidase [24] and carboxypeptidase A and B [27].

4. Degradation of the Tertiary and Secondary Structures of Proteins

4.1. Modification of the Functional Groups and Cleavage into Single Chains

In the elucidation of the primary structure of proteins, the sequence analysis is the final step, which must be preceded not only by the isolation and purification of the protein, but also by many controlled degradation processes, some of which are very complicated and laborious. By systematic degradation of the tertiary and secondary structure, the peptide chains are prepared for the sequence analysis after cleavage into fragments of suitable size. The "chains" referred to here are parts of the molecule that are not bound by hydrogen and/or disulfide bridges. By following the degradation steps shown in Scheme 1, it is necessary above all to answer four questions:

1. How many chains constitute a molecule?

2. What is the molecular weight of each chain?

3. What amino acids do the chains contain and in what quantities?

4. What is the sequence of the amino acids in the individual chains?

The steps that decide the success of the sequence analysis are:

1. the modification of the functional groups in the amino-acid side chains of the protein molecule;

2. the cleavage into single chains by breaking the hydrogen bonds (denaturation) and by opening the disulfide bridges;

3. the subsequent enzymatic or chemical cleavage into peptide subunits.

The non-covalent intermolecular and intramolecular bonds, particularly the hydrogen bonds in the helical regions, are broken by urea or by heat.

Several reactions are used to open intermolecular and intramolecular disulfide bridges in order to break the protein molecule down into single chains:

Reduction of the disulfide bridges with thioglycolate [28] or mercaptoethanol [29] yields thiol groups,

Scheme 1. Scheme of the systematic controlled degradation for the determination of the primary structure of proteins.

which can be carboxymethylated with iodoacetamide [30–32]. Simultaneous alkylation of the ε-amino group of lysine can be avoided by suitable choice of the reaction conditions.

A second possibility is the oxidation of the disulfide bridges with performic acid [33], in which cystine is converted into cysteic acid, and methionine into its sulfone. However, any tryptophan present in the chain will be quantitatively decomposed in this case.

The introduction of additional carboxyl groups into hydrophobic regions of the peptide chains, particularly those containing cystine, by carboxymethylation or by succinylation of the ε-amino groups of lysine makes the peptides formed on subsequent enzymatic cleavage more readily soluble in aqueous media.

[33] *G. Toennies* and *R. P. Homiller*, J. Amer. chem. Soc. *64*, 3054 (1942).

The principal enzymes used for enzymatic degradation are trypsin and pepsin, and in some cases also chymotrypsin and papain. The initial cleavage is usually carried out with the very specific trypsin, and then further cleavage with pepsin or other proteases. The end groups are determined in the chromatographically separated and isolated peptides, and it is usually possible to deduce the structure of the peptide from the overlapping sequences obtained in this way.

The enzymatic cleavage is very strongly influenced by modification of the functional groups of the molecule. For example, aminoethylation [34] of the thiol groups formed by reduction of the cross-linking disulfide bridges, which results in the conversion of cysteine into *S*-aminoethylcysteine, allows the cleavage of the peptide chain by trypsin at this point. Otherwise trypsin breaks only peptide linkages of the basic amino acids lysine and arginine, the cleavage occurring on the carboxyl side. Difficulties in structural elucidation due to the presence of trypsin-resistant "core" regions can in some cases be overcome in this way.

The peptide chain an also be selectively broken down by chemical methods. Thus cyanogen bromide [35] breaks the chain after methionine, while *N*-bromosuccinimide [36] breaks it after tryptophan. However, chemical degradation has the important disadvantage that no overlap occurs, with the result that the assignment of the fragments is more difficult.

5. Results of Sequence Analysis

The first great success for sequence analysis was the elucidation of the primary structure of insulin. The sequences of the A and B polypeptide chains of this hypoglycemic pancreatic hormone, which contains a total of 51 amino acids, were determined by *Sanger* [13] between 1945 and 1954 by the DNP method. Neither amino-acid analysis by automatic column chromatography nor a sophisticated method for the Edman degradation was available at that time.

Between 1956 and 1960, the amino-acid sequence of ribonuclease, a chain of 124 amino acids, was published by *Hirs, Stein*, and *Moore* [37] and by *Anfinsen* [38]. Important contributory factors in the success of this work were the automatic amino-acid analysis method published in 1958 [39,40], and the Edman degradation, which had by that time been reported.

[40] *S. Moore, D. H. Spackman*, and *W. H. Stein*, Analytic. Chem. *30*, 1190 (1958).

Further important sequence analyses then appeared in quick succession: in 1960/1961, *Tsugita*[41] and *Schramm et al.*[42] reported that elucidation of the protein of tobacco mosaic virus, which contains a total of 158 amino acids; in 1961, *Braunitzer et al.*[43] established the sequence of human hemoglobin A, consisting of two α and two β chains with a total of 574 amino acids.

We now know, in whole or in part, the sequences of lysozyme, chymotrypsinogen, cytochrome c, catalase, myoglobin, and corticotropin, as well as many other peptide hormones and enzymes. Chains of 500 and more amino acid residues can nowadays be sequenced without great difficulty by the Edman method. So far, 12000 primary structures have been published.

6. The Edman-Begg Protein Sequenator

6.1. The Improved Edman Degradation

By spectroscopic investigation of the reaction course in the degradation, *Edman*[3,4] was able to establish optimum conditions for the automatic sequence analysis. He found that the cyclizing cleavage [eq. (b)] and hence the formation of the thiazolinone *(2)*, which is unstable and therefore unsuitable for detection, proceeds very rapidly under mild conditions in the presence of anhydrous acids, while the rearrangement (c) is relatively slow. It therefore seemed reasonable, in a departure from the manual degradation procedure, to separate the two reactions. The revised procedure involved extraction of the thiazolinone *(2)* and conversion into the stable phenylthiohydantoin *(3)* by hand outside the newly developed instrument. By the removal and separate rearrangement of the thiazolinone, the residual protein with one amino acid less is removed from the action of strong acid in aqueous media, and the danger of hydrolysis of the peptide chain is thus avoided.

Finally, *Edman* found that the phenylthiocarbamyl grouping is very readily desulfurized by oxygen. This side reaction, which brings the degradation to a standstill, can be avoided by working under nitrogen.

The question how many successive degradation steps are possible on one peptide or protein depends on the maximum yield obtainable in each. If we assume, like *Edman*, that the overall yield after n degradation cycles has fallen to 30% and that further degradation seems undesirable in view of the increasing complexity of the results, then with an average yield of 97, 98, or 99% per degradation step we find that a total of 40, 60, or 120 degradation cycles are possible. By means of the above improvements in the reaction conditions, and by automation of the process with the sequenator, *Edman* achieved an average yield of 98% per degradation cycle, and hence a total of 60 degradation steps, for myoglobin.

6.2. A Novel Principle for the Reaction of the Protein

The physically novel principle first used by *Edman* for all the reaction, centrifugation, extraction, and drying processes required for a complete degradation cycle consists in the use of a cylindrical glass vessel rotating under an evacuable glass bell (see Fig. 2). The protein is deposited on the inner wall of the vessel as a very thin film on removal of the solvent under vacuum.

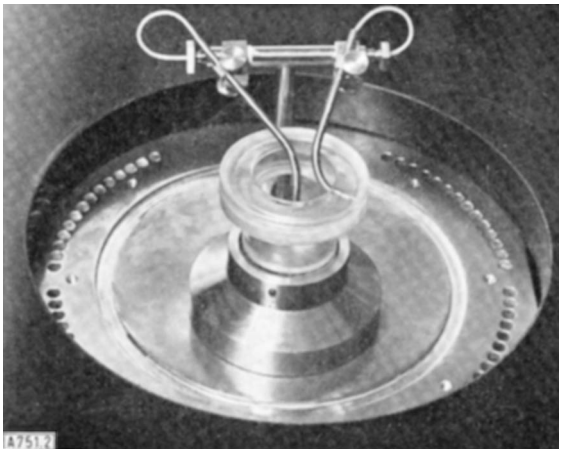

Fig. 2. Rotating reaction vessel of the Edman-Begg protein sequenator with glass bell removed. The figure shows the Teflon tube through which reagents and solvents are added, and the draw-off tube which is arranged tangentially in a groove at the edge of the vessel, and which is connected *via* a three-way valve with the fraction or drainage collector. Inlet and outlet holes for the circulating hot air (50 °C, temperature constant to within ± 0.2 °C) can be seen on the heatable base plate. Diameter of the base plate 18 cm. (Works photograph of Beckman Instruments GmbH, München).

The coupling reaction [eq. (a)] is now carried out on this protein film under nitrogen by dropwise addition of reagent and buffer through a capillary tube. The centrifugal force causes the reagents to rise slowly in a thin layer on the wall of the vessel until the protein is completely covered. After the reaction, the glass bell is evacuated again to remove the solvent and most of the excess reagent from the vessel.

The subsequent extraction of the buffer and of the residual phenyl isothiocyanate is carried out with a thin film of solvent, which runs over the protein layer and is finally sucked off from a groove in the upper third of the reaction vessel by a tangential Teflon tube. The vacuum drying after the extraction is greatly facilitated by the large surface and the stabilizing centrifugal force. Finally, the cleavage [eq. (b)] with anhydrous n-heptafluorobutyric acid is carried out under nitrogen by the same principle. After removal of the acid under vacuum, the thiazolinone *(2)* formed is extracted as described with 1-chlorobutane and collected in a fraction collector.

The purity of the reagents and solvents is extremely important in the automatic Edman method. Thus the smallest traces of aldehydes must be completely removed, since these form Schiff bases with the amino end groups and rapidly reduce the yields.

6.3. Identification of the Degradation Products

The rearrangement of the unstable thiazolinone-amino acids *(2)* collected into the PTH-amino acids

[41] *A. Tsugita, D. T. Gish, J. Young, H. Fraenkel-Vonrat, C. A. Knight,* and *W. M. Stanley,* Proc. nat. Acad. Sci. USA *46*, 1463 (1960).

[42] *F. A. Anderer, H. Uhlig, E. Weber,* and *G. Schramm,* Nature (London) *186*, 922 (1960).

[43] *G. Braunitzer, R. Gehring-Müller, N. Hilschmann, K. Hilse, G. Hobom, V. Rudloff,* and *B. Wittmann-Liebold,* Hoppe-Seylers Z. physiol. Chem. *325*, 283 (1961).

(3) in accordance with eq. (c) is carried out by hand outside the instrument in 1 N HCl at 80 °C within 10 minutes. Numerous methods have been devised for the identification of the PTH-amino acids. The thin layer chromatography method, which was formerly regarded as the best, has now been displaced by the gas-chromatographic determination of free or silylated PTH-amino acids, which has been considerably improved by *Pisano et al.* [43a]. Apart from its speed and its great sensitivity, the principal advantage of gas-chromatography is that it enables the entire degradation process to be followed accurately and quantitatively, a need that very soon appeared in the first investigations using the sequenator.

The following methods may be used for the identification of the PTH-amino acids:

1. Paper chromatography [44–46].
2. Partition column chromatography [47].
3. Thin layer chromatography on silica gel [48,49] and polyamide plates [50].
4. Gas chromatography [51–55]. However, this leads to partial decomposition of the PTH derivatives of Ser, Thr, Asn, and Gln, as well as of the basic amino acids.
5. Improved gas chromatography [43a].
6. Mass spectrometry [56, 57].
7. Cleavage by alkaline or acid hydrolysis [58] followed by identification after *Stein* and *Moore*. In this case, difficulties arise in the detection of Asn and Gln, which undergo the amide cleavage. PTH- Ser and PTH-Thr are also degraded to Gly, and PTH-Arg to Orn. The yields are poor in every case.
8. Thin layer electrophoresis for PTH-Arg and PTH-His [4, 59].

Mention should be made here of two indirect detection methods, which have acquired importance in particular in the determination of the constitution of short-chain peptides.

In the subtraction method [60], the rearrangement and identification of the thiazolinone-amino acids *(2)* removed are omitted. An aliquot is taken instead from the residual peptide after each degradation step, and used after hydrolysis for the column-chromatographic identification of the amino-acid components. The sequence is found from the missing amino acid.

In the combined Edman-dansyl method [61,62], an aliquot of the peptide is used before each degradation step for end-group determination by the dansyl method. After total hydrolysis, the terminal amino acid is identified by thin layer chromatography. The next amino acid, which is now known, is then split off. In this way the Edman degradation can be continuously checked by the end-group determination.

An important disadvantage of both methods is the relatively large quantities of material required.

7. Limitations of the Method

The universal applicability of the automatic Edman degradation in the sequenator is unfortunately subject to certain limitations:

1. Owing to the progressive decrease in the yields as a result of non-specific hydrolysis during the degradation and to the overlap of successive steps when reactions (a) and (b) are incomplete, there is a limit beyond which the results can no longer be interpreted.
2. Very long chains consisting mainly of hydrophobic amino acids present solubility problems, despite the introduction of additional hydrophilic groups.
3. The degradation cannot be continued to the carboxyl end, since the solubility differences between short-chain peptides and the thiazolinone amino acids are so small that the latter compounds can no longer be extracted. For the same reasons, the method cannot yet be applied to short-chain peptides (for preliminary experiments see [54]).
4. PTH-Asn and PTH-Gln suffer partial hydrolysis to PTH-Asp and PTH-Glu. PTH-Ser and PTH-Try are partly decomposed by the anhydrous acid used for the cyclizing cleavage.

8. Conclusions

The method of automatic sequence analysis described above opens up a number of new prospects and possibilities:

1. The systematic degradation of the primary structure by enzymatic and chemical cleavage will become simpler and less time-consuming, and may be com-

pletely eliminated in some cases, since much longer chains can now be sequenced than formerly.

2. Because of the good yields in the sequenator and the increased detection sensitivity for amino acids, the quantity of material required for sequence analysis will be considerably reduced.

3. The time required for the actual sequence analysis has already been greatly reduced, and 15 degradation steps can now be carried out in 24 hours. (The determination of the sequence of insulin by the DNP method took *Sanger* and three coworkers ten years, while *Braunitzer* and five colleagues, using a greatly improved method, spent six years on the sequencing of hemoglobin. The determination of the sequence of a chain of 150 amino acids by the classical manual Edman method takes two people about two years.)

4. It may be possible to apply the Edman principle of automatic degradation to other macromolecular substances, such as nucleic acids, if repeatable degradation reactions can be developed for these compounds.

5. It is not unlikely that one of the reactions allowing controlled successive degradation from the C-terminus can be improved sufficiently to allow this degradation reaction [26] to be carried out in the sequenator. This would allow the sequence analysis to be carried out from both ends of the chain. The assignment would be greatly facilitated by overlapping in the middle of the chain.

6. It may be possible to overcome the problem presented by the similar solubilities of short-chain peptides and of thiazolinone amino acids by modification of the peptides or by the use of more suitable solvents. The latter alternative has already been followed successfully by *Niall et al.* [54] in studies on pig thyrocalcitonin, a distinctly hydrophobic peptide hormone consisting of 32 amino acids.

7. Thought must also be given to the fixation of the carboxyl end of the peptide to a polymeric support by covalent bonds [57,63,64] that can be broken again under mild conditions. In the automatic Edman method the support is the residual molecule itself, which is extracted toward the end.

8. An interesting new contribution to the strategy of sequence analysis is the simultaneous analysis of peptide mixtures proposed by *Gray* [65]. This method appears to allow the simultaneous automatic analysis of a mixture of ten or more peptides with different sequences, with the result that the time required for the elucidation of primary structures is again drastically reduced.

Problems and Possibilities of the Free-Radical Addition of Thiols to Unsaturated Compounds [**]

By Karl Griesbaum [*]

In view of the growing importance of photochemically initiated reactions in industry, the use of free-radical additions of thiols to unsaturated compounds also seems promising. The present article is intended to demonstrate the possibilities and limitations of reactions of this type in organic synthesis.

1. Introduction

Since its discovery [1] and its much later formulation as a free-radical chain reaction [2], the anti-Markownikoff addition of thiols to unsaturated compounds has been the subject of many reviews [3].

The present article was stimulated mainly by recent developments as a result of which the economical industrial use of such reactions has for the first time become a possibility. Free-radical additions originally

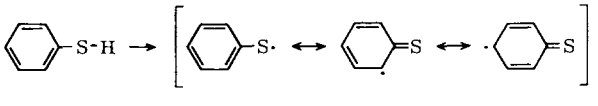
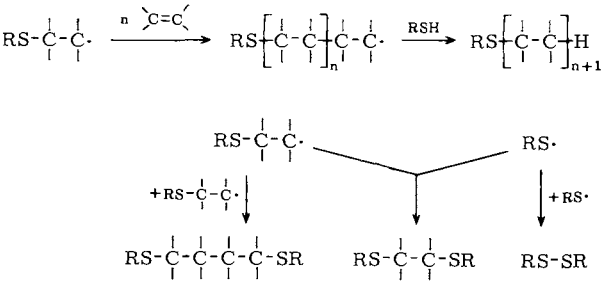
had to be initiated either by exposure to UV radiation or by additon of chemical initiators. In the first case special apparatus was required, in the second case undesirable by-products were formed. This situation has changed with the successful use of radioactive waste products as initiators. With ^{60}Co radiation sources, for instance, free-radical reactions can nowadays be carried out safely and reliably on an industrial scale [4] without serious restrictions as to the material or the design of the reactor. Consequently, even free-radical reactions that require high pressures or extreme purity can now be carried out on an industrial scale.

2. Reaction Course



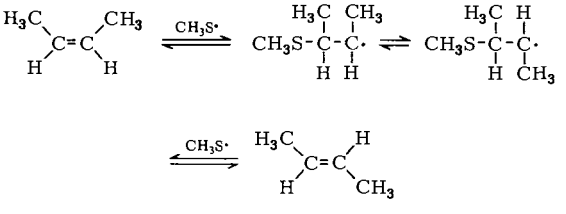
2.1. The Steps of the Reaction

The free-radical addition of thiols is a typical chain reaction, and is accordingly initiated by the addition of peroxides, azo compounds, *etc.* or by exposure to UV or other radiation. The initial products are alkylthiyl or arylthiyl radicals, which subsequently add to the unsaturated substrate to form a C radical, the latter usually being reversible. The C radical then reacts with a thiol molecule to give the final product and a new thiyl radical, thus propagating the radical chain.



Both the addition of the thiyl radicals (referred to below as the primary reaction) and the chain transfer are normally exothermic, with the result that the overall reaction is fast and has kinetic chain lengths between a few hundred and several thousand cycles [5]. Most of these additions can therefore be treated kinetically as steady state systems.

The chain transfer is generally the rate-determining step. Since this involves the cleavage of a S–H bond, its rate will be strongly influenced by the structure of the thiol to be added. Thus, aromatic thiols are better chain transfer agents than aliphatic thiols, since in the former case the energy required to break the S–H bond is lowered by the resonance stabilization of the thiyl radical formed.



The rate of the chain transfer influences all the variables that depend on the lifetime of the intermediate C radical, such as the degree of reversibility of the primary reaction, the stereochemical course of the overall reaction, possible rearrangements of the intermediate C radical, and the extent of telomerization and chain termination reactions. Telomerization occurs when on an average the intermediate C radical reacts more rapidly with the unsaturated substrate than with the chain-transferring thiol, while chain termination occurs when combinations of free radicals can compete with the chain transfer.

2.2. The Reversibility of the Primary Reaction and Possible Consequences

The first indication for possible reversibility of the addition of thiyl radicals to unsaturated compounds was provided by the overall activation energy, which was found to be negative in several reactions [6]. Chemical evidence is provided by the fast *cis/trans* isomerization of the 2-butenes by small quantities of methanethiol [7] and by the reversibility of the co-addition of thiol and carbon monoxide to ethylene [8].

As can be seen from the isomerization of the butenes, the reversibility can have important practical consequences. For example, attempts to make the addition proceed stereospecifically often fail due to previous isomerization of the substrate.

However, the degree of reversibility of the primary reaction can have a decisive influence not only on the stereochemistry but also on the direction of the reaction. Thus, the reaction of equimolar quantities of ethanethiol and allyl phenyl sulfide *(1)* gave a mixture of adducts that contained only 6% of the expected

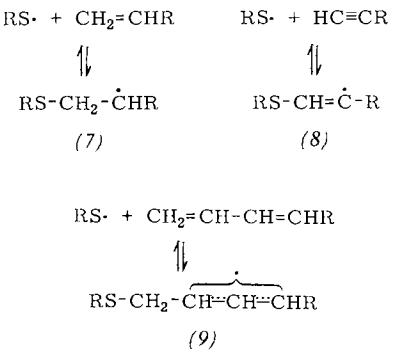
mixed bis-sulfide *(5)*, together with 62% and 32%, respectively, of the sulfides *(3)* and *(4)* [9].



The decisive factor here is the tendency of the intermediate radical *(2)* to decompose into the resonance-stabilized phenylthiyl radical and allyl ethyl sulfide *(3)* prior to the chain transfer (β'-elimination, see Section 4.1.3).

The extent of reversibility of C–S bond formation depends mainly on the structure. The addition of thiyl radicals to terminal olefins, to olefins that lead to resonance stabilized free-radical intermediates and in particular to monosubstituted alkynes [10] is much less reversible than the addition to olefins with non-terminal double bonds. This reversibility can also be suppressed to a greater or lesser degree, *e.g.* by lowering the reaction temperature [*] or by accelerating the hydrogen transfer. Hydrogen transfer can be accelerated by the use of a thiol having a labile S–H bond in high concentration or by the use of a particularly active hydrogen donor (*e.g.* HBr) as a chain transfer agent [12]. The success of such measures is shown by the synthesis of the mixed bis-sulfide *(5)*, the selectivity of which could be increased from its original value of 6% to 100% [9].

2.3. Orientation and Stereochemistry of the Addition

As in other free-radical additions, the anti-Markownikoff orientation in the addition of thiols to unsymmetrically substituted multiple bonds is explained by the preferred formation of the more stable intermediate C radical [**]. Accordingly, the addition of thiyl radicals to simple olefins, alkynes, or conjugated olefins, takes place preferentially at the less substituted end of the unsaturated system to give the more highly substituted and hence more stable alkyl *(7)*, vinyl *(8)*, or allyl radical *(9)*.

Though the preferred direction of attack of the primary addition can be predicted fairly reliably by this principle, the final result of the addition depends on a number of other factors, which are discussed in Section 4.

The stereochemical course of thiol additions is strongly dependent on whether the intermediate radical can retain its stereochemical identity up to the chain transfer. If so, addition occurs preferentially in a *trans* (*anti*) direction, *i.e.* the chain-transferring thiol attacks the C radical on the side opposite to that of the RS group.

Stereoselectivity has been observed in the addition of thiols to some cyclic olefins [15–19] and to alkynes [20, 21]. The stereoselectivity in the former case is probably due to the restriction of free rotation. This explanation has been advanced for the preferred formation of the *cis*-adduct *(11)* from 1-chlorocyclohexene by axial attack of the RS group and rapid saturation of the resulting radical *(10)*. Since the chlorine in *(10)* assumes a quasi-equatorial position and the thiyl substituent an

[**] Two more recent suggestions, according to which the orientation in the addition depends on the selective cleavage of an intermediate bridged radical [13] or on the relative bond strengths of the two possible C–S bonds [14] lead to the same predictions, and will therefore not be dealt with in more detail here.

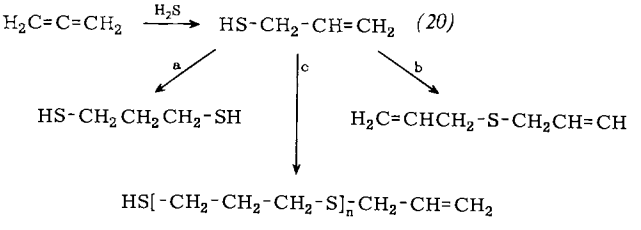
axial position, the chain transfer takes place from the axial direction to give the *cis*-adduct *(11)*, provided that the chain transfer is faster than the conversion of *(10)* into *(12)*. Both the *cis-(11)* and the *trans*-adduct *(13)* could be formed if *(12)* is an intermediate, since in this case both substituents are in the equatorial position and thus attack of the thiol on the free-radical center can take place from either side. In agreement with this explanation, the *cis*-selectivity can be considerably increased by acceleration of the chain transfer [15].

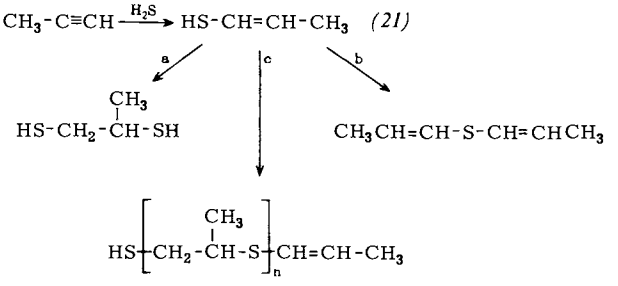
Additions to acyclic olefins, on the other hand, are not stereoselective. In cases where the addition of the thiyl radical is reversible and the substrate isomerizes before the actual addition reaction, the non-stereospecificity is self-explanatory. Even when isomerization of the substrate was suppressed by the use of very low temperatures, however, the addition of CH_3SD to *cis*- and to *trans*-2-butene gave the same mixture of *threo*- *(16)* and *erythro*-3-deuterio-2-methylthiobutane *(17)*. Evidently the incipient free radicals *(14)* and *(15)* are mutually converted by rotation before chain transfer occured [12].

3. Influence of the Structure of the Addend

The reaction course described is valid for the addition of many classes of thiols to unsaturated compounds. Depending on the structure of the addend, however, slight differences may occur, which in some circumstances necessitate changes in the reaction conditions. Two such examples are described below.



3.1. The Addition of Hydrogen Sulfide

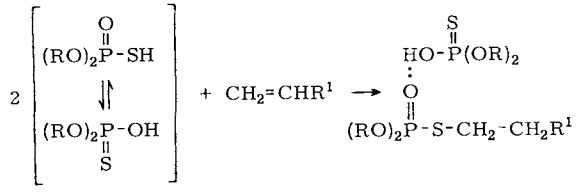


The free-radical addition of hydrogen sulfide to unsaturated compounds yields thiols by the usual reaction scheme *(18)* [3f]. Since thiols are generally more reactive than hydrogen sulfide, some of the thiol formed immediately reacts further to form the symmetrical sulfide *(19)*.

$$CH_2{=}CHR + H_2S \rightarrow HS{-}CH_2{-}CH_2R \qquad (18)$$

$$HS{-}CH_2{-}CH_2R + CH_2{=}CHR \rightarrow RCH_2{-}CH_2{-}S{-}CH_2{-}CH_2R \qquad (19)$$

Hence, if the products required are thiols *(18)*, the reaction must be carried out with a large excess of hydrogen sulfide. However, this procedure is unsuitable when the addition of H_2S is required to yield an unsaturated thiol such as allylthiol *(20)* (obtained from allene [22]) or vinylthiols *(21)* (obtained from alkynes [23]). In this case there are three competing reactions in which the original thiol is consumed. These are (a) the formation of dithiol with excess H_2S, (b) the formation of sulfide with excess substrate, and (c) the self-addition (polymerization) of the monothiol.



Since hydrogen sulfide is not a particularly good chain transfer agent, telomerization of the substrate also occurs in many cases (see Section 2.1). Some of these secondary reactions oppose one another. The measures for increasing the selectivity are therefore often very limited, and the optimum conditions must be worked out separately for each individual case.

[22] *K. Griesbaum, A. A. Oswald, E. R. Quiram*, and *P. E. Butler*, J. org. Chemistry *30*, 261 (1965).

[23] See *e.g.* a) *F. W. Stacey* and *J. F. Harris jr.*, J. Amer. chem. Soc. *85*, 963 (1963); b) *O. P. Strausz, T. Hikida*, and *H. E. Gunning*, Canad. J. Chem. *43*, 717 (1965).

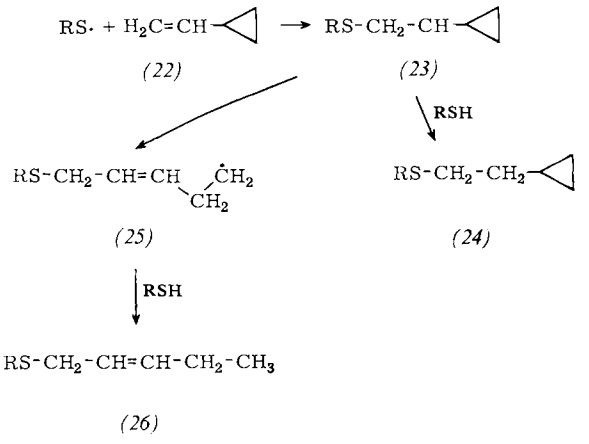
3.2. Addition of *O,O'*-Dialkylthiophosphoric Acids

Whereas in the addition of H_2S the monoadduct and the substrate enter into secondary reactions, part of the thiol is prematurely consumed in the addition of *O,O'*-dialkylthiophosphoric acids. On the basis of the stoichiometry (two moles of dialkylphosphoric acid are required per mole of unsaturated compound) and the spectroscopic detection of hydrogen bonds of the type $-P{=}O\cdots HO-$, it is assumed that one molecule of dialkylthiophosphoric acid is tied up by one molecule of the adduct [24].

Selective *S*-alkylation was always observed in the free-radical addition of the tautomeric *O,O'*-dialkylthiophosphoric acids [24], whereas, depending on the substrate [25], considerable *O*-alkylation has been observed in cationic additions.

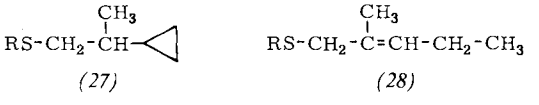
4. Influence of the Structure of the Unsaturated Compounds

The course of the addition depends mainly on the structure and the geometry of the unsaturated compound, which thus ultimately determines the orientation of the primary reaction, the nature of the intermediate free radical, and the result of the chain transfer.



4.1. Compounds with One CC Double Bond

4.1.1. Hydrocarbons

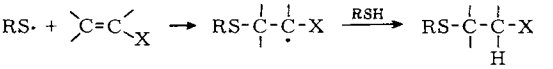


Additions to symmetrical molecules such as ethylene or the 2-butenes are generally slower than additions to olefins having an unsymmetrically substituted, particularly terminal, double bond.

Provided that the intermediate free radical is stable up to the chain transfer, additions to unsymmetrical olefins usually proceed in such a way that the principal product is derived from the more stable free radical intermediate. Thus, the anti-Markownikoff adducts of the terminal olefins styrene, propylene, and isobutylene and the adduct of the unsymmetrically trisubstituted olefin 2-methyl-2-butene have been obtained in very high yields (> 90 %) [3f].

Thiol additions to vinylcyclopropanes *(22)* occasionally follow a more complicated course. The first step leads to a free radical *(23)* which, depending on the rate of the chain transfer [*], either gives the normal adduct *(24)* or *via* the isomeric allylmethyl radical *(25)* gives the open-chain adduct *(26)*.

In agreement with this explanation, the addition of the good chain transfer agent thiophenol to 2-cyclopropylpropene gave only the normal adduct *(27)*, whereas addition of the poorer chain transfer agent methanethiol gave both adducts *(27)* and *(28)*. By varying the methanethiol/olefin ratio in the latter case, the proportion of the ring cleavage product could be varied between 38 % (10.8-fold excess of thiol) and 88 % (5-fold excess of olefin) [27].



Vinylcyclopropane and ring-substituted vinylcyclopropanes behave similarly [28].

4.1.2. Substrates with Hetero Atoms or Hetero-Atom Groups in a Vinylic Position

Hetero atoms or hetero-atom groups have a strong activating and directing influence. If the double bond is substituted on only one side with such groups, the additions generally proceed very rapidly and very selectively (see Table 1).

If the double bond is substituted on both sides, but with different groups, it is sometimes difficult to pre-

[*] Free-radical cyclopropylmethyl/allylmethyl rearrangements have been repeatedly observed in recent years; they may involve homoallyl radicals as intermediates [26].

Table 1. Free-radical additions of thiols to substrates bearing hetero atoms or hetero-atom groups in the vinyl position [3f].

$RSH + R^1HC{=}CHX \rightarrow RS{-}CHR^1{-}CH_2X$

R	R^1	X	Yield (%)
$HOCH_2CH_2$	H	Cl	100
C_2H_5	H	OC_4H_9	97
CH_3	H	$OCOCH_3$	93
CH_3	H	CHO	86
$HOCH_2CH_2$	H	CN	91
$C_6H_5CH_2$	CH_3	COOH	95

dict the preferred orientation, since the orientation can often be decided by seemingly insignificant structural differences. For example, the orientation in the addition of aliphatic thiols to substituted methyl β-alkylthioacrylates or β-arylthioacrylates *(29)* is strongly dependent on the nature of the alkyl or aryl group R^1 [29].

$$RSH + R^1S{-}CH{=}CH{-}COOCH_3 \rightarrow R^1S{-}CH_2{-}\underset{SR}{CH}{-}COOCH_3$$
(29) *(30)*

+

$$\begin{matrix} RS \\ \diagdown \\ CH{-}CH_2{-}COOCH_3 \\ \diagup \\ R^1S \end{matrix}$$
(31)

R	R^1	*(30)*, Yield (%)
CH_3	C_6H_5	95
C_2H_5	CH_3	75
CH_3	CH_3CO	50

The ability of the double bond to take up thiyl radicals can be appreciably decreased by substitution of both sides with similar hetero atoms or hetero-atom groups.

Thus, diallyl maleate and diallyl fumarate are attacked only on the allyl double bond by methanethiol and trimethylenedithiol [30] whereas in allyl acrylate, the acrylic double bond, which is substituted on only one side, reacts preferentially [31].

4.1.3. Substrates with Hetero Atoms or Hetero-Atom Groups in an Allylic Position

Additions to substrates of the type *(32)* lead in the first step to a β,β′-disubstituted radical *(33)*, which can in principle react further in three ways, *i.e.* by dissociation into the starting components, β′-elimination to form the allyl sulfide *(34)*, or chain transfer to give the adduct *(35)*.

$$RS\cdot + CH_2{=}CH{-}CH_2X$$
(32)

$$\Downarrow\Uparrow$$

$$RS{-}CH_2{-}\dot{C}H{-}CH_2X \xrightarrow{RSH} RS{-}CH_2{-}CH_2{-}CH_2X$$
(33) *(35)*

$$\Downarrow\Uparrow$$

$$RS{-}CH_2{-}CH{=}CH_2 + X\cdot$$
(34)

The relative importance of these competing reactions depends on several factors, such as the relative stability of the radicals RS· and X· and the rate of the transfer step. The results of some thiol additions to allyl sulfides and allyl halides are listed in Table 2.

The first two examples in Table 2 again show the results of the thiol additions to allyl sulfides discussed in Section 2.2. A similar situation is found for allyl halides. Bromides suffer more β′-elimination than chlorides, and the β′-elimination in the case of chlorides can be almost completely suppressed by using the good hydrogen donor thiolacetic acid [32]. Additions to substrates with more than one halogen substituent in the allyl position [33,34] also proceed anomalously, as is shown by the following example:

$$C_6H_5SH + H_2C{=}CH{-}CCl_3 \rightarrow C_6H_5S{-}CH_2{-}CHCl{-}CHCl_2 + C_6H_5S{-}CH_2{-}CH{=}CCl_2$$

Table 2. Reaction products of allyl sulfides and allyl halides with equimolar quantities of thiols.

[a] Based on the sum of all the reaction products. The conversions are between 57 and 100%.

The additions to vinyloxiranes *(36)*, which result in ring cleavage, also belong to this group formally. However, since both a C–O and a C–C bond can be broken, depending on the substitution of the oxirane ring, and since vinylcyclopropanes can also undergo this reaction (see Section 4.1.1), the attachment of a hetero

[29] *W. H. Mueller*, J. org. Chemistry *31*, 3075 (1966). The reaction mechanism is further complicated by cleavage of thioacetoxyl (R = acetyl) from the primary radical.

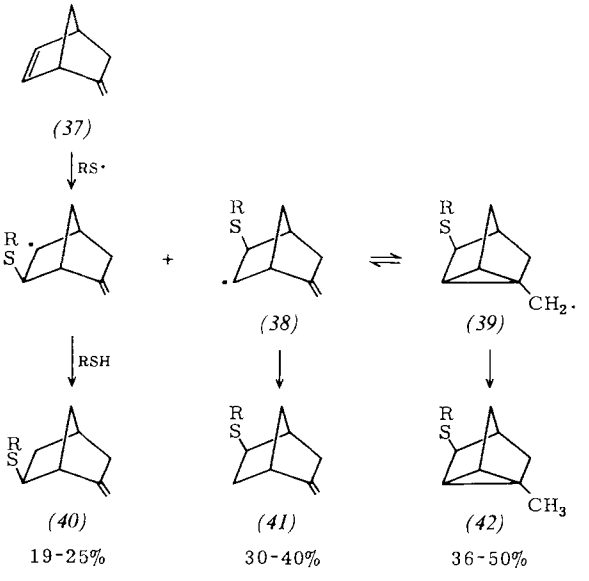
atom to the allyl position cannot be the sole reason for the anomalous course of the addition. There is one difference, however: while only partial ring opening occurs in the addition to vinylcyclopropanes, the heterocycle in vinyloxiranes is completely opened in one direction or the other [35].

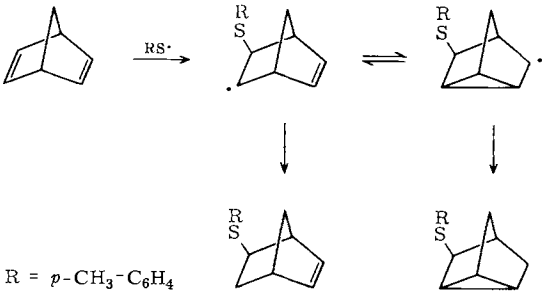
4.2. Compounds with Several CC Double Bonds

4.2.1. Isolated Double Bonds



On addition of thiols to compounds with two or more isolated double bonds, the double bonds are attacked independently of one another and in the ratio of their individual reactivities, unless special steric factors are operative. The additions are governed by the same rules as in the case of monoolefins.

If, on the other hand, the double bonds are unequally activated, selective addition is often possible. Examples for this behavior with acyclic substrates are the preferred reactivity of the acrylic double bond in allyl acrylate and -methacrylate [31] and the exclusive addition of thiols to the allyl double bonds in allyl maleate and allyl fumarate [30], as mentioned earlier:



$$2\,RSH + H_2C{=}CH{-}CH_2{-}OCOCH{=}CHCOO{-}CH_2{-}CH{=}CH_2 \rightarrow (RS{-}CH_2{-}CH_2{-}CH_2{-}OCOCH)_2$$

The selective addition is particularly pronounced for many cyclic diolefins. In dicyclopentadiene [36–38] and in 5-methylenenorbornene *(37)* [39], for example, attack takes place preferentially on the strained double bond in the bicyclic system, while the unchlorinated double bond is preferentially attacked in the chlorinated olefins aldrin [37,38], hexachloronorbornadiene *(44)* [40,41], and hexachloromethylenenorbornene *(43)* [42].

The addition to bicyclic systems of this nature is often accompanied by rearrangements. Thus the addition of thiophenol to *(37)* leads not only to the two isomers *(40)* and *(41)* to be expected from an *exo* addition to the more reactive double bond but also to considerable quantities of the tricyclic adduct *(42)* [39]. This latter product is evidently formed by intermediate cyclization of the homoallyl radical *(38)* to give the cyclopropylmethyl radical *(39)*.

The partial formation of tricyclic compounds has also been reported for the addition of *p*-thiocresol to norbornadiene [43].

The strong tendency for cyclopropylmethyl radicals to be formed in these cases is probably due to the special steric conditions in the bicycloheptane system. Addi-

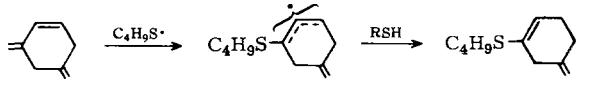
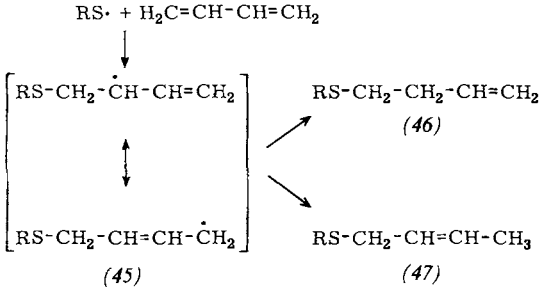
tions to vinylcyclopropanes and vinyloxiranes, on the other hand, are accompanied by ring opening, as discussed in Sections 4.1.1. and 4.1.3.

Unlike in the reactions of *(37)* and of norbornadiene, skeletal rearrangements were observed instead of homoallyl rearrangements in the addition of thiols [44] to the partly chlorinated systems *(43)* and *(44)*.



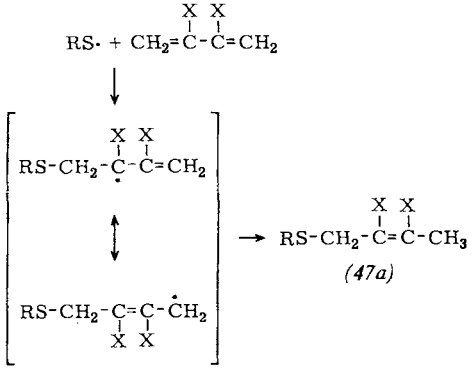
(43)

(44)



4.2.2. Conjugated Double Bonds

Additions to conjugated systems are generally faster than additions to comparable isolated double bonds, owing to the additional stabilization of the intermediate allyl radicals by resonance. Therefore, selective addition to the conjugated system can often occur in substrates that contain double bonds of both types [45].



However, this increased reaction rate is possible only if the double bonds are truly conjugated. This is not so *e.g.* in the ground state of *cis*-1,3-cyclooctadiene, since energy factors favor a conformation in which the arrangement of the double bond system is non-planar. In agreement with this, *cis*-1,3-cyclooctadiene reacts only 2.9 times faster than 1-octene with thiophenol, whereas the truly conjugated substrates 1,3-cyclohexadiene and 2,3-dimethylenebicyclo[2.2.1]heptane react 2520 and 3078 times faster, respectively [46].

The orientation is a more complicated problem in the additions of thiols to conjugated systems than in the additions to simple olefins. The primary attack of the thiyl radical is again such as to lead preferentially (but not always exclusively [47]) to the more highly substituted allyl radical. Since such a radical [*e.g. (45)*] has two potential reaction centers, however, the resulting orientation is now additionally dependent on the course of the chain-transfer reaction and can lead both to a 1,2- *(46)* and to a 1,4-adduct *(47)*.

(45) *(46)* *(47)*

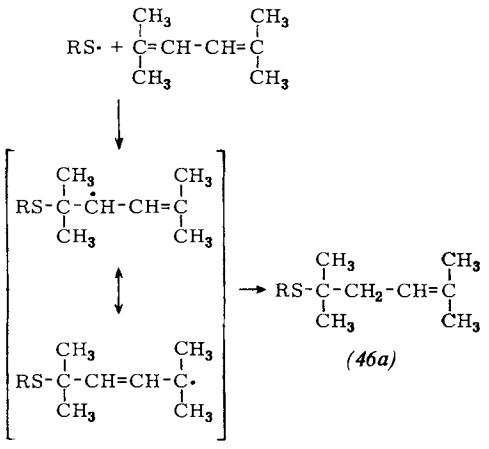
It has been shown in a detailed study however that the chain transfer occurs preferentially at the less substituted free-radical center of the intermediate allylic radical, with the preferential formation of adducts of a thermodynamically controlled reaction [48]. In agreement with this, additions to the non-terminally substituted dienes 2,3-dimethylenebicyclo[2.2.1]heptane [46],

(47a)

chloroprene, isoprene, and 2,3-dimethylbutadiene [48] lead with selectivities of 75–99 % to the 1,4-adducts *(47a)*, whereas the addition to the terminally substi-

[44] In the addition to *(43)*, only aliphatic thiols reacted at appreciable rates, whereas *(44)* also reacted rapidly with aromatic thiols.

[45] *R. E. Benson* and *R. V. Lindsey jr.*, J. Amer. chem. Soc. *81*, 4253 (1959).

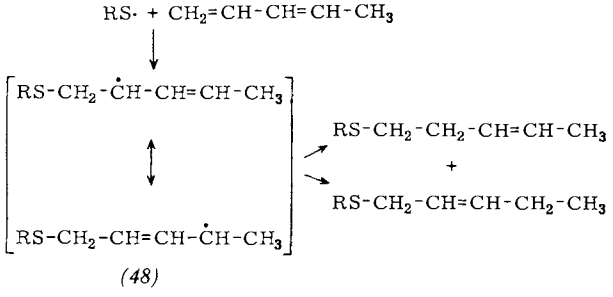


[46] *J. A. Claisse* and *D. I. Davies*, J. chem. Soc. (London) *1965*, 4894.

[47] Thus, in the addition to isoprene and piperylene, up to 25% and up to 20%, respectively, of the 4,1-adducts were found; these were presumably formed *via* the less stable radicals

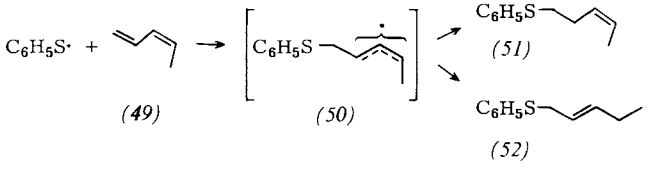
$RS-CH_2-\dot{C}H-CH=CH_2$ and

$RS-CH(CH_3)-\dot{C}H-CH=CH_2$.



[48] *A. A. Oswald, K. Griesbaum, W. A. Thaler*, and *B. E. Hudson jr.*, J. Amer. chem. Soc. *84*, 3897 (1962).

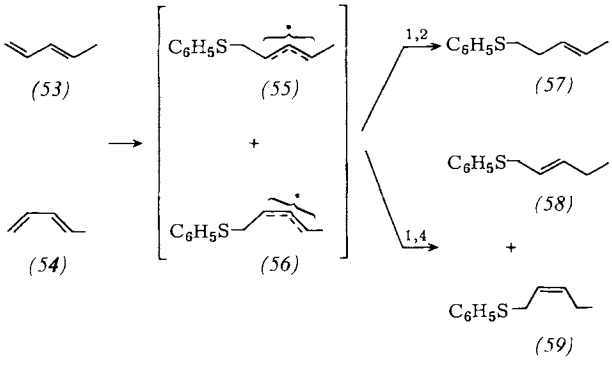
(46a)



tuted system of 2,5-dimethyl-2,4-hexadiene leads mainly to 1,2-adducts *(46a)* [49,50].

If the two free-radical centers of the intermediate allylic radical are comparably substituted, neither of the two orientations is appreciably favored. Examples of such cases are cyclopentadiene [46], cyclohexadiene [46], and piperylene [48], which give secondary allyl radicals such as *(48)*, and thus yield 1,2- and 1,4-adducts in roughly equal proportions [47].

(48)

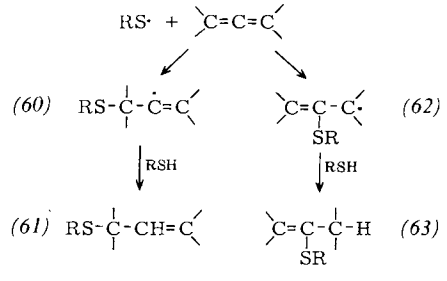


The stereochemistry of these additions has been examined in detail for the additions to piperylene [51]. With fast chain transfer [addition of thiophenol or co-oxidations (see Section 5.2)], the additions proceed stereoselectively with substantial retention of the geometry of the initially formed allyl radical. Thus the 1,2-adduct of thiophenol and *cis*-piperylene *(49)* contained 92 % of the *cis* isomer *(51)*, and the 1,4-adduct which was also obtained, contained 99.9 % of the *trans* isomer *(52)*. The following explanation was advanced for

(49) *(50)* *(51)* *(52)*

this result: *cis*-piperylene exists only in the transoid form *(49)*; thus, if the intermediate free radical *(50)* can retain its conformation until chain transfer occurs, it must give the adducts *(51)* and *(52)* obtained.

The 1,2-adduct obtained from *trans*-piperylene and thiophenol contained 96 % of the *trans* isomer *(57)*, while the 1,4-adduct contained the *cis* *(59)* and the *trans* isomer *(58)* in a ratio of 9:91, respectively. This is explained by assuming that *trans*-piperylene exists in a transoid form *(53)* and in a cisoid form *(54)*. If the geometry is retained in the allyl radical [*(55)* and *56)*], this must lead to two 1,4-adducts [*(58)* and *(59)*].



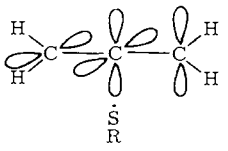
(53) *(54)* *(55)* *(56)* *(57)* *(58)* *(59)*

For the stereoselectivity observed with piperylene, it is an essential prerequisite that the olefin does not isomerize during the reaction, and that the chain transfer takes place before any possible isomerization of the intermediate allylic radical. The latter condition does not appear to be fulfilled in the addition of aliphatic thiols to piperylene, since these additions are not stereoselective, though piperylene does not isomerize during the addition [51].

4.2.3. Cumulated Double Bonds

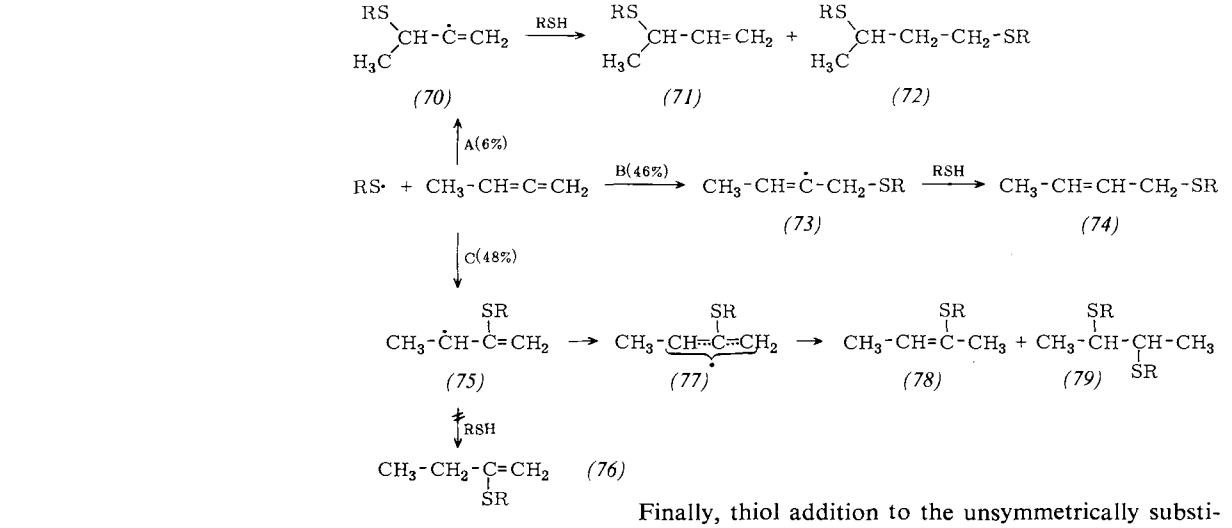
Additions to allenes can proceed in two directions. Attack on the end of the cumulated system leads to an allyl sulfide *(61)*, while attack at the center yields a vinyl sulfide *(63)*.

(60) *(61)* *(62)* *(63)*



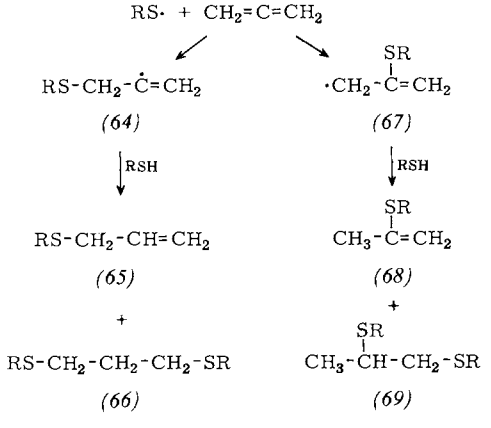
It may appear at first sight that the second path, *i.e.* attack on the central C atom, should be favored, since it involves a resonance stabilized allylic radical *(62)*, whereas a vinyl radical *(60)* is formed in the alternate case.

Since the double bonds are perpendicular to each other, however, resonance stabilization is impossible in the allene system; the first intermediate *(62)* is accordingly only an *alkyl* radical.



[49] *A. A. Oswald, B. E. Hudson jr., G. Rodgers,* and *F. Noel,* J. org. Chemistry *27*, 2439 (1962).

[50] Since no terminally substituted 1,3-dienes had been studied earlier only 1,4-additions were known for a long time. This occasionally led to the inaccurate conclusion that conjugated dienes undergo only 1,4-additions, irrespective of their structure [3f]. This hypothesis is no longer tenable according to [48, 49].



[51] *W. A. Thaler, A. A. Oswald,* and *B. E. Hudson jr.*, J. Amer. chem. Soc. *87*, 311 (1965).

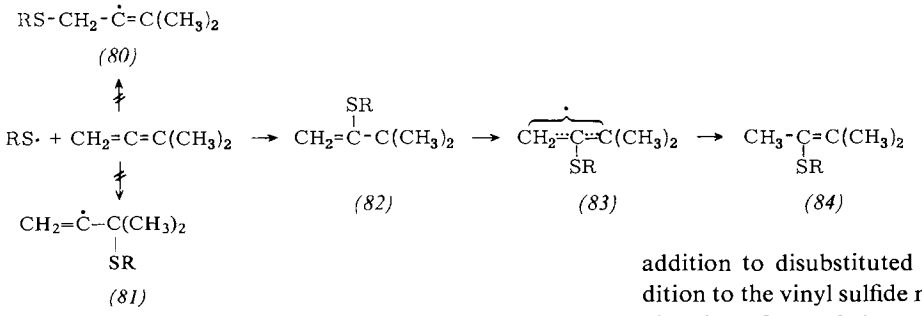
Hence, attack on the central C atom must not be energetically favored necessarily, since the difference in stability between vinyl and alkyl radicals is smaller than that between vinyl and allyl radicals. It has been found that the point of attack of the thiyl radical on the allene system at room temperature depends on the substitution of the allene [52]. Thus allene, in which a vinyl radical *(64)* competes with a primary radical *(67)*

gives only about 10 to 20 % of adducts resulting from attack on the central C atom [*(68)* and *(69)*], but 80 to 90 % of adducts formed by reaction on the terminal C atom [*(65)* and *(66)*] [52, 53].

In the case of methylallene, on the other hand, the first intermediates are vinyl [*(70)* and *(73)*] and secondary alkyl radicals [*(75)*] and the adducts *(78)* and *(79)* resulting from attack on the central C atom (path C) and the adducts *(71)*, *(72)*, and *(74)* resulting from the two possible attacks on the ends of the allene system (paths A and B) are formed in roughly equal quantities [52]. It is interesting to note that path C does not yield the adduct *(76)* to be expected on abstraction of hydrogen from *(75)* but rather the adducts *(78)* and *(79)*.

This can be explained by the conversion of the initial *secondary* radical *(75)* into the *allyl* radical *(77)* prior to chain transfer. The subsequent reaction of *(77)* will then be governed by the same rules as in the reactions of conjugated dienes, *i.e.* the hydrogen is transferred to the least substituted atom of the free-radical system. This leads to the thermodynamically more stable monoadduct *(78)*.

Finally, thiol addition to the unsymmetrically substituted 1,1-dimethylallene, in which vinyl [*(80)* and *(81)*] and tertiary alkyl radicals *(82)* could be formed, leads exclusively to the adduct *(84)* [52], which results from attack on the central C atom. As in the case of methylallene, the hydrogen is transferred to the least substituted atom of the free-radical system of the allylic radical *(83)* that evidently occurs as a secondary intermediate.



The dependence of the orientation on the reaction conditions has been investigated in some detail for allene. The selectivity for an attack on the end of the allenic system decreases with rising temperature [53, 54]. This phenomenon is particularly pronounced when the reactions are carried out in solvents. Thus, the reaction of a 1 molar solution of thiophenol and allene in benzene yields about 80 % of adducts resulting from a peripheral attack at 20 °C, about 51 % at 81 °C, about 31 % at 120 °C, and only 4 % at 140 °C [54, 55]. The thiol/allene ratio also appears to influence the orientation. The ratio of products resulting from peripheral attack to those formed by central attack increases linearly with increasing thiol concentration and reaches a constant value of approximately 3:1 if a threefold or higher excess of thiol is used [54].

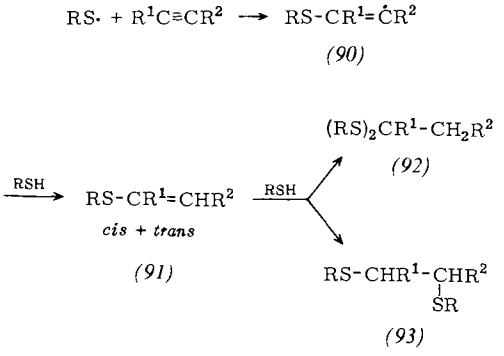
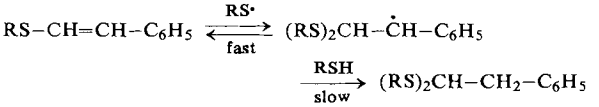
[54] *E. A. Haiba*, J. org. Chemistry *31*, 776 (1966).

[55] Similar observations were made earlier, though not in a systematic study of this matter: *H. J. Van der Ploeg, J. Knotnerus*, and *A. F. Bickel*, Recueil Trav. chim. Pays-Bas *81*, 775 (1962).

4.3. Compounds with CC Triple Bonds



The course of free-radical additions of thiols to alkynes is basically similar to that described for alkenes. The few comparative studies carried out so far have shown however, that alkenes react more rapidly than the analogous alkynes. For example, in an equimolar mixture of propene and propyne, the propene reacts about 1.2 times as rapidly as the propyne [10]. This difference is still more pronounced in vinylacetylene, which, depending on the thiol, gives between 10 and 100 % of the products *(88)* and *(89)* resulting from addition to the double bond [56]. The high selectivity in this case may, however, also be due to the fact that the radical *(87)* can be stabilized by resonance [57] whereas in the vinyl radical *(85)* this would require the loss of the double bond conjugation.



Addition to the triple bond leads *via* a vinyl radical *(90)* to *cis-trans* isomeric vinyl sulfide monoadducts *(91)* which can then add a further molecule of thiol more or less selectively and rapidly, depending on the substituents R, R^1, and R^2.

Thus the most important problems in such additions are: the orientation in the two addition steps and their relative rates, as well as the stereochemical course of the monoaddition.

The *orientation* is basically governed by the same rules as in the addition to alkenes. Monosubstituted acetylenes are attacked on C-1, whereas the position of the addition to disubstituted acetylenes and of the diaddition to the vinyl sulfide monoadducts depends on the directing effect of the substituents. Monoalkylacetylenes generally give vicinal diadducts [*(93)* where R^1 = H], while monoarylacetylenes give geminal diadducts [*(92)*, where R^1 = H].

Since the vinyl sulfides or vinyl thiols formed in the first addition step are generally more reactive than the alkynes from which they are derived, most thiol additions to alkynes are accompanied by at least partial diaddition. Exceptions to this rule are additions to aryl-substituted acetylenes, in which, owing to the stability of the intermediate benzyl radical *(94)*, the addition of the second thiyl radical is strongly reversible and thus reduces the extent of the diaddition:

The *stereochemistry of the addition* has been studied in detail on phenylacetylene [20] and 1-hexyne [21]. The stereoselectivity was strongly dependent on the molar ratio of the reactants, particularly in the additions to phenylacetylene. With excess thiol, the ratio of the isomers *(98)* and *(99)* corresponded to that of the thermodynamic equilibrium. If, on the other hand, equimolar quantities or an excess of the alkyne were used, the *cis*-adducts could be obtained with very high selectivities in some cases (Table 3).

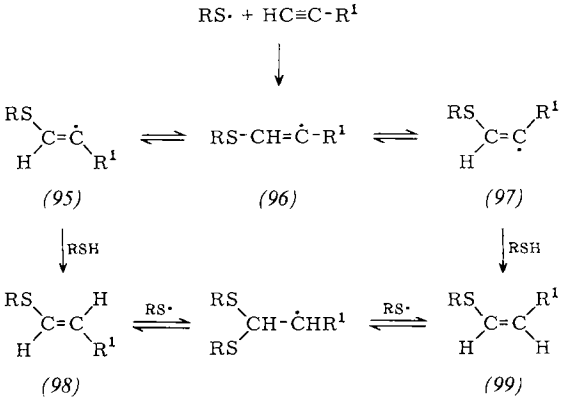


Table 3. Dependence of the stereochemical course of the additions to alkynes on the relative concentrations of the reactants.

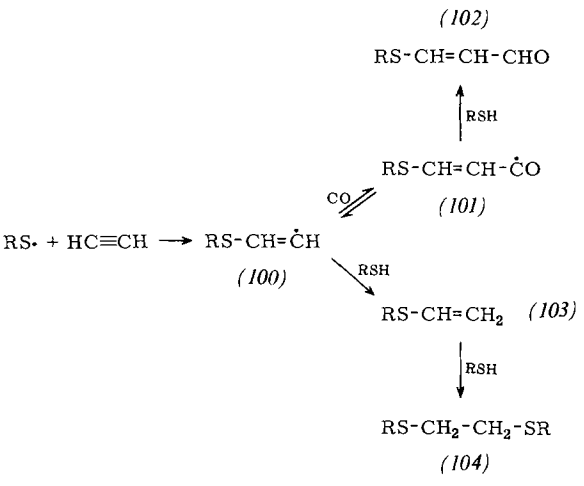
Thiol	Alkyne	Thiol : Alkyne	*cis*-Adduct (%)	Ref.
C_6H_5SH	$C_6H_5C{\equiv}CH$	20 : 1	16	[20]
C_6H_5SH	$C_6H_5C{\equiv}CH$	1 : 1	56	[20]
C_6H_5SH	$C_6H_5C{\equiv}CH$	0.05 : 1	>95	[20]
CH_3SH	$C_6H_5C{\equiv}CH$	1 : 1	84	[20]
CH_3COSH	$C_4H_9C{\equiv}CH$	1 : 1	73	[21]
CH_3COSH	$C_4H_9C{\equiv}CH$	0.002 : 1	83	[21]

[56] *I. G. Sulimov* and *A. A. Petrov*, Ž. obšč. Chim. *2*, 767 (1965).

[57] Propargyl radicals, like allyl radicals, can be considerably stabilized by delocalization: *M. M. Martin* and *E. B. Sanders*, J. Amer. chem. Soc. *89*, 3777 (1967).

The question of the course of these stereoselective additions is very closely linked with that concerning the geometry of the intermediate vinyl radical. While it has been suggested occasionally that, like the alkynes from which they are formed, these reactive intermediates have a linear structure *(96)*, it has been deduced from more recent results that this is not so [58], but that the radicals *(95)* and *(97)* have a bent structure and equilibrate very rapidly with a low energy barrier [58a]. It is not certain whether the preferential formation of the *cis*-adducts *(99)* is due to preferred formation of the *cis*-radical *(97)* or merely to preferred chain transfer of this radical as compared to the *trans*-radical *(95)* that exists in equilibrium with it. This question is difficult to answer, since attempts at intercepting these radicals with excess thiol are always accompanied by side effects (isomerization of the monoadducts and/or diadduct formation).

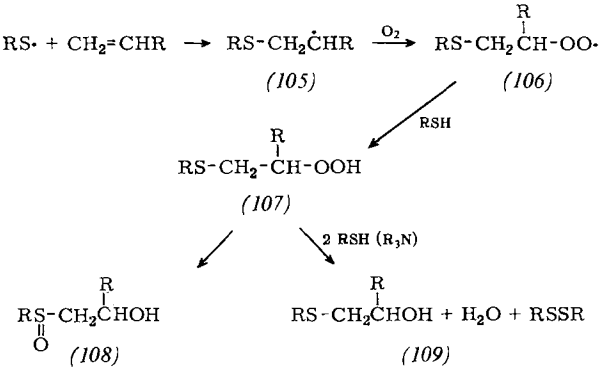
5. Three-Component Reactions



The addition of thiols to unsaturated compounds can be decisively modified by a third component. This third component may or may not be incorporated into the adduct.

5.1. Co-Carbonylations

The simultaneous action of thiols and carbon monoxide on alkenes [8] or alkynes [59] leads to partial formation of the ω-alkyl (or aryl) thioaldehyde containing one additional C atom, *e.g. (102)*. Since thiols are relatively good chain transfer agents, however, and since the reaction of the intermediate radical, *e.g. (100)*, with CO is reversible, these reactions also lead partly to the normal adducts, *e.g. (103)* and *(104)* even at high CO pressures.



[58] For recent work on this problem see: a) *J. A. Kampmeier* and *R. M. Fantazier*, J. Amer. chem. Soc. *88*, 1959 (1966); b) *R. M. Fantazier* and *J. A. Kampmeier*, *ibid. 88*, 5219 (1966); c) *L. A. Singer* and *N. P. Kong*, *ibid. 88*, 5213 (1966); d) *O. Simamura*, *K. Tokumaru*, and *H. Yui*, Tetrahedron Letters *1966*, 5141; e) *L. A. Singer* and *N. P. Kong*, *ibid. 1966*, 2089; f) J. Amer. chem. Soc. *89*, 5251 (1967); g) Tetrahedron Letters *1967*, 643; h) *P. H. Kasai* and *E. B. Whipple*, J. Amer. chem. Soc. *89*, 1033 (1967).

[59] *J. C. Sauer*, J. Amer. chem. Soc. *79*, 5314 (1957).

5.2. Co-Oxidations

Upon simultaneous interaction of oxygen and thiols with unsaturated compounds, the initially formed C radical [*(105)* and *(110)*] combines spontaneously with the O_2-diradical. The resulting peroxy radical [*(106)* and *(111)*] then undergoes chain transfer with the thiol to form a hydroperoxide [*(107)* and *(112)*]. In the presence of sufficient oxygen, therefore, a free-radical combination step is inserted between the addition of the thiyl radical and the normal chain transfer [60, 61].

The initially formed hydroperoxides *(107)* have been isolated in several cases of co-oxidations of alkenes [62–65]. On prolonged standing, however, particularly in solution, they are transformed into the isomeric hydroxy sulfoxides *(108)*. On the other hand, they can also be converted into the alkylthio or arylthio alcohols *(109)* by amine-catalyzed reduction with an excess of thiol. Since the addend and the reducing agent are identical in this case (RSH), the co-oxidation

[63] *A. A. Oswald* and *F. Noel*, J. org. Chemistry *26*, 3948 (1961).

[64] *A. A. Oswald*, *B. E. Hudson jr.*, *G. Rodgers*, and *F. Noel* J. org. Chemistry *27*, 2439 (1962).

[65] *A. A. Oswald*, *K. Griesbaum*, and *W. Naegele*, J. Amer. chem. Soc. *86*, 3791 (1964).

can also be directed in such a way that the alcohols *(109)* are formed directly by the use of an excess of thiol and addition of a tertiary amine as a catalyst [66].

$$3\ RSH + CH_2{=}CHR + O_2 \xrightarrow{(R_3N)} RS{-}CH_2{-}\underset{R}{CHOH} + RSSR + H_2O$$

(109)

The co-oxidation of thiols and phenylacetylene leads to the phenylglyoxal monothiohemiacetals *(113)*, presumably *via* the unstable vinyl hydroperoxide *(112)* [67].

$$RS\cdot + HC{\equiv}C{-}C_6H_5 \longrightarrow [RS{-}CH{=}\dot{C}{-}C_6H_5 \xrightarrow{O_2}$$

(110)

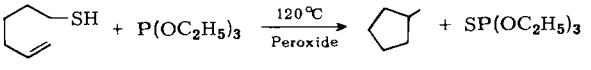
$$RS{-}CH{=}C(C_6H_5)OO\cdot \xrightarrow{RSH} RS{-}CH{=}C(C_6H_5)OOH]$$

(111) *(112)*

$$\rightarrow RS{-}\underset{HO}{CH}{-}\overset{O}{C}{-}C_6H_5$$

(113)

5.3. Thiol-Phosphite-Olefin Reactions



By combination of the well-known individual reactions (a) to (c)

$$RS^{\bullet} + P(OC_2H_5)_3 \rightarrow R^{\bullet} + SP(OC_2H_5)_3 \quad (a)$$

$$R^{\bullet} + CH_2{=}CHR^1 \rightarrow RCH_2{-}\dot{C}HR^1 \quad (b)$$

$$RSH + RCH_2{-}\dot{C}HR^1 \rightarrow RS^{\bullet} + RCH_2{-}CH_2R^1 \quad (c)$$

5-hexenylthiol *(114)* has been converted into the sulfur-free cyclization product *(115)* with a selectivity of up to 50 % [68].

(114) *(115)*

Preliminary attempts to extend this reaction principle to intermolecular alkylations have so far been unsuccessful.

6. Potential Applications

Derivatives of monothiophosphoric and dithiophosphoric acids, some of which have proved to be very active insecticides, play an important part in modern agricultural chemistry. Examples of such compounds are metasystox *(116)* and malathion *(117)* [69].

$$(CH_3O)_2P(O){-}S{-}CH_2{-}CH_2{-}SO{-}C_2H_5$$

(116)

$$(CH_3O)_2P(S){-}S{-}CH(CH_2{-}COOC_2H_5)COOC_2H_5$$

(117)

Compounds of this nature have in the past mainly been prepared by ionic substitutions or additions of *O,O'*-dialkyl monothiophosphates and -dithiophosphates with halogen compounds or unsaturated compounds respectively [70]. Compounds of this type have recently also been synthesized by direct free-radical addition of *O,O'*-diesters of monothiophosphoric and dithiophosphoric acids to dienes and alkynes [71]. These reactions led mainly to unsaturated adducts, of which *e.g.* the 1,4-monoadducts *(118a)–(118c)* with conjugated olefins and the 1,2-adducts *(119a)* and *(119b)* with allene have been described as very effective pesticides [72].

$(RO)_2P(S){-}S{-}CH_2{-}CX{=}CH{-}CH_3$ *(118)*

(a), R = CH_3, X = H
(b), R = C_2H_5, X = H
(c), R = C_2H_5, X = CH_3

$(RO)_2P(S){-}S{-}CH_2{-}CH{=}CH_2$ *(119)*

(a), R = CH_3
(b), R = C_2H_5

Derivatives of *O,O'*-dialkyldithiophosphoric acid are also important as oxidation inhibitors, and are widely used in motor oils [73]. Adducts formed by free-radical addition of *O,O'*-dialkyldithiophosphoric acids to dienes have recently also proved useful in this application [72, 74].

Among the co-oxidations, the reaction of the acetylenes, which leads to substituted glyoxal monothiohemiacetals *(120)* as the first isolable products (see Section 5.2), could be of preparative interest. These compounds are thermally very unstable, and can be decomposed in good yields into the corresponding thiol and glyoxal *(121)* by simple vacuum distillation, particularly when a very volatile thiol is used. Since the thiol is recovered, the overall reaction is thus a selective addition of one molecule of oxygen to the CC triple bond under the directing influence of a thiol [75].

$$RSH + O_2 + HC{\equiv}C{-}R^1 \rightarrow RS{-}CHOH{-}CO{-}R^1 \quad (120)$$

$$RS{-}CHOH{-}CO{-}R^1 \xrightarrow{\Delta} RSH + OHC{-}CO{-}R^1 \quad (121)$$

$$HC{\equiv}C{-}R^1 + O_2 \xrightarrow{(RSH)} OHC{-}CO{-}R^1$$

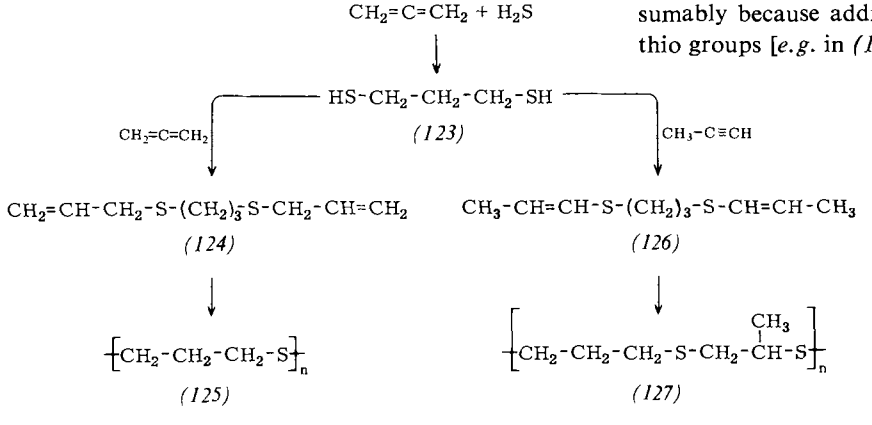
Polymers containing sulfur atoms in the chain are more or less resistant to hydrocarbon solvents, depending on their sulfur content, and are very widely used because of this property. The most important class are the Thiokols, which consist of alternating alkyl or alkoxy and polysulfide groups. Polymers containing only monosulfide groups, on the other hand, have so far found little use. The principal attempts to prepare such polymers were based on the polyaddition of dithiols to α,ω-dienes [76]. This approach had the disadvantage that the only readily obtainable α,ω-dienes, *i.e.* conjugated dienes, led to an adduct *(122)* with non-terminal double bonds, which are relatively inactive for further chain growth:

$$H{-}S{-}R{-}S{-}H + 2\ CH_2{=}CH{-}CH{=}CH_2 \rightarrow CH_3{-}CH{=}CH{-}CH_2{-}S{-}R{-}S{-}CH_2{-}CH{=}CH{-}CH_3$$

(122)

On the other hand, reactions of dithiols with allene or with propyne yield the adducts *(124)* and *(126)* respectively, which are more reactive than allene and propyne, and thus allow rapid chain growth. It was possible in this way to synthesize a series of polythioethers [77, 78]. The dithiol used was mainly trimethylenedithiol *(123)*, which is obtainable from allene and hydrogen sulfide [22, 79].



When this dithiol reacts with allene, the predominant addition to the terminal C atoms [53, 54] leads to a substantially linear polymer *(125)*, in which linear C_3 groups are separated by sulfur atoms. In accordance with this linear structure, polymers of this type are crystalline even at relatively low molecular weights [77]. On the other hand, the reaction of trimethylenedithiol with an alkyne, *e.g.* propyne, yields a polymer *(127)* in which linear and branched C_3 groups are separated by sulfur atoms [79]. This reaction is therefore suitable for the synthesis of strictly alternating copolymers *(127)* [78].

(131)

Such copolymers *(127)* do not tend to crystallize, presumably because additions of dithiols to 1-propenylthio groups [*e.g.* in *(126)*] do not proceed stereoselectively and thus lead to atactic products. Hence, these polymers are suitable for use as prepolymers for elastomers [78]. Owing to the simple stepwise growth, definite end groups can be introduced. An excess of dithiol gives polymers with terminal thiol groups, which can be used for vulcanization reactions or converted into other reactive end groups.

The stepwise growth also permits the introduction of additional functional groups into polymers of this type. For example the addition of a trithiol to the monomer

[78] *A. A. Oswald, D. N. Hall, K. Griesbaum*, and *W. H. Mueller*, Preprints of Papers, American Chemical Society Meeting, San Francisco, April 1968, Polymer Division, Vol. 9, No. 1, p. 648ff and p. 657ff.

[79] *K. Griesbaum* and *A. A. Oswald*, US-Pat. 3488270 (1970), Esso.

mixture gives trifunctional polymers, *e.g. (131)*, in quantities corresponding to the quantity of this third component added. These polymers are capable of undergoing the oxidative vulcanization with lead dioxide that is commonly used in Thiokol technology. The same result can be achieved by the addition of a reactive triolefin such as trivinylcyclohexane *(129)* to the reaction mixture. This method has the advantage that the initially formed trithiol *(130)* is as reactive as the dithiol *(128)* used for further growth [78].

An interesting variant is the introduction of hidden functional groups into the polymer chain. By making use of the difference in reactivity between the allyl and the central double bond [30] (see Section 4.2.1), for example, diallyl maleate or diallyl fumarate *(133)* can be

built into the growing chain *(132)* in such a way that the central double bond is retained. On the other hand, since this double bond reacts very rapidly with thiols under ionic conditions, the initially formed linear polymer *(134)* can be crosslinked to give vulcanizates of the type *(135)* [78] simply by addition of catalytic quantities of an amine and without adding special vulcanizing agents.

These examples may suffice to illustrate the possibilities of the free-radical addition of thiols to unsaturated compounds. It has been reported for most of the examples described that the reactions were initiated both by UV radiation and by γ radiation and that no difference was found in the selectivity of the reactions. This is a very important observation, since fears have occasionally been expressed that undesirable reactions, particularly ionic additions, which are known to exhibit different orientation effects, could compete or even dominate under the action of high-energy γ radiation. It may therefore be assumed that interest in the industrial use of thiol additions will grow concurrently with the increasing use of γ-ray sources in industry.

The Differential Calorimetric Study of the Reactivity of Unstable Compounds

By Erhard Koch[*]

The detection of unstable intermediates in chemical, photochemical, and radiation-chemical reactions can be greatly facilitated by the use of thermoanalytical methods. Special advantages are offered by differential thermal analysis (DTA), since it permits fast, easy investigation, from about −150 °C upward in some cases, over a wide temperature range. In this way processes that under normal conditions follow one another with immeasurable rapidity can be separated on the basis of their different temperature dependences. The great sensitivity of the method also allows the use of very dilute solutions, so that the studies can be confined to unimolecular processes.

The value of the method for the determination of energetic and kinetic data is illustrated by its application to the photochemically obtainable, unstable, ozonide-like epidioxydihydrofurans.

1. Introduction

Chemical reactions in solution usually comprise several individual processes, sometimes proceeding concurrently and sometimes consecutively. The strongest possible evidence of the fundamental correctness of an assumed reaction mechanism is the detection of an expected intermediate. However, the preparative isolation of substances that occur as intermediates is usually difficult. This is true in particular in radiation-chemical and photochemical reactions, in which the processes directly following the electronic excitation are so fast as to defy direct investigation.

Unstable intermediates can be made accessible even in these cases by the use of low temperatures if their further reaction requires appreciably higher activation energies than their formation. Even in photochemical processes, whose first propagation steps have very small activation energies [1–3], it is often possible to intercept intermediates, sometimes at extremely low temperatures [4–7].

However, attempts to isolate and identify unstable substances at low temperatures are frustrated by further difficulties in practice. On the one hand any concentration of reactive substances causes an increase in the importance of bimolecular processes, in which the substances change further. On the other hand, detection in solution is often difficult, since the current methods, such as NMR, IR, and UV spectroscopy, are not always selective enough, with the result that they also register solvents, catalysts, sensitizers, and starting materials.

These difficulties vanish if instead of the intermediates themselves, one investigates their reactions in solution. Since practically every reaction liberates or consumes heat, the change in temperature may be used as a general measuring criterion. Thus if a solution of an unstable substance is steadily heated, temperature changes characteristic of reactions of the intermediate are superimposed. Conversely, the absence of thermal effects in this investigation indicates that no unstable product was present.

This is the method of differential thermal analysis (DTA), which has found increasing use in the study of physical and chemical problems [8–12] since its discovery by *le Chatelier* (1887), *Callendar* (1897), and *Stansfield* (1898). These investigations were at first concerned with solid samples in the fields of geology, mineralogy, ceramics, metallurgy, and inorganic chemistry. The introduction of special thermocouples later made the use of temperatures above 2000 °C possible [13]. The extension of the working range to low temperatures [14–17] also opened the way to new applications.

In the investigation of liquid systems, it was possible to approach the investigation technique of isothermal calorimetry; owing to the uniformity of temperature that could be achieved in this case, the situation could be expected to be simpler than in the solid phase. With adequate mixing, it was possible to obtain experimental curves that allowed the determination not only of the thermochemical data but also of reaction rate constants over a wide temperature range (over 100 °C), and hence of activation energies and frequency factors [18–24].

By the further development of the temperature measuring and recording techniques, the attainable sensitivity of DTA equipment has been increased to such a degree that transformations of $< 10^{-7}$ mole of a substance in a small sample of a 10^{-4} M solution can nowadays be detected with certainty [22–24]. In contrast with conventional isothermal methods, the application of which took several days, the DTA method allows the determination of the enthalpy, activation energy, and entropy of a reaction in a few hours and from a single experiment, though sometimes with a loss of accuracy in the enthalpy. However, these values are often sufficiently accurate for rapidly accessible basic information.

These characteristics of the DTA method make it eminently suitable for the investigation of the thermal stability of chemical compounds even in dilute solutions and open up new possibilities for the detection of intermediates. Photochemical processes are particularly suitable for thermoanalytical investigation, since the energy drop between the starting materials and the final products is very large.

2. Measuring Technique

In differential thermal analysis, the test sample is steadily heated from a temperature at which no reaction occurs. The temperature of the sample is recorded directly, and simultaneously as the difference from the temperature of an inert, thermally equivalent reference sample [10, 11, 25]. By suitable design it is possible to ensure that a DTA apparatus is a serviceable adiabatic calorimeter (ideal case: no heat exchange with the environment), while the system under examination still follows the imposed temperature variation sufficiently quickly (ideal case: best possible heat exchange with the environment). Since the two requirements oppose each other, any instrument must be a compromise.

It seemed to us that what was needed was a design in which the thermal separation of the two systems, *i.e.* the external system whose temperature variation can be predicted and the internal system under investigation, was so decisive that each had its own uniform temperature. An arrangement that has proved its worth is one (Fig. 1) whose operation is formally similar to that of an apparatus for the cryoscopic determination of molecular weights [24]. Its features are:

1. a thermally insulated aluminum heating block having a uniform temperature, with two test tubes for 5 ml of sample and the same amount of reference solution;

2. a poor but definite heat transfer between the test tubes and the block *via* variable PVC, Cr—Ni steel, or Teflon inserts;

3. uniform thermostating of the sample and the reference sample by Teflon stirring disks, which are moved by a pulse-controlled solenoid;

4. very accurate measurement of the temperature difference (to within a few thousandths of a degree, copper-constantan thermocouples, pen recorder with a minimum measurement zone of 50 μV) [24, 26].

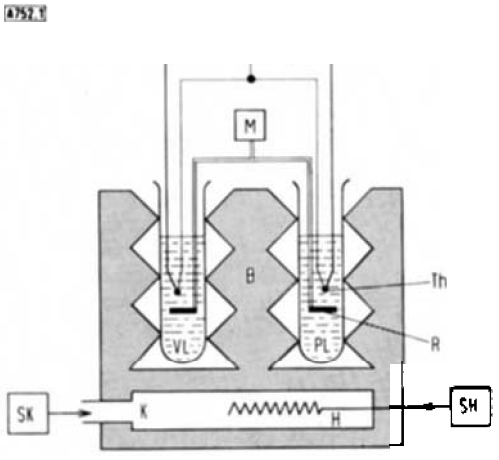

Fig. 1. Apparatus for differential thermal analyses in solution (schematic). B = heating block; H = heater; K = coolant inlet; M = solenoid; PL = sample solution; R = stirrer; SH = heating control unit; SK = cooling control unit; VL = reference solution; T = absolute temperature (°K); ΔT = temperature difference (°C); Th = thermocouple.

The apparatus can be cooled to about —150 °C and thermostated until the start of heating *e.g.* by finely metered injection of liquid nitrogen or of gaseous cold nitrogen.

The heating should be variable over a wide range. Control units ensuring a constant rate of temperature rise facilitate evaluation, since they allow adherence to standard conditions.

3. Evaluation of Recorded Curves

The result of DTA measurements is usually the variation of the temperature difference with time (thermogram).

As soon as the continuously heated system under examination reaches temperatures at which an exothermic (or endothermic) reaction begins, a finite temperature difference appears, rises (or falls) to a maximum (or minimum), and then returns to zero after the reaction (Fig. 2a). This is due to competition between the heat produced (or consumed) by the reaction and the heat exchange with the surroundings. The course

[25] See ref. [11], p. 117 ff.

[26] *B. Jankowsky*, Silikattechnik (1) *17*, 20 (1966); Chem. Abstr. *65*, 1358f. (1966).

of a DTA curve can thus be used to obtain information about the *kinetics* of the reaction in question, while the *reaction enthalpy* ΔH can be deduced from the overall thermal effect. The quantitative relation is [27–29]:

$$\Delta H = c\, Q_T/n_0 \int_0^\infty \Delta T/\mathrm{d}t \qquad (1)$$

In this equation, ΔT is the temperature difference between the sample container and the reference container, recorded as a function of time t (Fig. 2a), n_0 is the number of moles of reacting substance, Q_T is the heat content of the entire sample system, and c is a cell constant that describes the heat transfer behavior of the system.

Whereas in an adiabatic calorimeter the heat effect is found from the heat content and the temperature difference in relation to the initial state, extrapolated to time $t = 0$, the quantity in which we are interested in DTA is the area between the curve and the abscissa. The heat transfer, which is taken into account only for correction of the enthalpy value in the case of a calorimeter, becomes the principal factor in DTA.

For a constant heating rate (linear temperature rise in the reference container, see Fig. 2b), the reaction order is approximately given by:

$$m \approx 1.26 \sqrt{b/a} \qquad (2)$$

where a and b are fixed by the inflectional tangent of the DTA curve [11, 30, 31] (Fig. 2a).

Finally, for an irreversible reaction, the rate constant can be found for each point of the thermogram, and hence for each temperature in the range under investigation [19, 24, 31–36]:

$$k\,[T(t)] = \left[\frac{V|\Delta H|}{Q_T}\right]^{m-1} \frac{c\,\Delta T + \dfrac{\mathrm{d}\,\Delta T}{\mathrm{d}t}}{\left[c\int_t^\infty \Delta T\,\mathrm{d}t - \Delta T\right]^m} \qquad (3)$$

V = volume of sample solution.

This can be used to find the activation energy ΔE and the reaction entropy ΔS from the Arrhenius equation. A logarithmic plot of k against $1/T$ also provides a check on the reaction orders given by eq. (2), which are only approximate, since a straight line can be obtained only if the order adopted is correct.

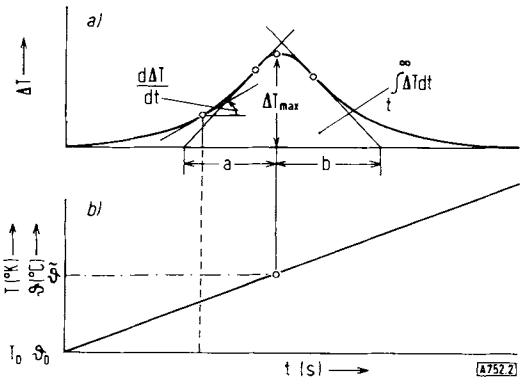

Fig. 2. a) Schematic course of a DTA curve. b) Temperature variation in the reference container.

The heat content Q_T of the sample system is the sum of the water equivalent of the vessel, stirrer, and thermocouple and the heat contents of the sample and reference solutions. The water equivalent is obtained from mixing experiments with liquids at various temperatures or by following a reaction having a known heat effect, *e.g.* a neutralization. Calibration by electric heating is also very simple. The specific heats of dilute solutions are practically the same as that of the pure solvent, which can be found for various temperatures from tables. If the reaction under investigation takes place within a sufficiently narrow temperature range (<30 °C) it can be based on the temperature at the maximum of the DTA curve.

The cell constant c is directly proportional to the effective thermal conductivity between the internal system under investigation and the external temperature-determining system, but inversely proportional to the specific heat (of the internal system) [28, 29]. To determine its value, *e.g.* equal quantities of the solvent to be used are placed in the sample tube and in the reference tube. After equalization of the temperatures, one heats slightly above the temperature of the external system, which is kept constant, and waits until the temperature difference has vanished. The cell constant is now found from the temperature difference extrapolated to time $t = 0$ and the total area above the abscissa [eq. (5a)], or at any point on the curve from its variation with time [eq. (5b)].

$$c = -[\Delta T]_0 / \int_0^\infty \Delta T \mathrm{d}t \qquad (5a)$$

$$c = -\frac{1}{[\Delta T]_t} \cdot \left[\frac{\mathrm{d}\,\Delta T}{\mathrm{d}t}\right]_t \qquad (5b)$$

4. General Notes on Application to Reactions in Solution

Simple information about the course of the reaction under investigation is obtainable merely from the shape of the thermogram (Fig. 3).

A preliminary investigation is often necessary first in order to establish whether the observed effect is due to a chemical or to a physical process. Thus phase transitions, for example, also cause temperature changes (cf. Scheme 1). Interference of this nature can be recognized by repetition of the DTA with the same sample; they usually disappear at sufficiently high dilutions.

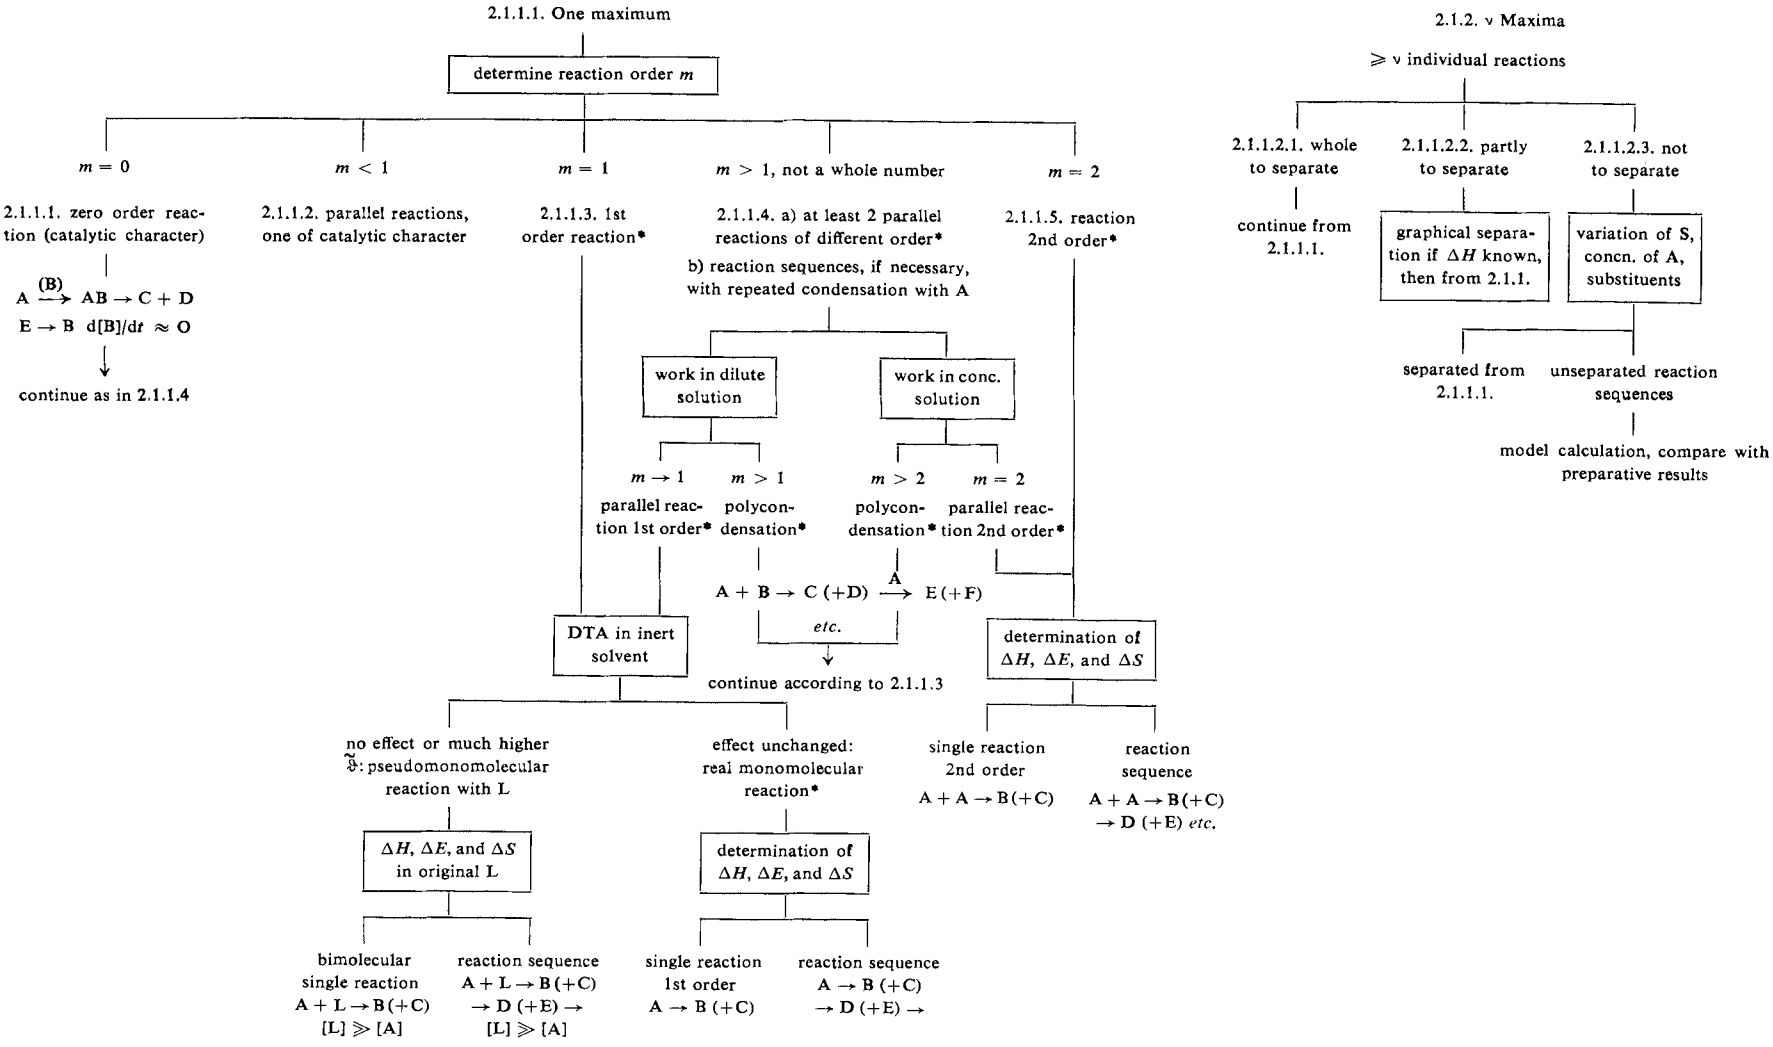
The pure solvent can generally be used as the reference solution for dilute solutions. If higher reactant concentrations are necessary, the appropriate quantity of a substance that corresponds as closely as possible in its physical data (solubility, specific heat, vapor pressure depression) to the mean of the values of the starting materials and of the final products must be added to the reference sample.

If only *one* reaction takes place during the measurement, the DTA curve also contains only one maximum, and the reaction order is found from the inflectional tangents (types a–d in Fig. 3). On the other hand, it cannot always be assumed from the presence of only one maximum that only one reaction occurs.



If a whole-number reaction order m is obtained with only one maximum, an exact kinetic evaluation is possible if ln k varies linearly with $1/T$. The first estimate of enthalpies, rate constants, and activation energies is obtained from the height of the ΔT maximum (ΔT_{max}) at a constant heating rate $\dot{\vartheta}$ and the temperature of the reference solution at the time of this maximum ($\tilde{\vartheta}$, referred to in the following discussion as the reaction temperature), which are particularly suitable for fast characterization and for comparison of different thermograms. The enthalpy ΔH of a first order reaction in thoroughly mixed solutions is given [37] by

$$\Delta H \approx 0.034\, c \cdot \Delta T_{max}/(n_0 \dot{\vartheta}^{0.6}) \qquad (6)$$

[37] *E. Koch*, unpublished.

Scheme 2. Examination of unknown systems by DTA.

A = unstable substance used; L = solvent. * possibly with secondary reaction(s) that is (are) fast in relation to the initiation reaction.

$\tilde{\vartheta}$ temperature of the reference solution at ΔT_{max} (reaction temperature).

It has been shown for many examples[24,37] that rate constants of 10^{-2} to 10^{-3} s^{-1} are found at the maximum for $\dot{\vartheta} = 1.5$ °C/min under the same conditions. For a frequency factor of 10^{13} s^{-1}, such a reaction has a half-life of one hour about 20 °C below $\tilde{\vartheta}$, irrespective of the reaction enthalpy.

Fractional reaction orders point to parallel reactions of different orders or sequences of reactions in which repeated condensation of intermediates with the starting material can occur. In these cases the type of curve must depend on the concentration, and this allows the separation of parallel steps (cf Scheme 2).

Several maxima in the DTA curve are always evidence of at least as many reactions. A reliable quantitative evaluation is possible if the areas corresponding to the various processes overlap only slightly, or if the heat effects and reaction orders of the various processes are known where overlapping is pronounced (cf. Fig. 3, types f and g). A detailed mechanistic study requires a systematic variation of the parameters of the DTA (heating rate $\dot{\vartheta}$[24,30,31,38], starting temperature ϑ_0, and possibly the composition of the reference solution) and of the composition of the sample. Other diagnostic possibilities are offered by interruption of the analyses for a short time to allow intermediates already present to react with added substances at a constant block temperature, after which the temperature is further raised.

An example of the combined application of isothermal and non-isothermal methods is the diazotization of an aromatic amine at 0 °C (determination of ΔH; type a in Fig. 3) and the subsequent loss of nitrogen on continuous heating to form the phenol (determination of ΔH, ΔE, and ΔS; type c in Fig. 3). The thermodynamic quantities found in this way agree well with those obtained by conventional methods[19,24,39].

The non-isothermal methods[40] are preferable for the investigation of unknown systems, since only then is a universal check for secondary reactions possible. Schemes 1 and 2 show that the reaction course can often be recognized by suitable DTA programs without the use of other methods. If the processes can be separated, the reaction enthalpies found in accordance with Hess's law often allow the assignment of the reactions studied to a proposed mechanism. The increments for the energies of formation at temperatures down to −80 °C differ by at most a few kilocalories from the standard values at +20 °C. In photochemical reactions, moreover, the differences in the heats of solvation and vaporization between the starting materials and the final products are relatively small in comparison with the total energy decrease, so that the best results are to be expected here.

If the processes cannot be separated, *e.g.* in a unimolecular reaction sequence in which the initiating reaction is rate-determining, the reaction enthalpy obtained must be assigned to the overall process. However, the activation energy found and the reaction entropy refer only to the first process. The detection of an intermediate and the determination of its activation parameters are then possible only if it can be produced from another unstable starting material that decomposes at a much lower temperature, and even then does so more rapidly than the intermediate.

In the case of complex reactions that are only partly separable can be clarified only by the use of preparative and of other diagnostic methods in conjunction with DTA, and by mathematical analysis of the curves with a computer.

5. Investigation of Photochemical Reactions

If the energy required to initiate a reaction is supplied to the system as light, the first step is the formation of biradical excitation products, which can often undergo fast secondary processes with non-radical components to give other biradical products. In many cases the activation energies of such secondary reactions are so low that the formation of the intermediates is immeasurably fast even at very low temperatures[1].

This behavior is observed in the photosensitized cycloadditions of O_2 to dienes and olefins[2,41–48], and also in the direct photolysis of diazomethane, alkyl azides, and hydrazoic acid[3,7,49,50], and to a lesser degree in the photosensitized synthesis of 1,2-dioxacyclohexanes and cyclobutanes[51–57]. Processes of this type contrast with the much more temperature-dependent photochemical reactions in which monoradical intermediates are formed, such as the photosensitized aut-

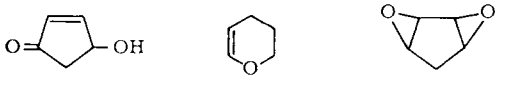
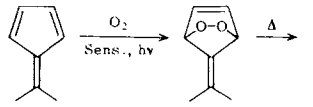
oxidation of alcohols introduced by dehydrogenation [45, 46, 58], sulfochlorination by *Reed*'s method, or light-induced polymerizations [59, 60].



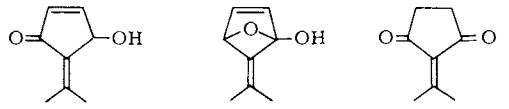
We chose systems of the first type for the investigation of unstable compounds, since intermediates of these reactions can occur even at very low temperatures, and thermograms can be obtained over a wide temperature range. Reactions that proceed with liberation or absorption of gases are favorable, since the quantity of primary product can be readily determined in these cases. Peroxides that are readily obtainable by photosensitized oxygen transfer, and whose preparative study requires extensive safety precautions in view of their tendency to decompose explosively, were very suitable for this purpose, particularly since it is known that oxygen bound in ozonide-like form can in certain circumstances be transferred to cyclic dienes with formation of epidioxides [37, 61–65].

The differential-calorimetric study of solutions that had been irradiated at −60 to −90 °C [6] showed firstly that in all cases where products different from those obtained at +20 °C were formed, thermal effects also occurred. Double maxima (*e.g.* for furfural, furfuryl alcohol), very broad, spread-out maxima (*e.g.* for β-ionone, 2-methylfuran in toluene) or fractional reaction orders (*e.g.* for furfurylamine) point to two or more partly concurrent processes. If heat effects observed are found not to be proportional to the photochemical primary conversion, the intermediates are unstable even during the exposure to light. Thermal secondary reactions will frequently be involved.

Interference due to secondary photochemical reactions can be recognized by further exposure to light after the principal process is complete. Thus in the photosensitized transfer of oxygen to cyclopentadiene *(1)* at

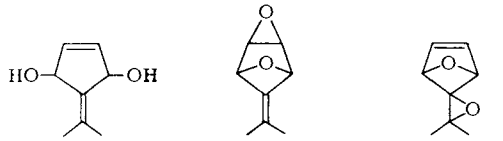


(1) *(2)*



(3) *(4)* *(5)*

20 °C, the compound *(3)* and possibly *(4)* formed *via (5)* are obtained, as well as unknown substances, on concentration and working up, whereas the primary peroxide (5,6-dioxanorbornene) *(2)* can be isolated at −10 °C [4]. This is photoisomerized in a way that is not yet known with Bengal pink as the sensitizer and with polychromatic light. Accordingly, the evolution of heat in differential thermal analysis always decreases further on exposure to light after the uptake of oxygen is complete. However, the photoisomerization (which does not take place when sodium vapor lamps are used in any case) can be eliminated from the energy discussion by extrapolation to exposure time $t = 0$. The agreement of the value of 60 kcal/mole found thermoanalytically for the reaction enthalpy with the difference in the heats of formation of *(3)* and *(2)* and the fact that the reaction order is around unity show that 4-hydroxy-2-cyclopenten-1-one *(3)* is formed here as the primary product of the rearrangement of the peroxide *(2)*. This shows clearly the analogy to 2,5-epidioxydihydrofuran (5,6,7-trioxanorbornene) [*(21)*, $R^1 = R^2 = H$], from which 5-methoxy-2(5*H*)-furanone *(34)* (malealdehydic acid pseudoester) is formed [5, 66–68].



After the photosensitized O_2 transfer to ω-dimethylfulvene *(6)* at +20 °C, only polymeric reaction mixtures, which were assumed to contain the compounds *(8)*–*(17)* of products of further reactions, could be iso-

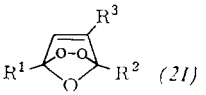
lated in some cases[69]. *(8)–(17)* are thought to be formed *via* the peroxide *(7)*. The reaction evidently stops at the peroxide stage at −80 °C. This can be shown thermoanalytically. In a 0.005 M photo-oxidized methanolic solution, 69 kcal/mole are liberated in a first order reaction; this is in agreement with the formation of the compounds *(8)*, *(9)*, and/or *(10)* from *(7)*. Thus seven of the ten formulated compounds can be ruled out on energy grounds in this case. Other processes, some of them endothermic, occur above +50 °C.

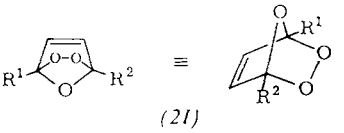


The peroxides formed by sensitized photoadditions at low temperatures liberate very large quantities of energy (up to ≈90 kcal/mole), on decomposing. On the other hand, the products formed in the cold by the photolysis reactions investigated so far, *e.g.* in the elimination of N_2 from diazoacetic ester or azides, exhibit only small energy transformations, if any. Thus the absence of DTA effects in the case of methyl azide solutions photolyzed at −80 °C[3] indicates that the stable final product, hexamethylenetetramine, is formed even at this temperature. In the case of hydrazoic acid, on the other hand, the photolysis of which in methanolic solution leads to ammonium azide, it should be possible to intercept the intermediates, since several exothermic and endothermic rearrangements are observed here, depending on the exposure time and concentration. According to investigations carried out

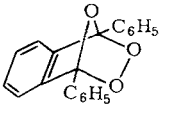
so far[3,70], excited HN_3 should first give diimide *(18)* in this case, but a side reaction with methanol should also lead by formal insertion of NH to the unstable aminomethanol *(19)*, which would give formaldehyde by loss of ammonia, and methylimine *(20)* by loss of water.

6. Behavior of the Ozonide-Like Epidioxydihydrofurans (5,6,7-Trioxanorbornenes)

A reaction that proceeds rapidly even at very low temperatures in solution is the photosensitized cycloaddition of oxygen to the furan ring[2,5,66,71]. This process, which is of the Diels-Alder type, leads initially to the ozonide-like epidioxydihydrofurans *(21)* with a vanishingly small activation energy. However these are generally no longer stable at 20 °C, and only reaction products or polymeric peroxides are isolated. Only in the case of diphenylisobenzofuran has the oxonide-like peroxide *(22)* (which is explosive above 20 °C)



(21)



been isolated in the crystalline form[72]. *(21a)*, $R_1 = R_2 = H$, the mono-oxonide of cyclobutadiene, which is the simplest member of this new class of compounds, was isolated at −100 °C[5]. Similar compounds are known in the cyclobutane series[73–75].

On exposure to light in methanol at 20 °C, 2-methyl-, 2,5-dimethyl-, 1,2,3,4,5,6,7,8-octahydrodibenzo-, and 3,6-dimethyl-4,5,6,7-tetrahydrobenzo[b]furan (menthofuran) give the alkoxyhydroperoxydihydrofurans *(25)* and *(26)* as stable products of the addition of methanol to the initially formed ozonides[71].

The malealdehydic acid pseudoester *(34)* is formed as the stable end product from furan in methanol. This product is also formed, after removal of the side chain, from furfural, furfuryl alcohol, furfuryl methyl ether, and *N*-acetylfurfurylamine[5,43,66–68].

(21)

(22)

The peroxide of ethyl furan-2-carboxylate decomposes by a different route. The side chain is again removed, but maleic acid and the monoester of maleic acid *(30)* are formed as well as the cyclic reaction product *(29)* ($R^2 = H$)[76,77].

This tendency to form open-chain decomposition products is also found with furfurylamine, which presumably gives β-glycylacrylic acid [*(27)*, $R^2 = CH_2NH_2$] as the principal product, together with 3-hydroxypyridine[43,76,78]. However, dimeric and polymeric products are also formed.

Reduction of the epidioxide solutions obtained below −30 °C from furan, 2-methylfuran, and 2,5-dimethylfuran with triphenylphosphine in the cold gave 1,4-dicarbonyl compounds[5,66,71] [reaction (2a)].

Various reaction products, some built up from two or more furan rings, have been isolated on conventional working-up of the photo-oxidized solutions. Owing to the many possible reactions of the furan ring[79], the yields of identifiable products were often by no means quantitative, high molecular weight resinification products being obtained instead. A large part of these products was presumably due to the increase in the

steps would be to examine the epidioxydihydrofurans formed in dilute solution and at low temperatures over a wide temperature range by differential calorimetry.

The photochemical synthesis of the oxonide-like peroxides was carried out in methanol, toluene or tetrahydrofuran at −85 °C under pure oxygen (furan: 0.05 to 0.5 mole/l, sensitizer: Bengal pink or diacenaphthyleno [1,2-*b*; 1′,2′-*d*] thiophen (dinaphthylenethiophen), 2×10^{-4} to 3×10^{-4} mole/l). 1 mole of O_2 was taken up per mole of furan with a quantum yield $\varphi \approx 1$.

The thermograms of the solutions kept at −85 °C show three typical behavior patterns between −85 and +50 °C, so that the epidioxides *(21)* investigated here can be divided into three groups (Fig. 4).

Group 1: The epidioxides from 2-alkyl and 2,5-dialkylfurans give a weakly exothermic reaction in methanol at $\tilde{\vartheta}$ = −40 to −10 °C. The heat effects, which are found to be 5–10 kcal/mole, correspond to the addition of methanol to the hydroperoxymethoxydihydrofurans *(25)* and *(26)* (which have already been isolated in some cases) with cleavage of the peroxide bridge [71]. The suggested reaction course [5,71] is thus also confirmed by energy considerations for group 1 [see reaction (2c) and further reactions]. Whereas the hydroperoxides *(25)* and *(26)* generally remain unchanged up to room temperature, the hydroperoxide of 2-vinylfuran, which can be isolated at +20 °C, tends to polymerize [37].

The tendency toward the formation of dimers and polymers [reaction (2b)] is small for the compounds of group 1 in methanol, since the addition (2c) proceeds with first order kinetics. The epidioxide *(21g)* of 2,5-dimethylfuran forms a dimer in apolar solvents such as toluene and petroleum ether [71] [reaction (2b)]. The other epidioxides of group 1 react under these conditions or in tetrahydrofuran only at higher temperatures and in a more complicated manner, in some cases with small heat effects or endothermically.

Group 2: Furan, furfural, furfuryl alcohol, and furfuryl methyl ether behave differently. The reaction in methanol is strongly exothermic (60–70 kcal/mole, formally first order) at $\tilde{\vartheta}$ values of about 10 to 30 °C. 5-Methoxy-2(5*H*)-furanone [*(29)*, R^2=H, R^3=CH_3; reactions (2c) and (3c)] is formed.

Group 3: These compounds are characterized by the formation of open-chain reaction products. Strongly exothermic reactions occur in methanol, toluene, or tetrahydrofuran even at reaction temperatures $\tilde{\vartheta}$ of −40 to −10 °C. In contrast with the reactions of other groups, this reaction has an order of >2 in more concentrated solutions (> 0.2 mole/l). The solutions become dark above about −20 °C, owing to the formation of high molecular weight products or resins. The heats of reaction increase with increasing dilution up to a maximum of ≈85 kcal/mole, while the reaction order falls from ≈3 almost to 1 (Fig. 5a and 5b). These observations are readily reconciled with the assumption

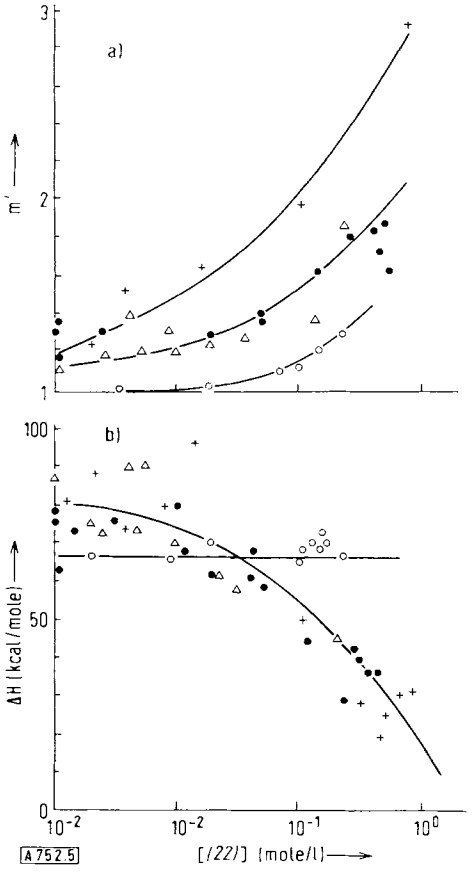

Fig. 5. a) Apparent reaction order m' in the decomposition of the epidioxydihydrofurans at various concentrations. b) Reaction enthalpy for the decomposition of epidioxydihydrofurans at various concentrations. Solvent: methanol. o = *(21a)*; ●: *(21b)*; +: *(21c)*; △: *(21d)*.

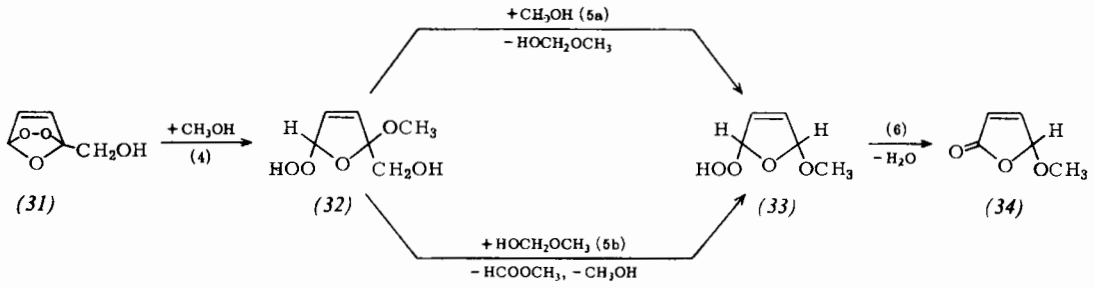
of the simultaneous occurrence of a strongly exothermic unimolecular reaction (type c in Fig. 3) and a weakly exothermic bimolecular reaction sequence (type e in Fig. 3) (cf. Section 6.1).

If the reaction mixture is allowed to come slowly to 20 °C and is then carefully worked up, the reaction products contain no methoxy groups. Nevertheless, the question arises whether the cleavage of the peroxide bridge in *(21)* is introduced by addition of methanol and whether the addition and the subsequent reactions, as in the case of furan, take place in practically the same temperature range.

6.1. Formation of the Hydroperoxides



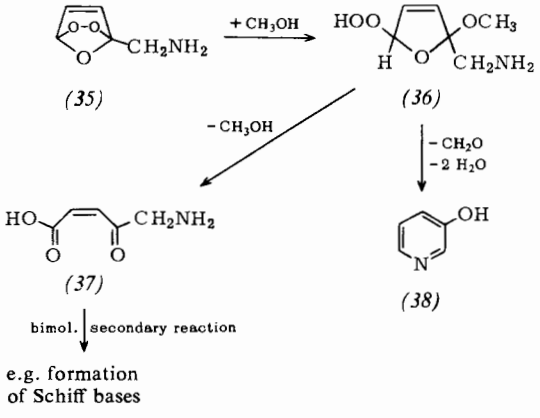
With the block temperature kept constant at −90 °C, we added 0.5 ml of methanol to the epidioxides prepared in 5 ml of toluene or THF at −90 °C and to the reference solution. Distinct heat effects (ΔH = 5–15 kcal/mole) occurred for furfurylamine, *N*-methyl- and *N*,*N*-dimethylfurfurylamines, furfuryl alcohol, and furfuryl methyl ether. These point to a reaction between the methanol and the epidioxides with formation of the methoxy hydroperoxides *(25)* and *(26)*.

The homogeneity of the solutions in THF allows the reactions to be followed kinetically. Their rate constants are between 3×10^{-3} and 10×10^{-3} mole·l^{-1}·s^{-1}; with a plausible A factor of 5×10^{10} mole·l^{-1}·s^{-1} this would correspond to activation energies of only 10–15 kcal/mole. Compounds of group 1 undergo appreciable addition of methanol only above −40 °C. The ease of cleavage of the peroxide bridge is evidently greatly increased in 2-substituted epidioxydihydrofurans by functional groups in the substituent.

On preparative low-temperature working-up of epidioxide solutions of furfuryl alcohol and furfuryl methyl ether, removal of the methanol by distillation below −30 °C and high-vacuum sublimation at 0 °C gave unstable colorless oils, which were identified as hydroperoxides [37]. However, differential thermal analyses showed conclusively that the hydroperoxide of furfuryl alcohol (5-hydroperoxy-2-furanylmethanol) undergoes a change at −20 °C, with loss of the side chain, to reach the energy stage of malealdehydic acid [reactions (5a) and (6)].

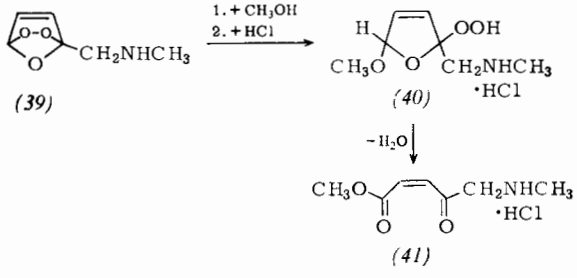
The formaldehyde hemiacetal formed in reaction (5a) evidently reacts with further hydroperoxide to give the furanone *(34)* and methyl formate, which is also detected [reactions (5b) and (6)].

The thermograms of 5-hydroperoxy-2-furanylmethanol in THF, both in the presence and in the absence of methanol, have a double maximum at $\tilde{\vartheta}$ = +22 °C (heating rate $\dot{\vartheta}$ = 1.5 °C/min) that is practically inseparable (type h in Fig. 3). This suggests on the one hand that the loss of the side chain may occur even without methanol by formaldehyde formation shortly before the loss of water, and on the other that the 2-hydroperoxy-5-methoxy-2,5-dihydrofuran *(33)* formed above −20 °C in reactions (5a) and (5b) exists for a short time.



The epidioxydihydrofuran *(21a)* in methanol also gives two maxima situated close together at roughly equal reaction temperatures. However, since methanol adds to *(21a)* only at $\vartheta = 20\,^{\circ}C$ (cf. above and Fig. 4), the first maximum in this case must be assigned to the formation of the hydroperoxide, and the second to its fragmentation to give the furanone *(34)*.

If water is added instead of 10 % of methanol to a solution of *(21a)* in THF, the analogous reaction takes place at $\approx 2\,^{\circ}C$. The difference between the reaction temperatures of the two maxima increases from 2 to 20 °C, and the reaction enthalpy for the addition of water is about 5 kcal/mole.



The epidioxide of furfuryl methyl ether behaves in a similar manner to that of furfuryl alcohol. Methanol is added at −90 °C, but the loss of the side chain occurs only above −20 °C, and is immediately followed by that of water to give the furanone *(34)*, as can again be seen from the presence of a double maximum. The last two reactions take place at roughly the same temperature as the reactions of the epidioxide of furan and furfuryl alcohol, since *(33)* again occurs as an intermediate. Two similar reactions also occur in the case of furfural.

Different behavior is found for furfurylamine. Methanol addition products are formed at −85 °C; these products are stable up to $\approx$ −40 °C, and must consist mainly of 2-(aminomethyl)-5-hydroperoxy-2-methoxydihydrofuran *(36)*, since the final product formed above −20 °C, *i.e.* β-glycylacrylic acid *(37)*, is obtained unesterified, though in dimerized and more highly condensed forms [37].

3-Hydroxypyridine *(38)*, which has also been found on low-temperature working-up of photo-oxidized methanolic furfurylamine solutions [37], could also be formed from the hydroperoxide *(36)* in a side reaction [76, 78]. Unlike the removal of the side chain in the cases of furfural, furfuryl alcohol, *etc.* this rearrangement would have to begin with a ring cleavage before the pyridine ring can be closed by the still bound methanol.

The epidioxide of *N*-methylfurfurylamine *(39)* also adds methanol at −90 °C to give a methoxyhydroperoxide that is partly precipitated as the hydrochloride *(40)* on addition of methanolic HCl at this temperature [37]. *(40)* decomposes slowly (half life $\approx$ 1 h) even at −50 °C, so that a rapidly recorded IR spectrum (the sample temperature rises to at most −20 °C during the recording) contains bands due to the decomposition product *(41)*.

It is surprising to find that the arrangement of the OCH_3 and OOH groups here is evidently opposite to that in the product from furfurylamine; the isomeric product may be too soluble to be precipitated as the salt from methanol, or the isomer ratio may depend on the pH value.

In the case of epidioxides of group 3, the concentration dependence of the heat of reaction and reaction order show particularly clearly that the pure unimolecular formation of the β-glycylacrylic acids, which makes the greatest energy contribution, occurs preferentially only in very dilute solution. In more concentrated solutions, *i.e.* on working up *e.g.* by evaporation of the solvent, different, bimolecular processes become predominant. Owing to the reaction orders of much more than 2 in some cases in the thermograms, repeated reactions with the starting material (type e in Fig. 3) must occur in this case.

The much more inert epidioxides of the 2- and 5-substituted alkylfurans are appreciably more reactive in the presence of HCl, as is shown by the depression of the reaction temperatures by 20 to 40 °C (Fig. 4). In the case of 2,5-dimethylfuran, the methoxy hydroperoxide [*(25)*, $R^1=R^2=CH_3$], which is normally stable at $\approx$ 50 °C, decomposes at this temperature.

Water is also added much more rapidly than methanol by the alkylfurans (Fig. 4). The reaction enthalpy also

indicates that the 5-hydroperoxydihydrofuran-2-ols are to be expected here. The thermogram (type *f* in Fig. 3) allows an approximate separation of the double maximum. However, the kinetics of the reaction with water have not yet been fully elucidated, since the reaction order cannot be determined directly owing to the overlap. Unrealistically high frequency factors result if a bimolecular reaction is assumed. It is nevertheless found that the intermediates are stable below −10 °C.

6.2. Enthalpies of Formation of the Epidioxydihydrofurans

Further confirmation of the views developed is provided by the calculation of the enthalpies of formation of the ozonides *(21)* from the enthalpies of formation of the final products and the reaction enthalpies ΔH. These quantities cannot be determined by conventional methods, since the explosive pure ozonides can be handled only at very low temperatures (below −80 °C), and even then not without danger.

However, the heat effects in dilute solutions can be determined by DTA. Despite the diversity of the final products, the heats of formation found for the epidioxides *(21a)* and *(21e)—(21k)* (groups 1 and 2) differ only slightly from those estimated from the bond increments[80] if −50 kcal/mole is used in the calculation for the peroxide bridge (Table 1)[81].

The deviations are partly explained by the fact that the same increment is used in every case, since the peroxide bridge should be weakened with increasing polarization by asymmetric substitution in position 2. Moreover, side reactions may lead to polymeric peroxides, which should give much lower energy values than the isomerization to give the malealdehydic acid.

Table 1. Enthalpies of formation of unstable epidioxydihydrofurans and kinetic parameters of their cleavage. Solvent: methanol. A = action constant (s^{-1}).

Epidioxide *(21)*	Enthalpy of formation (kcal/mole) calc.	meas.	Activation energy (kcal/mole)	log *A*
Group 1				
e	− 81.7	− 77.0	17.0	7.5
f	− 47.2	− 53.4	≈16	10.8
g	− 80.6	− 89.0	20.2	10.1
h	− 71.7	− 82.5	20.0	10.2
Group 2				
a	− 62.8	− 63.6	20.0 [a]	10.2
i	−106.7	−101.7	12.7	(11)
j	−121.7	−117.4	13.1	(11)
k	− 94.5	−101.4	—	—
Group 3				
b	− 63.8	− 17.4	12.5	(11)
c	− 64.7	− 17.5	13.1	(11)
d	− 67.7	− 20.5	13.8	(11)

[a] Practically the same value is found with ethanol, propanol, and butanol as solvents, while the action constants decrease.

It is clear in the case of the epidioxide *(21j)* of furfuryl methyl ether that here, in contrast with that of furfuryl alcohol *(21i)*, the formaldehyde acetal formed no longer reacts further with the hydroperoxide; this is supported by preparative results. The enthalpy of formation of *(21a)* (≈ −60 kcal/mole) has recently been verified by compensation of the energy liberated during the photo-oxidation with a calibrated Peltier element[82].

Thus the validity of reactions (1), (2a), (2c), and (3a)—(3c) for the examples described here is also demonstrated on energy grounds (see also Section 6.3).

The measured heats of formation of the nitrogenous epidioxides *(21b)—(21d)* of group 3 differ by 46 to 48 kcal/mole from the expected values. However, the final products, being amino acids, exist partly in the form of zwitterions in solution; much more positive values must therefore evidently be used for their energies of formation than those calculated from the increments.

6.3. Reduction of the Epidioxydihydrofurans with Triphenylphosphine

The epidioxides examined differ in their reactivity to triphenylphosphine (Fig. 4)[83,84]. Whereas the compounds of groups 2 and 3 react even below −60 °C ($\tilde{\vartheta}$ = −50 to −30 °C), the reaction temperatures for group 1 are much higher (−30 to +21 °C). The reactivity of the epidioxydihydrofuran *(21a)* is thus increased by the *N*-methylaminomethyl or aminomethyl group in position 2, but greatly decreased by an alkyl group. The epidioxide *(21g)* of 2,5-dimethylfuran reacts only at $\tilde{\vartheta}$ = +21 °C, and is thus the least reactive.

This cannot be due to the absence of polarization of the peroxide bridge, since furan itself reacts very readily ($\tilde{\vartheta}$ = −36 °C); it is probably caused by steric factors.

By comparison of the heats of formation ΔH_f of compounds such as Br_3P, Br_3PO, Cl_3P, and Cl_3PO[60], a heat effect $-\Delta H_{PO}$ of about 70–80 kcal is found for

$$(C_6H_5)_3P + 1/2\ O_2 \xrightarrow{+\Delta H_{PO}} (C_6H_5)_3PO$$

Approximately the same values are obtained from the thermoanalytically determined heat effects if it is assumed that vicinal diacylethylenes such as *(23)* are formed. Occasional deviations are explained by a different reaction course, *e.g.* by partial loss of side chains in the cases of furfuryl alcohol and furfuryl methyl ether, by bimolecular competing reactions in the case of *N,N*-dimethylfurfurylamine, or by solvation effects in general. The initial step is almost conclusively the formation of the unsaturated 1,4-dicarbonyl compound such as *(23)*. However, it is difficult to obtain[71] in good yields because of its sometimes considerable reactivity.

6.4. Comparison of the Kinetic and Energetic Results

The formally different processes of bimolecular addition [reaction (2c)] and monomolecular decomposition of the hydroperoxides [(reactions (3a)/(3c)] and the re-

arrangement of the epidioxydihydrofurans [reactions (2d)/(2e)] can proceed only with cleavage of an O–O bond. Similar activation energies (around 20 kcal/mole) are often found for the addition to furans and alkylfurans (Table 1). The ease of cleavage of the O–O bond does not appear to be strongly influenced either by alkyl substituents on the furan ring or by the nature of the alcohol added. The activation energy, and hence also the reaction temperature (Fig. 4), of the alkylfurans is distinctly increased only in the absence of polar addends when the process is carried out in tetrahydrofuran or toluene.

Asymmetrical substitution with functional groups strongly reduces the activation energies for addition and decomposition. The hydroperoxides of groups 2 and 3 are formed even at −90 °C and decompose well below 0 °C and below −20 °C respectively. In the cases of *N*-methylfurfurylamine and *N*,*N*-dimethylfurfurylamine, the epidioxides and hydroperoxides are so unstable that bimolecular reactions can no longer occur (Fig. 4).

The frequency factors are of the expected order of magnitude of $10^{14} - 10^{15}$ s^{-1} for the decomposition of the hydroperoxides [85], and much lower in some cases for the epidioxides (Table 1).

The energy diagram (Fig. 6) shows the sums of the heats of formation of all the compounds and transition states involved in the reaction sequence (1) → (2c) → (3c) for furan, as found from the measured enthalpies and activation energies. After the absorption of a photon by the sensitizer, the oxygen is first brought into the $^1\Delta g$ state [2, 48, 86], which lies 22.6 kcal/mole above the ground state. Practically no further activation energy is required for the cycloaddition to the acceptor [2, 45], and 50 kcal/mole are in fact immediately liberated. The hydroperoxide can be formed if a further 20 kcal/mole are supplied; this is so only above

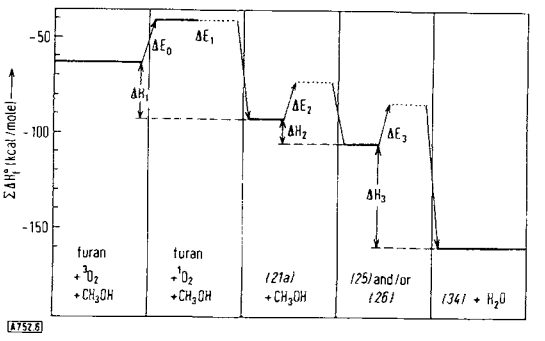

Fig. 6. Arrhenius activation energies and reaction enthalpies for the photosensitized cycloaddition of O_2 to furan (schematic). (All values in kcal/mole).

$\Delta E_0 = 22.6$
$\Delta E_1 = 0.2$ $\quad \Delta H_1 = -30$(g) -26(liq.)
$\Delta E_2 = 20.0$ $\quad \Delta H_2 = -13$(g) $- 2.4$(liq.)
$\Delta E_3 = 21$ $\quad \Delta H_3 = -54$(g) -67(liq.)

−20 °C. At this temperature, however, water is eliminated with an activation energy that is also around 20 kcal/mole [reaction (3c)]. The final product is immediately formed with liberation of a further 55–60 kcal/mole.

The activation energies of the hydroperoxide formation for all the substituted furans examined are much lower than those of the decomposition reactions. The hydroperoxides can therefore be isolated in favorable temperature ranges in these cases.

The stimulus for instrumental development in the field of low-temperature photochemistry came from Professor G. O. Schenck. I am grateful to him and to Prof. Dr. O. E. Polansky, G. von Bünau, F. Schaller, M. Barthels, G. Lindner, and H. Siepmann for their support, valuable advice, and stimulating discussions.

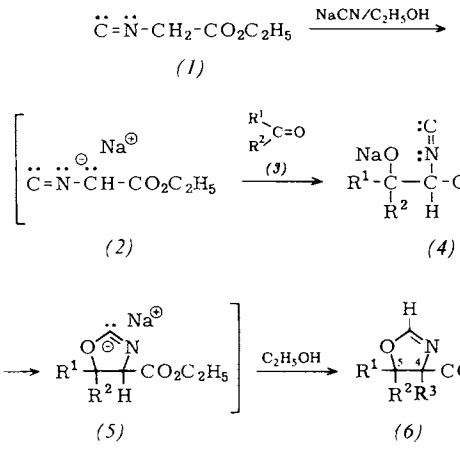
Ethyl 2-Oxazoline-5-carboxylate from Ethyl Isocyanoacetate and Carbonyl Compounds[1]

By *Dieter Hoppe* and *Ulrich Schöllkopf*[*]

Ethyl 2-oxazoline-4-carboxylates *(6)* are readily hydrolyzed to serines [2, 3] and are of particular interest as model substances for the study of base-induced electrocyclic ring-opening [4].



The esters *(6)*, R^3 = H, cannot be prepared by a method given previously in the literature [5] for the synthesis of oxazolines, since, under the conditions mentioned, they are converted by ring scission into the β-substituted ethyl α-formylaminoacrylates [4]. They can be prepared in good yields, however, by treating ethyl isocyanoacetate [6] *(1)* in ethanol with carbonyl compounds *(3)* in presence of a small amount of (suspended) sodium cyanide. The catalyst undergoes partial alcoholysis and thus provides a weakly basic medium in which *(1)* is partially converted into its sodium derivative *(2)*, the (alkali-labile) oxazolines *(6)*, R^3 = H, on the other hand, not undergoing any further decomposition. Presumably, in addition to *(2)*, the carbonyl adducts *(4)* and the metalated oxazolines *(5)* are present as intermediates.

Reaction with aldehydes leads almost exclusively to formation of the *trans* compounds, which on hydrolysis afford the *threo* forms of the β-substituted serines.

As experiments with ethyl α-isocyanopropionate and formaldehyde, acetone, or benzaldehyde have shown, the method is also applicable to α-substituted ethyl isocyanoacetates.

Ethyl trans-5-phenyl-2-oxazoline-4-carboxylate (6c):

A solution of ethyl isocyanoacetate [6] (4.52 g, 0.04 mole) and benzaldehyde (4.26 g, 0.04 mole) in dry ethanol (15 ml) is added dropwise with vigorous stirring at 15 °C to a suspension of sodium cyanide (0.25 g) in dry ethanol (10 ml). The mixture is stirred for one hour and the solvent is then removed (water-jet vacuum, bath temp. 50–80 °C). The residue is taken up in carbon tetrachloride (50 ml) and the

Ethyl Lithiodiazoacetate[1]

By *Ulrich Schöllkopf* and *Hubert Frasnelli* [*]

In spite of the extensive work that has been carried out in diazo chemistry[2] there is still a lack of methods available for exchange of ligands attached to the carbon atom of readily accessible diazomethyl compounds. Since a *C*-lithium atom is replaceable by a variety of other substituents[3], we have directed our attention toward possible routes leading from diazo compounds to *C*-lithium derivatives[4].

We have now found that ethyl lithiodiazoacetate *(2)* is obtained when a) diethyl mercuriobis(diazoacetate)[5] *(1)* in tetrahydrofuran is allowed to react at *ca.* −70 °C with phenyl- or butyllithium or with lithium thiolates, or b) ethyl diazoacetate *(3)* is metalated at −110 °C in ether or ether/tetrahydrofuran. The lithium compound *(2)* is stable only below −50 °C[6]; it can be intercepted, *e.g.*, by trialkylstannyl or trialkylsilyl chlorides, by carbonyl compounds, or by alkyl halides and thus be utilized in preparative work. Since method a) is relatively involved and not without attendant danger, owing to the poisonous nature of the mercury compounds formed, metalation according to b) is probably the more suitable method for preparative purposes.

Ethyl 2-diazo-3-hydroxy-3-phenylpropionate

A solution containing 47 mmoles of butyllithium (21.5 ml of a 2.2 M solution in pentane) precooled to −70 °C is added dropwise at −110 °C to a solution of ethyl diazoacetate (5.47 g, 47 mmoles) in ether (150 ml) and tetrahydrofuran (50 ml) over a period of 30 min. A solution of benzaldehyde (5 g, 47 mmoles) in tetrahydrofuran (30 ml) which has been cooled to −70 °C is then added dropwise at −110 °C and the reaction mixture is allowed to warm to −25 °C, whereupon a solution of glacial acetic acid (2.85 g, 47 mmoles) in tetrahydrofuran (30 ml) that has been cooled to −70 °C is also added. On reaching room temperature, the solution is filtered and the solvent removed under water-pump vacuum (rotary evaporator, 30 °C). The residue is taken up in 500 ml of light petroleum (b.p. 40–50 °C) and shaken with *ca.* 1 g of active charcoal. After filtration the solvent is removed under water-pump vacuum. There remained 4.3 g (41%) of crude ethyl 2-diazo-3-hydroxy-3-phenylpropionate [IR spectrum (film): 3500 (νOH), 2100 (νN_2), 1680 (νCO) cm^{-1}; NMR spectrum

(CCl_4): τ = 2.52 (m), 4.24 (s), 5.82 (s), 5.4 (q), 8.77 (t)]. — A part of the residue was purified by chromatography on aluminum oxide (neutral, activity grade 3), elution with light petroleum first affording a little benzaldehyde and subsequent elution with ether yielding the diazo compound.

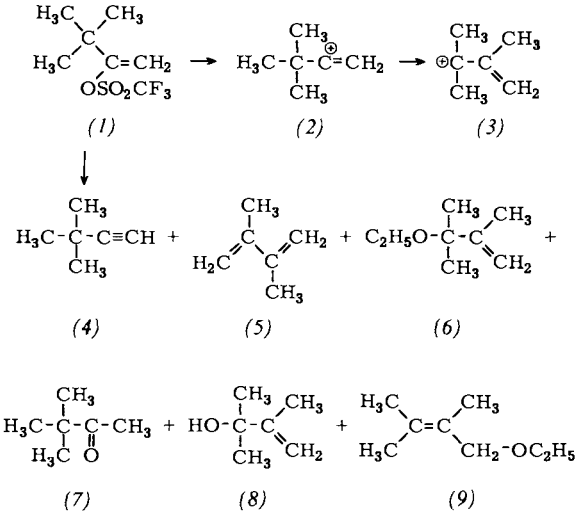
1-*tert*-Butylvinyl Trifluoromethanesulfonate: Solvolysis and Rearrangement *via* a Vinyl Cation[**]

By *Antonio Garcia Martinez, Michael Hanack, Richard H. Summerville, Paul von Ragué Schleyer,* and *Peter J. Stang*[*]

Solvolysis of simple acyclic and cyclic vinyl halides and vinyl sulfonates could proceed *via* vinyl cations as intermediates[1]. Formation of rearranged solvolysis products would indicate such a reaction course.



Rearrangements of vinyl cations generated by protonation of alkynes are known[2]; in contrast, occurrence of isomerizations of this kind during the solvolysis of simple acyclic vinyl derivatives has not hitherto been described[3].

For the generation of vinyl cations by solvolysis of vinyl sulfonates the fast-reacting trifluoromethanesulfonates[4] prove particularly suitable[5]. We now report on the solvolysis of 1-*tert*-butylvinyl trifluoromethanesulfonate *(1)* which gives rise to rearranged products.

Compound *(1)* was prepared by slow dropwise addition of trifluoromethanesulfonic acid[6] at —20 °C to 3,3-dimethyl-1-butyne *(4)*. After 30 min the reaction mixture was neutralized by addition of a solution of $NaHCO_3$ and extracted with ether. The extract was dried, and after evaporation of the ether, compound *(1)* could be isolated by distillation [yield 40–60%, b.p. 45–50 °C/15 torr; NMR spectrum: τ = 4.95 (2H/q, J = 4 Hz); 8.80 (9H/s)]. *(1)* was found to be homogeneous on gas chromatography (3 m polyethylene glycol 20000, 10%, column, 100 °C); no rearrangement products were formed during the addition.

Compound *(1)* was solvolyzed in pyridine-buffered 80% aqueous ethanol for three days at 80 °C. There were formed: 27% of 3,3-dimethyl-1-butyne *(4)*; 13% of 2,3-dimethylbutadiene *(5)*; 24% of 3-ethoxy-2,3-dimethyl-1-butene *(6)*; 1% of pinacolone *(7)*; 10% of 2,3-dimethyl-3-buten-2-ol *(8)*; and 25% of higher boiling substances (mean values from five experiments). After separation by gas chromatography the products were identified, *inter alia*, by their NMR, IR, and mass spectra, and by comparison with authentic samples (except for *(6)*).

On solvolysis of *(1)* in non-buffered 50% aqueous ethanol (75 °C, 4 h) we obtained 76% of *(4)*, 14% of *(5)*, 1.5% of *(6)*, 2% of *(7)*, 1.5% of *(8)*, and 5% of 1-ethoxy-2,3-dimethyl-2-butene *(9)*.

(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)* *(8)* *(9)*

The formation of the rearranged products *(5)*, *(6)*, *(8)*, and *(9)* proves the intermediacy of a vinyl cation *(2)*, which is converted into the more stable ion *(3)* by migration of a methyl group. *(3)* yields the butadiene *(5)* by elimination, and the ethers *(6)* and *(9)*, as well as the alcohol *(8)*, by substitution. The major product *(4)* can, in principle, also arise from the vinyl cation *(2)*; however, a concerted elimination reaction of *(1)* with the solvent as base cannot be ruled out[7].

The reaction of the trifluoromethanesulfonate *(1)* in 50% aqueous ethanol was characterized by a rate constant k = 9.14×10^{-4} s^{-1} (at 75.4 °C) and k = 6.03×10^{-5} s^{-1} (at 50.4 °C); $\Delta H^{\neq}$ = 23.7 kcal/mole; $\Delta S^{\neq}$ = —4.8 e.u. Thus *(1)* reacts three times as fast as isopropenyl trifluoromethanesulfonate, which was solvolyzed by *Stang* and *Summerville*[5b] under the same conditions (k = 1.95×10^{-5} s^{-1} at 50 °C).

Tricyclo[4.3.1.0^{1,6}]deca-2,4-dienetricarbonylchromium, a Homoaromatic Transition Metal Complex

By *Wolf-Eckhard Bleck*, *Wolfram Grimme*, *Harald Günther*, and *Emanuel Vogel*[*]

Classification of the norcaradiene hydrocarbon tricyclo-[4.3.1.0^{1,6}]deca-2,4-diene[1] *(1)*, which owes its existence to the bracketing effect of the trimethylene group, as a homoaromatic compound[2], *i.e.* a derivative of the hypothetical species homobenzene, appears unjustifiable on the basis of its chemical and spectral properties[1,3]. However, if *(1)* assumes the role of a ligand in a transition metal complex whose central atom bonds preferentially to a 6π-system, the electrons of the double bonds and the three-membered ring might reorganize to give a homoaromatic structure [as in *(2a)*] or, alternatively, a cycloheptatriene structure [as in *(2b)*]. Synthesis and structure of a carbonylchromium complex of *(1)* warrant attention in this respect.

(1) *(2a)* *(2b)*

Reaction of the hydrocarbon *(1)* with triamminetricarbonylchromium [$(NH_3)_3Cr(CO)_3$][4] in boiling *n*-hexane (48 h) leads to a dark red solution which, after filtration, affords red-violet crystals of a complex $C_{10}H_{12} \cdot Cr(CO)_3$ *(2)* (*m/e* 268) on cooling to −15 °C. The complex, which is stable on exposure to air, was obtained in analytically pure form (sinters above 95 °C with decomposition) by sublimation (90 °C, 10^{-4} torr) and subsequent recrystallization from *n*-hexane; yield 67% (based on $(NH_3)_3Cr(CO)_3$). Since *(2)* contains three CO groups, six electrons of the $C_{10}H_{12}$ ligand must be involved in bonding with the chromium atom. This finding, together with the observation that *(2)* regenerates the starting hydrocarbon on treatment with 2,2'-diaminodiethylamine[5] restricts the possible structures to the two alternatives *(2a)* and *(2b)* given above.

The IR spectrum (in CS_2) of *(2)* contains three strong CO bands at 1967, 1900, and 1868 cm^{-1}. The UV spectrum [maximum at 412 (ε = 3500) with shoulders at 300 (4500) and 540 nm (650); in *n*-hexane] differs markedly from that of the complex 1,6-dimethylcycloheptatrienetricarbonylchromium[6] *(3)* [maxima at 352 (ε = 3900) and 490 nm (570), and shoulders at 272 (8100) and 400 nm (3000); in *n*-hexane)] and is similar to the spectrum of 1,6-methano-[10]annulenetricarbonylchromium *(4)* [maxima at 253 (ε = 23600) and 402 nm (8200), and shoulders at 300 (5600) and 550 nm (710); in *n*-hexane].

A clearer insight into the π-electron structure of *(2)* is provided by the ^{1}H-NMR spectrum (in C_6D_6). Thus the four olefinic protons give rise to an AA'XX' system with $\tau_{2,5}$ = 4.29 and $\tau_{3,4}$ = 5.51, the two bridge protons to an AB systems with τ = 10.82 and 12.43 (J = 3.4 Hz), and the six protons of the $(CH_2)_3$ bracket to a multiplet between τ = 8.2 and 9.7. Analysis of the AA'XX' system gave the following coupling constants: $J_{2,3} = J_{4,5}$ = 6.73 Hz, $J_{3,4}$ = 6.18 Hz, $J_{2,4} = J_{3,5}$ = 0.69 Hz, and $J_{2,5}$ = 1.09 Hz. Another important NMR parameter is the ^{13}C—H coupling constant obtained for one of the bridge protons (H_{syn}), which was found to have the value 164 ± 2 Hz. The relatively high value of this constant parallels the small geminal coupling of the bridge protons.

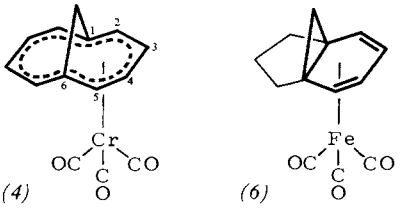

Table 1. H,H coupling constants J (in Hz) of the olefinic protons in *(2)*, *(3)*, *(4)*, and *(6)*.

	$J_{2,3} = J_{4,5}$	$J_{3,4}$	$J_{2,4} = J_{3,5}$	$J_{2,5}$
(2)	6.73	6.18	0.69	1.09
(4)	7.05	7.31	0.37	1.18
(3)	6.83	8.49	0.71	0.29
(6)	6.77	4.06	1.51	~0

On the basis of the coupling constants, the possibility that the complex possesses the cycloheptatriene structure *(2b)* seems to be ruled out. As can be seen from Table 1, *(2)* shows more similarity to *(4)* than to *(3)* as regards the coupling of the olefinic protons. This is particularly true of the relative magnitudes of $J_{2,3}$ and $J_{3,4}$ and of $J_{2,4}$ and $J_{2,5}$. Whereas the relationships $J_{2,3} \approx J_{3,4}$ and $J_{2,4} < J_{2,5}$ are valid for *(2)* and *(4)*, in the case of *(3)* $J_{2,3} < J_{3,4}$ and $J_{2,4} > J_{2,5}$. The finding that, in the case of *(2)*, the geminal coupling and the ^{13}C—H coupling of the bridge protons have hardly changed from the corresponding constants in the free ligand *(1)* [1] is even more informative. The interatomic distance C-1—C-6 in *(2)* is therefore unlikely to be much larger than that in *(1)*.

The question whether *(2)* may be regarded as homoaromatic should prove most readily answerable on the basis of the chemical shifts. As shown in Table 2, the transition of *(1)* into the tricarbonylchromium complex *(2)* has the effect of shifting the resonances of the bridge protons upfield by 2.13 (H_{syn}) and 2.18 ppm (H_{anti}), respectively, and those of the olefinic protons upfield by 1.33 (H-3, H-4) and 0.44 ppm (H-2, H-5). In order to judge to what extent these changes in the chemical shifts are caused by complex formation as such, a comparison may be made with the ligand-complex pair 1,6-methano-[10]annulene *(5)* — 1,6-methano-[10]annulenetricarbonylchromium *(4)* in which the geometrical conditions should resemble those in the present system. According to the results of NMR analyses[7] and X-ray structural studies[8,9], both ligand and complex are aromatic in this case, so that it is justifiable to assign the resonance shifts observed mainly to complex formation.

The data in Table 2 reveal that in *(2)* the resonance frequencies of the bridge protons H_{syn} and H_{anti} lie surprisingly far upfield and those of the olefinic protons unexpectedly far

(4) *(6)*

Table 2. Chemical shifts (τ values in ppm; in C_6D_6) of the protons in *(1)*, *(2)*, *(4)*, *(5)*, and *(6)*.

	$H_{2,5}$	Δτ	$H_{3,4}$	Δτ	H_{syn}	Δτ	H_{anti}	Δτ	Ref.
(1)	3.85		4.18		10.30 [a]		8.64 [a]		[b]
		0.44		1.33		2.13		2.18	
(2)	4.29		5.51		12.43 [a]		10.82 [a]		[b]
(5)	2.79		3.08		10.40		10.40		[7]
		1.01		2.59		0.74		1.37	
(4)	3.80		5.67		11.14		11.77		[7]
(6)	6.62		5.10		9.10 [a]		8.89 [a]		[b]

[a] This assignment is based on the observed long-range coupling of H_{syn} with the methylene protons of the five-membered ring; it was confirmed for *(1)* and *(2)* by complete deuteration in the five-membered ring. [b] This communication.

downfield. Thus on complex formation of *(1)*, additional shielding and deshielding effects occur which can be explained in terms of a diamagnetic ring current in complex *(2)*. We therefore propose the homoaromatic structure *(2a)* for the complex. Further support for this assignment comes from the fact that tricyclo[4.3.1.0^{1,6}]deca-2,4-dienetricarbonyliron[10] *(6)* [m.p. 49 °C; UV spectrum: maxima 247 (ε = 17500) and 305 (3500) with a shoulder at 390 nm (350); in *n*-hexane], whose central atom bonds only with the four π-electrons of the ligand, is shown by its NMR parameters[11] (cf. Tables 1 and 2) and by its UV spectrum[12] to be a normal diene complex.

The interatomic distances in *(2)*, especially the distance C-1—C-6 = 1.65 Å (*d* C-1—C-6 in 2,5-dimethyl-7,7-dicyanonorcaradiene = 1.50 Å[14]), which have recently been determined in an X-ray structure analysis by *Mills et al.*[13], may be regarded as further confirmation of the homoaromatic structure *(2a)*[15].

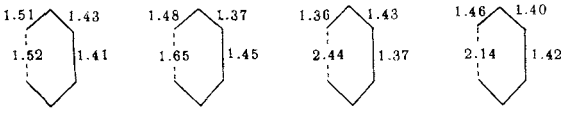
Crystal Structure of Tricarbonyl Complexes of Chromium(0) and Iron(0) with Tricyclo[4.3.1.0^{1,6}]-deca-2,4-diene

By *R. L. Beddoes, P. F. Lindley*, and *O. S. Mills*[*]

Unsaturated hydrocarbons only infrequently form stable complexes with both the dienophile $Fe(CO)_3$ and the trienophile $Cr(CO)_3$. Such behavior can be associated with valence isomerism of the ligand. Recently it has been shown that tricyclo[4.3.1.0^{1,6}]deca-2,4-diene[1] forms such complexes[2]. Whilst all the physical and chemical evidence supports structure *(1a)* for the free ligand, nevertheless structures based on *(1b)* and *(1c)* may have to be considered for the metal complexes.

(1a) *(1b)* *(1c)*

The 4 π-electron system in *(1a)* could well be used for bonding in the tricarbonyliron complex *(2)*, which would then be comparable with cyclohexadienetricarbonyliron[3] and, by analogy with the determined structure of 1,3-butadienetricarbonyliron[4], the tricarbonylmetal group would be expected to take the orientation shown in (A).



(A) (B)

The tricarbonylchromium complex *(3)* of the cycloheptatriene ligand *(1b)* would, by comparison with *exo*-7-phenylcycloheptatrienetricarbonylchromium[5] *(4)*, also take the form (A) unless prevented from so doing through the steric interference between the trimethylene chain and the nearest CO group attached to the metal atom. In 1,6-methano-[10]-annulenetricarbonylchromium *(5)* on the other hand[6], the orientation of the $M(CO)_3$ group corresponds to (B) although the bond lengths of the ligand are non-alternating and resonance persists through participation of the uncomplexed ring. By contrast, conjugation with a second ring is not possible in *(1)*. A comparison of the NMR spectra[2] of the free ligand $C_{10}H_{12}$ and both complexes suggests that the ligand in *(2)* may more closely resemble *(1a)* than that in *(3)*. Thus whilst *(2)* may contain the norcaradiene arrangement, the chromium complex may favor lengthening the bond between C-1 and C-6 either to the value found in *(5)*, 2.1 Å, or to some intermediate value.

Complex *(2)*, $C_{10}H_{12}Fe(CO)_3$, has the structure (A) expected for a substituted cyclohexadienetricarbonyliron. The molecule possesses crystallographic mirror symmetry (as does butadienetricarbonyliron)[4] with Fe—C-2 = 2.17 and Fe—C-3 = 2.05 Å [$C_4H_6Fe(CO)_3$: Fe—C = 2.14 and 2.06 Å]. The C—C distances in the "butadiene" portion do not differ significantly (1.43 (2×) and 1.41 Å). The C-1—C-6 distance is 1.52 Å which shows that the ligand is in the tricyclic norcaradiene arrangement in the complex. This form has previously been found[7] in 2,5-dimethyl-7,7-dicyanonorcaradiene where the corresponding distance is 1.50 Å which does not differ significantly from our value, bearing in mind the standard deviation of a C—C bond length, 0.02 Å, in our analyses.

Complex *(3)*, $C_{10}H_{12}Cr(CO)_3$, also contains a crystallographic plane of symmetry on which the metal atom and one CO group must lie. We find that the $M(CO)_3$ group is oriented according to (B). As is the case with *(5)*, the chromium atom makes four contacts $\approx$ 2.18 Å to C-2 to C-5 and longer ones, $\approx$ 2.50 Å, to C-1 and C-6. The C-1—C-6 distance has increased to 1.65 Å, which indicates that the ligand apparently no longer has the tricyclic form. However, this distance is 0.5 Å shorter than that found in *(5)*. Such a shortened bond length could be examined from two standpoints; (i) the atoms C-1 and C-6 repel each other but are prevented from moving farther apart by the steric requirements of the trimethylene chain, (ii) there may be bonding in a homoaromatic sense [as in *(1c)*] between these atoms. The former argument is unconvincing since the C-1—C-6 distance could increase to 2.01 Å if the C—C—C bond angles at the methylene carbons were to open out to 113 °, the usual value.

Confirmation of independence from chain length could be provided by the completed analysis of tricarbonylbicyclo[4.4.1]-undeca-1,3,5-trienechromium currently under investigation. A comparison of the bond lengths (Å) found in the systems bound to the metal atom is given for *(2)*–*(5)*:

(2) *(3)* *(4)* *(5)*

The Figure, which is a superposition of the projections of the two structures *(2)* and *(3)* onto their respective mirror planes, shows that, relative to the iron complex in which the metal atom makes only four contacts with the ligand, the chromium atom is moved sideways thus participating more with the ligand as a whole. These relative positions are in accord with the ideas of 4- and 6 π-electron involvement, respectively, by the $M(CO)_3$ groups.

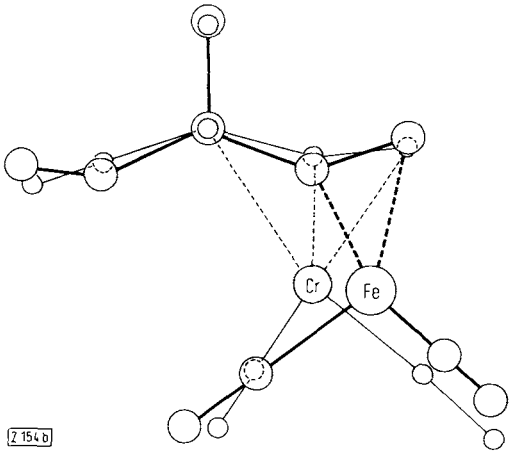


Figure: Superposition of the tricarbonyl complexes of iron(0) and chromium(0) with tricyclo[4.3.1.$0^{1,6}$]deca-2,4-diene, *(2)* and *(3)*, respectively. The molecules are made to coincide in the projection along the direction C-1—C-6. The larger circles refer to complex *(2)*.

n-Ionization Potentials of Alkyl Bromides[1]

By *Joseph A. Hashmall* and *Edgar Heilbronner*[*]

The lone pairs (n) of the σ-bonded bromine atom of an alkyl bromide RBr occupy the atomic orbitals 4 $p\pi_+$ and 4 $p\pi_-$, and, to a first approximation, 4 pσ. In the present communication we wish to demonstrate that the photoelectron (PE) spectroscopic determination of the ionization potential $I(n)$ of those processes $RBr \rightarrow RBr^+ + e$, in which the electron e comes from the atomic orbital 4 $p\pi_+$ or 4 $p\pi_-$, is a convenient and sensitive tool for the investigation of inductive and (hyper)conjugative effects. σ-Bonded bromine atoms represent an ideal probe for the measurement of such effects for the following reasons:

1. The n-ionization potential of their 4 pπ electrons lies between 9.5 and 11 eV, *i.e.* in a range between the normal ionization potentials of the C=C π electrons (≈9 eV) and the C—C σ- and C—H σ-electrons (≈ > 10.5 eV).

2. Owing to the nonbonding character of the 4 pπ atomic orbitals of the bromine atom, the n-ionization bands observed in the PE spectrum of RBr exhibit sharp 0—0 transitions (cf. Fig. 1) which are clearly distinguishable from the other broad bands. They are easy to locate and can be measured with high precision (cf. ref. [2]).

3. With few exceptions (see below), the PE spectrum of RBr shows two sharp bands separated by 0.30 ± 0.01 eV and which correspond to n-ionization (cf. Fig. 1). This makes their identification even easier and increases the accuracy of the measurement of the ionization potential.

4. Alkyl bromides are more readily accessible, more stable, and more suitable for PE spectroscopy than the corresponding iodides.

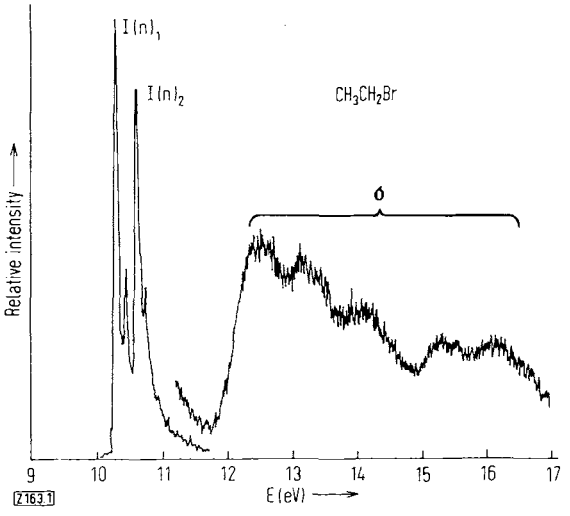

Figure 1. Photoelectron spectrum of ethyl bromide (recorded with a modified spectrometer [7] manufactured by Perkin-Elmer Ltd. (Beaconsfield, England). The n band is recorded at reduced sensitivity. The decrease in intensity with increasing energy is in part due to the instrument.

The method is illustrated by the following Table of ionization potentials $I(n)_1$, $I(n)_2$ of a series of alkyl bromides RBr, their mean values $\overline{I(n)} = (I(n)_1 + I(n)_2)/2$, and their differences $\Delta(n) = I(n)_1 - I(n)_2$.

Table: n-Ionization potentials of alkyl bromides RBr (in eV). Mean error *ca.* ±0.01$_5$ eV. $I(n)_1$ and $I(n)_2$ correspond to the 0-0 transition.

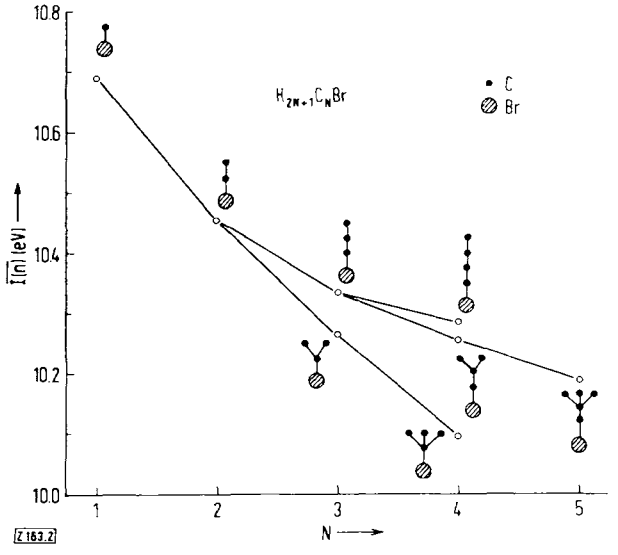
R	$I(n)_1$	$I(n)_2$	$\overline{I(n)}$	$-\Delta(n)$
CH_3	10.53	10.85	10.69	0.32
CH_3CH_2	10.30	10.61	10.45$_5$	0.31
$CH_3CH_2CH_2$	10.18	10.49	10.33$_5$	0.31
$CH_3CH_2CH_2CH_2$	10.13	10.44	10.28$_5$	0.31
$(CH_3)_2CH$	10.12	10.41	10.26$_5$	0.29
$(CH_3)_3C$	9.95	10.24	10.09$_5$	0.29
$(CH_3)_2CHCH_2$	10.10	10.41	10.25$_5$	0.31
$(CH_3)_3CCH_2$	10.04	10.34	10.19	0.30

Remarks:

1. In the case of the radical cations RBr^+ with R = methyl or *tert*-butyl, in which the bromine atom is situated on a threefold axis, $I(n)_1$ and $I(n)_2$ correspond to the states $^2\Pi_{3/2}$ and

$^2\Pi_{1/2}$, which show a —0.31 eV splitting due to spin-orbit coupling[3]. This splitting is still observed even when RBr no longer possesses a threefold axis of symmetry. Apparently, the local cylindrical symmetry at the bromine atom is disturbed to a negligible extent by an alkyl group of low symmetry. This is shown by the fact that the splitting Δ(n) remains constant within the limits of experimental error.

2. Figure 2 shows the dependence of the mean ionization potential $\overline{I(n)}$ on R. On the average, $\overline{I(n)}$ is shifted by —0.2 eV per α-methyl substituent and by —0.09 eV per β-methyl substituent.



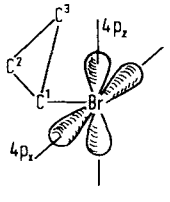


Fig. 2. Variation of the mean n-ionization potential of the alkyl bromides RBr as a function of the alkyl group R.

3. With reference to the first band in the PE spectrum of RH[4], the corresponding band of the series of σ bands in the PE spectrum of the alkyl bromide RBr is shifted by 0.4 eV towards higher energies if we confine our attention to the adiabatic ionization potentials.

4. While the results for cycloalkyl bromides (*e.g.*, cyclohexyl bromide, $\overline{I(n)}$ = 10.02 eV; Δ(n) = —0.29 eV) are in line with the predicted values, the group R = cyclopropyl represents a special case. The PE spectrum of cyclopropyl bromide contains only one clear n-ionization band with a sharp 0—0 transition at 10.41 eV, which can be ascribed to the 4 p_z lone pair.

The 4 p_x orbital, which is oriented parallel to the C^2—C^3 bond of the cyclopropyl group, conjugates with one of the Walsh orbitals[5] of this group and thus gives rise to a fine-structured, broad band at 9.53 (adiabatic) and 9.66 eV (vertical) (cf. ref.[6]).

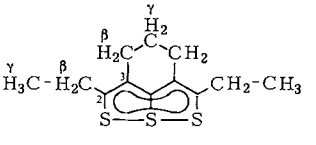
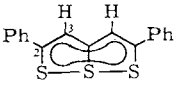
ESR Spectra of Radical Anions of Some 6a-Thiathiophthene Derivatives[1]



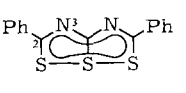
By *Fabian Gerson, Rolf Gleiter, Josef Heinzer*, and *Hans Behringer*[*]

The results of the ESR studies reported in this communication present an opportunity for testing the MO models proposed[2,3] for 6a-thiathiophthene. The experimental data allow conclusions to be drawn regarding the symmetry of the system in general and the form of the lowest vacant orbital in particular.

Tables 1 and 2 list the coupling constants of the magnetic nuclei for the radical anions of the 6a-thiathiophthene derivatives *(1)* to *(4)*[4]. The experimental values were refined with the aid of a computer program[5]; thus the relative experimental error should not exceed 1%. Wherever the assignment could not be deduced directly from the ESR spectrum it was made on the basis of analogy with the corresponding data for known radical anions. (The number of



(1)



(2)

equivalent nuclei, which are responsible for the coupling constant, is given in parentheses.)

The radical anions were generated either by electrolytic reduction in *N,N*-dimethylformamide ($(1)^{\ominus}$ and $(2)^{\ominus}$) or by reaction with potassium in 1,2-dimethoxyethane ($(3)^{\ominus}$ and $(4)^{\ominus}$).

In anticipation of a more detailed discussion of the experimental results, the following remarks can be made:

1. With respect to the ESR time scale and in the temperature range investigated (+25 to −40 °C), the results are consistent with a plane of symmetry passing through the central S atom and vertical to the plane of the molecule.

2. The π-spin population at atom 2 is relatively large (0.2 to 0.3), whereas at atom 3 it has a smaller value (0.06 to 0.08). A spin distribution of this kind is in accord with the form of the relevant orbital in the MO model [2].

3. As expected [6], the trimethylene chain in $(2)^{\ominus}$ can occur in two equivalent conformations which undergo rapid interconversion (frequency $>10^7\ s^{-1}$) at room temperature. Cooling of the solution reduces the frequency of interconversion: the spectrum recorded at −40 °C is already typical of a "frozen" conformation. The decrease in temperature also causes one of the two methylene protons in the 2-ethyl substituent to assume a position in which — on time average and relative to the freely rotating methyl group — hyperconjugation is still less favored [7] (compare data for $(2)^{\ominus}$ with those for $(1)^{\ominus}$).

Chemiluminescence on Oxidative Formation of Triplet States of Anthrasemiquinone- and Anthraquinone-2-sulfonate

By *Joachim Stauff* and *Peter Bartolmes* [*]

Hydroquinones that reduce O_2 to H_2O_2 emit a weak light while doing so; this light can be registered with a sensitive photodetector. Emission of this kind is also observed when *e.g.* anthraquinone-2-sulfonate is reduced to the semiquinone under argon at a Pt cathode at pH 12.5 and is then exposed to the action of O_2. Although the hydroquinone is also present under these conditions, owing to the equilibrium $Q + HQ \rightleftharpoons 2\,SQ$ (Q = quinone, SQ = semiquinone, HQ = hydroquinone), the possible formation of O_2^- radical anions according to $SQ + O_2 \rightarrow O_2^-$ cannot be immediately ruled out. In such a case, the chemiluminescence could be due to singlet oxygen [1] formed by recombination of O_2H radicals which are produced by O_2^- and H^+. A chemiluminescence of the same kind is also observed, however, on oxidation of HQ or SQ with $K_3[Fe(CN)_6]$ in the complete absence of oxygen (Ar atmosphere); the excited states that emit the photons must therefore arise from the participating organic molecules and not from oxygen species. The quantum yield of the reaction is about 10^{-10} Einstein/mole. The fact that the reaction appears to number among the exceptional cases in which chemiluminescence can be produced without the participation of oxygen or peroxides [2] makes it all the more interesting.

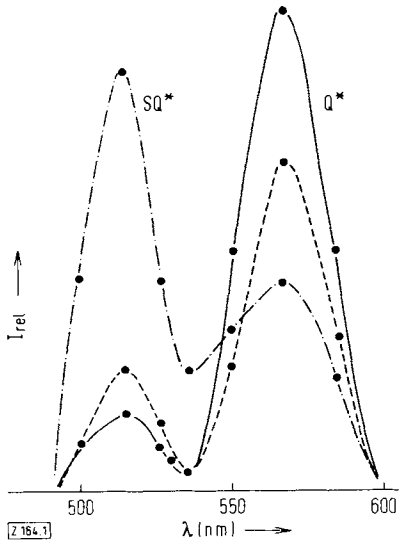

Figure. Chemiluminescence spectra of the reactions: anthrasemiquinone-2-sulfonate + hexacyanoferrate(III) (——); anthrahydroquinone-2-sulfonate + hexacyanoferrate(III) (— — —); and anthrahydroquinone-2-sulfonate + O_2 (—·—·—).

Since oxidation with hexacyanoferrate(III) can only proceed in a series of one-electron steps, variation of the ratio $q = Fe(CN)_6^{3-}$/reductant should reveal which of the reactions

$$HQ + [Fe(CN)_6]^{3-} \rightarrow SQ^*;\ SQ^* \rightarrow SQ + h\nu_1 \qquad (1)$$

and

$$SQ + [Fe(CN)_6]^{3-} \rightarrow Q^*;\ Q^* \rightarrow Q + h\nu_2 \qquad (2)$$

is responsible for the emission. It was found that with HQ as reductant the maximum intensity of luminescence occurs at $q = 2$, and for SQ, on the other hand, at $q = 1$; moreover, the luminescence yield in the former case was double that in the latter. Thus light is emitted during both reaction (1) and reaction (2). The only possible explanation is that removal of an electron and formation of a $>C=O$ group each lead to an excited state of the reaction product which releases part of its energy in the form of light. Whereas SQ can yield only one $>C=O$ group, HQ can form two and thus initiate twice as many emission processes.

This hypothesis derived further support from an approximate plot of the emission spectra recorded with the aid of filters. The figure shows that both oxidation of HQ and SQ with $[Fe(CN)_6]^{3-}$ or O_2 invariably gives rise to two bands that can be attributed to the emission of SQ* and Q*. Owing to the equilibrium between HQ, Q, and SQ, both reactions (1) and (2) must occur together; it was, however, to be expected that the relative intensity of one of the two bands, corresponding to SQ* or Q*, would be higher than that of the other, depending upon which starting material was used. In fact, with HQ as starting material the band at 515 nm is the stronger one, and the converse is true in the case of SQ. The band at 515 nm is therefore ascribed to the excited semiquinone and that at 568 nm to the excited quinone. This assignment is consistent with the concept that reaction (1), as a processes involving doubly and trebly charged anions, must be slower than reaction (2) between singly and trebly charged anions, and that the intensity of the quinone band must be greater than that of the semiquinone band. More-

over, in the spectrum of the reaction HQ + O_2, the 515-nm band is twice as strong as the 568-nm band. Since the rate of reaction of O_2 with HQ, having two $-O^-$ groups, must statistically be twice as high as that of O_2 with SQ, having one $-O^-$ group, the same relationship is to be expected between the intensities of the emission bands.

Since the singlet states of anthraquinonesulfonate lie at 260 ($\pi \rightarrow \pi^*$) and 320 nm ($n \rightarrow \pi^*$), SQ* and Q* must be triplet states. This means that removal of an electron from a group like $\rangle \dot{C}-\ddot{O}:^{\ominus}$ leaves the $\rangle C=O$ group not in the bonding π state but initially in the antibonding π^* state. Owing to the considerably lower energy required for its formation (49 instead of 88 kcal/mole), the antibonding state should be a triplet state which undergoes transition into the singlet ground state in a subsequent step, thereby emitting a very small portion of its energy as light.

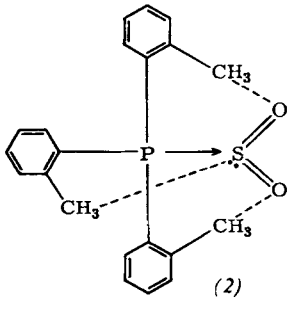
Reactions of Tritolylphosphines

By *S. I. A. El Sheikh, B. C. Smith,* and *M. E. Sobeir* [*]

Tri-*p*- *(1a)* and tri-*m*-tolylphosphine *(1b)* resemble triphenylphosphine in their oxidation behavior, whereas tri-*o*-tolylphosphine *(1c)* differs in its reactions with several oxidizing agents. Thus *(1a)* and *(1b)* react with thionyl chloride in boiling benzene to give the phosphine oxide and disulfur dichloride [1].

$$3\ R_3P + 2\ SOCl_2 \rightarrow 2\ R_3PO + S_2Cl_2 + (R_3PCl_2) \downarrow R_3PO$$



(1a), R = *p*-$CH_3C_6H_4$
(1b), R = *m*-$CH_3C_6H_4$

The initially formed triaryldichlorophosphorane undergoes subsequent conversion into the phosphine oxide. Under similar conditions *(1c)* gives a mixture of the phosphine oxide and phosphine sulfide.

(1a) and *(1b)* recrystallize unchanged from liquid sulfur dioxide, but undergo oxidation when the yellow solutions are heated in sealed tubes (185 °C/2 days):

$$3\ (1a, b) + SO_2 \rightarrow 2\ R_3PO + R_3PS$$

In contrast, the isomer *(1c)* reacts with liquid SO_2 to give an orange precipitate of the complex [(*o*-$CH_3C_6H_4)_3P \cdot SO_2$] *(2)*, which is stabilized by specific attractions between *o*-methyl groups and ligands. The phosphine oxide and phosphine sulfide are not formed, even on heating with an excess of SO_2 at 185 °C for 8 days.

(2)

Compounds *(1a)* and *(1b)* react with SeO_2 in boiling benzene to give the phosphine oxide and either selenium or the phosphine selenide, depending on the relative proportions of the reagents.

$$2\ (1a, b) + SeO_2 \rightarrow 2\ R_3PO + Se$$

$$3\ (1a, b) + SeO_2 \rightarrow 2\ R_3PO + R_3PSe$$

The phosphine *(1c)* does not react under these conditions.

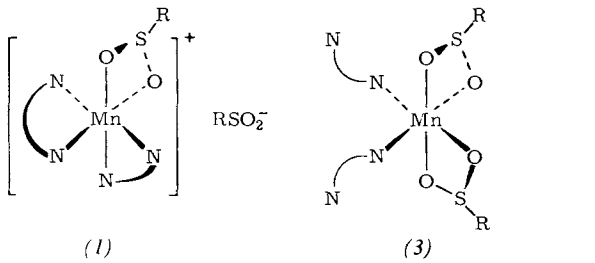
Ionization Isomerism of Sulfinato Complexes of Transition Metals

By *Ekkehard Lindner* and *Günter Vitzthum* [*]

Sulfinato complexes are eminently suitable subjects for the detection of various isomerism phenomena: alongside stereo- [1] and valence isomers [2] we have now observed, for the first time, ionization isomers.

Reaction of the potentially bidentate ligand ethylenediamine (en) with the sulfinato-*O,O'* complex (*p*-$CH_3C_6H_4SO_2)_2Mn(OH_2)_2$ [3] in ethanol at room temperature affords the ionic compound [*p*-$CH_3C_6H_4SO_2Mn\ en_2$] [*p*-$CH_3C_6H_4SO_2$] *(1)* (yield about 70%). Compound *(1)* exhibits conductivity in ethanol and its cation could be characterized in the form of [*p*-$CH_3C_6H_4SO_2Mn\ en_2$] [$B(C_6H_5)_4$] *(2)*.

On repeated recrystallization from ethanol with tetrahydrofuran the metastable compound *(1)* is converted irreversibly into the non-polar isomer (*p*-$CH_3C_6H_4SO_2)_2Mn\ en_2$ *(3)*, which is insoluble in all organic solvents. Composition and structure of the almost colorless sulfinato-*O,O'* derivatives *(1)*—*(3)* were established by complete elemental analysis and by the electronic and IR spectra, which indicate a pseudo-octahedral environment of the Mn^{2+} ion (see Table).



In every case, the *coordinated* *p*-$CH_3C_6H_4SO_2^-$ ligand is bonded to the central ion *via* both oxygen atoms (*O,O'* type) [4].

Table: SO_2 stretching vibrations (in cm^{-1}) of complexes *(1)*—*(3)* and of *p*-$CH_3C_6H_4SO_2Na$ *(4)*.

	$\nu_s(SO_2)$	$\nu_{as}(SO_2)$
(1)	979 s	1027 vs (anion) 1009 vs
(2)	970 vs	1000 vs, b
(3)	977 s	1012 vs
(4)	979 m	1027 m

The IR spectrum of *(1)* also contains the SO_2 stretching vibrations of the *anion* *p*-$CH_3C_6H_4SO_2^-$ (cf. spectrum of *(4)*), which are absent from that of *(2)*. Thus ethylenediamine is *bidentate* in *(1)* and *(2)*, but *monodentate* in *(3)*.

Possible stereoisomerism (*cis-trans*) in *(3)* cannot be detected owing to the insufficient frequency splitting of $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$.

Tris(*N*-trimethylsilylimido)sulfur and Bis(*N*-trimethylsilylimido)sulfur Difluoride

By *Oskar Glemser* and *Joachim Wegener*[*]

We have now succeeded in synthesizing, for the first time, a derivative of the hitherto unknown sulfur triimide, namely tris(*N*-trimethylsilylimido)sulfur *(1)*, by reaction of sulfur nitride trifluoride with lithium bis(trimethylsilyl)amide in light petroleum at 0 °C; the reaction also affords bis(*N*-trimethylsilylimido)sulfur difluoride *(2)*. *(1)* is the only compound to have been discovered so far that contains 3-coordinate sulfur in the oxidation state +6 and yet does not polymerize[1].

(1) (2)

R = CH_3

Compound *(1)* is a stable colorless liquid (b.p. 204 °C/748 torr), whose composition has been confirmed by elemental analysis and cryoscopic molecular-weight determination (calc. 293.67; found 304) in benzene. The ^{1}H-NMR spectrum contains only one signal at δ = −0.15 ppm (TMS as external standard).

Mass spectrum (relative intensities): molecular ion $S[NSi(CH_3)_3]_3^+$ (3), $Si(CH_3)_3^+$ (100), $S[NSi(CH_3)_3]_2NSi(CH_3)_2^+$ (25), $S[NSi(CH_3)_3]_2NSiHCH_3^+$ (14), $S[NSi(CH_3)_3]NSi(CH_3)_2^+$ (6), NSN^+ (5), NS^+ (5).

IR (cm^{-1}): 72 w, 175 w, 228 s, 272 s, 430 w, 619 s, 696 s, 738 w, 758 w, 840 vs, 1260 vs, 1290 vs, 3000 vs.

Raman (cm^{-1}): 97.5 dp, 130 pp, 175 dp, 212 dp, 230 dp, 257 pp, 280 p, 306 dp, 533 p, 644 p, 697 p, 760 p, 1005 p, 1127 p, 1262 p, 1290 p.

If the SN_3 group is assumed to have a planar-trigonal structure (symmetry D_{3h}), as is most probably the case, the double bands at 1290 and 1260 cm^{-1} in the IR and at 1290 and 1262 cm^{-1} in the Raman can be assigned to a ν_3 mode, and the strong, IR-inactive band at 1127 cm^{-1} to a ν_1 mode.

The product *(2)* is also a stable, colorless liquid (b.p. 158 °C/749 torr); m.wt.: calc. 244.47, found 243, in benzene. ^{1}H-NMR: singlet at δ = −0.15 ppm (TMS as external standard); ^{19}F-NMR: singlet at δ = −77.4 ppm ($CFCl_3$ as external standard).

Mass spectrum (relative intensities): molecular ion $SF_2[NSi(CH_3)_3]_2^+$ (8), $Si(CH_3)_3^+$ (100), $SF_2N_2Si_2(CH_3)_5^+$ (72), $SN_2Si(CH_3)_3^+$ (28), $SiCH_3^+$ (25), SN_2^+ (14), SN^+ (14), $SFNSi(CH_3)_3^+$ (7.5), $NSF_2[NSi(CH_3)_3]^+$ (3), $SF_2NSi(CH_3)_3^+$ (3), $SF[NSi(CH_3)_3]_2^+$ (2), $SF_2N_2Si_2(CH_3)_3^+$ (2).

IR (cm^{-1}): 580 w, 620 s, 638 s, 700 w, 710 w, 735 w, 760 w, 787 w, 840 w, 889 w, 1258 s, 1302 s, 1430 vs, 2200 s, 3000 vs.

Raman (cm^{-1}): 182, 195, 255, 338, 350, 582, 595, 620, 640, 698, 765, 790, 888, 1265, 1307, 1416, 1425.

Procedure:

NSF_3 (30 g, 0.29 mole) is added dropwise to a stirred solution of $LiN[Si(CH_3)_3]_2$ (110 g, 0.66 mole) in light petroleum (b.p. 40–60 °C) (150 ml) at 0 °C over a period of 1 h. After removal of solvent under reduced pressure, the products are fractionated in a high vacuum; yield of *(1)* about 10 g, of *(2)*, 15 g.

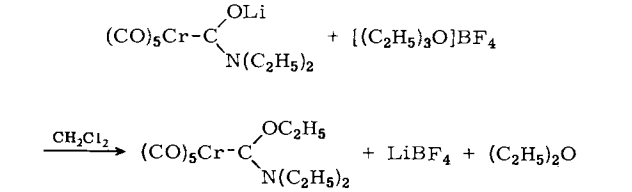
Ethoxydiethylaminocarbenepentacarbonylchromium(0)[1]

By *Ernst O. Fischer* and *Hans J. Kollmeier*[*]



Alkyl- and aryllithium compounds react with transition metal carbonyls to give lithium acylcarbonylmetalates, which can be converted into alkoxyalkyl- or alkoxyaryl complexes by alkylation[2]. We have now investigated whether lithium amides can be made to react in the same manner.

Reaction of lithium diethylamide and hexacarbonylchromium in ether affords a colorless, crystalline product which we regard as a 1 : 1 adduct and which, according to its ^{1}H-NMR spectrum, is coordinated to approximately one molecule of ether.

(1)

The IR spectrum (THF, LiF optics) of *(1)* contains four $\nu_{C\equiv O}$ bands at 2034 m, 1939 w, 1897 vs, and 1870 s cm^{-1}. In the ^{1}H-NMR spectrum ([D_6]-acetone), the signals due to the OC_2H_5 protons appear at τ = 6.6 (q) and 8.9 (t), and those of the NC_2H_5 protons at τ = 7.45 (q) and 9.0 (t) in the intensity ratio of approximately 1 : 1. The lithium salt *(1)* was ethylated with triethyloxonium tetrafluoroborate in methylene chloride to give ethoxydiethylaminocarbenepentacarbonylchromium(0) *(2)* as pale yellow crystals (m.p. 29 °C).

(2)

The structure of *(2)* was determined from the mode of preparation, complete elemental analysis, and spectroscopic findings. The IR spectrum (*n*-hexane, LiF optics) reveals two CO stretching vibrations at 2057 m (A_1) and 1927 cm^{-1} vs (A_1, E).

For an octahedral configuration of the complex, the $Cr(CO)_5$ group should have approximately C_{4v} symmetry and exhibit three IR-active fundamental vibrations: two of class A_1 and one of class E. Since only two bands are actually observed, it must be assumed that the E vibration and the second A_1 vibration coincide[3].

The ^{1}H-NMR spectrum (benzene) recorded at 25 °C contains signals due to three different ethyl groups in the intensity ratio 1 : 1 : 1. The two quartets at τ = 6.29 and 7.10 are slightly broadened as a result of quadrupole coupling with the nitrogen atom and are therefore assigned to the NCH_2 protons; the quartet corresponding to the OCH_2 protons appears at τ = 5.49. The triplets due to the CH_3 protons of the three ethyl groups are seen at τ = 8.96, 9.07, 9.25.

The positions of the $\nu_{C\equiv O}$ bands show that the (d→p)π back-donation Cr→$C_{carbene}$ in *(2)* can only be weak. The electron deficiency at the $C_{carbene}$ atom must therefore be cancelled mainly by way of π-electron interactions with the lone pairs of the two hetero atoms. The non-equivalence of the *N*-ethyl groups further supports the high bond order of the $C_{carbene}$–N bond; that of the $C_{carbene}$–O bond, however, must by considerably lower since the occurrence of only one group of signals for the C_2H_5 group rules out the existence of stable *cis-trans* isomers.

A marked double-bond character of the C–N bond in alkoxyaminocarbenes bonded to a metal was previously suspected in the Hg^{2+} complexes, also on the basis of non-equivalent *N*-alkyl groups (^{1}H-NMR)[4], and recently confirmed by an X-ray structure determination of *cis*-$Cl_2P(C_2H_5)_3$–$PtC(OC_2H_5)NHC_6H_5$[5] (the $C_{carbene}$–O bonds in this complex were also found to be considerably shorter than expected for a C–O single bond). The dipole moment of *(2)* was determined as μ_{20} = 5.75 ± 0.1 D in cyclohexane.

The mass spectrum of *(2)* provides independent proof of its structure[6]: molecular ion at *m/e* 321; there follow five peaks corresponding to the stepwise loss of five CO groups: the most intense peak at *m/e* 181 is due to the fragment $CrC(OC_2H_5)N(C_2H_5)_2^+$.

Procedure:

All operations must be carried out in the absence of air and in N_2-saturated, anhydrous solvents.

$LiN(C_2H_5)_2$ (10.0 mmoles) in ether (100 ml) is slowly added dropwise to an ice-cooled, stirred suspension of $Cr(CO)_6$ (2.2 g, 10.0 mmoles) in ether (200 ml). The yellow solution is concentrated to a volume of about 50 ml and filtered, and *(1)* is precipitated by addition of *n*-hexane. To a stirred, ice-cooled suspension of *(1)* (1.86 g, 5.0 mmoles) in methylene chloride (25 ml) is added portionwise a solution of $[(C_2H_5)_3O]BF_4$ (0.95 g, 5.0 mmoles) in methylene chloride (25 ml). After removal of solvent the yellowish-brown, oily residue is extracted with two 20-ml portions of *n*-hexane, the extract is concentrated to a volume of 10 ml and filtered, and *(2)* is precipitated by cooling to –50 °C. The crystals can be sublimed at 30 °C in a high vacuum; yield about 20% [based on $Cr(CO)_6$].

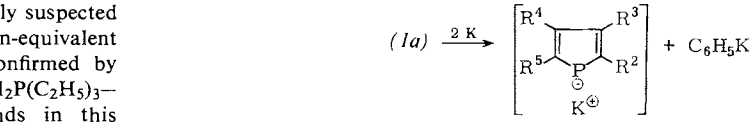
Novel Radicals from the Reaction of Phospholes with Potassium



By *Colin Thomson* and *D. Kilcast*[*]

During the investigation of the room temperature and low temperature reactions of various substituted phospholes *(1)* with potassium in dimethoxyethane (DME) and tetrahydrofuran (THF), anomalous ESR signals have been observed, similar to those found in the reduction of benzene with Na–K alloy in DME/THF[1–3].

(1)

The reaction of *(1a)* (with R^1 = phenyl) with potassium in DME at room temperature has been found to proceed as follows[4]:

We have observed three strong, distinct and interconvertible signals during the reduction of 1,2,5-triphenylphosphole *(1b)*, and of pentaphenylphosphole *(1c)* with potassium, both in DME and in THF.

Signal A consists of a 1 : 2 : 1 triplet (a_H = 6.1 gauss) split into a 1 : 4 : 6 : 4 : 1 quintet (a_H = 1.7 gauss); the signal contour corresponds to a 15 line spectrum already mentioned several times in the literature[1–3]. Under high resolution and low microwave power level, each line is split further into approximately 12 lines (separation about 0.13 gauss; cf.[3]).

Signal B consists of a doublet (a_H = 6.3 gauss) split into seven or nine lines (a_H = 1.7 gauss; cf. Fig. 1). As with A, further resolution is observed at low powers, but varying linewidths make the number of additional lines uncertain, although the separation is about 0.14 gauss.

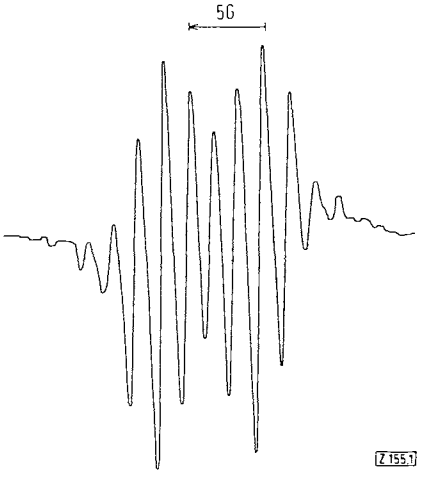


Fig. 1. ESR spectrum "B", from pentaphenylphosphole with potassium in THF at 25 °C. (Moderate resolution.)

Signal C consists of nine lines (a_H = 1.7 gauss), which have further structure at low power levels, the separation being about 0.3 gauss (Fig. 2).

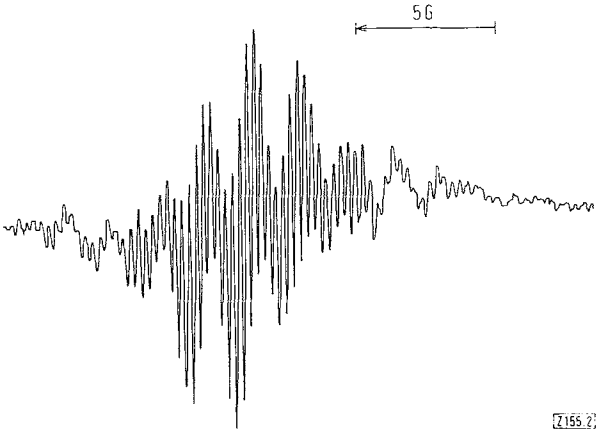

Fig. 2. ESR spectrum "C", from pentaphenylphosphole with potassium in DME at 25 °C. (High resolution.)

The g-values of all three signals, measured with respect to Frémy's salt (g = 2.0055) are g = 2.0027.

All three signals have been observed from each phosphole in both DME and THF, in no particular sequence, although signal C is usually the ultimate signal. We consider signal A to be identical to that reported in references [1–3].

That these signals are associated with the phenyl group is confirmed by the fact that no such signals are observed when R^1 = alkyl. We consider that whichever radical is produced initially, whether A, B, or C, this is a result of a radical polymerization of the cleaved phenyl group; this could occur *via* a dehydrobenzene type of intermediate, which has already been postulated for the reaction of benzene with alkali metal in hexamethylphosphoric triamide [5]. A high polymer is indicated by the large number of hyperfine lines. Since our solvent drying procedure also involved the use of $LiAlH_4$ (cf. [1–3]), the reaction would seem to be catalyzed by some impurity derived from the use of this compound. We do not consider the initial radical to undergo further polymerization, as this should change the g-values and the spin distributions. In fact, the coupling constants of the major splittings remain the same, and only the number of lines change (the largest and smallest splittings are lost in Spectrum C). This could arise from some form of rearrangement of the initial radical to one with a closely related structure.

The radicals are not the anions of the phospholes, as the spectra of these show a large phosphorus doublet [6].

No such radicals have been observed on reaction with Na or Li, the former not cleaving the phosphole, the latter reacting too slowly to give any observable radicals.

Geometry of the Transition State in Polar Cycloadditions[1] [**]

By *Richard R. Schmidt* and *Rudolf Machat* [*]

The specific *cis*-addition of amidomethylium ions *(1)* to olefins [2] is a prerequisite for, but no proof of, a synchronous process [3]. Polar cycloadditions, however, may possibly proceed in two steps, even though orbital symmetry considerations formally suggest a synchronous formation of the two new σ bonds. In order to make a decision between these two possibilities we have carried out investigations on the geometry of the transition state.

(1)

(2), R = C_6H_5-CH(OCH$_3$)-

(3) *(4)*

The reactions of *(2)* with olefins confirmed the regio- and stereospecific *cis*-addition [2]. Since R is chiral, the two diastereoisomeric oxazine derivatives *(3)* and *(4)* were obtained in varying amounts [5] (see Table 1) as a result of asymmetric induction [4].

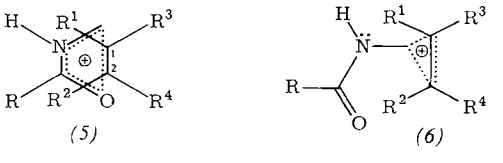

Table 1. Diastereomeric 2-(α-methoxybenzyl)-5,6-dihydro-4*H*-1,3-oxazines *(3)* and *(4)* synthesized from *(2)* and olefins.

	R^1	R^2	R^3	R^4	Yield *(3)* + *(4)* (%)	$J_{a,b}$ (Hz)	*(3)*/*(4)* [a]
(a)	H	Ha	Hb	H_5C_6	78	8.9	1.8 : 1
(b)	H	CH_3	H	H_5C_6	82	—	1.1 : 1
(c)	CH_3	Ha	Hb	H_5C_6	69	9.2	1.8 : 1
(d)	C_2H_5	Ha	Hb	H_5C_6	78	8.4	1.8 : 1
(e)	*n*-C_3H_7	Ha	Hb	H_5C_6	63	8.0	1.7 : 1
(f)	H	H	$-(CH_2)_3-$		69	—	1.4 : 1
(g)	H	H	$-(CH_2)_4-$		72	—	1.6 : 1
(h)	Hb	Ha	1,3-cyclopentylene		70	7.9 [8]	6.7 : 1

[a] Determined by NMR spectroscopy.

The ratio of diastereoisomers ought to depend upon the substituents of the olefin which are adjacent to the chiral center R. If the sizes of R^1 and R^2, and R^3 and R^4, are comparable or equal, the geometry of the transition state can readily be established. The ratio *(3a)*/*(4a)* can be used as a reference in the addition of styrene; the ratio *(3)*/*(4)* in the adducts of the styrene derivatives *(b)*—*(e)* is influenced mainly by the nature of R^2 and practically not by the nature of R^1. In the transition state of this reaction, therefore, R^2 is very much nearer to R than is R^1.

This finding is consistent only with the transition state *(5)* previously discussed for synchronous cycloadditions [6] and not with the typical transition state [7] *(6)* for the primary electrophilic attack of *(2)* on olefins, since the ratio R^1—R/R^2—R (R^1 = R^2 = CH_3) is 2.6 : 1 in the case of *(5)* and 1.1 : 1 in

(5) *(6)*

the case of *(6)*. The large increase in the ratio *(3)*/*(4)* in the series of cycloolefin derivatives *(f)*—*(h)* supports the cyclic transition state *(5)*. This and the strong influence of the methyl group in *(b)* provide evidence for the C-2 atom being situated about two bond lengths distant from the asymmetric C atom in R; such is the case only in *(5)*.

Experimental:

A mixture of *(2)* (0.01 mole) and olefin (0.015 mole) in glacial acetic acid (20 ml) was treated with a solution of conc. sulfuric acid (1.25 g) in glacial acetic acid (5 ml) (added over a period of 5 minutes). After 4 hours the reaction mixture was added with stirring to a mixture of 8 N NaOH (100 ml) and chloroform (100 ml) at 0 °C. The chloroform phase was separated off, dried over potash, and the compounds *(3)* and *(4)* isolated by distillation.

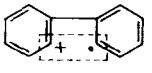
Single-Step Synthesis of Biphenylene from 9-Fluorenone in a Discharge Plasma



By *Harald Suhr* and *Rudolf I. Weiss* [*]

Decarbonylations by electron impact are well known in mass spectroscopy; thus, *e.g.*, 9-fluorenone *(1)*, which is very stable towards the action of light and heat, decomposes into CO and a $C_{12}H_8$ fragment,

(1) (1)

which has been formulated by *Beynon et al.* [1] as containing a one-electron bond:

Since the primary processes in mass spectroscopy and in plasmas are very similar [2] — particularly at high electron temperatures and low gas temperatures (cold plasmas) — reaction (1) should also take place on a preparative scale in a glow-discharge plasma. When compound *(1)* was fed as vapor through a high-frequency glow discharge at reduced pressure (≈ 1 torr), the main product formed was biphenylene *(2)* (see Table).

Yields of biphenylene in a glow-discharge plasma; composition of reaction products formed from 9-fluorenone (in wt.-%) at various RF energies.

Energy consumption of emitter (VA)	*(1)*	*(2)*	Naphthalene	Biphenyl	Polymer
30	90	10	≈0.1	≈0.1	—
41	82.5	17.5	≈0.1	≈0.1	—
60	79.5	20.5	≈0.1	≈0.1	—
93	16	1.8	0.8	1.4	80

When the vapor pressure of *(1)* is kept constant, the amount of *(2)* in the condensed reaction mixture increases to about 20 wt.-% on increasing the emission energy. A further increase in energy results in decomposition of *(1)* and *(2)* with formation of black, insoluble polymers.

Most of the compound *(2)* that is formed can be separated from unreacted *(1)* by vacuum distillation and then purified chromatographically. The reaction probably proceeds *via* cleavage of CO from the molecular ion of *(1)* with subsequent stabilization by electron capture (three-body collision or wall reaction) to give *(2)*.

A discharge apparatus having the oscillation coil of a push-pull LC oscillator (25—27 Hz) wound around it proved suitable for the experiments [3]. Both the chamber used for vaporization of the fluorenone and the reaction tube were double-walled and were thermostated at 130—131 °C by recirculating oil. In each of the experiments, 10 g of compound *(1)* was passed through the reaction tube in a period of 60—70 minutes; the reaction products were collected in a cold trap at −78 °C. After gas chromatographic analysis of the reaction products [FM 5750, 2 m, 20% silicone oil MS 710; 220 °C; 37 ml N_2/min] the fraction distilling at temperatures up to 120 °C (2×10^{-3} torr) was separated off for identification and subsequent isolation of the biphenylene. This was achieved by chromatographic separation with petroleum ether on an 80 cm Al_2O_3 column (Woelm, basic) semisaturated with picric acid [4]. After repeated recrystallization the biphenylene thus obtained had m.p. 110.9 to 111.2 °C. The UV spectrum agreed with that given in the literature [5].

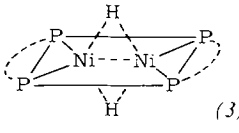
Hydrogen Bonds in a Ni–Ni System

By *Klaus Jonas* and *Günther Wilke* [*]

The Ni^0 complex $(L_2Ni)_2N_2$ (L = $(C_6H_{11})_3P$) [1], in which two nickel atoms are bound to one nitrogen molecule can be used as starting material for the preparation of hydridonickel complexes having the composition L_2NiHX (where X, for example, is Cl, CH_3COO, C_6H_5O or CH_3, C_6H_5) [2]. In the following paper we report on hydridonickel complexes,

which contain only chelating α,ω-alkanediphosphines and hydrogen as ligands.

If Ni^{II} complexes of type *(1)*, which can be prepared from $NiCl_2 \cdot 6\,H_2O$ and the corresponding phosphines[3] in alcohol, are allowed to react with $Na[HB(CH_3)_3]$ deep red crystals of the complex *(2)* are obtained.



$R = C_6H_{11}$

(2a), n = 2; *(2b)*, n = 3; *(2c)*, n = 4

According to their mass spectra — and also cryoscopic measurements in benzene in the case of *(2a)* — the compounds *(2)* are dimeric. While the IR spectra of the monomeric complexes L_2NiHX[2] show intense bands (νNiH) between 1800 and 1950 cm^{-1}, the IR spectra of the dimeric hydridonickel complexes *(2)* are void of bands in this region.

In the ^{1}H-NMR spectrum[4] of *(2)*, the signal of the hydrogen atom bound to nickel shows splitting of first order into quintets with $J_{P-H} = 23.5$ Hz, $\tau = 21.4$ for *(2a)* and $J_{P-H} = 15$ Hz, $\tau = 20.4$ for *(2c)*, *i.e.* two equivalent H atoms and four equivalent P atoms are present.

Thus, the IR and ^{1}H-NMR spectra suggest a structure in which the two nickel atoms and four phosphorus atoms lie in one plane, the two bridging hydrogen atoms, however, are situated symmetrically above and below the plane:

(3)

The complex of type *(2)* formally comprises two paramagnetic Ni units $\{R_2P(CH_2)_nPR_2\}NiH$ but is diamagnetic (NMR spectra). We presume, therefore, that *(2)* contains a Ni—Ni bond superposed by hydrogen bridge bonds in the sense of multicenter bonds as are characteristic for boranes and higher alkylboranes. That *(2)* could also occur by interation of two $\{R_2P(CH_2)_nPR_2\}Ni^0$ units with a hydrogen molecule cannot be ruled out.

The complexes *(2a)* and *(2b)* are thermally very stable. Thus *(2a)* decomposes in mesitylene solution, with evolution of H_2, only at the boiling temperature. Hydrogen is replaced even at room temperature by triphenylphosphine, olefins such as ethylene, propylene, and *cis*-butene as well as by benzonitrile or tolan; in each case the calculated amount of H_2 and the corresponding Ni^0 complexes, which have not as yet been examined closely, are formed. Compound *(2a)* reacts with *(1a)*, undergoing comproportionation to give $\{R_2P(CH_2)_2PR_2\}NiCl$ and a stoichiometric amount of H_2; reaction of *(2a)* and I_2 likewise leads to formation of H_2 and the Ni^I compound $\{R_2P(CH_2)_2PR_2\}NiI$.

Experimental:

A suspension of *(1a)* (15 g, 27 mmoles) in toluene (600 ml) is added dropwise with stirring at room temperature to a solution of $Na[HB(CH_3)_3]$ (4.8 g, 60 mmoles) in toluene (100 ml). After three hours' stirring the NaCl formed is separated off by filtration and the filtrate is evaporated to dryness under reduced pressure. The residue is dissolved in hot toluene (50 ml at about 80 °C); after addition of ether (50 ml) pure *(2a)* (10 g, 75% yield) crystallizes out.

X-Ray Structure Analysis of a 1,2,3,6,7,8-Hexathiecane[1]

By *Friedhelm Lemmer* and *Franz Fehér*[*], and *Alfred Gieren*, *Siegfried Hechtfischer*, and *Walter Hoppe*[**]

Perhydrodibenzo[1,2,3,6,7,8]hexathiecin $(C_{12}H_{20}S_6)$[2] *(1)* contains a ten-membered ring in which there are six sulfur atoms. The structure of this compound is of interest because the conformation of sulfur analogs of cyclodecane has not as yet been established[3].

We have used monoclinic single crystals (from bromobenzene) for the three-dimensional X-ray structure analysis. Crystallographic data: $a = 10.76_8$, $b = 9.10_4$, $c = 8.34_2$ Å; $\beta = 99.6_5°$; $d_{exp} = 1.48$ g/cm³; space group $P2_1/n$. The asymmetric unit cell consists of half a formula unit of *(1)* ($d_{calc} = 1.47$ g/cm³). All reflections having $\theta \leq 26°$ were measured with $Mo_{K\alpha}$-radiation on a Siemens single crystal diffractometer ($\theta/2\theta$ scan, 5-point measurement). Of 1573 independent reflections, only 271 were unobserved ($I < 2\sigma_I$).

Signs for the 300 largest unitary structural factors were determined by means of the triple product method using a program previously developed by us[4]. All sulfur and carbon atoms were visible in a successive Fourier synthesis of the phased U-values. Refinement was carried out by the method of least squares (full matrix), at first isotropically and finally anisotropically (R = 6.5%). In a difference Fourier synthesis the ten largest maxima could be assigned to the hydrogen atoms. Further refinement with the hydrogen atoms (S and C anisotropic, H isotropic) closed with an R value of 4.8% (for the observed reflections). In the last cycle the change in the parameters was on average 0.27 of the respective standard deviation.

The molecular structure is shown in Figure 1. The molecule has a crystallographic center of symmetry; deviations from the higher 2/m symmetry are not significant. The ten-membered ring has a conformation analogous to that of cyclodecane[5] with eight synclinal and two antiperiplanar partial conformations; the ring in *(1)* is, however, less strained. Replacement of the carbon atoms by sulfur atoms increases the distance between the interannular hydrogen atoms (H12—H22* and H12*—H22) from 1.8 ± 0.1 to 2.3 ± 0.1 Å. The dihedral angles in hexathiecane differ markedly from those in cyclodecane; the C—S—S—S and S—S—C—C dihedral angles are 81 and 52° respectively, the S—C—C—S dihedral angle is 164°.

The position of the sulfur atoms bound to C1 and C2 is transdiaxial with respect to the cyclohexane ring. The incorporation of the atoms C1 and C2 in the hexathiecane ring leads to a flattening of the chair conformation of the cyclohexane ring the change being most prominent at C1 and C2. The deviation of the dihedral angle of the antiperiplanar conformation of the S1—C1—C2—S2 fragment from the ideal value (180°) is −16°, in contrast to −27° in the corresponding partial con-

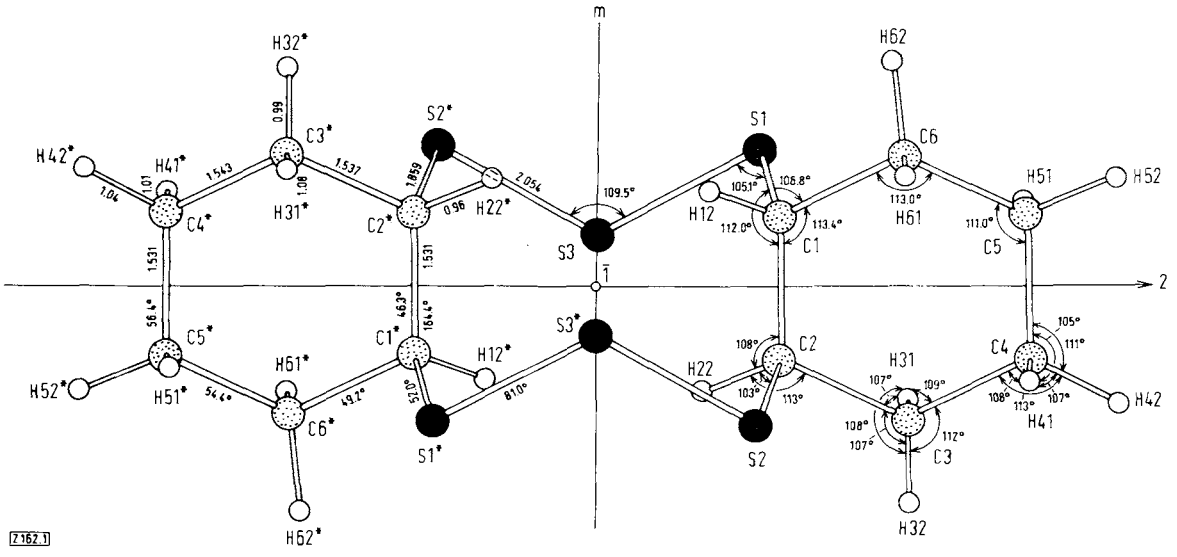

Fig. 1. Perhydrodibenzo[1,2,3,6,7,8]hexathiecin *(1)*: Projection on the C1-C2-C1* (C2*) plane.
The atoms marked with an asterisk are symmetry-equivalent to the unmarked ($\bar{1}$). The bond lengths (Å) and angles (°) were averaged according to the full symmetry of the molecule (2/m). Standard deviations of the bond lengths and angles (without averaging): σ_{S-S}, σ_{S-C}: 0.001–0.004 Å; σ_{C-C}: 0.005–0.007 Å; σ_{C-H}: 0.04–0.06 Å; σ_{S-S-S}, σ_{S-S-C}, σ_{S-C-C}: 0.1–0.3 °; σ_{C-C-C}: 0.3–0.4 °; σ_{S-C-H}, σ_{C-C-H}: 3 °; σ_{H-C-H}: 4 °. The dihedral angles in the ten-membered ring and in the six-membered ring are also given.

formation in the cyclodecane skeleton. A larger deviation from the ideal value would have led to a greater degree of flattening of the cyclohexane ring.

The C–S (1.86 Å) and S–S–S (2.05 Å) bond lengths are indicative of single bonding. The S–S–S angle (109.5 °) corresponds to a tetrahedral angle while the angle at S1 is about 4.5 ° smaller. All intermolecular distances are equal to (or greater than) the sum of the van der Waals radii. It can be concluded, therefore, that crystal packing has little influence on the conformation of the molecule.

CONFERENCE REPORTS

Kinetics of Fast Thermal Reactions in Bituminous Coal

By *Werner Peters*[*]

The by-product oven, grate firing, and fixed bed generators are used in the traditional processes for the utilization of coal. Recent developments initiated by the introduction of fluidized-bed gasification by *Winkler* in the early 1920's had the aim of improving reactor performance by increasing the reaction rates. This aim is still pursued nowadays in projects at the Bergbau-Forschung, Essen, that are just starting or are already in progress on, *e.g.* continuous coking processes, magnetohydrodynamic energy conversion, and dust gasification with process heat from nuclear reactors.

The starting point for the study of the kinetics of fast thermal reactions is based on the fact that a pyrolysis reaction, whose rate depends primarily on the temperature and thus on the heat and mass transfer, precedes heterogeneous reactions of gasification and combustion. If the physical conditions remain constant it is possible to analyze the kinetics due only to the chemical processes in specifically designed apparatus. Since the duration of a reaction is only a few hundredths of a second at heating rates of up to 10^5 °C/min the instruments must have a high resolving power with regard to time. High speed photography (40000 frames/s) and time-of-flight mass spectrometry (10000 analyses/s) have proved effective in such work.

The curves for gas evolution which were recorded at linear heating rates afford activation energies and frequency factors for the products of individual components which are valid for the relevant pyrolysis reactions. The kinetic data recorded for coals at very different heating rates (10^{-3} to 10^5 °C/min) show that the same decomposition reactions take place both during carbonification on the geological time scale and during the very fast reactions occurring in a dust flame. The experimentally determined kinetic results for pyrolysis permit deduction of the combination of pyrolysis and reaction with the gasification agent. Measurements confirm the calculated data.

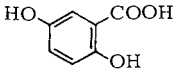
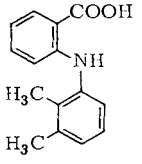
Recent Lines of Development in the Field of Antiinflammatory Agents

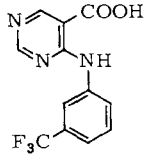


By *Alfred Kreutzberger* [*]

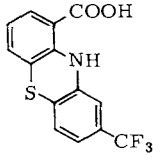
The term "antiinflammatory agents" is to be considered as a collective name for substances used in the treatment of local reactions of the vascular and supporting tissue system to local tissue damage. The discovery of very different types of active substances and numerous investigations on structural modifications (with the aim of increasing the activity and decreasing undesirable side effects) have led to a very heterogeneous class of drugs.



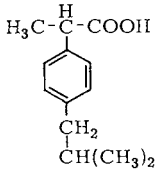
Well known fundamental types often serve as leitmotiv of such developments; *e.g.* the antiinflammatory chlorothenoxazine *(1)* [1] contains essential structural elements of the



(1)

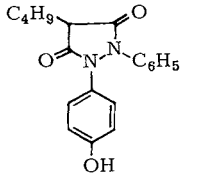


(2)

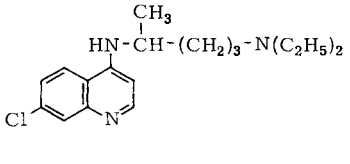


(3)

(4)

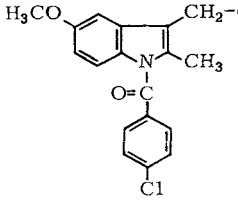


(5)



(6)

salicylic acid skeleton. Investigations on metabolism are another major source of information about substances having an improved spectrum of action. Thus the introduction of gentisic acid *(2)* into therapy followed the discovery that this substance occurs as a metabolite of salicylic acid [2]. The discovery of the highly active [3] compound mefenamic acid *(3)* resulted in the development of numerous structurally related agents such as *(4)* [4] and *(5)* [5]. Studies on the arylacetic acid systems have led to ibuprofen *(6)*, which proved to be 20 times as effective as acetylsalicylic acid in the UV erythema test [6]. Arylacetic acids can also act as antiinflammatory agents when present as part of a heterocyclic system [7].



Investigations on the metabolism of phenylbutazone inspired the introduction of oxyphenbutazone *(7)* into chemotherapy [8]. Chloroquine *(8)*, which was originally developed for the chemotherapy of malaria, is being used today in the treatment of rheumatic illnesses. Several derivatives of hydrogenated isoquinoline, which are readily accessible by reaction of carbonium ions with nitriles, have also proved to exhibit strong antiinflammatory properties [9]. An annelated heterocyclic ring is the common structural feature of another group of antiinflammatory agents, which are derived from indole, *e.g.* indometacin *(9)* [10], from indazole, like benzydamine *(10)* [11], from benzimidazole [12] or from benzotriazole [13].

Syntheses in the Cyclopeptide Series

By *Theodor Wieland* [*]

Cyclopeptides, which are produced by higher and lower organisms, have recently acquired significance as antibiotics, uncouplers of oxidative phosphorylation, toxins, and antitoxins. In the author's laboratory, analytical and synthetic studies on the cyclic peptides of the green death cup fungus (*Amanita phalloides*) have been in progress for some time.

The phallotoxins and amatoxins are respectively hepta- and octacyclopeptides whose ring is divided by a thioether or a sulfoxide bridge to position 2 of the indole ring of the tryptophan lying in the opposite position of the ring. They contain, *inter alia*, γ-hydroxylated leucine or isoleucine as an important structural unit. While the γ-OH of phallotoxins can be replaced by H without any loss of toxicity [norphalloin (LD_{50} = 1.5 mg/g white mouse) is even more toxic than phalloidin (LD_{50} = 2.5 mg)], its absence from amatoxins leads to loss of toxicity. Both the naturally occurring amanullin — having isoleucine in place of γ-hydroxyleucine — and an "aldoamanitin", prepared oxidatively and containing an aldehyde function in the γ-position, are non-toxic. Whereas α-amanitin clearly inhibits [1] the function of an RNA polymerase of mammalian cell nuclei at a concentration of 0.02 μg/ml, aldoamanitin again has no toxic action.

Norphalloin has been obtained by total synthesis[2]. Such a preparation of amatoxins remains to be accomplished. However, several syntheses of the antitoxin antamanide[3] are known, including one based on a Merrifield synthesis which gives a linear decapeptide that is subsequently cyclized. Suitable processes are the mixed anhydride method or the use of dicyclohexylcarbodiimide with addition of *N*-hydroxysuccinimide.

Antamanide, an antagonist of phalloidin, lowers the vapor pressure of an alcoholic NaBr solution and reduces the electrochemical activity of an alcoholic NaBr solution at the Na^+ sensitive glass electrode; further, its ORD spectrum shows a marked change in the presence of Na^+ ions and to a much lesser degree in the presence of K^+ ions. Since phalloidin leads to liberation of K^+ ions in an isolated perfused rat-liver preparation[4], a biological action *via* alkali metal ions cannot be ruled out.

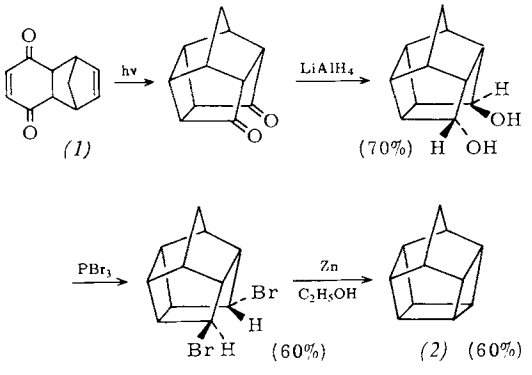
SELECTED ABSTRACTS

Liquid ethyl azide can explode. A brief communication dealing with the explosion of azides in the laboratory reports on a recent observation by *E. Koch* of a 300 ml stoppered flask containing 70 g ethyl azide exploding, without any outside influence, 3—4 minutes after having been transferred from storage at −55 °C to the laboratory bench. It is assumed that the explosion was not due to the presence of contaminants but rather the gradual increase in pressure in the flask that was stoppered with an ungreased glass stopper. Either the stopper became loose as a result of shaking or the flask cracked, so that the ethyl azide could have been brought to the point of explosion mechanically. — Ethyl azide is known as a distillable liquid that explodes only at temperatures above 200 °C or when subject to mechanical stress. / Nachr. Chem. Techn. *18*, 26 (1970) / —Kr. [Rd 154 IE]

***n*-Butyllithium cleaves carboxamides,** as has been established by *H. A. Smith* and *C. R. Hauser* for 2,2,2-triphenyl- and 2,2-biphenylacetamide. 2,2-Triphenylacetamide in THF was heated for 6 h with 1.2 mol. equiv. of *n*-butyllithium in hexane and, after work-up, afforded triphenylmethane (65 %)



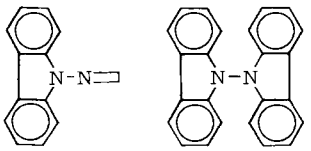
(1) *(2)*

alongside starting material (21 %). It is assumed that the reaction proceeds *via* the dilithium compound *(1)* and leads initially to tritylllithium *(2)* and lithium cyanate. / J. Amer. chem. Soc. *91*, 7774 (1969) / —Kr. [Rd 159 IE]

A method for analysis of the surface layer of solids is described by *A. Benninghoven*. The surface is bombarded with argon ions of suitable energy (a few keV) at a very low current density (of the order of 10^{-9} Å cm^{-2}); the secondary ions liberated are analyzed by mass spectrometry. The energy of the primary ions is chosen such that the secondary ions are emitted almost exclusively from the first surface layer. The time required for degradation of a monolayer is of the order of 10^4 s. The variation in the intensity of the mass peaks of a particular ionic species with time permits an unequivocal decision whether the species arises only in the first layer or also in deeper layers. The facts that sufficiently stable surface compounds can be detected and that isotopes can be separated represent advantages of the present method over the other technique of surface layer analysis, Auger electron spectroscopy. / Z. Physik *230*, 403 (1970) / —Hz. [Rd 162 IE]

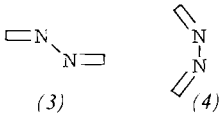
Homopentaprismane, hexacyclo[5.4.0.0^{2,6}.0^{3,10}.0^{5,9}.0^{8,11}]undecane *(2)*, a new cage compound, has been synthesized by *G. R. Underwood* and *B. Ramamoorthy* from the *p*-benzoquinone/cyclopentadiene adduct *(1)* *via* the following simple route:

(2) is a white, volatile compound, m.p. 98—100 °C, which is resistant to attack by Br_2 in CCl_4. / Chem. Commun. *1970*, 12 / —Ma. [Rd 160 IE]



The existence and the oxidation potential of heptavalent neptunium was investigated by *A. J. Zielen* and *D. Cohen*. In sodium hydroxide solutions, Np^{VII} and Np^{VI} form a reversible redox couple; the potential determining reaction was shown to be

$$e^- + NpO_5^{3-} + H_2O \rightleftharpoons NPO_4^{2-} + 2\ OH^-.$$

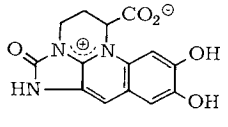


The formal potential of the system in 1 N NaOH at 25 °C is 582.1 ± 0.45 mV *vs.* the normal hydrogen electrode. Besides ozone oxidation of neptunium(V) hydroxide, electrolysis was found to be a good preparative method for heptavalent neptunium. In its infrared spectrum in aqueous alkaline solution, Np^{VII} exhibits a single band at about 1100 cm^{-1}, as does Np^{VI}. / J. physic. Chem. *74*, 394 (1970) / —Hz. [Rd 165 IE]

Magnetophotoselection was used by *G. P. Rabold* and *J. M. Gaidis* to distinguish between several possible structures *(1)*—*(4)* of 9,9′-bicarbazole. If a rigid solution of bicarbazole is irradiated at 77 °K with polarized light only those molecules will be excited that have a transition moment, for the wavelength used, closely parallel to the direction of polarization of the exciting light. The triplet states generated by

subsequent intersystem crossing can be identified by ESR measurements. With the aid of Hückel MO theory, ESR spectra were calculated for *(1)*—*(4)* and compared with the

(1) *(2)*



(3) *(4)*

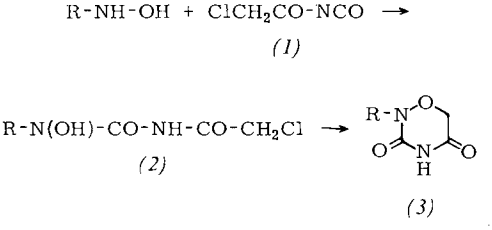
experimental spectra taking into account the relative orientation of magnetic field and plarization plane of the exciting light. The agreement between prediction and experiment strongly favors structure *(1)* with sp^2 hybridization of the nitrogen atoms. / J. physic. Chem. *74*, 227 (1970) / —Hz.

[Rd 166 IE]

The Mössbauer spectra of hexaammineiron(II) chloride are reported by *L. Asch, J. P. Adloff, J. M. Friedt*, and *J. Danon*. At room temperature, the salt exhibits a single line, characteristic of a perfectly octahedral environment. Upon cooling, two other lines, symmetrical about the former, appear at 109.5 °K; at 107 °K, the single line has disappeared. Upon heating, the single line reappears at 110 °K, the doublet has vanished at 116 °K. The splitting at low temperature can be explained in terms of frozen rotation of the NH_3 ligands around the Fe—N axes. At high temperature, however, the rotation is free and fast enough to produce an octahedral average symmetry around the iron ion. The hysteresis is also known from ESR investigations on nickel(II) hexaamines and is characteristic for order-disorder transitions with cooperative interaction between neighboring complexes. / Chem. Physics Letters *5*, 105 (1970) / —Hz. [Rd 167 IE]

The crystal structure of the chromophore from the yellow-green fluorescent peptide produced by iron-deficient *Azotobacter vinelandii* has been determined by *J. L. Corbin, I. L. Karle*, and *J. Karle* by X-ray crystallographic examination of a methylated derivative. The structure is that shown in *(1)*. The

(1)



unusual heterocyclic structure of the chromophore has not heretofore been observed in any naturally occurring system. Chem. Commun. *1970*, 186 / —Ma. [Rd 171 IE]

A new separation method for gas molecules of different mass is discussed by *R. Campargue*. The shock wave system of a supersonic gas jet in the pressure range 10^{-2}—1 torr tends to aspirate gas molecules from its surroundings. When a gas mixture is introduced into the nozzle chamber outside the jet boundary, the light molecules are selectively carried away by the jet and can be enriched by "skimming" the jet. The separation efficiency is superior to that of gas diffusion: the separation factor defined by

$$S = f_2(1-f_0)/f_0(1-f_2)$$

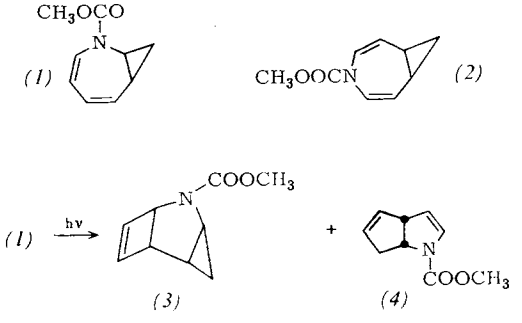
(f is the mole fraction of the light component, the subscripts 0 and 2 refer to starting and final mixture, respectively) for example, reaches, with optimum conditions, 1.01 for $^{32}SF_6$ $^{34}SF_6$ with N_2 as the carrier gas, as compared to the diffusion separation factor of 1.0068. / J. chem. Physics *52*, 1795 (1970) —Hz. [Rd 169 IE]

A new method for the synthesis of the 1,2,4-oxadiazine ring system is described by *P. Rajagopalan* and *B. G. Advani*. Chloroacetyl isocyanate *(1)*, which can easily be prepared from chloroacetamide, reacts with *N*-monosubstituted hydroxylamines in anhydrous benzene medium to yield the *N*-chloroacetyl-*N'*-hydroxyureas *(2)*. Compounds *(2)* readily

undergo cyclization in 2 % aqueous NaOH to afford, upon acidification, 2-substituted 2*H*-1,2,4-oxadiazine-3,5(4*H*,6*H*)-diones *(3)* (overall yield 30—60 %). / Chem. Commun. *1970*, 167 / —Ma. [Rd 172 IE]

R = isopropyl, phenyl, 4-chlorophenyl, 4-methoxyphenyl, 3-nitrophenyl, 2,5-dichlorophenyl

Formamides from carbon dioxide, amines, and hydrogen in the presence of transition metal complexes is the subject of a report by *P. Haynes, L. S. Slaugh*, and *J. F. Kohnle*.



$$R_2NH + CO_2 + H_2 \rightarrow R_2NCHO + H_2O$$

The amines employed included, *inter alia*, dimethylamine, di-*n*-propylamine, and piperidine. Typical catalysts were $[(C_6H_5)_2P{-}CH_2{-}CH_2{-}P(C_6H_5)_2]_2CoH$, $[(C_6H_5)_3P]_3RhCl$, and $[(C_6H_5)_3P]_2(CO)IrCl$. Although the reaction is not fast at 100—125 °C, it is clearly catalyzed. In the DMF synthesis, tetramethylurea does not occur as intermediate. The following reactions are — at least for the irdium system — consistent with the results obtained.

$$LxMH + CO_2 \rightarrow LxMOCHO \xrightarrow{HN(CH_3)_2} LxMOH + DMF$$
$$LxMOH + H_2 \rightarrow LxMH + H_2O$$

Tetrahedron Letters *1970*, 365 / —Kr. [Rd 175 IE]

The synthesis and photoisomerization of homo-1*H*-azepine derivatives is described by *L. A. Paquette* and *R. J. Haluska*. On heating a solution of methyl azidoformate in cyclohepta-

(1) *(2)*

(3) *(4)*

triene (4 h, 127–128 °C) a mixture of the homo-1*H*-azepines *(1)* and *(2)* was formed (total yield 35 %) which was separated by preparative gas chromatography. Presumably the compounds are formed by valence isomerization of initially formed methoxycarbonylaziridines. The NMR spectra of *(1)* and *(2)* are not temperature dependent, *i.e.* valence isomerization does not now take place. *(1)* and *(2)* do not enter into cycloadditions. Irradiation of *(1)* gives a mixture of *(3)* and *(4)* while *(2)* is virtually unaffected. / J. org. Chemistry *35*, 132 (1970) / —Kr. [Rd 176 IE]

Tetrakis(acetatomercurio)methane, $C(HgOCOCH_3)_4$, a crystalline, stable, water soluble substance has been prepared in good yields by *D. S. Matteson, R. B. Castle,* and *G. L. Larson* by heating a mixture of $C[B(OCH_3)_2]_4$ and $Hg(OCOCH_3)_2$ under reflux. Pure $C(HgOCOCH_3)_4$, m.p. 265–285 °C (dec), gives a white precipitate with NaOH and with $SnCl_2$. An iodine compound $C(HgI)_4$, m.p. > 300 °C, can also be formed. The stability of the C—Hg bond may be explained by the shielding of the carbon atom by the four Hg atoms. / J. Amer. chem. Soc. *92*, 231 (1970) / —Kr. [Rd 178 IE]

BOOK REVIEWS

Inverse Polarographie und Voltammetrie Inverse Polarography and Voltammetry). By *R. Neeb*. Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., xii + 256 pp., 139 figures, 33 tables, plastic, DM 48.—.

The high detection sensitivity of electrochemical analytical methods has contributed to the widespread use of polarography. The sensitivity of any analytical method can be substantially increased by integrating processes. Inverse polarography constitutes such a process, in which substances present in an electrolyte solution are collected by deposition on a stationary mercury drop or mercury pool or on other electrodes made of suitable materials with simultaneous selection by the applied potential. The process is therefore particularly suitable for trace analysis.

The present work gives the first really comprehensive and up-to-date treatment of this process. The first section contains a concise and very lucid review of the principles of the enrichment process. The second section deals with the electrochemical methods used for the quantitative determination of the collected substances. A detailed experimental section follows, in which emphasis is given to the description of the electrodes and the apparatus employed. This section also contains a discussion of the sources of error. The second part of the work deals with the methods used to determine particular elements and includes the relevant literature data. The highly informative book can be recommended without reservation to everyone interested in this field.

Heinz Gerischer [NB 855 IE]

Terminologie Chimique Franco-Anglaise. French-English Chemical Terminology. An Introduction to Chemistry in French and English. By *H. Fromherz* and *A. King*. Translated by *J. Jousset*. Verlag Chemie GmbH, Weinheim/Bergstr. and Gauthier-Villors, Paris 1968, 1st Edit., xix + 561 pp., linen, DM 66.—.

As far as the average chemist is concerned, technical dictionaries are often unsatisfactory. Despite the fact that he is perfectly capable of understanding "Keton", "ketone", or "cétone" without their help, they nevertheless burden the luckless reader with pages of translations for terms that are obvious to anyone expert in the subject. Certain dictionaries in the chemical field omit these terms; such dictionaries simplify the problem for the chemist who is trying to read a paper in his own subject[1]. If, however, a paper is to be translated into the foreign language, there still remains the problem of the correct usage of words, the problem, in short, of terminology.

The present book is not a dictionary but a series of parallel texts, the French and the English versions being printed on facing pages. In this way, in the guise of a very simple but comprehensive introduction to chemistry, it actually provides a comparison of the terminology used. A wide range of topics in physical, inorganic, organic and analytical chemistry is covered. It must be admitted that in places the material is rather outdated. (In 1934, when the original German-English version of the book was published[2], it may well have been true to say that "Sugden's parachor method is much used in Britain!") As an introduction to chemistry, however, the book is surprisingly clear and free from errors. The presentation is in general limited to facts and to theories that have stood the test of time. With a few exceptions, the French translation faithfully reproduces current usage, and should provide a quick way for the English-speaking reader to get to grips with this terminology; in the same way, French-speaking readers will be able to acquaint themselves with contemporary English usage. I am convinced that both groups will learn to value this book, and in many cases will make use of it as a chemically-orientated dictionary and language textbook.

In a book like this errors are particularly dangerous though possibly, in view of the breadth of coverage, unavoidable. Thus "Cardiac glycosides" are not "les glycosides du coeur"; "ribose" is "le" and not "la"; DNA has a "structure en double hélice", not "à double filet"; adrenalin is "une hydroxy-amine", not "une hydroxylamine"; ESR is "RPE", never "RPM"; chemical displacements are "déplacements chimiques", not "transferts chimiques". Fortunately mistranslations such as these occur in only a few chapters, and these are generally more up-to-date than the rest of the book and thus offer the reader fewer difficulties in other respects.

Guy Ourisson [NB 857 IE]

[1] *R. Cornubert:* Dictionnaire Chimique Allemand-Français. Chemisches Wörterbuch Deutsch-Französisch, Dunod, Paris 1967, 3rd Edit..

Dispersions of Powders in Liquids, with Special Reference to Pigments. By *G. D. Parfitt*. Elsevier Publishing Company, Amsterdam-London-New York 1969. 1st Edit., xiii + 354 pp., numerous figures and tables, bound, Dfl. 52.—.

Nine contributions from eleven eminent authors, including the editor, have been effectively combined into one homogeneous work. The subject is approached from various points of view. The book has been written for scientists in whose work highly dispersed solids play a role. Particular attention is given to problems of interest to manufacturers and users of pigments wishing to keep up with the latest developments. One should not be dismayed by the fact that the dispersion process is influenced by numerous factors that are difficult or impossible to define in practice. The editor lays stress on the fact that the sensible use of certain guidelines can lead to better dispersions and a better understanding of the dispersion process. This alone is a good enough reason for "students" of all ages to peruse this book.

The first two chapters (I: *M. J. Jaycock*; II: *A. L. Smith*) deal with the scientific principles concerned in solid-liquid interfaces. Starting with the forces between atoms, ions, and molecules, the authors go on to discuss boundary surface energy, wetting, adsorption, and, finally, electric double layers and zeta potentials, covering innumerable surface properties and

[2] Cf. Angew. Chem. *75*, 696 (1963).

concepts. The principles of the dispersion process, dispersibility, and stability or flocculation of dispersion form the subject of the next chapter (*G. D. Parfitt*). Obviously, in the given context consideration must be given to agglomerates and aggregates. After all, these structural formations of powdered substances are the reason why dispersion is necessary. These processes are mentioned in the fourth chapter (*A. G. Walton*), which gives a general survey of the formation and growth of nuclei in precipitation reactions. The few facts on the problem of agglomeration in precipitation for which space could be found suggest that further research is needed.

The fifth chapter (*S. H. Bell* and *V. T. Crowl*) is devoted to industrial applications of dispersions and the relevant methods of measurement. It is followed by a chapter (*W. Black*) on the effects of surface-active agents. The industrial aspects of dispersion classified according to dispersion machines and products are summarized in the seventh chapter (*R. Sheppard*). The book ends with chapters on inorganic (*H. D. Jefferies*) and organic (*H. D. Brearley* and *F. M. Smith*) pigments giving information on pigment-specific dispersion and other application problems.

The references are given at the end of each chapter, and the book contains about 500 in all. A short but adequate index is provided. The presentation of the material is good, the photographic reproductions being of satisfactory quality and the schematic drawings clear and distinct. The book deserves every success.

B. Honigmann [NB 865 IE]

Introduction to Quantum Chemistry. By *J. M. Anderson*. W. A. Benjamin, Inc., New York 1969. 1st. Edit., xiv, 445 pp., numerous Figs. and Tables, bound $ 14.95.

Since quantum mechanics or quantum chemistry became one of standard courses in chemistry departments about fifteen years ago, numerous and varied textbooks on this subject have been published. Although many excellent quantum mechanics textbooks are available today (*Messiah:* Quantum Mechanics; *Dike* and *Wittke*: Introduction to Quantum Mechanics; *Saxon*: Elementary Quantum Mechanics; *Merzbacher*: Quantum Mechanics, *Gotterfied*: Quantum Mechanics, *etc.*), it is still quite difficult to find a suitable text for a one-semester introductory quantum mechanics or quantum chemistry course for chemists. The reason for this is that most excellent quantum mechanics textbooks are primarily written for physicists and some good quantum chemistry books (*Pauling* and *Wilson*: Quantum Mechanics; *Eyring, Walter*, and *Kimball*: Quantum Chemistry: *Kanzman*: Quantum Chemistry, *etc.*), are out of date. In the reviewer's opinion this book can fill in the gap and can serve very well as a textbook for a one-semester introductory quantum chemistry course. This book has four striking features: (1) The *Heisenberg* and *Schrödinger* viewpoints are developed and used simultaneously throughout and the emphasis is on the formulation of quantum mechanics. In doing so, students can get a more general and more rigorous view of quantum mechanics. (2) The notation used is in line with that found in the current literature. This enables students to follow the papers on quantum chemistry which appear in modern chemical and physical journals. (3) Some problems in the book are solved by computer. This makes students able to appreciate the importance of the computer in modern quantum chemistry. (4) Topics chosen in the book are important and useful to chemists. However, the book also has some shortcomings, namely: (1) Some presentations are too sloppy or unclear. (2) There are quite a few typographical errors.

The author begins his presentation with the discussions on some intuitions and some experiments in quantum mechanics; then follows a postulational introduction to quantum mechanics. Both matrix mechanics viewpoint and wave mechanics viewpoint are introduced and developed simultaneously by a very fresh approach – one which differs from most competing texts of quantum chemistry. Constant potential problems such as the free particle, the particle in a box, the motion of a particle in region of several constant potentials *etc.* are discussed. The quantum mechanical concepts of these problems are emphasized. After briefly describing the many-body, many-coordinate systems, angular momentum is introduced. Following this the harmonic oscillator and the hydrogen atom are treated in quite an elegant manner.

The second part of the book considers the approximation methods in quantum chemistry. Variational method and perturbation theory are explained in detail. The applications of variational method and perturbation theory to atomic and molecular systems are illustrated very well. The molecular orbital theory, valence bond theory, Hartree-Fock SCF and LCAO are discussed. Time-dependent theory and spectroscopic theory are also presented. The author concludes the book with a descriptive treatment of scattering theory.

Overall, the presentations are good and the approaches are fresh. However, in some places, I think that there would be a more effective way to convince readers, but the author just throws up his hands by asking readers to believe him (*e.g.* p. 27 lines 6 and 7). For a textbook of this level (intended for seniors and first year graduate students), in some places the presentations should be more detailed. For example, on p. 37, the derivation of Eq. (1—41) is presented poorly. On p. 347, without discussing properties of Dirac Delta function or mentioning it, the author just states: "now $\int_{-\infty}^{\infty} e^{i(k'-k)} = 0$; ..." (Readers have to believe it!) Despite these minor shortcomings, I still highly recommend this book to be used as a textbook for the one-semester introductory quantum chemistry course.

Yuh Kang Pan [NB 869 IE]

Amino Acids Determination – Methods and Techniques. By *S. Blackburn*. Marcel Dekker, Inc., New York-London 1968, 1st Edit., xi + 271 pp., numerous figures, bound, approx. DM 52.—.

This book is intended for the man at the bench in amino acid analytical laboratories, research institutes, and in industry. The title theme is the unifying thread that holds the whole volume together. The concise and practical nature of the work is lost sight of only in the opening chapter on the history and importance of amino acids analysis, and the chapter might well have been shortened to make room for more operating instructions and recommendations. This would have been to the advantage of the more important first half of the book, which deals with ion-exchange chromatography and the associated technology and use of modern automatic analyzers, highlighting the author's knowledge and experience of the subject. The very latest developments in theory and practice have been covered, as far as this is possible in a widely ramified field characterized by continuous improvements in equipment. The plentiful literature references in each section are treated only briefly and in review fashion in the text; occasionally a definite evaluation would perhaps be preferable.

The second half of the book deals, with acceptable brevity, with such vital methods and techniques as paper and gas chromatography, infrared and mass spectrometry, and the proven high-voltage electrophoresis. All things considered, the treatment of the analysis of physiological fluids is definitely too short. Despite this, the book is highly recommended to anyone who uses or runs an amino-acid analyzer.

Mineralöle und verwandte Produkte. (Mineral Oils and Related Products). A handbook for laboratory and industrial use, in two volumes. Edited by *C. Zerbe*. Springer-Verlag, Berlin-Heidelberg-New York 1969, 2nd Edit., 1834 pp., 582 figures, bound DM 348.—.

This work contains more than would be expected from the title. Written by 42 well-known specialists, it is first and foremost a laboratory handbook for the testing and evaluation

of mineral oils in the widest sense. The first chapter, "General Methods of Testing", reviews methods of determining physical properties and describes various chemical tests, including the methods for the statistical determination of constitution. In addition, it includes a section by *H. Luther* on physicochemical tests, which in its 260 pages provides a comprehensive handbook on modern physicochemical methods of analysis in organic chemistry, going far beyond the analysis of hydrocarbon mixtures. There are 10 chapters on specific analytical methods. Each chapter is preceded by a state of the art review, which deals with the processes concerned and gives statistical data.

Almost all sections of the book have been rewritten for the second edition. It is a pity that the division into chapters is still the same as in the first edition, since this division has a confusing effect. In the chapter "Petroleum and petroleum products" we find as subsections "Gasoline", "Fuel oil", and "Bitumen"; these are not really comparable, since the sections on "Fuel oil" and "Bitumen" are principally concerned with test methods, while the section on "Gasoline" is primarily concerned with process descriptions. To find test methods for gasolines it is necessary to consult another chapter on "Fuels". Although it is justifiable to have a chapter on "Fuels" and another on "Lubricants", I find it difficult to understand why a chapter is devoted to the Fischer-Tropsch synthesis. It does not seem likely that any user of this book will be working in a Fischer-Tropsch plant. The inclusion of a chapter on "Fuller's earth" is also puzzling, since this is not a mineral oil product, and in any case other materials used in petroleum processing (*e.g.* catalysts) are of greater significance. The appearance of sections such as "Natural gas" or "Town gas from mineral oils" in the chapter on "Fuels" is not an aid to clear understanding.

The literature has been carefully sifted, and an ample (though alas not uniform) selection of references is provided. The wealth of information supplied is sufficient recompense even for the somewhat high price. In any mineral oil laboratory this book is indispensable and irreplaceable by any other book, so that it really needs no recommendation. Every oil chemist should have a copy. *H. J. Neumann* [NB 867 IE]

Mathematics for Quantum Chemistry. By *J. M. Anderson*. W. A. Benjamin, Inc., New York 1966. 1st Edit., x, 154 pp., numerous Figs. and Tables, bound $ 3.95.

This is a readable but somewhat superficial (monograph) booklet on physical and mathematical preparation for quantum chemistry. The author begins with a brief discussion of eigenvalue problems in quantum mechanics and classical mechanics, then introduces the concepts of orthogonality and normalization, expansion in terms of orthonormal functions, the Fourier series, construction of orthonormal functions, the Legendre polynomials, associated Legendre polynomials, Laguerre polynomials, and Hermite polynomials. After the chapter on orthogonal functions, the essential topics of linear algebra such as matrices, determinants, linear transformations, and linear operators are discussed. Following these the conservation laws, generalized coordinates, Lagrange's equations, Hamilton's equations, vibrations of a mechanical system, and rotations of a rigid mechanical system are presented. Finally, the bridge between classical and quantum mechanics, the synthesis of matrix and wave mechanics is discussed. Overall, the presentations are quite clear even for the average junior or senior. The topics chosen in the book are useful to students of chemistry who intend to take quantum chemistry course(s) in the future. The author does not exhaust all important mathematical background topics of quantum chemistry as he states in his preface; in the reviewer's opinion, at least the Dirac delta function and elementary integral transforms should be introduced or briefly described. In the chapter on linear algebra, pieces of information are loosely put together without the beauty of logic. The beautiful logical structure of linear algebra and its implications to the formation of quantum mechanics are not fully explored. In some places the presentations are too brief to be consistent with overall development of the book (*e.g.* on p. 29 the derivations of Eqs. (2—56) and (2—57), on p. 81 the derivation of Eq. (3—60), on p. 90 to 91 the example of the projection operator *etc.*). Besides these, there are a few typographical errors in the text and some mistakes in the answers to problems. For example, p. 36 line 10, a_0 should be a_1; p. 37, line 7 from the bottom, $(n+1)$ should be $(l+1)$; p. 37 line 5 from the bottom the last term $2 \times n \frac{d^{l+1}y}{d\chi^{l+1}}$ should be $2 \times l \frac{d^{l+1}y}{d\chi^{l+1}}$; p. 37 line 4 from the bottom, $2n\,(n+1) \frac{d^l y}{d\chi^l}$ should be $2l\,(l+1) \frac{d^l y}{d\chi^l}$; p. 38 right hand side of Eq. (2—97) should be $-\frac{1}{2^l l!} \frac{d^l}{d\chi^l}(1-\chi^2)^l$ or $\frac{1}{2l!} \frac{d^l}{d\chi^l}(\chi^2-1)^l$ p. 72 line 8, —4 should be +4 *etc.* Despite these shortcomings, it is still a very good supplementary reading for quantum chemistry course(s) and a mathematical course for chemists. Because the scope of the book is not sufficiently broad nor its degree of sophistication sufficiently deep, I do not recommend this book to be used as the main textbook for an "Applied Mathematics for Chemists" course for seniors or first year graduate students. *Yuh Kang Pan* [NB 868 IE]

Modern Steroid Problems

By Rudolf Wiechert[*]

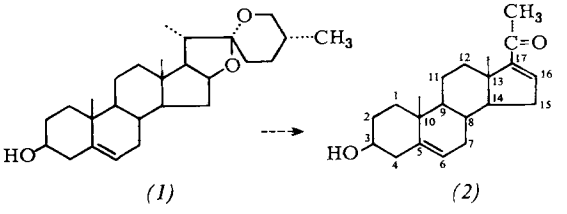
Dedicated to Professor R. Tschesche on the occasion of his 65th birthday

The present article is concerned primarily with the latest developments in the fields of steroids exhibiting contraceptive, antiandrogenic, or cardiac activity and of steroid metamorphosis hormones. Both the biological action and the current sources of raw materials are considered.

1. Introduction

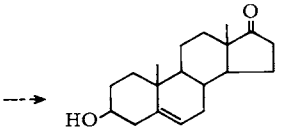
Of all the natural products, no group has had more time and work devoted to it by a variety of scientists than the steroids.

The history of the steroids is rich in scientific climaxes, such as the isolation, structural elucidation, and synthesis of the sex hormones in the 1930's, and the beneficial discovery of the antiarthritic and antiinflammatory effects of the adrenocortical hormones.



The diversity of the biological effects of steroids and their potentiation and variation by chemical modification are unequalled among the natural products.

As an extreme example of the versatility of these substances, the male sex hormone testosterone[1] and several pregnane derivatives[2–4] have been found in surprising quantities as active substances in the prothoracic defensive gland secretions of some water beetles.



The purpose of the present article is to provide a picture of the latest developments and of some of the problems that await solution. The evaluation and selection of the topics are naturally subjective. Thus no mention is made, for example, of the use of steroids in mechanistic and steric studies or in the development of new physical methods.

2. Sources of Raw Materials

The raw material for by far most of the steroids produced at present is diosgenin *(1)*. The development of this natural product, which occurs in the roots of several types of Dioscorea, is due to the work of *R. E. Marker*[5]. The dried roots of the plants, which grow wild, *e.g.* in Mexico, Guatemala, India, China, and South Africa, contain about 5–6% of diosgenin.

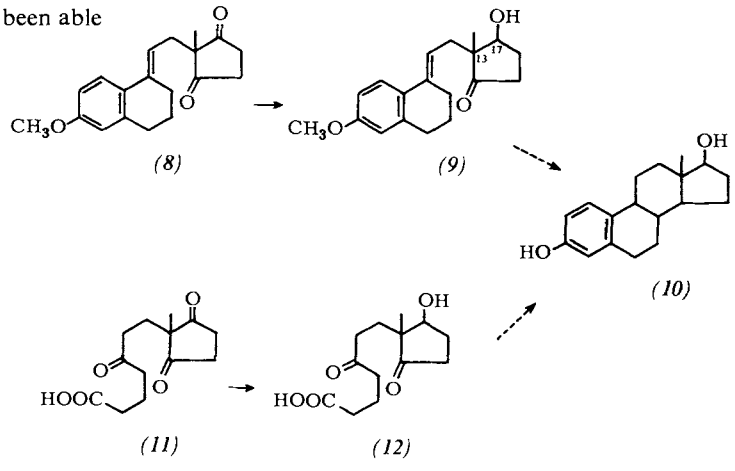
Nearly all the steroids in therapeutic use can now be obtained on the industrial scale from diosgenin *via* 3β-hydroxy-5,16-pregnadien-20-one *(2)* and 3β-hydroxy-5-androsten-17-one *(3)* [6].

Stigmasterol from soybean sterols is of limited importance as a raw material for the synthesis of corticosteroids.

As a result of the development of new microbiological processes, cholesterol *(4)* or β-sitosterol could regain interest as raw materials in the future, particularly for the synthesis of 19-nor steroids. Whereas the oxidative chemical degradation of the C-17 side chains, as used in the past, gave only small yields, the microbiological degradation to 17-ketones gives yields of more than 70% in some cases.

Using cultures of *Mycobacterium phlei* with added nickel sulfate, a group of Dutch workers has been able to degrade cholesterol *(4)*, with simultaneous oxidation, double-bond isomerization, and dehydrogenation at C-1 and C-2, to the 1,4-diene-3,17-dione *(5)* [7].



(4) *(5)* *(6)* *(7)*

Sih et al. [8] converted 19-hydroxycholesterol 3-acetate *(6)* directly into estrone *(7)* by means of a microorganism isolated from soil samples (CSA-10). *(6)* is obtainable from cholesterol in only three steps [9].

Progress in stereochemistry, and particularly the recognition of the stereoelectronic principle in additions to carbonyl and olefinic double bonds and of the importance of the energy of intermediates, as well as the estimation of the accessibility of reaction centers, have recently led to the development of total estrone syntheses for industrial use by the research groups of *Velluz* [10,11], *H. Smith* [12–14], and *Anachenko* and *Torgov* [15–17].

The successful use of enzymatic asymmetric reduction has made total steroid syntheses capable of competing economically with partial syntheses from plant or animal material.

(8) *(9)* *(10)* *(11)* *(12)*

By enzymatic reduction of one keto group in the prochiral diketone *(8)*, *Gibian et al.* [18,19] obtained the compound *(9)*, in which the later centers of asymmetry C-13 and C-17 already have the same configuration as

the natural steroids. With *Saccharomyces uvarum* (CBS 1508), this reduction gave a yield of 75%.

Another prochiral intermediate, the triketone *(11)*, also undergoes stereoselective enzymatic reduction to *(12)* with *Rhizopus arrhizus* Fischer [20].

An entirely new approach is found in a total synthesis of racemic 16,17-didehydroprogesterone *(16)* that was recently reported by *Johnson et al.* [21]. The key reaction is a non-enzymatic biogenesis-like olefin cyclization with stereospecific formation of five centers of asymmetry.

(13) *(14)* *(15)* *(16)*

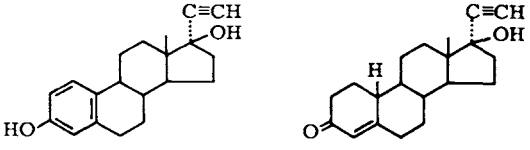
The tetraenol *(13)* is stereospecifically cyclized to the tetracyclic diene *(14)* by the action of trifluoroacetic acid at −78 °C, and oxidation with osmium tetroxide followed by double alkaline ring closure in the intermediate triketo aldehyde *(15)* yields *(16)*.

In view of the constantly growing demand for steroids and the limited quantities of natural raw materials, total syntheses can be expected to increase in importance in the future. Total syntheses also have the advantage of a wide scope for variation in the preparation of new steroids.

3. Contraceptive Steroids

The groundbreaking work of *Pincus* [22] has led in the last decade to the use of steroids for fertility control.

The sociopolitical and biological consequences of hormonal contraception are among the most discussed topics of our time. According to *Mohr* [23], the greatest dangers to man's existence at present are ideologies, atomic or microbiological warfare, and population explosion. It should be possible to entrust the first two problems to the sagacity of the politicians. Birth control could offer an escape from the dangers that will come with the huge increase in the earth's population even in the next few decades.



The possibility of hormonal birth control has found remarkably rapid acceptance by women. In the Federal Republic of Germany, about one woman in every seven of child-bearing age now uses steroid contraceptives.

The steroids used are thought to act by reducing the secretion of a series of proteohormones and so preventing maturation and release of the ovum [24]. The administration of gestagenic and estrogenic hormones inhibits ovulation as a result of their braking action on the hypothalamus and pituitary gland.

The steroids are mainly administered as a mixture of the two components over a period extending from the 5th to the 24th day of the cycle. Sequential therapy, which is based on the natural rhythmic formation conditions of the hormones, represents another method of administration. Only estrogens are given in this case from the 5th to the 19th day of the cycle, and a combination of gestagens and estrogens is then given from the 19th to the 24th day. The subsequent pause in consumption is followed in both cases by withdrawal bleeding resembling menstruation.

Since the natural ovulation inhibitors, *i.e.* the estrogens (estrone, estradiol, estriol) and the endogenous gestagen progesterone are inactive when administered orally, it was necessary to develop orally active compounds.

The only estrogenic components in use at present are 17α-ethynylestradiol *(17)* [25] or its 3-methyl ether.

(17) *(18)*

In the great majority of preparations, the gestagen is a 17α-ethynyl-17-hydroxy-19-nor steroid. The interesting chemical history of the first compound of this type, 17α-ethynyl-17-hydroxy-19-nor-4-androsten-3-one *(18)* [26] has recently been described by *Djerassi* [27].

Development began as early as 1938 with the ethynylation of the 17-keto group by *Inhoffen et al.* [25] and the first synthesis of a 19-nor progesterone by *Ehrenstein* in 1944 [28].

Variants of the compound *(2)* that have proved themselves in clinical trials were obtained by displacement of the C-4–C-5 double bond into the 5(10) position to give *(19)* [29], acetylation of the 17-hydroxyl group to form *(20)* [30], and introduction of additional double bonds into positions 9 and 11 to give *(21)* [31], and of a methyl group into position *(18)* to give *(22)* [14].

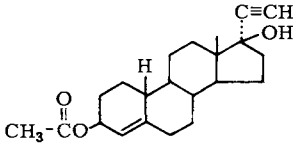
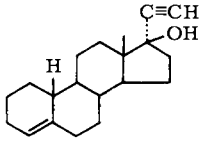
(19)

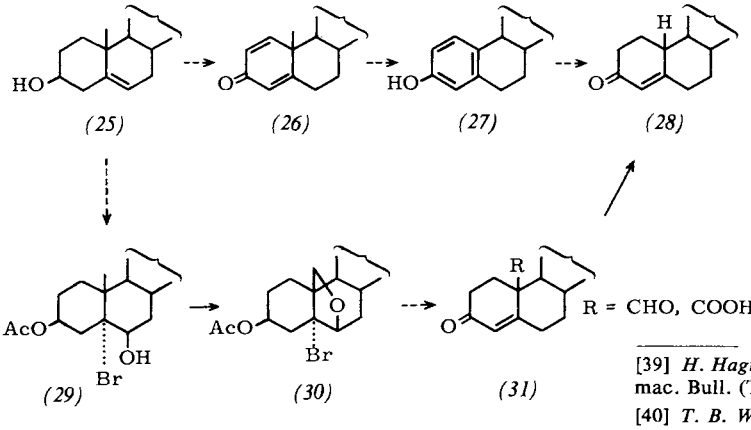


(20)



(21)

(22)

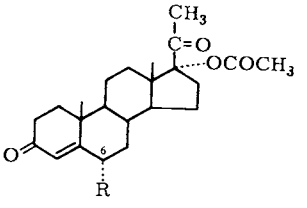


(23)

(24)

Further changes in the A ring gave the 3β-acetoxy-4-ene *(23)* [32] and the 3-deoxy-4-ene *(24)* [33]. The steroids *(21)* and *(22)* are prepared by total synthesis.

In the synthesis of 19-nor steroids from compounds of animal or plant origin, a technically satisfactory solution to the central problem, *i.e.* the elimination of the methyl group from C-10, has now also been found.



(25) (26) (27) (28) (29) (30) (31)

R = CHO, COOH

In addition to the thermal free-radical aromatization [34,35] of 1,4-dien-3-ones *(26)*, a low-temperature ionic aromatization with lithium in biphenyl solution has also been known since 1963 [36]. 19-Nor-4-en-3-ones *(28)* and 5(10)-en-3-ones are then formed from *(27)* *via* 3-methoxy-2,5-(10)-dienes by Birch reduction [37,38].

A second route that can be used for the practical synthesis of 19-nor steroids *(28)* is the elimination of the methyl group from C-10 [39,40] after oxidation to the formyl or carboxyl group [*(31)*→*(28)*].

The key reaction in this multi-step sequence from *(25)* *via* *(29)*, *(30)*, and *(31)* to *(28)* is a 1,3-diaxial "functionalization" of the unactivated angular methyl group *via* intermediate 6β oxygen radicals [*(29)*→*(30)*] [41] which are produced by nitrite photolysis [42], hypoiodite reaction [43], or direct oxidation with lead tetraacetate [44].

(32a), R = H
(32b), R = CH_3 [45]
(32c), R = CH_3 + Δ^6 [46, 47]
(32d), R = Cl + Δ^6 [48, 49]

The second group of progestagenic steroids that are currently used with estrogens for fertility control are the 17α-acetoxyprogesterones *(32a)*–*(32d)*, which are structurally much closer to progesterone than the 19-nor-17α-ethynyl compounds *(18)* to *(24)*.

The development of these compounds followed from *Junkmann*'s observation [50] that esterification of the

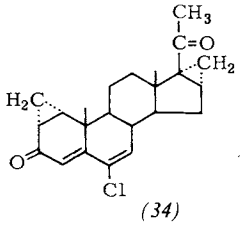
progestationally inactive 17α-hydroxyprogesterone to *(32a)* gives a gestagen that exhibits strong activity when administered subcutaneously or orally.

The gestagen/estrogen combinations do not always prevent conception by inhibiting ovulation. According to investigations by *Goldzieher et al.* [51], ovulation was not suppressed in about 7% of the cycles in women.



With the compound *(32d)*, almost total fertility prevention could be achieved without the addition of estrogens by daily oral administration of 0.5 mg, while ovulation was maintained [52–55].

This new principle of action of the gestagens probably results from a change in the cervical mucus and prevention of penetration by the sperm. It may be expected that future work on contraceptives will be concerned less with the synthesis and investigation of new ovulation-inhibiting steroids with stronger or longer-lasting effects than with the investigation of new modes of action. Increasingly difficult methods will be used, *e.g.* to try to obtain information about sperm transport, sperm capacitation, egg transport, and implantation.

Indications that the biological spectrum, particularly of progesterone derivatives, can be varied by chemical modification are shown in Table 1. The variation of the partial effects in both directions is very clearly recognizable in the 6,7β-epoxide *(33)* [56] and in the 1α, 2α; 16α, 17α-dimethylene steroid *(34)* [57].

(33)

(34)

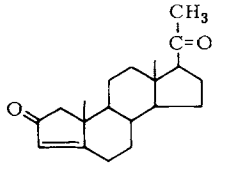
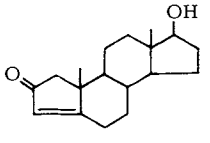
It has been known since 1938 that the actions of androgenic hormones are influenced by estrogens [58]. However, this effect occurs indirectly *via* gonadotropin inhibition.



The term "antiandrogen" should be applied to compounds that directly influence the receptors of all organs or systems of organs that are in any way functionally or morphologically androgen-dependent [59]. They thus have no effect on the biosynthesis of testosterone.

This action has been found in various types of steroids in recent years in the systematic search for antiandrogenic substances. The antiandrogenic steroids that have been investigated belong mainly to the androstane and pregnane series.



Compounds from the pregnane series that exhibit antiandrogenic effects include progesterone *(35a)* [60–62], its derivatives with methyl, hydroxyl, or halogeno substituents in positions 2, 6, 11, 16, 17, and 21, *e.g.* *(35b)–(35h)* [60–65], 19-norprogesterone *(35i)* [63], and A-norprogesterone *(36)* [63,66].

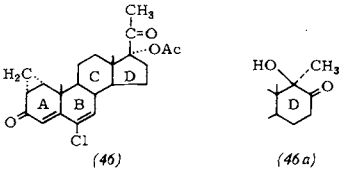
Active androstane derivatives include compounds such as A-nortestosterone *(37)* [66–68], the B-nor *(38)* [69,70] and 18-nor compounds *(39)* [63,71], and D-ring lactones *(40)* [63,72].

Hamada, *Neumann*, and *Junkmann* [73] discovered a new, extremely powerful antiandrogen in 1963 by accidental observation of intrauterine feminization phenomena in animal experiments. Pregnant rats treated with this substance apparently bore only female offspring. The development of the rudimentary male genitalia had been suppressed.

This compound, 6-chloro-1α,2α-methylene-17-acetoxy-4,6-pregnadiene-3,20-dione *(46)* (cyproterone acetate) had been synthesized for the purpose of the development of luteohormones [74,75].

(41) *(42)* *(43)* *(44)* *(45)* *(46)*



The synthesis of the antiandrogen begins with the trienedione *(41)* [76]. 1,3-Dipolar addition of diazomethane leads stereoselectively, by α-side attack on the C-1—C-2 double bond, to the 1-pyrazoline *(42)*. Thermal or Lewis acid catalyzed cleavage of *(42)* gives the 1α,2α-methylene compound *(43)* [77], which is also formed by direct methylenation [78] of the trienone system *(41)* with dimethyloxosulfonium methylide [79]. Because of a side reaction of the α-acetoxy ketone side chain, however, hydrolysis of *(41)* is essential as an intermediate operation [80]. Stereoselective epoxidation with peroxy acids leads from *(43)* to the 6α,7α-epoxide *(44)*. On treatment of *(44)* with hydrogen chloride in glacial acetic acid, *(45)* is obtained by diaxial epoxide cleavage and elimination of hydrogen with simultaneous opening of the 1α,2α three-membered ring. Treatment of *(45)* for a short time with a base finally leads to *(46)*.

To illustrate purely empirical relations between structure and antiandrogenic action, Table 2 shows the most active of the many subsequently investigated compounds with structures similar to cyproterone acetate. The complete inhibition of the effects of exogenous testosterone propionate on the seminal vesicles and prostates of rats requires 30 times as much cyproterone acetate, while 10 times as much is required to inhibit the effect on cocks' combs.

Replacement of the 6-chloro substituent with fluorine or alteration of the stereochemistry of the three-membered ring to a 1β,2β methylene group leads in *(46)* to total loss of the antiandrogenic action.

The first observations by *Hamada*, *Neumann*, and *Junkmann* [73] and their logical interpretation as an antiandrogenic effect led to a series of biological and clinical studies with new antagonists.

Table 2. Relative antiandrogenic action [81] of derivatives of cyproterone acetate *(46)* against the effect of testosterone propionate on subcutaneous application in rats.

It was possible for the first time to eliminate the effects of testosterone by means of cyproterone acetate, without disturbing other factors that are important to sexual differentiation [88].

Studies on male fetuses have provided important information on the decisive early role of testosterone in the development of the genital tract [88–92] and of the sexual center in the brain [93–98].

Information about the differentiation of the mammary glands was also obtained by treatment of pregnant animals with antiandrogens. Male rats and mice do not normally develop nipples. Feminized males, on the other hand, had nipples that were indistinguishable from those of female animals [99–101].

Central processes induced by testosterone, *e.g.* testicular functions in male animals [102–104] and ovulation in females [105, 106], can be inhibited in adult animals.

The activity and size of the sebaceous glands of humans [107, 108] and of animals [109, 110] depend on androgens. The antihormones were found to eliminate the effect of testosterone on the sebaceous glands [111]. The atrophy of the sebaceous glands as a result of treatment with cyproterone acetate is clear in Figures 1a and 1b.

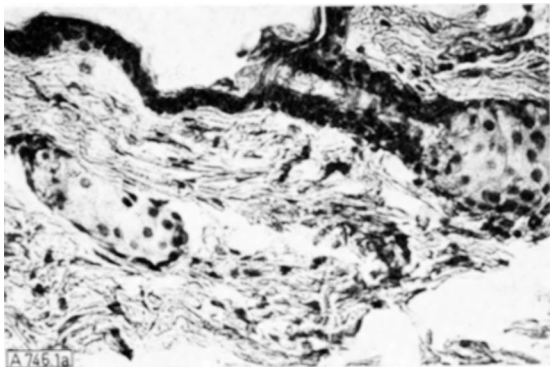

Fig. 1a. Skin section intact male mouse, untreated (magnification 300×).

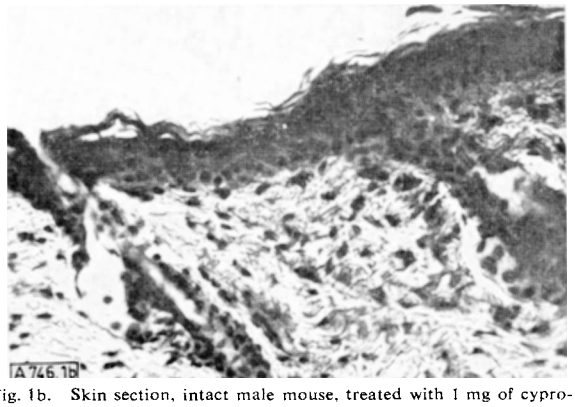

Fig. 1b. Skin section, intact male mouse, treated with 1 mg of cyproterone acetate (i.m.) every second day for 4 weeks (magnification 300×).

Since testosterone is presumably an important contributory cause of acne, this skin disorder should be alleviated by antiandrogens [112–114].

Another interesting clinical possibility is the use of antiandrogens to control the libido of males with disturbed instincts, such as sexual offenders [115–117].

Investigations on the inhibition of the partly androgen-dependent growth of carcinomas of the prostate by antiandrogens could also be important [118, 119].

5. Cardioactive Steroids

Steroid glycosides from several types of digitalis have been in use for almost 200 years for the treatment of cardiac insufficiency. Plant extracts have been increasingly replaced in recent years by homogeneous pure glycosides.

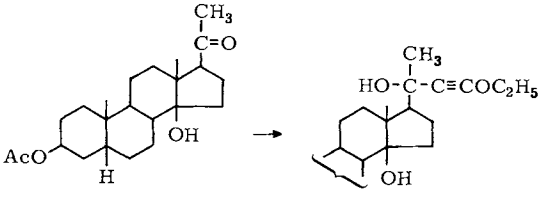
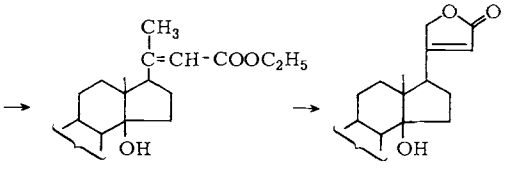
The historical development of this field, the contributions of various laboratories, and the biological mode of action of this class of substances have been described by *Tschesche*[120], *Fieser*[5], and *Haede* and *Lindner*[121]. The chemistry of the sugar residues is summarized in articles by *Zorbach*[122] and *Reichstein*[123].



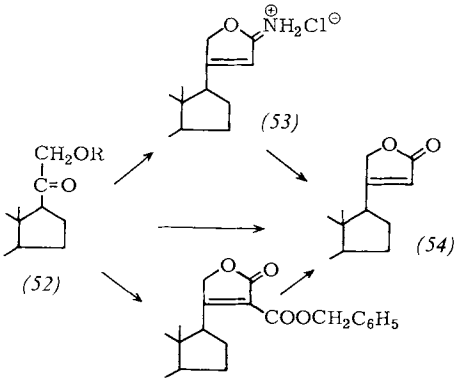
The most difficult problem in the synthesis of the steroid part of the digitalis ingredients, *e.g.* of digitoxigenin *(47)* from readily obtainable steroids is the preparation of the 14-hydroxy-CD-*cis*-17β-butenolide structure.



(47)

The 14β-hydroxyl group is easily removed. Another difficulty is the fact that the 17β-side chain in CD *cis*-fused steroids is thermodynamically less stable than the 17α side chain. Furthermore, undesirable side reactions frequently occur between the 17β side chain and the 14β hydroxyl group as a result of the steric arrangement.

Following the fundamental work carried out in the 1940's by the research groups of *Plattner*, *Reichstein*, *Ruzicka*, and *Elderfield*, an elegant synthesis of digitoxigenin from the 20-oxo pregnane derivative *(48)* was achieved in 1962 by *Danieli*, *Mazur*, and *Sondheimer*[124].



(48) *(49)*

(50) *(51)*

Mild acid treatment of the ethoxyacetylene alcohol *(49)* gave *(50)* which reacted with selenium dioxide in boiling benzene to give the butenolide *(51)*.

14β-Hydroxy steroids have become more readily obtainable through the possibility of microbiological hydroxylation in the 14α, 15α, or 15β position[125].

(52) *(53)* *(54)* *(55)*

(a), R = $OCOCH_3$
(b), R = H
(c), R = $OCOCH_2-COOCH_2C_6H_5$
(d), R = $OCOCH_2-\overset{\oplus}{P}(C_6H_5)_3Br^{\ominus}$
(e), R = $OCOCH_2-PO(OC_2H_5)_2$

The partial formulas *(52)–(55)* are to be understood as representing the synthesis of other butenolides from the corticosterone side chains.

(54) was obtained from *(52a)* by Horner olefination with diethyl cyanomethyl phosphate *via* the imino lactone[126].

Fritzsch, *Stache*, and *Ruschig*[127] obtained the butenolide ring directly from *(52b)* with diethyl methoxycarbonylmethyl phosphate.

The same authors synthesized *(54)* *via* *(55)* from *(52c)* by intramolecular cyclization[128, 129].

The necessary activation of the condensing methylene group can also be achieved with phosphonate ester or phosphonium salt groups. Thus the butenolide ring was obtained in this way from *(52d)* or *(52e)* in yields of up to 50%[130].

Another cardenolide synthesis is based on the ability of 17β-furyl steroids to be converted into cardenolides[131].

The second group of cardioactive steroids are the bufadienolides, which occur in toad secretions and plants. The characteristic structural features of these compounds are an α-pyrone ring in the 17β position and either a hydroxyl group in the 14β position or a 14β,15β-epoxide.

The first natural bufadienolides to be synthesized (*Sondheimer et al.*[132]) were bufalin *(56)* and resibufalin *(57)*.

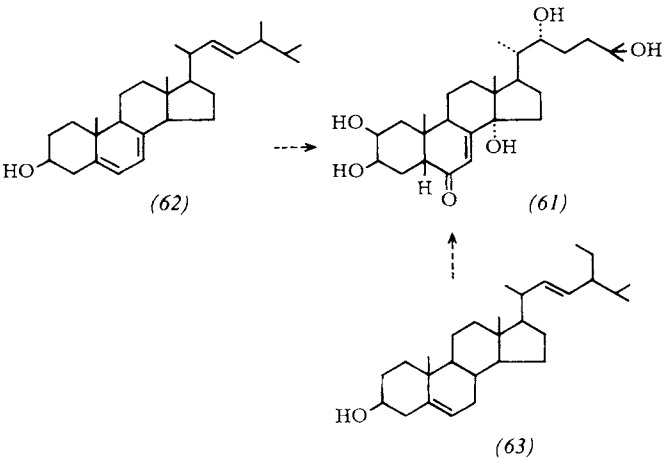
(56)

(57)

Starting from a readily obtainable 14α,17α,21-trihydroxy 20-one *(58)*, these authors synthesized the α-pyrone structure *(60)* by an interesting multistage synthesis with final Reformatzky reaction of an enolized β-dialdehyde *(59)* with methyl bromoacetate.

(58) (59) (60)

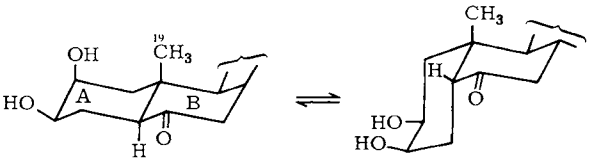
While great progress has been made in the synthesis of cardioactive steroids, treatment with those compounds has advanced very little.



The therapeutic range is extremely narrow, and the use of the drugs is consequently difficult. However, the use of these steroids for nearly two hundred years shows their value as drugs that are as yet irreplaceable. It remains to be seen whether structural modifications, as in the case of steroid hormones, lead to fundamental or advantageous changes in the biological effects of the natural steroids.

In this connection, mention should be made of the cytotoxic effects observed with cardenolides[133–137].

6. Steroid Metamorphosis Hormones



In 1954, *Butenandt* and *Karlson*[138] succeeded in isolating the hormone responsible for molting in the development of insects, which they called ecdysone, from the pupae of silkworm moths. The steroid structure of ecdysone was recognized nine years later[139], and after a further two years its complete structure was found by X-ray analysis[140] as 22*R*-2β,3β,14α,22,25-pentahydroxy-5β-cholest-7-en-6-one *(61)*.

Two independent multi-stage syntheses of the molting hormone starting with ergosterol *(62)*[141–144] and stigmasterol *(63)*[145,146] were published in 1966.

(62) (61) (63)

The syntheses were based on the ability of 2β,3β-dihydroxy-6-oxo-AB-*trans* steroids *(64)* to be converted into AB-*cis* 6-ketones *(65)*, which had first been postulated from models and then demonstrated.

(64) (65)

The preferred stable AB ring fusion of 6-oxo steroids is the *trans* linkage. The 1,3-diaxial interaction between the 2β-hydroxyl group and the 19-methyl group in *(64)* favors the displacement of the equilibrium toward the *cis* compound *(65)*.

A second insect molting hormone, which also initiates molting in crustaceans, is 20-hydroxyecdysone (crustecdysone). It can be isolated from insects[147–150] and lobsters[151], and has now also been synthesized[152,153]. A 20,26-dihydroxyecdysone has been

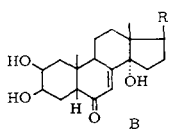
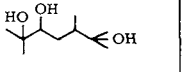
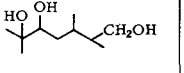
isolated from the tobacco hornworm (*Protoparce sexta*)[154].

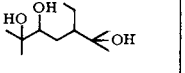


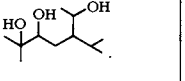
A wave of publications, which has not yet stopped, resulted from the surprising first isolation of ecdysone-like compounds, the ponasterones, from the conifer *Podocarpus nakii* by *Nakanishi et al.*[155]. Ecdysone[156,157] and 20-hydroxyecdysone[156–161] have also been found in the plant kingdom. To provide some idea of the range, Table 3 shows the structures and names of steroids related in structure and action to the natural molting hormones and isolated from the leaves, wood, or roots of Podocarpaceae, Taxaceae, Polypodiceae, Amaranthaceae, and Verbenaceae.

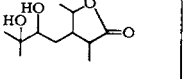
Table 3. Plant steroids having an ecdysone-like action [a].

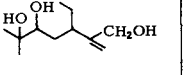


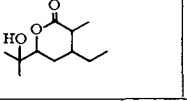


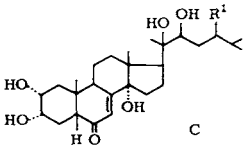












A

R^1	R^2	R^3	R^4	R^5	
H	OH	H	OH	H	polypodine [162, 163]
H	H	H	H	H	ponasterone A [155, 164–166]
H	H	H	H	OH	inokosterone [167]
H	H	OH	H	H	pterosterone [168]
$C_6H_{10}O_5$	H	H	H	H	ponasteroside A [166]

B

R = 	makisterone A [169, 170]
R = 	makisterone B [169, 170]
R = 	makisterone C [169–171]
R = 	makisterone D [169, 170]
R = 	cyasterone [172, 173]
R = 	ajugasterone B [174]
R = 	capitasterone [175]

C

R^1 = H, ponasterone B [176]

R^1 = OH, ponasterone C [176]

[a] The configuration of the side chain is unknown in sections B and C.

The side chain attached to C-17 of ecdysone can be varied within certain limits without loss of molting hormone activity.

Table 4 lists a number of results which were obtained under identical conditions in the Calliphora test and which illustrate relationships between structure and activity.

The significance of the 14α-hydroxy group and the high activity of the compound having an unsubstituted cholesterol side chain are worthy of note, while changes in the stereochemistry or a shortening or loss of the side chain practically leads to inactivation.

A complete change in the action of this class of compounds occurs on inversion of the AB ring linkage to give the *trans* series. Certain ecdysone-antagonistic effects, such as inhibition of post-ecdysonal molting and sclerotization of the larva cuticulae were observed, *inter alia*, with a number of 2,3-dihydroxy-6-oxo-5α steroids of the pregnane *(66a)*, *(66b)* and cholestane series[177,178] *(66c)–(66e)*.

The investigations on the role of ecdysone in protein synthesis proceed beyond the bounds of entomology, and are of general importance. It has been shown experimentally that ecdysone increases and initiates DNA and RNA synthesis [180–183]. *Karlson* [184] derived a general hypothesis on the mode of action of hormones on the basis of the direct activation of certain gene sites as observed together with *Clever* [185].

Molting hormones were also found to cause a dose-dependent increase in the incorporation of ^{14}C-leucine into the protein of mammalian livers [186]. Some ecdysone-like steroids have protein-anabolic effects on mice [187, 188].

The possibility of obtaining molting hormones readily by synthesis or from plants provides a broad base for biological studies on this interesting class of compounds *e.g.* in plant protection, in pharmacology, or for fundamental growth processes in warm-blooded animals.

7. Novel Steroids

From cultures of the aquatic fungus *Achlya bisexualis*, *McMorris* and *Barksdale* (1967) [189] isolated a crystalline substance that causes the growth of cell filaments or hair-like outgrowths at points where the propagative cells develop in the male plant. It thus induces the sexual reproduction in this species. This plant sex hormone, which the authors called antheridiol, has the structure of the steroid lactone *(67)* [190].

(67)

Antheridiol has now been synthesized from stigmasterol [191]. This presents possibilities for a broad investigation of this interesting steroid.

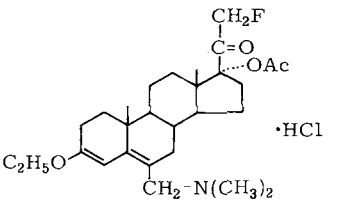
The Cholo Indians of western Colombia use the venom of the poison frog (*Phyllobates aurotaenia*) for hunting. *Witkop et al.* were able to isolate several poisons, the batrachotoxins, from the secretion obtained from the animals on heating [192]. These compounds are the strongest known cardiotoxins. Paralysis and convulsions are followed by death within a few minutes.

An artifact of the batrachotoxins is batrachotoxinin A *(68)*, which is equivalent to strychnine in its toxicity. X-ray structure analysis [193] of *(68)* gave the unusual steroid alkaloid structure indicated.



Interesting new synthetic developments in the steroid field include the bis-quaternary piperidinium compound *(69)* and the 21-fluoro-6-dimethylaminomethyl-17α-acetoxyprogesterone derivative *(70)*.

(68)

(69)

(70)

When the compound *(69)* is administered to humans in small doses, it causes a neuromuscular block, which can be removed by neostigmine [194]. The authors classify the action as being of the curare type.

A remarkable analgesic action, which is superior to that of codeine and cannot be eliminated by morphine antagonists, is shown by the steroid *(70)* in animal experiments [195].

I am grateful to Dr. H. Steinbeck and Dr. A. Jäger (Schering AG) for supplying the biological results in Tables 1, 2, and 4.

Macromolecular Chemistry and Medicine

By Garth W. Hastings [*]

Macromolecular substances are used in medicine both as materials and as reagents. In the former category polymers serve as replacements for soft tissue, as cardiovascular and orthopedic implants, and as adhesives. When employed as reagents, macromolecules interact with living tissue and play an active part in bodily repair processes.

1. Introduction

One of the earliest uses of a macromolecular material in surgery was that of celluloid in 1890, but only the past decade has seen really significant developments in this field. One of the factors in this increasing application is that the needs of the surgeon have changed, as the whole concept of surgical care has been transformed from a passive repair role to a much more aggressive attack upon disease embracing reconstruction or replacement of diseased or damaged organs. There are problems associated with the collection and storage of human organs, in addition to the questions of possible rejection of the transplant by the host tissues, and in consequence there has been great use of non-biological materials. The use of metals for devices intended for permanent implantation within the human body dates back to the sixteenth century. Nowadays, and in the future too, metals continue to play an important role in surgery. Metals undoubtedly offer a satisfactory solution where strength and resistance to the bodily environment are required, but limitations have led to the search for alternative materials. Metallic corrosion is one factor in the very hostile bodily environment, but there is no agreement as to its importance. A more serious limitation is that

[*] Dr. G. W. Hastings
Department of Polymer Science
University of New South Wales
Sydney (Australia)

the metal implant cannot match the properties of the tissues in which it is placed.

Mechanical and frictional properties of a normal hip joint are very different from those of a prosthetic joint where two metal surfaces are in contact, and since the tissues which are the source of the synovial fluid lubricant in the normal joint have been removed, the joint may be very poorly lubricated. It is very doubtful if synovial fluid can ever be expected to lubricate the hard impermeable metal surface when this is compared with the resilient, sponge-like nature of cartilage which can hold lubricant in the interstices[1]. The weight of metal prostheses represents a further disadvantage.

2. Choice of Macromolecular Materials

The favorable mechanical, thermal, electrical, and optical properties of synthetic organic polymers stimulated interest in their widespread use as a new class of materials. Developments in textiles, plastics, rubbers, adhesives, and other new systems meant inevitably that the performance of these materials in medical applications would be tested.

In nature, organic polymers provide not only the framework of living organisms, but also serve to carry the life functions themselves. Fibrous proteins provide the main structural elements in animals, and water soluble proteins, polysaccharides, and nucleic acids, carry on the processes of life. The use of organic macromolecules to replace tissues damaged by injury or disease is a development of the understanding of the role played by such structures in nature.

There are two ways in which synthetic macromolecules can be considered for medical applications. The first of these, typifying the current surgical applications, is as materials, plastics, fibers, elastomers, or adhesives. The emphasis is then principally on mechanical properties and biostability. Modern macromolecular materials science endeavors to relate these properties to the basic polymeric structure, and this has led to a high degree of predictability of the behavior of new

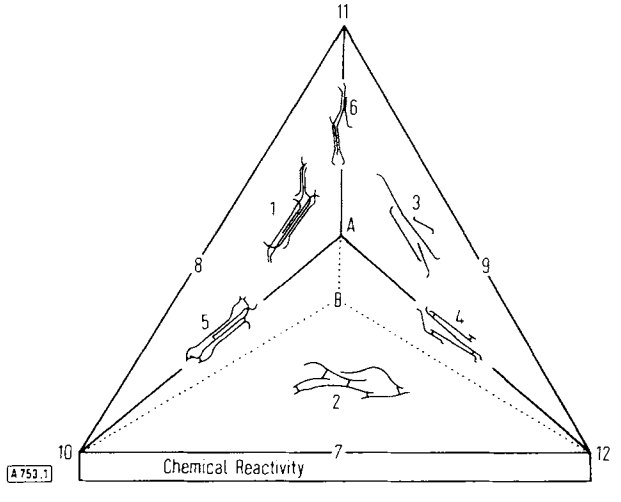

Fig. 1. Structure-property pyramid for polymers used in surgery (see also Table 1).

[1] *J. Charnley*, New Scientist *6*, 60 (1959).

Table 1. List of polymers having potential surgical applications. The combination of various macromolecular characteristics enables considerable modifications to be made to properties. (The numbers and letters in the first column refer to Fig. 1.)

No.	Nature	Typical materials	Surgical use, if any
1	Flexible and crystallizable	polyolefins	very high density material in joint replacements
		polyethylene	
		polyvinylchloride	catheters
		polyamides - nylons	sutures
2	Crosslinked amorphous networks	vulcanized natural rubber	tubing
		silicone rubber	tubing, heart valves
		polyurethane rubbers	artificial limbs
		formalized polyvinyl alcohol	soft tissue replacement (foam)
		epoxy resins	adhesives
3	Stiffened chains — substituent groups	a) polystyrene	joint prostheses — discontinued
		polymethyl methacrylate	
		polymethyl α-cyanoacrylate	adhesive
	Rigid backbone	b) polyimides	
		ladder polymers	
		polycarbonates	in heart valve assembly
		epoxy resins	adhesives
4	Crystalline rigid chains	polyester fiber	arterial replacement (woven)
		cellulose ester fibers	
5	Crystalline crosslinked chains	synthetic rubbers — *e.g.* neoprene	
		collagen	catgut sutures, in reconstituted form as various prostheses
		proteins	
6	Rigid chains, crosslinked	rigid epoxies	
A	Rigid chains, crystalline and crosslinked	modified cellulose fibers	
7	Crosslinked, chemically reactive	hydrophilic gels	breast augmentation
			tubing
			prostheses
8	Crystalline, chemically reactive		
9	Stiff chains, chemically reactive	nonthrombogenic polycarbonates	heart valve components
		modified adhesives	dental adhesives
10	Crosslinked, crystallizable, chemically reactive		
11	Crystallizable, rigid chains, chemically reactive	characteristic of naturally occurring macromolecules, *e.g.* enzymes, viruses, immunologically active compounds	
12	Crosslinked, rigid chains, chemically reactive		
B	Rigid chains, crosslinked, crystallized, and reactive	the ultimate combination of all principles	

polymers, and the possibility of designing materials for specific applications, eliminating empirical synthetic efforts, and simplifying subsequent formulations since plasticizing and other functions can be built into the macromolecule. Adaptability *via* structural modification gives a means by which the materials may be modified to meet the requirements of surgical technique and of *in vivo* conditions (see Fig. 1 and Table 1).

The alternative to this approach is to consider the macromolecules, not as materials, but as chemical reagents. They will be the catalysts or stabilizers involved in processes of bodily repair, and will take part in the functions of the organism. This way has, until recently, received little attention in relation to surgical uses, but has been followed in research into the structure of proteins, enzyme action, and the nature of the specific groups involved in this or in immunological reactions, *i.e.* topics which can be studied by the use of synthetic macromolecular analogs.

This "reagent" approach has received little attention in surgical research, because the main objective here has been to obtain an inert material. By this the surgeon does not mean the absence of any tissue-polymer reaction, but rather that any reaction produced is not harmful to healing and restoration of function. Since certain polymers have not met this requirement (polyurethanes and cyanoacrylates, see Sections 3.2.2, 3.4, 4.3, and 4.2.2.1), there has been an increasing concern to use completely inert materials.

It is suggested that the Food and Drug Administration (FDA) in the United States will require proof of the inertness of a material for prosthetic application. This could seriously limit the applications of plastics if, thereby, research is directed towards finding non-reactive polymers. Any implant material will cause inflammation in the tissues since this is the defensive reaction of the living body to any irritant, physical (*e.g.* burns), chemical (*e.g.* toxins), or bacterial. The trauma of the surgeon's knife evokes an inflammatory response, and so do surgical sutures; in these cases the action is only transitory in nature.

Implants intended to remain permanently in the body should produce no irreparable tissue damage nor initiate any long-term pathological state, *e.g.* carcinogenesis. It may be advantageous to promote an implant-tissue reaction, for example, to improve an adhesive bond, and for this reason it may be better to define a *benign reactivity* or a *benignly reactive material.*

For the present, there is no certainty that any plastics material will perform its intended role over the whole lifetime of the recipient.

3. Surgical and Biochemical Problems

There is no unique surgical problem and hence no single solution but this situation is well fitted to the versatility of plastics. At the same time, this very versatility has resulted in a failure to realize that terms such as PVC used in the plastics industry by no means specify a definite material. Add to this the complications of additives used in compounding or contaminants picked up during processing, together with unreacted monomers and catalysts from the polymerization, and it will be seen that one of the most acute problems for satisfactory surgical use is a clear specification of the material. The standardization of materials for medical use is, and will rightly remain, of great importance[2]. Adequate standards specification will require critical examination of the resistance of the material to the biochemical environment, which involves a systematic study of the chemistry of the degradation processes.

3.1. Skin or Temporary Tissue Contact

Contact with the skin or temporary contact with the tissues imposes the least stringent requirements, although as the time of contact increases beyond a few hours restrictions on the usability of materials will increase. This is illustrated by the common incidence of dermatitis as an occupational disease in the plastics industry[3,4].

The cases where a plastic device in contact with skin has caused a reaction may be due to the abrasive nature of the surface, and attention to the particle size and shape of filler particles may eliminate this factor. A chemical cause is to be found in toxic catalyst residues or other additives in the material. Unreacted amines can be leached out of cured epoxy resins, and these are well known to be a causative factor in dermatitis.

Tissue contact increases the problems since the implant is in contact with enzymes and other degradative systems, and the presence of tissue fluids increases the likelihood of leaching out of toxic substances.

For short term use, say for under six to seven hours, unless there is gross surface contamination from *e.g.* exuded plasticizer, or a readily leachable component, the criteria are similar to those for skin contact.

With longer term use, *i.e.* up to three weeks, the problems arise from toxic ingredients leached out or from the abrasive action of the surface. The first case is illustrated by a series of administration devices, from different sources, but all fabricated from polyvinyl chloride. Twenty-five out of forty-eight showed toxic reactions in animal tests, and the most probable irritants are the organometallic stabilizers[5].

Even the process of sterilization can introduce irritative materials. Ethylene oxide gas is readily retained by plastics, and leads to subsequent hemolysis[6], accountable for by its ready reaction with the NH_2 or OH groups in proteins.

[2] In the United States the F-4 committee of ASTM is considering tests to be used for evaluation of surgical plastics. In Australia, committee MD3 of the Standards Association of Australia is engaged on the same problems. Great Britain also has a Ministry of Health committee.

[6] *T. Hirose, R. Goldstein*, and *C. P. Bailey*, J. thoracic cardiovasc. Surg. *45*, 245 (1963).

Another gaseous sterilant, β-propiolactone is suspect as a carcinogen [7]. Acrylic contact lenses readily absorb up to 7 per cent of a quaternary ammonium halide sterilant solution, and corneal burns can result [8].

Toxic compounds are avoidable by precise formulation and by processing under clean conditions with strict product control. The absence of standards is a major barrier at present.

The second, or surface irritative effect, is poorly documented in terms of a precise correlation between surface morphology and tissue reaction. Gross roughness, protruding filler particles, and hard areas are the most probable sources of trouble.

Incidences of irritation arising from catheters are known, but not studied in relation to the nature of the plastic. A serious case, which may be a surface effect, is the destruction of a child's larynx by the use of an endotracheal tube for a three week period [9].

3.2. Permanent Implantation

Here are considered, *inter alia*, orthopedic and cardiovascular [10] uses, where the period of implantation in difficultly accessible, deep seated tissue is limited only by the lifetime of the recipient and the behavior of the material. Not only is the number of suitable materials much less, but the tissue/implant reactions are not well understood. The biophysical lifetime required without mechanical failure or tissue reaction may exceed 250000 hours. The task lies not only in designing an adequate prosthetic device, but in doing so within the performance limits of the available materials.

The applications of chemical principles and known structure/property relationships to the production of materials having expected performance are seen industrially, in the design of new textile fibers and in the development of high temperature resistant materials. The use of plastics as materials has dominated the surgical area, yet in general there has been little systematic design of these materials.

Polydimethyl siloxane (silicone) elastomers have been studied extensively to determine their suitability as non-reactive implant materials [11]. Studies with blood-compatible polymers have led to a more systematic approach (see later), and attempts to reduce the toxicity of α-cyanoacrylate adhesives have led to the use of higher esters. However, there are still large unexplained areas in the chemistry and poorly substantiated conclusions.

3.2.1. Soft Tissue Replacement

In addition to non-toxicity and long-term biostability, the principal requirement is comformability to contours and tissue softness. These latter requirements are best met by the use of foams, preferably of closed pore structure, to prevent excessive ingrowth of tissue which may lead to hardening. An alternative method has been to use a viscous polydimethyl siloxane gel enclosed in an elastomeric bag [12].

3.2.2. Cardiovascular System

This presents a more complex problem since it also involves the reaction of blood with the prosthetic surface. Not only must the mechanical properties of a blood vessel be reproduced, in terms of elasticity to accommodate the regular pulsation of blood flow, flexibility without kinking, porosity sufficient to permit ingrowth of tissues but able to prevent leakage of blood, but the surface properties must not promote damage to blood platelets or their adherence to the wall.

In heart valve replacements, the correct haemodynamics is related to valve design in the mechanical sense, but also to the blood/plastic interaction. The ability of the material to withstand the continual flexing of valve movement imposes a primary limitation on the choice of material, but even a well designed valve may fail within a short time due to clotting. The surface properties are related to hardness and/or roughness, chemical groups present in the surface layers, and a consequent charge distribution on the surface. Crystalline/amorphous ratios in the plastic will also affect surface structure.

Any plastic implant will change the natural environment and cause some effect on blood flow and properties. When normal blood vessels become calcified, the hard areas result in changes in blood constituents. Adherence of platelets is followed by fibrin deposition and a clot forms. If the area is small, it is possible for the clot to be incorporated into a new vessel-lining by normal repair processes. If it is large, the clot may increase in size, the vessel may be obstructed, or portions of clot may be detached to form emboli.

When a plastic device is used, the changes occurring are similar, but the possibility of natural repair is reduced. Porosity permits cell penetration and the synthetic vessel becomes lined with a surface similar to that of the host vessel [13]. In large replacements, a new vessel lining may only be formed at the junction with the natural vessel and the probability of embolus formation increases.

3.2.3. Orthopedic Implants

These implants are subject to the mechanical stresses of weight bearing and movement. There are two main uses: fracture repair and joint replacement. The former is primarily an adhesives application. Design of joint prostheses involves the chemist or materials scientist in the production of dimensionally stable plastics, with no creep, stress cracking, or other fatigue symptoms, which will operate as a bearing surface in contact with the articular cartilage of the normal joint (a fibrous collagen-polysaccharide system), or with another plastic or with metal (see also Section 1).

In walking one kilometer with the acceleration and deceleration of movement, over 600 reversals are involved. Normal joints have an inbuilt shock absorbing mechanism, and since the forces on a joint may be 5 to 7 times the body weight, this may represent a continued impact of 300–500 kilograms. The internal structure of a bone is adapted to the mechanical requirements, and the modulus of elasticity may vary segmentally, and in cross section, along a bone. Enormous reserves exist in the body for adaptation to demands. The enormous distension of womb and abdominal wall structures during pregnancy illustrates this. No form of implant can achieve all of the many properties of living tissue, nor have the capacity for self-healing or replenishment.

A bone adhesive is required to function in conditious which are, in general, the very opposite of those with which an adhesive designer usually chooses to work. The environment is wet, blood will be present, and fat from the marrow in the medulla contaminates the surfaces to be bonded. It is obviously not possible to use high pressures and temperatures to effect curing. Solvent based adhesives are not usable: water-based will not harden in the tissues, and organic solvent-based are usually toxic. The limitation of body-temperature curing, low exotherm, low toxicity adhesives, restricts the choice of materials.

3.3. Effect of Implant on Tissues

3.3.1. Additives

The aim in surgical work should always be to use the plastic in the most pure state possible. As already stated, industrially acceptable materials will contain various nonmacromolecular materials. Residual monomer or initiators, mold release agents, and lubricants are common, but there are also antioxidants, plasticizers and other added chemicals. Whereas a flexible polyvinyl chloride, containing 40–60 per cent of additives may be acceptable in tubing for non-medical use, it is not cleared for implantation. Even acceptance as food packaging is no safeguard. Toxicity quotient [14] and other standards [15] are a guide, but more precise information is needed.

Highly toxic additives have been found in tubing actually in use in catheters [16]. These sorts of devices are being left *in situ* for increasingly long times, *e.g.* with developments in intermittent dialysis for renal failure, where the arterial and venous limbs through which blood flows to the dialysis unit are a more or less permanent implant. The most satisfactory material to date has been silicone rubber tubing.

However, these direct effects are complemented by indirect effects from devices not specifically designed for implantation. Syringes, transfusion units, containers for collection and storage of drugs and nutriments, are made from plastics. The rubber plungers of syringes have been shown to release contaminants to solvents placed in the syringe [17]. In heart-lung machines, some types of tubing were shown to affect the blood passing through them [16], and the adhesives used in a membrane oxygenator were found to be toxic upon extraction [18].

The important element in these indirect effects is the time factor. In general the concentration of substances extracted is low, but any effect may be cumulative, and for an already ill patient can be serious. The most usual effect of extraction of toxic materials is local cell death or local inflammation. Unless the causative effect is only minor, local inflammation is not self-contained. Toxins or bacteria present may rapidly bring on constitutional reactions, *e.g.* fever.

In studies on skin dermatoses, two classes of chemical are differentiated: the primary irritant and the sensitizing substance. The two are not a clear-cut classification, since a primary irritant may act also as a sensitizer. The former always produce a direct effect on the tissues, either physical or chemical, combining with or removing vital components. Examples of the more aggressive primary irritants include oxidants (peroxides), solvents or emulsifiers for fats (organic solvents and basic detergents), keratin solvents (soaps), substances damaging to proteins causing cross-linking or "tanning" (heavy metal salts), which may be present in some plastics formulations.

The mode of action of the sensitizing substances is not so clear, and the behavior has been likened to antigen-antibody reactions. Since histamine will produce a reaction, some authors have proposed that sensitizing substances must be histamine-like although distinct from histamine [19].

The major studies of these substances have been related to contact dermatoses arising in the plastics industry and other industries. It is important, in formulating materials for surgical use, that known irritants or sensitizers should be avoided. In epoxy resin technology, use is made of the decreased dermatitis potential achieved by using polyamines or amine adducts for curing agents.

3.3.2. The Polymeric Material

The reaction of the polymer to the tissues can be discussed from chemical and physical effects. Overlapping both divisions is the problem of carcinogenesis, and this will be reviewed separately.

Most of the reactions are related to small amounts of nonpolymeric materials or degradation products leaching out. The question of degraded polymer fragments will be dealt with in the section on the effect of the tissues on plastics. Polymers containing obviously irritant chemical groupings are not used in surgery. One exception is the alkyl α-cyanoacrylates used as tissue adhesives. These have an unfortunate history of toxic reactions, but this appears to be related more to the mode of biodegradation and the nature of the degradation products, believed to be formaldehyde and a cyanoacetic ester, than to the polymer itself considered as a reagent [10, 20, 21] (see Sections 3.4 and 4.3).

[14] Second report of the Toxicity Subcommittee of the Main Technical Committee, British Plastics Federation, London 1962.

[15] A series of reports in the Federal German Health Gazette between Vol. 1, (No. 15), p. 235 (1958), and Vol. 6, (No. 15), p. 239 (1963), illustrate this.

[21] *F. Leonard, R. K. Kulkarni, G. Brandes, J. Nelson*, and *J. J. Cameron*, J. appl. Polymer Sci. *10*, 259 (1966).

The activating effect of the electrophilic C≡N and the COOR groups on the same carbon atom contribute to the ready polymerization of the monomer, and it is suggested that initiation of polymerization by NH_2 groups of tissue proteins gives direct primary bonds between the proteins and the terminal unit of the polymer chain. Primary chemical bonding, to increase adhesive strength, between polymer and tissues is also utilized in dentistry [22].

The polar nature of the surface of most surgical plastics has important implications. During processing, contaminants are retained on the surface, *e.g.* oils, release agents, or grease from fingerprints. Even when the surface is clean, chemical or gaseous sterilants are adsorbed and retained by the plastic. Upon implantation, tissue compounds may be specifically adsorbed with consequent change in surface properties, and of the immediate environment of the implant. This latter factor has important consequences for plastics in contact with blood where the problems of coagulation and hemolysis are obstacles to the use of many plastics. The surface rapidly adsorbs blood proteins, and the blood is thus rapidly in contact, not with the plastic, but with a protein layer. It is not possible to correlate zeta potentials to thrombogenicity since the initially negative zeta potential is rapidly changed due to protein adsorption [23]. Neither can wettability be correlated with thrombogenic properties, probably for similar reasons [24].

The physical effects of polymers on tissues are even less well understood than the chemical effects. Since it is the surface which is in direct, intimate contact with the tissues, an understanding of the role played by surface physical phenomena is essential. A wide range of properties may be exhibited by a small area of surface. Smoothness would be thought to be a necessary factor, but thrombogenic properties, for example, are considered not to depend on this. In this case, the main factor is non-turbulent flow through the prosthesis [25]. Hard, abrasive filler particles protruding from the surface, oxidized areas which have hardened, irregularities resulting from cutting or machining which have a hardness different from the bulk material, are sources of potential tissue damage. Blood vessels are damaged, and local bleeding, clot formation, and invasion by fibrous tissue results in encapsulation of the implant by thick scar tissue. In extreme cases, migration through the tissues can occur.

Crystallinity affects the nature and mechanical behavior of polymers. The properties of polyethylene are dependent not only on molecular weight, but also on the crystalline/amorphous ratio [26]. Cellulose hydrolysis is retarded in the crystalline regions as a result of the closer, more ordered, packing of the chains [27]. The density variations between crystalline and noncrystalline regions, leading to differences in surface hardness, may be an important factor at the level of cellular response.

The major protein of connective tissue, collagen, can be reconstituted from solutions in differing structures representing different crystal forms [28], only one of which is specific for calcium phosphate nucleation from saturated solutions. This epitactic relationship is observed during *in vivo* studies of calcification of tissues [29, 30]. This may be related to the tissue reactions of certain plastics.

3.3.3. Carcinogenic Properties

The implantation of Bakelite (phenol-formaldehyde resin) discs in rats for long periods of time gave rise to sarcomas at the implant site [31]. *Oppenheimer et al.* first observed tumor formation in rats whose kidneys were wrapped with cellophane film [32].

This team believe that the form of the physical implant is more important than the material itself. Studies have been performed on films of a great range of materials, including cellophane, fluorocarbons, glass, nylon, polystyrene, polyesters, silicone elastomers, as well as stainless steel, silver, and other metals. Perforation of the material greatly reduced tumor formation, and when powders, sponges, or fibers were used, there was almost no tumor incidence. They argue for physical forces between the plastic and tissues, and show that once a fiber pocket has formed round the implant, tumor growth proceeds even on removal of the plastic [16, 33]. In an earlier paper [34], *Oppenheimer et al.* had discussed the unsatisfactory hypothesis of "metabolic interference by mere physical obstacles", and favored a chemical or physicochemical interaction between the polymer, or its degradation products, and cell components. Either active centers in the polymer, or free radicals, both possible products of degradation, were suggested as the actual carcinogenic entities.

A chemical activation is favored by *Hueper* [35], who induced cancers with both water-soluble and water-insoluble polymers.

The carcinogenic free radicals are not likely to be those remaining from the addition polymerization, since these would be deactivated during processing. In any case, radicals in the bulk of the material could not diffuse to the surface to interact with the tissues. However, oxidative degradation in normal polymers takes place by a free radical mechanism, and since

certain biological oxidations appear to involve odd electron intermediates [36], these could lead to polymer degradation. It was observed, for example, that polyethylene implanted in rats was degraded *in vivo*, and when a ^{14}C-labeled material was used, radioactivity was observed in the urine within 26 weeks [34]. The carcinogenic activity then arises from the nature of the degradation product, perhaps by inhibition of cellular free radical processes.

To put these observations of tumor formation into perspective it should be emphasized that up to the present time, no tumor formation in man has been traced to an implanted polymer. In 8000 human cases, involving 16000 foam implants for mammoplasty, no malignancy was observed [37]. More recently, it has been suggested that polyethylene intrauterine contraceptive devices might be a causative factor in cervical cancer of females, but this is not established [38].

The evidence for tumor formation comes from animal work, and there will always be uncertainty in applying results from small animals (rats) to humans. *Oppenheimer* believes that what happens in two years in a rat may take 20—30 years in humans, if in fact it occurs at all. It is always necessary to evaluate carefully the risks involved. The use of plastics for cardiac valve replacements is a case where the risk of death from refusal to use an implant is greater than the long-term hazard of cancer. A plastic hip joint in an aged person of 70 years poses different considerations than the case of a young person in their twenties.

The nature of the causative factor is still unknown, and it is not yet possible to separate physical or "solid surface" carcinogenesis from chemical activation. The human record is good, but indiscriminate use of medical plastics should be avoided.

3.4. Effect of Tissues on Implant

There is a scarcity of information in this area, perhaps because a long time interval is needed to determine if changes have occurred in an implanted material. Body fluids resemble dilute sea water [39] in composition: Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, PO_4^{3-}, and SO_4^{2-} are present along with oxygen and carbon dioxide, although in certain necrosed tissues there may be an anaerobic state. Then there are the proteins, polysaccharides, and macromolecular complexes, plus trace element components, together with enzymes involved in varying metabolic functions. At cellular level local pH variations occur.

Only the most inert polymers will be chemically or physically unaffected in long term implantation. Polyurethanes are extensively degraded and for this reason are no longer used in fracture repair [40]. Nylon was found to lose approximately 80% of its tensile strength over three years of implantation. Polytetrafluoroethylene solid sheet was invaded by tissues in mice and made water-permeable [41]. Embrittlement was also found by other workers [42], and the rapid abrasion of Teflon when used as the acetabular cup in a hip joint prosthesis, with consequent severe tissue inflammation by the abraded particles, led to abandonment of the technique [43] (see below).

Changes in tensile strengths of different fabrics after implantation in canine aortas are listed in Table 2 [44].

Table 2. Loss of tensile strength of different fabrics after implantation in canine aortas [44].

Fabric	Implanted (days)	Tensile strength loss (%)
Nylon	1073	80.7
Dacron	780	11.4
Orlon	735	23.8
	670	1.0
Teflon	677	5.3
	675	7.0

The degradation of ^{14}C-labeled polyethylene was mentioned above (Section 3.3.3), and polystyrene and polymethylmethacrylate behave similarly. When foamed polyvinyl formal (polyvinyl alcohol crosslinked with formaldehyde) was implanted, it became hard as the pores were invaded by tissues, and eventually contained calcium deposits [45]. This is confirmed in clinical practice in augmentation mammaplasty. The physical character of the polymeric material is important. Crystallinity affects swelling in water, and in turn the rate of hydrolysis [27,46].

Silicone rubber balls used in heart valves were always considered to be inert, but a few cases of altered characteristics in balls used in the aortic valve have been reported [47]. The material appeared to have adsorbed a fat-like substance, but laboratory tests could not duplicate the findings. A fatal case occurred where the ball extruded through the metal cage of the valve and lodged in the aorta. This ball had decreased in size, and was opaque and irregularly worn [48].

In tissue adhesives, and other applications, controlled biodegradability is an advantage. Collagen-Dacron composite vascular grafts are an example where the graft is initially impermeable, but the progressive removal of the degradable collagen permits ingrowth of tissue without loss of impermeability.

Alkyl α-cyanoacrylate adhesives are slowly degraded in the body and removed from the site of application. This is an ideal property for an adhesive in vascular and other applications, but the toxic nature of the degradation products severely limits the usefulness. ^{14}C-tracer studies on animal implantation showed that the methyl polymer was degraded more rapidly than the higher esters, and that no degradation products were stored in the tissues. It is believed that the

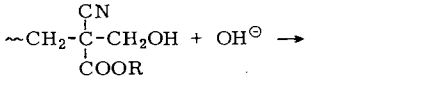
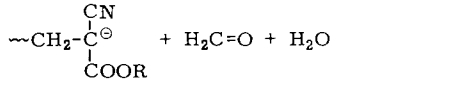
toxicity results from the formation of formaldehyde and a cyanoacetate. It has been suggested[21] that main chain hydrolysis occurs, catalyzed by OH^-:



(1)



(2)

(3)

Further degradation according to equation (2) is expected to yield cyanic esters as further products. It is argued that lower concentrations of these toxic products are given by the less rapidly degradable higher esters, and that this accounts for their lower toxicity. The less toxic isobutyl ester is currently being evaluated for clinical use[20].

Knowledge of biodegradation mechanisms of plastics can lead to ways of improving performance by possible structure modification. Polyesters, polyurethanes, and nylons may be hydrolyzed under the influence of H^+ or OH^- ions, or hydrolytic enzymes may be involved. Hydrocarbon polymers may be oxidized by tissue components. It is always the nature and fate of the degraded chain fragments which is important, in addition to the impairment of the properties of the plastic material.

For example, polymethylmethacrylate used as a ball head in a femoral head prosthesis (*Judet*) became crazed and cracked, and quite unsuitable for use[10]. With a polytetrafluoroethylene acetabular cup, abrasive wear was so great that the metal femoral head protruded through to the posterior side, and diffusion of fragments into the tissues caused irritation and toxic reaction[43]. In some applications, 10 years may be needed before the prosthetic device causes problems to the patient due to malfunction. The majority of defects are found within three to five years. It is reasonable that for adequate evaluation this period of time must be given to a trial under proposed conditions of use.

At the Royal National Orthopaedic Hospital, Stanmore, England, *Scales* is using a simulator which will impart all the possible motions and forces of a hip joint to a prosthesis[50], using physiological lubricants. For a suitable chemical environment, immersion in boiling 2% peracetic acid has been suggested[49].

[50] *J. T. Scales*, Proc. Instn. mechan. Engr. *181*, part 3, (1966/1967).

In certain cases, the adverse reaction caused by an implant is not restricted to the localized tissues. There may be a fever or other generalized reaction. The polymer itself may also evoke an antigen-antibody response. Local trauma and necrosis of tissues act as centers of infection, with the infection itself being systemic in nature. Thus it is necessary to consider an implant as not causing adverse body reactions for satisfactory application.

Biomechanical design, *e.g.* of a hip joint, must consider the replacement in relation to the overall pattern of forces at rest and during motion. Plastics do not of course regenerate and will not respond to changing demands of growth or of aging. The body in turn must continually readjust to a replacement with a different function from that of the normal organ. This can impose a continuous trauma or stress, with resulting secondary manifestations in other organs or tissues. This is important to remember as more elaborate implants are being designed, and in such cases these biophysical factors may be of greater importance than the choice of a right material[9].

4. Current Uses of Plastics Implants in Surgery

4.1. Cardiovascular Surgery

The first recorded attempt at human arterial repair was in 1759[51], but significant work only began at the beginning of this century. Glass, gold, silver, rubber, aluminum, and tubes lined with paraffin wax were used, but only temporary patency was obtained[52].

Between 1944 and 1946 methylmethacrylate polymers tested in dogs showed that under certain conditions prostheses made from these materials resisted thrombosis. This was the now classic work of *Hufnagel* using a rigid, solid wall tube for permanent implantation[53]. Certain simple factors were utilized in prevention of thromboses. A hemorepellant surface was suggested by the longer clotting time of blood in paraffin wax lined tubes.

Water absorption appeared to promote clot formation, and hence plastics with a lack of water absorption were sought for. Mechanical smoothness of the surface of the material in the biological interface was another requirement. The factors of toxicity and tissue tolerance already discussed were also accounted for. However, these criteria alone are not sufficient to prevent thrombus formation.

4.1.1. Vascular Prostheses

In 1952 *Voorhees et al.*[54] introduced the concept of a porous arterial prosthesis, and a number of synthetic fibers were found to have satisfactory performance.

[51] *Hallowel*, cited in ref. [10], p. 73.

[52] *A. Carrel*, Surgery Gynecol. Obstetr. *15*, 245 (1912).

[53] *C. A. Hufnagel*, Arch. Surgery *54*, 382 (1947).

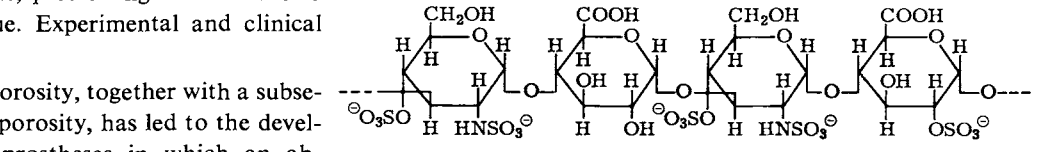
[54] *A. B. Voorhees et al.*, Ann. Surgery *135*, 332 (1952).

Nylon (polyamide), Dacron (polyester), and polytetrafluoroethylene have been the materials most used, with Dacron being widely accepted. Flexibility must be coupled with a resistance to kinking, or to collapse. The tube should also be seamless, be nonfraying when cut, and give ease of suturing and handling. The extent of porosity is a subject of argument, but some is needed so that the initially deposited fibrin layer may be replaced by fibrous tissue, which eventually produces an inner surface similar to that of the host vessel. Kinking in the initial stages is largely overcome by the use of a crimped tube. Textile technology demonstrates that a material may eventually show no elastic recovery after a series of stress cycles. Thus nylon loses tensile strength too rapidly to be of value.

One problem still centers around the question of porosity, and whether it is to be porosity to tissues, or only to ions. Noncorrosive metals, *e.g.* platinum, where there should be no surface contaminant complication, thrombose relatively quickly, and there is of course no ion-permeability[55]. Too great a tissue-porosity may be a disadvantage. Development of solid wall prostheses must await developments in surface structures.

Porous prostheses will continue to be used and one important trend is towards the use of extremely fine yarn bundles – *Gossamer Concept*. A knitted material with a needle density of 40 needles/inch (usual prosthesis 22 to 30) which does not need to employ stretch, bulk, or texturized yarns, has given a prosthesis which is much more akin to natural tissues. Although the material is highly porous, preclotting reduces this to 10% of the initial value. Experimental and clinical results look promising.

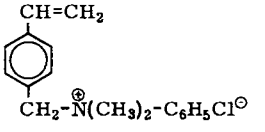
A desire for low initial porosity, together with a subsequent higher biological porosity, has led to the development of compound prostheses in which an absorbable coating of, *e.g.*, collagen is incorporated with the permanent material The challenge is to develop a material for implantation into a child which will not inhibit natural growth, and will remain complication-free for the lifetime of the individual.



4.1.2. Heart Valves

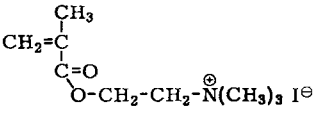
Polytetrafluoroethylene, polycarbonate, silicone rubber, polyester fabric, polymethylmethacrylate, and stainless steel have been the main materials of choice. Provided that the valve performs its hemodynamic function satisfactorily, it need not necessarily resemble the natural valve which it is intended to replace. The design must avoid embolic and hemolytic dangers. Opening and closing must be gentle but rapid, with minimum turbulence and pressure gradient across the prosthesis, and the seal should be competent without trauma to the blood cells.

One of the first clinical uses was by *Hufnagel* in 1952 [56] and was a simple, silicone-rubber ball valve, several of which are still functioning in patients up to 13 years later. The more well-known ball valve is the Starr-Edwards prosthesis which employs a silicone rubber ball in a stainless steel cage, and has an artificial stroma of the cloth around the base. *Hufnagel* has also developed a tricuspid leaflet valve of silicone rubber coated Dacron, and in another more recent leaflet valve due to *Gott* [57] the leaflets are of Teflon fabric, reinforced at the hinge with percale fabric, and silicone rubber coated. The rigid housing is a polycarbonate. Teflon and polypropylene are used in the Alvarez mitral valve prosthesis. The Smeloff-Cutter prosthesis is a double-caged valve using titanium for the cage. Sutureless valves use retractable curved pins to grasp the tissues, and silicone rubber cuffs.



There were still problems with these valves in terms of an adequate lifetime of the ball or the leaflets, and in terms of tendency to thrombus formation. Newer materials and composite designs have helped to increase the lifetime. The Gott valve uses a reinforced Teflon fabric, and *Hufnagel* has employed a polypropylene cloth as the core material for the leaflets.

The first significant step towards thrombus prevention was in the Gott valve [57] with the use of heparinized surfaces. The polycarbonate was first graphite coated, and then a benzalkonium compound was adsorbed on to this. Heparin *(1)* could then be bonded to this surface, and the plastic was non-thrombogenic *in vitro* and *in vivo*. Clinical trials are promising.



(1)

Heparin is known to form insoluble complexes with quaternary ammonium compounds and this has been the basis for synthesizing polymers to which heparin could be bonded directly. Chloromethylation of polystyrene with an $AlCl_3/ClCH_2OCH_3$ mixture in nitrobenzene, followed by treatment with a methanol solution of dimethylaniline gave a quaternary ammonium salt *(2)*, which would bond sodium heparinate.

(2)

(3)

Trimethyl[2-(2-methyl-1-oxo-2-propenyloxy)ethyl]-ammonium iodide *(3)* is a polymerizable quaternary ammonium salt. Butadiene-co-vinylpyridine polymers have been quaternized and treated with heparin.

(Various plastics and elastomers have been prepared and are being evaluated [58].) The final development is in the fully artificial implant.

4.2. Orthopedics

4.2.1. Prosthetics

There have been important developments in the uses of plastics materials in orthopedics, particularly in the use of adhesives. Some of the earliest uses were of celluloid plates to repair cranial defects during World War I but were not particularly successful. Acrylic plates were used towards the end of World War II but some reports indicated a loosening, and doubt has been cast on the value of this approach. An acrylic (polymethylmethacrylate) was the material from which the Judet femoral head prosthesis (see Fig. 2)

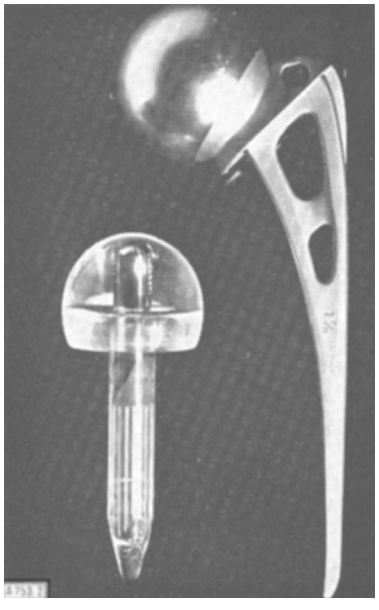

Fig. 2. Left: Judet femoral head prosthesis in polymethylmethacrylate. Right: Austin-Moore femoral head prosthesis in stainless steel. Early attempts to use plastics in hip surgery were unsuccessful due to excessive wear of surface [58a].

was constructed [10], but these gave unsatisfactory results, wearing badly, and also crazing on the surface. This crazing may have resulted from strains imparted during fitting the stem, or during insertion into the bone, or it may be a true tissue reaction. The property of creep (cold flow) shown by acrylics would indicate against their use in a continuously stressed location. This, and the mechanical failure resulting from crazing, is a factor against use of these materials in weight bearing prostheses.

Nylon has been tried for intramedullary nails, and nylon membrane in arthroplasty of the knee in chronic arthritis [59], but is unsuitable for hip or shoulder prostheses since abrasion is too rapid [43]. The particles of nylon released lead to a tissue reaction which can cause bone destruction [50]. Dacron polyester fabric has been used to replace ligaments in the knee. Polytetrafluoroethylene implants have also been used in the knee in arthroplasty [60], but this material is unsuitable for hip prostheses because of excessive wear and fragmentation [43].

High density polyethylene (Ruhr-Chemie-Hoechst RCH 1000) is used by *Charnley* as the acetabular cup, in combination with a stainless steel femoral head, for total replacement of the hip joint. A cold-curing acrylic resin is used to bond both components to underlying living bone. A meticulous technique and close attention to perfection of surface finish gives a highly successful prosthesis. There is some wear of the polyethylene cup, but no adverse tissue reaction is observed over a four- to five-year follow up.

4.2.2. Adhesives

4.2.2.1. Polyurethanes

Adhesive uses have seen three main developments. The application of polyurethane foam *in situ* to support fractures was one of the very controversial uses of this material [40,61].

The mixed, uncured ingredients were applied to a trough cut into the bone surfaces, around the fracture site, and a hard, rigid foam was produced at the fracture site. The progressive replacement and absorption of the foam was of interest, and after 12 months only 1/4 to 1/6 remained. Early workers reported no toxic effects. Subsequent workers reported a high incidence of non-union and infection, with a difficulty in obtaining reproducible curing and adhesion to the bone.

The real problems are:

1. Poor mechanical and cohesive strength.

2. Unknown nature of breakdown or route of excretion.

3. Volume spread of foam at operation site makes removal difficult.

4. Numerous complications in clinical use necessitated difficult removal operations, and studies showed that the material did not possess any of the properties claimed for it.

5. Animal results later indicated that polyurethane gave rise to appreciable foreign-body reaction, tended to retard bone union, and became encapsulated in fibrous tissue.

One report showed that out of 51 operations (42 patients) only 9 resulted in stable fixation and healing; in 37 cases the plastic broke in the medullary canal or loosened. 21 were complicated by infection and the development subsequently of draining sinuses [40].

4.2.2.2. Epoxy Resins

Golovin [63] originally used the material in a technique similar to that used for polyurethane, but then used it as a glue between fracture ends, supplemented by bonded sliding grafts or bone transplants. He stressed the importance of dried surfaces. In 32 patients successful healing was obtained. *Bloch* [62] originally applied the resin as a cuff of resin-impregnated glass fiber around the bone ends, using also polyethylene plugs inserted into the medulla. Experiments in sheep showed rapid restoration of function, with weight bearing in 2 days. In 2 human cases, there was rapid restoration of function but necrosis occurred in one. However, one patient is still trouble free nearly 10 years later.

More recently we have used a filled resin to cement femoral head prostheses in place [64]. In 3 recent human cases over the past 2 years, satisfactory fixation has been obtained and one successfully sustained a heavy fall which actually bent the metal prosthesis without loosening the glue line (Fig. 3). The mixed resin is one

Fig. 3. Left: a room temperature hardening epoxy resin was used to anchor the stem of this specially designed hip prosthesis into the remaining bone. Right: the same prosthesis two years later after a severe fall. The adhesive joint was secure and the stem was successfully straightened [58a, 64].

developed for adhesion to wet surfaces and for curing in a wet environment. Polyamide is used to cure the resin instead of the toxic amines. The whole medulla is filled *via* a nylon tube from an injecting gun nozzle. Sterilization of all resin ingredients and equipment has been by gamma irradiation. Hardening occurs about 1/4 hour after insertion of the prosthesis, and temperature rise is negligible.

Reitz [65], using a different resin system, found that hardening was delayed in the stratum next to the bone. His technique, in rabbits, using a glass-fiber reinforced cuff was not successful in 1/3 of the cases, due to lack of adhesion between bone and cuff.

4.2.2.3. Acrylics

The usual cold cure system is a mixture of two components, a fine powder of polymethylmethacrylate, containing a suitable initiator, and a liquid monomer, containing an amine as activator. On mixing, the polymer is swollen by the monomer, polymerization in the monomer phase is initiated, and after a few minutes, and considerable evolution of heat, a fairly homogeneous solid is obtained. Methyl methacrylate was used in neurosurgery for cranioplasty [66] and many workers report absence of complications. The use for aneurysm investment also appears successful. In 1951 it was first used for fixation of an acrylic hip prosthesis and for a metal prosthesis in 1953. *Charnley* has used the technique very extensively, using a large amount of plastic to fill the complete space between prostheses and bone [67]. He has reported on 455 cases with no evidence of loosening or bone reaction, and has given considerable attention to the biomechanics of the system. He claims that this method eliminates fretting between bone and implant and gives an even weight distribution. Other workers adapted the technique to fixing pertrochanteric fractures of the femor in combination with a pin and plate, but reported complications [68]. It should be noted that free monomer appears to be toxic to the tissues but in *Charnley*'s technique the material is used as a dough. *Reitz*, using the material for fixing femoral prostheses in dogs, obtained only 3 out of 14 successful results with maintained fixation and stability. He puts it down to malfitting and malalignment of the prosthesis, and incomplete filling with the plastic.

It appears that there is a place for the acrylics, and modifications to the systems used may give desirable improvements of increased adhesion and matching of the tissue properties.

4.3. Tissue Adhesives

There is some overlap here between this and the preceeding section, though the problems in orthopedics are made more acute by the mechanical demands of weight bearing and movement.

Work on suitable adhesives has taken place over the past ten years. Some was stimulated by the results on reinforcing intercranial aneurysms, where adhesion to the tissues was found to be satisfactory.

The attractions of adhesives are:

1. The rapidity with which repair may be accomplished.

2. Possibility of complete closure with lack of seepage.

3. Bond formation without undue deformation of tissue.

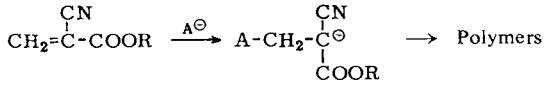
[68] *G. Scheuba*, cited in ref. [65].



4. Enhanced repair of weakened tissue resulting from age or disease.

In addition to the requirements of non-toxicity and absorbance, the adhesive must have a high degree of initial tack, to hold while hardening is completed, and must bond rapidly to tissue.

The NH_2, OH, and COOH groups present in the collagen of connective tissue are available for primary bond formation with an adhesive. However, water present in the tissues will often react more readily with some of the possible adhesives. Hardening which takes place by polymerization of monomers or of low molecular weight polymers is the most profitable area for study. Solvent removal will be less satisfactory, since the organic solvents will be undesirable, and water soluble adhesives do not usually have sufficient water resistance. For this latter reason, emulsions are not expected to be so satisfactory. Another group which is promising is that where polymerization is initiated by interaction with the bodily environment. Speed of cure is another limiting factor, and would rule out *e.g.* epoxy resins for soft tissue applications, in spite of their low toxicity and the fact that curing is only slightly exothermic.

Methyl α-cyanoacrylate was the first material to come into prominence and has been used in a wide range of applications. These include anastomoses of small blood vessels, nonsuture closing of skin, applying patches to arteries, reinforcement of suture lines, nephrotomy, *etc.* Its use in bone surgery has also been reported.

Polymerization is believed to be base-catalyzed and initiated even by water, alcohols, other weak bases, or possibly the NH_2 groups of tissue proteins[21]. Only a few seconds are required for reaction.

The alkyl α-cyanoacrylates are increasingly difficult to polymerize as the length of the α-alkyl group (C_2 to C_{10}) increases. The higher esters appear to be less toxic and since they spread more rapidly and completely on the tissues to form continuous films their polymerization is initiated more readily by water. A reverse effect is observed when spreading and polymerization are studied on distilled water.

4.4. Polymer Membranes

In many areas of the body macromolecular membranes are of great biological importance, especially in connection with selective permeability. Synthetic polymer membranes have been used for purification purposes in artificial kidneys, lungs, and liver.

The uses and problems of plastics for connecting patients to the hemodialyzer (artificial kidney) have already been mentioned (Section 3.3.1). In the dialysis apparatus, cellophane has been employed for the membrane, and acts essentially as a microporous barrier. Selectivity is small for related molecules of similar size, unless this is approximately the size of the pore, when the interactions between polymer, surface, and solute will affect the rate of transfer. The rate of transfer through cellulose membranes is slow, but pore size can be increased by biaxial stretching of the film[43]. Cellulose acetate films which are deacetylated give a more porous film.

If a membrane could be designed, in which interaction between solute molecules and membrane were high, this could give to the membrane a partitioning function. Work has been carried out to produce membranes which are water swellable and partitioning, yet are mechanically strong. Block copolymers have been evaluated. These are polymers based upon two (perhaps more) component monomers, in which the monomer units are incorporated into the polymer as macrosegments of sufficient length, such that the properties of each component are imparted to the material. Hence for a partitioning membrane, one component would give mechanical strength, the other would impart the swelling and extracting properties. The molecular structure must be such that a good membrane, free from pinholes, can be produced in a reproducible manner, and this in general implies a linear molecule, for casting from solution, or melt pressing. Compatibility with blood is an important factor also.

Block copolymers of polyoxyethylene glycol with ethylene terephthalate were tested, and appear to offer a partitioning mechanism. In another version[69], the more hydrophobic polyethylene-terephthalate sections were replaced with polyurethane segments to test the effect of structural changes, and indicated that in this type of membrane there is also an effect due to the hydrophobic segments. Some animal work has been reported[49].

As an artificial lung, the membrane separates blood from gas, and acts to control the exchange of O_2 and CO_2. Polytetrafluoroethylene and silicones appear to have the right properties of permeability and selectivity. Blood damage, and blood clotting are problems, and the turbulence caused by the high flow rate necessary for the required degree of oxygenation also increases the damage. Nonthrombogenic surfaces represent the next step forward in design of more satisfactory oxygenators. Direct exposure of the blood to the gas is prevented with these membranes.

5. Polymers as Reagents

5.1. Bioplastic Materials

The name Bioplast has been used for polymers of natural origin which are adapted for surgical use. They may have been partly modified by chemical means, *e.g.* cross-linked to reduce biodegradability, and/or produced in a different form, *e.g.* molded.

A typical use of bioplasts is the preparation of molded prostheses from a pure form of fibrin[70]. One application was as a cup implant over the femoral head in arthroplasty of the hip. Within six months, the fibrin had been absorbed, and healthy cartilage had regenerated. Fibrin films[71] and foam[72] and regenerated collagen[73] have all been used in surgery.

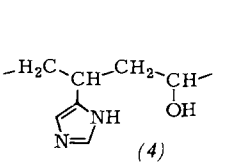
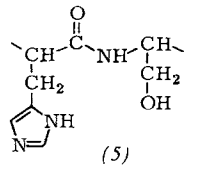
[73] *D. G. Kline*, Arch. Surgery *91*, 924 (1965).

In the field of plasma expanders, gelatin of molecular weight approx. 37000 has been used in aqueous solution [10]. Reaction with succinic anhydride has led to the stable product called "Modified Fluid Gelatin". Gelatin sponge has a wide use in surgery, generally as a hemostatic agent or a resorbable dressing [74].



The attraction of bioplastic materials is that they are not completely foreign to the body, and would be expected to be more compatible than purely synthetic materials. The criterion of success would be a capacity to integrate with the living tissue and allow its regeneration, without antigenic and inflammatory response, while still retaining the desired mechanical properties.

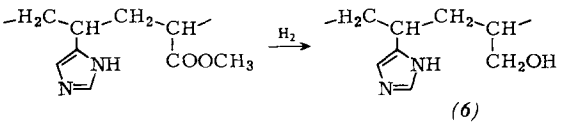
5.2. An Analytical Tool in Medical Science



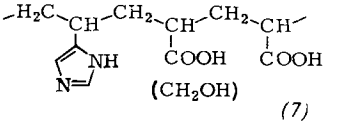
Studies of muscle action are studies of the contractile properties of proteins under the action of chemical or neurological stimulants. Much of the earlier work on protein structure was carried out on fibers, wool, and keratin using X-ray diffraction methods [75], and it was possible to show than an extended β-form and a folded α-form could both exist. However, there was little quantitative data on the relationship between the two forms, and the environmental or free energy changes associated with transitions. Synthetic polypeptides of known chemical composition gave an important tool and permitted proposals to be made for an exact structural model of the polypeptide helix [76]. X-ray determinations of periodic spacings in the molecule were compared with results from natural proteins, and eventually the elucidation of the natural structure was possible. The advantage of the synthetic model is that materials having definite structures can be prepared, and substituted at will.—The synthesis of polymers having a nonthrombogenic group as an integral part of the molecule gives interesting possibilities to investigate the mechanism of blood clotting (see Section 4.1.2).

Polymers have also been used in studying enzyme activity and especially the mode of action of thiol groups [77]. In another direction the proteolytic activity of enzymes, *e.g.* papain, is known to be retained even if part of the molecule is degraded, and thus appears to be related to the interactions of certain functional groups, rather than of the whole molecule. Copolymers containing imidazole and benzimidazole groups were prepared and their esterolytic action was observed [78]. Background studies on chymotrypsin indicated that the imidazole group of the histidine unit was the reactive center, and that activity was enhanced by a neighboring OH group from a serine unit, which could complex with the imidazole group. The synthetic polymers were made containing a pendant imidazole group from 4- (or 5) -vinyl imidazole, and other functional groups, OH or COOH as required. It was hoped to achieve the correct steric relationship between the groups by the chain coiling in solution, and hence enhance the activity over that for a single imidazole compound, or a polymer with imidazole groups alone.

A hydrolyzed copolymer *(4)* of 4-vinylimidazole and vinyl acetate is similar to a peptide *(5)* with neighboring histidine and serine



(4)



(5)

except that the secondary OH is less reactive. Hence use of methyl acrylate followed by reduction would give a primary alcohol *(6)*.

(6)

Polymers *(7)* containing an additional acidic group could be provided by terpolymerization, or by partial reduction of an acrylic acid copolymer which had adjacent carboxyl groups.

(7)

Hydrolysis of *o*-nitrophenylacetate and 3-nitro-4-acetoxybenzoic acid was found to be catalyzed more effectively by poly-5-(6)-vinylbenzimidazole than by poly-4(5)-vinylimidazole; both compounds proved 50 times as effective as benzimidazole and imidazole, respectively, at pH 10.

Thus even in a homopolymer, the spatial arrangement of the groups is significant. The copolymer of 4(5)-vinylimidazole with acrylic acid affords an opportunity of studying the effect of a negatively charged chain. With uncharged esters the copolymer is not very effective, but for positively charged esters the copolymer was up to four times more active above pH 9. Conversely, positively charged polymers (copolymer with methylimidazolium groups) were very effective for anionic ester substrates [79]. The binding of a charged substrate by the polyanion of opposite charge, giving increased catalytic activity of neighboring groups, was confirmed by experiments in which a highly charged polyanion preferentially binds a cationic substrate, thereby protecting it from hydrolysis. The hydrolyzing $-OH^{\ominus}$ groups were repelled by the highly anionic polymer chain.

These carefully designed polymers will undoubtedly be followed by others which can assume some of the functions of natural proteins and can be used in surgery.

Some Aspects of the Active Transport of Amino Acids[**]

By Klaus Ring[*]

Active transport is the transport of substances against their activity gradients. In the cell, metabolic processes provide the energy for active transport through the membrane, during which amino acids are coupled with a carrier system located in the membrane. Some of the proteins involved in the translocation of amino acids have now been isolated from E. coli.

1. Introduction

The purpose of the present article is to describe some aspects of the transport of amino acids through biological membranes (see[1]). Amino acids are very important compounds since they participate in a great variety of metabolic processes; their permeation through membranes depends on their predominantly hydrophilic character, so that coupling with carrier systems must be assumed for their transport. Another feature is the structural variety of their side chains, which necessitates many specific carrier systems since transport processes are often as specific as enzymatic reactions.

Owing to the large amounts of amino acids required by growing cells for protein synthesis and intermediate metabolism, there is a close relation between transport and metabolism, which is reflected in the often considerable capacity of the transport systems and in the many ways in which they can be regulated.

The main emphasis in the investigation of active transport has shifted in recent years from a physiological aspect to a more biochemical one. The chemistry of active transport can already be better understood through the combination of enzymological, physicochemical, and genetic techniques. *Skou*[2] discovered the first enzyme that could be regarded as a component of an active transport system; *Kaback* and *Stadtman*[3] were able to prepare from *E. coli* pure membranes capable of actively transporting amino acids and sugars. Finally, proteins that may be regarded as components of transport systems have been isolated from microorganisms in several laboratories.

"Transport research" has now reached the stage at which it is no longer possible to present an exhaustive survey, even of only a limited field such as the active transport of amino acids, within the framework of a brief review article. The subject matter will therefore be restricted, of necessity rather arbitrarily, to the more recent aspects of biochemical interest. In addition to enzymological and preparative topics, we shall be concerned with questions of regulation, which may be important to the economy of the cell in view of the large quantities of energy required for amino acid transport. (For comprehensive reviews, see[4–19].)

2. Processes Involved in Permeation

The description of the permeation processes will be limited here to what is necessary for an understanding of the following sections. (For detailed descriptions, see[1,6,7,10,12,13,19].)

There are three ways, of widely differing physiological significance, in which metabolites can pass through biological membranes.

2.1. Free Diffusion

Free diffusion is approximately realized only for a few low molecular weight metabolites such as amino acids (but see[19], p. 106 for non-electrolytes). Owing to their hydrophilic character as electrolytes, these

substances require water-filled pores in the membrane; the size of such pores, however, is limited. *Kromphardt* was able to show conclusively that the transport of taurine in Ehrlich ascites tumor cells (EMAT cells) involves a diffusion component of this nature [20].

A special case of free diffusion in which the particles move consecutively in a linear chain and cannot change their places in this chain, is assumed for the flow through very narrow pores [21–23]. This "single-file" diffusion can be distinguished kinetically from the normal free diffusion. One of its characteristics is the saturation of the flux with increasing particle concentration. The importance of "single-file" diffusion in the permeation of amino acids through biological membranes is unknown.

2.2. Facilitated Diffusion

Facilitated diffusion is also a "passive" flux, the driving force of which can be entirely derived from the concentration gradient (or electrochemical potential gradient) of the particles between the two sides of the membrane. Facilitated diffusion, unlike free diffusion, is characterized by high specificity. The particle flux can be saturated with increasing particle concentration in front of the membrane. A sub-phenomenon of facilitated diffusion is "counterflow" [6]. Many substances can mutually accelerate one another's flux if they are situated on opposite sides of the membrane.

The difference between facilitated diffusion and that form of passive permeation known as free diffusion can be very satisfactorily explained by assuming the participation of a carrier. In this view, a specific carrier molecule, which may itself be unable to permeate the membrane, forms a complex with its transport substrate on or in the membrane. The complex dissolves in the membrane, through which it is then able to pass by diffusion, rotation, oscillation, contraction and expansion, or the like, and dissociate on the other side.

An important characteristic of facilitated diffusion is that it proceeds with no perceptible chemical change in the partners involved; the only chemical reactions are the association and dissociation of the carrier and the substrate. This kind of diffusion may be discontinuous or continuous; in the former case, association and dissociation take place only on the outsides of the membrane, while in the latter, as exemplified by the transport of O_2 by hemoglobin, these processes also occur during passage through the membrane [24].

Facilitated diffusion appears to be of considerable importance in the absorption of some amino acids in microorganisms. *Brock* and *Moo-Penn* [25] found that in *Streptococcus faecium*, extracellular serine, glycine, and threonine, which are essential amino acids for these cells, are transported into the interior of the cells against their concentration gradients by a specific system without the direct expenditure of energy. This is due to an obligate coupling of these inward fluxes with the efflux of alanine, which is synthesized in large quantities in the cells. The concentration gradient for alanine from the inside outward is thus used to pump extracellular amino acids into the cell against their concentration gradients.

Kaback and *Stadtman* [26] have shown that though the accumulation of glycine through isolated membrane preparations from *E. coli* is energy-dependent as an overall process, the actual transport (translocation) through the osmotic barrier occurs by facilitated diffusion, *i.e.* independently of energy.

2.3. Active Transport

Active or uphill transport exhibits the same kinetic characteristics as facilitated diffusion, *i.e.* saturation of the flux at high substrate concentrations, usually high specificity, susceptibility to competitive inhibition, exchange diffusion, and the "preloading effect" [27–30]. A carrier mechanism is therefore generally assumed to operate here also. The essential difference between this and facilitated diffusion is that in active transport the particle flow is directly coupled with the free energy of a chemical reaction taking place in the transport region. The energy liberated is converted into pumping work, and so allows the accumulation of the particles against their osmotic or electrochemical gradient.

Active transport generally leads to the establishment of a steady state in which the distribution of the substrate between the intracellular and extracellular space is constant. The accumulation depends on the capacity of the transporting system, the magnitude of the efflux (free diffusion and/or exchange diffusion), and the rate of breakdown of the substrate inside the cell. Cases of enrichment by a factor of more than a thousand are not uncommon. *Johnstone* and *Scholefield* [31] have reported that under certain conditions, about 50% of the cellular ATP can be utilized for the accumulation of glycine in EMAT cells. *Quastel* [11] has pointed out the great selection advantage that cells with efficient active transport systems can have in their development as compared with cells having lower transport capacities. For example, tumor cells, which are among the most active of animal cells as far as transport is concerned, can withdraw important nutrients from neighboring cells.

[31] *R. M. Johnstone* and *P. G. Scholefield*, Advances Cancer Res. *9*, (1965), see [11].

As was first shown by *Heinz* [27–29] for the transport of glycine in EMAT cells, the total flow of this amino acid involves an appreciable exchange diffusion component. In the steady state more than 90% of the intracellular glycine is exchanged for extracellular glycine within a period of five minutes [28]. The exchange fluxes are about five times as fast as the net transport [32]; this means that about 80% of the total flux is due to the exchange diffusion. The reason for this is thought to be that the charged carrier is more mobile (soluble) in the membrane than the uncharged carrier [16, 29, 30]. As a component of an active carrier system, exchange diffusion, like facilitated diffusion, is independent of energy; both can be attributed to the same type of reaction.

To illustrate the individual reactions to be expected in the transport of amino acids, we shall first consider the carrier model proposed by *Heinz* and *Walsh* [29] (Fig. 1).

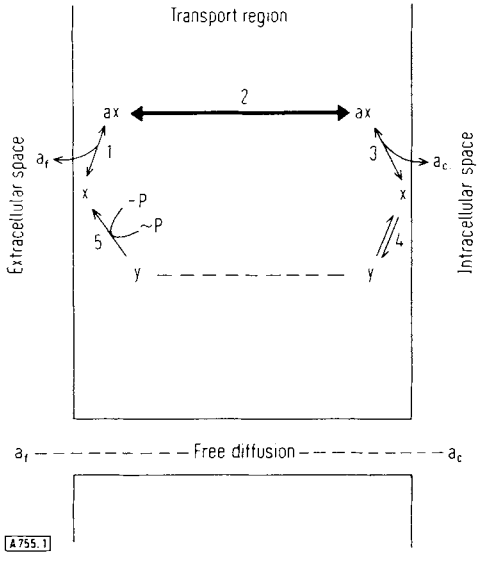

Fig. 1. Model of the amino acid transport in Ehrlich ascites tumor cells, after *Heinz* and *Walsh* [29]. a_f and a_c: extracellular and intracellular transport substrate; x active carrier, y inactive carrier ax carrier-substrate complex; ~ P and —P substrate and product of an exergonic reaction coupled with the transport. For explanations, see text.

The amino acid a combines temporarily with its own specific carrier x to form ax (formally comparable to an enzyme-substrate complex), which passes through the membrane. On the inside of the membrane ax dissociates into a_c + x. It is assumed that the binding and the dissociation of a are fast in relation to the translocation of ax. Exchange diffusion involves the reactions 1–3, which must be reversible. The accumulation inside the cell results from the fact that after the dissociation of ax, x is inactivated by conversion into y, as a result of which the affinity for a is completely or at least partly lost. After diffusion to the outside of the membrane, y is reactivated by conversion back into x by the energy-dependent reaction 5. According to kinetic findings, the diffusion of y or reaction 5 is rate-determining.

This model satisfies all the requirements apparent from investigations on the transport of amino acids in EMAT cells, and appears to be applicable to some microbial systems [33], though not unrestrictedly so. Thus some of the amino acid transport systems studied by us in *Streptomyces hydrogenans* lack the exchange diffusion component [34].

The model originally proposed by *Kepes* [35] for β-galactoside transport in *E. coli* and later extended by *Koch* [36, 37] (permease model) is also based on a carrier. Unlike the carrier model described above and the almost identical "permease model" of *Cohen* and *Monod* [5], *Kepes*' model involves two catalytic components, *i.e.* a specific permease (P) and a less specific transporter (T) (Fig. 2). P is firmly fixed to the outside of the membrane and catalyzes the binding of the substrate (G) to the transporter. The complex GT passes through the membrane and dissociates on the inside into T and G. The actual translocation is again reversible. The active transport requires the participation of ATP in the synthesis of the active transporter T ~ R.

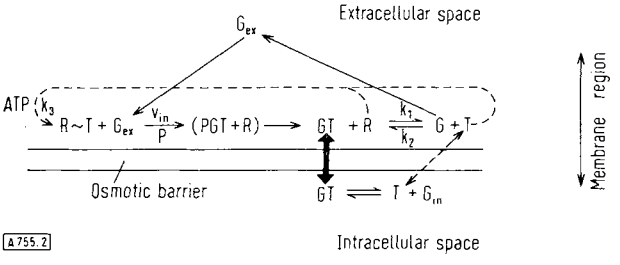

Fig. 2. Model of the β-galactoside transport in *E. coli* (permease model) after *Kepes* [35]. P = permease, T = transporter, G = substrate, R ~ T = activated transporter. For explanations, see text.

Observations on *E. coli* [36] and genetic studies on the transport of sugars in *Staphylococcus aureus* [38] have provided indications of a two-component system of this type with a multifunctional carrier. However, this also seems to be limited in its applicability. Thus the exchange diffusion of amino acids in many microorganisms is strictly specific; this means that either a specific transporter must be involved as well as the permease, or a second permease must be present on the inside of the membrane [*].

3. Enzymes as Components of Transport Systems

It is not clear at present how the active transport of amino acids is connected with the energy metabolism ("chemo-osmotic coupling"), though direct links have

[39] *W. Wilbrandt*, see [9], p. 112.

been found in recent years between several enzyme systems that catalyze the energy-transferring reactions and the active transport of solutes. One of these systems, the membrane ATPase discovered by *Skou* [2,40], is a component of the transport system for K^+ and Na^+ in animal cells. Its reaction sequence includes a phosphate transfer from ATP to a membrane protein and subsequent dephosphorylation of the latter. The first step requires Na^+, and the second K^+. The enzyme can be inhibited by strophanthin (for review, see [12, 16–18, 40]). ATPases have also been detected in bacterial membranes; however, they differ considerably from enzyme preparations of animal origin in their cation dependence and their sensitivity to strophanthin [41–52]. It is not yet certain how far ATPases are directly (*i.e.* independently of a symporter mechanism, see Section 4) involved in amino acid transport.

Kundig et al. [53] isolated from *E. coli* a phosphotransferase system that is involved in the active transport of sugars, and which consists of two enzymes (I and II) and low molecular weight, heat-stable protein, HPr. The membrane-bound enzyme II is decisive for the substrate specificity of the reaction. Phosphoenol pyruvate acts as the energy donor:

$$\text{Phosphoenol pyruvate} + \text{HPr} \underset{\text{I}}{\overset{Mg^{2+}}{\rightleftharpoons}} \text{pyruvate} + \text{phospho-HPr}$$

$$\text{Phospho-HPr} + \text{sugar} \xrightarrow[\text{II}]{Mg^{2+}} \text{sugar 6-phosphate} + \text{HPr}$$

$$\text{Phosphoenol pyruvate} + \text{sugar} \xrightarrow[\text{I}+\text{II}]{Mg^{2+}+\text{HPr}} \text{sugar 6-phosphate} + \text{pyruvate}$$

Considerable evidence has recently been adduced to show that this energy transfer system is an integral part of a series of sugar transporting systems in various microorganisms [54–60]. In contrast with earlier views, the substrate is modified by covalent bonds during transport in these cases.

Van Steveninck [61,62] has described a system in yeast that also phosphorylates the transport substrate, and which is a constituent of an energy-dependent sugar "permease". The energy donor in this system is polyphosphate.

The models described appear to be restricted to the transport of cations or sugars. There is no evidence of the participation of comparable reactions in the active transport of amino acids; in particular there is no evidence that amino acids even temporarily enter into covalent bonds during translocation.

4. Ion Dependence of Amino Acid Transport

Interesting relationships between amino acid transport and monovalent cations have been found in particular in animal cells. The absorption of amino acids in various types of cells can be influenced by the ionic medium in the extracellular space. The transport of amino acids in animal cells (EMAT cells, erythrocytes, mucosa cells, pancreas cells, *etc.*), like the transport of sugars in many tissues, depends on the extracellular Na^+ concentration [9,63–68]. The maximum accumulation of glycine in EMAT cells requires a Na^+ concentration of about 130 mmole/l.

Many kinetic and electrophysiological studies have been carried out in attempts to explain the influence of Na^+ on the transport of amino acids and sugars (for literature review and discussions, see [11,12,15,16,18,19]). According to the hypothesis most often advanced nowadays [67,68], the amino acid (or sugar) influx is assumed to be coupled with the Na^+ influx. The two transport substrates use a common carrier, and pass through the membrane in a ternary complex ("symporter" in *Mitchell*'s nomenclature [12]). Inside the cell, the Na^+ and the amino acid (or sugar) dissociate from the carrier molecule. The Na^+ that has penetrated is carried out of the cell by the Na^+ pump ("membrane ATPase"), so that if the pump capacity is sufficient, the intracellular Na^+ concentration is low in relation to the extracellular concentration. Thus a gradient for Na^+ is maintained across the cell membrane from outside to inside, and this is the driving force for the simultaneous influx of Na^+ and amino acid. The accumulation of the amino acid is consequently a function of the Na^+ gradient.

Owing to the high physiological outside concentration of Na^+, the Michaelis constant K_m for the amino acid is reduced; inside the cell, at a low Na^+ concentration, the high K^+ concentration built up by the inward-directed K^+ pump increases K_m, so that the carrier loses part of its affinity for the amino acid. Thus a further driving force for the inward flow of the amino acid is provided by the asymmetric distribution of K^+.

According to this hypothesis, the Na^+-dependent transport of amino acids in the cells in question is not true active "primary transport", but must be regarded as facilitated diffusion. Owing to its dependence on the active transport of K^+ and Na^+, it can be inhibited by all inhibitors of the cation pump, such as strophanthin.

A similar Na^+-dependence was found by *Kleber* and *Aurich*[69] for the active transport of carnitine in *Pseudomonas aeruginosa;* K^+ and Mg^{2+} also have activating effects. It was surprising to find that g-strophanthin inhibits carnitine transport. On the basis of these findings, the authors assume that the transport of carnitine involves a strophanthin-sensitive membrane ATPase that can be stimulated by K^+ or Na^+. A symporter mechanism may also occur here.

Some halophilic microorganisms also require sodium ions for their amino acid transport[70–73]; unlike in the cases described above, however, they act only in combination with chloride. High salt concentrations are also required to maintain the extremely labile structure of these organisms and to activate some enzymatic reactions. It is therefore not very likely that the dependence of the amino acid uptake on NaCl can be explained in this case too by a symporter hypothesis.

However, monovalent cations can also influence the active transport of amino acids in another way. *Gross*[74] found that the active glutamate transport in *Streptomyces hydrogenans* is significantly activated by K^+ and Rb^+. The interpretation of the findings was made difficult by the fact that enzymatic reactions are also activated by these ions. Since, however, the intracellular K^+ concentration increases with the intracellular glutamate concentration, it may be assumed that K^+ enters the cell with the anionic glutamate. These findings confirm earlier studies by *Gale*[4], *Davies et al.*[75], and *Eddy* and *Indge*[76], according to which the absorption of glutamate in many microorganisms is associated with a gain in intracellular K^+.

On the other hand, the absorption of neutral amino acids by *Streptomyces hydrogenans* is independent of monovalent cations, provided that their concentration does not exceed about 5×10^{-2} mole/l[77,78]. Higher concentrations inhibit the amino acid transport. The inhibition is reversible, nonspecific, and competitive, and is not due to an osmotic effect. Monovalent cations in high concentrations probably prevent the bonding of the neutral amino acids to the transport system by occupying the anionic bonding sites on the carrier molecule in competition with the NH_3^+ groups of the amino acids[78].

Christensen and *Handlogton*[79] found that the transport of basic amino acids in EMAT cells is inhibited by neutral amino acids in combination with sodium ions. The results are interpreted as indicating that neutral amino acids can occupy the bonding site for basic amino acids on the carrier molecule and inhibit their transport if an accompanying cation such as Na^+ occupies the binding site for the distal cationic group of the basic amino acid.

5. Regulation of Amino Acid Transport

The regulation of the active transport of amino acids is of special physiological importance. It is evidently the same as or very similar to the control of enzymatic processes. It is necessary to distinguish between two independent control cycles, one of which appears to act *via* the change in the *concentration*, and the other *via* the change in the *activation state*, of the transport system. The first control cycle acts on the genetic level. A transport substrate can specifically induce the *de novo* synthesis of the transport system, or repress it in case of an excessive supply in the nutrient medium. Adjustments of this nature require a certain time lag. The second control cycle acts instantaneously, and can be interpreted as a sort of feedback, in which the transported substrate or one of its metabolic products inside the cell inhibits or stimulates the active transport of further molecules. Examples of all four possibilities have been found, though almost exclusively in microorganisms so far.

5.1. Induction and Repression

Many genetically controlled microbial transport systems have been described in recent years. These include, above all, systems for the absorption of the many metabolically utilizable carbohydrates and other substances involved in catabolism. The ability of bacterial cells to induce absorption systems for such a wide variety of physiological energy donors is undoubtedly associated with a selection advantage. Thus only the transport system needed by the cell at the moment in question is synthesized. The capacity of a single system is sufficient to satisfy all the carbohydrate requirements of the cell[80].

On the other hand, only a few inducible transport systems for amino acids are known at present. This was not surprising, since the inducibility of the amino acid transport would not necessarily mean a selection advantage [80]. It must be remembered that the cells are generally capable of satisfying their requirements of the twenty or so amino acids, according to the medium, either by absorption from the nutrient medium or by synthesis for themselves. Biosynthesis, which requires more energy, is known to be provided in some synthesis sequences with a feedback control, the regulation circuit of which works most effectively if the amino acids present in the outer solution are very rapidly absorbed into the interior of the cell, where they can exercise their control function as required. However, this is possible only if the transport systems involved are permanently present in their maximum concentration, irrespective of the external concentration of their substrate.

Some cell species, on the other hand, appear to have inducible capacity reserves available, and these can be advantageous if the culture medium contains high concentrations of only one or just a few amino acids. The cell is then enabled to satisfy its nitrogen requirements wholly or partly from the exogenous amino acid nitrogen.

The first inducible uptake system for amino acids was discovered by *Boezi* and *DeMoss* [81] in the investigation of the absorption of tryptophan by a tryptophan-auxotrophic mutant, *E. coli* T_3A. Another inducible tryptophan transport system observed in *Ps. acidovorans* has been described by *Rosenfeld* and *Feigelson* [82]. Both transport systems are energy-dependent; their specificity is limited to tryptophan and structurally related derivatives. Maximum induction of the *E. coli* system requires 500 μg of tryptophan/ml of culture medium, and increases the transport by a factor of ten; even "uninduced" cells have a measurable transport capacity.

In *Ps. acidovorans*, the tryptophan transport is induced by 5 mmole/l of L-tryptophan in an inorganic medium containing asparagine; maximum induction requires incubation for about six hours. Two tryptophan-degrading enzymes are induced simultaneously with the transport, though not strictly coordinated with it. The key position in the induction appears to be occupied, not by the transport substance, tryptophan itself, but by its degradation product kynurenine; this product can also induce the tryptophan transport, as well as its own transport system. Induction by tryptophan presumably does not occur directly, but only after endogenous conversion into kynurenine. There should thus be a close relationship between metabolic activity and transport induction.

A relationship of this nature is also found in the induction of citrulline transport in *Streptococcus faecalis* [83]. This microorganism converts arginine into citrulline, and the latter into ornithine. Cells grown in inorganic medium have a relatively poor permeability for citrulline; on addition of arginine to the culture medium, the permeability to citrulline is increased by a factor of four. This increase in transport is selective; the concentration of the citrullinase is not affected. Maximum induction requires a relatively long incubation, and is complete after 12–16 hours. The inducer is presumably again not the added amino acid, arginine, but the degradation product citrulline accumulated in the cell.

An inducible active transport system for L-glutamate in mycobacteria has been described by *Lyon et al.* [84]. The inducer is the transport substrate, L-glutamate. Maximum induction requires the relatively high inducer concentration of 2×10^{-2} mole/l. A basic transport activity is again present in "uninduced" cells, and induction increases this transport by a factor of about three.

It was also found for the inducible oxidative degradation of L-hydroxyproline to α-ketoglutarate in *Ps. putida* [85] that hydroxyproline together with the degrading enzymes again induces its transport system. It is not yet known to what extent the induction of the enzymes and of the "permease" is coordinated.

The microorganism used by us, *Streptomyces hydrogenans*, has an inducible transport system for neutral amino acids, as was first reported by *Hübener* [86]. Further investigations [87,88] were performed on the kinetic characterization of the induced system. The induction was carried out in an inorganic medium with succinate and glucose as energy sources and NH_4Cl as a nitrogen donor. Despite the absence of amino acids, the cells develop a sometimes considerable transport capacity for neutral amino acids in this medium. The addition of some neutral amino acids to the culture medium increases the maximum transport by a factor of ten. Glycine and alanine are good inducers, as is also α-aminoisobutyric acid (AIB), an amino acid that is similar in structure to glycine and alanine, but which is not metabolizable. This observation is important to the interpretation of the experiments, since it shows that the transport substrate itself, and not one of its metabolic products, is the inducer.

Maximum induction requires an inducer concentration of about 10^{-1} mole/l. This value seems very high at first sight, but becomes understandable when compared with the intracellular alanine and glycine concentration. Next to glutamate, alanine is the principal constituent of the amino acid pool in this organism; its concentration in the cell fluid is about 10 mmole/l, and that of glycine is about half of this. It is obvious

that induction can occur only at inducer concentrations above this value.

The physiological function of a regulation of this nature was discussed in Section 5. Let us consider here whether the basic transport capacity in uninduced cells might not even be the product of an incomplete induction that is permanently stimulated by the intracellular amino acids. This assumption is supported by the observation that the basic transport activity appears to depend on the quality of the growth and varies widely and that the Michaelis constants of the transport systems for α-aminobutyric acid in induced and uninduced cells are indistinguishable (see below).

The induction is inhibited by chloramphenicol, actinomycin C, proflavine, and mitomycin, thus showing that intact DNA as well as RNA and protein synthesis are necessary. Addition of non-inducing amino acids such as asparagine has a strong promoting effect [88], but the function of these amino acids is not yet clear.

According to kinetic studies, induction increases the maximum rate of the influx without affecting the affinity between the transport system and the substrate. Besides the influx, the enrichment in the steady state and the efflux are also increased. The kinetic parameters of an experiment of this type are summarized in Table 1. Since both undirectional fluxes, *i.e.* influx and efflux, can be seen to increase, it might be assumed at first that the increase in influx is due to an increase in the mobility of the carrier in the membrane. However, the dependence on protein synthesis would be difficult to understand if this were so.

Table 1. Kinetic parameters of the transport of α-aminoisobutyric acid of induced and "uninduced" cells of *Streptomyces hydrogenans* (from [88]). The "uninduced" cells were cultured for 13 h in inorganic medium, and the induced cells in inorganic medium containing 2×10^{-1} mole/l of DL-alanine.

Parameter	"uninduced"	induced
Influx constant (k_{in}) (ml × g^{-1} × min^{-1})	10.20	37.82
Efflux constant (k_{ex}) (ml × g^{-1} × min^{-1})	0.136	0.244
Influx (v_{in}) (μmole × g^{-1} × min^{-1})	25.2	81.0
Distribution ratio (1 min) (R_a 1 min) [a]	28.0	90.0
Distribution ratio (steady state) ($R_{a\infty}$)	300.0	620.0
"Michaelis constant" (mole/l)	2.73×10^{-5}	2.73×10^{-5}

[a] The distribution ratio (R_a) is the ratio of the intracellular amino acid concentration (a_c) to the extracellular (a_f): $R_a = a_c/a_f$. The rate of absorption du/dt of AIB can be described by the following equation: $du/dt = \Phi^{in}_{max}\, a_f/(a_f + K_m) - k_{ex} \times a_c$, where Φ^{in}_{max} is the maximum influx. In the steady state, $R_a = k_{in}/k_{ex}$.

The observations can be more readily explained if it is assumed that the induced cells have a greater number of active carrier molecules available in the membrane. The increase in both flow constants, k_{in} and k_{ex}, means that the induced protein must be accessible to the substrate from both sides of the membrane.

Attempts to interpret the results on the basis of the permease model in Fig. 2 leads to difficulties when one regards the "permease" as the only inducible component of the entire system, since it is arranged asymmetrically in the membrane and with respect to the transporter. On the other hand, the findings are compatible with the carrier model in Fig. 1, provided that the carrier is assumed to be inducible. Difficulty arises, however, in the interpretation of the kinetic data, since k_{in} increases more than k_{ex}. No plausible mechanistic explanation has yet been advanced.

An opposing regulation of the transport of neutral amino acids was observed by *Inui* and *Akedo* [89] in *E. coli* K10, and was interpreted as repression. An excess of a single amino acid, *e.g.* leucine, in the nutrient solution leads to a decrease in the absorption of the same and structurally related amino acids. No inhibition develops in resting cells on incubation in nitrogen-free solution or in the presence of chloramphenicol; mitomycin C, on the other hand, has no effect. The inhibition is specific for amino acid transport; α-methylglycoside transport and the Na^+ and K^+ distribution remain constant. Kinetic studies have shown that the influx in particular is affected. The distribution of the amino acid between the intracellular and the extracellular spaces in the steady state is reduced to 1/10 of the normal value, the efflux has increased by a factor of only three. It is therefore unlikely that an efflux-specific transport system has been induced during preincubation.

5.2. Feedback Control

A control of the active transport of amino acids that is independent of the genetic regulation, and which acts on the level of the transport system like a feedback control, was first described a few years ago. As we found in the case of *Streptomyces hydrogenans*, all the amino acid transporting systems are subject to control by two opposing regulating systems, one of which inhibits the active absorption of amino acids, while the other promotes it [33,90–93]. Both effects can be demonstrated for the absorption of ^{14}C-labeled α-aminoisobutyric acid (AIB) by cells that have received different pretreatments. If the cells are preloaded with unlabeled AIB for one hour, the absorption decreases, whereas it increases after preloading for one hour with L-glutamate. These preincubations influence both the initial rate of absorption and the distribution of the test amino acid in the steady state.

5.2.1. Transport Inhibition

The inhibition of the AIB influx is a function of the intracellular concentration of the inhibitor AIB. The inhibition increases with increasing internal AIB con-

[89] *Y. Inui* and *H. Akedo*, Biochim. biophysica Acta *94*, 143 (1965).

[90] *E. Heinz*, *K. Ring*, and *W. Gross*, Federat. Proc. *26*, 393 (1967).

[91] *K. Ring*, *W. Gross*, and *E. Heinz*, Ber. Bunsenges. physik. Chem. *71*, 893 (1967).

[92] *K. Ring*, *W. Gross*, and *E. Heinz*, Arch. Biochem. Biophysics *137*, 243 (1970).

[93] *W. Gross*, *K. Ring*, and *E. Heinz*, Arch. Biochem. Biophysics *137*, 253 (1970).

centration until a maximum value is reached; the maximum inhibition by loading with AIB varies between 40 and 70%, depending on the cell material. However, only the inward flux is decreased when the AIB concentration on the other side of the membrane ("transconcentration") is increased; the efflux of labeled AIB increases with increasing transconcentration. Whereas the last observation can be readily explained by the carrier model in the sense of the preloading [27–30] or counterflow effect [6], additional assumptions are necessary to explain the inhibition of the influx (see below).

The influx inhibition ("transinhibition") is characterized kinetically as non-competitive, since the apparent Michaelis constant remains unchanged while the maximum rate of influx decreases. Other kinetic findings show that preloading influences only the influx, whereas the efflux remains constant. It may therefore be concluded that the transinhibitor does not affect the mobility of the carrier-substrate complex in the membrane.

It has also been shown that the transinhibition begins immediately and with maximum effect when the inhibitor reaches the inside of the cell. The inhibition is reversible and, after the inhibitor has been washed out, can be repeated by renewed preloading. The preloaded amino acid thus reduces the activity of its transport system from the inside of the cell.

The inhibition of transport by loading with AIB is not very specific; all the amino acid transport systems examined (for glutamate and aspartate, methionine, phenylalanine, leucine, proline, lysine, arginine, tryptophan, histidine) are partly inhibited. However, the inhibition appears to be confined to the transport of amino acids; neither the transport of potassium nor that of sorbose is affected by loading with AIB.

AIB was used as the inhibitor in all the experiments described so far, since this amino acid is not metabolized by *Streptomyces hydrogenans*, even on prolonged incubation. Other amino acids that are normal components of the cell amino acid pool also act as transport inhibitors. All the neutral amino acids studied so far, as well as arginine and lysine, can inhibit the active transport of amino acids from inside the cell (Table 2); other amino acids, such as aspartate or glutamate, evidently have no effect.

Table 2. Transinhibition of the [^{14}C]-AIB influx by intracellular amino acids. Measurement of the AIB absorption after preloading of the cells at −2 °C (20 min) with the amino acids indicated (20 mmole/l) followed by centrifugation and resuspension in a buffer containing no amino acid.

Preloaded with	Inhibition (%)
–	0
AIB	55.1
Cycloleucine [a]	87.3
Glycine	19.3
L-Alanine	56
L-Valine	50
L-Leucine	48.5
L-Isoleucine	46.7
L-Methionine	18
L-Lysine	17
L-Arginine	38
L-Aspartate	3

[a] 1-Aminocyclopentane-1-carboxylic acid.

The amino acids listed in Table 2 were introduced into the cells by cold shock treatment. The permeability of *Streptomyces hydrogenans* is greatly increased at temperatures around 0 °C [94,95], so that small molecules such as amino acids can pass rapidly through the membrane (see also [96–99]). Since the change in permeability is reversible, it can be used to introduce molecules rapidly into the inside of the cell or to remove substances from inside the cell. In this way, a metabolic attack on the amino acid during transport can be overcome. This process is thus comparable in its effect with the reversed hemolysis of erythrocytes [100, 101]. In connection with the transinhibition, it offered the only possibility of testing the inhibitor properties of rapidly metabolizable amino acids. Another advantage was that the "shocked-in" amino acids can always be brought to the same concentration, and a quantitative comparison of their inhibitor properties is therefore possible. However, this is so only if the amino acids are completely equilibrated between the intracellular and the extracellular spaces during the cold shock. This method has also been used to shock the normal culture medium for *Str. hydrogenans*, a nutrient broth containing casein hydrolyzate and yeast extract, into the cells and to test their action on the transport of AIB. An inhibition of up to 40% was observed.

A possible interpretation of the observations is that certain amino acids from the cell pool control the amino acid transport as effectors after the fashion of feedback regulation. It may be assumed that the inhibitor controls a limiting reaction in the overall transport process, which is inserted into the energy coupling between the transport and energy metabolism [92]. On the basis of the carrier model in Fig. 1, this would be step 5 of the cycle. It must be assumed that this reaction is common to all transport systems for amino acids.

Alanine, which is present inside the cell in an adequate concentration and which has very good inhibitor properties, could act as a physiological key substance in this control cycle.

A similar mode of amino acid transport appears to operate in *Bac. subtilis* [101a].

The observations described here are in agreement with results obtained by *Wiley* and *Matchett* [102], according

to which the active transport of tryptophan in *N. crassa* is regulated by the intracellular tryptophan concentration. However, the transport inhibition is more specific than in *Strept. hydrogenans*, since it is limited to the amino acids transported by the tryptophan system. Independently of us, *Wiley* and *Matchett* have also reached the hypothesis that inhibition is the result of feedback control by the transport substrate that has accumulated in the cell.

Similar instances of feedback regulation have been described by *Benko et al.* [103,104]. In these cases, however, the inhibitor is not the transport substrate but one of its metabolic products. The active transport of methionine in *Penicillium* and *Aspergillus spec.* is inhibited by one of its sulfur-containing degradation products [103]. In the state of inhibition, the apparent Michaelis constant for methionine is increased by about two orders of magnitude; V_{max}, on the other hand, is only slightly changed. Evidence has also been produced [104] to show that a second, non-specific amino acid permease is also subject to feedback regulation; the effector appears to be NH_4^+.

Specific transport inhibition by degradation products of other metabolites is involved in the absorption of sulfate in *E. coli* [105], *Penicillium chrysogenum* [106,107], and *Salm. typhimurium* [108], the absorption of glucose in muscle cells [109] and *E. coli* [110,111] and of monosaccharides in baker's yeast [112], and the nucleotide transport in *Bac. subtilis* [113].

5.2.2. Stimulation of Transport

The AIB transport in *Streptomyces hydrogenans* cells is increased by preincubation for one hour with L-glutamate ("transstimulation" [93]). Unlike transinhibition, transstimulation cannot be detected immediately after the penetration of the effector into the cell, but only after about 15–20 minutes. This is seen in the time-absorption curve for glutamate in *Strept. hydrogenans* from the fact that the net absorption increases again at this instant, *i.e.* the curve becomes steeper and finally tends toward a new steady state [114]. Like transinhibition, transstimulation is non-specific with respect to the transport systems for amino acids, but is confined to these. Potential stimulators are metabolizable amino acids such as L-glutamate, L-lysine, L-proline, and L-aspartate.

Kinetic studies show that the transstimulation, like inhibition, does not affect the mobility of the carrier-substrate complex in the membrane. The affinity of the transport system for the substrate was also unaffected. A preloading or counterflow effect was also ruled out as a possible cause of the increased flux.

The lag phase indicates that the stimulation is preceded by a metabolic change in the amino acid. In view of the uniformity of action of such different amino acids as glutamate, leucine, or lysine, it was to be assumed that the stimulator is one of their common metabolites. All attempts to identify it have been unsuccessful. The simplest explanation at present is provided by the hypothesis that the stimulation is effected by the aminoacyl-t-RNA derivative, and is thus closely related to protein synthesis. This assumption is supported by observations that RNA appears to be essential to transstimulation. Prolonged preincubation of the cells with inhibitors of the RNA synthesis prevents transstimulation; this action is not observed with inhibitors of DNA or protein synthesis.

Both feedback systems appear to ensure rapid adjustment of the amino acid transport to the different requirements of the cells during growth.

Another means by which the cell could adjust its amino acid transport to meet the requirements for an optimum supply was recently described for *N. crassa* [115]. A relatively specific transport system prevails in young, rapidly growing cells; in older cultures, on the other hand, the absorption is effected by a second system having very little specificity. Its physiological function appears to be the supply of residues of exogenous amino acids to the cell metabolism.

6. Relationship Between Amino Acid Transport and Protein Synthesis

It has been found in recent years that amino acid transport systems both of animal and of microbiological origin exhibit a striking sensitivity to inhibitors of protein and RNA synthesis [82,102,104,116–121]. However, the inhibitors do not act immediately, but cause a gradual loss of transport activity. The most spectacular example of this is the transport of tryptophan in *Neurospora crassa*; 50% of the transport activity is lost

only 15 min after the addition of cycloheximide (4-[2-(3,5-dimethyl-2-oxocyclohexyl)-2-hydroxyethyl]-piperidine-2,6-dione), whereas the tryptophan-degrading enzyme kynureninase is unaffected [102]. The protein synthesis must evidently remain intact to maintain the transport function.

Two hypotheses have so far been proposed to explain the inhibition. *Elsas* and *Rosenberg* [116] and *Holden* and *Utech* [118] attributed the susceptibility of the transport system to inhibition to a particularly high turnover rate of a transport protein. An equilibrium exists between degradation and resynthesis in uninhibited cells. This equilibrium is disturbed by the addition of an inhibitor of the RNA or protein synthesis, so that the relatively fast degradation can no longer be compensated by resynthesis. *Grenson et al.* [117], on the other hand, believe that the transport inhibition is indirect, and is due to the increase in the intracellular amino acid pool as a result of the uncompensated protein degradation; the inhibition is thus interpreted mainly as feedback inhibition.

Since the amino acid transport in *Streptomyces hydrogenans* can also be inhibited by chloramphenicol, actinomycin, and related inhibitors, while it is also regulated by feedback control, we have investigated the applicability of the second hypothesis to this system [119]. Use was made of the fact that the cell amino acid pool can be removed very rapidly by cold shock treatment. When the cells are washed out by this method, the transport inhibition is reduced by only 10–20%, though the feedback inhibition due to preloading with AIB is completely reversible under these conditions [92]. It has also been found that the transport in chloramphenicol-inhibited cells can be inhibited by loading with AIB to almost the same degree as in chloramphenicol-free cells. Since the feedback inhibition in *Streptomyces hydrogenans* depends on the intracellular concentration of the transinhibitor and reaches a maximum at a concentration of only about 30 mmole/l, AIB together with the considerable quantities of amino acids liberated by the action of chloramphenicol cannot cause any additional inhibition. This observation is thus incompatible with the theory proposed by *Grenson et al.* [117]. Finally, kinetic measurements have shown that the influx and efflux of AIB both decrease by the same factor under the influence of chloramphenicol, an observation that is compatible only with the first hypothesis. We therefore assume that a protein involved in the carrier transport in *Streptomyces hydrogenans* has a much higher turnover than the other proteins.

The physiological significance of this special case is not yet clear. It is possible that there is again a relationship with the control of the transport.

7. Isolation of Transport Proteins

Many attempts have been made in recent years to label and isolate membrane components that are involved in the translocation of small particles such as amino acids, sugars, or ions, through the cell membrane. Owing to the important advances and the general importance to transport research the principal efforts will be described in some detail, though they are only partly concerned with the transport systems for amino acids. We shall not consider the special case of the phosphotransferase system (Section 3) [53].

It is still assumed that the transport substrate in the active transport of amino acids passes unchanged through the membrane and only the transporting agent is the substrate of an enzymatic reaction. The translocation of the substrate is thus not directly affected by the energy-dependent reaction. These assumptions are in agreement with the investigations on facilitated diffusion and exchange diffusion. However, they make clear the difficulties opposing the isolation of the translocator. All that can be said is that it must be a protein that can reversibly bind an amino acid. No measurable enzymatic activities are to be expected.

With few exceptions, the successful isolation attempts were carried out on microorganisms. The first transport protein, a component of the glucose transport system, was obtained by *Rogers* [122] from *E. coli* A by extraction with warm buffer at pH 7.3 under conditions in which the transport of glucose into these cells is known to be unstable. The transport protein has not yet been characterized in detail.

The preparative methods subsequently used were based on two requirements:

1. Specific labeling of the transport proteins with ^{14}C or ^{3}H; in this case the transport system must be inducible.

2. Solubilization of the proteins by osmotic shock in the cold; this is based on labile bonding of the proteins to the cell surface.

With the aid of the first method, *Fox* and *Kennedy* [123] isolated and purified an "M protein" (membrane protein) that is a component of the active transport system for β-galactosides in *E. coli*. This system is inducible, is coded by the y gene of the lactose operon, and together with the other two genes for β-galactosidase and β-galactoside transacetylase, is controlled by the regulator gene i. The authors used cells poisoned with azide, which can no longer accumulate the transport substrate; however, solute flux by facilitated diffusion is possible.

It was known from earlier observations that the transport of β-galactosides involves thiol groups, which can be protected against alkylation by bonding of a transport substrate, such as thiodigalactoside (TDG). With substrate protection of this nature, all the accessible SH groups that were not involved in the transport of galactoside were first blocked by reaction with *N*-ethylmaleimide (NEM) in induced and uninduced cells. In the second phase of the experiment, TDG was removed and the now liberated transport-specific SH groups were alkylated with radioactively labeled NEM, the induced cells receiving [^{14}C]-NEM and the uninduced controls [^{3}H]-NEM. After the reaction, equal parts of both lots were mixed and the cells were disrupted and fractionated.

Under these conditions all the accessible reactive proteins are doubly labeled, since induced and uninduced cells synthesize the same proteins, with the exception of those controlled by the lactose operon. These are practically absent from uninduced cells, but present in high concentrations in induced cells. On fractionation of the protein and investigation of its ^{3}H and ^{14}C fractions, an inducible protein should be recognizable by an increased $^{14}C/^{3}H$ ratio, provided that it is attacked by NEM [*].

[122] *D. Rogers*, J. Bacteriol. *88*, 279 (1964).

[123] *C. F. Fox* and *E. P. Kennedy*, Proc. nat. Acad. Sci. USA *54*, 891 (1965).

[*] β-Galactosidase and transacetylase are not labeled by NEM.

This technique allowed the discovery and isolation of a protein fraction that comes from the plasma membrane and has no enzymatic activity. This M protein is fixed in the cell membrane by nonionic bonds, and is readily dissolved out by Triton X-100, a nonionic detergent. Estimation of the content of M protein in the cells indicated that *E. coli* ML 308 contains about 9000 reactive functional units of the M protein, if one SH group of the M protein is assumed to be protected by one bound molecule of TDG [124]. Investigations on numerous mutants have confirmed [124] that the M protein is the product of the y gene from the Lac operon, and is thus coded by the same gene as the previously purely functionally and genetically characterized "β-galactoside permease".

However, the function of the M protein within the transport system is not yet known; according to *Kepes*' permease model, it may be the "permease" or the "transporter", *i.e.* the recognizing and selecting or the transporting agent. It is certainly not involved in the energy coupling between metabolism and transport, since the "active" component of the transport was blocked by azide.

The M protein has now been purified to an electrophoretically homogeneous state, and its molecular weight has been found to be 31000 [125].

Despite the great importance of these investigations to permeability research, it must not be overlooked that the protein molecules are irreversibly inactivated by labeling with NEM. *Kolber* and *Stein* [126] were able to overcome this disadvantage by the use of a different labeling technique for the isolation of the same protein from *E. coli*. These authors also used a double labeling technique. After cultivation of induced cells in the presence of [^{14}C]-phenylalanine and of uninduced cells in the presence of [^{3}H]-phenylalanine, the two cultures were mixed, the cells were disrupted, and a membrane fraction and a souble fraction were obtained from the digest. After chromatographic separation, ^{14}C and ^{3}H contents of the eluted proteins were determined. As expected, a total of three proteins having high ^{14}C/^{3}H ratios were isolated; two of these were identified as β-galactosidase and transacetylase. The third protein fraction had no measurable enzyme activity. Corresponding experiments with mutants without permease or galactosidase showed that the third fraction may be regarded as a product of the y gene, and so contains a transport protein. Though this protein should be identical with the M protein, it was found in the soluble supernatant instead of in the membrane fraction on centrifugation. This important and unexpected discrepancy has not yet been explained.

The same double labeling technique was used by *Haskovec* and *Kotyk* [127] to isolate the carrier of the galactose transport from baker's yeast. This transport system is also inducible; it differs fundamentally from the systems discussed already in this section in that it can catalyze only facilitated diffusion. It is thus one of the simplest carrier systems of all, and should be particularly suitable for investigations of this nature.

An entirely different isolation technique is based on the observation by *Neu* and *Heppel* [128] that osmotic shock in the cold causes certain gram-negative bacteria to give up enzymes and proteins to the shock liquid, without losing their viability. These proteins appear to come from the cell surface. It therefore seemed reasonable to extend these investigations to transport proteins. It was found that, in many microorganisms, some transport systems are particularly sensitive to shock, whereas others are practically unaffected.

Kundig et al. [129] found by this method that *E. coli* W 2244 lost 50—85% of its transport capacity for certain sugars as a result of shock, and simultaneously lost 50—80% of the "heat-stable protein" HPr, which is a part of the phosphoenol pyruvate-dependent phosphotransferase system. However, the original transport capacity could be restored if the shocked cells were incubated with isolated and purified HPr.

At the same time, in *Pardee*'s laboratory, it was found that about 80% of a protein involved in the active transport of sulfate in *Salmonella typhimurium* can be brought into solution by osmotic shock [130]. Spheroplasts give up this sulfate-binding protein readily without shock treatment; this is an indication of its weak bonding and its localization on the cell surface [131]. The molecular weight of the highly purified protein is 34000; it contains no lipids, carbohydrates, or phosphorus. Unlike the M protein, it contains no thiol groups [133]. One sulfate ion is bound per molecule of protein (but no calcium [132]). Its bonding is very strong; the dissociation constant of the sulfate complex is 0.1×10^{-6}. The fixation of the sulfate depends on the ionic strength of the solution; the bonding is reversible and independent of ATP. No conversion of the bound sulfate into a derivative can be detected. The protein accordingly exhibits no enzyme activity, and is not identical with the HPr. In view of the many features shared by the protein isolated and the *in vivo* transport system, it can be concluded that it is a component of this system. The common features include binding specificities for various anions, the occurrence after derepression, and susceptibility to genetic regulation; both systems are also sensitive to shock, and both are lost by the same mutation [131]. The protein has recently been obtained in the crystalline state [132, 134].

Oxender et al. [135, 136] used the shock method to obtain and characterize a leucine-binding membrane component from *E. coli* K 12 after finding that the active transport of leucine and valine, which occurs *via* the same system, is also sensitive to shock. The active transport of proline and alanine, on the other hand, was found to be resistant to shock. The leucine-binding factor was detected in the shock liquid, classified as a protein, chromatographically purified, and crystallized. This preparation was used for further characterization.

The protein was found to be homogeneous in the ultracentrifuge, on polyacrylamide disk electrophoresis, and in *Ouchterlony*'s immune diffusion test. Its molecular weight is 24000 according to measurements in the ultracentrifuge, 36000 according to gel filtration, and 34000 according to amino acid analysis. The binding properties for amino acids and derivatives as found by equilibrium dialysis correspond to those of the *in vivo* transport system. Optimum binding occurs between pH = 4 and pH = 9; the ionic strength has practically no effect between 0.004 and 0.8 equiv/l. There is no evidence of the presence of metal ions. As was to be expected from the amino acid analysis, *N*-ethylmale-

imide (NEM) is not bound by the protein and does not affect the binding of leucine. Like the transport proteins discussed so far, this protein showed no enzyme activity. It is interesting to note that the binding of the substrate to the isolated protein is strongly inhibited by a specific antiserum, whereas the transport in intact cells is not. The protein is evidently not localized *directly* on the membrane surface, and it is therefore protected from the antibody in intact cells.

After cultivation of the cells in a medium having a high amino acid content, the protein is not detected in the shock liquid; the transport of leucine is repressed under these conditions. A direct correlation exists between the transport capacity for leucine after cultivation under various conditions and the concentration of the leucine-binding protein in the shock fluid. All these observations provide strong evidence that the isolated protein is an essential component of the leucine transport system in *E. coli*.

Almost identical evidence was reported at about the same time by *Anraku* [137–139], who isolated a leucine-binding protein as well as the galactose-binding protein from *E. coli* K 12. Unlike *Penrose et al.* [136], *Anraku* found two leucine-binding fractions after chromatography on DEAE cellulose; the smaller of these fractions has not, however, been further characterized. The chemical and physical properties of the leucine-binding proteins from the laboratories of *Oxender* and *Anraku* largely agree. The two proteins have very similar affinities for their substrates leucine and isoleucine and a high binding specificity. As was also found by *Anraku* [138], the binding of leucine is not appreciably inhibited by iodoacetic acid, NEM, or other agents such as Zn^{2+} or EDTA, though these are known to be strong inhibitors of the active transport of leucine. The leucine-binding proteins isolated thus do not appear to belong to the energy-transferring part of the active transport of leucine. According to the models, therefore, their functions must again be merely recognition and/or translocation.

The most important additional information obtained by *Anraku* is the observation that, after osmotic shock, the leucine transport can be regenerated if the purified leucine-binding protein and a second protein from the shock liquid, which has not yet been characterized, are added to the cells [139]. The same is true of the galactose transport. The "recovery" depends on the energy metabolism; it signifies a true increase in the active transport capacity. The binding capacity of the shocked cells for purified protein exhibits saturation behavior. Another shock-sensitive transport system for the active uptake of arginine was studied by *Wilson* and *Holden* [140, 141] in *E. coli*. Arginine is actively transported by a specific system and is very rapidly metabolized by several pathways inside the cell. Osmotic shock treatment upsets both the active transport of arginine and the degradation induced by the arginine decarboxylase. The proteins in the shock liquid were fractionated chromatographically; four of these could bind arginine to a considerable extent. The fractions I and III have the highest specific affinity for arginine, which is bound about 20 times as strongly as lysine. The dissociation constants of the two complexes are the same, and lie between 0.5×10^{-6} and 1×10^{-6}. Neither fraction exhibits enzymatic activity toward arginine.

As in *Aranku*'s experiments, the transport capacity of the cells can be (at least largely) restored after reduction by shock. The reconstitution is concentration dependent; fraction I appears to affect the initial absorption rate more, whereas fraction II affects the distribution in the steady state. The other arginine-binding fractions have no influence on the reconstitution of the transport. Moreover, the reconstitution by fractions I and II is specific for arginine, since neither the transport of leucine nor that of lysine is regenerated.

Though all the observations in this case again indicate that the proteins isolated are part of a transport system, their role within the system as a whole is not yet known. As in the other systems that can be regenerated, it is particularly interesting that a certain membrane function is lost by relatively mild physical treatment of the cells, but is easily restored, evidently with no need for extensive reorganization or new synthesis of the membrane.

Development of and Problems in the Chemistry of Mercury-Nitrogen Compounds

By Dietrich Breitinger and Klaus Brodersen[*]

There have been few recent additions to the group of mercury-nitrogen compounds. Current developments in this field are mainly concerned with the elucidation of the structures of these compounds. The structures of coordination-polymeric Hg–N compounds may be considered from the point of view of their relationship with silicates. The bond parameters of the Hg–N grouping are compared with the parameters of bonds between mercury and elements adjacent to nitrogen in the periodic system.

1. Introduction

The mercury-nitrogen compounds, which have been known and obtained in large numbers for a long time, have recently been systematized; their structure and bonding have been elucidated in many cases, and are now better understood than before. The recent developments started with the X-ray investigation of the structure of "fusible white precipitate" $(NH_3)_2HgCl_2$ by *MacGillavry* and *Bijvoet*[1]. Working on a broader basis, *Lipscomb*[2,3] and *Rüdorff* and *Brodersen*[4] undertook the X-ray structure analysis of related compounds.

The positions of nitrogen atoms can be found only very inaccurately in the presence of mercury, owing to the great difference in the X-ray scattering powers of the two types of atoms. Additional structural information was therefore obtained by other physical methods, such as broad line NMR[5], IR[6], and Raman spectrometry[7].

Vibration spectrometry has been used in combination with high-resolution NMR spectrometry in the study of liquid or soluble Hg–N compounds[8].

The situation regarding X-ray studies on coordination-polymeric mercury-nitrogen compounds is presented in reviews by *Lipscomb*[9] and *Grdenić*[10], while *Brodersen*[11] has correlated the results of X-ray structure analyses with IR-spectrometric findings.

On the basis of all the known facts, a great deal of Hg–N compounds can be assigned to one of two groups:

1. Those containing formally uncharged, electronegatively substituted nitrogen having a coordination number or valence of 3.

2. Those containing formally positive, electropositively substituted nitrogen having a coordination number of 4.

Within both groups it is possible to distinguish species of low molecular weight and high polymers. On the basis of this classification, the principal features of the chemistry of mercury compounds containing nitrogen having a negative oxidation number will be discussed with the aid of some typical examples.

2. Compounds Containing Nitrogen Having a Coordination Number or Valence of 3

The group of compounds in which nitrogen has a coordination number of 3 (Hg always having the characteristic coordination number of 2, cf.[10]) includes species of low molecular weight and high polymers in which the electron density on the nitrogen is reduced by two electronegative ligands, which are often identical. Considered from another point of view, the H–N analogs of the Hg–N compounds of this group are more acidic than ammonia (reduced basicity and nucleophilicity of the N atom). The nitrogen atom is accordingly in or close to the sp^2-hybridized state, as has been shown for a number of examples.

2.1. Mercury Trifluoromethylamides and Trimethylsilylamides

The simplest compound of this type is mercury bis[bis(trifluoromethyl)amide] *(1)*, which is formed by addition of mercury(II) fluoride to pentafluoro-*N*-methylenemethylamine in an autoclave at 100 °C[12], and which

$$2\ F_3C{-}N{=}CF_2 + HgF_2 \rightarrow [(F_3C)_2N]_2Hg \quad (1)$$

is also obtained on fluorination of cyanogen or cyanogen chloride with HgF_2 [13]. The physical properties (m.p. 17.5 °C, b.p. 127 °C) indicate a molecular structure, but no detailed structural investigations have been carried out as yet. It is to be expected that the N–Hg–N grouping is linear and that the bond angle at the nitrogen is increased by the interaction of the trifluoromethyl groups.

The reactive, readily hydrolyzable diamide *(I)* can be used as a reagent for the transfer of the bis(trifluoromethyl)amino group, as is shown by its reaction with halogens to form *N*-halogenobis(trifluoromethyl)-amines $(F_3C)_2NX$ and mercury halides [12,14]. The *N*-halogenoamines can be used in turn for the synthesis of asymmetric mercury(II) bis(trifluoromethyl)amides

$$(F_3C)_2NX + HgR_2 \xrightarrow{20\,^\circ C} (F_3C)_2NHgR + RX$$
$$X = Cl, Br; \quad R = CH_3, SCF_3$$

which are chemically very similar to the symmetrical parent compounds [14]. Closely related compounds that should be mentioned here are mercury bis[tris(trifluoromethyl)hydrazide] $[(F_3C)_2NN(CF_3)]_2Hg$ [15] and mercury bis(trifluoromethylpentafluorothioamide) $[F_5SN(CF_3)]_2Hg$ [16], which, like *(I)*, are obtainable by addition of HgF_2 to appropriate fluorinated azomethines, and which also have similar properties. No measurements from which structural parameters could be deduced have been carried out in any of these cases.

Whereas the decrease in the electron density on the nitrogen was due to purely inductive effects in the above examples, the mesomeric effect predominates in mercury bis[bis(trimethylsilyl)amide] [8], in which $(p \rightarrow d)\pi$ bond components operate between the nitrogen and the silicon. This compound, which can be easily prepared at room temperature in ether by the reaction

$$2\,[(H_3C)_3Si]_2NNa + HgBr_2 \rightarrow 2\,NaBr + \{[(H_3C)_3Si]_2N\}_2Hg$$

was investigated by ^{1}H-NMR and vibration spectroscopy [8]. The vibration spectra are readily explained by a molecular model of point group D_{2h} or D_{2d}, with a linear N–Hg–N grouping and trigonal-planar coordination at the nitrogen. Force constant calculations indicate Si–N–Si bond angles of between 130 and 140 °, and the force constant k(Hg–N) is found to be between 2.4 and 2.2 mdyne/Å.

2.2. Mercury Carboxamides

Unlike the *N*-substituted mercury amides discussed so far, the many *N*-mercurated carboxamides are resistant to solvolysis.

A typical member of this group of compounds is mercury bis(acetamide) [17], which has been known since the turn of the century, and which was deduced from its reactions to contain Hg–N bonds [18]. A similar conclusion was drawn from the bathochromic shift found for the amide (I) absorption in relation to free acetamide in a brief IR spectroscopic study between 2.5 and 15 μm [19]. The Raman spectrum [20] and the IR spectrum between 4000 and 400 cm^{-1} [21], on the other hand, were interpreted as indicating chelate bonding of the acetamide to the mercury *via* the nitrogen and the oxygen. The true situation in the solid state is shown by X-ray structure analysis [22], according to which planar $(H_3CCONH)_2Hg$ molecules (point group C_{2h}) with collinear Hg–N bonds (d(Hg–N) = 2.06 Å) are linked by O · · · H · · · N bonds into ribbons (Fig. 1). In the observed space group C_{2h}^5, the molecules must have the site symmetry C_i [23], which implies mutual exclusion in the IR and Raman spectra. However, substantial coincidence is found in the published IR and Raman spectra. It would appear that thorough checking of the vibration spectra is necessary.

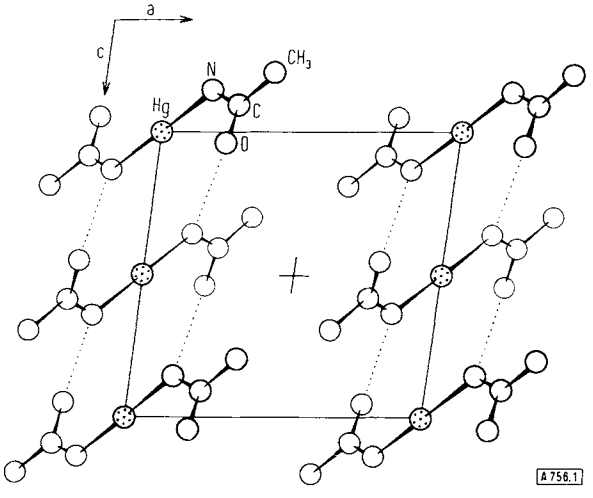

Fig. 1. Projection of the crystal structure of mercury bis(acetamide) in the *a*,*c* plane. H bonds are shown dotted [22].

The reaction of mercury bis(acetamide) with diacetohydrazide in water leads by transmercuration to insoluble mercury diacetohydrazide.

$$(H_3CCO)_2N_2H_2 + (H_3CCONH)_2Hg \rightarrow (H_3CCO)_2N_2Hg + 2\,H_3CCONH_2$$

On the basis of its properties, its IR spectrum, and the electron density distribution calculated from Debye-Scherrer diagrams, this product is assumed to have a

polymeric chain structure with the structural groups $-Hg-N(OCCH_3)-N(OCCH_3)-$[24]. The structure of the colorless mercury bis(trifluoroaceto)hydrazide $(F_3CCO)_2N_2Hg$ that precipitates on reaction of mercury(II) acetate with bis(trifluoroaceto)hydrazide in aqueous solution[25], and which is stable up to 350 °C, has not been studied, but the compound is assumed to have a similar polymeric structure.

2.3. Mercury Sulfur Imides

A few preparative studies on ternary mercury-nitrogen-sulfur compounds have been reported. Heptasulfur imide reacts in a simple manner with mercury(II) acetate in methanol at −18 °C to give the yellowish-white labile derivative $(S_7N)_2Hg$[26].

$$2\ S_7NH + Hg(OOCCH_3)_2 \rightarrow (S_7N)_2Hg + 2\ HOOCCH_3$$

Tetrasulfur tetraimide $(SNH)_4$ reacts similarly with $Hg(OOCCH_3)_2$ in pyridine to give the yellow compound $(SN)_2Hg$, which is stable up to 160 °C; on alteration of the conditions, the reaction yields yellow-green $(SN)_8Hg_5$, which is thought to contain both Hg^{II} and Hg^{I}[27].

The sulfur diimide $S(NH)_2$ expected as an intermediate on ammonolysis of trithiazyl chloride has been intercepted as the greenish-yellow adduct $(SN_2)Hg \cdot NH_3$, which loses NH_3 on thermal degradation to give yellow, stable $(SN_2)Hg$[28].

$$N_3S_3Cl_3 \xrightarrow{NH_3(l)} 3\ S(NH)_2 \xrightarrow{HgI_2} (SN_2)Hg \cdot NH_3 \xrightarrow{-NH_3} (SN_2)Hg$$

No structural investigations have been carried out so far on any of these interesting compounds.

The crystal structure of mercury bis(sulfur difluoride imide) *(2)*, which was recently prepared[29] from *N*-fluoroformylimidosulfur difluoride and HgF_2 in accordance with

$$2\ FCONSF_2 + HgF_2 \rightarrow (F_2SN)_2Hg + 2\ COF_2 \qquad (1)$$

is, on the other hand, known[30]. In the isolated molecules, both the Hg–N bond length (2.05 Å) and the N–Hg–N bond angle (178 °, *i.e.* practically linear arrangement) lie in the expected region. The relatively large Hg–N–S angle (131 °) and the short N–S distance (1.44 Å), together with the high N–S bond force constant (9.90 mdyne/Å), point to strengthening of the N–S bond, so that the nitrogen, which is directly linked to only two neighboring atoms, tends distinctly toward an overall valence of 4. In the reactions studied so far (cleavage with halogens), *(2)* exhibits great similarity to *(1)*.

Corresponding to the preparation of *(2)*, $(F_2OSN)_2Hg$ probably occurs as an intermediate and in the solid residue in the reaction of *N*-fluoroformylimidosulfur oxide difluoride $FCONSF_2O$ with HgF_2 to form *N,N'*-carbonylbis(sulfur oxide difluoride imide)[31]. Mercury bis(sulfinylamide) is obtained from trimethylsilylsulfinylamine[32].

2.4. Mercury Amidosulfates

A series of Hg–N compounds can be obtained by mercuration of NH-acid aza-analogous sulfuric acid derivatives. Thus dipyridinium bis(amidosulfato)-mercurate $(C_5H_6N)_2[(O_3SNH)_2Hg]$ has been synthesized from esters of amidosulfuric acid and mercury(II) acetate[11] in methanol/pyridine; like the closely related bis(amidobissulfato)mercurate $M_4\{[(O_3S)_2N]_2Hg\}$[33], the above product probably contains a low molecular weight anion with a group structure. Special mention should be made of bis-(diamminemercury) bis(amidobissulfato)mercurate, $[(NH_3)_2Hg]_2\{[(O_3S)_2N]_2Hg\}$, in which mercury is linked to nitrogens having coordination numbers both of 3 and of 4.

According to studies by *Capestan et al.*[34,35], thermal degradation of bis(amidobissulfato)mercurates between 150 and 250 °C in the presence of water leads to pyrohydrolysis in which, irrespective of the cation M, mercury (amidosulfato)mercurate *(3)* is formed.

$$3\ M_4\{[(O_3S)_2N]_2Hg\} + 10\ H_2O \xrightarrow{150\,^\circ C} Hg[O_3SNHg]_2 + 10\ (0.6\ M,\ 0.2\ NH_4,\ 0.2\ H)_2SO_4 \qquad (3)$$

(3) is relatively stable, and decomposes above 380 °C into $HgSO_4$, Hg, SO_2, and N_2[36].

The mercuration of amidosulfates in the presence of strong bases yields (amidosulfato)mercurates $M[O_3SNHg]$ even with other cations[36,37]; these

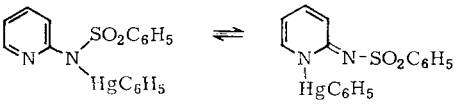
products are assumed [11,38] to have a polymer chain structure in the anion.

The IR spectrum of $Na[O_3SNHg]$ in the region above 400 cm^{-1} has been briefly discussed on the basis of this assumption [39]. Thermolysis of these salts in the presence of moisture regenerates *(3)*

$$4\ M[O_3SNHg] + 2\ H_2O \xrightarrow{300\,^\circ C} (3) + 2\ M_2SO_4 + 4/3\ NH_3 + 1/3\ N_2 + Hg$$

which is also formed from mercury(II) oxide and ammonium sulfate above 200 °C [36],

$$3\ HgO + 2\ (NH_4)_2SO_4 \rightarrow (3) + 2\ NH_3 + 5\ H_2O$$



while bis(amidobissulfato)mercurates are formed under vacuum as intermediates [40] in accordance with

$$4\ M[O_3SNHg] \rightarrow M_4\{[(O_3S)_2N]_2Hg\} + 3\ Hg + N_2$$

Whereas the mercuration of the amidosulfates gives only one product, the reaction of sulfamide with mercury compounds in aqueous media yields complex mixtures whose compositions are strongly dependent on the mercuration reagent and on the reaction conditions [41]. This can be explained by incomplete mercuration, fluctuation of the degree of polymerization, and the possibility of two different monomer units in the polymer, *i.e.* [–NH–SO_2–NH–Hg–] and [–NH–SO(NH)–O–Hg–]. A simpler situation is found in the reaction of $Hg(ClO_4)_2$ with hydroxylamidosulfuric acid to form oxonium (hydroxylamidosulfato)mercurate $[H_3O][(O_3SNO)Hg]$, for which a chain structure consisting of [–O–N(SO_3)–Hg–] units is postulated [41]; this means that mercury is no longer bonded only to nitrogen, but is linked to both nitrogen and oxygen.

Alternative or simultaneous bonding of mercury to nitrogen or/and oxygen is conceivable for the mercury salt of trimeric sulfimide [42]. If the bonding found in the analogous silver salt on the basis of a preliminary X-ray analysis [43] is also valid here, Hg–N bonding should be favored.

Mention should also be made here of the interesting case of a "mercuriotropic" rearrangement with establishment of a tautomeric equilibrium between two different *N*-mercurated compounds, which was reported by *Kravcov* [44]. The results of a spectrometric study on the phenylmercuration of 2-phenylsulfonylaminopyridine in solution are interpreted by this author on the assumption of an equilibrium between an aminopyridine form and a dihydropyridinimine form:

the dihydropyridinimine form being favored by increasing polarity of the solvent. The rearrangement is thought to proceed *via* a four-membered ring chelate.

To close this section, we point out that there have been no published reports of attempts to prepare mercurated derivatives of oxoacid amides of other elements, such as nitroamine (*N*-methylnitroamine is reported to be mercurated on the oxygen [17]), phosphorus(V) acid amides, or chlorine(VII) acid amides.

3. Compounds Containing Nitrogen with a Coordination Number of 4 (Mercurioammonium Complexes)

The compounds discussed so far, apart from $(F_2SN)_2Hg$, $(F_2OSN)_2Hg$, and $(OSN)_2Hg$, contain N atoms having a total coordination number of 3 and Hg atoms having a coordination number of 2, and may therefore be regarded as dinuclear or polymeric complexes of formally uncharged nitrogen in which the coordination centers are linked by bidentate Hg ligand atoms. This metallocomplex character [45] becomes more distinct in the following section. All the coordination sites on formally monopositive nitrogen having a coordination number of 4 can be successively occupied by mercury, so that mercurioammonium complexes of various degrees of substitution are formed. The second bond of the mercury ligand may form a bridge to another ammonium nitrogen, and dinuclear and polynuclear complexes can be formed in this way. The formation of coordination polymers of this nature is prevented if one valence of the Hg^{II} is blocked by an inert, coordinately monodentate ligand; this leads to mononuclear, two-shell mercurioammonium complexes.

3.1. Mononuclear Complexes

The second valence of the Hg^{II} is most easily blocked with organic groups yielding organomercurioammonium complexes. Reports of such complexes have

[38] *Ar. Weiss* and *E. Michel*, Z. Naturforsch. *15b*, 679 (1960).

[39] *J. Frei* and *E. Steger*, Z. anorg. allg. Chem. *342*, 195 (1966).

[45] *G. Bergerhoff*, Angew. Chem. *76*, 697 (1964); Angew. Chem. internat. Edit. *3*, 686 (1964).

so far been sporadic[46–48]. In studies on the coordination chemistry of the methylmercury cation, the equilibrium constant for the reaction

$$H_3CHg^+ + NH_3 \rightleftarrows H_3CHgNH_3^+$$
(or more accurately: $H_3CHgOH_2^+ + NH_3 \rightleftarrows H_3CHgNH_3^+ + H_2O$)

was measured in aqueous solution[49].

To be able to collect structural data (X-ray data for single crystals and vibration-spectroscopic data also for solutions) with the aid of mononuclear model substances for the coordination-polymeric Hg–N compounds of the type ${}^{n-1}_{\infty}[NH_{4-n}Hg_{n/2}]^+X^-$, methylmercurioammonium complexes $[NH_{4-n}(HgCH_3)_n]^+$[50] and $[NH_{4-(m+n)}(CH_3)_m(HgCH_3)_n]^+$[51,52] have recently been systematically prepared in accordance with

$$[NH_{4-(m+n-1)}(CH_3)_m(HgCH_3)_{n-1}]^+ + H_3CHgOH \rightarrow [NH_{4-(m+n)}(CH_3)_m(HgCH_3)_n]^+ + H_2O$$

and studied.

A preliminary normal coordinate analysis was carried out for the series $[NH_{4-n}(HgCH_3)_n]^+ClO_4$ and $[ND_{4-n}(HgCH_3)_n]^+ClO_4$ (n = 1–4), ignoring the atoms that are not directly bonded to the nitrogen, and the result was compared with the IR and in part with the Raman spectra[53]. A calculation in accordance with the general valence force field model with constant parameters for the Hg–N bond [d(Hg–N) 2.07 Å, k(Hg–N) 3.00 mdyne/Å] gives vibration frequencies that show increasingly positive deviations from the observed frequencies with increasing values of n, both for the symmetrical (nondegenerate) and for the antisymmetrical (degenerate) vibrational modes. This trend of the frequencies can be interpreted as follows, taking into account the results of ^{1}H-NMR measurements on the series of compounds $[NH_{4-n}(HgCH_3)_n]^+ClO_4$[51]: As the degree of substitution n increases, the charge on the cation is increasingly spread over the coordinated highly polarizable Hg atoms. Thus the relative positive charge on a single Hg atom decreases, *i.e.* the electron density increases, with increasing n. This leads to increasing mutual repulsion of the Hg atoms. Since no appreciable deformation of the tetrahedral bond angles at the nitrogen is to be expected, this repulsion should lead to lengthening of the Hg–N bonds. This means a decrease in the Hg–N force constant and hence in the Hg–N vibration frequencies. X-ray structure analyses are being carried out to check this view[54].

3.2. Polynuclear Complexes

Complexes of the type $[(NH_3)_2Hg]^{2+}$ are usually regarded as having mercury as the central atom and ammonia as the ligands (diamminemercury complex). There are, however, arguments in favor of treating them as dinuclear, Hg-bridged ammonium complexes, and hence as metallocomplexes (μ-mercuriodiammonium complex). The second approach will be favored in the present context on systematic grounds.

3.2.1. Situation in Solution

The formation of ammine complexes of transition metals, and particularly of mercury, was studied by *Bjerrum*[55]. High and roughly equal complex formation constants are found for the first two steps of the addition of NH_3 to Hg^{2+} ($\log \beta_1$ = 8.8; $\log \beta_2$ = 8.7); the constants for the third and fourth steps, which are again very similar to each other, are about eight orders of magnitude smaller than β_1 and β_2. At medium NH_3 concentrations and pH values, therefore, practically the only complexes present in aqueous solution are $[(NH_3)Hg]^{2+}$ and $[(NH_3)_2Hg]^{2+}$; it is only at very high NH_3 concentrations and pH values that triammine and tetrammine complexes become important. *Bjerrum*'s results were confirmed and extended in studies by *Wirth* and *Davidson*, who also found a linear relation between the first formation constants for ammine-mercury complexes and the dissociation constants of the protonated amines[56,57].

3.2.2. Situation in Solids of the Type ${}^{n-1}_{\infty}[NH_{4-n}Hg_{n/2}]^+X^-$

The most thorough structural investigations using the greatest variety of methods have been carried out on dinuclear (n = 1) and coordination-polymeric (n = 2, 3, 4) mercurioammonium complexes ${}^{n-1}_{\infty}[NH_{4-n}Hg_{n/2}]^+X^-$ as solids. The structure of these complexes are well understood, though a few details still remain to be clarified. Diammine complexes with ammonia or simple alkylamines[58,59] are usually formed as the only products on reaction of a binary or quasibinary mercury salt with the pure amine, possibly in organic solvents of low polarity. Compounds of this

type can be obtained from aqueous solution under the simultaneous action of the amine and the corresponding ammonium salt in certain concentrations [11, 58–60]. The influence of the ammonium salt concentration can be seen on dilution of an ammonium chloride solution that has been adjusted to the equilibrium concentration over solid $(NH_3)_2HgCl_2$ [61]:

$$(NH_3)_2HgCl_2 \rightarrow NH_2HgCl + NH_4Cl$$

The thermolysis of the diammine complex occasionally leads uniquely to the monoammine stage [58, 59], but this can also be reached by other routes, as is shown by the example of $(NH_3)HgSO_4$ [62]:

$$HgO + NH_4HSO_4 \rightarrow (NH_3)HgSO_4 + H_2O$$

Whereas the crystal structures of the monoammine complexes are not yet known, those of the diamminemercury halides $(NH_3)_2HgX_2$ (X = Cl, Br) appear to have been established [1, 9, 67]. Linear $^+H_3N-Hg-NH_3^+$ groups are arranged along the axes of a primitive cubic halide lattice with statistical orientation such that four halide ions are identically coordinated in a plane normal to the N–Hg–N line. The mercury thus has an effective coordination number of 6 (Fig. 2). The same structure is assigned to $(NH_3)_2HgI_2$ [60].

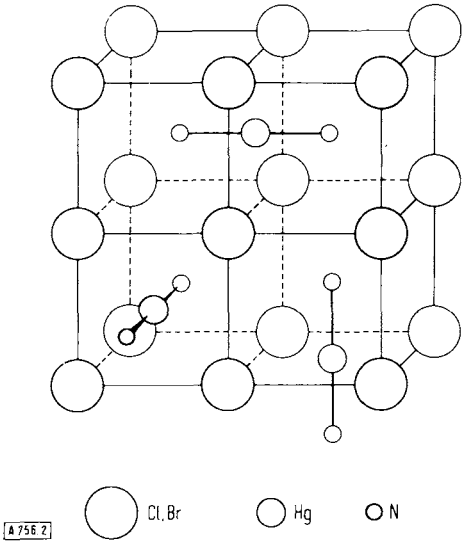

Fig. 2. Section of the structure of $[(NH_3)_2Hg]X_2$ with randomly oriented $^+H_3N-Hg-NH_3^+$ groups [1, 9, 67].

Numerous spectroscopic studies have been carried out on the diamminemercury halides on the basis of the knowledge of their structures. An early and important finding from the broad-line proton resonance is the free rotation of the coordinated NH_3 ligands about the Hg–N bond [5].

Partly on the basis of false structural assumptions [63] and partly without [6, 64] or with consideration of the rotation of the NH_3 ligands [65, 66], IR spectra alone as well as IR and Raman spectra [7] have been interpreted and the assignments confirmed in many cases by normal coordinate analyses. However, site symmetry effects were not considered in any of these cases. Comparison of the Urey-Bradley force constants for the metal-nitrogen bond in various amminemetal complexes shows [66] that the Hg–N bond has the highest force constant, $k(Hg-N) = 2.05$ mdyne/Å, and the strongest covalence, and so heads the series

$$Hg^{II} > Co^{III} > Cr^{III} > Cu^{II} > Ni^{II} > Co^{II}$$

Thus the vibration-spectroscopic behavior of the diamminemercury halides is largely elucidated; there is still some uncertainty due to the fact that the asymmetric stretching vibration of the N–Hg–N group is very weak, and is often completely absent.

On the basis of IR studies, dihydrazinemercury dichloride is assumed to contain cationic complexes $[(N_2H_4)_2Hg]^{2+}$ analogous to the diammine complexes $[(NH_3)_2Hg]^{2+}$, while coordination-polymeric chains $(-\overset{+}{N}H_2-\overset{+}{N}H_2-Hg-)$ or $^1_\infty[(N_2H_4)Hg_{2/2}]^{2+}$ are assumed for monohydrazinemercury halides $(N_2H_4)HgX_2$ (X = Cl, Br) [68].

The "infusible precipitates" formed directly or from the diamminemercury dihalides at lower ammonium salt concentrations and higher pH values have been thoroughly investigated in the form of the chlorides and bromides, and identified as coordination-polymeric mercurioammonium halides $^1_\infty[NH_2Hg_{2/2}]^+X^-$.

The crystal structure of the cubic NH_2HgBr is very similar to that of $(NH_3)_2HgBr_2$, which is also cubic; this similarity is also shown by the formation of solid solutions of these two compounds [4,67].

Chains that bend at the nitrogens

thread their way through the primitive cubic bromide lattice with no preferred orientation; mercury has effectively octahedral coordination in this lattice (Fig. 3). The incorporation of small quantities of $HgBr_2$ into NH_2HgBr leads to stabilization of a rhombic mixed phase in which the chains are oriented parallel to the crystallographic c axis [69,70]. Pure NH_2HgCl forms a similar oriented rhombic structure [3] (Fig. 4).

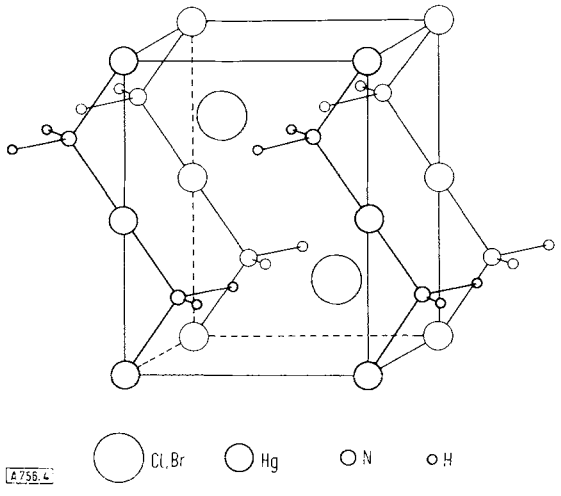

Fig. 4. Structure of rhombic $[NH_2Hg]X$ [69,70].

On the basis of the IR spectra a bond angle of 90° at the ammonium nitrogen was assumed for the cubic NH_2HgBr [6]. Normal coordinate analyses for the polymer chains in NH_2HgCl [71] and in NH_2HgBr [72] show that the observed and calculated frequencies agree well, largely irrespective of any deviation from the tetrahedral bond angle. However, the value deduced from the ^{1}H-NMR spectrum of NH_2HgCl for the distance between the protons in the NH_2 group points to the tetrahedral angle [5]. The question of the bond angle in the cubic NH_2HgBr thus cannot yet be definitely answered.

Mention should be made of the existence of a mercuriomethylammonium bromide $NHCH_3HgBr$ isotypic with the cubic NH_2HgBr [73]; with the aid of *N*- and *C*-deuterated derivatives, it has been possible to achieve a substantially definite assignment of the IR spectrum in the region 4000–200 cm^{-1} [74].

A remarkable structural relationship between NH_2HgCl and "mercury hydrazinochloride" (dimercuriohydrazinium dichloride) $[(N_2H_2)Hg_2]Cl_2$, which is also rhombic, has been demonstrated by X-ray and IR studies [68,75]. The compounds have unit cells with very similar dimensions, in which the mercury atoms occupy the same positions. In NH_2HgCl, the chains are held together in the b direction mainly by hydrogen bonds $H\cdots Cl\cdots H$, whereas $[(N_2H_2)Hg_2]Cl_2$ has covalent N–N bonds in the same lattice direction; this leads to the formation of puckered $^2_\infty[(N_2H_2)Hg_{4/2}]^{2+}$ layers parallel to the b,c plane.

This provides a connection with the layer structure of the hexagonal "mercury imidobromide" (trimercuriodiammonium tribromomercurate bromide) $NHHg_2Br_2$, which is better formulated as $^2_\infty[(NH)_2Hg_3]^{2+}Br^- \cdot HgBr_3$ on the basis of X-ray structure analysis [76,77] and as $^2_\infty[(NH)Hg_{3/2}]^+ \cdot 0.5\ Br^- \cdot 0.5\ HgBr_3^-$ when the coordination in the cation is taken into account. An interesting feature here is the presence of two structurally different types of Hg atoms. Mercury in the cationic layer forms a very distorted, effectively octahedral coordination polyhedron; linear polymer chains $^2_\infty[HgBr_3Br_{2/2}]^{2-}$ with effectively trigonal-bipyramidal coordination of the mercury pass through the lattice normal to the layers and along the c axis (Fig. 5).

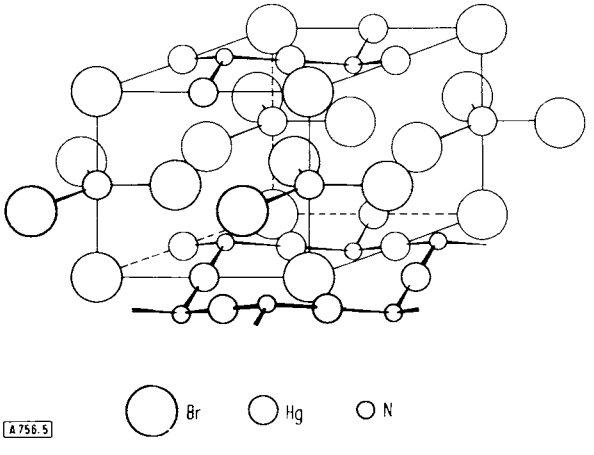

Fig. 5. Unit cell of "mercury imidobromide" $NHHg_2Br_2$ with completed mesh of the $^2_\infty[(NH)Hg_{3/2}]^+$ network [76,77].

Compounds having analogous compositions, such as $NHHg_2Cl_2$ and $(NR)Hg_2X_2$ were synthesized by *Meuwsen* and *Weiss* [78]; their structures have not yet been established. They are insoluble in water and in organic solvents; as solid phases in the presence of the solvents, they give up HgX_2 reversibly into the solvent, the composition $[(NR)_2Hg_3]X_2$ being reached in the

limiting case. $[(NR)_2Hg_3]X_2$ can be obtained directly by reaction of amines and mercury halides in alkaline media at high temperatures [58]. Studies of the structure of these polymeric substances seem desirable. A start has been made by the definite assignment of the IR spectra of $[(NCH_3)_2Hg_3]Br_2$ and its deuterium analogs [74].
