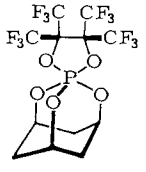
[*] *Note added in proof:* The mechanistic alternatives for the positional exchange of pentacoordinate molecules belong to different classes of the permutation group S_5. Pseudorotation of D_{3h} trigonal bipyramidal molecules correspond to the alternating permutations (a e a' e') of the apical a and a' and equatorial e, e'' and e''' ligand indices whereas turnstile processes by permutations (a e) (e'' e' a') from the class of (2 + 3) cycles. As a consequence of the skeletal symmetry of VII the permutations (a e) (e'' e' a'), (a' e) (e'' e' a), (a' e') (e'' e a) and (a e a' e') are equivalent. For instance, the pseudorotation isomerizer (2435) as well as the four different but equivalent turnstile isomerizers (24) (135), (25) (134), (34) (125) and (35) (124) all transform *(28b)* (≡**E**) into the same isomer. During the equivalent turnstile process, the pivot L_1 of the pseudorotation mechanism replaces one of the equatorial ligands (L_2 or L_3). It must be noted that during a turnstile process, the pair has an approximate local C_2 skeletal symmetry and undergoes a corresponding rotation about the local C_2 axis while the trio has an approximate local C_3 skeletal symmetry and simultaneously undergoes a rotation about the local C_3 axis with opposite angular momentum.

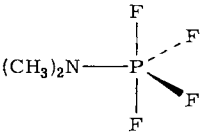


The BPR (Berry pseudorotation or (1+4)-pseudorotation) and TR ((2+3)-turnstile rotation) differ fundamentally by the pathways by which they occur and by the intermediate species involved. The BPR, as it is defined, is the combination of two synchronized bending motions of a pair of equatorial and a pair of apical bonds respectively, and does not involve any internal rotation. The TR process, by contrast, involves internal rotation.

In cyclic pentacoordinate compounds, enforcing BPR upon a molecule invariably involves internal rotation of the cyclic moiety *vs.* the remaining ligands and thus becomes a TR unless the BPR involves the interconversion of a diequatorial ring and an apical-equatorial or a diapical ring respectively which is quite unlikely and only reasonably conceivable for sufficiently large rings.

rotation of the ligands 1, 2, and 4 *vs.* 3 and 5. We propose that the regular pentacoordinate isomerizations occur by a (2+3)-internal rotation through a (2+3)-intermediate or an interconvertible set of (2+3)-intermediates rather than by the generally accepted (1+4)-pseudorotation mechanism. Both processes can, in the idealized case, occur with conservation of angular momentum. While there is experimental evidence which contradicts the (1+4)-pseudorotation mechanism, all data are in accordance with the (2+3)-turnstile concept.

Intermediate species of the type *(29b)* or *(29d)* in the (2+3)-internal rotation concept can only be characterized in terms of the permutational symmetry of the skeletal coordinates and not by a particular geometry. Species *(29b)* for instance, is characterized only by the fact that it can be represented by five skeletal coordinates of which a pair (3′ and 5′) and a triple (1′, 2′, and 4′) are equivalent and permutable. If all of the possible (2+3)- intermediates of a given set of 20 pentacoordinate topological isomers are interconvertible, this is represented by complete equivalence of the five skeletal coordinates which are interconverted by 5! permutations. Such a state cannot be described by geometry or the conventional concept of symmetry because it is not possible to place five points mutually equidistant on the surface of a sphere. Since it can be assumed that the (2+3)-intermediates are short-lived species, a geometrical description loses its meaning in any case, due to the uncertainty principle.



Example 25

(30)

The ^{1}H- and ^{19}F-NMR data of *(30)* [29b] indicate rapid positional exchange (permutational isomerization) of the ligands of the pentacoordinate phosphorus. This can only be interpreted by a (2+3)-turnstile process; the (1+4)-pseudorotation is not possible as a consequence of the structure and the strain it imposes. Even if one forces *(30)* into the pseudorotation pathway by overcoming the structural limitations, the result would involve relative internal rotation of the adamantanoid moiety *vs.* the five membered ring, a superposition of the turnstile upon pseudorotation.

Whitesides and *Mitchell* [28q] analyzed the temperature dependence of the ^{31}P-NMR spectrum of *(31)*, and were able to show that at low temperatures ($T \leq -100\,°C$) structure *(31)* is frozen, *i.e.*, the dimethylamino group and two of the fluorines occupy equatorial positions, and two of the P–F bonds are apical, without any exchange of the equatorial and apical fluorines. Above $-50\,°C$ all four fluorines become completely equivalent, but there is an intermediate temperature range in which the equatorial pair of fluorines replaces the apical pair of fluorines and *vice versa* in a single concerted step. This result was invoked by the authors as proof that none of the published ("non-Berry") alternatives to the (1+4)-pseudorotation mechanism of pentatopal rearrangements could be responsible for the F-exchange of *(31)*. However, the (2+3)-process corresponds exactly, like the (1+4)-pseudorotation process, to all the assumptions that entered *Whitesides'* and *Mitchell's* evaluation of their experimental data.

(31)

If such a (2+3)-internal rotation is terminated with the dimethylamino group in the equatorial position, the result is an exchange of the equatorial and apical pairs of fluorine atoms.

3.2. Chemical Reactions and Transition States

3.2.1. General Considerations

The mechanisms of chemical reactions can be described on various levels and in a variety of terms [30]. In any detailed discussion of the mechanisms of a chemical reaction the transition complex, which is often called the transition state, plays a central role [31]. The transition state corresponds to a complex which contains all participants in a reaction such that the reactants have already lost some of their characteristics, and in which the characteristics of the products are not yet fully developed. The transition complex is a short-lived state, or better, a statistical ensemble of short-lived states, which corresponds to the peak of an energy barrier between starting materials and products. These transition complexes, as statistical entities, cannot be characterized in geometrical terms (as has been attempted, often with admirable imagination), since they do not represent a uniform long-lived species, but a collection of different, short-lived states.

Even if we could observe one single, isolated transition complex of an "ultimate kinetic unit" [31b], a geometrical description would not be possible. As a consequence of the *uncertainty principle*, the geometrical features (distance) of short-lived species are not subject to an accurate observation [32].

The reader of current chemical literature could be led to believe that there exists a wealth of detailed knowledge on transition complexes. However, a critical analysis of the statements often reveals assertions which go far beyond the evidence or, in some cases, even contain violations of basic principles.

There seems to be a tradition, among mechanistically oriented chemists, to describe reaction mechanisms ac-

cording to accepted terminologies and formalisms, without ascertaining the pertinence of the proceedings. The occurrence of a chemical reaction is frequently expounded in detailed geometrical terms. Conclusions are drawn about the transition complex from the so-called "reaction coordinate diagram", in which the only thing less certain than the ordinate is the abscissa.

To interpret and predict the steric course of stereoselective reactions, often one arbitrarily chosen conformation of the transition complex is discussed. The geometrical distribution of nuclei and electrons of this choice, of which at best, only its relative free energy, origin, and destination are known, is quite often the basis of interpretation and prediction of the steric course of stereoselective reactions.

3.2.2. Relations between Reacting Entities

These current extrapolations of the transition state theory [31] result from the fact, that there are many things which can and should be said about transition states, but no formalized framework of thought has been available to support these statements. The quantum mechanical description of reacting systems must be interpreted with caution as the assumptions one requires are not made on the basis of a complete understanding of the phenomenon [**]. Further, with the proper choice of assumptions, one can produce the result one intuitively feels is the most adequate.

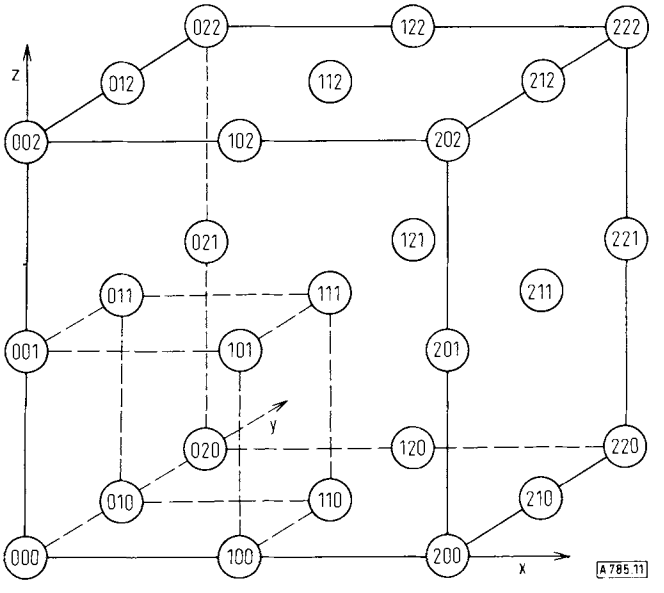
A description of chemical reactions and their states employing mathematical structures, offers less to visualize but substantially avoids unjustifiable statements. It is beyond the scope of this article to discuss, in a detailed manner, the major objectives of mechanistic chemistry. We wish to generate a partially symmetrized topological coordinate system in order to discuss some examples of reactions whose mechanisms have previously been critically analyzed on the basis of sound experimental evidence.

A topological description yields some information on reaction mechanisms because the coordinates of the relevant particles, including the phase of the wave functions of the reacting species can be chosen in such a manner that there is conservation of coordinates during the reaction.

It is possible to choose the coordinates of certain parts of the reacting species in such a manner that the reactions can be described by permutation operators in analogy to the "isomerizer" description of isomerizations. Relative to the description of isomerization mechanisms, by virtue of the partitioning of the permutation groups S_n into their distinct classes [29a] of conjugate elements, it will also be possible to classify the mechanisms of the reaction between two (and more) reactants.
On this basis, it will be possible to establish rules concerning mechanistic alternatives in certain types of reactions.

The following brief discussion of certain symmetrical sets of lattice points will also be useful for the latter discussion of the topology of chemical reactions.

The lattice points |000|, |022|, |202|, and |220| are the vertices of a regular tetrahedron (T_d), as are the points |002|, |200|, |020|, and |222|. These eight points are also the vertices of a cube (O_h) or two interlocking tetrahedra, the di-dodecahedron (T_h). The six points |011|, |101|, |110|, |112|, |121|, and |211| lie in the centers of the faces of that cube and at the vertices of an octahedron (O_h). There are also sets of points which correspond to the vertices of a trigonal bipyramid (D_{3h}), *e.g.* |000|, |222| (the apical points), |021|, |102|, and |210|; if the points |012|, |120|, and |201| are added to the latter set, we have a hexagonal bipyramid (D_{6h}).



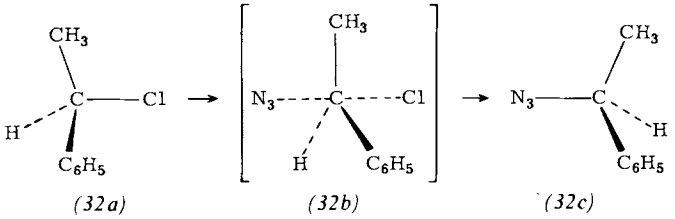


Fig. 11. Sets of points in a cubic lattice.

Finite sets of points belonging to the cubic point lattice and lattices which are contained within the cubic lattice are useful for the construction of coordinate systems with suitable permutational transformation properties and neighborhood relations to be applied to chemical reactions. A topology whose open sets contain the above mentioned finite sets of points as internal points can be chosen as a topological coordinate system for chemical reactions such that the coordinates of all relevant parts of the molecule are preserved throughout the reaction, from the starting material through the transition state to the final products.

Example 26

(32a) *(32b)* *(32c)*

The classical configurational correlation [33] of (+)-α-phenylethyl chloride *(32a)* and (−)-α-phenylethyl azide *(32c)* is chosen to illustrate the topological approach to a chemical reaction and its transition state.

[**] Cf., *e.g.*, Chem. Eng. News *48*, No. 22, 12 (1970).

[33] *E. D. Hughes, C. K. Ingold,* and *C. S. Patel,* J. Chem. Soc. *1933*, 526; see also: *E. D. Hughes* and *C. K. Ingold, ibid. 1933*, 1571; *1935*, 244; *J. L. Gleave, E. D. Hughes,* and *C. K. Ingold, ibid. 1935*, 255.

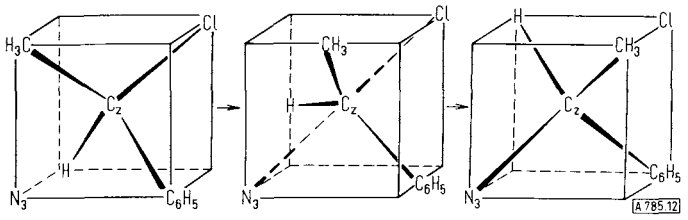

Fig. 12. Reaction *(32a)* → *(32b)* → *(32c)* in a topology oriented coordinate system.

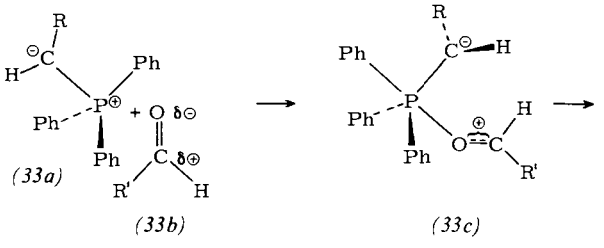
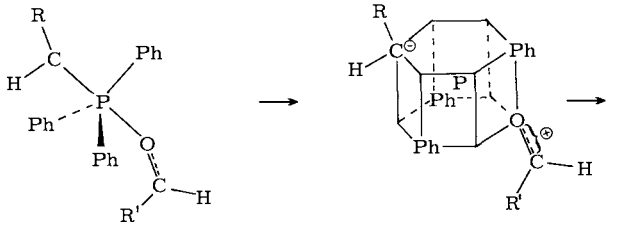
The process whereby *(32a)* → *(32b)* → *(32c)* can be described in terms of a topology oriented skeletal coordinate system that applies to all participating species is pictured using the cubic lattice point set as follows:

$C_6H_5 \in \tau_1$, $CH_3 \in \tau_2$, $H \in \tau_3$, $Cl \in \tau_4$, $N_3 \in \tau_5$
$[000] \in \tau_5$, $\{[002], [102], [202]\} \in \tau_2$
$\{[020], [021], [022]\} \in \tau_3$
$\{[200], [210], [220]\} \in \tau_1$, $[222] \in \tau_4$



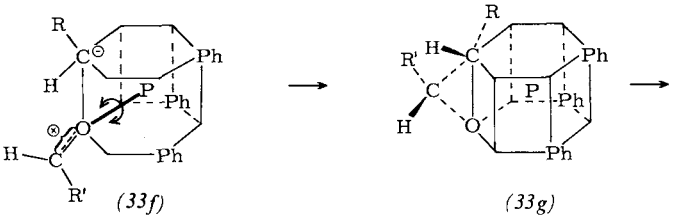
The central atom C_Z is represented by a distinguished point at the cross-section of the coordinates $\tau_1 - \tau_5$. Conservation of these coordinates throughout the process *(32a)* → *(32b)* → *(32c)* is characteristic of the S_n2 mechanism and is equivalent to a correlation of the configuration of *(32a)* and *(32c)*.

Example 27

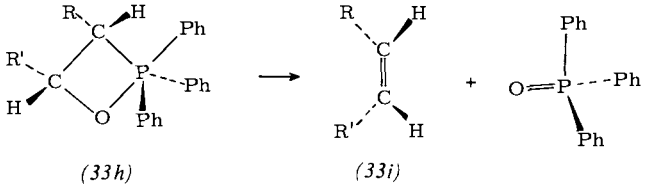


A trigonal bipyramidal adduct of the ylide *(33a)* and aldehyde *(33b)* has been suggested as an intermediate in the Wittig olefin synthesis [28f, 34]. This concept was recently invoked in an attempt to explain the preferential formation of *cis* isomers *(33i)* by *Wittig*'s kinetically controlled synthesis of 1,2-disubstituted olefins [34b].

Here it was assumed that the nucleophilic oxygen of an aldehyde *(33b)* attacks the electrophilic phosphorus of the ylide *(33a)* such that a trigonal bipyramidal adduct *(33c)* with an apical P–O bond and an equatorial P-carbanion bond was formed directly. It was further assumed that the *erythro*-intermediate *(33d)* was formed from *(33c)* by "a small anticlockwise rotation about the C–O bond" [28f]. A corresponding clockwise rotation would yield the *threo*-isomer of *(33c)* and thus the *trans*-olefin. Employment of the (2+3)-turnstile process (see Section 3.1.3.2) provides an alternate interpretation for the formation of these *cis*-olefins *(33i)* by the Wittig reaction in salt free, non-polar solvents at low temperatures [35].



If the hypothesis of the "open-pyramid mechanism" is invoked at all, it is reasonable to assume that the nucleophilic oxygen of the aldehyde *(33b)* attacks the electrophilic phosphorus of the ylide *(33a)* on the side opposite the P-carbanion bond to give the trigonal bipyramidal intermediate *(33d)*.



(33a) *(33b)* *(33c)*

(33d) *(33e)*

(33f) *(33g)*

(33h) *(33i)*

This is analogous to formation of an S_N2 transition state. The primary adduct *(33d)* is transformed by the (2+3)-turnstile mechanism into the intermediate species *(33f)* *via* *(33e)*. It is reasonable to assume that the conformations of *(33e)* and *(33f)* occur such that the (2+3)-turnstile process suffers minimal steric hindrance from the bulky groups R and R'. The stereochemical transformation of *(33f)* into *(33g)* arises from the fact that the carbonium ion moiety of *(33f)* can approach its carbanion moiety only through a rotation about the P–O bond. This is explained by observing that while resonance stability of the carbonium ion moiety of *(33f)* exists, groups H, C, R', O, and P must occupy a coplanar set of positions. A clockwise rotation about the P–O bond of *(33f)* leads to *(33g)*, the counterclockwise rotation generates the antipode of *(33g)*. Both *(33g)* and its antipode are intermediates of the *cis*-olefin formation. As long as there is no rotation about the C–O bond of the carbonium ion moiety, there can be no formation of the *trans*-olefin *via* the *threo*-isomer of *(33g)* or *(33h)* respectively.

The isocyanide-nitrile rearrangements [36] (and the S_Ni reactions) probably also occur through an intermediate state which resembles topologically the intermediate states of the (2+3)-turnstile rearrangement. It is even conceivable that some [37] of the reactions which have heretofore been considered to occur by an S_N2 mechanism do involve a (2+3)-turnstile type process. The topological consideration of this section may also be useful for the discussion of the pentacoordinate carbon systems [38].

We will refer to *Dewar*'s PMO formulation of the more than 30 year old Evans' rule as the Dewar-Evans' rule [39,40] of electrocyclic and related reactions:

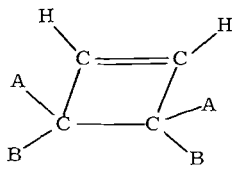
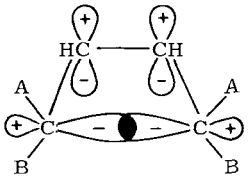
"Thermal electrocyclic reactions take place *via* aromatic transition states. Photochemical electrocyclic reactions take place through excited forms of aromatic transition states" [40c].



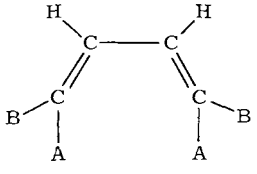
The thermal electrocyclic reactions can be considered as that class of reactions whose transition states are topologically equivalent to the aromatic hydrocarbons. Although *Dewar* did not use a topological formalism as the basis of his treatment of electrocyclic reactions, he was fully aware of the topological nature of the problem. He describes the transition states of the Diels-Alder reactions as "delocalized systems – topologically equivalent to, or isoconjugate with the π system in benzene" [40a]. The Dewar-Evans' Rule can be applied to an individual case by selecting such a topological coordinate system for the transition state that this system also applies to the isoconjugate hydrocarbon. By conserving the topology and suitably choosing coordinates throughout a chemical reaction one can correlate the features of interest (*e.g.* the stereochemistry) in the starting materials and products of the electrocyclic process.

Both in their essential content and consequences, the Dewar-Evans' rules are roughly an equivalent to the frontier-orbital [41] or correlation diagram [42] based Woodward-Hoffmann rules of orbital symmetry conservation [43].

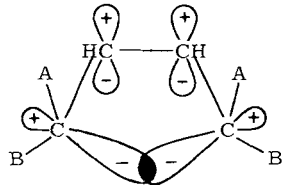


Yet, in some aspects, these rules differ. There are cases in which the application of the essentially topological Dewar-Evans' rules seem to be more simple and allow one to analyze a chemical situation more clearly, as in the case of the Cope rearrangement [40b] and the Diels-Alder synthesis [40,43]. Recently, *Mulder* and *Oosterhoff* [44] announced rules concerning the conservation of permutational symmetry which seem to be particularly clear, general, and theoretically well founded in their application to electrocyclic reactions and related processes.

The Woodward-Hoffmann rules [43] are primarily oriented towards geometrical symmetry. They can also be stated in the form of topological skeletal coordinate conservation.

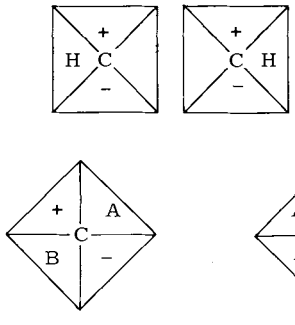


Example 28

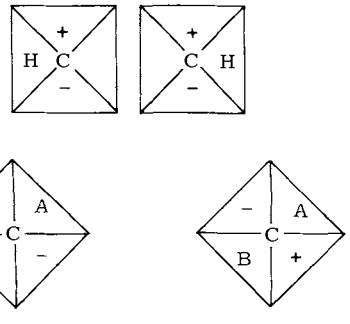


(34a)

(34b)



(34d)



(34c)

The prediction of the stereochemistry of the process *(34a)* to *(34d)* by the Woodward-Hoffmann frontier orbital treatment is symbolized by the disrotatory opening *(34c)* → *(34d)*.

The topological equivalent of the process *(34a)* → *(34d)* results from the conservation of the topological coordinates during the entire reaction.

(34e)

(34f)

As can be seen immediately, the set of coordinates of *(34e)* apply to the transition state *(34c)* of the disrotatory process as well as the initial and final states *(34a)* and *(34d)*. This treatment could also be represented algebraically by mapping the set of indices to those parts of the involved species of interest onto the set of their coordinates but in this case the simple graph suffices.

There is no set of coordinates conserved during the contrarotatory analog of the process *(34a)* → *(34d)* if one forbids the overlap of orbitals which are not in phase. For example, if one takes the coordinates of *(34f)* of a conrotatory transition state, the in-phase overlap of the C–C σ bond of *(34a)* that is being opened has as a consequence an out-of-phase π overlap of *(34d)* and *vice versa*.

4. Conclusion

The authors' intention was clearly not to expound and exemplify all the aspects and applications of modern mathematics to chemistry. Neither is this an effort to present a complete and perfect discussion of the utility of mathematical structures to chemistry. In many areas, our treatment is open to profound improvement. Often, only the surface is scratched, hopefully deeply enough to stimulate interest and to point in a promising direction for further develop-

ment. It should be noted that this paper is a compromise between imperative mathematical rigor and the desire to present a document that will be readable and comprehensible.

The apparent overemphasis of classification problems and nomenclature resulted from the obvious application of elementary topological and group theoretical concepts to these problems, and the desire to illustrate the direct applications of basic mathematical structures. Further, the definition of a nomenclature is only useful if it is complete with regard to its whole scope and its limitations, which, for our case, is all of chemistry. Macromolecules could have been included by some additional definitions, but the authors feel that this would over-extend the introduction of the present concept.

Many different systems of chemical nomenclature have been peopoaed, some specifically designed for convenient handling of rather limited sets of very similar compounds, such as the cholestane derivatives, whereas others are defined to serve as a universal nomenclature. Some of these proposed nomenclatures have found general acceptance, while others were never mentioned again, quite often undeservedly.

The present permutational nomenclature differs considerably in some essential features from any previous attempt to create a universal chemical nomenclature which does not break down in "pathological cases", *i.e.* for molecules with complicated skeletons and involved stereochemistry. In contrast to other systems, the permutation nomenclature deals with the molecule as an entity, and dissects it only in exceptional cases, which are described separately, as is done with the (*R*),(*S*)-nomenclature of molecules with more than one element of chirality. In contrast to the systems of nomenclature in current use, the descriptor does not tell "what a molecule looks like", but it is an instruction on how to draw or let a computer draw the steric formula of the molecule, or (which is often more easily done) how to construct a steric model of the molecule, *e.g.* a Dreiding model. The descriptors of molecules are based upon the representation of the molecule by an algebraic formalism, which in fact, is a general principle of order in chemistry and provides a framework of thought which helps to understand the steric aspects of chemistry.

There are many cases in which the conventional nomenclatures are fully adequate and more convenient to use than this descriptor system. For open chain chiral compounds (of *class* ***a***) with only a few elements of chirality (*e.g.* "asymmetric carbons") the (*R*),(*S*)-nomenclature works well and is easier to use than the descriptors. On the other hand, the (*R*),(*S*)-nomenclature is very cumbersome to use or fails completely with compounds like *(3)*, for which, to our knowledge, there is no other adequate system of nomenclature than the present. The metal complexes with a coordination number higher than four are compounds for which the permutational nomenclature seems to be the only acceptable solution to the nomenclature problem [45].

For molecules with a polycyclic skeleton and complicated stereochemistry the permutational nomenclature is superior and often the only satisfactory description of the molecule, with the exception of some classes of very similar compounds which have their own specific reference system and nomenclature, like the steroids.

[45] Cf. *K. A. Jensen*, Inorg. Chem. *9*, 1 (1970).

Some of the computer-oriented nomenclature systems [46] which have been developed recently are called topological nomenclature systems. These systems do not use the concept of topological spaces for the representation of steric features, but represent the chemical constitution of molecules in terms of graph theory.

Since the treatment of enantiotopicity [47], diastereotopicity [47], and prochirality [48] according to the present formalism follows in a straightforward manner from the principles presented, in addition to the definitions and procedures included herein, no chapter on these subjects will be found.

Within the framework of thought, as presented here, chirality appears only as a secondary aspect of permutational isomerism. Chirality is, however, a phenomenon which is relevant to chemistry, and a test for any theoretical treatment of the steric aspects of chemistry. A formalism which fails to deal adequately with chirality is severely limited in its application to stereochemistry.

The present formalism does not represent the mirror image of a chiral object as the mirror image "as reflected by a plane mirror"; it does, however, represent molecules in such a manner that the algebraic representations of mirror images differ, and it deals with chiroids of both *classes*, ***a*** and ***b***, adequately.

The discussion of an alternate mechanism for pentacoordinate isomerization was introduced in an effort to show how the extension of the algebraic formalisms led to the reinvestigation of a reaction. The mechanism proposed for the Wittig reaction on the basis of the turnstile discussions illustrates the use of the formalism further.

The utility of topological concepts for the discussion of reaction mechanisms has already been recognized by several authors. *Evans* [39] and *Dewar* [40] applied the topological concept of isoconjugation to transition complexes, a particularly important contribution in this context.

The present authors will discuss the relation of mathematical structures and chemical reactions in greater detail in the near future. A promising field of application is biochemistry. Hydrophobic interactions, quaternary structures of proteins, the nucleic acid structures, and enzymatic processes are some of the problems to which the present concept could be applied.

We gratefully acknowledge the contributions of Professor J. Dugundji whose advice, many suggestions, and discussions guided us substantially and of Professor E. Ruch who stimulated us with his lectures and lengthy discussions during his visit to Los Angeles in October–November 1969. The authors are further indebted to Professors M. Eigen, F. Hawthorne, K. Kirschner, G. A. Segal, and W. K. Wilmarth as well as Dr. G. Kaufhold for helpful hints and discussions, and to Mrs. P. Gillespie, Mrs. D. Marquarding, and Mrs. V. Schneider for their valuable help in preparing the manuscript.

4-Isothiocyanatobenzenesulfonic Acid as Reagent for Edman Peptide Degradation

By *Christian Birr*, *Christian Reitel*, and *Theodor Wieland*[*]

The method developed by *Edman*[1] for the sequential analysis of peptides — in which the N-terminal amino acid of a protein is made to react with phenyl isothiocyanate, cleaved off as 5-thiazolinone, and subsequently detected after rearrangement to the thiohydantoin derivative — has been modified in many ways. All variants of the degradation, however, suffer from a common failing: Incompletely degraded portions of peptide are present in the next degradation cycle; hence, from step to step in the degradation reaction there appear more and more thiohydantoins so that after a few cycles it becomes more difficult and finally impossible to identify the main product of degradation. This is particularly true in the case of monotonous peptide sequences.

We have now found that the use of 4-isothiocyanatobenzenesulfonic acid, as suggested by *Just*[2], affords a simple means of identifying the degradation products of a peptide sequence. The sulfonated phenylthiocarbamoyl peptide *(1)* occurring in this Edman degradation can be separated quite easily from unreacted peptides by ion-exchange chromatography on DEAE Sephadex (Cl^- form, diameter 1.5 cm, length 20 cm) using 0.1 N HCl as eluent. On evaporating the acid eluate the N-terminal amino acid derivative is cleaved from the peptide and immediately rearranges to the 4-sulfophenylthiohydantoin *(2)*. The peptide, which is now shorter by one amino acid is separated from the cleaved amino acid derivative by further chromatography on the DEAE Sephadex column before carrying out the next degradation step. The compound *(2)* eluted from the column can be unequivocally identified as the pure substance by thin-layer chromatography using an authentic sample for comparison.

We tested the new variant of the degradation on the tripeptide Phe-Ala-Val which we had treated according to the procedure given by *Edman*[1]. The peptide (2 mmole, 670.8 mg) was dissolved in pyridine/water (1:1; 25 ml); the pH of the solution was adjusted to 8.7 by addition of 1 N NaOH. The addition of sodium 4-isothiocyanatobenzenesulfonate (4 mmoles, 950 mg) dissolved in pyridine/water (1:1) was carried out at this pH and 40 °C. Reaction was complete after 25 minutes. The reaction mixture was then extracted twice with benzene and the aqueous phase neutralized and evaporated at 30 °C under vacuum. The resulting residue was dissolved in water and transferred to the above mentioned DEAE Sephadex column; this was eluted with 0.1 N HCl. The unreacted peptide (<10 %) passed through the column along with the neutral front and was collected after *ca.* 2 minutes at a high throughput rate; the sulfonated thiocarbonyl peptide *(1)*, on the other hand, was contained in the acid eluate collected after about 30 minutes. On evaporation at 30 °C under vacuum, the dipeptide was cleaved and the substituted phenylalanine simultaneously cyclized to the 4-sulfophenylaminothiohydantoin derivative *(2a)*. The separation of the components was, once again, achieved by ion-exchange chromatography. The second and third degradation step was carried out in the same way using 0.26 mmole (50 mg) of Ala-Val and 25 mg of valine and gave the alanine derivative *(2b)* and valine derivative *(2c)* respectively. The authentic amino acid derivatives *(2a)—(2c)* (S-PTH derivatives) were characterized by elemental analysis, IR spectroscopy (carbonyl absorption 1755—1760 cm^{-1}), UV spectroscopy (λ_{max} = 273 nm), and thin-layer chromatography [2-butanone/glacial acetic acid/water (20:1:4); *(2a)*: R_f = 0.55; *(2b)*: R_f = 0.40; *(2c)*: R_f = 0.50].

If the degradation steps are not carried out in the absence of oxygen, then small amounts of hydantoin amino acid derivatives are formed from the thiohydantoin during the chromatographic separation; however, the sequence analysis remains unimpaired. This type of degradation can be readily mechanized.

Reactions of Azirines. Synthesis and Properties of a 1-Azetine[**]

By *Alfred Hassner*, *J. O. Currie, Jr.*, *A. S. Steinfeld*, and *R. F. Atkinson*[*]

In connection with our studies on azirines[1] we found that addition of dichlorocarbene to 3-methyl-2-phenylazirine *(1)* does not lead to substituted azabicyclobutanes but to the open ring products *(2)*. Stepwise nucleophilic addition of trichloromethyllithium to *(1)* followed by treatment with base gave 2,3-dichloro-*cis*-4-methyl-3-phenyl-1-azetine *(6a)*, presumably *via* the azabicyclobutane *(5b)* as intermediate. Azetines represent a rare class of heterocycles of which only few 2-alkoxy or thioalkyl derivatives have been reported[2,3].

Azirine *(1)*[4] on refluxing with $C_6H_5HgCCl_3$ (a source of dichlorocarbene[6]) led in 60 % conversion to the dichloromethyleneamine *(2)*, which is converted by sodium azide to tetrazole *(3)* and by aqueous acid to propiophenone. On the other hand, treatment of *(1)* with trichloromethyllithium at −100 °C gave after distillation (80 °C/0.5 torr) *cis*-3-methyl-2-phenyl-2-trichloromethylaziridine *(4)* in 75 % yield [IR (neat): ν = 3290 cm^{-1} (NH); NMR (CCl_4): τ = 2.3—2.8 (5-phenyl-H/m), 7.10 (1 C—H/q), J = 5.7 Hz, 8.1 (1 N—H/br. s), 9.07 (3-methyl-H/d), J = 5.7 Hz].

Slow addition of potassium *tert*-butoxide to a solution of *(4)* in DMSO gave a product which on preparative thin layer chromatography (PF_{254} silica gel) with chloroform furnished 2,3-dichloro-*cis*-4-methyl-3-phenyl-1-azetine *(6a)* in 51 % yield. The ^{1}H-NMR spectrum of *(6a)* in carbon tetrachloride shows τ = 2.62 (5 phenyl-H/s), 5.58 (1 C—H/q), J = 6.7 Hz, and 9.07 (3 methyl-H/d), J = 6.7 Hz. The isomeric azabicyclobutane structure *(5b)* was discarded on the basis of

(6a), R = Cl
(6b), R = OCH_3

the ^{13}C-NMR spectrum and since the ^1H-NMR spectrum of *(5a)*, prepared by dimethylsulfonium methylide addition[7] to *(1)*, shows its *endo* ring proton absorption at $\tau = 8.6$. The mass spectrum and elemental analysis also support the structure *(6a)*. The strong IR band at 1580 cm^{-1} is consistent with the C=N in four-membered rings.

The reactivity of azetine *(6a)* was significantly different from that of azabicyclobutanes which are very acid sensitive. Although mild sensitivity to air was observed, *(6a)* was recovered unchanged (80 % yield) on stirring in anhydrous ether saturated with HCl for 40 h at 25 °C. In 10 % aqueous HCl, 3-chloro-*cis*-4-methyl-3-phenyl-2-azetidinone *(7)* was obtained [IR (CCl_4), 1770 cm^{-1} (C=O); NMR ($CDCl_3$): τ = 2.6 (5 phenyl-H and 1 N—H/m), 5.81 (1 C—H/q), J = 6.4 Hz, 9.11 (3-methyl-H/d), J = 6.4 Hz]. An isomeric 3-azetidinone structure was excluded by the exact mass spectrum of *(7)*. Chloroazetine *(6a)* is slowly converted to the ether *(6b)* with $NaOCH_3$.

1,2,4,5-Hexatetraene (Biallenyl)

By *Henning Hopf*[*]

When propargyl bromide *(1)* is treated with magnesium in tetrahydrofuran, 1,5-hexadiyne *(2)*, 1,2-hexadien-5-yne *(3)*, and 1,2,4,5-hexatetraene (biallenyl) *(4)* are formed[1]. Of these products, only *(2)* has so far been characterized in detail.

By adopting *Groizeleau-Miginiac*'s procedure[1d], we have now succeeded in isolating 1,2,4,5-hexatetraene *(4)*, which on heating is isomerized to 3,4-dimethylenecyclobutene *(5)*.

Gas-chromatographic analysis of the mixture of C_6H_6 isomers obtained from *(1)* shows that it consists of 60 % of *(2)*, 25 % of *(3)*, and 15 % of *(4)*. Pure biallenyl may be obtained by preparative-scale gas chromatography on either a DBP column at 30 °C or a carbowax column at 60 °C. The compound (n_D^{20} = 1.5356) crystallizes as needles (m.p. −36 °C) at −78 °C and is stable for a few hours at this temperature. At room temperature it discolors and a brownish-yellow polymeric material is precipitated. Solutions in tetrahydrofuran, diethyl ether, or pentane are stable for months at −35 °C.

The spectra exhibit features that are typical for allenes: NMR (δ, ppm): 4.92 (4 H/m), 5.63 (2 H/m). IR (CCl_4): 1951 and 851 cm^{-1} (no bands at 3300 and 2100 cm^{-1}). UV (*n*-hexane): shoulder at 225 nm (ε = 15000). Mass spectrum: *m/e* 78 (M), 63, 51, 39[2].

1,2,4,5-Hexatetraene *(4)* has been suggested as an intermediate in the thermal isomerization of 1,5-hexadiyne *(2)* to 3,4-dimethylenecyclobutene[3–5]. We have found that *(4)* is pyrolyzed quantitatively to *(5)* (200 ± 1 °C/35–65 torr, 15 min). A number of substituted 1,2,4,5-hexatetraenes are known to behave analogously[3,6]. The gas chromatogram of the fresh pyrolyzate shows a single peak whose retention time and mass spectrum are identical with those of an authentic sample of *(5)*[2].

The half-life for the conversion of *(4)* into *(5)* at 151 ± 1 °C is about 10 min. Using the kinetic data of *Huntsman* and *Wristers*[4], a half-life of 16 days is calculated for the isomerization of *(2)* to *(5)* at 151 °C. Provided that *(4)* is an intermediate in this process, the conversion of *(2)* into *(4)*, which may be formulated as a Cope-type rearrangement, is the rate-determining step in the cyclization of *(2)* to *(5)*.

The Adduct of Tetramethoxyallene and Tetracyanoethylene

By *R. W. Hoffmann* and *W. Schäfer* [*]

We report here on a two-step (2 + 2) cycloaddition, in which the second step is reversible at room temperature [1]: On mixing toluene solutions of tetramethoxyallene *(1)* [2] and tetracyanoethylene the color of the toluene-tetracyanoethylene CT complex immediately disappeared. Colorless crystals of an unstable 1:1 adduct (decomp. pt. 105–110 °C) gradually separated (yield 93 %) whose NMR spectrum ($CDCl_3$) exhibits only one singlet at $\tau = 6.23$. This is *prima facie* hardly consistent with structure *(3)*, which corresponds *e.g.* to that of the (2 + 2) cycloadduct *(4)* of *(1)* and phenyl isocyanate [3]. On the other hand, one can equally well discount the presence of the 1,4-dipole *(2)*, since the tetramethoxyallyl cation shows a resonance signal at $\tau = 5.75$ [4].

That a dynamic phenomenon is involved here was shown by recording the NMR spectra during cooling of a CD_2Cl_2 solution: below −50 °C a broadening of the signal at $\tau = 6.23$ was observed; at lower temperatures the signals expected for *(3)* at $\tau = 5.75$, 5.90, and 6.30 (1:1:2, half-width at −95 °C still 4 Hz) became recognizable. Accordingly, at −65 °C there is a rapid exchange process ($k > 60$ s^{-1}) of all methoxy groups in *(3)*. This is not due to complete reversibility of the cycloaddition, for no tetramethoxyallene *(1)* can be trapped from solutions of *(3)*: On addition of phenyl isocyanate to a solution of *(3)* the adduct *(3)* was recovered unchanged, whereas treatment of *(1)* under the same conditions led to the ready formation of *(4)*. Compound *(4)* did not react with tetracyanoethylene. Moreover, treatment of a solution of *(3)* with methanol did not yield hexamethyl orthomalonate [2]; instead the 1,4-dipole *(2)* underwent methanolysis to *(5)* [1] — as the NMR spectra of the solution after treatment with CH_3OH [s at $\tau = 4.83$, 6.11, 6.13, and 6.67 (1:3:3:9)] or CD_3OD [s at $\tau = 6.11$, 6.13, 6.67 (3:3:6)] suggest. Hence, at room temperature *(2)* and *(3)* are fully equilibrated while decomposition of *(2)* into its components could not be detected.

The equilibrium between *(2)* and *(3)* lies predominantly on the side of *(2)*. This follows from a comparison of the chemical shifts of the methoxy signals of the equilibrating mixture in CD_2Cl_2 ($\tau = 6.16$) with the average value of the signals of *(3)* at −95 °C ($\tau = 6.06$) and with the signal of the tetramethoxyallyl cation ($\tau = 5.75$, $CHCl_3$).

Simple Synthesis of Phosphorofluoridous Acid, $H[PHO_2F]$ [**]

By *Hans Falius* [*]

While the fluoro acids $H_2[PO_3F]$ and $H[PO_2F_2]$ derived from orthophosphoric acid have been known for a long time, phosphorofluoridous acid $H[PHO_2F]$ *(1)* has so far defied all attempts at isolation in pure form. The formation of *(1)* in the hydrolysis product of PF_3 and in an aqueous solution of $H_2[PHO_3]$ and HF has been established by *Blaser* and *Worms* [1] on the basis of the reaction behavior. *Centofanti* and *Parry* [2] obtained milligram quantities of the acid, contaminated with PF_3, on dismutation of liquid $PHOF_2$. The product obtained by *Heinz* and *Röhner* [3] from P_4O_6 and HF, however, appears to be the adduct $HF \cdot H_2[PHO_3]$ instead of $H[PHO_2F] \cdot H_2O$ [4].

The hexatomic compound *(1)* is the first to contain just one H atom and one F atom bound to the same atom of phosphorus. It is formed rapidly according to the equation:

$$PCl_3 + 2\,H_2O + HF \rightarrow \underset{(1)}{H[PHO_2F]} + 3\,HCl$$

Formation of $H_2[PHO_3]$ *(2)* and $H_2[P_2H_2O_5]$ *(3)* as by-products of the reaction cannot be suppressed. On use of DF and D_2O the reaction yields the deuterated acid $D[PDO_2F]$ *(4)*.

The acid *(1)* is a liquid at room temperature ($d_4^{20} = 1.587$ g cm^{-3}; $n_D^{20} = 1.3682$). On heating it decomposes above about 70 °C with foaming (phosphine formation); when cooled it solidifies to a glass at about −100 °C. Extrapolation of a few vapor-pressure measurements between 0 and 30 °C gave b.p. 209 °C. The heat of vaporization is $\Delta H_{298} = 8300$ cal $mole^{-1}$, and the entropy of vaporization is $\Delta S_{298} = 17.2$ e.u. Thus association occurs in the vapor state.

Since *(1)* is hydrolyzed in aqueous solution, salts cannot be prepared in that medium. The acid is insoluble in apolar solvents. The first salts to be prepared, *i.e.* $Li[PHO_2F]$ *(5)* and $Li[PDO_2F]$ *(6)*, were obtained smoothly by reaction of ethereal solutions of *(1)* and *(4)*, respectively, with LiBr.

In each of the ^1H-, ^{19}F-, and ^{31}P-NMR spectra (external standards: $(CH_3)_4Si$; CF_3COOH, 85 % H_3PO_4) of *(1)* (cf. ref. [2]), a doublet of doublets is observed, as expected for an AMX system; the ^1H-NMR spectrum contains an additional singlet for the OH proton.

^1H-NMR: $\delta_{HP} = -7.89$, $\delta_{HO} = -14.2$ ppm; $J_{HP} = 779$, $J_{HF} = 113$ Hz.

^{19}F-NMR: $\delta = -15.5$ ppm; $J_{FP} = 1032$, $J_{FH} = 115$ Hz.

^{31}P-NMR: $\delta = -2.97$ ppm; $J_{PH} = 785$, $J_{PF} = 1032$ Hz.

The spectra of *(4)* each contain a doublet of triplets having

^{19}F-NMR: $\delta = -14.6$ ppm; $J_{FP} = 1030$, $J_{FD} = 17.3$ Hz and

^{31}P-NMR: $\delta = +2.1$ ppm; $J_{PD} = 119$, $J_{PF} = 1027$ Hz.

The frequency of νPH in *(1)* is remarkably high; $PHOF_2$ also gives a similarly high value of 2503 cm^{-1} [2].

IR and Raman spectra:

H[PHO$_2$F] *(1)* Raman	D[PDO$_2$F] *(4)* Raman	Li[PHO$_2$F] *(5)* IR	Li[PDO$_2$F] *(6)* IR

Experimental:

A solution of 40 % HF (10.0 g, 0.2 mole) in ether (80 ml) is added dropwise with ice-cooling to a stirred solution of PCl_3 (27.5 g, 0.2 mole) in anhydrous ether (30 ml). The ether must be dry in order that a check may be kept on the amount of water present. After removal of ether and HCl at reduced pressure, the oily residue, consisting of *(1)*, *(2)*, and *(3)*, is fractionated in a high vacuum below 50 °C: *(1)* is collected in a cold trap at −23 °C (CCl_4 solid/liquid). After two more distillations under the same conditions, most conveniently into traps connected in series, the yield is about 5 g (30 %).

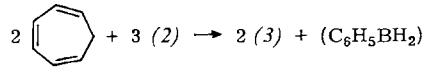
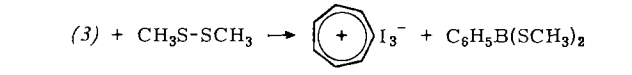
Tropylium Triiodophenylborate[1]

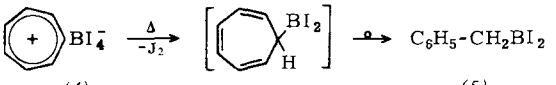


By *Walter Siebert*[*]

Although the iodide ion is a rather weak Lewis base, it reacts with triiodoborane in the presence of the stabilizing trityl cation to form the tetraiodoborate ion[2]. We have now been able to synthesize the first example of the monosubstituted complex ion $[R-BI_3]^{\ominus}$ by allowing tropylium iodide *(1)* to react with diiodophenylborane, a weaker Lewis acid than BI_3.



(1) *(2)* *(3)*



Tropylium triiodophenylborate *(3)* can be obtained in a 71 % yield in a more refined method from cycloheptatriene and *(2)* by hydride transfer from carbon to boron; the non-isolable phenylborane is thought to be formed in the reaction.

Like tropylium tetraiodoborate *(4)*[2], which is prepared from C_7H_8 and BI_3, the compound *(3)* has a brilliant yellow color which rapidly turns brown in moist air. Ether cleavage, a characteristic reaction for B—I compounds, leads in the case of *(3)* to the formation of *(1)*, ethyl iodide, and di(ethoxy)phenylborane. Both *(3)* and *(4)* undergo a redox reaction with dimethyldisulfane — the former yielding tropylium triiodide and di(methylthio)phenylborane and the latter yielding tropylium triiodide, tri(methylthio)-borane, and iodine.

We assume that the disulfane does not attack the sp^3-hybridized boron atom in *(3)* or *(4)* but rather the sp^2-hybridized starting compounds *(2)* and BI_3 which are in equilibrium with *(3)* and *(4)*, respectively. No formation of methylthioborates was observed in the reaction. Thermal decomposition of *(3)* leads mainly to *(1)* and *(2)*; however, an intramolecular redox reaction with formation of iodine also takes place. An analogous elimination of halogen is observed on heating of tropylium tetrachloroborate which leads to the formation of benzyldichloroborane in 31 % yield[3]. Although iodine ought to be a much more favorable leaving group than chlorine, the cleavage of iodine from *(4)* followed by ring contraction has not yet been used for the preparation of benzyldiiodoborane *(5)*, first synthesized by *Paetzold*[4], since the yields are only about 10 %.

(4) *(5)*

The presence of the triiodophenylborate is confirmed by elemental analysis, the redox reaction, and the ether cleavage, as well as from the IR spectrum[5] which shows a broad νBI band at 534 cm^{-1} that is slightly shifted to higher frequency in contrast to the νBI band at 517 cm^{-1} of $NH_4^+BI_4^-$[6].

Experimental procedure:

Since the reactants and products are sensitive to hydrolysis and oxidation, the reactions must be carried out in presence of an inert gas (N_2).

a) Compound *(2)* (1.4 g, 4.1 mmoles) is added dropwise with vigorous stirring to a solution of *(1)* (0.51 g, 3.2 mmoles) in methylene dichloride (100 ml). The suspension brightens as the red compound *(1)* goes completely into solution. The yellow crystals of *(3)* which separate after a few minutes are isolated, washed with CH_2Cl_2, and dried *in vacuo*: yield 0.8 g [62 % w.r.t *(1)*]; m.p. 121 °C (dec).

b) C_7H_8 (7.38 g, 80.2 mmoles) is added dropwise to a solution of *(2)* (8.87 g, 26.0 mmoles) in methylene dichloride (100 ml). A yellow precipitate forms immediately; this is isolated after 12 hours: yield 6.9 g (71.1 % w.r.t. *(2)*).

Azido Metal Complexes as N_3 Generators

By *Wolfgang Beck* and *Karl Schorpp* [*]

The deep red solutions of tetraphenylarsonium salts with the complex anions $[Au(N_3)_4]^-$ and $[Pb(N_3)_6]^{2-}$ [1] in tetrahydrofuran (THF) or methylene dichloride are rapidly decolorized by the action of diffuse daylight, the central metal ion being reduced to form gold(I) and lead(II) complexes, respectively, and nitrogen being formed as oxidation product of the azide ligand:

$$\overset{+3}{[Au(N_3)_4]^-} \rightarrow \overset{+1}{[Au(N_3)_2]^-} + 3\ N_2$$

The color of these Au^{III} and Pb^{IV} complexes arises from CT transitions, which can be regarded as electron transfer from the azide ligand to the metal [1]. Formation of nitrogen is preceded by the following primary process [2]:

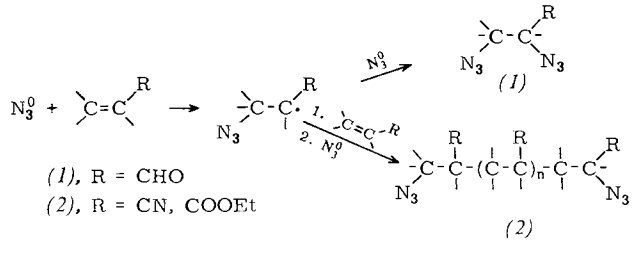
$$[M^{z+}(N_3^-)_n]^{(n-z)-} \xrightarrow{h\nu} [M^{(z-1)+}(N_3^0)\,(N_3^-)_{n-1}]^{(n-z)-}$$

In accordance with this scheme, it was possible to detect a one-electron reduction proceeding *via* Au^{II} for tetrachloroaurate(III) [3].

We attempted to detect the expected species N_3^0 by interception with olefins. Thus $AsPh_4[Au(N_3)_4]$ was dissolved in acrylonitrile, ethyl acrylate, or acrolein and the course of reaction followed by IR and NMR spectroscopy. When the solutions are exposed to daylight, the $\nu_{as}N_3$ bands of the complex $[Au(N_3)_4]^-$ become less intense and the characteristic absorptions of organic azides appear (Table 1).

Table 1. $\nu_{as}N_3$ bands of organic azides formed from azido complexes and olefins.

olefin	$\nu_{as}N_3$ (cm^{-1}) [a]
acrylonitrile	2112
ethyl acrylate	2132, 2107
acrolein	2157, 2110
cyclohexene	2141, 2114



[a] The $\nu_{as}N_3$ bands of the azido complexes ($\approx$ 2030 cm^{-1}) differ appreciably from those of the organic azides.

In the ^1H-NMR spectrum, the effect of exposure to light is to reduce the intensity of the olefinic proton signals while simultaneously giving rise to new aliphatic proton signals.

Reaction of $(AsPh_4)_2[Pb(N_3)_6]$ with acrylonitrile or acrolein gives the same products.

On prolonged action of light on solutions of $AsPh_4[Au(N_3)_4]$ in the olefins mentioned above, the Au^{III} present is reduced to the metal; with acrolein in particular a coherent film of gold appears on the wall of the reaction vessel within a few hours at room temperature.

Photochemical reaction of the azido complexes with ethyl acrylate or acrylonitrile leads to polymerization [4]. The stability of the solutions in the dark and the observation that polymerization starts at the side of the reaction vessel that is turned to the light suggest a free-radical chain mechanism in which N_3^0 acts as chain initiator. The following reaction course is consistent with the experimental data [5]:

The reaction of $AsPh_4[Au(N_3)_4]$ with cyclohexene in THF, however, probably leads, by analogy with the reaction of cyclohexene with *N*-bromosuccinimide or highly dilute bromine, not to addition to the double bond but to substitution in the allylic position: the mass spectrum of the reaction solution was shown to contain the molecular ion of diazidocyclohexene.

N_3 transfer also occurs in the reaction of $Pt^0(PPh_3)_n$ (n = 3,4) with $AsPh_4[Au(N_3)_4]$ in THF/benzene. In these reactions N_3 behaves formally as a pseudohalogen in an oxidative addition, as in the reactions of halogens [6] or cyanogen [7] with $Pt(PPh_3)_n$. However, the reaction probably follows a bridge mechanism [8].

$$Pt(PPh_3)_n \rightleftharpoons Pt(PPh_3)_2 + (n-2)PPh_3$$

$$\overset{+3}{[Au(N_3)_4]^-} + \overset{0}{Pt(PPh_3)_2} \rightarrow \left(\begin{array}{c} N_3 \quad N_3 \quad PPh_3 \\ N_3 - Au - Pt \\ N_3 \quad N_3 \quad PPh_3 \end{array}\right)^{\ominus}$$

$$\rightarrow \overset{+1}{[Au(N_3)_2]^-} + \begin{array}{c} N_3 \quad PPh_3 \\ \overset{+2}{Pt} \\ N_3 \quad PPh_3 \end{array}$$

Hofmann- and Lossen-Rearrangements of Metal Carbonyl Complexes

By *Wolfgang Beck* and *Boris Lindenberg* [*]

Reactions of metal carbonyl complexes in which a nucleophile attacks the positively charged C atom of a CO ligand include those with alkyl- and aryllithium compounds [1], hydroxide and alkoxide ions [2], ammonia [3] and amines [4], hydrazine [5], and the azide ion [6]. The latter reactions, *i.e.* of N_2H_4 or N_3^- with metal hexacarbonyls of chromium, molybdenum, and tungsten, lead to isocyanato complexes as stable end products.

We have now found that isocyanatopentacarbonylmetalates(0) $[M(CO)_5NCO]^-$ (M = Cr, Mo, W) are also formed under mild conditions in the reaction of $M(CO)_6$ with hydroxylamine or chloramine, presumably in accordance with the following reaction mechanism:

X = OH, Cl

The intermediates *(1)*, which can be formulated as the hydroxamic acid R—C(O)-NHOH or *N*-halogeno acid amide R—C(O)—NHCl (R = $M(CO)_5$), form stable isocyanato complexes by loss of H_2O or HCl respectively: this corresponds to the rearrangement in the Lossen degradation of hydroxamic acids and in the Hofmann degradation of carboxylic amides, in the same way that the reaction of $M(CO)_6$ with N_3^- [6] corresponds to the Curtius degradation of carboxylic azides. In contrast to organic isocyanates, which give primary amines and urethanes respectively on reaction with water or alcohol, the isocyanato complexes are stable toward solvolysis.

In reactions of longer duration both chloramine and hydroxylamine react oxidatively toward hexacarbonyls with formation of CO_2 and metal oxides. Furthermore, $W(CO)_5NH_3$ was detected as secondary product; in this case ammonia is present as a result of reduction or disproportionation of hydroxylamine. Other metal carbonyl compounds, *e.g.* $Mn(CO)_5Br$, react with NH_2OH to give isocyanato complexes.

Experimental procedure:

On uniting a suspension of the hexacarbonylmetal complex in ethanol with an ethanolic solution of hydroxylamine or chloramine (molar ratio $M(CO)_6:NH_2X$ = 1:4) the mixture immediately turns yellow. After a few minutes the tetraphenylarsonium salt of *(2)* [6] can be precipitated from the filtered solution with $[As(C_6H_5)_4]Cl$ by addition of water.

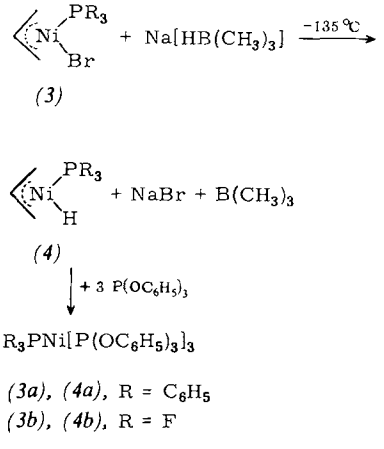
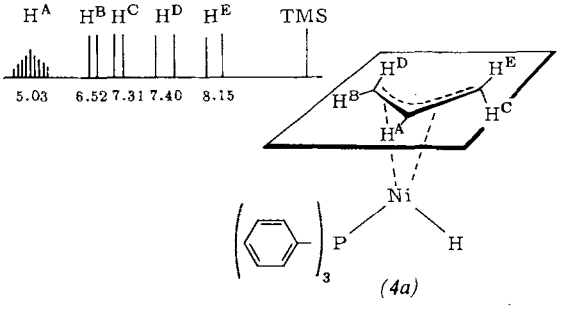
π-Allylhydridonickel Compounds[1]



By *Helmut Bönnemann*[*]

The thermally labile compound π-allylmethylnickel [2] decomposes at temperatures above —80 °C with ligand exchange to give predominantly the *trans* isomer of bis(π-allyl)nickel [3].

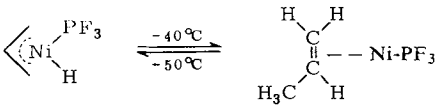
The corresponding π-allylhydrido complex of nickel, which is not stabilized by further ligands, undergoes such a disproportionation even at extremely low temperatures. Thus, reaction of π-allylbromonickel with $Na[HB(CH_3)_3]$ [4] at —140 °C yields bis(π-allyl)nickel, which, according to the ^{1}H-NMR spectrum [5], is mainly present as the *trans* isomer *(2)* (94 %).



If, however, the 1:1 adducts *(3)* of phosphines and π-allylbromonickel are used as starting material then reaction with $Na[HB(CH_3)_3]$ at —130 °C gives the red-brown crystalline π-allylhydridonickel compound *(4)*, which reacts with an excess of triphenyl phosphite with transfer of the hydrogen bound to nickel to the π-allyl group and loss of propene.

(3a), *(4a)*, R = C_6H_5
(3b), *(4b)*, R = F

The triphenylphosphine addition compound *(4a)* is stable up to —30 °C. It can be seen from the ^{1}H-NMR spectrum [5] that the *syn*- and *anti* protons are not equivalent so far as pairing is concerned, thus suggesting a tetragonal-planar arrangement of ligands. The H atom attached to the nickel does not give a resonance signal in the region up to τ = 15.



(4a)

The ^{1}H-NMR spectrum [5] of the trifluorophosphine adduct *(4b)* is remarkably dependent upon temperature. At —75 °C the characteristic signals of a symmetrically arranged π-allyl group appear at τ = 5.30 (*meso*), 7.27 (*syn*), and 8.50 (*anti*). If the sample is allowed to warm over a few hours to —40 °C the spectrum shows three further signals (multiplet, τ = 4.15; double doublet, centered at τ = 4.85; doublet at τ = 8.43) in the intensity ratio 1:2:3, which can

be assigned to a metal-bonded propene molecule. On recooling to −50 °C this process proved to be reversible.

Accordingly, a temperature-dependent equilibrium exists between the π-allylhydridonickel compound *(4b)* and a propene-Ni^0 complex *(5)*.

(4b) *(5)*

This is the first direct indication for the so-called "π-allyl mechanism" of olefin isomerization at a transition metal[6], which is believed to proceed *via* a 1,3-H shift: At −40 °C the hydrogen attached to the nickel transfers to the π-allyl group while at lower temperatures allylic C—H bonds of the olefin are cleaved from the nickel-ligand system with regeneration of the π-allyl group. If *(4b)* is replaced by the corresponding π-allyldeuterionickel compound it can be shown by ^{1}H-NMR spectroscopy that exclusively the C-1 and C-3 atoms of the propene in *(5)* are deuterated.

The Si-Si Group as a Structural Unit in Open-Chain and Cyclic Phosphorus Ylides[1]

By *Hubert Schmidbaur* and *Wolfgang Vornberger*[*]

It is known that various ylide functions are considerably stabilized by silyl groups, and various possible explanations have been offered for this "silicon effect"[1,2]. Since a transition from the simple silyl group to structural units containing a chain of silicon atoms generally leads to far-reaching changes in bonding, which could arise from the formation of a (d-d)π system[3], we have now also studied alkyldisilanyl-substituted ylides.

Introduction of one pentamethyldisilanyl group proceeds readily:Pentamethyldisilanylmethylenetrimethylphosphorane *(2)* is obtained smoothly, both by dehydrohalogenation of the corresponding phosphonium salt *(1)* by butyllithium and by direct transylidation *in situ*.

$$(CH_3)_3PCH_2 + (CH_3)_3SiSi(CH_3)_2Cl \longrightarrow [(CH_3)_3\overset{\oplus}{P}\text{-}CH_2\text{-}Si(CH_3)_2Si(CH_3)_3]\,Cl^{\ominus} \quad (1)$$

$$(1) \xrightarrow{C_4H_9Li} (CH_3)_3P{=}CH\text{-}Si(CH_3)_2Si(CH_3)_3 \quad (2)$$

$$2\,(CH_3)_3PCH_2 + (CH_3)_3SiSi(CH_3)_2Cl \xrightarrow[-[(CH_3)_4P]Cl]{} (2)$$

The occurrence of deprotonation at the methylene bridge of the phosphonium salt affords a proof of the stabilizing effect that the $(CH_3)_5Si_2$ group exerts on the ylidic function; the effect is comparable with that of a $(CH_3)_3Si$ group. However, whereas a second silylation of the ylidic C atom occurs in the case of the $(CH_3)_3Si$ group, thus leading to an additional stabilization, the second disilanyl group always takes up a position in a side chain of the ylide to yield a product of type *(3)*.

$$3\,(CH_3)_3PCH_2 + 2\,(CH_3)_5Si_2Cl \xrightarrow[-2\,[(CH_3)_4P]Cl]{}$$

$$(CH_3)_2P(=CH\text{-}Si(CH_3)_2Si(CH_3)_3)(CH_2\text{-}Si(CH_3)_2Si(CH_3)_3) \quad (3)$$

$$\downarrow$$

$$(CH_3)_3P{=}C(Si(CH_3)_2Si(CH_3)_3)_2 \quad (4)$$

Compounds *(3)* undergo neither thermal nor catalytic rearrangement to the isomer *(4)*[4], a fact which we attribute to a steric effect of the β-silyl groups.

Confirmatory evidence is provided primarily by the ease with which cyclic ylides are formed in which the repulsive interaction of the substituents is eliminated by direct linkages:

$$(CH_3)_3P{=}CH\text{-}Si(CH_3)_3 \xrightarrow[2.\ C_4H_9Li]{1.\ (CH_3)_4Si_2Cl_2} (CH_3)_2P(=CH_2)(C(Si(CH_3)_2)_2Si(CH_3)_3) \quad (5)$$

$$6\,(CH_3)_3PCH_2 + 2\,(CH_3)_4Si_2Cl_2 \xrightarrow[-4\,[(CH_3)_4P]Cl]{} (CH_3)_2Si(C(P(CH_3)_3)Si(CH_3)_2)_2 \quad (6)$$

$$2\,(CH_3)_3P{=}C(Si(CH_3)_2Cl)_2 \xrightarrow{Li\ in\ THF} (6)$$

The stabilization of ylidic centers by Si—Si chains can be explained in terms of a delocalization of the carbanionic charge into the vacant orbitals of the silicon atoms of the p→(d-d)π type. The increased shielding of the β-methylsilyl protons in *(2)*, which even exceeds that of the α-methylsilyl protons, further supports this assumption:

$$R_3\overset{\oplus}{P}\text{-}\underset{H}{C}\text{-}SiR_2\text{-}\overset{\ominus}{SiR_3}$$

Experimental:

Preparation from 10 mmole amounts of starting materials afforded *(1)* in 80% yield: m.p. > 300 °C; ^{1}H—NMR ($CHCl_3$): δ CH_3P—134 Hz, d, $J(H_3CP)$ 13.9; δ CH_2—119 Hz, d, $J(H_2CP)$ 19.0; δ CH_3Si_α—23 Hz, s; δ CH_3Si_β—13 Hz, s; intensity ratio 9:2:6:9. — Reaction of *(1)* with C_4H_9Li affords the ylide *(2)*, yield greater than 50% (as in the trans-

ylidation also); m.p. −10 °C, b.p. 35 °C/0.1 torr; ^{1}H—NMR (without solvent): δ CH_3P −75 Hz, d, $J(H_3CP)$ 12.1; δ CH + 57.5 Hz, d, J(HCP) 6.5; δ CH_3Si_α + 6 Hz, s; δ CH_3Si_β + 8 Hz, s; intensity ratio 9:1:6:9.

(3) is formed from $(CH_3)_3PCH_2$ (52 mmoles) and $(CH_3)_5Si_2Cl$ (35 mmoles) as a colorless nondistillable liquid (yield 61 %); ^{1}H—NMR: δ CH_3P −34 Hz, d, $J(H_3CP)$ 12.0; δ CH_2 −17 Hz, d, $J(H_2CP)$ 15.5; δ CH + 65 Hz, d, J(HCP) 6.5; δ $CH_3Si_2CH_2$ + 15 Hz, s; δ CH_3SiCH_2 + 11 Hz, s; δ CH_3Si_2CH + 26 Hz, s; δ CH_3SiCH + 20.5 Hz, s; intensity ratio 6:2:1:9:6:9:6.

Treatment of the salt formed from $(CH_3)_3PCHSi(CH_3)_3$ (77 mmoles) and $(CH_3)_4Si_2Cl_2$ (39 mmoles) with C_4H_9Li (65 mmoles) gives a 20 % yield of *(5)*: b.p. 65 °C/0.1 torr; ^{1}H—NMR (without solvent): δ CH_3P −75 Hz, d, $J(H_3CP)$ 11.5; δ CH_2 −54 Hz, d, $J(H_2CP)$ 12.5; δ$(CH_3)_3Si$ + 1.5, s; δ $(CH_3)_2SiCH_2$ −5.5 Hz, s; δ $(CH_3)_2SiC$ −2 Hz, s; intensity ratio 6:2:9:6:6. Reaction of $(CH_3)_3PCH_2$ (55 mmoles) with $(CH_3)_4Si_2Cl_2$ (14 mmoles) in ether followed by filtration, distillation, and resublimation affords 17 % of *(6)*: m.p. 126–128 °C, sublimes at 138 °C/0.1 torr. Compound *(6)* is also formed in 30 % yield on reaction of $(CH_3)_3PC[Si(CH_3)_2Cl]_2$ [5] (20 mmoles) and finely divided lithium (300 mmoles) in THF (40 h, reflux); ^{1}H—NMR (benzene): δ CH_3P −25.5 Hz, d, J(HCP) 11.5; δ CH_3Si + 9 Hz, s; intensity ratio 3:4 [6].

MINDO/2 Treatment of Species Present in Carbon Vapor[1]

By *Michael J. S. Dewar*, *Edwin Haselbach*, and *Muthanna Shanshal* [*]

The nature and properties of the species present in carbon vapor have aroused much interest in recent years; we have accordingly studied three of these, *i.e.* C_2, C_3, and C_5, using a recently developed semiempirical SCF MO method (MINDO/2 [3]), which has been shown to give good estimates of geometries and heats of formation for a wide range of carbon compounds. In its current form, the treatment cannot be applied satisfactorily to triplet states; C_4 had therefore to be excluded.

Calculations were carried out for various possible geometries of the various species and the equilibrium geometries were then estimated by parabolic interpolation.

Both C_3 and C_5 are predicted to be linear; CC stretching force constants were calculated from the variation in total energy with bond length. The results are compared with experimental values, where available, in the Table; while the geometry of C_5 has not yet been studied, that of C_3 is linear, as predicted.

The agreement between the calculated and observed heats of formation is reasonably good in view of the uncertainties in the experimental values (cf. [8]).

Species	Heat of formation (kcal/mole)		Bond length (Å)		Force constant (dyne/cm × 10^{-5})	
	calc.	obs.	calc.	obs.	calc.	obs.
C_2	167.5	183 ± 10 [4]	1.160	1.24 [5]	15.2	12.17 [5]
C_3	226.5	200 ± 10 [4]	1.275	1.280 [6]	9.54	10.3 [6]
C_5	273.0	240.5 ± 58 [7]	1.260	(terminal)	9.72	—
			1.305	(central)	10.55	—

The calculated CC bond length and stretching force constant for C_3 are in excellent agreement with experiment. In the case of C_2, the discrepancy between theory and experiment is greater, though still not excessive; the differences are consistent in that too short a bond length should correspond to too large a force constant.

The species discussed here are "electron deficient" in that their valence shell orbitals are not completely utilized; apparently the MINDO/2 method can be extended satisfactorily to such systems and it should therefore be equally applicable to a study of their reactions [9].

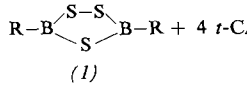
Cleavage of a Carbon-Sulfur Bond by Organodihaloboranes



By *Max Schmidt* and *Falk R. Rittig* [*]

Reaction of iodoboranes with disulfanes results in liberation of iodine and cleavage of the sulfur-sulfur bond in a redox reaction to give the corresponding thioboranes [1], *e.g.*:

$$RBI_2 + R'SSR' \rightarrow RB(SR')_2 + I_2 \qquad (1)$$

We have now found that di-*tert*-butyldisulfane reacts differently with organodiiodoboranes: Substitution occurs with C—S cleavage to give 3,5-diorgano-1,2,4,3,5-trithiadiborolanes *(1)*, *tert*-butyl iodide, and sulfur.

$$2\ RBI_2 + 2(t\text{-}C_4H_9)_2S_2 \rightarrow$$

$$+\ 4\ t\text{-}C_4H_9I + 1/8\ S_8 \qquad (2)$$

(1)

In this new synthesis of the five-membered boron-sulfur ring the reactants are mixed together at room temperature, *e.g.*, in hexane; after several hours' stirring the volatile components are removed under reduced pressure and the crystalline residue is recrystallized.

In these reactions, which in contrast to the other redox reactions of organoboranes are not particularly exothermic, liberation of iodine is observed, especially on dropwise addition of disulfane to the iodoborane, thus indicating a redox reaction of the sulfur formed with unused iodoborane[2]:

$$2\ RBI_2 + 3/8\ S_8 \rightarrow (1) + 2\ I_2 \qquad (3)$$

An analogous reaction is basically also possible with the weaker Lewis acid phenyldichloroborane, albeit only at higher temperatures.

Experimental data for reactions of organodihaloboranes with di-*tert*-butyldisulfane.

RBX_2	Reaction time (h)	Product *(1)*	Yield (%)	B.p. (°C/torr)	M.p. (°C)
n-$C_4H_9BI_2$	24	$(n\text{-}C_4H_9B)_2S_3$ [a]	77.6	73–75/0.1	
$C_6H_5BI_2$	24 [b]	$(C_6H_5B)_2S_3$	90.4		115–117
p-CH_3-$C_6H_4BI_2$	24 [b]	$(p\text{-}CH_3\text{-}C_6H_4B)_2S_3$	86.8		124–126
$C_6H_5BCl_2$	16 [c]	$(C_6H_5B)_2S_3$	44.1		114–115

[a] Formation of polymer as by-product; [b] in n-hexane; [c] reflux (bath temperature 160–170 °C).

All operations were carried out under nitrogen in carefully dried solvents, and the products were identified by elemental analysis and by their IR and NMR spectra.

As in the cleavage of di-*tert*-butylsulfanes by haloboranes *via* the 1:1 adducts as intermediates[3] and in the scission of unsymmetrical ethers by haloboranes[4], the substitution in the reaction formulated in (2) should be promoted by the intermediacy of an energetically favorable carbonium ion; similar cleavages of di-*tert*-butyl peroxide are currently being studied.

C–S cleavages in di-*tert*-butyldisulfane are also known in the case of the reactions with dichlorocarbene[5] and hexacarbonylmolybdenum.

Tetracarbonylbis(1,3-dimethyl-4-imidazolin-2-ylidene)chromium(0)[1]

By *Karl Öfele* and *Max Herberhold*[*]

The synthesis of transition metal-carbene compounds by transformation of a carbonyl[2] or isocyanide group[3] that is already coordinated to the central metal into a carbene ligand has hitherto afforded only neutral complexes having just one carbene ligand. The reactions of heteroaromatic cations with the hydrogencarbonylmetalate ions $[HCr(CO)_5]^-$ [4,5] and $[HFe(CO)_4]^-$ [5], and of 3,3-dichlorocyclopropene derivatives with either $Na_2Cr(CO)_5$ [6] or palladium metal[7] also result in the introduction of only one carbene ligand into the complex. The only compounds so far known to contain two carbene groups per metal atom are mercury complexes of the type $[Hg(carbene)_2]^{2+}$ [8]; it is, however, uncertain to what extent the mercury-carbon bond in these cations is comparable with the metal-carbene coordinative bond in the above neutral complexes.

We have now been able to show that a second carbene ligand can be introduced into pentacarbonyl(1,3-dimethyl-4-imidazolin-2-ylidene)chromium(0) *(1) via* photoinduced substitution of a carbonyl group. On irradiation of a solution of *(1)* in boiling tetrahydrofuran (THF) a small amount of the yellow complex *cis*-[tetracarbonylbis(1,3-dimethyl-4-imidazolin-2-ylidene)chromium(0)] *(2)* is formed which is readily separable from *(1)* owing to its insolubility in diethyl ether. The reaction can be interpreted as a "dismutation":

(1) *(2)*

The slight decomposition observed in THF solution can be almost completely suppressed by addition of a small amount of pyridine or acetonitrile to the reaction mixture. We assume that these donor ligands play a role in the stabilization of coordinatively unsaturated carbonylmetal fragments. Transfer of a carbene ligand onto complex fragments such as $[Fe(CO)_4]$ has recently been exploited by *E. O. Fischer et al.* in the synthesis of tetracarbonyl(methoxyphenylcarbene)iron(0) [9].

The yellow, air-stable crystals of *(2)*, m.p. 227–230 °C (decomp.), sublime at 120 °/$\approx 10^{-3}$ torr with partial decomposition; they are sparingly soluble in most organic solvents except THF. The composition $Cr(CO)_4(C_5H_8N_2)_2$ was established by elemental analysis and molecular-weight determination (osmometry in benzene) as well as by the mass spectrum[10]: The molecular ion $Cr(CO)_4L_2^+$ (*m/e* 356) is accompanied *inter alia* by fragments of the type CrL_2^+ (244), CrL^+ (148), and L^+ (96) (L = $C_5H_8N_2$).

The *cis* relationship of the two carbene ligands in the octahedral complex *(2)* is revealed by the number of IR-active C≡O stretching vibrations; in agreement with the local symmetry C_{2v}, four absorptions are observed (1986, 1870, 1847, and 1825 sh cm^{-1}; in $CHCl_3$). Further support for this structure comes from the dipole moment of $\mu = 9.66 \pm 0.1$ D (in benzene), which is considerably higher than that of *(1)* ($\mu = 7.0 \pm 0.1$ D). Simple vector addition of two *cis* partial moments of 7.00 D enclosing an angle of 90 ° would give an overall moment of 9.90 D.

Apart from the C≡O stretching region, the IR spectra of the carbene complexes *(1)* and *(2)* are almost identical. The UV absorption spectrum of *(2)* in ethanol contains two broad maxima at 365 (log ε = 3.35) and 258 nm (log

$\varepsilon = 4.39$); the absorption curve of *(2)* is shifted somewhat toward longer wavelengths compared with that of *(1)* [350 (log $\varepsilon = 3.48$) and 253 nm (log $\varepsilon = 4.60$); in ethanol].

The ^{1}H-NMR spectrum of *(2)* ([D$_6$]acetone; 25 °C) consists of two sharp singlets at $\tau = 6.48$ and 2.93 (intensity ratio 3:1) for the *N*-methyl and ring protons, respectively. The corresponding signals of *(1)* occur at $\tau = 6.13$ and 3.12[4].

Experimental:

$Cr(CO)_5C_5H_8N_2$ *(1)* is prepared in 90 % yield by heating bis(1,3-dimethyl-4-imidazolium)decacarbonyldichromate-(-I) $(C_5H_9N_2)_2[Cr_2(CO)_{10}]$ to 120 °C in a high vacuum[11], in a modification of a previous method[4].

A solution of *(1)* (1.0 g, 3.47 mmoles) and acetonitrile (0.16 g, 4 mmoles) in dry, degassed THF (75 ml) in a Duran glass Schlenk tube fitted with reflux condenser is exposed to the light emitted by a high-pressure mercury vapor lamp (Hanovia, type L, 450 W); the lamp is enclosed in a water-cooled quartz jacket during irradiation. The reaction solution rapidly comes to boiling. After 4 h, the solution is filtered under suction through a G 4 frit covered with filtration aid and the filtrate is evaporated to dryness *in vacuo*. Unreacted *(1)* can be dissolved out of the pale yellow residue with diethyl ether. The remaining yellow crystals of *(2)* are recrystallized from THF/*n*-hexane; yield 50 mg (≈ 8 %).

The "Silver Salt" of *cis*-1,2-Dicyano-1,2-ethylenedithiol

By *Hermann Wernet*[*] and *Gerhard Bähr* (deceased)

The reaction of *cis*-1,2-dicyano-1,2-ethylenedithiolate (L^{2-}) with silver ions in aqueous solution was initially described as simple salt formation[1,2].

A complex anion $[AgL_2]^{3-}$ was later also considered as a possible product[3].

On the basis of further studies we have now been able to show that this reaction actually leads to the complex $Ag_2[Ag_2L_2]$ containing two sets of differently bonded silver atoms. Sulfide ions react successively with the microcrystalline salt disilver bis(*cis*-1,2-dicyano-1,2-ethylenedithio)diargentate(I), which is practically insoluble in water, according to the equations

$$Ag_2[Ag_2L_2] + S^{2-} \rightarrow [Ag_2L_2]^{2-} + Ag_2S \quad (1)$$

$$[Ag_2L_2]^{2-} + S^{2-} \rightarrow 2\,L^{2-} + Ag_2S \quad (2)$$

The reaction steps (1) and (2) overlap; however, (1) is much faster. Iodide coordinates only with the cationic silver. In contrast, cyanide is able to displace the dithiolate ligand when present in excess.

$$Ag_2[Ag_2L_2] + 4\,I^- \rightarrow [Ag_2L_2]^{2-} + 2\,[AgI_2]^-$$

$$Ag_2[Ag_2L_2] + 4\,CN^- \rightarrow [Ag_2L_2]^{2-} + 2\,[Ag(CN)_2]^-$$

$$Ag_2[Ag_2L_2] + 8\,CN^- \rightarrow 2\,L^{2-} + 4\,[Ag(CN)_2]^-$$

The anion $[Ag_2L_2]^{2-}$ reacts with tetraethylammonium ions to give a salt that is sparingly soluble in water. The yellow crystals have a sharp melting- and decomposition point of 219 °C; they dissolve most readily in acetone and are sensitive to light, especially when moist.

We have also succeeded in preparing addition compounds of the silver salt and in determining their composition by elemental analysis; *e.g.* $Ag_2[Ag_2L_2]\cdot 2\,KCN$, $Ag_2[Ag_2L_2]\cdot 2[N(C_2H_5)_4]CN$, $Ag_2[Ag_2L_2]\cdot 2\,AgNO_3$, $Ag_2[Ag_2L_2]\cdot 2(en)$.

Reaction of L^{2-} with Ag^+ always leads first to the soluble anionic complex,

$$2\,L^{2-} + 2\,Ag^+ \rightarrow [Ag_2L_2]^{2-}$$

which is precipitated by an excess of silver ions.

$$[Ag_2L_2]^{2-} + 2\,Ag^+ \rightarrow Ag_2[Ag_2L_2]$$

On further addition of ligand the cationic silver is eventually also coordinated.

$$Ag_2[Ag_2L_2] + 2\,L^{2-} \rightarrow 2\,[Ag_2L_2]^{2-}$$

Is There an Energy Difference between Enantiomorphic Structures?

By *Wolfram Thiemann* and *Klaus Wagener*[*]

Sodium ammonium DL-tartrate consists of enantiomeric, optically active molecules (ratio of configurations 1:1) which are precipitated as a racemic mixture of pure, enantiomorphic crystals (containing only D or only L molecules) from its saturated aqueous solution below 27 °C[1]. We used this salt in the following experiment: A saturated solution of about 30 g of racemate was allowed to reach equilibrium with precipitated material at 25.5 °C. After removal of the precipitate, the solution was diluted with pure solvent (water) until the solubility limit was about

0 °C. When the temperature of the solution was allowed to fall slightly below the new solubility limit only a small precipitate was formed (about 50 mg). After equilibration under carefully controlled conditions, the precipitate and solution were separated, the precipitate was dissolved in water, and its optical activity was measured with respect to the solution as standard. After many preliminary experiments, ten measurements performed under very strict conditions all gave the same negative optical rotation[2] of the precipitate, namely $\alpha \approx 10^{-3}$ °.

In our search for an explanation of this remarkable phenomenon we considered the following possible causes: 1. Systematic errors in the measuring technique; they could be ruled out by switching the cells, repeated measurements, *etc.* — 2. Optically active impurities; this could be discounted on the basis of fractional (chromatographic) purification processes. — 3. Bacterial contamination of the solution, which would result in preferential degradation of the dextrorotatory[2] (natural) tartrate. We devoted the most attention to this last possible source of error and found: a) Concentrated solutions in open vessels are not infected at all within a week. b) If the observed activity were nevertheless due to an attack by bacteria then any variation in the time between precipitations would alter the magnitude of the effect. This was not the case. c) Addition of the bactericide toluene to the solution had no influence on the effect. — 4. The thought that external fields (such as the earth's magnetic field) could lead to D/L discrimination is untenable.

At the present time, the only remaining interpretation of our findings involves the assumption of different heats of solution for D and L crystals of sodium ammonium tartrate. And this means effectively that the lattice energies of the enantiomorphic crystals must differ, which in turn can only result from an asymmetric contribution to the interaction. Our measurements would indicate a relative difference in the heats of solution (or lattice energies) of a few 10^{-5}. We are currently examining the consequences of this phenomenon by other techniques and for other systems.

[2] Sign and magnitude of the optical rotation of a compound depend upon the wavelength of the polarized light. We used a Cary 60 spectropolarimeter, produced by Cary Instruments/Varian, and worked at $\lambda = 280$ nm.

Errata

In the communication "Aminoazimines by Addition of Aminonitrenes to α-Carbonylazo Compounds" by *K. H. Koch* and *E. Fahr*, Volume 9, August 1970, the following corrections should be made:

On page 634, right-hand column, line 30 "alcohol-free glacial acetic acid" should read "alcohol-free ethyl acetate".

On page 635, left-hand column, line 1 "*(1a)–(1f)*" should read "*(1d)–(1f)*".

CONFERENCE REPORTS

Homolytic Reactions of the Alkyl-Metal Bond

By *Alwyn G. Davies*[*]

Bimolecular homolytic substitution (S_H2) reactions are normally recognized to occur at peripheral hydrogen atoms [eq. (1)] or, less commonly, at halogen, oxygen, or sulfur atoms.

$$X^{\bullet} + H{-}R \xrightarrow{k_1} H{-}X + R^{\bullet} \qquad (1)$$

Recent stereochemical, kinetic, and ESR studies have shown that this process will also take place, often much more rapidly, at a multivalent metallic center [eq. (2); M = *e.g.* Mg, Zn, Cd, B, Al, Sn, P, As, Sb, Bi], and provides the key to the interpretation of many organometallic reactions.

$$X^{\bullet} + MR_n \xrightarrow{k_2} X{-}MR_{n-1} + R^{\bullet} \qquad (2)$$

Reaction (2) can be studied as a step in a non-chain process if the radical $X^{\bullet}$ (*e.g.* $(CH_3)_3CO^{\bullet}$ [1], $(CH_3)_3CS^{\bullet}$ [2], or $(CH_3)_2N^{\bullet}$ [3]) is generated photolytically (from $(CH_3)_3C{-}O{-}O{-}C(CH_3)_3$, $(CH_3)_3C{-}S{-}S{-}C(CH_3)_3$, or $(CH_3)_2N{-}N{=}N{-}N(CH_3)_2$, respectively) in the cavity of an ESR spectrometer, when the spectrum of the displaced radical $R^{\bullet}$ can be observed.

Reaction (2) can also occur as a propagation step in a chain process if a reagent XY is chosen so that the chain carrier $X^{\bullet}$ is rapidly regenerated by the reaction (3).

$$R^{\bullet} + XY \longrightarrow RY + X^{\bullet} \qquad (3)$$

The overall reaction is that shown in eq. (4).

$$XY + MR_n \longrightarrow X{-}MR_{n-1} + RY \qquad (4)$$

Chain reactions of this type have been established for the radicals $R'C(CH_3)_2O^{\bullet}$ [4], $C_6H_5S^{\bullet}$ [5], $(CH_3)_2N^{\bullet}$ [6], and succinimidyl[7] where the reagent XY is $R'C(CH_3)_2OCl$, C_6H_5SH, $(CH_3)_2NCl$, and bromosuccinimide respectively.

The reaction which has been studied most thoroughly, however, is the autoxidation of an organometallic compound, where the overall addition process (5) involves the propagation steps (6) and (7)[8,9].

$$O_2 + MR_n \longrightarrow ROOMR_{n-1} \qquad (5)$$

$$ROO^{\bullet} + MR_n \longrightarrow ROOMR_{n-1} + R^{\bullet} \qquad (6)$$

$$R^{\bullet} + O_2 \longrightarrow ROO^{\bullet} \qquad (7)$$

The absolute rate constants, k_2, for a number of these S_H2 replacements at metal centers have been determined by a variety of techniques. Some of the values obtained, compared

Table. Rate constants k_1 and k_2 ($mole^{-1}s^{-1}$) for a few S_H2 reactions (Bu = butyl).

X·	HR	k_1	MR_n	k_2	T (°C)
ROO· [9]	$CH_3C_6H_5$	0.24	BBu_3	2×10^6	30
t-BuO· [4]	$(CH_2)_5$	5×10^4	BBu_3	7×10^6	40
$(CH_2CO)_2N$· [7]	—	—	$SnBu_4$	8×10^3	35

with the corresponding values, k_1, for reaction at hydrogen centers, are given in the Table [eq. (1)].

Biogenesis of Steroids in Higher Plants

By *Herwig Hulpke*[*]

A great variety of steroids is encountered as natural products in the animal and plant kingdoms. For this reason an early interest was shown in elucidation of the biogenetic pathways leading to steroids. Tracer studies with acetic and mevalonic acids labeled specifically with radiocarbon revealed a characteristic incorporation of radioactivity into the steroid formed (labeling pattern). *Bloch* and *Lynen* have used this technique to determine the biogenesis of animal steroids.

The following simplified account may now be regarded as valid: Three molecules of acetyl-coenzyme A unite to give mevalonic acid which is converted into "biological isoprene" by dehydration and decarboxylation. Squalene is formed *via* farnesyl phosphate as intermediate and then undergoes a concerted reaction to give lanosterol, from which the steroids are formed.

This pathway was first established for the animal cell, but there is strong evidence suggesting that a similar route is followed in plants. The first cyclization product formed from squalene is cycloartenol, a triterpene common to many plants.

Among the phytosterols, the cardenolides are known as highly cardioactive substances. They differ from most other steroids in a number of characteristic features: Rings A and B are *cis*-linked; C-14 bears a β-OH group; and an α,β-unsaturated lactone ring (butenolide ring) is found at C-17. In biogenesis studies with specifically labeled mevalonic acid in *Digitalis* species, it is seen from the degradation of the butenolide ring that it contains more than one and less than three carbon atoms from the side chain of an "original steroid". Thus the cardenolides are possibly formed from a steroid containing 21 C atoms. Additional support for this concept comes from the observation that steroids containing 21 C atoms — termed digitenols by *R. Tschesche* — can be isolated from plants known to contain particularly large amounts of cardenolides. If [21-^{14}C]hydroxypregnenone[**] is administered to *Digitalis lanata* in the form of the glucoside, the plant is found to produce the cardenolides digitoxigenin, xysmalogenin, digoxigenin, and gitoxigenin.

Further elucidation of the biogenetic pathway has shown that this route leads from hydroxypregnenone to progesterone, then to a C_{21} steroid having a 14β-OH group, and finally to the cardenolides. Steroids having a butenolide ring on C-17 but no 14β-OH group are not converted into cardenolides.

Hydroxypregnenone also plays a significant role in the biogenesis of other plant steroids.

For instance, the formation of hellebrigenin (a cardioactive bufadienolide from the Christmas rose) and conessin (a steroidal alkaloid) from radioactive hydroxypregnenone has been established. As in animals, this precursor can also be formed from cholesterol in plants. Indeed, cholesterol is very important in the biogenesis of plant steroids containing 27 carbon atoms. Steroid saponins such as spirostanols, tigogenin, diosgenin, and gitogenin are formed from administered radioactive cholesterol. Alkaloids having a steroid structure, tomatidin and solanidin, are also formed from cholesterol.

The relatively good yields observed in these incorporations rule out the possibility of the products being formed in side reactions. The metabolic utilization of hydroxypregnenone and of cholesterol in plant tissues and the formation of phytosterols from these typical zoosterols shows that cholesterol and hydroxypregnenone play an important role in the biogenetic processes of higher plants.

Carcinogenic Alkylating Substances, Chemical Constitution and Action[**]

By *Hermann Druckrey*[*]

The prevention of cancer calls for an elucidation of the potential causes and their modes of action. At the same time it is important to produce in experimental animals the various types of tumor which are required as "models" for morphogenetic, biochemical, immunological, and chemotherapeutic studies. In order to achieve specific effects, the "transport principle", which has previously proved useful in cancer chemotherapy, (Honvan, Endoxan) has been used, *i.e.* the use of substances from which the actual "active form" occurs only after metabolic activation. Three groups of substances have been systematically investigated: *N*-nitroso compounds; hydrazo-, azo-, and azoxyalkanes; and 1-aryl-3,3-dialkyltriazenes. The first and decisive step in the activation of these groups of compounds is an enzymatic α-C hydroxylation of an alkyl residue, which is then cleaved off as the corresponding aldehyde. Thus, probably an alkyl diazohydroxide or an alkyldiazonium ion occurs as an alkylating intermediate. The alkylation of nucleic acids, particularly at N-7 in guanine, has been observed and the resulting change of the genetic code in the cells is looked upon as the initiation of their carcinogenic transformation.

These investigations revealed highly specific effects. *Symmetrical* dialkylnitrosamines, for instance, induce predominantly liver cancer, whereas the *asymmetrical* compounds produce carcinoma of the esophagus. Methylbutylnitrosamine proved to be carcinogenic when inhaled even at concentrations as low as 0.05 ppm. However, acylalkylnitrosamides, which undergo easy heterolysis, have a local effect and produce cancer of the forestomach when administered orally; *acetyl*-methylnitrosourea, on the other hand, specifically causes cancer of the glandular stomach. In contrast, the stable and chemically important *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide proved to be comparatively harmless. Striking differences were observed when injecting the compounds intra-

venously: Methylnitroso*urethane* led to lung cancer, methylnitroso*urea* to cancer of the brain.

In the series of hydrazo-, azo-, and azoxyalkanes the methyl compounds selectively produced cancer of the colon and rectum, whereas the ethyl homologs did not; the latter, however, produced malignant tumors of the brain, the olfactory bulbs, cancer of the breast, and leukemias. 1-Methyl-2-benzylhydrazine had an intermediate effect. Azoisobutyronitrile, which is important as an initiator of radical reactions, was not carcinogenic, nor were aliphatic hydrazides azines, and hydrazones; *N*-methyl-benzaldehyde- and -nicotinealdehyde-hydrazone, however, were carcinogenic.

1-Aryl-3,3-dialkyltriazenes proved to be potent *neurotropic* carcinogens. The potency increases in the order: phenyl, 3-pyridyl, pyridyl-*N*-oxide, and methyl, ethyl, respectively. The monoalkyl compounds which, according to *O. Dimroth* (1905) are "stabilized diazoalkanes" and act as alkylating agents, produce local tumors. Methylation of guanine at N-7 could be demonstrated *in vitro* and *in vivo*.

In *transplacental* experiments, a single small dose of an *ethyl* compound from any one of the three classes of substances, when administered to pregnant rats, led to malignant tumors in the brain and nervous system of practically all the progeny, azoethane even after inhalation. The *methyl* homologs, however, were either completely inactive or only slightly carcinogenic to the fetus, as were dialkylnitrosamines.

Since the "active forms" in all three groups of substances are the same *i.e.* alkyldiazonium compounds, the specificity of the effects must be attributed to the whole molecule of the "transport forms" or to their enzymatic activation. The detection of carcinogenic properties in diazomethane and diazoacetate as well as in directly acting alkylating agents such as alkyl halides, aziridines, dialkyl sulfates, and 1,3-propane sultone gives considerable support to the alkylation theory. The potential risk of contact with direct or indirect alkylating agents is emphatically pointed out.

The Significance of Monoterpene Chemistry Today

By *Gunther Ohloff*[*]

Their great structural variety, known stereochemistry, and easy accessibility make the monoterpenes ideal model compounds for the elucidation of many problems in modern organic chemistry. This has been demonstrated in the case of the following two topics: 1. Thermally induced reactions. 2. Chirality of α-ionone and its relation to that of corresponding carotinoids.

The common mechanistic character of the thermal isomerization of the diastereomers of pinane, 2-pinanol, verbenol, as well as of α- and β-pinene, and verbenene, is the stepwise homolysis of the cyclobutane ring. Several series of sigmatropic 1,5-H-shifts take place as secondary reactions, which, in the case of the unsaturated monoterpenes, are accompanied by electrocyclic processes. Thus, *e.g.* (+)-*trans*-verbenol *(1)* is in homolytic equilibrium with *trans*-chrysanthenol *(2)* which subsequently decomposes to (+)-2,2,4-trimethyl-3-cyclohexene-1-carbaldehyde *(3)*.

(+)-Terpin-1-en-4-ol *(4)* is thermally converted, with induction of the center of chirality, into (+)-6*S*-2,6-dimethyl-7-octen-3-one *(5)* [1]. This concerted process is photochemically reversible [2]. The thermal cyclization of linalool (intramolecular ene reaction), the formation of isopulegol from β-citronellal (intramolecular thermal Prins reaction), and the deconjugation of α,β-unsaturated carbonyl compounds are concerted reactions of the sigmatropic 1,5-H-shift type.

The symmetry-permitted process of a sigmatropic homo-1,5-H shift was first reported for 4-carene and related compounds [3].

The configurational relation of α-ionone with degradation products of farnesiferol B and manool led to the establishment of the center of chirality on C-6 of all known carotinoids [4].

These examples illustrate the present significance of monoterpene chemistry for the solution of reaction mechanism and stereochemical problems. Monoterpenes are indispensible as precursors for the industrial preparation of odoriferous substances.

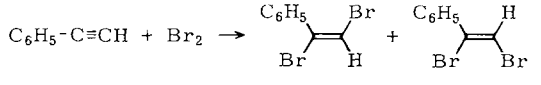
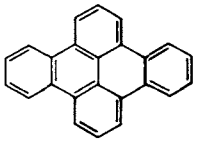
Phenyl nitrones *(1)* have been obtained from nitrosobenzene and phenylhydrazones by *D. W. Berry, R. W. Bryant, J. K. Smith,* and *R. G. Landolt.* The reactions are carried out in absence of solvent or in one of the common solvents at room temperature and preferably under nitrogen.

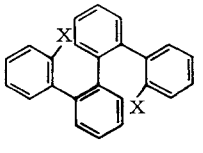


(1)

Of the many compounds suitable as starting materials are the phenylhydrazones of benzaldehyde, substituted benzaldehydes, and fluorenones. The yields are good. / J. org. Chemistry *35*, 845 (1970) / —Kr. [Rd 219 IE]

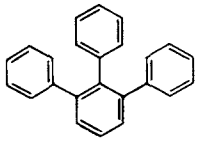


Pure *cis-* and *trans*-α,β-dibromostyrene have been synthesized and characterized by *J. König* and *V. Wolf.* Reaction of phenylacetylene with one equivalent of bromine at 10 °C in glacial acetic acid or chloroform gave *trans-* and *cis-(1)* in the ratio 70 : 30 or 82 : 18 resp. In glacial acetic acid the ratio increases to 97 : 3 on addition of 0.5 equivalent of LiBr;

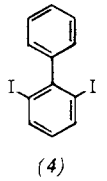


trans-(1) *cis-(2)*

trans-(1) was distilled off at 49 °C/0.02 torr. Pure *cis-(1)* can be readily isolated since *trans-(1)* is preferentially debrominated when a mixture of *cis-* and *trans-(1)* is treated with Zn dust and $ZnCl_2$ in ethanol at 25 °C. The structures were determined spectroscopically. / Tetrahedron Letters *1970*, 1629 / —Kr. [Rd 221 IE]

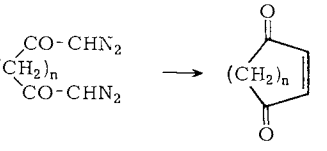


The photo-aryl coupling reaction opens up a new route to the synthesis of polycondensed aromatics. *T. Sato, S. Shimada,* and *K. Hata* obtained dibenzo [*fg,op*]naphthacene *(1)* by irradiation of the following compounds in benzene with a mercury vapor lamp (20—22 hours): *(2)* in presence of an



(1)

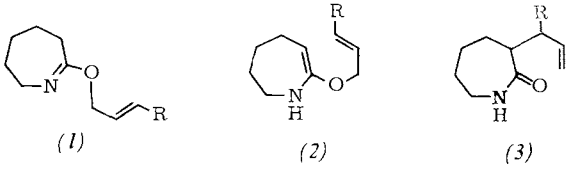
(2), X = H; *(5)*, X = Cl



(3)

(4)

equimolar amount of iodine gave *(1)* in 57 % yield; *(3)* + I_2 → 21 % *(1)*; *(4)* → small amount of *(1)* + 42 % triphenylene + 24 % *(3)*; *(5)* → 67 % *(1)*. The dehydrohalogenative cyclization reaction was successfully used for the synthesis of triphenylene. Irradiation of 2-chloro- and 2-bromo-2′-iodobiphenyl in benzene gave triphenylene in 37 and 25 % yields respectively. / Chem. Commun. *1970*, 766 / —Ma. [Rd 223 IE]



The intramolecular cyclization of bis(α-diazoketones) to cycloalk-2-ene-1,4-diones *(1)* has been achieved by *J. Font, F. Serratosa,* and *J. Valls* by catalytic decomposition in inert solvents using the high dilution principle. For example, the intramolecular cyclization of 1,7-bis(diazo)heptane-2,6-dione in boiling toluene with copper-bronze catalyst affords cyclohept-2-ene-1,4-dione in 20 % yield; by using soluble copper

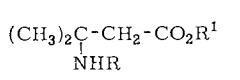
(1)

chelates as catalyst the yield is increased to 32 %. Decomposition of 1,7-bis(diazo)-4-chloroheptane-2,6-dione with copper pentanedionate leads to 6-chlorocyclohept-2-ene-1,4-dione (15 %) from which 4-hydroxytropone (γ-tropolone) can be prepared in 70–75 % yield by promoted loss of HCl on treatment with weak bases. / Chem. Commun. *1970*, 721 / —Ma. [Rd 222 IE]

An extension of the Claisen rearrangement is reported by *D. St. C. Black* and *A. M. Wade.* Caprolactim *O*-allyl ether *(1a)* and *O*-cinnamyl ether *(1b)* undergo rearrangement to 3-allyl- *(3a)*, m.p. 87 °C, 60 %, and 3-cinnamylcaprolactam *(3b)*, m.p. 116—117 °C, respectively, on heating for several

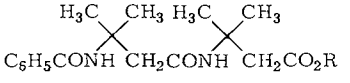
(1) *(2)* *(3)*

a, R = H; *b*, R = C_6H_5



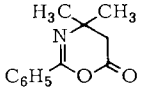
hours in a sealed tube at about 210 °C. Small amounts of *N*-allyl- and *N*-(1-phenyl-1-propenyl)caprolactam are formed as by-products. At higher temperatures compounds *(1)* afford products that are formed by migration of groups to the nitrogen. The isomerization product *(2)* is an intermediate in the formation of *(3)*. / Chem. Commun. *1970*, 871 / —Ma. [Rd 224 IE]

A new contribution to the chemistry of the halogen incandescent lamp is given by *E. G. Zubler.* The kinetics of the tungsten-oxygen-bromine reaction has been investigated. The weight loss of a tungsten sample was monitored in a flow system with 10^{-4}—10^{-2} torr O_2 and 0.3—2.7 torr Br_2 at 600—950 °C (carrier gas, N_2). The reaction was zero order with respect to bromine and first order with respect to oxygen. The function of the bromine is to remove the oxidation product by formation of volatile WO_2Br_2, presumably by the reaction



$$WO_2 \text{ (surface)} + Br_2 = WO_2Br_2.$$

This reaction is independent of the dissociative state of the gaseous bromine and permits the oxidation to proceed as it would at higher temperatures where the oxide is volatile. An empirical rate equation with an apparent activation energy of 31.0 kcal mole^{-1} was established; this activation energy is in good agreement with data for tungsten oxidation at similar pressure, but higher temperatures. / J. physic. Chem. *74*, 2479 (1970) / —Hz. [Rd 228 IE]



Synthesis of peptides from β-amino acids *via* oxazinone intermediates has been accomplished by *J. Lowbridge* and *C. N. C. Drey*. While preparation of peptides from 3-amino-3-methylbutyric acid is very difficult with the usual coupling agents, aminolysis of the intermediate oxazinone proceeds readily to yield the desired product. Thus compound *(1)* gives the oxazinone *(2)* from the dipeptide *(4)* which is formed on aminolysis with the ester *(3)*. Treatment of *(4)* with acetic

(1), R = COC_6H_5, R^1 = H
(3), R = H, R^1 = CH_3

(4)

(2)

anhydride (after hydrolysis) affords the "dipeptide-oxazinone", which gives the tripeptide on reaction with the ester *(3)*. / Chem. Commun. *1970*, 791 / —Ma. [Rd 225 IE]

A nuclear magnetic resonance study of the 2,6-lutidine/water system in the critical region is reported by *Y. Arata* and *T. Fukumi*. In this system, a lower critical point of mixing occurs at 33.93 °C and 29.94 % (w/w) lutidine. Below the critical temperature, the water proton chemical shift moves upfield almost linearly with increasing temperature, but shifts downfield abruptly by about 2 Hz at the critical point. This is interpreted as due to an anomalous increase in the ratio of the hydrogen-bonded to free water molecules. With about 0.2 % tris(1,3-pentanedionato)chromium(III) added, the linewidth of the water proton resonance goes through a sharp maximum at the same temperature (33.02 °C) where the sample exhibits critical opalescence (the critical temperature is lowered by the presence of the chromium "impurity"). These results show that NMR measurements can be useful in investigations of critical phenomena in binary liquid mixtures. / Molecular Physics *19*, 135 (1970) / —Hz. [Rd 229 IE]

The Hall effect and electrical conductivity of lithium-ammonia solutions were measured by *R. D. Nasby* and *J. C. Thompson* at concentrations of 1.2 to 14 mole-% lithium and 200 to 240 °K, except in the miscibility gap (consolute temperature about 210 °K). Above 9 mole-% Li, the Hall coefficients are those expected for free electrons; below this concentration, they increase to about twice the free-electron value. Below 8 mole-% Li, the mobility of the conduction electrons seems to be thermally activated, with a maximum of the activation energy (0.15 eV) at about 3 mole-% Li. These results show that the solutions behave as liquid metals above 9 mole-% Li; at lower concentrations, metallic conduction behavior gradually recedes, and the characteristics of solvated electrons emerge. At 3 mole-% Li the influence of free electrons can no longer be detected. / J. chem. Physics *53*, 109 (1970) / —Hz. [Rd 230 IE]

Oligomeric molecules in acetone, methanol, and formic acid vapors were detected by *H. Knof* and *D. Krafft* in a specially designed mass spectrometer *via* their negative ions. In this mass spectrometer electron source and collision chamber are separated by a tube cooled with liquid air. With electrons of *ca.* 200 eV entering the collision chamber and a vapor pressure of some 10^{-4} torr the yield of negative ions without fragmentation was an optimum. The pressure dependence of the corresponding mass peaks indicates that the negative ions are formed preferentially by electron attachment and not by ion molecule reactions. Appearance of the dimers of acetone and formic acid and of trimeric methanol was verified. With benzene, however, only the monomeric molecule ion was found, and only fragments with cyclohexane, under the same conditions. From intensity ratios it is concluded that a permanent dipole moment is essential for the formation of the oligomers whereas polarizabilities do not seem to play an important role. / Z. Naturforsch. *25a*, 849 (1970) / —Hz. [Rd 231 IE]

The specific heat of [2.2]paracyclophane was measured by *J. T. S. Andrews* and *E. F. Westrum jr.* with the aid of a quasi-adiabatic calorimeter at 10—350 °K. Near 50 °K the temperature dependence of the heat capacity is characteristic of a second-order phase transition. The thermodynamic data of this transition are T_{max} = 55.5 °K, ΔS = 1 ± 0.5 cal mol^{-1}deg^{-1}, and ΔH = 51 cal mol^{-1}. The uncertainty of the transition entropy is due to uncertainties in the extrapolation of the lattice heat capacity. The following explanation for this transition is advanced as most plausible: the strain of the molecule is partly due to the eclipsed conformation of the hydrogen atoms in the bridges. This strain can be reduced by a small twist of the CH_2 links. At low temperatures, the mutual conversion of the two possible conformations is frozen; at temperatures higher than the transition region, the two conformers are interconverted by a torsional vibration. The room temperature X-ray structure of the molecule is the time average of this torsional vibration. / J. physic. Chem. *74*, 2170 (1970) / —Hz. [Rd 232 IE]

Relaxation of sulfur hexafluoride after excitation with 10.6 μ radiation from a pulsed CO_2 laser was studied by *J. I. Steinfeld*, *I. Burak*, *D. G. Sutton*, and *A. V. Nowak*. The time dependence of infrared absorption was followed by means of a second continuous CO_2 laser tunable through several lines in the range 931—954 cm^{-1}. The laser pulse effects overpopulation of some vibration-rotation levels of SF_6 located in the available energy range, thereby causing the corresponding absorption lines to disappear for a short time. Rotational energy transfer fills in this "hole" in the absorption spectrum in not more than two collisions (some 100 nanoseconds). Vibrational energy is dissipated at essentially the same time over all excited vibrational states. The rate-controlling step on returning to thermal equilibrium is vibration-translation relaxation of the lowest excited vibrational level at 363 cm^{-1} with a time constant of 122 ± 8 μsec·torr in pure SF_6. / J. chem. Physics *52*, 5421 (1970) / —Hz. [Rd 233 IE]

The Virial Coefficients of Gases. A Critical Compilation. By *J. H. Dymond* and *E. B. Smith* (Oxford Science Research Papers No. 2) Clarendon Press: Oxford University Press, London, 1969. 1st Edit., xv + 231 pp., bound, 45 s.

Knowledge of the virial coefficients of a gas is very important both from the point of view of industrial applications and for theoretical investigations. This compilation of virial coefficients available up to the beginning of 1968 is therefore most welcome.

The authors begin with a clear and concise introduction to the power expansion of the equation of state for gases, and explain the relationship between the virial coefficients and intermolecular potential. In addition, they give formulas for the calculation of the thermodynamic properties of gases from virial coefficients (fugacity, internal energy, enthalpy, molar heat, entropy, and Joule-Thomson coefficients).

The tables of the virial coefficients of gases stem from earlier work by *McGlashan* dating back to 1955. The substances are arranged according to the Chemical Abstracts system. The search for a given gas is also facilitated by a list of contents arranged according to chemical formulas, as well as an alphabetical one arranged according to the common names.

The publications from which virial coefficients can be determined are given in chronological order for each substance. In most cases there is a brief note stating the method of measurement, the number of coefficients in the power expansion of the equation of state, the maximum pressure and temperature region, and remarks on the accuracy of the measurements and on the agreement between the latter and the data published by other authors. This is followed by tables of values for the second and, where possible, third virial coefficient as a function of temperature, taken from the original literature. The temperatures are always quoted in K. The virial coefficients were always converted to the usual dimensions of $cm^3/mole$ and $cm^6/mole^2$ (for the second and third virial coefficients). Whenever results showing satisfactory agreement were available from several authors, a smooth curve was drawn through all the measurements. The literature data are preceded by the resulting virial coefficients or "best values", for which the estimated error is also stated. This inclusion of "best" values together with the limits of error, the critical remarks on individual literature data, and, not least, the conversion of the data cited to the same dimensions, make *Dymond* and *Smith*'s book a valuable tool for everyone engaged in the study of real gases and intermolecular forces.

Klaus Schäfer [NB 890 IE]

An Introduction to Physical Organic Chemistry. By *E. M. Kosower*. Wiley and Sons, Inc., New York-London-Sydney 1968. 1st Edit., xvi, 503 pp., numerous figures and tables, 115 s.

Once more an American author presents a book on a topic that, since the appearance of *Hammett*'s "Physical Organic Chemistry", should be represented in the library of every chemistry student. The successful textbooks on this subject so far concentrate either on a comprehensive discussion of reaction mechanisms (*Hine*, *Gould*) or on the detailed description of methods (*Wiberg*, *Streitwieser*).

E. M. Kosower includes his introduction in the first group and divides it into three parts: 1. Substituent effects (250 pp.), 2. Solvent effects (120 pp.), and 3. Intermediates and unusual molecules (70 pp.).

In the first part, the acidity of organic compounds and the substituent constants are dealt with first under the heading "Polar Transition States" (130 pp.). Reaction mechanisms follow in the sections on nucleophilic substitution and carbonium ions. The reactions with free-radical and apolar (isopolar) transition states are then given 50 and 60 pages respectively.

The treatment of the various fields is right up to date if one considers the year of publication of the book (the references extend up to 1967). Thus cycloadditions and rearrangements are discussed in the light of the Woodward-Hoffmann rules. Considerable space is also devoted to the discussion of carbonium ion chemistry and of free-radical reactions. However, the text is incomplete in other respects. Reactions of the carbonyl group are practically ignored. Thus one will search in vain for the aldol condensation and the Wittig reaction to name only two examples. As for aromatic substitutions, only the nucleophilic variant is mentioned to illustrate solvent effects. No mention is made of elimination reactions, electrophilic substitutions, or a large number of rearrangements that do not proceed concertedly.

The best rounded-off part of the book is undoubtedly the chapter on solvent effects. The reader is familiarized here with the significance and the problems of this field, which is very important to our deeper understanding of chemical reactions.

Finally, the third part of the book is not satisfactory. Here we again find more or less detailed discussions of carbonium ions, carbanions, and free radicals, which should really have been included in the first part. Thus the temperature-dependent NMR spectrum of the norbornyl cation appears on p. 410, whereas it is discussed on p. 137. Carbene chemistry, which is sought in vain in Part 1, is dealt with here in 15 pages. A few "unusual" molecules are shown in a diagram, but are not discussed further.

In the reviewer's opinion, the book is unsuitable as an introduction, since it omits many important reactions. On the other hand, it offers stimulating reading for the advanced reader. The detailed discussion of solvent effects is very welcome, and the introduction of a new nomenclature for substitution reactions that takes into account the reaction mechanism (with or without intermediate) deserves discussion. The use of the term "methylenoid" instead of "carbenoid", on the other hand, seems less successful. Results of spectroscopic studies are mentioned in gratifying numbers. In view of the large volume of material, it has not always been possible to describe the methods mentioned in detail, so that references to relevant monographs were essential. A detailed grounding of the Woodward-Hoffmann rules would however have been welcome (the non-crossing rule is not mentioned). The book is excellently presented, and 184 examples for practice provide an opportunity reinforcing what has been read. The figures are also clear throughout. In the graphical representation of qualitative Hückel-molecular orbitals (pp. 204, 206), however, the electrons should not have been added as dots at discrete points of the wave function.

Harald Günther [NB 879 IE]

Grundzüge der anorganischen Kristallchemie. Mit einer Einführung in die Theorie der chemischen Bindung (Fundamentals of Inorganic Crystal Chemistry. With an Introduction to the Theory of the Chemical Bond). By *H. Krebs*. Ferdinand Enke Verlag, Stuttgart 1968. 1st Edit., xii + 376 pp., 254 figures, 41 tables, bound DM 45.—.

A wide readership should derive benefit from this excellent introduction to the problems of crystal chemistry. The subtitle gives an indication of the broad area which the author sees as relevant to crystal chemistry (one third of the book). Such a framework does, of course, mean that much appears in unconventional presentation, but the logical application of quantum-chemical theory to a few types of structure is extremely valuable to those interested in this subject. The

material has been subjected to highly judicious pruning so as to preserve clarity and facilitate understanding of the seemingly boundless data. The form and arrangement of the individual sections (atomic structure; bond systems and their utilization; description and explanation of the structures of elements, binary and ternary compounds, alloys and glasses) are novel and are completely subordinated to the chemical problems involved in structural geometry, stoichiometry, and bonding.

A drawback of the book is the scant treatment given to metals and intermetallic phases. One also notes the total absence of complex compounds in the narrower sense. This despite the fact that, in view of the selected framework, the structures of these substances would have been of considerable importance. Furthermore, to the quantum chemist the facts may appear to be clear and understandable – but is this in fact the case?

H.-G. v. Schnering [NB 891 IE]

Enamines. Synthesis, Structure, and Reactions. Edited by *A. G. Cook*. Marcel Dekker Inc., New York-London 1969. 1st ed., xi, 515 pp., numerous formulas and tables, $ 35.75.

The first review of enamines (113 pp.) was written in 1963 in "Advances in Organic Chemistry" by a single author, *J. Szmuszkovicz*. The present second review, which is also the first book on enamines, has eight authors, each of whom contributed a self-contained chapter.

In the first chapter, "Structure and physical properties of enamines" (54 pp.), *S. K. Malhotra* discusses the influence of steric and electronic factors, taking the cyclanone enamines as examples. Only a little information is found on the other enamines in the short sections on IR-, UV-, mass-, and particularly NMR-spectroscopy. No coupling constants or chemical shifts of R_2N–CH=, vinylogous amides, dienamines, enediamines, ketene aminals, and immonium salts or comparisons with the values for other nucleophilic olefins are given here.

The second chapter (46 pp.), "Methods and mechanisms of enamine formation" by *L. W. Haynes*, is mainly confined to tertiary enamines with no functional groups. An excellent survey is presented, though the fundamental work by *Sauer* and *Prahl* on the *cis,trans* isomerism of the enamines deserves a more detailed (and more positive) discussion.

The third chapter (13 pp.), "Hydrolysis of enamines" by *E. J. Stamhuis*, presents a thorough discussion of the kinetics and mechanism of the hydrolysis as a function of the pH value and the structure of the enamine. It shows how the C-protonation, as the rate-determining step, is replaced with decreasing pH by the hydration of the immonium ion and then by the decomposition of the amino alcohol.

In the fourth chapter (54 pp.), "Electrophilic substitutions and additions to enamines", *G. H. Alt* discusses protonation, alkylation, acylation, and reactions with other electrophiles, all reactions that reappear in other chapters. This is only observed later; too late, many readers will think, as they bemoan the lack of coordination. Following the demonstration, by many examples, of the close relationship of electrophilic substitutions and additions with cycloadditions, it would perhaps have been better to consider these reactions together in one large chapter. Mention should be made of the improbable formulation of the reaction with acrolein (pp. 128/129) and to exceptions (ref. 22) to O-protonation and O-alkylation of the acetylacetone enamines.

J. V. Paukstelis gives a very good, concise review of "Nucleophilic addition to iminium salts" in the fifth chapter (41 pp.).

In the sixth chapter (42 pp.), "Cycloaddition reactions of enamines", *A. G. Cook* surprises the reader with his liberal interpretation of the term "cycloaddition" and by his failure to include orbital symmetry considerations. He assumes a two-step mechanism for all cycloadditions, and this is probably why he is rather sparing with formulated mechanisms and with formulas in general. The range of addends includes not only alkenes, alkynes, cumulenes, O_2, isobenzofuroxane, carbenes, carbenoids, and 1,3-dipoles, but also cyclopropanes, cyclopropenes, aziridines, quinones, cumulenes + S, and cumulenes + isocyanide.

In the lengthy seventh chapter (60 pp.), "Heterocyclic enamines" by *O. Červinka*, the preparation, structure, properties, and reactions are followed by a section on aldol reactions of heterocyclic enamines and their importance to the biosynthesis of alkaloids.

The eighth chapter (156 pp.), "Enamines in organic synthesis" by *M. E. Kuehne*, is an excellently written survey. It is characterized by equations in the short form without numbering, more formulas than text, and everything presented in an extremely concentrated manner, though even the most out-of-the-way literature is covered. This chapter is recommended to anyone who wishes a quick survey on enamines.

Rigorous dividing lines between the various chapters have been deliberately avoided, with the result that an unusual amount of overlap occurs. Repetitions, which are quite useful here and there in different contexts, become a problem when *e.g.* alkylation and acylation are discussed in four chapters, and cycloaddition in two chapters besides the chapter devoted to this topic. The number of authors and the number of pages reflect not only the rapid development of enamine chemistry, but also the individual plan of the book: "The objective of this book is to review and correlate in depth the synthetic, mechanistic, and physical properties of enamines. This has been done by surveying the field from eight different perspectives. Since these prespectives have certain common areas between them, and since it seemed desirable to allow each contributor to tell his story in its fullest scope and in his own style, there is some overlapping of material between the chapters. However, it is hoped that the difference of viewpoints and context in which this material appears in these chapters will provide the reader with fresh insights and stimulate further research".

This has led to a very comprehensive but readily readable book. Variety is provided by the different styles of the authors. However, what is an advantage for reading is a disadvantage for reference. Though searches are facilitated by detailed author and subject indexes, it is usually necessary to refer to several chapters (in some cases with the same examples, different nomenclature, and relatively many printing errors and inaccuracies). Apart from the unnecessary overlapping, however, the shortcomings are unimportant against the abundance of information that is provided without verbosity.

The monograph is the most comprehensive review so far of the preparation, structure, physical properties, and reactions of the enamines, mainly the simple enamines with no functional groups on the double bond. The book is generously provided with formulas. Reaction mechanisms are given in varying depths of detail. The literature is covered up to 1968. There is no comparable book on the market, and it is hoped that the price will not prove an excessively severe obstacle to its wide use.

Günter Opitz [NB 883 IE]

Fuel Cells and Fuel Batteries. By *H. A. Liebhafsky* and *E. J. Cairns*. J. Wiley and Sons, Inc., New York-London-Sydney-Toronto 1968. 1st ed., x, 692 pp., 190 figures, 3 tables, bound 258 s.

The book is subtitled "A Guide to Their Research and Development". This points out the main purpose of the authors. They are not concerned predominantly with describing the present position of research and technology in the field on fuel cells, but with showing the reader *how*, *i.e.* by what paths (and detours) this position has been reached, where the main problems lie, and in what direction further investigation seems necessary and worthwhile. This has led to a sort of textbook on battery research, and in fact a textbook of electrochemistry. The first nine chapters (about half of the book) deal with fundamental electrochemical

problems, which are important to electrochemists in general. The special applications to fuel cells are certainly kept in the foreground, but only as a continuous theme that allows these general facts to be illustrated for a particular example.

A brief introduction (Chapter 1) is followed by a historical survey, beginning in 1839 (*Grove*) and ending in 1933 (*Baur* and *Tobler*). This chapter is thus "historical", but not in the sense that we can nowadays pass over it with a tolerant smile. It is in fact here that we see clearly that though refined methods of investigation and advanced technology have led in the meantime to important progress, the fundamental problems have hardly changed, and in particular, the idea postulated by *Baur* is still surprisingly current.

The next few chapters (3—9) present what was described above as a textbook. The thermodynamics and the kinetics of electrode reactions are dealt with in detail; the concept of irreversibility, the types of overpotential, electrocatalysis, and the shape of the current-voltage curve are discussed. The authors attach special importance to the study of transport processes, which are often regarded as being of minor significance, and consequently go into great detail in this chapter (79 pages). The next sections lead us more toward the practice of fuel cells; these are the chapters on the electrode structure, experimental methods, and the oxygen and hydrogen electrodes.

This first, general part of the book has already presented all the theoretical and practical information about "normal" fuel cells (H_2/O_2 in aqueous electrolytes) that is worth knowing, so that only special types remain to be discussed separately in the succeeding chapters (10—13). These are systems that use liquid fuels, those that utilize hydrogen indirectly, *i.e.* after conversion of hydrocarbons, those that burn hydrocarbons directly, and those in which non-aqueous electrolytes, *i.e.* molten salts or solid electrolytes, are used. The discussion of ion exchangers as electrolytes (Chapter 14) leads over to the description of complete fuel batteries (Chapters 14 and 15). The authors confine themselves here to two types that have already proved themselves in practice, *i.e.* the batteries developed by General Electric for the Gemini space missions and the methanol batteries constructed by Brown-Boveri for the long-term supply of power to television translators. This limitation is justified on the grounds of the enormous amount of data, which cannot be covered in a single book. On the other hand, because of this very abundance of material, the reader would expect such a comprehensive work to contain a critical selection of fundamentally or technically interesting prototypes, even if these have not yet come into practical use, even at the risk of being proved wrong in the assessment of future prospects. Instead of this the last chapter, which deals with the decisive step from the fuel *cell* to the fuel *battery*, closes with a consideration of the main problems involved, though further information can be obtained from references. The surprising brevity of the discussion of the technique of battery construction is compensated for, however, by a more thorough account of the development and practical testing of the Gemini batteries, interesting details of which can be provided by the authors as former employees of General Electric.

The book on the whole is thorough, comprehensive, and flowingly written in the "dry" theoretical sections. Its main value probably lies in the fact that it is a valuable source of information for the expert, but is equally suitable for use by the non-expert as an understandable introduction to what is for him a new field. Despite the continuous theme, each chapter, and particularly those that are predominantly theoretical, is self-contained (some of them have already been published as independent articles), so that special sections may be skipped for a general picture. This is particularly worthy of mention in that in this age of space travel, which has provided the most spectacular demonstration so far of the value of fuel cells, even many who are not electrochemists may be expected to have an interest in these modern sources of current.

Helmut Schmidt [NB 877 IE]

The Use of Chemical Literature. Published by *R. T. Bottle*. In the series "Information Sources for Research and Development". Butterworth, London 1969. 2nd Edit., xii + 294 pp., numerous illustrations and tables, bound 65 s.

The present book is the first in the series "Information Sources for Research and Development" published by *D. J. Foskett* and *R. T. Bottle*. Since important changes have taken place in the field of information since the appearance of the first edition (1962)[*] the authors have revised and expanded almost every chapter. Thus, sections have been added on spectroscopic data, physical methods, literature on analytical chemistry, and sources relating to prices and manufacturers of chemicals. The original chapters on data collections, physicochemical literature, literature on inorganic chemistry, nuclear chemistry, organic chemistry with a special chapter on Beilstein, and patents have been supplemented by a chapter on polymer chemistry. New also is the chapter on less conventional sources of information like market reports, personalities (Who's Who?) *etc.*

Although the work is designed predominantly for scientists from the English-speaking world, as the publisher emphasizes at the beginning, and the directions for the use of the chemical literature were written from this standpoint, the book should be generally useful to all readers interested in this field. The chapters on the work of libraries, primary literature (journals, reports, dissertations), secondary literature, in which the well-known larger abstracting services are described in detail, and works of reference give a particularly good survey even though the German-language services, which of course are important for the German scientist, are given only incomplete coverage.

A special chapter is devoted to translations and translation journals. A reference section for Russian literature is also supplied. The list of acronyms used in the literature and their meanings (Appendix I) is extremely useful. Appendix II contains exercises (with answers) on problems broached in the book.

It is difficult to see why Dissertation Abstracts and information services are mentioned under primary sources, while there is no reference to patents in this section. Furthermore, the Signal Information from the All-Union Institute for Scientific and Technical Information, Moscow, is not included in the section on information services while the reference to Express Information is inappropriate at this point.

The index at the end of the book is valuable, like every aid to search, but unfortunately random checks showed that it is not complete (no entry under CA Condensates and Basic Journal Abstracts and no reference to the paragraph on ASLIB on p. 18).

Despite its minor shortcomings, however, this book can be recommended to those interested in the field of information.

Christian Weiske [NB 887 IE]

The Biochemistry of Folic Acid and Related Pteridines. Vol. 13 in the series "Frontiers of Biology". By *R. L. Blakley*. North Holland Publ. Co., Amsterdam-London 1969. 1st ed., xxi, 569 pp., Dfl. 90.—.

The chemist knows the pterins only as an unusual class of rather intractable heterocyclic natural pigments that lead a somewhat aloof existence in the wings of the brimstone butterfly or in the skin of frogs. The biochemist also knows that pteridines and pteridine derivatives occupy key positions in metabolism as cofactors of several reactions. They have recently attracted increasing attention from plant physiologists as primary photoelectron acceptors in green leaves, from which the best-known conjugated pteridine derivative, folic acid, takes its name. However, relatively simple unconjugated pterins are active here and in the hydroxylation of aromatic rings; the more complex folic acid, on the other

[*] See Angew. Chem. *75*, 740 (1963).

hand, must be reduced to the tetrahydrogenated cofactor before it acquires its coenzyme functions in the metabolism of the active C_1 units, their transfer, and their interconversion. This enables them to act in the degradation of histidine and serine, in the synthesis of purines and nucleic acids, in the biosynthesis of methionine, in the formation of methane, and finally as an induction cofactor for protein synthesis in bacteria and cell organelles. Vitamin B_{12} derivatives also take part in some reactions of the C_1 compounds, and this leads to a system of vitamin interrelations that has not yet been fully elucidated. The pteridines are biosynthesized from the purines (the cell synthesis of which is itself folate-dependent); the biosynthesis of the folate cofactors also requires *p*-aminobenzoic acid, and can be blocked by sulfonamides, as well as by folate antagonists that inhibit the folic acid reductases. This offers various possibilities of chemotherapeutic interventions in the metabolism, which have become very widely used, as is well known.

All these confusing facts are presented carefully and faultlessly by *R. L. Blakley*, a pioneer of several fields of the chemistry and biochemistry of folic acid coenzymes, in this fine volume. The subject matter ranges from the nomenclature of conjugated and unconjugated pteridines, their occurrence in nature, and their chemistry and biochemistry to the enzymatic reactions catalyzed by them and carried out with them (in some cases in conjunction with the corrin cofactors) for absorption, storage, and analysis. The extensive original literature up to 1967 has been almost completely sorted, ordered, and critically evaluated. This skill in the assessment of the arguments is seen in the analysis of the data and observations reported by various groups of workers, which are discussed fairly and never without a careful and reasonable judgement based on experience with the difficult material and the experimental traps that result from premature interpretations. This is an excellent book in every respect, in which the answers to all relevant questions can be found. The factual information and the comparison of hypotheses will provide the reader with welcome stimuli as well as warnings. The presentation of the book is also extremely good, free from errors, and an aesthetic pleasure, particularly in the clear formulas.

L. Jaenicke [NB 885 IE]

The Structure and Action of Proteins. By *R. E. Dickerson* and *I. Geis*. Harper and Row, Publishers, New York-Evanston-London 1969. 1st Edit., viii + 120 pp., numerous figures, paperback, DM 20.50.

In conjunction with the determination of amino-acid sequences, X-ray structural analysis of crystallized proteins has opened up completely new horizons for the understanding of enzymes. The importance of this development has not so far been adequately reflected in introductory biochemistry textbooks. One does of course find the obligatory illustration of the hemoglobin molecule, but the accompanying text is invariably so meager as to contribute very little to one's understanding of protein structure; at best it can merely highlight the current importance of this field.

In the circumstances it is gratifying to report that the beginner will find X-ray enzymology very clearly explained in the present book by *Dickerson*, of the California Institute of Technology, who has himself taken part in a number of X-ray structural investigations. Starting with amino acids, a description is given of the rules according to which a peptide chain can fold itself to the secondary structure, and of the stability conditions (using the Ramachandran diagram). This is followed by a lucid and detailed, though not overelaborate discussion of the form of structural proteins (silk fibers, α-keratin, collagen), molecular carrier proteins, (myoglobin, hemoglobin, cytochrome c), and enzymes (lysozyme, ribonuclease, chymotrypsin, papaine, carboxypeptidase).

The book ends with a chapter on electron-microscope studies of proteins, which are built up from a number of subunits. Just to whet the appetite, the author refers briefly, when considering future prospects, to the complement system from the standpoint of the enzymologist. Nowhere will the reader find himself bogged down in purely descriptive, morphological treatment, every effort being made to bridge the gap between structure and function. Proteins are regarded as machines on the molecular scale, with the atoms as moving parts. A decisive contribution to didactic clarity has been made by *Irving Geis*, who has already gained world-wide acclaim for his brilliantly executed illustrations in the Scientific American. Both text and the illustrations in this introductory textbook are exemplary. A supplement containing 55 stereo illustrations of nine of the proteins discussed in the book and accompanied by a simple viewer constitute another useful feature. The book may be warmly recommended to everyone interested in the development of modern biochemistry.

Guido Hartmann [NB 892 IE]

Methoden der organischen Chemie (Houben-Weyl). Bd. VII, Teil 4: Sauerstoffverbindungen II (Methods of Organic Chemistry (Houben-Weyl). Vol. VII, Part 4: Oxygen Compounds II). Edited by *Eugen Müller*. Georg Thieme Verlag, Stuttgart 1968. 4th Edit., ix, 508 pp., numerous formulas, bound DM 178.—.

The present volume describes the preparation and transformation of isatins, thionaphthenequinones, ketenes, carbon suboxide, and ketene derivatives.

The first two chapters, on isatins and thionaphthenequinones (including 3-hydroxythionaphthenes) (pp. 1—51) provide the dye chemists with a detailed survey of historically interesting and now apparently closed field of indigoid dyes.

Most of the volume (pp. 53—447) deals with the diversified field of ketenes and ketene derivatives, which is of great importance to the preparative organic chemist. In addition to the preparation methods which are already regarded as "classical", such as the pyrolysis of ketones and carboxylic acid derivatives, the modern photochemical methods (pp. 73—75) and the photofragmentation method (p. 106) for the preparation of ketenes are also described.

Considerable space (pp. 113—225) is devoted to the many applications of the extremely reactive ketenes. In addition to their use as acylating agents for compounds which contain active hydrogen, the addition reactions, which frequently proceed with cyclization (*e.g.* formation of β-lactams and dihydropyridines, 1,4-cycloadditions, additions of ketenes to enamines, vinyl ethers, and isocyanates), and which have led to a wide range of novel heterocyclic compounds, are also discussed. Reactions with carbonyl compounds, which lead to different products depending on the reaction (*e.g.* to β- or γ-lactones), are then dealt with. Separate chapters are finally devoted to reactions with halogens, inorganic acid halides, and organometallic and nonmetallic organoelement compounds.

The next section (pp. 226—285) deals with the preparation and transformation of diketenes and of oligomers and polymers of ketenes. One of the most important properties of diketene is its ability to act as an acetoacetylating agent (3-oxobutanoylating agent) for hydroxy and amino compounds. In suitable cases these compounds react further to give heterocyclic compounds, in the same way as acetoacetic ester. A subsection deals with the use of diketene for *C*-acetoacetylation in the presence of Lewis acids. The preparation and reactivity of alkylketene dimers, ketoketene dimers, ketene oligomers, and ketene polymers are then discussed. As in the other chapters, the material is presented clearly here with the aid of numerous tables.

Carbon suboxide is described in monograph (pp. 286—311) form. The preparative chemist is still very interested in this fourfold heterocumulene. It is therefore particularly pleasing to find that its many reactions have now been described in

detail. The sulfur analogs thioketene and carbon subsulfide are also mentioned briefly.

The last part of the volume (pp. 323–447) describes the preparation and transformation of ketene derivatives, *i.e.* ketenimines, ketene *O,O*- and *O,N*-acetals, and ketene mercaptals and aminals (*N,N*-acetals). The syntheses and properties of this class of compounds have only recently been investigated in detail. Owing to their relationship with the ketenes, the preparative organic chemist will find here reactive starting compounds for the preparation of many heterocyclic ring systems and other valuable intermediates, such as amidines, esters of carboxylic acids, ortho esters, acetoacetic ester derivatives, and cyclobutane derivatives.

Though more up-to-date formulations of the reaction mechanisms would appear desirable in some places (*e.g.* diazoketone rearrangement p. 87ff., 2-halogenocyclobutanone rearrangement p. 103, acyl-sulfonium ylide rearrangement p. 107, carboxylic acid imide formation p. 336), the present volume provides an excellent survey of the varied material. It is presented lucidly, and is well supplemented by many practical examples. The literature has been covered up to the end of 1967. The evaluation of many patents and BIOS and FIAT Reports makes this work an up-to-date, valuable aid for the preparative chemist, which fills a marked need.

Kinetic Evidence for Reactive Intermediates[**]

By Rolf Huisgen[*]

Spectroscopic methods have recently been developed that allow the direct detection of reactive intermediates under favorable circumstances. The most general and reliable method, however, is still the indirect one, which makes use of the principle of kinetic competition; this method is based on the freedom of the intermediate to choose between several reaction possibilities. The following discussion is addressed less to the specialist in reaction mechanisms than to the outsider who wishes to obtain some idea of the value and limitations of the kinetic method.

1. Fundamental Concepts

It is not true that chemists became interested in reaction mechanisms only about 40 years ago. The reaction event fascinated even the chemist of earlier periods, but the knowledge and methods required for the experimental testing of views on reaction mechanisms were lacking. These workers, consequently, often had to be satisfied with determining the stoichiometry of a reaction.

The methods that have been developed in the meantime have led to a rapid growth of our knowledge of reaction mechanisms. The term *reaction mechanism* leads us first to think of the *structural changes* in the components during the reaction event. Changes in the distance functions and bond lengths can be described, possibly supplemented by electron density and charge separation. The conceptual clarity of these pictures and models was enhanced by the introduction of *energy relations*. At the beginning of his course, the chemistry student of today is taught to look on the interplay of the molecules as an "energy landscape". Depending on their internal energy content, the molecules or collision complexes move up and down in their potential troughs. The reaction event is associated with escape from such a trough, *i.e.* with passage over its rim.

[*] Prof. R. Huisgen
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[**] Based on a GDCh training course from October 6–9, 1969 in Munich.

The structural and energetic approaches are combined in the *energy profile*. The chemical potential of the reacting system is plotted on the ordinate, preferably as the free energy, and the abscissa is the *reaction coordinate*, a geometrical parameter symbolizing the interplay of successive breakage and formation of bonds. The energy profile may consist of a single barrier, the summit of which is referred to as the *transition state*; the *activation energy* $\Delta G^{\ddagger}$ must be supplied in order to reach this peak. This is followed by a descent into a trough with liberation of energy; the amount by which the energy set free exceeds the activation energy is known as the heat of reaction. The molecules or collision complexes usually leave their potential trough at the lowest point, even if this reaction path does not lead to the product with the maximum bond energy. The chemical reaction is controlled *kinetically*, *i.e.* by the height of the activation barrier, and not *thermodynamically* by the quality of the product, unless a series of forward and reverse reactions allows the thermodynamically favored outcome.

Many reactions that were described earlier by a simple activation peak (Fig. 1a) have turned out to be more complicated systems, frequently even involving several intermediates (Fig. 1b).

Transition states are not really "states" with finite lifetimes, but snapshots. On the other hand the dips in the energy profile, *i.e.* the intermediates, have definite lifetimes. Energy profiles can resemble a cross section through the Alps. A feature that they share with a mountain panorama is that only the *first* peak can usually be seen from the bottom, and one certainly

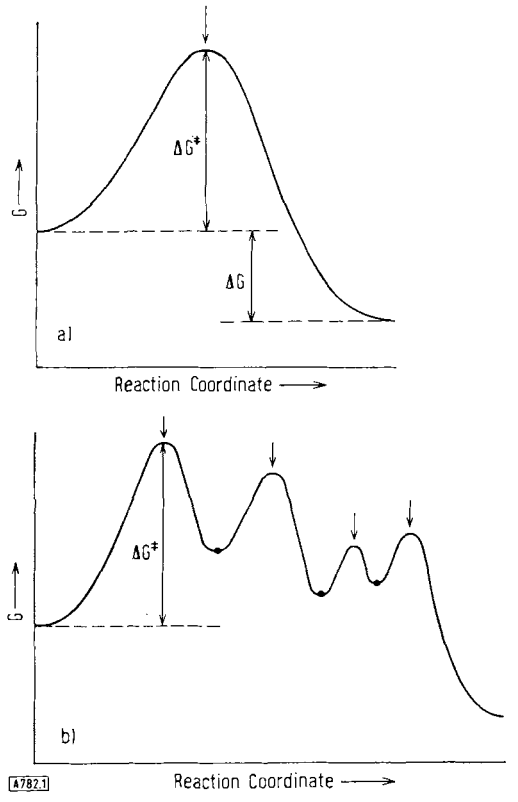

Fig. 1. Energy profiles of reactions (a) without and (b) with intermediates.
↓ : transition states; • : intermediates.

cannot see over the highest ridge. The rate-determining step of the system is the conquest of the highest peak. This is the only peak about which information is provided by the *overall kinetics* with the activation enthalpy and the activation entropy.

How does one obtain information about what happens behind the first high ridge? In other words, how does one detect *intermediates*? Only a few decades ago it was considered irresponsible to postulate intermediates that could not be isolated and stored in flasks. Nowadays scepticism is aroused by any claim to the isolation of a reactive intermediate as such. The substance in question is all too often a compound from a side-equilibrium of the kinetic system. The walls of the energy trough in which the reactive intermediate lies are often so low that the material cannot collect here, but flows away rapidly with formation of the products. To detect short-lived intermediates directly, it is necessary either to produce a sufficiently high stationary concentration, as occurs *e.g.* in flash photolysis, or to use an extremely sensitive method of analysis; ESR spectroscopy, for example, responds even to very small concentrations of free radicals. Though such spectroscopic methods provide valuable information on the nature of intermediates, they are not free from the above shortcoming in the distinction of main path and side-equilibria.

Elegant and reliable criteria for the detection of unisolable intermediates are based on *kinetic competition*. If there is only one energy peak between the reactants and the product, the product cannot contain anything that was not already present in the starting system, *i.e.* that did not enter into the rate-determining activation process; the energy profile is unambiguous. A dip in the energy profile, on the other hand, may be interpreted as a "breather" of the reacting system. The system comes to rest here, and can choose between several possible reactions. It can enter bonding interactions with molecules that were not involved in the first, rate-determining step, *i.e.* in the formation of the intermediate.

$$A \longrightarrow \underset{\text{Intermediate B}}{B} \longrightarrow C \qquad B \rightleftarrows A \longrightarrow C$$

in main path — in side-equilibrium

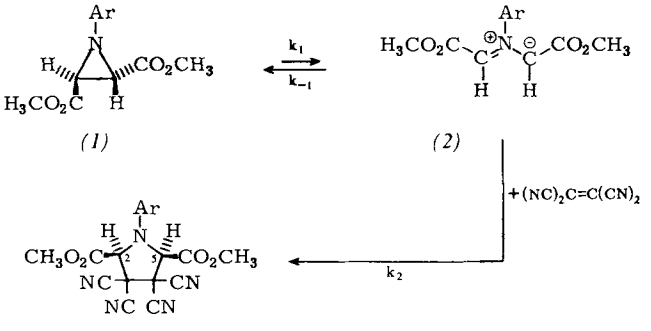
A well-chosen competition system gives reliable evidence for an intermediate, but not much more. Information about its nature is limited; such information may be available from the type of the reactions between which the intermediate chooses. As to the structure of the intermediate, analogies or the introduction of further experimental criteria, such as the steric course of the reaction, are necessary. Some role must also be given to chemical intuition here, though not to utter fantasy. Great caution should be exercised in the postulation of new elementary reaction steps or in the assumption of more intermediates than are verified experimentally and by convincing analogy. A principle that applies in all natural sciences, and which is known as *Occam*'s razor[1], enjoins the use of the simplest possible description: *Entia non sunt multiplicanda praeter necessitatem.*

What are reactive intermediates? It is not easy to add chemically to the above definition as a "dip in the energy profile". One usually thinks first of short-lived radicals, carbonium ions, carbanions, carbenes, azenes (nitrenes), and the like; some compounds of these classes can be intercepted and isolated. However, the range extends far beyond the electron-deficient and electron-rich compounds, as is shown by singlet oxygen[2], diimine[3], strained ring systems, unstable oxidation states, or energetically unfavored valence tautomers. Photo-excited states all belong to this group. Close relatives of classes of compounds that are known to be stable sometimes also defy isolation, and kinetic detection then becomes necessary, as illustrated later for diphenylnitrilimine.

If many of the examples described below are taken from our own work, this is not because we attach particular importance to it, but is rather intended to show that the kinetic detection of intermediates is a routine method for research on reaction mechanisms.

2. Reaction Order as Evidence for Intermediates

If the reaction product contains a structural unit that does not appear in the rate equation of the determining step, it is logical to conclude that an inter-



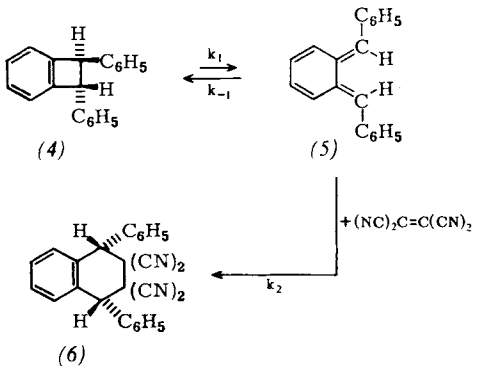
[1] *William of Occam*, born near London in 1285, died at Munich 1349.
[2] *C. S. Foote*, Accounts chem. Res. *1*, 104 (1968).
[3] For a review, see *S. Hünig, H. R. Müller*, and *W. Thier*, Angew. Chem. *77*, 368 (1965); Angew. Chem. internat. Edit. *4*, 271 (1965).

mediate is involved. The rate equation in this case does not reflect the stoichiometry of the process as a whole.

Aziridines of the type *(1)* can enter into cycloadditions in which the CC bond is broken [4, 5]. If we follow the adduct formation with tetracyanoethylene at 100 °C dilatometrically, we find that the rate equation does not contain the concentration of tetracyanoethylene, as long as it is present in an at least equimolar amount [6]. The equation is

$$d\,[\text{adduct}]/dt = k_1\,[\text{aziridine } (1)]$$

Experiments with 10, 20, and 30 equivalents of tetracyanoethylene gave the same dilatometric first order rate constant.



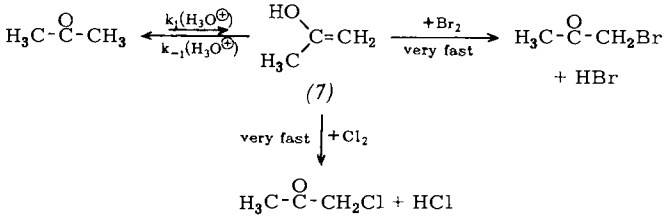
(1) *(2)* *(3)*

Ar = $C_6H_4OCH_3$-*p*

A step preceding the cycloaddition must therefore alone be rate-determining. It is not the aziridine *(1)*, but the azomethine ylide *(2)*, which is present in a low equilibrium concentration and combines as a 1,3-dipole with the olefinic dipolarophile. The reaction with tetracyanoethylene is so fast that the reverse reaction *(2)*→*(1)* is completely suppressed and the rate of the adduct formation is determined only by the ring cleavage *(1)*→*(2)*, *i.e.* by k_1.

The intermediate *(2)* can be detected stereochemically as well as kinetically. The aziridine-*trans*-2,3-dicarboxylic ester *(1)* gives a cycloadduct *(3)* with ester groups in the *cis*-2,5 positions. Such a steric course is inconceivable in a one-step process. A satisfactory explanation is provided by the *conrotatory* ring cleavage *(1)*→*(2)* [5].

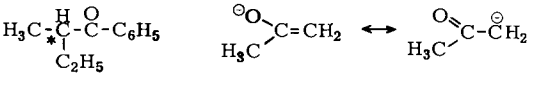
Interrelations of benzocyclobutenes with *o*-quinodimethanes have been postulated, but the valence tautomerism *(4)*⇌*(5)* was demonstrated only by kinetic measurement of the adduct formation with tetracyanoethylene. As in the last example, the reaction rate depends only on the concentration of the 7,8-diphenylbenzocyclobutene. The constant k_2 is so large that the reverse reaction *(5)*→*(4)* is of no importance. The steric course also confirms the occurrence of the



(4) *(5)* *(6)*

o-quinodimethane *(5)* as an intermediate, since the *trans*-diphenyl compound *(4)* gives a Diels-Alder adduct *(6)* with *cis*-phenyl residues [7].

A classic example of the discrepancy between stoichiometry and the rate equation is found in the halogenation of acetone in aqueous acid. *Lapworth* [8] discovered that bromine participates with "zero order" and that the rate is determined by the concentrations of acetone and of acid:



$$-\,d\,[\text{acetone}]/dt = k_2\,[H_3O^+]\,[\text{acetone}]$$

The chlorination proceeds with the same rate constant as bromination; in both cases an intermediate is intercepted by the halogen, the formation of this intermediate determining the overall rate of the reaction.

(7)

Regarding the nature of the intermediate, all we can learn from the kinetic investigation is its high rate of halogenation. Since the acid-catalyzed iodination and racemization of (+)-methylethylacetophenone *(8)* also show the same rate constant [9], it seems likely that the enol form *(7)* of acetone is involved. Kinetic measurements give equal rate constants for the base-catalyzed iodination and bromination of acetone, the reactions being of zero order with respect to NaOCl and NaOBr, respectively [10]. The decisive role of the enolate ion *(9)* was underlined by the observation that alkali-catalyzed racemization and H,D-exchange in the optically active ketone *(8)* proceed with equal rate constants [11].

3. Competition of Forward and Reverse Reaction

In all the examples considered above, the rate-determining process was a tautomerization. In the absence of an intercepting reagent, the reactive tautomers occur in equilibrium concentrations so small that they cannot be detected directly. This means that the formation of the reactive tautomer (rate k_1) is much slower than its reverse reaction (k_{-1}). A reaction order of zero for the intercepting reagent indicates that the combination of this reagent with the intermediate is even much faster than the reverse reaction mentioned.

If k_{-1} and k_2 are of the same order of magnitude, this does not affect the reliability of detection of the intermediate. The rate equation becomes somewhat more complicated, and the intercepting reagent is now involved as a function of its concentration. The Diels-Alder reactions of cyclooctatetraene, which are accompanied by rearrangement, may be taken as an example. The addition of tetracyanoethylene is preceded by tautomerization to bicyclo[4.2.0]octatriene

(11); the equilibrium concentration of *(11)* found indirectly from kinetic data is only 0.01 % in dioxane at 100 °C [12].

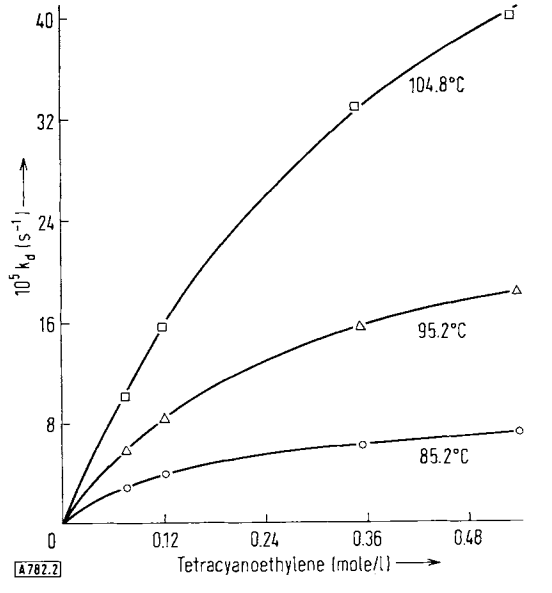

Fig. 2. Dilatometric rate constants k_d for the reaction of cyclooctatetraene (0.02 mole/l) with excess tetracyanoethylene in dioxane at various temperatures.

[12] *R. Huisgen* and *F. Mietzsch*, Angew. Chem. *76*, 36 (1964); Angew. Chem. internat. Edit. *3*, 85 (1964).

The formation of *(12)* is followed dilatometrically, evaluation as a first or pseudo-first order reaction being allowed by the use of a sufficiently large excess of dienophile. Figure 2 shows dilatometric constants (k_d) of this type as a function of the excess of dienophile and of the temperature. If the bimolecular combination with the dienophile alone were rate-determining, the results should be straight lines passing through the origin; $k_d = k_{1\psi}$ should be proportional to [D] (dienophile concentration).

The quantitative evaluation of the competition of reverse and forward reactions makes use of the *steady state* approximation (Bodenstein theorem) [13,14]. The change in the concentration of the intermediate *(11)* is negligible compared with those of *(10)* and *(12)*, and is equated to zero.

$$\frac{d\,[(11)]}{dt} = 0 = k_1\,[(10)] - k_{-1}\,[(11)] - k_2\,[D]\,[(11)]$$

$$[(11)] = \frac{k_1\,[(10)]}{k_{-1} + k_2\,[D]}$$

$[(11)]$ can be substituted in the rate equation for the adduct formation:

$$\frac{d\,[(12)]}{dt} = k_2\,[D]\,[(11)] = \frac{k_1 k_2\,[(10)]\,[D]}{k_{-1} + k_2\,[D]}$$

Comparison with the overall equation for the dilatometric measurement

$$d\,[(12)]/dt = k_d\,[(10)]$$

yields k_d as a function of [D]:

$$k_d = \frac{k_1 k_2\,[D]}{k_{-1} + k_2\,[D]}$$

Simple transformation gives the equation of a straight line for a plot of k_d against $k_d/[D]$; k_1 is the intercept on the ordinate and $-k_{-1}/k_2$ is the slope.

$$k_d = k_1 - \frac{k_{-1}}{k_2}\,\frac{k_d}{[D]}$$

In the extreme case $k_2/[D] \gg k_{-1}$, which was dealt with in Section 2, this expression becomes $k_d = k_1$. Since the k_d values in Figure 2 give straight lines in this new type of plot (Fig. 3), the kinetic system must be correct. The competition of a first order reverse reaction with a second order cycloaddition proves the occurrence of an intermediate in this case. At an infinitely high dienophile concentration, *i.e.* for $k_d/[D] = 0$, we obtain $k_d = k_1$. From the temperature dependence of the extrapolated k_1 values, the following values result for the activation process of the valence tautomerization: $\Delta H^{\ddagger} = 28.1$ kcal/mole; $\Delta S^{\ddagger} = +1$ e.u. [15].

[15] *F. Mietzsch*, Dissertation, Universität München 1965.

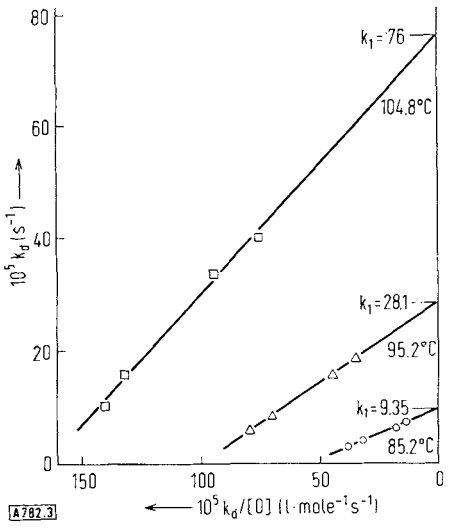

Fig. 3. Dilatometric constants of Fig. 2 plotted against $k_d/[D]$.

This tells us nothing about the nature of the intermediate. Bicyclooctatriene *(11)* has the quasi-planar diene system required for the Diels-Alder reaction, while *(10)* has not. In the equilibrium *(13)*⇌*(14)*, in which both tautomers can be isolated, only *(14)* again adds dienophiles[16]. The extrapolated k_1 values should be independent of the nature of the dienophile, as has in fact been shown for *(10)* and its phenyl derivative[13]. *Vogel, Kiefer,* and *Roth*[17] were able to confirm the existence of *(11)* by its preparation at −78 °C; *(11)* changes into *(10)* even below 0 °C.

(13) *(14)*

(15) *(16)*

The Diels-Alder adducts of cycloheptatriene *(15)* are structurally derived from norcaradiene *(16)*[18]. Kinetic measurements on the reaction with tetracyanoethylene gave k_d values that were proportional to the dienophile concentration over the entire range measured[19]. This means that the establishment of the equilibrium *(15)*⇌*(16)* is fast in comparison with the Diels-Alder reaction. The intermediate cannot be detected kinetically in this case. If it is assumed that the diene activity of *(16)* can be equated to that of *(14)* (equal k_2 values for the addition of tetracyanoethylene to the cyclohexadiene portion of the two molecules), a 0.1 % equilibrium concentration of *(16)* at 20 °C would lead to k_d values of the order found.

The classification of nucleophilic aliphatic substitutions as S_N1 and S_N2 by *Hughes* and *Ingold* is based on the kinetic criterion[20]. An ionization was postulated as the rate determining step for the first order substitution. It is interesting to note that kinetic evidence for the carbonium intermediate comes only from the deviations from the first order.

$$R{-}Cl \underset{k_2}{\overset{k_1}{\rightleftarrows}} R^{\oplus} + Cl^{\ominus} \xrightarrow[k_\psi]{+\,2H_2O} R{-}OH + H_3O^{\oplus} + Cl^{\ominus}$$

The ionization of 4,4′-dimethylbenzhydryl chloride *(17)* in aqueous acetone leads to a rather selective carbonium ion, which can not only react with water to give benzhydrol *(19)* but can also combine with chloride ion formed to regenerate the starting material. The kinetic situation, a combination of a reversible and a consecutive system, is similar to that described above, except that a second order reverse reaction (k_2) now competes with a pseudo-first order forward reaction (k_ψ) (since water is a component of the solvent, its concentration remains practically constant) for the intermediate. As above, the Bodenstein theorem is applied.

$$d[R^{\oplus}]/dt = k_1[RCl] - k_2[R^{\oplus}][Cl^{\ominus}] - k_\psi[R^{\oplus}] = 0$$

$$-\frac{d[RX]}{dt} = \frac{k_1[RCl]}{(k_2[Cl^{\ominus}]/k_\psi) + 1} \approx k_{overall}[RCl]$$

The ratio $k_2[Cl^{\ominus}]/k_\psi$ in the denominator is the competition constant of the reverse reaction and the carbinol formation. The hydrolysis of dimethylbenzhydryl chloride thus begins with the rate constant k_1 as long as no chloride ions are present. As the reaction proceeds, the liberated chloride ions cause a decrease in the overall hydrolysis constant. $k_{overall}$ is thus no longer really a "constant", and the treatment as a first order reaction is no longer a permissible approximation. In the special case, $k_{overall}$ falls to 72% of the initial value after 90% conversion when a 0.04 M solution of *(17)* in 85% aqueous acetone is used[21]. If the chloride ion is present in the solution from the outset, *e.g.* as 0.06 M LiCl, the hydrolysis begins with only 54% of the $k_{overall}$ value found without the addition of the salt. The hydrolysis constant of triphenylmethyl chloride in 85% acetone is decreased by a factor of 4 on addition of 0.02 M NaCl[22].

The influence of the chloride ion on the hydrolysis constant is even greater than appears from the above data. The kinetic scheme is further complicated by the

fact that salts in general cause an increase in the ionization rate by increasing the ionic strength of the solvent [23]. This acceleration by the salt effect is overcompensated in the case of the chloride ion by the regeneration of the organic chloride.

4. Rate-Product Discrepancy

This term covers the evidence for intermediates on the basis of incompatibility of the rate equation with the stoichiometry (see Section 2). We shall use the term rate-product discrepancy primarily to denote the absence of *quantitative* agreement.

If 0.05 M sodium azide is added to a solution of 4,4'-dimethylbenzhydryl chloride *(17)* in 85% acetone, the rate constant of the solvolysis increases by 48%; the product contains 60% of the organic azide *(18)* and 40% of the carbinol *(19)* [23]. If the increase in rate were due to a direct reaction of the chloride *(17)* with the azide ion, only 32% of *(18)*

should be expected. The rate acceleration is in fact a salt effect, which occurs to an equal degree on addition of 0.05 M tetramethylammonium nitrate. The reaction with the azide ion thus takes place only at the carbonium stage, where azide and water are competing.

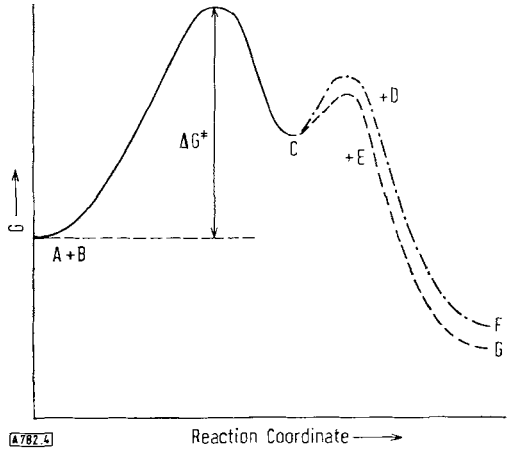

Fig. 4. Competition of two reaction components D and E for an intermediate C.

How does one define and determine competition constants? In Figure 4, the reactants D and E compete for the intermediate C with formation of the products F and G.

$$+ d[F]/dt = - d[D]/dt = k_D [C][D]$$
$$+ d[G]/dt = - d[E]/dt = k_E [C][E]$$

Division of the first differential equation by the second gives

$$\frac{d[D]}{d[E]} = \frac{k_D}{k_E} \frac{[D]}{[E]}$$

and furnishes, after transformation, the competition constant:

$$\varkappa = \frac{k_D}{k_E} = \frac{d[D]}{[D]} \frac{[E]}{d[E]} = \frac{d \ln [D]}{d \ln [E]}$$

The replacement of the differentials by finite differences is allowed. If $[D]_0$ and $[E]_0$ are the initial concentrations of the competing reactants and $[D]_e$ and $[E]_e$ their concentrations at the end of the reaction, we obtain an expression that contains only quantities that are experimentally accessible.

$$\varkappa = \frac{\log [D]_0 - \log [D]_e}{\log [E]_0 - \log [E]_e} = \frac{\log [D]_0 - \log ([D]_0 - [F]_e)}{\log [E]_0 - \log ([E]_0 - [G]_e)}$$

The validity of this equation is unrestricted. If D and E are present in a very large excess, there will be practically no change in their concentrations during the reaction. $[D]_0$ and $[E]_0$ are now constants, and integration leads to the even simpler expression:

$$\varkappa = \frac{k_D}{k_E} = \frac{d[D]}{d[E]} \frac{[E]_0}{[D]_0} = \frac{d[F]}{d[G]} \frac{[E]_0}{[D]_0} = \frac{[F]_e}{[G]_e} \frac{[E]_0}{[D]_0}$$

The experimental procedure is to allow D and E to compete for C in various ratios and to determine the concentrations of the products F and G. The reliability of the method is then shown by agreement in the competition constants $\varkappa$.

This can be illustrated by the detection of benzyne as an intermediate in the nucleophilic substitution of halobenzenes by phenyllithium or lithium piperidide. The substitution of unactivated aryl halides with strong nucleophiles proceeds with primary elimination, as is revealed by a characteristic change in the position of the substituent (cine substitution) [24].

The liberation of benzyne *(21)* from fluorobenzene in ether at 20 °C proceeds 25 times as rapidly with lithium

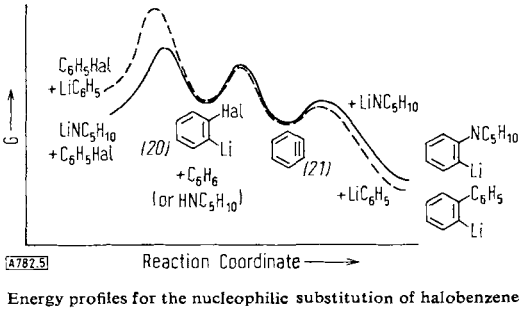

Fig. 5. Energy profiles for the nucleophilic substitution of halobenzene with phenyllithium and with lithium piperidide.

[23] *L. C. Bateman, M. G. Church, E. D. Hughes, C. K. Ingold,* and *N. A. Taher*, J. chem. Soc. (London) *1940*, 979.

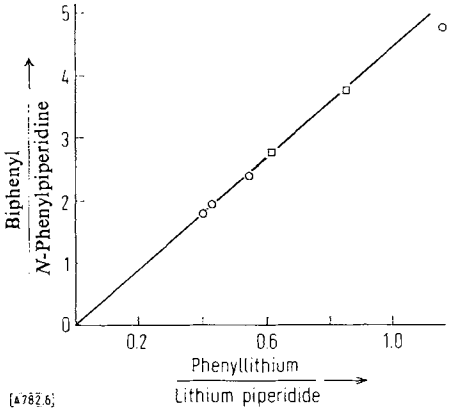
piperidide as with phenyllithium[25]. The energy profile (Fig. 5) contains an additional dip; the first intermediate is the *o*-lithiohalobenzene *(20)*, which can also be intercepted. The slow, rate-determining formation of benzyne is followed by fast additions of nucleophilic agents to the short-lived intermediate. Competition tests with lithium piperidide and phenyllithium in various ratios give $\varkappa = 0.23$. Though slower by a factor of 25 in the liberation of benzyne, phenyllithium is 4.4 times as fast as lithium piperidide in the addition to *(21)*[26]. This discrepancy between the overall kinetics and the product composition makes the assumption of an intermediate *(20)* unavoidable.



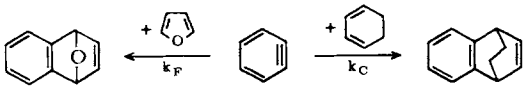


Fig. 6. Competition of phenyllithium and lithium piperidide in the addition to benzyne. Experiments with fluorobenzene (□) and chlorobenzene (○) in boiling ether [26].

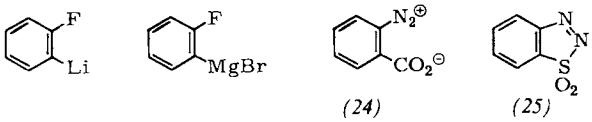
Figure 6 shows a plot of the concentration ratio of the competing reactants against that of the products. The experimental data give a straight line passing through the origin. The agreement of the $\varkappa$ values for experiments with fluorobenzene and with chlorobenzene indicates that the intermediate responsible for the product formation is free from halogen. Can any other information be obtained?

5. Common Intermediate from Different Precursors

If one and the same intermediate is formed from different starting systems, the nature of the generating systems often provides evidence on the structure of the intermediate. The occurrence of a common intermediate should not be concluded merely from qualitative preparative findings. Rigid proof can be provided only by agreement of the competition constants in a quantitative competition test.



A pertinent example is again offered by the structure of benzyne; C_6H_4 was at first regarded with much suspicion. In addition to the above path *via* metalated halobenzenes, other precursors became known, in particular benzenediazonium *o*-carboxylate *(24)*[27] and benzo[*d*]thiadiazole 1,1-dioxide *(25)*[28]. The competing reactants for the detection of an identical intermediate in all these systems must be compounds that are neither electrophilic nor strongly nucleophilic, since reactions with the precursors of the benzyne must be avoided.

(22) *(21)* *(23)*

The cycloadditions to furan and cyclohexadiene to form *(22)* and *(23)* were found to be suitable. Under identical conditions, the benzyne from various sources adds to the two dienes with the same competition constant (Table 1) of 21.5 (average value)[29]. In view of the difference in the starting systems, it is difficult to imagine an intermediate other than C_6H_4 *(21)* as a "common denominator"; the only other possibility would be a complex of *(21)* with the solvent.

Table 1. Competitive addition of furan (k_F) and cyclohexadiene (k_C) to benzyne *(21)* from various precursors in tetrahydrofuran at 50 °C [29].

			(24)	*(25)*
k_F/k_C	20.8	21.2	21.4	22.4

A recent study made use of the competitive addition of benzyne to the 1,4- and 9,10-positions of 1,4-dimethoxyanthracene[30]. The competing reactants thus belong to one and the same molecule. The identity of the intermediate was confirmed and extended to two other starting systems. However, the competition constant was only 2.3.

One critical point is that the conclusion of a common intermediate is permissible only if the competition constant is sufficiently different from 1. Very "hot" intermediates react with the first partner encountered, *i.e.* randomly. Competition constants of 0.5 to 2 do not rule out the possibility of substantially *diffusion-controlled* processes. In such cases, independent experiments with different ratios of the competing reactants are particularly important.

Phenylations of aromatic compounds have been known for more than 70 years. They were ascribed to the free phenyl radical by *Wieland*[31] and by *Hey*[32].

Such phenylations have been observed *e.g.* in the homolysis of nitrosoacetanilide *(26)*, phenylazotri-

[25] *R. Huisgen* and *J. Sauer*, Chem. Ber. *92*, 192 (1959).

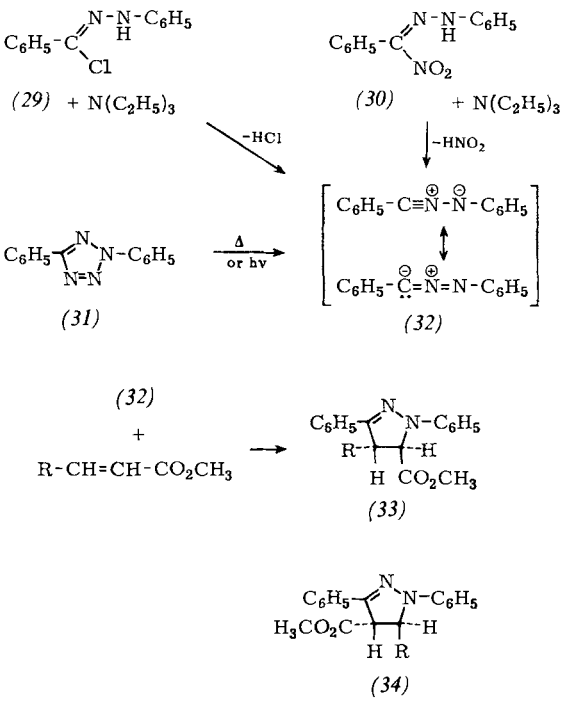
phenylmethane *(27)*, and dibenzoyl peroxide *(28)* in aromatic solvents C_6H_5S (S = substituent).



Competitive phenylations again confirm the identity of the intermediate responsible for the aromatic substitution in the decomposition of *(26)*–*(28)* (Table 2). The *o*-, *m*-, and *p*-positions of monosubstituted benzenes can compete *intramolecularly* for the phenyl radical, and this leads to a definite isomer ratio of the monosubstituted biphenyls. Mixtures of aromatic compounds allow the determination of *intermolecular* competition constants, as is shown in Table 2 for the example naphthalene/benzene.

Table 2. Isomer ratios in the free-radical substitution (phenylation) of aromatic compounds using nitrosoacetanilide *(26)*, phenylazotriphenylmethane *(27)*, or dibenzoyl peroxide *(28)* as phenyl generator.

% 1-	79	80	81
% 2-	21	20	19
(Naphthalene/benzene) [35]	13	14	11

Benzonitrile oxide is an isolable compound, but dimerizes rapidly in solution to give diphenylfuroxane. All efforts to isolate the related diphenylnitrilimine *(32)* have been unsuccessful because of its fast further reactions. However, cycloadditions can be readily carried out with *(32) in situ*, *i.e.* on liberation in the presence of suitable dipolarophiles, and this reaction has provided preparative routes to five-membered heterocycles.

Systems as different as the base-induced elimination of HX from (α-chlorobenzylidene)phenylhydrazine *(29)* and (α-nitrobenzylidene)phenylhydrazine *(30)* and photolysis or 160 °C-thermolysis of 2,5-diphenyltetrazole *(31)* produce the same cycloadducts with multiple bond systems. The occurrence of a common

intermediate is demonstrated conclusively by the numerical determination of competition constants. Hardly any intermediate other than *(32)* could conceivably be common to the above four systems [36].

Table 3. Cycloadditions of diphenylnitrilimine *(32)* to α,β-unsaturated carboxylic esters to form the pyrazolines *(33)* and *(34)*; intramolecular competition of the two addition directions [36].

Generator of *(32)*	Yield of *(33)* + *(34)* (%)	*(33)* : *(34)*
a) Methyl cinnamate (R = C_6H_5)		
(29) + $N(C_2H_5)_3$ at 80 °C in benzene	95	67 : 33
(30) + $N(C_2H_5)_3$ + NaI in acetonitrile	67	63 : 37
(29) + $N(C_4H_9)_3$ in anisole at 160 °C	79	57 : 43
(31) in anisole at 160 °C	65	59 : 41
b) Methyl crotonate (R = CH_3)		
(29) + $N(C_2H_5)_3$ in benzene at 20 °C	71	72 : 28
Photolysis of *(31)* in benzene at 20 °C	78	76 : 24

In the 1,3-dipolar cycloaddition of diphenylnitrilimine *(32)* to methyl cinnamate, the two addition paths leading to *(33)* and *(34)*, R = C_6H_5, compete with each other. The systems yielding *(32)* are compared in pairs in Table 3; care must be taken to ensure comparability of the reaction conditions with regard to temperature and solvent. The competition constant is independent of the temperature only if the competing reactions happen to have the same activation enthalpy.

In the case of methyl crotonate, the photolysis of diphenyltetrazole *(31)* was also examined. Though the ratios *(33)* : *(34)* agree satisfactorily within the series of experiments a or b, their values are only 1.3 : 1 and 3 : 1 respectively.

The *intermolecular* competition of two olefinic dipolarophiles for diphenylnitrilimine was therefore also

[33] *R. Huisgen* and *R. Grashey*, Liebigs Ann. Chem. *607*, 46 (1957).

measured (Table 4). The thermolysis of diphenyltetrazole *(31)* gives constants that agreed with that of the reaction *(29)* + tributylamine when tributylamine and tributylammonium chloride were added, *i.e.* when the medium is made identical. The magnitude of the competition constant, $\varkappa = 7.5$, makes the common intermediate convincing.

Table 4. Competition of ethyl cinnamate and indene for diphenylnitrilimine *(32)* in anisole at 160 °C [36].

Generator of *(32)*	Cinnamate adduct / Indene adduct
(29) + $N(C_4H_9)_3$	7.57, 7.36
(31) + $N(C_4H_9)_3$ + $\overset{\oplus}{H}N(C_4H_9)_3Cl^{\ominus}$	7.67, 7.36
(31) alone	9.50, 9.22

6. Selectivity of the Intermediate

If the intermediate lies in a relatively deep energy trough, it has sufficient time to choose carefully between the components D and E (Fig. 7). The size of the competition constant $\varkappa$ provides a measure of the *selectivity* of an intermediate. Highly selective intermediates are commonly referred to as "cold". These are contrasted with the "hot" intermediates, which react with the components D and E over very low activation barriers. The extreme case of a hot intermediate is one that reacts on the first collision with D or E, *i.e.* whose reaction is diffusion-controlled. The terms "hot" and "cold" should preferably be used in comparisons between several structurally related intermediates rather than in an absolute sense.

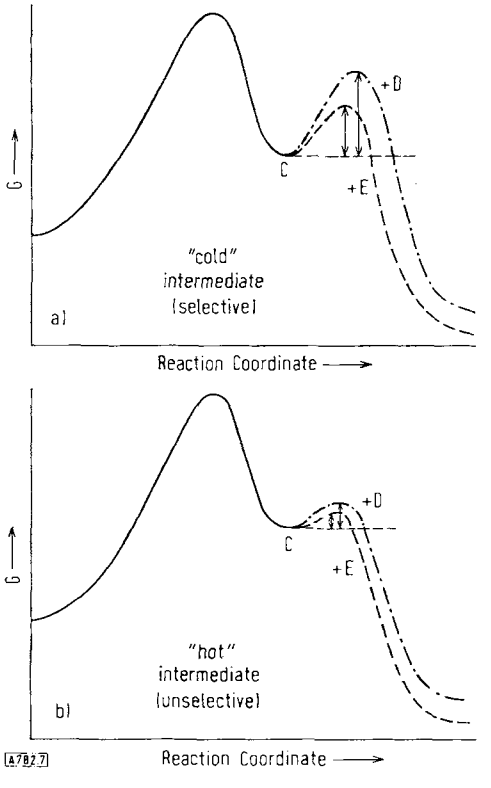

Fig. 7. Energy profiles (a) with a "cold" and (b) with a "hot" intermediate.

Substituents may stabilize or destabilize intermediates. A measure of this is provided by the selectivities as measured by the competition constants in a standard system D + E.

In the S_N1 hydrolysis of alkyl halides, the recombination of the ions competes with the reaction of the carbonium ion with water (Section 3). The quantitative evaluation gives $\varkappa = k_{Cl^{\ominus}}/k_{H_2O}$. Though the data in Table 5 are only approximate values, the decreasing selectivities clearly reflect the diminishing resonance stabilization of the carbonium intermediate.

Table 5. Competition constants for the reactions of carbonium ions with pairs of nucleophiles. $Cl^{\ominus}/H_2O$ (hydrolysis of RHal), and $N_3^{\ominus}/H_2O$ [21—23, 37].

R—Hal	$k_{Cl^{\ominus}}/k_{H_2O}$	$k_{N_3^{\ominus}}/k_{H_2O}$
Triphenylmethyl chloride	3100	280000
4,4'-Dimethylbenzhydryl chloride	600	240
4-Methylbenzhydryl chloride	320	
Benzhydryl chloride	120	170
tert-Butyl chloride	4	4

The selectivity of an intermediate may be influenced not only by substituents but also by the medium. The photochlorination of saturated hydrocarbons proceeds by a free-radical chain; the position of the substitution is determined by the abstraction of hydrogen from the alkane in the reaction with the chlorine atom. In the chlorination of 2,3-dimethylbutane *(35)* the hydrogen may be removed from a tertiary or from a primary carbon. Since the tertiary alkyl radical *(37)* is energetically favored over the primary one *(36)*, the tertiary hydrogen reacts preferentially. The competition con-

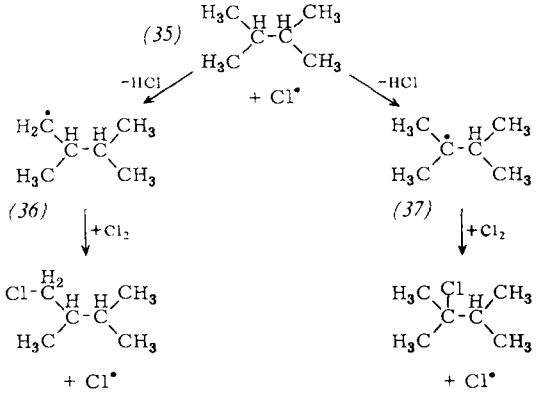

Table 6. Photochlorination of 2,3-dimethylbutane *(35)* at 55 °C; solvent dependence of the competition constant for the substitution on the tertiary and primary carbon atoms [38].

Solvent (concentration in moles/l)	$k_{tert.}/k_{prim.}$

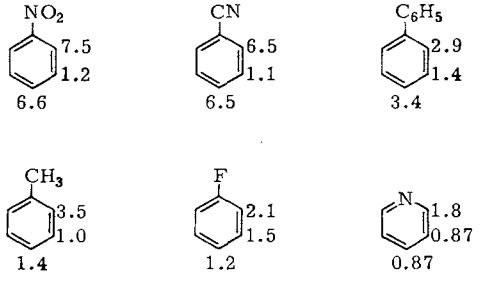
Nitromethane (4.0)	3.3
Propionitrile (4.0)	4.0
Dioxane (4.0)	5.6
Chlorobenzene (4.0)	10
Benzene (2.0, 4.0, 8.0)	8.0, 15, 32
p-Xylene (4.0)	19
Mesitylene	25

[37] *A. G. Ogston, E. R. Holiday, J. S. L. Philpot,* and *L. A. Stocken,* Trans. Faraday Soc. *44*, 45 (1948).



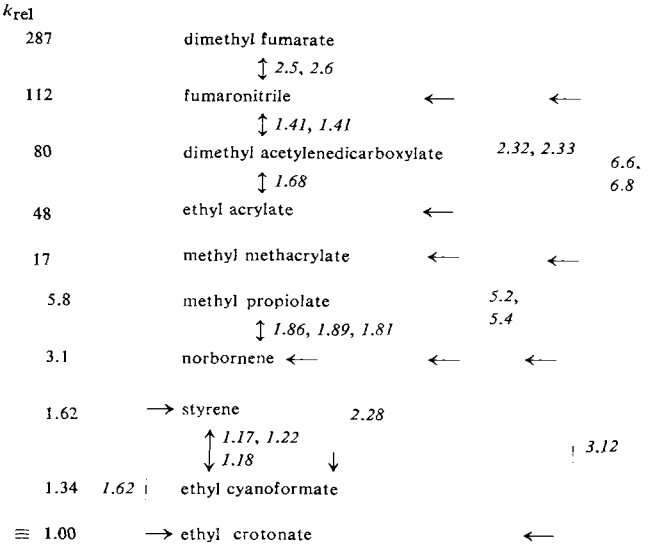
[38] *G. A. Russell,* J. Amer. chem. Soc. *80*, 4987 (1958).

stant can be determined from the ratio of the two substitution products (Table 6), taking into account the fact that *(35)* contains 12 primary and 2 tertiary hydrogens.

The preference for the tertiary H is relatively small, the competition constant being 3.7; the chlorine atom is a "hot" species. *Russell*[38] observed a striking increase in selectivity if the chlorination is carried out in aromatic solvents (Table 5). It must therefore be concluded that a stabilizing interaction occurs with the aromatic compound; the chlorine atom becomes "colder". A π-complex of the chlorine atom with the aromatic system is postulated as an intermediate.

The measurement of competition constants also allows the determination of the relative rates of many substrates with a given intermediate. This leads *e.g.* to the substitution rules for free-radical phenylation when *many* experiments of the type shown in Table 2 are carried out. After the determination of the $o : m : p$ ratio in the reaction of the phenyl radical with monosubstituted benzenes, it was necessary to determine the intermolecular competition constant of benzene with its monosubstituted derivatives. The combination of these data gives the "partial rate factors" of Table 7; these are relative values based on a value of 1.0 for H in benzene. The rate constants of the electrophilic bromination of monosubstituted benzenes extend over 24 powers of ten. In the free-radical substitution, the substituent effect is compressed to less than one power of ten; thus the phenyl radical is a less selective intermediate.

Table 7. Partial rate factors of the free-radical phenylation of aromatic compounds [39].



The detection of diphenylnitrilimine *(32)* as a common intermediate was described in Section 5. The same method was used for the stepwise construction of the characteristic scale of dipolarophile activities by competition of various pairs of dipolarophiles for the 1,3-dipole. Part of a larger volume of data is shown in Table 8[40]. Each double arrow denotes a pair competing for diphenylnitrilimine. To keep the experimental errors within limits, frequent additional pairings are recommended. The arbitrary assignment of a value of 1.0 to the addition constant k_2 (ethyl crotonate) leads to the relative rate constants (on left in Table 8).

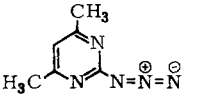
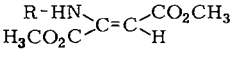
Table 8. Competition of dipolarophile pairs for diphenylnitrilimine *(32)* in benzene at 80 °C; experimental x values in italics, the first column giving the relative addition constants.

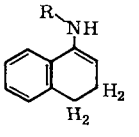


7. Kinetic Differentiation of Simultaneous Mechanisms

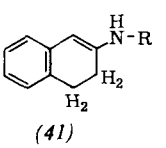


A multiplicity of products may be formed *via* a common intermediate or *via* energy profiles that are separated from the outset. It is not too rare to find that one and the same product is formed from the same precursor by different reaction paths.

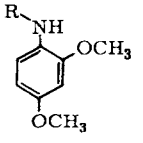
Thus it is now known that in the chlorination of olefins in the liquid phase, both the addition to the double bond *and* the allylic substitution can proceed by a free-radical or by a cationic mechanism[40a]. The free-radical chain can be suppressed by operation under oxygen.



When the pyrimidyl azide *(38)* is heated to 150–160 °C with diethyl fumarate, 1,2-dihydronaphthalene, 1,3-dimethoxybenzene, or aniline, the substitution products



(38) = R-N_3



(39)

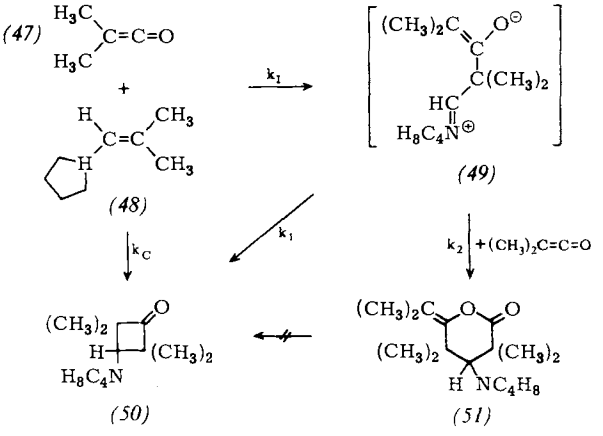
(39), or *(40)* plus *(41)*, or *(42)* plus *(43)*, or *(44)* are formed with elimination of nitrogen [41,42]. Do these formally similar reactions proceed by the same mechanism? The rate of nitrogen evolution from *(38)* was measured in chloronaphthalene with and without additives (Table 9). This experiment discloses a dichotomy of the reaction paths.

Table 9. Kinetics of nitrogen evolution from 2-azido-4,6-dimethylpyrimidine *(38)* (69 mmoles/l) in chloronaphthalene at 180 °C [41].



Additive (mmoles/l)	$10^5 k_1$ (s^{-1})	$10^5 k_2$ (l $mole^{-1}$ s^{-1})
Diethyl fumarate (948)	167	170
Diethyl fumarate (357)	63	168
Diethyl fumarate (231)	42	170
1,2-Dihydronaphthalene (948)	95	97
trans-Stilbene (911)	20	19
None	3.1	
1,3-Dimethoxybenzene (948)	3.0	
Aniline (948)	3.0	
Benzonitrile (948)	2.8	

Fumaric ester and olefins "induce" the liberation of nitrogen from the azide *(38)*; they enter into the rate equation. Division of the pseudo-first order constants, measured with excess fumaric ester, by the fumaric ester concentration gives constant k_2 values. This contrasts with the aromatic compounds, the addition of which does not increase the rate of the self-decomposition of *(38)*. k_1(self-decomposition) also varies only slightly in a large number of solvents. Despite the formal similarity of the products, therefore, two fundamentally different reaction paths are used. The CC double bond combines with the azide *before* the release of the nitrogen to form the Δ^2-triazoline *(45)*, which very rapidly loses nitrogen at the high reaction temperature. Enamines add azides particularly rapidly and allow the isolation of corresponding cycloadducts with *(38)* even at low temperatures [43].

On the other hand, the elimination of nitrogen from *(38)* to form the pyrimidylazene *(46)* precedes the interaction with phenol ethers or with aniline. It is therefore possible to distinguish between the azide cycloaddition and the azene reaction by a simple kinetic measurement. *(45)* and *(46)* are reactive intermediates; the olefinic component is involved only in the formation of *(45)*.

The last example will illustrate the simultaneous occurrence of two reaction paths in one and the same system producing the same product. The formation of cyclobutanones from ketenes and olefins has recently been the subject of mechanistic studies, in which most criteria point to a one-step multicenter addition, *i.e.* a simple activation peak (Fig. 1a), between the starting components and the product [44]. The second possible reaction path, which passes through a zwitterionic intermediate, occurs only in the addition of ketenes to enamines; in this case optimum stabilization of the intermediate is possible in accordance with *(49)*. Depending on whether 1-pyrrolidinoisobutene *(48)* or dimethylketene *(47)* is chosen in excess, the reaction yields more of the cyclobutanone *(50)* or of the 1 : 2 adduct *(51)* [45]. This points to a common intermediate *(49)*, which either undergoes ring closure to form *(50)* or enters into cycloaddition with a second molecule of dimethylketene to form *(51)*.

Kinetic measurements show that the rate is first order with respect to *(47)* and *(48)*. The dependence of the k value on the polarity of the solvent would be rather small for the formation of the zwitterion *(49)* in the rate-determining step: k(acetonitrile)/k(cyclohexane) = 78.

It was only the quantitative competition experiment that showed the simultaneous occurrence of the concerted formation (k_C) of the cycloadduct *(50)* and of the path involving the zwitterion (k_I) [46]. The enamine *(48)* was allowed to react with six equivalents of *(47)* in increasing dilution with the solvent. If the reaction proceeded entirely *via* the intermediate *(49)*, the yields of *(50)* and *(51)* should be related as follows:

$$\frac{[(50)]}{[(51)]} = \frac{k_1}{k_2}\,[(47)]$$

This simple mass law relation was not obeyed. Only after the subtraction of a quantity of the cyclobutanone *(50)* formed by the path with k_C which is

[41] *R. Huisgen, K. v. Fraunberg*, and *H. J. Sturm*, Tetrahedron Letters *1969*, 2589.

[43] *R. Fusco, S. Rossi*, and *S. Maiorana*, Tetrahedron Letters *1965*, 1965.

[44] *R. Huisgen, L. A. Feiler*, and *G. Binsch*, Chem. Ber. *102*, 3460 (1969).

[45] *P. Otto, L. A. Feiler*, and *R. Huisgen*, Angew. Chem. *80*, 759 (1968); Angew. Chem. internat. Edit. *9*, 737 (1968).

[46] *R. Huisgen* and *P. Otto*, J. Amer. chem. Soc. *91*, 5922 (1969).

characteristic for each solvent [43 % of the *(50)* formed in acetonitrile, 63 % in chloroform, 92 % in cyclohexane] was the above relation valid for the remainder of the material. The difference in the solvent dependence of the two branches of the overall reaction is typical:

	k(acetonitrile)/k(cyclohexane)
Overall reaction	78
Concerted addition (k_C)	36
Path *via* the zwitterion (k_I)	560

The formation of the zwitterion *(49)* is associated with strong charge separation, corresponding to an increase in solvation during the activation process, *i.e.* to strong promotion by the polarity of the solvent.

8. Closing Remarks

It is meaningless to ask which method is the most significant in the elucidation of reaction mechanisms and in the detection of reactive intermediates. Without chemical kinetics [47], our knowledge would be much poorer and more fragmentary. The kinetic method can often positively rule out postulated reaction paths; it can show with certainty the *occurrence* of an intermediate. Information on the *nature* of the intermediate is not provided with the same certainty, since several mechanisms sometimes follow the same kinetic scheme. However, the number of possible intermediates can be cut down by the methods described in Section 5, and it may also be possible to establish the structure of the intermediate *per exclusionem*.

Our knowledge of reaction mechanisms has swelled over the last 40 years into a broad stream fed from many tributaries. The work of *Hughes* and *Ingold* [20], who first made systematic use of the kinetic method in the elucidation of nucleophilic aliphatic substitution, played an important part in the early phase of this development.

Recent Results in Carbanion Chemistry[**]

By Ulrich Schöllkopf[*]

The Wittig rearrangement of ethers metalated in the alpha position with alkali metals is a 1,2-shift to an atom with a lone pair of electrons. The alkyl shift proceeds with racemization (and partial retention) at the migrating carbon atom. The experimental observations suggest a cleavage-recombination mechanism involving a radical pair, as must also be assumed for the ylide rearrangements. In the allyl migration, the double bond is displaced within the migrating residue (allyl inversion). This is readily explained by a one-step S_Ni' mechanism, the transition state of which is allowed on symmetry grounds. In the case of benzyl 2-butynyl ether metalated on the butynyl residue, the ortho isomerization (corresponding to the Sommelet rearrangement) predominates. – α-Metalated alkyl isocyanides can react with carbonyl compounds to form olefins and metal cyanate (carbonyl olefination). Isocyanoacetic esters occupy a special place; they react with aldehydes and ketones to form β-substituted α-formylaminoacrylates (formylaminoalkoxycarbonylmethylenation), which can enter into a wide range of reactions. β-Hydroxyalkyl isocyanides or 2-oxazolines can be isolated as intermediates in the carbonyl olefination. α-Metalated isocyanides react with acylating agents to form β-ketoalkyl isocyanides, which cyclize to give oxazoles.

1. Introduction

Like all branches of our science, carbanion chemistry is currently in a state of rapid development [1–4]. The present article cannot, therefore, be a review, but can merely point out individual facets of research in this field.

The first part of the article deals with the mechanism of Wittig rearrangements, and will show that carbanion chemistry holds questions as intriguing as those in cation or free-radical chemistry to the chemist who is interested in reaction mechanisms. The second part deals with syntheses using alkyl isocyanides α-metalated with alkali metals. This part will show that research in carbanion chemistry, which has already provided the preparative organic chemist with an abundance of valuable processes, is still capable of yielding new synthetic methods.

2. Mechanism of the Wittig Rearrangement

2.1. General

The Wittig rearrangement is the isomerization of ethers metalated in the α-position with alkali metals to form alkali metal alkoxides (cf. Scheme 1) [5–13].

Scheme 1. Reaction scheme of the Wittig rearrangement. Examples:

$R^1 = C_6H_5$, $R^2 = H$
$R^1 = R^2 = C_6H_5$
$R^1 + R^2$ = *o,o'*-biphenylylene
$R^1 = CH{=}CH_2$, $R^2 = H$

R^3 = alkyl, aryl, allyl
M = alkali metal

The metal atom is lithium or, less commonly, sodium or potassium. The migrating group (R^3 in Scheme 1) may be an alkyl, allyl, or aryl group (cf. below). The stationary metalated groups (R^1 and R^2 in Scheme 1) may be benzyl, benzhydryl, fluorenyl, phenacyl, or

allyl groups. A characteristic shared by all these groups is that they can effectively delocalize a pair of electrons. These metalated ethers consequently possess an ionic carbon-metal bond [14–16], particularly in the ionization-promoting tetrahydrofuran that is normally used as the solvent. The cation and the anion are not, however, dissociated (or at least not to any appreciable extent), but form a contact or solvent-separated ion pair [3].

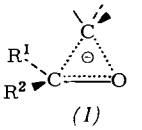
It has been shown conclusively in the rearrangement of metalated benzhydryl phenyl ethers to triphenylmethoxides [10] ($R^1 = R^2 = R^3 = C_6H_5$, M = Li, K, Na, in Scheme 1) that the Wittig rearrangement is in fact the isomerization of an anionic residue of the molecule and not of a covalent organometallic compound. The species that is capable of isomerizing is red, as is to be expected for an anionic benzhydryl derivative. The rates of the rearrangements are almost totally independent of the nature of the cation [17]. The same is true of the electronic spectra of the three compounds [17], which also obey the Beer-Lambert law (in dilute solution in tetrahydrofuran), an indication of complete ionization. The lithium compound reacts with zinc or magnesium chloride to form colorless organometallic compounds with covalent carbon-metal bonds, which can no longer rearrange. Lithiomethyl methyl ether ($R^1 = R^2 = H$, $R^3 = CH_3$ in Scheme 1), which probably has a covalent structure (even in tetrahydrofuran), does not isomerize [18].

Table 1. 1.2-Shift to an atom with a lone pair of electrons.

	Wittig rearrangement
	Stevens rearrangement
	Sulfonium ylide-sulfide rearrangement
	Meisenheimer rearrangement
	Grovenstein-Zimmerman rearrangement
	Sulfenic ester-sulfoxide rearrangement
	Sulfinic ester-sulfone rearrangement
	Sulfoxylic ester sulfinic ester rearrangement
	Phosphinous ester-phosphine oxide rearrangement
	Phosphonous diester-phosphinic ester rearrangement

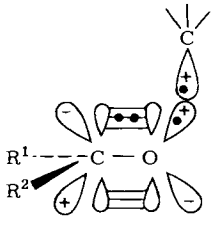
[14] On the nature of benzyllithium, see *P. West* and *R. Waack*, J. Amer. Chem. Soc. *89*, 4395 (1967), earlier literature cited there.

[15] On the nature of fluorenyllithium, see *A. Streitwieser jr.* and *J. I. Braumann*, J. Amer. Chem. Soc. *85*, 2633 (1963); *T. E. Hogen-Esch* and *J. Smid*, *ibid. 88*, 307, 318 (1966); cf. also [3].



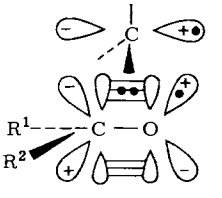
[16] On the nature of allyllithium, see *P. West*, *J. I. Purmort*, and *S. V. McKinley*, J. Amer. Chem. Soc. *90*, 797 (1968).

[17] Slight differences are to be expected, since the interaction between the cation and the carbanion should differ in the three metal cation-carbanion pairs, so that the energy levels of the ground states will also be different.



Broadly speaking, the Wittig rearrangement is a 1,2-shift to an atom with a lone pair of electrons (cf. Table 1). This is the formal counterpart of the sextet rearrangement, and corresponds to the scheme shown at the top of Table 1, where X and Z may be positively or negatively charged or electrically neutral atoms. The rearrangements could all proceed by the same mechanism, since the reacting systems are isoelectronic.

2.2. Mechanism of the Alkyl Migration



The migration of a saturated carbon atom in rearrangements of this type was initially formulated as an intramolecular nucleophilic substitution with a transition state involving a three-membered ring, as indicated in *(1)* [11, 12, 19]. This seemed plausible, since *Ingold* [20] had previously postulated a nucleophilic substitution with simultaneous ligand exchange "from the front side" (S_Ni) for the thermolysis of alkyl chlorosulfites and since approximately 98 % retention of the configuration at the migrating carbon atom, as is to be expected for a mechanism of this type, had been found for the migration of the α-phenylethyl residue in the Stevens rearrangement (cf. Table 1) [21].

(1)

(2)

(3)

It is now known that retention of configuration is not conclusive proof of an S_Ni mechanism (see below). The thermolysis of chlorosulfites, which was formulated by *Ingold* as a one-step reaction, really proceeds by way of a short-lived ion pair [22], in which the chloride ion remains at the "front side" of the carbon cation under certain conditions, so that the recombination yields an alkyl chloride with no change in the configuration [22]. The stereochemistry of the Stevens rearrangement can be explained in a similar manner, but with a short-lived radical pair as the intermediate [23].

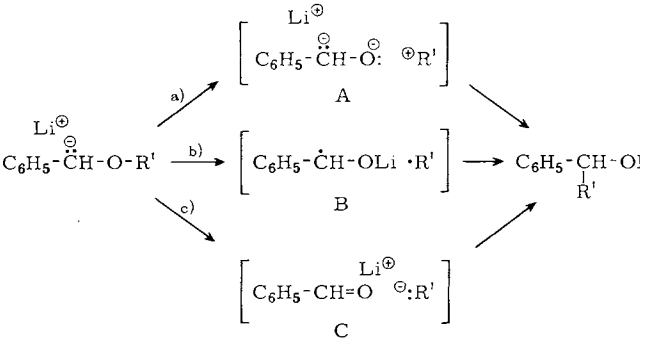
[22] *E. S. Lewis* and *C. E. Boozer*, J. Amer. Chem. Soc. *74*, 308 (1952); *D. J. Cram*, *ibid. 75*, 332 (1953).

[23] See also *U. Schöllkopf*, *U. Ludwig*, *G. Ostermann*, and *M. Patsch*, Tetrahedron Lett. *1969*, 3415.

If the 1,2-shift is regarded as a sigmatropic shift [24], the synchronous course with retention of configuration [corresponding to the S_Ni process *(1)*] is forbidden by symmetry [cf. *(2)*]. The migrating carbon atom cannot be involved simultaneously in a bonding interaction both with the oxygen and with the carbon of the stationary residue *via* its sp^3 orbital, since the π^* function of a carbonyl group is antisymmetric. On the other hand, the one-step reaction course with inversion of the configuration is allowed according to the Woodward-Hoffmann rules, since parts of orbitals with like signs come together in the (sterically unfavorable) transition state *(3)*, in which the migrating atom is in interaction with the stationary group *via* a p function.

If the reaction proceeded in one step, the carbon atom should migrate either with total retention or with total inversion. To check this question, we studied the stereochemistry of the rearrangement of optically active lithiobenzyl *sec*-butyl ether *(6)* into lithium 2-methyl-1-phenyl-1-butoxide *(8)* [25] and of the phenyl derivative *(7)* into *(9)* [26] (cf. Scheme 2).



The metalated ethers *(6)* and *(7)* are obtained from the ethers *(4)* and *(5)* with butyllithium in tetrahydrofuran. The alkoxides *(8)* and *(9)* were hydrolyzed and oxidized to the ketones *(10)* and *(11)*, the rotation values of which were measured. The relative configurations of *(4)* and *(10)* and of *(5)* and *(11)* and the optical purities of these compounds could be readily determined or found from the literature [25, 26]. *(6)* and *(7)* as well as *(8)* and *(9)* were found to be configurationally stable under the reaction conditions.

Scheme 2. Reaction scheme for the determination of the stereochemistry of the Wittig rearrangement.

The isomerizations *(6)*→*(8)* and *(7)*→*(9)* (in tetrahydrofuran at about −60 °C) proceed with about 80 and about 20% racemization respectively, the configuration being retained in the unracemized portion. In other words, about 60% of the *sec*-butyl groups migrate with retention of configuration (and about 40% with inversion), while about 90% of the 2-phenylbutyl groups migrate with retention (and about 10% with inversion).

The stereochemical findings opposed a one-step course for the rearrangement (cf. above) and pointed to a two-step cleavage-recombination mechanism. This offers three possibilities (cf. Scheme 3): (a) the alkyl residue migrates as a cation *via* an ion pair of the type A, (b) it migrates as a radical *via* a radical pair B, or (c) it migrates anionically *via* the intermediate C.

Scheme 3. Possibilities for the two-step course of the Wittig rearrangement.

It was possible to rule out path (a), since alkyl groups giving unstable cations migrate without rearrangement of the skeleton. Thus lithiobenzyl cyclobutyl ether *(12)* isomerizes to lithium cyclobutylphenylmethoxide *(13)*, whereas the isomers *(14)* and *(15)* cannot be detected [27]. On the other hand lithiobenzyl cyclopropylmethyl ether *(16)* gives small quantities of *(15)* together with the alkoxide *(14)*, but not *(13)* [27, 28]. No conclusions can be drawn from the formation of small quantities of *(15)* from *(16)*, since cyclopropylmethyl anions and cyclopropylmethyl radicals can both rearrange to form homoallyl anions and radicals respectively [29, 30]. Lithiobenzyl 2,2-dimethylcyclopropyl ether *(17)* gives lithium (2,2-dimethylcyclopropyl)phenylmethoxide *(18)* (though only in yields of about 30%, together with high-boiling resins), but neither of the allyl derivatives *(19)* and *(20)* [31, 32].

Armstrong*, Theor. Chim. Acta *13*, 365 (1969).

It was possible to decide between the radical and the carbanion mechanisms on the basis of a series of observations, of which only the most important will be mentioned here. Lithiobenzyl 1-adamantyl ether *(21)* undergoes rearrangement, while lithiobenzyl 1-norbornyl ether *(22)* does not [33]. Since the adamantyl radical is more stable than the norbornyl radical [34], whereas the reverse is true of the organolithium compounds [35], and hence probably of the carbanions, this observation supports the radical path (b). This is also supported by the migration tendency of alkyl groups (determined for the rearrangement of lithiobenzyl alkyl ethers), which increases in the order methyl, ethyl, isopropyl, *tert*-butyl (k_{rel} = 1:40:162:2080) [36]. It is known that the rate of formation of alkyl radicals increases in this order [37], whereas that of carbanions decreases [3]. A linear relationship exists (cf. Fig. 1) between the dissociation energies of primary, secondary, and tertiary C–H bonds and the ln k_{rel} values of the rearrangement, which are in turn proportional to the differences between the activation energies; this indicates that the four alkyl residues all migrate by a similar mechanism.

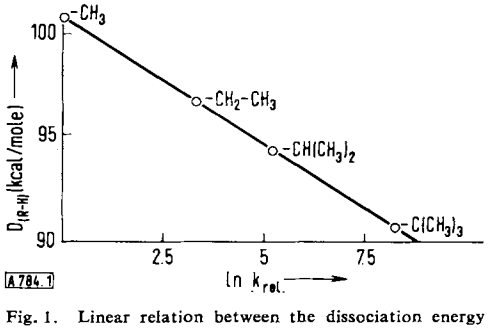

Fig. 1. Linear relation between the dissociation energy D of C–H bonds and the logarithm of the k_{rel} values for the rearrangement of alkyl groups in the reaction
C_6H_5–CHLi–O–R → C_6H_5–CHR–OLi
in tetrahydrofuran at −60 °C.

The lithium phenyl-*tert*-butylmethoxide formed on isomerization of lithiobenzyl *tert*-butyl ether exhibits a chemically induced proton spin polarization, which is recognizable in the NMR spectrum (cf. Fig. 2) [39]. This must be regarded as evidence of the intermediate formation of a radical pair of the type B during the rearrangement, since a CINP [40] is to be expected only in products formed from free-radical precursors.

[37] *Ch. Rüchardt* has recently pointed out [38] that the usual opinion that the ground state stability of alkyl radicals should increase in the order primary, secondary, tertiary cannot be verified experimentally. The D_{C-H} values and the activation energies of radical-forming reactions evidently run parallel only for endothermic reactions, *i.e.* when the transition state is very similar to the free radicals.

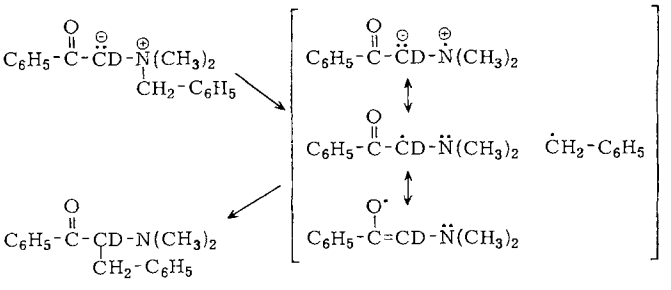
Finally, let us consider briefly how the stereochemical result, *i.e.* racemization with partial retention on the migrating carbon (cf. above), can be explained in a two-step rearrangement (cf. Scheme 4). In the radical pair B′ formed from the ionized ether *(23)* by homolysis, which has the same configuration as the starting material, some of the alkyl radicals may rotate through 180° to give the enantiomer B″ before the recombination, which occurs in the solvent cage (cage recombination)[41]. It should be noted that B′ and B″ are chiral overall, though the alkyl radicals themselves (which are assumed to be planar) are achiral, since they possess a symmetry plane. Depending on whether the recombination takes place from B′ or B″, the rearrangement product exhibits either retention or inversion of the configuration [*(24)* or *(25)*]. The ratio of retention to inversion depends on the ratio of the constants k_1 and k_2 in accordance with the relation

$$\% \text{ retention}/\% \text{ inversion} = k_2/k_1 + 1 \quad [42]$$

If $k_2/k_1 > 30$, the cage recombination proceeds with more than 97% retention, *i.e.* it is then impossible to distinguish stereochemically between an S_Ni course [in accordance with *(1)*] and a two-step mechanism. This appears to be the situation in the Stevens rearrangement (with α-phenylethyl as the migrating group)[23].



Scheme 4. Interpretation of the stereochemistry of the Wittig rearrangement (cf. text).

[41] A cross experiment has shown that the rearrangement *(6)*→*(8)* proceeds "intramolecularly" to an extent of about 90% at −60 °C; *U. Schöllkopf* and *D. Walter*, Liebigs Ann. Chem. *654*, 27 (1962).

[42] Cf. [25]; the rearrangement is formulated there as involving ion pairs, but this relation should also be valid for a radical-pair mechanism.

2.3. Mechanism of the Alkyl Migration in the Ylide Rearrangements

As was mentioned, the reacting systems of the rearrangements listed in Table 1 are isoelectronic, and the reaction courses may therefore be assumed to be similar. It has in fact recently been shown that in the ylide isomerizations[43], *i.e.* in the Stevens rearrangement[23,44], the sulfonium ylide-sulfide rearrangement[45,46], and the Meisenheimer rearrangement[47,48], the benzyl migration probably proceeds *via* a radical pair. Figures 3–5 show the courses of these rearrangement, without comment, for some typical examples, together with the characteristic NMR signals of the isomerization products. In agreement with the assumed course *via* a radical pair,

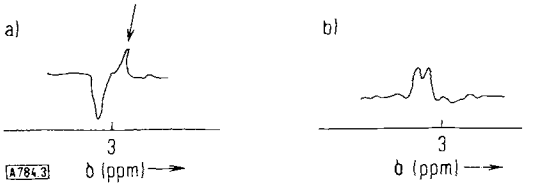


Fig. 3. Course of the Stevens rearrangement of benzyldimethylphenacylammonium ylide (in CD_3OD/CD_3ONa); NMR signal [23] of the benzyl protons of the rearrangement product (a) immediately after the isomerization, (b) after decay of the spin polarization; arrow: signal of the CH_2 protons of the by-product bibenzyl.

(Standard: tetramethylsilane).

[43] For the definition of the term ylide, see *G. Wittig* and *G. Felletschin*, Liebigs Ann. Chem. *555*, 133 (1944).

each of the three products exhibits a chemically induced proton spin polarization [40] immediately after the rearrangement.

2.4. Mechanism of the Allyl Migration

In every case examined so far, the allyl migration is accompanied by displacement of the double bond within the allyl group (allyl inversion); this can be readily explained by a one-step S_Ni' mechanism [transition state *(26)*]. Such a process is allowed according to the Woodward-Hoffmann rules [23]; the ψ_2 function of the allyl system and the π^* function of the carbonyl group are antisymmetric, so that bonding between the ends of the allyl system and the carbon and oxygen atoms of the stationary residue in *(26)* is possible [cf. *(27)*].

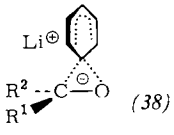
9-Lithio-9-fluorenyl 1-methallyl ether *(28)* gives lithium 9-*trans*-crotylfluorenolate *(29)* (>99 % *trans*), whereas the isomeric ether *(30)* changes spontaneously into lithium 9-(1-methylallyl)fluorenolate *(31)* [49–51]. Both rearrangements proceed spontaneously even at −50 to −60 °C. Lithiobenzyl crotyl ether *(32)* also isomerizes with allyl inversion, the product being a 1:2 mixture of *threo*- and *erythro*-*(33)* [52].

The preferential formation of the *erythro* isomer in this last rearrangement is as expected, since the transition state *(34)* leading to the *threo* form, in

[49] *U. Schöllkopf* and *K. Fellenberger*, Liebigs Ann. Chem. *698*, 80 (1966).

[50] *K. Fellenberger*, Diplomarbeit, Universität Heidelberg 1964.

[51] Cf. also *Y. Makisumi* and *S. Notzumoto*, Tetrahedron Lett. *1966*, 6393.

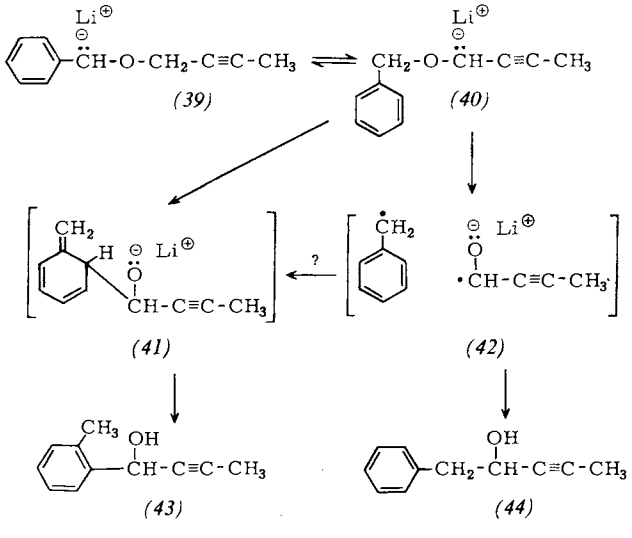


[52] *U. Schöllkopf*, *K. Fellenberger*, and *M. Rizk*, Liebigs Ann. Chem. *734*, 106 (1970). The *erythro* diastereoisomer is taken as that in which the phenyl and vinyl groups are opposite in the eclipsed conformation.

which the methyl group and the phenyl group are eclipsed, has a higher energy than the transition state *(35)* leading to the *erythro* form. On the other hand, the stereoselectivity of the rearrangement *(28)*→*(29)* (>99% *trans*[49,50]) is remarkable. The transition states *(36)* and *(37)* must differ by about 2 kcal/mole, a difference that is probably greater than that of the *cis-trans* isomeric rearrangement products *(29)*.

The results obtained in the rearrangements of *(28)* and *(30)* apparently disagree with literature data[53], according to which the isomerization not only of *(28)* but also of *(30)* (Na instead of Li, in boiling butanol with sodium butoxide) yields *(29)*; this was interpreted[54] as showing that *(28)* isomerizes by an S_Ni' mechanism and *(30)* by an S_Ni mechanism. However, the authors[53] failed to observe that under their reaction conditions *(31)* changes into *(29)*[49,50].

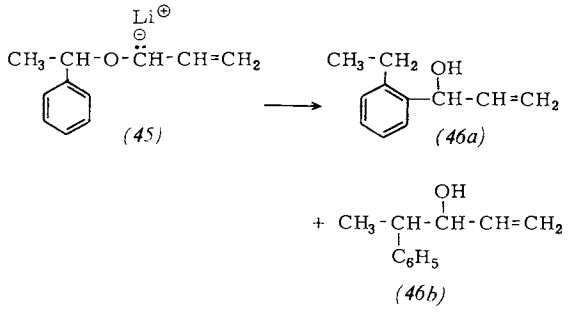
2.5. Mechanism of the Aryl Migration



Nothing definite is known about the mechanism of the aryl migration. We regard it as an intramolecular nucleophilic substitution by the addition-elimination mechanism [intermediate *(38)*], but a cleavage-recombination mechanism *via* a radical or ion pair (cf. Scheme 3, R′ = aryl) cannot be ruled out.

(38)

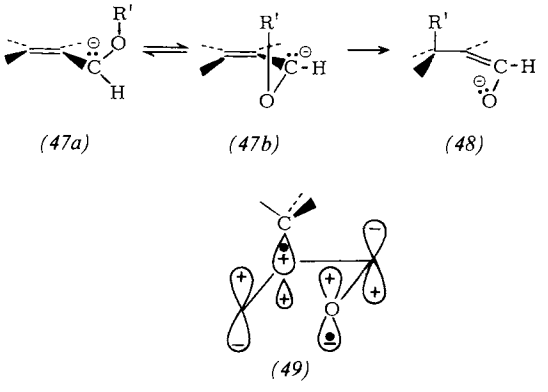
2.6. *ortho* Rearrangement in Anionized Ethers



On reaction of benzyl 2-butynyl ether with butyllithium (in tetrahydrofuran at about −30 °C), 45% of 1-(*o*-tolyl)-2-butyn-1-ol *(43)* can be isolated after hydrolysis, as well as 18% of 1-phenyl-3-pentyn-2-ol *(44)*[52]. The reaction presumably leads first to lithiobenzyl 2-butynyl ether *(39)*; this is in dynamic equilibrium with 1-lithio-2-butynyl benzyl ether *(40)*, which reacts further to form *(43)* and *(44)*. *(44)* is probably formed *via* the radical pair *(42)* (cf. above), while an "allyl shift" leads to *(41)*, which rapidly tautomerizes. Owing to the resonance in the benzyl radical, however, it is conceivable that *(41)* is formed *via (42)*.

(39) *(40)* *(41)* *(42)* *(43)* *(44)*

The rearrangement *(40)*→*(43)* corresponds to the Sommelet rearrangement[55] in ammonium ylides, which has been known for some time.



1-Lithioallyl α-methylbenzyl ether *(45)*, which is prepared from the ether and methyllithium, also undergoes *ortho* isomerization to give 1-(*o*-ethylphenyl)-2-propen-1-ol *(46a)* (after hydrolysis), as well as a Wittig rearrangement to form *(46b)*[52].

(45) *(46a)* *(46b)*

2.7. The Question of 1,4-Migration in Metalated Allyl Alkyl Ethers

According to the Woodward-Hoffmann rules, the one-step (*i.e.* suprafacial) 1,4-alkyl shift *(47)*→*(48)* is allowed by symmetry [transition state *(49)*], though it should only be possible from the "horse-shoe conformation" *(47b)* [cf. also *(49)*]. The problem has not yet been examined from this point of view. However, preparative observations[56] show that the 1,4-migration can compete successfully with the 1,2-shift in allyl alkyl ethers of the type *(47)*. Both rearrangements are formulated as proceeding *via* the same radical pair[56]. If this were so, not only the 1,2-shift but also the 1,4-migration should proceed with racemization and partial retention at the migrating carbon

(47a) *(47b)* *(48)* *(49)*

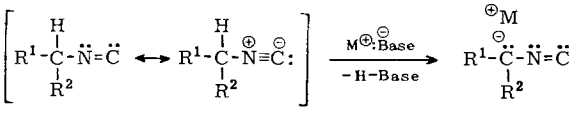
[55] For definition and distinction from the Stevens rearrangement, see *G. Wittig, R. Mangold,* and *G. Felletschin,* Liebigs Ann. Chem. *560,* 116 (1948); cf. also [2].

[56] *H. Felkin* and *A. Tambuté,* Tetrahedron Lett. *1969,* 821.



atom. If on the other hand the 1,4-migration was a sigmatropic shift, it should take place with total retention of the configuration.

In the rearrangement of (racemic) lithiobenzyl *sec*-butyl ether *(6)*, *p-sec*-butylbenzaldehyde, the result of a 1,6-migration (with subsequent hydride abstraction), can be isolated in a yield of about 4% [25]. The formation of this product can be readily explained *via* a radical pair of the type B (see Scheme 3), but not by a sigmatropic shift, since the ψ_4 of the hexatriene system is anti- symmetric.

3. Syntheses Using α-Metalated Alkyl Isocyanides

3.1. General

The α-hydrogen atoms of alkyl isocyanides [57] *[(50a)↔(50b)]* are relatively acidic, probably mainly because of the partial positive charge on the nitrogen atom [58], and can be replaced by metal with the aid of sufficiently strong bases such as butyllithium, sodium hydride, and alkali metal alkoxide [59].

(50a) *(50b)* *(51)*

M = alkali metal

The α-metalated alkyl isocyanides *(51)*, in the short time since their discovery [59], have already shown themselves to be valuable reagents, though all conceivable applications have not yet been explored [*]. They open up new possibilities for the use of isocyanides, whose chemistry was until recently thought [62] to be confined to α-elimination and α-addition at the "dicoordinate" carbon.

[57] On the syntheses of isocyanides, see *I. Ugi, U. Fetzer, U. Eholzer, H. Knupfer*, and *K. Offermann*, Angew. Chem. *77*, 492 (1965); Angew. Chem. internat. Edit. *4*, 472 (1965).

[59] *U. Schöllkopf* and *F. Gerhart*, Angew. Chem. *80*, 842 (1968); Angew. Chem. internat. Edit. *7*, 805 (1968); German Pat. Appl. 1812099/1 (Nov. 29, 1968), Badische Anilin- u. Soda-Fabrik; US Pat. Appl. 867941 (Nov. 20, 1969), Badische Anilin- u. Soda-Fabrik. As expected, α-alkyl substitution makes the metalation more difficult; it remains to be seen whether the butyllithium-tetramethylethylenediamine complex [60, 61] is more suitable as a metalating agent than butyllithium itself.

[62] See [57], p. 493.

3.2. Carbonyl Olefination

The α-metalated isocyanides *(51)* can react with aldehydes and ketones *(52)* to form olefins *(55)* and metal cyanate *(56)* [59] (cf. Table 2), the carbonyl group being replaced by the double bond.

This novel exchange reaction begins with the nucleophilic addition of *(51)* to the carbonyl group to form *(53)*. This cyclizes (presumably reversibly) to give the metalated oxazoline *(54)*, which fragments into *(55)* and *(56)* (cf. Scheme 5).

(51) *(52)* *(53)* *(55)* *(56)* *(54)*

Scheme 5. Course of the carbonyl olefination with α-metalated isocyanides *(51)*.

Table 2. Olefins *(55)* prepared by carbonyl olefination with α-metalated isocyanides [59].

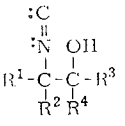
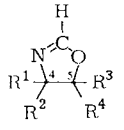
b	H	C_6H_5	Cinnam-aldehyde	1,4-Diphenyl-1,3-butadiene	35 [a]
b	H	C_6H_5	Cyclo-hexanone	Benzylidene-cyclohexane	11 [a]
b	H	C_6H_5	Benzo-phenone	Triphenyl ethylene	74 [b]
c	C_6H_5	C_6H_5	Benzaldehyde	Triphenylethylene	30 [a]
d	H	$CH=CH_2$	Benzophenone	1,1-Diphenyl-1,3-butadiene	40 [b]
e	H	$CH=C(CH_3)_2$	Acetophenone	1,4,4-Trimethyl-1-phenyl-1,3-butadiene	57 [b]



[a] In tetrahydrofuran under reflux. [b] In tetrahydrofuran at −60 °C.

In every case investigated so far the carbonyl addition (in tetrahydrofuran) proceeds very rapidly even at about −70 °C. The same is true of the cyclization *(53)→(54)*, though the equilibrium probably lies well to the left. The elimination of cyanate also proceeds at low temperatures, provided that it leads to a particularly stable olefin (cf. Table 2). In general, however, more or less prolonged refluxing in tetrahydrofuran (or standing at room temperature) will be necessary.



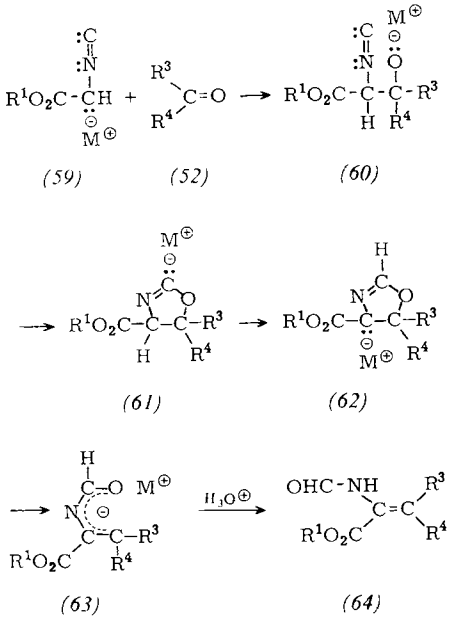
Apart from the cases in which the reaction leads to to *(55)* and *(56)* even at about −70 °C, it is possible, by suitable treatment of the reaction mixture, to iso-

late either the adducts *(53)* in the form of β-hydroxyalkyl isocyanides *(57)* or the metalated oxazolines *(54)* as oxazolines *(58)* (cf. below).

The hydroxy compounds *(57)*, which are important as precursors for the preparation of α,β-unsaturated alkyl isocyanides[63] and 2-amino 1-alcohols, are obtained by addition of the carbonyl compound *(52)* to a solution or suspension of *(51)* in tetrahydrofuran at −70 °C, followed after a few minutes by neutralization with glacial acetic acid[64]. In this way, isocyanomethyllithium *(51a)* reacts with acetophenone to give 1-isocyano-2-phenyl-2-propanol *(57a)* in 80% yield, and with benzaldehyde to give 2-isocyano-1-phenylethanol *(57b)* (75% yield)[64]. Addition of benzoyl chloride instead of glacial acetic acid gave the benzoyl derivative of *(57b)* in 78% yield[65].

(57)

(58)



(a), $R^1 = R^2 = H$, $R^3 = C_6H_5$, $R^4 = CH_3$
(b), $R^1 = R^2 = R^3 = H$, $R^4 = C_6H_5$

Since they are less acidic than triphenylalkylphosphonium salts, alkyl isocyanides *(50)* cannot be metalated so easily. On the other hand, the compounds *(51)* add more readily to the carbonyl group than the Wittig reagents[66]. Thus α-lithiobenzyl isocyanide *(51b)* reacts with benzophenone even at −70 °C to give triphenylethylene (74%), whereas the analogous reaction with benzylidenetriphenylphosphorane proceeds only slowly even at 75 °C (in ether)[67]. α-Lithiobenzhydryl isocyanide *(51c)* also reacts readily (at about −70 °C) with benzaldehyde (cf. Table 2), whereas diphenylmethylenetriphenylphosphorane is inert toward aldehydes and ketones[68].

3.3. Formylaminoalkoxycarbonylmethylenation of Carbonyl Compounds

The reaction of metalated isocyanoacetic esters *(59)*, prepared from isocyanoacetic esters and *e.g.* butyllithium, sodium hydride, or sodium ethoxide (cf. Table 3) with aldehydes and ketones, in aprotic solvents, follows a surprising course. It leads (on acid hydrolysis) to β-substituted α-formylaminoacrylic esters *(64)*[69] (cf. Table 3), and so allows the replacement of the carbonyl oxygen by the formylaminoalkoxycarbonylmethylene group in a single operation.

Like the carbonyl olefination (cf. Section 3.2), this exchange reaction probably begins with the nucleophilic addition of *(59)* to the carbonyl group (cf. Scheme 6); this yields *(60)*, which cyclizes to form *(61)*. An intramolecular proton shift, favored by the acidity of the hydrogen atom on C-4, now leads to the 4-anionized oxazoline *(62)*, which gives the "pentadienyl anion" *(63)* by electrocyclic ring cleavage[70]. This anion can be isolated in the form of *(64)*.

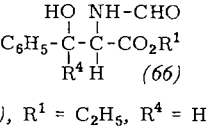
[70] Check experiments with 2-oxazolines having an ethoxycarbonyl group on C-4 have shown that anions of the type *(62)* suffer ring cleavage; *M. T. Reetz*, unpublished; isoelectronic ring cleavages cf. *H. Kloosterziel*, *I. A. A. van Drunen*, and *P. Galama*, Chem. Commun. *1969*, 885.

(Erlenmeyer synthesis)[71]. However, this process requires forcing conditions, and is practically confined to carbonyl compounds that cannot undergo aldol condensation[70]. On the other hand, the reaction of *(59)*, M = Li, with cyclohexanone, which has a tendency to undergo self-addition, gives the acrylic ester in a yield of 87% (cf. Table 3).



α-Acylaminoacrylic esters of the type *(64)* are of interest because of the various transformations that they can undergo, *e.g.* into α-keto and α-amino acids[71]. Unlike the acrylic acids formed in the Erlenmeyer synthesis[71], the esters *(64)* can evidently add suitable nucleophiles to their double bond after the manner of a Michael addition.

For example, if phenylmethanethiol is added to the reaction mixtures with benzaldehyde or acetone (in tetrahydrofuran with butyllithium, sodium hydride, or potassium *tert*-butoxide as the base[72]) after formation of *(64)*, the ester group then being hydrolyzed by heating with sodium hydroxide solution during isolation of the product, the reaction gives *S*-benzyl-*N*-formyl-β-phenylcysteine *(65a)* in a yield of about 70% or *S*-benzyl-*N*-formylpenicillamine *(65b)* in a yield of about 61%[73].

(66)

(a), $R^1 = C_2H_5$, $R^4 = H$
(b), $R^1 = R^4 = H$
(c), $R^1 = H$, $R^4 = CH_3$

The formation of *N*-formyl-β-phenylserine ethyl ester *(66a)* from benzaldehyde and ethyl sodioisocyanoacetate in ethanol (cf. Table 3) cannot yet be explained. It is possible that in competition with the proton migration, the intermediate *(61)* or *(62)*, $R^1 = C_2H_5$, $R^3 = C_6H_5$, $R^4 = H$, M = Na, is protonated by the solvent to form the oxazoline (cf. below). In the alkaline medium this takes up ethanol on the double bond and *(67)* is formed, which gives *(66a)* on subsequent hydrolysis in dilute acid.

(67)

N-Formyl-β-phenylserine *(66b)* and *N*-formyl-β-phenylthreonine *(66c)* can be isolated in yields of about 65 and about 50% respectively on dropwise addition of a solution of equimolar quantities of ethyl isocyanoacetate and benzaldehyde or acetophenone to a suspension of excess powdered sodium hydroxide in tetrahydrofuran, followed by stirring for a short time[74]. The details of the reaction course are again unclear.

3.4. 2-Oxazolines from α-Metalated Isocyanides and Carbonyl Compounds

If instead of glacial acetic acid (see above), methanol or water is added in the reaction of α-metalated isocyanides *(51)* with aldehydes and ketones *(52)*, *i.e.* if the reaction mixture is worked up in the alkaline state, 2-oxazolines *(58)* can be isolated (cf. Table 3)[75].

The carbonyl adducts *(53)* (cf. Scheme 5) are evidently reversibly protonated, and the metalated oxazolines *(54)* irreversibly, in the alkaline medium. 2-Oxazolines are also formed from β-hydroxyalkyl isocyanides of the type *(57)* on treatment with methanolic sodium methoxide[64, 76].

Table 4. 2-Oxazolines *(58)* from α-metalated isocyanides *(51)* and carbonyl compounds *(52)* [75].

(51)	*(52)*	*(58)*	Yield (%)
(51a)	Benzaldehyde	5-Phenyl-2-oxazoline	60 (85) [a]
(51a)	Cinnamaldehyde	5-Styryl-2-oxazoline	58
(51a)	Furfural	5-Furyl-2-oxazoline	44
(51a)	Acetone	5,5-Dimethyl-2-oxazoline	31
(51a)	Cyclohexanone	Cyclohexanespiro-5′-(2-oxazoline)	30
(51a)	Acetophenone	5-Methyl-5-phenyl-2-oxazoline	69 (80) [a]
(51d)	Cyclohexanone	Cyclohexanespiro-5′-(4-vinyl-2-oxazoline)	13
(51b)	Cyclohexanone	Cyclohexanespiro-5′-(4-phenyl-2-oxazoline)	26
(51b)	Acetaldehyde	5-Methyl-4-phenyl-2-oxazoline	17 [77]
(51c)	Cyclohexanone	Cyclohexanespiro-5′-(4,4-diphenyl-2-oxazoline)	72
(51e)	Acetophenone	4-(β,β-Dimethylvinyl)-5-methyl-5-phenyl-2-oxazoline	46 [a]
Ethyl α-sodio-α-isocyanoacetate	Formaldehyde	4-Ethoxycarbonyl-2-oxazoline	53 [b]
[*(59)*, $R^1 = C_2H_5$, M = Na]	Benzaldehyde	4-Ethoxycarbonyl-5-phenyl-2-oxazoline	72 [b]
Ethyl α-sodio α-isocyanopropionate	Benzaldehyde	4-Ethoxycarbonyl-4-methyl-5-phenyl-2-oxazoline	86 [b]

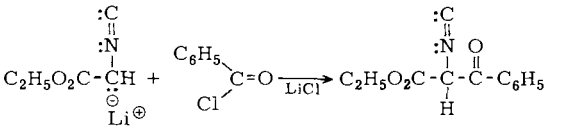
[a] *A. Nürrenbach* and *W. A. Böll*, private communication [methanolysis a few minutes after addition of *(52)* to *(51)* in tetrahydrofuran at −70 °C].

[b] In ethanol and a little sodium cyanide as catalyst [73].

The syntheses known at present for 2-oxazolines start from *N*-acyl 2-amino 1-alcohols[78, 79], which relatively readily undergo ring closure[79], but become increasingly difficult to obtain with increasing substitution on the carbon atoms[79]. The advantage of the new synthesis is that the C-4–C-5

[76] On the cyclization of β-hydroxy isocyanides to form 2-oxazolines, see also *I. Hagedorn*, Angew. Chem. *75*, 305 (1963).

[77] *M. T. Reetz*, unpublished.



[78] Cf. *J. W. Cornforth* in *R. C. Elderfield*: Heterocyclic Compounds. Wiley, New York 1957, Vol. 5, p. 377ff.

bond is formed during the reaction. The synthesis should provide a route to substituted 2-amino 1-alcohols, since 2-oxazolines are readily hydrolyzed in acidic media [78]. A synthesis of 2-amino 1-alcohols that allows wide scope for variation of the substituents on the carbon is of great interest, since many substances of this class are biologically active. In this connection, mention should be made of the 4-ethoxycarbonyl-2-oxazolines (cf. Table 4, last three lines), which can be obtained from ethyl α-isocyanoacetate or-propionate and aldehydes in ethanol with sodium cyanide as catalyst. Their hydrolysis in aqueous ethanol with a little triethylamine affords ethyl esters of *N*-formylserine and derivatives substituted in the α- or β-position [73].

3.5. Oxazoles from α-Metalated Isocyanides and Acylating Agents

On addition of benzoyl chloride to a suspension of ethyl lithioisocyanoacetate *(59a)* in tetrahydrofuran at −70 °C followed by acidic working up, 4-ethoxycarbonyl-5-phenyloxazole *(69)* can be isolated in a yield of about 80% [74]. This synthesis probably proceeds *via* the β-keto isocyanide *(68)*, which enolizes and cyclizes during working up [80]. 5-Phenyloxazole *(69)* is obtained by reaction of isocyanomethyllithium *(51a)* with *N*-methylbenzanilide and addition of methanol before working up [64]. Similarly, the oxazole *(69)* can be obtained in a yield

(59a) *(68)*

(69)

(a), $R^1 = CO_2C_2H_5$, $R^2 = C_6H_5$
(b), $R^1 = H$, $R^2 = C_6H_5$
(c), $R^1 = CH{=}C(CH_3)_2$,
$R^2 = -\overset{O}{\overset{\|}{C}}-\overset{O}{\underset{H}{\triangle}}-C(CH_3)_2$

of 50% from 1-lithio-3,3-dimethylallyl isocyanide *(51e)* and β,β-dimethylglycidic acid ethyl ester [64].

Isocyanomethyllithium *(51a)* does not appear to react uniformly with esters of carboxylic acids [64]; systematic studies will be required in order to establish which acylating reagents are most suitable for each of the compounds *(51)*.

I am grateful to Dr. W. Fabian, Dr. D. Walter, Dr. H. Schäfer, Dr. K. Fellenberger, Dr. M. Rizk, Dr. F. Gerhart, Dipl.-Chem. D. Hoppe, and R. Schröder for their enthusiastic cooperation. We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Badische Anilin- & Soda-Fabrik for their support of these investigations. Thanks are also due to Dr. A. Nürrenbach and Dr. W. A. Böll, Badische Anilin- & Soda-Fabrik, for the use of unpublished results.

Chemical Lasers[**]

By K. L. Kompa[*]

Chemical lasers are based on the new principle of obtaining energy in the form of coherent radiation from chemical reactions. Since the discovery of the first laser of this type in 1965, laser emission has been investigated in a considerable number of fast gas-phase reactions. In physical chemistry such lasers provide a diagnostic tool for the detailed investigation of the energy distribution in elementary reactions. The barrier to technological use has probably also been overcome by the recent continuous operation of a chemical hydrogen fluoride laser. An attempt is made in the present article to trace the development of this still youthful field and to demonstrate the possibilities and limitations of the generation of energy with chemical lasers.

1. Introduction

Besides the well-known methods of energy production by chemical means, such as are used for heating, lighting, and driving machinery, a new principle of chemical production of energy has recently been developed. This is the total or partial liberation of the heat of a chemical reaction as stimulated emission of one or more reaction products. Reaction systems of this nature are known as chemical lasers, since the

[*] Dr. K. L. Kompa

8 München 2, Meiserstrasse 1 (Germany)

[**] Based on a lecture given at the General Meeting of the GDCh, September 15 to 20, Hamburg 1969.

excitation energy of the molecules, which appears as laser emission, stems from a chemical reaction. The laser is therefore chemically pumped. This principle can best be illustrated by the following specific example.

In the exothermic reaction of a fluorine atom with a hydrogen molecule to form hydrogen fluoride

$$F + H_2 \rightarrow HF + H \qquad (1)$$

(activation energy E_A = 1.7 kcal, reaction enthalpy $\Delta H = -31.6$ kcal/mole), 33.3 kcal/mole are liberated. This energy can be distributed over the translational degrees of freedom ($E_{trans.}$) of HF and H and can lead to the excitation of rotation ($E_{rot.}$) and vibration ($E_{vib.}$) of the hydrogen fluoride molecules. Electronic excitation of the reaction products requires much more energy, and is not possible here. The total energy of the hydrogen fluoride is thus

$$E = E_{vib.} + E_{rot.} + E_{trans.}$$

Provided that the system is in thermal equilibrium, the concentration of vibrationally excited molecules is given by the Boltzmann equation:

$$N_{excited} = N_0 \cdot \exp\left(-\frac{\Delta E}{kT}\right)$$

(N_0 = concentration of unexcited molecules, k = Boltzmann const., T = absolute temperature). Based on the vibrational excitation of hydrogen fluoride, with ΔE (energy for the excitation of the first vibrational state) $\approx$12 kcal or $\approx$4000 cm^{-1}, the concentration $N_{excited}$ found for room temperature, *i.e.* with $kT \approx 200\ cm^{-1}$, is negligible. However, the Boltzmann equilibrium with the environment may be considerably disturbed during or shortly after a fast chemical reaction in the gas phase, and certain molecular states may be overpopulated under these conditions of disequilibrium. The population densities of excited states may then be inverted with respect to the numbers of the Boltzmann distribution.

If one still tries to express such an inversion of population by means of a Boltzmann relation, a negative temperature value appears in the formula given. Since equilibrium is reached more rapidly for translation and rotation than for vibrational excitation, population inversions are most readily found among vibrational states. A reaction system with an overpopulation of excited molecular states constitutes a molecular amplifier, as can be easily shown. According to Beer-Lambert's law, the decrease in the intensity of a photon beam during passage through an absorbing medium is described by

$$\frac{dI}{I} = -\varepsilon c l \quad \text{or} \quad I = I_0 \cdot \exp(-\varepsilon c l)$$

(I = intensity after passing through the medium, I_0 = incident intensity, l = thickness of absorbing layer, c = concentration). If the populations of the ground and excited states are interchanged (I becomes greater than I_0), the absorption coefficient ε must become positive, and is then better named amplification coefficient. The amplification process is complementary to the absorption process.

A preliminary estimation may serve to show the energy output that can be expected from such chemical laser amplifiers. If a reaction volume of 10 l can be filled in a sufficiently short time with a total pressure of 150 torr of a 1:1 mixture of fluorine atoms and hydrogen molecules [cf. eq. (1)], corresponding to 45 mmole of each reactant, and if half of the hydrogen fluoride molecules (22.5 mmole) formed emit a vibrational quantum corresponding to $\approx$ 12 kcal/mole or $\approx$ 50 kWs/mole, the radiation pulse emitted will have an energy of >1000 Ws, which exceeds the pulsed energy output of any of the high power laser systems described so far[*]. However, it will be necessary to modify this estimate repeatedly in the course of the following discussion. A chemical laser can be constructed at relatively low experimental cost, since it merely involves a chemiluminescence experiment in a suitable optical resonator. Various methods have been used for the production of the initial concentration of a reactive species, like, for instance, fluorine atoms in the above example. Before proceeding to the description of experimental details, let us consider the reaction types and some of the reaction systems in which chemical laser emission has been observed up to now.

2. Reaction Principles

Table 1 shows the types of reaction that can lead to chemical lasers. The range extends from the photodissociation type through a number of bimolecular exchange reactions to elimination and photoelimination. All the chemical lasers described so far in the literature are listed in Table 2. The photodissociation lasers, which can only be regarded with reservation as chemical lasers, have been arranged in a separate chronological list. This list includes the first example in the production of excited iodine atoms by flash photolysis of alkyl iodides, preferably trifluoromethyl iodide. The resulting iodine laser, whose emission occurs at 1.315 μm, has an optical amplification of more than 100 dB/m[**], which is greater than that of any other known gas laser. Lasers of this type operate pulsewise, since the reaction mixture must be renewed after each "shot". Continuous operation is in principle possible in a flow system with a continuous throughput of the reaction material. The iodine atom and the bromine atom lasers are the only examples in Table 2 in which electronically excited reaction products appear. In all other cases known at present, with the exception of a hydrogen fluoride

[*] In conventional high power lasers ruby or neodymium glass is mostly used as amplifying material.

[**] dB/m = decibels per meter length of laser tube; decibel = 10 × log (output power/input power) of an amplifier.

Table 1. Types of reactions in which chemical laser emission has been observed.

Reaction type	Example	Refs.
Photodissociation	$CF_3I \xrightarrow{h\nu} I^* + CF_3$	[19, 20, 26]
Photoelimination	$CH_2CHF \xrightarrow{h\nu} HF^\dagger + C_2H_2$	[1, 17]
Abstraction	$Cl + HI \longrightarrow HCl^\dagger + I$	[10, 11, 13]

laser based on pure rotational excitation, vibrational-rotational emission is observed in the infrared region of the spectrum. The first really chemical laser as opposed to photodissociation was discovered in 1965 by *Kasper* and *Pimentel* in the flash-photolytically initiated hydrogen/chlorine explosion (Table 2). Vibrationally excited hydrogen chloride is formed here in the reaction of a hydrogen atom with molecular chlorine [eq. (4)]. The hydrogen atoms required are formed in the preceding reaction step (3):

$$Cl_2 \xrightarrow{h\nu} 2\ Cl \tag{2}$$

$$Cl + H_2 \rightarrow HCl + H \quad \Delta H = +1\ \text{kcal} \tag{3}$$

$$H + Cl_2 \rightarrow HCl + Cl \quad \Delta H = -45\ \text{kcal} \tag{4}$$

The nearly thermoneutral reaction (3) yields only "cold", non-vibrationally excited hydrogen chloride. In the formation of hydrogen fluoride [eq. (1)], on the other hand, even the first step of the chain reaction is exothermic, and it was this, among other reasons, that led to the discovery of hydrogen fluoride laser emission in 1967 by *Kompa* and *Pimentel*. Similar considerations also led to the development of a more effective hydrogen chloride laser, which is pumped by the reaction of chlorine atoms with hydrogen iodide molecules (Table 2). The carbon monoxide laser from the oxidation of carbon disulfide has so far received comparatively little attention. Molecular fluorine did not seem very suitable as a source of fluorine atoms for a laser according to eq. (1), owing to its problems of handling and to its low photochemical yield of fluorine atoms. On the other hand, a large number of volatile inorganic fluorides constitute photochemical fluorine atom sources with high absorption coefficients for the photolysis light; they present no difficulty in handling, even in mixtures with hydrogen, and do not attack the laser apparatus. The various fluorides exhibit characteristic differences in the emission spectra of the corresponding laser system.

Among the many hydrogen fluoride lasers, those in which excited hydrogen fluoride molecules are formed

by photoelimination from fluoroalkenes are a special case. It may be supposed that conclusions concerning the stereochemical course of the elimination could be drawn from the differences in the laser emission observed with *cis* and with *trans* alkenes. Laser emission is also observed on spontaneous decomposition of molecules formed by combination of free alkyl and fluoroalkyl radicals. Pure rotational laser emission has occasionally been observed to accompany the vibrational-rotational emission of hydrogen fluoride under certain conditions (cf. Table 1).

The excited vibrational states of hydrogen halide molecules are subject to extremely effective deactivation processes, which always compete with the stimulated emission. It may therefore be advantageous to transfer the excitation energy initially present in the reaction products to added molecules of an admixture that is capable of better energy storage. A number of carbon dioxide lasers can be pumped indirectly in this way. The situation is particularly favorable in the transfer of energy from hydrogen chloride or from deuterium fluoride to carbon dioxide, which is a near-resonance process. This principle of laser-pumping may be called chemosensitization. Finally, we should also mention a carbon dioxide laser that can be pumped by the oxidation of carbon compounds (Table 2). The group of indirectly chemically pumped lasers can undoubtedly be expanded further, and it is unlikely that carbon dioxide will remain the only example.

3. Experimental Arrangements

The experimental problems that arise in the operation of chemical lasers will be illustrated for the example of the flash-initiated hydrogen fluoride laser. "Classical" flash photolysis, the successful development of which earned the Nobel Prize for *R. G. W. Norrish* and *G. Porter* in 1967 [28], uses a pulse capacitor discharge through a xenon-filled quartz tube as the light source. Flash durations of between 10 and 50 μs can be achieved with discharge energies of a few thousand Ws. The half-life of reaction (1) for initial concentrations >1 torr, however, is considerably less than 1 μs. Shorter flashes are therefore desirable to achieve the full possible radiation density, *i.e.* to make full use of the possibilities offered by the high reaction rate for the fast build-up of the hydrogen fluoride concentration. An arrangement that has proved suitable for this purpose is described by *Welge et al.* [29], in which a series of spark gaps (arranged in a nitrogen atmosphere along the absorption tube) is used instead of closed xenon flash tubes for the generation of light [5, 30].

The construction principles of this apparatus are shown in Figure 1. The eight spark gaps are supplied by eight high-voltage pulse capacitors [*] (1 μF/20 kV each, E_{max} = 200 Ws). The discharge gaps are connected as in a Marx generator, and can therefore be triggered synchronously. Figure 1a shows the lucite spark chamber with the eight pairs of electrodes and the absorption tube, which is made of fused quartz with a high optical transparency, along the axis of the cylinder. Photolysis light sources of this type are characterized by good accessibility of the vacuum UV (below 2000 Å) and high reliability, as well as by the short duration of the flash. However, xenon flash tubes will retain their place for studies in which a high light yield and a good optical coupling between the photolysis lamp and the absorption cell are of primary importance. The light characteristic of such lamps can be greatly improved, with a simultaneous increase in lifetime, by effective preionization. The energy from the laser oscillator can be coupled out for instance by a partly reflecting take-off plate placed in the beam path as shown in Figure 1. A beam splitter then cuts off part of the signal for recording of the total pulse shape, while the main part of the emission is spectrally analyzed in an infrared monochromator. The individual lines in the emission signal are then recorded by a second detector placed behind the monochromator exit slit.

The total signal (or alternatively the flash profile) and the single-line emission are displayed on a double-beam oscilloscope and photographed.

4. Build-Up of the Laser Emission

The build-up of the laser emission is illustrated in Figure 2. The spark chamber with the eight spark gaps, the laser tube with the end windows at Brewster's angle, and the resonator mirrors are shown schematically. The photons entering the tube from the sparks first produce reactive particles, *e.g.* chlorine atoms in accordance with eq. (2) or fluorine atoms. After a certain number of collisions of the fluorine atoms with hydrogen molecules, vibrationally excited hydrogen fluoride is formed. Some of the molecules formed emit spontaneously in various directions in space and form the noise background of the oscillator. The noise components that lie in the axis of the tube undergo feedback by reflection at the mirror surfaces, are amplified, and cause the laser to start oscillating. In the arrangement shown in Figure 2, part of the power is coupled

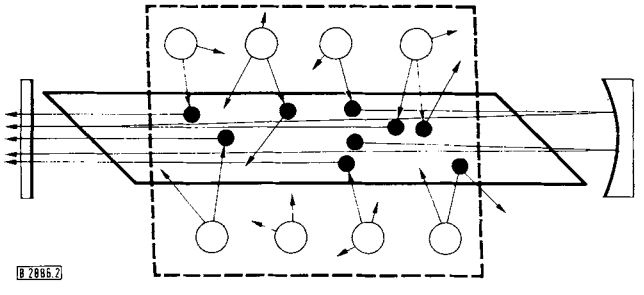

Fig. 2. Build-up of the laser emission (for explanations see text).

out by the semitransparent plane mirror shown on the left. The emission signal of a laser oscillator of this type can be further amplified by passage through other tube volumes that contain excited molecules produced in the same manner. Two additional experimental aspects deserve mention in this connection. These are the production of giant pulses and the tuning of resonators with the aid of a grating instead of a resonator mirror. The buildup of the laser emission (see Figure 2) can be divided into three steps: 1) the primary photolysis; 2) the production of energy by the chemical reaction; 3) the output of energy by stimulated emission, which occurs under the conditions described as soon as a certain threshold value is exceeded. A limited period of storage of energy in the molecules may be inserted between steps 2 and 3. To achieve this, the resonator is switched on (at a predetermined time after the photolysis flash) only when the energy is far in excess of the threshold value. Controlled switching of the resonator quality ("q-switching") leads to emission of the stored excitation energy in a very short time (a few nanoseconds) and hence to very much higher peak power outputs [31]. Variation of the switch-on time also yields information on the time dependence of the storage, and so allows conclusions to be drawn regarding the relaxation and deactivation processes in chemical laser systems [32]. Chemical lasers, like other molecular lasers, emit not only single lines but a spectrum that is more or less rich in lines. However, if a dispersing element is inserted, *e.g.* a prism or a grating in the resonator, the resonator condition can be satisfied only for a limited range of wavelengths, and hence usually only for one emission line. The resonator can then be tuned over the entire emission spectrum by grating rotation. The usefulness of such line selection in physical-chemical studies becomes apparent in the use of chemical lasers as spectroscopic light sources. On the other hand, the possibility of studying isolated single transitions allows the investigation of coupling phenomena and questions of communication between the molecular energy states involved in the emission [30].

5. Pulsed Operation of Chemical Lasers, Energy Yield

The discussion so far has been confined to the pulsed operation of chemical lasers. In every case the pumping reaction must be started by an external auxiliary energy source that provides an igniting pulse. The oscillogram in Figure 3 shows the initiating photolysis flash of an arrangement as shown in Figure 1, as well as the laser emission signal produced by it. It can be seen that the flash has a half-peak duration of 1.2 μs, whereas the laser signal lasts up to 8 μs. The laser was produced here by photolysis of a mixture of iodine pentafluoride as a source of fluorine atoms and hydrogen. Figure 4 shows a comparison of two single-line signals, which were not recorded directly in this case, but were measured with an RC integrator for better comparability of the line intensities. The change in the shape of the total emission signal as compared with Figure 3 is explained by the

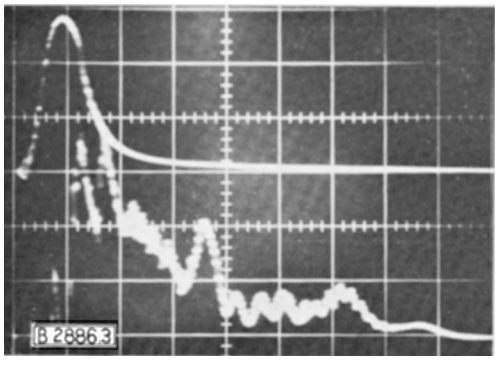

Fig. 3. Time profiles of the photolysis flash (upper trace) and of the hydrogen fluoride laser emission (lower trace): 30th illumination of a mixture of iodine pentafluoride (13 torr) and hydrogen (13 torr), time scale 1 μs/division.

fact that tungsten hexafluoride was used as the source of fluorine atoms in this case.

If the emission in a photolytically initiated laser is pumped by only one reaction step, *e.g.* reaction (1), the radiation output of the laser is limited by the available amount of photolysis light, provided that not more than one photon can be emitted per hydrogen fluoride molecule. The quantum yield of the conversion of flash light into laser radiation cannot exceed 1. The yield can be increased in two ways. On excitation of sufficiently high vibrational states, several photons can be emitted from each hydrogen fluoride molecule formed, *e.g.* by an emission cascade *via* several vibrational states. Moreover, the use of chain reactions enables a large number of hydrogen fluoride molecules to be obtained for each fluorine atom that reacts initially. In particular, branched, self-accelerating chain reactions[33] give quantum yields that can be as high as 10^5 for the formation of hydrogen fluoride from hydrogen and molecular fluorine, depending on the reaction conditions[14]. A very small trigger pulse is then sufficient for the production of a high hydrogen fluoride concentration, and this is perhaps the greatest technological stimulus for the development of chemical lasers. The "ideal" chemical laser is thus largely or even totally independent of external energy sources. Lasers having these properties have very recently come within the bounds of technical feasibility[5,16].

[33] *N. N. Semenov*, Some Problems of Chemical Kinetics and Reactivity, Vol. II, Pergamon Press, Oxford 1959; cf. also *K. J. Laidler*, Chemical Kinetics, McGraw-Hill Book Comp., New York, Toronto-London 1950, p. 180ff.

A chain reaction for the formation of hydrogen fluoride may proceed as follows[14,33].

$$F_2 \xrightarrow{E_{diss}} 2\,F \qquad (5)$$

$$F + H_2 \rightarrow HF^* + H \qquad \Delta H \triangleq -32\ \text{kcal} \qquad (1)$$

$$H + F_2 \rightarrow HF^* + F \qquad \Delta H \triangleq -98\ \text{kcal} \qquad (6)$$

$$HF^* + F_2 \rightarrow HF + 2\,F \qquad (7)$$

Chain branching occurs here in reaction (7), where vibrationally excited hydrogen fluoride from the preceding step (6) causes fluorine molecules to dissociate in collisions. It can be seen that reaction (7) competes with the equally possible stimulated emission of the hydrogen fluoride molecules formed in (6). Chain branching therefore occurs only at certain pressures and under certain reaction conditions. Lasers having reaction (6) in addition to reaction (1) as a pumping step, which therefore have a chain length >1, have been found not only in the hydrogen/fluorine system, but also in the flash photolysis of iodine pentafluoride/hydrogen mixtures[5]. However, so far there have been no reports on accurate quantum yield determinations and energy conversion data.

6. Continuous Wave Operation

In addition to the pulsed mode described, continuous operation of a chemical laser is possible for instance in a self-propagating chain reaction. Figure 5 shows

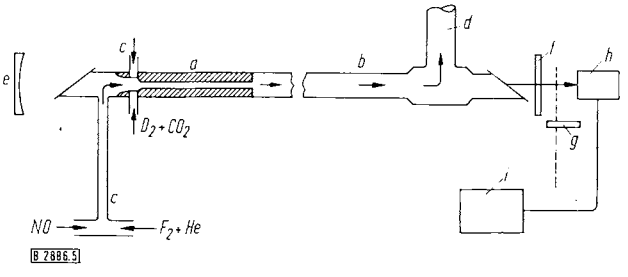

Fig. 5. Continuous operation of a hydrogen fluoride laser (after [16]). a) Teflon reaction capillary, b) Pyrex glass tube, c) gas injectors, d) to cold trap and pump, e) highly reflecting resonator mirror, f) plane mirror (0.5% transmission), g) chopper. h) bolometer, i) tuned amplifier.

the experimental arrangement used in this case. The initial concentration of fluorine atoms is produced here by the reaction:

$$NO + F_2 \rightarrow NOF + F \qquad (8)$$

The maximum output of this laser, which is still a very small device operating with a fluorine throughput of 390 μmole/s, was reported to be 0.23 W. Though this laser can be operated both as a hydrogen fluoride and as a deuterium fluoride laser, the energy transfer to carbon dioxide is advantageous.

The main reason for this is that the energy transfer largely eliminates the strong self-deactivation of the

excited hydrogen halides [*]. Another approach to the problem of self-quenching in hydrogen fluoride lasers is the use of gas-dynamic principles in addition to chemical pumping. Such a device has yielded the notable energy conversion of 12% [**] with a cw-power output of nearly 500 W [35]. Figure 5a illustrates its principles of operation. First nitrogen

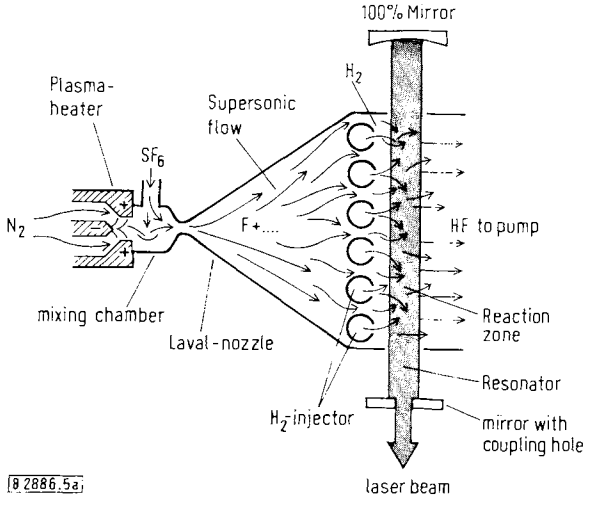

Fig. 5a. Chemical and gas-dynamic hydrogen fluoride laser.

molecules are heated to 2300 °K in a plasma heater. By subsequent mixing with sulfur hexafluoride fluorine atoms are produced thermally. The atomic fluorine flow is 0.03 moles/s. This mixture which has been cooled by rapid expansion behind a Laval nozzle to nearly room temperature is brought together with molecular hydrogen in a special injection system. The reaction zone of the mixture that is still moving with supersonic velocity is placed in an optical resonator, whose active length is only 17 cm. The number of experimental cw-laser set-ups of this type is considerably increasing at present.

7. Physico-Chemical Conditions

The choice of hydrogen fluoride for the system used as an example in the present discussion will now be explained. Figure 6 shows some energy profiles corresponding to reaction (1) for formation of various vibrational states of hydrogen fluoride. Since the energy associated with the excitation of a vibrational quantum is approximately 12 kcal/mole, the highest excited state that can be reached with the heat of reaction of this process is the third vibrational level (v = 3). The rotational states that subdivide each vibrational state are not shown in the diagram. The observed laser emission lines correspond to transitions between vibrational-rotational states, the vibrational quantum number v always changing by 1. An important advantage of the hydrogen fluoride molecule over other diatomic molecules containing heavy atoms and over compounds with three or more atoms is the relatively small number of energy states that can be occupied. Because of this, no excessive energy "dilution" occurs. Figure 6 illustrates rate

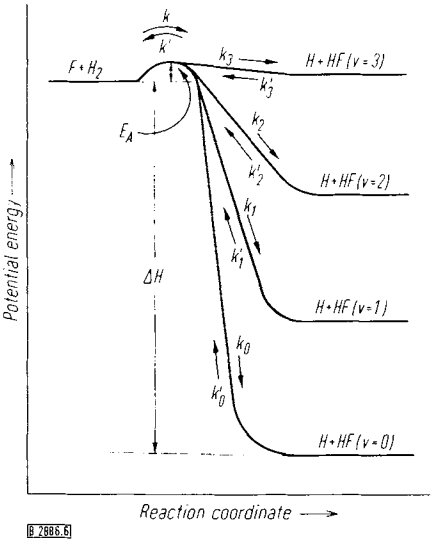

Fig. 6. Relative energies of the vibrational levels of hydrogen fluoride that can be populated by the reaction F + H_2 → H + HF (further explanations in text).

constants k_v that differ fromt he overall rate constants of the reactions in that they give the specific rates of formation of hydrogen fluoride for definite vibrational states. The differences in the constants k_v then determine the differences in the populations of the various states:

$$N_v \sim k_v \quad \text{or} \quad \frac{N_v}{N_{v-1}} = \frac{k_v}{k_{v-1}}$$

The constants k_v can be derived from the characteristics of the laser emission, which contain the excess populations of certain excitation states and hence the differences in population as the principal parameters [1,6,17,18]. The determination of these constants is of great importance to the understanding of elementary chemical reactions, and therefore appears as an important goal of chemical laser studies in physical chemistry. Investigations of this nature have given a value of 5.5 for the population ratio $N_{v=2}/N_{v=1} = k_{v=2}/k_{v=1}$ [6]. Other determinations carried out by the alternative method of observing spontaneous infrared chemiluminescence [34] gave $k_{v=2}/k_{v=1} = 3.5$ and $k_{v=3}/k_{v=2} = 0.47$. Moreover, the part of the total energy available in reaction (1) that leads to vibrational excitation, E_v/E_{total}, is found to be 57%, while only 6% appears as rotational energy and 37% as translational energy. These values show an effective conversion of the heat of reaction into vibrational energy, and also

[*] Note added in proof: A CO_2 laser operating in the arrangement shown in Fig. 5 has now been reported to have a conversion efficiency of 4% (*T. A. Cool* and *R. R. Stevens*, Appl. Phys. Lett. *16*, 55 (1970)).

[**] One should note for comparison that the carbon dioxide laser which is the most efficiently pumped gas laser so far has 15–20% energy conversion.

[34] *J. C. Polanyi* and *D. C. Tardy*, J. chem. Physics, in press; for a description of the method of investigation cf. *K. G. Anlauf, P. J. Kuntz, D. H. Maylotte, P. D. Pacey*, and *J. C. Polanyi*, Discuss. Faraday Soc. *44*, 183 (1967).

[35] *D. J. Spencer, H. Mirels, T. A. Jacobs*, and *R. W. F. Gross*, Appl. Phys. Lett. *16*, 235 (1970).

indicate a strong preference for the formation of hydrogen fluoride with v = 2. Accordingly transitions from v = 2 to v = 1 also occur preferentially in lasers pumped by reaction (1). This emission appears in the infrared region between 2.7 and 2.9 μm. In laser systems in which the additional reaction (6) contributes to the pumping, higher vibrational states up to v = 6 are excited. The emission at about 3 μm corresponds to a large number of vibrational-rotational lines, but no detailed rate constants have been published so far [5, 14]. This description of the parameters of chemical laser emission has been confined to hydrogen fluoride lasers as the area that has been most extensively studied. In view of the intense activity in this field, however, similar results may be expected in the near future for other, new chemical lasers.

8. Possible Applications

There is considerable scope for the use of these lasers in various fields. In chemistry, sources of strong monochromatic infrared radiation offer the long-term prospect of use as a "selective Bunsen burner" with the object of carrying out chemical reactions with a controlled supply of energy in certain vibrational degrees of freedom of a reaction system. Chemical lasers are also already being used as spectroscopic light sources for IR fluorescence studies [13]. An obvious point of technological interest is the possible freedom from dependence on external energy sources. Despite great hopes, it is not yet clear whether the possibly very high conversion efficiency of these lasers would make their use in high energy applications (*e.g.* for plasma production) seem interesting. No chemical laser with a pulse energy of more than 1 Ws has yet been described, but pulse energies of the order of 10^3 Ws, which correspond to the value estimated at the beginning of this article, have been predicted for laboratory systems.

Financial support of our work in this field by the Stiftung Volkswagenwerk, the Deutsche Forschungsgemeinschaft, and the NATO Office of Scientific Research is gratefully acknowledged. I also wish to thank Dipl.-Phys. Jochen Wanner and Dipl.-Chem. Peter Gensel for their independent and enthusiastic cooperation.

Developments in Inorganic Arc Plasma Chemistry

By U. Landt [*]

For some 10 to 15 years, plasma chemistry has been in a state of rapid development on the research side, whereas only a few reactions are at present carried out industrially in a plasma jet. After a short description of the properties of thermal plasmas, the technique of production and stabilization of arc plasmas and the various types of arc plasma generators are discussed. The course of chemical reactions at plasma temperatures is then considered, with particular reference to kinetic and thermodynamic aspects. A special part of the review is devoted to a detailed description of the inorganic reactions that have been carried out in the plasma jet (preparation e.g. of compounds containing nitrogen, C–N and C–F compounds, ozone, nitrides, cyanides, carbides, metal oxides, and metals from metal oxides and from halides).

1. Development and Present Position of Plasma Chemistry

A plasma is nowadays generally taken to be a partly or completely ionized gas that is externally electrically neutral, conducts electricity, and has a higher internal energy than an un-ionized gas. The energy required for the production and maintenance of a plasma can be supplied as heat or as electrical or mechanical energy. The most important methods for the supply of electrical energy are arc and glow discharges and electrodeless discharges (high frequency and microwave discharges). Only the arc plasma and its use will be discussed here.

The term "plasma chemistry" is at present used only reluctantly in the literature. Since chemical bonds do not exist at the high temperatures characteristic of most types of plasma, the term is really self-contradictory. Nevertheless, it is shorter than any of the

[*] Dr. U. Landt
Knapsack AG
5033 Knapsack bei Köln (Germany)

alternatives, and will therefore be used here in the sense of the performance of chemical reactions in or with the aid of plasmas.

Chemical plasma processes have been known since the industrial production of oxides of nitrogen by "combustion of air" in the flame arc furnace (*Birkeland* and *Eyde*; *Schönherr* and *Pauling*). The development of plasma chemistry stopped for a long time after the replacement of this process by the cheaper combustion of ammonia. This standstill was mainly due to the high cost of electricity and technical problems.

For some 10 to 15 years, however, plasma chemistry has been developing rapidly, at least on the research side. The intense activity in high-temperature physics in connection with nuclear fusion, the problems encountered in space flight and supersonic technology (re-entry into the atmosphere, rocket propulsion, *etc.*), and the prospect of cheaper electricity from nuclear power stations have also led to a marked growth of interest in chemical plasma technology. This is particularly clear from the IUPAC Symposium in Moscow in 1965 on "Properties and Use of Low-Temperature Plasmas" and the Symposium on "Chemical Reactions in Electrical Discharges" at the 153rd meeting of the American Chemical Society in Miami in 1967 [1].

A number of chemical reactions under plasma conditions have been particularly intensively studied. These include the preparation of acetylene from other hydrocarbons, the chemical fixation of atmospheric nitrogen, and fluorine/carbon reactions. Many other inorganic reactions have also been carried out. Though plasma generators with powers of up to several MW have been developed, practically no use is currently being made of plasma processes in industry, apart from the arc processes for the production of acetylene (Hüls process [2], Du Pont process [3], MHD Research process [4], Knapsack AG's hydrogen arc pyrolysis process [5]). The reasons for this situation are the present high cost of power for most processes, as well as lack of knowledge of the physico-chemical principles underlying processes at plasma temperatures.

It is now becoming increasingly clear that plasma chemistry has reached a point where, after years of a predominantly empirical approach, it is necessary to make a broader study of the theoretical principles and to build up a scientifically and economically supported conceptual basis for profitable industrial use.

2. Properties of the Thermal Plasma

A plasma produced at a pressure ≥ 1 atm is characterized by high charge-carrier densities (of the order of $10^{14}/cm^3$) and a large number of collisions between electrons, ions, atoms, and molecules. To a first approximation, a plasma of this nature may be regarded as being in thermal equilibrium; it is known as a thermal plasma, and is the type that is of most interest to chemists, since all kinetic and reaction equilibria, as well as the other properties of the plasma (mean velocity of the particles, thermal conductivity, electrical conductivity, *etc.*) are functions of the temperature at constant pressure. Thermal plasmas are mainly produced by electric arcs.

At pressures lower than 1 atm, the electron and atom (or gas) temperatures differ considerably; the electron temperature can be several orders of magnitude higher than the gas temperature in such "non-thermal" plasmas.

The changes in the properties of a plasma with temperature are of the greatest importance to its practical use. Figure 1 shows the composition of a nitrogen plasma as a function of temperature. The thermal dissociation of the nitrogen molecules starts below 5000 °K, and is complete at about 12000 °K. Single ionization of the nitrogen atoms starts to become noticeable at 8000 °K and reaches a level of 50% at 15000 °K, with the result that the electrical conductivity is then comparable to that of some metals.

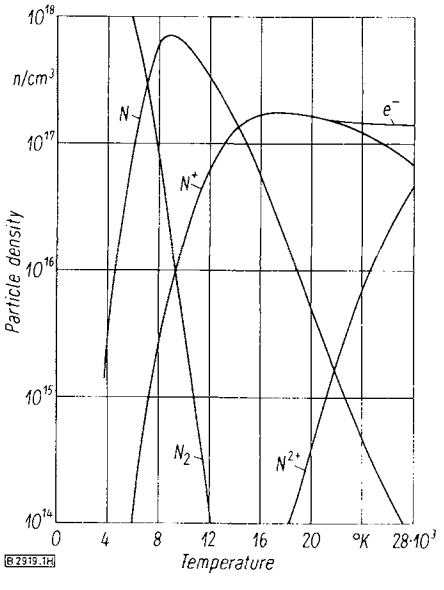

Fig. 1. Composition of nitrogen plasma as a function of the temperature (after *Burhorn* and *Wienecke* [6]); $p = 1$ atm.

The change in the enthalpies of some gases as a function of temperature is shown in Figure 2. Diatomic gases have a much higher energy content than monatomic at temperatures above 2000 °K, owing to the stored work of dissociation, and can therefore give up correspondingly greater quantities of heat without appreciably lowering the temperature of the plasma. Conversely the temperature of a monatomic

gas for a given value of the energy introduced into the plasma is much higher than that of a diatomic gas, as can be seen from the comparison of nitrogen and argon in Figure 3.

3. Technology of the Arc Plasma

3.1. Technique of Production and Stabilization of Plasma Arcs

The principle of the production of plasma arcs is based on a development of the low-current carbon arc, which was known in the 19th century, and which has a column temperature of about 5000 to 6000 °C. To obtain higher arc column temperatures the current density must be increased, but the main result of an increase in the current intensity for an unconfined arc is an increase in the column volume and in the area of the anode focus. A decisive advance was achieved in 1922 by *Gerdien* and *Lotz*[9], who constricted a carbon arc to a diameter of a few millimeters by means of a water vortex; it was possible in this way to increase the current density to 10000 A/cm². The highest known arc temperature of somewhat more than 50000 °K was measured in 1951 by *Burhorn, Maecker*, and *Peters*[10] in a steam-stabilized high-current arc of this type at a current intensity of 1500 A. Though other steam-stabilized plasma jet generators have recently been constructed[11,12], this arrangement is not used in industry.

The methods used to stabilize and constrict the arc in the equipment in current use are as follows:

(a) Tangential injection of gas so that the arc becomes enclosed in a rotationally symmetrical vortex of gas (vortex or aerodynamic stabilization).

(b) Surrounding the arc with a water-cooled metal ring, which may also serve as the anode (wall stabilization).

(c) Action of a magnetic field produced either externally or inductively by the action of the arc itself (magnetic stabilization).

The constriction produced by a gas vortex or a metal ring is known as the "thermal pinch effect", and is based on the fact that the colder outer layer of gas acts as an insulator because of its low thermal and electrical conductivity, and so causes contraction of the arc. The effect produced by a magnetic field is known as the "magnetic pinch effect"; this again acts in the radial direction of the arc.

3.2. Common Types of Plasma Generators

In most modern plasma generators the arc is constricted and stabilized by a combination of the three methods described. Figure 4 shows a section through a plasma jet generator used at Knapsack AG. The arc is struck between a rod cathode, which generally consists of tungsten (+2% of thorium to reduce the work function of the electrons) or graphite, and an encircling funnel-shaped, water-cooled copper nozzle that acts as the anode. The gas, which is injected tangentially or even axially above the cathode, passes through the nozzle at a high velocity and absorbs most of the energy of the arc; while it also prevents premature striking of the arc at sporadic points on the inner wall of the nozzle. The arc can also be stabilized by an external magnet coil. The plasma jet produced by devices of this design can reach velocities ranging from subsonic to several times the speed

of sound, depending on the diameter of the nozzle drilling; the temperatures at the core of the plasma jet can range from 8000 to 30000 °K. The temperature gradient in plasma jets is very steep (Fig. 5).

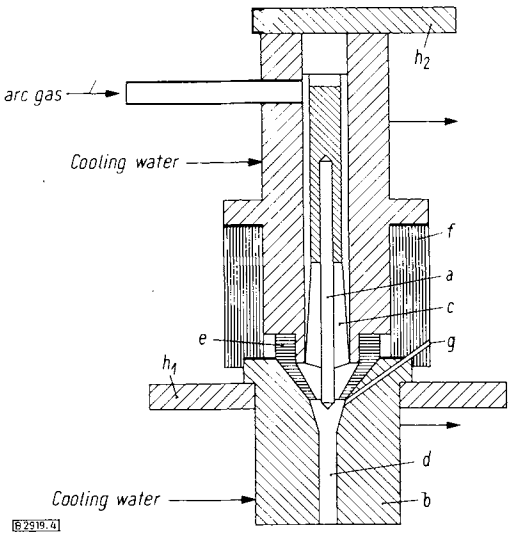

Fig. 4. Direct current plasma jet generator (Knapsack AG, Knapsack). a) Tungsten cathode, b) copper anode, c) brass clamp, d) nozzle drilling, e) ceramic body, f) insulator, g) drilling, h_1) cable terminal (+), h_2) cable terminal (−).

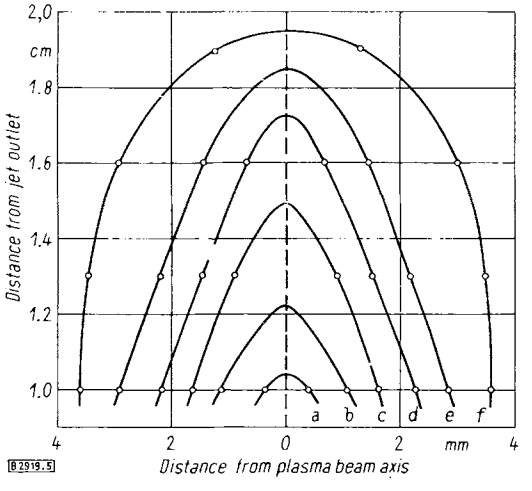

Fig. 5. Isotherms in a N_2 plasma jet (measured spectroscopically, after *Jahn* [13]).
Temperature [°K]: a) 11500, b) 11000, c) 10500, d) 10000, e) 9500, f) 9000.

Plasma generators of this design operate at voltages between 25 and 150 V, depending on the gases used. The power can be up to 100 kW; higher current densities lead to excessively strong heating of the electrodes. The thermoelectric efficiency can reach a maximum of 85 %, but is usually lower. Only argon, hydrogen, and nitrogen (and also helium in the USA) are normally used for operation of the plasma jet generators, since oxidizing gases and gases containing carbon very quickly destroy the electrodes. Corrosive reactants are introduced into the plasma jet and mixed with it underneath the anode. The plasma gas thus acts as a heat-transfer medium, though it may also be a reactant.

[13] *R. E. Jahn*, Brit. J. Appl. Physics *14*, 585 (1963).

Devices have recently been developed to allow the direct introduction of corrosive gases such as oxygen or halogens into the arc space. The normal tungsten cathode may be protected by a separate stream of inert gas or by very intensive cooling [14], or may be replaced by a zirconium cathode [15].

A plasma jet generator developed by the Westinghouse Electric Corp., Pittsburgh, Pa./USA [16, 17], in which magnetic stabilization and wall stabilization are combined, allows power consumptions of up to 20 MW and permits the direct heating of oxidizing and reducing gases (Fig. 6). A very strong external magnetic field causes the arc, which burns between two annular water-cooled copper electrodes, to rotate at a speed of about 60000 rpm; the current density can be increased in this way to 1000 A/cm². The plasma is then constricted by a water-cooled copper nozzle. This high-current arc heater can be operated either with direct current or with single-phase or multiphase alternating current.

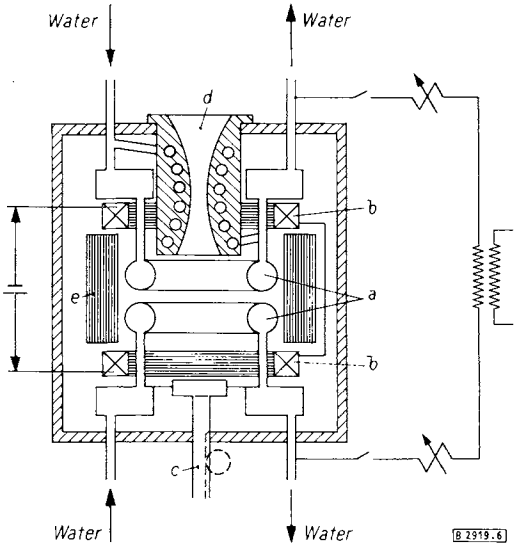

Fig. 6. Westinghouse electric-arc heater.
a) Copper electrodes, b) Magnet coils, c) Igniting device, d) water-cooled nozzle, e) heat shield.

Interest in alternating current plasma devices has recently grown because of the relatively high cost of rectifiers [18–20]. One unit of this type is the three-phase arc heater developed by Knapsack AG, Knapsack [5] for the synthesis of acetylene by the hydrogen arc pyrolysis process, which has graphite electrodes and a maximum power of 10 MW.

[20] *W. K. Roots* and *A. H. Kadhim*, Elektrowärme int. *27*, p. 364 (1969).

Aerodynamically stabilized high-voltage plasma generators are particularly suitable for reactions with corrosive gases. *Schönherr*[21] used this principle in 1909 for the construction of an arc furnace for the production of acetylene; in this furnace, an arc 6 m long was produced between a water-cooled pot anode and a tube cathode at 4000 V and 100 A. The 8 MW arc heater used by the Chemische Werke Hüls AG, Marl, also for the production of acetylene, operates by the same principle. Aerodynamically stabilized plasma generators have recently been developed by *Thorpe*[22], *Eschenbach et al.*[23,24] (Linde Co., New York, USA), and *Browning et al*[25] (Thermal Dynamics, Lebanon, N.H./USA). Devices of this type operate in the range of 5–10 MW at voltages of 5000 to 10000 V. The enthalpy capacity is about 8000 to 11000 kcal/kg. An efficiency of 75% can be achieved.

A wall-stabilized version of the normal direct current plasma generator is the "constricted arc heater", which was first described by *Maecker*[26,27]. The cathode and the anode are separated by a series of water-cooled, mutually insulated copper rings, as shown schematically in Figure 7. Devices of this type give better transfer of the electrical energy to the arc gas than other plasma jet generators with Joule heating. Investigations and developments along this line have recently been carried out *e.g.* by *Morris et al.*[29], *Shepard et al.*[30] (NASA), and *Marlotte et al.*[31].

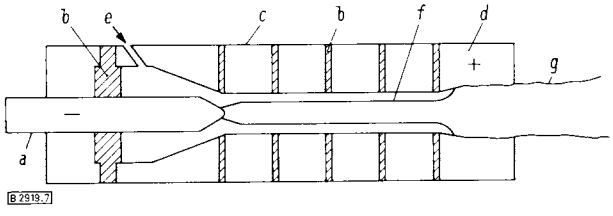

Fig. 7. Schematic cross section through a constricted arc generator (after *John* [28], cited in [65]).
a) cathode, b) insulating rings, c) water-cooled copper rings, d) anode, e) gas inlet, f) constricted arc, g) plasma jet.

A generator of this type developed by NASA, with a power of 2 MW (approx. 1500 V, 1500 A), produces *e.g.* a plasma gas with an enthalpy of about 28000 kcal/kg at pressures of 1 to 5 atm[32].

Another arrangement for the production of plasma jets was first described by *Sheer*[33,34], who used a porous, gas-cooled graphite anode instead of a water-cooled copper anode. This system, which is known as "transpiration cooling", can give an efficiency of 90%[35–40].

The plasma generators described so far produce an indirect or "non-transferred" plasma jet. If a copper or graphite crucible is situated under the copper nozzle anode of a plasma gun and connected in parallel with the anode, the resulting elongated plasma jet allows reactions with solids to be carried out directly in the crucible[22]. This arrangement is referred to as a direct or "transferred" plasma jet.

Reactions with solid reactants are often carried out with the aid of the high intensity arc; according to a comparative study by *Hall*[41] (US Naval Research Laboratory), this is much more suitable for the purpose than the conventional plasma jet. An arc of this type is produced by using relatively thin positive carbons to increase the anode current of a carbon arc to such a degree that the anode material evaporates. A long, brightly glowing jet of vapor leaves the face of the anode with a velocity of 10^3 to 10^4 cm/s and a temperature of up to 10000 °K (Fig. 8). Whereas all low-current arcs have a falling characteristic, the current intensity increases with the voltage in the high-intensity arc. 70 to 90% of the energy supplied is transformed at the anode, and since only a small portion can be dissipated by radiation or conduction through the uncooled anode, most of the energy is taken up by the plasma jet. Solids that are to react may be used in mixtures with carbon as anodes. Hollow anodes may also be used for the introduction of solid reactants. The phenomenon of the evaporating-anode high-intensity arc was discovered by *Beck* in 1910[42], and this type of electrical

4. The Course of Chemical Reactions at Plasma Temperatures

4.1. General

Two steps must be distinguished in plasma-chemical processes:

(a) The introduction and mixing of the reactants with the plasma jet. The reactants are thus heated to plasma temperatures, and equilibration occurs in homogeneous gas reactions, despite the short residence times (10^{-3} to 10^{-5} s). The mixing and the energy exchange are very important to the course and the yield of plasma reactions[50–54].

(b) Quenching of the plasma jet to fix the reaction equilibria produced at high temperatures or to enable the kinetically favored recombination reactions to proceed. To be effective, the cooling rates must be of the order of 10^7 °K/s. Various quenching methods have been proposed. These include cooling the plasma jet with cooled surfaces or cold fingers, or injection of cooling liquids into the plasma jet[55,56]. The cooling liquids may also be reactants, such as liquid ammonia in the hydrazine synthesis[57] or liquid oxygen in the production of ozone[58]. Quenching processes using fluidized beds have also been devised[59–61].

4.2. Thermodynamics and Kinetics

The thermodynamic properties of gases can be calculated very accurately up to temperatures of several thousand degrees if the species existing in equilibrium are known. Where there are several reactants, however, the usual thermodynamic predictions of the equilibrium are of limited value because of the possible occurrence of unknown species. Equilibrium calculations can nevertheless be used to define the conditions for the maximum yield of the desired compound. The results of such calculations generally agree satisfactorily with the experimental observations, as is shown by detailed investigations on the systems C/H/N[62,63], C/N/F[64], and N/O[65]. Since the free enthalpy of reaction ΔG, according to the Gibbs-Helmholtz equation $\Delta G = \Delta H - T\Delta S$, is determined at very high temperatures by the entropy change ΔS, endothermic reactions resulting in an increase in entropy, which would not proceed at lower temperatures, can be carried out under plasma conditions. The products of such reactions can be obtained in high yields by quenching.

If radicals that are unstable at lower temperatures are formed in the plasma, the recombination reactions that take place during quenching are kinetically controlled, since equilibration is impossible because of the short time available. The formation of thermodynamically favored condensed molecules during quenching is therefore much slower than the formation of the less stable gaseous products ("condensation barrier", *Reed*[66]). In this way, gaseous compounds can be obtained in concentrations much higher than the equilibrium concentrations calculated for room temperature.

The following reactions and systems are thus possible in plasma chemistry:

(a) Endothermic or weakly exothermic reactions whose products are stabilized at high temperatures by an increase in entropy, but are metastable at room temperature and can be obtained by rapid cooling (*e.g.* C_2H_2, NO, HCN, C_2N_2).

(b) Systems in which radicals that are normally unstable are formed at high temperatures, and recombine (on kinetic grounds) to form new compounds on quenching (*e.g.* the C/H/F system).

(c) Reactions that are thermodynamically favored at normal and high temperatures, but which require high temperatures to reach a satisfactory rate (*e.g.* the preparation of boron nitride).

Systems of types (a) and (b) may be regarded as promising for the discovery of new reactions and substances with the aid of plasma technology.

The use of plasma processes in industry is of interest only if the reaction step is particularly difficult and expensive in relation to the separation and purification steps and if the product is very valuable, *i.e.* if it has a value at least of the order of several DM/kg[67].

5. Inorganic Reactions in the Plasma Jet

5.1. Preparation of NO, HCN, C_2N_2, and N_2H_4

The problem of the direct fixation of atmospheric nitrogen with the aid of the arc process has again been extensively studied in recent years. The reasons for the renewed interest are the great importance of nitrogen compounds in the chemical industry, the favorable thermodynamics of the formation of the endothermic compounds NO, HCN, and C_2N_2 at high temperatures, and the fact that these compounds consist of small molecules having fairly simple structures. The fixation of atmospheric nitrogen with the aid of arc processes has been discussed in detail by *Timmins* and *Ammann*[65].

[66] *T. B. Reed*, Chemical Uses of Induction Plasmas, 57th Ann. Meeting, A.I.Ch.E., Boston (Mass.) Dec. 1964, publ. in: The Application of Plasmas to Chemical Processing, MIT Press, Cambridge (Mass.), London 1967, p. 32.

[67] *R. F. Baddour* and *R. S. Timmins*, in: Application of Plasmas to Chemical Processing, MIT Press, Cambridge (Mass.), London 1967, p. 12.

5.1.1. Nitrogen Monoxide

Several equilibrium calculations for the N/O system have already been published. According to these calculations, the maximum equilibrium concentration of NO at 1 atm is 5.2% at 3500 °K[65], while that at 10 to 12 atm is 8.2% between 4000 and 4500 °K[68]. *Philipps* and *Ferguson*[69] have examined important factors in the production of NO (and C_2H_2) in the plasma jet.

The maximum NO concentration obtained in the industrial arc process around the turn of the century (*Birkeland* and *Eyde*, *etc.*) was 2%. *Stokes* and *Knipe*[70] obtained an average yield of 2% (based on O_2) by injection of O_2 into a nitrogen plasma and quenching to −80 °C (laboratory scale). A similar result was obtained by *Grosse et al.*[71,72].

Using a constricted arc heater with a very small gas exit cross section, which ensures a very high quenching rate, *Timmins* and *Ammann*[65,73] were able to increase the NO concentration in the exhaust gas to 6–7%. The authors generally consider it possible to reach an NO concentration of 5% by heating air in the arc to an optimum temperature of 3500 °K, followed by very rapid quenching. With an electrothermal efficiency of 65%, the power consumption would be about 44 kWh/kg of NO, and the cost of power would thus be many times that for the production of NH_3[65]. Recent Russian investigations show that industrially acceptable NO concentrations can be obtained by reaction of an N_2 plasma jet with H_2O or superheated steam, or by injection of an excess of O_2 into the N_2 plasma at 3000 to 4000 °K, followed by quenching. Calculations have shown that NO can be produced more cheaply in a plasma jet at 3100 to 3200 °K and 20 to 30 atm than by the combustion of NH_3. Experiments at 5 to 10 atm have been reported, though no yields are indicated[74].

Kozlov et al.[75] used a 40 kW plasmatron and obtained NO concentrations of up to 12% by blowing H_2O or steam into an N_2 plasma. The dependence of the NO yield on the N_2/H_2O ratio and on the flow rate were also investigated.

[75] *G. I. Kozlov*, *G. N. Khudyakov*, and *Yu. N. Kobzev*, Chim. Vys. Energ. *1*, 495 (1967).

According to reports by other Russian authors, the maximum NO yield obtained by injection of air into an N_2 plasma at atmospheric pressure is only 3.6% [76]. *Kozlov et al.* have patented the production of NO by injection of superheated steam into an N_2 plasma at 6000 °K [77].

5.1.2. Hydrocyanic Acid

Various processes for the production of HCN in the plasma arc have been tried on the semi-industrial scale. The starting materials are H_2, N_2, NH_3, and C or CH_4. Equilibrium calculations carried out by *Marynowski et al.* (Stanford Research Institute) [62] for the system C/H/N show that the maximum equlibrium concentration of HCN occurs at 3000 °K. *Freeman et al.* (American Cyanamid Co., New York) [50, 78–80] have investigated the production of HCN by heating an N_2/CH_4 mixture in a 24 kW direct current plasma jet. They obtained a yield of 0.115 mole of HCN/mole of N_2 at a power consumption of 68 kWh/kg of HCN. *Stokes, Leutner et al.* (Research Institute of Temple University) [71, 81, 82] carried out a series of investigations. *Leutner* [82] reported the investigation of four reactions for the production of HCN: 1) from the elements in accordance with the equation $2C + H_2 + N_2 \rightarrow 2HCN$ using a consumable graphite cathode as the source of carbon; 2) from C and NH_3 (again with a graphite cathode); 3) from CH_4 and N_2; and 4) from CH_4 and NH_3.

A conversion of more than 50% (based on the carbon introduced) was achieved; the main by-product was C_2H_2. The highest yields were obtained with the elements as the starting materials. The most important parameter in all the experiments was the cooling rate.

5.1.3. Cyanogen

According to calculations by Russian authors [83], the maximum equilibrium concentration of CN occurs at about 4000 °K. They claim to have obtained a conversion of about 60% in their experiments on the synthesis of C_2N_2 from the elements. The power consumption was 0.48 kWh/mole of C_2N_2.

Suzuki et al. [84] studied the formation of C_2N_2 from coal gas, natural gas, or propane and nitrogen in an arc between carbon and tungsten electrodes. However, the yields were small. *Stokes* and *Knipe* [70] prepared C_2N_2 by injection of fluidized carbon powder into an N_2 plasma; the conversion (based on carbon) was 2%. Conversions of up to 15% (based on C) were obtained by the use of a plasma reactor with a graphite cathode and N_2 or an N_2/Ar mixture as the plasma gas [71, 86]. The problem of using vaporizing graphite electrodes as the source of carbon (high-intensity arc) was examined in detail by *Blanchet* and *Baddour* [87] and by *Ammann et al.* [88].

5.1.4. Hydrazine

Though the formation of N_2H_4, both from the elements and from NH_3, is endothermic, it is associated with a decrease in entropy, unlike the formation of the other nitrogen compounds discussed. Hydrazine formation may therefore be expected only *via* free radicals. The yields in the plasma process are correspondingly low. In the direct reaction of H_2 with N_2, N_2H_4 is formed only in traces [71]. According to *Harnisch, Heymer,* and *Schallus* [57] the synthesis proceeds in a yield of about 0.5% (based on the NH_3 throughput) on injection of liquid NH_3 into an N_2 or Ar plasma. *Neubeck* [54] obtained a yield of only 0.02% at a power of about 4 kW in his investigations on the influence of various factors on the synthesis of N_2H_4.

5.2. Synthesis of Carbon-Fluorine and Nitrogen-Fluorine compounds

A comprehensive review on the preparation of fluorine compounds in a plasma has been published by *Bronfin* [89]. The article also contains detailed thermodynamic data on the systems C/F, N/F, and C/N/F as well as the corresponding references.

5.2.1. C–F Compounds

Numerous studies have been carried out on the preparation of C–F compounds in arcs, in most cases using a high-intensity arc. In this arrangement, the carbon evaporating from the graphite anode can take part in the reaction. The procedure used by

Baddour and *Bronfin* [90,91] for the conversion of CF_4 into C_2F_4 in a carbon arc is representative of a whole series of fluorocarbon syntheses in a thermal plasma. The highest C_2F_4 concentration of 69 mole-% was obtained at 0.1 atm and 17 kW. The C_2F_4 yield decreased with rising pressure and increased with increasing electric power. The quenched gas contained only a small quantity of other fluorocarbons (C_2F_6, C_3F_8), the remainder being CF_4. *Denison et al.* [92] led CF_4 into a high-intensity arc at 75 torr and quenched the reaction gas with the aid of a fluidized carbon bed. They obtained a C_2F_4 concentration of 75 mole-%. PF_5, SF_6, or AsF_3 may be used instead of CF_4 as the fluorinating agent.

The preparation of C_2F_4 in the carbon arc is described in a number of patents. The Du Pont de Nemours Co., Inc., Wilmington, Del./USA has patented a furnace with a rotating arc, in which *e.g.* C_2F_4 can be prepared from CF_4 or PF_5 to give a concentration of 81 % in the quenched gas [93]. The principal product formed from CF_4, as also from higher fluorocarbons is C_2F_4 [94–96]; the same result is obtained when CF_4 is allowed to react with various hydrocarbons in the carbon arc [97]. The presence of hydrogen (*e.g.* as HF) leads to the formation of partly fluorinated hydrocarbons [98], whereas mixed chlorofluorocarbons are formed in the presence of chlorine [99, 100]. It is interesting to note that the principal product obtained on heating CF_2Cl_2 or $C_2F_4Cl_2$ is again C_2F_4 [100]. Further information may be found in the more detailed review by *Bronfin* [89].

5.2.2. N–F Compounds

Interest in the N/F system is evidently focused mainly on the compounds NF_3, N_2F_4, and N_2F_2. However, the concentration of the nitrogen fluorides formed is low in most arc syntheses. *Bronfin* and *Hazlett* [64] used a 20 kW N_2 plasma jet, into which CF_4 or SF_6 was injected as the fluorinating agent. The addition of CF_4 leads to a mixture of nitrogen fluorides and fluorocarbons, with NF_3 as the main product; only NF_3 was formed on introduction of SF_6. However, the conversion of nitrogen into nitrogen fluorides was only 1 mole-% in both cases. *Lipscomb* [101] obtained an NF_3 concentration of 1.7 to 2.5 mole-% in the exhaust gas in the reaction of CF_4 with NO in a 2 kW low-current carbon arc at about 50 torr. Other syntheses in the C/N/F system with a carbon arc have been carried out by *Lipscomb* and *Smith* [102] and by *Farlow* [103].

5.3. Other Gas/Gas and Gas/Liquid Reactions

5.3.1. Carbon Disulfide

Plasmachem. Inc. (Newport Beach, Calif./USA) proposed the preparation of CS_2 from H_2S and CH_4 or natural gas by a plasma-chemical process (presumably in the plasma arc). The cost of construction of a plant having a capacity of 50000 t/year is claimed to be only one half to two thirds of the cost of a plant based on the catalytic process. No further details were published [104].

5.3.2. Ozone

Stokes and *Streng* [58] described a new method for the synthesis of O_3. Liquid oxygen is injected into a helium plasma, and the O_3 formed is quenched in excess O_2. The conversion is low; the production rate is 0.5 kg/h at a power of 10 kW. *Grosse* and *Stokes* have patented this process [105].

5.3.3. Oxygen from Carbon Dioxide

Experiments have recently been carried out on the cleavage of CO_2 into CO and O_2 in a plasma jet [106, 107]. However, the O_2 yield was barely 3 % at a burner power of 6 kW.

5.4. Nitrides, Cyanides, and Carbides

5.4.1. Nitrides and Cyanides

Harnisch and *Heymer* [57, 108, 109] have produced finely divided nitrides (particle size <0.1 μm) of the elements boron, aluminum, silicon, titanium, and zirconium in yields of 90 to almost 100 % by reaction of the vaporized halides of the elements with NH_3 in

a direct current H_2 or N_2 plasma jet. A similar process for the production of ultrafine nitrides of refractory metals has been published by *Neuenschwander* [110] (Ciba AG, Basel), who prepared *e.g.* TaN from the chloride in an H_2/N_2 plasma jet. Other methods start with metal powders. However, these methods are very unsatisfactory because of the very short times spent by the reactants in the plasma jet (of the order of 10^{-3} to 10^{-5} s), the small size of the hot zone, the steep temperature gradient, and the difficulties presented by the introduction of solids into the plasma jet. *Stokes* and *Knipe* [70] prepared TiN and Mg_3N_2 in yields of 30 to 40% by blowing the metal powder into a nitrogen plasma. *Stokes* [111] reported an improvement of the process for the production of TiN, and also described the preparation of tungsten nitride WN. Fine BN was prepared by *Bosch* and *De Vynck* [112] by introduction of powdered boron into an N_2/NH_3 plasma jet. No information on yields was given. Nitrides and oxide nitrides of metals have been obtained from the oxides in an Ar/N_2 plasma jet [113].

The use of a "transferred" plasma jet for the preparation of the nitrides of Ta [114], Mo [115], W [116], Ti [117], Al [118], and Zr [119] from the metals and from the oxides [120–122] has been described in a series of Japanese papers. The starting materials were nitrated with a N_2 plasma jet in a water-cooled copper crucible or in a graphite crucible, which acted as a second anode. Physico-chemical and analytical data for these reactions have been reported [122]. The procedure appears to be of value only for laboratory investigations. The preparation of AlN, Si_3N_4, ZrN, TiN, and HfN is described in another Japanese study [123, 124], in which yields of more than 80% were obtained. No further details are known. *Winterhager* and *Hanusch* [125] recently examined the current methods for the production of TiN in direct current plasma jets. The dependence of the yield on various parameters was investigated. The production of metal cyanides from metal oxide and graphite powder or propane in a N_2 plasma jet has been investigated by *De Vynck* [126]. However, the yields were unsatisfactory.

5.4.2. Carbides

A process for the production of finely divided transition metal carbides has been described by *Neuenschwander* (Ciba AG, Basel) [110, 127]. The carbides of Ta, Nb, and Ti were prepared in a hydrogen plasma with addition of CH_4. The products have particle sizes of 0.01 to 0.1 μm.

The same is true of the reactions with solid starting materials as in the case of the nitrides. *Correa, Stokes et al.* [128–130] obtained tantalum carbides by treatment of tantalum powder or Ta_2O_5 with CH_4 in an H_2 plasma jet. The yields of TaC and Ta_2C were 46 and 86% respectively. It was found in a similar study that the metal powder is a better starting material than the trioxide for the preparation of tungsten carbides. The conversion in this case is about 50%.

Small quantities of magnesium carbides and Al_4C_3 were formed on reaction of Mg or MgO and of Al_2O_3 with propane in an Ar/H_2 plasma jet [126]. B_4C is obtained on introduction of boron powder into a H_2/Ar plasma and injection of a propane/butane mixture. The yield here was again low [112]. ZrC was prepared by reaction of zirconium powder or ZrO_2 with benzene vapor in an argon plasma [113, 131]. NbC has been obtained from a mixture of Nb_2O_5 and C in a copper crucible with the aid of a "transferred" plasma flame [132].

The reactions

$$MO + 3\,C \rightarrow MC + 2\,CO \quad (M = Ti, Si)$$

$$M_2O_5 + 7\,C \rightarrow 2\,MC + 5\,CO \quad (M = V, Ta)$$

were evidently also carried out and investigated in a "transferred" plasma flame [133].

The high-intensity arc is much more suitable than the plasma jet for the production of carbides from solid

starting materials[41]. *Korman, Sheer et al.*[134] (Vitro Laboratories, West Orange, N.J./USA) have made a detailed study of the use of the high-intensity arc for chemical reactions involving solid starting materials; the production of uranium carbide has already been carried out on the 20 t scale. In this process, UO_2 and carbon are compressed into electrically conducting rods, sintered, and used in this form as consumable anodes. The uranium carbide is obtained in the form of spherical fused particles[135].

5.5. Preparation of Metal Oxides

Many attempts have been made to prepare finely divided metal oxides by oxidation of metal powders or metal chlorides with the aid of plasma techniques[136]. Attempts of this nature are usually made in an induction plasma, since corrosion problems can arise when an electrode plasma is used. However, devices have been developed to allow the introduction even of oxygen (or halogens) into the plasma jet without attack of the electrodes[137,138].

Processes and equipment for the production of finely divided metal and metalloid oxides, particularly TiO_2 as a white pigment, ZrO_2, SiO_2, Al_2O_3, Fe_2O_3, and antimony oxide, by oxidation of the corresponding halides, especially the chlorides, have been patented by a number of companies[139–144]. The Farbenfabriken Bayer AG[145] has proposed that at least one of the two preheated reactants be brought to a sufficiently high temperature by a high-voltage discharge between two electrodes. According to another suggestion, an oxidizing gas is heated in a high-intensity arc, and is then allowed to react with the metal chloride vapor. In this case the carbon electrodes should contain 20 to 70% of oxides, carbides, or halides of the corresponding metal as nucleating material[146].

The vaporization of coarse TiO_2 or SiO_2 in a plasma jet followed by condensation to form a fine powder has also been suggested[147,148].

Sheer and *Korman* have described a method for the production of finely divided SiO_2 by vaporization of SiO_2 from the anode of a high-intensity arc, followed by condensation[134].

5.6. Reductions

5.6.1. Reduction of Metal Oxides and Oxide Ores

TiO_2 is reduced to titanium in a plasma reactor in which the continuously introduced oxide is first melted. The finely divided liquid oxide droplets are reduced with a H_2 plasma jet to fine droplets of metal. The resulting titanium is reported to have a purity of 99.8%[149]. The production of tungsten powder by reduction of WO_3 in an Ar/H_2 plasma was studied by *Tsetkov et al.*[150], who also developed an industrial method for the production of ultrafine powders with spherical particles. Metallic vanadium has been prepared by reduction of a $V_2O_3/CaCl_2$ melt with calcium vapor produced under the action of an argon plasma. The vanadium is removed from the liquid slag by centrifugation (Centre National de la Recherche Scientifique, Paris)[151].

Grosse, Stokes et al.[152] described the reduction of WO_3 (95% yield), Fe_2O_3 (100%), Ta_2O_5 (26%), and Al_2O_3 (2 to 5%) with a hydrogen plasma. It was not possible to reduce TiO_2 and ZrO_2 by this method. The Ciba AG, Basel, has patented a process[153] in which the oxides of Re, Mo, and W, as well as ammonium tungstate, are reduced to fine metal powders by introduction into a horizontal H_2 plasma jet. The dependence of the grain size of the metal powder on the experimental conditions for the reduction of oxides in a plasma jet has been investigated by *Panfilov* and *Tsetkov*[154].

The feasibility of the carbothermic reduction of metal oxides in the vapor phase with the aid of a high-

[154] *S. A. Panfilov* and *Yu. V. Tsvetkov*, Met. Tsvet. Redk. Metal. Akad. Nauk SSSR, Inst. Met. *1967*, p. 128.

intensity arc has been studied by *Sheer* and *Korman* [134, 155, 156]. The principal problem in such a process is the prevention of the reoxidation of the metals by fast and efficient quenching.

Kusch [157] used hollow graphite anodes for his reduction experiments in the high-intensity arc, the metal oxide/carbon moldings being introduced through these anodes. The reaction products were deposited on cooled surfaces. The yields of metal (*e.g.* Fe, Al, Mg) were up to 80%.

The Union Carbide Co., New York, has patented the reduction of molten oxide ores over a liquid metal by an inert gas plasma to which *e.g.* CH_4 is added [158].

The reduction of iron ores by plasma techniques has been discussed by *Gilles* [159], who obtained degrees of reduction of 33 to 69% with a H_2 plasma jet at temperatures ranging from about 3000 to 5700 °K. This author assumed that the most important factor influencing the reduction process is the heat transfer. The reduction of molten iron ores with reducing gases heated by one or more plasma generators is described in two patents [160, 161]. The consumption of electrical power is reported to be 1110 kWh/t of crude iron.

5.6.2. Reduction of Halides

Finely divided, nonpyrophoric powders of the metals of groups IVb, Vb, and VIb and of the actinide metals can be obtained by introduction of the corresponding chlorides (or oxide chlorides), with Ar as a carrier gas, into a hydrogen plasma. An excess of 5–10 moles of H_2/mole of metal halide is necessary, and the yields obtained were around 90% [162].

A complicated process for the reduction of the halides of Ti, Zr, Nb, Ta, Mo, and W is described in two patents granted to the Rio Algom Mines Ltd., Toronto, Ontario/Canada [163]. The halides are introduced into a plasma jet together with liquid Na or powdered Mg as the reducing agent. Pure titanium is obtained in a yield of 80 to 90% from $TiCl_4$ and liquid Na.

WF_6 can be reduced to the metal with a H_2 plasma jet. The resulting powder has a specific surface area of between 3 and 35 m^2/g [164]. Powders of other refractory metals can be prepared in the same manner. The reduction of the halides of Be, B, Al, Si, Ti, Nb, Ta, Cr, Mo, and W in a hydrogen plasma is described in a patent by the Union Carbide Co., New York [165]; yields and the power consumption are also given.

The production of boron is described in a U.S. Atomic Energy Commission report [166]. BF_3 or BCl_3 was reduced in a H_2 arc plasma; the yields were 30 and 60% respectively. Silicon and titanium halides can be reduced in a similar manner to very pure metals [167].

A reduction of silicon and titanium halides that does not yield the metal is also possible. *Harnisch et al.* [57, 168] have prepared $TiCl_3$ by reaction of $TiCl_4$ in a H_2 plasma jet at temperatures between 2500 and 3000 °K followed by quenching at −120 °C. By maintaining a molar ratio $H_2/TiCl_4 < 6$, it was possible to obtain almost pure $TiCl_3$. By reducing $SiCl_4$ under similar conditions, the same authors obtained a mixture of chlorosilanes from which the principal product, $SiHCl_3$, could be readily obtained by fractional distillation [57, 169]. Trichlorosilane is a very suitable starting material for the production of high-purity silicon. The power consumption is reported to be 4 kWh/kg of $SiHCl_3$.

5.7. Various Other Plasma Reactions

Korman and *Sheer* have devised further uses of the high-intensity arc. Thus, because of the very short reaction times in the vapor phase, complex oxides can be decomposed into simpler oxides with no possibility of reformation of the original complexes [134]. The method has been successfully used for the decomposition of the manganese ore rhodonite ($MnSiO_3$); the condensate contained MnO and SiO_2 [170]. The same method has been suggested for the preparation of metals such as uranium, beryllium, and lithium.

This pyrolysis method has very recently been applied to iron titanates in the USSR and in Poland. With anodes containing 70% of ilmenite/30% of graphite and use of O_2 for arc operation, the oxides TiO_2,

[170] *V. Harris*, *J. Holmgren*, *S. Korman*, and *C. Sheer*, J. Electrochem. Soc. *106*, 874 (1959).

Fe_2O_3, Fe_3O_4, and SiO_2 were found in the condensate; the TiO_2 (90%) collected mainly in the reaction zone[171]. With N_2 as the arc gas, the main products were Fe, TiC, and CO together with TiN[172]. The decomposition of ilmenite in a thermal plasma has been examined in another Polish investigation[173]. $ZrSiO_4$ can also be decomposed into ZrO_2 and SiO_2 by this method[174].

Another use of carbon arc is for the vapor-phase halogenation of oxides[134]. On evaporation of an anode containing ore in an atmosphere of chlorine, the oxide is quantitatively converted into the chloride in accordance with the equation

$$MO + Cl_2 + C \rightarrow MCl_2 + CO$$

This method has been used by *Warren* and *Shimizu*[174], for the preparation of $NbCl_5$ from Nb_2O_5 and of $AlCl_3$ from Al_2O_3. *Orbach et al.*[175] have patented a process for the halogenation of BeO in a plasma burner with nonreacting electrodes. BeO is introduced into the N_2 plasma jet together with petroleum coke and Cl_2. The conversion is 62.6%.

The production of mixed oxides *e.g.* from ZrO_2 and Cr_2O_3[176] or from TiO_2 and other oxides[177] and the preparation of spinels[178] in plasma jets have also been described. *Papp*[179] studied the possibility of using plasma techniques for the production of phosphorus, mainly from the thermodynamic standpoint.

A combination of a fluidized bed reactor and a plasma jet has been developed by *Goldberger*[59,60,180], at the Battelle Institute. The fluidized bed may be used as a quenching device or as an inert heat store; however, if it consists of electrically conducting particles (*e.g.* carbon), it can also act as an "electrode" for the formation of the plasma arc. The preparation of phosphorus by reduction of $Ca_3(PO_4)_2$ with this arrangement has been investigated in detail; the thermal efficiency increased with the throughput and reached a maximum of 70%. CaC_2 has also been prepared by this method.

The synthesis of H_2S from the elements in a plasma jet has been reported by *Stokes* and *Cahill*[129]. H_2S was obtained in a yield of 37% (based on S) on introduction of sulfur powder into a He/H_2 plasma (electric power 7.75 kW).

Very recent Russian articles describe investigations on the possibility of thermal decomposition of phosphate ores in a plasma jet[181,182]. It is shown that insoluble P_2O_5 can be converted into citric acid-soluble P_2O_5 in a yield of 96.5% by treatment of a phosphate ore/SiO_2 mixture (30% SiO_2) in a plasma jet at 4130 °K. The power consumption found in the experiments was between 3150 and 6850 kWh/t of starting crude phosphate.

6. Closing Remarks

It can be seen from the large number of investigations described here that the plasma jet is a very interesting and valuable new aid for the research chemist. There is no doubt that some of the known plasma-chemical processes, and probably also some that have not yet been developed, will be used industrially in the future, though it cannot be said at present when this will be.

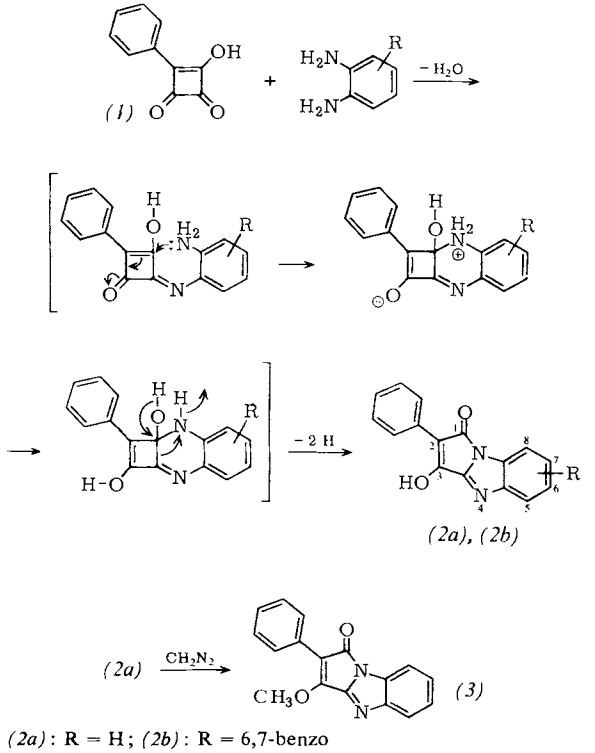
Novel Ring Opening of Hydroxyphenylcyclobutenedione[1] [**]

By *Walter Ried* and *Günter Isenbruck*[*]



Dedicated to Professor H. Beyer on the occasion of his 65th birthday

3-Hydroxy-4-phenyl-3-cyclobutene-1,2-dione *(1)* reacts with primary aromatic amines to give 2-anilino-4-phenylcyclobutenediylium diolates [2], and with aliphatic amines to give ammonium salts which can be converted into the 2-amino-4-phenylcyclobutenediylium diolates[3].

Compound *(1)* reacts with aromatic 1,2-diamines with loss of H_2O and 2H to give a red crystalline substance[4], whose IR spectrum contains a carbonyl absorption at 1755 cm^{-1} indicative of a carbonyl group in a four or five membered ring. If *(2)* is assumed to have the structure given below, then methylation of *(2a)* with diazomethane must lead to formation of *(3)*.

The UV spectrum of *(3)* in CH_3OH shows absorption maxima at 229, 267, and 269, and a broad maximum at 323 nm ($\log \varepsilon = 4.07$) that is characteristic of pyrroloimidazole[5]. 2,3-Diphenylpyrrolo[1,2-*a*]benzimidazol-1-one, which is formed on condensation of diphenylmaleic anhydride and *o*-phenylenediamine[6], also shows a broad maximum at 325 nm ($\log \varepsilon = 3.88$) and a carbonyl absorption at 1755 cm^{-1}.

According to the spectra, elemental analysis, and molecular weight determination (262), compound *(2a)* can be formulated as 3-hydroxy-2-phenylpyrrolo[1,2-*a*]benzimidazol-1-one. Since hydroxyphenylmaleic anhydride does not react under the conditions used for the preparation of *(2)* it cannot be formed as intermediate. We suggest, therefore, the following reaction mechanism.

(2a): R = H; *(2b)*: R = 6,7-benzo

Experimental:

To a solution of *(1)* (5 mmoles, 870 mg) in glacial acetic acid (30 ml) is added with stirring a solution of the diamine (5–6 mmoles) in glacial acetic acid (20 ml) at room temperature. The solution turns deep red and gradually becomes cloudy. Precipitation is brought to completion by stirring for a few hours; the product is recrystallized from DMF/CH_3OH, yield 70–75 %.

Dependence of Solvatochromism on the Ground State in 1,4-Heterobutadienecarbonylmolybdenum Complexes

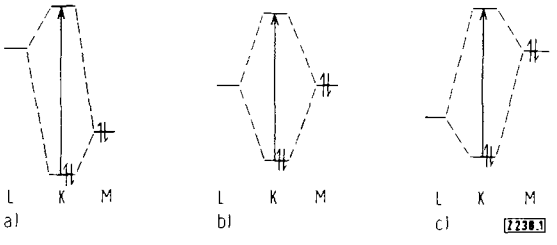
By *Heindirk tom Dieck* and *Ingo W. Renk*[*]

The color of solutions of *N,N'*-di-*tert*-butyl-1,4-diazabutadienetetracarbonylmolybdenum *(1)*, as well as of other 1,4-diazabutadienecarbonylmetal complexes[1], depends considerably on the polarity of the solvent (cf. Table)[2].

Strong solvatochromism is to be expected when the ground state of the dissolved complex is polar, *i.e.* when the polar solvent molecules exhibit a high degree of short range order. The excitation ought to be antiparallel to the ground-state dipole moment μ_G since a particularly strong destabilizing solvation then occurs in the excited state.

(1), R = $C(CH_3)_3$

In complexes of Type *(1)* with C_{2v} symmetry the z-axis and direction of μ_G are coincident; in C_{2v} both are totally symmetric. Electron excitations in $\pm z$ direction must have ground and excited states of the same symmetry since with the given symmetry of the z vector only the product of two identical representations of C_{2v} gives a totally symmetric integrand of the transition moment and thereby a permitted transition.



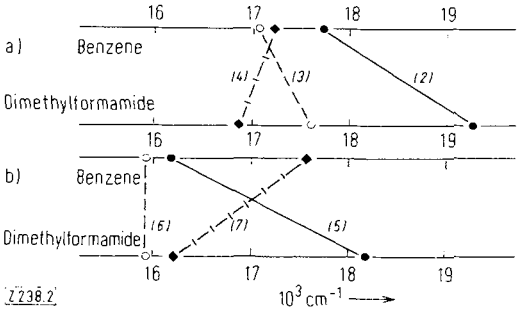
In *(1)* the occupied metal d-orbitals fall into the symmetry classes A_1, A_2, and B_2. The lowest unoccupied orbital is ψ_3 on the four-center π system which likewise has symmetry B_2.

In B_2, metal and ligand orbital also have the strongest overlapping which is of importance for the magnitude of the interaction term and the intensity of the electron excitation.

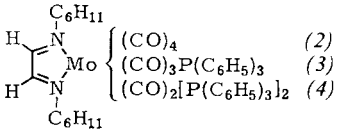
According to the values given in the Table, the longest wavelength transition of *(1)* with extinctions between 12000 (cyclohexane) and 5000 l $mole^{-1}$ cm^{-1} (dimethyl

sulfoxide) shows a solvatochromic effect, which can only occur by excitation from the metal to the four-center ligand — antiparallel to μ_G; the excitation can be considered as a metal-ligand charge transfer (CT), despite the interaction terms $\langle b_2/b_2 \rangle$ to be expected.

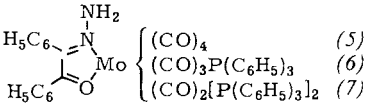
Electron spectroscopic measurements give no indication of the magnitude of this interaction or whether the solvatochromism occurs as a result of a stabilization of the ground state or of a destabilization of the excited state. In addition to ν_{CT} values, the Table contains the wave numbers of the four IR-active carbonyl frequencies. An unusually strong solvent dependence is found for the CO groups CO-1 and CO-2 situated *trans* to the diazabutadiene ligands (L), whereas in the case of CO-3 and CO-4 the changes lie within the error of measurement. This indicates, however, that considerable solvent-dependent polarization occurs in the ground state in the z direction [3]. As expected, the ν_{CT} and ν_{CO} values are linearly dependent quantities. Slight deviations from linearity are observed in the case of solvents such as chloroform and boron trifluoride-dibutyl ether, which interact particularly strongly with the carbonyl oxygen atoms [5].



Scheme 1. L = ligand, K = complex M = metal.



The invariance of $\nu_{CO-3,4}$ is interpreted as a good indication of the possible inductive (!) perturbation of the metal terms, *e.g.*, in the substitution of these carbonyl groups by phosphanes [5].



If, in accordance with Scheme 1a, the metal orbital is originally lower [6] than the ligand orbital, the coefficient of the former in the ground state is $> \sqrt{0.5}$, and the excitation will have metal→ligand CT character (Case 1). Correspondingly, the same negative solvatochromism will also occur as in *(1)*. Raising the metal orbital or lowering the ligand orbital reduces solvatochromism, which vanishes completely at energy balance; in this case the interaction term can be determined experimentally (Case 2): it is equal to half the excitation energy. If the metal orbital (Scheme 1c) is raised so as to be slightly higher than ψ_3, the complex ground state is predominantly a ligand state without μ_G changing its direction. Here, excitation occurs from the ligand to the metal, *i.e.* in the direction of μ_G; the solvatochromism is positive (Case 3).

In Scheme 2 the absorption maxima for two complex groups with increasingly destabilized metal d-electrons in two rather extreme solvents, benzene and dimethyl formamide (cf. Table), are outlined. Scheme (2a) contains the values for *N,N'*-dicyclohexyl-1,4-diazabutadienecarbonylmolybdenum complexes *(2)*, *(3)*, and *(4)* with four [4], three, and two CO groups and correspondingly none, one, or two triphenylphosphanes in place of CO-3 or CO-4 — (2b) shows the behavior of the analogous *N*-amino-2,3-diphenyl-1-oxa-4-azabutadiene complexes *(5)*, *(6)*, and *(7)* [5].

Compounds *(1)*, *(2)*, *(3)*, and *(5)* are examples of Case 1 and, therefore, according to their ground state configuration are metal(0) complexes insofar as assignment of oxidation numbers for metals in low valence states appears reasonable. In the case of *(6)*, the position of ν_m is found to be exactly the same in all common solvents [5]; this is a case of accidental degeneracy b_2/b_2. The interaction term, in this instance the stabilization by π back-donation, corresponds to $1/2\ \nu_m \approx 8000\ cm^{-1}$.

Scheme 2. Magnitude and direction of the solvatochromism in diaza- and oxaazabutadienecarbonylmolybdenum complexes.

Compounds *(4)* and *(7)* with positive solvatochromism correspond to Case 3 and are to be regarded as cation complexes of the metal.

Table. Solvent-dependence of the CT absorption and the CO frequencies (in cm^{-1}) of *(1)*.

Solvent	CT Absorption	CO-1 A_1	CO-2 B_1	CO-3 A_1	CO-4 B_2
Dimethyl sulfoxide	21120	1878	1828	2023	1908
Dimethylformamide	20960	1880	1832	2024	1908
Acetonitrile	20830	1883	1832	2024	1912
Acetone	20400	1887	1836	2024	1912
$(C_4H_9)_2O \cdot BF_3$	20200	1882	1832	2024	1912
Nitropropane	20190	1885	1835	2024	1912
Methanol	19880	1887	1838	2024	1913
Methylene chloride	19380	1886	1835	2026	1912
Dioxane	19230	1892	1842	2022	Sch
Chloroform	18930	1890	1838	2024	1915
Mesitylene	18590	1901	1848	2024	1910
Carbon tetrachloride	18020	1910	1855	2024	1915
Carbon disulfide	17950	(1913)	1860	2024	(1913)
Cyclohexane	17745	1914	1864	2024	1923

Thus, these complexes of 1,4-diazabutadienes and 1-oxa-4-azabutadienes are systems having a delocalized ground state, similar to many transition complexes of the four center system S—C—C—S [7]. Generally, there is no need for ascribing aromatic character to such five-membered chelate rings [4].

Substitution at any center of the ligand π system, by exchange of carbonyl groups for other ligands or by changing the metal, affords a suitable model which is explained quite well by an extended perturbation theory and is supported by ESR [8] and polarographic [5] experiments.

Procedures:

Stable tetracarbonyl compounds such as *(1)* can be prepared by heating of ligand and metal hexacarbonyl in benzene: Boiling a mixture of *N,N'*-di-*tert*-butyl-1,4-diazabutadiene [9] (1.5 g) and $MoCO_6$ (2.34 g) (9 moles of each) for 6 hours yields fine long needles (3.2 g, 94%; decomp. 217 °C) of the desired compound.

Less stable tetracarbonyl compounds such as *(5)* are obtained from bis(dialkylcyanamide)- or bis(triphenylphosphine oxide)tetracarbonylmolybdenum by substitution below room temperature [10].

Tricarbonyl compounds such as *(3)* or *(6)* can be prepared — if the tetracarbonyls are not sufficiently stable — by reaction of tris(acetonitrile)tricarbonylmolybdenum with equimolar quantities of $P(C_6H_5)_3$ and chelate ligand: A mixture of $(CH_3CN)_3Mo(CO)_3$ (0.76 g), $P(C_6H_5)_3$ (0.66 g), and benzilmonohydrazone (0.65 g) (2.5 mmoles of each) is stirred for 14 h at 18 °C; deep-blue soluble crystals of *(6)* having a copper luster are formed [0.9 g (54%), (further 0.7 g from mother liquid); decomp. 104 °C].

The thermally labile *dicarbonyl compounds* such as *(4)* and *(7)* are obtained from bis(acetonitrile)bis(triphenylphosphine)dicarbonylmolybdenum by substituting acetonitrile below room temperature[11]. Reaction of equimolar amounts proceeds quantitatively if the acetonitrile liberated is pumped off from the higher boiling solvent. Recrystallization leads to disproportionation products.

Addition of Nitroacetylenes to Enamines and Ynamines[1]

By *Volker Jäger* and *Heinz Günter Viehe* [*]

Owing to the strong and inverse polarization of the reactants, nitroacetylenes *(1)*[2] add exothermally to enamines *(2)* and ynamines *(3)*[3]. Thus 1-nitro-3,3-dimethyl-1-butyne *(1a)* and 1-pyrrolidinocyclopentene *(2a)* undergo a generalizable C_2-ring expansion reaction[4,5] to give the nitrocycloheptadienylamine *(4)*. This affords the α-nitro ketone *(5)*[6] on hydrolysis.

Reaction of *(1a)* with ynamines *(3a)* and *(3b)* yields not the electronically and sterically stabilized cyclobutadienes *(6)*[7] but their isomers, the nitrile oxides *(7a)* and *(7b)*, respectively. The structures of *(7a)* and *(7b)* were established by spectroscopic means and by their reaction with additional *(1a)* to give the isoxazoles *(8a)* and *(8b)*, respectively. The orientation of the substituents in *(8)* is formulated by analogy with the results of previous 1,3-dipolar cycloadditions of nitrile oxides[8]. Degradation of the nitrile oxide *(7b)* by reduction[9] to the nitrile *(9b)* and subsequent hydrolysis gives the maleic anhydride *(10)*. This compound is remarkable because of its adjacent *tert*-butyl groups.

(a), $R^2=R^3=CH_3$; *(b)*, $R^2=CH_3$, $R^3=C_6H_5$, + = $(CH_3)_3C$

Reactants	Product	Yield (%)	M.p. (°C)
(1a) + *(3a)* 1:1	*(7a)*	29 [a]	82–83
(1a) + *(3a)* 2:1	*(8a)*	44	115
(1a) + *(3b)* 1:1	*(7b)*	21	138
	and *(8b)*	41	131–132
(1a) + *(3b)* 1:4	*(7b)*	66	138

[a] Formed quantitatively according to IR spectrum but decomposes on recrystallization.

3-tert-Butyl-2-nitro-1-pyrrolidino-1,3-cycloheptadiene (4)

Compound *(1a)* (636.5 mg, 5.0 mmoles) in ether (10 ml) is added dropwise at 0 °C to *(2a)* (688 mg, 5.0 mmoles), also in ether (10 ml). Removal of solvent and recrystallization from CH_2Cl_2/light petroleum (b.p. 40–60 °C) gave compound *(4)* (yield 826 mg, 62%) as yellow needles, m.p. 187–188 °C (decomp.); NMR ($CDCl_3$, δ_{TMS} = 0): olefinic proton at δ = 6.05 ppm, $J \approx 6.5$ Hz; UV (C_2H_5OH): λ_{max} = 277.5 nm (log ε = 3.7), 391.5 (4.0).

2,3-Di-tert-butyl-4-(N-methyl-N-phenylamino)-4-oxo-2-butenenitrile oxide (7b) and di-tert-butylmaleic anhydride (10)

Compound *(1a)* (640 mg, 5.04 mmoles) in ether (4 ml) is added slowly to a solution of *N*-methyl-*N*-phenyl-3,3-dimethyl-1-butynylamine *(3b)* (4.0 g, 21.4 mmoles) in ether (5 ml). After 12 h, the precipitated colorless crystals are washed several times with *n*-pentane; yield of *(7b)* = 1.04 g (66%), m.p. 138 °C, IR (in KBr): 2285, 1330, (C≡N→O); 1635 (C=O), 1598 and 1495 cm^{-1} (aromatic).

Reduction of *(7b)*[9] gives the nitrile *(9b)* in 90% yield; m.p. 146 °C, IR (in KBr): 2205 (C≡N), 1635 (C=O), 1595 and 1495 cm^{-1} (aromatic).

Compound *(9b)* (190 mg) was heated to 160 °C in 85% phosphoric acid (5 ml) for 20 h; after neutralization with a concentrated solution of $NaHCO_3$ the product was ex-

tracted with ether. Recrystallization from *n*-pentane/ether gave 130 mg (97 %) of the anhydride *(10)*, m.p. 88.5–89.5 °C, IR (in KBr): 1835, 1755, 1260 cm^{-1} (CO stretching); UV (*n*-hexane): λ_{max} = 209 nm (log ε = 3.9); 251.5 (3.8).

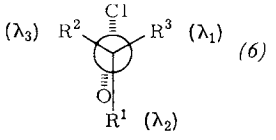
New Method for Determination of the Absolute Configuration of Carboxylic Acids [1]

By *Hans-Jürgen Bestmann, Herbert Scholz,* and *Eckart Kranz* [*]

When two moles of the racemate of benzylidene(methyl)(phenyl)(*n*-propyl)phosphorane *(1)* is treated with one mole of an optically active acid chloride *(2)*, partial kinetic resolution occurs [2]: the acylated phosphonium salt *(3)* is formed from *(1)* and *(2)* and, since *(2)* reacts preferentially with one of the enantiomers of *(1)*, the other enantiomer becomes enriched in solution and then reacts by transylidation [3] with the initial product *(3)*; this affords the optically active phosphonium chloride *(4)* which is precipitated, while the diastereoisomeric acyl ylide *(5)* remains dissolved in the tetrahydrofuran solution. The absolute configuration of *(4)* was proved by chemical correlation with the configuration of the corresponding bromide that had been determined by X-ray structure analysis [4].

(1) *(2)* *(3)*



(4) *(5)*

Using this reaction we have now developed a method of determining the absolute configuration of centrochiral carboxylic acids [5] by qualitative application of *Ugi*'s [6] and *Ruch*'s [7,8] stereochemical structural model without the necessity of considering conformations.

For this purpose two equivalents of *(1)* are treated with one equivalent of the optically active acid chloride *(2)* whose absolute configuration is to be determined; then the specific rotation of the precipitated phosphonium chloride *(4)* is measured (see below).

The ligand constants λ_n of the three ligands of the acid chloride are next assigned as described by *Ugi* and *Ruch* [6–8] and are numbered clockwise; for our purposes it is immaterial with which λ the enumeration begins but it is important that the reacting acid chloride group be placed behind the projection plane of the Newman projection. This is illustrated in *(6)*.

(6)

The asymmetric induction of the acid chloride is then given by a chirality product χ determined from the equation:

$$\chi = (\lambda_1 - \lambda_2)(\lambda_2 - \lambda_3)(\lambda_3 - \lambda_1).$$

We have found that the mathematical sign of the chirality product χ of the optically active acid chloride *(2)* agrees with the sign of the specific rotation of the precipitated phosphonium salt *(4)* (measured in methanol at 589 nm) in all cases where *(2)* has been written in the correct absolute configuration [9].

When the specific rotation of *(4)* has been determined, the substituents R^1, R^3, and R^3 of *(2)* are arranged arbitrarily around the asymmetric carbon atom, *e.g.*, as in *(6)*, and their ligand constants are numbered clockwise. A qualitative order for the numerical magnitudes of the λ values is then set up by using the known constants [6] and, for unknown λ, by basing them on the space-filling by the substituents. Such a series is, for instance, $\lambda_2 > \lambda_1 > \lambda_3$. The mathematical sign of λ is now determined qualitatively. For the relative series just stated the value of χ is found to be positive. If this sign agrees with the sign of the specific rotation of the phosphonium chloride *(4)* as obtained in the kinetic resolution, then the arbitrarily assigned absolute configuration of the acid chloride is correct. If these two signs are of opposite sense, then the positions of two ligands must be exchanged, *e.g.*, R^2 and R^3; then, to retain the clockwise numbering of λ_n, the ligand constants must be assigned as $R^2 = \lambda_1$ and R^3 as λ_3; the order of magnitude of the λ values thus becomes $\lambda_2 > \lambda_3 > \lambda_1$, and, since the equation for χ is inversion-asymmetric, the sign of χ changes when the relative sizes of two λ values are changed: in our case χ becomes negative, and the exchange of two ligands which results in a change of absolute configuration thus leads to the required agreement between the sign of χ and the sign found for the specific rotation of *(4)*.

The Table sets out the results of our experiments: in all cases the absolute configurations determined by the new rule agrees with those recorded in the literature.

Examples 9 and 10 are of particular interest: here a phthaloylimido group has been replaced by a methoxy group but both compounds belong to the (*S*)-series; in no. 9 $\lambda_{N\text{-phthaloyl}} > \lambda_{CH_3}$, but according to *Ugi* [6] in no. 10 $\lambda_{CH_3} > \lambda_{OCH_3}$; it thus transpires that, although no. 10 is still in the (*S*)-configuration, the sign of its χ becomes negative; our rule requires that the sign of the optical rotation of *(4)* must then also become negative, and that is the experimental result. Comparison of examples 6 and 7 gives qualitatively similar results. It follows further from the Table that

$\lambda_{CH_3} > \lambda_{acetoxy}$, $\lambda_{CH_3} > \lambda_{benzoyloxy}$, and $\lambda_{Cl} > \lambda_{CH_3}$.

19	(−)-Menthyloxyformyl	+	+	3*R*	3*R*
20	(−)-3β-Acetoxy-Δ5-etiocholenoyl	+	+	17*R*	unknown

Experimental:

A filtered solution of the ylide *(1)* in tetrahydrofuran is prepared from benzyl(methyl)(phenyl)(*n*-propyl)phosphonium bromide (6.76 g, 20 mmoles) by the sodium amide method (0.5 g of sodium)[3,12]. A solution of the optically active acid chloride *(2)* (10 mmoles) in anhydrous tetrahydrofuran is dropped into this solution with stirring at room temperature. This precipitates *(4)*, and the orange color of the solution of *(1)* changes to the yellow color of *(5)*. Up to this point the work must be with protection by nitrogen and exclusion of moisture. The phosphonium chloride *(4)* is then filtered off, washed with benzene, collected, and dried, after which its specific rotation is determined. The optical yield is 6—7%. The following values were found for (+)-(*S*)-(4) with an optical purity of 86%: $[\alpha]_{589} = +36.2$, $[\alpha]_{578} = +38.5$, $[\alpha]_{546} = +44.9$, $[\alpha]_{436} = +84.6$, $[\alpha]_{365} = +150.7$ (*c* = 0.54 in methanol).

Synthesis and Reactions of Substituted (Dibenzoyldioxyiodo)benzenes; A New Class of Organic Oxidants[**]

By *Božo Plesničar* and *Glen A. Russell*[*]

The reaction of iodosobenzenes with substituted perbenzoic acids in chloroform/methanol (8:1) at 0 °C yields highly reactive (dibenzoyldioxyiodo)benzenes *(1)* containing trivalent iodine.

$$X\text{–}Ar\text{–}IO + 2\ Y\text{–}Ar\text{–}CO_3H \rightarrow X\text{-}Ar\text{-}I(O\text{–}O\text{–}CO\text{–}Ar\text{–}Y)_2 \quad (1)$$

$$X\text{–}Ar\text{–}IO + 2\ Y\text{–}Ar\text{–}CO_2H \rightarrow X\text{–}Ar\text{–}I(O\text{–}CO\text{–}Ar\text{–}Y)_2 \quad (2)$$

[a] In Nujol. [b] Determined iodometrically. [c] M.p. 209 °C [1].

The (dibenzoyldioxyiodo)benzenes *(1)* are white or yellow amorphous compounds which detonate at 80—120 °C and which may undergo spontaneous ignition or detonation upon manipulation in the solid state at room temperature. They react with iodide ion to liberate 3 moles of iodine per mole of *(1)*.

The Table summarizes the physical properties of compounds *(1)* as well as the properties of the corresponding (dibenzoyloxyiodo)benzenes *(2)* formed from the reaction of iodosobenzene and benzoic acids in chloroform/methanol (5:1) [1].

We were surprised that the (dibenzoyldioxyiodo)benzenes *(1)* could be isolated. They are more powerful oxidizing agents than the peracids. Moreover, they appear to transfer two oxygen atoms to substrates such as sulfides or aryl iodides (Scheme 1); compound *(2)* was the reduction product in each case except for iodide ion and for triphenylphosphine where iodobenzene was formed. Dibenzyl sulfide and iodobenzene were still oxidized to the sulfone and iodoxybenzene when a great excess of the substrate was employed (reactions followed by NMR).

(1a) + CH_3SOCH_3 → $CH_3SO_2CH_3$ + *(2a)* (20 min, 100 %)

(1a) + $C_6H_5CH_2SCH_2C_6H_5$ → $C_6H_5CH_2SO_2CH_2C_6H_5$ + *(2a)* (20 min, 100 %)

(1a) + pyridine → pyridine *N*-oxide + *(2a)* (30 min, 85 %)

(1a) + C_6H_5I → $C_6H_5IO_2$ + *(2a)* (60 min, 72 %)

(1a) + $(C_6H_5)_3P$ → $(C_6H_5)_3PO$ + C_6H_5I (10 min, 85 %)

(1a) + styrene → styrene oxide + *(2a)* (45 min, > 80 %)

(1a) + *trans*-stilbene → *trans*-stilbene oxide + *(2a)* (90 min, > 90 %)

Scheme 1. Reactions of [bis(*m*-chlorobenzoyldioxy)iodo]benzene *(1a)* at 28 °C in CH_2Cl_2, 20 % excess of *(1a)* (calculated on the assumption that *(1a)* contains two active oxygen atoms).

The low solubilities of (dibenzoyldioxyiodo)benzenes *(1)* made homogeneous decomposition studies difficult. Solutions of *(1a)* and *(1b)* (0.02 M) in methylene chloride and chloroform yielded iodoxybenzene *(3)*, the diaroyl peroxide, and the arenecarboxylic acid after a few hours at room temperature. Decomposition was faster in chloroform than in methylene chloride but in neither solvent was biphenyl or carbon dioxide detected. This suggests that the (dibenzoyldioxyiodo)benzene *(1)* are excellent traps for aroyloxy radicals. Hydrolysis of compounds *(1)* by traces of moisture may be a complicating factor [2], but we believe the major decomposition route is one of homolysis.

(1a) $\xrightarrow[28\,^\circ C]{5\ h,\ CHCl_3}$ $C_6H_5IO_2$ + *m*-$ClC_6H_4CO_2H$ + (*m*-$ClC_6H_4CO_2)_2$

(1.0 mole) *(3)* (0.8 mole) (1.7 mole) (0.1 mole)

(1b) $\xrightarrow[28\,^\circ C]{5\ h,\ CHCl_3}$ $C_6H_5IO_2$ + *p*-$NO_2C_6H_4CO_2H$ + (*p*-$NO_2C_6H_4CO_2)_2$

(1.0 mole) *(3)* (0.9 mole) (1.4 mole) (0.5 mole)

Preparation of (dibenzoyldioxyiodo)benzenes (1):

The substituted perbenzoic acid (15 mmoles) was dissolved in 100 ml of chloroform/methanol (8:1) at 0—5 °C. Iodosobenzene (5 mmoles) was added with stirring. After 15 minutes' stirring, most of the solvent was removed in a rotary evaporator. The precipitate was washed twice with dilute sodium bicarbonate (20 ml of 5 % solution), with ether, and dried *in vacuo* over P_2O_5. The crude products, which were estimated to be 98—99 % pure by infrared spectroscopy, were purified by dissolution in methylene chloride, the solution being quickly filtered to remove traces of iodosobenzene or iodoxybenzene. The solvent was quickly evaporated and the product dried under vacuum.

Warning: All the (dibenzoyldioxyiodo)benzenes *(1)* are explosive when dry, and manipulation with metal spatulas is not recommended. Avoid any heating.

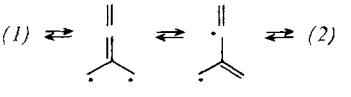
Dimethylenecyclopropane

By *Robert Bloch*, *Pierre Le Perchec*, and *Jean-Marie Conia* [*]

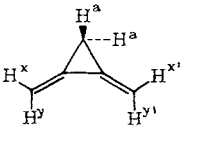


Although derivatives of dimethylenecyclopropane are known and have attracted considerable interest on account of their heat of formation and strain energy [1,2], the parent compound *(2)* has not hitherto been obtained. We are now able to report the preparation of this highly volatile and unstable species.

(1) *(2)*

On heating to 320 °C under vacuum for 3 min (static gas-phase technique), vinylidenecyclopropane *(1)* [3] gives a mixture of *(2)* (30 %) and *(1)* (20 %) and polymers, which are easily separated by gas chromatography.

This simple thermal conversion, already observed with methyl derivatives of *(2)* [2], is apparently promoted by a cyclopropane ring cleavage which leads to a highly delocalized biradical closely related to trimethylenemethane.



The low yield of the conversion of *(1)* into *(2)* is due to the unavoidable polymerization of *(2)*. Even at −10 °C a white solid is precipitated from a pure sample of *(2)* after one hour's standing. Attempts to form the tetracyanoethylene adduct under the usual conditions were unsuccessful. The structure of *(2)* is established by spectrometry.

Mass spectrum: *m/e* 39 (100 %), 65 ($(M-1)^+$, 92 %, characteristic of many cyclopropane derivatives [4]), 66 (M^+, 87 %).

IR (in CCl_4): ν = 3.24, 3.33, 3.35, 3.40 (νC—H), 5.65 s, 6.20 (νC=C), 9.90 μm (cyclopropane).

UV (in hexane): λ_{max} = 232 (ε = 11000), 225 (9700), 240 nm (10000) [cf. 1,2-dimethylenecyclopentane: 248 (ε = 10400) and 1,2-dimethylenecyclobutane: 248 nm (10100)].

NMR: $A_2XX'YY'$ system with three symmetric multiplets (9 lines each) centered respectively at δ = 1.56 ($2H^a$), 5.27 (H^x,$H^{x'}$), 5.50 ppm (H^y,$H^{y'}$); J_{ay} = 2.6, J_{ax} = 1.7,

$J_{x'y,xy'} = {}^1/_2 (J_{x',y} + J_{y',x}) = \pm 0.85$ Hz[**]. The magnitude of J_{ay} and J_{ax} suggests a large σ-π overlap and therefore a large external H^a—C—H^a angle.

Monohetero Derivatives of Bis- and Trishomobenzenes[1] [**]

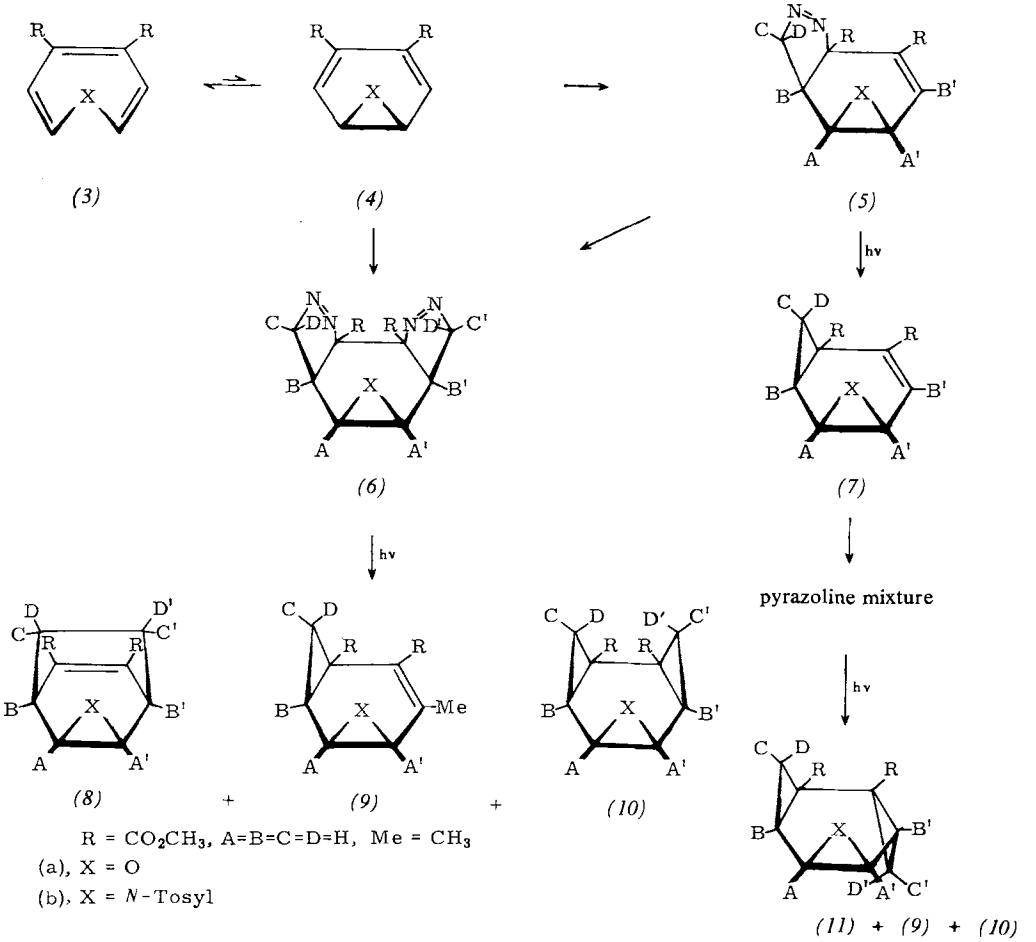
By *Horst Prinzbach* and *Dieter Stusche* [*]

In this communication we report on the compounds *(10a)*, *(10b)*, and *(11a)*, which are the first isolable monohetero derivatives of the trishomobenzene series *(1a)* and *(1b)*; we have also prepared *(7a)*, *(9a)*, and *(9b)* as hetero derivatives of the bishomobenzene series *(2)* [2].

4,5-Bis(methoxycarbonyl)oxepin *(3a)* [3] and -*N*-tosylazepine *(3b)* [4] add diazomethane, reacting as the bicyclic structures *(4a)* and *(4b)* [5], respectively; the preferred

(1a) *(1b)* *(2)*

products are the all-*cis*-pyrazolines *(5a)*, *(6a)*, and *(6b)* respectively.



The monoadduct *(5a)* crystallizes out when diazomethane (0.5 g, 12 mmoles) is added to a solution of *(3a)* (2.1 g, 10 mmoles) in ether (100 ml) in a yield of 65–70 %. The bisadduct *(6a)* was prepared by the same method as was previously used for *(6b)* [5], *i.e.* by precipitation with ether from a mixture of *(3a)* (1 g, 4.7 mmoles) and diazomethane (0.42 g, 10 mmoles) in dichloromethane (100 ml) that has been allowed to stand for 72 h (yield 65–70 %).

On photolysis (300 ml solvent, −20 °C, Hanau Q 81 high pressure mercury lamp), *(5a)* (0.6 g, 2.4 mmoles; methanol; 2 h) affords the oxabishomobenzene *(7a)* (80–90 %); *(6a)* and *(6b)* (4.0 mmoles; acetone; 2 h) give *(8a)* and *(8b)* (60–65 %), *(9a)* and *(9b)* (5–10 %), and *(10a)* and *(10b)* (20–25 %), respectively, after thin-layer chromatography (silica gel/benzene).

The product ratio in the photolysis of *(6a)* and *(6b)* varies with the solvent. In methanol the amount of *(9a)* and *(9b)* is increased considerably at the expense of *(8a)* and *(8b)*.

The bishomobenzene *(7a)* adds diazomethane [0.5 g, 2.2 mmoles of *(7a)* in ether (100 ml); 0.13 g, 3.1 mmoles of CH_2N_2; 1 week; 10 °C] to give a mixture of pyrazolines, which is photolyzed directly (methanol; 2 h). The crude product consists of *(9a)* (12 %), *(10a)* (25 %), and *(11a)* (27 %) (separated by preparative thin layer chromatography; silica gel/benzene).

The structures of the new compounds prepared were confirmed by elemental analysis and spectral data (see Table). In the case of the pyrazolines *(5a)*, *(6a)*, and *(6b)*, the ex-

[a] In $CDCl_3$. [b] In C_6H_6. [c] In CCl_4. [d] In CH_3OH. [e] Molecular ion *m/e* 238. [f] Molecular ion *m/e* 391.

pected $n \rightarrow \pi^*$ bands and the typically large coupling constants of the methylene protons were observed. The spatial relationships of the three-membered rings in *(7a)*, *(10a)*, *(10b)*, and *(11a)*, and hence those also of the rings in *(5a)*, *(6a)*, and *(6b)*, follow from J_{AB} and $J_{A'B'}$ [6]. Compound *(8a)* is identical with the partially hydrogenated adduct of dimethyl acetylenedicarboxylate and oxepin [7]. Its formation from *(6a)* affords additional proof of the *cis* arrangement of the three hetero rings in *(6a)*.

The crystalline trishomobenzenes *(10a)*, *(10b)*, and *(11a)*, which are stable at room temperature, differ considerably in their thermal behavior. Whereas *(11a)* remains unchanged at temperatures up to about 160 °C, *(10a)* and *(10b)* isomerize smoothly at 70 °C to form hetero-2,5,8-cyclononatriene derivatives [8].

Stable Complexes of Bullvalene [**]

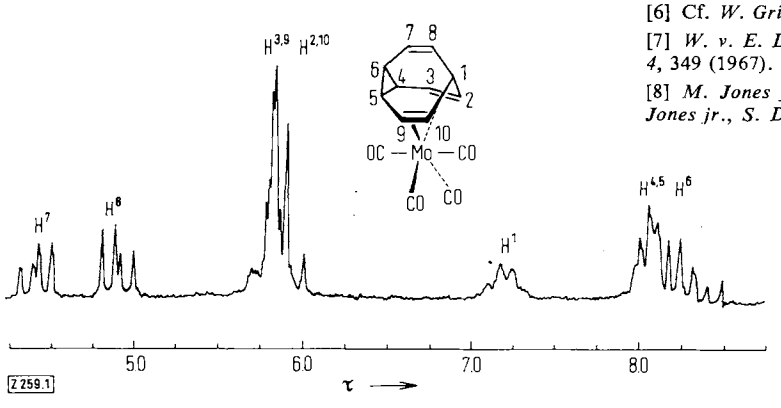
By *Rudolf Aumann* [*]

Bullvalene [1] *(1)* is a notorious case of a molecule with degenerate valence isomerization, in which all the H atoms are magnetically equivalent on the NMR time scale at temperatures above 80 °C. This degeneracy disappears with introduction of a substituent into *(1)*. In this connection, particular interest attaches to the study of metal complexes

in which the bullvalene skeleton is unchanged, but where two double bonds are employed in coordination to the metal. Previous attempts[2] to prepare such complexes were unsuccessful, except for a bullvalene-$Ag(H_2O)^+$ complex[3], because of the great ease with which compound *(1)* rearranges in the presence of metals. We have now been able to prepare stable bullvalene complexes of composition bullvalene-$M(CO)_4$ *(2)* [*(2a)*: M = Cr (dec. 120 °C); *(2b)*: M = Mo (dec. 119 to 120 °C); *(2c)*: M = W (dec. 135 to 136 °C)] by reaction of *(1)* with the corresponding acetonitrile-$M(CO)_3$ complexes in dioxane[4] in 40—70% yield, and have analyzed them by spectroscopy.

The presence of a rigid bullvalene skeleton with an intact cyclopropane ring in *(2b)* and *(2c)* was established by a ^{1}H-NMR double resonance experiment. H^7 and H^8 of the uncomplexed vinyl group form an AB system (cf. Figure), $J_{7,8}$ = 11 Hz, with further splitting in the A ($J_{6,7}$ = 8 Hz; $J_{1,7}$ = 1 Hz) and B parts ($J_{1,8}$ = 8 Hz). In the complexed vinyl group, $J_{2,3}$ (= $J_{9,10}$) is reduced to 7 Hz. It was not possible to demonstrate a degenerate Cope rearrangement with cyclopropane ring shift from skeletal positions 4, 5, 6 to 1, 2, 10 with a concomitant metal shift on the NMR time scale, either by line broadening of the peaks or by use of the Forsén-Hoffman method[5].

Unlike *(2b)* and *(2c)*, which decompose irreversibly to paramagnetic products on heating, even in inert solvents such as cyclohexane, compound *(2a)* rearranges quantitatively to a new complex *(3)* (m.p. 161—162 °C) above about 80 °C. Complex *(3)* was identified by its ^{1}H-NMR spectrum (in C_6D_6 with TMS as internal standard; chemical shifts[6] in τ: $H^{1,6}$ = 7.26, $H^{2,5}$ = 6.56, $H^{3,4}$ = 5.65, $H^{7,8}$ = 6.71, $H^{9,10}$ = 4.81; assigned by double resonance experiments), as well as by its IR and mass spectra.



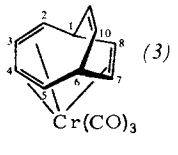


Figure: ^{1}H-NMR spectrum of *(2b)*; C_6D_6 solution, TMS as internal standard, 100 MHz.

(2a) —80°C→ *(3)*

In the presence of NH_3, complex *(3)* slowly decomposes to $(NH_3)_3Cr(CO)_3$ and bicyclo[4.2.2]deca-2,4,7,9-tetraene *(4)*. *(4)* could be identified by its IR and ^{1}H-NMR spectra[7] after isolation by gas chromatography.

Remarkably, *(4)* is not formed on thermolysis[7] of *(1)* but only on photolysis[8]; this demonstrates that under the influence of the metal a rearrangement occurs that is otherwise only permitted photochemically.

The complexes *(2)* are stable as crystals for several months under argon. In benzene they decompose slowly at 30 °C to benzene-$M(CO)_3$ and *(1)*. In the presence of carbon monoxide, rapid decomposition to *(1)* and to the corresponding $M(CO)_6$ complex occurs. After isolation by gas chromatography, *(1)* was identified by its IR and ^{1}H-NMR spectra.

In the 20-eV mass spectra of *(2)*, the molecular ions with the expected isotopic ratios are accompanied by fragments resulting from the successive loss of the four CO groups.

The IR spectra (cyclohexane solution) of *(2)* contain four ν_{CO} bands in intensity ratios that are characteristic of tetracarbonylmetal moieties (ν_{CO} in cm^{-1}: *(2a)* 2028, 1946, 1930, 1904; *(2b)* 2039, 1947, 1941, 1902; *(2c)* 2039, 1947, 1941, 1902).

New Tetrachalcogenide Chelates[**]

By *Hartmut Köpf*, *Werner Kahl*, and *Alexander Wirl*[*]

Bis(π-cyclopentadienyl)tetrasulfidomolybdenum(IV) *(1)*, which is formed according to the reaction scheme (M^{IV} = Mo; X = S):

$$(C_5H_5)_2M^{IV}Cl_2 + M^{I}{}_2X_5 \longrightarrow (C_5H_5)_2M^{IV}\begin{matrix}X\\X\\X\\X\end{matrix} \quad (1)\text{-}(4)$$

$$+ 2\ M^{I}Cl + \tfrac{1}{8}X_8$$

was recently characterized as the first chelate complex of a dianionic tetrachalcogenide ligand[1]. We have now also successfully carried out this reaction with M^{IV} = W and X = Se and obtained the tetrachalcogenides $(C_5H_5)_2WS_4$ *(2)*, $(C_5H_5)_2WSe_4$ *(3)*, and $(C_5H_5)_2MoSe_4$ *(4)* as further examples of the selective formation of polychalcogenide five-membered ring chelates with central ions having a d^2 electronic configuration. In contrast, only the six-membered ring chelates $(C_5H_5)_2TiX_5$ could be isolated with the d^0 central ion Ti^{IV}, irrespective of the chalcogen (X = S or Se)[2]. Compounds *(2)* and *(3)* are the first polychalcogenide chelates of tungsten, and *(3)* and *(4)* are the first hetero derivatives of the yet unknown cyclopentaselenium system.

On reaction of bis(π-cyclopentadienyl)metal(IV) chlorides[3] with ammonium pentasulfide in aqueous ethanol or with sodium pentaselenide in ethanol, *(2)—(4)* are obtained as brown precipitates that are only sparingly soluble in all the usual solvents except dimethylformamide (DMF) and dimethyl sulfoxide (DMSO). Recrystallization under mild conditions from DMF affords deeply colored crystals that are stable towards air and which appear uniform under a microscope. The composition $(C_5H_5)_2MX_4$ was established unequivocally by elemental analysis. Although the solubility of the compounds decreases rapidly along the series *(1)* > *(2)* ⋙ *(3)* ≈ *(4)*, the molecular weights determined cryoscopically in DMSO[4] after calibration with $(C_5H_5)_2TiS_5$ show that *(2)—(4)* are also present in the monomeric ring form in their solutions.

Like that of *(1)*[1], the ^{1}H-NMR spectra of *(2)—(4)* recorded in DMF show, in the expected region[5,6], a sharp singlet for the cyclopentadienyl protons which is not split, even when the temperature is lowered[7] to −60 °C.

	M^{IV}	X	M^I	Decomp. (°C)	τC_5H_5 (ppm) [a]	νCH (cm^{-1}) [b]	ωCC	δCH	γCH	ωSS	not assigned
(2)	W	S	NH_4	above 180	4.85 [c]	3080 m	1435 s 1410 s 1360 w 1115 w	1075 m 1063 w 1020 m 1010 s 998 vs	950 w 924 w 874 s 836 vs 824 vs	488 m [d]	587 w 405 w 364 m

(4)	Mo	Se	Na	215	4.83	3085 w	1425 m 1405 m 1360 Sh 1110 w	1060 w 1012 m 993 m	860 Sh 830 Sh 816 vs		388 s

[a] In DMF; TMS as external standard. [b] KBr disks. [c] Cf. *(1)*: 4.86. [d] Cf. *(1)*: 482 w.

Such behavior at low temperature indicates that the five-membered MX_4 rings of *(2)—(4)* adopt a non-planar conformation similar to that postulated for *(1)*[1].

Bis(π-cyclopentadienyl)tetrasulfidotungsten(IV) (2), -tetraselenidotungsten(IV) (3), and tetraselenidomolybdenum(IV) (4)

An aqueous solution of $(NH_4)_2S_5$ obtained according to ref.[8] is used for further reaction without any attempt being made to crystallize $(NH_4)_2S_5$. An air-sensitive, alcoholic solution of 2 mmoles of Na_2Se_5 is prepared under an inert gas (argon or nitrogen) by dissolution of sodium (0.09 g, 4 mg-atoms) and red selenium (0.79 g, 10 mg-atoms) in liquid ammonia (50 ml), evaporation of the ammonia in a stream of inert gas, and dissolution of the residue in degassed ethanol (25 ml). — Under an inert gas a stirred suspension of $(C_5H_5)_2WCl_2$[3] (0.77 g, 2 mmoles) in degassed ethanol (25 ml) is treated with 2 ml of the solution of $(NH_4)_2S_5$ containing about 2.5 mmoles/ml or added dropwise to the Na_2Se_5 solution and the stirred reaction mixture is brought almost to boiling over a period of one hour. The brown precipitate is filtered off, washed with aqueous ethanol and carbon disulfide, and dried *in vacuo*. Extraction with DMF at *ca.* 80 °C and recrystallization at −30 °C affords *(2)* (0.66 g, 75%) as brownish-red crystals that are also slightly soluble in acetone or *(3)* (1.08 g, 86%) as brownish-violet platelets; similarly, $(C_5H_5)_2MoCl_2$[3] (0.59 g, 2 mmoles) gives a somewhat lower yield of *(4)* (0.39 g, 36%) as lustrous reddish-black platelets.

Tellurium Halide Systems: Te_2Br and Te_3Cl_2

By *Albrecht Rabenau, Hans Rau*, and *Götz Rosenstein*[*]

Of the lower tellurium halides Te_yX (X = Cl, Br, I; $y \geq 1$), only the iodides have hitherto been described[1–3]. According to thermoanalytical findings by *Damiens*[4], such compounds should also be formed in the systems tellurium-bromine and tellurium-chlorine (regarded as solid solutions of tellurium in the respective tetrahalide by the author!). In connection with our studies on the systems formed by tellurium with its tetrahalides, we have now been able to isolate and identify the compounds Te_2Br and Te_3Cl_2. They cannot be prepared in pure form by reaction of stoichiometric amounts of the elements; instead their synthesis requires starting materials containing more halogen.

One arm of a two-arm quartz-glass tube contains powdered tellurium and the other arm contains liquid halogen in the ratio 1 Te: 1 Br or 1 Te : 2 Cl. The tellurium is heated to 220—260 °C; in the other arm the bromine is heated slowly from room temperature to 50 °C, or the chlorine from 0 °C to room temperature, as the reaction progresses. After consumption of the free halogen, the reaction tube is heated to 300—350 °C (muffle furnace) and shaken. The homogeneous melt is quenched with water and the product is then annealed for 2—3 weeks at 165 (bromide) or 180 °C (chloride) to promote solid-state equilibrium. Reaction to Te_2Br and $TeBr_4$ or Te_3Cl_2 and $TeCl_4$ is then complete. Gray needle-like crystals (up to 5 mm length) of Te_2Br or silver-gray compact crystals (1 mm) of Te_3Cl_2 are formed at various parts of the wall of the tube; the crystals prove suitable for X-ray studies.

Larger amounts of Te_2Br or Te_3Cl_2 are obtained by extraction of the tetrahalide from the respective reaction mixture by organic solvents. Here, however, the reactions

$$4\ Te_2Br_{(solid)} \rightleftharpoons 7\ Te_{(solid)} + TeBr_{4(dissolved)}$$

$$2\ Te_3Cl_{2(solid)} \rightleftharpoons 5\ Te_{(solid)} + TeCl_{4(dissolved)}$$

play a role.

Since the concentration of dissolved tetrahalide in equilibrium with the solid Te_2Br or Te_3Cl_2 is lower than the saturation concentration under the same conditions, the end of the separation process is indicated when the concentration falls below the latter value. Thus it is first necessary to determine the saturation concentration in a suitable solvent (diethyl phthalate at 80 °C for the bromides and toluene/light petroleum (b.p. 100—140 °C) (1:1) at room temperature for the chlorides). The reaction mixture is first stirred with the dry solvent for a few minutes in absence of air. Part of the solution is then removed by filtration under suction and replaced by fresh solvent. The concentration of halide in the extract, and thus the amount of halogen extracted, can be determined potentiometrically. The process is repeated — in small steps near the desired composition — until the concentration falls below the value at saturation. Only a single solid phase is then present. Depending on the solvent used, the last traces thereof are removed *in vacuo* or by washing with light petroleum. According to X-ray studies and elemental analysis, this technique yields pure Te_2Br or Te_3Cl_2. It is essential that the operation be carried out rapidly, particularly with the chlorides because $TeCl_4$ reacts with the solvent.

Te_2Br and Te_3Cl_2 melt peritectically at 224 and 238 °C respectively. Both compounds are stable towards air. They are soluble in hot acids and bases.

X-ray data: Te_2Br, orthorhombic: $a = 15.04$, $b = 12.96$, $c = 4.030$ Å; $Z = 8$; $d_{X\text{-ray}} = 5.67$, $d_{exp} = 5.61$ g cm^{-3}; probable space groups $Pna2_1$ and Pnam. Te_3Cl_2, monoclinic: $a = 7.069$, $b = 8.652$, $c = 11.26$ Å; $\beta = 117.51°$; $Z = 4$; $d_{X\text{-ray}} = 4.93$, $d_{exp} = 4.90$ g cm^{-3}; probable space group $P2_1/c$.

The tellurium halides known to date — except the fluorides — are summarized in the Table.

Table. Tellurium halides.

Fourier-Transform ^{13}C-NMR Spectroscopy of Polyols[**]

By *Wolfgang Voelter, Eberhard Breitmaier, Günther Jung, Toni Keller*, and *Dieter Hiss*[*]

The electron distribution in organic molecules, which can be approximated by quantum-mechanical calculations and described by molecular orbitals and substituent effects, is concerned primarily with the carbon atoms. The consideration of open-chain aliphatic polyalcohols shows that ^{13}C-NMR often provides more direct information about molecular configurations than proton magnetic resonance. Polyols widely occur in nature and are important for the characterization of sugars as their reduction products.

The Table lists the chemical shifts of the C atoms of a number of polyols measured relative to CS_2 as external standard. The shifts are determined from the accumulated Fourier-transform ^{13}C-NMR spectra decoupled from the ^{1}H noise. The following points warrant attention:

1) Replacement of an H atom in a polyol (*e.g.* 1,2-propanediol with $\delta_{C\text{-}3} = 171.05$ ppm) by a further OH group causes a downfield shift that is much greater than as observed in ^{1}H resonance (*e.g.* glycerol with $\delta_{C\text{-}1,3} = 127.1$).

2) The ^{13}C signals of primary C atoms in vicinal polyols are found between 126 and 130 ppm.

3) The ^{13}C signals of secondary C atoms in vicinal polyols are located between 117 and 122 ppm.

4) For polyols having a symmetric configuration such as ribitol *(9)* and xylitol *(10)* and D-mannitol *(12)* and galactitol *(14)*, the ^{13}C signals for C-1,5, C-2,4, and C-1,6, C-2,5, C-3,4, respectively, are found in pairs, so that only three signals are observed (Fig. 1a).

5) For polyols having an asymmetric configuration such as D-arabitol *(11)* and D-sorbitol *(13)* one signal for each C atom (Fig. 1b) is observed.

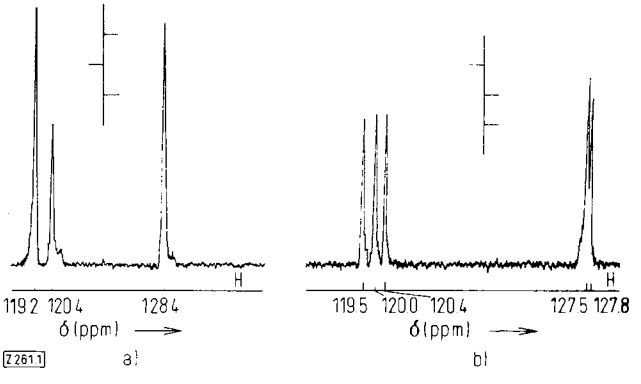

Fig. 1. Fourier-transform ^{13}C-NMR spectrum of a) xylitol *(10)* and b) D-arabitol *(11)*.

The signals of *(2)* to *(7)* are assigned by considering the ^{13}C-^{1}H spin multiplets of the partially decoupled spectra. The ^{13}C signals of the compounds *(8)* to *(10)* can be assigned unequivocally from the intensity ratios. Thus the signal for C-3 in *(10)* appears upfield, and the corresponding signal of *(9)* downfield, from the unresolved signal for C-2,4 (see Table). On the basis of this finding, a partial assignment of the spectra of the polyols *(11)* to *(14)* is possible by comparison of configurations (see Table). For instance, the configurations of C-1,4 in xylitol and D-sorbitol are the same; consequently, the ^{13}C signal for C-3 of D-sorbitol is found upfield ($\delta = 121.1$ ppm) and the signal for C-5 downfield ($\delta = 117.9$ ppm) when compared with those of the C-2,4 group ($\delta = 119.5$ and 119.7 ppm).

The ^{1}H-noise-decoupled Fourier-transform ^{13}C-NMR spectra were recorded with 20% aqueous solutions on a Bruker HX 90 14″ spectrometer at 50 °C, 22.63 MHz, and

Radical 1,3-Migration of Arylazo Groups – CIDNP Effect with *p*-Tolyl Protons

By *Jochen Hollaender* and *Wilhelm P. Neumann* [*]

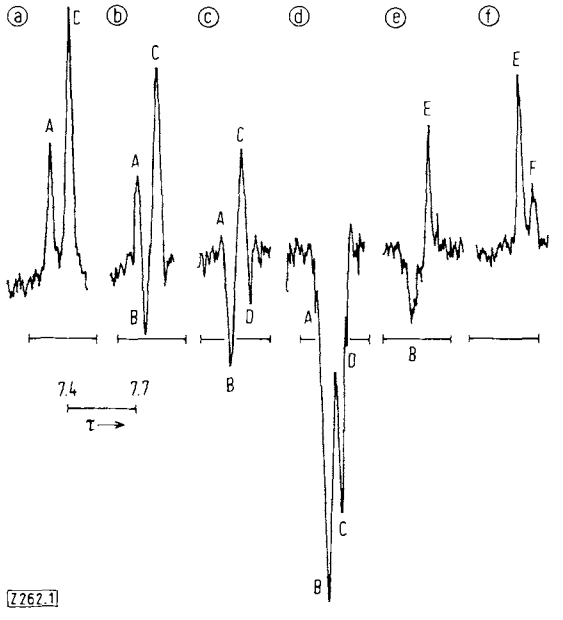
In our investigations of free radical reactions of azo compounds [1] we examined the spontaneous decomposition of 1,3,5-triarylpentazadienes *(1)*—*(4)* [2]. It proceeds in accordance with eq. (1) [3].

However, we also found that a very rapid 1,3-migration of arylazo groups occurs which affords mixtures of *(2a)* and *(2b)* and of *(3a)* and *(3b)* from *(2a)* and *(3a)* respectively. This migration must proceed intramolecularly since no mixed pentazadienes *(2)* or *(3)* occur in the mixture of triphenyl- *(1)* and tri-*p*-tolyl derivative *(4)*. A radical pair is formed (in a solvent cage) as intermediate, as we were able to confirm by the appearance of a "chemically induced dynamic nuclear polarization" (CIDNP) [4] of the methyl protons in the ^1H-NMR spectrum of *(2)*—*(4)* [5].

$$Ar^1\text{-}N{=}N\text{-}\underset{\bullet}{N}\text{-}Ar^3 + \dot{A}r^5 \xrightarrow{-N_2} \underset{\text{(1)-(4)}}{Ar^1\text{-}N{=}N\text{-}\underset{\displaystyle Ar^3}{\underset{|}{N}}\text{-}N{=}N\text{-}Ar^5} \xrightarrow{-N_2} \dot{A}r^1 + Ar^3\text{-}\dot{N}\text{-}N{=}N\text{-}Ar^5 \qquad (1)$$

	Ar^1	Ar^2	Ar^5
(1)	C_6H_5	C_6H_5	C_6H_5
(2a)	C_6H_5	C_6H_5	p-CH_3—C_6H_4
(2b)	C_6H_5	p-CH_3—C_6H_4	C_6H_5
(3a)	p-CH_3—C_6H_4	p-CH_3—C_6H_4	C_6H_5
(3b)	p-CH_3—C_6H_4	C_6H_5	p-CH_3—C_6H_4
(4)	p-CH_3—C_6H_4	p-CH_3—C_6H_4	p-CH_3—C_6H_4

In the case of *(4)* reactants and rearrangement products are chemically identical [eq. (2)]. An NMR signal of the CH_3 protons (τ = 7.96 in benzene, 70 °C) appears momentarily as emission (negative polarization) and then later, after quenching the mixture, as normal absorption. The situation is much clearer in chloroform solution at 40 °C (cf. Figure).



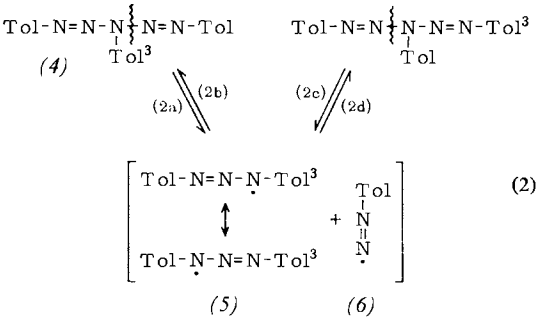


Figure. ^1H-NMR spectrum of 1,3,5-tri-*p*-tolylpentazadiene *(4)* during decomposition in $CHCl_3$: a—e) within 50 s, f) after 1h. A—C: see text; D—F: signals of products [6].

The CH_3 signals of the central *p*-tolyl group like those of the terminal *p*-tolyl groups A and C (τ = 7.49 and 7.57 resp.) appear as emission caused by radical pair recombination without isomerization, *i.e.* corresponding to eq. (2a) + (2b) and (2c) + (2d). In recombination with isomerization, *i.e.* according to eq. (2a) + (2d) and (2c) + (2b), central and terminal tolyl groups exchange positions, thus leading to a new orientation of the CH_3 protons. We ascribe the strongest emission B at τ = 7.52, which must be referred to as a coalescence signal [6], to this effect.

(2)

The above mentioned emissions can be ascribed to that part of the molecule which is formed from the intermediate spin-delocalized triazenyl radical *(5)* in the recombination. The part arising from the *p*-tolylazo radical *(6)* apparently does not play any effective role in the polarization of CH_3 protons, as we have been able to show in our experiments with *p*-tolylazotriphenylmethane.

These findings confirm the existence of arylazo radicals, *e.g. (6)*, which have already been formulated on many occasions as reactive intermediates[7] and support the idea of CIDNP in radical pair recombination in the solvent cage[4c].

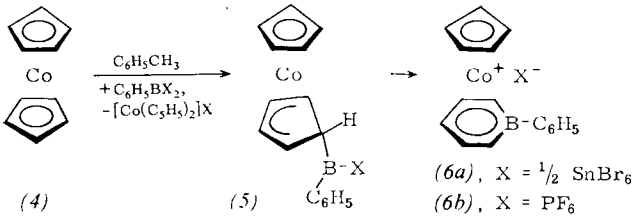
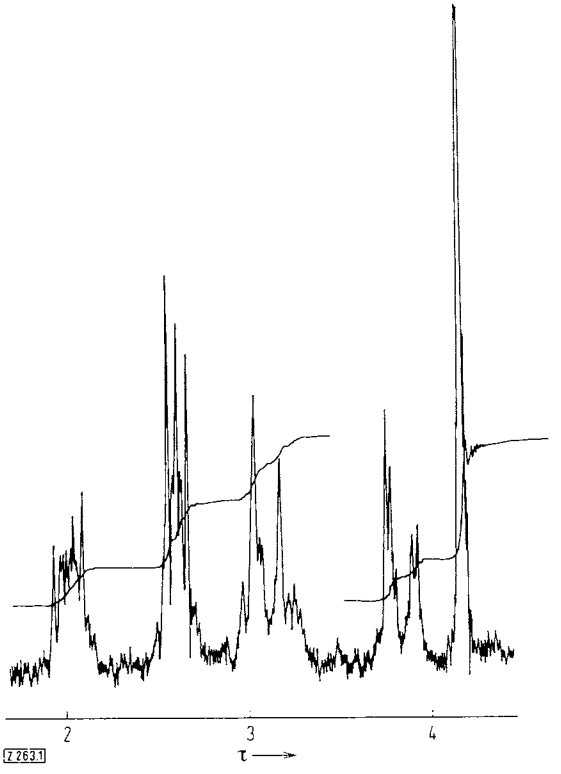
A Novel Aromatic Boron Heterocycle as Ligand in a Transition Metal π-Complex[**]

By *Gerhard E. Herberich, Georg Greiss,* and *Horst F. Heil*[*]



Pyridinium ion *(1)*, benzene *(2)*, and the hitherto unknown hydridoborinate ion *(3)* are members of an isoelectronic series:

(1) *(2)* *(3)*



We have now synthesized the first transition metal π-complexes containing ligands of type *(3)* by using bis(cyclopentadienyl)cobalt *(4)* and boron halides or organoboron halides as starting materials.

By analogy with previous investigations on the reaction of *(4)* with organohalides[1,2] and on the ring expansion of the 5-*exo*-halogenomethyl derivatives of cyclopentadiene-cyclopentadienylcobalt[3,4] one could expect a reaction scheme for the reaction of *(4)* with boron halides and organoboron halides as exemplified here for phenylboron dibromide (with X = Br):

(4) *(5)* *(6a)*, X = ½ $SnBr_6$ *(6b)*, X = PF_6

In fact *(4)* reacts with phenylboron dibromide[5] at –50 °C in toluene to give bis(cyclopentadienyl)cobalt bromide and a red unstable solution[6]. Salts *(6)* separate upon treatment with halide acceptors at room temperature. Thus addition of $SnBr_4$ produces the hexabromostannate *(6a)*, which can be converted into the hexafluorophosphate *(6b)* (orange red needles, m.p. 139 °C, stable in air) by hydrolysis and subsequent precipitation with NH_4PF_6 solution.

The ^{1}H-NMR spectrum (see Figure) of *(6b)* (in CD_3COCD_3, TMS as internal standard, at 60 MHz, 30 °C) contains the singlet of the cyclopentadienyl ring at τ = 4.16, two multiplets of the phenyl group at τ = 2.0 and 2.6, and two multiplets of the remaining five protons at τ = 3.1 and 3.83. The latter signals appear within a remarkably narrow range of less than 0.8 ppm and further downfield than the signal of the C_5H_5 ring. The ^{11}B-NMR spectrum[7] (in CD_3COCD_3, external $BF_3 \cdot O(C_2H_5)_2$, at 100 MHz, room temperature) shows a singlet at δ = –23.3 ppm. These data indicate a planar benzenoid six-membered ring structure[8] of the C_5H_5B grouping in *(6)*. The boron atom, thus being part of a 6π electron system, fully participates in the bonding to the metal. Alternative structures with aliphatic protons, B–H bonds, or a diene grouping can be disregarded[9]. Furthermore, a non-planar structure similar to that of cyclohexadienyl ligands[10], in which the phenylborylene group would be displaced by about 40–50° from the

plane of the dienyl carbon atoms, is not consistent with the NMR data[9,11].

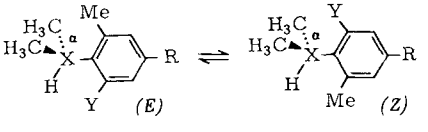
[11] For such a structure having tricovalent boron an ^{11}B-resonance would be expected at $\delta = -50$ to -80 ppm; the signals of the dienyl protons should appear in the range $\tau = 2.5$ to 6.0; cf. [3, 9].

Conformations of *ortho*-Disubstituted Aniline and Toluene Derivatives. Proton Magnetic Resonance and Semiempirical Energy Calculation[1] [**]

By *Albrecht Mannschreck, Ludger Ernst*, and *Elmar Keck* [*]

Compared to the situation at sp^3-sp^3 and sp^2-sp^2 valences, little is known about the conformations resulting from rotation about sp^2-sp^3 bonds or about their relative energies. Compounds of types *(1)* and *(2)* are suited to experimental study of the possible conformers because their lifetimes are especially long. Such rotamers have been

(1), X = $N^{\oplus}$
(2), X = C



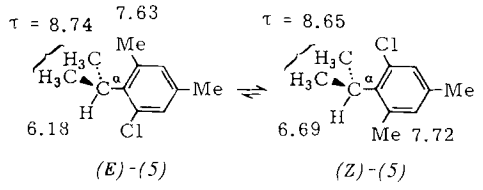
described for *N,N*-dibenzylanilinium ions *(1)*[2] and for 9-arylfluorenes[3], which may be regarded as toluene derivatives *(2)*. It has repeatedly been suggested[2–6] that those conformations are most favored in which the proton at the sp^3 center eclipses an *ortho* substituent. This assumption is now strongly supported by semiempirical energy calculations on toluenes *(2)* for which we also determined, for the first time, the most unfavorable conformation, *i.e.* the transition state of the sp^2-sp^3 rotation. Moreover our calculations reproduce the rotamer equilibria which we were able to measure for the structurally simple toluenes *(5)* and *(6)* and for the isoelectronic *N,N*-dimethylanilinium ions *(3)* and *(4)*.

Reaction of 6-chloro-2-methylaniline and 6-bromo-2,4-dimethylaniline, respectively, with dimethyl sulfate yielded the corresponding *N,N*-dimethyl compounds (b.p. 84-85 °C/12 torr, n_D^{25} 1.5248, and b.p. 65–67 °C/0.001 torr, n_D^{25} 1.5433, resp.) which on dissolution in CF_3CO_2H gave the anilinium ions *(3)* and *(4)*. We obtained *(5)* from 5-chloro-1,3-dimethylbenzene and isopropanol/H_2SO_4; after purification by GLC the sample of *(5)* still contained 5 % of 5-chloro-1,3-dimethyl-2-isopropylbenzene. Bromination of 4-nitro-2-methyl-1-isopropylbenzene[7] in the presence of Ag_2SO_4/H_2SO_4 yielded *(6)* which, after separation by GLC, was still contaminated by 25 % of 5-bromo-4-nitro-2-methyl-1-isopropylbenzene (m.p. 50–52 °C). The absorptions of this by-product, however, did not interfere with those of *(6)*.

For *(3)* and *(4)* in CF_3CO_2H at +27 °C as well as for *(5)* and *(6)* in CS_2 at −55 °C we found two sets of ^1H-NMR signals which are due to rotamers (*E*) and (*Z*) (Table) and coalesce upon raising the temperature[5]. The assignment of signals to rotamers will be explained for the case of (*E*)-*(5)* and (*Z*)-*(5)*. The α-CH septet at $\tau = 6.69$ (CH) is due to isomer (*Z*)-*(5)* where the methine proton and the *ortho* methyl group experience the same environment as in the symmetrical toluene *(7)* showing $\tau = 6.81$ (CH) (CS_2, −60 °C)[5]. In (*E*)-*(5)*, however, the methine proton is adjacent to the chlorine atom, which causes a deshielding through space and shifts the α-CH resonance to $\tau = 6.18$ (CH) (septet). The α-methyl protons of (*E*)-*(5)* and (*Z*)-*(5)* give rise to doublets at $\tau = 8.74$ and 8.65, respectively, which were correlated in the same way.

The energy *E* of a conformation was calculated by addition of the following partial energies[8]: a) stretching energy

Table. Rotamer percentages P and chemical shifts τ in anilinium ions (X=$N^{\oplus}$, CF_3CO_2H, + 27 °C) and toluenes (X=C, CS_2, −55 °C) as determined by ^1H-NMR.



(*E*) ⇌ (*Z*)

	X	Y	R	(*E*) P (%)	(*E*) τ(α-CH_3) [a]	(*E*) τ(*o*-CH_3)	(*Z*) P (%)	(*Z*) τ(α-CH_3) [a]	(*Z*) τ(*o*-CH_3)
(3)	$N^{\oplus}$	Cl	H	45	6.34	7.22	55	6.24	7.34
(4)	$N^{\oplus}$	Br	Me	62	6.37	7.27	38	6.25	7.39
(5)	C	Cl	Me	33	8.74	7.63	67	8.65	7.72

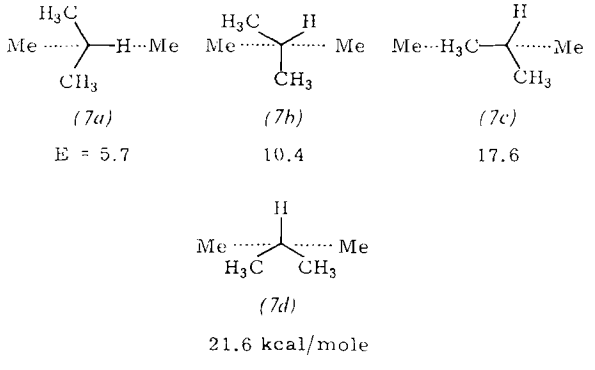
of the bond between the α-C atom and the benzene ring; b) bending energy of the angles at the α-C atom and the angles formed by the bonds of the *ortho* substituents and the



(E)-(5) *(Z)-(5)*

(7)

C—C bonds of the benzene ring; c) nonbonded interactions[9] between each *ortho* substituent and the neighboring *meta* proton on the one hand and the three α-substituents CH_3, CH_3, and H on the other. The specific geometry of a conformation was found by varying the C-aryl bond length and the above mentioned angles in small steps and by calculating the energies of all resulting combinations. The lowest energy combination was regarded as representing the geometry of that conformation.

(7a) *(7b)* *(7c)* *(7d)*

E = 5.7 10.4 17.6

21.6 kcal/mole

Thus for α,α,2,4,6-pentamethyltoluene *(7)* we found that conformation *(7a)* indeed shows the lowest energy. Compared to *(7a)*, *(7b)* is destabilized both by additional bond angle deformations and by a more unfavorable Me/CH_3 interaction. As shown by our calculation, this Me/CH_3 interaction (dihedral angle 0 °) is less repulsive in *(7c)* than the corresponding interaction *via ca.* 30 ° in *(7d)* which has to be counted twice. The transition state of the sp^2-sp^3 rotation is thus represented by *(7d)*. We obtained analogous results for α,α,2,4,6-pentachlorotoluene[6] as well as for *(5)* and *(6)*.

The calculation for these two toluene derivatives yielded energy differences between the (*E*)- and (*Z*)-rotamers. From these differences we obtained (with $\Delta S = 0$) rotamer equilibria (33 % (*E*)-*(5)* and 50 % (*E*)-*(6)*, resp.) which agree fairly well with the NMR results (Table). As to the corresponding anilinium ions *(3)* and *(4)*, their (*E*)-isomers are somewhat more favorable (Table) than (*E*)-*(5)* and (*E*)-*(6)*. This is perhaps due to weak intramolecular hydrogen bonds N—H···Y in (*E*)-*(3)* and (*E*)-*(4)* which, however, have still to be proved.

"Single Vessel Reaction" for the Synthesis of Various Types of Substituted Phosphanes $PR^1R^2R^3$

By *Max Schmidt* and *Wolf-Rainer Neeff*[*]

Issleib and *Krech*[1] have recently investigated the nucleophilic cleavage of "phenylphosphorus" with phenyllithium and, on the basis of their findings, quite justifiably postulated the existence of an analogy between elemental sulfur $(-S-)_x$, and cyclopolyphosphanes $(-PR-)_x$. Such a working hypothesis served as a starting point for investigations which we have been carrying out for some time now[2] on the degradation reactions of cyclopolyphosphanes with Lewis bases as a parallel to the many examples already known in the case of sulfur[3]. According to this hypothesis one would expect the cyclic phosphanes $(RP)_n$ to react with organolithium compounds as follows:

$$(R^1P)_n + n\,LiR^2 \rightarrow n\,LiPR^1R^2$$

The lithium phosphides then formed could react with organohalides according to:

$$LiPR^1R^2 + R^3X \rightarrow LiX + PR^1R^2R^3$$

In fact we have been able to show that various types of organophosphanes can be prepared quite easily, and in manageable yields according to this principle in a "single vessel reaction" with exclusion of air and moisture, if solutions of an organolithium compound LiR^2 and an organochloride R^3Cl are added simultaneously to a solution of cyclopolyphosphane $(R^1P)_n$:

$$(R^1P)_n + n\,LiR^2 + n\,R^3Cl \rightarrow n\,PR^1R^2R^3 + n\,LiCl$$

The phosphanes thus obtained react as expected with methyl iodide to give the corresponding phosphonium salts (with R^1, R^2, and $R^3 \neq CH_3$, completely unsymmetrical). If triorgano-silyl, -germyl, or -stannyl chlorides are used instead of RCl the analogous phosphanes containing P—Si, P—Ge, or P—Sn bonds respectively are obtained.

Obvious side reactions, which lower the yields of the mononuclear phosphanes (some of which – depending on the substituents are difficult to handle and occasionally ignite

spontaneously in air) in this apparently general method of synthesis will not be considered here. The limitations of the method become apparent when bifunctional halogenoalkanes are used; the above mentioned side reactions then predominate and as a result the isolation of homogeneous reaction products is made impossible.

We have successfully coupled to phosphorus various combinations of the same or different residues R where R is: CH_3, C_2H_5, C_3H_7, *n*-C_4H_9, *t*-C_4H_9, C_6H_5, $(CH_3)_3Si$, $(CH_3)_3Ge$, and $(CH_3)_3Sn$.

Typical procedure:

Solutions of LiC_4H_9 (0.64 g, 10 mmoles) and C_3H_7Cl (0.79 g, 10 mmoles) in pentane (10 ml) are added dropwise and simultaneously to a solution of $(C_2H_5P)_4$ (0.6 g; 2.5 mmoles) in boiling pentane (50 ml) with exclusion of oxygen and moisture. The resulting yellow mixture is heated under reflux for 12 h and then stirred for a further 48 h at room temperature. The yellow color vanishes, and a white precipitate (LiCl) separates out. Fractional distillation at 58—59 °C/1 torr yields colorless ethylpropylbutylphosphane $P(C_2H_5)(n\text{-}C_3H_7)(n\text{-}C_4H_9)$. On treatment with methyl iodide in ether it is converted into methylethylpropylbutylphosphonium iodide $[(CH_3)(C_2H_5)(C_3H_7)(C_4H_9)P]I$.

Iodophosphanes PH_2I and PHI_2

By *Max Schmidt* and *Helmut H. J. Schröder* [*]

Between phosphane, PH_3 and the four phosphorus trihalides, PX_3 (X = F, Cl, Br, I), there are, in principle, eight possible halogenophosphanes PH_2X and PHX_2, of which only the difluorophosphane PHF_2 has, as yet, been characterized [1]. However, in view of the drastic difference between fluorine on the one hand and the heavier halogens on the other this compound can hardly be compared with the other formally possible halogenophosphanes.

Alkyl and aryl iodophosphanes, RPI_2 and R_2PI, have been known for some time. We set out to isolate the formal fundamental members of this class of compounds, HPI_2 and H_2PI. We were able to detect them for the first time as intermediates in the electrophilic degradation of white phosphorus, P_4, with anhydrous hydriodic acid, which led to P_2I_4 and PH_3 [2]. We have now been able to synthesize the new iodophosphanes PH_2I and PHI_2 by hydrogen-iodine exchange reactions of phosphane with PI_3, P_2I_4 or I_2:

$$PH_3 + 2\,PI_3 \rightleftharpoons 3\,PHI_2$$
$$2\,PH_3 + PI_3 \rightleftharpoons 3\,PH_2I$$
$$PH_4I + P_2I_4 \rightleftharpoons 2\,PHI_2 + PH_2I$$
$$PH_3 + 2\,I_2 \rightleftharpoons PHI_2 + 2\,HI$$
$$PH_3 + I_2 \rightleftharpoons PH_2I + HI$$

In anhydrous solvents such as CS_2, the products are stable only in equilibrium with the reactants and with hydriodic acid. All attempts at isolating them failed since HI cleavage takes place, the final products being PI_3 and P_2I_4.

^{1}H-NMR spectrum (TMS, internal): PHI_2 in CS_2: doublet −5.03 ppm, J_{P-H} = 145 Hz; PH_2I in CS_2: doublet −2.95 ppm, J_{P-H} = 168 Hz; PHI_2 in C_6D_6: doublet −3.40 ppm, J_{P-H} = 147 Hz; PH_2I in C_6D_6: doublet −1.42 ppm, J_{P-H} = 171 Hz.

^{31}P-NMR spectrum (85 % H_3PO_4, external): PHI_2 in CS_2: doublet +9 ppm, J_{P-H} = 145 Hz, PH_2I in CS_2: triplet +156 ppm, J_{P-H} = 168 Hz.

These NMR data can be attributed to a transition from p to sp^3 orbitals for the bonds along the series $PH_3 \rightarrow PH_2I \rightarrow PHI_2 \rightarrow PI_3$.

On the basis of the IR spectra (4000—260 cm^{-1}) of the solutions obtained in CS_2 in the above mentioned reactions the following frequencies can be assigned to PHI_2: νPH 2260—2270, δPH 781—782, ν_{as}PI 327—329, ν_sPI 320—322 cm^{-1}; and to PH_2I: νPH 2360, δPH 750 cm^{-1}.

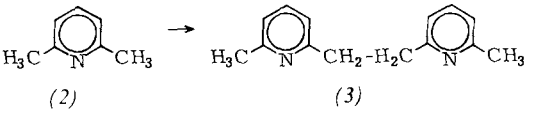
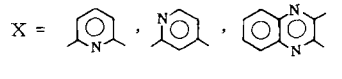
Selective Metalation of 1,2-Bis(6-methyl-2-pyridyl)-ethane and its Preparative Uses [1] [**]

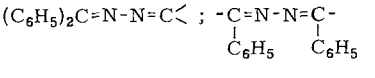
By *Thomas Kauffmann, Gerhard Beissner, Wilfried Sahm,* and *Annegret Woltermann* [*]



The coupling of organic ligands bound to mono- or divalent copper is a convenient method for linking sp^3 C atoms if an activating group X is present which permits direct alkali metalation (hydrogen-metal exchange) and subsequent introduction of copper by transmetalation [2].

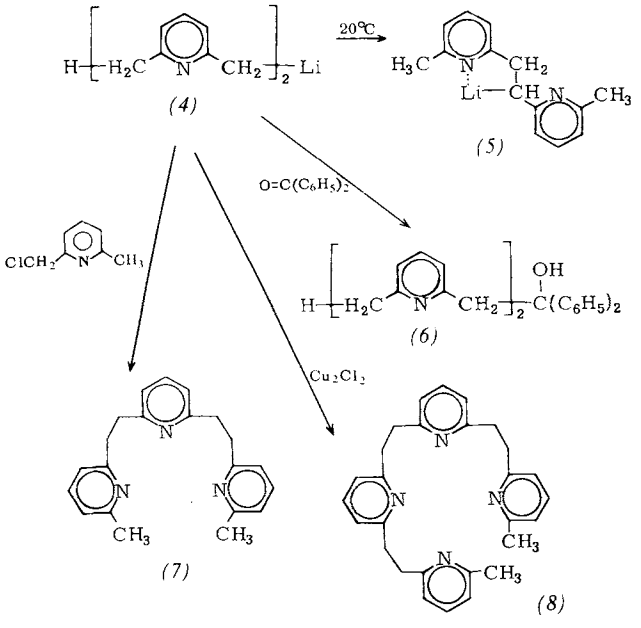


If X is bound, as in *(2)*, to two methyl groups, this ligand coupling leads to formation of the second member (n = 2) of the homologous series *(1)* containing the given group X [3, 5].



(1)

(2) *(3)*



A selective metalation at the methyl groups of the second member would prove advantageous for the preparation of higher members. We have succeeded in carrying out such a metalation in the case of compound *(3)*: On reacting 1,2-bis(6-methyl-2-pyridyl)ethane *(3)* in THF/*n*-hexane (*ca.*

10:1) at −70 °C (≙ "standard conditions") with *n*-butyllithium in the molar ratio 1:1 or 1:2 the methyl/methylene metalation ratio was 83/17 in each case (NMR analysis of D_2O-hydrolysis product). The monolithium compound *(4)* obtained as main product (yield 62%) in the solution after reaction with one molar equivalent of *n*-butyllithium rearranges irreversibly on warming at +20 °C to the methylene metalation product *(5)*, whose higher thermodynamic stability can be explained by the given chelate structure[6].

Reaction of *(4)* under "standard conditions" (see above) with 2-chloromethyl-6-methylpyridine[7] or $CuCl_2$[8] (in the molar ratio 1:1 in each case) leads to the formation of 2,6-bis[2-(6-methyl-2-pyridylethyl]pyridine *(7)* (60%; m.p. 108 °C)[9] or 1,2-bis{6-[2-(6-methyl-2-pyridyl)ethyl]-2-pyridyl}ethane *(8)* (48%; m.p. 145 °C), the third and fourth members respectively of the homologous series *(1)* (X = 2,6-pyridinediyl). The corresponding reaction with benzophenone leads to the alcohol *(6)* (61%, m.p. 95 °C)[10].

(4) *(5)* *(6)* *(7)* *(8)*

The dilithium compound *(9)*, which is obtained in 82% yield by reaction of *(3)* with two mol. equiv. of *n*-butyllithium, reacts with Cu_2Cl_2 (2 mol. equiv.) under standard conditions[8] to give the previously reported[11] pyridinophanes *(11)* and *(12)* in 1% and 4% yields respectively; application of the dilution principle does not increase the yields. Mass spectrometric analysis of the reaction products revealed the presence — in addition to that of *(11)* and *(12)* — of the cyclic dehydrohexamer of *(2)* and to the open-chain dehydropolymer having 4,6,8, and 10 pyridine nuclei.

Compound *(9)* reacts with 2 mol. equiv. of 2-chloromethyl-6-methylpyridine or benzophenone to give *(8)* (67%) or *(10)* (79%, m.p. 244 °C) respectively.

Unlike compound *(3)*, the higher homologs *(7)* and *(8)* do not undergo selective metalation at the methyl groups on reaction with *n*-butyllithium (under standard conditions with 2 moles of butyllithium, ratio of methyl/methylene metalation ≈ 55/45 and 19/81 resp.). The low methyl metalation in the case of *(8)* cannot be explained only as being due to the unfavorable ratio of methyl/methylene protons (33/67).

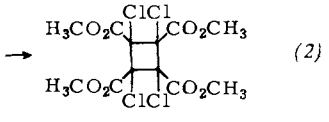
[1,2,3,4-Tetrakis(methoxycarbonyl)cyclobutadiene]-tetracarbonylmolybdenum[**]

By *H. D. Scharf* and *K. R. Stahlke*[*]

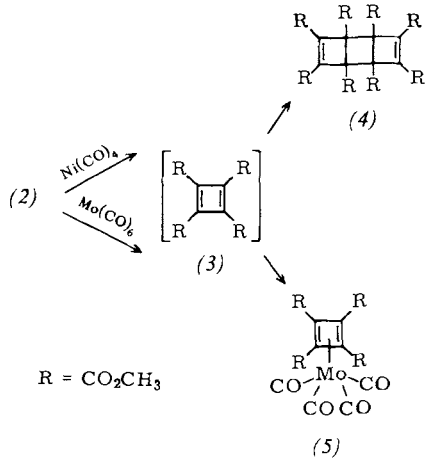


In a previous communication we reported on the photochemical (2+2)-cyclodimerization of dichloro- and dibromomaleimides in dioxane[1]. No dimerization products were formed on photolysis of solutions of the corresponding maleic anhydrides at the same concentrations (0.2 M solutions).

We have now found that irradiation of a concentrated solution of dichloromaleic anhydride in acetone (optimum concentration 2.5—3.0 moles/l) at room temperature with light of wavelength $\lambda > 290$ nm[2] yields a dimeric dichloromaleic anhydride *(1)*; m.p. 280 °C (dioxane)[3], IR spectrum: $\tilde{\nu}$ = 1800 (C=O), 1880 (C=O), 785 cm^{-1} (C—Cl).

Since the reaction is not quenched by triplet quenchers and since only one isomer of *(1)* is formed, we assume that a singlet reaction is involved, probably *via* an excimer mechanism. Because of the very short lifetime of singlet excited molecules it is reasonable that dimerization is to be observed only in concentrated solutions.

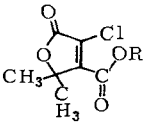
(1)



(2)

Reaction of *(1)* with diazomethane yields the tetramethyl ester *(2)* [m.p. 106 °C (methanol); IR spectrum: $\tilde{\nu}$ = 2840 (methyl stretching vibration); 1750 (C=O); 1250 (C—O—C), 710 cm^{-1} (C—Cl); ^{1}H-NMR spectrum: τ = 6.15 (s)[4]].

It was of interest to examine the influence of electronegative substituents[5], in this case of the ester group, on the stability of the cyclobutadiene system. Only the tricyclic compound *(4)* [m.p. 158 °C (methanol); IR spectrum: $\tilde{\nu}$ = 1730 (C=O), 1630 cm^{-1} (C=C); ^{1}H-NMR spectrum: τ = 6.14 (12 H/s), 6.30 (12 H/s)] could be obtained on dehalogenation of *(2)* with $Ni(CO)_4$.



However, in the dehalogenation of *(2)* with $Mo(CO)_6$ the tetrakis(methoxycarbonyl)cyclobutadiene *(3)* could be isolated in small amounts as the tetracarbonylmolybdenum complex *(5)* along with the tricyclic compound *(4)*. The deep red square crystals melt at 180—182 °C (methanol); IR spectrum: $\tilde{\nu}$ = 1910 and 1990 cm^{-1} (symmetric and antisymmetric CO vibration)[6]; ^{1}H-NMR spectrum: τ = 6.5 (s).

(4)

(5)

On the basis of spectroscopic data[7] we assign the α-chlorodehydroterebic acid structure to the secondary product *(6)* [m.p. 104—105 °C (CCl_4)] formed in the prolonged irradiation of dichloromaleic anhydride. The acid *(6)* can be esterified to *(7)* by reaction with diazomethane. The mode of formation of *(6)* is reminiscent of the synthesis of terebic acid from isopropanol and maleic acid[8] under similar conditions.

(6), R = H
(7), R = CH_3

1,2,3,4-Tetrachlorocyclobutanetetracarboxylic dianhydride (1)

A solution of dichloromaleic anhydride (52 g, multisublimed) in anhydrous acetone (100 ml) is irradiated for three days[2]; the dimer *(1)* formed is filtered off and recrystallized from anhydrous dioxane. The yield of *(1)* can be increased to 6 g (12%) by further irradiation of the filtrate for 200 h. The yield is very much dependent on the purity of the dichloromaleic anhydride.

3-Methylcyclopropene from 1-Chloro-2-butenes

By *Roland Köster*, *Someshwar Arora*, and *Paul Binger*[*]

We have devised a simple method for the preparation of pure 3-methylcyclopropene *(1)* in yields of up to *ca.* 35% from 1-chloro-2-butenes (*cis*- and *trans*-crotyl chloride)[2] (cf.[1]). Compound *(1)* had been previously prepared in only 2% yields from 1-chloro-*trans*-2-butene and sodium amide in tetrahydrofuran[3].

Dropwise addition of crotyl chloride[2] to a suspension of lithium amide in boiling dioxane leads to the formation of *(1)* in *ca.* 35% yield. Up to 80% of the calculated amount [eq. (a)] of ammonia is liberated as gas along with *(1)*. From this gas mixture *(1)* (IR[4], mass, and ^{1}H-NMR spectra[4]) is recovered in 30% yield and 98% purity. It is essential that the suspension contain traces of water or alternatively small amounts of LiOH.

The use of sodium amide in different ethers results in varying yields of *(1)* (diethyl ether 11%, diethylene glycol di-

(1)

methyl ether 21%, dioxane 34%). 1,3-Butadiene and 1-methylcyclopropene are the usual by-products and therefore it has never been possible to achieve higher than 90% purity. Potassium amide cleaves boiling dioxane and is therefore not suitable for this synthesis.

A particular advantage of the $LiNH_2$ method is that the thermally unstable *(1)* is immediately formed in a very pure form. Even at 0 °C the exothermic oligomerization of *(1)* results in numerous hydrocarbons $(C_4H_6)_n$ where $n = 2$ ($\geq$2 isomers), $n = 3$ ($\geq$6 isomers), and $n = 4$ ($\geq$7 isomers), which can be detected by a combination of GC—MS. On the other hand, dropwise addition of a pre-cooled (—78 °C) 3—4 M solution of *(1)* in pentane to ethyldiborane at —5 °C leads to high yields of ethyl-(2-methylcyclopropyl)boranes whose retention times in the gas chromatogram are identical with those of the ethyl-(*trans*-2-methylcyclopropyl)boranes formed from 1-methylcyclopropene[5]. Oligomerization of *(1)* during hydroboration occurs only up to a maximum of 20%.

The $LiNH_2$ method is also superior to the $NaNH_2$ method in tetrahydrofuran[6] or in dioxane[7] for the preparation of 1-methylcyclopropene from 3-chloro-2-methylpropene (methallyl chloride) (yield *ca.* 40%; 97% purity). The experimental procedure is entirely analogous to that described below.

3-Methylcyclopropene (1)

1-Chloro-2-butene[2] (118 g, 1.3 moles) is added dropwise over a period of 6 hours to a well stirred suspension of $LiNH_2$ (30 g, 1.31 moles) in boiling dioxane (140 ml) containing about 0.6 g H_2O. The resulting gas mixture is carried in a stream of argon, bubbled through 5 N H_2SO_4 (300 ml), and trapped at —78 °C.

Compound *(1)* is obtained in 30% yield (21.5 g; 98% purity) along with traces (GC) of 1,3-butadiene and some unidentified compounds (1.5%); b.p. —4 °C (unstable). — Mass spectrum: 54 (50) ($M^{\oplus}$) with fragment ions (rel. intensity), 53 (43.5), 39 (100), 28 (45.8), 27 (61.8), and 26 (30.1). — ^{1}H-NMR spectrum (—40 °C, neat): τ = 2.82 (d, $J \approx 1$ Hz), 8.54 (m), and 9.03 ppm (d, $J = 5$ Hz) in the ratio 1.9:1.2:2.9 (calc. 2:1:3).

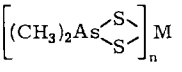
Sodium Dimethyldithioarsinate, a New Complexing Agent

By *Malte Förster, Herwig Hertel,* and *Wilhelm Kuchen*[*]



In contrast to the extensively investigated metal complexes $[R_2PS_2]_nM$ of dithiophosphinic acids the corresponding compounds of dithioarsinic acids have, to the best of our knowledge, not previously been reported[**].

By passing hydrogen sulfide into a boiling ethanolic solution of sodium dimethylarsinate *(1)* we have been able to prepare sodium dimethyldithioarsinate *(2)* and to isolate

$$(CH_3)_2As(O)ONa + 2\ H_2S \rightleftharpoons (CH_3)_2As(S)SNa + 2\ H_2O$$
(1) *(2)*

it in almost quantitative yield as the dihydrate (stable, colorless crystals, m.p. 181—182 °C).

In water/ethanol this compound reacts with numerous metal ions to give complexes of the type *(3)*, most of which are intensely colored.

(3)

(3), M	Color	M.p. (°C)	Magnetic moment (B.M.)
Cr(III)	dark blue	223—225 (dec.)	3.90 (298 °K)
Ni(II)	brown-violet	145—146 (dec.)	diamagnetic
Co(II)	green	decomp. above 200	4.40 (298 °K)
Zn(II)	colorless	decomp. above 200	—
Cd(II)	colorless	decomp. above 200	—

The complexes are insoluble in water. Only the octahedral Cr(III) and the planar Ni(II) complexes dissolve in benzene, carbon tetrachloride, chloroform, or methylene chloride. According to osmometric measurements the Cr(III) complex is present as the monomer in chloroform. The magnetic moment found for the Co(II) complex corresponds to a tetrahedral environment of the metal, as is also to be expected for the Zn and Cd complexes. We explain the insolubility of the tetrahedral complexes as being due to association *via* ligand bridges as have been detected in the analogous dithiophosphinato complexes[1] and which according to model considerations ought to be more likely in the arsinato complexes[2].

The electron spectrum of the Cr(III) complex yielded the ligand field parameters $\Delta = 13740\ cm^{-1}$ and $\beta = 0.455$ ($B_0 = 918\ cm^{-1}$). Consequently, the ligand $(CH_3)_2As(S)S^-$ can be placed in the spectrochemical series as follows,

$$I^- < Br^- < (CH_3)_2P(S)S^- < (CH_3)_2As(S)S^- < Cl^- < dtp^-\ [3] < F^-$$

while in the nephelauxetic series it occupies the position shown below:

$$F^- < H_2O < NH_3 < Cl^- < Br^- < (CH_3)_2P(S)S^-\ [4] < (CH_3)_2As(S)S^- < dtp^-$$

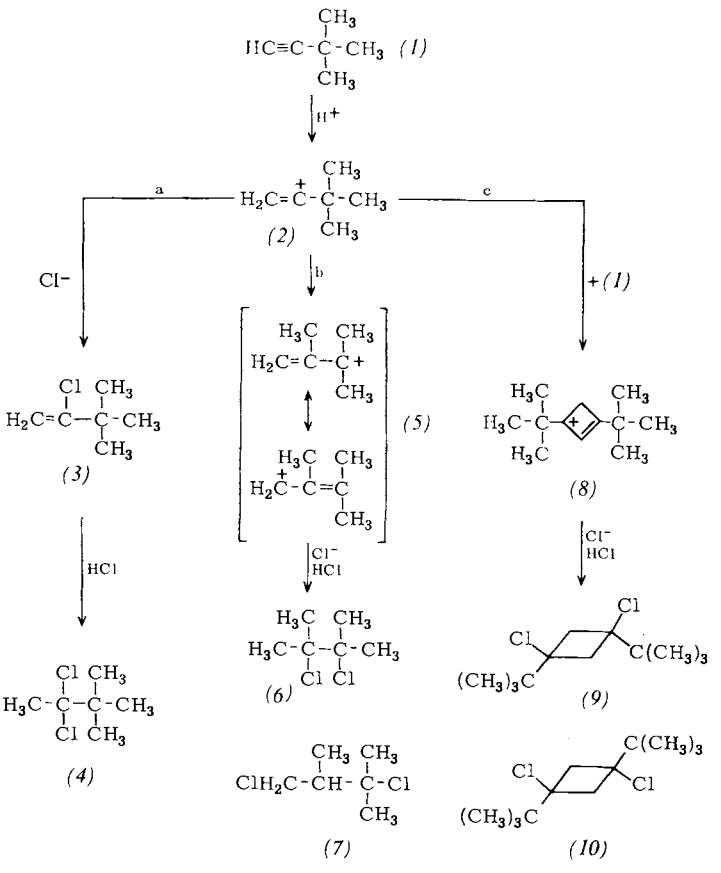
Electrophilic Cyclodimerization of *tert*-Butylacetylene with Hydrogen Chloride[1]

By *Karl Griesbaum*, *Zillur Rehman*, and *Uwe-Ingomar Záhorszky*[*]

Reaction of *tert*-butylacetylene *(1)* with anhydrous hydrogen chloride at room temperature[2] leads to the normal adducts *(3)* and *(4)*, and to the adducts *(6)* and *(7)*, which are formed by a 1,2-methyl shift to the vinyl cation *(2)*. Besides these, the gas chromatogram of the crude adduct mixture showed the presence of a few additional components, but only in the amount of or less than 1% each.

Two of these unknown components, having higher retention times in the gas chromatogram than either of the diadducts *(4)*, *(6)*, or *(7)*, were of interest from the point of view of a possible cyclodimerization. We have been able to isolate both components as crystalline, colorless substances by a combination of fractional distillation and preparative gas chromatography (3 m Carbowax-20M column).



The substance having the higher retention time (67 min) has a m.p. 175—177 °C and its mass spectrum contains a molecular ion triplet typical of dichloro compounds at m/e = 236, 238, 240 corresponding to the empirical formula $C_{12}H_{22}Cl_2$, *i.e.* to an adduct of two molecules of HCl and two molecules of *tert*-butylacetylene. An intense doublet at m/e = 118, 120 (M/2) indicates ready splitting of the molecule into two equal fragments and thus to the presence of a symmetrical cyclic structure. Further typical fragment ions occur at m/e = 200, 202 (M — HCl), m/e = 185, 187 (M — CH_3 — HCl), m/e = 165 (M — HCl — Cl), m/e = 103, 105 (M/2 — CH_3), m/e = 57 (*tert*-butyl), and m/e = 56 (isobutene).

The NMR spectrum (CCl_4) showed a singlet at δ = 1.02 ppm and a four-line pattern centered at 2.79 ppm in the intensity ratio 9:2. The four-line pattern is obviously due to a AA'BB' system (J_{AB} = 13 Hz), whose individual signals are further split by a small — presumably diagonal — coupling of *ca.* 3 Hz.

This data is in accord with the structure of a *cis*-1,3-di-*tert*-butyl-1,3-dichlorocyclobutane *(9)*, which was supported by comparison of the NMR spectrum with that of the corresponding *cis*-1,3-dichloro-1,3-dimethylcyclobutane[3].

The second component, *i.e.* the substance having the lower retention time (48 min), has a m.p. 115—118 °C and shows the same signals in the mass spectrum as *(9)* although with different relative intensities. The NMR spectrum showed only two singlets at δ = 1.12 ppm and δ = 3.01 ppm in the intensity ratio 9:2. This data is consistent with the structure of the *trans*-compound *(10)* which is isomeric with *(9)*.

These investigations indicate that three reaction routes are open to the vinyl cation *(2)*: a) simple combination with Cl^- ions or with Cl^- and HCl to give the normal adducts *(3)* and *(4)*; b) rearrangement to the resonance-stabilized allyl cation *(5)*[4]; and c) cycloaddition to form the allyl cation *(8)* with subsequent formation of *(9)* and *(10)*.

To the best of our knowledge, the synthesis of *(9)* and *(10)* represents the first case of a merely acid-catalyzed cyclodimerization *via* vinyl cations, in which no isomerization of the acetylenic substrate to allenic structures can occur.

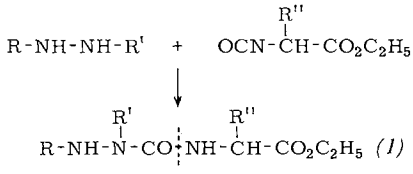
Azapeptides, A Novel Class of Peptide Analogs

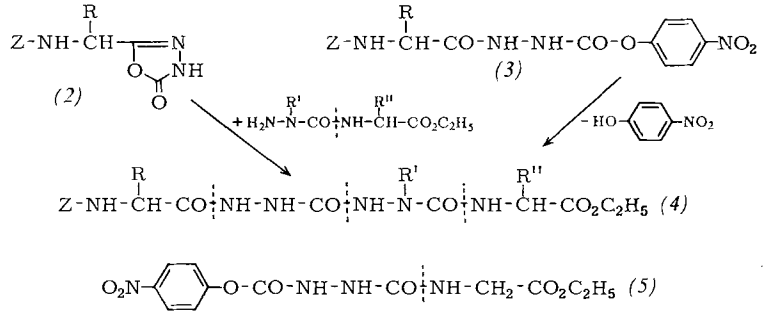
By *Joachim Gante*[*]



In the "azapeptides", a novel system of compounds analogous to the peptides, a few of the α-CH groups of the amino acid esters of the peptide chain are replaced by N-atoms:

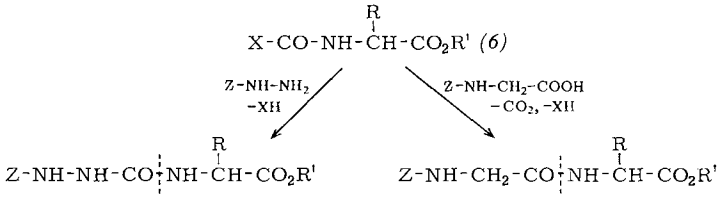
peptide chain azapeptide chain

The side-chain R remains unchanged.



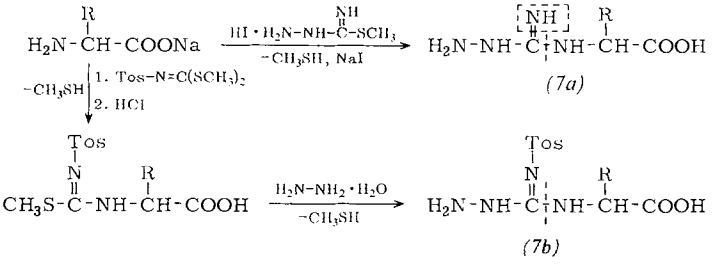
Various new synthetic routes for these compounds have been developed in our laboratories[1]. For example, hydrazine hydrate and alkyl- and acylhydrazines are added to ethyl α-isocyanatocarboxylates to give "alternating" products *(1)* (containing alternately azaamino acid and amino acid residues).

R = H, benzyloxycarbonyl (Z), tosyl (Tos)
R′ = R″ = H, alkyl



Long-chain peptide analogs can be prepared by alternate reaction of *N*-protected azapeptide esters with hydrazines and isocyanato fatty acids.

2-(Benzyloxycarbonylaminoalkyl)-1,3,4-oxadiazol-5-ones *(2)* and "activated" benzyloxycarbonylaminoacylazaglycyl-*p*-nitrophenyl esters *(3)* react with azapeptides unprotected on the amino group to give higher peptide analogs *(4)* having directly coupled azaamino acid residues.



The azapeptide *(5)*, which is activated on the amino group correspondingly reacts with lengthening of the chain at the amino end.

The *N*-activated amino acid esters *(6a)*[2], *(6b)*[3], and *(6c)*[4] can be used for both azapeptide and peptide synthesis with chain lengthening at the amino end.

(6a), X = 2,4-dinitrophenoxy-; *(6b)* X = 1-imidazolyl-;
(6c), X = 1,2,4-triazol-1-yl.

Reaction of sodium salts of amino acids with *S*-methylisothiosemicarbazide hydrogen iodide leads to unprotected "azaimidopeptides" *(7a)*, a further class of azapeptide analogs, in which the carbonyl oxygen of an azaamino acid ester is replaced by NR[5].

Reaction of sodium salts of amino acids with dimethyl tosyl iminodithiocarbonate and subsequent reaction of the (isolable) intermediates with hydrazine hydrate yields azaimidopeptides *(7b)* having tosyl-protected imino groups[5].

The properties of the new peptide analogs closely resemble those of the peptides. The reactions commonly used in the synthesis of peptides — *e.g.* cleavage of the *N*-protecting group, hydrolysis of the ester, coupling of fragments to yield large molecules by well known methods — can also be used in the case of the azapeptides.

Biochemistry of the Central Nervous System. Some Observations on Mass Transport

By *Eberhard Riedel*[*]

The biochemical reactions occurring in the central nervous system are closely related to neurophysiologically measurable processes and cannot be fully understood without consideration of neuroanatomical features of brain structure. In the central nervous system particular attention attaches to membrane structures of the cell and vessel walls and to the transport occurring there. Apart from physical transport, active transport plays an especially important role in the central nervous system. In addition, barrier systems (blood-brain barrier, liquor-brain barrier) make for a strict selection in exchange processes with the supply system of the blood circulation. Physical transport with

pore-free membranes (solution diffusion) and with membranes containing pores were discussed. In order to investigate such processes we developed new methods of determining permeation using capacitative, conductometric, and other detectors (gas chromatography) and have been able to detect not only solution diffusion but also pore diffusion (model studies) on synthetic high polymers (polyesters, low-pressure polyethylenes). Facilitated diffusion (*Danielli*) represents a special case and cannot properly be termed activated diffusion.

The morphology of the cellular elements of the central nervous system is of importance to the biochemist with regard to membrane structure and membrane transport. Information transfer in the central nervous system is by electrical impulses within a widely branched neuron network (10^9 neurons in the human brain) which is nourished by the neuroglia, a supply and support tissue system exhibiting an extremely high degree of metabolic activity.

Of the various theories of the active K—Na transport (K—Na pump), which is of great significance for the transport of electrical signals, the assumption of a redox pump must apparently be ruled out since ion transport is not blocked by respiratory inhibitors (cyanide). The carrier theory (*Hodgkin, Whitman*) provides satisfactory explanations. *Hokin* also mentioned K/Na-active phospholipid systems. It appears that a symporter mechanism (*Mitchell*) is mainly responsible for the transport of amino acids, glucose *etc.*

Work in our laboratories is concerned with the susceptibility of the central nervous system to convulsive seizures. In the brains of experimentally epileptic animals (Kopeloff method) we have been able to observe changes in the K and Na content which are dependent on the development of an attack and which have to be interpreted in terms of the phenomena mentioned above.

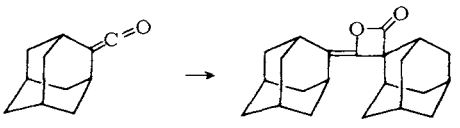
Charge Distribution in Ionic Crystals

By *Alarich Weiss* [*]

Various methods are used for the determination of the charge distribution in crystals. The earliest experiment was the probing of a crystal with fast charged particles *e.g.* protons. When the crystals are available as thin films, channels of low charge density can be recognized in the crystal lattice from the intensity distribution in the proton beam.

The most important method for the study of charge distribution is the diffraction of X-rays in the crystal lattice. It can be concluded from the few quantitative results reported that in the simplest cases, such as the alkali halides, practically spherical ions are present in the lattice. The radii determined from the electron density distribution differ considerably from the Goldschmidt radii, but are in good agreement with the radii calculated by *Tosi* on the basis of the Madelung-Born-Mayer model. The surprising fact that the cations in the alkali halides are larger than the "free" ions, while the anions are smaller, appears reasonable from quantum-mechanical model calculations. The wave functions obtained from such model lattice calculations can be used for the calculation of physical properties such as the diamagnetic susceptibility and the dipole polarizability. The resulting values agree better with the experimental values than when the radii of the "free" ions are used.



Studies of the nuclear magnetic resonance spectrum of some ions in simple crystals can also furnish information about the charge distribution in crystals. The charge distribution must be deduced from the nuclear magnetic resonance spectra by means of model calculations. Such models of charge distribution can be based upon a simple point charge model. The multipole moments induced in the ions in the lattice, particularly dipole and quadrupole moments, demand careful attention, as is shown by model calculations on simple lattices. Moreover, valuable information about the charge distribution in ionic crystals can be obtained from Mössbauer spectroscopy and from the longwave IR spectra.

Lecture at Göttingen on April 23, 1970 [VB 251 IE]

SELECTED ABSTRACTS

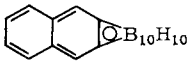
Bis(adamantylidene)methane *(3)*, an allene of theoretical interest, has been synthesized by *J. Strating, A. H. Alberts,* and *H. Wynberg.* In the presence of catalytic amounts of $AlCl_3$ in boiling ether, the ketene *(1)* dimerizes directly to the

(1) *(2)*

(3)

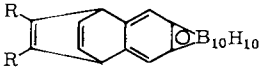
β-lactone *(2)* in 50 % yield. Pyrolysis of *(2)* at 260 °C affords *(3)*, m.p. 224—116 °C, 95 % yield, with liberation of CO_2. The IR and NMR spectra are in accord with the allene structure. / Chem. Commun. *1970*, 818 / —Ma. [Rd 226 IE]

The ESR spectrum of triplet methylene was measured for the first time by *R. A. Bernheim, H. W. Bernard, P. S. Wang, L. S. Wood,* and *P. S. Skell.* Methylene was generated by photolysis of diazirine in a xenon matrix (proportion *ca.* 1 : 10^4) at 4.2 °K. The ESR data show that triplet methylene is slightly bent under these conditions. The signal is constant for several hours at 4.2 °K; therefore the triplet state should be the electronic ground state. On warming to 20 °K and cooling back to 4.2 °K the spectrum does not change. After warming to 77 °K, however, it disappears irreversibly. / J. chem. Physics *53*, 1280 (1970) / —Hz. [Rd 234 IE]



Simultaneous excitation of two absorbing centers by one photon is postulated by *H. J. Schugar, G. R. Rossman, J. Thibeault,* and *H. B. Gray* for the interpretation of the electronic spectra of some binuclear iron(III) complexes. As the most important example, the spectrum of $[(HEDTAFe)_2O]^{2-}$ (ethylenediammonium salt in aqueous solution) is analyzed; HEDTA stands for the pentadentate ligand $R'RNCH_2CH_2NR_2$ with $R=CH_2COO^-$ and $R'=CH_2CH_2OH$. The four transitions at the longest wavelengths (11—24 × 10^3 cm^{-1}) are essentially the same as those of a mononuclear

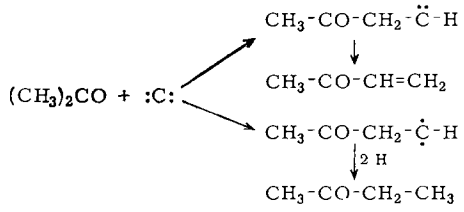
octahedral high-spin iron(III) complex. At shorter wavelengths a group of bands follows which is not encountered in mononuclear complexes as $[HEDTAFeOH]^-$ or $[HEDTAFeOH_2]$. The energies of these bands are all readily displayed as the energy sums of two of the long-wavelength bands. This could mean that excitation of both metal ions is effected by absorption of one photon. This phenomenon was known hitherto only with crystals, and is now demonstrated for the first time on a discrete complex. / Chem. Physics Letters *6*, 26 (1970) / --Hz. [Rd 227 IE]



Electron-transfer bands between unlike transition-metal ions in the UV spectra of perovskites are discussed by *J. Ferguson* and *H. J. Guggenheim*. Crystals of the compositions $KMn_xNi_{1-x}F_3$ and $KZn_{1-x-y}Mn_xNi_yF_3$ show an intense ultraviolet band ($\tilde{\nu}_{max} > 50000\ cm^{-1}$). As the absorption of crystals containing Ni and Mn exceeds the absorption of those containing only one metal the absorption is ascribed to the excitation of the chromophore $Mn^{2+} \cdot\cdot F^- \cdot\cdot Ni^{2+}$ to $Mn^{1+} \cdot\cdot F^- \cdot\cdot Ni^{3+}$. Polarization data on $BaMn_{0.5}Ni_{0.5}F_4$ with a similar structure, corroborate this suggestion. On substitution of Cu^{2+} and Mn^{2+} into $KZnF_3$ crystals, a broad structured band with $\tilde{\nu}_{max} = 41500\ cm^{-1}$ is observed the intensity of which increases on cooling. All these features can be rationalized with the transition $Mn^{2+}(3d^5)$, $Cu^{2+}(3d^9)$ to $Mn^{1+}(3d^54s)$, $Cu^{3+}(3d^8)$. In addition, the magnetic properties of these types of crystals can be interpreted on the basis of the energy level diagrams derived. / Phys. Rev. [3] *B 1*, 4223 (1970) / —Hz. [Rd 235 IE]

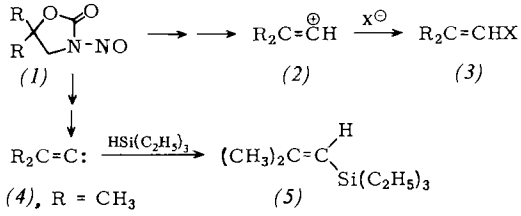
Chromosome damage in lead workers is the subject of a report by *G. Schwanitz*, *G. Lehnert*, and *E. Gebhart*. The authors found a higher proportion of mitoses with secondary chromosome aberrations than in a control group. Not only chromosome breaks and translocations but also spiralization defects, adhesion, and pulverization were observed. These effects could also be produced *in vitro* by 10^{-4}—10^{-6} M lead acetate solutions; the number of defective mitoses appeared substantially independent of the lead concentration. / Dtsch. Med. Wschr. *95*, 1636 (1970) / —Kr. [Rd 236 IE]

Naphtho[2,3-*a*]-*o*-carborane *(1)* has been synthesized by *D. S. Matteson* and *R. A. Davis* from α,α'-dibromo-*o*-xylene and dilithio-*o*-carborane. The resulting dihydronaphthocarborane could be dibrominated with *N*-bromosuccinimide and was converted into *(1)* by treatment with sodium iodide (58% yield). Compound *(1)*, fluorescent yellow crystals, melts at 152—159 °C in a sealed tube. The NMR



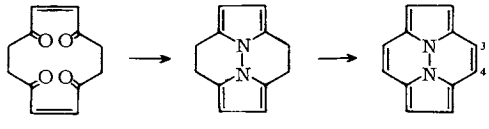
(1)

(2), R = CH_3OCO



spectrum suggests weakly aromatic character. Bromine adds to the inner ring, and the action of atmospheric oxygen leads to formation of polymeric peroxides. For steric reasons, dienophiles are able to attack only the outer naphthalene ring to form, *e.g.*, *(2)* or its analog with maleic anhydride. Tetracyanoethylene does not react. / Chem. Commun. *1970*, 669 / —Kr. [Rd 237 IE]

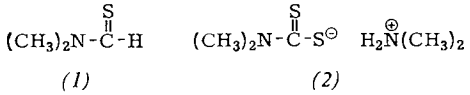
Insertion of atomic carbon (^3P) into C—H bonds was studied by *P. S. Skell*, *J. H. Plonka*, and *L. S. Wood*. For instance, acetaldehyde and carbon vapor form acetone (consumption of two H atoms, yield 5% based on C). Pure acetone is converted into 3-buten-2-one and 2-butanone (yields 2.5



and 3.0%, respectively). Addition of butadiene lowers the yield of 2-butanone to 1%, this being interpreted in terms of the intermediacy of singlet and triplet acetonylcarbene. / Chem. Commun. *1970*, 710 / —Kr. [Rd 238 IE]

New syntheses of vinyl halides and vinylsilanes, *(3)* and *(5)*, respectively, are described by *M. S. Newman* and *C. D. Beard*. These authors treated 5,5-dialkyl-*N*-nitrosooxazolidone *(1)* with lithium 2-methoxyethoxide and NaI, LiBr, or LiCl in 2-methoxyethanol to give the vinyl halides *(3)*

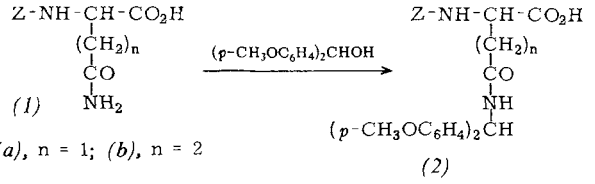
(yields about 80%). The reactions proceed *via* the unsaturated cations *(2)*. Hardly any vinyl ethers are formed. Reaction of *(1)*, R = CH_3, with alkoxide in benzene containing triethylsilane gives the triethyl(2-methyl-1-propenyl)silane *(5)* in 61% yield. The unsaturated carbene *(4)* occurs as intermediate. / J. Amer. Chem. Soc. *92*, 4309 (1970) / —Kr. [Rd 239 IE]



A nitrogen-bridged [12]annulene *(3)* [8b,8c-diazacyclopent-[*fg*]acenaphthylene] has been synthesized by *W. W. Paudler* and *E. A. Stephan*. Reaction of the tetraone *(1)* with hydrazine in the presence of oxygen afforded the tetracyclic compound *(2)*, which can be reduced to *(3)* with *e.g.* dichlorodicyanobenzoquinone. While the 3,4-dihydro derivative of *(3)* must be regarded as aromatic on the basis of its

(1) *(2)* *(3)*

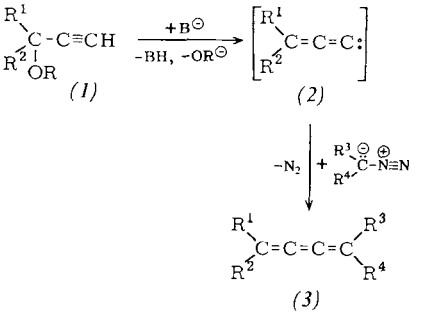
NMR spectrum, the NMR spectrum of *(3)* shows a considerable weakening of the ring current. The substance possibly exists in the form of the isomeric tricyclic compound having no N—N bond, or the two forms may be in valence-tautomeric equilibrium. / J. Amer. Chem. Soc. *92*, 4468 (1970) / —Kr. [Rd 240 IE]



Thioformamides and dithiocarbamates have been obtained by *L. Maier* by heating of a mixture of sulfur, formaldehyde, and amines in ethanol/water to 80 °C. Dimethylamine yields mainly dimethylthioformamide *(1)* and di-

(1) *(2)*

methylammonium dimethylthiocarbamate *(2)*, alongside a very small amount of dimethylformamide. The yields of *(1)* and *(2)* depend on the molar ratio of the reactants and the solvent. Diethylamine gives the analogs of *(1)* and *(2)* as well as $(C_2H_5)_2NSOH \cdot 1/2\ H_2O$, which is the first stable derivative of an *N*-sulfenic acid (m.p. 132—135 °C, decomp.). Primary amines afford only thioformamides. / Helv. Chim. Acta *53*, 1216 (1970) / —Kr. [Rd 241 IE]



A new amide protecting group for the synthesis of peptides with amides such as asparagine and glutamine is the subject of a report by *W. König* and *R. Geiger*. The authors have shown that the 4,4-dimethoxybenzhydryl group proves to be a useful protecting group in such syntheses; it can be introduced into the system almost as easily as can the xanthenyl residue. 4,4'-Dimethoxybenzhydrol, which can be readily obtained from the ketone by reduction with $NaBH_4$, reacts with benzoyloxycarbonylglutamine *(1a)*

(1) *(a)*, n = 1; *(b)*, n = 2 *(2)*

and -asparagine *(1b)* in glacial acetic acid under acid catalysis to give the protected amides *(2a)* and *(2b)* resp. Unsubstituted amides and peptides themselves can also be protected in this way. 4,4'-Dimethoxybenzhydrylamides are stable towards catalytic hydrogenation. *(2a)* and *(2b)* can be converted to peptides by the usual methods. The protecting group can be cleaved with trifluoroacetic acid/anisole. / Chem. Ber. *103*, 2041 (1970) / —Kr. [Rd 243 IE]

A new method for the synthesis of cumulenes has been described by *H. Reimlinger* and *R. Paulissen*. α-Ethynyl alcohols *(1)* are converted by bases into the vinylidenecarbenes *(2)*, which, in the presence of diazo compounds, yield the cumulenes *(3)*. This method is suitable only for

(1) *(2)* *(3)*

the preparation of butatriene derivatives. For example: $R^1 + R^2$ = *o,o'*-biphenylylene, $R^3 = R^4 = C_6H_5$, yield 26%; $R^1 = R^2 = (CH_3)_2CH$, $R^3 + R^4$ = *o,o'*-biphenylylene, yield 5%. / Tetrahedron Lett. *1970*, 3143 / —Kr. [Rd 244 IE]

BOOK REVIEWS

Introduction to the Chemical Analysis of Plastics. By *A. Krause* and *A. Lange*. Iliffe Books Ltd., London 1969. 1st ed., 326 pp., numerous tables, 60 s.

This is an English translation of the first German edition of "Kunststoff-Bestimmungsmöglichkeiten" [1], which was published in 1965. The book contains a large number of well-tried simple tests for the identification of unknown plastics, *e.g.* by solubility tests, color reactions, combustion tests, *etc.* Most of the book is devoted to collections of test methods for the various classes of plastics; additives and aids for the processing and use of plastics, *e.g.* stabilizers, plasticizers, and fillers, are dealt with relatively briefly. The book ends with a list of standard (mostly DIN) methods for the quality and input control of industrial polymers and recommendations of the Commission for the Assessment of Plastics in connection with the food law. The book contains a bibliography and an index, though the latter does not make up for the very brief list of contents, which offers little assistance to the user. A very detailed list of contents would be a desirable feature in any future edition.

The book, which has already proved its worth in the German edition, will undoubtedly also have a wide circle of users in the English version, though it must be pointed out that there is always a danger, in the choice of simple methods of analysis, that the inexpert reader will reach the wrong conclusions. Advice on this point would be very useful.

Dietrich Braun [NB 884 IE]

Electrochemistry at Solid Electrodes. Monographs in Electroanalytical Chemistry and Electrochemistry. By *R. N. Adams*. Marcel Dekker, Inc., New York 1969. 1st Edit., xiii + 402 pp., numerous figures, bound $ 18.75.

The content of this book does not justify the comprehensiveness of its title. What the author has compiled is essentially confined to a narrow segment of the electrochemistry with solid electrodes, namely the application of the latter to *voltammetric* investigations of *organic* compounds. Considered in the light of this more restrictive title, the book offers experimenters some useful information concerning work with solid electrodes, although it must be said that a more systematic approach would not have been out of place.

In the first part of the book the author seeks to impart to the reader the indispensable theoretical background. His selection of the by now well known fundamentals seems to the reviewer to be highly arbitrary, especially as regards the electrode-kinetic relationships. Reference should have been made at this point to corrosive effects and to the influence of mixed potentials.

The treatment of diffusion processes is very detailed, if highly idealized. Adsorption phenomena are not discussed. The terse statement in the foreword, to the effect that adsorption would not be considered since it did not constitute the most important part of an electrode reaction, strikes one as a rather weak argument.

The second part of the book is concerned mainly with experimental work and applications. Here, at any rate, the author is able to display the extent of his experience, giving the reader a valuable, self-contained section which for the first time presents data on the available investigations on organic compounds. Less commendable are the occasionally incomprehensible circuit diagrams accompanying the text on instrumentation, and also one or two electrode arrangements which are clearly taken from the author's sketchbook. The author might have demonstrated his originality in other ways, by appropriate treatment of the subject-matter.

Advances in Structure Research by Diffraction Methods Vol.3. – Fortschritte der Strukturforschung mit Beugungsmethoden, Bd. 3. Edited by *R. Brill* and *R. Mason*. Friedr. Vieweg u. Sohn, Braunschweig 1970. 1st Edit., iii, 251 pp., 77 figures, linen DM 48.—.

Like the first two volumes[1], the present third volume again contains contributions by well-known authors. The four articles are written in English by French, German, and Russian authors.

A. Authier presents a 50-page treatment of "Ewald Waves in Theory and Experiment (Dynamical Theory of X-Ray Diffraction)". The counterpart of this in some sense is an article (48 pp) on "Dynamical Theory of Electron Diffraction" by *K. Kambe* and *K. Molière*.

R. Hosemann, A. Schönfeld, and *W. Wilke* write in 72 pages on "Small Angle Scattering". The particularly extensive bibliography here follows on that given by *Yudowitch* in the book by *Guinier* and *Fournet* on the same subject, and covers the period from 1955 to 1967 "as fully as possible" with 530 references.

The fourth and last contribution (75 pp.) is an article by *A. I. Kitajgorodskij* entitled "General View on Molecular Packing".

The articles are aimed at readers who have had contact in their work with the material in question. They should be of great value to such readers. On the other hand, they are probably too difficult for the interested non-specialist, for whom they are not really intended in any case.

Dietrich Mootz [NB 895 IE]

Kunststoff-Handbuch. Aufbau, Verarbeitung, Eigenschaften und Anwendung der synthetischen Werkstoffe. Bd. V: Polystyrol. (Plastics Handbook. Structure, Processing, Properties, and Uses of Synthetic Materials. Vol. V. Polystyrene). Edited by *R. Vieweg* and *G. Daumiller*. Carl Hanser Verlag, München 1969. 1st Edit., xxi, 876 pp., 675 figures, 126 tables, linen DM 234.—.

The present volume[2] on polystyrene, which occupies the third place in economic importance among plastics, is particularly successful, since the contributions on its production, processing, properties, and uses are well matched both in size and in content. So much is known about this plastic that the collation of the various contributions from outstanding specialists into a coherent chapter is in itself a creative process, in which the editors have been very successful. The arrangement of the material is systematic and clear; the references and the subject index make it easy to find one's way around, and the text is well supported by tables and by good illustrations.

An introduction describing the history and the economic importance of polystyrene is followed by sections on its polymerization and processing, in which considerable space is devoted to rheology. In addition to injection molding, extrusion, deep drawing, compression molding, and sintering, further processing, such as the joining of polystyrene moldings by cementing and welding, as well as metalizing and printing (in an appendix), is also described. The section on properties, in which copolymers and high-impact modified polystyrenes are also discussed, covers the mechanical, thermal, electrical, and aging behavior of this group of plastics. Two outstanding and excellently illustrated sections are devoted to the use of polystyrene and polystyrene foams.

The authors of the various chapters, who are carefully selected experts in their fields, have brought together a wealth of experience that provides the user of the volume with a coherent, valuable, and rapid source of information.

The volume can be warmly recommended to processors, engineers, chemists, physicists, and students who wish information on special problems in connection with polystyrene.

The Chemistry of Fluorine and its Compounds. By *H. J. Emeléus*, Academic Press, New York-London 1969. 1st Edit., ix, 133 pp., numerous formulas, bound 65 s.

This monograph is not intended to present every individual item of knowledge about fluorine and its compounds. The author's intention is merely to provide a brief survey of the very extensive chemistry of fluorine. Instead of trying to present exhaustive information, he tries above all to demonstrate the shortage of physical data and to point out unsolved problems of fluorine chemistry in order to attract young scientists to this field.

The fluorine chemistry of the elements of the main groups of the periodic table is discussed chapter by chapter in a very informative manner, and great attention is given to unsolved problems. Short, clear summaries of the chemistry of hypofluorites, perfluoro organometallic compounds, perfluoro aromatic compounds, and fluoroalkyl and fluoroaryl derivatives of the transition metals form a logical supplement. A brief introduction is devoted to the properties of fluorine and deals with all the peculiarities that give fluorine a special place among the halogens and make it so interesting to chemists in all fields.

The presentation and print are very pleasing, and the book is written in a flowing and lucid manner and is free from printing errors. The arrangement and the choice of material show that the author, who has greatly enriched the chemistry of fluorine and paved the way for new developments over the past 30 years by his own scientific work, has a complete picture of the subject matter. The book can be wholeheartedly recommended to all chemists, and particularly to all undergraduates, graduate students, and chemistry lecturers.

Alois Haas [NB 897 IE]

Reagents for Organic Synthesis. Vol. 2. By *Mary Fieser* and *L. F. Fieser*. Wiley-Interscience, New York-London-Sydney-Toronto 1969. 1st Edit., 538 pp., bound DM 72.—.

The first volume of this handbook[1] has proved an indispensable aid in the reviewer's laboratory. It is now undoubtedly one of the standard works for the organic chemistry laboratory. The present second volume covers the literature of the next $2^1/_2$ years up to January 1969. It contains 1320 further references on 320 reagents that were discussed in the first volume, as well as 550 references on 226 reagents that are mentioned in the book for the first time. The alphabetic arrangement and the well-proven plan of the text on the individual reagents have been retained. This second part is again liberally provided with structural formulas to explain the examples of applications, and this makes for greater ease of scanning.

Special attention is paid in this volume to the organometallic reagents, as befits their steadily growing importance. European companies are now also listed among the suppliers. The positive impression of the first volume can also be claimed unreservedly for the second. If any criticism is necessary, it relates only to the organization of the book and not to its content.

In our opinion, the decision to update the handbook by supplementary volumes, though convenient, is rather shortsighted. If a supplementary volume of about 500 pages is required to cover the literature of only $2^1/_2$ years, it can be seen that this work will lose the character of a laboratory handbook in a short time. Moreover, the ease of scanning will certainly not be helped by the addition of a large number of supplementary volumes.

We feel that it would have been much better to revise and expand the main volume at short intervals. This would preserve its character as a laboratory handbook, and would also have the advantage that the authors would constantly be forced to deal with the reagents and examples in accordance

[1] Cf. Angew. Chem. internat. Edit. *8*, 398 (1969).

with their true importance. Many reagents that were highly praised by their discoverers have subsequently fallen short of expectations. Similarly, many examples of special applications may be omitted if they should later show little scope for generalization. The actual value of this book would undoubtedly be greatly increased by such periodic revisions and expansions.

Hermann Stetter [NB 900 IE]

The Biochemistry of the Nucleic Acids. By *J. N. Davidson.* Methuen & Co. Ltd., London 1969. 6th Edit., xvi, 352 pp., numerous illustrations, bound 50 s.

The latest edition of the present book is intended by the author as an introduction to the biochemistry of nucleic acids for students of biochemistry and chemistry. The book justifies this claim in full, since it not only presents the established results in this field skillfully, accurately, and in an understandable manner, but also describes the aims and problems of current research in the biochemistry of the nucleic acids. This introduction has been written in the style of a monograph, and the reader is accordingly not entirely dependent on the author's authority. More than two thousand literature references enable the reader to acquire a deeper understanding of important relations and problems by reading the original literature. Another pleasing feature is that the reader is not confronted with religious, philosophical, and ethical speculations on questions of molecular biology. It is to be hoped that this book will be made available to a wider circle of students of biology, biochemistry, and chemistry by translation into German.

Karl-Heinz Scheit [NB 901 IE]

Anorganische Chemie. Eine grundlegende Betrachtung (Inorganic Chemistry — A Fundamental Approach). By *Z. G. Szabó.* From the Heidelberger Taschenbücher series, Vol. 63. Springer Verlag, Berlin-Heidelberg-New York 1969. 1st Edit. VIII, 159 pp., 16 figures, 20 tables, bound, DM 14.80.

"The sole aim of a modern lecture on inorganic chemistry must be to offer such a selection of fundamental data as will permit a whole range of technical aspects to be derived". The present book follows this principle, which is enunciated in the foreword. All the fundamentals of general chemistry are discussed, for example the periodic system, structure of the electron shells, chemical bonding, electronegativity, polymorphism, physical properties of the elements, acids and bases, kinetics and energetics of chemical reactions, solubility, complexes, and redox processes.

The physical properties of the elements are given starting with hydrogen, followed by the noble gases, then the other nonmetallic elements, finally the semimetals, the alkali metals and alkaline earth metals, other metals, the transition metals, the lanthanoids, and the actinoids. The author describes in turn the hydrides, halides, oxides, hydroxides, sulfides, oxo-acids, peroxides, and complexes. The last few chapters are devoted to the biological importance, the geochemical occurrence and the abundance of elements, and to the preparation and utilization of elements and compounds.

All this material is presented in a highly compressed form. To benefit from reading it the beginner must simultaneously study a comprehensive textbook. One would hope to find a number of improvements in a later edition. The sections on chemical bonding, including special cases such as boron hydrides and complexes, should be modernized. The properties of acids and bases are best discussed on the basis of Brønstedt's definition. Redox reactions with normal potentials belong in the initial chapters and not at the end of the book; only then will the reader understand reactions such as

$$Cl_2 + 2Br^- \rightarrow Br_2 + 2Cl^-.$$

Some reworking is also called for in the section on compounds. Examples of nonexistent compounds are NiH_2, Ni_2O_3, CuOH, $Pb(OH)_4$, $(NH_4)_2S$ in water. On the other hand, HCl_2^-, more than six boranes, *etc.*, do exist. Anyone lecturing in inorganic chemistry will find it worth his while to read this book.

Oskar Glemser [NB 904 IE]

Die Acidität der CH-Säuren (The Acidity of CH Acids). By *H. F. Ebel.* Georg Thieme Verlag, Stuttgart 1969. 1st Edit., iv, 100 pp., 8 tables, board, DM 21.—.

The first one-third of the book contains a comprehensive summary of the various possible methods of measuring acidity, particularly detailed attention being given to the generally less familiar techniques for determining very low acidities (*e.g.* from the rates of metalation reactions, base-catalyzed halogenation, or base-catalyzed H/D exchange). The main section of the book offers the reader a tabulated survey of the acidities of approximately 200 CH acids measured in aqueous solution, in polar protonic or aprotic solvents, and finally also in relatively or completely nonpolar aprotic media. The pK values varied over the extremely broad range from <-11 (pentacyanocyclopentadiene) to $+37$ (isopropylbenzene). Finally, the last and shortest part is devoted to a discussion of the importance of the various intermolecular effects (in particular the inductive and conjugation effects, and also, to a smaller extent, hybridization) capable of giving rise to the appearance of CH acidity.

All in all, this little book contains so much useful information, presented in some cases with a novel approach, that it will quickly be found indispensable by everyone in any way concerned with the problems of CH acidity.

Metal-Boron Compounds – Problems and Perspectives

By Günter Schmid [*]

"True" metal-boron compounds have been known for about ten years. The bonding between the metal and boron atoms can vary widely in nature: Not only simple covalent bonds are encountered but also coordinate bonds and boron-metal multicenter bonds. Furthermore, π complexes of transition metals with boron-nitrogen systems and metal complexes containing boron(I) compounds as ligands have recently also been prepared.

1. Introduction

It is remarkable that until a few years ago only nonmetallic and metalloidal elements were to be found as ligands in boron compounds. Thus, with the exception of the metal borides [**], which have been known for a comparatively long time, no compounds of boron with metals were known up to about 1960. Although various reports of such compounds had appeared previously, present knowledge shows that the substances so described cannot be regarded as true metal-boron compounds since they contain no direct bonds between the metal and boron. As examples we can name the alkali-metal adducts of arylboranes such as $(C_6H_5)_3BNa$, which was reported by *Krause* [1] as long ago as 1924. This species should, however, be looked upon as $Na_2[(C_6H_5)_3B-C_6H_4-B(C_6H_5)_3]$, which contains no metal-boron bonds [2]. Similar problems occur with "dibutylboronpotassium" $(n\text{-}C_4H_9)_2BK$ [3–5]; all that we can say with certainty about this compound is that it can transfer dibutylboryl on to various reactants; this led *inter alia* to the discovery of boryl ketones $(n\text{-}C_4H_9)_2B-CO-R$ [4].

The past decade has seen the discovery of a wealth of "true" metal-boron compounds characterized by a wide variety of bonds between boron and metal atoms. In view of the many boron-nonmetal compounds this is hardly surprising, particularly as there is no fundamental distinction, but only one of degree, between *e.g.* a covalent bond between boron and carbon and one between boron and metal. In fact, it is precisely the electronegativity difference between metals and boron that would indicate the possibility of stable bonds between these elements.

2. Coordinate Metal-Boron Bonds

In most of its compounds boron is in a trigonal-planar ligand environment and is therefore assigned an sp^2 configuration. It can assume sp^3 character on rehybridization, which entails a gain in energy; in the process, its coordination number increases to 4, the L shell being fully occupied by an octet of electrons. Rehybridization of this kind is promoted by adduct formation with electron donors.

$$D: + BR_3 \rightarrow \overset{\delta+}{D}:\rightarrow\overset{\delta-}{B}R_3 \qquad (1)$$

(D = donor)

The stability of donor-acceptor bonds naturally depends on the donor and acceptor strengths of the components. For instance, as strong Lewis acids boron halides form stable addition compounds with amines, phosphanes, ethers, or sulfides.

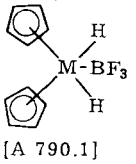
Many metal complexes have lone pairs of electrons and therefore behave as Lewis bases. Addition of such bases to the Lewis acids BR_3 affords coordinate metal-boron bonds, provided that the borane does not attack another part of the molecule. The cyclopentadienyl hydrides of molybdenum, tungsten, and rhenium represent typical metallic bases. Group B metals in complex anions are also endowed with lone pairs. Thus the very first synthesis of a metal-boron compound having a coordinate bond was accomplished with triphenylgermanate(II) as the base component [6].

$$LiGe(C_6H_5)_3 + B(C_6H_5)_3 \rightarrow Li[(C_6H_5)_3Ge{-}B(C_6H_5)_3] \quad (2)$$

Further compounds of this kind have since been discovered; they are best prepared directly from tetraphenylarsonium salts $[(C_6H_5)_4As]MX_3$ and borane derivatives BR_3 [7,8]:



$$[(C_6H_5)_4As]MCl_3 + BF_3 \rightarrow [(C_6H_5)_4As][Cl_3M{-}BF_3] \quad (3)$$
$M = Ge, Sn$

Borane adducts of transition metal complexes have been studied much more thoroughly. The carbonylmetalate ions of manganese, rhenium, and cobalt equilibrate with diborane-6 [9]:

$$(BH_3)_2 + 2\,[M(CO)_nL]^- \rightleftharpoons 2\,[H_3B{-}M(CO)_nL]^- \quad (4)$$
$M = Mn, Re, Co;\quad L = CO, P(C_6H_5)_3;\quad n = 3,4$

Whereas one mol. equiv. $[Re(CO)_5]^-$ in tetrahydrofuran consumes two of BH_3, the equilibrium lies far to the left-hand side for M = Co. Above −25 °C, $[H_3B{-}Mn(CO)_5]^-$ also liberates diborane. Replacement of one CO group by phosphane effects such a profound increase in the basicity of the metal atom that for M = Mn and L = $P(C_6H_5)_3$ the equilibrium (4) is shifted largely to the right.

Johnson and *Shriver* [10,11] first exploited the basic character of cyclopentadienylmetal hydrides to promote their addition to boranes BR_3. Thus $(\pi\text{-}C_5H_5)_2MoH_2$, $(\pi\text{-}C_5H_5)_2WH_2$, and $(\pi\text{-}C_5H_5)_2ReH$ react with BF_3 and BCl_3 to give 1:1 adducts having a metal-boron coordinate bond (see Fig. 1).

[A 790.1]

Fig. 1. Proposed structure of $(\pi\text{-}C_5H_5)_2MH_2 \cdot BF_3$.

Surprisingly, BH_3 does not form corresponding stable adducts although the acidity towards amines follows the series $BH_3 > BF_3$. According to *Pearson* [12] this is explained by the fact that the metal hydrides are "hard" bases and therefore react preferentially with the "hard" acids BF_3 and BCl_3; BH_3 is a "soft" acid.

Square-planar d^8 complexes also have lone pairs in the d_{z^2} orbital. For instance, $L_2Ir(CO)X$ and $L_2Rh(CO)X$ (L = $P(C_6H_5)_3$, $As(C_6H_5)_3$; X = halogen) readily undergo "oxidative addition reactions" with HCl [13,14], CH_3I [15], halogen [16], Cl_3SiH [17], and even H_2 [18], to give octahedral d^6 complexes. However, if $[(C_6H_5)_3P]_2Rh(CO)X$ is treated with boron halides in benzene, the reaction

$$[(C_6H_5)_3P]_2(CO)RhX + BX'_3 \rightarrow [(C_6H_5)_3P]_2(CO)Rh(X)BX'_3 \quad (5)$$
$X,X' = Cl, Br$

takes place with formation of pentacoordinated Rh^I complexes [19]; "reductive" cleavage of a boron-halogen bond does not occur. With complexes containing different halogens (X = X'), partial halogen exchange takes place leading to mixtures of isomers. The νCO bands in the IR spectra of the adducts are shifted by 20 to 70 cm^{-1} towards shorter wavelengths compared with those of the boron-free rhodium compounds, corresponding to an increased partial positive charge on the metal atom. Confirmation of a direct Rh–B bond is provided by the ^{11}B-NMR spectra, which display Rh–B coupling (J_{Rh-B} = 145–146 Hz).

3. Covalent Metal-Boron Bonds

Covalent bonds between boron and metals and boron and non-metals are similar in character. Compounds in which an sp^2-hybridized boron atom is linked directly to a metal atom or metal ion can also be regarded as simple derivatives of borane R_2BM, where M denotes a coordinately saturated metal atom.

The stability of the metal-boron bond depends primarily upon the other ligands attached to B and M. The empty boron p_z orbital can interact with the ligands R provided that they can engage in back-donation. Should this not be the case (the ligands then exerting an electron-withdrawing effect), the metal must be able to satisfy the electron requirements of the boron atom. This can be done by interaction between the d

electrons of the metal and the empty p_z orbital. A metal-boron linkage of this kind resembles the covalent metal-metal bonds or metal-metalloid bonds frequently met in practice. The $(d\rightarrow d)\pi$ contributions that determine the character of a metal-metal bond are replaced by $(d\rightarrow p)\pi$ contributions in the metal-boron bond; however, the less favorable degree of overlapping of the participating atomic orbitals renders the metal-boron bond much less stable.

3.1. Borylcarbonylmetal Compounds

Carbonylmetal complexes and their phosphane or cyclopentadienyl derivatives are particularly suitable as starting materials for the synthesis of covalent boron-metal compounds. Since stable coordination is usually encountered, ligand exchange reactions and rearrangements can most probably be ruled out.

3.1.1. Preparation

Introduction of a boryl group into carbonylmetal complexes is readily accomplished by reaction of haloboranes with alkali-metal carbonylmetalates in ethers at room temperature.

$$R_{3-n}BX_n + n\ Na[M(CO)_m] \rightarrow R_{3-n}B[M(CO)_m]_n + n\ NaX \quad (6)$$

Cleavage of metal-metal bonds by haloboranes also leads to metal-boron compounds, although the reaction is of a less general nature.

$$[(CH_3)_2N]_2BCl + Co_2(CO)_8 \rightarrow [(CH_3)_2N]_2B{-}Co(CO)_4 + ClCo(CO)_4 \quad (7)$$

Phosphane- and cyclopentadienyl-substituted borylcarbonylmetal compounds are also obtainable by analogy with eq. (6) and according to eq. (8). The phosphane complexes are far more stable than the pure carbonylmetal derivatives.

$$R_{3-n}BX_n + n\ Na[M(CO)_{m-1}L] \rightarrow R_{3-n}B[M(CO)_{m-1}L]_n + n\ NaX \quad (8)$$

$L = PR'_3,\ \pi\text{-}C_5H_5$

A number of complexes prepared according to eq. (6) to (8) are listed in Table 1.

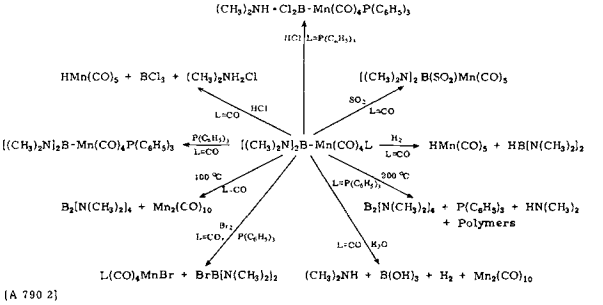
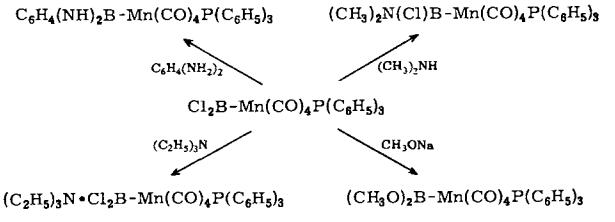
3.1.2. Chemical Properties



It is generally possible to distinguish three potential sites of reaction responsible for the chemical properties of the borylcarbonylmetal compounds:

a) The boron-metal bond.

b) The ligands attached to boron.



c) The ligands attached to the metal.

While the boron-metal bond proves reactive in almost every case, the reactivity of the *B*- and *M*-ligands depends upon their nature. The schemes depicted in Figures 2 and 3 illustrate the most important reactions of Mn–B compounds of this kind [21, 23].

[A 790.2]

Fig. 2. Reactions of $[(CH_3)_2N]_2B{-}Mn(CO)_4L$.

[A 790.3]

Fig. 3. Reactions of $Cl_2B{-}Mn(CO)_4P(C_6H_5)_3$.

3.1.3. Bonding and Structure

An insight into the bonding and structure of borylcarbonylmetal compounds is afforded by IR and ^{11}B-NMR spectroscopy.

The CO stretching vibrations of these molecules are very sensitive to ligand effects leading to changes in bond order between the C and the O atom. An effect of this kind is known to occur on replacement of CO ligands in carbonylmetal complexes by phosphanes [25–27]; frequency shifts towards small wave

[26] *A. Reckziegel* and *M. Bigorgne*, J. Organometal. Chem. *3*, 341 (1965).

[27] *M. Pankowski* and *M. Bigorgne*, C. R. Acad. Sci. Paris *264*, 1382 (1967).

numbers are always observed. The phenomenon is due to an increase in the relative negative charge on the metal atom caused by the new ligand, and is readily appreciated on consideration of the resonance structures:

$$\ddot{M}\leftarrow C\equiv O: \longleftrightarrow M \rightleftarrows C=\ddot{O}$$

As expected, borylcarbonylmetal compounds behave similarly. The influence of the R_2B groups on the CO bond order warrant more interest. The combined inductive and resonance effects of the ligand R affect the frequency of the CO vibrations in the same way as is observed on introduction of phosphane groups. This affords proof of π-bonding contributions to the metal-boron bond.

It may be seen from Fig. 4 that there is a linear relationship between the inductive effect of the R_2B group and the positions of the νCO frequencies in the IR spectrum: Plots of *e.g.*, the Taft constants σ^* for R in $R_2B-Mn(CO)_4P(C_6H_5)_3$ *vs.* the three strongest νCO bands (a–c), or *vs.* the two strongest (a and b) in the case of $R_2B-Co(CO)_4$, turn out to be straight lines.

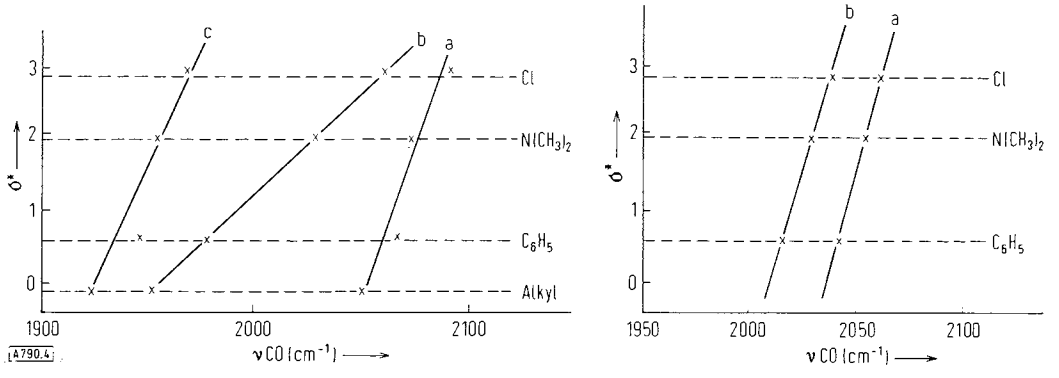

Fig. 4. Plot of the linear relationship between σ^* for R and νCO of compounds $R_2B-Mn(CO)_4P(C_6H_5)_3$ (left) and $R_2B-Co(CO)_4$ (right).

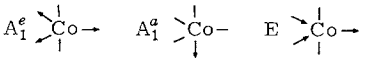
The σ^* values for R=Cl, C_6H_5, and alkyl are those given by *Taft*[28] while for R=$N(CH_3)_2$ σ^* was determined from the position of νCO (in the cases given the values determined in this way are in good agreement). *Bigorgne* found the same relation ship between σ^* and νCO for the compounds $R_3Si-Co(CO)_4$[25].



A further criterion for the correlation between σ^* and the CO bond order comes from a comparison of σ^* with the valence force constants of the CO bond. According to *Cotton* and *Kraihanzel*[29], and to *McDiarmid et al.*[30,31] the force constants k_e (for equatorial CO groups) and k_a (for axial CO groups) can be expressed in the forms

$$k_e = \mu(\lambda_{A_1^e} + 2\,\lambda_E)/3$$

and

$$k_a = \mu\lambda_{A_1^a},$$

where λ = wavelength[*]; μ = reduced mass; and A_1^e, A_1^a, and E correspond to the vibrational modes:

A plot of 10^2 (k_e-k_a) *vs.* σ^* for $R_2B-Co(CO)_4$ is also a straight line.

The relationships between the inductive effect of the R_2B group and the positions of the CO bands in the IR spectrum provide only limited information about the electronic environment of the boron atom, a feature of particular interest. We can, however, glean valuable evidence from ^{11}B-NMR spectroscopy. Owing to the considerable role played by resonance effects, the electron density on the boron atom is not necessarily reduced by the increasing electronegativity of its ligands. It may even be that the third ligand, the metal group, is able to compensate for the lack of back-donation by the other ligands. Indeed, it is reasonable to expect that the electron-donation by the metal to the boron-metal bond will increase with increasing acceptor character of these ligands. Table 2 compares the chemical shifts of a number of borylcarbonylmetals with those of the corresponding haloboranes.

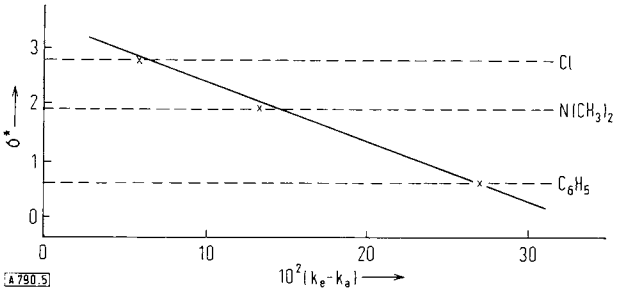


Fig. 5. Plot of the linear relationship between σ^* for R and $10^2(k_e-k_a)$ of $R_2B-Co(CO)_4$ (k values in mdyne/Å).

$(C_6H_5)_2B-Co(CO)_3P(OC_6H_5)_3$	−42.5		
$(C_6H_5)_2B-Co(CO)_3P(C_4H_9)_3$	−42.7		
$(C_6H_5)_2B-Co(CO)_3As(C_6H_5)_3$	−42.8		

Apart from the bis(dimethylamino)boranes, some considerable discrepancies are apparent between the chemical shifts of the boron-metal compounds and those of their chloro analogs. The chloro derivatives R_2BCl exhibit an increasing downfield shift along the series $R = N(CH_3)_2 < Cl < C_6H_5$. On replacement of Cl by the metallic group $Mn(CO)_4L$ or $Co(CO)_3L$ the order changes to $Cl < N(CH_3)_2 < C_6H_5$. If it is assumed, as is perfectly reasonable, that the neighboring-group anisotropic effects of the ligands of a given type of compound remain unaltered, this finding is best interpreted in terms of an increased π-bonding contribution to the boron-metal bond, which is attributable to the metal.

The most reliable structural information so far has been obtained for $R_2B-Co(CO)_3PR'_3$ and $R_2B-Mn(CO)_4PR'_3$ [5, 21, 23]. The two strong CO bands (A_1 and E respectively) found for the phosphane-substituted boron-cobalt compounds suggest a *trans* bipyramidal structure of C_{3v} symmetry. The three or four strong CO bands in boron-manganese compounds of this type would indicate an octahedral *cis* configuration of the ligands surrounding the Mn atom.

[A 790.6]

Fig. 6. Proposed structure of the compounds $R_2B-Co(CO)_3PR'_3$ (a) and $R_2B-Mn(CO)_4PR'_3$ (b).

3.2. Borylphosphanemetal Compounds

Complexes in which a metal atom bonded to a boryl group completes its coordination sphere with phosphane ligands are particularly stable. Organophosphanes are more effective donors than carbon monoxide and thus render the metal atom more strongly negative. In contrast, the acceptor properties predominate in the case of PF_3, thus leading to a pronounced positive charge on the metal.

3.2.1. Preparation

The routes available for the synthesis of borylphosphanemetal complexes are depicted by equations (9) to (12).

$$(R'_3P)_nM + R_2BX \rightarrow (R'_3P)_{n-m}M(X)BR_2 + m\ PR'_3 \quad (9)$$

$$(R'_3P)_nM-H + R_2BX \rightarrow (R'_3P)_nM-BR_2 + HX \quad (10)$$

$$(R'_3P)_nM-M' + R_2BX \rightarrow (R'_3P)_nM-BR_2 + M'X \quad (11)$$

M′ = alkali metal

$$2\ (PP)_2M-H + R_2BX \rightarrow (PP)_2MX_2 + (PP)_2M(BR_2)_2 + H_2 \quad (12)$$

PP = diphosphine

Platinum and cobalt complexes are obtained particularly readily by "oxidative addition" as shown in eq. (9) [32]. Tetrakis(triphenylphosphane)platinum(0) reacts, *e.g.* with diphenylchloroborane, diphenylbromoborane, or tribromoborane in cyclohexane to give the compounds *cis*-$[(C_6H_5)_3P]_2Pt(X)BR_2$ (X = Cl, Br; R = C_6H_5, Br). Two $P(C_6H_5)_3$ ligands can be replaced by $(C_6H_5)_2P-CH_2-CH_2-P(C_6H_5)_2$ (TPE). According to the same principle, *cis*-$(TPE)_2Co(X)BR_2$ (X = Cl, Br, I; R = C_6H_5, Br, I) is formed from $(TPE)_2Co$ and R_2BX in boiling benzene [32].

Reactions between metal hydrides and haloboranes in accordance with eq. (10) are known in the case of platinum and iridium complexes. The pale yellow compound $[(C_6H_5)_3P]_2ClPt-B(C_6H_5)_2$ is formed by elimination of HCl from $(C_6H_5)_2BCl$ and $[(C_2H_5)_3P]_2Pt(Cl)H$ in boiling xylene, and the beige compound $[(C_6H_5)_3P]_3Cl_2Ir-B(C_6H_5)_2$ is formed similarly on addition of triethylamine.

Reaction (11), which can be regarded as a variant of (10), has hitherto only been used for the preparation of boryltrifluorophosphanecobalt compounds: The compound $(F_3P)_4Co-K$ synthesized by *Kruck* [33] reacts in ether with the haloboranes $[(CH_3)_2N]_2BCl$, $C_{12}H_8BCl$ ($C_{12}H_8B$ = borafluorenyl), and $(C_6H_5)_2BCl$ to give $[(CH_3)_2N]_2B-Co(PF_3)_4$, $C_{12}H_8B-Co(PF_3)_4$, and $(C_6H_5)_2B-Co(PF_3)_4$, respectively, which are crystalline, yellow to brown products with covalent cobalt-boron bonds [22, 34].

The greatest interest attaches to reaction (12) although it has hitherto been limited to only one type of complex: (TPE)Co−H reacts with R_2BX (X = Cl, Br, I; R = Br, I, C_6H_5; BR_2 = borafluorenyl) in boiling benzene or xylene to give complexes $(TPE)_2Co(BR_2)_2$ containing two Co−B bonds [35–37]. Both the unexpected reaction course, with liberation of molecular hydrogen, and certain peculiarities in the behavior of the compounds attract attention.

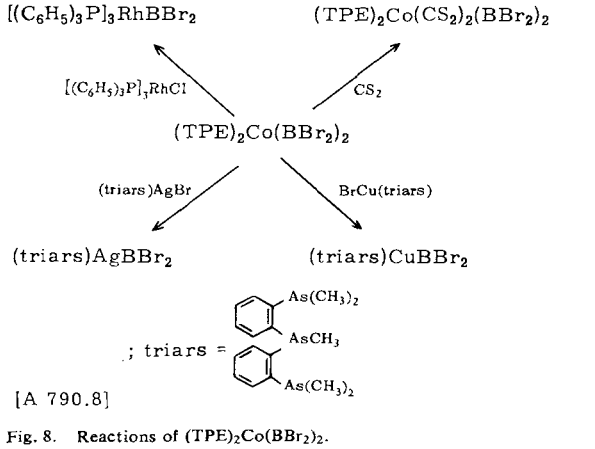
3.2.2. Chemical Properties

The covalent boron-metal bonds in the borylplatinum and boryliridium complexes mentioned above differ from those in the borylcarbonylmetal complexes (Section 3.1.2) in their greatly enhanced stability. For instance, they are much more resistant to oxygen. However, even these bonds are cleaved by strong oxidizing agents such as bromine [35]:

$$(R_3P)_2Pt(Cl)B(C_6H_5)_2 + Br_2 \rightarrow (R_3P)_2Pt(Cl)Br + (C_6H_5)_2BBr \quad (13)$$



$(TPE)_2Co(BR_2)_2$ behaves somewhat differently. The extreme sensitivity of the Co–B bond is revealed by, among other things, its spontaneous oxidation by atmospheric oxygen. The magnetic moment of $(TPE)_2Co[B(C_6H_5)_2]_2$, $\mu = 2.84\,\mu_B$, is consistent only with a paramagnetic d^7 low-spin complex. However, this moment is much too high for an unpaired electron and thus indicates a large orbital contribution to the total moment, as has been observed with square-planar Co^{II} complexes [38]. Accordingly, the compound is easily reduced to diamagnetic $Na[(TPE)_2Co[B(C_6H_5)_2]_2$ by sodium [36]. The R_2B group in $(TPE)_2Co(BR_2)_2$ can be exchanged for other metal complexes [36].

$$(TPE)_2Co(BR_2)_2 + 2\,L_nM{-}Hal \rightarrow (TPE)_2CoHal_2 + 2\,L_nM{-}BR_2 \quad (14)$$

[A 790.7]

Fig. 7. Reactions of $(TPE)_2Co[B(C_6H_5)_2]_2$.

[A 790.8]

Fig. 8. Reactions of $(TPE)_2Co(BBr_2)_2$.

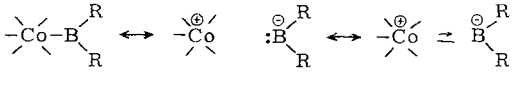
[38] *F. A. Cotton* and *R. H. Holm*, J. Amer. Chem. Soc. *82*, 2983 (1960).

This reaction can be used for the synthesis of new metal-boron compounds $L_nM{-}BR_2$ (L = ligand) that are inaccessible by other routes (cf. Figures 7 and 8).

By this method, we prepared the first molecules containing covalent boron-copper, boron-silver, boron-gold, boron-nickel, boron-rhodium, and boron-lead bonds [36, 37, 39]. Boron-tin derivatives were formerly prepared by eq. (15) [40].

$$(R_2N)_2BCl + LiSnR'_3 \rightarrow (R_2N)_2B{-}SnR'_3 + LiCl \quad (15)$$

However, it proves impossible to introduce arylboryl groups by this method, whereas no difficulties are encountered in reaction (14) [41]. Even the hitherto unknown borylplumbanes can be prepared by this technique [39].



3.2.3. Bonding and Structure

The chemical peculiarities of the complexes $(TPE)_2Co(BR_2)_2$ stem from the nature of their Co–B bond. This is illustrated most vividly by the chemical shifts $\delta^{11}B$. While the borylcarbonylmetals, like the borylphosphaneplatinum and borylphosphaneiridium compounds give normal ^{11}B-NMR spectra, *i.e.* behave as molecules with typical trivalent boron atoms, the first-named complexes differ considerably. The δ values observed, ranging from +15.0 to +23.5 ppm, are very similar to those measured for molecules having tetravalent boron atoms [42].

Table 3. ^{11}B-NMR data for compounds $(PP)_2Co(BR_2)_2$ [external standard: $BF_3 \cdot O(C_2H_5)_2$].

	δ (ppm)
$(TPE)_2Co[B(C_6H_5)_2]_2$	+23.0
$(TPE)_2Co(BBr_2)_2$	+23.0
$\{C_6H_4[P(CH_3)_2]_2\}_2Co[B(C_6H_5)_2]_2$	+23.5
$\{C_6H_4[P(CH_3)_2]_2\}_2Co(BC_{12}H_8)_2$	+15.0

If these findings are interpreted solely in terms of the increase in negative charge on the boron atom with neglect of any possible paramagnetic contact shift, each boron atom carries a unit negative charge. The likely bonding is illustrated by the following resonance structures:

Since the central form can be regarded as a pseudocarbene, such complexes are often designated "borene-metal complexes". Such an interpretation assists our understanding of not only the ligand-exchange reactions and the presence of Co^{II} in the complexes, but also the results of magnetic measure-

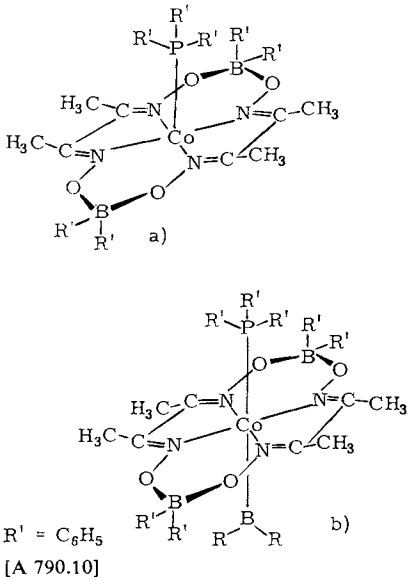
ments that suggest a tetragonal-bipyramidal structure with the two R_2B groups separated by a relatively large distance and *trans* to each other (Jahn-Teller distortion of octahedral d^7 complexes).



[A 790.9]

Fig. 9. Proposed structure of the compounds $(PP)_2Co(BR_2)_2$

3.3. Bis(2,3-butanedionedioximato)cobalt-Boron Compounds[43]

The compound bis(2,3-butanedionedioximato)chlorotriphenylphosphanecobalt(III), which is formulated as $(C_6H_5)_3P(DMGH)_2CoCl$[*] and was described by *Tschugaeff*[44] in 1907, can be used for the preparation of compounds $(C_6H_5)_3P(DMGBR'_2)_2Co-BR_2$ containing covalent metal-boron bonds. Reduction with potassium in tetrahydrofuran and reaction with diphenylchloroborane initially leads to bridged $(C_6H_5)_3P[DMGB(C_6H_5)_2]_2Co$ (Fig. 10a). Repeated alkali-metal reduction leading to formation of $(C_6H_5)_3P[DMGB(C_6H_5)_2]_2Co-K$ followed by treatment with R_2BCl finally affords compounds having the structure shown in Fig. 10b (R = C_6H_5, $N(CH_3)_2$, Cl or R_2B = borafluorenyl).

$R' = C_6H_5$

[A 790.10]

Fig. 10. Proposed structure of compounds $(C_6H_5)_3P[DMGB(C_6H_5)_2]_2Co$ (a) and $(C_6H_5)_3P(DGMB(C_6H_5)_2]_2Co-BR_2$ (b).

[43] *G. Schmid, P. Powell,* and *H. Nöth,* Chem. Ber. *101,* 1205 (1968).

[*] DMGH = $\begin{matrix} H_3C-C=NO^- \\ | \\ H_3C-C=NOH \end{matrix}$.

[44] *L. Tschugaeff,* Ber. Dtsch. Chem. Ges. *40,* 3498 (1907).

Like the complexes $(TPE)_2Co(BR_2)_2$ (see Section 3.2), these complexes can also undergo ligand exchange; similar bonding therefore appears probable.

$$(C_6H_5)_3P[DMGB(C_6H_5)_2]_2Co-BR_2 + L_nM\text{-}Hal \rightarrow (C_6H_5)_3P[DMGB(C_6H_5)_2]_2Co-Hal + L_nM-BR_2 \quad (16)$$

Interestingly, the metal-boron stretching frequency at 530–540 cm^{-1} was first assigned with a high degree of certainty in the IR spectrum of these complexes.

4. Cage Compounds Containing Boron and Metal Atoms

closo and *nido* compounds of boron have been known for some time. Higher boranes and the carboranes have been the focal points of many intense studies in recent years[45–52]. Alongside the usual covalent B–H and B–B bonds, they contain characteristic multicenter bonds. Metal atoms having vacant d orbitals can also participate in such electron-deficient bonds, especially when in their higher oxidation states since the number of vacant d orbitals is then larger.

4.1. Dicarbollyl Derivatives of Transition Metals[*]

Since the carbollylmetal complexes closely resemble the metallocenes and their derivatives, they were designated π-carbollylmetal complexes by their discoverer *Hawthorne*, although there are actually fundamental differences in bonding between the two types. Classification of these complexes as compounds containing multicenter bonds appears more reasonable.

In 1965[51] *Hawthorne et al.* succeeded in preparing undecahydrodicarba-*nido*-undecaborate(2-). This species can exist in two isomeric forms, namely (3)-1,2- and (3)-1,7-$B_9C_2H_{11}^{2-}$ [**] (Fig. 11).

The isomeric, singly protonated "dicarbollide" ions (3)-1,2-$B_9C_2H_{12}^-$ and (3)-1,7-$B_9C_2H_{12}^-$, which yield

[*] The suffix "ollyl" in the trivial names for carbaborate ligands and "ollide" for the corresponding anions are derived from the Spanish word "*olla*" meaning basket.

[**] See [53] and Inorg. Chem. *7,* 1945 (1968) for the nomenclature of this system.

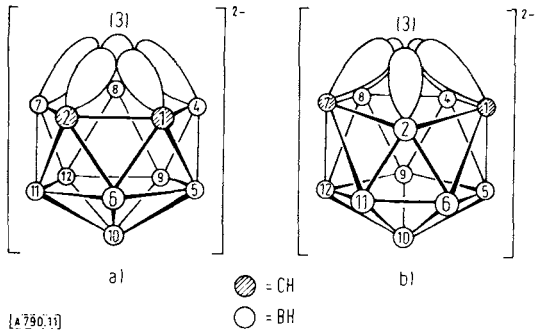

Fig. 11. Structures of the isomers (3)-1,2-$B_9C_2H_{11}^{2-}$ (a) and (3)-1,7-$B_9C_2H_{11}^{2-}$ (b).

the dianions according to eq. (17), contain a hydrogen atom attached to an icosahedral apex [53] which is replaced by a metal atom in the dicarbollyl complexes.

$$B_9C_2H_{12}^- + NaH \rightarrow Na^+ + B_9C_2H_{11}^{2-} + H_2 \quad (17)$$

4.1.1. Preparation

Of the many dicarbollyl complexes of metals known at present we shall now consider a few selected examples.

$FeCl_2$ reacts with (3)-1,2-$B_9C_2H_{11}^{2-}$ to give the ferrocene analog $[Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-}$ [54] which can be isolated as the tetramethylammonium salt. *C*-Substituted derivatives can also be synthesized by the same technique. The reddish-brown Fe^{II} complex is readily oxidized on exposure to air to the red anion $[Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^-$:

$$2\,(3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-} + FeCl_2 \rightarrow [Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-} + 2\,Cl^- \quad (18)$$

$$[Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-} \rightarrow e^- + [Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^- \quad (19)$$

The cyclopentadienyl-like properties of (3)-1,2-$B_9C_2H_{11}^{2-}$ are again apparent in the Fe^{III} complex $[(\pi\text{-}C_5H_5)Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})]$ [55], whose synthesis proceeds as shown in eq. (20). Eq. (21) and (22) represent the formation of tricarbonyl-manganese and -rhenium derivatives [56a]:

$$C_5H_5^- + (3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-} + FeCl_2 \rightarrow [(\pi\text{-}C_5H_5)Fe((3)\text{-}1,2\text{-}B_9C_2H_{11})] + 2\,Cl^- + e^- \quad (20)$$

$$(3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-} + BrM(CO)_5 \rightarrow [((3)\text{-}1,2\text{-}B_9C_2H_{11})M(CO)_5]^- + Br^- \quad (21)$$

$$[((3)\text{-}1,2\text{-}B_9C_2H_{11})M(CO)_5]^- \rightarrow [((3)\text{-}1,2\text{-}B_9C_2H_{11})M(CO)_3]^- + 2\,CO \quad (22)$$

M = Mn, Re

[54] *M. F. Hawthorne, D. C. Young,* and *P. A. Wegner,* J. Amer. Chem. Soc. *87,* 1818 (1965).

[55] *M. F. Hawthorne* and *R. L. Pilling,* J. Amer. Chem. Soc. *87,* 3987 (1965).

[56] a) *M. F. Hawthorne* and *T. D. Andrews,* J. Amer. Chem. Soc. *87,* 2496 (1965); b) Chem. Commun. *1965,* 443.

$CoCl_2$ reacts similarly to $FeCl_2$ with (3)-1,2-$B_9C_2H_{11}^{2-}$ to give $[Co((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^-$ containing Co^{III} [56b] The cesium and tetramethylammonium salts of this complex are readily reduced to the red cobaltocene analog $[Co((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-}$, the Co^{III} complex being regenerated on exposure to atmospheric oxygen.

Nickel and palladium exist in a great variety of oxidation states in carbollyl complexes [53,57]. The compounds $[M^{n+}((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{n-4}$ (M = Ni, Pd) and their *C*-substituted derivatives can contain the metal atoms in the formal oxidation states +2, +3, and +4. The compound $[Ni((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-}$ is formed, *e.g.*, from $NiCl_2$ and (3)-1,2-$B_9C_2H_{11}^{2-}$; $[Pd((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-}$ is formed similarly. The M^{IV} complex can be attained by reaction of the metal acetylacetonates with dicarbollide ions. Comproportionation of the M^{II} and M^{IV} complexes gives compounds containing M^{III}.

$[\pi\text{-}(C_6H_5)_4C_4]Pd((3)\text{-}1,2\text{-}B_9C_2H_{11})$, which is prepared according to eq. (23), may be cited as an example of a palladium complex with mixed ligands:

$$2\,Na_2((3)\text{-}1,2\text{-}B_9C_2H_{11}) + [\pi\text{-}(C_6H_5)_4C_4PdCl_2]_2 \rightarrow 2\,[\pi\text{-}(C_6H_5)_4C_4]Pd((3)\text{-}1,2\text{-}B_9C_2H_{11}) + 4\,NaCl \quad (23)$$

The first dicarbollyl derivative of platinum (1,5-C_8H_{12})Pt((3)-1,2-$B_9C_2H_{11}$) was prepared recently [57b]. There is also a large number of chromium, molybdenum, and tungsten complexes. It will suffice here to mention $[Cr((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^-$ [58], $[((3)\text{-}1,2\text{-}B_9C_2H_{11})Mo(W)(CO)_3]^{2-}$, $[((3)\text{-}1,2\text{-}BC_2H_{11})W_2(CO)_8]^{2-}$, or $[((3)\text{-}1,2\text{-}B_9C_2H_{11})MoW(CO)_8]^{2-}$, which are obtained from $CrCl_3$ and $Mo(CO)_6$ or/and $W(CO)_6$ by reaction with the dicarbollide ion [53].

Copper and gold are also represented in the series of carbollyl complexes, in the form of $[M((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{2-}$ (M = Cu, Au) [59,60].

In 1967, *Hawthorne* described the carbollide ion undecahydrodicarba-*nido*-nonaborate(2-), $B_7C_2H_{11}^{2-}$ [61], which seems quite as suitable as the $B_9C_2H_{11}^{2-}$ system for carbollyl complex formation. Reaction (24) yields 3,3′-*commo*-bis[nonahydro-1,2-dicarba-3-cobalta-*closo*-decaborate](2-), which is oxidized by an excess of $CoCl_2$ in tetrahydrofuran [62,63]:

$$2\,B_7C_2H_{11}^{2-} + CoCl_2 \rightarrow 2\,H_2 + [Co(B_7C_2H_9)_2]^{2-} + 2\,Cl^- \quad (24)$$

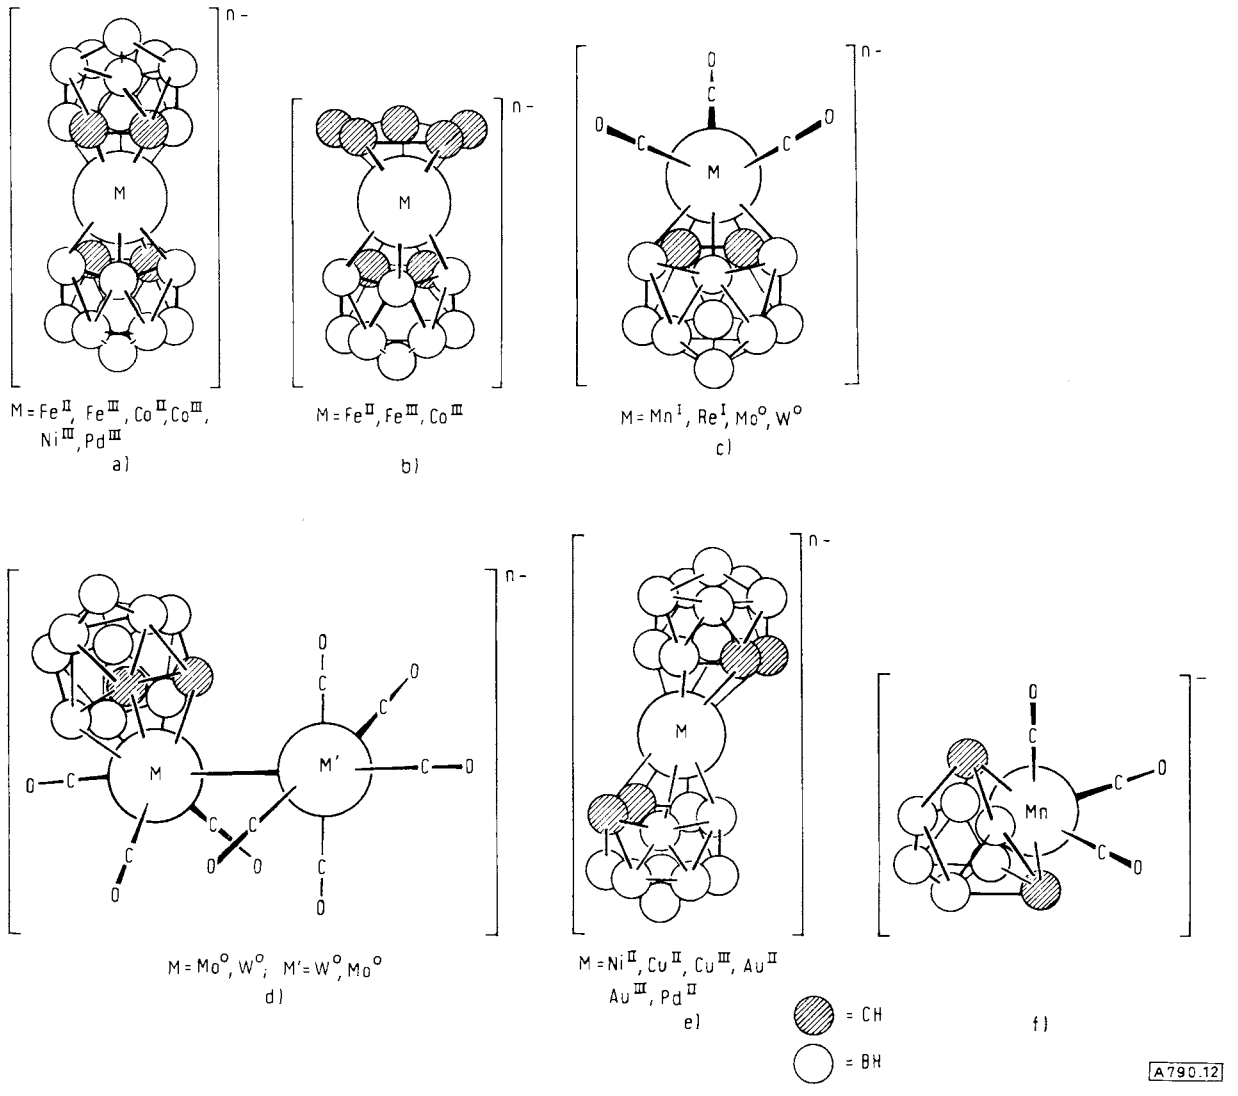

Fig. 12. Structures of dicarbollylmetal complexes: $[M((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{n-}$ (a), $[(\pi\text{-}C_5H_5)M((3)\text{-}1,2\text{-}B_9C_2H_{11})]^{n-}$ (b), $[((3)\text{-}1,2\text{-}B_9C_2H_{11})M(CO)_3]^{n-}$ (c), $[((3)\text{-}1,2\text{-}B_9C_2H_{11})MM'(CO)_8]^{n-}$ (d), $[M((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{n-}$ (e), $[(B_6C_2H_8)Mn(CO)_3]^-$ (f).

$$[Co(B_7C_2H_9)_2]^{2-} + 1/2\ CoCl_2 \rightarrow 1/2\ Co + Cl^- + [(B_7C_2H_9)_2Co]^- \quad (25)$$

A metal atom is readily incorporated into a carborane skeleton on reaction of $B_7C_2H_{11}^{2-}$ with $BrMn(CO)_5$: $[(B_6C_2H_8)Mn(CO)_3]^-$ (Fig. 12f) is formed in boiling tetrahydrofuran [63].

4.1.2. Structure

The structures of a number of characteristic dicarbollylmetal complexes, most of which were determined by X-ray studies [57b,64–67], are depicted in Fig. 12a–f.

4.2. Phosphacarbollylmetal Complexes

(3)-1,2- and (3)-1,7-phosphacarbollides also prove suitable for complex formation with metal ions. Thus *Todd et al.* were able to prepare the first complexes $[M((3)\text{-}1,7\text{-}B_9H_9CHPCH_3)_2]$ and $[M((3)\text{-}1,2\text{-}B_9H_9CHPCH_3)_2]$ (M = Fe, Co, Ni) and to determine their structures [68a, b], which were found to resemble those of the dicarbollyl complexes. Replacement of a phosphacarbollyl ligand by allyl, cyclopropenyl, or nitrosyl has recently been accomplished [68c].

4.3. Gallacarboranes

Although carboranes form cage-like structures with a wide variety of transition metals, a carborane structure containing a Group IIIB metal was only

[64] *A. Zalkin, D. H. Templeton,* and *T. E. Hopkins,* J. Amer. Chem. Soc. *87,* 3988 (1965).

discovered very recently. However, there is every reason to believe that such complexes will become available in large numbers.

Trimethylgallium reacts *e.g.* with 2,3-dicarbahexaborane-8, $C_2B_4H_8$, in the gaseous state at 215 °C to give 1-methyl-1-galla-2,3-dicarba-*closo*-heptaborane-7, $CH_3GaC_2B_4H_6$ [68d], which is assigned the structure shown in Fig. 13 on the basis of its ^{1}H-NMR, ^{11}B-NMR, IR, and mass spectra.

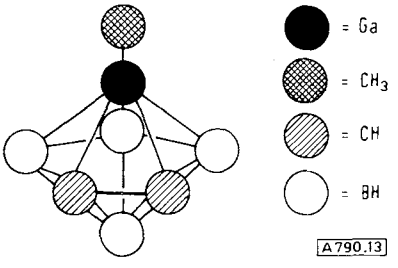

Fig. 13. Proposed structure for $CH_3GaC_2B_4H_6$.

4.4. Thiaboratometal Complexes

The assumption that the carbollylmetal complexes are not classical π-complexes but boron-metal multicenter complexes leads to the conclusion that the existence of such compounds cannot be limited to carborane systems.

The first thiaborane complexes were reported by *Muetterties et al.* [69]: The readily accessible anion $B_{10}H_{10}S^{2-}$ reacts with transition metal ions to give complexes of the kind $[M(B_{10}H_{10}S)_2]^{n-}$ (M = Fe^{II}, Fe^{III}, or Co^{II}). Structural analogies exist between these complexes and the system $[M((3)\text{-}1,2\text{-}B_9C_2H_{11})_2]^{n-}$. The compounds $(B_{10}H_{10}S)Pt[P(C_2H_5)_3]_2$ and $[(B_{10}H_{10}S)Re(CO)_3]^-$ are also examples taken from a new branch of complex chemistry that is still in its infancy.

4.5. Decaboranemetal Complexes

Finally, mention should be made of a class of metal-boron cage compounds that can be derived from pure boron hydrides without any hetero atoms. *Greenwood et al.* succeeded in preparing the first complexes [70, 71] $[B_{10}H_{12}AlH_2]^- \cdot nO(C_2H_5)_2$ and $[B_{10}H_{12}GaH_2]^-$ by reaction of $(CH_3)_3NAlH_3$, $(CH_3)_3NAlH_2Cl$, and $(CH_3)_3NGaH_3$, respectively, with $B_{10}H_{14}$. In the same way, $B_{10}H_{14}$ reacts with alkyl derivatives of zinc, cadmium, and mercury to give products of composition $B_{10}H_{12}M \cdot nS$ [72–75] (S = solvent). Treatment of $(C_5H_5N)_4FeBr_2$ with $B_{10}H_{14}$ in benzene or tetrahydrofuran furnishes the tetrahedral high-spin complex $[Br_2Fe(B_{10}H_{13})(NC_5H_5)]$ [76].

The scope of the reaction was extended by *Muetterties et al.*, who were also able to throw some light on the hitherto unsolved structural problems [77].

$$4\ B_{10}H_{13}^- + [(C_6H_5)_3P]_2NiCl_2 \rightarrow [Ni(B_{10}H_{12})_2]^{2-} + 2\ B_{10}H_{14} + 2\ (C_6H_5)_3P + 2\ Cl^- \quad (26)$$

$$2\ B_{10}H_{13}^- + [(C_2H_5)_3P]_2PtCl_2 \rightarrow [(C_2H_5)_3P]_2Pt(B_{10}H_{12}) + B_{10}H_{14} + 2\ Cl^- \quad (27)$$

$$2\ B_{10}H_{13}^- + [(C_6H_5)_3P]_2(CO)IrCl \rightarrow \{[(C_6H_5)_3P]_2(CO)Ir(B_{10}H_{12})\}^- + B_{10}H_{14} + Cl^- \quad (28)$$

Reactions (26)–(28) represent a series of simple preparations from the readily accessible $B_{10}H_{13}^-$ ion. The yellow to red crystalline complexes exhibit remarkable thermal stability, some of them not decomposing below 300 °C.

The structures proposed are based on the assumption that instead of fulfilling a 6,9 bridging function (Fig. 14a), as was initially supposed, the metal atom occupies the open plane formed by four boron atoms (in positions 5, 6, 9, 10) to give an icosahedral fragment. Its stability is apparent from the foregoing discussion. Thus the $B_{10}H_{12}^{2-}$ ligand conforms to the systems $B_9C_2H_{11}^{-2}$, $B_{10}CH_{11}^{3-}$ [78, 79], or $B_{10}SH_{10}^{2-}$.

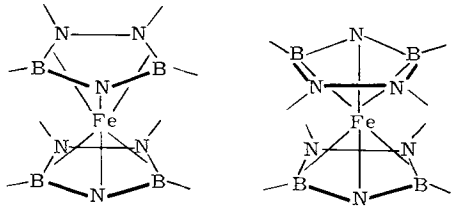
5. Aminoboranes as Ligands in Metal Complexes

Boron-nitrogen chemistry and carbon chemistry have many common features as a result of isosteric relationships. The benzene-borazole analogy [80] is probably one of the best known. Nevertheless, all the other boron-nitrogen systems resemble the corresponding carbon compounds within certain limits. One of the most significant features was discovered only comparatively recently, *i.e.* the ability of B=N double bond systems to form π-complexes analogous to those of C=C compounds. In 1967, hexamethylborazine $(CH_3)_6B_3N_3$ was successfully used as a π-complex ligand in $(CO)_3Cr[B_3N_3(CH_3)_6]$ [81,82]. Many chemical and physical properties of this complex, which may be prepared in accordance with eq. (29), are analogous to those of $[(CH_3)_6C_6]Cr(CO)_3$:



$$(CH_3CN)_3Cr(CO)_3 + B_3N_3(CH_3)_6 \rightarrow [B_3N_3(CH_3)_6]Cr(CO)_3 + 3\ CH_3CN \quad (29)$$

It forms orange-red crystals that sublime above 90 °C in a high vacuum. The IR spectra resemble each other, as do also the ^{1}H-NMR spectra [82]. The chemical shifts $\delta^{11}B$ and $\delta^{15}N$, which appear 8.2 and 47 ppm farther upfield in $[(CH_3)_6B_3N_3]Cr(CO)_3$ than in free borazine, provide additional evidence for the presence of B=N-metal π bonds. The shift of the νCO bands towards shorter wavelengths compared with $Cr(CO)_6$ rules out a pure acceptor function of borazole and shows it instead to be a typical donor-acceptor ligand.

The complex prepared by eq. (30) can be viewed as a ferrocene analog whose possible structures are shown in Fig. 15 [83].

(30)

[A 790.15]

Fig. 15. Possible structures of $Fe[(CH_3)_2N_3B_2(C_6H_5)_2]_2$.

This compound also shows a positive shift of the ^{11}B-resonance signal, thus indicating a bonding similar to that in the borazine complex.

That the boron-nitrogen system is, in principle, able to form π-complexes is apparent from the addition of simple acyclic aminoboranes to transition metals.

$$(CH_3CN)_3M(CO)_3 + [(CH_3)_2N]_3B \rightarrow [(CH_3)_2N]_3BM(CO)_3 + 3\ CH_3CN \quad (31)$$

M = Cr, W

According to eq (31) tris(acetonitrile)tricarbonylchromium(tungsten) reacts [84] with tris(dimethylamino)borane to give yellow, readily sublimable crystalline products that are clearly seen to be π complexes from their properties.

The same is true of the compounds $(CO)_3Fe[(CH_3)_2N]_2BCH_3$ [85a], $Cl_2Pd[(CH_3)_2N]_2BCH_3$, $Cl_2Pd[(CH_3)_2N]_2BCl$ [85b], $(CO)_3Fe[CH_2=CH-B(Br)N(CH_3)_2]$, and $(\pi\text{-}C_3H_5)Ni[(CH_3)_2B-N(CH_3)_2]_2$ [85a]. In the complex $(CO)_3Fe[(CH_3)_2N]_2BCH_3$, formed as orange crystals in accordance with eq. (32), as well as in the Pd^{II} complexes, bis(dimethylamino)borane acts as a

$$Fe_2(CO)_9 + [(CH_3)_2N]_2BCH_3 \rightarrow (CO)_3Fe[(CH_3)_2N]_2BCH_3 + Fe(CO)_5 + CO \quad (32)$$

bidentate ligand that can replace, *e.g.*, two CO groups in $Fe(CO)_5$. In $(\pi\text{-}C_3H_5)Ni[(CH_3)_2B-N(CH_3)_2]_2$, one allyl group of $Ni(\pi\text{-}C_3H_5)_2$ has formally been replaced by two substituents analogous to ethylene.

6. The :B–X Group as a Ligand in Metal Complexes

Our discussion would not be complete without a brief mention of a new, little-studied class of compounds containing a :B–X moiety coordinated to the metal by way of the lone pair on the monovalent boron atom. It behaves as a neutral substituent analogous to CO or PR_3 : $L_nM \leftarrow B-X$ [86]. X must be a strongly electron-repelling group that can satisfy the electronic requirements of the boron atom. So far, reaction (33) has been used to prepare a dimethylaminoborylene derivative of pentacarbonyliron(0) which closely resembles the parent compound in its

$$Fe_2(CO)_9 + Br_2BN(CH_3)_2 \rightarrow FeBr_2 + 5\ CO + (CO)_4Fe \leftarrow BN(CH_3)_2 \quad (33)$$

physical properties (state of aggregation, vapor pressure); however, it differs from $Fe(CO)_5$ in its extreme sensitivity to air oxidation, which is attributable to the presence of Fe–B bonds. The borylene complex is formed in only low yield along with a

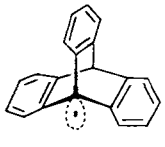
Relations Between Structure and Reactivity in Free-Radical Chemistry[1]

By Christoph Rüchardt [*]

An analysis of the relations between structure and reactivity in free-radical chemistry has shown that the usual interpretation of reactivities by means of the stability of the radicals involved is greatly simplified and often incorrect. The C–X bond energies of the alkanes and simple alkyl derivatives can be explained qualitatively by strain effects in the ground state on the basis of the VSEPR theory and nonbonding interactions. To be able to explain reactivities in free-radical chemistry, it is necessary to deduce information about the geometry of the transition states during free-radical formation from experimental measurements. The relations between structure and reactivity in free-radical chemistry are interpreted in terms of bond dissociation energies, as well as polar and steric effects.



1. Introduction

The chemistry of free radicals [2] has developed into an important section of organic chemistry since the discovery of the triphenylmethyl radical by *Gomberg* [3] in 1900. Free radicals are involved in well-known industrial syntheses such as polymerization, air oxidations, cracking processes, and chlorinations. Interest in the knowledge of the relations between structure and reactivity in the chemistry of free radicals is therefore not confined to chemists who are concerned with reaction mechanisms or engaged in preparative work.

Before the problems encountered are defined, a brief mention of the stereochemistry of free radicals is necessary. The preferred geometry of tricoordinated carbon radicals is now well known from their spectra [4]. Skillfully designed experiments have made it possible to record the ESR spectra of short-lived free radicals. A planar or nearly planar preferred configuration has been deduced from the β-C–H and ^{13}C coupling constants of simple alkyl radicals. The vacuum UV spectrum of the methyl radical led to the same result [4a]. Quantum-chemical calculations are also compatible with the assumption of planar radicals [4a, 5]. Other experimental observations indicate, however, that free radicals are not so strictly bound to the planar configuration as *e.g.* carbonium ions, *i.e.* they accept an angular deformation more

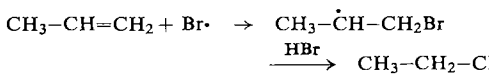
readily than the latter [4a, 5]. Thus nonplanar bridgehead radicals such as the 1-norbornyl *(1)* or the 9-triptycyl radical *(2)* can be produced under comparatively mild conditions [4a].

Free-radical reactions usually proceed as radical chains [2]. These consist of chain initiation, the propagation steps which determine the conversion, and the chain termination reactions, as illustrated for the chlorination of alkanes.



Most propagation steps are exothermic. It is understandable [6] that only very fast reactions, *i.e.* exothermic reactions, can compete with the extremely fast bimolecular chain termination reactions of dimerization and disproportionation [2, 7]. Dimerizations and disproportionations have to overcome only very low activation barriers, usually lower than 1 kcal/mole [2, 7]. The first propagation step, in which an alkyl radical is formed, determines the product distribution of the reaction. Thus in free-radical substitutions, *e.g.* the chlorination (X = Cl·) or autoxidation (X = ROO·) of 2-methylbutane *(3)*, the tertiary hydrogen is substituted in preference to the secondary or primary hydrogens.

(3)

The orientation in free-radical additions [2, 8] is contrary to *Markownikoff*'s rule. The peroxide-initiated addition of HBr to propylene leads to 1-bromopropane

and the addition to vinyl monomers in polymerization is almost exclusively terminal.

It is clear from these results that radicals with the smallest possible number of hydrogen atoms at the radical center are formed preferentially. This difference in the formation tendency of primary, secondary, and tertiary radicals, as well as radicals substituted in the α-position, is the decisive phenomenon in the discussion of the relations between structure and reactivity in free-radical chemistry. Highly alkylated radicals and radicals with phenyl or vinyl groups or with hetero atoms in the α-position have the greatest formation tendency. Aryl radicals do not occur as chain carriers in substitutions and additions. The following discussion will be concerned mainly with simple alkyl radicals.

2. The Different Formation Tendencies of Alkyl Radicals

A quantitative analysis of the formation tendencies of various radicals forms the basis of the understanding of the relation between their structure and their reactivity. However, it is relatively difficult to follow the kinetics of radical formation directly in the extremely fast propagation steps [9]. Reactivities are therefore generally compared by determining the relative extents to which competing reaction paths are followed. The statistically corrected competition constants found in this way for substitution express *e.g.* the ratio in which radicals X· attack tertiary, secondary, and primary C–H bonds (for examples, see Table 1 [10]).

Table 1. Relative reactivities (per H atom) of C–H bonds in free-radical substitutions [10]. R = Alkyl.

X	H–Ċ–			D_{H-X} [a] (kcal/mole)
	R–CH_3	R–CH_2–R	R_3CH	
F	≡ 1.0	1.2	1.4	136
Cl	≡ 1.0	4.7	9.8	103
$(CH_3)_3CO\cdot$	≡ 1.0	10	44	102
C_6H_5	≡ 1.0	9.3	44	103
Br	≡ 1.0	250	6300	87

[a] Bond dissociation energy of H–X [11].

The higher formation tendency of tertiary radicals as compared with primary or secondary radicals is independent of the attacking agent. However, the various substitutions described differ greatly in their *selectivity*. The greater the bond energy of the new H–X bond, the less selective is the attack of X·.

According to the Hammond principle [12], there is only a weak H–X bond in the transition state for the exothermic propagation steps of Table 1. The more strongly exothermic the reaction is, the earlier is the position of the transition state on the reaction coordinate, the smaller is the extent to which the C–H bond is broken in the transition state, and the less selective is the reaction. An intuitive explanation is provided in Sections 4 and 6.

[12] *G. S. Hammond*, J. Amer. Chem. Soc. *77*, 334 (1955).

The formation tendencies of radicals can also be compared directly on the basis of the kinetics of the thermolysis of free-radical initiators, as is illustrated by a number of decomposition constants of peroxy esters and azoalkanes in Table 2 [13, 14].

Table 2. Rates of formation of radicals from simple peroxy esters (1) and azoalkanes (b) [13, 14]. $t_{1/2}$ (rel.) = relative half-life of the radical formation.

$$R{-}COO{-}OC(CH_3)_3 \rightarrow R\cdot + CO_2 + \cdot OC(CH_3)_3 \quad (a)$$

$$R{-}N{=}N{-}R \rightarrow R\cdot + N_2 + \cdot R \quad (b)$$

R	(a) $t_{1/2}$ (rel.) at 60 °C	(b) $t_{1/2}$ (rel.) at 300 °C
CH_3	(1670)	13000
$CH_3{-}CH_2$	(700)	1170
$(CH_3)_2CH$	333	117
$(CH_3)_3C$	≡ 1	≡ 1

As far as is known at present, in both reactions of Table 2 the radical R· is formed in the rate-determining step [13, 14]. The rate of formation of this radical may therefore be equated to the rate of decomposition of the initiator. The values in parentheses are not quite comparable, since it is thought that only the peroxide bond is initially broken in these examples [13].

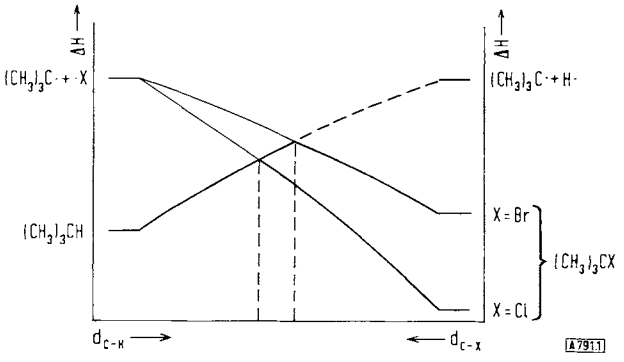
It can be seen from Table 2 that the half-life of radical formation decreases rapidly with increasing alkylation, *i.e.* the formation tendency of the radicals increases as in the propagation steps discussed above. *This result is usually interpreted in the literature as being due to a stabilizing action of α-alkyl groups on the radicals formed* [15].

3. The Transition States of Free-Radical Formation

The interpretation of the radical formation tendency as resulting from specific stabilization of the radical center by substituents has by no means been verified, and is even contradictory, as we shall see. The reaction coordinates of the above-mentioned reactions of free-radical substitution and addition and of the thermolysis of peroxy esters and azoalkanes differ in their shapes.

3.1. The Radical-Forming Propagation Steps

The radical-forming propagation steps of aliphatic substitutions or additions are exothermic to thermoneutral. The removal of the tertiary hydrogen from isobutane by chlorine is exothermic (13 kcal/mole), while the removal by bromine is slightly endothermic (see Fig. 1). According to the Hammond principle [12], therefore, the transition state of the formation of HCl from chlorine and isobutane strongly resembles the starting compound, and even in the almost thermoneutral bromination, there is little stretching of the C–H bond, *i.e.* little free-radical character has developed, in the transition stage.



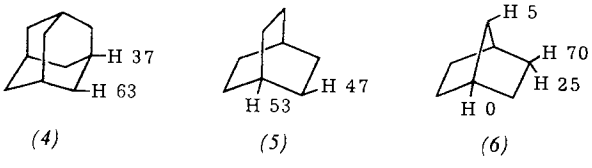


Fig. 1. Reaction coordinate of the free radical aliphatic substitution of isobutane.

$$(CH_3)_3CH + \cdot X \rightarrow (CH_3)_3C\cdot + HX$$

X	ΔH_R (kcal/mole)	E_a (kcal/mole)
Cl	−13	≈1
Br	+ 3	7

This is shown by the ease of chlorination of adamantane *(4)* and bicyclo[2.2.2]octane *(5)* at the bridgehead [4a]. The transition state still resembles the sp^3-hybridized initial state. Only in the highly strained norborane *(6)* is the reactivity of the bridgehead hydrogen so low that its substitution cannot compete with that in other positions (Fig. 2).

(4) *(5)* *(6)*

[A 791.2]

Fig. 2. Product distribution in the chlorination of bicyclic and tricyclic hydrocarbons (values in %).

3.2. The Decomposition of Peroxy Esters

The decomposition of simple peroxy esters *(8)* is endothermic. The homolytic fragmentation [13] of *tert*-butyl peroxypivalate *(7)* has a reaction enthalpy of +10 kcal/mole [16]. The strong influence of the alkyl residue R on the rate of decomposition confirms the assumed course of the fragmentation [13]. The C_α–CO bond is however only slightly stretched in the transition state (see Fig. 3).

[13] For a review, see *C. Rüchardt*, Fortschr. Chem. Forsch. *6*, 251 (1966).

[14] *S. Seltzer*, J. Amer. Chem. Soc. *85*, 14 (1963); *S. Seltzer* and *F. T. Dunne*, *ibid. 87*, 2628 (1965); *S. F. Nelson* and *P. D. Bartlett*, *ibid. 88*, 137 (1966), and literature cited there.

[15] See, *e.g.*, a) *W. Lwowski*, Angew. Chem. *79*, 922 (1967); Angew. Chem. internat. Edit. *6*, 897 (1967); b) *D. S. Breslow*, *E. I. Edwards*, *R. Leone*, and *P. v. R. Schleyer*, J. Amer. Chem. Soc. *90*, 7097 (1968); c) [2b], p. 128; d) [2d], p. 82; e) *R. W. Lenz*: Organic Chemistry of Synthetic High Polymers. Interscience, New York 1967, p. 282; f) [2a], p. 52; g) *N. Isenberg* and *M. Grdinic*, J. Chem. Educ. *46*, 601 (1969).

[16] This is calculated from the activation energy of 38 kcal/mole for O–O thermolysis of *tert*-butyl peracetate [13] (which corresponds to the O–O bond dissociation energy) and the heat of reaction of 20 kcals/mole for the decarboxylation of acetoxy radicals [11], as well as the difference of 8 kcal/mole between the C–C bond energies of ethane and neopentane.

$$(CH_3)_3C{-}COO{-}OC(CH_3)_3 \xrightarrow{60\,^\circ C} (CH_3)_3C\cdot + CO_2 + \cdot OC(CH_3)_3$$

$\Delta H^{\neq} = +31$ kcal/mole; $\Delta S^{\neq} = +13$ e.u.;
$\Delta H_R \approx 10$ kcal/mole.

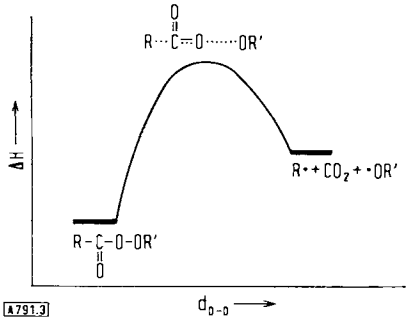

Fig. 3. Reaction coordinate of the decomposition of peroxy esters *(8)*.

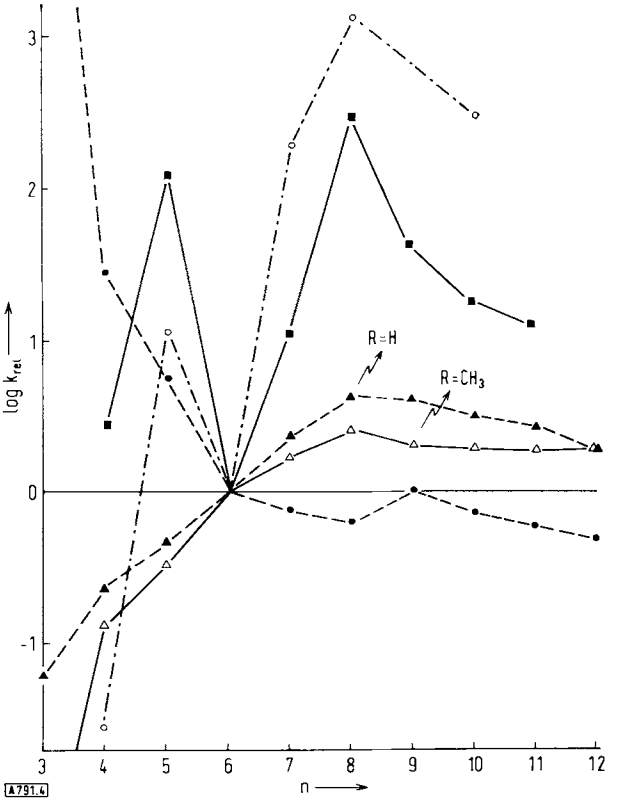
$$R{-}COO{-}OR' \rightarrow R\cdot + CO_2 + \cdot OR'$$
(8)

This is clearly illustrated by the relation between the rate of decomposition of esters of cycloalkyl peroxy acids and the ring size[17] (see Fig. 4). The ease of introduction of an sp^2 center into sp^3-hybridized cycloalkyl compounds depends on the ring size[18]. For example, 1-methylcyclopentyl chloride is solvolyzed more rapidly than 1-methylcyclohexyl chloride, since the formation of an sp^2 center leads to a decrease in conformational strain in the case of the five membered ring and to an increase in the case of the six-membered ring. The high solvolysis constants of 1-methylcycloalkyl chlorides with medium-sized rings are also due to the decrease in ring strain on replacement of an sp^3 center ($\sphericalangle \approx 109\,^\circ$) by an sp^2 center ($\sphericalangle \approx 120\,^\circ$)[18].

The rate of formation of carbanions (which are known to have pyramidal structures[4a]) decreases from the three-membered to the twelve-membered ring (see Fig. 4)[19]. According to *Streitwieser*'s investigations, it decreases with decreasing electronegativity of the ring carbon atoms[19].

An entirely different picture is shown by the rate of formation of free radicals from cycloalkyl peroxy esters (see Fig. 4)[17]. The rate of decomposition does not pass through a minimum for the six-membered ring, and the peroxy esters with medium-sized rings are not distinguished by any particular ease of decomposition. The same result was found in the kinetic study of the thermolysis of 1-phenylcycloalkyl peroxy esters[17a], though the decomposition constant of the five-membered peroxy ester is only slightly smaller than that of the six-membered compound in



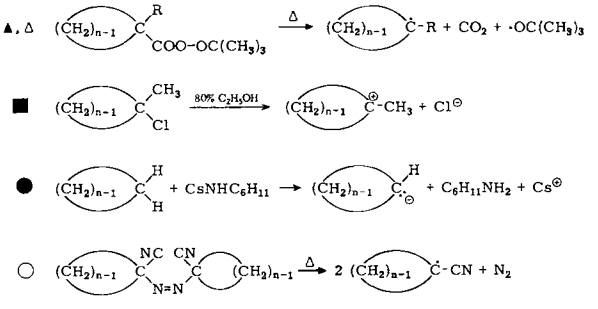


Fig. 4. Dependence of the rate of formation of cyclic carbonium ions, carbanions, and radicals on the ring size.
n = number of ring members.

this example. The rate of homolytic fragmentation of the peroxy esters, on the other hand, decreases roughly as the electronegativity of the ring carbon atoms increases. This is evident from Figure 5, which shows the relation between the decomposition constants and the ^{13}C coupling constants of the corresponding cycloalkanes[17]. The decomposition rate is evidently mainly influenced by a polar effect[13] (see Section 5).

Ring strain effects thus have no appreciable influence on the decomposition of peroxy esters. In the transition state of radical formation, the α-C atom is still substantially pyramidal, and its free-radical character is not yet developed[20].

Kinetic studies on the thermolysis of bridgehead bicycloalkyl and tricycloalkyl peroxy esters point in the same direction[21].

oxy esters, so that (unlike in carbonium-ion formation in solvolysis reactions [4a]) the ring strain, which increases with loosening of the bond, has little effect on the activation energy. It is only in the highly strained norbornane system that any increase in the angle, however small, requires too much energy, so that only the peroxide bond is broken in the initial step. The small secondary kinetic isotope effect in the thermolysis of *tert*-butyl [α-D]-α-phenylperoxypropionate *(15)* also indicates that the transition state of

(15)

the fragmentation of peroxy esters occurs early on the reaction coordinate in relation to the C–C cleavage [23].

There are two possible reasons for the apparent discrepancy of these results with the relatively high

The decomposition constants of compounds *(7)* to *(13)* in Table 3 differ by a factor of only 10 from the thermolysis constant of the peroxypivalic ester *(7)*, which was taken as the reference point. Only the ester of the highly strained 1-norbornaneperoxycarboxylic

(14)		1.57×10^{-3}	[21c]

acid *(14)* is appreciably more stable. It decomposes with cleavage of only the peroxide bond in the rate-determining step [13, 22]. These results also show that the C_α–CO bond is stretched only slightly in the transition state of free-radical formation from per-

activation energy of the decomposition of peroxy esters (see Fig. 3), which, according to the Hammond principle, pointed to a radical-like transition state for the fragmentation of peroxy esters. The peroxide cleavage could be a fast equilibrium step, the subsequent exothermic decarboxylation being rate-determining. It should be possible to establish this by isotope equilibration during the decomposition of peroxy esters specifically labeled with ^{18}O in the carbonyl group [24]. A more probable answer, however, is the assumption [13] of an unsymmetrical peroxy ester fragmentation in which only the weak O–O bond is substantially broken in the transition state, while the stronger C–C bond is only partly broken, so that the α-C atom is still similar to that in the pyramidal state (see Fig. 3). The weaker the C_α–CO bond, the more uniform is the cleavage of both bonds in the fragmentation of *(8)*. This is shown *e.g.* by the influence of α-phenyl substitution on the decomposition constants of cyclic peroxy esters (see above) [17a].

3.3. The Decomposition of Azoalkanes

In contrast with these two reactions, the transition state occurs late on the reaction coordinate in the pyrolysis of azoalkanes. Its geometry is closer to that of the planar radical (see Fig. 6). This can be seen from the pronounced influence of the ring size on the rate of formation of radicals from cycloalkylazo-

nitriles[25] and 1-methylazocycloalkanes[24a] (see Fig. 4). As in the solvolysis of 1-methylcycloalkyl chlorides, this influence can only be explained by an almost planar transition state. This would also explain the decomposition constants of bridgehead-linked bicycloalkyl and tricycloalkyl azo compounds[26] even allowing for a statistical correction (Table 4). They differ greatly from the decomposition constants of the corresponding peroxy esters (see Table 3). The rate of thermolysis of azoadamantane *(21)* is slower by a factor of 3000, that of azobicyclo-[2.2.2]octane *(20)* by a factor of 20000 [like 1-azobicyclo[3.2.1]octane *(19)* and 1-azotwistane *(18)*], and that of azonorbornane *(17)* by a factor of 500000, than that of azoisobutane *(16)* (see Table 4).

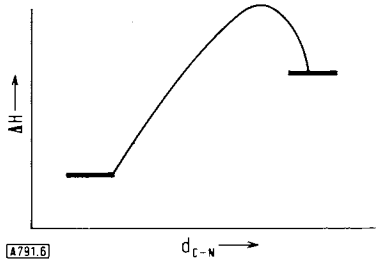

Fig. 6. Reaction coordinate of the decomposition of azoalkanes at 300 °C.

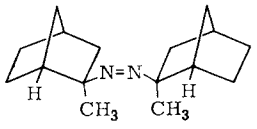
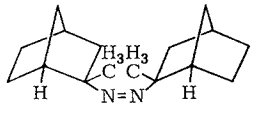
$\Delta H_R \approx 20{-}25$ kcal/mole; $\Delta H^{\neq} = 44$ kcal/mole; $\Delta S^{\neq}$ 17 e.u.

Table 4. Rates of thermolysis of bicycloalkyl and tricycloalkyl azo compounds at 300 °C in C_6H_6.



R	R–N=N–R		R–N=N–C(CH$_3$)$_3$	
	No.	k_1 (rel.)	No.	k_1 (rel.)
$(CH_3)_3C$–	*(16)*	≡ 1	*(16)*	≡ 1
	*(17)*	1.98×10^{-6}	*(22)*	4.64×10^{-3}
	*(18)*	3.51×10^{-5}		
	*(19)*	3.67×10^{-5}		
	*(20)*	5.06×10^{-5}	*(23)*	2.04×10^{-2}
	*(21)*	4.02×10^{-4}	*(24)*	4.36×10^{-2}



The ring system has less influence on the thermolysis of bicycloalkyl- and tricycloalkylazoisobutanes *(22)* to *(24)*, in agreement with the simultaneous but non-uniform cleavage of both C–N bonds in the course of the thermolysis[27]. The cleavage of the N-*tert*-butyl bond is certainly much farther advanced than that of the other C–N bond in the transition state. This roughly corresponds to the situation in the fragmentation of peroxy esters (see above).

The secondary kinetic isotope effect in the thermolysis of α,α′-dimethyl-α-azotoluene *(25)* also shows that extensive rehybridization of the α-C atom has taken place in the transition state[28].

(25) $k_H/k_D = 1.15$

To check the structure of the transition state in the pyrolysis of azoalkanes, we synthesized and thermolyzed *exo*- and *endo*-2,2′-dimethyl-2-azonorbornane *(26a)* and *(26b)*[29].

(26a)

(26b)

There is no torsional strain barrier to be overcome (hydrogen atom on C-1) to allow the methyl group in *(26a)* to swing into the planar arrangement of the thermolysis transition state, whereas such a barrier is encountered in *(26b)*[30]. In fact, *(26a)* thermolyzes 68 times as rapidly as *(26b)*[29]. The fact that the rates of acetolysis of *exo*- and *endo*-2-norbornyl *p*-toluenesulfonate at 25 °C differ by a factor of 350[30] is probably partly due to a similar steric effect, so that only a smaller factor remains to be explained by neighboring group participation and the formation of the nonclassical norbornyl cation. The rates of decomposition of the *tert*-butyl esters of *exo*- and *endo*-2-norbornaneperoxycarboxylic acids, on the other hand, differ by a factor of only 3–7[31], since torsional strain effects are less active in the pyramidal transition state of the peroxy ester fragmentation. It is not to be expected, however, that torsional strain effects exhibit a linear correlation with the amount of bond stretching[31]. This point can be verified by the study of unsymmetrical azo compounds. The investigation of the rates of formation of other isomeric *exo* and *endo* bicycloalkyl azo compounds

should therefore be of great importance for the estimation of steric effects in solvolysis reactions.

Thus the transition states of the three radical-forming reactions discussed are fundamentally different. The exothermic propagation steps of free-radical substitutions and additions and of the decomposition of peroxy esters pass through transition states in which the C atom is geometrically very close to the initial state. In the endothermic thermolysis of azoalkanes (see Fig. 6), on the other hand, the C–N bonds are already extensively broken and the two planar radicals are already strongly anticipated at the energy peak of the transition state. A blanket explanation of the difference in the formation tendencies of primary, secondary, and tertiary radicals by specific stabilization of the radicals formed by α-alkyl groups is therefore unacceptable. Different rules also apply to carbonium ion formation in endothermic solvolysis reactions and to the exothermic decomposition of aliphatic diazonium ions [32]. For example, bridgehead carbonium ions are formed readily only in exothermic ionization such as the decomposition of diazonium ions [4a], since the bridgehead atom carries very little positive charge in the transition state.

How, then, can we account for the popularity of the explanation of radical formation tendencies by differences in the stability of the radicals formed? In our opinion this is due to the hasty assumption of an analogy between the effects of α-alkylation on the rates of free-radical formation and on the C–H bond energies, which are also decreased by α-substitution.

4. Bond Dissociation Energies [11, 33]

Figure 7a shows the definition of the bond dissociation energy on the basis of reaction coordinates. Bond dissociation does not proceed *via* a transition state with an energy maximum, since the back-reaction corresponds to a dimerization of free radicals. Dimerizations of free radicals have no appreciable activation energy; they are mostly diffusion-controlled [2, 7, 34]. Any specific stabilization of a free-radical C atom by substituents must therefore lead to a decrease in the bond dissociation energy. Figure 7b shows the dissociation energies of C–H bonds in methane and simple alkanes, together with their usual interpretation [35]. As was mentioned earlier, it is assumed that the α-alkylation leads to specific stabilization of the free-radical center without specifically stabilizing or destabilizing the ground state. The agreement of the influence of alkylation on the rate of radical formation (kinetic quantity) and on the bond dissociation energy (thermodynamic quantity) does in fact suggest a common reason for both effects. On the other hand, is this reason the specific stabilization of the radicals?

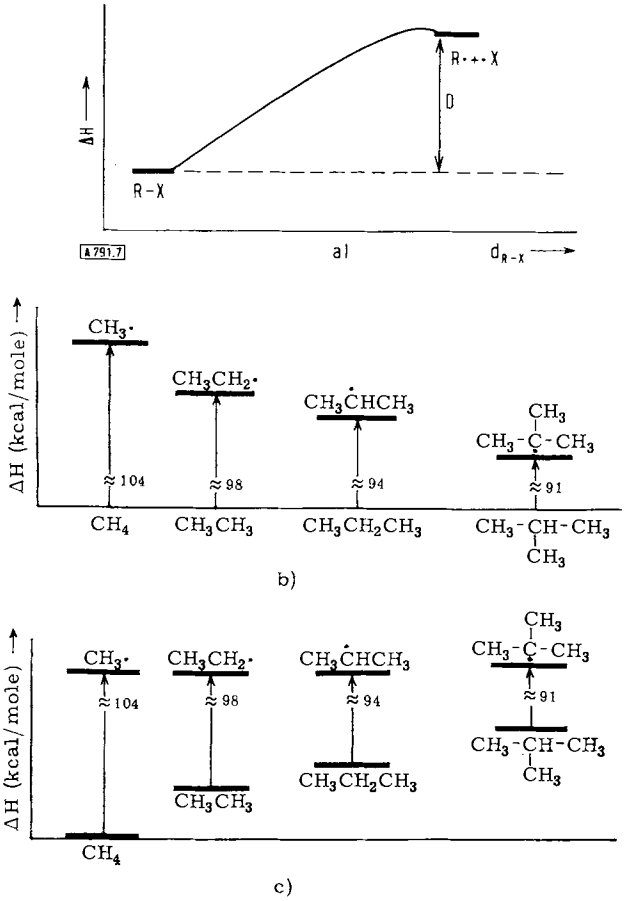

Fig. 7. Dissociation energies *D* of C–X bonds. (a) Definition; (b) usual interpretation [35]; (c) alternative interpretation.

The following arguments oppose this assumption:

It has been deduced from the β-C–H coupling constants of the ESR spectra of short-lived radicals [4] that each methyl group reduces the spin density on the central C atom of the radical by only about 8% [36]. Moreover, the radical is by no means fully developed in the transition state of radical formation. For these two reasons, α-alkyl hyperconjugation should have only a very small effect on the rate of radical formation. Substituents that can enter into resonance with the radical center (as in the benzyl and allyl radicals) should cause a particularly marked increase in the rate of radical formation. The fact that the C–H bonds of cyclohexane are more reactive than the α-C–H bonds of toluene in chlorination [37] shows that even this possibility does not necessarily determine the rate in exothermic free-radical formation. In the other extreme, the bond

[37] See ref. [2a], p. 360.

dissociation energies could also be explained by a destabilizing effect of higher alkyl substituents in the ground state, as illustrated in Figure 7c, without the need for a specific radical-stabilizing action.

Before any detailed discussion is possible it is necessary to answer the question how one can decide between these two interpretations. If the effect of α-alkylation were mainly or exclusively to stabilize the radical, the difference in the dissociation energy on transition from methyl to ethyl, isopropyl, and *tert*-butyl derivatives would be independent of the eliminated group X, and the gradation of the dissociation energies of C–H bonds in Figure 7 should also be found for C-halogen, C–O, and *e.g.* C–N bonds with practically no change in magnitude.

The validity of this requirement can be seen from bond dissociation energies of benzyl and allyl derivatives, where the radicals are stabilized by resonance with a π-electron system. It can be seen from Table 5 that, irrespective of the eliminated group X, the difference in dissociation energy between the benzyl and methyl compounds and between the allyl and methyl compounds is constant, and correponds roughly to the resonance energy of the benzyl or allyl radical [38].

Table 5. Bond dissociation energies [11] of benzyl and allyl compounds (in kcal/mole).

X =	H	OH	I	CH_3	C_2H_5	*i*-C_3H_7	*t*-C_4H_9	C_6H_5
CH_3–X	104	91	56	88	85	84	80	93
C_6H_5–CH_2–X	85	77	40	72	69	67	64	78
CH_2=CH–CH_2–X	85	77	41	72	69	67	63	77
Δ methyl-benzyl	19	14	16	16	16	17	16	15
Δ methyl-allyl	19	14	15	16	16	17	17	16

Figure 8 shows the bond dissociation energies of several methyl, ethyl, isopropyl, and *tert*-butyl derivatives. It can be seen that the difference in the bond dissociation energies of methyl, ethyl, isopropyl, and *tert*-butyl derivatives is by no means independent of the eliminated group X. On the contrary, the difference between the methyl and *tert*-butyl derivatives varies between 0 and 13 kcal/mole. No relation with the absolute value of the bond dissociation energy can be recognized. It would therefore be contrary to this experimental observation to explain the differences by differences in the degree of stabilization of the radical. Conversely, it may be deduced from the low dependence of the C–F and C–OCH_3 bond dissociation energies on the degree of alkylation that alkyl groups do not appreciably stabilize the radicals. The example of the C–H bond dissociation energy that is always quoted is in fact an extreme case.

To explain the variation of the bond dissociation energies with the degree of alkylation, therefore, it is also necessary to consider the increasing strain in the ground state with increasing alkylation (see Fig. 7c).

[38] See also *A. Streitwieser*: Molecular Orbital Theory for Organic Chemists. Wiley, New York 1961, p. 393; however, see *D. M. Golden, N. A. Gac*, and *S. W. Benson*, J. Amer. Chem. Soc. *91*, 2136 (1969).

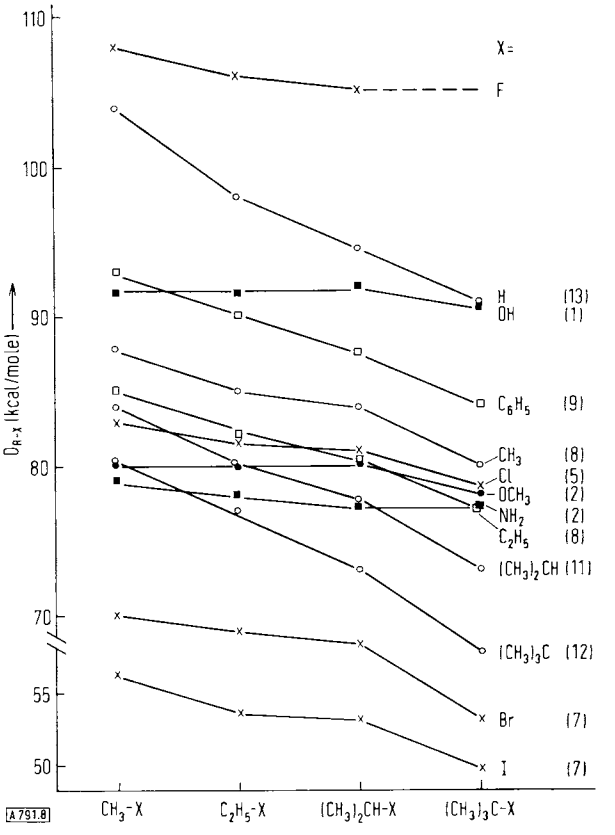

Fig. 8. Bond dissociation energies D_{R-X} of methyl, ethyl, isopropyl, and *tert*-butyl compounds. The numbers in brackets on the right hand edge show the differences in bond dissociation energy (in kcal/mole) between the methyl and *tert*-butyl compounds having the same X.

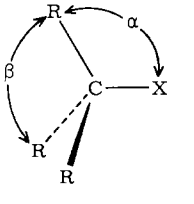

The following discussion is based on the electron pair repulsion model (Valence Shell Electron Pair Repulsion theory, VSEPR) of *Sidgwick, Powell, Gillespie, Nyholm*, and others [39], taking non-bonding interactions [40] into account.

There are three destabilizing factors to be considered in the ground state. These are usually referred to collectively as steric effects:

a) The mutual repulsion of the nuclei.

b) The mutual repulsion of the bonding electrons [39].

c) The repulsion of atoms that are not bound to one another over distances corresponding to the van der Waals radii [40].

(27)

Any influence that tends to reduce the angle between the orbitals or bonds consequently encounters strong resistance [39], whereas an increase in the angle is energetically favored. Since the transition to the planar radical is associated with an increase in the bond angles β, all repulsive effects become smaller.

[39] *R. J. Gillespie*, Angew. Chem. *79*, 885 (1967); Angew. Chem. internat. Edit. *6*, 819 (1967); J. Chem. Educ. *40*, 295 (1963).

[40] *L. S. Bartel*, J. Chem. Educ. *45*, 754 (1968).

The greater the "steric pressure" in the ground state, the more pronounced this phenomenon becomes. This allows a qualitative interpretation of the bond dissociation energies (see Fig. 7c). As can be seen from Figure 8, in almost all examples their differences increase most strongly on transition from the isopropyl to the *tert*-butyl compound, in agreement with the fact that steric repulsion effects usually increase exponentially with the degree of alkylation. If the bond dissociation energies were explained by electronic stabilization of the radicals, the converse would be expected.

The difference in the bond dissociation energies of methyl and *tert*-butyl compounds within a series of similarly substituted compounds increases with the size of the eliminated group X. This is easily recognized in the arrangement of Table 6.

Table 6. Difference in the bond dissociation energies ΔD_{R-X} of CH_3-X and $(CH_3)_3C-X$.

X	ΔD_{R-X} (kcal/mole)	X	ΔD_{R-X} (kcal/mole)
H	13	I	7
$C(CH_3)_3$	12	Br	7
$CH(CH_3)_2$	11	Cl	5
C_6H_5	9	F	(2)
C_2H_5	8	OH	≈ 1–2
CH_3	8	OCH_3	
		NH_2	

It may be assumed that the relaxation of the strain on transition from the tetrahedral C atom to the sp^2-hybridized trigonal center promotes the reaction more strongly for large substituents X than for small substituents. The mutual repulsion of the nuclei or the mutual repulsion of the alkyl groups over distances of the order of the van der Waals radii decreases by the largest amount on dissociation.

Replacement of the H atoms in *(27)*, R=H, by alkyl groups leads to an increase in the angle β (in propane and isopropane, the angle CCC is 111.5° [41]), and hence to a decrease in the angle α. Since the repulsion of the bonding electrons increases exponentially with decreasing α, the reason for the large difference in the C–H bond dissociation energy between butane and isobutane is clear. Besides the bulk of the substituent X, the length of the C–X bond is also important, since this is the only possible explanation why the difference in the bond dissociation energies of the methyl and *tert*-butyl compounds is greatest for the cleavage of the C–H bond (see Fig. 8 and Table 6). The shorter the C–X bond, the higher is the electron density at the bond axis close to the central C atom, and hence the greater is the repulsion between the electrons of the C–X bond and the electrons of the other bonds.

Electronegative groups X such as fluorine, methoxy, and NH_2 strongly attract the bonding electrons away from the central C atom [33]. The electronic repulsion over the angle α in *(27)* is therefore reduced, and the decrease in the angle on introduction of alkyl residues is not accompanied by a large increase in the electronic repulsion.

This approach allows a qualitative interpretation of the differences in the bond dissociation energies.

Can we also explain the acceleration of radical formation by alkyl groups in the examples discussed above, and is this explanation satisfactory even when the transition state of the radical formation occurs early on the reaction coordinate, so that the angles are only slightly increased, as in the decomposition of peroxy esters or in chain chlorination?

The answer to this question is an emphatic "yes" [41a]. Since steric effects, *i.e.* the strain in the ground state, decrease exponentially (see Fig. 9), even a small increase in the angle during radical formation will lead to the elimination of most of the strain of the ground state.

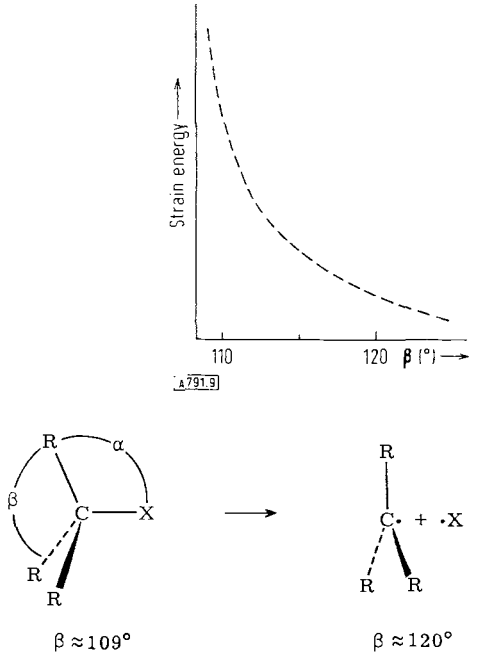

Fig. 9. Decrease in the strain energy on dissociation, expressed as an increase in the angle β.

It is now also possible to understand why the selectivity of free radicals decrease in the order chlorine > *tert*-butoxy > bromine, as shown in Table 1. The transition state of the removal of H by chlorine occurs earliest on the reaction coordinate, since this is the most strongly exothermic process. The increase in the angle in the transition state is therefore smallest in this case, and the difference between *tert*-C–H and CH_3–H cleavage is least.

A refined analysis is now also possible for the difference in the sequence of reactivities of bridgehead peroxy esters and bridgehead azo compounds on thermolysis. Figure 10 shows a logarithmic plot of the decomposition constants against the known solvolysis constants [41b] of the bridgehead bromides in

[41] *Y. Youkawa*: Handbook of Organic Structural Analysis. W. A. Benjamin, New York 1965.

[41a] See also *R. F. Bridger* and *G. A. Russell*, J. Amer. Chem. Soc. *85*, 3754 (1963), particularly p. 3762.

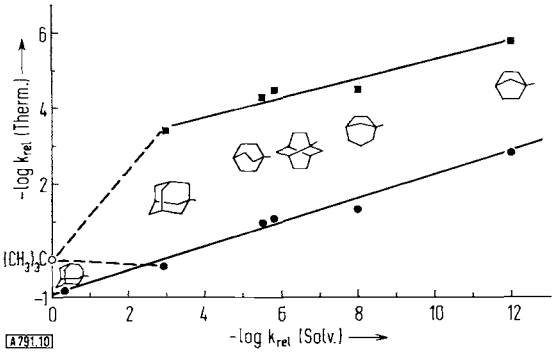
80% ethanol. There are two points of interest here. Firstly, the rates of thermolysis of *tert*-butyl and 1-adamantyl peroxy esters are almost the same, whereas azoisobutane decomposes almost 2500 times as rapidly as 1-azoadamantane. The increase in the angles of the *tert*-butyl group is well advanced in the transition state only for the thermolysis of the azo compound, and not for the peroxy ester fragmentation. In the rigid tricyclic adamantyl system, however, no corresponding increase in angle is possible during either the decomposition of the peroxy ester or the thermolysis of the azoalkane. The second point that emerges is that a linear relationship is found between the thermolysis constants of both fragmentations of bridgehead compounds and the rate of solvolysis of the alkyl bromides, and even the slopes of the two lines in Figure 10 are very similar. Ionization and radical formation are evidently inhibited by the same strain effects [41b], but the formation of the carbonium ion reacts more strongly to these effects. The similarity of the slopes of the straight lines in Figure 10 suggests that the maximum deformation or additional straining of the bicyclic ring that is possible in radical formation is reached even in the transition state of the thermolysis of peroxy esters.



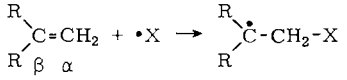


Fig. 10. Linear relation between free energies of thermolysis and of solvolysis of bridgehead compounds. Thermolysis of R—N=N—R at 300 °C in benzene (see Table 4); thermolysis of R—COO—$OC(CH_3)_3$ at 80 °C (see Table 3); solvolysis of RBr in 80% ethanol at 25 °C. ■: azo compounds; ●: peroxy esters.

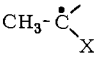
With the aid of this interpretation of the bond energies, it also recently became possible to explain the influence of α-methyl groups on the rate of thermolysis of peroxy esters [41c].

This approach cannot be used directly to explain the anti-Markownikoff orientation in free-radical additions [8, 15g] and polymerizations [15c]. Since these are



exothermic propagation steps, it is again to be expected from the Hammond principle [12] that the structure of the transition state is still similar to that of the olefin. The decrease in the angle that accompanies radical formation on the α-C atom is thus not very far advanced in the transition state. The strain energy curve in Figure 9 is now followed from right to left. The strain energy increases appreciably only with a large decrease in the angle at the α-C atom. The anti-Markownikoff orientation of these reactions is therefore presumably due simply to the stronger steric screening of the more highly alkylated β-C atom. This hypothesis was discussed by *Walling* as an adequate explanation [2a].

Competition constants for free-radical additions should be capable of providing verification of this. Only a few investigations of this type have been carried out so far [42,43]. Ethylene and isobutylene have comparable methyl affinities, which are 5 to 10 times as great as those of *cis*- and *trans*-2-butene [42]. This can be explained by the stronger screening of the secondary C atom in the butenes. The reactivity of olefins with cyclopropyl radicals actually decreases monotonically with alkylation; this has been explained by a transition state resembling a π-complex [43a]. The reactivity of the olefins is strongly increased only by substituents having π-bond systems [42,43]. This may also be partly due to polar effects [44]. The fact that only terminal olefins polymerize readily points in the same direction. These views also make the orientations in intramolecular free-radical additions seem less remarkable [44a].

5. Polar Effects in Free-Radical Reactions

The discussion has so far been confined to unsubstituted alkyl radicals. Besides the phenyl and vinyl groups mentioned earlier, however, there are also other substituents that can stabilize adjacent free-radical centers by resonance. On the other hand, the ESR spectra of such radicals show that this effect should not be overestimated. The β-CH_3 coupling constants of the radicals *(28)* are proportional to the spin

(28)

density on the β-C atom [4b]. The β-C—H coupling constants are therefore a good measure of the ability of substituents X to reduce the spin density on the α-C atom by resonance [45]. It can be seen from Table 7 [4b] that the maximum decrease in the spin density on the α-C atom with the substituents indicated is

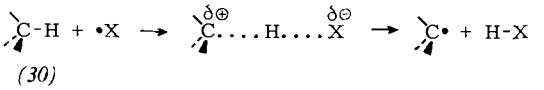
Table 7. Decrease in the spin density on the α-C atom in *(28)* by substituents X [4b].

X	CH_3	CH_2OH	COOR	CN	COC_2H_5	OH	OC_2H_5
Rel. spin density (H = 100%)	91.9	92.1	92.8	85.2	83.8	84.0	82.2

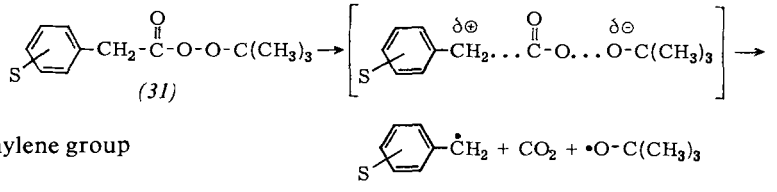
only 17%, and that the alkoxycarbonyl group is comparable in this respect to *e.g.* a methyl group.



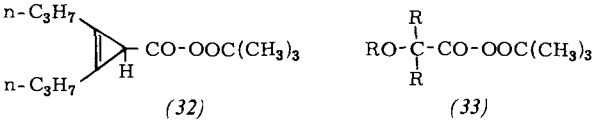
The decrease in the spin density is a qualitative indication of the radical-stabilizing effect of a substituent. It must therefore be expected that this relatively small effect accelerates the formation of radicals only when the transition state occurs late on the reaction coordinate, and so already has a strong radical character. No kinetic data have been reported in which this radical-stabilizing substituent effect could be observed in isolation. Substituent effects in free-radical chemistry have mostly been investigated in exothermic reactions in which the transition state still resembles the starting compound. How, then, can substituents affect the energy level of a transition state that is not yet very like the radical? It was found that the influence of one and the same substituent, *e.g.* on the rate of radical formation by hydrogen transfer, differs with the attacking radical. Thus

esters of carboxylic acids are preferentially attacked by methyl radicals on the α-methylene group of the acid, whereas in autoxidation by peroxy radicals, the attack occurs preferentially on the α-methylene group of the alcohol [46].

Similarly, the abstraction of hydrogen from α-benzylmalonates by methyl radicals occurs preferentially from the benzyl position, while methoxy radicals remove the tertiary hydrogen from the α-position with respect to the carbonyl group [47]. Ether functions activate α-hydrogen atoms much more strongly for the attack of a *tert*-butoxy or peroxy radical in autoxidations [48] than for the attack of a phenyl radical [49]. The free-radical chlorination of butyric acid occurs mainly in the β-position, whereas methyl radicals prefer the α-position [50]. The list of examples of this apparently contradictory reactivity behavior is almost endless [51].



An explanation for the dependence of the reactivity on the attacking radical is provided by consideration of the charge separation in the transition state of free-radical reactions, which is referred to as "polar effects" in free-radical reactions [51, 52]. When a radical X with an electronegative central atom attacks a C–H bond *(30)*, the electrons are drawn more strongly to the attacking radical in the transition state. This leads to partial charges, the delocalization of which by adjacent substituents lowers the energy level of the transition state, and so increases the rate of radical formation.



(30)

The mesomeric charge distribution in the transition state explains why the reactivities of substituted toluenes with halogen atoms or with trichloromethyl or peroxy radicals can be described by the substituent constants σ and σ^+ [52]. The greater the electronegativity of X, the greater are the charge separation and the substituent effect. Polar effects of this nature were first recognized in copolymerization, and have been studied particularly extensively in this connection [44]. α-Alkyl groups can also influence radical formation by a polar effect.

Polar effects also have a strong influence on the rate of fragmentation of peroxy esters [13, 41c]. Thus the rates of decomposition of substituted *tert*-butyl peroxyphenylacetates *(31)* follow a σ^+ relation [53]. The

low thermal stabilities of *tert*-butyl dipropylcyclopropenylpercarboxylate *(32)* and of the α-alkoxy and α-aryloxy peroxy esters *(33)* have been explained by

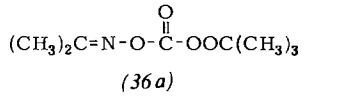
polar effects on the charge distributions in the transition state of the homolytic fragmentation [13, 54, 55]. However, alkoxy groups in the α-position, as in *(34b)*, do not decisively change the rate of decomposition of the azo compound *(34a)* [56]. As expected, therefore, polar effects are of no great importance in the

(34a), X = CH_2, $\Delta H^{\neq}$ = 35.6 kcal/mole, $\Delta S^{\neq}$ = +4.1 e.u.

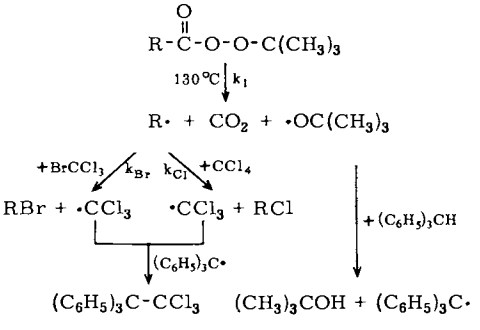


(34b), X = O, $\Delta H^{\neq}$ = 32.3 kcal/mole, $\Delta S^{\neq}$ = −2.5 e.u.

thermolysis of symmetrical azoalkanes. It also follows from this result that α-alkoxy groups cannot have any great radical-stabilizing influence. This is also shown by the fact that *(35a)* is thermally more stable than *(35b)* [57].

(35a), X = CH_3O
(35b), X = CH_3

The dominating influence of polar effects on radical formation reactions in which the transition state occurs early on the reaction coordinate, such as the fragmentation of peroxy esters, can also be seen from the high thermal stability of acetone *O-tert*-butylperoxycarbonyloxime *(36a)* [58]. Though a fragmentation could lead directly to the oxime radical *(36b)*,



(36a) *(36b)*

the stability of which is known [59], *(36a)* decomposes as slowly as *tert*-butyl perbenzoate, and hence probably with simple cleavage of the peroxide bond in the slow step of the thermolysis [13]. No decomposition-promoting polar effect such as that found in *(31)* is to be expected in *(36a)*. The above-mentioned influence of the ring size on the rate of decomposition of cycloalkyl peroxy esters and its correlation with the ^{13}C coupling constants of the cycloalkanes also agree with the action of polar effects on the decomposition of peroxy esters. Since the chain-carrying radicals in free-radical substitutions and additions usually have a central hetero atom or strongly electronegative substituents, their reactivity is always influenced in a similar manner by polar effects. Until very recently, therefore, it was often assumed that the observed reactivity sequences were due to the stability of the radicals formed in the propagation steps. Since the relations found between structure and reactivity largely corresponded to those for the formation of carbonium ions (understandably, in view of the concept of polar effects), it was assumed that the stabilities of free radicals and of carbonium ions depend in the same manner on the structure. However, this conclusion is invalid, since the free radical character is not very well developed in the transition state of the exothermic propagation steps.

6. Selectivity of Free-Radicals

Another method of obtaining information about the stabilization of free radicals could be the determination of their selectivity in competing reactions. A relationship is often assumed to exist between the reactivity of an agent and its selectivity [59a]. The more reactive or the less stabilized a particle is, the lower its selectivity is expected to be. This selectivity principle was very successfully used by *H. C. Brown* in the investigation of electrophilic aromatic substitutions [60]. To determine the selectivity of aryl or alkyl radicals, the ratio of the rates of reaction of these radicals with CCl_4 and bromotrichloromethane were determined.

This competition system was tested in many respects. It was found that reliable competition constants $r = k_{Br}/k_{Cl}$ can be obtained on addition of triphenylmethane as an inhibitor. The analytical determination of the alkyl bromides and alkyl chlorides obtained is very simple. The competition constant r is calculated from these values with the aid of the following equations (the subscript e denotes the end of the reaction):

$$\frac{d[RBr]}{d[RCl]} = \frac{[RBr]_e}{[RCl]_e} = \frac{k_{Br}\,[BrCCl_3]}{k_{Cl}\,[CCl_4]}$$

$$r = \frac{k_{Br}}{k_{Cl}} = \frac{[RBr]_e\,[CCl_4]}{[RCl]_e\,[BrCCl_3]}$$

An important factor in the choice of this competition system was that the leaving group is the same, *i.e.* the CCl_3 radical, in both transfer reactions. Polar effects

should thus be approximately the same in both competing reactions. This is confirmed by the results in Table 8 [61].

Substituted phenyl radicals differ by only about 20% in their selectivity. Even steric effects due to *o*-substituents have no great influence. It is interesting to compare these competition constants with those of aliphatic radicals. The difference between the selectivities of primary and secondary alkyl radicals is very small; however, their selectivity is about five times as great as that of the phenyl radical. If the selectivity is assumed to be determined by the stability of the radical, it may be concluded that primary and secondary alkyl radicals have roughly equal stabilities, whereas aryl radicals are more reactive. However, the competition constant of the secondary radical is probably lowered slightly by a steric effect, so that the difference between primary and secondary radicals should be greater in value and opposite in direction. A steric effect of this type is found for the neooctyl radical. The competition constants of cyclic radicals are rather lower than those of open-chain radicals. The change in r with ring size is probably again due to increased steric screening of the radical center in rings of medium size.

[a] From phenylazotriphenylmethane.

The selectivity of the bridgehead radicals listed is interesting. One is inclined to draw the same conclusion from this as from the other experiments, *i.e.* that alkyl radicals prefer a planar arrangement, and any deviation from this is associated with an increase in energy and a decrease in selectivity. The small value for the adamantyl radical and the large value for the homocubyl radical are surprising. The screening of the radical center probably also plays some part here.

Why do radicals that differ so widely in their structures differ so little in their selectivities? We are again dealing with exothermic reactions, *i.e.* the R · · · Hal bond is only weakly developed in the transition state of the halogen transfer. The arrangement at the central C atom in R is still substantially unchanged or planar. A strain that varies strongly from radical to radical is to be expected only if the angle is considerably reduced in the transition state. We thus observe a process that is exactly the reverse of the radical formation discussed earlier.

The results presented show that many of the usual views on the relations between structure and reactivity in free-radical chemistry are in need of revision. In the absence of substituents, the strain in the ground state and the position of the transition state on the reaction coordinate are quantities that may explain the dependence of the reactivity on the structure. Polar effects and radical-stabilizing effects of unsaturated substituents such as vinyl and phenyl groups must be considered separately. The analysis carried out should be regarded merely as a starting point for the detailed explanation of reactivities in free-radical chemistry.

What is needed to enable a quantitative theory to grow from this starting point? Firstly, more kinetic data are required, particularly on the selectivity of free radicals. Secondly, more accurate information about the transition state of aliphatic free-radical propagation steps, *e.g.* in substitution, is necessary. A very promising line of investigation in this respect appears to be the molecular beam scattering experi-

[61] *C. Rüchardt, K. Herwig,* and *S. Eichler,* Tetrahedron Lett. *1969,* 421; unpublished results obtained by *K. Herwig* and *P. Lorenz.*

ments[62] which provides quantities such as the reaction cross section, and with which collision complexes can be studied. Finally, more detailed information on the energy relations in the ground state of the reaction, for example a quantitative theory of bond dissociation energies, is also necessary[11]. The quantum-chemical treatment of the σ bond may assume special importance here.

The Ionization (Heterolysis) of Covalent Compounds as a Coordination-Chemical Phenomenon

By Viktor Gutmann[*]

The ionization of a covalent compound into a cation and an anion is a coordination-chemical phenomenon. The ions are formed with coordination either by nucleophilic attack of an electron pair donor or by electrophilic attack of an electron pair acceptor. The dielectrically controlled component of the ionization affects only the degree to which it occurs. It is shown that the ionization generally increases with increasing donor strength of the donor or with increasing acceptor strength of the acceptor. For a given M, the ease of ionization of the M–X bond increases in the order X = fluoride < chloride < bromide < iodide. These general aspects are discussed with the aid of examples.

1. Introduction[**]

The ionizing power of a substance, *e.g.* a solvent, is its ability to form cations and anions from molecules. However, the conditions required for ion formation by heterolysis of a covalent bond have remained largely uncertain over the decades since Arrhenius, particularly because of the frequent failure to distinguish between the concepts of ionization (ion formation) and ion dissociation (dissociation of ion associates).

An ionizing solvent is usually taken to be one that can form electrically conducting solutions. However, the electrical conductivity of a solution is due only to unassociated ions, whereas ion associates such as ion pairs make little or no contribution.

Since the dissociation of ion associates is largely dependent on the dielectric constant (ε) of the solution, it is not surprising that attempts have been made to use the dielectric constant of the solvent as a measure of its ionizing power. This necessarily led to innumerable contradictions, however, since the ionization of a covalent bond cannot be induced merely by a high dielectric constant. Perchloric acid is completely dissociated in water (ε = 81) but completely undissociated in anhydrous sulfuric acid (ε = 80), while triphenylcarbinol is not dissociated in water but is almost completely dissociated in anhydrous sulfuric acid.

[**] The following abbreviations are used in this article: acac: 2,4-pentanedionate (acetylacetonate); en: ethylenediamine; Et: ethyl; Me: methyl; Ph: phenyl. The abbreviations for the solvents are given in Table 2.

2. The Electrostatic Model

When a substance consisting of ions, *i.e.* an ionic crystal, is dissolved, the energy required for the dissolution process is at least mostly supplied by solvation of the ions. The solvate bonds between the ion and the solvent molecule are often partly electrostatic in nature, so that the solvation depends in part on the polarity of the solvent molecules. Since the dielectric constant is also important to the solvation of ions if the interaction is purely electrostatic, the di-

electric constant and the dipole moment are regarded as criteria of the ionizing properties of a solvent [1–4].

These views do not, however, allow a satisfactory description of the formation of ions as a result of the heterolysis of a covalent bond.

3. General Description of Ionization by Coordination

Though *Meerwein* [5] pointed out the importance of complex formation "for increasing the ionizability of weak electrolytes", he had not recognized ionization as a coordination-chemical process. The coordination-chemical approach plays an important part in organic chemistry in the interpretation of the reaction event as a whole, including reactions that proceed by an ionic mechanism. In these reactions the ions are in equilibrium (if equilibrium is in fact reached), but they are usually present only in very low concentrations, and their formation as intermediates is usually shown only by the reaction mechanism.

Though the importance of coordination for ionization and hence for the establishment of ion equilibria in solution (including nonaqueous solvents) has been referred to in several reviews [6–14] during the past few years, this view is not widely enough known and evidently has not been presented in sufficient detail.

Numerous additions or modifications will still have to be made to the description of the ionization of a covalent compound as a coordination phenomenon, particularly in relation to quantitative treatment and reaction mechanisms. Nevertheless, its significance is so general that there appears to be justification for presenting it with the aid of some examples.

A molecule containing predominantly covalent bonds is not ionized by a substantially non-coordinating, though polar, solvent having a high dielectric constant, such as nitrobenzene, and forms nonconducting solutions in such solvents [9]. As will be shown later by numerous examples, ionization occurs only as a result of coordination [9–14], but the degree of ionization also depends on the dielectric constant of the medium. It is therefore convenient to deal separately with the coordination-dependent component of the ionization and the dielectric-dependent component.

3.1. The Coordination-Dependent Component

The case of heterolysis of a covalent bond between unlike atoms,

$$\overset{\delta+}{M}-\overset{\delta-}{X}$$

will increase with increasing attraction or repulsion of electrons from the more electropositive M to the more electronegative X. This is brought about

(a) by nucleophilic attack of an electron donor D at M:

$$D\rightarrow \overset{\delta+}{M}-\overset{\delta-}{X}$$

(b) by electrophilic attack of an electron acceptor A at X:

$$\overset{\delta+}{M}-\overset{\delta-}{X}\rightarrow A$$

Coordination with electron donors in accordance with (a) stabilizes the resulting cations, *e.g.*:

$$(CH_3)_3SnI + D \rightleftharpoons [(CH_3)_3SnD]^+ + I^-$$

Coordination with electron acceptors in accordance with (b), on the other hand, stabilizes the resulting anions: *e.g.*:

$$Ph_3CCl + A \rightleftharpoons [Ph_3C]^+ + [ACl]^-$$

Water owes its outstanding ionizing properties in part to the fact that it can coordinate both with electron pair acceptors (such as protons or many metal ions (*via* the oxygen)) and with electron pair donors, such as anions (with formation of hydrogen bonds) [9].

Whereas the ionization of inorganic compounds is frequently effected by nucleophilic attack by a donor, this is more difficult in organic compounds containing tetracoordinated carbon, and the ionization of organic substances usually results from electrophilic attack by an acceptor.

Finally, it will be shown in Section 7 that even pure covalent bonds, such as occur *e.g.* in the iodine molecule, are ionized by sufficiently strong coordination.

The ionization reactions can be described as substitution reactions. Case (a) is the substitution of X by D at M, and case (b) is the substitution of M by A at X.

The reactions can be precisely described by thermodynamic quantities. The equilibrium positions are determined by the changes in the free enthalpy. The

enthalpy change $\Delta H_{D\cdot A}$ for the formation of the adduct D·A in the gas phase or in an "inert" medium is a measure of the strength of the donor-acceptor bond formed. The degree of ionization will increase with the strength of the resulting coordinate bonds in relation to that of the bonds that are broken.

Increased ionic character of the M–X bond, *i.e.* increased difference in the electronegativities of M and X, means higher bond strengths, with the result that the ionization becomes more difficult. Since the ionization results from a displacement of electrons in the region of the M–X bond, the polarizabilities are important; the greater the polarizabilities, the easier is the ionization. Iodides therefore generally ionize more readily than fluorides. For example, the ease of ionization of the hydrogen halides increases in the order HF $\ll$ HCl $<$ HBr $<$ HI.

In a medium having a low dielectric constant, coordination-induced ionization leads to ion associates, such as ion pairs:

$$\begin{aligned} D + M{-}X &\rightleftharpoons \{[DM]^+[X]^-\}^0 \\ \text{or } M{-}X + A &\rightleftharpoons \{[M]^+[AX]^-\}^0 \end{aligned} \quad (1);\ K_{ion}$$

which make no contribution to the electrical conductivity of the solution. The ionization constant K_{ion} is to be understood as the formation constant of the ion associates in accordance with eq. (1) in a medium having $\varepsilon = 1$.

Large differences in reaction entropy are to be expected between complex formation by neutral donors and by anionic donors, and particularly on transition from weakly solvating to strongly solvating solvents, as will be shown later.

3.2. The Dielectric-Dependent Component

The degree of dissociation [eq. (2)] of the ion associates formed by coordination [eq. (1)] into ions that can migrate independently of each other depends on the dielectric constant (ε) of the medium; the dissociation constant K_{diss} increases with increasing dielectric constant.

$$\begin{aligned} \{[DM]^+[X]^-\}^0 &\rightleftharpoons [DM]^+[X]^- \\ \text{or } \{[M]^+[AX]^-\}^0 &\rightleftharpoons [M]^+[AX]^- \end{aligned} \quad (2);\ K_{diss}$$

The dielectric properties of aprotic donor solvents can be qualitatively described by the dissociation constants K_{diss} found for quaternary ammonium salts in solution in these solvents.

Since the concentration of the ion associates formed in accordance with eq. (1) is decreased by increasing dissociation in accordance with eq. (2), the ionization equilibrium of eq. (1) is disturbed by the dissociation of eq. (2) [9].

The dielectric-dependent component of the ionization is of practically no importance in the comparison of two donor solvents having similar dielectric constant. It must, however, be taken into account in the comparison of solvents having different dielectric constants; its importance increases with decreasing donor strength of the solvents and with increasing difference between their dielectric constants [9].

However, the ionization is always brought about by the coordination-dependent component, while the degree to which it occurs is determined by the interplay of the coordination-dependent and the dielectric-dependent components, as is shown by the following example.

Let three aprotic donor solvents be available for the ionization of the compound M–X, *i.e.*

D_1 with $\varepsilon = 10$ and medium donor strength,

D_2 with $\varepsilon = 35$ and medium donor strength,

D_3 with $\varepsilon = 10$ and high donor strength.

Let us assume that in the two solvents of medium donor strength (D_1 and D_2), the ionization constants for the coordination-dependent ion pair formation in accordance with eq. (1) is $K_{ion} = 1$, and let the corresponding constant in the solvent of high donor strength (D_3) be $K_{ion} = 3$. On the basis of the assumed dielectric constants, the dissociation constants for the dissociation of the ion associates in accordance with eq. (2) are $K_{diss} \approx 10^{-4}$ for D_1 and D_3, and $K_{diss} \approx 10^{-2}$ for D_2. Calculation now shows that M–X can be ionized to a greater degree in a solvent having a low dielectric constant but a high donor strength (D_3) than in a solvent having a high dielectric constant but only a medium donor strength (D_2) (Table 1).

Table 1. Extent of ionization of M–X at $c = 10^{-2}$ mole/l under the arbitrarily assumed conditions.

Solvent	Assumed ε	K_{diss}	Donor strength	Assumed K_{ion}	% Ionization
D_1	10	10^{-4}	medium	1	53
D_2	35	10^{-2}	medium	1	75
D_3	10	10^{-4}	high	3	77

The dissociation constants of acids and bases may therefore be used for comparison of the acid strengths or base strengths in a given solvent, *i.e.* at a fixed dielectric constant, but the dissociation constants of a given acid or base in solvents with different dielectric constants cannot be compared. Though NH_3 is a stronger donor than water, hydrogen chloride has a much smaller acid constant in liquid ammonia than in water. The reason for this is that though the ionization in accordance with eq. (1) takes place to approximately the same extent in both solvents, the dissociation of the ion pairs in accordance with eq. (2) is more extensive in water, owing to the high dielectric constant of this solvent. On the other hand, the acid constant of acetic acid is about the same in both solvents, since acetic acid is much more strongly ionized in accordance with eq. (1) in liquid ammonia.

Thus the coordination in accordance with eq. (1) is always the initiating factor, and the dielectric constant of the solvent is the regulating factor, in the ionization of a covalent compound.

4. Ionization by Nucleophilic Attack by Donors

The degree of ionization of a given compound M–X by nucleophilic attack of a neutral donor increases with increasing stability of the resulting cation $[DM]^+$ in comparison with that of the unionized M–X [9–14a]. In many cases this is the same as saying that the coordinate bond D–M formed must be stronger than the M–X bond that must be broken.

The strength of a coordinate bond depends on:

1. the donor properties of the donor,
2. the acceptor properties of the acceptor,
3. steric effects, and
4. specific interactions such as hydrogen bonding.

4.1. Donor Properties of Donors

The donor strength of a molecule for the formation of charge-transfer complexes is considered to be given as an absolute property of the molecule by the ionization energy [15].

Since the ionization potential of a molecule is defined as the energy required to remove an electron completely from the gaseous molecule, whereas the electron remains in the molecule in the formation of a donor-acceptor bond, it is clear that no information about the electron pair donor properties can be obtained from the ionization potentials [14a]. For example, the ionization potentials of pyridine and xylene are very similar, as are those of methylamine and benzene; CS_2 has roughly the same ionization potential as NH_3 or $(CH_3)_2O$, and those of hexane and ethanol are also roughly equal.

It is therefore convenient to define the donor strength as a relative quantity with respect to a reference acceptor [16]. The experimental determination of the degree of interaction between a donor and the reference acceptor is also simple, since ΔH and ΔG values for donor-acceptor reactions in a substantially inert solvent are relatively easy to obtain.

Antimony(v) chloride was chosen as the reference acceptor, since it forms 1:1 adducts with many donors.

$$D + SbCl_5 \rightleftharpoons D{\cdot}SbCl_5; \quad -\Delta H_{D\cdot SbCl_5}$$

$$K_{D\cdot SbCl_5} = \frac{a_{D\cdot SbCl_5}}{a_D{}^a \times a_{SbCl_5}}$$

On investigation of this reaction with several neutral donors in highly dilute solution in a fairly inert medium, *i.e.* 1,2-dichloroethane, it was found that $\log K_{D\cdot SbCl_5}$ is proportional to $-\Delta H_{D\cdot SbCl_5}$ [10 to 12, 14, 16, 17] (Fig. 1); the entropy contributions are therefore constant in these reactions

$$a \log K_{D\cdot SbCl_5} + b = -\Delta H_{D\cdot SbCl_5} = DN_{SbCl_5} \equiv Dn$$

It is therefore justifiable to use the ΔH value as a measure of the donor properties with respect to $SbCl_5$. The negative $\Delta H_{D\cdot SbCl_5}$ value is known as the donor number DN_{SbCl_5}, donor intensity, or donicity Dn [10–12, 14, 16, 17]. It is also a measure of the nucleophilicity or the Lewis base strength.

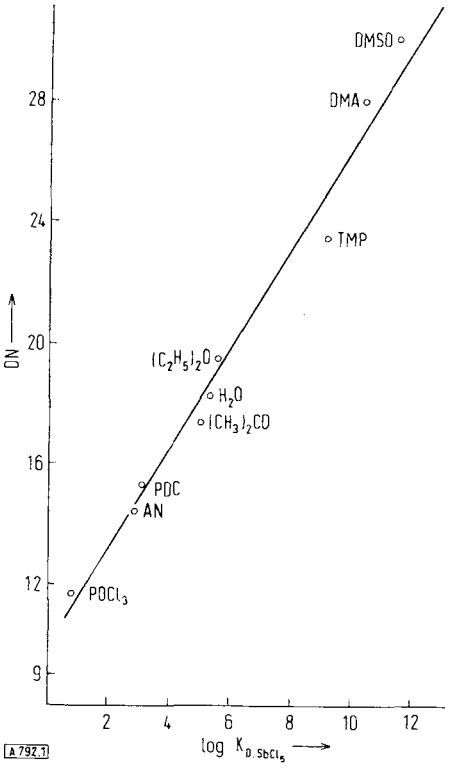

Fig. 1. Relation between Dn ($-\Delta H_{D\cdot SbCl_5}$) and log $K_{D\cdot SbCl_5}$ for several donors D.

The donicity expresses the total interaction of a donor with $SbCl_5$, including the electrostatic interactions. The reaction enthalpies of many donor-acceptor reactions using the same donor D are proportional to the acceptor strength of A, *e.g.* iodine, phenol, trimethyltin chloride, and many ions of d metals [10, 16]. The entropy components are again constant here.

The donicity of a donor solvent thus also approximately expresses the donor strength with respect to this acceptor. It would be an unrealistic, though very useful, approximation to regard the donicity as a molecular property; it cannot be determined strictly quantitatively, since the ability to form a coordinate bond also depends on the properties of the other

reactant. Donicity is therefore a qualitative, at best semiquantitative value, like electronegativity, which is nevertheless extremely useful.

In this sense, the donicity has proved to be a valuable guide in the assessment of the ionizing power of a donor. The ionizing power of a donor solvent generally increases with its donicity and its dielectric constant (Table 2).

Hexamethylphosphoramide (HMPA)	(38.8) [a]	30.0

[a] Under the conditions of the calorimetric measurement, partial ionization of the adduct $SbCl_5$ · HMPA is found to take place.

Conductivity measurements on the donor-acceptor system in a substantially inert solvent having a sufficiently high dielectric constant, such as nitrobenzene (*Dn* = 4.4; ε = 34.8 at 25 °C) [9], may be used for the determination of the coordination-dependent contribution.

Figures 2 and 3 show the changes in the equivalent conductivities of $(CH_3)_3SnI$ solutions in nitrobenzene ($c \approx 7 \times 10^{-2}$ mole/l) on addition of donors. A comparison of the conductivities at given molar ratios of donor to acceptor show that they increase with increasing donicity of the donor (exception: pyridine). The conductivity in nitrobenzene is a measure only of the content of free ions, and not of the content of associated ions. The content of associated ions is proportional to the content of free ions if the association constants of the associated ion pairs are approximately the same [9]. This is in fact so in this case, as is shown by conductivity measurements on $(CH_3)_3SnI$ in the strong donor solvents HMPA, DMSO, DMF, and pyridine and their evaluation by the method of *Fuoss* and *Kraus*, according to which $(CH_3)_3SnI$ is completely ionized as a 1,1 electrolyte in HMPA, DMSO, or DMF [9].

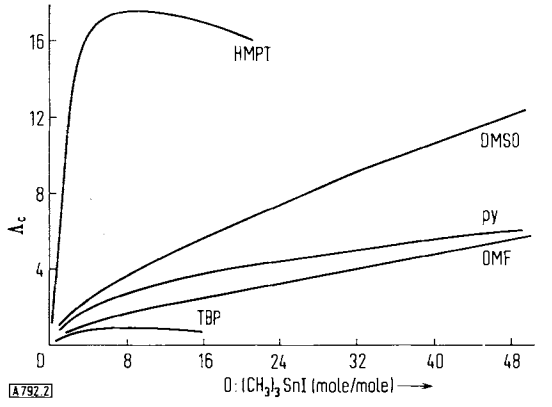

Fig. 2. Equivalent conductivity of 7×10^{-2} M $(CH_3)_3SnI$ solutions in nitrobenzene in the presence of aprotic donor solvents, upper region (HMPT = HMPA).

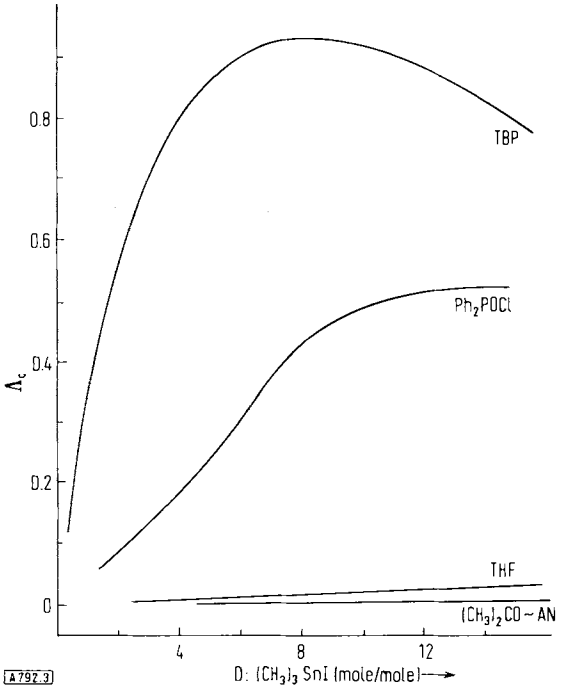

Fig. 3. Equivalent conductivity of 7×10^{-2} M $(CH_3)_3SnI$ solutions in nitrobenzene in the presence of aprotic donor solvents, lower region.

It follows that comparison of the equivalent conductivities at a constant molar ratio in nitrobenzene gives a direct measure of the relative ionizing power of donor solvents, which increases in the order nitrobenzene < acetonitrile < acetone < THF < Ph_2POCl < tributyl phosphate < DMF (?) < pyridine < DMSO < HMPA.

The proportionality between the donicity and the ionizing power of a donor solvent for $(CH_3)_3SnI$ can be demonstrated directly only if the donor strengths of the donors toward $(CH_3)_3SnI$ are known. These

thermodynamic data are not obtainable, but quantitative data on the $\Delta H_{D\cdot A}$ values have been reported for the adduct formation between $(CH_3)_3SnCl$ and the donors investigated. Since the corresponding enthalpies of adduct formation for the acceptor molecules $(CH_3)_3SnCl$ and $(CH_3)_3SnI$ will be proportional, the relation between the donicity and the ionizing power appears to be obvious.

Another example of the increasing ionization of a metal compound with increasing donicity of the donor solvent is found in the behavior of cobalt(II) iodide[10,13,14]. In nitromethane (NM; *Dn* = 2.7, ε = 35.9), this compound forms a tetrahedral adduct $CoI_2(NM)_2$, which is molecularly dissolved[18]. Partial ionization with self-complexing (see Section 6) occurs in propylene carbonate (*Dn* = 15.1, ε = 69), while complete ionization occurs in a solvent having a high donicity (DMSO; *Dn* = 29.8)[19], *e.g.*

$$CoI_2 + 6\,DMSO \rightleftharpoons [Co(DMSO)_6]^{2+} + 2\,I^-$$

Even when a large supply of iodide ions is present, iodide ions do not enter the coordination sphere of the hexasolvated metal ion, since the donor properties of the solvent molecule are incomparably better than those of the iodide ion[14,19]. Since the donor properties of the chloride ion are much better and the strength of the Co–Cl bond is similar to that of the Co–DMSO bond, $CoCl_2$ is not completely ionized in DMSO[10,19,20].

4.2. The Solvation of Anions in Donor Solvents

Ionization by nucleophilic attack can naturally be effected not only by neutral donors but also by ions. Thus the halide and pseudohalide ions are donors. In a donor solvent, the anions must compete with the solvent molecules, and may therefore be regarded, in relation to these molecules, as competing ligands. Ionization by anions is therefore possible in a non-coordinating or weakly coordinating solvent.

$$M{-}X + n\,X^- \rightleftharpoons [MX_{(n+1)}]^{n-} \qquad (3)$$

As was mentioned earlier, both $(CH_3)_3SnI$ and CoI_2 form nonconducting solutions in the practically non-coordinating solvent nitromethane (*Dn* = 2.7, ε = 35.9). If iodide ions are added, the stoichiometric quantity is sufficient for the formation of the iodo complex.

In a donor solvent whose donor properties are not very different from those of the iodide ions, on the other hand, an excess of iodide ions must be used to achieve complete formation of the iodo complex. Finally, with a neutral donor whose donor properties are much better than those of the competing ligand, ionization by nucleophilic attack of D takes place instead of formation of the halogenometalate, even when X^- is present in a large excess[19] (Table 3).

Table 3. Molar ratio X^- : Co^{2+} required for quantitative formation of $[CoX_4]^{2-}$ from Co^{2+} and X^- in solvents having different donicities.

Donor	*Dn*	N_3^-	Cl^-	Br^-	I^-
NM	2.7	4	4	4	5
PDC	15.1	4	4.5	4.3	7.8
AN	14.1	8	16	40	[a]
DMA	27.8	4	16	[a]	[a]
DMSO	29.8	20	200	[a]	[a]
HMPA	38.8	27	460	[a]	[a]

[a] No formation of $[CoX_4]^{2-}$ even at molar ratios greater than 200.

Any attempt to fix the donicity for competing ligands X^-, *e.g.* halide and pseudohalide ions, meets with fundamental difficulties, since the assumption that has been tacitly made so far, *i.e.* that the strength of the metal-ligand bond depends mainly on the nature of the ligand and not on the nature of the acceptor, is invalid.

Measurements on the equilibria between bis(2,4-pentanedionato)oxovanadium $[VO(acac)_2]$ and X^- show[21] that the order of the donor strengths of halide and pseudohalide ions toward $VO(acac)_2$ is: $I^- < Br^- < Cl^- < (F^-) \approx NCS^- < N_3^- \approx (CN^-)$. Their donor properties are roughly compared in Figure 4 with those of a number of solvent molecules

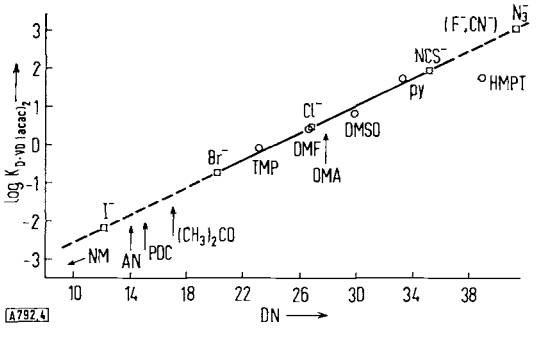

Fig. 4. log $K_{D\cdot VO(acac)_2}$ values for halide and pseudohalide ions and aprotic donor solvents, and their relation to *Dn* (HMPT = HMPA).

Table 4. ΔG^0 values for the reactions of halide and pseudohalide ions and neutral donors with $VO(acac)_2$ in acetonitrile, and donicities of the donors.

Donor	$G^0_{D\cdot VO(acac)_2}$	*Dn*
N_3^-	−4.2	(42)
CN^-	−4.2	(42)
NCS^-	−2.7	(35)
F^-	−2.7	(35)

PDC	+1.75	15.1
I^-	2.0	(14)

[18] *V. Gutmann* and *K. H. Wegleitner*, Monatsh. Chem. *99*, 368 (1968).

[19] *V. Gutmann* and *O. Bohunovsky*, Monatsh. Chem. *99*, 740 (1968).

[20] *V. Gutmann* and *L. Hübner*, Monatsh. Chem. *93*, 1261 (1962).

[21] *V. Gutmann* and *U. Mayer*, Monatsh. Chem. *99*, 1382 (1968).

(neutral donors), but it should be emphasized that the "donicities" for X^- ions are not identical with the reaction enthalpies $-\Delta H_{X^-\cdot SnCl_5}$, and are therefore given in parentheses in Table 4.

Table 5 shows that the entropies of solvation of halide ions are much higher in DMSO than in water, since water has a more pronounced liquid structure than DMSO. In general, the donor strength of X^- decreases with increasing solvation [14a].

Table 5. ΔG^0, ΔH^0, and ΔS^0 for the solvation of halide ions in DMSO and H_2O.

	Solvent	Cl^-	Br^-	I^-
ΔG^0	DMSO	−56.4	−52.6	−47.5
(kcal · mole^{-1})	H_2O	−67.4	−60.4	−51.3
ΔH^0	DMSO	−67.9	−63.4	−56.8
(kcal · mole^{-1})	H_2O	−72.8	−64.7	−54.3
ΔS^0	DMSO	−38.4	−36.1	−31.4
(cal · mole^{-1} deg^{-1})	H_2O	−18.2	−14.4	−10.1

According to Table 6, the free enthalpies of solvation of the halide ions are lower in HMPA than in the other donor solvents, *i.e.* HMPA is only weakly solvating. The difference between the ΔG^0 values for the Cl^- ion in DMSO and in HMPA is 4.5 kcal · mole^{-1}. The donor strength of the Cl^- ion is accordingly higher in HMPA than in DMSO. The formation of the $[CoCl_4]^{2-}$ complex in HMPA (with a large excess of Cl^-), which is unexpected on the basis of the donicity, is explained by the relative increase in the donor strength of the chloride ion due to the extremely low solvation [14a].

Table 6. Free enthalpies of solvation ΔG^0 (kcal · mole^{-1}) of halide ions in donor solvents.

Donor	Cl^-	Br^-	I^-
AN	−55.4	−51.8	−46.0
Sulfolane	−56.0	—	−46.0
H_2O	−67.4	−60.4	−51.4
DMF	−55.1	−50.8	−45.7
DMA	−53.3	−49.4	−45.1
DMSO	−56.4	−52.6	−47.5
HMPA	−51.9	−47.8	—

However, the formation of the $[CoCl_4]^{2-}$ ion in DMSO is also unexpected, since the chloride ion in acetonitrile is a weaker donor than DMSO. Thus the decrease in the donor strength of an X^- ion on transition from the gas phase into a solvating medium also depends on the ratio of the free enthalpy of solvation to the free enthalpy of reaction of the complex formation process as a whole. The greater the latter value, the weaker is the influence of solvation [14a]. Since this thermodynamic effect and the solvation effect (the Cl^- ion is more strongly solvated in DMSO than in acetonitrile) partly balance each other, $[CoCl_4]^{2-}$ is formed in DMSO only in the presence of a large supply of chloride ions. In dimethylacetamide (DMA), on the other hand, these two effects reinforce each other, so that the complex is formed much more readily in DMA, despite the similarity of the donicities of DMSO and DMA [14a].

The tendency to solvate anions decreases in the series: $H_2O > ROH \gg DMSO \approx ES > AN \approx NM > DMF > DMA > HMPA$.

4.3. Acceptor Properties of MX

The $\Delta H_{D\cdot A}$ values are roughly proportional to the donicity of the donor for A = iodine, phenol, trimethyltin chloride, and antimony(III) chloride, and the entropy contributions are constant in these cases (Fig. 5) so that for the interaction of the donors with these acceptors, the donicity of the donor is an approximate measure of the ionization of the acceptor.

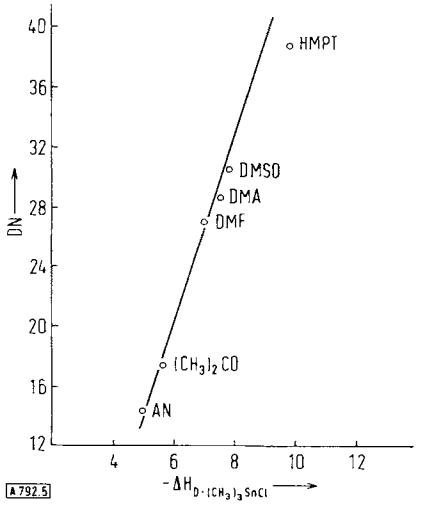

Fig. 5. Relation between *Dn* and $-\Delta H_{D\cdot(CH_3)_3SnCl}$ (HMPT = HMPA).

Polarographic studies, which will not be described in detail here [22], have shown that numerous metal ions, *e.g.* Mn^{2+}, Zn^{2+}, Cr^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+}, also approximately satisfy the conditions mentioned. As will be shown later, however, the situation may be more complicated because of the higher coordination numbers toward the donor molecules.

The deviations from the donicity-ionizing power relation become pronounced in the case of very "hard" or very "soft" metal ions [23].

Hard ions, such as the alkali metal ions, may be ignored in the present discussion in view of their low tendency to form covalent bonds, but the situation presented by very soft metal ions may be discussed.

The readily polarizable, soft metal ions include in particular the ions of noble metals in low oxidation states [23], *e.g.* Pd^{2+}, Pt^{2+}, Ag^+, and Hg_2^{2+}. These ions react preferentially with readily polarizable donor atoms, *i.e.* I > Br > Cl ≫ F; Te ≈ Se ≈ S ≫ O; Sb ≈ As ≈ P ≫ N. Their iodides are thus more difficult to ionize than their chlorides. The ionizability of silver halides in water increases in the order AgI < AgBr < AgCl ≪ AgF, and is generally increased by interaction with the strong donor ammonia.

[22] *V. Gutmann* and *R. Schmid*, Monatsh. Chem. *100*, 2113 (1969).

[23] *R. G. Pearson*, J. Amer. Chem. Soc. *85*, 3533 (1963).

Moreover, the concept of the donicity can no longer be used, since the neutral donors with S or P donor atoms, *e.g.* triphenylphosphine, can stabilize the cations better than the O and N donors discussed so far.

Whereas tin(IV) iodide, as expected, is extensively ionized in DMSO (high donicity of DMSO and low donicity of the iodide ion), the same solvent causes practically no ionization of mercury(II) iodide, the metal ion of which is soft [24]. This is partly because $mercury^{II}$ binds iodide ions much more strongly than tin^{IV}, and partly because DMSO is preferentially coordinated *via* the sulfur to the mercury(II) ion, but *via* the oxygen to tin(IV) iodide. Since the Hg^{II}-S bond is weaker than the Sn^{IV}-O bond and the Hg^{II}-I bond is stronger than the Sn^{IV}-I bond, ionization of HgI_2 in DMSO is practically impossible, and iodo complexes can in fact be formed in this medium [24]:

$$\begin{array}{rcl} SnI_4 + 4\,DMSO & \rightleftharpoons & [SnI_2(DMSO)_4]^{2+} + 2I^- \\ HgI_2 + 2\,I^- & \rightleftharpoons & [HgI_4]^{2-} \\ \hline SnI_4 + 4\,DMSO + HgI_2 & \rightleftharpoons & [SnI_2(DMSO)_4]^{2+}[HgI_4]^{2-} \end{array}$$

The assumption made in the early sections that the donor-acceptor interaction is almost independent of the properties of the acceptor is thus valid only for a certain group of acceptors, *i.e.* those that are neither very hard nor very soft, and for these acceptors the concept of donicity can be used.

4.4. Steric Effects

Steric effects will become apparent above all when the acceptor ions or molecules are small and have a high coordination number with respect to the donors, and/or when the donor molecules are very bulky.

Whereas the cobalt(II) ion is octahedrally coordinated by nearly all the solvent molecules listed in Table 1 [10,19], tetrahedral coordination occurs in hexamethylphosphoric triamide (HMPA) [25], evidently because of the great bulk of the donor molecules. The enthalpy of solvation of the $[Co(HMPA)_4]^{2+}$ ion is much lower than one would expect from the donicity of HMPA, whereas the enthalpy of solvation of $CoI_2(HMPA)_2$ is roughly as expected [26]. It has already been mentioned that iodide ions cannot enter the coordination sphere of the cobalt(II) ion solvated with DMSO. Though HMPA has a higher donicity than DMSO, it is easy to replace an HMPA molecule by iodide on cobalt [26]:

$$[Co(HMPA)_4]^{2+} + I^- \rightleftharpoons [Co(HMPA)_3I]^+ + HMPA$$

It is clear from these two phenomena that the solvating bonds are significantly weaker in $[Co(HMPA)_4]^{2+}$ than in $CoX_2(HMPA)_2$.

Investigation of the solvent complexes with the aid of broad-line NMR spectroscopy have also shown that the coordination center in $[Co(HMPA)_4]^{2+}$ moves in relation to the ligand shell at room temperature [26]. The cobalt(II) ion "rattles", so to speak, in the relatively rigid ligand framework formed by four HMPA molecules. This "rattling effect" does not occur in $CoX_2(HMPA)_2$, since the HMPA molecules no longer hinder each other and can move close enough to the coordination center to form relatively rigid solvating bonds. Accordingly, it is practically impossible to substitute the last two HMPA molecules, whereas the first HMPA molecule in $[Co(HMPA)_4]^{2+}$ can be displaced even by a weak donor such as the iodide ion [26]. The ease of substitution increases with the donicity of the competing ligand ($I^- < Br^- < Cl^-$). All four possible complexes are formed in the chloro system, only the first two, *i.e.* $[Co(HMPA)_3Br]^+$ and $[Co(HMPA)_2Br_2]$, in the bromo system, and essentially only $[Co(HMPA)_3I]^+$ in the iodo system, since CoI_2 is largely ionized in HMPA [27].

$$[Co(HMPA)_2I_2] + HMPA \rightleftharpoons [Co(HMPA)_3I]^+ + I^-$$

4.5. Specific Donor-Acceptor Interactions

"Specific donor-acceptor interactions" refers collectively to all the factors that have not yet been discussed and that influence the degree of the coordination-dependent ionization, except kinetic effects. These factors are mostly concerned with the nature of the donor-acceptor bond. It is known, for example, that the free enthalpies of hydration of some metal ions, *e.g.* Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Cd^{2+}, are greater than one would expect from the donicity [11]. This effect has been attributed to the additional bonding of the water molecules coordinated to the metal ion by hydrogen bonds, and the hydration shell reinforced in this way has been referred to as the "Royal Core of Water Molecules" [28–31]. It has recently been shown that this effect occurs particularly with softer metal ions, but not with the alkali or alkaline earth metal ions [11].

It can be seen from the behavior of $(CH_3)_3SnI$ described above that pyridine and dimethylformamide have approximately equal ionizing properties for $(CH_3)_3SnI$ in nitrobenzene, whereas DMF should have a weaker action than pyridine according to the donicities. Evaluation of the results of conductivity measurements on solution of $(CH_3)_3SnI$ in pure DMF shows that the ion association here is higher than expected. This ion association is chemical in nature; the acidity of the formyl protons is probably

[29] *C. K. Jørgensen*: Inorganic Complexes. Academic Press, New York 1963, p. 21 ff.

[30] *L. I. Katzin*, J. Chem. Phys. *23*, 2055 (1955).

[31] *L. I. Katzin*, J. Chem. Phys. *36*, 3034 (1962).

increased to such an extent by coordination of DMF to Sn that hydrogen bonds are formed to the iodide ions. This interpretation agrees with the results of ^{1}H-NMR studies. Only in infinitely dilute solution do the coordinated DMF molecules lose their ability to coordinate with the iodide ions, and they can then coordinate only with the solvent molecules. The coordinated $[Sn(CH_3)_3]^+$ cation carries with it a "second" solvent layer, and is therefore rather less mobile [9].

This interpretation does not conflict with the fact that alkali metal halides are practically completely dissociated in DMF. On the contrary, it is possible to see the analogy with the acidities of aqueous solutions of alkali metal ions, which do not exercise any acidic function, since the partly electrostatic hydration leaves the bonding in the water molecules of the hydrate almost unchanged from that in the free water molecules [11]. On the other hand, coordination of water with formation of more strongly covalent bonds, *i.e.* with soft metal ions, leads to increased acidity and to an increased tendency toward hydrogen bond formation [11] (see Table 7).

Table 7. Enthalpies of hydration and pK_a of pairs of hydrated ions of the same charge and of similar ionic radius.

Aquo ions	Property	r_0 (ion) (Å)	$-\Delta H$ (kcal/mole)	pK_a in water at 25 °C
Na^+	hard	0.96	93	14
Cu^+	soft	0.95	115	11
K^+	hard	1.33	73	14
Ag^+	soft	1.26	112	10
Mg^{2+}	hard	0.65	437	12.2
Cu^{2+}	soft	0.69	499	7.3
Ca^{2+}	hard	0.99	362	12.6
Cd^{2+}	soft	0.97	428	9.0
Sr^{2+}	hard	1.13	327	13.1
Hg^{2+}	very soft	1.10	443	3.6

The specific interactions also include π-donor interactions of some donors with certain acceptors. The donicity of benzene is very low, since it has practically no n-donor properties and exhibits no π-donor properties toward $SbCl_5$. It can, however, act as a π-donor *e.g.* toward iodine or aluminum halides. $AlBr_3$ and benzene exhibit considerable electrical conductivity, particularly in the presence of hydrogen halide [32, 33].

5. Ionization by Electrophilic Attack of Acceptors

Triphenylchloromethane is molecularly dissolved in most donor solvents, for example acetonitrile, and is ionized only on addition of acceptors. The acceptor strength, which is a direct measure of the electron affinity, is important to the degree of ionization. In addition to the coordination-dependent component of the ionization, the dielectric-dependent component must also be considered. This component can be eliminated to allow the study of the coordination-dependent component by carrying out the investigations in an inert solvent having a suitable dielectric constant, *e.g.* acetonitrile. The behavior of triphenylchloromethane in acetonitrile on addition of various acceptors is determined by the acceptor strengths of acetonitrile and of the additives. Trihalides and pentahalides are found to be strong acceptors for chloride ions, while dihalides and tetrahalides are much weaker. The $[Ph_3C]^+$ ion is always formed in the same unsolvated state, irrespective of the acceptor and the solvent [34]. Dichlorides, trichlorides, and pentachlorides coordinate with one chloride ion to form mononuclear complexes, while tetrachlorides coordinate either with one chloride ion to form dinuclear complexes or with two chloride ions per acceptor molecule to form mononuclear anionic complexes. However, the ion pair does not dissociate to the expected degree.

The formation constants of the chloro complexes depend both on the nature of the acceptor and on the solvent. As is shown by Table 8, the formation constants are greater in acetonitrile (Dn = 14.1) than in phenylphosphorus oxide dichloride (Dn = 18.5) [35], as expected.

Table 8. log K values of the $[Ph_3C]^+[MCl_{(n+1)}]^-$ complexes in acetonitrile (AN) and $PhPOCl_2$.

Acceptor chloride	Chloro complex	log K in AN	log K in $PhPOCl_2$

PCl_5	$[PCl_6]^-$	0.5	−2.50
$SbCl_5$	$[SbCl_6]^-$	5.1	1.56

For metals of the same period, chlorides with even numbers of ligands (dichlorides and tetrachlorides) are weaker chloride ion acceptors than those with odd numbers of ligands (trichlorides and pentachlorides). Lone pairs of electrons act as pseudoligands; for example, $SbCl_3$ acts as a pseudotetrachloride and $TeCl_4$ as a pseudopentachloride. However, the lone pairs of electrons basically reduce the affinity for chloride ions, so that $SbCl_3$ is a weaker chloride ion acceptor than $SnCl_4$, and $TeCl_4$ is weaker than $SbCl_5$. The chlorometalate ions also follow this rule. Moreover, the formation constants also depend on the size of the acceptor; for chlorides of a given group they increase from the first period to the fifth, but decrease slightly in the sixth [35]: $BCl_3 < AlCl_3 < GaCl_3 < InCl_3 < TiCl_3$; $SiCl_4 < GeCl_4 < SnCl_4 < PbCl_4$.

[35] *M. Baaz*, *V. Gutmann*, and *O. Kunze*, Monatsh. Chem. *93*, 1162 (1962).

In the absence of an "inert" medium, triphenylchloromethane ionizes in acceptor solvents, *e.g.*

$$Ph_3CCl + HCl \rightleftharpoons [Ph_3C]^+[HCl_2]^-$$
$$Ph_3CCl + AsCl_3 \rightleftharpoons [Ph_3C]^+[AsCl_4]^-$$

the degree of ionization increasing with the acceptor strength of the solvent and with its dielectric constant. Ph_3CCl is practically 100% ionized and dissociated in anhydrous sulfuric acid.

Further examples of ionization by electrophilic attack of an acceptor are the formation of nitrosyl compounds from nitrosyl halide and acceptor halide [36–39]:

$$NOCl + FeCl_3 \rightleftharpoons [NO]^+ + [FeCl_4]^-$$
$$NOF + BrF_3 \rightleftharpoons [NO]^+ + [BrF_4]^-$$

the ionization of $SbCl_5$ in excess Ph_2POCl [40]:

$$Ph_2POCl + SbCl_5 \rightleftharpoons [Ph_2PO]^+ + [SbCl_6]^-$$

and the ionization of acceptors in weak acceptor solvents, *e.g.* in liquid bromine(III) fluoride [41]:

$$(BrF_3)_{(n+1)} + NbF_5 \rightleftharpoons [(BrF_3)_nBrF_2]^+ + [NbF_6]^-$$

or in liquid sulfur dioxide [42]:

$$SbCl_5 \cdot CH_3COCl \overset{SO_2}{\rightleftharpoons} [CH_3CO]^+ + [SbCl_6]^-$$

6. Autocomplexing (Ligand Disproportionation)

It has already been said that the degree of ionization in a donor solvent increases with decreasing donor strength of the competing ligand X^-, and that there is a relatively high tendency toward the formation of anionic complexes in a solvent having a very low donicity [10, 14]:

$$MX + n\,X^- \rightleftharpoons [MX_{n+1}]^{n-} \qquad (3)$$

If the bond energies of M–D and M–X are not too different, both processes, *i.e.* ionization and complex formation with competing ligands, can occur together. The competing ligands X^- liberated by ionization of M–X bonds in accordance with reaction (1) can compete with the neutral donors in a nucleophilic attack on unionized M–X units in accordance with reaction (3) to form anionic complexes. The result is known as autocomplexing or ligand disproportionation [eq. (4)]:

$$2\,MX + n\,D \rightleftharpoons [MD_n]^+[MX_2]^- \qquad (4)$$

The dielectric constant naturally also plays a part in autocomplexing. If two solvents having equal donicities but different dielectric constants are available, stronger autocomplexing is to be expected in the solvent with the higher dielectric constant.

Tin(IV) iodide forms a yellow, non-conducting solution in nitrobenzene [43]. On addition of a donor, the solution becomes electrically conducting. At $D:SnI_4 = 4:1$, the conductivity increases with the *Dn* of the donor: THF < TBP < DMF < DMSO < HMPA (Fig. 6). At $D:SnI_4 = 2:1$, autocomplexing predominates, with formation of the red ion $[SnI_6]^{2-}$.

$$3\,SnI_4D_2 \rightleftharpoons 2\,[SnI_3D_3]^+ + [SnI_6]^{2-}$$

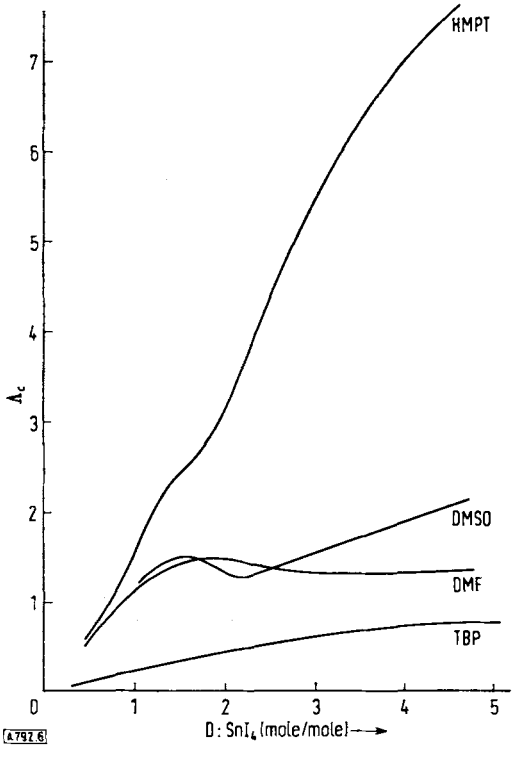

Fig. 6. Equivalent conductivity of $\approx 10^{-2}$ M SnI_4 solutions in nitrobenzene in the presence of aprotic donor solvents (HMPT = HMPA).

Breakdown of the hexaiodostannate ion begins at higher donor concentrations:

$$[SnI_6]^{2-} + 2\,D \rightleftharpoons [SnI_4D_2] + 2\,I^-$$

The iodide ions liberated react with the cation, again with reformation of the adduct [43]

$$[SnI_3D_3]^+ + I^- \rightleftharpoons [SnI_4D_2] + D$$

This is the reason for the change in the course of the curve in the region of $D:SnI_4 = 2:1$, as well as for the decrease in the intensity of the spectrum of the

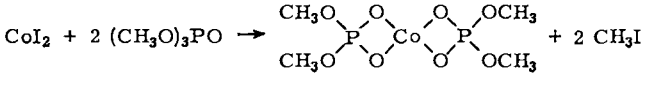
hexaiodostannate ion. The increase in conductivity on further addition of donor, which is observed particularly in HMPA, is due to the ionization of the adduct [43]:

$$[SnI_4D_2] + n\,D \rightleftharpoons [SnI_{(4-n)}\ D_{(n+2)}]^{n+} + n\,I^-$$

SnI_4 gives yellow solutions in nitrobenzene (molecularly dissolved SnI_4), slightly orange-yellow in THF (weak autocomplexing), deep red in tributyl phosphate (extensive autocomplexing), pale red in DMF (autocomplexing and ionization to form free iodide ions), and colorless in DMSO (no autocomplexing, but ionization) [43]. According to *Gaizer* and *Beck* [24], the ionization in very dilute DMSO solution may proceed as far as the formation of the solvated Sn^{4+} ion [24].

Cobalt(II) iodide is molecularly dissolved in nitromethane (NM; $Dn = 2.7$) [13]. Partial autocomplexing occurs in acetonitrile (AN; $Dn = 14.1$), and autocomplexing is practically complete in propylene carbonate (PDC; $Dn = 15.1$, $\varepsilon = 69$) [14,18]:



$$CoI_2 + 2\,NM \rightleftharpoons [CoI_2(NM)_2]$$

$$2\,CoI_2 + 6\,PDC \rightleftharpoons [Co(PDC)_6]^{2+} + [CoI_4]^{2-}$$

In DMSO ($Dn = 29.8$), the cationic solvate $[Co(DMSO)_6]^{2+}$ is so much more stable than Co units with iodide as ligands that complete ionization occurs instead of autocomplexing [19].

$$CoI_2 + 6\,DMSO \rightleftharpoons [Co(DMSO)_6]^{2+} + 2\,I^-$$

The situation in trimethyl phosphate is special, in that chelation can occur [44], *e.g.*

The self-ionization of water may also be regarded as coordination-induced autocomplexing, since the ionization of the covalent H–O bonds is a consequence of the coordination of water molecules by water molecules (with formation of hydrogen bonds). The self-ionization of the solvent therefore increases with increasing energy of the hydrogen bonds in the order $NH_3 < ROH < H_2O < HF$. Accordingly, weakly coordinating solvents such as liquid sulfur dioxide exhibit practically no self-ionization.

7. Some Further Examples of Coordination-Induced Ionization

Though numerous observations in nonaqueous solutions have been reported, it is difficult in most cases to coordinate the results, owing to the difference in the conditions under which they were obtained. Though a complete and above all critical discussion would be beyond the scope of this article, some arbitrarily chosen examples will be presented to illustrate what has been said in previous sections.

7.1. Boron(III) Halides

The ionization of boron(III) halides increases with increasing donicity of the solvent ($POCl_3 <$ $PhPOF_2 <$ $PhPOFCl <$ $PhPOCl_2 <$ $Ph_2POF <$ $Ph_2POCl <$ TBP < TMP < Ph_3PO < py < HMPA) and with decreasing strength of the B–X bond (*i.e.* $BF_3 <$ $BCl_3 <$ BI_3). The trihalides form adducts in nitrobenzene that do not make the solution conducting.

BF_3 and phosphoryl donors give adducts $R_3PO(BF_3)_2$ as well as those having the composition $R_3PO{\cdot}BF_3$. The equilibrium constants $K_{D\cdot BF_3}$ for the reactions

$$PhPOCl_2 \cdot BF_3 + D \rightleftharpoons PhPOCl_2 + D \cdot BF_3;\quad K_{D\cdot BF_3}$$

increase with the *Dn* of the donor [45]. The conductivity of the solutions in nitrobenzene at the composition $D \cdot BF_3$ is due to the presence of the ions formed by weak autocomplexing [45]:

$$2\,D \cdot BF_3 \rightleftharpoons [D_2BF_2]^+ + [BF_4]^-$$

The molar conductivities of the corresponding systems with boron(III) chloride are higher than those with BF_3, and at a molar ratio $D:BCl_3 = 1:1$ they increase with the *Dn* of the donor [40] ($POCl_3 <$ $PhPOF_2 <$ $PhPOFCl <$ $PhPOCl_2 <$ $Ph_2POCl <$ HMPA). The conductivity curves (Fig. 7) have a change of slope at a molar ratio $D:BCl_3 = 1:1$, which is due to the ionization by autocomplexing that has occurred up to this point:

$$2\,D \cdot BCl_3 \rightleftharpoons [D_2BCl_2]^+ + [BCl_4]^-$$

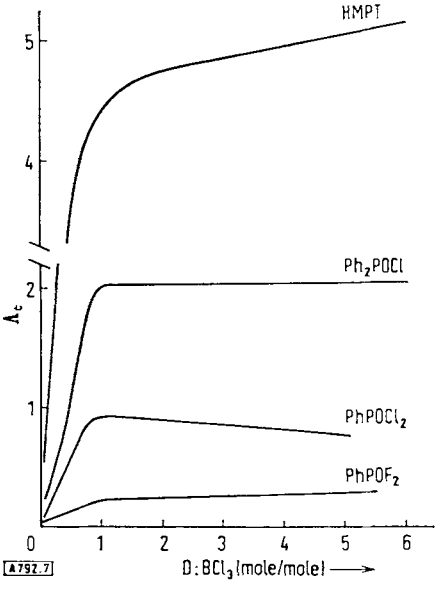


Fig. 7. Equivalent conductivity of $\approx 10^{-2}$ M BCl_3 solutions in nitrobenzene in the presence of aprotic donor solvents (HMPT = HMPA).

[44] *V. Gutmann* and *K. Fenkart*, Monatsh. Chem. *99*, 1452 (1968).

[45] *V. Gutmann* and *J. Imhof*, Inorg. Chim. Acta *4*, 171 (1970).

This interpretation agrees with cryoscopic and NMR investigations [40], according to which further reactions take place in the BCl_3 systems with trimethyl and tributyl phosphates and with Ph_2POF. The two phosphates react with BCl_3 to give chelate formation and elimination of alkyl chloride, as with chlorides of various transition metals [44,46,47], and so give conductivity values that vary with time until the reaction is complete.

Autocomplexing also occurs with pyridine [40]:

$$2\,py + 2\,BCl_3 \rightleftharpoons [py_2BCl_2]^+ + [BCl_4]^-$$

Finally, the behavior [48] of the boron(III) iodide-pyridine complex, which has been described as "anomalous", is perfectly normal. Since the B–I bonds are significantly weaker than the boron-pyridine bonds, the $[BI_4]^-$ ion is unstable in the presence of pyridine, and ionization now occurs instead of autocomplexing. The adduct has the composition $BI_3(py)_2$, and is formulated as $[(py)_2BI_2]^+I^-$ [48]. These ions are also present in acetonitrile, where the iodide ions react further with iodine to form triiodide ions.

7.2. Organic Compounds

Many reactions in organic chemistry proceed *via* ions, but these are often present only in very small concentrations at equilibrium, and in many cases their formation as intermediates can only be deduced from the kinetic findings. OH^- ions often act as donors, and H^+ ions as acceptors.

A successful attack on the tetracoordinated C atom by a donor molecule with formation of a complex cation is difficult. An example of this is the formation of tetraalkylammonium salts from an amine and an alkyl halide:

$$RBr + NR_3 \rightarrow [NR_4]^+Br^-$$

The formation of the pentachlorocarbonate ion [49] in accordance with

$$CCl_4 + Cl^- \rightarrow [CCl_5]^-$$

has recently been described, and the possibility $[Cl_3-C-Cl-Cl]^-$ has been discussed for its structure. The reactions of CX_4 with strong donors, *e.g.* HMPA, could begin with an attack by this donor on a coordinated X ligand, and could lead in this way to ionization, *e.g.*

$$CCl_4 + HMPA \rightleftharpoons Cl_3CCl(HMPA) \rightleftharpoons [Cl_3C(HMPA)]^+Cl^-$$

The attack by the azide group could also follow this path, *e.g.* in the reaction [50]

$$CCl_4 + 3\,Cl_4SbN_3 \rightleftharpoons [C(N_3)_3]^+[SbCl_6]^- + 2\,SbCl_5$$

If the C atom is the more electronegative of the bonded atoms, *e.g.* in

$$\overset{\delta-}{F_3C}-\overset{\delta+}{I}$$

ionization by nucleophilic attack on the iodine by strong donors may be expected:

$$F_3C-I + 2\,D \rightleftharpoons [D_2I]^+[CF_3]^-$$

The ionization of compounds containing tetracoordinated carbon is possible by attack of an acceptor molecule, *e.g.*

$$(C_6H_5)_3CCl + HCl \rightleftharpoons [(C_6H_5)_3C]^+ + [HCl_2]^-$$
$$t\text{-}C_4H_9F + AsF_5 \rightleftharpoons [t\text{-}C_4H_9]^+ + [AsF_6]^-$$

Intermediate ionized complexes play a special part in many Friedel-Crafts reactions [51].

The ionization of a compound containing tricoordinated carbon results mainly from attack by a donor, as is shown by the ionic reactions of fluoroolefins, in the course of which very reactive anions are formed [52]. The ionization reactions are represented as follows [52–54]:

$$[RO]^- + F_2C{=}CF_2 \rightarrow [RO{-}CF_2{-}CF_2]^-$$
$$[C_6H_5NH]^- + F_2C{=}CF_2 \rightarrow [C_6H_5NH{-}CF_2{-}CF_2]^-$$
$$F^- + F_2C{=}CF{-}CF_3 \rightarrow [CF_3{-}CF{-}CF_3]^-$$

7.3. Organometallic Compounds

An example of the ionization of an organometallic compound by nucleophilic attack of a donor is provided by the reaction of benzylmagnesium chloride with HMPA, which gives the red color of the benzyl anion [55],

$$C_6H_5CH_2MgCl + HMPA \rightleftharpoons [(HMPA)MgCl]^+[C_6H_5CH_2]^-$$

a reaction that no longer occurs in DMSO, the coordinating power of which is only slightly weaker. On the other hand, trimethyltritylstannane cannot be ionized by coordination of HMPA with the tin to form a triphenylcarbanion, since the Sn–C bond is too stable [56].

[56] *V. Gutmann* and *R. Schmid*, Monatsh. Chem. *100*, 721 (1969).

Carbonylmetal compounds can be ionized by donors with stabilization of the cations [57–61]. This usually leads to a hexacoordinated cation and a polynuclear carbonylmetalate ion, which is decomposed by heat. The ionizations proceed with simultaneous redox disproportionations [58, 59]:

$$4\ Fe(CO)_5 + 6\ py \rightleftharpoons [Fe(py)_6]^{2+}[Fe_3(CO)_{11}]^{2-} + 9\ CO$$

$$4\ Fe_3(CO)_{12} + 9\ en \rightleftharpoons 3\ [Fe(en)_3]^{2+}[Fe_3(CO)_{11}]^{2-} + 15\ CO$$

The conductivity of the pyridine compound in pyridine roughly corresponds to that of potassium picrate in the same solvent [60]. DMSO, alcohols, and ammonia give similar reactions [58,62]:

$$3\ Co_4(CO)_{12} + 24\ D \rightleftharpoons 4\ [CoD_6][Co(CO)_4]_2 + 4\ CO$$

$$Co_6(CO)_{16} + 12\ D \rightleftharpoons 2\ [CoD_6][Co(CO)_4]_2$$

Octacarbonyldicobalt is also ionized by coordination with triphenylphosphine, with stabilization of the cation [63]:

$$Co_2(CO)_8 + 3\ PPh_3 \rightleftharpoons [Co(CO)_3(PPh_3)_3]^+[Co(CO)_4]^- + CO$$

Another example of ionization by soft donors is provided by the behavior of $PdCl(\pi\text{-}C_4H_7)_2$, which gives the cationic complex with excess P-donors such as triphenylphosphine [64]:

$$PdCl(\pi\text{-}C_4H_7)_2 + 2\ PPh_3 \rightleftharpoons [(PPh_3)_2Pd(\pi\text{-}C_4H_7)_2]^+ + Cl^-$$

The conductivities in acetonitrile increase in the order $PPh_3 < PMe_2Ph < PEt_2Ph < PEt_3$ and increase until a molar ratio of 1:2 is reached; the increase in conductivity in the order $I < Br < Cl$ corresponds to the donor strengths of the halide ions toward soft acceptors.

Ionization by electrophilic attack of the acceptor $AlCl_3$ is probably responsible for the substitution of the Mn–Cl bond by CO in the presence of aluminum chloride [65]:

$$(CO)_3Mn(en)Cl + CO + AlCl_3 \rightleftharpoons [(CO)_4Mn(en)]^+[AlCl_4]^-$$

in the same way as carbonyl halides are ionized by acceptors:

$$Mn(CO)_5Cl + AlCl_3 \rightleftharpoons [Mn(CO)_5]^+[AlCl_4]^-$$

On the other hand, the interaction of halide ions with hexacarbonylmetal compounds leads to substitution of a carbonyl group with formation of complex anions [66–68]

$$M(CO)_6 + X^- \rightleftharpoons [M(CO)_5X]^- + CO$$

M = Cr, Mo, W; X = Cl, Br, I

7.4. Silicon Halides

Both the Si–F and the Si–Cl bonds are generally too strong to be ionized by coordination, even with strong donors. SiF_4 reacts with donors to form adducts having the composition SiF_4D_2, which are molecularly dissolved even in media having high dielectric constants. The dissociation deduced from cryoscopic measurements on $SiCl_4(py)_2$ in nitrobenzene [69] has not been verified, nor has the reported [70] conductivity of alkylchlorosilanes with 2,2′-bipyridyl in acetonitrile [71].

On the other hand, silyl cations can be formed by reaction of bromides and particularly of iodides with strong donors. *Wannagat* [72, 73] suggested an ionic structure for the compound $SiI_4(py)_4$, which was also formulated by *Schnell* [74] as $[Si(py)_4]^{4+} + 4I^-$. According to IR spectroscopic data, the cation contains hexacoordinated silicon [75, 76]:

$$[(py)_4SiI_2]^{2+} + 2\ I^-$$

On the basis of the spectra, the complexes of silyl bromides and silyl iodides with strong bases must be assumed to have an ionic structure with pentacoordinated silicon [77], *e.g.*:

$$[SiH_3(py)_2]^+Br^- \text{ and } [SiH_3(py)_2]^+I^-$$

They give highly conducting solutions in acetonitrile, unlike the compounds of the corresponding chlorides or fluorides [77].

Similarly, triphenylsilyl iodide is ionized in methylene chloride in the presence of 2,2′-bipyridyl (bipy) [78] (Fig. 8), as is shown by the IR spectra.

$$Ph_3SiI + bipy \rightleftharpoons [Ph_3Si(bipy)]^+I^-$$

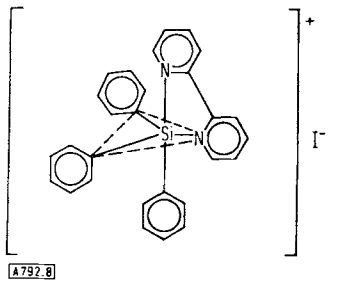

Fig. 8. Probable structure of $[Ph_3Si(bipy)]^+I^-$.

The conductivity of the compound in acetonitrile is roughly the same as that of $[H(bipy)]^+I^-$.

Silyl cations are formed by ionization of silyltetracarbonylcobalt $H_3SiCo(CO)_4$ or silylpentacarbonylmanganese $H_3SiMn(CO)_5$ under the influence of trimethylamine or pyridine. According to their IR spectra, the complexes are ionic [79]

$$H_3SiMn(CO)_5 + 2\ py \rightleftharpoons [H_3Si(py)_2]^+[Mn(CO)_5]^-$$

and are decomposed by hydrogen chloride:

$$[H_3Si(py)_2]^+[Mn(CO)_5] + 3\ HCl \xrightarrow{-100\,^\circ C} H_3SiCl + HMn(CO)_5 + 2\ pyHCl$$

7.5. Phosphoranes, Arsoranes, Stiboranes

R_3PI_2 is ionized in nitromethane,

$$R_3PI_2 \rightleftharpoons [R_3PI]^+ + I^-$$

whereas R_3PBr_2 and R_3PCl_2 are not. However, all three undergo ionization by complex formation with strong acceptors [80].

$$R_3PCl_2 + SbCl_5 \rightleftharpoons [R_3PCl]^+ + [SbCl_6]^-$$
$$R_3PI_2 + HgI_2 \rightleftharpoons [R_3PI]^+ + [HgI_3]^-$$

The ionization is also favored in a stronger donor solvent. The conductivities of phosphoranes, arsoranes, and stiboranes in acetonitrile [81] are given in Table 9; they decrease in the orders P > As > Sb and I > Br > Cl.

Table 9. Molar conductivities of phosphoranes, arsoranes, and stiboranes at $c = 10^{-2}$ mole/l in acetonitrile at 25 °C.

Compound	Λ (Ω^{-1} cm^2 mole^{-1})	Compound	Λ (Ω^{-1} cm^2 mole^{-1})
Ph_3PCl_2	78.1	Ph_3PBr_2	73.2
Ph_3AsCl_2	4.0	Ph_3AsBr_2	25.3
Ph_3SbCl_2	1.0	Ph_3SbBr_2	1.0

The following ionic equilibria have been postulated on the basis of electrolysis studies [82]:

$$2\ Ph_3PCl_2 \rightleftharpoons [Ph_3PCl]^+ + [Ph_3PCl_3]^-$$
$$Ph_3PBr_2 \rightleftharpoons [Ph_3PBr]^+ + Br^-$$

The particularly high conductivities of the iodides are due not only to greater ease of ionization of the El–I bonds but also to the partial decomposition of these compounds with formation of iodine, which acts as an acceptor and so stabilizes the anion:

$$Ph_3PI_2 \nearrow [PH_3PI]^+ + I^-$$
$$Ph_3PI_2 \searrow \tfrac{1}{2}\ Ph_3P + \tfrac{1}{2}\ [Ph_3PI]^+ + \tfrac{1}{2}\ I_3^-$$

7.6. Arsenic(III) Halides

Arsenic(III) chloride does not form adducts with ether, but does so with stronger donors such as tributyl phosphate (TBP), whose solutions are assumed from the Raman spectra to contain 1:2 adducts [83]. In these adducts, the donor molecules are situated at the apices of a distorted octahedron, and the lone pair of electrons occupies an equatorial position [84]. The ΔH values increase in the orders $AsCl_3 < AsBr_3 < AsI_3$ and TBP < DMA < HMPA [85]. The conductivities in HMPT also increase in the orders $AsCl_3 < AsBr_3 < AsI_3$ and TBP < DMA < HMPA, corresponding to the decrease in the donicities of the halide ions and the increase in the donicities of the donor molecules. The ionization of the adducts is attributed to the ligand exchange halide → donor on the arsenic^{III}:

$$AsX_3D + n\ D \rightleftharpoons [AsX_{(3-m)}D_{(n+1)}]^{m+} + m\ X^- \text{ with } m \leqslant 3$$

The ease of ionization increases with increasing *Dn* of the donor solvent and decreasing *Dn* of the competing ligand X^-.

Ionization also occurs with bidentate strong donors. The adducts AsX_3(2,2′-bipyridyl) give highly conducting solutions in nitrobenzene [86],

$$AsX_3 + bipy \rightleftharpoons [AsX_3(bipy)] \rightleftharpoons [AsX_2(bipy)]^+ + X^-$$

like the adduct formed from arsenic(III) iodide and *o*-phenylenebis(dimethylamine) [87].

7.7. Antimony(III) Halides

The ΔH values of the interaction SbX_3–HMPA in dichloroethane increase with increasing donicity of the solvent and with decreasing *Dn* of the halide ligands [85].

The conductivities of SbX_3–HMPA systems in nitrobenzene also increase in the same way. The con-

ductivity curves suggest that several equilibria are superimposed:

$$SbX_3D + n\,D \rightleftharpoons [SbX_{(3-m)}D_{(n+1)}]^{m+} + m\,X^- \text{ with } m \leqslant 3$$

7.8. Antimony(V) Halides

Antimony(v) chloride is a stronger acceptor than boron(III) chloride. It forms unionized solutions in nitrobenzene and in acetonitrile [88]. Addition of $POCl_3$, $PhPOF_2$, PhPOFCl, or $PhPOCl_2$ leads to the formation of adducts that are molecularly disperse, and not ionized, in nitrobenzene. On addition of stronger donors, *i.e.* Ph_2POF, Ph_2POCl, TMP, TBP, or Ph_3PO, there is practically no increase in conductivity up to a molar ratio of 1:1, since the nonconducting adducts are formed. The adducts are ionized only in the presence of an excess of donor (Fig. 9), presumably with autocomplexing [40].

$$2\,D \cdot SbCl_5 \rightleftharpoons [D_2SbCl_4]^+ + [SbCl_6]^-$$

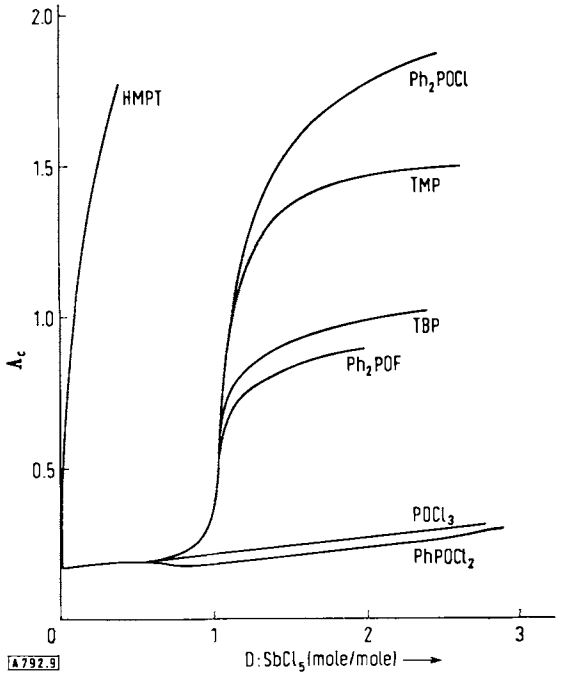

Fig. 9. Equivalent conductivity of $\approx 10^{-2}$ M $SbCl_5$ solutions in nitrobenzene in the presence of aprotic donor solvents (HMPT = HMPA).

With a very strong donor such as HMPA, the conductivity increases rapidly up to a molar ratio D:$SbCl_5$ = 1:1, since an ionized product is formed. The results of cryoscopic measurements agree with the postulated autocomplexing [40]:

$$2\,HMPA + 2\,SbCl_5 \rightleftharpoons [(HMPA)_2SbCl_4]^+ + [SbCl_6]^-$$

In the system $SbCl_5$–Ph_2POCl, the molecular weight found cryoscopically in the presence of an excess of donor is lower than it should be for the adduct $Ph_2POCl \cdot SbCl_5$, whereas autocomplexing should not affect the number of particles. The conductivity diagram shows that the ionization occurs only when the donor is present in excess, and corresponds to

$$Ph_2POCl + SbCl_5 \rightleftharpoons [Ph_2PO]^+ + [SbCl_6]^-$$

as has been found in principle, though to a much smaller extent, in solutions of $POCl_3$ or $PhPOCl_2$ [89]. The large excesses of donor required agree with the very weak chloride ion donor properties of the phosphorus oxide chlorides.

The ionizing properties of the donor solvents increase in the same order toward antimony(v) chloride as toward boron(III) chloride, but $SbCl_5$ is much less readily ionized with a given donor. This is partly due to the relatively high strength of the Sb–Cl bond, and partly to the higher coordinating power of boron(III) chloride toward oxygen donors. This also agrees with the fact that the observed affinity of antimony(v) chloride for chloride ions in $POCl_3$ and $PhPOCl_2$ is higher than that of boron(III) chloride [87].

The strong acceptor SbF_5 forms only one adduct with pyridine [90].

7.9. Iodine, Iodine Monochloride, and Iodine Bromide

Whereas we have so far been concerned with the ionization of covalent bonds having polar character, the ionization of a pure covalent bond will now be discussed with the iodine molecule as an example. Charge-transfer complexes of iodine are known, and the ΔH values for the interaction with donors generally increase with increasing donicity of the donor [10] (Table 10).

Table 10. Reaction enthalpies for adduct formation between iodine and donors having different donicities.

Donor	*Dn*	$-\Delta H_{D\cdot I_2}$
AN	14.1	1.9
Methyl acetate	16.5	2.5
Acetone	17.0	2.5
TBP	23.7	3.8
DMF	26.6	3.7
DMA	27.8	4.0
DMSO	29.8	4.4
py	33.1	7.8

The conductivities of the donor-iodine systems in nitrobenzene in the presence of light are relatively low, but again increase with the donicity of the donor [91].

The solutions of pyridine and iodine contain I_3^- anions and $[(py)_2I]^+$ cations, the existence of which

[88] *I. R. Beattie, P. J. Jones,* and *M. Webster,* J. Chem. Soc. *A 1969,* 218.

[89] *V. Gutmann* in *V. Gutmann*: Halogen Chemistry. Academic Press, New York 1968, Vol. 2, p. 399.

[90] *E. L. Muetterties,* Adv. Chem. Coord. Comp. *1961,* 513.

[91] *V. Gutmann* and *W. Frantsits,* Monatsh. Chem., in press.

appears to have been verified by the isolation of $[py_2I]\,[ClO_4]$ [92].

$$py + I_2 \rightleftharpoons py \cdot I_2$$
$$2\,pyI_2 \rightleftharpoons [(py)_2I]^+ + I_3^-$$

2,2'-Bipyridyl also exhibits double coordination to the iodine cation, with formation of a polymeric cation [93].

$$n\ bipy\ (ICl)_2 \rightleftharpoons [(bipy\ I)_n]^{n+} + n\ [ICl_2]^-$$

The ionization with a given donor increase with the polarity of the bond, *i.e.* in the order $I_2 < IBr < ICl$. For a given molar ratio the conductivities of the donor-acceptor systems in nitrobenzene increase from iodine to iodine monochloride, as well as with increasing donicity of the donor (*i.e.* TBP < DMA < DMSO < py < HMPA). The conductivity curves exhibit an irregular course at certain molar ratios [91], *e.g.* at D:A = 1:1 in the system D–ICl in nitrobenzene (Fig. 10). The autocomplexing observed up to this point

$$2\,D + 2\,ICl \rightleftharpoons [D_2I]^+ + [ICl_2]^-$$

is partly replaced at a molar ratio of 1:1 by the reformation of the charge transfer complex by decomposition of the $[ICl_2]^-$ ion, and the resulting chloride ions partly decompose the $[D_2I]^+$ ions:

$$[ICl_2]^- + D \rightleftharpoons ICl \cdot D + Cl^-$$
$$[D_2I]^+ + Cl^- \rightleftharpoons ICl \cdot D + D$$

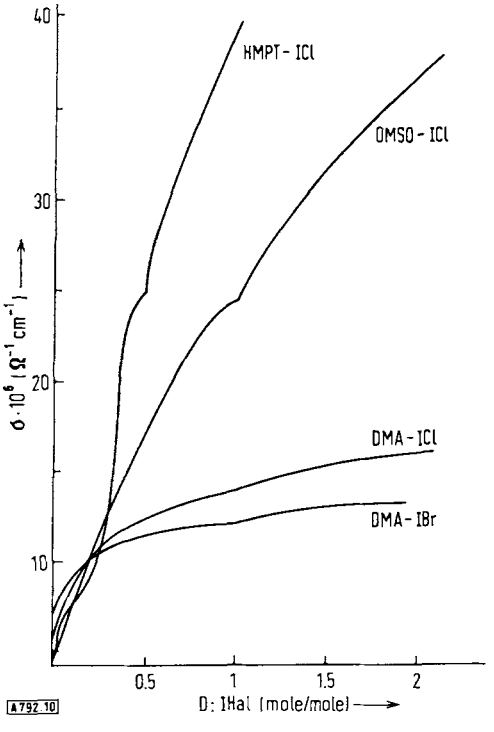

Fig. 10. Specific conductivity of 5×10^{-3} M iodine halide solutions in nitrobenzene in the presence of aprotic donor solvents (HMPT = HMPA).

[92] *H. Carlson*: Über eine neue Klasse von Verbindungen des positiv einwertigen Jods. S. Hirzel, Leipzig 1932.

[93] *A. I. Popov* and *R. T. Pflaum*, J. Amer. Chem. Soc. *79*, 570 (1957).

On further addition of donor, the conductivity again increases, and the extinction of the $[ICl_2]^-$ ion decreases, since ionization now predominates:

$$D + ICl \cdot D \rightleftharpoons [D_2I]^+ + Cl^-$$

The ionization of IBr and ICl is also possible only by electrophilic attack by a strong acceptor. The compounds $AlCl_3 \cdot 2ICl$ and $AlBr_3 \cdot 2IBr$ are good conductors of electricity in the fused state, and the results of transport measurements agree with the existence of the equilibria [94,95]:

$$AlCl_3 \cdot 2\,ICl \rightleftharpoons [I_2Cl]^+ + [AlCl_4]^-$$
$$AlBr_3 \cdot 2\,IBr \rightleftharpoons [I_2Br]^+ + [AlBr_4]^-$$

$SnCl_4$, $SbCl_5$, VCl_4, and $NbCl_5$ react similarly with iodine monochloride [95a], whereas $[ICl_2]^-$ ions are formed with PCl_5 [95a,95b]:

$$PCl_5 + ICl \rightleftharpoons [PCl_4]^+ + [ICl_2]^-$$

7.10. Titanium Halides

Titanium(III) chloride and titanium(III) bromide give acetonitrile (AN) adducts having the composition $TiX_3(AN)_3$ [96]. Their ionization *e.g.* in acetonitrile increases with increasing donor strength of the donor and from the chloride to the bromide. The molar conductivity of $(TiBr_3)_2(bipy)_3$ in acetonitrile is twice as high as that of $(TiCl_3)_2\,(bipy)_3$ [97]. According to spectral observations, the ionization can be formulated as follows:

$$(TiX_3)_2(bipy)_3 \rightleftharpoons \cdot[TiX_2(bipy)_2]^+ + [TiX_4(bipy)]^-$$

Anionic complexes are formed from titanium(III) halides both in acetonitrile and in propylene carbonate by addition of halide ions [98]:

$$TiX_3D_3 + X^- \rightleftharpoons [TiX_4D_2]^- + D$$
$$[TiX_4D_2]^- + 2\,X^- \rightleftharpoons [TiX_6]^{3-} + 2\,D$$

Complex cations are formed on addition of strong acceptors, *e.g.* $SbCl_5$ [98], as in the cases of VX_3 and CrX_3, in acetonitrile [99].

[99] *V. Gutmann*, *G. Hampel*, and *W. Lux*, Monatsh. Chem. *96*, 533 (1965).

Titanium(IV) chloride forms adducts with many donors [100]. In $[Cl_3PO]_2TiCl_4$, the electron repulsion of the donor molecules, even when they are present in large excess, *e.g.* as the solvent, is not sufficient to ionize a Ti–Cl bond [89]. The ionization is brought about only by the additional attraction of electrons by a strong acceptor [101, 102]:

$$D \rightarrow \overset{\frown}{Ti-X} \rightarrow A$$

$$POCl_3 + (Cl_3PO)_2TiCl_4 + SbCl_5 \rightleftharpoons [(Cl_3PO)_3TiCl_3]^+[SbCl_6]^-$$

On the other hand, hexachlorotitanate is formed on addition of chloride ions [103]. Dimeric anions [35] are obtained from triphenylchloromethane and $TiCl_4$ in $POCl_3$ [104], $PhPOCl_2$ [105], and PhCOCl [106].

$$2\ Ph_3CCl + 2\ TiCl_4 \rightleftharpoons 2\ [Ph_3C]^+ + [Ti_2Cl_{10}]^{2-}$$

Table 11. Stability constant K of the complex $[Ph_3C]_2[Ti_2Cl_{10}]$ in solvents having different donicities.

Solvent	*Dn*	$K_{[Ph_3C]_2[Ti_2Cl_{10}]}$
$PhPOCl_2$	18.5	5.3
$POCl_3$	11.7	16
PhCOCl	2.3	58

The stability constant of the complex decreases, as expected, with increasing donicity of the solvent [107] (Table 11).

7.11. Rhenium(III) Halides

The metal cluster structures in rhenium(III) halides are retained in donor solvents [107–110], and rhenium has a coordination number of seven in the resulting adducts $Re_3X_9L_3$. In solvents of medium *Dn*, such as acetonitrile and tetrahydrofuran, Re_3Cl_9 is ionized only in the presence of strong donors, *e.g.* bipyridyl [108].

The ionization in DMSO has been formulated as follows [107]:

$$Re_3Cl_9(DMSO)_3 + 3\ DMSO \rightleftharpoons [Re_3Cl_6(DMSO)_6]^{3+} + 3Cl^-$$

It may be assumed that Re_3Br_9 is ionized to a greater degree under similar conditions. In the bisarsenate complex $Re_3Br_3(AsO_4)_2(DMSO)_3$, six of the nine bromide ligands of Re_3Br_9 are substituted [111].

7.12. Thorium and Uranium Halides

The measured conductivities of the donor complexes of thorium halides and uranium(IV) halides in nitromethane are not strictly comparable, since the compositions of the complexes are different. The influence is seen clearly *e.g.* on comparison of $ThBr_4(HMPA)_2$ and $ThBr_4(HMPA)_3$. The conductivities increase from the chloride *via* the bromide to the iodide for a given donor, as well as with increasing donicity of the donor (Table 12).

Table 12. Molar conductivities of thorium(IV) halide and uranium(IV) halide complexes in nitromethane at $c \approx 10^{-3}$ mole/l.

8. Conclusion

The electrostatic model of dissociation allows an extensive description of the behavior of ionic compounds in solution. The enthalpy of solvation is used for the dissolution process, and the degree of dissociation in solution is largely dependent on the dielectric constant of the medium. The description of the ionization of covalent compounds, on the other hand,

requires a coordination-chemical interaction between the solute and the solvent or an added complexing agent, the complexing agent acting either as a donor or as an acceptor. The degree of ionization is essentially determined by the coordination-induced ionization and by the dissociation of the ion associates, which depends on the dielectric constant of the medium.

The few arbitrarily chosen examples show the significance of the coordination-induced ionization of covalent compounds to numerous important reaction types in every field of chemistry and electrochemistry, in aqueous and in nonaqueous solutions. The donicity is a more than qualitative, possibly even semiquantitative characteristic for electron pair donors, and facilitates the choice of a suitable solvent for ionization or for certain reactions.

The relations presented allow the removal of a number of contradictions or uncertainties in the literature and the logical classification of many individual facts in general categories. Incentives are also provided to further systematic and particularly quantitative studies, *e.g.* of a kinetic, thermochemical, or structural nature. Finally, it is to be hoped that the present article will promote the use of strong donors or acceptors both as solvents and as reactants, and hence also chemistry in nonaqueous media.

Degenerate Carbonium Ions[***]

By Ronald E. Leone and Paul von R. Schleyer[*]

Carbonium ions are called "degenerate" when they rearrange through finite energy barriers to give products whose gross structures are identical with those of the starting ions. In such degenerate rearrangements ("automerizations"), individual atoms and groups become mixed but the overall structure is conserved. Automerizations can be observed by noting the dispersal of isotopic labels, the loss of optical activity, or the temperature dependence of NMR spectra. In certain cases, a combination of well-known rearrangement processes results in complete mixing of all atoms, C or H. The 2-norbornyl and 9-barbaralyl cations are examples of fully degenerate systems; conditions can be found where both give but single-line NMR spectra.

1. Introduction

Chemists have always been especially interested in rearrangements because they violate the principle of minimum structural change [1]. Originally rearrangements leading to changes in molecular or structural formula were examined. Clearly there must also be a class of degenerate rearrangements in which individual atoms and bonds become interchanged, but which only lead to products of the same gross structure (*i.e.*, identical except for the special features which enable detection of the rearrangement) as that of the starting material. These transformations can only be followed by special techniques such as the loss of optical activity, the dispersal of an isotopic label, the observation of equivalence by NMR, *etc.* The most striking of these degenerate rearrangements are those capable of mixing all atoms of a given kind completely. Bullvalene is the best known organic molecule of this type; every Cope rearrangement returns to bullvalene and at only a little above room temperature all hydrogen and carbon atoms become equivalent on the NMR time scale [2].

Carbonium ions are particularly prone to rearrangement [3], and it would be expected that many examples of degeneracy could be found within this class of reaction intermediates. In recent years considerable effort has been directed toward the study of carbonium ions, either as stable cations or as solvolysis intermediates, capable of undergoing degenerate rearrangements. It is this group of carbonium ions which will be reviewed here, with major emphasis placed on ions capable of multiple degeneracy. *Balaban* has recently developed a mathematical treatment of multiple 1,2-shifts in carbonium ions on the basis of the theory of graphs [4].

A degenerate carbonium ion shall be defined as a carbonium ion which can rearrange through a finite energy barrier in such a fashion as to regenerate the same gross structure (as defined above) as that of the starting ion. The degen-

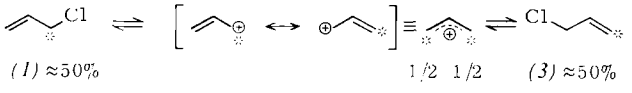
[4] *A. T. Balaban, D. Färcasiu*, and *R. Bănică*, Rev. Roum. Chim. *11*, 1205 (1966).

erate rearrangement of such an ion is an automerization [5], *i.e.*, a reaction process in which both the molecular formula and structural formula of the starting material are conserved (see Table 1). The preservation of enantiomeric purity shall not be a necessary requirement. Thus enantiomeric cations and their racemic mixtures, but not diastereomeric cations, will be assumed to have the same gross structure.

We will consider rearrangements whereby an optically active cation is racemized by an automerization or an isotopic label dispersed by an automerization to be examples of degeneracy. In fact, automerizations can often be detected by the techniques of using optically active or isotopically tagged precursors.

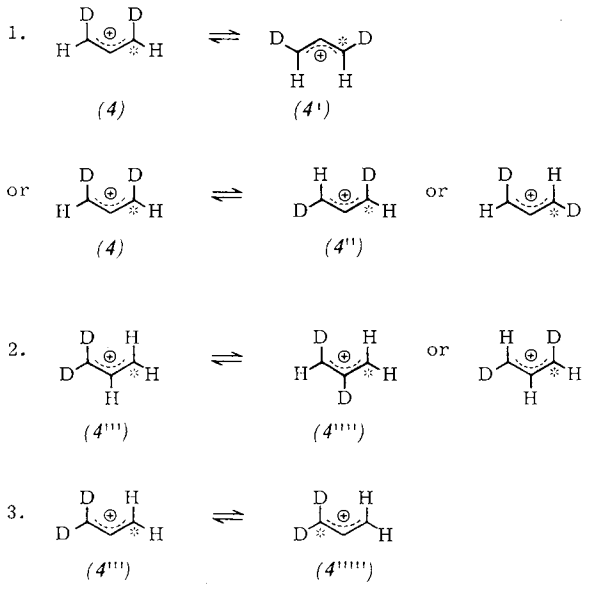
Table 1. Definition of rearrangement, isomerization, and automerization (based on ref. [5])[a].



Molecular formula	Structural formula [b]	Name
not conserved	not conserved	rearrangement
conserved	not conserved	isomerization
conserved	conserved	automerization

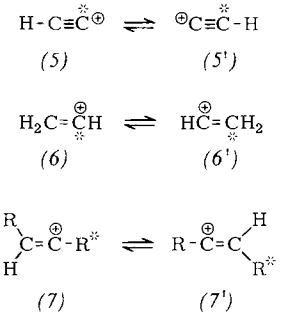
[a] Because of historical precedent, we believe it is better to regard these categories as being *inclusive* rather than *exclusive*. Thus, an isomerization is a special kind of rearrangement and an automerization is a special kind of isomerization (or rearrangement).

[b] For convenience, enantiomers and isotopically labeled compounds, but not diastereomers, will be considered here to have the same structural formula.



A number of carbonium ions, through resonance, possess equivalent ("homotopic") [6] atoms or groups. Examples are the termini of the allyl cation and all the carbon-hydrogen units in the tropylium ion. Such systems do not involve degenerate rearrangements in the sense of the above definition, but for the purposes of this review it is nevertheless convenient to discuss some of these cases since resonance (*e.g.*, allyl resonance) is also important in helping to achieve degeneracy in some cations. In these instances, resonance contributes to the overall rearrangement mechanism whereby the original ion structure is regenerated.

The problem of distinguishing between a degenerate cation rearrangement and equivalence through resonance can be illustrated by the allyl cation. The labeled allyl chloride *(1)* shown below generates on solvolysis an allyl cation *(2)* which contains two positions made equivalent by reso-



nance [7]. The chloride product contains a label at the two positions shown in *(1)* and *(3)*. The interconversion of the chlorides, *(1)* into *(3)*, is degenerate, but cation *(2)* does not undergo a degenerate rearrangement (in the sense of our definition) since the equivalence of positions in *(2)*, a *single* species, arises through resonance. However, automerizations are in principle possible for the allyl cation. Three types of potentially degenerate processes serve as examples, of which only the first has actually been observed: 1) *cis-trans* isomerization [8]; 2) interchange of hydrogens; and 3) interchange of carbon atoms.

These last three processes differ from the one described above in that they require interchange of atoms and passage

over an energy barrier to render positions equivalent (degenerate rearrangement) while the above case involves no interchange of atoms and no energy barrier (equivalence through resonance).

Based on the definition of a degenerate carbonium ion presented above, it appears that the simplest degenerate rearrangements possible in cations are *(5)* ⇌ *(5')*, *(6)* ⇌

(6'), and *(7)* ⇌ *(7')*. In these cases simple hydrogen interchanges produce degeneracy of the carbonium ions.

Experimentally, investigations have not yet been carried out to detect these possible degeneracies. However, the possibility of a degenerate 1,2-hydride shift in the ethyl cation *(8)* has been investigated [9]. To achieve full degeneracy in *(8)* all five hydrogens must be exchanged, but this has not yet been realized.

$$\underset{(8)}{CD_3-CH_2^{\oplus}} \rightleftharpoons \underset{(8')}{{}^{\oplus}CD_2-CH_2D} \rightleftharpoons \textit{etc.}$$

The potential degenerate rearrangements of the allyl cation discussed above represent a higher level of complexity. These allyl and ethyl cation examples illustrate the definition of a degenerate carbonium ion. More complicated degenerate cations will be reviewed as outlined below. We will discuss two main categories of degenerate ions: 1) those of the formula $(CH)_n^+$ where n is odd (see Section 3) and 2) those of the type not having the $(CH)_n^+$ empirical formula (see Section 4).

A classification of degenerate carbonium ions may also be made on the basis of the atoms or groups undergoing interchange. In priciple there are three kinds of ions: 1) those exhibiting carbon atom degeneracy; 2) those exhibiting hydrogen atom degeneracy; and 3) those exhibiting combined carbon and hydrogen atom degeneracy. In practice all three types of degenerate carbonium ions have been observed.

Carbon atom degeneracy involves the interchange of carbon atoms with or without their respective attached hydrogen. Complete carbon degeneracy means that all carbon atoms are capable of interchanging and becoming equivalent. Partial carbon degeneracy implies that only some of the carbons in the ion become equivalent. In theory carbon degeneracy can be detected by ^{13}C scrambling within the ion. However, experimentally this form of degeneracy is usually determined by proton label scrambling. Carbon degeneracy should give rise to a single NMR signal for the protons attached to the interchangeable carbon atoms and scrambling of a hydrogen istope label at the interchangeable positions. Recent developments in ^{13}C-NMR spectroscopy have opened up the way to direct observation of carbon degeneracies.

Hydrogen atom degeneracy involves interchange of hydrogens while the carbon skeleton of the ion remains fixed. Complete hydrogen degeneracy means the interchange and equivalence of all hydrogen atoms on the carbon surface of the molecule. Such a process will result in a single peak for the ^1H-NMR spectrum of the ion. Partial hydrogen degeneracy refers to the interchange of only some hydrogen atoms in the ion without altering the basic carbon framework.

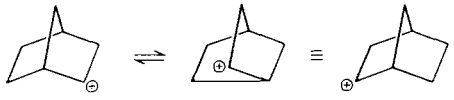
Combination of both carbon and hydrogen atom degeneracies is possible and this can also result in the equivalence of all carbons and hydrogens of the carbonium ion. Specific examples of the forms of degeneracy mentioned above will be discussed in detail later in this paper. It has been observed experimentally that degenerate ions of the $(CH)_n^+$ series show degenerate properties only through carbon degeneracy and are often capable of complete mixing of all carbon atoms. Degenerate ions outside the $(CH)_n^+$ series can exhibit all types of degeneracy, but often these ions are not capable of complete degeneracy.

The interest in studying degenerate carbonium ions revolves around the following three questions:

1) Can degeneracy be achieved, and if so, to what extent?

2) What is the mechanism whereby the degeneracy is achieved?

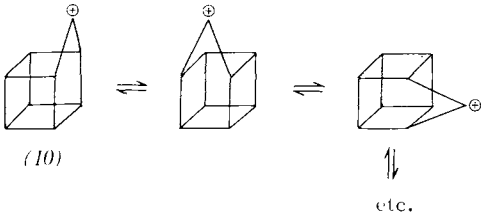
3) Are there any special properties resulting from degeneracy? For example, are the carbonium ions especially stable or especially unstable?



The degenerate carbonium ions already studied will be discussed in terms of these three considerations.

2. Reaction Processes Leading to Degeneracy

2.1. Wagner-Meerwein Rearrangement (1,2-Carbon Shift)



Probably the most important rearrangement process for degenerate carbonium ions is the Wagner-Meerwein rearrangement or 1,2-carbon shift [10,11]. This process allows interchange of carbon atoms and consequently is the basis for many observed carbon automerizations. The ions listed are examples of degenerate ions arising from 1,2-carbon shifts:

2-norbornyl cation *(9)* (see Section 4.6)

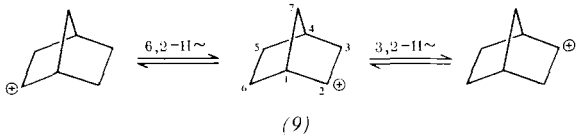
(9)

9-homocubyl cation *(10)* (see Section 3.4.1)

(10)

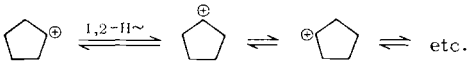
etc.

dimethyl-*tert*-butylcarbonium ion *(11)* (see Section 4.2).



(11)

2.2. 1,2-Hydride and 1,3-Hydride Shifts



Migration of a hydrogen from one adjacent carbon atom to another [12] is responsible for the hydrogen degeneracy observed in some ions. A hydride shift can only contribute to degeneracy when the two carbon atoms involved bear a symmetrical relationship to each other. Consider the examples shown below. Note that hydride shifts are not energetically favorable in the $(CH)_n^+$ ions since in all cases such shifts would result in bridgehead or vinyl carbonium ions:

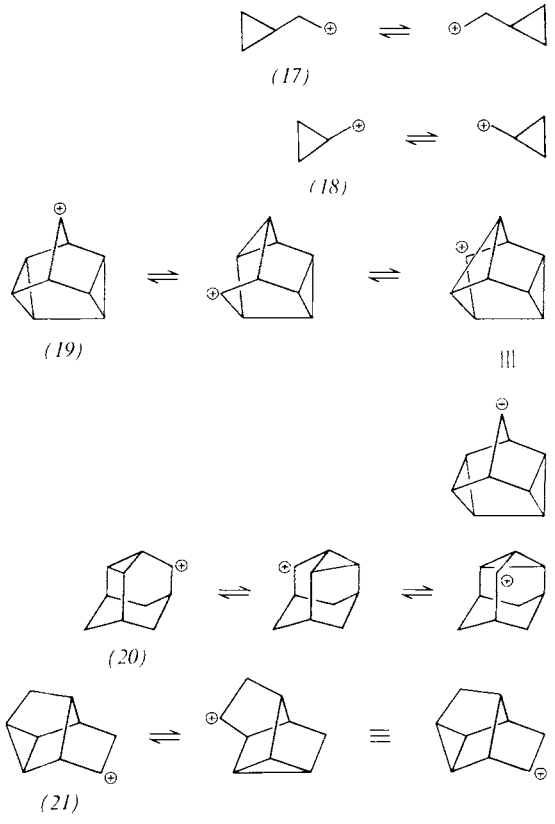
2.3. Double Bond Participation: 1,2-Vinyl Shift and Homoallylic Rearrangement

Double bond participation refers to the electronic participation of a carbon-carbon double bond in stabilizing a positive charge at a site two carbon atoms removed from the double bond [13,14]. In some cases this participation may result in a 1,2-vinyl shift or a homoallylic rearrangement. Both of these processes can contribute to carbon degeneracy. A 1,2-vinyl shift was observed in the degenerate norbornadienyl cation *(13)* (see Section 3.3.2) and may be potentially involved in the degeneracy of other ions *e.g. (14)* (see Section 3.4.4). Homoallylic rearrangement is presumably also involved in other ion degeneracies such as as *(15)* and *(16)* (see Sections 3.4.3 and 3.4.5 respectively).

(13)



(14)

(15)

(16)

2.4. Participation of a Cyclopropane Ring

The bonds of a cyclopropane ring are capable of participating in charge delocalization [15,16]. Such delocalization can give rise to either a degenerate homocyclopropylcarbinyl rearrangement [17] (cation *(17)* is the parent system) or a degenerate cyclopropylcarbinyl-cyclopropylcarbinyl rearrangement [18] (cation *(18)* is the parent system).

The 9-pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonyl cation *(19)* (see Section 3.4.2) and the 8-tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]nonyl cation *(21)* (see Section 4.11) are examples of the first type, and the 8,9-cyclo-2-adamantyl cation *(20)* (see Section 4.9) is an example of the second type.

2.5. Allyl Resonance

Allyl resonance [7], as applied to degenerate carbonium ions, refers to the simultaneous delocalization of positive charge over two allylic carbon atoms which are symmetrically disposed in the ion. The resonance can render two positions on an ion equivalent and can contribute to carbon degeneracy when coupled with one of the other rearrangement processes mentioned above. Cations *(14)* and *(16)* shown in Section 2.3 serve as examples.

3. $(CH)_n^+$ Series of Degenerate Carbonium Ions

Degenerate carbonium ions having the empirical formula $(CH)_n^+$ where n is odd are directly related to hydrocarbons of the form $(CH)_m$ where m is even. Recently *Balaban* published a mathematical treatment for the derivation of all possible valence isomers of $(CH)_m$ hydrocarbons [19]. Potentially degenerate carbonium ions can in theory be derived either by replacement of a carbon-carbon double bond in such a hydrocarbon by a $\rangle C^+-H$ unit or by insertion of a $\rangle C^+-H$ unit into any carbon-carbon single bond. The

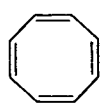
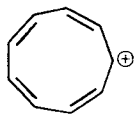
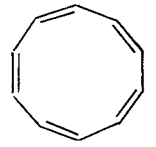
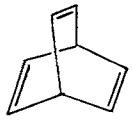
hydrocarbon isomers under consideration have four, six, eight, or ten carbon atoms and the corresponding carbonium ions contain three, five, seven, or nine carbon atoms. Table 2 shows the relationship between the carbonium ions and the hydrocarbons from which they can be derived. All of the ions shown in the Table have the potential for either complete or partial carbon degeneracy, although in fact this may not be observed. It should also be noted that certain ions, such as the cyclopropenyl cation *(22)* and the tropylium ion *(26)*, are not truly degenerate in the sense of our definition since in these ions all the carbon atoms are equivalent through resonance.

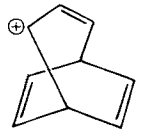
All the $(CH)_n^+$ carbonium ions are similar in that they are potentially capable of mixing carbon atoms only by carbon-carbon bond breaking and formation. In these cases the hydrogens also remain attached to the carbon atoms, thus making the interchanging carbon-hydrogen units equivalent. This degeneracy is of the same form as that observed in bullvalene *(51)*. Just as some of the $(CH)_m$ hydrocarbons represent interconvertible valence isomers, some of the $(CH)_n^+$ ions are also interconvertible.

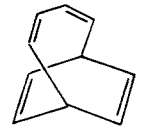


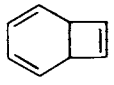


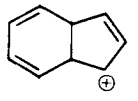


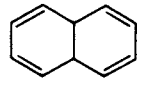


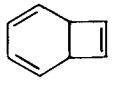


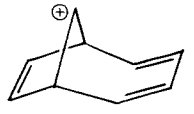


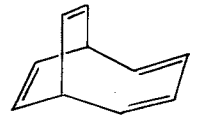


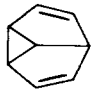


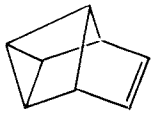


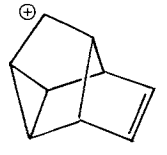


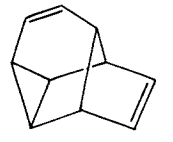


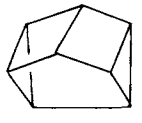


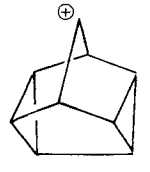


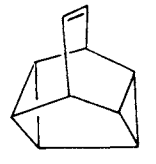


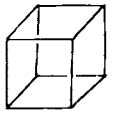


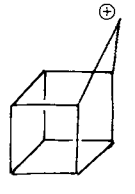


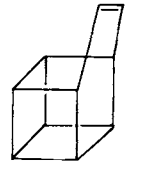












As an alternative to the derivation of $(CH)_n^+$ ions from $(CH)_m$ hydrocarbons, potentially degenerate $(CH)_n^+$ ions can also be constructed by noting that the ion must contain a $\rangle C^+-H$ unit, plus an appropriate number of single bonds, double bonds, and rings to maintain the $(CH)_n^+$ empirical formula. All carbon atoms in the ion must bear a hydrogen atom; but vinyl and acetylenic cations will be excluded. Consequently, $C_3H_3^+$, $C_5H_5^+$, $C_7H_7^+$, and $C_9H_9^+$ ions can have only certain structures.

In the $C_3H_3^+$ group there is only one possibility, the cyclopropenyl cation *(22)*, in which there is one ring and one double bond. For the $C_5H_5^+$ group there are three possible structures: the cyclopentadienyl cation *(23)*, monocyclic and containing two double bonds; the bicyclo[2.1.0]-pentenyl cation *(24)*, bicyclic and containing one double bond; the homotetrahedryl cation *(25)*, tricyclic and con-

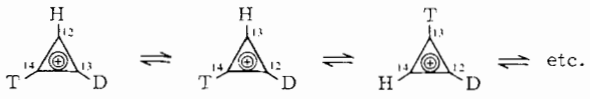
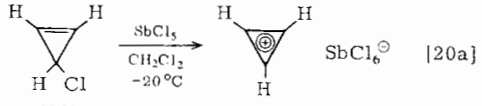
taining no double bonds. For the $C_7H_7^+$ group there are many possible structures of which only the more important ones will be considered here. The tropylium ion *(26)* is monocyclic and can be thought of as having three double bonds. The norbornadienyl cation *(13)* contains two rings and two double bonds; similarly, the bicyclo[3.2.0]heptadienyl cation *(27)* is bicyclic and contains two double bonds. The quadricyclyl cation *(28)* has four rings and no double bonds, and the homoprismyl cation *(29)* is tetracyclic with no double bonds.

Extension of this construction format to the $C_9H_9^+$ ions should be apparent and the multiplicity of possible structures increases with the larger number of carbon atoms. In this paper only those $C_9H_9^+$ ions which have been studied to some degree will be discussed (see Section 3.4). Their structures are shown in Table 2.



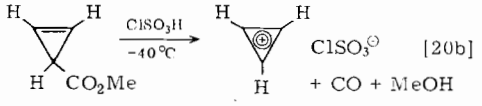
3.1. $C_3H_3^+$ Ions

The simplest example of a $(CH)_n^+$ potentially degenerate carbonium ion is the $C_3H_3^+$ cyclopropenyl cation *(22)*; all three carbon atoms can become equivalent by allyl resonance. This system is not degenerate by the definition



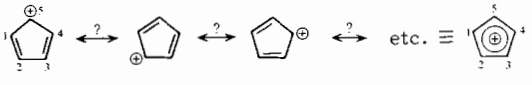
(22)

advanced in Section 1. However, in principle cation *(22)* could exhibit true degenerate rearrangements if the carbon atoms or the hydrogen atoms were to interchange positions. Such a possibility could be detected by studying ion *(55)* in which there are two sets of labels. Such an investigation, admittedly difficult to undertake, has not yet been carried



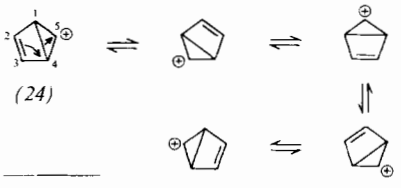
(55) *(55')* *(55'')*

out. Recently cation *(22)* was obtained by two independent routes [20], and the carbonium ion salt *(22')* showed a single peak at τ −0.87 in fluorosulfonic acid [20a]. These results indicate both the aromatic character of the ion and that all carbons and hydrogens are equivalent.



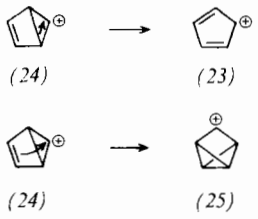
(56) *(22')* [20a]

(57) *(22'')* [20b]



3.2. $C_5H_5^+$ Ions

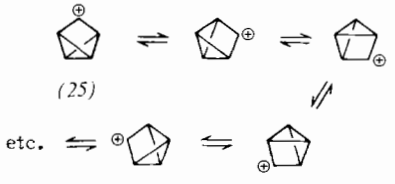
In the $C_5H_5^+$ family of cations there are three potentially degenerate carbonium ions. The first of these is the cyclopentadienyl cation *(23)*. Presumably all carbon atoms in this ion could become equivalent by resonance. However, as in the case of the cyclopropenyl cation, this is not an example of true carbon degeneracy. The cyclopentadienyl cation is thought not to be an aromatic system and is expected to be destabilized. The pentaphenyl [21a,22] and pentachloro [21b,22] derivatives have been prepared. The former has a singlet and the latter a triplet ground state [22].



(23)

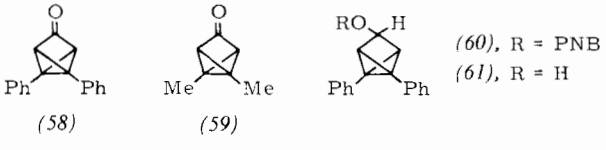
A second degenerate ion possibility in the $C_5H_5^+$ group is the bicyclo[2.1.0]pentenyl cation *(24)*. This ion is capable of rearranging to regenerate its own structure, but the carbon atoms do not interchange with each other. Cation *(24)* may also rearrange into the cyclopentadienyl cation *(23)* or the homotetrahedryl cation *(25)*.

(24)



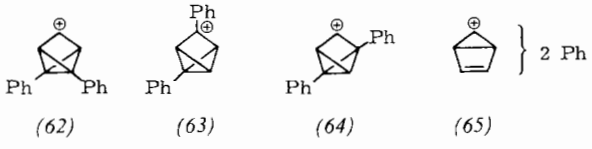
These rearrangement possibilities indicate to some degree the interconvertibility of the $C_5H_5^+$ ions. However, all the cations, *(23)*, *(24)*, and *(25)*, are destabilized by either

(24) *(23)* *(24)* *(25)*



ring strain or nonaromatic character. It is difficult to predict at present whether cation *(24)* would be stable enough to exist or undergo any of the rearrangements shown above.

The first example of a truly degenerate carbonium ion in the $(CH)_n^+$ series is the homotetrahedryl or tricyclo[2.1.0.0^{2,5}]pentyl cation *(25)*. In this ion there is the possibility of complete carbon degeneracy resulting in the positional exchange of all C−H units through 1,2-carbon shifts. If each C−H unit were somehow uniquely identified, it has been calculated ([no. of C atoms]! divided by the molecular symmetry number = 5!/2 = 60) there would be 60 possible arrangements for *(25)* [23].



(25)

The parent tricyclo[2.1.0.0^{2,5}]pentane system has not yet been synthesized, but 1,5-diphenyltricyclo[2.1.0.0^{2,5}]pentan-3-one *(58)* [24] and 1,5-dimethyltricyclo[2.1.0.0^{2,5}]-pentan-3-one *(59)* [25] have been prepared. Solvolysis of

(58) *(59)* *(60)*, R = PNB *(61)*, R = H

the *p*-nitrobenzoate *(60)* has been carried out [26], but no structure was assigned with certainty to the solvolysis products. Solvolysis of *(60)* in 70% acetone indicated definitely only that ionization was accelerated and that the product was not 1,5-diphenyltricyclo[2.1.0.0^{2,5}]pentan-3-ol. *(61)*. The absence of *(61)* from the reaction products indicates that ion *(62)* cannot be the immediate precursor of the products.

(62) *(63)* *(64)* *(65)* 2 Ph

Possibly the products arise from ions like *(63)*, *(64)*, or *(65)*, although further study is needed.

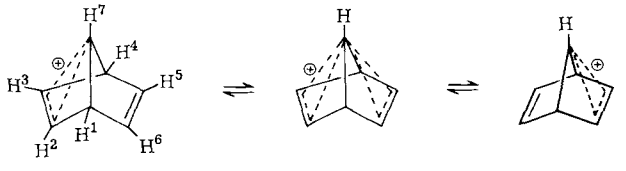
3.3. $C_7H_7^+$ Ions

3.3.1. Tropylium Cation

Within the $C_7H_7^+$ group of potentially degenerate carbonium ions, the monocyclic tropylium cation *(26)* represents the simplest example. This ion has been shown to possess aromatic character and a planar D_{7h} structure [27a]. All the carbon and hydrogen atoms are equivalent and the NMR spectrum of the tropylium ion consists of a single line. This system is not truly degenerate by our definition since the equivalence of all carbons and hydrogens arises through resonance and the atoms do not interchange positions. Cation *(26)* could in theory exhibit degenerate rearrangements if the carbons were to interchange as shown in *(26')*,

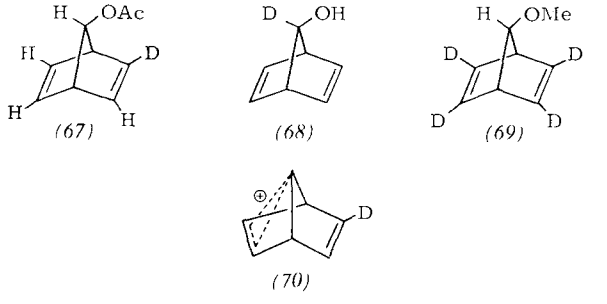


(26)

(26') *(26'')* *(26''')*

(26''), and *(26''')*. Such a labeling study has not yet been carried out [27b].

3.3.2. 7-Norbornadienyl Cation and Bicyclo[3.2.0]heptadienyl Cation

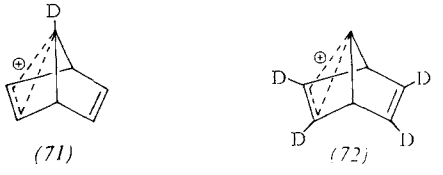


The 7-norbornadienyl cation *(13)* undergoes a degenerate rearrangement which leads to the equivalence of five carbon atoms in the ion [28]. In a search for "bridge flipping" (the

(13) *(66)* *(13')*

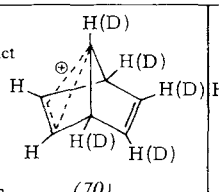
NMR spectrum of *(13)*: H-1 and H-4: τ = 4.88; H-5 and H-6: τ = 3.90; H-7: τ = 6.73; H-2 and H-3: τ = 2.54.

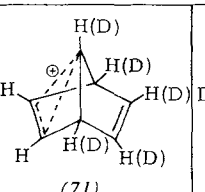
interconversion of *(13)* to *(13')* through *(66)*) in this species, it was observed that the NMR spectrum at −77 °C in FSO_3H showed a broadening of the signals for protons bound to carbons C-7, C-1 and C-4, C-5 and C-6, but not for those bound to C-3 or C-2. The nature of the rearrangement was determined by studying the NMR spectra of the ions derived from the labeled precursors *(67)*, *(68)*, and *(69)*.

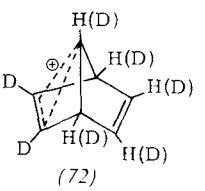


(67) *(68)* *(69)* *(70)*

[27] a) *D. Lloyd*: Carbocyclic Non-Benzenoid Aromatic Compounds. Elsevier, Amsterdam 1966, p. 98; b) cf. *A. S. Siegel*, J. Amer. Chem. Soc. *92*, 5277 (1970).

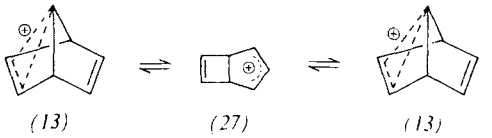






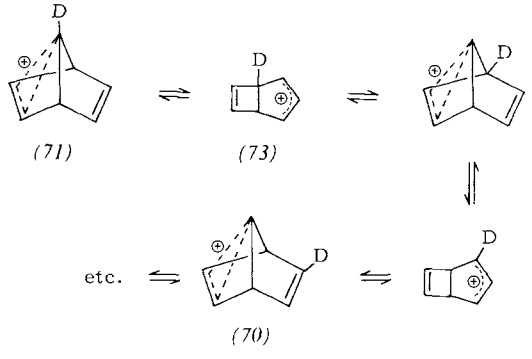
[28] *R. K. Lustgarten, M. Brookhart*, and *S. Winstein*, J. Amer. Chem. Soc. *89*, 6350 (1967).

In FSO_3H at −73 °C *(67)* exhibited the same four-signal spectrum as that of *(13)* with the intensity of the signal for H-5 and H-6 (unbound vinyl) one half that of the signal for H-2 and H-3 (bound vinyl). When the cation *(70)* solution was warmed to −47 °C, the deuterium label scrambled over positions 1, 7, 4, 5, and 6 with a rate constant of 3×10^{-4} s^{-1} but not over positions 2 and 3. This was evidenced in the NMR spectrum by the peak intensities approaching a ratio of 2:1.6:1.6:0.8 for the bound vinyl, unbound vinyl, bridgehead, and bridge protons, respectively. It was found that the deuterium label is incorporated sequentially at the different positions. The label appeared first at the bridgehead positions, 1 and 4, and then at the bridge position, 7. Similar rearrangements at similar rates were also observed for ions *(71)* and *(72)* derived from precursors *(68)* and *(69)* (see Table 3). These rearrangements indicate the existence of partial carbon degeneracy in the 7-norbornadienyl cation.



(71) *(72)*

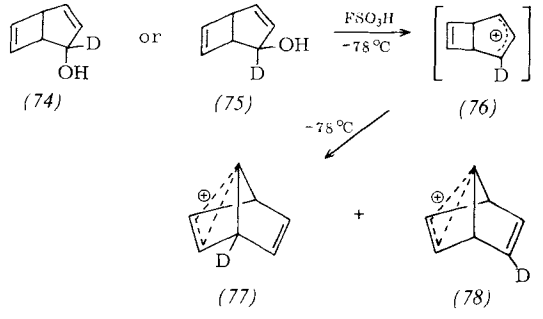
Table 3. Rates and free energies of activation of degenerate rearrangements of the 7-norbornadienyl cation (from ref. [28]).



Product			
Cation	*(70)*	*(71)*	*(72)*
	1/5 D	1/5 D	2/5 D
	at each C atom		at each of 5 C atoms
Temperature (°C)	−47	−55	−50
$10^4 k$ (s^{-1})	3	1.7	2
ΔG^+ (kcal/mole)	16.7	16.4	16.7

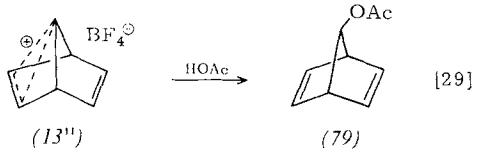
The mechanism proposed for the 5-carbon degenerate rearrangement is ring contraction to the bicyclo[3.2.0]hepta-

(13) *(27)* *(13)*



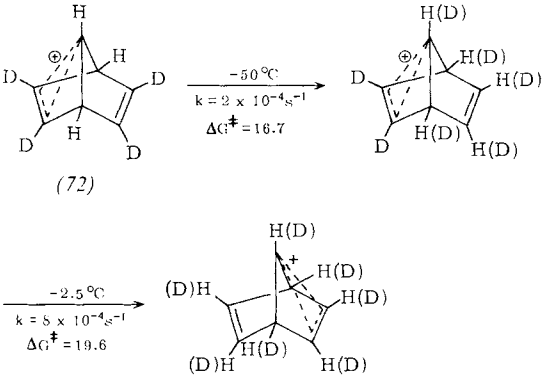
dienyl cation *(27)* followed by ring expansion back to the 7-norbornadienyl cation *(13)*. For labeled ion *(71)* this would give rise to a sequence in which the bound vinyl group moves stepwise around the five-membered ring of *(73)*.

(71) *(73)* *(70)*



Evidence to support this mechanism comes from the NMR spectra of ions derived from the deuterated *cis*- and *trans*-bicyclo[3.2.0]heptadienols *(74)* and *(75)*.

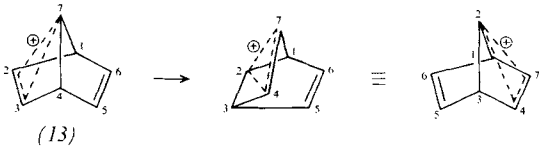
When either alcohol was extracted into FSO_3H at $-78\,^{\circ}C$, and the carbonium ion solution was observed within 120 s, the NMR spectrum was that of ion *(77)* plus ion *(78)* with no trace of signal for cation *(76)*.



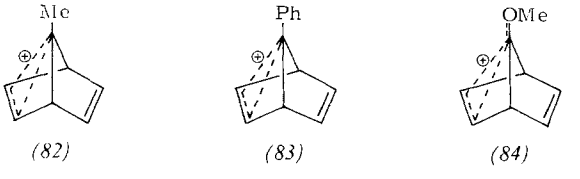
(74) *(75)* *(76)* *(77)* *(78)*

This result agrees with a mechanism in which the first formed [3.2.0] cation ring-expands to the [2.2.1] ion with either carbon of the cyclobutene vinyl function undergoing a 1,2-shift as the migrating vinyl group becomes the bound vinyl in *(77)* and *(78)*. The authors noted that neither ring contraction nor ring expansion of these systems occurs in solvolyzing solvents where carbonium ion lifetimes are very short compared to those in FSO_3H.

(13'') *(79)* *(80)* *(81)*



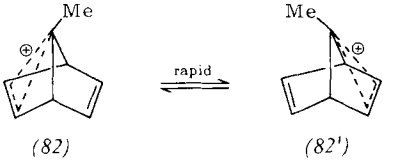
The 7-norbornadienyl cation *(13)* also undergoes a slower rearrangement which results in C-2 and C-3 becoming equivalent with C-5 and C-6 [31]. This equilibration of bound and unbound vinyl groups in *(13)* was studied by observing the NMR spectrum of cation *(72)* at higher temperatures. Cation *(72)* at $-50\,^{\circ}C$ has a deuterium atom at each bound vinyl position but only 2/5 of a deuterium atom at each unbound vinyl position as a result of degenerate five-carbon scrambling. At about $0\,^{\circ}C$ proton incorporation into the bound vinyl positions is observed, and the bound and unbound vinyl signals approach equal intensity.



(72)

The second rearrangement process requires 3 kcal/mole more activation energy than that for the five-carbon scrambling. Coupled with the more rapid degenerate five-carbon rearrangement, all seven carbon atoms of the 7-norbornadienyl cation *(13)* could become scrambled (complete carbon degeneracy). A possible mechanism for the second rearrangement process is bridge flipping and the value of $\Delta G^{\ddagger}$ for the rearrangement (19.6 kcal/mole) represents a lower limit on the energy barrier for this process.

Other mechanisms besides bridge flipping are possible for the equilibration of the two vinyl groups in *(13)* (for example, a 1,2-shift of an unbound vinyl carbon as shown below); some 7-substituted norbornadienyl cations were studied to further test this hypothesis. The 7-methylnorbornadienyl cation *(82)* was investigated [31]; the NMR spectrum of *(82)* in FSO_3H gave evidence for an unsymmetrical species at $-45\,^{\circ}C$.



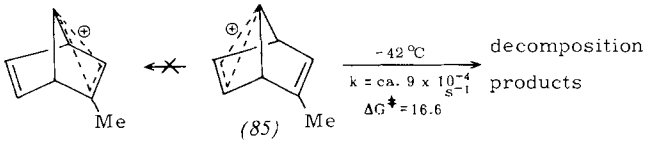
(13)

(82) *(83)* *(84)*

As the temperature was raised, the vinyl signals began to broaden and eventually coalesced at $-14\,^{\circ}C$. The methyl peak remained sharp at all times and the bridgehead signal sharpened to a pentuplet. These results indicated averaging of only the vinyl proton environments, which must have occurred by bridge flipping. The rate constant

(82) *(82')*

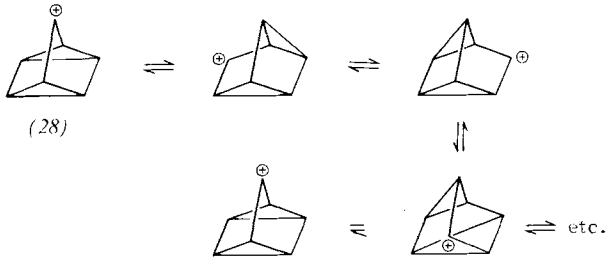
for this process at $-14\,^{\circ}C$ was 189 s^{-1} and $\Delta G^{\ddagger}$ was 12.4 kcal/mole. The 7-phenylnorbornadienyl *(83)* and 7-methoxynorbornadienyl *(84)* cations were also studied under the assumption that substituents better able to accommodate a positive charge would stabilize a symmetrical cation more than an unsymmetrical cation [32]. Both these cations at $-100\,^{\circ}C$ showed equivalence of all four vinyl protons. By examining the chemical shifts of the phenyl hydrogens in *(83)*, it was concluded that the phenyl group



[29] *P. R. Story* and *M. Saunders*, J. Amer. Chem. Soc. *84*, 4876 (1962).

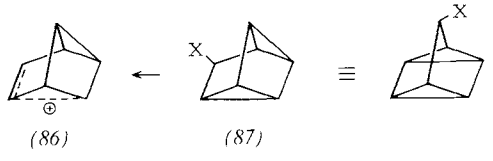
[30] *P. R. Story* and *B. J. A. Cooke*, Chem. Commun. *1968*, 1080.

[31] *M. Brookhart, R. K. Lustgarten*, and *S. Winstein*, J. Amer. Chem. Soc. *89*, 6352 (1967).

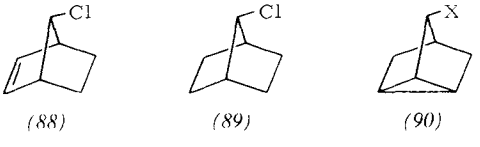


[32] *M. Brookhart, R. K. Lustgarten*, and *S. Winstein*, J. Amer. Chem. Soc. *89*, 6354 (1967).

was not sustaining considerable positive charge. Hence, it was concluded that *(83)* is best represented as unsymmetrical, yet undergoing rapid bridge-flipping with a barrier of < 7.6 kcal/mole. Recent work on the 2-methyl-7-norbornadienyl cation *(85)* indicates bridge flipping is not a favorable process when a substituent is located in one of the vinyl groups [33]. It was observed that *(85)* decomposed rather than undergoing bridge flipping.



3.3.3. Quadricyclyl or 3-Tetracyclo[3.2.0.0^{2,7}.0^{4,6}]-heptyl Cation



The quadricyclyl cation *(28)* has the potential for complete carbon degeneracy if continuous cyclopropylcarbinyl-cyclopropylcarbinyl rearrangements occur. The positive charge can be distributed to all carbons by such a mech-

anism involving both cyclopropyl rings. However, present evidence supports structure *(86)* as best representing the carbonium ion intermediate derived from the solvolysis of quadricyclane derivatives *(87)*. This charge delocalized cation would not necessarily exhibit the degenerate re-

arrangements as shown above. Cation *(86)* was first proposed to account for the remarkable reactivity of quadricyclane derivatives [34, 35]. It was found that 7-quadricyclyl chloride *(87)*, X = Cl, was less reactive than *anti*-7-norbornenyl chloride *(88)* by a factor of only 100 and more reactive than 7-norbornyl chloride *(89)* by approximately 10^9. Quadricyclane derivatives were found to be only about 30 – 40 times more reactive than the corresponding nortricyclane compounds *(90)* which contain only one cyclopropane ring [34]. The net effect of the second cyclopropane

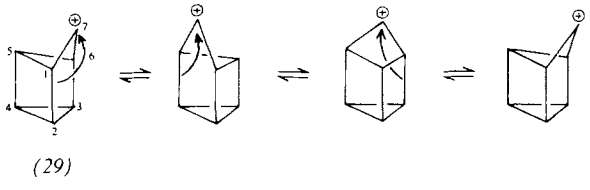
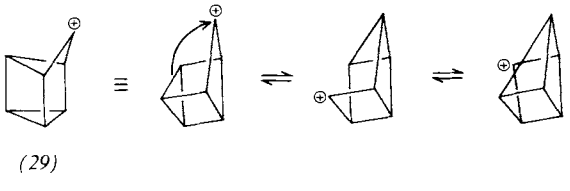
[34] *H. G. Richey, Jr.* and *N. C. Buckley,* J. Amer. Chem. Soc. *85*, 3057 (1963).

[35] *P. R. Story* and *S. R. Fahrenholtz,* J. Amer. Chem. Soc. *86*, 527 (1964).

ring appears to be negligible. This is similar to the participation of only one carbon-carbon double bond in the 7-norbornadienyl cation [31].



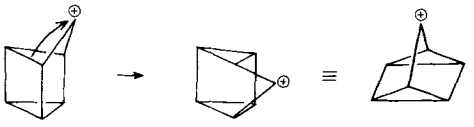
The solvolysis of 7-deuterioquadricyclyl tosylate *(91)* at 25 °C for 2 – 3 days in acetic acid containing an excess of



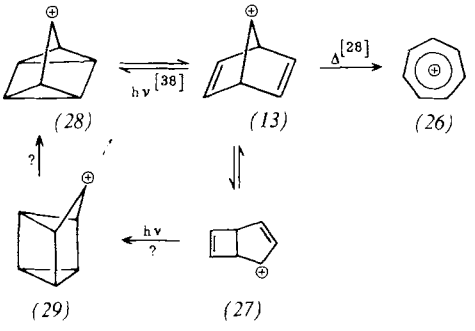
potassium acetate gave a 75% yield of a product mixture consisting of an approximately 50:50 ratio of *(94)* and *(95)* [36]. Both the quadricyclyl acetate *(94)* and the 7-norbornadienyl acetate *(95)* contained one deuterium by analysis of their NMR and mass spectra. This experiment indicates that the hydrogens of the quadricyclyl cation are not scrambled by rearrangement, thus ruling out a structure in which the positive charge is delocalized over two or more equivalent carbons. Hence, the quadricyclyl cation represents an example of a nondegenerate ion. The results above indicate the interconvertibility of the quadricyclyl and norbornadienyl cations *(92)* and *(93)*. The rearrangement of *(92)* to *(93)*, and subsequently to *(95)*, appears to be highly stereospecific.

3.3.4. Homoprismyl or 7-Tetracyclo[3.2.0.0^{2,4}.0^{3,6}]-heptyl Cation

The homoprismyl cation *(29)* represents another potentially degenerate $C_7H_7^+$ carbonium ion. This ion has not yet been studied, but is unique in that it may undergo several rearrangement possibilities. It could exhibit degenerate properties through Wagner-Meerwein rearrangements as shown below. This kind of process would result in fourfold partial carbon degeneracy; the four carbons of the cyclo-



butane ring bearing the positive charge would become equivalent. A second kind of process, participation of the three-membered ring in a homocyclopropylcarbinyl rearrangement, could serve to delocalize the positive charge over three carbons.

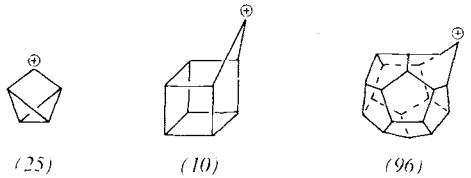


[36] *P. R. Story* and *S. R. Fahrenholtz,* J. Amer. Chem. Soc. *88*, 374 (1966).

(charge delocalization over all seven carbon atoms). However, a third rearrangement process exists for *(29)*, that of cyclobutane ring participation. This process would serve to destroy the homoprismyl ring system and generate the quadricyclyl cation *(28)*.

(29) *(28)*

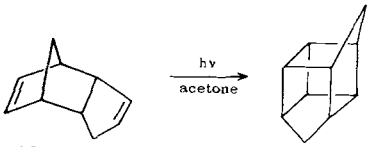
The last rearrangement mentioned above points out the relationship between the homoprismyl cation and other $C_7H_7^+$ ions. It is further interesting to note that *(29)* hypothetically could be formed by a photochemical cycloaddition within the bicyclo[3.2.0]heptadienyl cation [37].



(28) *(13)* *(26)* *(29)* *(27)*

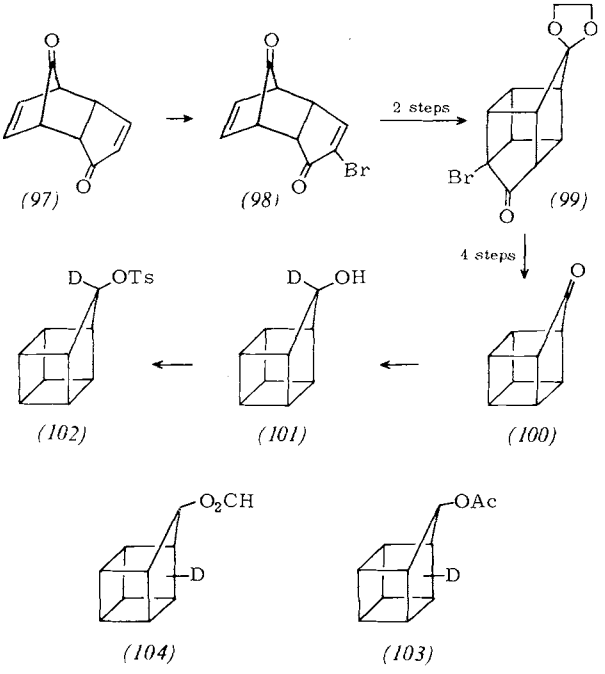
3.4. $C_9H_9^+$ Ions

3.4.1. 9-Homocubyl or 9-Pentacyclo-[4.3.0.0^{2,5}.0^{3,8}.0^{4,7}]nonyl Cation



The 9-homocubyl cation *(10)* represents one of the most interesting potentially degenerate carbonium ions within the $C_9H_9^+$ group. This cation, like the homotetrahedryl cation *(25)* (see Section 3.2) and the homododecahedryl cation *(96)*, belongs to a series of homologous ions based on regular polyhedra [23]. These three ions are similar in

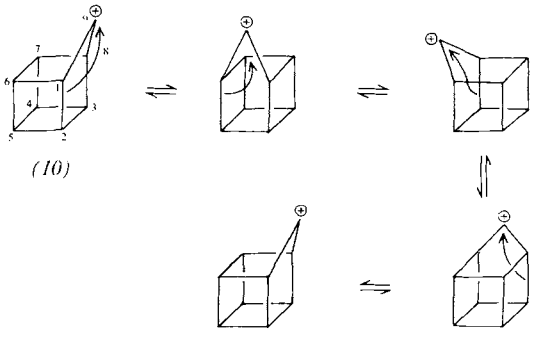
(25) *(10)* *(96)*



that they are all capable of complete carbon degeneracy by employing only 1,2-carbon shifts. All C-H units can exchange positions, thus making all carbon atoms and hydrogen atoms equivalent. The homododecahedryl cation *(96)* has not yet been investigated and the parent hydrocarbon, dodecahedron, has not been synthesized.

[37] An analogous reaction is the photosensitized intramolecular cyclization of cyclopentadiene dimer to pentacyclo[5.3.0.0^{2,5}.0^{3,9}.0^{4,8}]decane; see *G. O. Schenck* and *R. Steinmetz*, Chem. Ber. *96*, 520 (1963).

[38] The photochemical conversion of norbornadiene to quadricyclene has been carried out; see *W. G. Dauben* and *R. L. Cargill*, Tetrahedron *15*, 197 (1961); *G. S. Hammond, N. J. Turro*, and *A. Fischer*, J. Amer. Chem. Soc. *83*, 4674 (1961).



Investigations by workers at Smith, Kline and French Laboratories and Princeton University were first to indicate that the predicted degeneracy of the 9-homocubyl cation *(10)* could be achieved under solvolytic conditions [23]. The degeneracy of *(10)* was demonstrated by studying the deuterium labeling pattern obtained in the solvolysis products of the deuterated tosylate *(102)*. The synthesis of *(102)* involves photochemical cycloaddition of *(98)* to *(99)* and lithium tetradeuterioaluminate reduction of homocubanone *(100)* to form *(101)* as key steps. The NMR spectrum of *(102)* indicated essentially com-

(97) *(98)* *(99)* *(100)* *(101)* *(102)* *(103)* *(104)*

plete absence of the absorption peak for the proton at C-9. The course of the rearrangements was followed by the appearance and integration of this signal in the spectra of the solvolysis products. Solvolysis of deuterated 9-homocubyl tosylate *(102)* exhibited good first order kinetics in both acetic and formic acid, and in both cases the sole products isolated were 9-homocubyl acetate *(103)* and formate *(104)* with the deuterium label scrambled. The acetolysis rate constant at 25 °C was approximately 400 times faster than that expected from the carbonyl frequency of *(100)*. This enhanced rate suggests that the 9-homocubyl cation *(10)* may have a bridged structure.

There are two mechanistic possibilities for deuterium scrambling in *(10)*. One possibility is a stereospecific process involving bridged or rapidly equilibrating ions which This process combined with the Wagner-Meerwein rearrangement would result in complete carbon degeneracy

(10)

would make five carbon atoms and their attached hydrogens equivalent, provided no stereochemical leakage occurred. This mechanism, which is shown below, would scramble the deuterium label around only one five-membered ring.

A second possibility, a non-stereospecific reaction path, would allow distribution of the positive charge and the deuterium label to all nine carbons. This would also permit the interchange of all C–H units in the manner exhibited by bullvalene [2].

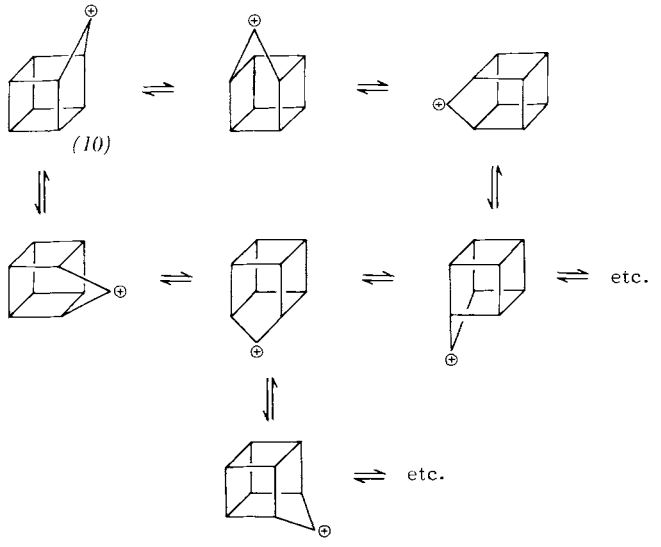


Table 4 shows the labeling pattern calculated for each process at each rearrangement stage.

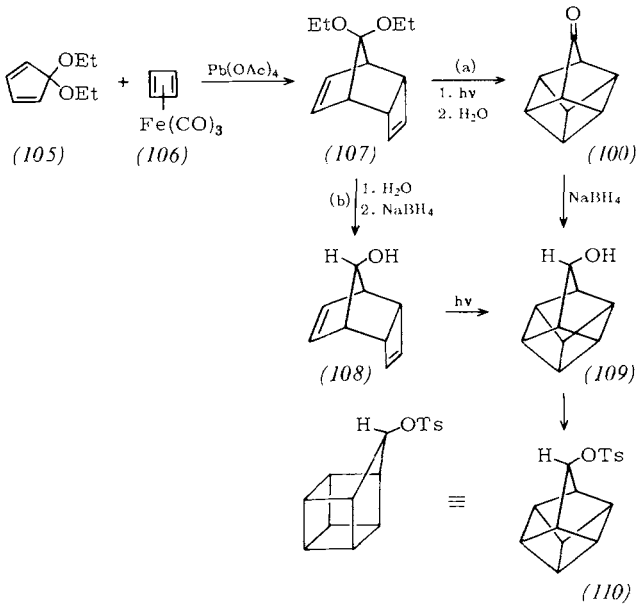
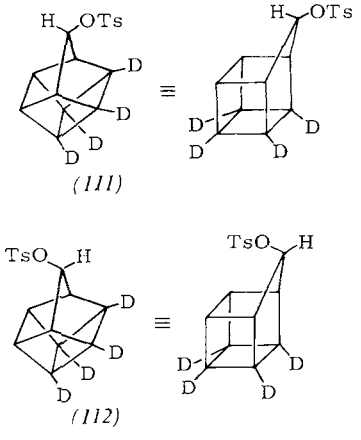
Table 4. Percentage of D remaining at C-9 in the 9-homocubyl system as a function of the number of 1,2-C,C rearrangements (from ref. [23]).

	No. of rearrangements								
	1	2	3	4	5	6	7	8	∞
%D at C-9, stereospecific process	50	37.5	31.3	27.3	24.8	23.1	22.1	21.4	20.0
%D at C-9, nonstereospecific process	50	37.5	31.3	27.0	23.7	21.2	19.3	17.7	11.1



The experimental results were the following: In buffered acetic acid at 125 °C for more than 10 half-lives, 36% D remained at C-9 after solvolysis. In unbuffered acetic acid at the same temperature and time, 22.5% D remained at C-9, indicating more than five rearrangements had occurred. In refluxing unbuffered formic acid only 10% D remained at C-9 with the other 90% D distributed throughout the molecule. This preliminary experiment in formolysis indicated that the full degeneracy of *(10)* could be achieved, but attempts to repeat this result have not succeeded [39].

Work by *Pettit* and *Barborak* on the homocubyl cation *(10)* further verified the findings described above [40]. These investigators employed both a different synthesis and a different deuterium labeling pattern to show that *(10)* when generated in acetic acid undergoes several stereospecific degenerate rearrangements before forming the acetate.

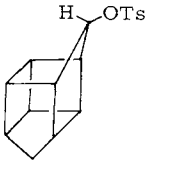


[39] *W. G. Dauben*, personal communication.

[40] *J. C. Barborak* and *R. Pettit*, J. Amer. Chem. Soc. *89*, 3080 (1967).

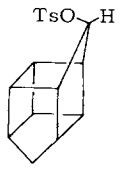
Two synthetic pathways (a) and (b) were used to prepare 9-homocubyl tosylate *(110)*. Substitution of perdeuteriocyclobutadienetricarbonyliron for *(106)* gave a tetra-

deuterio derivative of *(110)*. Path (a) afforded an equal mixture of the two tosylates *(111)* and *(112)*, while path (b) gave only isomer *(111)*.



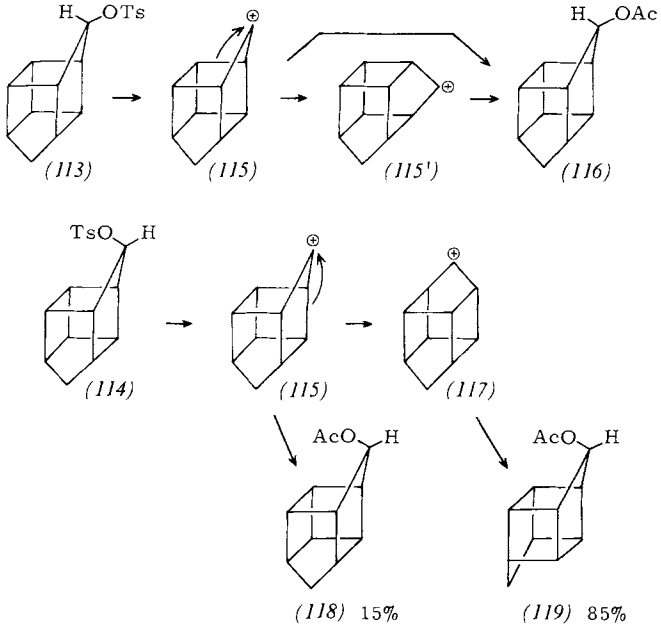
A sample of *(111)* and another consisting of an equal mixture of *(111)* and *(112)* was solvolyzed in acetic acid at 120 °C for 30 hours, and the acetates and unreacted tosylates were recovered. The percentage of deuterium at C-9 was measured to determine the extent of rearrangement. The amount of deuterium appearing at this position also depends on the stereospecificity of the rearrangement process. In a stereospecific process involving repeated migration of the carbon atom *trans* to the leaving group, *(111)* should show twice as much deuterium at C-9 as that of a mixture of *(111)* and *(112)* since *(112)* cannot generate deuterium at C-9 in such a process. In a nonstereospecific rearrangement process both samples should give the same amount of deuterium at C-9. The acetate formed from *(111)* showed 26.1% deuterium at C-9, while that from *(111)* and *(112)* showed 12.3%. The rearrangement appears to be stereospecific under these conditions. These results indicate that almost four Wagner-Meerwein shifts had occurred during solvolysis (see Table 5).

Table 5. Percentage of D at C-9 accompanying 1,2-shifts of *(111)* (from ref. [40]).



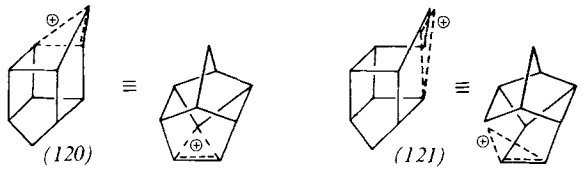
No. of 1,2-shifts	0	1	2	3	4	5	6	∞
% D at C-9	0	0	12.5	21.9	28.1	32.2	35.0	40.0

The above results compare favorably with those of the workers at Smith, Kline and French Laboratories and Princeton University. However, the recovered tosylates from *(111)* and *(112)* were also examined and these contained deuterium a C-9 to a larger degree than that observed for the acetates. Approximately twice as much deuterium appeared at C-9 in the reaction of *(111)* as with the mixture of *(111)* and *(112)*. This result indicates stereospecific rearrangement through internal return of the tosylate ion pair and contrasts with the result of the first group of workers which indicated that stereochemical leakage could at least occur in formolysis.

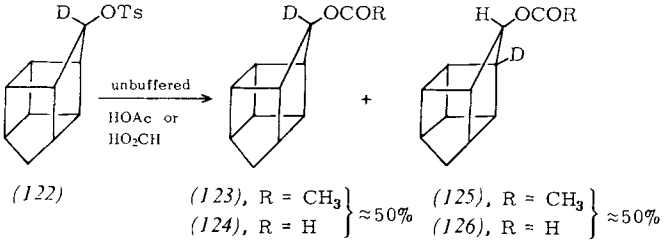


Studies have also been carried out on the bishomocubyl systems *(113)* and *(114)* [41]. The solvolysis of these tosylates is of interest since the cations generated from *(113)* and *(114)* undergo rearrangements similar to the homocubyl cation *(10)*. In these cases the migration of the second methano carbon bridge serves as a means of detecting the rearrangements. The acetolysis (unbuffered) of tosylates *(113)* and *(114)* gave the acetates *(116)* and *(119)* as major products, which can be rationalized as

(113)



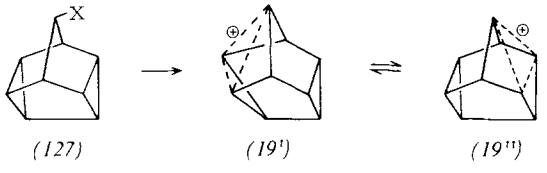
(114)



(118) 15% *(119)* 85%

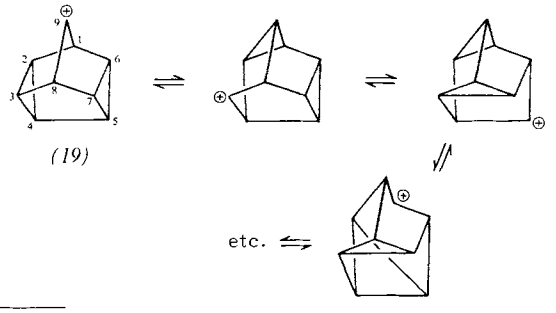
arising *via* 1,2-alkyl shifts through cations *(115)*, *(115')*, and *(117)* followed by substitution with retention of configuration. Alternatively, the results can be explained by assuming that the bridged carbonium ions *(120)* and *(121)* are intermediates in the solvolyses of *(113)* and *(114)*,

(120) *(121)*



respectively. Recent work on the deuterated tosylate *(122)* supports the intermediacy of the bridged ion *(12)* or its equivalent of two rapidly equilibrating classical ion pairs in the solvolysis of *(113)* [42]. The results of the solvolyses of the bishomocubyl systems are in direct analogy with those for the homocubyl compounds.

(122) *(123)*, R = CH_3 *(124)*, R = H ≈50% *(125)*, R = CH_3 *(126)*, R = H ≈50%



3.4.2. 9-Pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonyl Cation

The 9-pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonyl cation *(19)* is another ion of the $C_9H_9^+$ group which possesses the unique structural and symmetry properties that could result in multiple carbon degeneracy. Cation *(19')*, derived from the solvolysis of *(127)*, is an analog of the *cis*-3-bicyclo-[3.1.0]hexyl cation [43] (see Section 4.7) and should be capable of threefold degeneracy by means of a homocyclopropylcarbinyl rearrangement *(127)* → *(19')*. There is also the possibility of a bridge-flip rearrangement which can again regenerate a cation identical with the original. The combination of both processes at the same time would make all positions interchangeable and all nine carbon

(127) *(19')* *(19'')*

atoms would become equivalent. An alternative way of representing this possibility of complete degeneracy in *(19)* is by successive, discrete carbon-carbon bond shifts from the two participating cyclopropyl rings (all ions formed are identical).

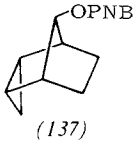
[43] *S. Winstein*, *E. C. Friedrich*, *R. Baker*, and *Y. Lin*, Tetrahedron Suppl. *8* [II], 621 (1966), and literature cited there.

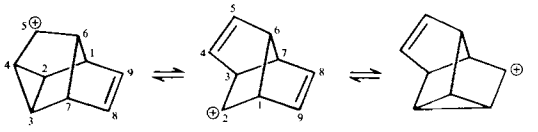
Recently, work on the synthesis and solvolysis of 9-deuteriopentacyclo[4.3.0.0^{2,4}.0^{3,8}.0^{5,7}]nonyl *p*-nitrobenzoate *(134)* was carried out by *Coates* and *Kirkpatrick* [44]. The synthetic scheme is outlined below. The most important steps in the synthesis are the acid-catalyzed rearrangement of the epoxide *(129)* to the bromohydrin *(130)* and the photochemical valence isomerization of the tetracyclic alcohol *(131)* to the desired pentacyclic alcohol *(132)*.



The solvolysis of the unlabeled *p*-nitrobenzoate *(135)* in 65% aqueous acetone at 125.0 °C exhibited good first order kinetics with a rate constant of $7.0 \times 10^{-5}\ s^{-1}$. Under the same conditions 7-norbornadienyl *p*-nitrobenzoate *(136)* solvolyzed with a first-order rate constant of $5.8 \times 10^{-4}\ s^{-1}$ [45]. Therefore, k_1 *(135)*/K_1 *(136)* equals 0.12 [16].

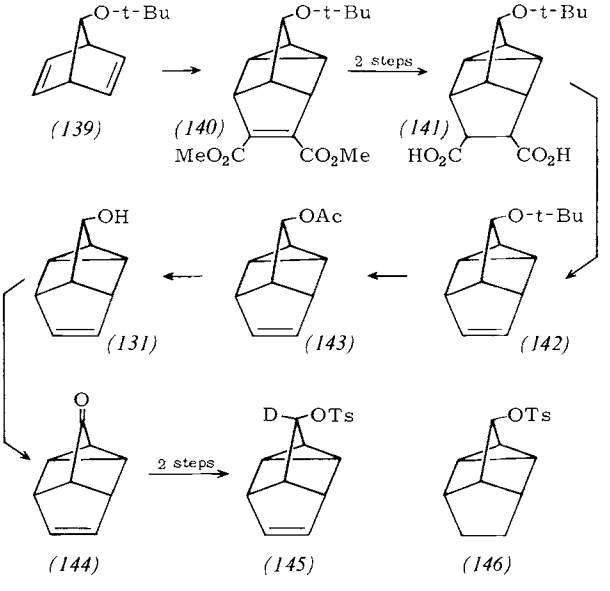
The large rate enhancement observed for *(135)* cannot be attributed to an overall relief of strain upon cyclopropane ring opening since *(132)* is the major reaction product. The acceleration most probably is a result of the geometry in this system which is particularly favorable for homocyclopropyl-carbinyl participation in the solvolysis transi-

tion state. This hypothesis was previously advanced for the similar *endo-anti*-8-tricyclo[3.2.1.0^{2,4}]octyl *p*-nitrobenzoate *(137)* [16], which solvolyzes approximately 80 times faster than *(135)*.



[44] *R. M. Coates* and *J. L. Kirkpatrick*, J. Amer. Chem. Soc. *90*, 4162 (1968); *92*, 4883 (1970).

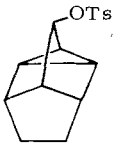
[45] *S. Winstein* and *C. Ordronneau*, J. Amer. Chem. Soc. *82*, 2084 (1960).



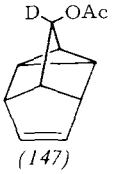
Solvolysis of *(134)* for 4–5 half lives regenerated *(132)* in which ^{1}H-NMR absorption at position C-9 had reappeared. The extent of the deuterium scrambling was determined by the ^{2}H- and ^{1}H-NMR spectrum of the product. The ^{2}H-NMR spectrum showed two peaks at τ 5.8 and 8.2 in a ratio of 1:2.05. This indicated that one-third of the deuterium label remained at C-9 and the other two-thirds were distributed between two other equivalent positions. Quantitative integration of the ^{1}H-NMR spectrum of scrambled *(132)* showed the presence of 0.67 proton at C-9. Also, the signal at τ 8.2 was reduced from an area of 2 to 1.3 protons while the remainder of the spectrum was essentially unchanged. These results provide evidence for the triply degenerate carbonium ion intermediate *(19')*. Further rearrangement through participation of the second cyclopropane ring did not occur under conditions employed.

3.4.3. Tetracyclo[4.3.0^{2,4}.0^{3,7}]non-8-en-5-yl Cation

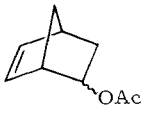
The tetracyclo[4.3.0.0^{2,4}.0^{3,7}]non-8-en-5-yl cation *(15)* is capable of partial carbon degeneracy through a combination of cyclopropylcarbinyl and homoallylic rearrangements. Transformation of *(15)* into ion *(138)* is readily conceivable; *(138)*, with a C_2 symmetry axis through C-2



and the midpoint of the C-6–C-7 bond, should be convertible into *(15')* or back into *(15)* by homoallylic rearrangement. If ion *(15)* contains a deuterium label at C-5, continuous operation of the above mechanism will eventually result in deuterium scrambling to the four positions C-4, C-5, C-8, and C-9 because of the equivalence of these four carbon atoms. The five carbon atoms of the central five-membered ring, C-1, C-2, C-3, C-6, and C-7, would also become equivalent by such a process, but would bear no deuterium label.

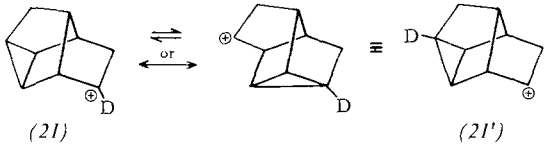


Schleyer and *Leone* were the first investigators to study cation *(15)* [46]. The synthesis is primarily based on the homo Diels-Alder reaction of dimethyl acetylenedicarboxylate with *(139)* to form *(140)*, which contains the desired tetracyclic ring system. Acid cleavage of the *tert*-butyl ether *(142)* to form acetate *(143)* is also an important step. Alcohol *(131)* is the same as that synthesized independently by *Coates* and *Kirkpatrick* (see Section 3.4.2) [44]. The saturated derivative *(146)* was also prepared for comparison purposes.



The solvolysis of *(145)* in acetic acid buffered with an excess of sodium acetate at 110 °C for three hours (over 10 half-lives) led to the formation of 5-deuterioacetate *(147)* as the sole product with the deuterium completely unscrambled. Attempts to study the solvolysis under more vigorous conditions with unbuffered acetic or formic acid failed due to solvent addition to the double bond. A summary of the acetolysis rate constants for the undeuterated tosylate *(148)*, the saturated derivative *(146)*, and nortricyclyl tosylate *(149)* are shown below in Table 6.

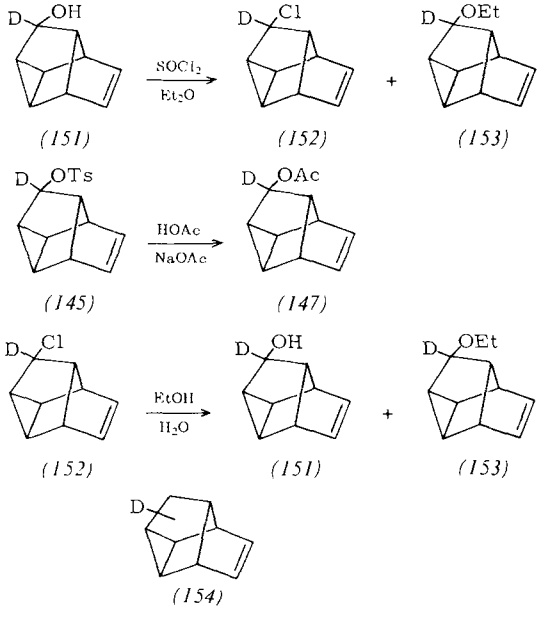
Table 6. Acetolysis of *(148)*, *(146)*, and *(149)* (from ref. [46]).



Compound	 *(148)*	 *(146)*	 *(149)*
k (s^{-1}) (75 °C)	1.85×10^{-4}	7.38×10^{-3}	1.62×10^{-3}
k_{rel}	0.11	4.6	1.0
ν_{CO} (cm^{-1})	1755	–	1762

The results obtained are somewhat surprising since the solvolysis of nortricyclyl tosylate *(149)* produces some rearranged product, norborn-2-en-5-yl acetate *(150)* [47].

(147)



(150)

Also, work by *Freeman* and *Balls* on the related 8-tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]nonyl cation *(21)* indicated facile rearrangement of the type shown below (see Section 4.11) [48].

(21) *(21')*

The fact that no deuterium scrambling occurred in the solvolysis of *(145)* shows that "leakage" to *(138)* and subsequent homoallylic rearrangement was unfavorable. Apparently cyclopropyl ring opening in *(15)* does not occur because the added two-carbon bridge (C-8 – C-9) causes more strain in the norbornene than in the nortricyclene system. Both the inductive effect and the steric effect of the carbon-carbon double bond may cause the solvolysis rate of *(148)* to be significantly slower than that of *(146)*. The carbonyl frequency of ketone *(144)* indicates that there is a significant rate acceleration in the ionization of *(148)*, probably due to cyclopropylcarbinyl delocalization.

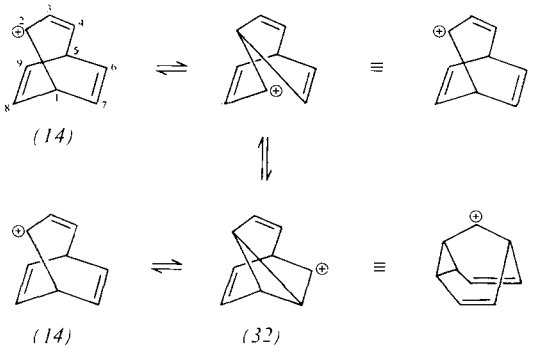
Work by *Klumpp* serves to independently verify the results obtained above on cation *(15)* [49]. By employing a synthesis related to that of *Schleyer* and *Leone*, the tetracyclic compounds *(151)*, *(145)*, and *(152)* were prepared. The solvolytic studies indicated were carried out in an attempt to generate a degenerate cation corresponding to *(15)*. No deuterium scrambling was observed in any of the cases studied. *Klumpp* feels that the cause for nonrearrangement is a high activation energy for the transfer of positive charge between two equivalent cyclopropylcarbinyl-homoallyl configurations within the same molecule [*(15)* and *(15')*]. The Grignard reagent of *(152)* was also prepared, hydrolyzed, and worked up for *(154)*. Interestingly enough, it was found that some deuterium (≈35%) scrambled to C-8 and C-9 under these conditions. An exact interpretation of this result still requires further investigation.

(151) *(152)* *(153)* *(145)* *(147)* *(152)* *(151)* *(153)* *(154)*

The results obtained by both workers clearly show that the tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-en-5-yl cation *(15)* is another example of a nondegenerate ion despite its possibilities for degenerate rearrangement. The fact that the Grignard reagent of this system rearranged (presumably through a carbanion type intermediate) may be significant, but further studies to determine the mechanism of deuterium scrambling are necessary.

3.4.4. Bicyclo[3.2.2]nona-3,6,8-trien-2-yl Cation

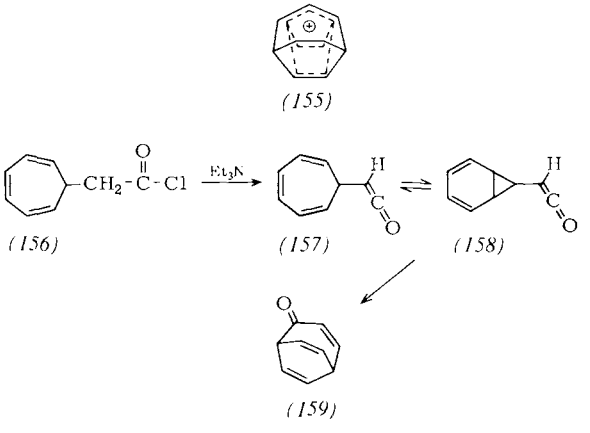
The bicyclo[3.2.2]nona-3,6,8-trien-2-yl cation *(14)*, a vinylog of the 7-norbornadienyl cation, can potentially exhibit degenerate properties through 1,2-vinyl shift mechanisms or through the equivalent homoallylic barbaralyl cations



[46] *P. von R. Schleyer* and *R. E. Leone*, J. Amer. Chem. Soc. *90*, 4164 (1968).

[47] *S. J. Cristol, M. K. Seifert, D. W. Johnson*, and *J. B. Juvale*, J. Amer. Chem. Soc. *84*, 3918 (1962).

[48] *P. K. Freeman* and *D. M. Balls*, Tetrahedron Lett. *1967*, 437; *P. K. Freeman, D. M. Balls*, and *J. N. Blazevich*, J. Amer. Chem. Soc. *92*, 2051 (1970).

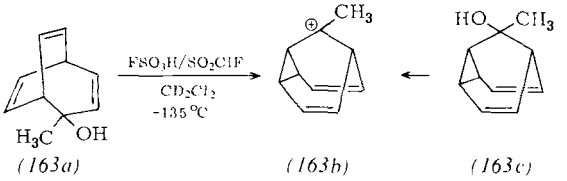


[49] *G. W. Klumpp*, Recl. Trav. Chim. Pays-Bas *87*, 1053 (1968).

(32). Combination of either of these rearrangement processes with allyl resonance (which delocalizes the positive charge between C-2 and C-4) would result in the eventual distribution of a deuterium at C-2 to all nine carbon atoms of the ion.

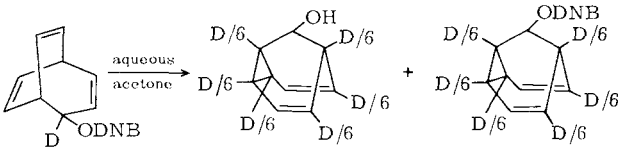
(14) *(14)* *(32)*

Goldstein and *Odell* sought to determine whether cation *(14)* might exhibit unusual stability or instability as a six π-electron "bicyclotropylium" ion *(155)* [50]. To this end bicyclo[3.2.2]nona-3,6,8-trien-2-one *(159)* was first synthesized. Reduction of *(159)* afforded bicyclo[3.2.2]nona-3,6,8-trien-2-ol *(160)*, which when treated with ethereal $AlCl_3$ gave a 58% yield of tricyclo[3.3.1.$0^{2,8}$]nona-3,6-dien-9-ol or "barbaralol" *(161)*. Similarly, reduction of *(159)* with $LiAlH_4$-$AlCl_3$ gave 30% barbaralol *(161)*, 30% barbaralane *(162)*, and 13% indan *(163)*. No bicyclo[3.2.2]-



(155)

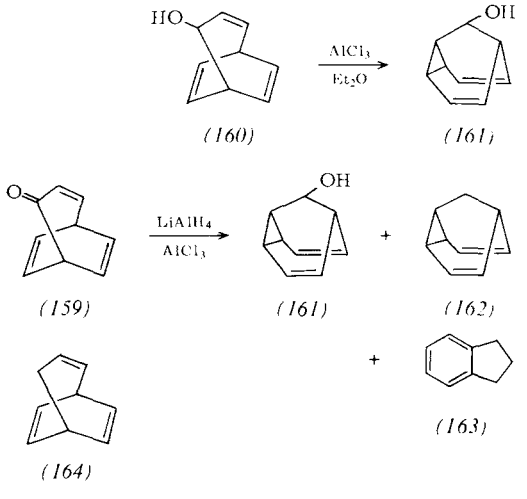
(156) *(157)* *(158)* *(159)*



nona-2,6,8-triene *(164)* was found in the product mixture. These observations suggested not only that the barbaralane skeleton is more stable than the bicyclo[3.2.2.]nona-2,6,8-trienyl skeleton, but also that the barbaralyl cation *(32)* is preferred over the bicyclononatrienyl cation *(14)*.

Recent, extensive investigations have confirmed this conclusion. 2-Methyl-2-bicyclo[3.2.2]nona-3,6,8-trienol *(163a)*, easily prepared from ketone *(159)*, gives the 9-methyl-9-barbaralyl cation *(163b)* at −135 °C in FSO_3H-SO_2ClF-CD_2Cl_2; the same ion can be obtained directly from *(163c)* [50a, 50b]. Similarly, under the same conditions *(160)* gives the 9-barbaralyl cation *(32)* [50c]. (The behavior of ions *(32)* and *(163b)* is discussed in Section 3.4.7.)

(163a) *(163b)* *(163c)*



Additional information is revealed by solvolysis of deuterium labeled bicyclo[3.2.2]nona-3,6,8-trien-2-yl 3,5-dinitrobenzoate *(163d)* [50d] and the corresponding *p*-nitrobenzoate [50e]. From *(163d)* only 9-barbaralol *(163e)* and

(163d) *(163e)* *(163f)*

the return product *(163f)* are obtained; in both these products the deuterium label has become virtually statistically scrambled to *six but to only six* of the *nine* available positions, as shown [*]. This demonstrates that the conversion of cation *(14)* to *(32)* is not a simple, direct process. (The possible mechanism whereby the observed scrambling takes place is discussed in Section 3.4.7.)

Experimental results seem to indicate that cation *(14)* possesses no unusual stability as might be depicted by formulation *(155)*. The solvolysis rates of bicyclo[3.2.2]-nona-3,6,8-trien-2-yl derivatives, *e.g.(163d)*, are not accelerated, and, perhaps, are even slower than one might anticipate for allyl-stabilized systems [50d, 50e]. *Goldstein* has attempted to give a theoretical justification for cation *(14)* not possessing exceptional stability in terms of "bicycloaromaticity" [51]. By using MO symmetry arguments,

(160) *(161)* *(159)* *(161)* *(162)* *(163)* *(164)*

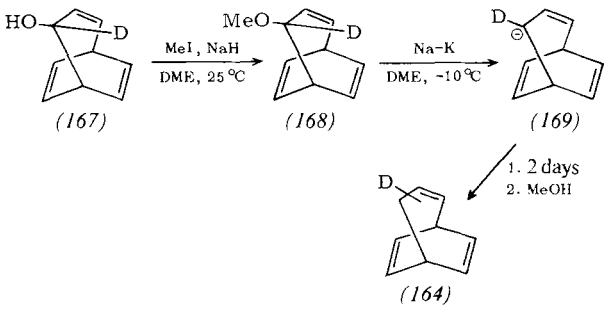
[*] It should be kept in mind that barbaralyl derivatives undergo rapid degenerate Cope rearrangements[58]which contribute to the extent of deuterium scrambling observed in the solvolysis products *(163e)* and *(163f)*.

[50d] *J. C. Barborak* and *P. von R. Schleyer*, J. Amer. Chem. Soc. *92*, 3184 (1970).

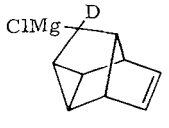
[50e] *J. B. Grutzner* and *S. Winstein*, J. Amer. Chem. Soc. *92*, 3186 (1970).

[51] *M. J. Goldstein*, J. Amer. Chem. Soc. *89*, 6357 (1967).

it was shown that the 2-bicyclo[3.2.2]nonatrienyl cation *(14)* should be *destabilized* and *antibicycloaromatic*, but that the corresponding anion *(165)* should be *stabilized* and *bicycloaromatic*. As an experimental verification of this prediction, anion *(165)* was recently prepared by *Winstein* and *Grutzner* and shown by its NMR spectrum to be a delocalized structure *(166)* [52].

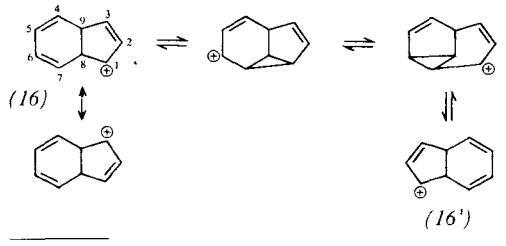


(165)

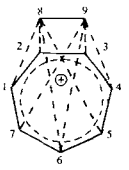


(166)

Another interesting observation was obtained in the work of *Winstein* and *Grutzner* concerning anion *(165)*. Their preliminary experiments indicated the occurrence of a degenerate nine-carbon rearrangement in *(165)* [52]. The sequence outlined below was carried out. The hydrocarbon *(164)* exhibited essentially complete deuterium scrambling to all carbon atoms. The NMR spectrum of *(169)* immediately after preparation showed no scrambling. This carbon degeneracy could be formulated as in the case of cation *(14)* as proceeding through a series of 1,2-vinyl shifts or through a barbaralyl intermediate. This degeneracy is still under investigation, but, together with the work of *Klumpp* on the rearrangements of *(17)* [49], it may indicate that the anions of certain potentially degenerate cation systems can exhibit degenerate properties although the cations do not.



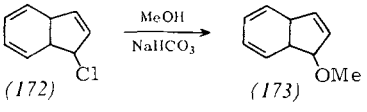
(167) *(168)* *(169)* *(164)*



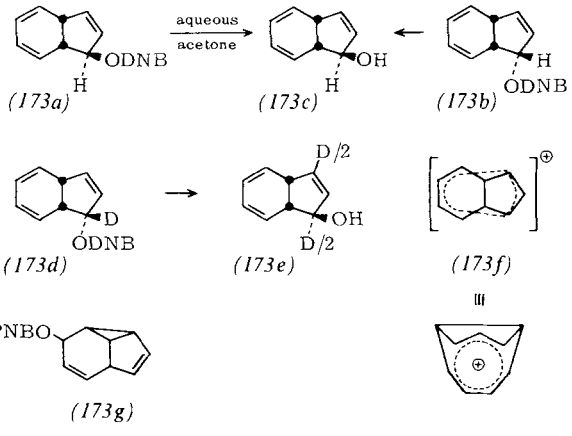
(170)

3.4.5. *cis*-8,9-Dihydro-1-indenyl Cation

The *cis*-8,9-dihydro-1-indenyl cation *(16)* could show degenerate properties through a homoallylic rearrangement followed by a cyclopropylcarbinyl-cyclopropylcarbinyl rearrangement. The combination of these processes with allyl resonance in *(16)* and *(16')* would result in the equivalence of carbon atoms C-1, C-2, C-3, C-4, C-5, C-6, and C-7. This is perhaps best represented by ion intermediate *(171)*, in which the seven equivalent carbons form a tropylium ion type ring with a two carbon bridge rotating above the ring.



(16) *(16')*



(171)

The above predictions for cation *(16)* have not yet been fully tested experimentally. The methanolysis of 1-chloro-8,9-dihydroindene *(172)* has been carried out, and the product was 1-methoxy-8,9-dihydroindene *(173)* [53]. More recently solvolysis of both *exo (173a)* [54a, 54b] and *endo (173b)* [54a] derivatives of 1-hydroxy-*cis*-8,9-dihydroindene have been studied. In aqueous acetone the product is 1-*exo*-hydroxy-*cis*-8,9-dihydroindene *(173c)*. Studies of labeled *(173d)* under the same conditions give a scrambling pattern in the product *(173e)* which indicates no degeneracy in the intermediate ion *(16)* other than that expected on the basis of allylic resonance [54a].

(172) *(173)*

(173a) *(173c)* *(173b)*

(173d) *(173e)* *(173f)*

(173g)

In particular, no evidence for the formation of the bishomotropylium ion *(173f) on solvolysis* is found, and the same is true for the solvolysis of *(173g)* [54b]. However, ion *(173f)* is formed in $FSO_3H/SO_2ClF/CD_2Cl_2$ solution at −125 to −135 °C from both *(173c)* and the alcohol related to *(173g)* [54b]. Under these conditions, *(173f)* appears to be one of the most stable $C_9H_9^+$ cations and it is the product of rearrangement of the 9-barbaralyl cation *(32)* [50c]. Even the tertiary 9-methyl-9-barbaralyl cation *(163b)* rearranges to a methyl-substituted bishomotropylium ion [50a, 50b].

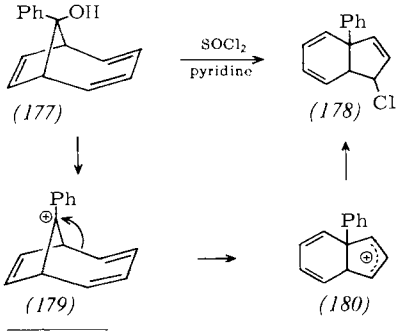
3.4.6. Bicyclo[4.2.1]nona-2,4,7-trien-9-yl Cation

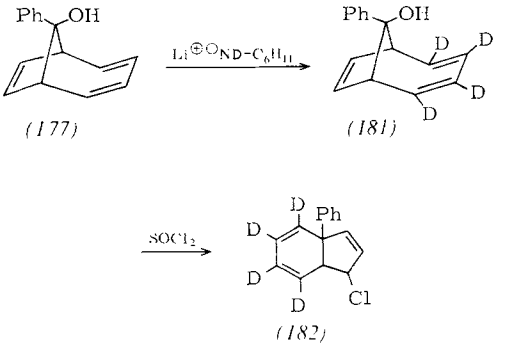
The bicyclo[4.2.1]nona-2,4,7-trien-9-yl cation *(31)*, another vinylog of the 7-norbornadienyl cation, may undergo two types of rearrangement processes which could lead to degeneracy. One of these would be the 1,2-vinyl shift of C-7 or C-8 to form intermediate ion *(174)*. Cation *(174)* after resonance interconversion to *(174')* could then ring expand back to cation *(31')*. Continuous operation of this



(31) *(174)* *(174')* *(31')*

process, in direct analogy with the mechanism of degeneracy observed for the 7-norbornadienyl cation (see Section 3.3.2), would result in the equivalence of carbon atoms C-1, C-2, C-3, C-4, C-5, C-6, and C-9. A second type of rearrangement in *(31)* would be a 1,2-vinyl shift of C-2 or C-5. This would result in the formation of the dihydroindenyl cation *(16)* which can exhibit degenerate properties as described in Section 3.4.5. The dihydroindenyl rearrangements mix carbon atoms C-2, C-3, C-4, C-5, C-6, C-7, and C-8. Work on the parent bicyclo[4.2.1]nona-2,4,7-trien-9-yl cation *(31)* has not yet been carried out. However, some experiments have been done with the 9-phenyl substituted system, which has been synthetically accessible through the work of *Cantrell* and *Shechter*. These workers prepared compound *(176)* from the reaction of dilithium cyclooctatetraenediide *(175)* with benzoyl chloride[55]. *Kende* and *Bogard* obtained alcohol *(177)* by alkaline hydrolysis of *(176)*[56].Alcohol *(177)* when treated with

(175) *(176)* *(177)*

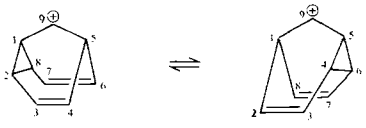


two equivalents of thionyl chloride and one equivalent of pyridine gave a high yield of 1-chloro-9-phenyl-*cis*-8,9-di-

(177) *(178)* *(179)* *(180)*

[55] *T. S. Cantrell* and *H. Shechter*, J. Amer. Chem. Soc. *87*, 3300 (1965).

hydroindene *(178)*[56]. Presumably, the mechanistic path through ions *(179)* and *(180)* is involved. This hypothesis was verified by a labeling experiment[57]. The results seem to indicate that the bicyclo[4.2.1]nonatrienyl cation *(31)*

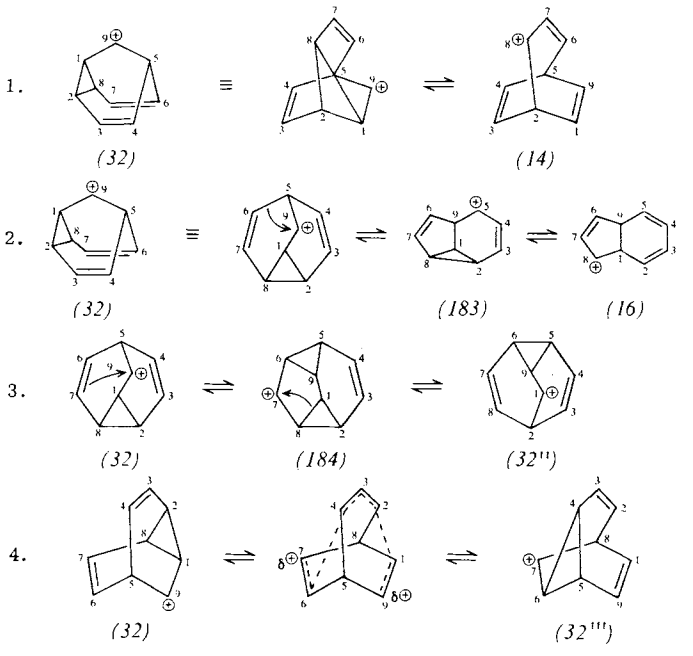


(177) *(181)* *(182)*

would rearrange to the dihydroindenyl cation *(16)*, but that the reverse process is not favorable. No deuterium scrambling was observed in product *(182)*, which indicates that the potential degenerate rearrangements in the dihydroindenyl cation *(16)* may not occur. The interconversion of two $C_9H_9^+$ type ions is also demonstrated by the above experiments.

3.4.7. Barbaralyl or Tricyclo[3.3.1.$0^{2,8}$]nona-3,6-dien-9-yl Cation

The barbaralyl cation *(32)* is unique among the potentially degenerate carbonium ions within the $C_9H_9^+$ group. This cation has the capacity to exhibit degeneracy through a combination of degenerate carbonium ion rearrangements and degenerate Cope rearrangements. The latter possibility exists because the barbaralyl cation *(32)*, like bullvalene[2], contains a homotropylidene structure. This



(32) *(32')*

rearrangement causes the interconversion and equivalence of carbon atoms C-1 and C-5, C-2 and C-4, and C-8 and C-6. Some of the potential carbonium ion rearrangements of *(32)* that could lead to degeneracy are shown in Scheme 1.

Mechanism 1) involves the interconversion of the 9-barbaralyl *(32)* and the bicyclo[3.2.2]nonatrienyl *(14)* cations. Since *(14)* has the potential of undergoing complete carbon degeneracy as described in Section 3.4.4, this mechanism would predict complete carbon scrambling in *(32)* also. Such degeneracy may be even easier to achieve. Because of symmetry in the allylic ion *(14)*, many of the carbons are equivalent. If the degenerate Cope rearrangement in *(32)* is rapid, the mere conversion of *(32)* into *(14)* and back again will lead eventually to complete degeneracy.

Mechanism 2) employs a 1,2-vinyl shift to form ion *(183)* which could give rise to either the dihydroindenyl *(16)* or the bishomotropylium *(184)* cations. If this process were reversible, *(32)* would eventually become completely de-

[56] *A. S. Kende* and *T. L. Bogard*, Tetrahedron Lett. *1967*, 3383.
[57] *A. S. Kende*, personal communication.

Scheme 1

generate. This mechanism seems unlikely since precursors to *(16)* and to *(183)* give no barbaralyl products either under solvolysis [53, 54a, 54b] or stable ion conditions [50c, 54b]. Mechanism 3) involves direct formation of the bishomotropylium ion *(184)* by homoallylic rearrangement from *(32)*. As shown [and as implied by *(171)*], ion *(184)* has the potential of extensive automerization, but this process is not rapid under stable ion conditions at $-125\,^{\circ}C$ [50c]. Furthermore, experimental observations show that *(184)* is more stable than *(32)* and does not reconvert, at least in super acid media [50a, 50c]. Thus, even though mechanism 3) can, in principle, give rise to complete scrambling in the 9-barbaralyl cation *(32)*, it does not, in fact, seem to take place.

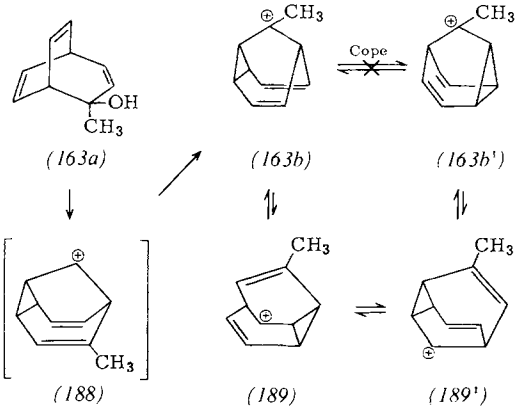
Mechanism 4) is a synchronous process involving the concerted migration of three bonds. This results in the direct reformation of the 9-barbaralyl cation *(32''')*, but with some of the carbon atoms mixed. After several such rearrangements, carbons 3,7, and 9 would become equivalent, as would the six remaining carbon atoms [keeping the degenerate Cope rearrangement *(32)* $\rightleftharpoons$ *(32')* in mind]. Only recently has the experimental picture of the barbaralyl cation *(32)* become clear. The first evidence was obtained by solvolysis [59]. Contrary to an earlier suggestion [58], 9-barbaralyl tosylate *(185)* was found to be quite reactive; in acetic acid at 16.5 °C it solvolyzed with a first order rate constant of $2.28 \times 10^{-3}\ s^{-1}$ [59]. Solvolysis of

(185) *(186)*

deuterated tosylate *(186)* in acetic acid (sodium acetate buffer, thirty minutes at 25 °C) and in aqueous acetone (80% acetone, one hour at 18 °C) gave barbaralyl acetate *(187)* and barbaralol *(161)*, respectively, as the main products with the deuterium label scrambled to every position [59]. Multiple integrations of the NMR spectra of the products from several solvolytic runs gave the average percentage deuterium distributions as shown in Table 7.

The results obtained show that the potential for carbon degeneracy in the barbaralyl cation *(32)* can be realized. However, the label distributions are not uniquely consistent

Table 7. Solvolysis products of barbaralyl tosylate *(186)* (mean values from several experiments).



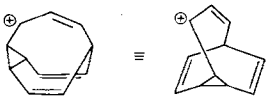
(187), R = Ac
(161), R = H

Position	Solvolysis with HOAc D (%)	Solvolysis with aq. acetone ± 3 %	Statistical D distribution D (%)
9	28.4	53.2	11.1
1,5	7.4	5.2	22.2
2,8,4,6	18.2	1.7	44.4
3,7	46.1	39.9	22.2

with any one mechanism postulated above. The first three mechanisms would predict a statistical deuterium distribution after many rearrangements. Mechanism 4) would predict 33.3% D at C-9 and 66.6% D at C-3, C-7 after many rearrangements. The observed experimental values do indicate a high proportion of deuterium at C-3, C-7, and C-9, particularly in the product derived from solvolysis in aqueous acetone. Thus, the results seem best explained by a combination of mechanism 4), or its equivalent, as the primary process responsible for deuterium scrambling with another mechanism that allows complete label scrambling.

The existence of the three-fold degenerate rearrangement process [mechanism 4)] in the 9-barbaralyl cation *(32)* has been confirmed in two additional ways. As described in Section 3.4.4, solvolysis of deuterium-labeled bicyclo-[3.2.2]nonatrien-2-yl derivatives, *e.g. (163d)*, gave rise to 9-barbaralyl products with the deuterium scrambled to six, but only to six positions, *e.g. (163e)* and *(163f)*, in accord with mechanism 4) [50d, 50e].

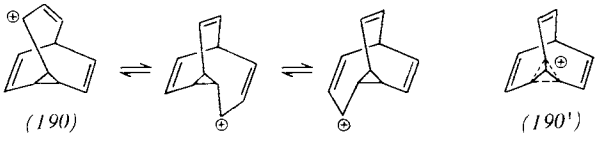
The "methyl-labeled" bicyclononatriene *(163a)* behaves somewhat differently in FSO_3H-SO_2ClF solution at low temperature [50a, 50b]. The expected ion *(188)* is not observed; rather the more stable tertiary species *(163b)* is first produced. This ion undergoes a degenerate rearrangement ($\Delta G^{\neq} = 7.3$ kcal/mole at $-121\,^{\circ}C$) which renders the "left-hand" and "right-hand" sides of the molecule equivalent [50b]. Although this equivalence might easily be



[58] *W. von E. Doering, B. M. Ferrier, E. T. Fossel, J. H. Hartenstein, M. Jones, Jr., G. Klumpp, R. M. Rubin,* and *M. Saunders,* Tetrahedron *23*, 3943 (1967).

[59] *J. C. Barborak, J. Daub, D. M. Follweiler,* and *P. von R. Schleyer,* J. Amer. Chem. Soc. *91*, 7760 (1969).

pictured as a degenerate Cope rearrangement, *(163b)* ⇌ *(163b')*, analysis of the NMR spectrum shows that this is not actually taking place. Rather, the interconversion probably occurs *via (189)* and *(189')*, *i.e.*, mechanism 4) [50b]. At slightly higher temperatures ($\Delta G^{\neq}$ = 11 kcal/mole at −116 °C) ion *(163b)* rearranges irreversibly to a methyl-substituted bishomotropylium ion [50a, 50b].

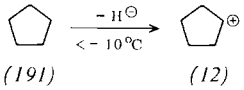


The crowning achievement is the direct observation of a single-line NMR spectrum for the 9-barbaralyl cation *(32)* [50c]. This demonstrates that even at −135 °C the degenerate rearrangements leading to complete scrambling of all nine (CH) units are fast on the NMR time scale! For bullvalene, the same result is not achieved until the temperature ist 200 °C higher [2]. Mechanism 1) [*via* the less stable ion *(14)*] is the process implicated for complete degeneracy; the process suggested by mechanism 4) must be even faster. At −125 °C, *(32)* rearranges irreversibly to *(184)*.

In connection with the barbaralyl cation *(32)* the carbonium ion *(190)* derived from homobullvalene is of interest. Cation *(190)*, a $C_{11}H_{11}^{+}$ vinylog of the barbaralyl cation

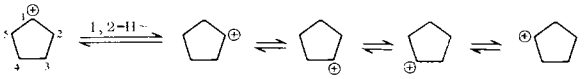
(190)

(32), also has the potential to combine degenerate carbonium ion rearrangements with degenerate Cope rearrangements to make *(190)* completely degenerate. Through cyclopropylcarbinyl-cyclopropylcarbinyl rearrangements, cation *(190)* could be viewed as structure *(190')*, or its equivalent, which has C_{3v} symmetry. This formulation makes cation *(190)* a carbonium-ion equivalent of bullvalene, which also has C_{3v} symmetry [2]. Combination of this charge delocalization with allyl resonance and the three-fold degenerate Cope rearrangement would distribute the positive charge to every carbon atom of cation *(190)*. The monohalocarbene adducts of bullvalene could presumably serve as solvolytic precursors to cation *(190)*.



(190) *(190')*

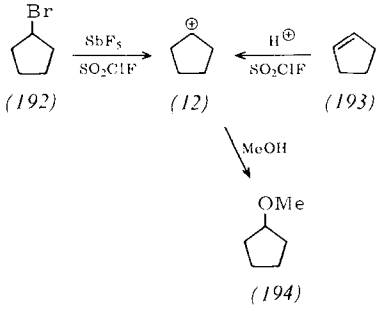
4. Other Degenerate Carbonium Ions



There are a number of degenerate carbonium ions not having a $(CH)_n^{+}$ empirical formula which have been studied in detail. These ions can exhibit forms of carbon degeneracy, hydrogen degeneracy, and combinations of both. Most ions of this type do not have the potential for complete degeneracy, and in this sense they contrast with ions of the $(CH)_n^{+}$ series. Also, there is no apparent systematization within this group of ions. Many of these cations have been generated in highly acidic solvents and studied directly by NMR.

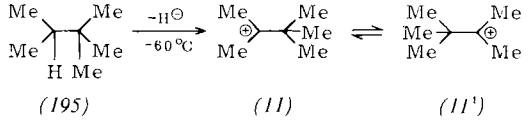
4.1. Cyclopentyl Cation

Olah and *Lukas* investigated the cyclopentyl cation *(12)* by examining the NMR spectrum of the ion generated in highly acidic solvents [60]. They found that when cyclopentane *(191)* was dissolved in FSO_3H-SbF_5 or HF-SbF_5 diluted with SO_2ClF below −10 °C, the cyclopentyl cation *(12)* was formed by hydride abstraction. The ion exhibited a single peak at δ 4.75 and the NMR spectrum remained unchanged down to −130 °C. This indicated that *(12)* was undergoing a series of rapid 1,2-hydride shifts that resulted in complete hydrogen degeneracy. No study of possible carbon degeneracy in ion *(12)* has been reported.



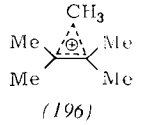
(191) *(12)*

(12)



Cation *(12)* was also generated from cyclopentyl bromide *(192)* and cyclopentene *(193)* as shown below [60]. Quenching of these solutions of *(12)* with methanol gave cyclopentyl methyl ether *(194)* in high yield.

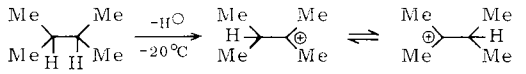
(192) *(12)* *(193)* *(194)*



4.2. Dimethyl-*tert*-butylcarbonium Ion

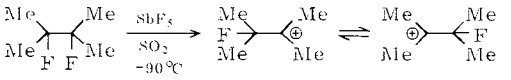
Olah and *Lukas* observed that when 2,2,3-trimethylbutane *(195)* was dissolved in $FSO_3H-SbF_5-SO_2ClF$ at −60 °C, the dimethyl-*tert*-butylcarbonium ion *(11)* was generated [61]. The NMR spectrum of *(11)* showed a single sharp singlet at δ 2.86. The equivalence of all five methyl groups in *(11)* was attributed to fast 1,2-methyl shifts. This carbonium ion serves as a good example of twofold partial

(195) *(11)* *(11')*



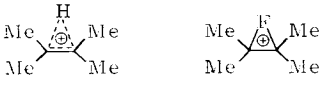
carbon degeneracy. The fact that only one peak was observed in the spectrum of *(11)* rules out a static nonclassical ion structure such as *(196)* which would exhibit two distinct methyl resonances.

(196)



[60] *G. A. Olah* and *J. Lukas*, J. Amer. Chem. Soc. *90*, 933 (1968).
[61] *G. A. Olah* and *J. Lukas*, J. Amer. Chem. Soc. *89*, 4739 (1967).

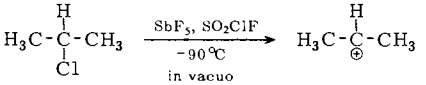
The dimethylisopropylcarbonium ion *(197)* and the dimethylfluoroisopropylcarbonium ion *(199)* both are similar to cation *(11)*. Ion *(197)*, generated from 2,3-dimethylbutane *(198)* in FSO_3H-SbF_5 exhibited only a doublet at δ 3.32 (J = 4.2 Hz) for the four methyl groups [61]. The equivalence of all methyl groups was best interpreted in



(198) *(197)* *(197')*

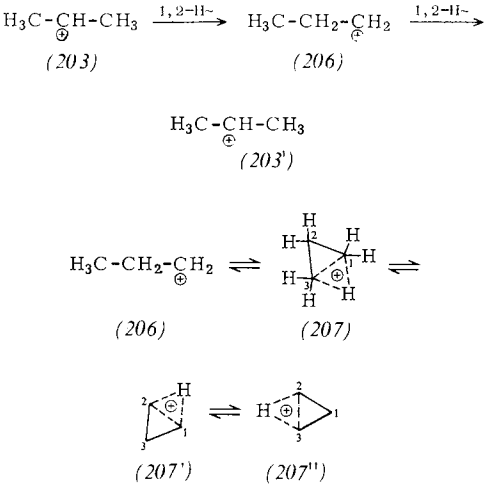
terms of the rapidly equilibrating ions *(197)* and *(197')* in which the single hydrogen undergoes a degenerate 1,2-shift. Ion *(199)*, obtained from 2,3-difluoro-2,3-dimethylbutane *(200)*, showed a single doublet at δ 3.10 (J = 11 Hz) for the

(200) *(199)* *(199')*



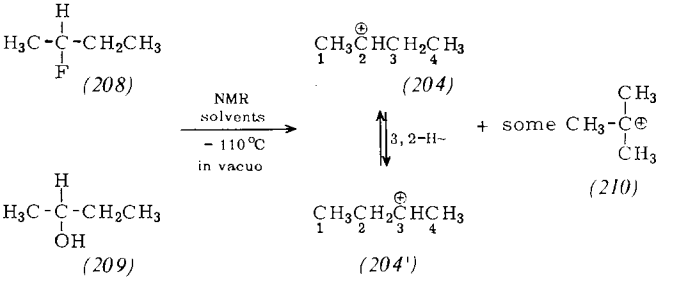
proton resonance spectrum [62]. This observation is compatible with ion *(199)* existing as the doubly degenerate equilibrating cation pair *(199)* and *(199')*. Rapid 1,2-fluorine shifts are responsible for the equivalence of the four methyl groups. Structures *(201)* and *(202)* were ruled out on the basis of chemical shift comparisons of the hydrogen and fluorine in *(197)* and *(199)* with known species of similar structure.

(201) *(202)*



4.3. Isopropyl Cation and *sec*-Butyl Cation

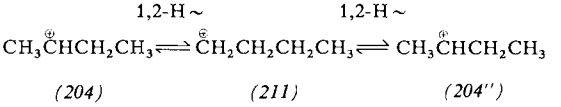
Saunders and *Hagen* have studied the isopropyl cation *(203)* and found that this ion exhibited degenerate properties in NMR solvents [63]. The cation was prepared from isopropyl chloride *(205)* as shown below. At temperatures below 0 °C ion *(203)* showed two peaks, a doublet for the



(205) *(203)*

methyl groups at high field and a septet for the methine hydrogen at lower field strength. Over the range from 0 to 40 °C the spectrum changed in a manner indicating interchange between the two types of protons present. The simplest mechanism for this interchange is reversible rearrangement to *n*-propyl cation *(206)*. The activation energy determined for this mechanism was 16.4 ± 0.4 kcal/mole. A further process which might be involved is rearrangement of the intermediate *n*-propyl cation *(206)* to protonated cyclopropane *(207)* before return to *(203)*. Proton scrambling in protonated cyclopropane *(207)* is well documented, so complete mixing of all protons could occur before return to *(206)* [64].

(203) *(206)* *(203')* *(206)* *(207)* *(207')* *(207'')*



Saunders and his co-workers also studied the *sec*-butyl cation *(204)*, prepared by reaction of 2-fluorobutane *(208)* or 2-butanol *(209)* with strongly acidic NMR solvents at −110 °C in a vacuum line [65]. The NMR spectrum at low temperature consisted of two peaks (plus a sharp singlet due to *tert*-butyl cation *(210)* impurity, formed in the preparation). These two peaks were assigned to the 1 and

(208) *(204)* *(209)* *(204')* *(210)*

4 and 2 and 3 protons of *(204)* averaged by rapid degenerate 3,2-hydride shifts (see above). The activation energy for this process was estimated as approximately 6 kcal/mole. As the cation *(204)* sample was warmed from −110 to −40 °C the two peaks broadened and then coalesced to a sharp singlet. The *tert*-butyl peak remained unchanged in this temperature range. Above −40 °C conversion of *(204)* into *(210)* occurred fairly rapidly.

The single absorption peak for all positions in *(204)* at higher temperatures indicates complete equivalence of all hydrogens. One process for this could be reversible rearrangement to the primary *n*-butyl cation *(211)*; this is one of the possible mechanisms advanced for the isopropyl cation *(203)*. However, the energy barrier for the complete proton equivalence in *(204)* is much lower than in

(204) *(211)* *(204'')*

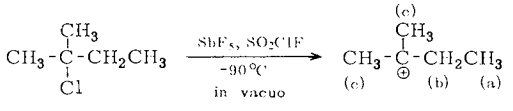
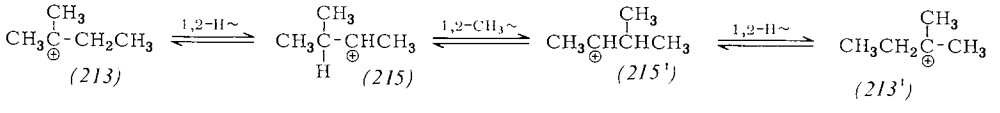
[65] *M. Saunders*, *E. L. Hagen*, and *J. Rosenfeld*, J. Amer. Chem. Soc. *90*, 6882 (1968).

(203); this tends to disfavor such a mechanism for *(204)*. A better mechanism appears to be cyclization to a protonated methylcyclopropane *(212)*, followed by proton scrambling and reopening to *(204)*. This mechanism



(204) *(212)* *(212')* *(212'')*

would predict an activation energy of approximately 7.5 ± 0.1 kcal/mole for complete mixing of all hydrogens (compare to value of 16.4 ± 0.4 kcal/mole obtained for the process of complete hydrogen mixing in the isopropyl cation).

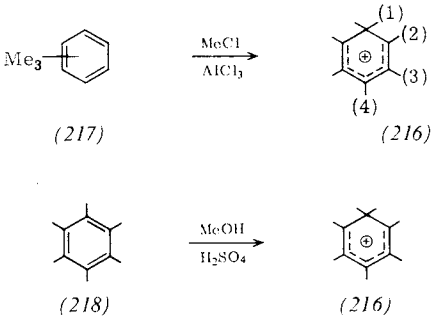


4.4. *tert*-Amyl Cation

Saunders and *Hagen* studied the temperature dependent NMR spectrum of the *tert*-amyl cation *(213)* and observed that this ion exhibited partial degeneracy [66]. Cation *(213)* was prepared by allowing 2-chloro-2-methylbutane *(214)* to react with an excess of antimony pentafluoride in sulfuryl chlorofluoride in a vacuum line at −90 °C. Below −40 °C the NMR spectrum consisted of peaks at τ 7.70 (triplet), 5.58 (triplet), and 5.25 (multiplet) assigned to protons a, c, and b, respectively. As the cation solution was warmed above −40 °C, the triplets for the methyl protons

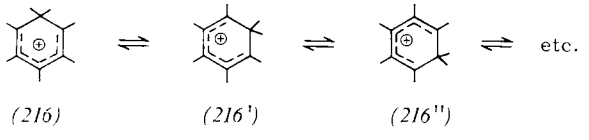
(214) *(213)*

broadened and then coalesced, but the multiplet for the methylene protons remained unchanged. Upon recooling the sample, the original spectrum was reobtained. The spectral changes demonstrated interchange of the two types of methyl groups without mixing in the CH_2 protons. This is best explained by a mechanistic scheme in which first a 1,2-hydride shift occurs, then a degenerate 1,2-methyl shift followed by another hydride shift. Mechanisms



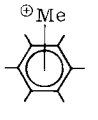
(213) *(215)* *(215')* *(213')*

involving primary carbonium ions are considered less likely and could also involve complete mixing of all types of hydrogens. *Brouwer* and *Mackor* also studied the *tert*-amyl cation *(213)* in $HF-SbF_5$ solution and observed the same reversible line broadening at temperatures above −20 °C for the different methyl groups [67a]. *Brouwer* [67b] examined the system in detail and independently came to the same conclusions as *Saunders* and *Hagen* concerning the nature of the equilibrium process. Recently, higher-temperature studies have shown that above 130 °C the methyl and methylene signals coalesce [68].



4.5. Heptamethylbenzenonium Ion

The heptamethylbenzenonium ion *(216)* represents one of the earliest studied examples of a degenerate carbonium ion. Cation *(216)* was originally synthesized over ten years ago by the exhaustive methylation of trimethylbenzenes *(217)* with methyl chloride in the presence of aluminum chloride or by the reaction of hexamethylbenzene *(218)* with methanol in the presence of concentrated sulfuric acid [69]. The NMR spectrum of ion *(216)* at 25 °C showed



(217) *(216)* *(218)* *(216)*

four resonance signals in the ratio of 1:2:2:2 with the three lowest field peaks assigned to the methyl groups labeled (4), (3), and (2), respectively, and the highest field peak due to the gem dimethyl groups labeled (1). *Saunders* studied the NMR spectrum of *(216)* at higher temperatures and observed that the three low field peaks coalesced into a broad singlet while the high field peak remained a singlet, although broadened, at ≈70 °C [70]. This was interpreted in terms of *(216)* undergoing a series of rapid degenerate 1,2-methyl shifts.

(216) *(216')* *(216'')*

Alternatively, a "random" shift mechanism could be imagined in which a methyl group leaving the saturated carbon might jump from one ring carbon to another in a series of steps before becoming reattached to one of the ring carbons. The intermediate for such a process is represented by *(219)*. Recently, *Derendyaev*, *Mamatyuk*, and *Koptyug* studied the NMR spectrum of *(216)* with the aid

(219)

of multiple resonance techniques and established that the "random" migration of a methyl group did not play a

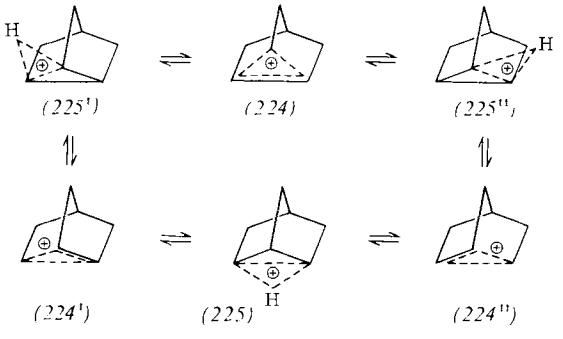
significant role in the rearrangement of *(216)* [71]. It was concluded that the intramolecular 1,2-methyl shift mechanism was responsible for the observed spectral changes. Analogous 1,2-hydride shifts have recently been demonstrated in the parent benzenonium ion [71a].

4.6. 2-Norbornyl Cation

Schleyer, Watts, Fort, Comisarow, and *Olah* were the first workers to report the direct observation of the NMR spectrum (60 MHz) of the 2-norbornyl cation *(9)* [72]. The ion was prepared by dissolving either 2-*exo*-norbornyl chloride *(220)* or 2-*exo*-norbornyl fluoride *(221)* in SbF_5 or in SbF_5-liquid SO_2. The NMR spectrum in the temperature range -5 to $+37\,°C$ consists of a single broad band at δ 3.75, indicating that all the protons (and probably all the carbons) are equivalent. At $-60\,°C$ the spectrum separates into three bands of relative areas 4 (δ 5.35), 1 (δ 3.15), and 6 (δ 2.20). Further cooling to $-120\,°C$ produced no other changes in the spectrum of *(9)*. Evidence for *(9)* in solution was obtained by quenching the cation solution with water; this produced 2-*exo*-norbornanol *(222)*. (The ion *(9)* is shown in classical form for convenience.)



The above results were interpreted in terms of the 2-norbornyl cation *(9)* undergoing three reaction processes: (a) a Wagner-Meerwein rearrangement *(9)* $\rightarrow$ *(9')*, occurring rapidly over the temperature range studied; (b) a 6,2-hydride shift *(9)* $\rightarrow$ *(9'')*, also occurring rapidly over the temperature range studied; and (c) a 3,2-hydride shift *(9)* $\rightarrow$ *(9''')*, which is fast at room temperature but slow below $-23\,°C$ (temperature of coalescence of the 3 observed peaks) [73].

At $-60\,°C$ the 3,2-hydride shift is not occurring rapidly enough to be significant. The three peak NMR spectrum can be interpreted in terms of positions made equivalent by the Wagner-Meerwein rearrangement and the 6,2-hydride shift. The peak of area 4 is due to protons at C-1, C-2, and C-6; the peak of area 1 is due to the one proton at C-4; the peak of area 6 is due to protons at C-3, C-5, and C-7. Addition of the 3,2-hydride shift at higher temperatures makes all positions equivalent by interchanging C-1 with C-4, C-2 with C-3, and C-5 with C-6. Thus, by this interpretation the 2-norbornyl cation *(9)* represents an example of combined carbon and hydrogen degeneracies which results in the equivalence of all carbon and hydrogen atoms.

Jensen and *Beck* observed that the best defined NMR spectrum (60 MHz) of the 2-norbornyl cation *(9)* was obtained by treating 2-norbornyl bromide *(223)* with gallium tribromide in SO_2 solvent [74]. The NMR spectrum of *(9)* obtained by these workers exhibited a fine structure not recorded by *Schleyer, Olah*, and co-workers. The spectrum recorded by *Jensen* and *Beck* at $-80\,°C$ consisted of resonance signals at δ 5.2, 3.1, and 2.1 with relative intensities of 4:1:6 and observed multiplicities of 7,1, and 6 respectively. These workers feel that the observed slow 3,2-hydride shifts are not consistent with a classical ion *(9)* being the stable species observed in the NMR studies, since secondary, secondary-hydride shifts should occur in classical *(9)* with a lower activation energy than that observed. They believe the observed spectrum and rates of proton exchange can be adequately accounted for on the basis that alkyl and hydrogen bridged ions *(224)* and *(225)* occur in the system as stable forms, or one of these forms is a transition state and the other a stable species.

Olah, Commeyras, and *Lui* generated the norbornyl cation in strong acid solutions from the precursors shown in Scheme 2 [75].

These workers obtained a 100 MHz NMR resonance spectrum of this cation which showed the fine structure reported by *Jensen* and *Beck*. They also obtained a Raman spectrum of the cation in strong acid solution and concluded that the ion was best represented as a protonated nortricyclene [75]. These authors felt that either a corner-protonated nortricyclonium ion *(224)* or an edge-protonated nortricyclonium ion *(225)* was most compatible with the NMR and Raman spectra. On this basis the observed high energy barrier for a 3,2-hydride shift in the 2-norbornyl cation *(9)* arises from the necessary transition of either ion

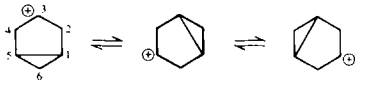
[73] *M. Saunders, P. von R. Schleyer*, and *G. A. Olah*, J. Amer. Chem. Soc. *86*, 5680 (1964).

[74] *F. R. Jensen* and *B. H. Beck*, Tetrahedron Lett. *1966*, 4287.

[75] *G. A. Olah, A. Commeyras*, and *C. Y. Lui*, J. Amer. Chem. Soc. *90*, 3882 (1968).

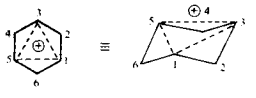
(224) or (225) to the classical 2-norbornyl cation (9) before the 3,2-hydride shift occurs. Ion (224) or (225) at low temperatures would then represent what was originally assigned for the 2-norbornyl cation (9) as the result of a combination of Wagner-Meerwein rearrangements and 6,2-hydride shifts.



Recently *Olah* and *White* examined the ^{13}C-NMR spectrum of the norbornyl cation generated in SbF_5-SO_2 from 2-*exo*-norbornyl chloride (220) at $-70\,^{\circ}C$[76,77]. This spectrum consisted of three peaks: 1) a pentuplet (J = 53.3 Hz) at 101.8 ppm (from $^{13}CS_2$) for three equivalent carbons associated with four equivalent protons; 2) a triplet (J = 140.2 Hz) at 162.5 ppm for three equivalent carbons each associated with two equivalent protons; and 3) a doublet (J = 153 Hz) at 156.1 ppm for one carbon associated with one proton.

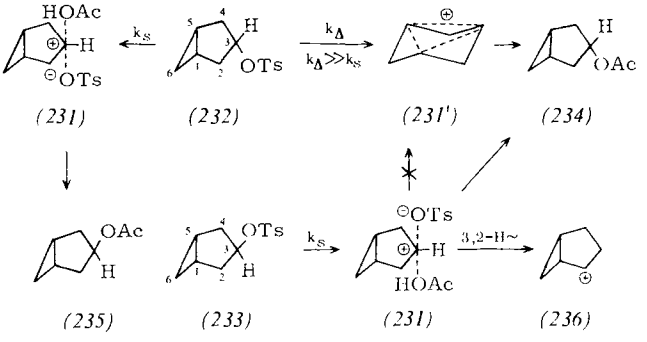
This spectrum is most consistent with rapidly interconverting edge-protonated nortricyclonium ions [(225), (225'), and (225'')] or with rapidly interconverting corner-protonated nortricyclonium ions [(224), (224'), and (224'')]. The equilibrating classical 2-norbornyl cation (9) is not in accord with the low-temperature Raman, proton, and carbon NMR spectra.

To determine whether the edge-protonated ion (225) or the corner-protonated species (224) is the more stable cation, *Olah* and *White* recorded the 100 MHz proton NMR spectrum of the norbornyl cation at temperatures down to $-156\,^{\circ}C$[76,77]. At $-120\,^{\circ}C$, the spectrum was identical with that described previously. In the temperature range -128 to $-150\,^{\circ}C$ the low-field peak due to the four equilibrating protonated cyclopropane ring protons broadened and then separated into two resonances each of relative area 2 at δ 3.05 and 6.59. The high-field resonance, due to the six methylene protons, also broadened, developing a shoulder at δ 1.70. The peak at δ 2.82 due to the single bridgehead proton remained unchanged. This spectrum is best explained (in conjunction with the data above) in terms of the nonclassical corner-protonated ion (224) structure. Cation (224) represents the most stable ion in strong acid solution with ions like (225) as transition states between forms of (224).



4.7. 3-Bicyclo[3.1.0]hexyl Cation

The 3-bicyclo[3.1.0]hexyl cation (231) could exhibit threefold carbon degeneracy by means of homocyclopropylcarbinyl rearrangements as shown below. Alternatively, this ion could exist in the trishomocyclopropenyl cation

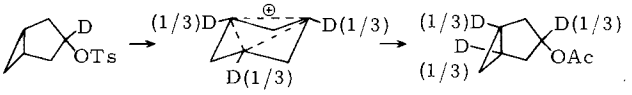


(231)

form (231'), in which positions 1, 3, and 5 as well as 2, 4, and 6 are equivalent to each other due to the charge delocalized structure. According to the definition advanced in Section 1, the 3-bicyclo[3.1.0]hexyl cation can only exhibit true degenerate rearrangements if it exists as the rapidly equilibrating set of ions. Structure (231') is a homoaromatic analog of the cyclopropenyl cation and would simply exhibit threefold equivalence of positions.

(231')

Winstein and his co-workers have studied thoroughly the solvolysis of *cis*-3-bicyclo[3.1.0]hexyl tosylate (232) and *trans*-3-bicyclo[3.1.0]hexyl tosylate (233)[43,78]. These investigations provide strong evidence that the acetolysis of the *cis* isomer proceeds primarily through the trishomocyclopropenyl cation (231'), while that of the *trans* isomer proceeds primarily through cation (231), which is not a rapidly equilibrating species.



Evidence for this mechanistic scheme is the following: 1) The rate of solvolysis of (232) is faster that that of (233). 2) The value of k_Δ is approximately 50 times that of k_s for the solvolysis of (232). 3) The solvolysis of (232) exhibits a special salt effect, while that of (233) does not. 4) The exclusive product of solvolysis of (232) is the *cis*-acetate (234) with essentially complete retention of configuration.

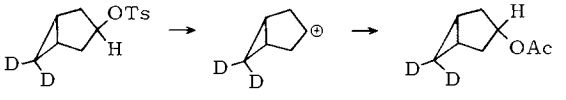
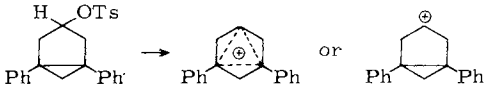
[78] *S. Winstein*, Aromaticity, Internat. Symp. in Sheffield. The Chemical Society, London, Special Publ. No. 21, p. 16.

The solvolysis of *(233)* gives several products, some of which are derived from ion *(236)*. 5) Solvolysis of *cis*-3-deuteriobicyclo[3.1.0]hexyl tosylate *(237)* gives product *cis*-acetate *(238)* with one-third of a deuterium distributed at positions 3, 5, and 1.

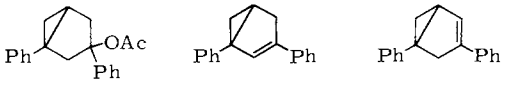


(237) *(238)*

Similarly, solvolysis of the 6,6-dideuterated isomer *(239)* gives a product *cis*-acetate with 1.35 cyclopropane methylene protons. This result is within experimental error of the value 1.33 predicted for the trishomocyclopropenyl intermediate. The *trans* isomer product *(242)* showed no cyclopropane methylene protons.

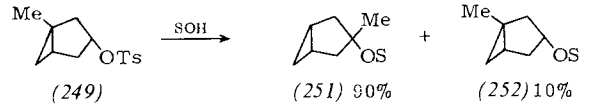


(239) *(240)*



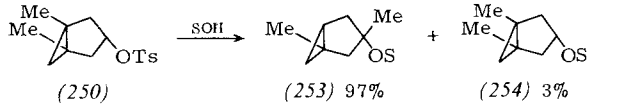
(241) *(242)*

Corey and *Uda* have studied the solvolysis of *cis*-1,5-diphenylbicyclo[3.1.0]hex-3-yl tosylate *(243)* to form either cation *(244)* or *(245)* [79]. Acetolysis of *(243)* gave a rate slower than that of *(232)* with the formation of *(246)*,



(243) *(244)* *(245)*

(247), and *(248)* as products. These authors feel that these results are inconsistent with the trishomocyclopropenyl



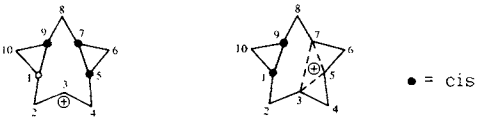
(246) *(247)* *(248)*

cation formulation *(244)*. However, phenyl substituent rate effects are notably complicated by opposing inductive and resonance effects [80]. *Winstein* has reported the solvolysis and products of the *cis*-monomethyl and *cis*-dimethyl-substituted bicyclo[3.1.0]hex-3-yl tosylates *(249)* and *(250)* [78]. The stereochemistry of the products and the relative rate increases of these methyl-substituted compounds compared to the parent system *(232)* were said to be consistent with the formation of the trishomocyclopropenyl cations *(255)* and *(256)* as intermediates in

(249) *(251)* 90% *(252)* 10%

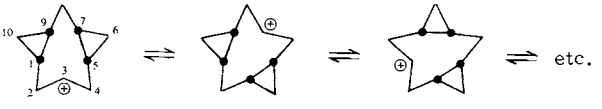
$k(249)/k(232) = 5.1$

(250) *(253)* 97% *(254)* 3%



$k(250)/k(232) = 7.0$

(231') *(255)* *(256)*



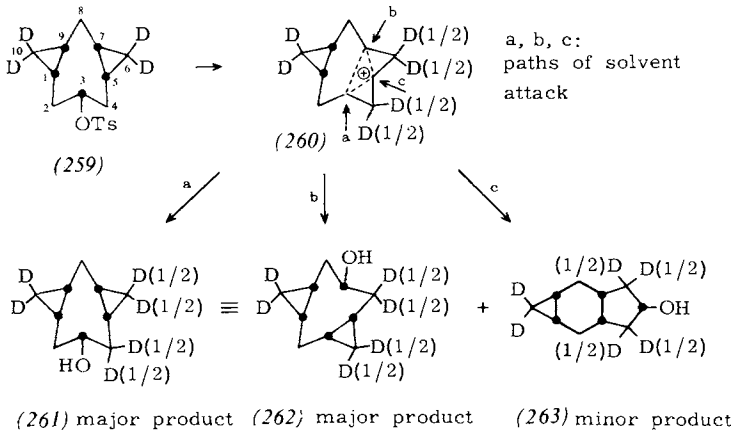
these solvolyses. However, based on previous examples for rate enhancements due to methyl substituents on charged delocalized structures [15,81], the value of 7.0 for $k(250)/k(232)$ is considerably lower than expected. The value should be closer to $(5.1)^2 = 26.1$ for the intermediate *(256)*.

In connection with the 3-bicyclo[3.1.0]hexyl cation, the 3-tricyclo[7.1.0.0^{5,7}]decyl cation *(257)* is also of interest [78].

(257) *(258)*

Ion *(257)* contains two *cis*-3-bicyclo[3.1.0]hexyl moieties within the same cation. If delocalization similar to that observed in the trishomocyclopropenyl cation *(231')* were to take place, ion *(258)* would be formed with positions 6 and 4 equivalent. On the other hand, if *(257)* were to exist as a rapidly equilibrating set of ions as shown then the positions 2, 4, 6, 8, and 10 would be equivalent and this would constitute an example of fivefold degeneracy. *Winstein*, *Bruck*, *Radlick*, and *Baker* studied the solvolysis of the tetradeuterated 3-tricyclo[7.1.0.0^{5,7}]decyl tosylate *(259)* and isolated the products [82].

(257)



The fully protonated starting tosylate shows 2.0 cyclopropane methylene protons at τ 10.3 in the NMR spectrum, while the tetradeuterated tosylate *(259)* gives acetolysis products *(261)* and *(262)* with 0.52 protons at τ 10.3. This is in accord with ion intermediate *(260)* shown above, but is not consistent with a rapidly equilibrating set of ions arising from *(257)*. The latter mechanism would predict 1.20 cyclopropane methylene protons at τ 10.3. These results indicate participation of only one cyclopropane ring in the 3-tricyclo[7.1.0.0^{5,7}]decyl cation even though participation by both rings would seem to be possible. This is a situation similar to that observed by *Coates* and *Kirkpatrick* for the 9-pentacyclo[4.3.0.0^{2,4}.0^{3,8}.0^{5,7}]nonyl cation *(19)* [44].

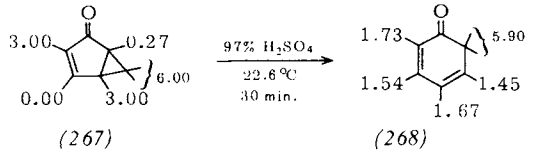
4.8. Bicyclo[3.1.0]hex-3-en-2-yl Cation

Swatton and *Hart* were the first to recognize the possibility that an appropriately substituted ion with the bicyclo-[3.1.0]hex-3-en-2-yl cation *(264)* structure could exhibit fivefold carbon degeneracy as shown below [83]. These investigators reported experiments that were best interpreted

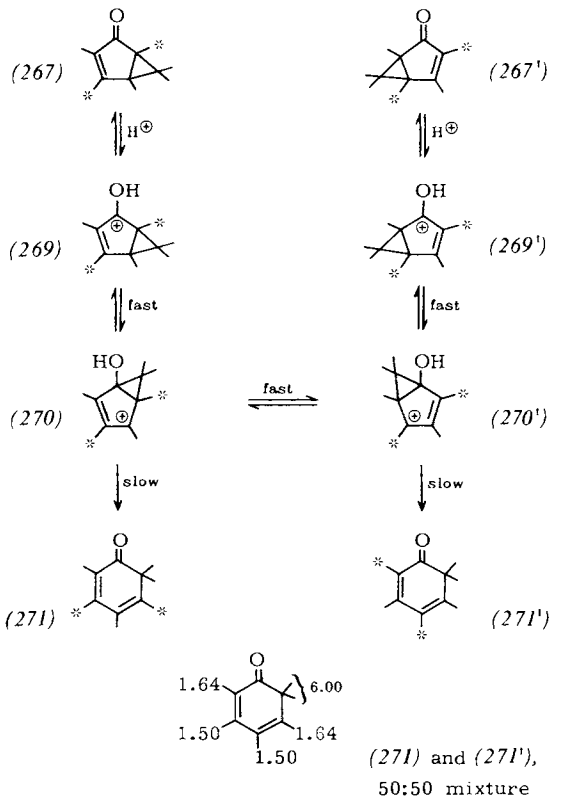


(264)

in terms of carbonium ions like *(264)* in which four or five such structures rapidly equilibrate [83]. When a solution of hexamethylbicyclo[3.1.0]hex-3-en-2-one *(265)* in 97% sulfuric acid was allowed to stand at 22.6 °C for 30 minutes and then hydrolyzed, a nearly quantitative yield of hexamethyl-2,4-cyclohexadienone *(266)* was obtained. To study the mechanism of this reaction the compound with two CD_3 groups *(267)* was rearranged to give *(268)* with the

(265) *(266)*

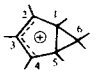
proton integrations for each methyl group as shown. This result is consistent with Scheme 3 in which *(270)* and *(270')* are rapidly equilibrated and each can collapse by proton loss to *(271)* and *(271')* ($-CD_3$ groups marked by an asterisk). Rapid equilibration of *(270)* and *(270')* prior



(267) *(268)*

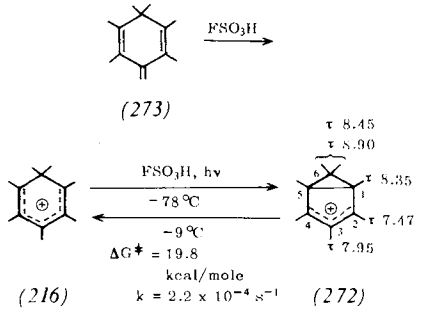
The figures indicate the numbers of protons at the respective positions.

to collapse should lead to a 1:1 mixture of *(271)* and *(271')* with the label distribution as indicated. This is in good agreement with the values obtained for product *(268)*.



[83] *D. W. Swatton* and *H. Hart*, J. Amer. Chem. Soc. *89*, 5075 (1967).

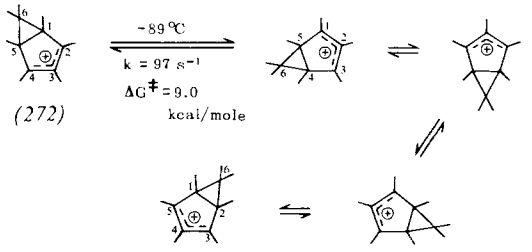
Scheme 3. Perdeuterated methyl groups are asterisked.



The rapid migration of the cyclopropane ring around four of the five sides of the cyclopentenyl ring is thus established.

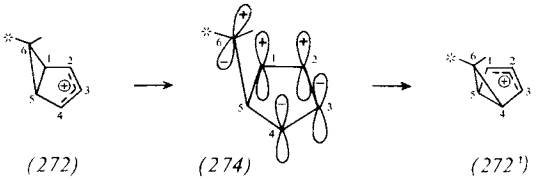
Childs and *Winstein* studied the heptamethylbicyclo[3.1.0]-hexenyl cation *(272)* and observed fivefold degenerate

(272)



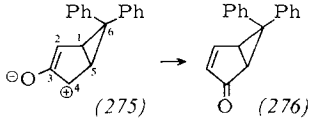
scrambling as predicted by *Swatton* and *Hart* [84]. Cation *(272)* was prepared by the irradiation of a solution of the heptamethylbenzenonium ion *(216)* in FSO_3H at −78 °C.

The reverse process, *(272)* to *(216)*, occurs smoothly on warming the solution of ion *(272)* up to −9 °C. Cation *(272)* displays a temperature-dependent NMR spectrum, and to permit lower temperature observations *(272)* was formed photochemically in a 2:1 $SO_2ClF-FSO_3H$ mixture. In this solvent the NMR spectrum of *(272)* could be observed over the temperature range −110 to −9 °C.



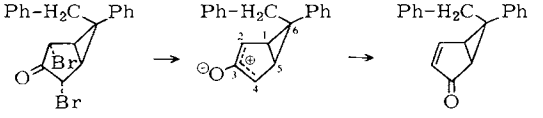
[84] *R. F. Childs* and *S. Winstein*, J. Amer. Chem. Soc. *90*, 7146 (1968).

Below −100 °C the spectrum is that shown above. At higher temperatures the signals for the five methyl groups on the cyclopentenyl ring broaden, then coalesce at about −87 °C and eventually become a sharp statistically averaged singlet (τ 7.90) at −48 °C. Although these five methyl groups become averaged at elevated temperatures, the two methyl groups on the cyclopropane methylene carbon atom C-6 remain distinct and show no sign of averaging up to −9 °C.



(272)

The observed fivefold degenerate scrambling in *(272)* involves migration of the cyclopropane methylene carbon C-6 around the cyclopentene ring as indicated. The key step is a concerted sigmatropic 1,4-shift of C-6 which, in the ring system *(272)*, must be suprafacial [85].



(272) (274) (272')

The symmetry of the highest occupied MO of this system, shown in *(274)*, predicts inversion of the anti-symmetric p orbital in each shift. Thus, the starred methyl group should always remain "outside" and the unstarred methyl group remain "inside" during the fivefold degenerate rearrangement. This agrees with the experimental observation that the two C-6 methyl groups maintain their identities when the other five methyl groups average rapidly. Recent work by *Hart*, *Rodgers*, and *Griffiths* on the stereochemistry of the rapid equilibration of protonated bicyclo[3.1.0]hexenones (see above) also indicates that these interconversions occur without interchange in the positions of substituents at C-6 [86]. Similarly, investigations by *Zimmerman* and *Crumrine* on the interconversion of *(275)* into *(276)* [87]

(275) (276)

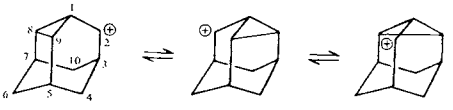
(277) (278) (279)

[85] *R. B. Woodward* and *R. Hoffmann*, J. Amer. Chem. Soc. *87*, 2511 (1965).

[86] *H. Hart*, *T. R. Rodgers*, and *J. Griffiths*, J. Amer. Chem. Soc. *91*, 754 (1969).

[87] *H. E. Zimmerman* and *D. S. Crumrine*, J. Amer. Chem. Soc. *90*, 5612 (1968).

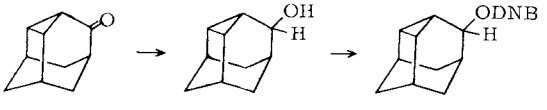
and by *Brennan* and *Hill* on the interconversion of *(278)* into *(279)* [88] indicate that these 1,4-sigmatropic rearrangements proceed with inversion of configuration at C-6. The 1,2,3,4,5,6-*anti*-hexamethylbicyclo[3.1.0]hex-3-en-2-yl cation (but not the 6-*syn* isomer) undergoes a fivefold degenerate rearrangement similar to *(272)* [88a]. The parent bicyclo[3.1.0]hex-3-en-2-yl cation also behaves similarly [88b].



4.9. 8,9-Cyclo-2-adamantyl Cation

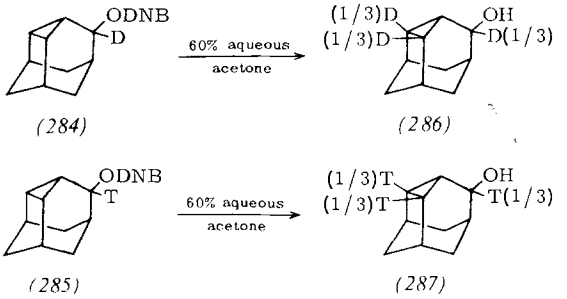
The degenerate cyclopropylcarbinyl-cyclopropylcarbinyl rearrangement, *(18)* ⇌ *(18')* [18], also takes place in more elaborate systems.

(18) (18')



The 8,9-cyclo-2-adamantyl cation *(280)* contains the proper symmetry such that continuous cyclopropylcarbinyl-cyclopropylcarbinyl rearrangements could lead to threefold carbon degeneracy as indicated below (classical ions shown for convenience). *Baldwin* and *Foglesong*

(280) (280') (280'')



studied the solvolysis of derivatives leading to the formation of cation *(280)* and observed the nearly complete equivalence of positions 2, 8, and 9 [89,90]. This provides evidence for the occurrence of degenerate cyclopropylcarbinyl-cyclopropylcarbinyl rearrangements within this system.

Reduction of 8,9-cyclo-2-adamantanone [90] *(281)* with sodium borohydride gave alcohol *(282)* which was converted to its 3,5-dinitrobenzoate *(283)*. Solvolysis of *(283)*

(281) (282) (283)

in 60% aqueous acetone afforded a 95% yield of *(282)*. The 2-deuterio and 2-tritio analogs of *(282)* were prepared with $NaBD_4$ and $NaBT_4$. Solvolysis of the labeled 3,5-dinitro-

(284) (286)

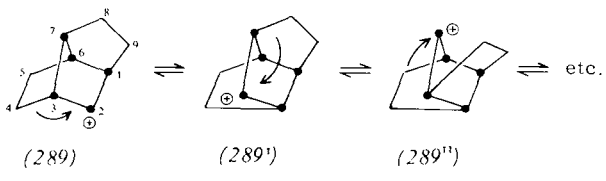
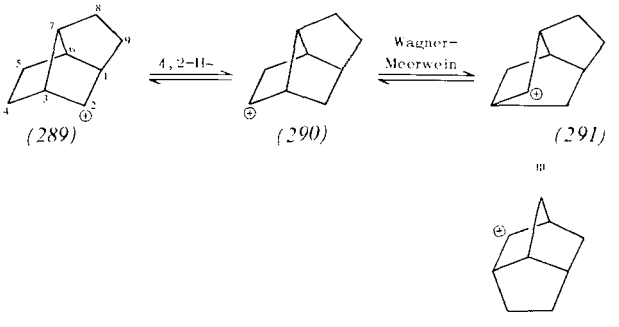
[90] *J. E. Baldwin* and *W. D. Foglesong*, J. Amer. Chem. Soc. *90*, 4303 (1968).

benzoates *(284)* and *(285)* gave product alcohols *(286)* and *(287)* with the label distributions as shown. The deuterium contents were determined by mass spectrometry and the tritium activities were determined by liquid scintillation counting.



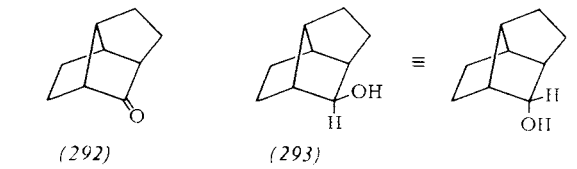
These results indicate that the 2, 8, and 9 positions of the 8,9-cycloadamantyl system attain a high degree of equivalence during the solvolysis reaction. The solvolysis rate constant for *(283)* indicates a substantial rate acceleration above that expected for classical ion *(280)*. Based on these two observations, the authors feel that the 8,9-cyclo-2-adamantyl cation is best represented as a set of rapidly equilibrating, charge delocalized, "bisected" [15] cyclopropylcarbinyl cations *(288)*, *(288')*, and *(288'')*.



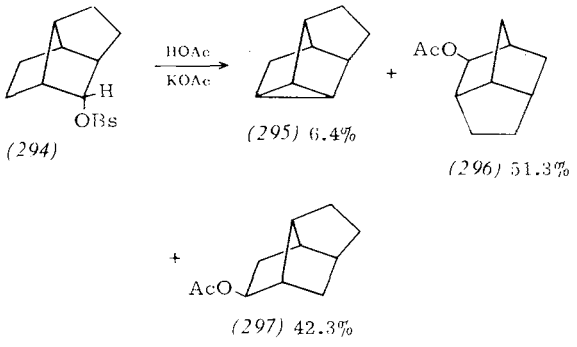
(288) *(288')* *(288'')*

4.10. 2-Brexyl or 2-Tricyclo[4.3.0.0^{3,7}]nonyl Cation

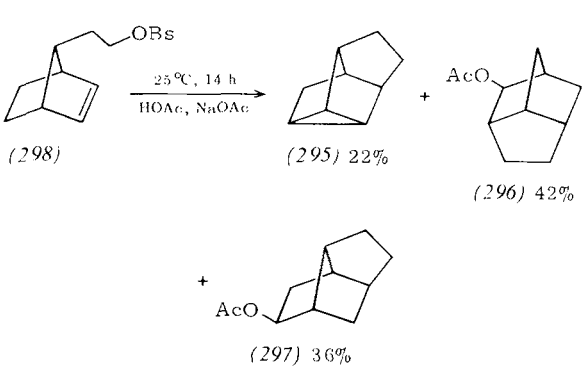
Nickon and co-workers pointed out the possibility that the 2-brexyl cation *(289)* could exhibit multiple degenerate properties [91]. Ion *(289)*, by consecutive Wagner-Meerwein rearrangements, could transfer the positive charge originally at C-2 to all five carbons of the central five-membered ring, which is identified in *(289)* by heavy dots. Repetition of this process many times would result in carbon atoms 1,2,3,6, and 7 becoming equivalent to each other and in carbon atoms 4,5,8, and 9 becoming equivalent to each other also. Thus, the theoretical NMR spectrum of cation *(289)* would contain two peaks of areas 5 and 8 if the above mechanism were operative. A second rearrangement possibility exists for *(289)*, that of a 4,2-hydride shift, which would lead to the 4-brexyl cation *(290)*, an ion not capable of multiple degeneracy. Wagner-Meerwein rearrangement in *(290)* produces the 2-brendyl cation *(291)* which can undergo no further rearrangement.



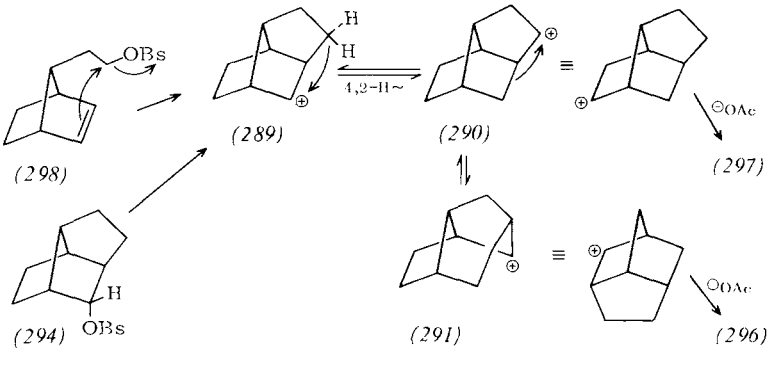
(289) *(289')* *(289'')*



(289) *(290)* *(291)*



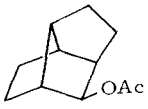
Nickon and his associates have synthesized brexan-2-one *(292)* and brexan-2-ol *(293)* [91]. The solvolysis of 2-brexyl brosylate *(294)* was carried out to give the product mixture shown below [92]. *Bly* and co-workers have reported the solvolysis of β-(*syn*-7-norbornenyl)ethyl brosylate *(298)* to give the same set of products [93]. Both sets of results are best explained in terms of initial formation of the 2-brexyl cation *(289)*, which then rapidly undergoes the 4,2-hydride shift to form cation *(290)*; *(290)* then yields *(291)* by Wagner-Meerwein rearrangement. The two acetate products arise from these ions. Lack of formation of acetate *(299)*, which would arise from the 2-brexyl cation *(289)*, indicates that this cation is not as stable as ions *(290)* and *(291)*.



(292) *(293)*

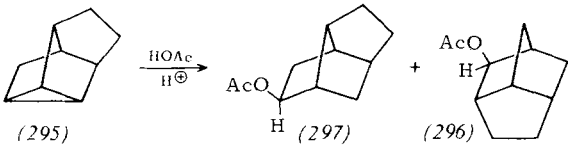
(294) *(295)* 6.4% *(296)* 51.3% *(297)* 42.3%

(298) *(295)* 22% *(296)* 42% *(297)* 36%



(298) *(289)* *(290)* *(297)* *(294)* *(291)* *(296)*

[91] *A. Nickon, H. Kwasnik, T. Swartz, R. O. Williams*, and *J. B. Di Giorgio*, J. Amer. Chem. Soc. *87*, 1613, 1615 (1965).

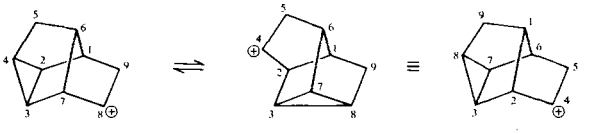


[92] *A. Nickon*, personal communication of unpublished results.

[93] *R. S. Bly, R. K. Bly, A. O. Bedenbaugh*, and *O. R. Vail*, J. Amer. Chem. Soc. *89*, 880 (1967).

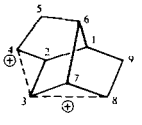
(299)

Nickon, *Pandit*, and *Williams* studied the acid catalyzed acetolysis of deltacyclane *(295)* and found only products *(296)* and *(297)* also [94]. The brendyl acetate *(296)* is the more stable of the two products and predominates almost exclusively if the acetolysis mixture is allowed to equili-



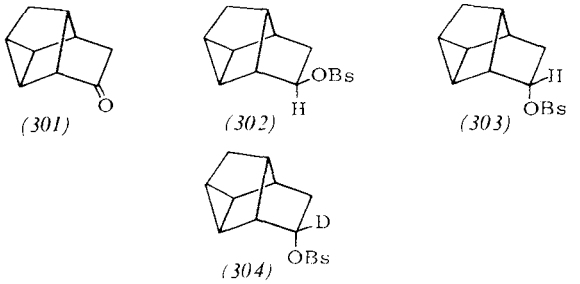
(295) (297) (296)

brate. Once again no product *(299)* due to the 2-brexyl cation was observed. This tends to indicate that the proposed degeneracy for the 2-brexyl cation *(289)* may never be observed due to the instability of the ion relative to other tricyclic cation isomers.



4.11. 8-Tetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonyl Cation

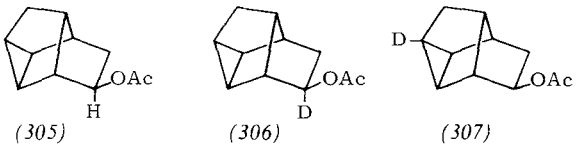
The 8-tetracyclo[4.3.0.0^{2,4}0.^{3,7}]nonyl cation *(21)* is capable of twofold carbon degeneracy if homocyclopropylcarbinyl rearrangements of the type shown below occur. Alternatively, it is possible that this cation could exist in



(21) (21')

the nonclassical form *(300)*, in which carbon atoms 8 and 4 are simply equivalent due to charge delocalization.

(300)

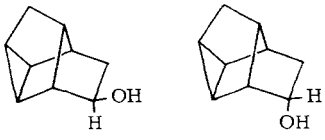


Freeman and *Balls* synthesized the tetracyclic ketone *(301)* and were able to prepare the derivatives *(302)*, *(303)*, and *(304)* for solvolysis [48]. The acetolysis of *(302)* and *(303)* gave only one acetate product *(305)*. Acetolysis of the

(301) (302) (303) (304)

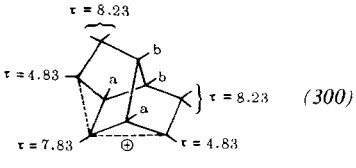
[94] *A. Nickon, G. D. Pandit*, and *R. O. Williams*, Tetrahedron Lett. *1967*, 2851

labeled compound *(304)* produced *exo*-acetate which according to infrared and NMR spectroscopy contained one-half of a deuterium at C-8 and one-half a deuterium in the cyclopropane ring. These results are consistent with



(305) (306) (307)

the formation of an equimolar mixture of acetates *(306)* and *(307)* in which the deuterium is distributed between C-8 and C-4.

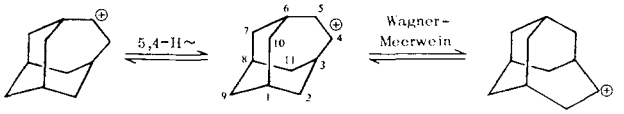


The rate constants for the acetolysis of *(302)* and *(303)* at 25 °C are 2.79 × 10^{-4} s^{-1} and 4.74 × 10^{-6} s^{-1}, respectively. From these values anchimeric assistance factors of $10^{5.9}$ for *(302)* and $10^{3.7}$ for *(303)* were calculated. Since the rate factor for anchimeric assistance in the 2-*exo*-norbornyl cation is only $10^{3.3}$, it appears that both the *exo* and *endo* isomers *(302)* and *(303)* of the tetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonyl system solvolyze with anchimeric assistance. It can be argued that this disfavors a rapid equilibration of classical cations *(21)* and *(21')* as the mechanism for the deuterium label scrambling since a classical ion derived from the *endo* compound *(303)* should show little anchimeric assistance. However, it is not clear why the *endo* isomer shows an accelerated rate; the nature of the participation has not been identified.

When either alcohol *(308)* or *(309)* is dissolved in FSO_3H-SO_2 at −78 °C, the same carbonium ion

(308) (309)

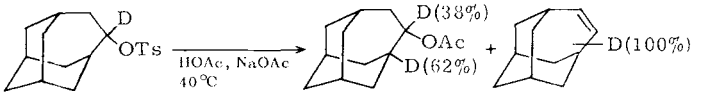
solution is observed. The NMR spectrum of this solution does not change significantly from −55 to −10 °C, and is characteristic of a cation showing absorptions at τ 4.83, 7.08, 7.50, 7.83, and 8.23 in the ratio 2:2:2:1:4, respectively. Quenching the cation solution with aqueous potassium hydroxide produces *(308)*. This spectrum is best interpreted in terms of ion structure *(300)* with the proton resonance signals assigned as shown. Based on the rate data, the deuterium label scrambling, and the NMR spectrum



(300)

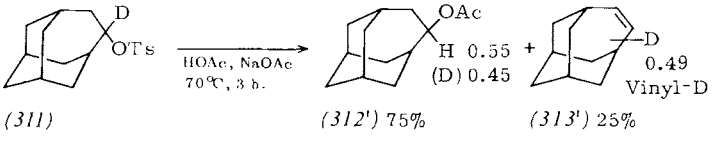
a protons τ = 7.08 or 7.50
b protons τ = 7.50 or 7.08

of the carbonium ion above, it appears that ion *(300)* best represents the structure of the carbonium ion derived from the solvolysis of 8-tetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonyl precursors.



4.12. 4-Homoadamantyl or 4-Tricyclo[4.3.1.1^{3,8}]-undecyl Cation

The 4-homoadamantyl cation *(310)*, as noted by *Nordlander*, is capable of exhibiting combined carbon and hydrogen degeneracy [95]. Cation *(310)* can be degenerate with respect to both Wagner-Meerwein rearrangement and vicinal hydride shifts. These two processes can be distinguished on the basis of deuterium label redistribution; a deuterium label originally at C-4 in *(310)* would appear at C-5 in *(310')*, but at C-3 in *(310'')*. Combination of both 1,2-carbon shifts and 1,2-hydride shifts could lead to elevenfold (complete) degeneracy in *(310)* if classical cations are involved. The degeneracy may be limited by ion pairing or by bridged cation formation.



(310') *(310)* *(310'')*

Nordlander and his associates have synthesized the deuterated 4-homoadamantyl tosylate *(311)* and solvolyzed it with the results indicated [95]. These results tend to indicate a 1,2-carbon shift as the primary process responsible for label redistribution (this predicts 50% D at C-3 and C-4), but intervention of hydride shifts could be responsible for part of the label scrambling. Work within these laboratories has involved an independent synthesis of *(311)* and a solvolysis with the results shown in Scheme 4 [96]. These data indicate a deuterium labeling distribution which is quite close to the predicted values for a degenerate 1,2-carbon shift occurring in *(310)*. The formolysis of *(311)* has also been carried out and the results are in accord with the acetolysis above [97]. The acetolyses of the dideuterated and trideuterated tosylates *(315)* and *(316)* were studied within these laboratories, and the acetate and olefin products showed label scrambling results which are inconsistent with a mechanism involving only a 1,2-carbon shift [97]. Tentatively, it has been concluded that hydride shifts are involved in the rearrangements of cation *(310)* although studies on *(310)* are still in progress.

5. Conclusion

At the beginning of this paper it was mentioned that the interest in studying degenerate carbonium ions revolved around three questions:

1) Can degeneracy be achieved, and if so, to what extent?
2) What is the mechanism whereby the degeneracy is achieved?
3) Are there any special properties resulting from degeneracy?

After surveying the work which has already been completed on degenerate cations, it is instructive to consider these questions once again.

Degeneracy in carbonium ions can obviously be achieved, as indicated by the many examples discussed in this paper. Degenerate cations have been generated under solvolytic conditions from appropriate precursors and in highly acidic NMR solvents. The latter conditions enhance cation stabilities and lifetimes and often enable the observation of degenerate rearrangements which might not occur during solvolysis in more nucleophilic solvents. The extent of degeneracy varies considerably; numerous carbonium ions exhibit twofold degeneracy, but only a few like the 9-homocubyl cation *(10)* show extensive degeneracy over several carbon atoms. Extensive degeneracy cannot be achieved easily, particularly under solvolytic conditions, and examples of this phenomenon will probably always be limited. Highly acidic NMR solvents increase the probability of multiple degeneracy, but the cation under consideration may not always be formed under these conditions. For example, attempts to form the 9-homocubyl cation *(10)* from 9-homocubanol *(109)* in such solvents have not been successful, evidently because of ring opening and degradation or polymerization [98]. However, the 9-barbaralyl cation *(32)* has been observed directly as a fully degenerate species [50d].

[97] *S. H. Liggero*, unpublished results.

[98] *G. A. Olah*, personal communication.

The basic mechanisms for degeneracy do not seem to be exceptional. Wagner-Meerwein rearrangements, hydride shifts, double bond participation, cyclopropane ring participation (homocyclopropylcarbinyl rearrangement and cyclopropylcarbinyl-cyclopropylcarbinyl rearrangement), allyl resonance, and combinations of these appear to account for the degeneracy of almost all the carbonium ions studied thus far. Barbaralyl cation *(32)* is unusual in that its most rapid automerization does not correspond to any normally predicted mechanism. Certain of the above processes are more prone to yield specific types of degeneracy. For example, hydride shifts and Wagner-Meerwein rearrangements often give rise to twofold degeneracy. Participation of a cyclopropane ring often gives rise to threefold degenerate cations.

Degeneracy within a carbonium ion does not seem in general to confer any special properties upon the cation involved aside from possible nonclassical resonance stabilization. Of the cations which have been studied, none appears conclusively to be destabilized by virtue of possessing degenerate properties. However, all evidence obtained thus far does indicate that the bicyclo[3.2.2]nona-3,6,8-trien-2-yl cation *(14)* is destabilized, but the available evidence cannot be regarded as conclusive. Some degenerate cations, such as the 9-homocubyl cation *(10)* and the 9-pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonyl cation *(19)*, appear to be stabilized by nonclassical resonance. The tetracyclo-[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-en-5-yl cation *(15)* also possesses nonclassical stabilization, but exhibited no degenerate properties. Thus, it cannot be inferred that degeneracy must be accompanied by nonclassical ion formation. The nonclassical stabilization in the 7-norbornadienyl cation *(13)* is evidenced by the distorted geometry of the ion and the energy barrier to bridge flipping. The anions of the bicyclo[3.2.2]nona-3,6,8-trien-2-yl and the tetracyclo-[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-en-5-yl systems appear more prone to degenerate rearrangement than the corresponding cations.

Further study is needed in the area of stability of degenerate carbonium ions, since this may provide information that is useful in predicting when degeneracy may or may not occur [*].

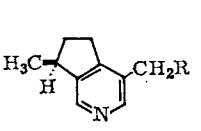
Valerianine, a Tertiary Monoterpene Alkaloid from Valerian[1]

By *Burchard Franck*, *Uwe Petersen*, and *Fritz Hüper*[*]

Dedicated to Professor Kurt Mothes on the occasion of his 70th birthday

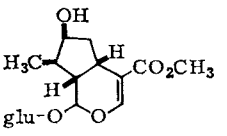
Although it has long been known that valerian (*Valeriana officinalis* L.), which is used medicinally because of its sedative action, contains alkaloids[2], it is only recently that two quaternary pyridine bases have been isolated from it and their structures determined[3].

We now report a new, sedative, tertiary, monoterpene alkaloid *(8)* from *Valeriana officinalis* and its total synthesis, which also opens a simple route to a group of related alkaloids from Actinidiaceae and Bignoniaceae[4].



(1) *(2)* *(3)* *(4)* *(5)*

Chromatographic separation (basified silica gel; $CHCl_3$/CH_3OH 10:1) of the tertiary base fraction of a methanol extract of fresh *Valeriana* roots gave an alkaloid valerianine, m.p. 134 °C, $[\alpha]_D^{20} = -10.5°$ (c = 0.370 in CH_3OH), which crystallizes as hydrochloride. The base has molecular formula $C_{11}H_{15}NO$, which together with its IR band (1585 cm^{-1} in KBr), UV absorption (λ_{max} = 261, 269 nm in CH_3OH), and NMR multiplet at δ = 8.37 ppm ($CDCl_3$, TMS = 0, —CH=N—CH=) indicate a pyridine derivative unsubstituted at positions 2 and 6. Since the NMR spectrum indicates also groups CH_3—CH< (1.32 ppm) and CH_3—O—CH_2—C< (3.40, 4.46 ppm), formula *(1)* can be assumed for valerianine subject to the proviso that the position of the methyl group on C-8 has only a biogenetic basis. This structure has been confirmed by synthesis.



A key compound for the synthesis was 9-methoxyiridodial *(2)*, which like glutardialdehyde should be susceptible to pyridine ring closure[5]. 5-Methyl-1-cyclopentenecarbaldehyde *(3)* is easily obtained from 4-methylpyrocatechol[6] and on diene condensation with 1,3-dimethoxypropene *(4)*[7] at 200—203 °C affords a 47% yield of the dihydropyranyl ether *(5)* which consists of three diastereoisomers. Since the chirality centers at C atoms 2, 3, and 4 disappear when the ether is converted into a pyridine derivative, it is unnecessary to separate the *cis/trans*-isomers *(4)* or the diastereoisomers *(5)* obtained by diene condensation. The ether *(5)* is hydrolyzed by acid to the desired 9-methoxyiridodial *(2)*, which, without isolation, is condensed to give *(1)* in 19% or 20% yield by $Fe(NH_4)(SO_4)_2$[5a] or by NH_2OH[5b], respectively.

The racemic hydrochloride of *(1)*, $C_{11}H_{16}NOCl$, m.p. 143 °C, is identical with valerianine hydrochloride in R_F value, and IR, NMR, and mass spectra.

The (—)-antipode obtained by resolution with dibenzoyltartaric acid also agrees with the alkaloid in its optical rotation ($[\alpha]_D^{20} = -11.6°$, c = 1.13 in CH_3OH). Since valerianine *(1)* corresponds in its chiral chromophore and optical rotation with actinidine *(6)* ($[\alpha]_D^{11} = -7.2°$, c = 17.54 in $CHCl_3$)[8] and tecostidine *(7)* ($[\alpha]_D^{22} = -4°$, c = 1.221 in $CHCl_3$)[9], it, like these two alkaloids, probably has the

(6), R = H
(7), R = OH
(8), R = OCH_3

(9)

S-configuration, and thus the complete formula *(8)* is proved. It is thus not improbable that loganin *(9)* is a biosynthetic precursor of valerianine *(8)* as it is for numerous monoterpene, isoquinoline, and indole alkaloids[10].

The synthesis of (—)-valerianine is also the first preparation of a derivative of (—)-tecostidine *(7)*[11]. Actinidine *(6)* can also be simply prepared in this way[13].

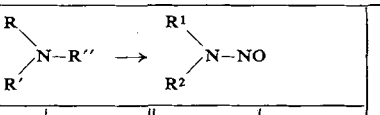
A New Degradation of Amines

By *Burchard Franck, Jens Conrad,* and *Peter Misbach*[*]

We have found a simple procedure for converting tertiary into secondary amines that consists of a combination of degradations by peroxide[1,2] and by nitrous acid[1,3] and gives good yields under very mild conditions.

$$(CH_3)_2CH\text{-}NO_2 + O_2 \xrightarrow{CuCl} (CH_3)_2C(OOH)(NO_2)$$



(1)

(2) *(3)* *(4)*

2-Nitroprop-2-yl hydroperoxide *(1)*, which is formed as intermediate during autoxidation of 2-nitropropane[4] and can be considered as an adduct of the hypothetical "peroxynitrous acid" to acetone, reacts with tertiary aliphatic amines with removal of one alkyl group as aldehyde or ketone and formation of a nitrosamine. To carry out the reaction it is only necessary to shake the tertiary amine in pyridine with 2-nitropropane and CuCl under oxygen. The nitrosamine formed can be easily separated and reduced to secondary amine. The tertiary amine remains unchanged in the absence of 2-nitropropane. Investigations of the reaction mechanism show that *(1)* oxidizes the amine to the amine oxide *(2)*, being converted itself into 2-nitro-2-propanol *(3)* which decomposes to acetone and HNO_2. The HNO_2 traps the secondary amine formed from the amine oxide *(2)* after rearrangement to the carbinol-amine *(4)* as nitrosamine.

The relative rates of removal of alkyl groups are k_{CH_3}: $k_{C_2H_5}$: $k_{n\text{-}C_3H_7}$: $k_{i\text{-}C_3H_7}$: $k_{tert\text{-}C_4H_9}$ = 100:62:57:(6—25):0, and correspond approximately to the relative numbers of protons in α-positions. It is remarkable that

R	R′	R″	R¹	R²	Yield (%)
C_2H_5	C_2H_5	C_2H_5	C_2H_5	C_2H_5	50

			$i\text{-}C_3H_7$	$t\text{-}C_4H_9$	59
CH_3	$-(CH_2)_5-$		$-(CH_2)_5-$		58

strongly hindered amines such as ethyldiisopropylamine (the Hünig base) and even *tert*-butylethylisopropylamine[5] which resist degradation by cyanogen bromide are dealkylated in particularly good yield. Amines whose nitrogen forms part of a five-membered ring are not degraded, and ring nitrosation is the predominant reaction of aromatic amines.

General procedure:

A solution of a tertiary amine (0.1 mole) in pyridine (100 ml) and CuCl (5 g, 0.05 mole) are placed in a double-walled flask that can be heated by connecting it with a thermostat and the mixture is saturated with O_2. The 2-nitropropane (30 ml, *ca.* 0.3 mole) is added and the mixture is shaken under O_2 at 50 °C. After 2—3 h (O_2 uptake 0.1—0.15 mole) the contents of the flask are poured on a mixture of ice (1 kg) and concentrated HCl (180 ml) and extracted with $CHCl_3$. The extract is dried over Na_2SO_4 and the residue obtained on evaporation is distilled from a bulb-tube and separated by layer chromatography on silica gel G. The quantitative composition of the nitrosamine mixture was determined by gas chromatography.

A Simple Synthesis of 1,2-Dihydropentalene and its Substitution Products

By *Reinhard Kaiser* and *Klaus Hafner*[*]

Whereas thermolysis of 6-(4-amino-1,3-butadienyl)fulvenes yields azulenes[11], it is not unexpected that the corresponding reaction of 6-(2-aminovinyl)fulvenes *(1)* does not lead to the desired but presumably highly thermolabile pentalene *(2)*[2]. Surprisingly, however, fulvenes of type *(1)* undergo ready cyclization to give 1,2-dihydropentalenes, of which only a few, multiply substituted representatives have hitherto been known[3].

During attempts to prepare stabilized pentalenes[4,5] from substituted 6-vinylfulvenes[4] we found that *N,N*-dialkyl derivatives of *(1)* are converted into 3-dialkylamino-1,2-dihydropentalenes *(4)* in boiling piperidine [*(4a)*, pale

Gas Chromatographic Identification of the Thiohydantoins of Degradation Products of Peptides and Proteins[**]

By *Harald Tschesche*, *Rainer Obermeier*, and *Sigrid Kupfer*[*]

Although the Edman degradation has been developed for the stepwise sequential determination of peptides and proteins and has been extensively schematized and even automated[1], a simple method (cf.[2]) for the identification of the cleaved amino acids — mainly in the form of phenylthiohydantoins *(1)* — has not yet been reported. The compounds *(1)* are not well suited for identification by gas chromatography[3] because of their decomposability and low volatility, which can only be overcome in part by silylation[4].

(1) *(2)*

We have found, however, that the methylthiohydantoins *(2)* are suitable for gas chromatographic identification. With the exception of arginine and histidine all the naturally occurring amino acids, including Phe, Asn, Gln, Tyr, and Trp, can be chromatographed in the form of their methylthiohydantoins; Asp, Glu, and His can be chromatographed after methylation or silylation; and the separation and identification of leucine and isoleucine do not present any difficulties. The dehydrated derivatives of Ser and Thr were prepared and identified (see Table). Preliminary experiments indicate the possibility of coupling with automatic sequenators[6].

Mass spectra were used for the characterization of methylthiohydantoins *(2)* (see Table).

Table. Detection of naturally occurring amino acids in the form of their methylthiohydantoins *(2)*. Varian gas chromatograph 1520 with linear temperature programming of 4 °C/min, starting temperature 130 °C, 2 m column 1/4", 5% OV-1 on Chromosorb W-AW-DMCS, 50 ml He/min.

Amino acid	Effusion temp. (°C)	Rel. retention time (min)	*m/e* [5]
Ala	152	6.3	144
Gly	157	7.6	130
Ser [a]	157	7.65	142
Val	164	10.0	172

Tyr	252	28.5	236
Trp	277	34.8	259

[a] Dehydrated compound.

Experimental

The peptide (1—5 μmole), dissolved in pyridine (0.5 ml, spectral grade) or pyridine/water (1:1), was coupled with methyl isothiocyanate (10 mg) under nitrogen at 0 or 40 °C for 60—90 min in a microflask in a rotary evaporator; solvent and unreacted reagent were removed under vacuum. After repeated extraction with toluene the residue was rubbed with ethyl acetate for separation of the dimethylthiourea and the carbamoyl peptide was centrifuged off. This procedure was repeated once. Trifluoroacetic acid or heptafluorobutyric acid were used for the cleavage and cyclization (50 °C, 45 min). Although the methylthiohydan-

toins of Ser and Thr are partially dehydrated with trifluoroacetic acid, with heptafluorobutyric acid we have obtained only the dehydrated derivative. After removal of acid and repeated extraction with toluene, the cleaved derivatives *(2)* were dried in vacuum and extracted with ethyl acetate. The residual peptide can be used for the next degradation.

Fourier Transform ^{13}C-NMR Spectroscopy of Biologically Active Cysteine Peptides[**]

By *Günther Jung*, *Eberhard Breitmaier*, *Wolfgang Voelter*, *Toni Keller*, and *Christian Tänzer*[*]

Nuclear magnetic resonance was hitherto unable to provide direct information concerning the carbon skeleton of large organic molecules owing to the low natural abundance of the ^{13}C isotope (1.1%). The Fourier transformation of accumulated pulse interferograms solves this problem, since it provides assignable ^{13}C-NMR spectra within a short time despite the small nuclear concentration.

The results of our Fourier transform ^{13}C measurements on amino acid derivatives[1] with natural abundance of ^{13}C, in conjunction with earlier measurements on ^{13}C-enriched amino acids[2] relative to tetramethylsilane as external standard, permit the following conclusions:

1) The ^{13}C-carbonyl signals of carboxyl, ester, amide, hydrazide, and peptide groups appear between —185 and —170 ppm. Acyl protecting groups such as benzyloxycarbonyl and *tert*-butyloxycarbonyl are characterized by signals between —160 and —150 ppm.

2) The $^{13}C_\alpha$ signals of amino acids appear between —65 and —40 ppm. They depend characteristically on the side chain.

3) The $^{13}C_\beta$ signals of amino acids appear between —70 and —15 ppm and are strongly influenced by hetero substituents such as SH and OH.

4) The ^{13}C signals of aromatic rings in the side chain are observed between —140 and —120 ppm.

The ^{1}H-noise-decoupled 22.63-MHz Fourier transform ^{13}C-NMR spectra (Fig. 1) of glutathione and its oxidized form in 0.2 M aqueous solution were measured relative to external TMS on a Bruker HX-90 multinuclear spectrometer at 25 °C. 4000 scans each of 0.4 s were accumulated using a pulse width of 40 μs, resulting in an overall measuring time of less than 30 min. The two examples (Fig. 1) illustrate how easily the ^{13}C spectra of polypeptides can be assigned from the ^{13}C data of amino acids.

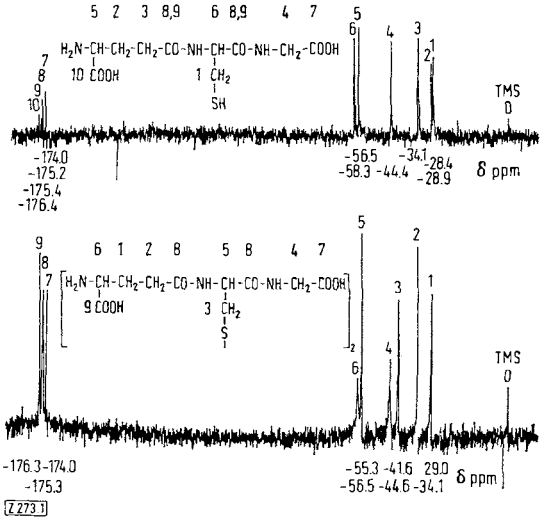

Fig. 1. ^{13}C-NMR spectra of glutathione (above) and its oxidized form (below).

In this way the carboxyl signals of the two peptides can be assigned by comparison with glutamic acid (—175.6 ppm) and glycine (—173.5 ppm). Further, the carbonyl resonance region contains the signals of the two peptide groups, which are split for glutathione (—175.2 and —175.4 ppm) but are superimposed for the oxidized form (—175.3 ppm). By a further comparison of the spectra of glutathione and its oxidized form it is shown that the ^{13}C signals of the methylene groups of glutamic acid (C_β —29.0, C_γ —34.1 ppm) and glycine (—44.6 ppm) are almost identical for the two peptides.

The most important results of our measurements are the large differences between the $^{13}C_\alpha$ and $^{13}C_\beta$ shifts of cysteine and cystine in glutathione and its oxidized form. The ^{13}C signal of C_β next to sulfur is shifted by 13 ppm to lower field on transition from glutathione (—CH_2SH) to the oxidized form (—CH_2SSCH_2—), and the ^{13}C signal of C_α is shifted by 3 ppm to higher field. Further increase in the oxidation state causes even greater shifts: thus the ^{13}C signal of C_β of cysteic acid (—CH_2SO_3H) at —52 ppm is shifted downfield by about 24 ppm in comparison with that of cysteine; the $^{13}C_\alpha$ signal of cysteic acid, however, appears about 5 ppm upfield.

These differences open up new pathways to the elucidation of the structure of cysteine peptides without loss of material. For example, we have also been able to recognize the ^{13}C signal of the —CH_2SSCH_2— group at —41.6 ppm in the Fourier transform ^{13}C-NMR spectra of the peptide hormones oxytocin, vasopressin, and insulin.

Preparation and Properties of a Crystalline Compound $Na_4Sn_9 \cdot 6$–8 Ethylenediamine[**]

By *Dieter Kummer* and *Lothar Diehl*[*]

About 40 years ago *Zintl* and his co-workers[1] discovered a class of salt-like intermetallic compounds that are soluble in liquid ammonia. This class includes Na_4Sn_9, Na_4Pb_9, and Na_3Sb_7 which exist in solution as Na^+ cations and complex anions such as Pb_9^{4-}. At that time *Zintl* proposed the designation polyanionous salts for such compounds.

In spite of the interest that these compounds aroused by their composition and properties, they have not previously been further characterized because it proved impossible to isolate them from their ammoniacal solutions in solid crystalline form. When the ammonia was removed, decomposition occurred giving metallic alloy phases of the same composition but no longer containing the (unknown) complex structure of the polyanions that exist in solution.

We have now prepared the compound Na_4Sn_9 in solid crystalline form by using various amines as solvents. Our experiments have shown that alloys of sodium and tin in atomic proportions 2:4 to 2:5 (obtained by melting the components together) dissolve not only in NH_3 but also (with a deep reddish-brown color) in ethylenediamine (en), *N,N'*-dimethylethylenediamine, diethylenetriamine, and triethylenetetramine. They do not dissolve in $N(CH_3)_3$, $NH(CH_3)_2$, $N(C_2H_5)_3$, $NH(C_2H_5)_2$, $NH_2C_2H_5$, or *N,N,N',N'*-tetramethylethylenediamine. The solutions are similar in color and metal composition (always Na_4Sn_9) to the ammonia solutions described by *Zintl*. In the absence of air and moisture they are stable almost indefinitely.

Ethers precipitate the metal compounds from the amine solutions. Thus diethylene glycol monoethyl ether (monoglyme) precipitates from an ethylenediamine solution reddish-brown crystals of composition $Na_4Sn_9 \cdot 6$–8 en, which give a characteristic X-ray diagram containing many reflections.

The degradation isotherm of this compound at 58 °C shows steps at the compositions $Na_4Sn_9 \cdot 8$ en (p = 24 torr), $Na_4Sn_9 \cdot 6$ en (p = 7 torr), $Na_4Sn_9 \cdot 4$ en (p = 4 torr), and Na_4Sn_9. Two of the diamine molecules in $Na_4Sn_9 \cdot 8$ en are so loosely bound that they are partially washed out on precipitation of the product by the ether; thus the diamine content of various preparations lies between 6 and 8. The products corresponding to these steps all give characteristic X-ray diagrams. It is interesting that the dark gray Na_4Sn_9 obtained free from ethylenediamine produces a different diffraction pattern from that of the starting alloy; careful removal of the ethylenediamine thus does not regenerate the starting material. If, however, this new Na_4Sn_9 is melted, its structure collapses and the metallic starting material (with its X-ray diagram) is again obtained, comprising a mixture of phases and containing, *inter alia*, metallic tin.

Magnetic measurements support these findings. The initial alloy shows paramagnetism, but the Na_4Sn_9 containing ethylenediamine and that freed from the diamine are diamagnetic. After melting, the diamagnetic Na_4Sn_9 has become paramagnetic again.

	χ_g [cm³/g] ± 0.10 × 10^{-6} at 25 °C [2]
Na/Sn alloy 4:10	+4.337 × 10^{-6}
$Na_4Sn_9 \cdot 6.4$ en	−0.604 × 10^{-6}
Na_4Sn_9	−0.488 × 10^{-6}
Na_4Sn_9 (melted)	+1.183 × 10^{-6}

The differences between the values for the initial alloy and the melted Na_4Sn_9 are to be ascribed to differences in composition.

The ^{119}Sn Mössbauer spectrum[2] of $Na_4Sn_9 \cdot 6$ en (absorber, exposure temperature 4.2 °K) contains one absorption line (isomeric shift δ = +0.15 mm/sec against α-Sn, halfwidth Γ = 1.90 mm/sec, source Mg_2Sn δ = −0.25 mm/sec against α-Sn). Quadrupole splitting could not be detected. This does not permit any unique determination of structure because other compounds of tin are known for which (contrary to expectation) no quadrupole splitting can be detected and which show only one Mössbauer line in spite of possessing chemically different tin atoms[3]. Our attempts to obtain structural information about Na_4Sn_9 by ^{119}Sn nuclear resonance measurements of its solutions in ethylenediamine failed because we could detect no absorption.

The facts given above, and particularly the relatively high diamagnetism, are in accord with the assumption of a Sn_9^{4-} polyhedron (a trigonal prism with pyramids set on each of its square faces). This structure has been found for the electronically equivalent unit Bi_9^{5+} of $Bi_{24}Cl_{28}$[4], and has also been suggested by analogy for Na_4Sn_9 and Na_4Pb_9[5]. Final solution of this problem will only come from an X-ray determination of structure, which is in progress (X-ray data for the unit cell: monoclinic, space group C2/c, Z = 8 on the assumption of Sn_9^{4-} units in connection with the observed density 2.05 ± 0.2 g/cm³; lattice constants a = 20.17, b = 11.64, c = 39.36 Å, β = 90.61 °)[6].

X-Ray Structure Analysis of 1,2,3,4-Tetrathiadecalin[**] [***]

By *Franz Fehér, Aloys Klaeren*, and *Karl-Heinz Linke*[*]

1,2,3,4-Tetrathiadecalin[1], which has been synthesized from cyclohexanedithiol and disulfur dichloride by the dilution technique, crystallizes as triclinic crystals with lattice constants a = 9.28₇ Å, b = 8.60₆ Å, c = 6.30₉ Å, α = 107.7 °, β = 102.4 °, and γ = 98.6 °. The observed pycnometric density is 1.55 g cm^{-3}, corresponding to a unit cell of two molecules ($d_{calc.}$ 1.528 g cm^{-3}). The space group $P\bar{1}$ has been derived from the statistics of the intensity distribution[2] and the external habit of the crystals.

For three-dimensional X-ray structure analysis the intensities of 962 independent reflections were determined from precession photographs. The sign was determined for 43 reflections of the *hk*0 projection and for 30 reflections of the *h*0*l* projection by means of the Harker-Kasper inequalities, and thence by a series of successive Fourier projections the initial parameters were obtained for three-dimensional refinement by the method of least squares, the sulfur atoms being treated anisotropically and the carbon atoms isotropically. The hydrogen atoms were left out of consideration. In these conditions the R value converged at 0.129. In the last cycle of refinement the change in all the atomic parameters was less than half the corresponding standard

deviation. Fig. 1 shows the bond lengths and bond angles found for 1,2,3,4-tetrathiadecalin.

1,2,3,4-Tetrathiadecalin exists in a chair-chair conformation. The sulfur atoms bound to C-1 and C-6 are trans-equatorial with respect to the cyclohexane ring. The intermolecular separation of the sulfur-carbon skeletons is in all

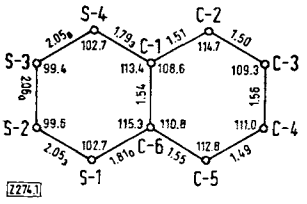

Fig. 1. Bond lengths (Å) and bond angles (°) in 1,2,3,4-tetrathiadecalin. Standard deviations of bond lengths and bond angles: σ_{S-S} 0.008 Å, σ_{S-C} 0.020–0.023 Å, σ_{C-C} 0.025–0.033 Å; σ_{S-S-S} 0.3°, σ_{S-S-C}, σ_{S-C-C}, σ_{C-C-C} 0.7–1.8°.

cases greater than 3.8 Å, so that crystal packing cannot exert any appreciable influence on the molecular conformation.

Deviations from two-fold symmetry of the molecule are not significant. Within the experimental error all the bond lengths lie within the values given in the literature. The relatively small values of the bond angles at sulfur, and particularly at S-2 and S-3 are due to incorporation of C-1 and C-6 in the sulfur ring. Noteworthy are the dihedral angles (C-6)—(S-1)—(S-2)—(S-3) = 66.1°, (S-1)—(S-2)—(S-3)—(S-4) = 69.1°, and (S-2)—(S-3)—(S-4)—(C-1) = 68.3°, which are significantly smaller than the corresponding angle in S_6-sulfur. *Pauling*[3] ascribed the difference between the bonding energies of the sulfur-sulfur bond in cyclohexa- and cycloocta-sulfur at a first approximation to the differing dihedral angles, and if we apply this view to the six-membered ring containing four sulfur atoms we can calculate from a mean dihedral angle of 68° that the bonding energy should be 1.9 kcal/mole per S—S bond greater than for cyclooctasulfur.

Preparation of Glutamic Acid Derivatives from α-Metalated Ethyl Isocyanoacetate and Acrylic Esters[1]

By *Ulrich Schöllkopf* and *Kurt Hantke*[*]

When ethyl isocyanoacetate *(1)*[2] is allowed to react with ethyl acrylate and its derivatives *(3)* in ethanol containing catalytic amounts of sodium ethoxide, ethyl α-isocyanoglutarate and its derivatives *(4)* can be isolated in satisfactory yields.

The decisive intermediate in this synthesis is the α-metalated ethyl isocyanoacetate *(2)* which adds to the activated double bond of the acrylic ester in a Michael addition.

(6a), R = H; *(6b)*, R = CH_3

Treating 3 equivalents of acrylic or methacrylic ester with one of the ester *(1)* at 50 °C in presence of 0.14 equivalent of the catalyst affords a 72% or 75% yield of the diadduct *(6a)* or *(6b)*, respectively.

Compounds of type *(4)* can be converted into ethyl *N*-formylglutamates *(5)* by treatment with *ca.* 2% ethanolic hydrochloric acid for *ca.* 1.5 hours.

(4), R^1 =	R^2	B.p. (°C/torr)	Yield (%)
H	H	150/10	48
CH_3	H	151/10	65
C_6H_5	H	165/1.5	42
$COOC_2H_5$	H	128/0.1	31
H	CH_3	80/0.1	40

Diethyl 2-isocyano-3-methylglutarate:

A mixture of ethyl isocyanoacetate (4.54 g, 40 mmoles) and ethyl crotonate (4.56 g, 40 mmoles) is added dropwise with stirring during *ca.* 0.5 h to a solution of sodium (0.15 g, 6.5 mmoles) in anhydrous ethanol (20 ml), the temperature rising to about 50 °C. The mixture is set aside for 24 h, then the ethanol is distilled off, and the residue is neutralized with 0.2 N-hydrochloric acid and extracted with ether (100 ml). The extract is dried over magnesium sulfate and evaporated, and the residue is fractionated, which affords diethyl 2-isocyano-3-methylglutarate, b.p. 151 °C/10 torr (*ca.* 60:40 mixture of diastereoisomers). — IR spectrum (film): 2145 cm^{-1} ($\nu_{N\equiv C}$), 1740 cm^{-1} ($\nu_{C=O}$). NMR spectrum (CCl_4, τ): 5.58 (d, $J \approx 3.5$ Hz), 5.42 (d, $J \approx 3$ Hz) for the proton α to the isocyano group.

A variant of this process is used for synthesis of the unsubstituted diethyl 2-isocyanoglutarate and diethyl 2-isocyano-4-methylglutarate. To avoid formation (very easy in this case) of the diadduct *(6a)* or *(6b)*, 2 equivalents of *(1)* are placed in ethanol containing sodium ethoxide, and 1 equivalent of *(3)* is added dropwise.

Diethyl N-formyl-β-methylglutamate:

Diethyl 2-isocyano-3-methylglutarate (4.59 g, 20 mmoles) is treated with ethanol (20 ml) and 35% hydrochloric acid (1 ml) and set aside at room temperature for 1.5 h, then neutralized with powdered potassium hydroxide (0.56 g, 10 mmoles), filtered from the precipitated potassium chloride, and fractionally distilled, yielding diethyl *N*-formyl-β-methylglutamate, b.p. 125 °C/0.07 torr. — IR

spectrum (film): 1690 cm^{-1} ($\nu_{C=O}$ amide), 1730 cm^{-1} ($\nu_{C=O}$ ester), 1520 cm^{-1} (ν_{NH}), and 3300 cm^{-1} (ν_{NH}). NMR spectrum (CCl_4, τ): 1.82 (HC=O).

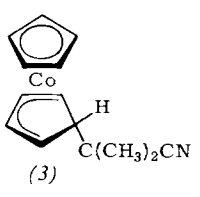
Free Radical Additions to Dicyclopentadienylcobalt[1] [**]

By *Gerhard E. Herberich* and *Johann Schwarzer*[*]

A two-step radical mechanism has been proposed[3] for the reaction of dicyclopentadienylcobalt *(1)* with organic halides[2–4], in which *(1)* acts both as one-electron donor [eq. (a)] and as radical trap [eq. (b)]:



$$Co(C_5H_5)_2 + RX \xrightarrow{slow} [Co(C_5H_5)_2]X + \{R\cdot\} \quad (a)$$
(1)

$$\{R\cdot\} + Co(C_5H_5)_2 \xrightarrow{fast} Co(C_5H_5)(C_5H_5R) \quad (b)$$

R = *e.g.* CCl_3 [2], $C_6H_5CH_2$ [3], CH_2I [4], or $CHBr_2$ [4]
X = Cl, Br, or I

We have found direct proof of the addition of a radical to *(1)*. Thermal decomposition of an excess of azoisobutyronitrile (AIBN) in boiling toluene containing *(1)* affords cyclopentadienyl-[5-*exo*-(1-cyano-1-methylethyl)cyclopentadiene]cobalt *(3)* almost quantitatively. This product forms red prisms, stable in air and melting at 93—94 °C; $\tilde{\nu}_{CN}$ = 2230 cm^{-1}; ^{1}H-NMR spectrum in C_6D_6: τ = 5.02 [$H_{(2)}$, $H_{(3)}$; "triplet"], τ = 5.54 (C_5H_5; singlet), τ = 7.32 [$H_{(endo)}$; triplet], τ = 7.46 [$H_{(1)}$, $H_{(4)}$; "quartet"], τ = 9.39 (2 CH_3; singlet); cf.[2,4]. As shown by the ^{1}H-NMR data for *(3)*, the addition occurs stereospecifically:

(1) + $\{\cdot C(CH_3)_2CN\}$ → *(3)*

The mechanistic alternative of an initial one-electron transfer from *(1)* to *(2)* with subsequent nucleophilic addition of $[C(CH_3)_2CN]^-$ to $[Co(C_5H_5)_2]^+$ can be excluded because *(3)* is also obtained in very good yield using 1-butanol as solvent at 100 °C.

On thermolysis of AIBN in styrene, only 50% of the radicals *(2)* formed are incorporated into the polymer chain[5]; the extensive dimerization is ascribed to a cage effect. However, decomposition of AIBN in presence of a small excess of *(1)* in dilute benzene solution affords more than 80% of the adduct *(3)*. These findings support the mechanism cited above and make it probable that *(1)* could add a variety of C-radicals in accord with eq. (b).

Experimental:

A solution of AIBN (148 mg, 0.90 mmole) and $Co(C_5H_5)_2$ (249 mg, 1.32 mmoles) in anhydrous toluene (5 ml) is refluxed (oil-bath temperature 130 °C) for 15 min with rigorous exclusion of O_2 (*ca.* 97% decomposition of AIBN[6]). The mixture is then cooled rapidly, filtered through a G4 frit, and freed from solvent and organic impurities at 20 °C in a high vacuum. Sublimation of the residue in a high vacuum then gives analytically pure *(3)* [330 mg, 97% based on *(1)*].

A solution of AIBN (117 mg, 0.71 mmole) and $Co(C_5H_5)_2$ (327 mg, 1.73 mmoles) in benzene (20 ml) is heated for 15 h under reflux (> 99% decomposition of the AIBN[6]). The excess of $Co(C_5H_5)_2$ is extracted with aqueous NH_4Cl solution, and the benzene phase is dried over $CaCl_2$. Further working up as above affords *(3)* (297 mg, 81% based on AIBN).

Hexathio-digermanates and -distannates: A New Type of Dimeric Tetrahedral Ion

By *Bernt Krebs, Siegfried Pohl*, and *Willy Schiwy*[*]

The only statements so far made about the nature of the thiogermanates(IV) that are formed from aqueous solution have been mutually contradictory[1]. Characterization of definite phases has been made difficult by formation of various hydration stages. The formal analogs of the anhydrous thiogermanates and ternary sulfides[2] that can be obtained by high-temperature methods are hydrated salts of probable fundamental composition $M^I_4GeS_4$, $M^I_2GeS_3$, and $M^I_2Ge_2S_5$ (each $\cdot xH_2O$; M^I = alkali metal)[1]; nothing is known about the structure of thiogermanate ions except for tetrahedral GeS_4^{4-} (*e.g.*[3,6]).

We have now obtained definite alkali metal salts containing the ion $Ge_2S_6^{4-}$ by dissolving GeS_2 in a concentrated aqueous solution of the alkali sulfide and precipitating the extremely water-soluble salts by a large excess of acetone (cf.[1a]) at constant pH (7—8). Higher members $(Ge_nS_{2n+2})^{4-}$ can also be prepared by altering the ratio M^I_2S : GeS_2 and the pH.

$Na_4Ge_2S_6 \cdot 14\,H_2O$ *(1)* was characterized by analysis, vibration spectra, and a complete X-ray structure analysis. These showed that "trithiogermanates" ("metathiogermanates") contain dimeric isolated $Ge_2S_6^{4-}$ anions with the structure shown in Fig. 1. This unexpected structure, which is novel for thio- and oxo-anions and consists of edge-sharing tetrahedra, corresponds to the structure of, *e.g.*, Al_2Cl_6 (in the gas phase), Al_2Br_6, and the thiohalides $(SCX_2)_2$ and $(SSiX_2)_2$ (X = halogen). Of the sulfides, only the chain-polymeric SiS_2 has this edge junction; GeS_2 does not[2].

(1) crystallizes in the triclinic system ($P\bar{1}$) with a = 9.978(6) Å, b = 7.020(5) Å, c = 9.601(6) Å, α = 108.41(4)°, β = 92.39(4)°, γ = 91.69(4)°, $d_{obs.}$ = 1.80, $d_{X\text{-ray}}$ = 1.778 g cm^{-3}, Z = 1. The $Ge_2S_6^{4-}$ ion in *(1)* has exact C_i sym-

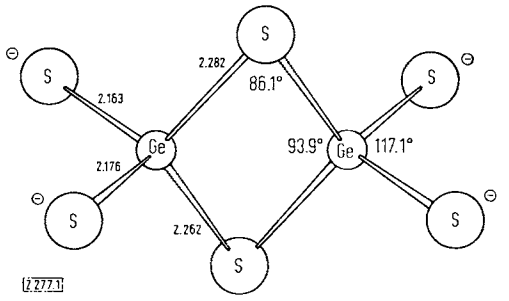

Fig. 1. Structure of the ions $Ge_2S_6^{4-}$ and $Sn_2S_6^{4-}$; bond lengths (in Å) and bond angles for $Ge_2S_6^{4-}$ in solid $Na_4Ge_2S_6 \cdot 14\ H_2O$.

metry, deviations from D_{2h} being very small. The terminal bonds have definite π-content, while the bridging Ge—S bonds correspond approximately to single bonds (sum of the covalent radii 2.26 Å). The bond angles S(terminal)-Ge-S(bridge) range between 110.1 and 111.8 °. The Raman spectrum of the solid, in which D_{2h} symmetry would require that 9 of the 18 fundamental vibrations be active, has lines at 457 (rel. int. 8), 452 (sh, 4), 402 (1), 378 (1), 350 (10), 221 (1), 191 (5), 180 (2), 143 (8), 101 (1), 81 (1), and 58 (1) cm^{-1}.

The "thiopyrogermanates" described by *Schwarz* and *Giese*[1a] do not exist as homogeneous phases — they consist of mixtures of $M_4^IGeS_4$ and $M_4^IGe_2S_6$.

It is especially remarkable that the same structure as shown in Fig. 1 applies to the corresponding tin ion which has been formally described as "metathiostannate" SnS_3^{2-}, but which has not been structurally characterized as yet. According to our X-ray results, the ion has to be formulated as hexathiodistannate(IV) $Sn_2S_6^{4-}$. The sodium salt, which has been isolated by *Jelley*[4] using a complicated procedure, was prepared by us analogously to the thiogermanate (pH 8—9). Li, K, Rb, and Cs form similar salts of various water contents.

$Na_4Sn_2S_6 \cdot 14\ H_2O$ (not $16\ H_2O$[4]) is isotypic with *(1)* and crystallizes with a = 10.114(6) Å, b = 7.027(5) Å, c = 9.801(6) Å, α = 108.30(4) °, β = 92.18(4) °, γ = 91.11(4) °, d_{obs} = 1.97, $d_{X\text{-ray}}$ 1.945 g cm^{-3}.

The bonding in $Sn_2S_6^{4-}$ ions is very similar to that in $Ge_2S_6^{4-}$. Raman spectrum: 391 (4), 377 (8), 341 (10), 281 (4), 190 (1), 178 (2), 151 (1), 136 (2), 118 (1), 96 (1), 59 (6), and 44 (1) cm^{-1}.

X-ray analysis of the orthothiostannate $Na_4SnS_4 \cdot 14\ H_2O$ *(2)*[5] (not $18\ H_2O$[4]) shows that here too tetrahedrally coordinated tin exists in the form of isolated SnS_4^{4-} ions (d_{Sn-S} = 2.380 Å) analogous to PS_4^{3-}, AsS_4^{3-}, SbS_4^{3-}, and GeS_4^{4-} and to the SnS_4 unit in ternary and quaternary sulfides[6]. The salt *(2)* crystallizes in the monoclinic system (C2/c) with a = 8.622(5) Å, b = 23.534(12) Å, c = 11.347(7) Å, β = 110.53(4) °, $d_{obs.}$ = 1.84, $d_{X\text{-ray}}$ = 1.835 g cm^{-3}, Z = 4.

Thus, contrary to previous assumptions[4], octahedral six-coordination [*e.g.*, as $Sn(OH)_3(SH)_3$] is unstable in solid hydrated thiostannates. Raman spectra, however, show that in aqueous solutions a pH-dependent equilibrium exists between various species, possibly including octahedrally coordinated ones.

Structure of 1,1-Bis(dimethylamino)-2,4,6-triphenylphosphorin

By *Ulf Thewalt*, *Charles E. Bugg*, and *Albert Hettche*[*]

Dimroth et al.[1] recently prepared a phosphorin with NR_2 substituents on the P atom, namely, the compound *(1)* with R = R′ = C_6H_5. The properties of the compound indicated aromatic character for the C_5P ring system.

(1)

An X-ray structure analysis of a compound of type *(1)* therefore seemed of interest, especially for comparison with *P*-alkyl and *P*-alkoxy phosphorins.

Yellow-fluorescing, plate-shaped, orthorhombic crystals of 1,1-bis(dimethylamino)-2,4,6-triphenylphosphorin *(1)*, R = CH_3, R′ = C_6H_5, were obtained by slow evaporation of an ethanolic solution. Crystal data: space group Pbca; a = 13.99 Å, b = 15.66 Å, c = 21.62 Å; Z = 8, $d_{X\text{-ray}}$ = 1.156, d_{obs} = 1.16 g/cm^3. The intensities of about 4000 independent reflections were measured on a Picker automated diffractometer using Cu—K_α radiation. The structure determination was based on the symbolic addition method[2] and was carried out with a FORTRAN program. To find the signs or symbols of the 237 strongest reflections ($E \geq 1.9$) required only a few minutes with a TR4 computer. An E map revealed the positions of all non-hydrogen atoms. Least-squares refinement of the structure — including the

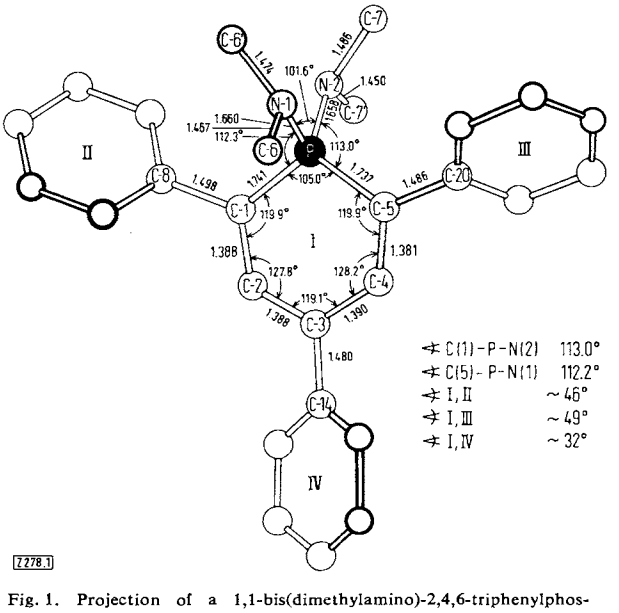

Fig. 1. Projection of a 1,1-bis(dimethylamino)-2,4,6-triphenylphosphorin molecule along the crystallographic *b*-axis. Standard deviations of the bond lengths (Å) are *ca.* 0.005 Å.

hydrogen atoms during the final cycles — led to a conventional R index of 9.1 % for all 3932 reflections. Fig. 1 shows a projection of the molecule along with selected bond distances and bond angles.

The PC_5 ring is almost planar; the deviations from the C(2)PC(4) plane are C(1) = −0.055 Å, C(3) = 0.026 Å, C(5) = 0.003 Å. The mean P—C bond length (1.739 Å) is intermediate between the lengths of P—C single and double bonds (1.82 and 1.66 Å, respectively [3]). The C—C bonds of the PC_5 ring compare well with each other (mean value 1.387 Å). This ring geometry and the coordination at the P atom [distorted tetrahedron; C—P—C and N—P—N angles distinctly smaller than the tetrahedral angle; N(1)-PN(2) plane perpendicular to the C(1)PC(5) plane] agree very well with those found for P-alkyl and P-alkoxy phosphorins [4, 5]. As in the case of these last compounds, conclusions as to the aromatic character of the PC_5 system can be drawn from bond lengths and angles within the central ring. Broadening of the ligand-P-ligand angle to 101.6° from the 93° of 1,1-dimethoxy-2,4,6-triphenylphosphorin [5] may be caused by the greater spatial demands of the NR_2 groups. The two P—N bonds of 1.66 Å are significantly shorter than a P—N single bond (1.77 ± 0.02 Å in $Na[PO_3NH_3]$ [6]). This indicates a $d_\pi p_\pi$ interaction superimposed on the single bonds. The arrangement of the three phenyl groups is propeller-like.

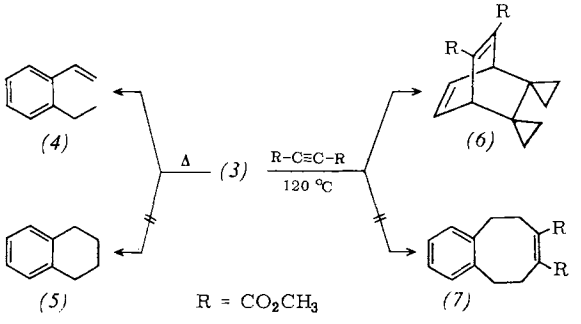
Dispiro[2.0.2.4]deca-7,9-diene, a Bishomo-*o*-quinodimethane



By *Armin de Meijere* [*]

The maximum electronic interaction between double bonds and cyclopropane rings occurs when the π-orbitals of the double bond are aligned parallel to the plane of the three-membered ring [1]. In the dispiro[2.0.2.4]deca-7,9-diene *(3)* such a favorable conformation is fixed, because the six-membered ring formed from six sp^2-hybridized carbon atoms [2] must be planar or nearly so. Compound *(3)* may thus be expected to show interesting chemical and physical properties.

Synthesis of *(3)* started from dispiro[2.0.2.4]dec-8-ene *(1)* [3]. Addition of bromine in methylene dichloride led to the dibromide *(2)*, and dehydrobromination of *(2)* by lithium chloride in hexamethylphosphoramide [4] then yielded *(3)* [5] [*ca.* 40 %, based on *(1)*]. The spectroscopic data are in accord with the proposed structure: In the mass spectrum the molecular ion appeared at m/e = 132. The ^{1}H-NMR spectrum (in CCl_4) showed one AA'XX' system for four olefinic protons at τ = 4.81, τ = 4.02, and another one for eight cyclopropyl protons at τ = 9.46, τ = 9.58.

Compound *(3)* resinifies on exposure to air for several days. Its thermal rearrangement, which proceeds relatively rapidly at 120 °C ($\tau_{1/2} \approx 3.5$ h), leads to *o*-ethylstyrene *(4)*. Surprisingly the bicyclopropyl-cyclohexene rearrangement [6], which is known for the parent compound and would have afforded tetralin *(5)* from *(3)*, does not occur.

Dimethyl acetylenedicarboxylate reacts smoothly with *(3)* at 120 °C in 1 hour to give the Diels-Alder adduct *(6)* [5], m.p. 93—94 °C, whose structure was proved by the ^{1}H-NMR spectrum. By analogy to the known reaction of quadricyclane [7] one might expect addition to the bicyclopropyl system in *(3)* which would lead to the benzocyclooctadiene derivative *(7)*, thus gaining aromatization energy. However, this has not yet been observed.

The NMR spectrum provided an answer to the question whether the six-membered ring in *(3)* contains a cyclically delocalized electron system. That there is no diamagnetic ring current can be concluded from the chemical shifts of the olefinic protons — on transition from the 1,3-cyclohexadiene *(8)* to *(3)*, essentially the resonances of H-1 and H-4 are moved by 0.49 ppm to higher field due to the diamagnetic anisotropy of the cyclopropane rings (Table 1). The vicinal H,H coupling constants in the olefinic AA'XX' system of *(3)* are intermediate between those of *(8)* and *(9)*

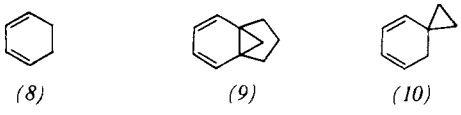


Table 1. Chemical shifts (τ values in ppm) and H,H coupling constants of the olefinic protons of some 1,3-cyclohexadiene systems.

	H-1, H-4	H-2, H-3	$J_{1,2} = J_{3,4}$	$J_{2,3}$	$J_{1,3} = J_{2,4}$	$J_{1,4}$	Ref.
(8)	4.32	4.17	9.66	5.04	1.02	1.12	[8]
(3)	4.81 [a]	4.02 [a]	9.20	5.46	0.82	1.12	[9]
(9)	3.93	4.29	9.25	5.94	0.58	1.31	[10]

[a] The assignment is supported by the observed long-range coupling of H-1, H-4 with the cyclopropyl protons.

(Table 1); this indicates that in *(3)* there is no additional equalization of bond orders due to cyclic delocalization of the π-electrons.

Compounds containing the dispiro[2.0.2.4]decadiene system have been, respectively, postulated and discussed as

intermediates in photoreactions of benzo-7-oxanorbornadiene[11] and benzonorbornadiene[12]. Therefore the UV spectrum of *(3)* is of special interest: λ_{max} = 284 nm (ε = 4800), without vibrational structure (in cyclohexane). The maximum of the longest-wavelength absorption band of spiro[2.5]octa-4,6-diene *(10)*, which was prepared for comparison[13], appears at 269 nm ($\varepsilon \approx 3000$), *i.e.* between those of *(3)* and *(8)* (λ_{max} = 250 nm[15]).

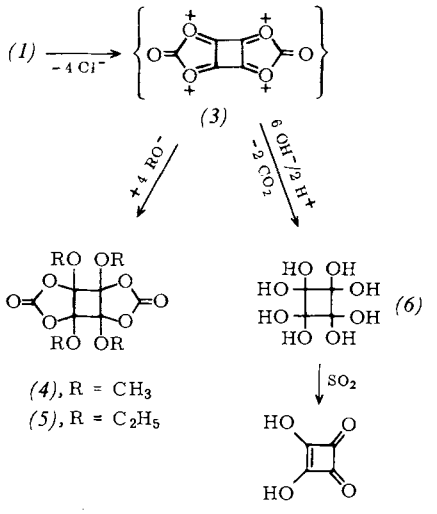
Derivatives of Tetrameric Carbon Monoxide[**]

By *Hans-Dieter Scharf* and *Helmut Seidler*[*]

Dichlorovinylene carbonate (4,5-dichloro-1,3-dioxol-2-one)[1] dimerizes when irradiated in concentrated solution in acetone by light of wavelength $\lambda \geq 290$ nm[2], affording the stereoisomeric 2+2 cycloadducts *(1)* and *(2)* in the ratio 3:1. Both products have the composition $C_6O_6Cl_4$[3].

(1)



(2)

When the solvent is cyclohexane the products are formed in the same ratio but the quantum yield in acetone is higher by a factor of 5, so that triplet-sensitization is very likely. Preference for the "*anti*" isomer is in agreement with this[4].

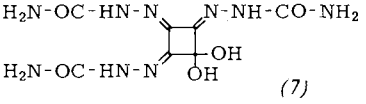
(1) crystallizes directly from the irradiated mixtures, but *(2)* must be isolated from enriched fractions by fractional crystallization.

The thermal stability of *(1)* is surprisingly high. The compound is unchanged when its melt is refluxed (b.p. 200 °C) for a considerable time. Hydrolysis with acetone-water leads quantitatively to cyclobutaneoctaol *(6)*[5], which is identical with the product formed by oxidation of squaric acid by nitric acid[6,7].

Compound *(6)* can be reduced to squaric acid by SO_2 using the method of *West et al.*[6].

Alcoholysis of *(1)* by methanol or ethanol also under S_N1 conditions leads very rapidly to compounds *(4)* and *(5)* with replacement of all four Cl atoms by OR groups, no products of partial exchange being detectable.

(4): $C_{10}H_{12}O_{10}$[3], m.p. 200 °C (acetone); IR, CO frequency 1830 cm^{-1}; NMR[8] ([D_6]acetone), singlet at τ = 6.28.



(5): $C_{14}H_{20}O_{10}$[3], m.p. 128 °C (ethanol); IR frequency 1810, 1855 (shoulder) cm^{-1}; NMR ([D_6]acetone), quartet at τ = 6.0 (2 H), triplet at τ = 8.65 (3 H), J = 6 Hz.

Surprisingly the carbonate group is not attacked under these conditions, although the alcoholic solution reacts distinctly acid[9]. To explain these facts a cation *(3)* is assumed to be formed as intermediate which is trapped by the nucleophilic OR groups.

When a 1:1 methanol-ethanol mixture is used, compound *(4)* is accompanied by two mixed substitution products, but *(5)* is not contained in the products.

Boiling *(4)* or *(5)* with dilute hydrochloric acid also leads to cyclobutaneoctaol *(6)*.

Compounds *(1)*, *(2)*, *(4)*, *(5)*, and *(6)* react with semicarbazide hydrochloride to give the same orange-colored semicarbazone, which on account of its composition $C_7H_{11}O_5N_9$ (mol. wt. 301.23) and IR-spectroscopic properties (OH and NH stretching vibrations at 3000 to 3500 cm^{-1}, ν_{CO} = 1680 cm^{-1}) is considered to be cyclobutanetetraone trissemicarbazone monohydrate *(7)*. This

(7)

substance can be recrystallized from glacial acetic acid and is shown by thin-layer chromatography[10] to be homogeneous. It deflagrates before its melting point is reached.

Preparation of (1) and (2):

4,5-Dichloro-1,3-dioxal-2-one (70 g) in anhydrous acetone (50 ml) is irradiated for 7 days at room temperature[2]. During this time product *(1)* is filtered off in portions (total 8.6 g). The mother liquor is concentrated without being heated, whereupon more *(1)* separates, and the amount can be increased by refrigeration. The mother liquor is then distilled in a high vacuum, much (*ca.* 50 g) starting material being recovered (b.p. 20—30 °C/3.5 torr). Finally there distills an oil (6 g, b.p. 110 °C/3.5 torr) that solidifies in the receiver and consists to the extent of about 80% of product *(2)*. Fractional crystallization from light

petroleum (b.p. 80–100 °C), in which *(1)* is less soluble than *(2)*, affords *(2)* in crystalline form. *(1)*: m.p. 157 °C. *(2)*: m.p. 97 °C, IR absorption ν_{CO} = 1840 and 1870 cm^{-1}.

Lone Pair Interaction in Pyridazine, Pyrimidine, and Pyrazine[1]

By *Rolf Gleiter, Edgar Heilbronner*, and *Volker Hornung*[*]

The orbital diagram of Figure 1 correlates the energy levels $\varepsilon(\psi_J)$ of the highest occupied orbitals ψ_J of benzene *(1)*, pyridine *(2)*, pyridazine *(3)*, pyrimidine *(4)*, and pyrazine *(5)*. The orbital energies $\varepsilon(\psi_J)$ correspond to the vertical ionization potentials $I_v(J)$ (Table 1), which were determined from high-resolution photoelectron spectra[2]: $\varepsilon(\psi)_J = -I_v(J)$. (For previous measurements see, *e.g.*, ref.[4].) The designation of the orbitals ψ_J characterizes, in the usual nomenclature, the symmetry behavior of the orbital with regard to symmetry operations of the symmetry group to which the molecule belongs. The letters S and A denote the behavior of the two degenerate π orbitals $e_S = (2\Phi_1 + \Phi_2 - \Phi_3 - 2\Phi_4 - \Phi_5 + \Phi_6)/\sqrt{12}$ and $e_A = (\Phi_2 + \Phi_3 - \Phi_5 - \Phi_6)/2$ of benzene on reflection in the *x,z* plane. In Figure 1, S and A are used solely in order to correlate the orbitals of the systems *(2)* to *(5)* with the "parent orbitals" of benzene from which they are derived. Linear combination of the atomic orbitals n_1 and n_2 of the two lone pairs in *(3)*, *(4)*, and *(5)*, which are regarded as localized, yields initially the orbitals $n_+ = (n_1 + n_2)/\sqrt{2}$ and $n_- = (n_1 - n_2)/\sqrt{2}$ of correct symmetry. Those molecular orbitals ψ_J to which n_+ or n_- make the greatest contribution are marked (+) and (—) respectively in Fig. 1.

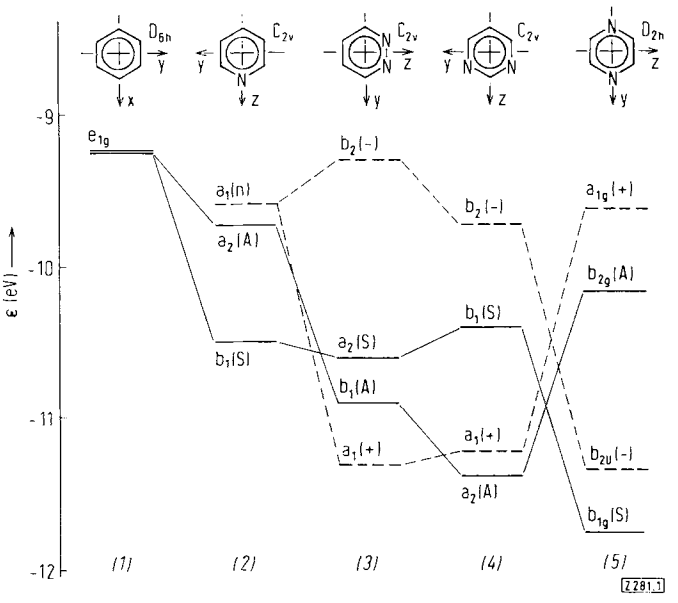

Fig. 1. Correlation diagram. It should be pointed out that (S) and (A) do *not* refer to the true symmetry of the molecule but solely to the parent orbital in *(1)* from which the respective π orbital is derived.

Assignment of the individual bands in the PE spectra to π and n/σ ionization processes is based on the characteristic shapes of π and n/σ bands as well as on model calculations. It may be deduced from the fine structure of the two n-bands of *(5)* that the first n-band ($I_v(1)$ = 9.63 eV) corresponds to an ionization process in which the photoelectron stems from an a_{1g} orbital containing the linear combination n_+, while the third band ($I_v(3)$ = 11.35 eV) must be assigned to the b_{2u} orbital containing the n_- combination[5].

Interaction between the lone pair orbitals n_1 and n_2 occurs mainly *via* two mechanisms: a) Direct overlapping, *i.e.* "through-space" interaction b) "through-bond" interaction with other bonding and/or antibonding σ orbitals of the molecule[6]. Mechanism a) always leads to the sequence $\varepsilon(\psi_-)$ above $\varepsilon(\psi_+)$, while mechanism b) leads to the same or to the reverse sequence, depending on the relative positions of the orbitals n_1 and n_2 in the molecule.

The molecules *(3)*, *(4)*, and *(5)* yield the following values for the splitting

$$\Delta_{exp} = \varepsilon(\psi_-) - \varepsilon(\psi_+) = I_v(\psi_+) - I_v(\psi_-)$$

which are compared with the theoretical values calculated from an EHT model[7].

	ψ_-	ψ_+	Δ_{exp} (eV)	Δ_{theor} (eV)
(3)	$b_2(n_-)$	$a_1(n_+)$	2.00	0.99
(4)	$b_2(n_-)$	$a_1(n_+)$	1.50	0.80
(5)	$b_{2u}(n_-)$	$a_{1g}(n_+)$	−1.72	−1.67

As can readily be understood on a qualitative basis, the contribution to the value of Δ that is attributable to mechanism a) decreases along the series *(3)*, *(4)*, *(5)* owing to

Table 1. Vertical ionization potentials $I_v(J)$ (in eV) [3].

	$I_v(1)$		$I_v(2)$		$I_v(3)$		$I_v(4)$	
(1) (D_{6h})	9.24	$e_{1g}(\pi)$						
(2) (C_{2v})	9.59	$a_1(n)$ [a]	9.73	$a_2(\pi, A)$ [a]	10.50	$b_1(\pi, S)$		
(3) (C_{2v})	9.31	$b_2(n_-)$	10.61	$a_2(\pi, S)$	10.9 [b]	$b_1(\pi, A)$	11.31	$a_1(n_+)$
(4) (C_{2v})	9.73	$b_2(n_-)$	10.41	$b_1(\pi, S)$	11.23	$a_1(n_+)$	11.39	$a_2(\pi, A)$
(5) (D_{2h})	9.63	$a_{1g}(n_+)$	10.18	$b_{2g}(\pi, A)$	11.35	$b_{2u}(n_-)$	11.77	$b_{1g}(\pi, S)$

[a] Partially resolved double band; the onset exhibits typical n band structure.
[b] Value uncertain because of overlapping with bands 2 and 4.

the increasing distance between n_1 and n_2. In contrast, mechanism b) contributes to about the same extent in all three cases. Since $\psi(n_+)$ interacts primarily with the lower-energy bonding σ orbitals of the same symmetry, and $\psi(n_-)$ mainly with the antibonding ones, mechanism b) has the effect of raising $\varepsilon(\psi(n_+))$ and lowering $\varepsilon(\psi(n_-))$. In *(5)* this leads to an inversion of the sequence of the orbitals $\psi(n_+)$, $\psi(n_-)$ relative to *(3)* and *(4)* and thus to a negative Δ value. Direct interaction between n_1 and n_2 (mechanism a)) dominates in *(3)* and *(4)*. Finally, the Δ values for *trans*-azomethane ($\Delta = -3.3$ eV)[8] and for 3,3-dimethyldiazirine ($\Delta = 3.5$ eV)[9] are given for the sake of comparison.

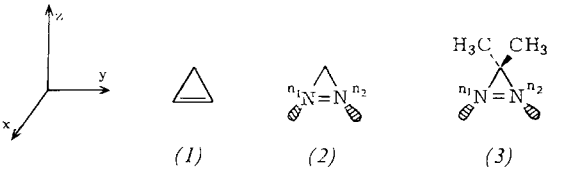
Lone Pair Interaction in 3,3-Dimethyldiazirine[1]

By *Edwin Haselbach, Edgar Heilbronner, Albrecht Mannschreck*, and *Werner Seitz*[*]

The photoelectron-spectroscopic determination of the interaction



$$\Delta = \varepsilon(\psi(n_-)) - \varepsilon(\psi(n_+))$$

between the lone pairs n_1 and n_2 of the *trans* azo group in azomethane has been reported previously[2] ($\Delta = -3.3$ eV; cf. ref.[3]). The functions $\psi(n_-)$ and $\psi(n_+)$ are those molecular orbitals to which the linear combinations

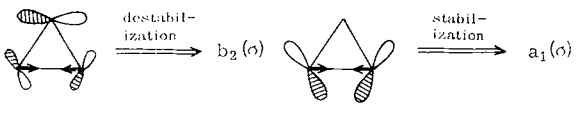
	Symmetry behavior	
	C_{2h}	C_{2v}
$n_- = \frac{1}{\sqrt{2}}(n_1 - n_2)$	B_u	B_2
$n_+ = \frac{1}{\sqrt{2}}(n_1 + n_2)$	A_g	A_1

make the greatest contribution. We have now also studied the interaction of n_1 and n_2 in a diazirine derivative, which contains the *cis* azo group.

Theoretically determined orbital energies ε for the five highest occupied MOs of cyclopropene *(1)*, diazirine *(2)*, and 3,3-dimethyldiazirine *(3)* are listed in Table 1.

(1) *(2)* *(3)*

Table 1. Calculated orbital energies ($-\varepsilon$) for cyclopropene *(1)*, diazirine *(2)*, and 3,3-dimethyldiazirine *(3)* [in eV].



(1)		*(2)*		*(3)*
ab initio	MINDO/2	*ab initio*	MINDO/2	MINDO/2
8.97 $b_1(\pi)$	9.54 $b_1(\pi)$	10.46 $b_2(n_-)$	10.47 $b_2(n_-)$	9.72 $b_2(n_-)$
10.58 $b_2(\sigma)$	9.95 $b_2(\sigma)$	12.31 $b_1(\pi)$	11.17 $b_1(\pi)$	10.51 $b_1(\pi)$
12.39 $a_1(\sigma)$	10.86 $a_1(\sigma)$	14.46 $a_1(n_+)$	11.76 $a_1(\sigma)$	11.46 $a_1(\sigma)$
15.11 $b_1(\pi)$	14.55 $a_1(\sigma)$	16.73 $a_1(\sigma)$	13.45 $a_1(n_+)$	11.95 $a_1(n_+)$
17.12 $a_1(\sigma)$	14.72 $b_1(\pi)$	17.44 $b_1(\pi)$	15.65 $b_1(\pi)$	12.25 $b_1(\pi)$

The orbital sequence for *(2)* calculated by the MINDO/2 technique[4] differs from that obtained by *Robin, Basch, Kuebler, Wiberg*, and *Ellison*[5] from an *ab initio* model in the order of the orbitals $a_1(n_+)$ and $a_1(\sigma)$. Experience shows that for unsaturated systems MINDO/2 yields σ orbitals at too high orbital energies, so that the appearance of $a_1(\sigma)$ between $b_1(\pi)$ and $a_1(n_+)$ in the case of *(2)* and *(3)* should be regarded as an artefact of the method. For an extended Hückel model of *(2)* the reader is referred to a paper by *Hoffmann*[6] and for a detailed discussion of the electronic structure of cyclopropane, *(1)*, and *(2)* to a publication by *Kochanski* and *Lehn*[7].

Table 2. Vertical ionization potentials $I_v(J)$ of the first three bands in the photoelectron spectrum of cyclopropene *(1)* and 3,3-dimethyldiazirine *(3)* [in eV].

	$I_v(1)$	$I_v(2)$	$I_v(3)$
(1)	9.86 ($\Delta\tilde{\nu} \approx 1250\,cm^{-1}$)	11.02	12.7 ($\Delta\tilde{\nu} \approx 1100\,cm^{-1}$)
(3)	9.76	12.11	13.31

Table 2 lists the vertical ionization potentials $I_v(J)$ as determined by PE spectroscopy[8], *i.e.* the maxima of the first three bands in the spectrum of *(1)* and *(3)*. The assignment is based on the theoretical data listed in Table 1 and on the following arguments: The form of band 1 at 9.9 eV in the PE spectrum of *(1)* is typical for a π band (vibrational fine structure; mean splitting 0.15 eV corresponding to $\Delta\tilde{\nu} \approx 1200\,cm^{-1}$). The next two σ bands (at 11.0 and 12.7 eV) correspond to the orbitals $b_2(\sigma)$ and $a_1(\sigma)$ which arise from the Walsh e′ orbitals[9] of cyclopropane (D_{3h}) on removal of their degeneracy when the distance between centers 1 and 2 is reduced by introduction of a double bond:

(This qualitative consideration also explains the appearance of a vibrational fine structure of $\Delta\tilde{\nu} \approx 1100\ cm^{-1}$ in band 3 (at 12.7 eV) in the spectrum of *(1)*.) Replacement of the carbon centers in *(1)* by nitrogen centers should lead to a lowering of the π orbital by an amount comparable with that occurring in the transition *trans*-2-butene ($\varepsilon(\pi) = -9.11$ eV) $\rightarrow$ *trans*-azomethane ($\varepsilon(\pi) = -11.84$ eV)[2,3]. Thus a value of $\varepsilon(b_1(\pi)) = -9.86 - 2.73 = -12.59$ eV is predicted for *(2)*. In the case of *(3)*, this value represents an upper limit since the two methyl groups raise the level of the π orbital relative to that in *(2)*. It is therefore most likely that the band at 12.1 eV in the PE spectrum of *(3)* has to be assigned to the $b_1(\pi)$ orbital, in agreement with the theoretical prediction —. However, it should be noted that the second band in the spectrum of *(3)* does not show the fine structure typical for a N=N bond, as in the case of azomethane[2,3]. This may be due to the fact that the $b_1(\pi)$ orbital also extends over the C—CH_3-σ bonds. As a result, the low-frequency, totally symmetric normal mode of the CH_3—C—CH_3 unit is also excited on relaxation of the radical cation *(3)*$^+$ after ejection of the photoelectron from $b_1(\pi)$.

The two orbitals $b_2(\sigma)$ and $a_1(\sigma)$ in *(1)*, which are related to the Walsh e′ orbitals correspond to the orbitals $b_2(n_-)$ and $a_1(n_+)$ of *(2)* and *(3)*. In the two last-named compounds the original C—C-σ orbitals are extensively mixed with the linear combinations n_- and n_+. This factor and the reduction in the distance between centers 1 and 2 relative to *(1)* increases the splitting $\varepsilon(b_2(\sigma)) - \varepsilon(a_1(\sigma))$ found for *(1)*.

Whereas this difference amounts to 1.7 eV for *(1)*, a value

$$\Delta = \varepsilon(b_2(n_-)) - \varepsilon(a_1(n_+)) = 3.55\ eV$$

is found for 3,3-dimethyldiazirine.

Delocalization of the orbitals of the lone pairs ($a_g(n_+)$ and $b_u(n_-)$ in the case of azomethane) has already been proposed on the basis of theoretical results[3]. It may now be concluded from the results of MINDO/2 calculations that the situation is even more extreme in compounds *(2)* and *(3)*. In fact, the calculations show that the two electrons in the orbital $b_2(n_-)$ of *(3)* are localized to an extent of only 56% on the two nitrogen atoms. For the lower orbital $a_1(n_+)$ this value becomes as low as 43%. In the light of these figures, the term "lone pair" loses much of its meaning. It is therefore important when interpreting properties of such systems to bear in mind that, in keeping with modern social trends, electrons also prefer to live in a commune, rather than in pairwise isolation[10].

Tetrakis(trimethylphosphane)nickel(0)[1]

By *Hans-Friedrich Klein* and *Hubert Schmidbaur*[*]

Present day concepts of bonding in phosphane complexes attach particular attention to the π-acceptor properties of the ligands. Thus the extensive accumulation of charge on the central atom due to the σ-donor effect of the ligands is believed to be reduced by π-back donation. The ready formation and high stability of trifluorophosphane and phosphite complexes appears to support such a concept since the inductive effect for the fluorine and oxygen atoms considerably increases the acceptor strength of the phosphorus atoms. It was consistent with this picture that metal(0) complexes having trialkylphosphanes as ligands were hitherto practically unknown[2,3]. We now report the synthesis and properties of tetrakis(trimethylphosphane)-nickel(0), which is of considerable interest in this connection.

Reduction of aqueous solutions of nickel(II) salts at pH > 7 with an excess of trimethylphosphane immediately affords the complex $Ni[P(CH_3)_3]_4$ *(1)*. Complex *(1)* is also formed on reaction of $[(CH_3)_3P]_2NiCl_2$ with an aqueous-alcoholic solution of potassium hydroxide or with sodium trimethylsilanolate in diethyl ether or tetrahydrofuran.

$$Ni^{2+} + 2\ OH^- + 5\ (CH_3)_3P \rightarrow (1) + (CH_3)_3PO + H_2O$$

$$5\ [(CH_3)_3P]_2NiCl_2 \xrightarrow{10\ OH^-} \begin{cases} 2\ (1) + 2\ (CH_3)_3PO + 3\ Ni(OH)_2 + 10\ Cl^- + 2\ H_2O \\ 2\ (1) + 2\ (CH_3)_3PO + 3\ Ni[OSi(CH_3)_3]_2 + 10\ NaCl + 2\ [(CH_3)_3Si]_2O \end{cases}$$

Compound *(1)*, which can be isolated by extraction with hexane or by sublimation under reduced pressure (80 °C/1 torr), forms pale yellow needle-like crystals (from alcohol) that decompose at 185—190 °C in a nitrogen atmosphere. The crystals are pyrophoric and deflagrate spontaneously upon admission of air. They are readily soluble in hydrocarbons, ethers, and organosilicon compounds such as tetramethylsilane or hexamethyldisiloxane; the yellow solutions become colorless on cooling to —50 °C. Cryoscopic measurements show the compound to be monomeric in benzene[4]; NMR measurements reveal its diamagnetic nature. The mass spectrum of *(1)* at 70 and at 20 eV displays only fragmentation of the ligand [$(CH_3)_3P^+ \rightarrow (CH_3)_2P^+$, $(CH_3)_2PCH_2^+$, CH_3P^+, *etc.*] but not of the intact complex which seems to decompose completely even under mild conditions in the mass spectrometer.

The ^{1}H-NMR spectrum recorded at 60 and 100 MHz contains only one proton signal whose half-width of 4 Hz remains constant between —50 and +80 °C (τ = 8.9 ppm against TMS in hexamethyldisiloxane). The ^{1}H-^{13}C coupling satellites, $^1J(HC) = 125.5$ Hz, exhibit the same signal broadening. Likewise the ^{31}P-NMR spectrum contains just a single broadened line ($\delta = +23.2$ ppm in benzene against 85% H_3PO_4 as external reference). This peak is shifted 39 ppm downfield compared with that of free $(CH_3)_3P$, thus resembling the difference found for the pair of compounds $Ni(PF_3)_4$—PF_3[5]. The forms of the signals can be regarded as arising from the complex spin-spin

nteractions occurring in a $[A_9X]_4$-T_d system[6]. Extensive P—Ni—P interactions cause the A part (^1H) and the X part (^{31}P) to lose the first-order structures expected. An interpretation of the spectra based on the assumption of exchange processes is ruled out largely by the lack of variation of the signal with temperature.

The Raman spectrum (He—Ne laser) of crystalline *(1)* contains a strong band at 196 cm^{-1} which, in agreement with measurements on $Ni(PF_3)_4$[7], can be assigned to a stretching vibration of the NiP_4 tetrahedron. In addition, all characteristic Raman and IR frequencies of the ligands are observed between 200 and 4000 cm^{-1}; they show alternating intensities owing to the tetrahedral geometry of the molecule.

The remarkable properties of $Ni[P(CH_3)_3]_4$ serve to illustrate that strongly electronegative substituents on the phosphorus atom are *not* a necessary condition for the stability of a metal(0)-phosphane complex. It is not surprising that similar complexes of iron and cobalt have now also been prepared[8] [**].

[**] *Note added in proof* (October 23, 1970): The synthesis of *(1)* has recently also been reported by *Ch. A. Tolman*, J. Amer. Chem. Soc. *92*, 2956 (1970). All data given in that paper (m.p. and ^1H- and ^{31}P-NMR) agree satisfactorily with our own results. The method of synthesis is different, however, and resembles the synthetic principle developed by *Wilke et al.* for the ethyl homolog [2].

Tetrakis(trimethylphosphane)hydridocobalt(I) and -dihydridoiron(II)

By *Hans-Friedrich Klein*[*]

The unexpected stability of tetrakis(trimethylphosphane)-nickel(0)[1] gave good reason for expecting the successful outcome of attempts to synthesize analogous tetrakis(trimethylphosphane)metal hydrides of the types L_4CoH and L_4FeH_2. Such compounds, which have recently attracted particular interest on account of their stereochemical nonrigidity[2,3], were hitherto known only with phosphanes L whose phosphorus atom bore at least one electron-attracting substituent[2–5].

The cobalt compound $[(CH_3)_3P]_4CoH$ *(1)* is readily obtained when an aqueous solution of Co^{2+} is reduced under alkaline conditions in the presence of trimethylphosphane using zinc dust. Isolation of the product by extraction with light petroleum and subsequent sublimation is essentially by the same method as was employed in the case of $Ni[P(CH_3)_3]_4$[1]. An alternative method of preparation is the reduction of $[(CH_3)_3P]_2CoCl_2$ with $LiAlH_4$ in tetrahydrofuran in the presence of $(CH_3)_3P$.

Similarly, reduction of $FeCl_2$ by $LiAlH_4$ in THF in the presence of trimethylphosphane affords $[(CH_3)_3P]_4FeH_2$ *(2)* which can be sublimed *in vacuo* after extraction with light petroleum of the residue left on removal of the solvent.

At room temperature, *(1)* and *(2)* form yellow and yellowish-brown crystals that sublime without decomposition at 70 and 80—90 °C/1 torr respectively, and which decompose only above 180—190 °C when heated under nitrogen. Both compounds are readily soluble in non-polar solvents and both the solutions and the solids are oxidized only slowly by atmospheric oxygen. Thus, unlike $Ni[P(CH_3)_3]_4$[1], the new compounds are not pyrophoric. NMR measurements reveal diamagnetism.

Alongside the $(CH_3)_3P$ proton resonances, the ^1H-NMR spectra[6] contain the multiply split signals of the hydride ligands. At 20 °C compound *(1)* gives the symmetrical 1:4:6:4:1 quintet having $|J(HCoP_4)| = 32$ Hz and $\tau = 26.5$ ppm relative to ext. TMS. Rapid exchange of the axial and equatorial phosphane ligands apparently leads to complete NMR equilibration of the phosphorus atoms of the trigonal pyramid at room temperature.

In the case of *(2)*, a little below room temperature the H_2Fe resonance still appears as a doublet of triplets which does not begin to coalesce until the sample is warmed to > 30 °C. For the pairs of axial and equatorial phosphorus atoms of a *cis*-octahedral configuration which are clearly non-equivalent at 10 °C we measured the values $|J(H_2FeP_{cis})| = 72$ and $|J(H_2FeP_{trans})| = 26$ Hz ($\tau = 23.3$ ppm). Thus in *(2)* ligand exchange is much slower than in the cobalt compound *(1)* and in the analogous octahedral hydrides L_4FeH_2[2–3], primarily for steric reasons. No evidence was obtained for the existence of a *trans*-octahedral isomer.

The IR spectra of *(1)* and *(2)* both contain strong absorption bands in the metal hydride region at 1885 (νCoH) and 1795 cm^{-1} (νFeH_2) that are shifted toward lower wave numbers compared with those of the analogous PF_3 complexes[5].

Remarkably, the hydride hydrogens in *(1)* and *(2)* *do not exhibit acidic character*, unlike those of analogous carbonyl or trifluorophosphanemetal hydrides. Deprotonation to the anion $[Co(P(CH_3)_3)_4]^-$ or $[Fe(P(CH_3)_3)_4]^{2-}$ cannot be achieved by treatment with either concentrated aqueous or alcoholic alkalis or the exceptionally strong base trimethylmethylenephosphorane[7]. Even prolonged heating of a mixture of $(CH_3)_3PCH_2$ and *(1)* does not effect proton transfer.

These observations emphasize the significance of the inductive effect of the ligands attached to phosphorus as regards the reactivity of the metal hydride function.

Novel Iminosulfur Oxydifluorides

By *Konrad Seppelt* and *Wolfgang Sundermeyer* [*]

As a rule, silicon-nitrogen bonds are readily attacked and completely cleaved by non-metallic halides and halogens [1]. However, we have now been able to prepare compound *(1)*, trimethylsilyliminosulfur oxydifluoride, one of the few exceptional cases in which an Si—N bond and an element-halogen bond are resident as immediate neighbors in the same molecule and do not interact with each other either inter- or intramolecularly. *(1)* was prepared from tris(trimethylsilyl)amine and sulfur oxytetrafluoride according to the following equation:

$$[(CH_3)_3Si]_3N + SOF_4 \rightarrow (CH_3)_3Si-N=S(F)=O + 2\,(CH_3)_3SiF$$

(1)

The reaction was carried out in an autoclave; the starting materials react above room temperature with moderate liberation of heat to give *(1)* in 85% yield.

Compound *(1)* can also be obtained by reaction of sulfur oxydifluoride with *N*-halogenobis(trimethylsilyl)amines, the most favorable synthesis (87% yield) being that from *N*-iodobis(trimethylsilyl)amine [2]:

$$6\,[(CH_3)_3Si]_2NI + SOF_4 \rightarrow 4\,(1) + 8\,(CH_3)_3SiF + 3\,I_2 + N_2$$

The reaction equation was confirmed by quantitative determination and by identification of by-products.

(1) is a water-clear liquid and only slightly sensitive to hydrolysis: m.p. —92 °C, b.p. 85.5 °C. It was purified by preparative gas chromatography and identified by elemental analysis and mass spectrometry [3] [*m/e* = 173 ($R_3SiNSOF_2$ 1.8%), 158 ($R_2SiNSOF_2$ 80%), 128 ($SiNSOF_2$ 2.7%), 81 (NSOF or $RSiF_2$ 90%), and 77 (R_2SiF) 100%) along with other typical fragments; 75 eV]. Both the most important absorptions in the IR spectrum [gaseous: 1495 (vs, νSO), 1275 (s, νNS), 852 (vs, ν_{as} SF), and 819 cm^{-1} (vs, ν_s SF)] and the corresponding Raman lines [3] (liquid: 1480, 1275, 853, and 810 cm^{-1}) as well as the ^{19}F-NMR spectrum (δ = —55.9 ppm against $CFCl_3$ as internal standard at 20 °C) give supporting evidence for structure *(1)* rather than for that of the isomeric compound $(CH_3)_3Si-O-SF_2\equiv N$, which was previously considered the more probable on the grounds of stability. In a heated autoclave, compound *(1)* starts to decompose at 250 °C; at 400 °C decomposition to $(CH_3)_3SiF$, SOF_2, N_2, SO_2, and S is complete.

Further evidence for the given structure is afforded by the reaction of *(1)* with mercury(II) fluoride in methylene chloride; this reaction leads to quantitative formation of mercury bis(imidosulfur oxydifluoride) *(2)*.

$$2\,(CH_3)_3Si-NSOF_2 + HgF_2 \rightarrow Hg(NSOF_2)_2 + 2\,(CH_3)_3SiF$$

(2)

This reaction parallels the synthesis of $Hg(NSO)_2$ [4]. The colorless crystals of *(2)* (m.p. 108 °C; sublimable in high vacuum at 130 °C) are only slightly sensitive to hydrolysis [5]. In air, *(2)* starts to decompose at 170 °C; the sole gaseous products formed on pyrolysis in high vacuum at 400—600 °C are SO_2, NSF and a little SiF_4 (from the glass) alongside Hg, HgF_2, S, and SN-polymers. Compound *(2)* is very soluble in ether, moderately soluble in methylene chloride, sparingly soluble in chloroform, and insoluble in petroleum ether. Its identification followed from elemental analysis and mass spectrometry [3] [*m/e* = 398—404 ($Hg(NSOF_2)_2$ 4.2%), 298—304 ($HgNSOF_2$ 6.1%), and 198—204 (Hg 100%) along with weaker signals; 75 eV]. The IR and Raman spectroscopic data [IR, Nujol: 1397 (vs, ν_{as}SO), 1362 (s, ν_sSO), 1231 (s, ν_{as}SN), and 1198 cm^{-1} (s, ν_sSN); Raman, solid: 1396 s, 1365 s, 1235 vs, and 1191 cm^{-1} m], as well as the ^{19}F-NMR spectrum [3] (δ = —58.7 ppm in methylene chloride, against $CFCl_3$ as external standard) are consistent with the structure given.

The imidosulfur oxydifluorides *(1)* and *(2)* react with halogens and halogen compounds in the manner described by us in a previous communication [6].

Crystal and Molecular Structure of $Zn_7O_8(CH_3)_{14}$ — a Dicubane [**]

By *Manfred L. Ziegler* and *Johannes Weiss* [*]

Coates and *Ridley* [1] obtained from the reaction of dimethylzinc and methanol the compound $Zn_4O_4(CH_3)_8$, which, according to X-ray investigations by *Shearer* and *Spencer* [2], has a cubane structure.

As *Eisenhuth* and *van Wazer* [3] were able to show, this methanolysis also leads to the formation of a product having the composition $Zn_7O_8(CH_3)_{14}$. According to NMR spectroscopic measurements this latter substance has a dicubane structure.

The triclinic unit cell (a = 10.08, b = 8.76, c = 10.61 Å; α = 115.4, β = 117.3, γ = 92.1 °; space group C_i^1—$P\bar{1}$) contains one formula unit $Zn_7O_8(CH_3)_{14}$. Since this substance is extremely sensitive to hydrolysis the crystals used for measurements must be sealed in a Mark tube.

The intensities of 1225 independent reflections obtained from Weissenberg photographs ("multiple film" method) about the a-axis were estimated visually and corrected in the usual manner. No corrections were carried out for absorption and extinction.

Since only one formula unit is found in the unit cell for a two-fold general equivalent position the molecule itself must be centrosymmetric, one of the zinc atoms being situated at the center of symmetry. The positions of the zinc atoms were determined by a three-dimensional Patterson synthesis; Fourier syntheses afforded the positions of the remaining atoms. Final refinement of the structural

parameters was carried out by the method of least squares with anisotropic temperature factors. After the final cycle including all observed F(*hkl*) the factor *R* had a value 0.10.

X-ray crystallographic investigation showed, that the previously unobserved structure of a dicubane is in fact present.

The cubes are distorted. All the Zn—O—Zn angles are smaller than 90° (81°—86°) and all the O—Zn—O angles are greater than 90° (93°—98°). The four atoms centered on the cube faces lie in one plane.

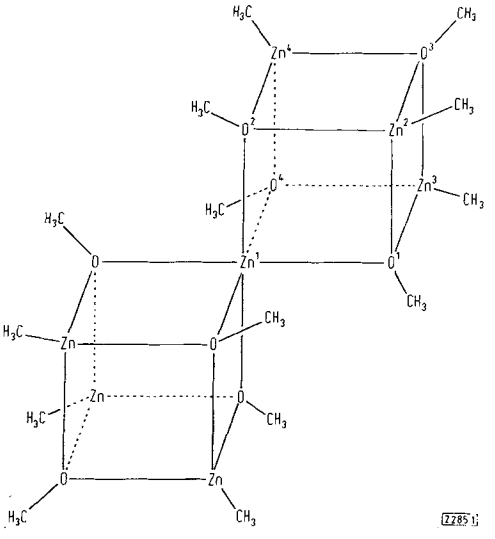

Table 2. Zn—Zn and Zn—O distances in Å.

Zn^1—Zn^2	3.068 (3)	Zn^2—Zn^3	3.033 (3)
Zn^1—Zn^3	3.134 (4)	Zn^2—Zn^4	3.095 (4)
Zn^1—Zn^4	3.173 (4)	Zn^3—Zn^4	3.033 (5)
Zn^1—O^1	2.068 (15)	Zn^3—O^1	2.103 (16)
Zn^1—O^2	2.077 (11)	Zn^3—O^3	2.069 (17)
Zn^1—O^4	2.170 (17)	Zn^3—O^4	2.026 (16)
Zn^2—O^1	2.039 (15)	Zn^4—O^2	2.147 (16)
Zn^2—O^2	2.038 (9)	Zn^4—O^3	2.041 (16)
Zn^2—O^3	2.122 (16)	Zn^4—O^4	2.039 (17)

One of the three bonds from a Zn atom to an O atom is always noticably longer than the other two (cf. Table 2) *i.e.* the cubes are elongated in one direction. The Zn—O distances at Zn^1 with CN 6 (in the center of symmetry of the molecule and in the symmetry center of the unit cell) are greater than the comparable distances at the other Zn atoms with CN 4.

The C atoms of the CH_3 groups are located in the direction of the space diagonals. The Zn—C distances have an average value of 1.953 Å, and the O—C distances between 1.42 and 1.49 Å.

The calculations were carried out (Siemens 2002) at the Astronomisches Recheninstitut der Universität Heidelberg; the refinements were carried out with the ORFLS program[4] at the Deutsches Rechenzentrum, Darmstadt.

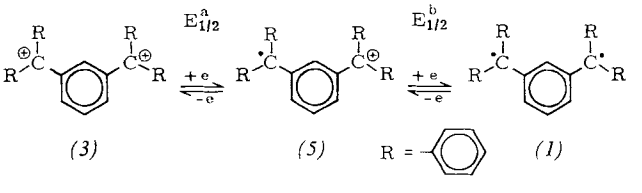
Schlenk's Biradical. — A Molecule in the Triplet Ground State

By *Gerd Kothe*, *Karl-Heinz Denkel*, and *Wolfgang Sümmermann*[*]

Molecules that by the MO approximation have two degenerate, singly occupied, highest one-electron orbitals in the energetically lowest state usually have a triplet ground state that is more stable by the Fermi correlation energy than the corresponding singlet. The HMO model provides criteria for the degeneracy of the one-electron levels. A distinction is made between degeneracy caused by symmetry and that caused by topology[1]. Molecules of the former type must possess a three-fold or higher symmetry axis which provides the possibility of transition by geometrical rearrangement into an energetically more stable singlet state of lower symmetry (Jahn-Teller effect). A triplet ground state has been confirmed experimentally for some symmetry-degenerate molecules[2–4].



Topologically degenerate molecules may have lower symmetry. For alternant aromatic hydrocarbons the HMO approximation provides a simple relation for determining the topological degeneracy[5]: according to this, the hydrocarbon *(1)* has two non-bonding HMOs which are occupied

by only two electrons in the ground state. Thus a triplet ground state is to be expected for *(1)* from predictions of the HMO theory.

On dehalogenating the dichloride *(2)* *Schlenk* and *Brauns* obtained a colorless product whose elemental analysis accorded with the molecular formula of *(1)*. Investigation showed *(1)* to be associated to a polymer[6]. ESR studies by *Reitz* and *Weissman* also indicated association of *(1)*[7].

We attempted to produce the monomeric compound *(1)* by polarographic reduction of *(3)* at a rotating platinum electrode.

The polarogram showed only a single broad reduction wave[8]. The limiting current of this wave corresponds to a two-electron transition. Coulombmetric measurements lead to the same result. By varying the rate of rotation of the disk electrode it was proved that the limiting current is diffusion-controlled. Thus pre-established equilibria do not influence the electrode reaction. The cyclic voltammogram at a stationary electrode shows cathodic and anodic peak currents of equal strength, proving that subsequent associ-

ation of *(1)* is slow and does not interfere with the electrode reaction. Logarithmic analysis of the broad reduction wave, by computer[9], demonstrated two one-electron transitions with similar half-wave potentials and equal limiting currents. The difference between the half-wave potentials $E^a_{1/2}$ and $E^b_{1/2}$ is 70 mV; this is a measure of the electrostatic repulsion energy of the two electrons in the highest occupied MO of *(1)*[10]. For the hydrocarbon *(4)*, the potential difference is 200 mV[8]. It becomes intelligible why these potential differences should not be identical if one assumes that *(1)* has a triplet ground state; *i.e.*, the electron correlation for the triplet state leads to a repulsion energy that is lower than that for the singlet.

ESR spectroscopic measurements were carried out with the object of detecting the triplet ground state of *(1)*. To avoid complete association of *(1)*, we dehalogenated a toluene solution of *(1)* for a short time with Ag powder, then filtered the solution, warmed it to 80 °C, and thereafter immediately cooled it to −180 °C. The ESR spectrum of the resulting glassy toluene solution showed, as well as an intense monoradical transition at 3250 G, several lines with $\Delta m = 1$ which are characteristic of a triplet molecule (Fig. 1). We assign the triplet spectrum to the monomeric hydrocarbon *(1)*. The zero-field splitting parameters determined from the lines with $\Delta m - 1$[11] have the following values: $|D| = 0.0079\ cm^{-1}$, $|E| \leqslant 0.0005\ cm^{-1}$. The resonance field strength of the extremely weak transition with $\Delta m = 2$ could not be measured.

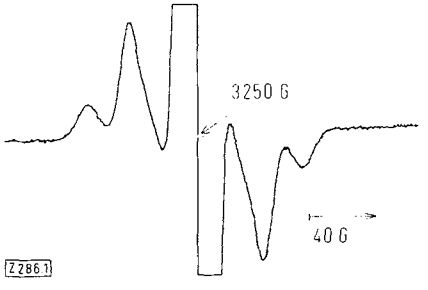


Fig. 1. ESR-Spectrum of *m*-phenylenebis(diphenylmethyl) *(1)* in glassy toluene at *ca.* −180 °C. Resonance field strength of the free electron $H_0 = 3251$ G.

We have determined the relation between the amplitudes of the transitions with $\Delta m = 1$ and temperature in the region 100–150 °K. If the effect of temperature T on signal amplitude I is interpreted as a result of a singlet-triplet equilibrium, the following relation applies[3]:

$$I = \frac{C}{T}\left(\frac{3e^{-\Delta E/RT}}{1 + 3e^{-\Delta E/RT}}\right)$$

where $\Delta E = E_{triplet} - E_{singlet}$ and C is a constant.

When $\Delta E = 0$, the relation simplifies to the Curie law, which is approximately followed for our measurements. We were unable to determine ΔE exactly from the divergences from the Curie law. Since the divergence from the equation of the simple Curie law must be appreciably smaller when $\Delta E < 0$ than when $\Delta E > 0$, our experimental findings indicate a triplet ground state for *(1)*.

To verify our results theoretically we have carried out SCF–CI calculations for *(1)* by the Pariser-Parr-Pople procedure[12–13]. The parameters used were gauged from the electron spectra of carbonium ions of the triphenylmethane series[14]. 41 singly excited configurations were introduced into the configuration interaction. The calculations were effected for a planar and for a twisted conformation of *(1)*, whose structure is related to that of the triphenylmethane carbonium ions. In each case the calculations gave a triplet ground state T_1 which is more stable than the singlet state S_0 by, respectively, 1.07 and 1.19 eV. The calculations thus confirm that *(1)* has a triplet ground state.

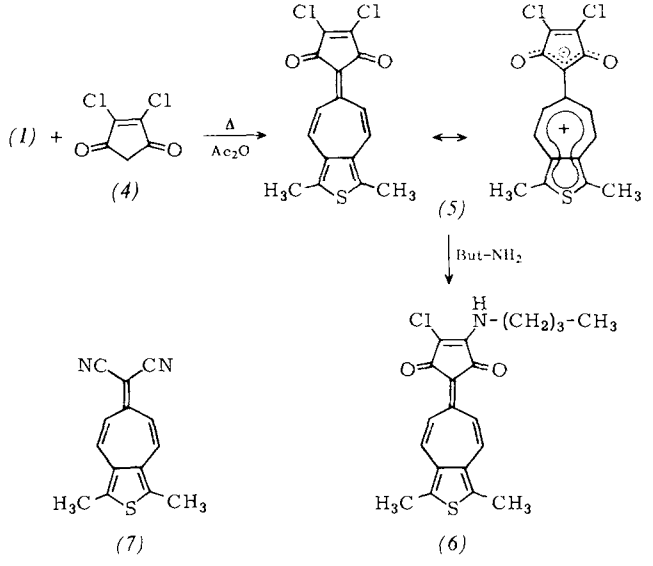
Condensation Reactions of 1,3-Dimethyl-6*H*-cyclohepta[*c*]thiophen-6-one[1,2]

By *Gunther Seitz* and *Heinrich Mönnighoff*[*]

By using the anhydride method[3] we have effected the first condensation reactions of compounds containing reactive methylene groups with 1,3-dimethyl-6*H*-cyclohepta[*c*]-thiophen-6-one *(1)*[4].

Heating *(1)* with 1,2,3,4-tetrachlorocyclopentadiene *(2)* in acetic anhydride gives the potentially dipolar 6π–10π system *(3a)*, m.p. >340 °C, in 35% yield as brownish-red crystals, and a similar reaction with pentamethyl 1,2,3,4,5-cyclopentadienepentacarboxylate[5] gives *(3)*,



(1) *(2)* *(3)*

(a), X = Cl
(b), X = CO_2CH_3

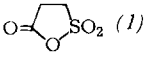
m.p. >340 °C, in 48% yield as permanganate-colored needles with a metallic sheen.

By the same method 4,5-dichlorocyclopentene-1,3-dione *(4)*[6] afforded the ocher-colored heterosesquifulvalene-quinone *(5)*, m.p. >305 °C (dec.) (43% yield), which we characterized by conversion by butylamine into the more soluble derivative *(6)*, m.p. 232 °C (dec.) (yield 76%).

Treating *(1)* with malonodinitrile led to the orange-yellow condensation product *(7)*, m.p. >330 °C (dec.), in 24% yield.

The new compounds were characterized by elemental analysis and spectroscopic properties. However, their low solubility prevented us from obtaining usable NMR spectra for *(3a)* and *(5)* even by the Cat procedure[7]. The NMR spectra of *(3a)* and *(7)* are characterized by an AB quartet (J = 12.5 Hz) for the four seven-membered ring protons, whose resonance positions were largely influenced by the anisotropic effects of the substituents, so that they yield no information on the polarity of the ground state. In *(6)* H-5 and H-7 are magnetically non-equivalent; they were recorded as a multiplet centered at 8.12 and 8.45 ppm, whereas the multiplet for H-4 and H-8 appeared at 7.03 ppm.

The IR spectra are characterized by an intense band in the region around 1610 cm^{-1} which is ascribed to a $\nu_{C=C}$ vibration.



The electron spectrum of *(3a)* is of the same shape as that of the iso-π-electronic 7-(tetrachlorocyclopentadienylidene)-7*H*-benzocycloheptene[8], whose longest-wave maximum is, however, shifted bathochromically by 20 nm. The positive solvatochromism established for all the compounds from the electron spectra indicates high occupancy of the apolar limiting formula in the ground state. This is confirmed by the position of the nitrile band in the IR spectrum of *(7)* at 2217 cm^{-1}, which is at 12 cm^{-1} shorter wavelength than it is for 8,8-dicyanoheptafulvene[9].

Separation of Compounds with Failure Sequences in the Solid-Phase Synthesis of Peptides by Means of the Anhydride of 3-Sulfopropionic Acid

By *Hans Wissmann* and *Rolf Geiger*[*]

The synthetic steps in the Merrifield solid-phase synthesis of peptides do not always afford homogeneous peptides in desirably high yields[1-3]. This leads to impurities and compounds with failure sequences that are often so similar to the desired end products that they cannot be separated from them by the available methods of purification. One way of overcoming this difficulty is to use an acylating agent to block the amino groups that escape reaction, a method that also facilitates removal of by-products. For this purpose *Wieland* and his co-workers[4] used 3-nitrophthalic anhydride. We use the cyclic anhydride of 3-sulfopropionic acid *(1)*[5], which reacts with the by-products to give N^{α}-(3-sulfopropionyl) derivatives that, owing to their high acidity, can be separated by simple filtration through a weakly basic ion-exchanger (acetate form). This treatment

(1)

with an ion-exchanger has usually to be undertaken in any case so as to afford the acetates from the peptides liberated from the carrier by HBr/trifluoroacetic acid; thus our purification does not require any additional experimental step.

If peptide bonds are also attacked under the conditions of acylation with *(1)*, the diacylamides can be cleaved by cautious aminolysis before the peptide is separated from the polymer. This would either regenerate the original peptide bond or, in the case of cleavage of the peptide chain, afford fragments that can be washed out or separated by means of the incorporated sulfo groups.

Experimental:

H-Cys(Bzl)-Tyr(Etoc)-Phe-Gln-Asn-Cys(Bzl)-Pro-Arg-(NO_2)-Gly-NH_2[6]: Boc-Gly polymer ester (10 g), prepared as described in ref.[1] with 0.36 mmole of Gly per g of resin, is deacylated and acylated with Boc-Arg(NO_2)-OH. The resin is then extracted with dimethylformamide (50-ml portions) by shaking four times, each for 3 min. During this period, *(1)* (4 g) is dissolved, with cooling, in anhydrous tetrahydrofuran (20 ml), and the cooled solution is added to the Boc-Arg(NO_2)-Gly polymer. *N*-Ethylmorpholine (7.5 ml) in dimethylformamide (15 ml) is then at once added and the whole is shaken for 1 hour at room temperature. The solvent is then filtered off and the solid is washed four times with ethanol (50-ml portions) and four times with glacial acetic acid (40-ml portions), after which the Boc group is removed by 1 N HCl in glacial acetic acid. The further amino acids are added by analogous procedures, the following derivatives being used: Boc-Pro-OH[7], Boc-Cys(Bzl)-OH[7], Nps-Asn(Mbh)-OH[8], Nps-Gln-(Mbh)-OH[8], Boc-Phe-OH[7], Boc-Tyr(Etoc)-OH[9]. — Yield: 14.9 g of peptide-polymer compound.

This compound (3.0 g) was treated with HBr/trifluoroacetic acid as described in ref.[1]. The crude peptide mixture was reprecipitated from ethanol by ether and then heated in trifluoroacetic acid/anisole (9:1) for 5 min for complete removal of the Mbh groups, and was finally precipitated by

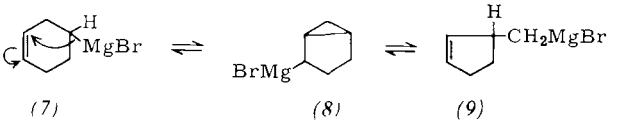
Ring Contraction on Rearrangement of 3-Cyclohexenyl Grignard Compounds [**]

By *Adalbert Maercker* and *Reinhart Geuss* [*]



Presence of cyclobutane derivatives has never been observed in the equilibrium mixtures resulting from rearrangement of homoallylic anions in contrast to rearrangements that occur by way of carbonium ions [1]. Even when a phenyl group was present in the 3-position relative to the metal, as in *(2)*, R = C_6H_5, the presence of *(1)* at equilibrium could be excluded [2]. Also, higher homologs of the 3-butenyl Grignard compound *(2)*, R = H, are in equilibrium only with the smaller of the possible cyclic compounds, *e.g.*, *(5)* only with *(6)* [3], although a reduction of about 20 kcal/mole in ring strain would be expected for *(4)*.

(1) *(2)* *(3)*

(4) *(5)* *(6)*

If a double bond is present in a six-membered ring *(7)*, the smaller and the larger ring must be formed simultaneously, while *(8)* arises during a rearrangement.

(7) *(8)* *(9)*

A solution of 3-cyclohexenylmagnesium bromide *(7)* in diethyl ether or tetrahydrofuran is stable for days at room temperature. If the solution is heated for some hours at 80 °C, 2-cyclopentenylmethylmagnesium bromide *(9)* is formed (its presence being proved by an α-proton doublet in the NMR spectrum on the far side of the TMS signal) and this must have been formed by way of the bicyclo[3.1.0]-hexane intermediate *(8)* although this could not be detected in the equilibrium mixture by NMR spectroscopy. An attempt to synthesize *(8)* by an independent route in diethyl ether led to a mixture of *(9)* and *(7)* in the proportion 5:1.

The equilibrium constant for the equilibrium *(7)*⇌*(9)* was determined by NMR spectroscopy and by carboxylation of the products. It is dependent on the concentration and on the solvent, being, *e.g.*, 8.08 ± 0.12 and 9.26 ± 0.11 for 1.3 M and 0.7 M solutions, respectively, in ether. Thence the energy difference ΔG between the two Grignard compounds can be calculated, showing that *(9)* is more stable than *(7)* by 1.46 or 1.55 kcal/mole, respectively, in spite of the greater ring strain in the former [4]. The driving force for ring contraction can be sought in the energy gain on conversion of the secondary into the primary carbanion.

This equilibrium *(7)*⇌*(9)* [5] thus enables the difference in stability between primary and secondary Grignard compounds to be estimated. Since the equilibrium constants between 80 and 120 °C were found to be independent of temperature, this difference in stability ought to be of the same order of magnitude as the difference in ring strain so that ΔH for the reaction becomes zero.

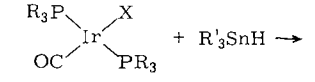
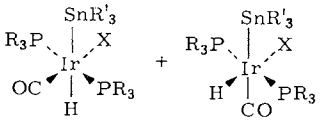
Binuclear Organometallic Compounds

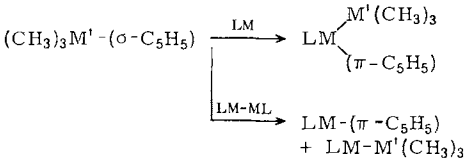
By *Michael F. Lappert* [*]



Binuclear organometallic compounds having bonds between a transition metal (M) and a Main Group metal (M') are conveniently synthesized by the amine elimination reaction. A better known synthesis is the salt elimination route.



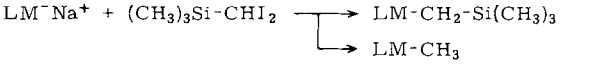
$$LM\text{-}H + L'M'\text{-}N(CH_3)_2 \rightarrow LM\text{-}M'L' + (CH_3)_2NH$$



The transition metals considered were, in the main, chromium, molybdenum, and tungsten; titanium, zirconium, hafnium; and, to a lesser extent, cobalt, rhodium, and platinum. The Main Group metals considered were silicon, germanium, and tin.

In some cases complications arise; an example of this is the situation wherein the hydride contains chlorine ligands, in which case dehydrochlorination can occur.

Examples of oxidative addition reactions for formation of M—M' bonds are provided by the following equations:



Physical properties of these complexes were examined, especially from the standpoint of the strength of the M'—M bond. In the compounds π-$C_5H_5M(CO)_3$—M'-$(CH_3)_3$, bond dissociation (mass spectral) energies increase along the series Cr < Mo < W and Si < Ge < Sn. Vibrational spectral (IR and Raman) data allowed identification of ν(M—M'). Regarding M—Si bonds, the uniquely long distance for Zr—Si in the compound $(\pi\text{-}C_5H_5)_2Zr(SiPh_3)Cl$ of 2.81 Å, which is at least 0.3 Å longer than other M—Si lengths, warrants particular attention. A possible interpretation is that in a d^0 complex π-bonding is not possible.

The compounds $LMCH_2Si(CH_3)_3$ are representatives of a novel series in which M and M' are not directly linked, but are bridged through a carbon atom. A particularly unexpected feature is that described by the reaction:

A deuterium labeling experiment using $(CH_3)_3SiCHDI$ led to the postulate that a transition metal carbene complex of the form $[LM{=}CH_2]^-$ occurs as an intermediate.

Catalyzed Reactions in Analytical Chemistry

By *Dieter Klockow* [*]

Kinetic methods of analysis employing catalyzed reactions can be said to be of great importance in modern trace analysis. Catalytically active substances can be detected in concentrations from a few ppm down to fractions of ppb, in some cases with marked selectivity (particularly in enzymatic reactions).

The methods used for determining catalyst concentrations from kinetic data can be divided into two main groups, *i.e.* into differential methods (differential form of the rate equation) and integral methods (integrated form of the rate equation). The former methods are limited to a relatively short period of a reaction in which the concentrations of the reactants, and thus also the reaction rate, remain practically constant.

A recently described determination of traces of molybdenum (0.01—0.2 ppm) may be regarded as a variant of these differential methods; the method involves use of a potentiostat [1] to follow quantitatively the course of the reaction

$$H_2O_2 + 2\,I^- + 2\,H^+ \rightarrow I_2 + 2\,H_2O$$

which is catalyzed by molybdenum. One of the reactants (hydrogen peroxide) is present in excess, and the other one (iodide) is added from an automatic burette to the reaction mixture at a rate sufficient to maintain a certain, defined electrochemical potential. The rate of addition from the burette is a measure of the reaction rate and thus also of the catalyst concentration.

The same technique has also been used to study the zirconium-catalyzed reaction between perborate and iodide. Under suitable conditions, fluoride has a strong inhibiting effect on this system and can consequently be determined in very low concentrations (0.4—4 ppb) [2].

Catalytic reactions have found an interesting new application as end-point indicators in volumetric analysis. If a catalyst K which accelerates the reaction between two substances A and B is stoichiometrically blocked by an inhibitor R, the end point of a titration of R with a solution of K in the presence of A and B as an indicator mixture can be recognized by the start of the reaction between A and B. As an example may be mentioned the titration of Ag^+ ions (R) with a standard solution of iodide (K) making use of the iodide-catalyzed reaction between Ce^{IV} and As^{III} (A and B).

Such titrations, in which a catalyst initiates a reaction at the end point, have been applied to precipitation titrations [3] and chelatometric determinations [3,4]. The start of the catalyzed reaction at the end point can be detected visually or instrumentally, *e.g.* potentiometrically [5] or thermo-

metrically[6,7]. Moreover, the substitution principle used in chelatometry can also be applied to these titrations[8]: The catalyst is added in an inactivated form as KR, together with A and B, to the sample solution to be titrated and is demasked by a titrant T when the end point is exceeded.

$$KR + T \rightarrow TR + K$$

The indicator reaction is thus initiated.

German version: Angew. Chem. *82*, 886 (1970)

All-Electron Calculations on Lithium Cyanide and Formamide

By *Børge Bak*[*]

All-electron calculations have been performed on lithium cyanide (LiCN), lithium isocyanide (LiNC), and formamide ($HCONH_2$). Linear combinations were carried out using atomic orbitals (LCAO) of the Gaussian-type. In referring to these, (*l*, *m*, *n*,) (*q*) means: *l* Gaussian functions (G.F.) of s-type symmetry (spherical), *m* G.F. of p-type ($\equiv m$ of p_x-, *m* of p_y-, and *m* of p_z-type), *n* G.F. of d-type symmetry for each "heavy" atom, and *q* G.F. of s-type for each hydrogen.

For LiCN and LiNC (7,3,0) and (11,7,0) basis sets were successively used. Since there are no vapor-phase data available for these species the calculated properties are true predictions of experimental results to be obtained.

Independent of the basis set the predicted dipole moments of LiCN and LiNC are, respectively, 3.7 "atomic units" (a.u.) (~9 D) and 3.4 a.u. For both species the predicted C≡N distance is 2.19 a.u. (1.15 Å). The predicted Li—C distance (in LiCN) is 3.63 a.u. (1.91 Å), the predicted Li—N distance (in LiNC) is 3.33 a.u. (1.75 Å). Gaseous LiNC is predicted to be 0.014 a.u. (10 kcal/mole) more stable than LiCN in the hypothetical vibrationless state. The vibrational zero-point energy difference is of the order 0.3 kcal/mole in favor of LiCN. The predicted normal vibration frequencies ν_3 (C≡N stretch), ν_2 (bending mode), and ν_1 are (for Li = ^{6}Li): 2375, 2367; not calculated, 250; 670, 785 cm^{-1} for LiCN and LiNC[1].

(11,7,0)(5) and (11,7,6)(5) basis sets were successively used for formamide[2] to reproduce experimentally the established properties (a)—(d):

(a) The amide hydrogens are slightly out-of-plane with coplanar HCON.

(b) The measured dipole moment is 3.6 Debye.

(c) The barrier to internal rotation about the C···N bond is 20 kcal/mole.

(d) The measured nitrogen quadrupole coupling constants χ_a,χ_b, and χ_c are 1.9, 1.7, and −3.6 MHz.

From qualitative valence theory we would expect that:

(e) the C···N bond must lose its "double bond character" when the NH_2 group is twisted 90° from its ground state position, showing up as a lengthening of the twisted bond. The (11,7,0)(5) set, reproduced (b)—(e) satisfactorily, but not (a). With the (11,7,6)(5) set, non-planar formamide was correctly found as being more stable than the planar by about 0.1 kcal/mole. The experimental value is 1 kcal/mole. The calculated dipole moment was 4.07 Debye, the calculated barrier to internal rotation 20.1 kcal/mole. The calculated χ_a, χ_b, and χ_c (assuming a nitrogen nuclear quadrupole moment of 1.60×10^{-26} cm^2) were 1.98, 1.94, and −3.92 MHz. The lengthening of the C···N bond upon 90° twist was 0.05 Å.

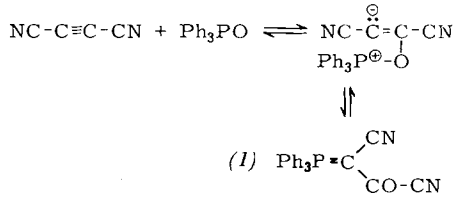
SELECTED ABSTRACTS

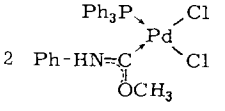


The synthesis of selenaheptathiocene, S_7Se, has been accomplished by *R. Cooper* and *J. V. Culka* by condensation of S_7Cl_2 with H_2Se. Separate solutions of both reactants were added very slowly to an anhydrous solution of diethyl ether cooled to 15 °C. After removal of part of the solvent by evaporation and subsequent cooling of the reaction mixture, yellow needles of S_7Se crystallized out. At higher temperatures this compound disproportionates to selenium-rich octatomic molecules, which could be readily detected by mass spectrometry; the mass spectrum shows very strong mass lines of S_8 and S_2. / J. Inorg. Nucl. Chem. *32*, 1857 (1970) / —Kr. [Rd 242 IE]

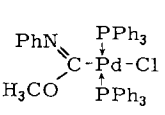
5-Tetrazolyl ylides have been investigated by *L. Huff, D. M. Forkey, D. W. Moore*, and *R. A. Henry*. Reaction of 5-dimethylaminotetrazole with benzyl chloride in aqueous ethanolic caustic soda leads to formation of the water-soluble ylide *(1)* (m.p. 205 °C, 29% yield) in addition to the expected 1- and 2-benzyl derivatives. The ethyl derivative can be obtained analogously. The structure was confirmed by NMR spectroscopy. A suspension of *(1)* in anhydrous ethanol can be kept for a period of weeks at room temperature; addition of methyl iodide leads to isomerization to the 2-benzyl derivative and to cleavage of the benzyl group. / J. Org. Chem. *35*, 2074 (1970) / —Kr. [Rd 245 IE]

(1)

Reverse Wittig reactions have been investigated by *E. Ciganek*. In the Wittig reaction a P—O bond is formed whereas in the reverse Wittig reaction it is cleaved. Thus, dicyanoacetylene and triphenylphosphine oxide react in

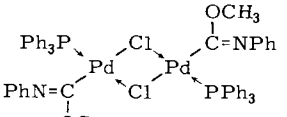


benzene at 160 °C to give the phosphorane *(1)* in 78% yield. On heating to 300 °C, compound *(1)* decomposes to the starting materials. Other acetylenes do not undergo



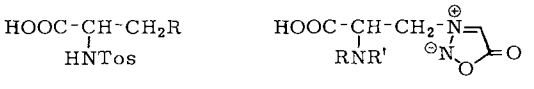
this reaction. Triphenylarsine oxide, however, also reacts *inter alia* with methyl propiolate, dimethyl acetylenedicarboxylate, and hexafluoro-2-butyne to give analogous compounds. / J. Org. Chem. *35*, 1725 (1970) / —Kr.

[Rd 246 IE]



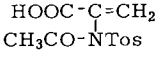
New compounds with palladium(II)-carbon σ-bonds can be obtained from carbene derivatives according to a report by *B. Crociani* and *T. Boschi*. Thus, the carbene derivative *(1)* reacts rapidly and almost quantitatively at room temperature with stoichiometric amounts of ethanolic potassium hydroxide; from the resulting red solution the brick-red compound *(2)* can be isolated in 92% yield. *(2)* dissolves

(1)



(3)

(2)

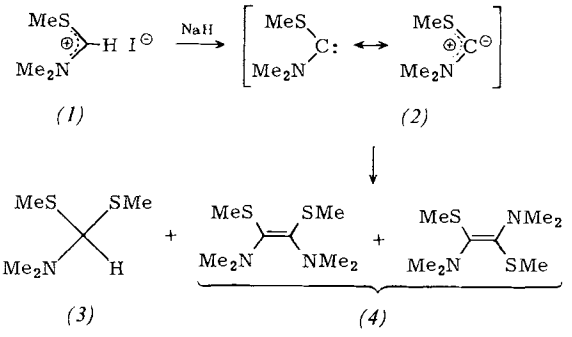


in 1,2-dichloroethane with partial dissociation and reacts with a stoichiometric amount of triphenylphosphine to give the complex *(3)* in quantitative yield. The reaction *(1)* →*(2)* is reversed on heating the reaction mixture under reflux with methanolic hydrochloric acid. / J. Organomet. Chem. *24*, C 1 (1970) / —Kr. [Rd 247 IE]

Fragmentation of a sydnone by elimination has been observed by *L. J. Fliedner jr.* and *I. Moyer Hunsberger*. Attempted preparation of the sydnone-substituted *(2a)* from *(1a)*, which was first converted in several steps into the *N*-nitroso-compound *(1b)*, yielded the acetyltosyl compound and/or

(1a), R = NH_2 *(2a)*, R = R' = H

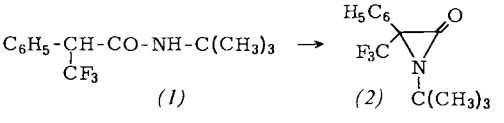
(1b), R = $N(NO)CH_2$-COOH *(2b)*, R = CH_3CO, R' = Tos



(3)

the fragmentation product *(3)*, depending upon the reaction conditions, instead of the expected *(2a)* during the final cyclodehydrogenation step with acetic anhydride. Compound *(3)* could also be prepared from *(2b)* by heating with acetic anhydride. The fate of the leaving group is still unknown. / J. Org. Chem. *35*, 2447 (1970) / —Ee.

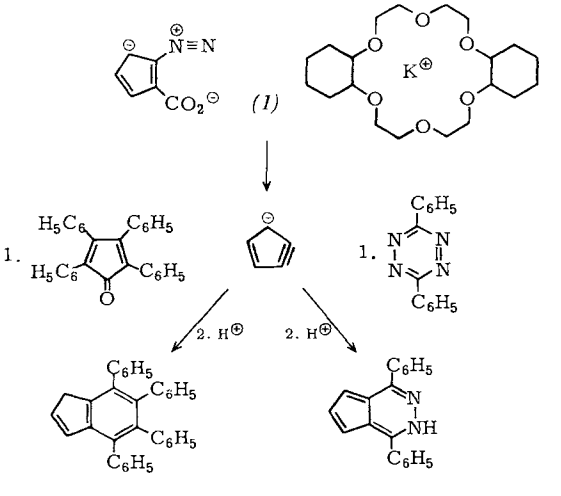
[Rd 249 IE]



α-Dimethylamino-α-methylthiocarbene *(2)* is formed, according to *T. Nakai* and *M. Okawara*, on deprotonation of *N,N*-dimethyl-*S*-methylthioformimidoyl iodide *(1)* with sodium hydride at 0—5 °C in THF and can be detected by the formation of the thioacetal *(3)* and the two isomeric olefins *(4)*. The isomerization of dimethyl maleate to di-

(1) *(2)* *(3)* *(4)*

methyl fumarate by a mixture of *(1)* and NaH is remarkable since neither component of the mixture is able to bring about such a reaction on its own. It was found that it was not the carbene but the product *(4)* that effects the isomerization. / Chem. Commun. *1970*, 907 / —Ee. [Rd 250 IE]



1-*tert*-Butyl-3-phenyl-3-[trifluoromethyl]aziridin-2-one *(2)*, an unusually stable trisubstituted α-lactam, has been investigated by *E. R. Talaty* and *C. M. Utermoehlen*. 3,3,3-Trifluoro-2-phenylpropionic acid was first converted into the amide *(1)*, which was subsequently transformed, by ring closure, to *(2)* by treatment with *tert*-butyl hypochlorite

(1) *(2)*

and potassium *tert*-butoxide. Compound *(2)* is sufficiently stable to survive purification procedures such as heating in high vacuum (<0.05 torr) at bath temperatures of 105 to 120 °C. Small amounts of *(2)* remain undecomposed even after 24 hours' refluxing in anhydrous methanol; decomposition at 90 °C is complete within 3.5 hours. / Tetrahedron Lett. *1970*, 3321 / —Kr. [Rd 253 IE]

The dehydrocyclopentadienyl anion, a new aryne, has been prepared by *J. C. Martin* and *D. R. Block* by pyrolysis of the complex *(1)*. Capture of such an anion is best achieved

by compounds which undergo a Diels-Alder reaction (1,4-cycloaddition) with the expected anion. Almost equivalent amounts of N_2 and CO_2 were transformed in the pyrolysis. / 160th Nat. Meeting of the Amer. Chem. Soc. 1970, Abstracts ORGN 26 / —Ma. [Rd 257 IE]

Cyclopentadienyl[trifluoromethyl]stannane has been used by *E. W. Abel, S. A. Keppie, M. F. Lappert,* and *S. Moorhouse* for the oxidative cleavage of the metal-metal bond in bi- or multinuclear carbonylmetal complexes. Such a cleavage is accomplished by heating the components under reflux in the absence of air, *i.e.* under nitrogen. Reaction proceeds almost quantitatively, but decomposition of the products sometimes takes place during attempts at their isolation. For example:

$$Mn_2(CO)_{10} + (CH_3)_3SnC_5H_5 \rightarrow \pi\text{-}C_5H_5Mn(CO)_3\ (54\%) + (CH_3)_3Sn\text{–}Mn(CO)_5\ (58\%)$$

$$[\pi\text{-}C_5H_5(CO)_2Fe]_2 + (CH_3)_3SnC_5H_5 \rightarrow (\pi\text{-}C_5H_5)_2Fe\ (33\%) + \pi\text{-}C_5H_5(CO)_2Fe\text{–}Sn(CH_3)_3\ (38\%)$$

/ J. Organomet. Chem. *22*, C 31 (1970) / —Kr.

BOOK REVIEWS

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry), 8th fully revised edition. Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH., Weinheim/Bergstr. [*].

System No. 6: Chlorine. Supplementary Volume. Part B, 2. Conclusion of the Compounds. Detection and Determination. Principal editor: *Hans Karl Kugler*. 1969. iv, xix, 308 pp., 40 figures, linen DM 376.

The present supplementary volume describes the compounds of chlorine with oxygen, nitrogen, and fluorine. The literature has been fully evaluated up to the end of 1966 and largely taken into account up to 1968. This volume concludes the monograph on the element chlorine. However, it can also be used independently of the earlier parts where the material of interest falls within the field covered. A completely updated collective work on the subject is of great value, since intensive investigations have been focused on the compounds of chlorine with oxygen, nitrogen, and fluorine over the past ten years in the search for strong oxidizing agents for rocket fuels.

Of the chlorine-oxygen compounds, which have only recently become known, we shall mention only Cl_2O_3. Advanced techniques are now allowing increasingly detailed studies on unstable radicals, such as ClClO, ClO, ClOO, and ClO_4. 106 pages are devoted to the oxo acids of chlorine, though there is nothing fundamentally new to be mentioned in this field. The same is true of a series of long-known chlorine-nitrogen compounds such as NCl_3 or nitrosyl and nitryl chlorides. On the other hand, there have been many new observations in connection with the corresponding perchlorates and with dichlorofluoramine NCl_2F and chlorodifluoramine $NClF_2$ (p. 588: printing error in the heading).

Among the brand-new compounds in the chapter on chlorine and fluorine, mention should be made of ClF_5, which can be obtained from the elements by heating if a large excess of fluorine is used, and of the difluorochlorates(I) and tetrafluorochlorates(III).

A number of new members have also been added to the class of chlorine-oxygen-fluorine compounds. The compounds ClOF, ClO_2F, $(ClO_2F_3)_n$, ClO_3F, and ClO_4F are now known.

A final chapter presents a survey of the methods for the detection and determination of chlorine and its compounds as well as of the isotopes of chlorine.

System No. 47: Lead. Part C, 1: Technical Production of Lead, Compounds of Lead (Lead and Inert Gases, Hydrogen, Oxygen, Nitrogen, Fluorine, Chlorine). Principal editor: *G. Hantke*. 1969, iv, xxii, 346 pp., 69 figures, linen DM 421.—.

Part C, 1 first describes the metallurgy of lead in 46 pages. A brief survey of the raw materials is followed by the description of the dry and wet metallurgical processes for the treatment of lead ores. The section on roast-reduction, which is the method most widely used today, is particularly thorough and detailed. Access to monographs and articles in collective works on the metallurgy of lead is provided by a bibliography at the beginning of the chapter.

Most of the volume (300 pages) is devoted to the compounds of lead with the elements mentioned above. While the lead-inert gas and lead-hydrogen systems cover only a few pages, the lead-oxygen system takes up more than 150 pages. The compounds of lead with oxygen include a series of products that are widely used in industry, such as litharge PbO, red lead Pb_3O_4, and PbO_2. Just as for all other compounds, their chemical and physical behavior is discussed in detail. However, practical examples of the preparation processes, standards, and purity tests are also given. Among the lead-nitrogen compounds, the greatest space is devoted to the chemistry of the nitrite and nitrate compounds, which form many basic salts. The basic salts (though often not well characterized) also help, together with the complex compounds, to increase the number of substances in the case of the chlorine compounds.

System No. 47: Lead. Part C, 2: Lead and Bromine, Iodine, Sulfur, Selenium, Tellurium, Polonium, Boron, Carbon. Principal editor: *G. Hantke*. 1969. iv, xxii, 460 pp., 115 figures, linen DM 555.—.

Part C, 2 continues the description of the lead halides with the bromine and iodine compounds. The mere size of this section (65 pp.) shows the multiplicity of the compounds, as well as the importance that is now assigned to this class of compounds. Many of the works cited originated in the last two decades, and the considerable proportion of Russian references is particularly striking. The careful search of the Russian literature, which is only inadequately represented in most libraries either in the original or in translations, deserves special praise, since this allows access to the articles of interest.

The next 194 pages are devoted to the lead-sulfur system, and within this system to the compound PbS. The lead-selenium and lead-tellurium systems are also discussed in surprising detail; as in the case of the lead-sulfur system, it is the electrical properties in particular that are dealt with thoroughly in the literature and that are of great importance in the electrical industry. The chemist will probably be more interested in the remainder of the volume, apart from the lead-polonium and lead-boron systems. The former covers only half a page, while the latter is dominated by the chemistry of boric acid rather than by that of lead. However, the section on the lead-carbon system is very interesting, and deals not only with lead carbonate but also with the many lead salts of organic acids such as hydrocyanic, cyanic, thiocyanic, formic, acetic, oxalic, and citric acids. Finally, it should be mentioned that measurement data that are of little importance to the result could have been omitted in many places (*e.g.* the measuring frequency for NMR spectra, p. 691).

System No. 63: Ruthenium. Supplementary volume. Principal editor: *E. Schleitze-Steinkopf*. 1970. vi, xviii, 586 pp., 86 figures, linen DM 689.—.

The present volume supplements the first volume on the ruthenium system, which was first published in 1938. In this

[*] Cf. Angew. Chem. internat. Edit. *6*, 100 (1967).

volume one finds many differences from the earlier conception of Gmelin's Handbook. The most important, in the reviewer's opinion, appears to be the successful abandonment of the historical but long outdated division into an inorganic and an organic section. A considerable part of the book is devoted to the organoruthenium compounds. If the same procedure is followed in future volumes, the value of "Gmelin" to the chemist will be greatly enhanced. Even a quick glance through the present volume gives the impression that it is a *chemical* reference book, and not merely a collection of physical constants, as many of the earlier volumes seemed to be.

Another innovation is the abandonment of the earlier, often excessively rigid arrangement in favor of a chemically more logical classification. Salts of complex acids of ruthenium are now dealt with under the various nonmetals. $LiRuF_6$, for example, is to be found in the section on "Ruthenium and Fluorine".

Finally, a very welcome change is that the present volume almost attains the currency of progress reports. The literature is completely evaluated up to the end of 1968, and many important publications from 1969 are also taken into account.

The first two main sections of the volume deal with the properties of the element and its alloys. Ruthenium, which was of no special importance in industry a relatively short time ago, has rapidly grown in importance during the past few years. It is an efficient catalyst in many hydrogenation reactions, and the nuclear chemist is concerned with its isotopes as fission products of uranium and plutonium, while some of its alloys have superconducting properties.

The third main section describes the compounds of ruthenium. Considerable space is devoted to the discussion of the very numerous nitrosyl compounds. This is followed by a description of the compounds with neutral and inner complex forming ligands, the carbonyl compounds, and the organometallic compounds of ruthenium.

A further innovation is found at the end of the volume in the form of an alphabetic subject index and a formula index for the ligands, which make it much easier to find groups of compounds and individual compounds.

Ekkehard Fluck [NB 894 IE]

Zahlentafeln zur Massenspektrometrie und Elementaranalyse (Numerical Tables for Mass Spectrometry and Elemental Analysis). By *G. Ege*. Verlag Chemie, Weinheim/Bergstr. 1970. 1st Edit., xxvi, 352 pp., 356 tables.

The determination of empirical formulas from elemental analyses is made much easier with *Ege*'s "Zahlentafeln zur Elementaranalyse" (Numerical Tables for Elemental Analysis). However, if an analysis is not exact, several possible formulas have to be considered; for example, the C and H analytical values of homologs are often situated so close together that it is impossible to decide in favor of one or the other compound. In such cases it is possible to reach a decision on the basis of the molecular weight, which can be determined mass-spectrometrically.

Acknowledging this fact, *Ege* has now expanded his original Tables into their present form.

To keep the volume of the material within reasonable limits the tables are restricted to carbon compounds with not more than 40 carbon, 6 nitrogen, 12 oxygen, and an appropriate number of hydrogen atoms. On the whole this should prove adequate. The numerical tables encompass compounds with molecular weights from 16 to 845 arranged according to increasing mass.

The idea of grouping the theoretical analytical values into groups of ten is commendable, since it greatly facilitates rapid location of the empirical formulas.

In addition, one column gives the exact molecular weight of each compound, so that the tables can also be used to determine empirical formulas with the aid of high-resolution mass spectra. In such cases elemental analysis becomes superfluous. Data on double bond equivalents constitute another welcome feature.

In contrast, the data on the intensity ratio of M^+ and $(M + 1)^+$ peaks could well have been omitted, since in practice the intensity ratios of M^+ and $(M + 1)^+$ ions obtainable from spectra are too inaccurate, at any rate in the case of compounds of higher molecular weight, to enable useful conclusions to be drawn.

Nevertheless, this point in no way detracts from the value of the tables, which can be warmly recommended to all laboratories engaged on the investigation of organic compounds.

Gerhard Spiteller [NB 910 IE]

Rechenseminar in physikalischer Chemie. (Problems in Physical Chemistry). By *K. Torkar*. Friedr. Vieweg u. Sohn, Braunschweig 1968. 1st Edit., xii, 172 pp., 48 figures, 38 tables, bound DM 9.80.

There are a considerable number of books dealing with physicochemical calculations. These generally list the laws of physical chemistry in a logical order and make use of them as a basis for examples of simple calculations. *K. Torkar* follows an entirely different plan. He confines his book to four problems:

1. Calculation of the pressure relations in an autoclave. 2. Calculation of a chemical equilibrium. 3. Boiling diagrams. 4. Chemical reaction kinetics.

Under these headings he deals with 1) the formation of boehmite in an autoclave or an automobile CO_2 fire extinguisher, 2) the reduction of chromium oxide by graphite or the conversion of carbon monoxide with steam, 3) the benzene-toluene system or the A-B system in general, and 4) reactions of the types $A \rightarrow$ products, $aA + bB \rightarrow$ products, or $H_2 + Br_2 \rightarrow 2\,HBr$.

The author thus starts with concrete problems from practice and explains the calculation procedure for the examples named in the smallest detail. He compares the various calculation methods, indicates where the necessary numerical values are to be found, and compares the data from different tabulated values. The clarity of presentation is improved by tables and graphs.

This book offers the student a bridge between formula and application, and should encourage the teacher to hold similar problem seminars.

Gerd Wedler [NB 898 IE]

Practical Manual of Gas Chromatography. Ed. by *J. Tranchant*. Elsevier Publishing Company, Amsterdam-London-New York 1969. 1st Edit., xix, 387 pp., numerous illustrations, bound, Dfl. 85.—. English translation of the second French edition.

When a book on chromatography is translated from the French into English and joins the long ranks of works already published in English in this field, it is only natural to wonder whether the translation was simply motivated by the existence of the wider readership, or whether this readership may itself derive some benefit. The far-reaching and most welcome exclusion of theoretical ballast — an intention already proclaimed by the title — as well as the typically Gallic conciseness and precision of the presentation add up to a positive reply to the latter question. The content of the book and its points of emphasis can be conveniently indicated by enumerating the titles and numbers of pages of the nine chapters contributed by six authors: 1. Principles and retention values (11 pp.); 2. Isothermal-isobaric chromatography (15 pp.); 3. Programmed chromatography (18 pp.); 4. Apparatus (37 pp.); 5. Columns (73 pp.); 6. Detectors (40 pp.); 7. Qualitative analysis; separation and identification (39

pp.); 8. Quantitative analysis (32 pp.); 9. Applications and techniques (92 pp.). The emphasis of the book is quite clearly on practical aspects. Nevertheless, all the important equations derived from theory are included in the most concise possible form. It would be wrong to regard this merely as a dutiful exercise in theory, since important practical conclusions are almost invariably derived from the relationships. The two chapters on columns and applications merit special mention. Containing 263 and 809 literature references respectively, they not only provide an excellent survey but represent well-balanced and self-contained treatises containing all the essential details.

Happily, there is none of the overlapping all too often observed in multi-author volumes. All the authors use the same symbols which are collected together in a single list. It is unfortunate that out-of-date statements, now recognized as incorrect, are made in the discussion of the van Deemter equation on p. 23, in connection with mass transport in the mobile and the stationary phase. This is evidently due to the fact that the author of this chapter has relied on a (cited) paper whose experimental conditions were inappropriate to the theoretical conclusions based upon them. In its nine chapters the book presents all the essential points of gas chromatography. It is particularly suitable for all those who are daily confronted by analytical and experimental problems of gas chromatography, and can be recommended as a really excellent work.

G. Deininger [NB 909 IE]

Methods in Free-Radical Chemistry. Edited by *E. S. Huyser*. Marcel Dekker Inc., New York 1969, 1st Edit., Vol. 1: 208 pp., numerous illustrations, bound $11.75. Vol. 2: xi, 242 pp., numerous illustrations, bound $12.75.

Since the publication of *C. Walling*'s book "Free Radicals in Solution" in 1957, such extensive progress has been made in this branch of chemistry that it would no longer be possible for a single author to present a comprehensive treatment. As in other fields, therefore, monographs in free-radical chemistry are being replaced by progress reports covering a limited area. The present new series can consequently claim a place of special importance alongside "Advances in Free-Radical Chemistry" [1]. A wide selection of the results of work carried out in free-radical chemistry over the past twelve years is discussed in a total of five sections by young authors working in this field.

The first two chapters (Free Radical Study by Electron Paramagnetic Resonance by *L. Kevan*, 35 pp.; Free Radical and Photochemical Reactions by *D. C. Neckers*, 44 pp.) are dominated by the discussion of the methods and their theoretical principles on the basis of selected results. Their value lies in the concise and lucid survey and in the references to the original literature. The sections "Free-Radical Chlorinations" (*M. L. Poutsma*, 114 pp.), "Free Radical Brominations" (*W. A. Thaler*, 106 pp.), and "Thiyl Radicals" (*R. M. Kellog*, 120 pp.), on the other hand, deal systematically from the preparative and mechanistic standpoints with free-radical substitutions and additions of free radicals. The important relations between structure and reactivity are clearly recognizable from the numerous tables and diagrams. These chapters undoubtedly constitute the more valuable part of the present work, since the literature, which would now be very difficult to scan, is reviewed critically and comprehensively up to the latest position.

In presentation and quality, the two volumes may be regarded as supplements to *Walling*'s classic work. They should therefore find a place in every library and are especially recommended to all those who are interested in free-radical chemistry.

Ch. Rüchardt [NB 902 IE]

[1] Cf. Angew. Chem. internat. Edit. *6*, 475 (1967).

Laser Raman Spectroscopy. By *T. R. Gilson* and *P. J. Hendra*. Wiley-Interscience, Division of J. Wiley and Sons, New York 1970. 1st Edit., ix, 266 pp., numerous illustrations, bound, 90s.

Although laser light sources have considerably simplified the techniques of Raman spectroscopy, the term "laser Raman spectroscopy" is no more appropriate than "Nernst-lamp infrared spectroscopy". This is one of the faults of the present book, which is meant to be "an introduction to Raman spectroscopy with particular emphasis on the developments resulting from the use of laser sources". It is divided into the following sections: 1. Introduction (20 pp.), 2. Experimental (40 pp.), 3. Raman Intensity and Depolarization Ratios (23 pp.), 4. Single-crystal Raman Spectroscopy (58 pp.), 5. Raman Spectra of Gases (11 pp.), 6. Powders, Liquids and Solutions (13 pp.), 7. Polymers (17 pp.), 8. Miscellaneous Raman Experiments (15 pp.), 9. Sources of Information (3 pp.). There are two appendices, one devoted to lasers (I, 6 pp.) and the other to "Results from Group Theory" (II, 47 pp.).

The first four chapters are instructive and useful. The beginner, however, would profit more from Chapter 4 and Appendix II if examples had been treated in detail and knowledge of the original work had not been presupposed, as is the case on pp. 109—123. The later chapters show evidence of unquelled enthusiasm over laser light sources ("Laser has revolutionized the study" (of polymers) p. 166). One learns a great deal about the successful recording of individual spectra but not enough about how useful this is. An unexperienced reader would doubtless get the impression that Raman spectroscopy was a very new method and that a large store of experience in the field of "mercury-lamp Raman spectroscopy", as collated for example in the books of *Kohlrausch*, *Herzberg*, and *Siebert*, did not exist. The book is also disappointing for the organic chemist. Only one page (155) is given to structural determination and there are only nine lines (p. 165), without references, on his main concern, the detection of compounds whose vibrations in the infrared are too weak. The reader is told nothing of the important problem of appropriate sample preparation and the dependence of intensity on the grain size in powders. Chapter 9 makes no mention either of the very useful DMS Reference Service "IR Raman Microwaves" which has been operating since 1963, or of the spectra collections of the API and in Landolt-Börnstein. Printing errors are rare. The book would be more useful for beginners and for specialists if the last chapters in particular were thoroughly revised.

Bernhard Schrader [NB 913 IE]

The Halides of the Lanthanides and Actinides. By *D. Brown*. John Wiley and Sons Ltd., London-New York-Sydney-Tokyo-Mexico City. 1968. 1st Edit., x, 280 pp., numerous illustrations, bound, *ca.* DM 43.—.

Until recently only two review papers have been available on the halides of the f transition elements, namely one on the lanthanoid halides [1][*] and one on the actinoid halides [2][*]. *D. Brown*, who is himself an authority in the field of the actinoid and lanthanoid halides, has now attempted to present a comparative description of the halides of all the f transition elements. This attempt may be regarded as highly successful. One's only regret is that the halides of the transcurium elements were discovered too recently to be included in this book.

[1] *R. E. Thoma*, ORNL-3804 (May 1965); Progr. Sci. Technol. Rare Earths 2, 90 (1966).

[2] *J. J. Katz* and *I. Sheft*, Advan. Inorg. Chem. Radiochem. *2*, 195 (1960).

[*] According to the IUPAC Commission on the Nomenclature of Inorganic Chemistry the names lanthanoids and actinoids should be used for elements 57–71 and 89–103 respectively; cf. C.R. XXIII IUPAC Conference, Paris 1965, p. 183.

The author begins with an introduction, in which he deals first with general properties such as electronic structure of the elements and oxidation states; the known halides and oxide-halides of the lanthanoids and actinoids are grouped together in four synoptic tables. A survey of ionic radii is followed by a brief summary of the most important nuclear properties of the actinoid nuclides suitable for preparative work, and a section — unfortunately rather short — on the micropreparative methods, particularly important with regard to the actinoid halides. The four chapters that follow are concerned with the compounds of the f elements with fluorine, chlorine, bromine, and iodine. Each of these chapters is subdivided strictly according to oxidation states in the sequence M^{6+}, M^{5+}, M^{4+}, M^{3+}, and M^{2+}. Each section dealing with an oxidation state is in turn further divided into subsections on "halides", "complex halides", "oxide halides", and "complex oxide halides", as the case may be. This very clear arrangement of the subject matter makes it possible to locate any given compound very rapidly.

The text is kept as brief as possible by confining it to chemical properties and methods of preparation. Numerical data, such as lattice constants, IR frequencies, vapor pressure parameters, and other physical data are conveniently offered in tabulated form. Data that would have been difficult to fit into the selected framework are collected separately at the back, so that we have thermodynamic data in Appendix A, certain IR data in Appendix B, and data on mixed halides of uranium and protactinium in Appendix C. The frequently highly complicated crystal structures of the halides and oxide-halides are explained with the aid of readily understandable illustrations.

A comprehensive list of references (numbered consecutively) is given at the end of each chapter, the total amounting to almost 1300. However, it is a pity that one finds so many printing errors in this material. Despite this shortcoming, which can in any event be eliminated in the next edition, the work can be highly recommended. It provides a veritable gold mine both for those working in the field of lanthanoid and actinoid halide chemistry, and for students with more general interests. The wealth of information stored in this book is such that it will enable practically any query relating to the halides of the f elements to be swiftly and reliably answered. This invaluable book is recommended without reservation, and no chemical library should be without it.

VOLUME 9 · NUMBER 12
DECEMBER 1970
PAGES 917–988

Volatile Flavoring Substances in Foodstuffs

By Hans Gerhard Maier [*]

The odor of most foods is produced by mixtures of many volatile flavoring substances. Over the past century, numerous food flavors have been analyzed in sufficient detail to allow a survey of the classes of substances responsible, the formation of individual flavoring substances, and their fixation in the foods. In addition to special biosynthetic pathways, the breakdown of fats and the Maillard reaction have been found to be particularly important to the formation of flavoring substances.

1. Introduction

Flavoring substances are important components of most foodstuffs. Without them, the foods are rejected even by hungry subjects, or if they are eaten, they are not digested so well [1]. The term "flavoring substances" refers here to the chemically definite compounds that cause the flavor of foodstuffs. "Flavor" is used in two senses, one of which is an overall impression left behind in the nose and tongue by odor-producing and taste-producing substances; the second meaning is a mixture or preparation of flavoring substances. The expression "essential oil", which is occasionally used instead of "flavor", should be reserved for the flavors from spices and expressly odoriferous plants [2]. The oils from the flavedo of citrus fruits occupy an intermediate position in this connection. The essential oils will not be considered in this article (but cf. [3]). The flavor of tobacco smoke is also largely disregarded (but cf. [4]).

It is difficult to distinguish between volatile flavoring substances and other volatile components of foodstuffs. Only a few volatile substances (*e.g.* N_2, O_2, inert gases) evoke no sensation of smell at all; the rest differ widely in the intensity of their odor. Some examples are shown in Table 1. The "threshold value" (limiting concentration) given in the table is the lowest concentration of the substance at which its presence is recognized in comparison with a blank test. It is not normally possible at this concentration to determine the nature of the odor. The values vary with the medium, as is shown in Table 2 by the results of the taste tests, in which the flavoring substances are also sensed by the nose. The threshold values are influenced by other flavoring substances [7,8]; for example, the odors of two flavoring substances may cancel each other out in suitable

Table 1. Odor threshold values of some volatile flavoring substances from foodstuffs in air (averages for several test subjects) [5, 6].

Flavoring substance	Threshold value (mg/l)
Methanol	8×10^{0}
Methyl salicylate	1×10^{-1}
Amyl acetate	4×10^{-2}
Safrole	5×10^{-3}
Hydrogen sulfide	2×10^{-4}
Coumarin	2×10^{-5}
Citral	3×10^{-6}
Ethanethiol	7×10^{-7}

Dimethyl sulfide	—	0.009	0.919	0.17

mixing ratios[9], or the odor of stronger-smelling components may be altered by components having only a very weak odor or none at all.

For these reasons, the classification of volatile substances as scented or odorless is more or less arbitrary[10]. All volatile substances, with the exception of the odorless "permanent gases" and water, should therefore be regarded as flavoring substances. However, flavoring substances that are either present in the foodstuffs in relatively high concentrations or have a very strong odor so that they can be effective even in low concentrations are particularly interesting.

Most foodstuff flavors consist of many flavoring substances, none of which is alone typical of the aroma in question – spices, of course, are an exception. The total content of flavoring substances in foods is roughly between 1 and about 1000 mg/kg (*e.g.* 10–100 mg/kg in fruit[12]). We know relatively little at present about the contents of individual flavoring substances; they may be assumed to range from <0.001 to 100 mg/kg. This is not so of spices, in which the quantities are greater (*e.g.* up to 29 g of vanillin per kg in vanilla pods).

Since flavoring substances are normally present only in small quantities, it is only during the last two decades that it has become possible to determine the complicated compositions of most flavors by the use of chromatographic methods, and particularly by combination of gas chromatography with mass spectrometry, IR spectroscopy, and thin layer chromatography. It was formerly thought in many cases that only a few flavoring substances were typical of a given foodstuff. The development of research on flavoring substances is illustrated in Figure 1, which shows a plot of the number of flavoring substances identified in roasted coffee since the 1920's. The total is now 370 substances, and approximately as many more have been isolated but have not yet been identified, so that it is estimated that 600–700 components must be present in all. Though the components that have not yet been identified are present in lower concentrations than the others, it may be assumed that these trace components also contribute to the flavor,

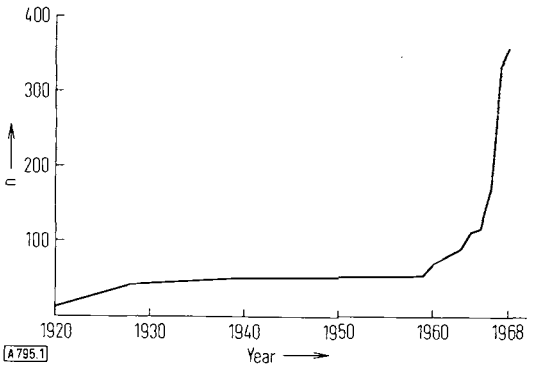

Fig. 1. Number *n* of flavoring substances identified in roasted coffee during the last few decades.

since no satisfactory coffee flavor has yet been produced by mixing the flavoring components that are already known.

Examples of the classes of substances from which some foodstuff flavors are built up are shown in Table 3. The qualitative composition tells us nothing about the importance of individual flavoring substances in determining the odor. This importance can only be roughly estimated if the threshold values of the various flavoring substances are known. Table 4 shows the percentage contributions of some steam-volatile components of carrots to the odor, as calculated from the contents and the threshold values of the substances[13]. According to these calculations the terpenes, which are present in relatively large

2-Decenal	0.04	0.3	0.8

quantities, contribute little, whereas the aldehydes, which are present in small quantities, make a very large contribution to the flavor. These results must be regarded with caution, since synergism or antagonism may occur. This is also true of the results in Table 5, in which some foods are listed together with characteristic flavoring substances. The list is intended only as an indication; examples are known in which a flavoring substance that smells similar to the entire aroma is present, but does not determine the

Table 5. Particularly characteristic flavoring substances in some foodstuffs.

Foodstuff	Flavoring substance	Ref.

aroma, since its concentration is too low; the mixture of all the other flavoring substances just happens to have a smell similar to that of the one flavoring substance in question. This is true *e.g.* of α-furylmethanethiol in coffee. Characteristic flavoring substances of this type may, however, be suitable for artificial flavoring.

2. General Formation Pathways

The groups of flavoring substances found in foodstuffs are discussed in Section 3, where they are arranged according to the class of substance, and where their formation is also described when possible. First, however, we shall outline some pathways by which various types of flavoring substances may be formed. Botanically closely related species often contain similar flavoring substances [34,35].

The flavoring substances present in living material are biosynthesized by widely differing routes [2,32,33]. Microbial, enzymatic, oxidative, and thermal changes occur on injury or death, as well as during the storage and processing of the plants. The degradation of *fats* plays a special part in these changes. In particular, the autoxidation of unsaturated fatty acids by a free-radical reaction mechanism leads *via* hydroperoxides to saturated and unsaturated aldehydes, alcohols, ketones, and lower fatty acids, which act as flavoring substances [41,43]. Lipoxygenases and alcohol dehydrogenases cause the formation of aldehydes and alcohols from unsaturated fatty acids [44–46]. Heating also results in the formation (favored by metal catalysis) of aldehydes, ketones, lactones, and lower fatty acids from saturated fatty acids [47,48].

Carbohydrates are important precursors of flavoring substances in heated foodstuffs. Pyrolysis of carbohydrates alone (known as caramelization in the case of sugars) results in the formation of many flavoring substances above 300 °C, among which furan derivatives, ketones, and aromatic hydrocarbons are particularly prominent [49,50]. Carbohydrates react with *amino acids* even at much lower temperatures, and occasionally even at room temperature. This complex of reactions, which is known as the Maillard reaction, leads to the formation of brown pigments and of flavoring substances that are characteristic of heated (and frequently also of stored) foodstuffs, and particularly of cooking and roasting flavors. The principal pathways by which flavoring substances can be formed in the Maillard reaction are summarized in Figure 2 [51–58].

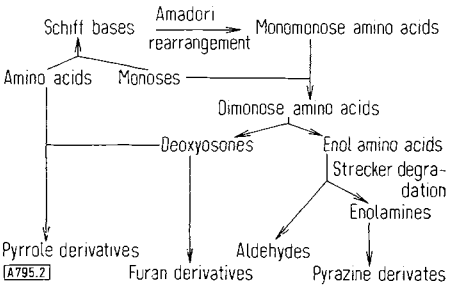

Figure 2. Principal pathways proposed for the formation of flavoring substances in the course of the Maillard reaction.

3. The Principal Flavoring Substances

3.1. Aliphatic and Alicyclic Compounds

Aliphatic hydrocarbons normally have very weak odors, and are therefore of practically no importance to the flavors of foodstuffs. They are present in small quantities in fruits [2] (*e.g.* ethylene and ethane in apples [59]). They are formed in rather greater quantities on heating of fats [60,61] and on storage of dehydrated potatoes [62]. The most important compounds in this class are probably the terpene hydrocarbons; these are the principal constituents of the essential oils of citrus fruits, where they are partly formed from linalool [63]. They are also present in large numbers in black currants [2]. The terpene hydrocarbons in roasted coffee are presumably formed by pyrolysis of the lipids (cafestol, kahweol, squalene) [64]. The terpene hydrocarbons present in hops (mainly myrcene, caryophyllene, and humulene) are not carried over into beer [65]. Nor do the terpenes

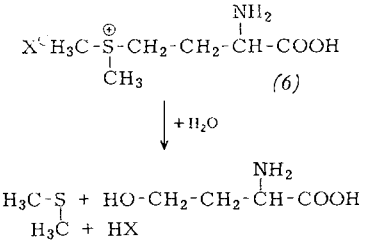
determine odor; they may, however, lead to a bad smell on storage of foodstuffs, as when the γ-terpinene in oil of lemon changes into *p*-cymene [12].

Alcohols are present in nearly all foodstuff flavors, but usually do not determine the odor, though they constitute the principal component from the point of view of quantity in many cases, *e.g.* in black tea [28] and in honey [66]. Exceptions are some unsaturated alcohols such as 1-octen-3-ol, whose mushroom-like odor occurs in oxidized lipids. It is also formed on swelling of raw soybeans in water [67]. Isoamyl alcohol is characteristic of the odor of over-ripe bananas [12]. Saturated and unsaturated alcohols are responsible for the odor of stored green peas (off-flavor). They are largely formed in accordance with Scheme 1 [45].

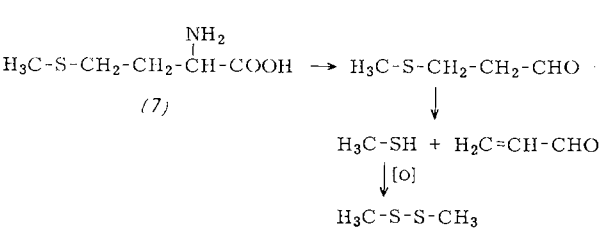
Scheme 1.

The higher alcohols known as "fusel oils" also determine the odor of alcoholic drinks. They are formed in various ways during the alcoholic fermentation [32], the Ehrlich mechanism predominating in the case of the branched-chain alcohols (Scheme 2).



Scheme 2.

Since alcoholic fermentation occurs during the preparation of yeast dough or leaven, alcohols of this type also occur in bread. Straight-chain alcohols are probably largely formed in plants by the acyl metabolism [33].



Aliphatic *ethers* occur only very rarely in foodstuff flavors, *e.g.* in apples and citrus fruits [2]. Compounds containing *epoxide* groups are occasionally found, mainly in citrus fruits [2] and in dehydrated carrots [68]. Acetals have been detected in the flavor concentrates of several fruits [2], in wine [69], and in Bourbon whisky [70]. It is possible that these were formed only on storage.

Sulfur compounds often have particularly low threshold values, and so make a considerable contribution to the flavor even in low concentrations. Hydrogen sulfide, methanethiol, dimethyl sulfide, and dimethyl disulfide are widely found in quantities of about 1 to 100 μg/kg. They are formed, often together with higher homologs, particularly on heating *e.g.* of meat, eggs, milk [52], tomatoes [71], potatoes [72], and strawberries [73]. Whereas the hydrogen sulfide is thought to be formed mainly from SH groups of (free or protein-bound) amino acids [74], methionine is a precursor of dimethyl sulfide. This compound is formed when methionine and pectin [42] are heated, but mostly from the *S*-methylsulfonium salt *(6)* of methionine, even in the cold, in milk, tea, tomatoes, sweet corn, cabbage, and asparagus [42, 74].

Too much dimethyl sulfide is responsible for the "feed flavor" of butter. Methanethiol and dimethyl disulfide can also be formed from methionine *(7)* by the action of light in the presence of riboflavin or by Strecker degradation [74].

Disulfides and trisulfides, particularly the propenyl derivatives, are characteristic of the aroma of cooked onions [75, 76]. The sulfenic and sulfinic acids and the isothiocyanates (mustard oils) that determine the flavor of raw onions, garlic, leeks, some varieties of

cabbage, radishes, mustard, and cress will merely be mentioned in passing, since numerous publications dealing with these flavoring substances have already appeared (cf. [77, 78]). Less common sulfur compounds

that deserve mention are 2-mercaptoethanol in butter, the methyl and ethyl esters of β-methylthiopropionic acid in pineapple, and lenthionine *(8)*, the odorous principle of the eastern Asian edible mushroom *Lentinus edodes* [79].

(8)

Volatile *amines* do not occur very widely in foodstuff flavors, but they usually have a very strong smell. Trimethylamine is found, together with numerous other amines, as a typical odorous substance in fish, in which it is formed enzymatically from trimethylamine oxide. It is also responsible for the fishy taste of condensed milk, where it is probably formed from lecithin. Nine volatile amines were detected in wine [80], nine in cocoa [15], five in raw potatoes [81], and three in apples, where they are probably formed from the aldehydes by transamination [82]. Ammonia is present in small quantities *e.g.* in cooked meat [52]. It is formed in fish from amino acids by the Stickland reaction.

Aldehydes are present in practically all foodstuff flavors, and often determine the flavor because of their strong smell, as *e.g.* in cucumbers [83] and in black tea together with theaspirone and dihydroactinidiolide *(9)* [27,28]. The most widespread as far as quantity is concerned is acetaldehyde [34], which is the principal flavoring substance of yoghurt [84], and is formed (in other milk products too) from pyruvate [85], but has a relatively weak odor. The *n*-alkanals, *n*-2-alkenals, and *n*-2,4-alkadienals containing more than two carbon atoms are more important. They are produced by breakdown of fats or amino acids, Maillard reaction, caramelization, or photosensitized decomposition ("sunlight flavor" [86]) of foodstuff components. They are formed in fruits and leaves only after the cells have been damaged [33], and can act as phytoncides (substances that protect higher plants against microorganisms) [87]. An exception is found in the citrus fruits, in which they are probably of native occurrence. The aldehydes in this case are higher members (octanal and decanal) than in other fruits [2], in which 2-methylbutanal and 2-hexenal are particularly common. The oily smell of fish is due to *n*-alkanals and *n*-alkenals containing 6 and 7 C atoms, and the rancid tallowy smell to those containing 8–10 C atoms.

Ketones also occur very widely (particularly acetone), but they are mostly present in smaller quantities than the aldehydes. They are also less important than the latter in determining odor. Exceptions are biacetyl (in butter and many other foodstuffs), 1-octen-3-one, which is responsible for the metallic taste of butter, and some methyl ketones, which make a substantial contribution to the flavor of blue cheese [88] and coconut [89], and to the taste of boiled milk [90]. These methyl ketones are formed in cheese by the action of molds on fatty acids containing one C atom more [91]. Biacetyl is formed in milk products and in beer from acetyllactic acid, which may be formed from lactose or citric acid *via* pyruvic acid [74,92]. Biacetyl is also formed on pyrolysis of sugars [51]. The formation of ketones is observed on oxidation of fats, in the Maillard reaction, and on caramelization [50]. Interesting ketones occurring in special cases include 2-hydroxy-2,6,6-trimethylcyclohexan-1-one (in tea and tomatoes [24,30]), α- and β-ionones (in tea and raspberries [2,24]), and several hydroxycyclopentenones, which occur in roasted coffee and are also formed in alkaline fructose solutions on heating [93].

Carboxylic acids are present in most foodstuff flavors. They determine the odor in many cheeses and in browned butter, and are responsible in particular for the rancid odor of foodstuffs [94]. They are mainly *n*-aliphatic acids formed by biosynthesis [95] or fat breakdown. β-Methylbutyric acid constitutes 50% of the flavor of cranberries [96].

A few *nitriles* occur in black tea as well as in coffee and cocoa. *Hydrogen cyanide* contributes to the flavor of some foodstuffs (bitter almonds, kirsch). It is formed on enzymatic hydrolysis of the cyanogenic glycosides and also occurs in the flesh of cherries and peaches [2], and in particular in quantities of up to 100 mg/kg in apricots, cherries, and plums canned with the stones [12].

Esters of carboxylic acids are present in particularly large quantities in fruit flavors, in which, together with alcohols and aldehydes, they determine the odor [12,23]. They are probably formed in the acyl

metabolism of the plants. Particularly common representatives are acetates and butyrates of alcohols that also occur free in the fruits. Several esters of carboxylic acids also occur in milk, coffee, bread, beer, and whisky [34,70,97]. Cherries, raspberries, grapefruit, and pineapple are relatively poor in esters [2].

Like the esters, the *lactones* also play an important part in foodstuff flavors, though they probably do not occur so widely. Simple γ- and δ-lactones are found in several fruits [98–100], in coconuts, in roasted peanuts [101], and in heated fats [102,103]. They are largely responsible for the flavor of dried milk, and they also contribute to the flavor of butter. They are formed in fats from γ- and δ-hydroxy fatty acids, which probably result *in vivo* from the oxidation of saturated fatty acids. The hydroxy fatty acids are liberated from the fats on heating, and change spontaneously into lactones [61,103]. The possibility of formation from ascorbic acid has been discussed [104]. Special lactones, apart from coumarin, include dihydroactinidiolide *(9)*, which is found in tobacco [105], black tea [27], tomatoes [30], and crispbread [31], and the phthalides, which, together with dihydrophthalides, determine the flavor of celery [106]. Bovolide *(11)*, which is present in butter, and probably comes from the green feed, also has a celery-like odor [74].

R = =CH-CH(CH$_3$)$_2$

R = =CH-CH$_2$-CH(CH$_3$)$_2$

3.2. Aromatic and Heterocyclic Compounds

Aromatic compounds occur in many foodstuff flavors. The aromatic hydrocarbons occur widely, but never in large quantities [29,107,108]. They could be formed from ethylene by biosynthesis [95], as well as from carotenoids, and possibly also from fats, on heating [107]. Among the alcohols, benzyl alcohol and 2-phenylethanol are worth mentioning. The latter is formed in alcoholic fermentation from phenylalanine. Phenols play a decisive part in many flavors, *e.g.* those of coffee [109] and of tobacco smoke. They are also abundant in the flavor of crispbread [31]. Pyrogallol *(13)*, hydroquinone *(14)*, *p*-vinylpyrocatechol *(15)*, and pyrocatechol *(16)* are formed when coffee is roasted, probably from chlorogenic acid *(12)* [51], while guaiacol and similar compounds are formed from esters of ferulic acid [110].

(13) *(14)* *(12)* *(15)* *(16)*

Among the aldehydes, benzaldehyde occurs particularly widely, mainly in fruits [98]. Vanillin is found in coffee, in alcoholic distillates that have been stored in wooden containers [111], and in heated milk, which also contains acetophenone [90]. The methyl and ethyl esters of anthranilic acid and *n*-butyl phthalate occur in many types of grapes [2], and the first of these esters is also present in citrus oils and citrus honeys [112]. Nitriles include benzonitrile in cocoa [17] and UHT milk (sterilized by injection of steam at 150 °C) [90], as well as phenylacetonitrile in tomatoes [30] and black tea [26]. Coumarin and its derivatives occur in raspberries and citrus fruits [2]. Particularly large numbers of aromatic compounds, mainly benzoic acid and its esters, are present in the flavors of cranberries and bilberries [35,96,113]. Aromatic alcohols and esters are essential to the type odor of natural honeys.

Furan derivatives are formed in the Maillard reaction and from carbohydrates or ascorbic acid on caramelization [104], and are therefore very often present in heated foods, *e.g.* in crispbread [31] and dried grapes [100]. The furan derivatives in roasted coffee could also be formed in part from the terpenes resulting from the breakdown of the lipids [64]. Furfural, hydroxymethylfurfural, and furfuryl alcohol are particularly common, though these usually

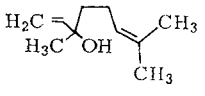
contribute little to the flavor. They are occasionally regarded as responsible for "cooked flavor" [114]. The furanone derivatives *(17)* and *(18)* are essential



(17)

(18)

(19)

(20)

to the odor of beef broth [115]. 2-Pentylfuran is responsible for the reversion flavor of fats [116]. Pineapple contains 2,5-dimethyl-4-hydroxy-3(2*H*)-furanone *(18)* [2] and *trans*-tetrahydro-α,α,5-trimethyl-5-vinylfurfuryl alcohol *(19)* [99]. *(19)* at least is probably formed from linalool *(20)*.

Thiophene, pyrrole, and *pyridine derivatives* are only occasionally found in foodstuffs, mostly in roasted coffee. It seems possible that these are formed in the Maillard reaction [100] and that thiophene derivatives are also formed from thiamine [117]. *N*-Methylpyrrole and pyridine are formed from trigonelline on roasting of coffee [51]. Pyridine plays an important part in the flavor of over-roasted coffee. However, the *pyrazine derivatives*, which occur in roasting flavors (coffee, cocoa, peanuts, potato chips [118], crispbread [31]) are generally more important. These are mostly made up from several compounds containing alkyl groups. They are formed in the Maillard reaction. The C atoms of these compounds are derived from the sugars, and the N atoms from the amino acids [58]. Derivatives of dioxolane [29], oxolanone [31], thiazole [30], oxazoline and trithiolane [119], and indole occur only very occasionally. Mention should be made of the γ-pyrone derivative maltol, which is found in malt coffee, pure coffee, and other foodstuffs [51], and is also used in concentrations of 0.005–0.025% as an artificial flavor reinforcer in sweet foods.

4. Fixation of the Flavoring Substances

Flavoring substances can be lost from the foodstuffs by oxidation, polymerization, reactions with other components of the food, and evaporation. Loss by evaporation at least can be retarded or prevented by suitable fixation of the flavoring substances. The term "fixation" is used here to denote a state in which the volatility of the flavoring substance is reduced, as well as a process by which the volatility is reduced. Only reversible fixation is of interest to the technologist, since the flavoring substance is lost in any case if the fixation is irreversible even during consumption. Good fixation of flavoring substances in foodstuffs is important during storage and prolonged transportation. This affects dehydrated products in particular, since flavoring substances, which can often no longer be fixed to a sufficient degree in the dried product, escape during production. This is so *e.g.* in the case of coffee extracts, whereas fixation of the flavor is very good in roasted coffee [120].

The fixation of the flavoring substances depends on the structure of the foodstuffs and on the substances present. Intact cells bind flavoring substances better than homogenized materials. The permeability to flavoring substances can be reduced by intercalation of suberin (a fatty substance found in cork cell walls) or by deposition of cutin (a polymerization product of hydroxylated fatty acids found on the surface of plant epidermis cells). Living cells have a lower permeability than dead cells for many substances, *e.g.* methanol [121].

The fixation of flavoring substances in cell systems has not been so thoroughly investigated as the semipermeable membrane that is formed on the surface of drying droplets of coffee extract or maltodextrin solution, which allows water to pass through it, but not flavoring substances [122]. It probably consists of macromolecular carbohydrates, and binds the flavoring substance after the manner of nonstoichiometric inclusion compounds. Inclusion compounds of this type are formed on drying of polysaccharides containing water and flavoring substances. They were first investigated for cellulose [123] and starch [124], but are also formed with dextrin, pectin, agar, and methylcellulose, and with foodstuffs that contain these substances [125]. Only very small molecules of flavoring substances, which can form particularly strong hydrogen bonds to the solids, such as methanol, ethanol, formic acid, and aliphatic amines, cannot be bound in this way. Since the other flavoring substances are bound indiscriminately, and since the fixation is due only to steric "imprisonment" in the ideal case, and not to principal valences or molecular forces (though the latter are involved to some extent in practice), the flavors are thus fixed gently and sub-

stantially completely. They can readily be liberated again by addition of water.

If no inclusion occurs, the greater part of the flavoring substances is bound to the foodstuff components by physical sorption (dissolution or adsorption). Liquid phases (water, fat) have greater sorption capacities than solid phases. Fats in particular are very good binders for food flavors [126, 127], since most flavoring substances are lipophilic. In emulsions, therefore, most of the flavoring matter should be situated in the lipid phase. Model experiments have been carried out with liquid paraffin/aqueous sodium sulfate solution [128].

The fixation of flavoring substances in foodstuffs containing water and having low fat contents is not only determined by the partition coefficients of the flavoring substances between air and water. Dissolved sugars and salts normally increase the vapor pressures of the flavoring substances, while casein decreases them [129, 130]. Table 6 shows the changes in the concentrations of flavoring substances in the vapor space over aqueous solutions on addition of 1 % of solid (dissolved or suspended).

Table 6. Changes in the concentrations of flavoring substances in the vapor space over their aqueous solutions (concentration given) on addition of 1 % of solid. Values as percentage of the initial value; negative values indicate a decrease in concentration, and positive values an increase. The values were determined by gas chromatography (those for the last four flavoring substances being determined alongside each other).

Additive	Flavoring substance				
	Acetone 0.01 mole/l	Ethanol 0.1 mole/l	Acetaldehyde 9×10^{-3} mole/l	Ethyl acetate 2.5×10^{-3} mole/l	Diethyl ether 0.9×10^{-3} mole/l
Casein	− 7.9	− 4.6	− 2.1	+ 4.0	−1.9
Dextrin	− 4.0	− 4.4	− 8.4	0	0
Fructose	− 0.5	+ 5.3	− 3.1	+ 4.9	+4.1
Gelatin	− 5.5	− 3.6	− 9.5	− 1.0	0
Methyl-cellulose	−10.0	−19.1	− 8.4	− 0.5	0
Ovalbumin	− 5.0	+ 5.3	−14.6	+ 1.0	+2.0
Pectin	−10.0	−23.6	−11.6	−10.0	−1.4
Saccharose	− 2.1	0	− 6.3	+ 1.5	+2.0
Sorbitol	− 6.2	− 5.3	−12.5	+ 1.0	−2.0
Starch	− 2.1	0	−11.5	− 1.5	+2.0

The sorption capacity of the solid components of the foodstuff, which depends on the available surface area, is usually small for crystalline low molecular weight substances and greater for macromolecular substances. Amines are particularly well sorbed on carbohydrates (Maillard reaction occasionally occurs), and alcohols, ketones, and aldehydes are also bound. Proteins bind alcohols particularly well, and then amines, aldehydes, and ketones. Carboxylic acids (except formic acid and acetic acid) and their esters are much less readily sorbed by both groups of substances, and thiols, ethers, and hydrocarbons less readily still [125]. If individual flavoring substances are allowed to act on dry foodstuff components, heats of sorption of the same order of magnitude as the heats of vaporization of the flavoring substances are normally found [131], while the IR absorption bands are only slightly displaced in relation to those in the vapor state. Both of these facts point to physical fixation. Chlorophyll can form chelates with flavoring substances [132, 133].

In special cases, the flavoring substances are bound by principal valence forces. This bonding naturally occurs during their formation; one then speaks of flavor precursors. However, the final flavoring substances may also form reversible principal valence bonds with nonvolatile food components. Thus salt formation has been detected between nonvolatile acids and volatile amines and ammonia, as well as between nonvolatile basic food components (*e.g.* proteins) and volatile acids. Acids and alcohols may be bound as esters, but this is only rarely observed in enzyme-free, solid foodstuffs [125].

The most reactive of the important flavoring substances are the aldehydes. These are particularly readily bound to NH_2 and SH groups. These bonds, particularly in the case of the higher homologs, are often reversible, at least partly on heating in water. Schiff bases are probably formed with proteins and amino acids, dialkylideneureas with urea, and 2-alkylthiazolidine-4-carboxylic acids with cysteine or cysteinium salts [134, 135]. The formation of hemiacetals, acetals, and ketals, which occurs readily with the pure substances, has not yet been observed under conditions approximating to those in foodstuffs. Dithiohemiacetals and monothiohemiacetals have so far been detected only in coffee flavor [136].

5. Outlook

Research in the field of foodstuff flavoring substances is proceeding in three directions.

Most of the articles being published at present deal with the *analysis of flavors*. The main emphasis is on the qualitative composition, and increasing interest is being shown in the trace components. Quantitative analyses of the individual flavoring substances are also being carried out with ever-increasing frequency. These are essential to the application of the results *e.g.* in the artificial preparation of flavors. The determination of the odor contributions of the various flavoring substances and the study of synergistic interactions will probably gain increasing importance in the future.

A growing number of articles deal with the *formation of the flavoring substances*. The process of inactivation of enzymes (*e.g.* by methanol [33]) in living systems during the analysis has led to important progress in recent years. Further progress is to be expected from the elucidation of the complicated processes involved in the oxidation of fats and in the Maillard reaction. Detailed knowledge about the formation of flavoring substances should enable us to develop these, when necessary, from nonvolatile precursors in dried foodstuffs that lack flavor. This is possible (by the action of enzymes) only in isolated cases at present [88].

The study of the *fixation and alteration of flavoring substances* has a direct bearing on technology. There are two main objects. Firstly, the flavoring substances of fresh foodstuffs should be retained during processing and storage, and secondly, attempts are being made to flavor an "artificial" foodstuff so that it smells and tastes like a known food. This is essential if it is to be consumed in large quantities, particularly in developing countries. The protein concentrates obtained from fish and from petroleum, and the foodstuffs from algae in particular, present a problem of worldwide importance in this respect.

Principles and Latest Developments in the Field of Metallic and Nonmetallic Hard Materials[**]

By Richard Kieffer and Peter Ettmayer [*]

A survey of some fundamental aspects of the theory of hardness is followed by a discussion of recent developments in the field of sintered hard metal alloys. For example, good results have been obtained by the addition of hafnium carbide to hard metals. Niobium carbide can sometimes replace the more expensive tantalum carbide; vanadium carbide can be used to inhibit grain growth, especially in the case of ultrafine carbides. A brief outline is given of the results of investigations on ternary and quaternary systems with the components TiC, HfC, NbC, TaC, and WC. The utilization of sintered nitride and carbonitride hard metals in the field of machining appears feasible. Recently developed high-pressure/high-temperature autoclaves permit work on nitride systems under a high nitrogen pressure. The authors comment on the latest work in the field of nonmetallic hard materials and on diamond synthesis.

1. Theory of Hardness

Even today the physical definition of hardness and its precise and reproducible measurement continue to pose serious problems since, being a mechanical quantity, it is to a certain extent dependent on the method of measurement. Nevertheless, numerous attempts have been made to relate hardness to physically measurable quantities, and above all to improve its predictability. Indubitably, hardness is a function of interatomic forces which it is at present impossible to measure directly. The type of structure and bonding must, of course, play an important part; more densely packed structures are harder for the same atomic distance than less highly coordinated lattices. For the same bonding energy, covalent bonding would give a substance greater hardness than predominantly metallic or ionic bonding. For these reasons hardness can be related to macroscopic physical data only in the case of isotypically crystallizing materials with the same type of bonding.

[*] Prof. Dr. R. Kieffer and Dipl.-Ing. Dr. P. Ettmayer
Institut für chemische Technologie anorganischer Stoffe
der Technischen Hochschule
1060 Wien, Getreidemarkt 9 (Austria)

[**] Lecture presented by *R. Kieffer* October 17, 1969 at the 161st Dechema Colloquium in Frankfurt/Main.

Starting from the premise that hardness is above all characterized by the resistance offered by structural components to mutual displacement, *Nowotny*[1] found the following relation for the hardness H:

$$H = C\nu = K\sqrt{(T_s - T)}V^{2/3}$$

where ν represents the oscillation frequency from the Lindemann formula, C and K are proportionality factors, T_s is the absolute melting temperature (°K), T the test temperature (°K), M the molecular weight, and V the molar volume. This formula, which provides excellent hardness indices especially in the case of pure metals, also gives good parallelism with the hardness series for isotypic, identically bonded monocarbides (Table 1). The tendency for the hardness to decrease in the direction TiC → HfC and VC → TaC is quite striking.

Table 1. Melting point, hardness, and frequency factors of carbides.

Carbide	Melting point (°K)	Microhardness (kg/mm²)	Frequency factor (according to *H. Nowotny* [1])
TiC	3400	3200	5.6
ZrC	3800	2600	4.2
HfC	4300	2200 [a]	3.4
VC	3100	2800	5.3
NbC	3730	2400	3.8
TaC	4150	1800 [b]	3.4

[a] The values vary between 1800 and 2700 kg/mm², and according to recent measurements between 2000 and 2400 kg/mm².
[b] 2000 to 2200 kg/mm² for slightly substoichiometric TaC.

Samsonov[2] postulates that hardness is essentially dependent on the statistical weight of the stable electron configuration of the metal and nonmetal atoms and on the number of electrons that contribute to the bond. Since the exact measurement of electron states in solids still involves considerable experimental problems, *Samsonov*'s theory at best indicates the direction of the hardness curve in structurally similar materials; the predictability of the hardness of new hard materials remains very poor.

It would be most interesting to develop already existing and highly promising formulas for the calculation of hardness, and to investigate whether relationships may not be found between hardness and free energy of formation, the melting points and the heats of fusion of the individual components, the modulus of elasticity, and so on.

2. Auxiliary Metal Bath Technique

From the point of view of the usefulness of hard materials in industry, hardness is for many applications, and especially the machining of metals, a necessary but by no means sufficient property. It must be accompanied by certain strength characteristics which enable a tool to absorb bending and torsional forces so as to enable it to withstand impact stresses. The art of making cemented carbides thus consists in combining the greatest possible hardness with optimal toughness. To some extent these properties are in mutual opposition, although there are effects which cause both properties to improve or to deteriorate simultaneously. The detrimental effects include the porosity of the cemented carbides, which may be due, for example, to nonoptimal sintering conditions and which can therefore be prevented by improving the sintering operation. The second cause of porosity is the content of oxygen and nitrogen in the sintered particles themselves. At the high sintering temperatures these impurities are liberated as elemental nitrogen or as carbon monoxide and give rise to microporosity. A typical example of microporosity in a cemented carbide is illustrated in Fig. 1; the

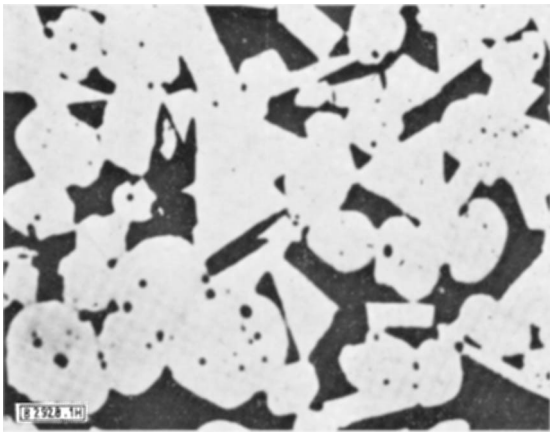

Fig. 1. Polished section of a cemented carbide of the type WC/TiC/Co sintered for a prolonged period. Micropores in the WC/TiC solid solution × 1000.

microcavities are located inside the carbide crystallites. To manufacture high-grade cemented carbides possessing good strength properties it is therefore important to use materials having low nitrogen and oxygen contents. The content of these undesirable impurities can best be determined by hot extraction analysis[3]. To improve degasification it is possible to select an auxiliary metal bath, generally iron, cobalt, nickel, or an alloy of these metals, which possess a certain dissolving capacity for the transition metal carbides and accelerate the liberation of gases. On cooling the carbides crystallize out of the metal melt and are highly pure as regards the oxygen, nitrogen, and hydrogen contents. We have developed this analytical technique into a preparative one, with the aid of which we have been able to prepare for investigation a series of carbides in high vacuum[4–6].

Table 2. Comparative analyses of some carbides.

a) Technical carbides produced by reacting the components in the solid state.

Carbide	C_{total} (%)	C_{free} (%)	O_2 (ppm)	N_2 (ppm)	Remarks
WC	6.12	0.04	800	—	
TiC	19.70	0.40	2000	800	
TaC	6.17	0.04	250	80	Nb < 500 ppm
NbC	11.10	0.056	800	400	Ta < 500 ppm

b) Carbides produced with an auxiliary metal bath.

Carbide	C_{total} (%)	C_{free} (%)	O_2 (ppm)	N_2 (ppm)	Remarks
WC	6.13	0.03	50	—	
TiC	20.0	0.3–0.50	300–500	80–120	
TaC	6.19	0.05	40	<10	Nb < 500 ppm
NbC	11.60	0.30	100	<10	Ta < 500 ppm

Table 2 shows the oxygen and nitrogen contents of conventional carbides produced by reaction in the solid state in comparison with those obtained by the auxiliary metal bath method. The use of a vacuum with the auxiliary metal bath purification is desirable although not absolutely essential, providing care is taken to ensure a reasonably clean, oxygen- and nitrogen-free protective gas atmosphere. In the U.S.A. this auxiliary metal bath technique at normal pressure is known as the "McKenna Menstruum process". The carbides of the transition metals can be isolated by acid treatment of the auxiliary metal. Coprecipitated graphite particles can be removed by decantation or floated away from the carbides. The carbides frequently occur in the form of beautiful crystals

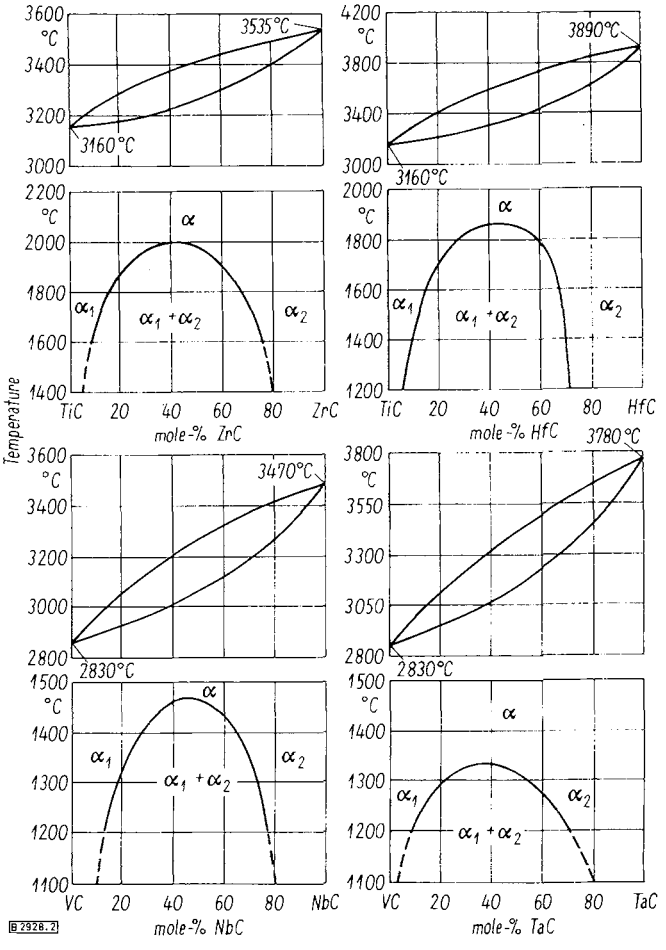

Fig. 2. Miscibility gaps in the TiC/ZrC, TiC/HfC, VC_{1-x}/NbC, and VC_{1-x}/TaC systems.

(*e.g.* TaC as golden yellow cubes or NbC as violet cubes), they have a high content of bound carbon, and with the exception of the chromium carbides they have a low content of the metal used for extraction (cf. Table 3).

The principle of producing carbides by the metal bath process can also be extended to carbide solid solutions [7]. The metallic solvent permits the minimum preparation temperature to be reduced to about 1400 °C. It was unexpectedly found that in the pseudobinary systems TiC/ZrC, TiC/HfC, VC_{1-x}/NbC, and VC_{1-x}/TaC miscibility gaps occur, the one in the TiC/HfC system being of particular interest from the point of view of cemented carbide technology. The form of the miscibility gaps is shown in Fig. 2.

It will be seen that the miscibility gaps are disposed somewhat asymetrically and are displaced toward the lower melting components (with the smaller molar volumes) [8].

3. Carbide Systems

The modern tendency to use multicomponent materials, a tendency that has spread to the cemented carbide sector, prompted us to undertake a more detailed investigation of some ternary and quaternary systems comprising carbides. The purpose of the investigation of the TiC/TaC/NbC/WC system (Fig. 3) was to study the solubility relationships of

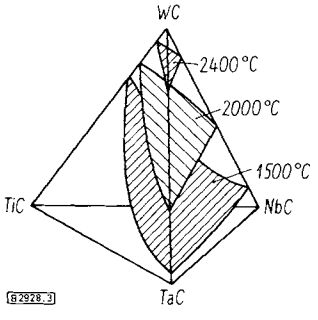

Fig. 3. The TiC/TaC/NbC/WC system (coordinates in wt-%).

the isotypic carbides TiC/NbC and TaC as well as their ability to dissolve WC [9]. TiC is known to be a good solvent for WC, whereas TaC possesses only a poor dissolving capacity for this carbide and also reduces its solubility in a solid solution of TiC/TaC. A partial replacement of TaC by NbC in TiC/TaC/WC compositions would be economically attractive, although the addition of NbC is said to make the material more brittle. The authors' investigations have shown, however, that in materials of the type TiC/TaC/WC with 10% Co one-third, and in many cases as much as one-half, of the TaC component can be replaced by NbC without any significant deterioration of the strength properties in comparison with materials containing no NbC [9] (cf. Fig. 4).

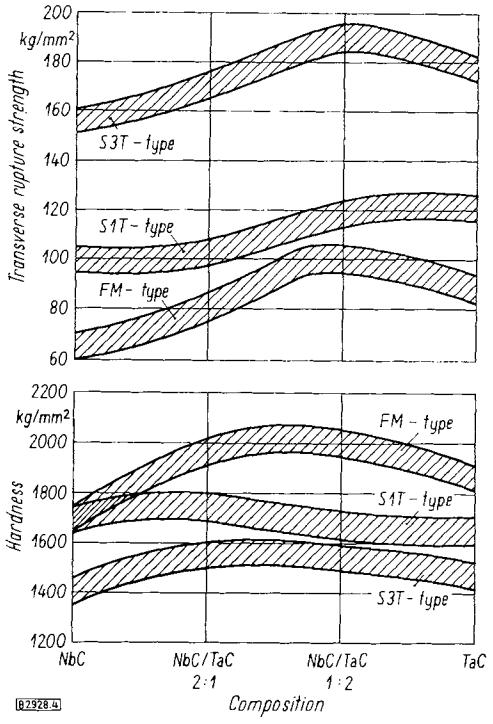

Fig. 4. Transverse rupture strength and hardness of cemented carbides of the type WC/TiC/TaC/Co with partial replacement of TaC by NbC. See Table 4 for type designations.

Hafnium carbide (HfC) is most promising as regards application in the cemented carbide industry. Obviously, like TaC [10], it is capable of bringing about a decisive improvement in the properties of the cemented carbides. Moreover, the initially high cost of HfC has ceased to be an obstacle now that HfC/NbC and

HfC/TaC solid solutions are available at the same price as TaC. It appears that the addition of HfC to TiC/TaC/WC can impart to the material not only an appreciable increase in hardness but also a notable abrasion and cratering resistance.

Studies on a series of systems with HfC as one of the components were carried out as a fundamental step in the development of cemented carbides. These investigations concerned the ternary systems TiC/HfC/WC (Fig. 5), HfC/NbC/WC (Fig. 6), and TiC/HfC/NbC (Fig. 7), as well as the quaternary system TiC/HfC/NbC/WC (Fig. 8)[9,11]. The TiC/HfC/WC system (Fig. 5) shows the interesting phenomenon that the miscibility gap existing in the TiC/HfC boundary system moves away from the boundary at about 2000 °C and occurs as an island of immiscibility surrounded on all sides by the single-phase region. At the normal sintering temperatures for cemented carbides of 1450 to 1550 °C one observes a three-phase region which contains HfC-rich ternary solid solution and WC in addition to TiC-rich ternary solid solution. It may be expected that cemented carbides with this carbide compositions will exhibit particularly interesting properties to which it would be well worthwhile devoting further attention. In the quaternary system TiC/HfC/NbC/WC (Fig. 8) the picture is not substantially changed. Once again in the case of this system a three-phase region with a TiC-rich solid solution, a HfC-rich solid solution, and WC is found at not too high NbC contents[11].

S3T	7	8	10	75
S1T	16	8	7	69
FM	40	8	7	45

Application experiments too have shown HfC to be a suitable additive. Table 4 shows the transverse rupture strengths and hardness values of conventional cemented carbides in which TaC was replaced either by NbC/HfC or by TaC/HfC solid solutions. The hardness values and transverse rupture strengths resulting from the substitution are invariably as good as, or even better than those of the original hard metals. If TaC in WC/TiC/TaC/Co compositions is replaced by a 1:1 solid solution of TaC/HfC or quantitatively by HfC, then in some cases the transverse rupture strength passes through a maximum[9] (cf. Fig. 9).

Excellent cutting results are obtained with HfC-containing cemented carbides. The wear on HfC-containing tools in the machining of steel is for the

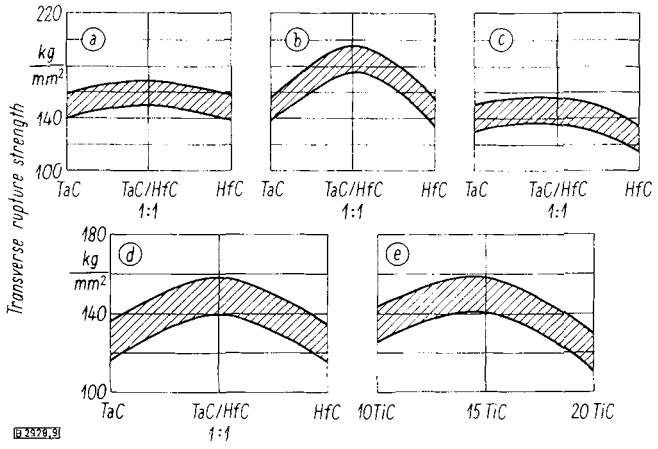

Fig. 9. Transverse rupture strength of cemented carbides of the type TiC/TaC/WC/Co with partial replacement of TaC by HfC.

most part lower than in the case of corresponding, hafnium-free alloys. This observation may be explained by the resistance to friction welding of HfC, which must be responsible for the smaller erosion and cratering by the departing chip.

HfC has also proved its worth as an additive to WC-free cemented carbides based on TiC/Mo_2C/Ni. This type of hard alloy has recently regained some popularity in the U.S.A. although the discovery of these materials goes back almost 40 years [10]. Unfortunately, the toughness of the cemented carbides produced at that time was so inadequate that they were unable to compete against the WC–TiC-containing compositions. A systematic investigation of this type of hard alloy yielded an unexpected result: in marked contrast to WC-containing cemented carbides, in

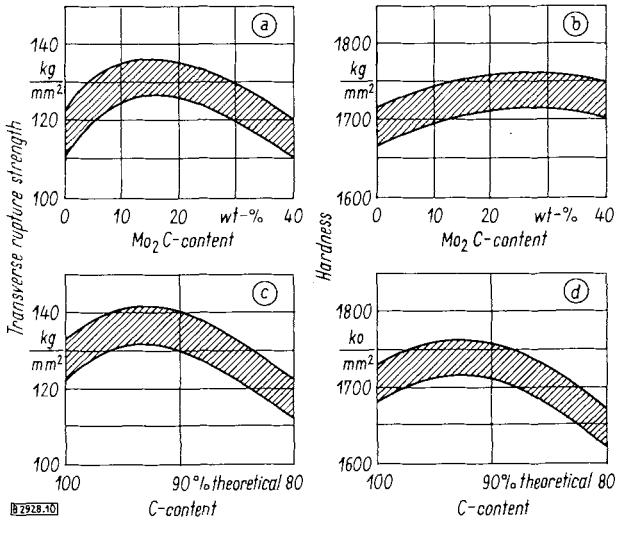

Fig. 10. Transverse rupture strength and hardness of WC-free cemented carbides based on Mo_2C/TiC/Ni with 14% Ni.

a) Transverse rupture strength as a function of the Mo_2C content in the solid solution; b) hardness as a function of the Mo_2C content in the solid solution; c) transverse rupture strength of a cemented carbide with a TiC/Mo_2C(80/20) solid solution (14% Ni binder) as a function of the carbon deficiency; d) hardness of a TiC/Mo_2C (80/20) cemented carbide as a function of the carbon deficiency.

TiC/Mo_2C/Ni alloys a certain carbon deficiency can produce a significant increase in both strength and hardness [12] (cf. Fig. 10).

Similar effects can be obtained by using classical Ni–Mo alloys containing a maximum of 25 wt-% of Mo in place of the pure nickel binder [10]. This observation also supports the postulate that the carbon deficiency causes part of the molybdenum to diffuse out of the (low carbon) solid solution into the nickel binder during sintering, thus producing a certain rise in the amount of the binder (increased toughness) as well as improving the hardness and strength of the binder by the formation of an alloy similar to Hastalloy. At a binder content of 10 to 14% Ni one obtains transverse rupture strengths of 125 to 140 kg/mm², almost double the values obtained in 1930 for alloys of the same composition. By hot pressing it is even possible to attain transverse rupture strengths of 150 to 170 kg/mm².

Further attempts to improve the classical cemented carbides were based on the known fact that it would be possible to increase the already outstanding properties of the hard alloys if a way could be found to reduce the size of the carbide particles in the hard alloy below the presently usual 2–4 μm (cf. the development of Widia H from Widia N). It is scarcely possible to bring the particle size down much below 1 μm by grinding, even with the most powerful grinders; in fact, pyrophoric properties are often observed in the case of such finely ground hard metals. Ciba of Basel and, independently, DuPont de Nemours in the U.S.A. have developed processes that permit the production of submicroscopically fine carbides [13]. In the Ciba technique, a mixture of metal halide vapor, methane, and hydrogen is heated in a plasma

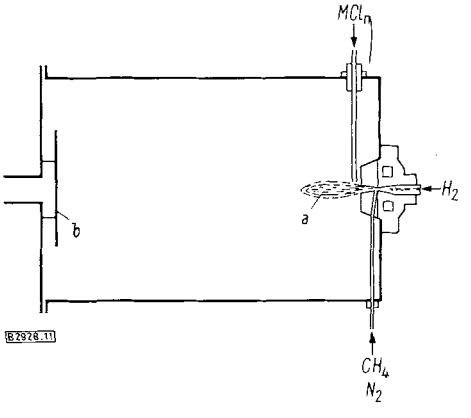

Fig. 11. Schematic representation of the Ciba apparatus for preparing ultrafine carbides and nitrides in a plasma jet:

a) plasma jet; b) baffle.

jet (Fig. 11) and the fine carbide particles are quenched on a baffle and removed. These ultrafine carbides (0.01 to 0.1 μm) of necessity have a higher oxygen content, which must be reduced in the usual way by

[12] *R. Kieffer, N. Reiter,* and *D. Fister,* BISRA-ISI-Conference on Materials for Metal Cutting, Scarborough 1970.

[13] *E. Neuenschwandter,* J. Less-Common Metals [Amsterdam] *11,* 365 (1966).

the formation of solid solutions with WC. In addition, these carbides display a strong tendency to grain growth on sintering which completely nullifies the initial advantage. Experiments undertaken jointly with *Krepler* [14] showed that grain growth can be inhibited by the addition of as little as a few tenths of one percent of VC_{1-x}, and to a lesser extent also by NbC or TaC, so that it is possible to obtain particle sizes $<1\ \mu m$ in the final cemented carbide.

The classical cemented carbides contain almost exclusively monocarbides as the hard constituents. In highly alloyed special steels, however, one is unlikely to find monocarbides but, instead, a variety of complex carbides which apparently play an important role in the hardening mechanism of such steels. The precise composition of these phases has generally been determined by residue analysis [15], preference being given recently to the use of the electron-beam microprobe analyzer. We have attempted to prepare some of these carbides synthetically and to investigate their suitability for special alloys [16, 17]. It should not, of course, be expected that these complex carbides will prove superior to the monocarbides as regards strength, but they could be of considerable interest for particular applications, as for example chromium carbides for non-scaling hard alloys. If these carbides are bound with less than 20% of auxiliary metals then alloys of the cemented carbide type are obtained; the use of about 30–50% of auxiliary metal matrix yields novel sintered steels that close the existing gap between high-speed steels (carbide content $\approx$20%) and cemented carbides (carbide content $\approx$70–90%). It is also possible to produce high-speed steels from synthesized special carbides and alloyed steel powder using powder metallurgical techniques and to modify their properties by suitable alloying additions.

In contrast to the monocarbides, the complex carbides are always in equilibrium with the binder metal; they sometimes display considerable solubility in the binder, and sometimes the binder dissolves in the complex carbide. Due attention must be given to this fact in the powder-metallurgical manufacture of sintered components from complex carbides and binder metal. The auxiliary metal bath technique can be used to determine the equilibrium composition of the complex carbide and the metal melt [4, 5]. The complex carbide isolated from the regulus has been in equilibrium with the melt. It is advantageous to use for the binder metal an alloy whose composition corresponds to the auxiliary metal phase [16].

With the aid of the auxiliary metal bath technique it is of course also possible to obtain other hard material phases, for example silicides and borides. Here again the composition of the auxiliary metal melt determines the composition of the hard material phases separated out. Depending on the silicon content of the copper melt, it is possible, for example, to obtain WSi_2 or W_5Si_3 crystals from the solidified regulus on the addition of tungsten [18].

4. Carbidothermic Reactions

A new field of application for the refractory carbides of the transition metals is the production of high-melting metals and alloys. One example of this is the reduction of niobium pentoxide by niobium carbide according to the equations

$$Nb_2O_5 + 7\,C \xrightarrow{H_2} 2\,NbC + 5\,CO$$

$$Nb_2O_5 + 5\,NbC \xrightarrow{\text{vacuum}} 7\,Nb + 5\,CO$$

which was used up to a few years ago by the Wah Chang Corporation of Albany, Oregon, U.S.A., for the production of pure niobium [19]. For this purpose mixtures of NbC and Nb_2O_5 were compressed in large isostatic presses and were reacted in high-frequency vacuum furnaces. With a careful choice of the amount of oxide and carbide one obtains technically pure niobium which is hydrided, comminuted, dehydrided, and remelted in an electron beam furnace. This principle has also been used to produce ductile vanadium [20], although in this case the experimental problems are much greater owing to the formation of low-melting oxide/carbide eutectics. In contrast to the metals of Groups VB and VIB of the periodic system, metals of Group IVB can only be prepared by carbidothermic reactions under extreme conditions and with high evaporation losses, if at all (cf. Table 5). Fig. 12 shows the relationship between the CO pressure, temperature, and phase composition predicted for the Ti/C/O and Zr/C/O systems by thermodynamic calculations. In agreement with the calculations, it was found possible to prepare detectable (by X-ray diffraction and analytical techniques) amounts of titanium with a purity of 96% at tem-

peratures of the order of 1700 °C and pressures $<10^{-5}$ torr [21]. In practice, however, it is impossible to prepare metals of Group IVB in the pure state by this technique. On the other hand, alloys of these metals with metals of Groups VB and VIB of the periodic system can be obtained carbidothermically by using a carbide of another metal for the reduction. An example of this is the reduction of MoO_2 with TiC and C. Titanium, which has a strong affinity for oxygen, is diluted by alloy formation with molybdenum, in which β-titanium is completely soluble at high temperatures, and its activity is thereby reduced. Figure 13 shows a plot of the CO equilibrium pressures based on thermodynamic calculations against the composition of the Ti/Mo alloy. It was shown experimentally that Ti/Mo alloys could be produced up to a composition of about 40 wt-% Ti and 60 wt-% Mo, the difficulties increasing with increasing Ti content. The results of an experiment carried out to produce a 40 Ti/60 Mo alloy are shown in Table 6. Starting with a TiO_2/Mo_2C mixture the metal content can be raised to 99.75 % [22]. It was likewise possible to produce alloys based on V/Nb, V/Ta, V/Cr, Nb/Zr, Ta/Hf/W, *etc.* [21,22].

5. Nitrides

Despite pronounced similarities to the hard and high-melting carbides, nitrides have gained relatively little popularity. The nitrides of the transition metals are hard, like the carbides, and many of them are also high-melting. They are electrically conducting and exhibit a metallic luster, and are completely miscible with the corresponding isotypic carbides [23]. Nitrides are somewhat less hard than carbides, they decompose under vacuum and at high temperatures, and their preparation is less straightforward than that of the carbides. Nevertheless, it seems desirable to undertake a systematic investigation of the nitrides and to study their properties in greater detail.

Titanium nitride and carbonitrides are distinguished, for example, by their characteristic color, which changes with rising carbon content from golden yellow in the case of titanium nitride through red-gold and bronze to violet-gray. With suitable binder metals, nitrides and carbonitrides can be processed to sintered hard alloys which, despite a considerable hardness, ranging from 1550 to 1700 kg/mm², still display transverse rupture strengths of 100–140 kg/mm². Nitrides and carbonitrides would therefore seem to be fundamentally suitable for application in the machining sector, in particular because nitrides

[22] *R. Kieffer, F. Lihl,* and *E. Effenberger,* 5. Internat. Leichtmetalltagung, Leoben 1968, p. 2, Aluminium-Verlag, Düsseldorf 1968.

[23] *R. Kieffer* and *F. Benesovsky*: Hartstoffe, Springer-Verlag, Wien 1963.

appear to be somewhat less susceptible to erosion (cratering) by the departing chip [12]. This property, which according to the experience obtained to date is specific to nitrides, also offers advantages in coating throwaway tips with nitrides. Carbide coatings have already proved their worth in practice; 5–10 μm-thick titanium carbide coatings on throwaway tips made of standard cemented carbide reduced cratering to between 25 and 30% [24]. With nitride- and carbonitride-coated hard metals it was even possible to reduce wear to between 10 and 15% [12].

The work performed on nitrides included a detailed investigation of the resistance of refractory carbides to nitrogen. In the temperature region from 1100 to 1800 °C and at pressures up to 300 at only TaC and WC of the carbides of the transition metals of Groups IVB, VB, and VIB of the periodic system are completely stable with respect to nitrogen [25]. NbC and Mo_2C react with nitrogen only to a small extent, and all other carbides react with nitrogen to carbonitrides with liberation of carbon. Quite in accordance with thermodynamic predictions, the tendency to carbonitride formation increases with rising nitrogen pressure and decreases with rising temperature. Chromium carbide (Cr_3C_2) reacts at 1400 °C with nitrogen at a pressure of 300 at with the formation of a ternary carbonitride phase, which had already been observed in the course of the investigation of the Cr/C/N system [26, 27]. The existence of this phase is of interest in that this was the first metallic compound to be discovered in which the otherwise so similar nitrogen and carbon atoms assume crystallographically non-equivalent positions [28].

For this work and for the investigations on nitride systems it was essential to develop large high-pressure/high-temperature autoclaves. All of these autoclaves are constructed on the principle of the internally heated autoclave with cooled wall and are designed for temperatures up to 2500 °C. The medium-pressure autoclave (see Fig. 14) which was built to our specifications by the furnace construction division of Degussa, Wolfgang b. Hanau, and which was inspired by an idea of *Nowotny et al.* [29], is designed for pressures up to 30 at. High-pressure autoclaves developed by us according to the same basic principle (cf. *e.g.* Fig. 15) operate at internal pressures of 1000 and 2000 at, respectively. Further details will be found in a recently published work [30].

A number of binary and ternary nitride systems have already been studied with the aid of these autoclaves. In addition to Cr/C/N [26, 27], they include the systems U/C/N [31], Ti/Cr/N [32], Zr/Cr/N [32], Hf/Cr/N [32], V/Cr/N [33], Mo/Cr/N [34], W/Cr/N [34], Mo/N [35], Mo/C/N [36], and Cr/Mn/N [37].

6. Nonmetallic Hard Materials

Apart from the hard oxides, the nonmetallic hard materials are formed from boron, carbon, nitrogen, and silicon. Whereas the binary systems B/C, B/N, B/Si, C/Si, and N/Si have been extensively studied, little is known about the ternary systems and practically nothing about the quaternary system. The Si/C/N system was investigated with the aid of the high-pressure/high-temperature autoclaves. Figure 16 shows the result of this work [38], which displays

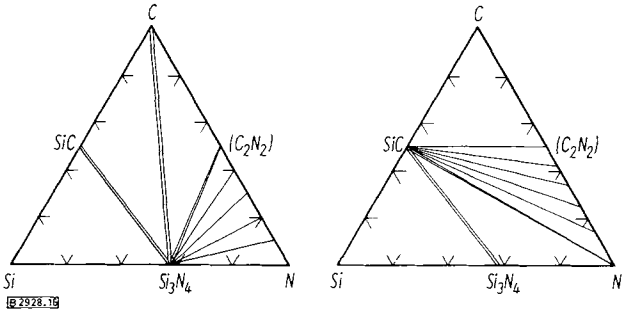

Fig. 16. Phase field divisions in the Si/C/N system at 1900 °K (left) and 2000 °K (right) and 1 at.

complete agreement with thermodynamic calculations [39]. No ternary carbonitride phase was found; the solubilities of carbon in silicon nitride and of nitrogen in silicon carbide is evidently very low. Nevertheless, hexagonal α-SiC can be transformed quantitatively into cubic β-SiC by nitrogen pressure above 2200 °C. The β-SiC obtained in this manner can be converted back into α-SiC by heating to 2500 °C *in vacuo* or in argon. Table 7 shows the experimental details of this nitrogen-induced transformation α-SiC ⇌ β-SiC [40]. This phase transformation has lent fresh strength to the old hypothesis that the polytypism observed in SiC may depend among other things on minute proportions of impurities (*e.g.* nitrogen, oxygen). Boron and aluminum are said to have similar effects on the structure of SiC.

In recent times SiC has claimed the interest not only of structural chemists and semiconductor researchers, but also of materials scientists attracted by the outstanding properties of this material. Great hardness, good oxidation stability up to about 1500 °C, and low density are only some of the interesting characteristics. Unfortunately, SiC is very brittle up to extremely high temperatures, and it is impossible to compact sufficiently either by hot pressing or by other sintering techniques. Consequently, efforts to make SiC with adequate strength characteristics have so far proved of little avail. One possible way of producing compact SiC shaped parts is to infiltrate porous SiC bodies with silicon so as to give practically compact materials, which then naturally contain considerable amounts of undesirable free silicon. However, by producing bodies that in addition to SiC also contain sufficient free carbon in the pores, one obtains infiltrated bodies which, together with small amounts of residual silicon metal, also contain considerable amounts of secondary SiC. The strength characteristics of the SiC parts made in this way are already sufficiently encouraging to make them potentially interesting for many industrial applications [41,42].

In conclusion, let us briefly consider the present state of development in the domain of diamond, the hardest material of all. Thanks to the progress made in physical chemistry, it was known from about the middle of the last century that the transformation of graphite into diamond could only occur at high pressure. *Bundy*'s phase diagram of carbon [43], shown in Figure 17, shows the pressure/temperature region in which an industrial diamond synthesis is carried out. It has never been conclusively established whether *Moissan* did not, after all, succeed, in the course of his attempt at diamond synthesis at the turn of the century, in producing the necessary pressure and obtaining microscopically small diamonds from the iron melt supersaturated with carbon. At present a substantial proportion of industrial diamonds is already being produced by catalytic high-pressure/high-temperature synthesis using nickel, iron/nickel, and recently also cobalt/niobium/copper alloys [44] as catalysts. Fine bort has recently been produced by

explosion shock waves using an iron catalyst (Du Pont), the technique being developed from *Moissan*'s experiments, and even a catalyst-free transformation seems feasible, although this could only be done at much higher pressures still, *i.e.* in the region of "metallic carbon" (see Fig. 17). The conditions so far attainable for diamond synthesis are still inadequate to produce large diamonds of gem quality. However, it is already possible to control specific properties of diamonds within certain limits, *e.g.* to vary the color by admixtures to the catalysts and to influence the habit of the diamond crystals. Nitrogen imparts semiconductor properties to diamond and gives it a yellow to brown coloration, boron is reported to make it blue. Figure 18 shows a schematic arrangement for

diamond synthesis. The carbon tube heating element, which is insulated with pyrophyllite, is introduced between cemented carbide anvils into annular shrunk cemented carbide dies. Cobalt-bonded tungsten carbide is used for the anvils and dies. This material continues to form the basis of the cemented carbide industry and synthetic diamonds would be inconceivable without it.

Modern Industrial Microbiological Fermentations and Their Effects on Technical Developments[**]

By H.-J. Rehm[*]

Owing to the development of many new processes and techniques, the production of primary and secondary metabolites with the aid of microorganisms has not only expanded greatly, but has also been simplified in many details, and has therefore become more widely feasible on the industrial scale. The present article surveys the principal fermentation processes and the main types of equipment, which shows a trend toward continuous processes and increasing automation. Some recent developments observed e.g. in the cultivation of animal cells or the production of electrical energy, and particularly in the production of proteins by microorganisms, are also described.

1. Isolation of Primary Metabolites

Man has been trying for thousands of years to develop apparatus for the controlled cultivation of microorganisms by processes and special techniques best suited to the needs of the microorganisms. Following the discovery of large numbers of microorganisms and the elucidation of many of their biochemical properties, cultivation methods that have proved adequate almost to the present day were developed in the late 1800's and early 1900's. The cultures were carried out in open or closed tanks, usually without protection against extraneous organisms. As far as

[**] Based on a lecture to the Dechema conference in Frankfurt/M. on June 26, 1969, and to the 2nd Symposium on Industrial Microbiology on April 14, 1970 in Berlin.

possible, the growth conditions were kept such that only the desired organisms could develop. The object of the process is essentially either the production of the cells themselves, as in the growth of yeast, or the production of their primary metabolites, such as ethanol, butanol, acetone, and glycerol, as well as of many simple organic acids. The first phase of industrial microbiology may be regarded, for simplicity, as the preparation of primary metabolites. This phase dates from the first attempts to obtain alcoholic drinks or organic acids up to around the middle of this century.

2. Isolation of Secondary Metabolites and Derived Processes

Penicillin was the first important secondary metabolite to be required in very large quantities. Its production led to the development of revolutionary new processes, which can be described collectively as sterile aerated submerged fermentation, and which allowed considerable simplification as compared with the extremely laborious sterile surface methods that were already known. The microorganisms are grown in aerated and stirred culture solution under constant conditions in large fermenters with effective capacities of 50000 to 250000 l, and there is no possibility of infection by extraneous organisms (for details, cf. [1–3]).

Many difficulties had to be overcome in the development of these processes:

1) The fermenter and the nutrient solution were sterilized by introducing superheated steam into the pipes and the fermenter, heating the culture solution as it flowed, and introducing the concentrated culture solution into the fermenter, the contents then being made up to the required volume with condensing steam.

2) The entire fermenter was kept sterile throughout the fermentation (which took several days) by ensuring that its internal pressure was slightly above atmospheric.

3) Sterilizable measuring equipment had to be developed.

4) For sterile foam reduction, automatic defoaming equipment was designed in which a sterile defoaming liquid was added to the substrate. The agents used are mainly fats, oils, higher fatty alcohols, and silicone oils.

5) The introduction of sterile air initially presented special difficulties. The air was first passed through wash towers containing acids, alkalis, or disinfectants, but was later forced through sterilizable glass wool-carbon filters.

The solution of these problems and the adaptation of microorganisms for submerged culture provided a fermentation method for the production of many other secondary metabolites as well as penicillin with the aid of microorganisms. The variety of products, which include most antibiotics, many enzymes, various alkaloids, polysaccharides, nucleotides, gibberellins, and various vitamins, frequently necessitated the design of new fermenters, and the result was an extremely diversified development.

The development of further microbiological processes naturally did not stop at the submerged process. Great interest was also stimulated in the production of laboratory shakers suitable for the cultivation of microorganisms under practically submerged conditions. Besides a number of variants based on the conventional principle, *e.g.* with constant temperature regulation, with special shaking speeds, *etc.*, completely new designs have also appeared. Because of the unfavorable center of gravity in conventional shakers, stabilization with several platforms (tablars) is often difficult. For this reason, *e.g.* the point of application of the drive in a new design by Infors AG (Basel/Switzerland) is situated exactly at the center of gravity of the moving upper part as well as of the counterweight.

Further work was also carried out on the surface process, which was still needed for the preparation of certain products. One example is the fermentation cup process (a method for surface culture) described by *Schröder* and *Brandl* (cf. [1]). These authors developed a sterile aerated surface process in which the

many laborious operations are largely combined and automated, *e.g.* automatic introduction of the culture medium, automatic sterilization of the many surface-growth dishes (making good use of experience gained in the submerged process), simple inoculation of the complete solution, possibility of sterile aeration, and simple temperature control (cf. Fig. 1).

3. Kinetics of Batch Submerged Fermentations

The submerged processes with their constant conditions for the growth of microorganisms made it possible for the first time to obtain really accurate information on the kinetics of the fermentation process. Since about 1946, and particularly since 1954, many articles dealing with this problem have been published.

3.1. Patterns of Development of the Microorganisms in the Fermenter

Whereas very long incubation times must be expected in normal microorganism cultures, the exponential phase of the growth of the microorganisms can be considerably prolonged and the incubation time shortened in the fermenter (cf. Fig. 2). Microbiological fermentations are influenced and characterized in particular by substrate consumption, occurrence of the end product, and development of the biomass. Movement of the substrate, aeration, accumulation and disappearance of intermediate products, and other factors such as temperature and pH changes, which can be relatively easily kept constant, are very important.

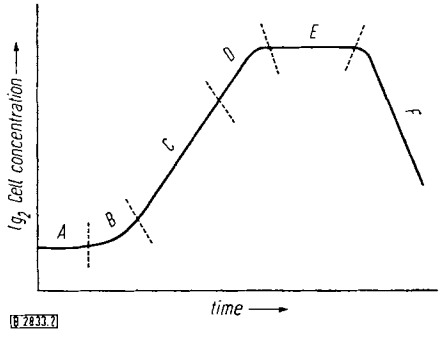

Fig. 2. Growth curve of bacteria (from [3]).
Various phases of development: A, incubation phase; B, acceleration phase; C, exponential growth phase; D, transition phase; E, stationary phase; F, lethal phase.

3.2. Patterns of Formation of the Fermentation Product

The fermentations are classified according to various rules. One classification that seems reasonable is that proposed by *E. L. Gaden* and *F. H. Deindorfer*, who distinguish three types (cf. [4]):

Type I: The main fermentation product is formed as a result of the primary energy metabolism. It is often formed on direct oxidation of the primary carbohydrate, *e.g.* in the alcoholic fermentation or the formation of lactic acid from glucose. The mass cultivation of many microorganism cells must also be regarded as fermentations of this type (Fig. 3a).

Type II: The main fermentation product is formed only indirectly from the energy metabolism. Examples are the formation of itaconic acid and of citric acid; the amino acid fermentations may also belong to this group. The reaction steps are complex, and inhibited or anomalous metabolism occurs. Figure 3b shows that the growth and the sugar consumption have two maxima. The specific yield curve

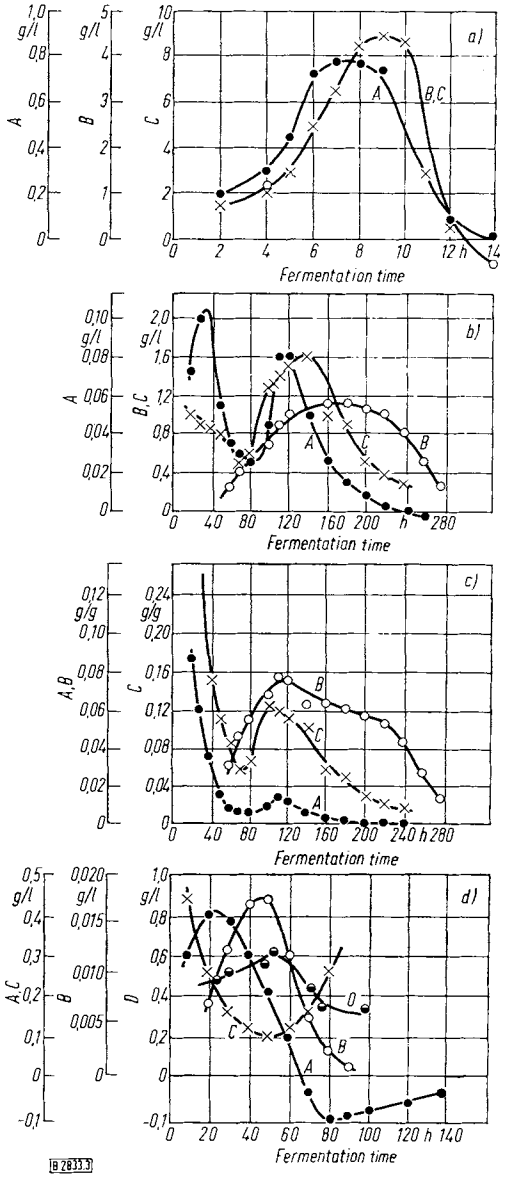

Fig. 3. Classification of fermentations according to *E. L. Gaden* and *F. H. Deindorfer* (cf. [4]).
a) Type I: Alcoholic fermentation. Volume growth rates; A, growth; B, alcohol synthesis; C, sugar consumption.
b) Type II: Citric acid formation. Volume growth rates; A, growth; B, citric acid formation; C, sugar consumption.
c) Type II: Citric acid formation. Specific growth rates; A, B, and C as in (b).
d) Type III: Penicillin formation. Volume growth rates; A, growth; B, penicillin formation; C, sugar consumption; D, oxygen absorption.

[4] *N. Blakebrough*: Biochemical and Biological Engineering Science, Vol. 1, Academic Press, London-New York 1967.

(Fig. 3c) shows that growth and sugar consumption are very closely related in the initial phase, whereas growth and product formation are closely related in the secondary phase.

Type III: This type of fermentation is found in all biosyntheses in which the main fermentation product is formed not from the energy metabolism, but relatively independently of it in the cell, *e.g.* in the formation of penicillin and streptomycin (Fig. 3d).

Thus, in Type I complex compounds are broken down into simpler compounds (catabolic processes), and in Type III complex molecules are formed from simple ones (biosyntheses, anabolic processes), while Type II lies between these.

4. Aeration of Microbiological Cultures

Aeration is one of the fundamental problems of aerobic microbiological fermentations. The oxygen requirement C of the cells varies widely, according to the nature of the microorganisms and the biochemical process taking place in the cells. The oxygen requirement per gram of newly formed dry cell substance [5] is:

$$C = A/Y - B$$

(A = theoretical quantity of oxygen necessary for the combustion of 1 g of substrate to CO_2, H_2O, and NH_3; B = theoretical quantity of oxygen necessary for the combustion of 1 g of dry cell substance to CO_2, H_2O, and NH_3; and Y = yield of dry cell substance per g of substrate consumed). The hourly consumption of oxygen per g of dry cell substance present Q_{O_2} is the product of the absolute oxygen requirement C and the growth rate k. For example, the hourly oxygen consumption for the formation of gluconic acid with *Pseudomonas ovalis* is 6.2 ml of O_2/100 ml h [6]. In the submerged formation of acetic acid by *Acetobacter suboxydans*, the oxygen consumption is 55 ml of O_2/100 ml h.

The rate of supply of oxygen is determined by the rate of transfer through the liquid film at the air bubble/nutrient solution interface. This transfer, and hence the entire oxygen supply, can be represented in the form of the general oxygen transfer equation (cf. [7,8]). The rate of oxygen transfer is thus the product of three factors:

1) The oxygen concentration gradient between the liquid film and the mass of the liquid (this concentration gradient is the driving force of the oxygen transfer).

2) The transfer area, which corresponds to the total surface area of all the gas bubbles present in the liquid.

3) A transfer coefficient, which is not a constant, but depends essentially on the thickness of the interfacial film and on the state of the interface.

The transfer rate is a maximum when the concentration of the oxygen dissolved in the liquid mass is zero, *i.e.* when the concentration gradient is greatest. However, the oxygen concentration must not fall to zero in cell cultures, but must always be greater than the critical oxygen concentration, at which the cell respiration starts to become affected. If the concentration of the dissolved oxygen is kept slightly above the critical value for the cells being grown, the rate of oxygen supply in cell cultures is optimal, and the capacity of an aeration system is fully utilized [9].

The development of oxygen-metering equipment has been greatly promoted by the fermentations. Many devices for the continuous determination of dissolved oxygen in fermentation cultures have been described in recent years. These make use of three principles:

1) paramagnetic measurements; 2) measurements based on the polarographic principle; and 3) measurements based on the galvanic principle.

Of the many aeration systems developed, the devices used for microbiological fermentations can be placed in the following basic groups (cf. *e.g.* [8]):

1) Bubble column fermenters. The air is finely distributed into individual bubbles at the base of the tank, and these ascend in the fermenter. The air is distributed in some cases by static (Fig. 4a) and in others by rotating (Fig. 4b) and oscillating (Fig. 4c) devices.

[9] *D. Hegner* and *H. Glossmann*, Z. Naturforsch. *20b*, 234 (1965).

2) Stirrer and air-jet fermenters. These have static fixed air distributors past which the liquid is pumped by built-in guide cylinders (principle of air lift pump) or stirrers (cf. Fig. 5).

3) Fermenter with rotating aerators. The air is distributed through hollow stirrers rotating at relatively high speed. Circular movement of the liquid is usually prevented by baffles on the walls of the container (cf. Fig. 6).

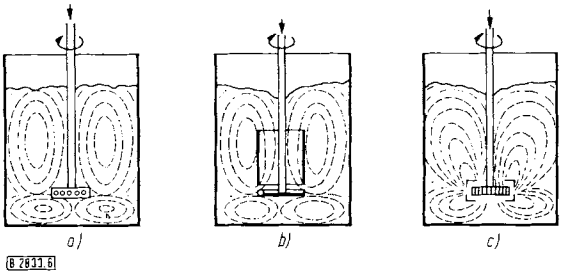

Fig. 6. Fermenters with rotating aerators.
a, hollow stirrer rotating freely; b, rotating aerator with guide cylinder; c, air sucked in by static inserts on the rotating aerator.

4) Shaking, rotating drum, vortex, and vibromix aeration. These types depend on movement of the culture liquid and absorption of oxygen from the air over the liquid (cf. Fig. 7).

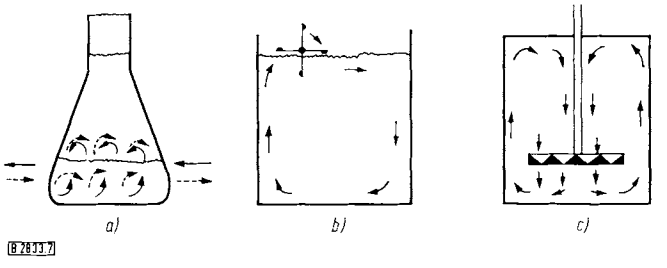

Fig. 7. Shaking, rotating drum, and vibro aeration (from [8]).
a, shaking flask; b, paddle aerator; c, vibromix aerator.

5) Surface aeration. In this case air is allowed to pass over the surface of the stationary culture solution (*e.g.* in the fermentation cup method) or is led past the solution by special devices (self-heating *e.g.* in the production of vinegar) (cf. Fig. 8).

It was only when a means of maintaining an adequate supply of oxygen to the microorganism cells in solutions had been found that it became possible to develop processes in which intensive biological oxidations could be carried out. Some examples are the sorbitol/sorbose oxidation with *Acetobacter* (including new biosyntheses for the production of vitamin C), the oxidation of ethanol to acetic acid, and many other oxidations with *Acetobacter* species, as well as steroid oxidations, particularly 11α-hydroxylations by microorganisms of various genera (*e.g.* for the production of cortisone/hydrocortisone or estrogen preparations), and finally oxidations of cardiac glycosides, antibiotics, and other substances.

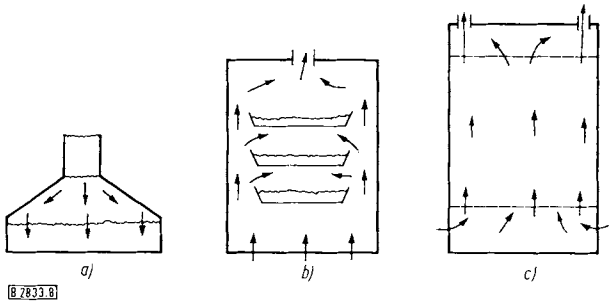

Fig. 8. Aeration of stationary surfaces.
a, stationary surface culture (Fernbach flask, penicillin flask); b, stationary surface culture (fermentation cups, enzyme production); c, filled tower.

5. Oxidations with High Oxygen Consumptions (Hydrocarbon Oxidations)

In the oxidation of steroids and of ethanol the microorganisms have a high oxygen consumption, but this can still just be satisfied by the aerators mentioned so far. Whereas only 33 moles of O_2 are consumed in the formation of 1 kg of cell material from 2.3 kg of glucose, about 75 moles of O_2 are necessary for the production of 1 kg of cell material from 1.1 kg of *n*-hexadecane [10]. This higher consumption is partly explained by the biochemistry of the oxidation of hydrocarbons. In this process a methyl group of a molecule that contains no oxygen is oxidized, first at one end and then possibly also at the other, to a carboxyl group, and ultimately, by continuous β or β and ω oxidation, to CO_2 and H_2O. If the degrading microorganisms are exposed to a reduced O_2 partial pressure, C_3, C_5, and C_7 fatty acids are formed in the substrate as intermediate products of incomplete degradation. For aromatic compounds we must first expect preoxidation, and then (as far as is known at present) three different types of ring cleavage, which can then lead by further oxidation to β-ketoadipic acid and finally also to CO_2 and H_2O.

The oxygen transfer in the four-phase system oil/water/microorganisms/air is a problem of primary importance. The more intensive the mixing of the air introduced with the substrate, the better is its utilization by the microorganisms. In many plants the air is finely emulsified in the substrate to provide the greatest possible surface and to allow optimum oxygen absorption for the oxidation of the hydrocarbons. Several types of fermenters have been developed for this purpose. In the multistage reactor of Chemap AG (Männedorf/Switzerland), for example, two-sided emulsifier wheels are fixed one above another on a central rotating shaft, and are surrounded by a multistage rotating tube with relatively fine outlet apertures (see Fig. 9). Midway between the wheels are large suction holes. At a speed of 2500 to 3000 rpm, the particle sizes of the insoluble phase are between 1 and 10 μm. The air supply can be increased to 5 v.v.m. [volumes of air/(volume of fermentation liquid × min)] in fermentations, so that oxidation

a, top bearing; b, cover; c, defoamer; d, reaction tube with emulsifier and suction holes; e, gas feed tube; f, double jacket; g, multistage propeller shaft with double-sided wheels; h, lower bearing; i, motor.

rates of 350 mmole/l h can be obtained. Other less complicated types allow aeration rates of 1 to 2 v.v.m. and oxidation rates of 150 to 200 mmole/l h.

The removal of the large quantities of foam formed during the extremely intensive aeration and motion is particularly important in such processes. When the usual defoaming agents are used, however, there is a danger of oxidation by the microorganisms (*e.g.* in the case of fats and oils), or else the substances must be separated later, and are also very expensive (silicone oils). A design that has given good results is a mechanical foam separator (cf. Fig. 10) in which inverted conical plates are fitted to a rotating hollow shaft. The defoaming action is increased by radial

a, motor; b, belt drive; c, slide ring seal, pressure equalizer; d, bearing; e, hollow shaft; f, rotating plate; g, foam inlet; h, liquid outlet; i, gas outlet; k, bearing housing with cooler; l, contents of tank.

baffles in the plates. The gas/liquid mixture passes upward in the fermenter into the rotating plate. Because of the speed of rotation, the liquid is thrown back into the fermenter vessel, while the lighter gas is forced through the hollow shaft and can escape.

Further problems are presented by the nature of the carbon source and the separation of the microorganisms from the oily substrate. Various industrial processes suitable for the oxidation of hydrocarbons can be derived from such biological fermentations with high oxidation rates, as is shown by the following examples:

1) One-step oxidation of pure paraffins. In these processes the paraffins have already been separated from other petroleum fractions. Such a process is currently being developed with yeast (species of *Candida* and *Torula*) by BP in Scotland.

2) One-step oxidation of paraffins without previous separation from the petroleum. The microorganisms in this case have the tasks of producing protein, *i.e.* cell material, on the one hand and freeing the petroleum from paraffins on the other. In a second stage the petroleum is processed further after separation of the microorganisms. BP are at present building a plant of this type in Southern France with a capacity of 16000 t/year, which is planned to start operation in 1970.

3) Multistage and complete microbial oxidation of petroleum. The long-chain paraffins are oxidized in the first stage, the cycloparaffins in the second, and the aromatic compounds in the third. Processes of this type are not very far advanced at present, and practical difficulties are being encountered because of the long times required for the oxidation of the aromatic compounds. One-step processes are also possible.

4) Production of metabolites (particularly secondary) from petroleum fractions. These processes are mostly one-step with respect to the carbon source. Paraffins that have already been separated from the petroleum are being used at present. The large-scale microbiological production of glutamic acid and 5'-nucleotides has already been in progress in Japan for several years. The industrial microbiological production of salicylic acid from naphthalene in the USA shows that there are also good prospects for the use of aromatic hydrocarbons as carbon sources for microorganisms.

These processes mark an entirely new development of microbiological fermentations. Many new secondary metabolites of microorganisms will soon be produced from hydrocarbons, and suitable processes for the various microorganisms and groups of substances will be devised.

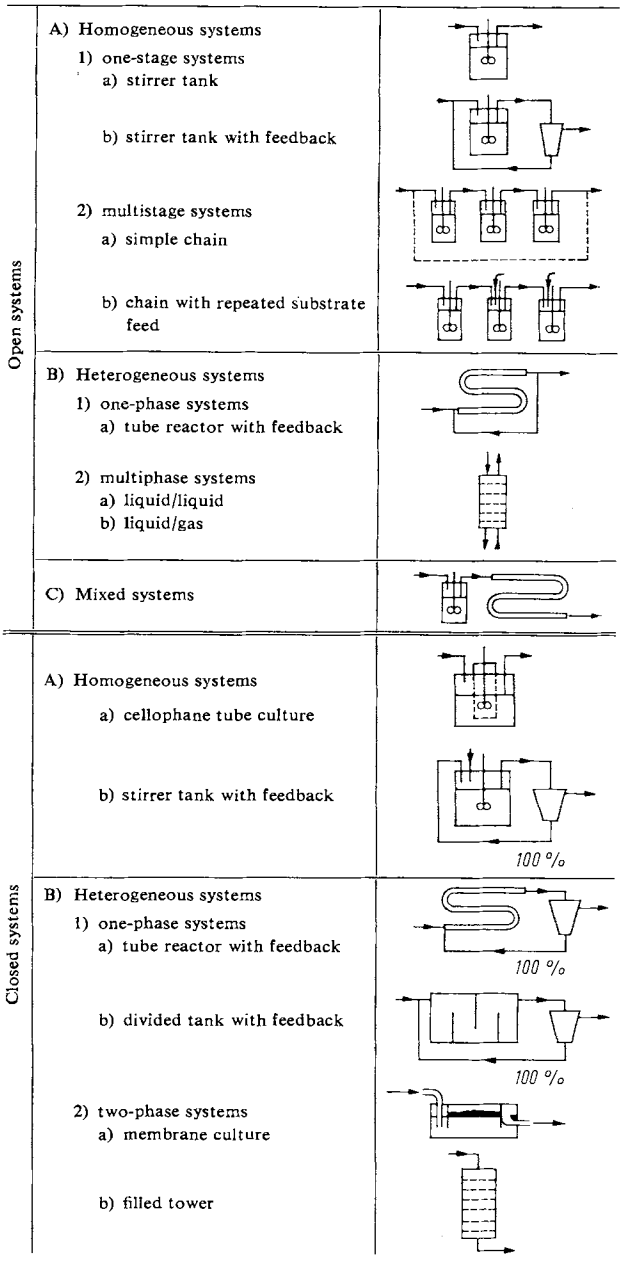
6. Promotion of Certain Phases of Microorganism Growth

Once the various phases of microorganism growth in industrial fermentation plants had been established, the next problem was to prolong the phase in which

the desired metabolite is formed as much as possible or to intensify activity in this phase in order to optimize the yield of this product and to minimize the often expensive secondary cultivation of cell material. Semicontinuous and continuous culture processes were developed for this purpose.

6.1. Semicontinuous Culture

The submerged culture mentioned earlier is carried out in batches, *i.e.* a tank is filled with substrate and inoculated. After the fermentation, the entire contents of the tank are emptied out and the operation is started anew. If part of the fermented solution is held back for inoculation of the fresh nutrient solution, the first step has been taken toward continuous fermentation, since part of the microorganisms grows continuously, provided that the fermentation of the "inoculation liquid" retained has not been interrupted.



A "semicontinuous process" of this type has proved effective *e.g.* for the production of vinegar, and has led to a complete change in the microbiological methods commonly used for this purpose [11]. In this process, which was developed by Messrs. Heinrich Frings (Bonn/Germany) only about 60% of the contents of the tank are discharged after the fermentation (*i.e.* the oxidation of ethanol to acetic acid) is complete, and the remaining 40% are left in the tank with the microorganisms (*Acetobacter suboxydans*). The tank is then refilled with fresh nutrient solution. Since the microorganisms are extremely sensitive to ethanol and acetic acid if insufficient oxygen is present, aeration is necessary during the discharging and refilling operations. An oxygen utilization of 70 to 80% is achieved by intensive mixing of air with the liquid. Using this method, vinegar can be produced with an acetic acid content of 12%. The alcohol content in the acetator is determined with an Alcograph, and when it reaches a value of 0.1 to 0.3% an automatic discharge mechanism is started up. This causes part of the contents of the tank to be drawn off, and fresh nutrient is added to the remainder.

6.2. Continuous Culture

If the fresh nutrient solution is added continuously instead of in batches, fermented nutrient solution must be drawn off at the same rate.

In one-stage continuous fermentation only a stirring fermenter is used (cf. Table 1). In this fermenter the growth of the microorganisms begins as in a batch plant. At a suitable moment, *e.g.* almost at the end of the exponential growth phase, fresh nutrient solution is allowed to flow into the tank, and an equal quantity of fermentation product is simultaneously allowed

Table 1. Continuous fermentation systems (from [3]).

to flow out. These methods are suitable for processes in which the object is to obtain either large quantities of microorganism cells or substances that are formed in the exponential growth phase.

In multi-stage continuous fermentation, a set of tanks are connected in series with one another. A fermentation is started up in the first tank, and the introduction of fresh substrate is started at a suitable instant. The overflow is not collected for isolation of the product, but is allowed to continue its fermentation in the second tank, until this is also full. A third tank is then filled with the overflow, and so on. In a series of this type one stage can be specially promoted, or suitable precursors may be added in certain stages.

There are also other continuous systems, among which filled towers (Table 1) are important in the fast production of vinegar, and will undoubtedly be important in the future for the fermentation of gaseous

[11] *H. Ebner* in: Arbeitsmethoden und aktuelle Ergebnisse der technischen Mikrobiologie. Fischer Verlag, Stuttgart 1967, p. 65.

products. In this system the microorganisms are grown on a solid support inside the tower. The nutrient solution trickles down over the microorganisms, and a gas (*e.g.* oxygen or gaseous hydrocarbons) is brought into contact with the microorganisms in countercurrent from the bottom. Two gases may also be used, *e.g.* a heavy gas from the top and a light gas from the bottom; in most cases a liquid must also be allowed to trickle downward as the nutrient solution.

Cellophane cultures or cultures in dialysis vessels are still difficult to carry out continuously for industrial purposes. The microorganisms are grown in the dialysis vessel (Cellophane) which is immersed in a tank containing concentrated nutrient solution. The nutrient solution diffuses through the Cellophane membrane to the microorganism culture under the influence of the concentration gradient, while the metabolites diffuse out.

A new thin layer fermentation plant has been developed by *Gorbach* [12]. The microorganisms are grown on rollers in a pipe system, which dips into a nutrient solution on rotating (cf. Fig. 11). The thin layers of microorganisms can be intensively aerated in this process. Removal of the metabolism products and the introduction of nutrients are also very easy. The plant, which operates continuously, can be considerably increased in size by the use of a large number of tubes, and can also be automated.

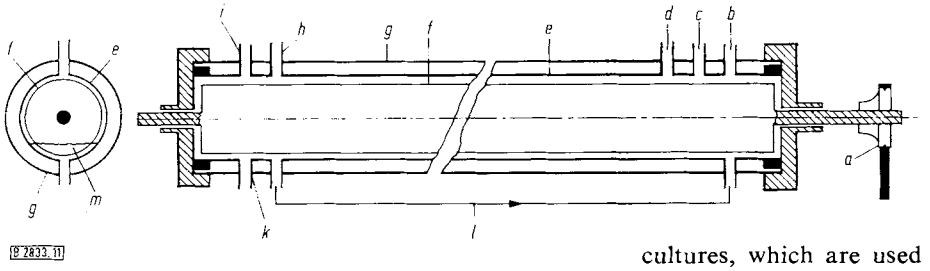


Fig. 11. Thin layer fermentation reactor (after [12]).

The trend toward continuous fermentation has resulted in a number of industrial developments. Since the periods of uninterrupted operation must be as long as possible, the provisions for sterility in the fermentation plants must be better than in plants for batch operation. The nutrient feed and the growth of the microorganisms must also be carefully matched. This is ensured by external or internal control systems. With external control systems the rate of growth of the microorganisms is kept somewhat below the maximum by limiting the nutrient concentration ("chemostat"). With the internal control system, which is particularly suitable for high growth rates, the density of the population is measured and used as a basis for the control of the feed of nutrient solution ("turbidostat"). In view of the many parameters involved in the continuous system, it seemed feasible to use analog computers to control and optimize the fermentation. Experiments with this in view have already yielded promising results.

Continuous processes have long been established in practice for the cultivation of cell material (yeasts, algae, *etc.*). However, they have so far been used only in a few sectors for the production of primary and secondary metabolites, though *e.g.* dextran, antibiotics, fermentation products (including beer), oxidation products, amino acids, vitamins, and organic acids can be produced continuously. Nevertheless, once our knowledge in this field has been extended, continuous fermentation will probably be preferred in the future.

7. Cultivation of Very Sensitive Cells

Since microbiological methods are used in the cultivation of cells and tissues, this is generally regarded as belonging to the realm of microbiology. Despite the difficulty of maintaining the sterility of the equipment for the production of suitable substrates, it is already possible to grow a whole range of animal cells and very sensitive microorganisms, *e.g.* tetanus bacilli (for antitoxin production), by submerged culture in fermenters. The animal cells are used for the cultivation of viruses or for the production of cell cultures, which are used in turn for the testing of cancer-inhibiting substances.

Vibration systems are used instead of stirring systems for the cultures, since the conventional propellor

a, motor; b, speed regulator; c, stirrer shaft; d, fermentation vessel; e, vibration plate; f, water jacket for cooling and heating; g, inoculation points (+ air inlet); h, opening for nutrient solution (↑ air inlet).

[12] *G. Gorbach*, Fette, Seife, Anstrichmittel *71*, 98 (1969).

stirrers would cause excessive damage to the cells. The action of the vibromixer shown in Figure 12 is based on the Bernoulli effect. Instead of a stirrer, the shaft inside the vessel is fitted with a plate having holes that taper in the downward direction. The plate is made to oscillate up and down, and so produces pressure differences in the holes, with the result that the liquid flows from the wide end to the narrow end of the holes. This ensures adequate movement of the cells and minimizes cell damage of the type caused by stirrers.

Since the metabolism products of growing cells are mostly the cause of cessation of growth of the cell cultures, *G. B. Gori*[13] developed a process for dialysis of the toxic metabolism products (see Fig. 13). A laboratory apparatus with an effective volume of 300 ml gives generation times of 40 to 50 h with high cell densities of up to 2.0 to 5.0 million cells/ml.

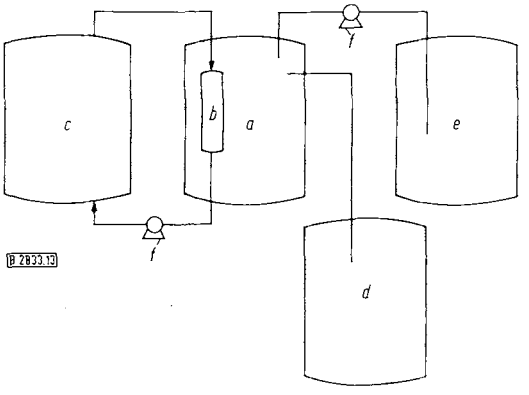

Fig. 13. Apparatus for continuous growth of animal cells in the submerged process with dialyzer (from [3]).

a, fermenter; b, dialysis membrane; c, reservoir for dialysis solution; d, reservoir for collected cells; e, reservoir for eluent; f, pumps.

The need for animal cells will undoubtedly increase greatly if it is desired to use apathogenically grown viruses which can only be cultured on animal cells, *e.g.* in aerosols for the mass immunization of whole population groups, as they are being used at present for the immunization of farm animals.

8. Continuous Culture of Hydrogen-Oxidizing Bacteria

Another group of microorganisms, known as hydrogen-oxidizing bacteria (species of *Hydrogenomonas*), can be used for the production of microorganism proteins. In a synthetic nutrient solution containing nitrogen, with CO_2 as the only carbon source and molecular hydrogen as the hydrogen donor, these bacteria produce organic substances, including proteins, as cell material under aerobic conditions. The oxidation proceeds with the aid of a hydrogenase in accordance with the following scheme:

$$\begin{array}{lll} 2\,H_2 + CO_2 & \rightarrow & (CH_2O) + H_2O \\ 4\,H_2 + 2\,O_2 & \rightarrow & 4\,H_2O \\ \hline H_2 + 2\,O_2 + CO_2 & \rightarrow & (CH_2O) + 5\,H_2O \end{array}$$

Thus the hydrogen-oxidizing reaction is carried out very slowly by the microorganisms. The resulting energy is used for the reduction of CO_2.

The introduction of the hydrogen-oxygen mixture into the bacterial culture in this fermentation is currently presenting a technical problem in large-scale plants. *Schlegel et al.*[14] have developed a continuously operating laboratory apparatus in which water is converted electrolytically into $H_2 + O_2$ in the nutrient solution itself, which contains no NaCl (cf. Fig. 14). Since some of the hydrogen is used for the reduction of CO_2, the corresponding part of the oxygen formed by electrolysis is available for other purposes. If CO_2 from the air were used in the plant, it could be developed as an air-regeneration system. Approximately 100 l of such a culture would be enough to regenerate the respiration air for one person. However, no suitable apparatus designs have been produced as yet.

a, storage vessel; b, pump; c, leveling vessel; d, magnetic valve; e, timer; f, contact; g, constant current source; h, H_2O electrolysis cell as fermenter; i, sampler; k, collecting vessel in cooling bath.

9. Production of Electrical Power by Microorganisms

Bacteria can change the redox potential of the nutrient substrate or its hydrogen-ion concentration, and can thus form a biological "half-cell" under certain

[13] *G. B. Gori*, Appl. Microbiol. *13*, 909 (1965).

[14] *H. G. Schlegel, F. Schuster*, and *Ch. König* in: Arbeitsmethoden und aktuelle Ergebnisse der technischen Mikrobiologie. Fischer Verlag, Stuttgart 1967, p. 73.

circumstances. A sterile medium can form another half-cell, which may be connected to the microorganism half-cell *e.g. via* a KCl/agar bridge to form an electric cell. The electric energy is produced by the metabolic activity of the microorganisms. Organic substances are oxidized, and the electrons ultimately flow to the oxygen.

Since the electron transport is not continuous but proceeds in steps, conditions must be provided such that a build-up of electrons is avoided, *i.e.* such that an electron flux occurs. A redox cell system with glucose as the substrate (combustion energy) and sea

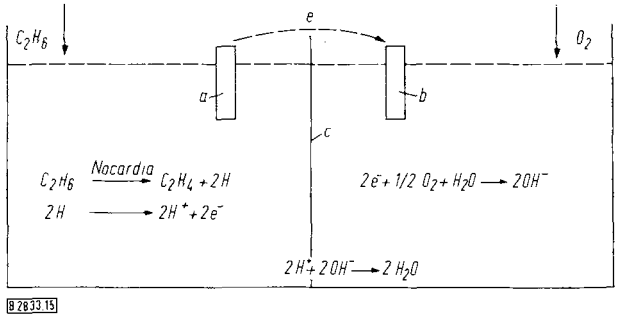

Fig. 15. Scheme of a cell for the biological production of energy (from [3]).

a, anode; b, cathode; c, semipermeable membrane.

water or other salt solutions as electrolytes may be regarded as a very simple form of half-cell (cf. Fig. 15). Gaseous hydrogen may be used instead of glucose as the fuel. Systems of this type have been tried with various microorganisms (*e.g. Escherichia coli, Desulfovibrio desulfuricans*, algae, and yeasts).

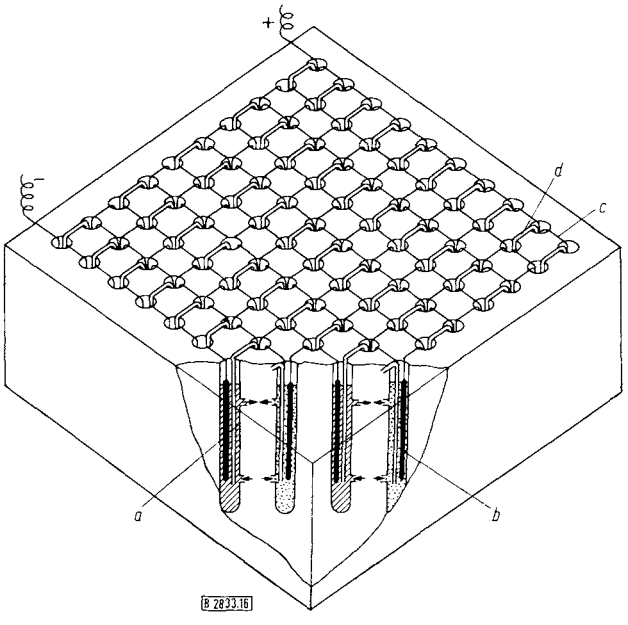

Fig. 16. System of biochemical-biological energy cells (from [3]).

a, tubes with reducing contents; b, tubes with oxidizing contents; e, wire; d, KCl/agar bridge.

Enzymes may be used instead of microorganisms. Thus a urease system by which NH_3 is formed from pure urea or from urine has proved suitable for this purpose. The anode consists *e.g.* of nickel, and the cathode is a glass cell with a fitted carbon stopper at the end, on which cathodic material such as aluminum is sprayed to produce an electrically active surface. An output of 20 W at 28 V has been obtained with a battery of 64 such cells (cf. *e.g.* Fig. 16). About 17 g of urea and 13.6 g of O_2/h were consumed over a working time of two weeks. Microbiological energy cells are still in the development stage at present, but they could be very important some day if naturally occurring reducing substances such as methane or ethane, or even effluent, could be used in this way for the direct production of electricity. This would present a totally new field of industrial microbiology.

10. Conclusions

In view of the quantity and diversity of the microbiological processes that are already being carried out, as well as those that seem promising or are still prospects for the "remote" future, it has only been possible to give a few examples in this review. Thus, no mention has been made of the mass growth of algae (which presents special technical problems), the submerged cultivation of mushrooms, attempts to obtain sulfur by industrial microbiological processes from water containing sulfate, sulfite, or hydrogen sulfide, and many other industrial microbiological processes. Many interesting metabolism products are being produced at present from and with the aid of microorganisms. However, there are also innumerable biochemical-microbiological reactions that could be utilized in practice, but which cannot be exploited at present. There are many reasons for this. One important reason is that most engineers who have the experience and know-how to develop an industrial microbiological process lack the necessary biochemical knowledge, while those who possess the biochemical knowledge do not know whether the development of these reactions might be of interest or which technical lines should be pursued. A future aim should therefore be to close the gaps by suitable training, to rise above classical fermentation technology, and to build up a modern science of biochemical-microbiological engineering.

NMR Spectroscopy of Paramagnetic Complexes

By Karl E. Schwarzhans[*]

Serviceable NMR spectra can, with a few exceptions [1,6], be recorded for paramagnetic complexes in solution. These spectra provide information about the structure of the complexes and the distribution of the unpaired electrons, and hence also about reactive centers in the molecule. The elucidation of intermolecular and intramolecular exchange phenomena, e.g. the determination of ligand exchange rate constants, the determination of rotation barriers, and the detection of contact complexes in solution, or even of occupation equilibria of the electrons, is possible in this way. It can be seen, therefore, that NMR studies on paramagnetic complexes can be a rich source of information.

1. Introduction

The investigation of paramagnetic compounds with the aid of nuclear magnetic resonance was ignored during the first decade of the application of this spectroscopic method to chemical problems. It is now known that NMR spectra can be recorded for nearly all paramagnetic complexes [1]; exceptions are rare. In general, however, the spectra of paramagnetic metal complexes are not so well resolved as those of corresponding diamagnetic compounds; nucleus-nucleus coupling is rarely observed is such spectra [2, 3]. The half-widths of the NMR signals are between 1 Hz and several thousand Hz for dissolved paramagnetic species. Like the half-widths, the shifts of the signals also extend in part over a range that is several orders of magnitude greater than for the analogous diamagnetic compounds [4]. Roughly speaking, the shifts behave in the same manner as the susceptibilities of these compounds.

The first report of an investigation on the ^{1}H-NMR spectra of (dissolved) paramagnetic complexes was published in 1958 [5]. Since then, the number of publications on this subject has increased to about 400. The theoretical principles of the application of NMR spectroscopy to the study of paramagnetic substances have been described by various authors (cf. *e.g.* [6–10]).

Several mechanisms have been detected by which the nuclei examined by NMR spectroscopy in metal complexes can be influenced by unpaired electrons. The effects can be roughly divided into two groups, *i.e.* signal shifts due to Fermi contact interactions and those due to pseudo-contact interactions. Since it is only possible occasionally to distinguish between the contributions of the various mechanisms to the total shift of a given NMR signal, it has recently been suggested [3] that signal shifts in the NMR spectra of paramagnetic compounds should be referred to generally as "Knight shifts" [11]. This name has the advantage that it does not specify any mechanism that contributes to or is alone responsible for the shift, as is the case in the terms "contact shift" and "pseudo-contact shift". The Knight shift is thus defined as the difference in shift between the signals of the paramagnetic complex and the corresponding diamagnetic model compound. This definition naturally excludes any effect of ligand exchange on the shift of the signal.

The mechanisms of electron-nucleus interaction that may be regarded as established for paramagnetic metal complexes will be outlined below.

1.1. Fermi Contact Interaction

The Fermi contact interaction is defined as the interaction of the nucleus in question with the density of unpaired electrons on the nucleus.

If this Fermi contact interaction essentially causes shielding of the nucleus in question, and hence a shift of its signal, "unpaired electron density" (also known as spin density) could conceivably reach the position of the resonating nucleus, or could in general reach the ligands of a paramagnetic metal complex, in the following ways:

(a) Unpaired d electrons of the metal fill unoccupied antibonding orbitals of the ligands that have σ- or π character. This mechanism is involved in particular

in the signal shifts in the NMR spectra of titanium(III) and vanadium(III) complexes[12]. Typical features pointing to an important contribution from this electron delocalization mechanism can also be found in the spectra of pyridine, pyridine *N*-oxide, and picoline adduct complexes of many 3d metals[13–15]. A particularly good example of the delocalization of spin density into the π system of the ligand is provided by the bis(2-amino-2,4,6-cycloheptatrieniminato)-nickel(II) complexes[16] (cf. Fig. 1).

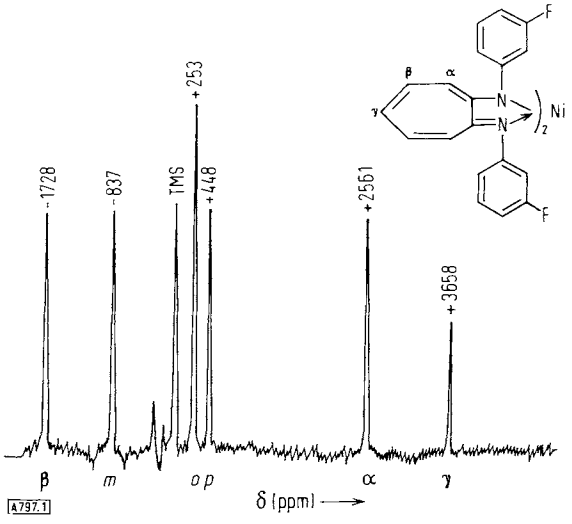

Fig. 1. ^{1}H-NMR spectrum of a bis(2-amino-2,4,6-cycloheptatrieniminato)nickel(II) complex in $CDCl_3$ (40 MHz).

These complexes are characterized by a very fast configuration change in solution between a square-planar diamagnetic form and a tetrahedral paramagnetic form. All the following mechanisms that can contribute to the Knight shift are averaged out by this process. The electrons of the C–H bonds are polarized by the free spin density[*] in the π system of the ligand in such a way that the spin density on the proton of the aromatic ligand is negative (shift to higher fields) for even numbers and alternately negative and positive (shift to lower fields) for odd numbers.

(b) Electrons in the highest occupied orbitals of the ligand or ligands are partly transferred into unoccupied or unfilled d orbitals of the metal. This transfer mechanism is possible in particular for the more highly charged ions of the 3d metals. A positive spin density also remains in the ligand orbitals, so that it is often practically impossible to distinguish between mechanisms (a) and (b).

(c) Partly occupied d orbitals of the metal overlap with occupied orbitals of ligand atoms having a sterically favorable arrangement, but which are not bonded directly (in the conventional sense of a chemical bond) to the metal atom or ion. This "direct interaction" is probably responsible *e.g.* for the strong negative shifts of the signals in the ^{1}H-NMR spectra of substituted and unsubstituted bis(cyclopentadienyl) complexes of vanadium(II) and chromium(II)[17]. In these compounds, positive spin density is transferred directly from the transition metal ion to the protons of the cyclopentadienyl rings, with the result that the signals of these protons are displaced by up to 360 ppm toward lower fields. Another very instructive example of the occurrence of a "direct interaction" is found in the ^{1}H-NMR spectra of iminodi(trimethyleniminomethyl-*o*-phenolato)-cobalt(II) (Fig. 2) and of the corresponding nickel(II) complex. Geminal protons in the alkyl chains of these compounds exhibit differences of up to 86 ppm in their shifts[18,19].

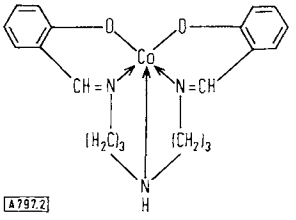

Fig. 2. Structural formula of iminodi(trimethyleniminomethyl-*o*-phenolato)cobalt(II).

Several reports dealing with the separation of the contributions of the types (a) to (c) to the Fermi contact shift for certain classes of complexes have been published during the past few years[12,20–26]. The clarification of this problem would enable information about the metal-ligand bond to be gained from the signal shifts of certain ligand nuclei.

1.2. Pseudo-Contact Interaction

The investigation of the NMR spectra of paramagnetic compounds is frequently made difficult by the fact that intramolecular (and also intermolecular in studies on solids) dipole-dipole interactions influence

the magnitude and sign of the shifts of the resonance signals in an extremely complicated manner that can only be determined in particularly simple cases. In complexes with extensive delocalization of electrons, the pseudo-contact contribution to the total shift of the resonance signals should be small, since the pseudo-contact model [27] is based on the assumption of a point charge localized on the central metal ion. It is not yet known, however, how much zero-field splitting, which is a property of all complexes with more than one unpaired electron, contributes to the pseudo-contact component of the shift. Information on this point should be obtainable from ESR experiments at very low temperatures [28].

2. Application and Results

Hetero-NMR measurements on paramagnetic complexes in solution have so far been confined to a few investigations on simple systems. For example, ^{17}O- and ^{14}N-NMR spectra of hexaaquo and hexaammine complexes respectively have been recorded for the determination of ligand exchange rates in these compounds [29, 30]. NMR experiments in which different types of atoms in a paramagnetic molecule are detected are therefore particularly interesting.

2.1. Investigations on Pyridine and Picoline Adducts of Bis(salicylaldehydato)iron(II), -cobalt(II), and -nickel(II)

Pyridine and simple methyl derivatives of pyridine form 2:1 adducts with paramagnetic bis(salicylaldehydato)metal(II) complexes, and these adducts are particularly suitable for NMR studies. They have a simple ligand system in a pseudo-octahedral arrangement, and are very readily soluble in organic solvents. The pyridine and picoline ligands readily undergo exchange with excess ligands, and this greatly facilitates the assignment of the resonance signals. Kinetic data for this exchange can also be determined from NMR studies.

2.1.1. ^1H-NMR Spectra

The data from the ^1H-NMR spectra of such adducts (Fig. 3) are presented in Tables 1 to 3. The assignment for the pyridine protons was possible on the basis of the signal intensities, by comparison of the spectra of the pyridine adducts with those of the β-picoline and γ-picoline adducts, and finally on the basis of the changes produced in the spectra by an exchange process on addition of small quantities of pyridine or picoline in excess. If the exchange frequency is very much greater than the difference in shift in Hz between the signals of the protons of the pyridine ligand in the paramagnetic complex and of free pyridine, an averaged signal appears in the NMR spectrum [31] at a position that depends on the ratio of the concentrations of the free ligand and of the complex. The ring protons of the salicylaldehyde ligands were assigned by comparison with the spectra of the derivatives with methyl substituents in position 3, 4, 5, or 6 of the ring [19]. The assumption that the symmetry of the complex changes only slightly on substitution appears to be confirmed by the invariance of the signal shifts of the pyridine and phenylene protons in the substituted and unsubstituted complexes.

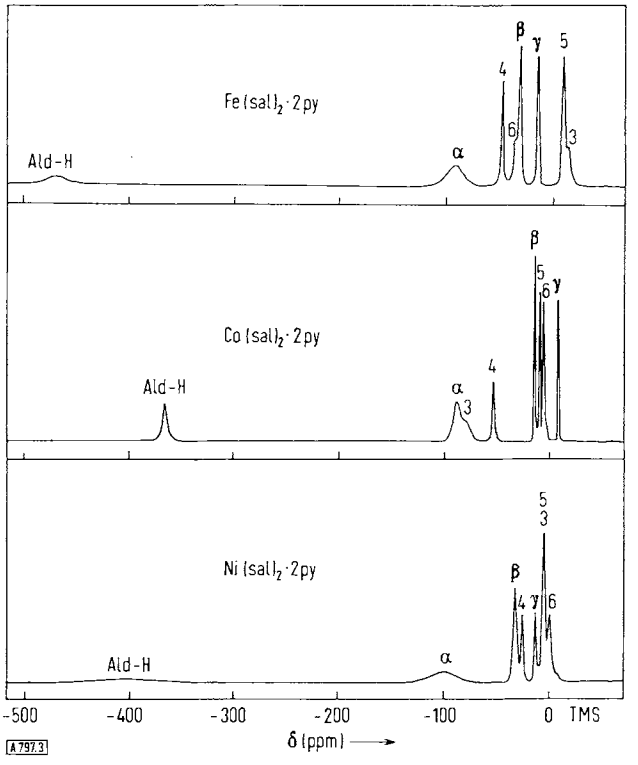

Fig. 3. ^1H-NMR spectra of bis(salicylaldehydato)bis(pyridine)metal(II) complexes in $CDCl_3$ (100 MHz).

The large shifts of the aldehydic protons, which change only slightly on substitution in the aromatic ring of the salicylaldehyde ligand are a characteristic feature of all the spectra.

Except in the case of complexes substituted in position 6 of the salicylaldehyde ligand (Fig. 4), the equivalent protons of the ligands generally give only one NMR signal. Methylation in position 6 evidently leads to moderate distortion of the complex. Separate resonance signals are found both for the two CH_3 groups and for the two aldehydic protons. A much greater distortion of the complex should be observed on replacement of the pyridine ligand by α-picoline.

However, no 2:1 adduct of α-picoline with any of the bis(salicylaldehydato)metal(II) complexes has yet been obtained. Axial entry of the α-picoline is presumably impossible in these compounds on steric grounds. If, however, measurements are carried out on an exchange system with α-picoline in solution together with bis(salicylaldehydato)bis(pyridine)-cobalt(II), all the proton resonance signals of the salicylaldehyde ligands split into doublets. The two aldehyde ligands in the complex are thus no longer magnetically equivalent, *i.e.* the symmetry of the dissolved complex is reduced. NMR studies on paramagnetic compounds can thus also serve as a sensitive test for changes in the geometry of the arrangement of the ligands, since the Knight shifts of the resonance signals, as was mentioned earlier, are strongly dependent on the arrangement of the ligands with respect to the central metal ion.

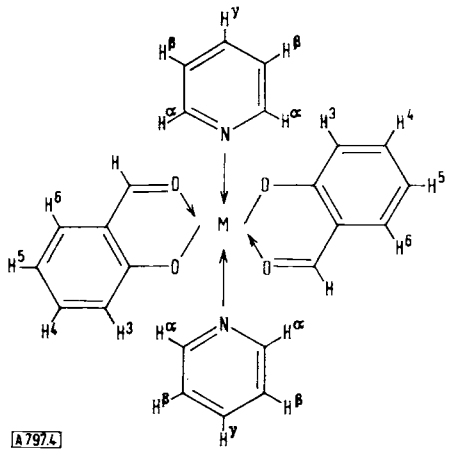

Fig. 4. Scheme of the structure of bis(salicylaldehydato)bis(pyridine) metal(II) complexes.

In a purely qualitative consideration of the ^{1}H-NMR shifts of this type of complex, the highest spin density is to be expected on the aldehyde grouping of the salicylaldehyde ligand. This position in the molecule should be particularly suitable for a free-radical reaction. The complexed salicylaldehyde is in fact oxidized by air to salicylic acid [32].

2.1.2. ^{14}N-NMR Spectra

The ^{14}N-NMR spectra of the bis(salicylaldehydato)-bis(pyridine)metal(II) complexes of iron, cobalt, and nickel could not be recorded with the pure compounds in solution. An important reason for this is the fact that the spectral sensitivity of the ^{14}N nucleus is lower by a factor of 10^3 than that of the proton. The complexes contain only a little nitrogen (about 6.1 %), so that even concentrated samples contain only a few ^{14}N nuclei. Moreover, because of the undoubtedly high spin density on the nitrogen atoms to be considered, the ^{14}N resonance signal is expected to be very broad [19]. It was possible to avoid both of these difficulties by measurements on the complex under the conditions of the exchange with excess pyridine. If the ^{14}N-NMR spectrum of pyridine is recorded with the addition of various quantities of the bis(salicylaldehydato)bis(pyridine)metal(II) complex, the shift of the ^{14}N signal varies linearly with the concentration of the complex in the case of the iron and cobalt compounds; for the analogous nickel compound, on the other hand, the ligand exchange rate constant must be much smaller. A Knight shift of −7800 ppm can be extrapolated for the Fe^{II} complex, and −5400 ppm for the Co^{II} complex, from the concentration dependence of the ^{14}N signals.

The ligand exchange rate constants found from these spectra, which merely indicate a lower limit for the exchange rate [33], differ only slightly for the two complexes ($k_{Fe^{II}} = 2.0 \times 10^5$, $k_{Co^{II}} = 1.8 \times 10^5$ Hz) [19]. The fall in rate constant from iron to nickel for exchange reactions on pseudo-octahedral complexes is a well-known phenomenon, and is associated with the ligand field stabilization energy in the trigonal-bipyramidal transition state [19, 34].

2.2. ^{1}H-NMR Studies on a Dimethylacetamide Adduct of Uranium Tetrabromide

Dimethylacetamide forms a 4:1 adduct with uranium tetrabromide. It was uncertain at first whether the bonding to the central metal ion occurs *via* the nitrogen or the oxygen atom of the ligand. Rotation about the C–N bond in free dimethylacetamide is hindered at room temperature; the two methyl groups on the nitrogen give different ^{1}H-NMR signals, showing that their chemical environments are different. If the spectrum is recorded at various temperatures the two signals of the $N-CH_3$ groups fuse at 49.8 °C, from which the height of the rotation barrier is found to be 12 ± 2 kcal [35].

Exactly the same behavior is found in the spectrum of the adduct. The two ^{1}H-NMR signals of the $N-CH_3$ groups, which are separated at lower temperatures, unite at 50 °C (Fig. 5). The height of the rotation barrier is therefore unchanged by the complex formation, and it follows that the dimethylacetamide cannot be bonded to the uranium ion *via* the nitrogen atom [36].

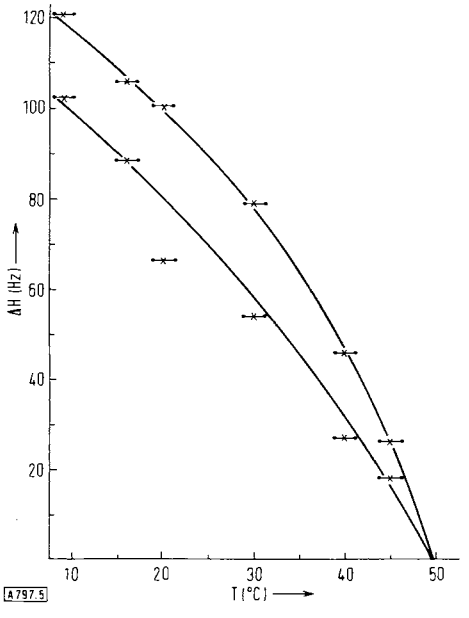

Fig. 5. Temperature dependence of the ^{1}H-NMR signal shifts of the $N-CH_3$ groups of dimethylacetamide in $(C_4H_9ON)_4UBr_4$ (dissolved in CH_2Br_2; 100 MHz).

Because of the greater signal shifts in the ^{1}H-NMR spectra of the diamagnetic tetrabutylammonium and tetraphenylarsonium cations in solutions containing paramagnetic complex anions, such as hexacyanoferrate(III) or tetrachloroniccolate(II), a number of authors [37–42] postulated the presence of "ion pairs". The unusual signal shifts were attributed to pseudo-contact interaction, which depends on the *g*-factor anisotropy of the unpaired electrons and on the distance and the fixed steric relation between the ions [6].

However, there are three serious objections to such an interpretation of the ^{1}H-NMR spectra on the basis of ion associates of this nature:

(a) All the paramagnetic anions and diamagnetic cations investigated have approximately spherical symmetry. There is therefore no reason to insist on a preferred steric arrangement for the ions in solution over a long measuring period, which would be fundamentally necessary in order to be able to observe pseudo-contact shifts. Without a sufficiently long-lasting, definite relation between the paramagnetic ion and the nucleus that is interacting magnetically with it, the dipole-dipole contribution to the signal shift is averaged out. It is clear from the ^{1}H-NMR spectra of the ion associates, however, that a very much faster ion exchange takes place in the solution when the diamagnetic cation is present in excess.

(b) The octahedral and tetrahedral symmetries of the hexacyanoferrate(III), hexacyanochromate(III), and tetrachloroniccolate(II) anions [43] do not allow any anisotropy of the *g* factor, which is also an assumption for pseudo-contact interaction.

(c) In complexes with strong delocalization of electrons, as was mentioned in Section 1.2, the pseudo-contact contribution to the signal shift should be small or zero [27]. At least for the complex anions triiodotriphenylphosphanecobaltate(II) and triiodotriphenylphosphaneniccolate(II), however, the large shifts of the ^{1}H-NMR signals of the aromatic protons of the triphenylphosphane ligands point to strong delocalization of electrons in these compounds.

2.3.1. ^{1}H-, ^{14}N-, and ^{31}P–NMR Spectra

The ^{1}H-NMR spectra recorded for the diamagnetic cations of the ion associates (given in Table 4 for the tetrabutylammonium salt of triiodotriphenylphosphanecobaltate(II) at various concentrations) can be satisfactorily explained only if one postulates a direct transfer of spin density from the central metal ion of the anionic complex *e.g.* to the ammonium nitrogen atom.

Table 4. ^{1}H and ^{14}N Knight shifts (in ppm) of $(C_4H_9)_4N^+$ in $[(C_4H_9)_4N][CoI_3(C_6H_5)_3P]$ (dissolved in $CDCl_3$; 100 and 7.22 MHz).

0.002	8.4	4.5	2.8	0.9	–
0.001	8.0	4.3	2.6	0.9	–

The monotonic decrease in the spin density transmitted along the σ bond skeleton of the carbon chain from the α- to the ω-C atom is typical of alkyl chains in paramagnetic transition metal complexes [44]. In $(C_4H_9)_4N^+$, the highest density of unpaired electrons should be localized on the nitrogen. On correct application of the pseudo-contact model [5, 27], a signal shift toward higher fields is to be expected for the nitrogen of the diamagnetic tetrabutylammonium ion [37]. In the case of a direct transfer of unpaired electrons from the central metal ion to the nitrogen atom, however, the ^{14}N resonance signal must be displaced to lower fields (negative sign) [42]. The positive spin density on the nitrogen atom would then pass over to the adjacent α-CH_2 group by configuration interaction [6].

Only shifts with negative signs were found for the ^{14}N and ^{31}P signals in the spectra of the ion associates with ammonium and phosphonium cations (Table 5).

Table 5. ^{14}N and ^{31}P Knight shifts of the diamagnetic cation in the ion associate (dissolved in $CDCl_3$; 7.22 and 40.5 MHz).

Compound	*c* (mole/l)	Shift (ppm) ^{14}N	Shift (ppm) ^{31}P
$[(C_4H_9)_4N]$ $[CoI_3(C_6H_5)_3P]$	0.53	−13	–
$[(C_4H_9)_4N]$ $[NiI_3(C_6H_5)_3P]$	0.52	− 7.1	–

2.3.2. Discussion

The negative signal shifts that are always found in the ^{14}N- and ^{31}P-NMR spectra of the cations (Table 5) clearly show the transfer of positive spin density from the central metal ion of the anionic complex to the nitrogen or phosphorus atom. It can also be seen from Table 4 that the position of the ^{1}H-NMR signals of the cation is strongly dependent on the concentration, whereas the Knight shifts of the anion remain

constant over the entire concentration range investigated. This is true of all the ion associates studied. In Figure 6, there are three easily recognizable regions at concentrations below 0.2 mole/l, in which the ratio of the change in shift to the change in concentration assumes different values.

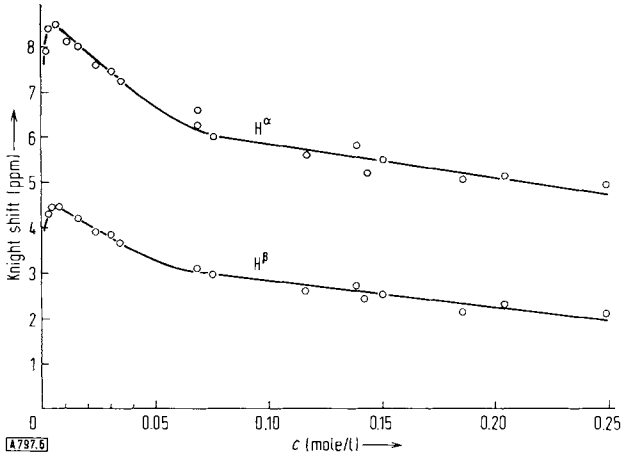

Fig. 6. Concentration dependence of the Knight shifts of the α and β protons of the tetrabutylammonium ion in $[C_4H_9)_4N][CoI_3(C_6H_5)_3P]$ (dissolved in $CDCl_3$).

This observation points to the presence of higher aggregates (associates), and is not compatible with the existence of "ion pairs" in solution. Such associates may be expected in solvents having low dielectric constants at relatively high salt concentrations [45]. There appear to be several definite aggregates, which evidently differ in their stability, and each of which is stable in a given concentration range.

2.4. ^{1}H-NMR Studies on the Occupation Equilibrium of the Electrons in Bis[4-(2-pyridyl)-2-(2-pyridylamino)-thiazolato]iron(II)

Complexes in which a temperature-dependent occupation equilibrium exists between the electronic ground state and nearby excited states are of interest in biochemistry. Examples of compounds belonging to this class are in the iron-porphyrin complexes, whose term diagrams show a change in the ground state with the nature of the other ligands as a result of crossover of two terms. The NMR-spectroscopic investigation of the anomalous magnetic behavior of such complexes is frequently found to be very difficult because of their extremely low solubility.

This anomalous magnetic behavior has been observed and studied by NMR spectroscopy for the electron configuration d^5 in dithiocarbamatoiron(III) complexes [46] and for the configuration d^7 in some chelate complexes of cobalt(II) iodide [47]. No example of such an anomaly is known as yet for the electron configuration d^4, while an iron(II) complex will be described here as a typical and confirmed example with the configuration d^6.

Though the anomalous magnetic properties of several bis(*o*-phenanthroline)iron(II) complexes [48] have been interpreted as a temperature-dependent quintet-singlet occupation equilibrium, the sudden change in the effective magnetic moment of these compounds at a certain temperature is definitely due to a phase change, *i.e.* to an intermolecular effect.

The complex bis[4-(2-pyridyl)-2-(2-pyridylamino)-thiazolato]iron(II) exhibits a characteristic decrease in its effective magnetic moment with falling temperature [49]. μ_{eff} is 4.96 μ_B at room temperature and 1.55 μ_B at −170 °C, and decreases steadily in the intervening range. If this behavior is due to an intramolecular effect, it can only be explained by the existence of a singlet-quintet occupation equilibrium, naturally with participation of interjacent triplet states in accordance with their energy levels. On the basis of the IR spectra recorded at various temperatures, it was possible to show that the magnetic anomalies of bis-[4-(2-pyridyl)-2-(2-pyridylamino)thiazolato]iron(II) are not due to any intermolecular effect [50]. Where a temperature-dependent occupation equilibrium exists between the singlet ground state and the lowest quintet state, the NMR spectra of the compound must show characteristic changes with temperature. The Knight shifts of the resonance signals of a paramagnetic compound are directly proportional to the density of the unpaired electrons on the nucleus in question, and inversely proportional to the absolute temperature [6–10]. Thus the signal shifts in the NMR spectra of paramagnetic substances normally increase with falling temperature. In our example, the effective magnetic moment decreases slowly with falling temperature, *i.e.* the singlet state becomes more highly populated and the free spin density in the molecule as a whole decreases. Two opposing effects are therefore operative in the spectrum of such a complex. In bis[4-(2-pyridyl)-2-(2-pyridylamino)-thiazolato]iron(II) at room temperature, the quintet state is predominantly populated (μ_{eff} = 4.96 μ_B). The Knight shifts of the resonance signals will therefore initially become larger with falling temperature, as is to be expected for any magnetically normal paramagnetic complex. Ultimately, however, the occupation of the singlet ground state becomes so high that the direction of the signal shift in the NMR spectrum is reversed; the Knight shifts thus pass through a maximum on cooling. The shifts then decrease rapidly with further population of the singlet ground state. This effect is shown in Table 6 for seven ^{1}H-NMR signals of the complex in question in the temperature range between +30 and −60 °C.

Table 6. Shifts of the ^{1}H-NMR signals 1 to 7 of bis[4-(2-pyridyl)-2-(2-pyridylamino)thiazolato]iron(II) in relation to TMS (internal) toward lower fields with falling temperature (100 MHz).

T (°C)	Knight shift (Hz)					
	1	2	3	4	5/6	7
30	4630	4410	2810	2580	2210	865
20	4980	4700	2930	2695	2280	860
10	5120	4800	3020	2740	2380	915
0	5150	4850	3040	2780	2405	915
−10	5220	4880	3050	2820	2450	(960?)
−20	5245	4900	3050	2840	2450	915
−30	5120	4815	3000	2790	2410	905
−40	4970	4700	2920	2780	2405	875
−50	4600	4300	2645	2565	2210	750
−60	4200	4200	2350	2350	2020	660

The signal shifts of the protons, which are not assigned, are measured in Hz. All the resonance signals pass through a maximum at −20 °C. The variation of the shifts (measured in solution) with falling temperature is directly parallel to the molar susceptibility (measured in the solid state [49]). These experimentally observed anomalies of bis[4-(2-pyridyl)-2-(2-pyridylamino)thiazolato]iron(II) are thus not due to an intermolecular effect, but they can be plausibly explained by a temperature-dependent occupation equilibrium of the electrons between the $^1A_1$ ground state and the energetically nearby excited $^5T_2$ state, *i.e.* by an intramolecular effect.

I am grateful to Dr. W. Gretner for his assistance with the work carried out by our own research group. I thank Dr. H. J. Keller for many valuable discussions, and the Principals of the Inorganic Chemistry Laboratories of the Technische Universität München, Professor H. P. Fritz and Professor E. O. Fischer, for the opportunity to use the NMR spectrometer. Thanks are due to the Deutsche Forschungsgemeinschaft for financial support.

Photoelectron Spectrum of Cyclobutane[1]

By *Peter Bischof, Edwin Haselbach,* and *Edgar Heilbronner*[*]

The vertical ionization potentials I_v of cyclobutane C_4H_8, as determined from the photoelectron spectrum[2], are listed in Table 1. An assignment to orbitals of particular symmetry can be performed, assuming the validity of Koopmans' theorem[3], on the basis of the orbital energies $\varepsilon = -I_v$ obtained for cyclobutane by a SCF *ab initio* technique[4], by the MINDO/2 method[5], or by the extended Hückel theory (EHT)[6] (see Table 1).

The *ab initio* and EHT results, which were made available to us by *L. Salem* and *J. S. Wright* (cf. ref. [7]), are based on the following structural parameters: Symmetry D_{4h}; C–C = 1.556 Å; C–H = 1.095 Å, ∢ HCH = 116 °[8]. In the MINDO/2 method the total energy of the cyclobutane molecule was minimized without any restriction of the topography except for C–H = 1.093 Å and HCH = 120 °. In this case, the calculation yields a D_{4h} structure with C–C = 1.534 Å within the convergence criteria of the minimization process. It should be noted that a D_{2d} structure is found experimentally for cyclobutane[9]. For this reason the classification of the orbitals according to D_{2d} symmetry is also included in Table 1.

Table 1. Vertical ionization potentials and orbital energies of cyclobutane.

Orbital		I_v (eV) ±0.1 eV	Calculated orbital energies (eV)			Orbital character
D_{4h}	D_{2d}		*ab initio* [a]	MINDO/2	EHT [a]	
$3e_u$	4e	10.7 [b]; 11.3 (JT) [c]	−10.50	− 9.88	−12.83	mixed; Walsh type
$1b_{1u}$	$4a_1$	11.7	−11.82	−10.35	−13.92	CH_2 (π)
$1b_{1g}$	$1b_1$	12.5	−12.47	−11.93	−14.09	CC (σ)
$1e_g$	3e	13.4; 13.6 (JT) [c]	−14.38	−13.17	−15.36	CH_2 (π)
$3a_{1g}$	$3a_1$	15.9	−16.05	−15.23	−15.68	$CH_2(\sigma)+CC(\sigma)$
$3a_{2u}$	$3b_2$	18.2	−17.53	−17.94	−16.81	CH_2 (π)

[a] See ref. [4]. [b] Electron impact value: 10.58 eV, cf. [13]. [c] Jahn-Teller splitting.

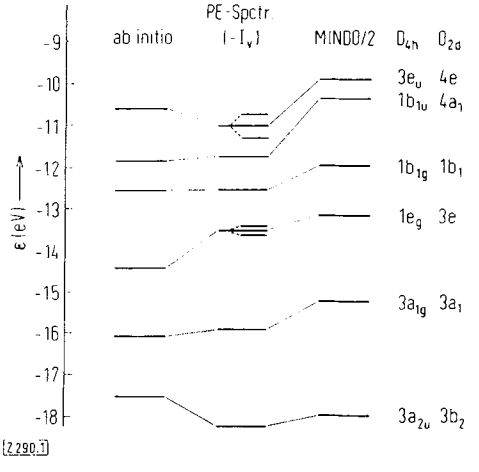

Fig. 1. Comparison of the calculated SCF orbital energies ε with the vertical ionization potential $I_v = -\varepsilon$ of cyclobutane.

As shown by the correlation diagram (Fig. 1), the experimental values are in excellent agreement with the calculated *ab initio* and MINDO/2 data. The reasonable results obtained from the EHT model are probably due to the high degree of symmetry of the molecule. As predicted, the first band in the PE spectrum (at 11 eV) is split into two partial bands separated by about 0.6 eV. Since the photoelectron vacates a degenerate orbital ($3e_u$ or 4e), the radical cation $C_4H_8^+$ must be subject to a Jahn-Teller distortion in its electronic ground state, which leads to the observed splitting. (Compare the analogous behavior of cyclopropane[10].) Similarly, the form of the band at 13.5 eV seems to indicate a small splitting of 0.2 eV, which would agree with the theoretical prediction that in this case the photoelectron is ejected from the $1e_g$ (or 3e) orbital. It should be noted that the PE spectroscopic findings confirm the prediction[7] that, by analogy to the situation prevailing in cyclopropane[10, 11], the highest occupied orbital in cyclobutane is also degenerate and can consequently be regarded as a kind of Walsh orbital.

The structure of the radical cation $C_4H_8^+$ (in the electronic ground state) has been studied in the course of an investi-

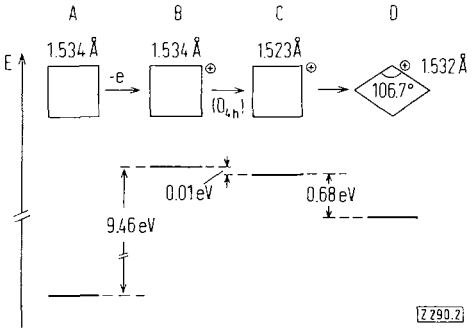

Fig. 2. Jahn-Teller distortion of the cyclobutane radical cation.

gation into the nature and extent of the Jahn-Teller distortion in the radical cations of cyclopropane and allene [12].

The results are summarized in Fig. 2. If the total energy of $C_4H_8^+$ (B) is calculated by MINDO/2 with the equilibrium distances found for C_4H_8 (A), the difference in the heats of formation yield a vertical ionization potential of 9.46 eV, *i.e.* 0.4 eV smaller than the value found from the orbital energies of A using Koopmans' theorem (see Table 1). If the total energy of $C_4H_8^+$ is minimized under the restrictive condition that the D_{4h} symmetry, the C—H distances, and the HCH angles are conserved, then the C—C distance is reduced to 1.523 Å and the system becomes more stable by 0.01 eV: B→C. Minimization without restricting the system to D_{4h} symmetry leads to a considerable gain in energy of 0.68 eV and the molecule distorts to a D_{2h} conformation (C→D in Fig. 2). If the structural parameters thus obtained are applied to a neutral cyclobutane molecule (*i.e.* a cyclobutane having a structure which corresponds to that of the radical cation D), the degeneracy of the $3e_u$ orbital of A is lifted and a Jahn-Teller splitting of 2.6 eV is predicted (regarding the discrepancy between this theoretical value and the experimental Jahn-Teller splitting of 0.6 eV (Table 1) cf. ref. [12]).

To conclude it should be noted that the theory predicts a shortening of the C—C bond as a consequence of ionization. It appears that in the cyclobutane radical cation ionization leads to a weakening of those repulsive interactions between diagonally opposed C centers which are considered responsible for the abnormally long C—C bonds in neutral cyclobutane [14].

Substituted Ethylenediazonium Salts

By *Kaspar Bott* [*]

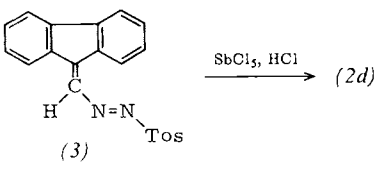
In contrast to the large number of known aromatic diazonium compounds, only 2,2-diethoxyethylenediazonium hexachloroantimonate [1] and the diazonium chelates derived from β-diketones [2, 3] have been described in the aliphatic series. By the action of antimony pentachloride on the *p*-toluenesulfonylhydrazones *(1)* of α-halo aldehydes we have found a simple and efficient synthesis (75—90% yields) of ethylenediazonium hexachloroantimonates *(2)*; their stabilities depend considerably on the nature of the residues R^1 and R^2.

Antimony pentafluoride, aluminum chloride, or tin tetrachloride may be used instead of antimony pentachloride, though the resulting salts do not crystallize so well as the hexachloroantimonates *(2)* [4]. As a variant of the scheme given above, the 2,2-(2,2'-biphenylylene)ethylenediazonium salt *(2d)* can also be synthesized from the halogen-free 9-fluorenecarbaldehyde toluenesulfonylhydrazone, the antimony pentachloride then acting both as oxidant and as complexing agent.

	R^1	R^2	Decomp. pt. (°C)	Color	IR: asym. $-N\equiv N$ (cm^{-1})
(2a)	Cl	Cl	above 116	colorless	2241 [a]
(2b) [b]	Br	Br	58	pale yellow	2238 [c]
(2c) [d]	Cl	$(CH_3)_3C$	86—87	colorless	2240 [e]
(2d)	2,2'-biphenylylene		95—96	deep green	2218 [f]
(2e) [d]	Cl	*p*-$CH_3O-C_6H_4$	112	yellowish-brown	2200 [f]

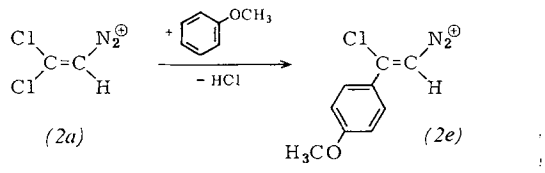
[a] In methylene dichloride.

[b] According to elemental analysis the anion consists of $SbCl_6$ (70%) and $SbCl_5Br$ (30%).



[c] In 1,2-dichloroethane.

[d] The NMR spectrum indicates the existence of only one isomer.



[e] Solid in Nujol.

[f] In nitrobenzene.

Formation of the compounds *(2a)* to *(2c)* probably occurs analogously to the *Chattaway* reaction [5] *via* an azo sulfone intermediate, the toluenesulfinate group being split off later. Further variants of this reaction sequence, leading to acetylenes, have been described by other authors [6–8]. The sulfonylhydrazone *(1d)*, Hal = Br, of 9-bromo-9-fluorenecarbaldehyde loses hydrogen bromide even during its preparation in ethanol, and the sulfonylazofulvene *(3)*, m.p. 125—126 °C, that can be isolated is converted by the Lewis acid and hydrogen chloride almost quantitatively into *(2d)*.

According to its strikingly short-wavelength N—N absorption band, the substance *(2a)*, which is the most stable of the series, has the greatest reactivity towards "basic" compounds[9]. Even below room temperature *(2a)* reacts with

anisole to give a 61% yield of the 2-chloro-2-(*p*-methoxyphenyl)ethylenediazonium compound *(2e)*; in reactions of the diazonium ion of *(2a)* "azo coupling" is apparently suppressed in favor of attack on the β-carbon atom.

2-tert-Butyl-2-chloroethylenediazonium hexachloroantimonate (2c)

A solution of 2,2-dichloro-3,3-dimethylbutyraldehyde *p*-toluenesulfonylhydrazone, m.p. 91 °C, (6.74 g) in methylene dichloride (30 ml) is added dropwise to a mixture of antimony pentachloride (13.5 g), methylene dichloride (30 ml), and carbon tetrachloride (60 ml) at 20 °C. After the mixture has been kept for 18 h at 0 °C, crude *(2c)* (93%) is filtered off; it is purified by dissolution in 1,2-dichloroethane (200 ml) and by precipitation with carbon tetrachloride (250 ml).

Cyclizing Condensation of 3,4-Pyrroledicarbaldehydes with Compounds Containing Acidic CH and NH Groups[1,2]

By *Richard Kreher* and *Günther Vogt*[*]

Bicyclic systems containing 3,4-fused pyrrole rings[1,4] have been synthesized by cyclizing condensation of 3,4-pyrroledicarbaldehydes with 1,3-bifunctional compounds containing acidic CH groups[3]. Building on this, we have now condensed 1,2,5-trimethyl-3,4-pyrroledicarbaldehyde *(1)* with components containing 1,2-bifunctional acidic NH and CH groups[5].

Thus the hitherto unknown 2*H*-pyrrolo[3,4-*c*]pyridines *(2)* could be prepared simply and in satisfactory yields from *(1)* and alkyl α-aminoacetates in presence of diethylamine as base. The condensation began with formation of an azomethine, from which water was liberated in an intramolecular reaction.

Use of hydrazine provided entry into the 6*H*-pyrrolo[3,4-*d*]-pyridazine series *(3)*, which has astonishing thermal stability. The nitrogen atoms at positions 5 and 6 confer on this system a basic character that is proved by monoalkylation by trialkyloxonium tetrafluoroborates and by solubility in 2N-hydrochloric acid. The reactivity with dienophiles is appreciably less than that of 2-alkylisoindoles[6]; thus, neither compounds of type *(3)* nor those of type *(2)* undergo Diels-Alder addition with *N*-phenylmaleimide at room temperature.

Reaction of *(1)* with 1,2-dicyano- or 1,2-dibenzoyl-ethane occurs with double removal of water, giving substituted isoindole derivatives *(4)*. The 5,6-dibenzoylisoindole derivative *(4)*, R' = C_6H_5CO-, can be converted by hydrazine into the intensely red tricyclic system *(5)*, which has very great thermal stability and absorbs at 535—537 nm.

Experimental:

For preparation of *(2)*, R = C_2H_5, *(1)* is allowed to react with an equivalent amount of glycine ethyl ester in ethanol in presence of diethylamine for 14 hours under reflux, and the product is purified by recrystallization from ethyl acetate. M.p. 168—172 °C; yield 48%; λ_{max} (in methanol) (log ε): 251 nm (4.57), 318 nm (3.92), 386 nm (3.47). — NMR: τ = 1.13—1.16 (1 H doublet), τ = 1.81—1.84 (1 H doublet), τ = 5.37—5.69 (2 H quartet), τ = 6.30 (3 H singlet), τ = 7.43 (3 H singlet), τ = 7.50 (3 H singlet), τ = 8.43—8.67 (3 H triplet)[7].

For preparation of *(3)*, *(1)* is heated with a 12-fold excess of hydrazine hydrate for 1 hour in ethanolic solution; purification is by recrystallization from acetonitrile. M.p. 184 to 190 °C; yield 82%; λ_{max} (in methanol) (log ε): 231 nm (4.28), 285 nm (3.57), 359 nm (3.33). — NMR: τ = 1.00 (2 H singlet), τ = 6.25 (3 H singlet), τ = 7.50 (6 H singlet).

For preparation of *(4)*, R' = CN, *(1)* is treated with an equimolar amount of 1,2-dicyanoethane in the presence of 2 equivalents of potassium *tert*-butoxide in *tert*-butyl alcohol. After 30 min the yellowish-green crystals are filtered off, purified by chromatography, and recrystallized from chloroform. M.p. 272–275 °C (dec.); yield 17%; λ_{max} (in

methanol) (log ε): 210 nm (4.13); 228 nm (4.13); 270 nm (4.80); 337 nm (2.79); 401—402 (3.30). — NMR: τ = 2.13 (2 H singlet); τ = 6.20 (3 H singlet); τ = 7.43 (6 H singlet).

For preparation of *(4)*, R' = C_6H_5CO-, *(1)* is refluxed for 2 hours with an equimolar amount of 1,2-dibenzoylethane in ethanolic potassium hydroxide solution. The yellowish-green crystals are filtered off and recrystallized from ethyl acetate/dimethylformamide (3:1). M.p. 217 °C (dec.); yield 50%; λ_{max} (in methanol) (log ε). 250 nm (4.57); 288 nm (4.37); 293 nm (4.86). — NMR: τ = 2.18—2.78 (12 H multiplet); τ = 6.25 (3 H singlet); τ = 7.49 (6 H singlet).

For conversion of *(4)*, R' = C_6H_5CO-, into *(5)* it is refluxed for 2 hours with a 25-fold excess of hydrazine hydrate in ethanol for 2 hours. The reddish-violet crystals are purified by recrystallization from 2-propanol. M.p. 210 °C (dec.); yield 26%; λ_{max} (in methanol) (log ε): 230 nm (4.48), 278 nm (4.50), 372 nm (3.76), 536 nm (3.35). — NMR: τ = 1.87 (2 H singlet), τ = 2.23 (10 H singlet), τ = 6.09 (3 H singlet), τ = 7.38 (6 H singlet).

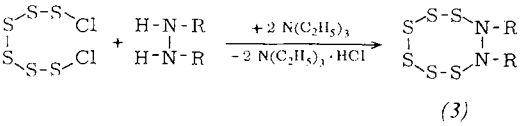
Preparation of Sulfur-Nitrogen Rings Containing Nitrogen-Nitrogen Bonds[**][1]

By *Herbert Lingmann* and *Karl-Heinz Linke*[*]

Sulfur-nitrogen compounds that can be considered as sulfane derivatives of hydrazine have not hitherto been described. The reaction of hydrazine with sulfur affords only nitrogen and hydrogen sulfide[2].

Treatment of diethyl 1,2-hydrazinedicarboxylate *(1)*, which is very resistant to oxidation, with dichlorodisulfane by the dilution technique in the presence of triethylamine as HCl-acceptor affords, besides polymeric substances, the two cyclic compounds tetraethyl 1,2,5,6,3,4,7,8-tetrathiatetraazacyclooctane-3,4,7,8-tetracarboxylate *(2)* and diethyl 1,2,3,4,5,6,7,8-hexathiadiazacyclooctane-7,8-dicarboxylate *(3)*.



(4) *(1)* *(2)*

R = $CO_2C_2H_5$

Preparation of *(2)* was effected in 22% yield by interaction of diethyl 1,2-bis(chlorodisulfanyl)-1,2-hydrazinedicarboxylate *(4)* with *(1)* and triethylamine:

Compound *(4)* is formed when *(1)* and the requisite amount of triethylamine in dioxane solution is added dropwise to a large excess of dichlorodisulfane; on filtration of the solution and removal of the dioxane and dichlorodisulfane it remains as an oily orange-colored residue.

The heterocyclic compound *(3)* is formed in 19% yield on reaction of dichlorohexasulfane[3] with *(1)* in the presence of triethylamine:

(3)

R = $CO_2C_2H_5$

The products *(2)* and *(3)* are isolated by preparative thin-layer chromatography in dichloromethane on silica gel H[4] (R_F values 0.23 and 0.62, respectively). Each of them is obtained from hexane as colorless crystals: *(2)* m.p. 110 °C; *(3)* m.p. 80 °C. They were characterized by elemental analyses, IR spectra, and mass spectra. The IR spectra of *(2)* and *(3)* show that neither molecule contains an NH group. The S—S bond absorbs at 475 cm^{-1}. A band at 1010 cm^{-1} can be assigned to the N—N bond.

The mass spectrum of *(2)* shows, alongside the molecular peak, important fragments that have the composition $(NCO_2C_2H_5)_2S_4N_2H$ and $(NCO_2C_2H_5)_2S_4H$. The first steps in the degradation of *(3)* in the mass spectrometer occur according to the same principles, the largest fragments having the composition S_6N_2H and S_6H.

The survival of the N—N bond, which can be recognized from the mass spectra by loss of two N atoms at a time, can also be proved by chemical degradations: the compound *(1)* is formed on desulfuration of *(2)* or *(3)* with Raney nickel.

General experimental technique:

Compound *(1)* (0.02 mole) and triethylamine (0.04 mole) are dissolved together in anhydrous dioxane and made up to a fixed volume (200 ml). An equimolar amount (0.02 mole) of S_nCl_2 (n = 2 or 6) or *(4)* (titration as described by *Böhme* and *Schneider*[5]) is diluted with ether (to 200 ml). These two solutions are simultaneously added dropwise over 4 hours to vigorously stirred anhydrous ether (1.5 liters). After reaction, the solution is filtered and the solvent is removed. A small amount of *(1)* can be filtered off after the residue has been taken up in a little dichloromethane. The product is worked up by chromatography.

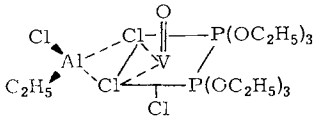
ESR Studies on Vanadyl-Phosphorus Complexes[1]

By *Gisela Henrici-Olivé* and *Salvador Olivé*[*]

Vanadyl chloride, which is insoluble in toluene, can be made to dissolve in the presence of an excess of triethylphosphine ($P/V \geq 4$). The solution exhibits the ESR spectrum shown in Fig. 1a. The intensity of the signal corresponds to essentially all the vanadium present in the solution. The signal is characteristic of the interaction of the unpaired electron of V(IV) with the ^{51}V nucleus (nuclear spin $I = 7/2$) and with two equivalent ^{31}P nuclei ($I = 1/2$), the latter interaction being responsible for the triplet splitting (1 : 2 : 1) of the eight vanadium lines. The ESR data, which are shown in Table 1, line 1, are consistent with structure *(1)* or *(2)*.



(1)

(2)

When the phosphine is replaced by triethyl phosphite, $VOCl_2$ again dissolves but the ESR spectrum of the solution consists mainly of the $VOCl_2$ signal (eight lines showing no splitting) overlapped by a low-intensity doublet signal (one phosphorus nucleus, $a_P \approx 110$ MHz). Addition of ethylaluminum dichloride ($Al/V \geq 6$), however, immediately gives a triplet signal (Fig. 1b and line 2 of Table 1). The Lewis-acid character of $VOCl_2$ is probably too low for a comparable EDA interaction to occur with the weaker base $(C_2H_5O)_3P$. However, complex formation between $VOCl_2$ and the alkylaluminum lowers the electron density on the vanadium and thereby permits an ESR-active interaction between V and P. A possible formulation which takes account of the equivalence of the two P nuclei is shown in *(3)*.

(3)

No ESR signal indicative of phosphorus nucleus interactions is obtained on treatment of vanadyl acetylacetonate $[VO(acac)_2]$ with phosphine or with phosphite. Instead, the unchanged eight-line signal of $VO(acac)_2$ is observed. On addition of $(C_2H_5)AlCl_2$, however, triplet spectra appear almost immediately which are in good experimental agreement with Fig. 1a (for ethylphosphine) and 1b (for ethyl phosphite) — see Table 1. These complexes are decomposed

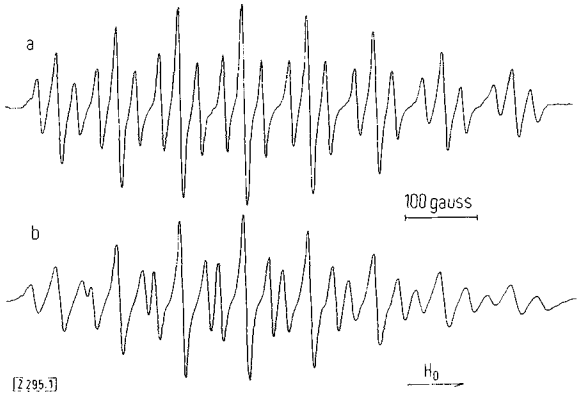


Fig. 1. ESR signals of vanadyl-phosphorus complexes in toluene $T = 20$ °C, $[VOCl_2] = 7 \times 10^{-3}$ mole/liter.
a) $[(C_2H_5)_3P] = 4 \times 10^{-2}$ mole/liter;
b) $[(C_2H_5O)_3P] = 4 \times 10^{-2}$ mole/liter;
$[(C_2H_5)AlCl_2] = 7 \times 10^{-2}$ mole/liter.

Table 1. ESR data of the complexes investigated (corrected for second-order effects). Solvent: toluene.

No.	System	g value	a_V (MHz)	a_P (MHz)
1	$VOCl_2/(C_2H_5)_3P$	1.981 ± 0.001	250 ± 2	71 ± 1
2	$VOCl_2/(C_2H_5O)_3P/(C_2H_5)AlCl_2$	1.980 ± 0.001	254 ± 2	100 ± 1
3	$VO(acac)_2/(C_2H_5)_3P/(C_2H_5)AlCl_2$	1.981 ± 0.001	250 ± 2	71 ± 1
4	$VO(acac)_2/(C_2H_5O)_3P/(C_2H_5)AlCl_2$	1.981 ± 0.001	252 ± 2	101 ± 1
5	$VOCl_2$ [a]	1.968 ± 0.001	300 ± 2	—
6	$VO(acac)_2$ [a]	1.970 ± 0.001	287 ± 2	—
7	System 4 + THF	1.965 ± 0.001	300 ± 2	—

[a] Measured in tetrahydrofuran for comparison with No. 7.

by tetrahydrofuran. The vanadyl signal then observed is no longer that of $VO(acac)_2$ but rather resembles that of $VOCl_2$ (line 7 in Table 1). We tentatively interpret this observation in terms of replacement of the (acac) ligands by Cl ligands and formation of the above-mentioned bridged complex in order to reduce the electron density at the vanadium to the required value. The processes appear to be very rapid.

Comparison of the a_P values in Table 1 shows that in the phosphite complexes the unpaired electron has a higher probability of being found at the phosphorus nucleus. Phosphites are better π acceptors and poorer σ donors than the corresponding phosphines. The electrons that effect π and σ bonding between transition metal and phosphorus compound are shifted more toward the phosphorus atom in the phosphite than in the phosphine. The highest occupied molecular orbital of the complex, the frontier orbital, which contains the unpaired electron, seems to reflect the general donor-acceptor properties of the ligands. Similar observations have already been made with other complexes[2].

In all those cases in which alkylaluminum is present in the reaction solution, a reduction V(IV) → V(III) is observed which is first order in V(IV). (Magnitudes measured: magnetic susceptibility and intensity of ESR signals.) Reduction is very slow with the phosphine complex ($t_{1/2} \approx 200$ h), significantly faster with the phosphite complex ($t_{1/2} \approx 50$ h), and faster by powers of ten when diethylaluminum chloride is used in place of ethylaluminum dichloride ($t_{1/2} \approx 10$ min for the phosphite complex of $VO(acac)_2$). Reduction presumably proceeds by the same route as that of similar titanium complexes[3], *i.e. via* alkylation of the transition metal and cleavage of the unstable V—C bond, the rate-determining step probably being that of alkylation. The higher electron density on vanadium in the phosphine complexes opposes alkylation.

Fluorine-Bridged Heteroadducts of Organometallic Lanthanoid and Actinoid Complexes[**]

By *Basil Kanellakopulos*, *Ernst Dornberger*, *Reinhard von Ammon*, and *Rainer Dieter Fischer*[*]

The *self*-association[1] of the complex[2] $(C_5H_5)_3UF$ *(1)* indicates that in monomeric *(1)* neither the central U(IV) ion nor its F(−I) ligand would be completely coordinately saturated. ^1H-NMR studies[1] have shown that *(1)* behaves

as a Lewis *acid* towards bases such as pyridine and tetrahydrofuran (THF). We have now been able to prepare two novel and remarkably stable *hetero*adducts of the type

$$\{(C_5H_5)_3UF \cdot M(C_5H_5)_3\} \qquad (M = Yb,\ U)$$

and have thus obtained independent evidence for the exceptionally high *basicity* of the fluorine compound *(1)*.

When equimolar solutions of *(1)* and the Lewis acid[3] $(C_5H_5)_3Yb(III)$ *(2)* are mixed and stirred at room temperature, a fine yellowish green crystalline precipitate is formed almost immediately; after the precipitate has been washed with pentane and dried under high vacuum it is found to have the composition of the 1:1 adduct

$$(C_5H_5)_3UF \cdot Yb(C_5H_5)_3 \qquad (3)$$

In a very similar reaction, the THF-ligand of $(C_5H_5)_3U(III) \cdot THF$ *(4)*[4] is substituted by *(1)* to give the bronze-colored complex *(5)*, which can be extracted with benzene without decomposition.

$$\frac{1}{n}[(C_5H_5)_3UF]_n + (C_5H_5)_3Yb \xrightarrow{\text{benzene, 25 °C}} \{(C_5H_5)_3UF \cdot Yb(C_5H_5)_3\}\downarrow$$

$$\frac{1}{n}[(C_5H_5)_3UF]_n + (C_5H_5)_3U \cdot THF \xrightarrow{\text{benzene, 25 °C}} \{(C_5H_5)_3UF \cdot U(C_5H_5)_3\}\downarrow + THF \qquad (5)$$

Surprisingly, no adduct of comparable stability is formed from *(1)* and $(C_5H_5)_3Tm(III)$ *(6)*[5]; the reaction of $(C_5H_5)_3U(IV)Cl$ *(7)* with *(2)* or *(3)* seems to proceed beyond the hypothetical Cl-bridged adduct[6].

Unlike their components, the adducts *(3)* and *(5)* are pyrophoric in air and are neither substantially soluble in C_6H_6 or THF nor sublimable in high vacuum. Whereas *(1)*, *(2)*, and *(4)* give rise to excellent mass spectra[7] below 200 °C[4,8], even the strongest signals of *(3)* and *(5)* are only detectable above 350 and 400 °C, respectively. The appearance of fragments of composition $(C_5H_5)_xUMF$ ($x = 0$ to 6; relative intensities: 0.5 to 7.0 based on $I(C_5H_5UF^+) = 100$) could indicate at least some volatility of the binary heteroadducts *(3)* and *(5)*.

Differences in fragmentation behavior suggest that the bond strength of the U · · · F · · · M bridge decreases along the series *(5)* ≥ *(3)* ≫ *(1)*.

The IR spectra of *(3)* and *(5)* are almost identical between 600 and 3000 cm^{-1} and compatible with the assumption of centrally coordinated C_5H_5 ligands. The absorption bands highly characteristic for the U · · · F · · · M group at 432 *(3)* and 423 cm^{-1} *(5)*, respectively, (see Fig. 1) show remarkable long-wave shifts compared with the relevant absorption bands of other M · · · F · · · M′ systems[9], including *(1)*[11]. Although in the case of *(5)*, in contrast to *(3)*, a molecular structure with a strictly symmetrical U · · · F · · · U bridge is conceivable, no support for such an assumption comes from the rather numerous absorption bands between about 100 and 350 cm^{-1} (range of metal-ring skeletal vibrations, see Fig. 1). Instead, similarities between the solid-state electronic spectra of the adducts and their components, as well as the results of magnetic susceptibility measurements between 4.2 and 300 °K, suggest rather the conservation of the original electronic configurations of U(IV), Yb(III), and U(III) (*i.e.* $5f^2$, $4f^{13}$, and $5f^3$). Unlike polycrystalline *(1)*, compounds *(3)* and *(5)* give no evidence for U · · · M spin exchange, even at low temperatures.

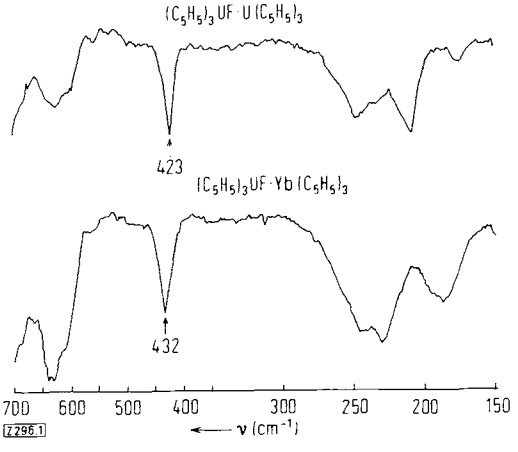

Fig. 1. FIR spectra of the adducts *(3)* and *(5)*. (Nujol mulls; Beckman Model IR 11 instrument).

Apart from a non-linear fluorine bridge (which could be stabilized by a C_5H_5 ligand with partial bridging character[10]) the possibility of an unsymmetrical linear[11] U · · · F · · · M arrangement is also open to discussion.

Structure of a Tricarbonyl-1-isopropoxycarbonyl-1,2-diazepineiron Complex

By *Rudolf Allmann*[*]

Substituted 1 *H*-1,2-diazepines *(2)* have been prepared from pyridinium imidates *(1)* by photochemically induced ring expansion[1].

In order to gain information about the conformation of the 1,2-diazepine ring and particularly about the existence of

an isolated imine bond —N=C— in the ring, an attempt was made to elucidate the structure of 1-isopropoxycarbonyl-1,2-diazepines *(2)*, R = $CO_2C_3H_7$. However, X-irradiation (CuK_α) decomposes this substance within 8 to 12 h.

Therefore the tricarbonyliron complex of this compound was studied: $C_{12}H_{12}N_2O_5Fe$, M = 320.1, m.p. 104 to 105 °C, yellow crystals, space group $P2_1/n$, a = 12.277 ± 3 Å, b = 17.241 ± 5 Å, c = 6.639 ± 2 Å, β = 101.60 ± 0.05 °, Z = 4, D_m = 1.53 ± 2, $D_{X\text{-ray}}$ = 1.545 g cm^{-3}. Out of 2112 independent reflections, 1800 could be measured (CuK_α, ϑ_{max} = 60 °). The iron atoms were found at x = 0.4446, y = 0.1958, z = 0.6276 by a Patterson map. The remaining atoms could be localized by two subsequent Fourier syntheses using the heavy atom method. After several least-squares cycles with anisotropic temperature factors the R ndex fell to 4.5 % for the observed reflections (4.7 % if the 26 unobserved reflections with $F_c > F_{min}$ are included). The anomalous scattering of the iron atoms was taken into account.

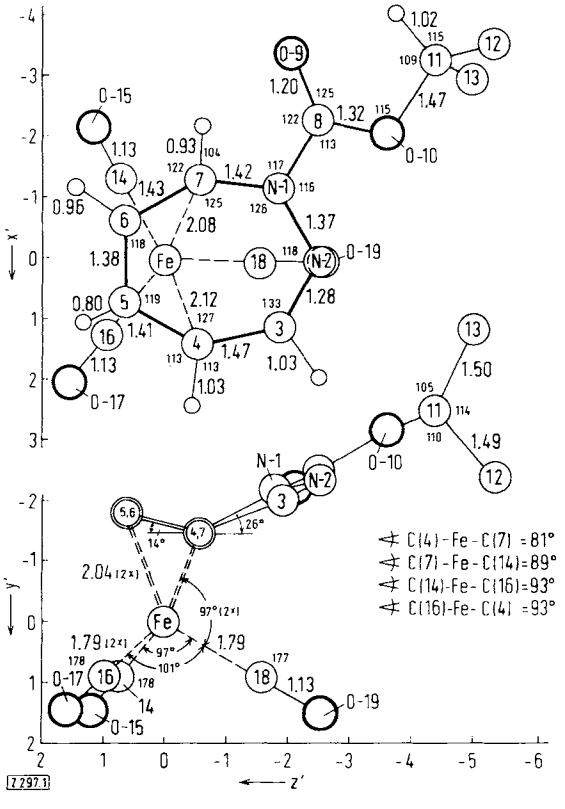

Fig. 1. Bond lengths (Å) and angles (degrees, small figures) in the tricarbonyliron complex of 1-isopropoxycarbonyl-1,2-diazepine.

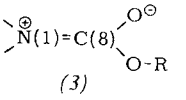
Upper part: Projection onto the plane through C(14), C(16), C(18) of the carbonyl groups. The protons of the methyl groups C(12) and C(13) have been omitted.



Lower part: Projection along C(4)—C(7) perpendicular to the above projection. All protons have been omitted.

The standard deviations are 0.01 Å except for C—H (0.1 Å). Scale in Å.

The resulting distances and angles are shown in Fig. 1. The tricarbonyliron group is attached not to the imine bond N(2)—C(3) but to the butadiene group of the ring [C(4) to C(7)] in such a manner that C(4) and C(7) have partial sp^3 character. As a result, H(4) and H(7) are displaced by 0.5 Å out of the planes C(3)—C(4)—C(5) and C(6)—C(7)—N(1), respectively, and away from the iron atom.

Apart from 5 and 6, the atoms 1 to 11 are almost coplanar. The diazepine ring is bent by 40 ° along the line C(4) to C(7). The iron atom is five-coordinated (tetragonal pyramid); it is shifted by 0.25 Å out of the C(4)—C(7)—C(14)—C(16) plane toward the apex of the pyramid C(18). In spite of the short distance of 2.04 Å, C(5) and C(6) appear only weakly bound to the iron atom. The imine bond N(2)—C(3) (1.28 Å) is very short, thus indicating an isolated double bond.

Compared with the bonding in similar ester groups, O(10) should be 0.03 Å closer to C(11), since C(8)—O(10) is too short (1.32 Å) and O(10)—C(11) is too long (1.47 Å), both

(3)

by *ca.* 0.03 Å. The bond N(1)—C(8) (1.40 Å) corresponds to a single bond, *i.e.* the resonance form *(3)* participates to only a limited extent in the bonding state.

Solvolysis of σ-2-Acetoxyalkylbis(biacetyldioximato)pyridinecobalt: Evidence for a Novel Intermediate Olefinic Complex[**]

By *B. T. Golding*, *H. L. Holland*, *U. Horn*, and *S. Sakrikar*[*]

Schrauzer and *Windgassen*[1] observed that bis(biacetyldioximato)-σ-2-hydroxyethylpyridinecobalt *(1a)* undergoes a rapid decomposition in aqueous hydrochloric acid, producing ethylene and the chloro compound *(2a)*.

(1a), R = CH_2CH_2OH
(1b), R = $CH_2CH_2OCOCH_3$
(1c), R = $CH_2CH(OCOCH_3)CH_3$
(1d), R = $CH_2CH_2OCH_3$
(1e), R = $CH_2CH_2OCH_2CH_3$
(1f), R = $CH_2CH(OCH_2CH_3)CH_3$
(1g), R = $CH_2CH(OH)CH_3$
(2a), R = Cl
(2b), R = OH

(3a) *(3b)* *(3c)*

We have considered the possibility that the symmetrical π-complex *(3a)* or the unsymmetrical species *(3b)* or *(3c)* could be intermediate(s) in this reaction[2,3] and that there might exist a solvolytic chemistry of other derivatives of *(1)* *via (3)*[5] as intermediate, akin to the known[6] rapid solvolyses which occur within certain ligands bound to transition metals.

We have found that σ-2-acetoxyethyl- *(1b)* [7,8] and σ-2-acetoxypropylbis(biacetyldioximato)pyridinecobalt *(1c)* [7,8] are compounds of extraordinary solvolytic reactivity. Their hydrolysis, methanolysis, and ethanolysis occur at 25 °C with half-lives of a few hours. High yields of products from these reactions have been isolated and identified as alcohols [*e.g. (1a)* from *(1b)*] from hydrolysis and *significantly* ethers from alcoholysis. Thus, methanolysis of *(1b)* gave the methyl ether *(1d)* [8]. Ethanolysis of *(1b)* gave *(1e)*, which was identified by comparison with a sample prepared by independent synthesis [1].

Good first-order kinetics [9] were observed for the solvolysis of *(1b)* in absolute ethanol at 25 °C [$k = 4.37 \pm 0.06 \times 10^{-6}$ s^{-1}, $E_a = 19.9 \pm 1.2$ kcal · $mole^{-1}$, $\Delta S^{\neq} = -18.2 \pm 4.2$ cal · deg^{-1} $mole^{-1}$]. Ethanolysis of *(1c)* gave *(1f)* [8] at a rate 20 times faster at 25 °C than the rate for *(1b)*. These values should be compared with data for other solvolytically reactive acetates [10]: *(1b)* and *(1c)* are of comparable reactivity to trityl acetate! Furthermore, ethanolysis of *(1b)* in ethanol saturated with propene and of *(1c)* in ethanol saturated with ethylene gave no crossed products [*e.g. (1e)* from *(1c)*], thereby eliminating a fragmentation-recombination mechanism from consideration. The σ-vinyl compound is not an intermediate, because alcoholysis of *(1b)* in [D_4]-methanol gave *(1d)* containing deuterium only in the methoxy group of the side-chain.

These results are in accord with a mechanism in which ionization of *(1b)* to *(3)* and of *(1c)* to methyl-substituted *(3)* is rate-determining followed by capture of these intermediates by solvent. A small amount of leakage occurs to give dealkylated products [*e.g. (2b)* in hydrolysis] presumably by loss of ethylene from *(3)* giving coordinatively unsaturated Co^{III} which reacts with solvent. A similar mechanism applies to the decomposition of *(1a)* in the presence of acid, except that the reaction is now equilibrium-controlled and leads to products of type *(2)* exclusively. The appreciable negative entropy of activation observed for ethanolysis of *(1b)* suggests that in *(3)* there is restriction of rotation about the C–C bond of the CH_2—CH_2 unit, which would be expected of any of the suggested structures for *(3)*.

Further evidence for the intermediacy of methyl-substituted *(3)* was obtained by carrying out hydrolysis of *(1c)* in dioxane / water (1 : 1) in the presence of $NaBH_4$ (3 eqvts. / *ca.* 5 °C / 90 min). In addition to the alcohol *(1g)* and products derived from reductive cleavage of the Co—C bond, 10% of the σ-propyl derivative was formed (identified by comparison with a sample prepared in the standard way [11]).

The acid-promoted decomposition of *(1a)* [1] resembles the acid-catalyzed deoxymercuration of 2-hydroxyalkylmercury(II) derivatives [12], whilst the solvolyses of *(1b)* and *(1c)* bear similarity to the neutral solvolytic chemistry of 2-acetoxyethylmercuric iodide [13]. The reactions of the mercuric derivatives have long been thought to proceed *via* a π-complex of Hg^{II} with alkene (mercurinium ion) [12], although the precise role and nature of this species is still uncertain [4c, 14]. *(3a)* corresponds to a symmetrical mercurinium ion. However, the present system differs clearly from deoxymercuration in that the loss of ethylene from *(3)* is kinetically slower than its capture by solvent, whereas in deoxymercuration, the contrary kinetic situation probably obtains.

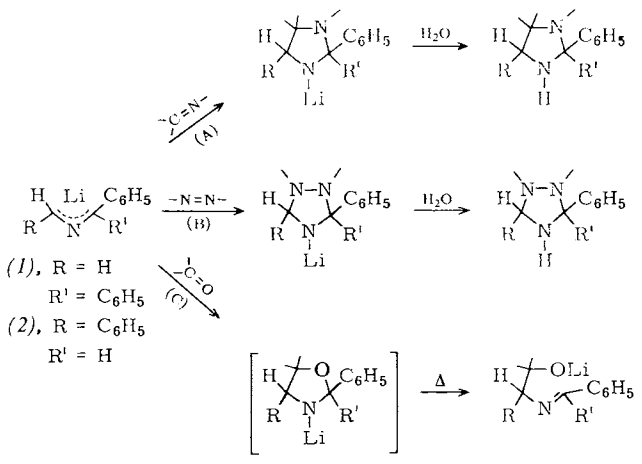
Anionic 3 + 2 Cycloaddition of 2-Azaallyllithium Compounds to CN and NN Double Bonds [1] [**]



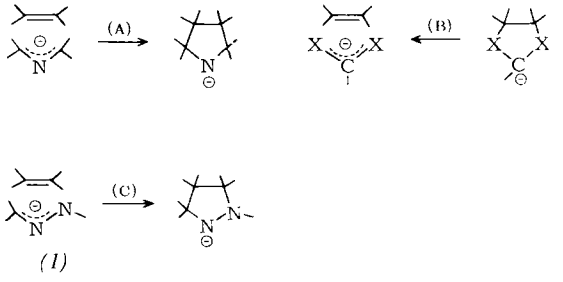
By *Thomas Kauffmann*, *Heike Berg*, *Elisabeth Ludorff*, and *Annegret Woltermann* [*]

2-Azaallyllithium compounds were recently reported [2] to react with olefinic CC double bonds to give anionic cycloadducts that afford pyrrolidines on hydrolysis with water.

We have now observed analogous anionic 3 + 2 cycloadditions [3] with azomethines and azo compounds. These reactions, designated (A) and (B) in the reaction scheme, take place when a solution of the 2-azaallyllithium compounds *(1)* and *(2)* [2] in THF/ether (9 : 1) is treated at −60 °C under nitrogen with an equimolar amount of one of the azomethines or azo compounds listed in the Table and then warmed. After hydrolysis of the reaction mixture with water the respective imidazolidine or 1,2,3-triazolidine could be isolated. The constitution of these apparently hitherto undescribed compounds follows from analyses, molecular-weight determinations, and the NMR, IR, and mass spectra.

These reactions represent the first application of a new synthetic method for the little-studied class of imidazolidines [4] and 1,2,3-triazolidines [5].

The reactions of 1,3-diphenyl-2-azaallyllithium *(2)* with azomethines or azobenzene, with should theoretically yield



(1), R = H, R' = C_6H_5
(2), R = C_6H_5, R' = H

Anionic 3 + 2 Cycloaddition of a 1,2-Diazaallyllithium Compound[1][**]

By *Thomas Kauffmann, Dieter Berger, Björn Scheerer,* and *Annegret Woltermann*[*]

The energy barrier to be overcome in anionic 3 + 2 cycloadditions according to (A)[2] and the corresponding cycloeliminations according to (B) (X = O, S)[3] should be low since the symmetry of the π orbitals is conserved[4,5]. The direction of reaction is dictated by the arrangement of the electronegative hetero atoms: The reaction that occurs is that in which the negative charge is transferred from the carbon to more electronegative atoms.

It therefore appeared questionable whether 1,2-diazaallyl anions *(1)* can add to olefinic double bonds as shown in (C) since this would involve only slight transfer of negative charge from a carbon to a nitrogen atom because of extensive localization of the negative charge on the peripheral nitrogen atom in *(1)*.

(1)

We have now found that benzeneazomethane *(1a)* undergoes extensive (> 88%) metalation to the hitherto unknown orange-red compound benzeneazomethyllithium *(2)* on treatment with 1.1 mol. equiv. of *n*-butyllithium in THF/*n*-hexane (*ca.* 9:1) at −70 °C[6]; moreover, the anion of *(2)*, 1,2-diazaallyl anion, is able to add to the angle-strained olefinic double bond of acenaphthylene (according to (C)). Addition of water to the reaction mixture yielded the hydrolysis product *(5)*[7] of the cycloadduct *(4)*; treatment with ethyl bromide instead of water gave the dehydrogenation product *(6)* (for reaction conditions and yields, see Table).

A corresponding cycloaddition did not occur with the 1,2-bisazaallyllithium compound *(3)*, which is obtained almost quantitatively as an orange-red solution (THF/*n*-hexane, *ca.* 5:1) on reaction of benzaldehyde phenylhydrazone and one mol. equiv. of *n*-butyllithium at −70 °C. This finding, together with the fact that neither *(2)* nor *(3)* could be induced to add to styrene, *trans*-stilbene, or tolan, confirms the prediction that 1,2-diazaallyllithium compounds are less prone to 3 + 2 cycloaddition than 2-azaallyllithium compounds[2].

Addition of benzeneazomethyllithium to carbonyl compounds (see Table) leads — possibly *via* an unstable

2-Azaallyl cpd.	Azomethine or azo cpd.	Temp. (°C) [a]	Product	Yield (%) [b]	M.p. (°C)
(1)	Benzylideneaniline	20	2,2,3,4-Tetraphenylimidazolidine	43	121–122
(2)	Benzylideneaniline	20	2,3,4,5-Tetraphenylimidazolidine	52	111–113
(1)	2-Pyridinecarbaldehydeanil	20	2,2,3-Triphenyl-4-(2-pyridyl)imidazolidine	41	164
(2)	2-Pyridinecarbaldehydeanil	20	2,3,5-Triphenyl-4-(2-pyridyl)imidazolidine	54	153–155
(1)	Azobenzene	20	1,2,3,3-Tetraphenyl-1,2,4-triazolidine	43	139
(2)	Azobenzene	20	1,2,3,5-Tetraphenyl-1,2,4-triazolidine	50	190–191
(1)	*p,p'*-Azotoluene	65	3,3-Diphenyl-1,2-di-*p*-tolyl-1,2,4-triazolidine	58	139–140
(1)	3,3'-Azopyridine	65	3,3-Diphenyl-1,2-di(3-pyridyl)-1,2,4-triazolidine	10	184–186

[a] After addition of the azomethine or the azo compound to a solution of the lithium compound at −60 °C the reaction mixture was slowly warmed to the temperature given. [b] Yield not optimized.

four racemic imidazolidines or give one meso and one racemic 1,2,4-triazolidine, were found to give only one imidazolidine or triazolidine. The apparent stereospecificity strongly suggests that the cycloaddition of *(2)* to CN and NN double bonds is a concerted process, as predicted by the Woodward-Hoffmann rules[6].

It would also appear likely, from the close similarity between the CN and the CO double bond, that the reactions of 2-azaallyllithium compounds with carbonyl compounds, which leads to open-chain hydroxy azomethines[7], are also initiated by a concerted 4π + 2π cycloaddition and therefore proceed *via* a 1,3-oxazolidine-lithium compound.

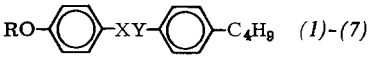
[5] On cycloaddition of 1,3-diphenyl-2-azaallyllithium to *cis*- and *trans*-stilbene the configuration is conserved completely, thus suggesting a concerted cycloaddition process (*E. Köppelmann*, Planned Dissertation, Universität Münster, probably 1971).

[6] The instability of formaldehyde phenylhydrazone prohibits any preparation of (2) from this compound.



[7] The constitution of the reaction products, which, with one exception (see Table), apparently have not been described previously, follows from analyses, molecular-weight determinations, and NMR, IR, and mass spectra.

Liquid Crystalline Phases Having Particularly Low Freezing Points

By *Hans Kelker, Bruno Scheurle, Rolf Hatz*, and *Werner Bartsch* [*]

In continuation of earlier work [1,2] on the synthesis of low-melting nematogenic substances such as (1) and (2) we have prepared new azo and azoxy compounds (see Table).

For optical and electro-optical experiments, we chose azo compounds in order to obtain substances having a low

(1)-(7)

Compound	R	X Y	M.p. (°C)	Transition point (°C), behavior
(1)	CH_3	CH=N	22	47—48 (nemat.) [a] [2]
(2)	C_2H_5	CH=N	37	80 (nemat.) [2]
(3)	CH_3	N=N	32	42 (nemat.)
(4)	C_2H_5	N=N	48	81 (nemat.)
(5)	CH_3	N(O)=N	43	≥71 (nemat.) [b]
(6)	CH_3	N=N(O)	41	≥69 (nemat.) [b]
(7)	H	N=N	82	— (isotrop.)

[a] This value is valid for extremely pure (1), *e.g.* after purification by electrodialysis [3]. The value given in [2] is to be corrected.

[b] The melting and clearing points of (5) and (6) were obtained with chromatographically isolated substances (*ca.* 30 mg in each case). Since the mixed clearing point of these fractions was determined as 69—70 °C and the mixture of pure isomers before separation showed an even higher clearing point (75—76 °C), it can be assumed that the clearing points the pure components on working up larger quantities of substances of could also reach a value of 75—76 °C.

melting point and no central dipole, and azoxy compounds so as to have available compounds with a relatively high permanent moment. The new azo and azoxy compounds *(3)* - - *(6)* listed in the Table form nematic phases.

Compounds *(3)* and *(4)* were prepared by coupling of diazotized *p-n*-butylaniline with phenol; compound *(7)* is formed first and this is reacted either with diazomethane or — better — with dimethyl sulfate to give the methyl ether *(3)* or with ethyl iodide/sodium ethoxide to give the ethyl ether *(4)*. The reaction with dimethyl sulfate affords very pure *(3)* after two recrystallizations from petroleum ether.

Compounds *(5)* and *(6)* were obtained by the known[4] method of oxidation of *(3)* with 30% hydrogen peroxide in acetic acid; a mixture of isomers is formed (m.p. 19 °C, N/I transition point 75—76 °C) that can be separated chromatographically[**].

Remarkably, uniaxially oriented layers exhibit clearly defined dichroism in the IR spectra of substances *(1)*, *(3)*, *(5)*, and *(6)*. Thus, for example, in the case of *(3)* the extinction coefficient ε(isotropic) for the wave numbers 1292 and 1178 cm^{-1} is considerably higher than that of the uniaxially oriented phase $\varepsilon\perp$. The order of the ε-values is reversed at 1100 cm^{-1}, *i.e.* $\varepsilon\perp >$ ε(isotropic). Similar effects occur in the case of the other substances. Investigations on this anisotropic effect are still in progress.

The position of the O atoms in *(5)* and *(6)* was determined by mass spectrometry. Whereas in the oxidation mixture the fragmentation masses 137 $(CH_3O—C_6H_4—NO)^+$ and 163 $(C_4H_9—C_6H_4—NO)^+$ occur in the ratio of about 3:1, the component more strongly absorbed on silica gel (later eluted with methylene chloride) [*(5)*] showed the mass 137 but not $M = 163$, the other isomer [*(6)*] showed mass 163, while $M = 137$ was absent. Since each isomer forms its own nematic phase it follows that the *trans* compound is involved in each case. The ratio of the isomers occurring in the oxidation is *ca.* 60% *(5)* and 40% *(6)*.

α-Diimine-Metal Chelates: Cyclic Delocalization of π-Electrons and ^{13}C Chemical Shifts[***]

By *Christian Tänzer*, *Roger Price*, *Eberhard Breitmaier*, *Günther Jung*, and *Wolfgang Voelter*[*]

IR spectroscopic determination of the MO π-bonding order[1], as well as ^1H-NMR studies[2], indicate cyclic delocalization of π-electrons in α-diimine-metal chelates *(1)—(3)*. Since ^{13}C chemical shifts depend characteristically on the π-electron density at each C atom[3], a comparison of the chemical shifts of ^{13}C-NMR signals of some non-benzenoid aromatic compounds of known π-electron distribution with the corresponding shifts for some α-diimine-metal chelates should provide further evidence about the so-called aromaticity[1,4] of these chelates.

(1) *(2)* *(3)*

The ^{13}C signals in NMR spectra are shifted upfield by 29.9 and 46.6 ppm when, respectively, cyclopentadiene and cyclooctatetraene are converted into the aromatic cyclopentadienyl and cyclooctatetraenyl anions[3]: the opposite effect is, however, observed on conversion of cycloheptatriene into the cycloheptatrienyl cation, namely, a downfield shift of the three olefinic ^{13}C signals by 24.7, 28.9, and 35.2 ppm[3].

Comparison of the Fourier transform ^{13}C-NMR spectra of some α-diimine-metal chelates with those of the free di-

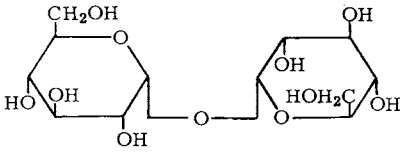
[b] The entries in the Table refer to the signals of the magnetically nonequivalent ring carbon atoms in the α,β, or γ positions relative to the nitrogen.



imines shows that the coordinative bonding of the metal ion to the chelating agent causes a downfield shift of all the ^{13}C signals of the ligands. The shifts increase with decreasing distance between the metal ion and the C atom responsible for the ^{13}C signal in question: the magnetic shielding of the C atom of a chelating agent is thus weakened by incorporation of a metal ion into the structure. This corresponds to a decrease in the π-electron density at each sp^2-hybridized C atom on transition of a chelating agent into a chelate, an effect that can also be interpreted as cyclic delocalization of the π-electrons in the α-diimine-metal chelate ring. The downfield shift of the ^{13}C signals on transition from chelating agent to chelate must be weakened or reversed if the metal cation in the chelate ring is replaced by a zerovalent metal, as in tetracarbonyl-α-diiminemolybdenum[2,5]. Experimentally, the ^{13}C signal of the sp^2-hybridized carbon is shifted by 3.3 ppm to higher field on conversion of *N,N'*-di-*tert*-butylethanediimine into tetracarbonyl-(*N,N'*-di-*tert*-butylethane-1,2-diimine)-molybdenum (Tabelle 1).

Determination of the Type of Linkage in Disaccharides by Measurement of Circular Dichroism[**]

By *Wolfgang Voelter, Gisela Kuhfittig*, and *Ernst Bayer*[*]

A problem most frequently met with in the structure elucidation of naturally occurring disaccharides is the differentiation between 6-*O*-pyranosyl and 4-*O*-pyranosyl sugars. By classical methods this entails a great deal of experimental effort: by our new method relevant information for such a differentiation can be obtained rapidly and easily. The circular dichroism spectra (CD spectra) of molybdate complexes of monosaccharides can be correlated with the configuration on C-1 to C-3 of the pyranose ring[1–3]. The results of CD investigations on disaccharide-molybdate complexes can be summarized as follows:

a) Non-reducing disaccharides, *e.g.* α,α-trehalose *(2)*, like methylglycosides[1–3], *e.g.* methyl α-D-glucopyranoside *(1)*, do not react with molybdate; consequently, molybdate-containing solutions of these sugars do not exhibit a Cotton effect at wavelengths >200 nm. Sugars of the trehalose type again demonstrate that only carbohydrates possessing free glycosidic hydroxyl groups yield molybdate complexes under the conditions given.

b) No molybdate complexes are formed in the case of 2-, 3-, and 4-*O*-pyranosyl sugars such as, *e.g.*, maltose *(3)*. Since the three hydroxyl groups necessary for complex formation with molybdate are present on C-1 to C-3 of the pyranose residue in 4-*O*-pyranosylpyranoses the reaction must, in this instance, be hindered energetically or sterically[4].

c) Molybdate-containing aqueous solutions of 6-*O*-pyranosyl-pyranoses, *e.g.* gentiobiose *(4)*, on the other hand, exhibit Cotton effect bands above 200 nm; hence, such disaccharides form molybdate complexes. Thus, a

[4] Only pyranosyl sugars of Group I were considered (cf. [3]).

negative Cotton effect is observed at 242 nm ([Θ] = —7100) and a positive Cotton effect at 275 nm ([Θ] = 2500) in the CD spectrum of the gentiobiose molybdate complex (0.02 mole/l gentiobiose +0.04 mole/l sodium molybdate in water, adjusted to pH = 5.19 with hydrochloric acid).

The spectrum thus resembles that of D-glucose[1–3]; the glucose residue functions as the complexing agent. Furthermore, the complexing ratio, which was determined according to *Job*'s method, is also in agreement with that found for the glucose-molybdate complex (gentiobiose: molybdate = 2:1).

The CD spectrum of a disaccharide-molybdate solution thus permits the following conclusions to be drawn:

1. If a Cotton effect appears at wavelengths > 200 nm then a 6-*O*-pyranosyl sugar type is present[4].

2. If the solutions do not exhibit a Cotton effect then either a linkage of the type mentioned above in a) (trehalose type) or in b) is present. Sugars of the trehalose type can be differentiated quite easily from 2-, 3-, and 4-*O*-pyranosyl sugars by their non-reducing properties.

CONFERENCE REPORTS

Transition between Metallic and Ionic Bonding in the Silicides of the Alkali and Alkaline Earth Metals

By *Herbert Schäfer*[*]

Intermetallic compounds of the alkali and alkaline earth metals with silicon can be classified into three groups according to structure.

a) The majority of these silicides fit into the scheme proposed by *Klemm* and *Busmann*. In the formal ionic formulation according to this concept the base metal donates electrons to the more noble partner of the alloy, the "anion former". In the phases treated here, the silicon is the electron acceptor. If N is the number of outer electrons of the Si "anion", then as many bonds participate in the anionic part of the lattice as correspond to the $8N$-rule. In those compounds in which the silicon carries a fractional charge the concept is preserved by charge sharing — according to stoichiometry — between the nearest whole number values (see Table 1).

b) The compounds most rich in alkali or alkaline earth metal form metallic lattices. $Li_{10}Si_3$ and $Li_{22}Si_5$ correspond, according to structure type (cubic, "γ-brass" type) and concentration of valence electrons (VEC) (21 : 12.4, 21 : 13.5), to Hume-Rothery phases. Cubic close-packing of the alkaline earth metal atoms occurs in Ca_7Si, Sr_7Si, and Ba_7Si.

c) The silicon atoms in K_8Si_{46}, Na_8Si_{46}, and $Na_{11}Si_{136}$ are tetrahedrally surrounded by neighbors of the same kind as in the element itself. A three-dimensional network is formed which corresponds to that found in the gas hydrates $8X \cdot 46\,H_2O$ or $11X \cdot 136\,H_2O$. The silicon atoms take up the positions of the water molecules. The alkali metal atoms are distributed in cage-like holes (pentagonal dodecahedral holes, fourteen-sided holes, sixteen-sided holes).

Transfer Paths in Heterogeneous Catalysis

By *John Happel*[*]

Atomic transfer rates furnish a useful method for characterizing the structure of heterogeneous catalytic reactions. Such transfer rates may be measured by means of isotopes of appropriate elements. Reaction rate expressions may be developed from such information more effectively than by means of the usual techniques based on net reaction rates of molecular species.

Transfer of atomic species proceeds through a number of paths, each consisting of a single unbroken series of mechanistics steps whereby a given atomic species can move from a chosen reactant to a chosen product or the reverse. If we assume a steady state is attained, it is possible to make simple material balances to determine how overall transport rates are related to the velocities of individual mechanistic steps.

This concept has been applied to studies of the kinetics and mechanism of several heterogeneous catalytic reactions of industrial importance.

Studies using a differential flow type reactor were conducted in which iso- and *n*-butane were dehydrogenated over a chromia-alumina catalyst. Radioactive ^{14}C was used to trace the unidirectional rate of atomic carbon transfer. In both cases it was found possible to express the rate in the form

$$v = v_+ \left[1 - \frac{p_{H_2}\, p_{ENE}}{p_{ANE}\, K}\right]$$

where v_+ is the forward rate in terms of carbon transfer; p_{H_2}, p_{ENE}, p_{ANE} are partial pressures; K is the equilibrium constant. In the case of isobutane dehydrogenation v_+ can be expressed as a simple one term function of the Langmuir-Hinshelwood type. However, a more complicated expression is necessary for v_+ in the case of *n*-butane. A mechanistic interpretation of the data indicates that the rate controlling step or steps occur in the reaction steps involving the carbon skeleton of the species involved.

Oxidation of SO_2 was also studied in a recirculating type reactor over a vanadium pentoxide catalyst using radioactive ^{35}S as a tracer. It was not possible to express the result in the form of equation used for butanes above in which a potential factor can be separated. It appears that at low concentrations of SO_2 reactions involving sulfur are rate determining but that at higher concentrations adsorption of oxygen becomes increasingly important.

The technique should be useful in planning exploratory research for catalyst development as well as for modeling reaction kinetics.

Accurate MO Calculations of Chemical Reactivity

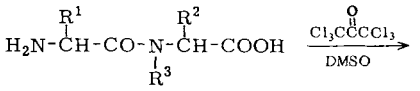
By *Michael J. S. Dewar*[*]

While the structures of molecules can be determined experimentally, there is no way of observing directly the intermediate phases in a chemical reaction. If therefore these could be calculated theoretically, the resulting treatment would serve as a practical chemical tool in the study of reaction mechanisms and chemical reactivity.

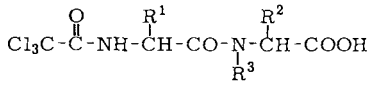
To be of practical value, such calculations must be both accurate and reliable. Since only approximate quantum mechanical treatments are available, these must first be checked against experiment for systems (*i.e.* normal molecules) where experimental data are available. Unless these properties are reproduced with "chemical" accuracy (order of magnitude of errors in dissociation energies, ±1 kcal/mole; in bond lengths, ±0.01 Å; in bond angles, ±1 °; in valence force constants, ±10 %), corresponding calculations of potential surfaces, and so of reaction paths, are meaningless. It is also necessary that the calculations should be feasible for systems large enough to be of chemical interest. Since it is necessary in such cases to calculate several thousand points on the potential surface to define the reaction path, it is essential that each calculation take seconds rather than hours, or even minutes; for otherwise the cost of the calculation is too great in relation to its chemical value.

Until recently, available procedures (*ab initio* SCF, CNDO/2, extended Hückel) failed completely to meet these requirements, the errors in dissociation energies in particular being of the order of 1000 kcal/mole. The time required for *ab initio* calculations is also utterly prohibitive; calculations of this kind have for this reason usually been carried out with assumed geometries, an unacceptable simplification which leads to gross errors.

We have now developed a semiempirical SCF MO treatment (MINDO/2) which comes reasonably close to meeting the required specifications and which has given encouraging results for a number of simple chemical reactions; *e.g.* rotational barriers in ethylene and the cumulenes, valence tautomerism in cyclobutadiene and diphenylcyclobutadiene, tub →tub inversion and bond exchange in cyclooctatetraene, chair →boat isomerization of cyclohexane, hydrogen abstraction from methane by methyl radicals, and insertion of carbon atoms into olefins to give allenes. In the latter case, our calculations account for the fact that excited (^1S) carbon atoms seem to be needed, and for the failure of the intermediate cyclopropyl carbene to rearrange if generated by other means.



The most elaborate application so far has been to the Cope rearrangement of biallyl where we correctly predict the "chair" transition state to be more stable than the "boat" and by the right amount (calc. 6.6; obs. 5.7 kcal/mole). We also correctly predict the difference (calc. 2.0; obs. 1.5 kcal/mole) between conformers of the chair transition state with an equatorial or axial methyl substituent. Furthermore, we have established that the difference in energy between the chair and boat transition states arises entirely from an antibonding 2,5 interaction in the latter. This calculation not only reproduced the results of two extensive experimental studies but also established additional details concerning the mechanism, at much less cost (1 man month + 5 hours CDC 6600 computer time, *i.e.* <20 000 DM).



While our present procedure is far from perfect, it is also far from fully developed. This type of approach therefore seems much the most promising at present available and likely to soon become an important practical chemical tool.

Lecture at Freiburg on June 12, 1970 [VB 255 IE]

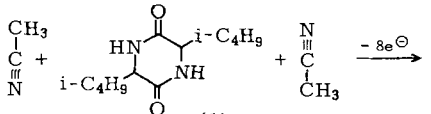
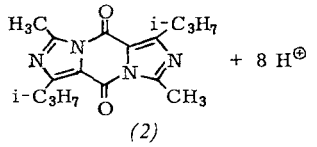
The trichloroacetylation of peptides with hexachloroacetone in almost neutral solution at room temperature has been described by *C. A. Panetta* and *T. G. Casanova*. Dimethyl

sulfoxide is used as solvent; chloroform is eliminated. *N*-Trichloroacetyldipeptides were hitherto unknown. / J. Org. Chem. *35*, 2423 (1970) / —Ee. [Rd 248 IE]

A new dichlorocarbene generator has been discovered by *N. J. Bremer*, *A. B. Cutcliffe*, and *M. F. Farona*. On refluxing dicyclohexylcarbodiimide with $Fe(CO)_6$ in heptane the authors obtained the complex *(1)* in the form of red diamagnetic crystals. The structure was proved by spectroscopic data (mass, NMR, and IR spectra) and by acid hydrolysis to $C(NHC_6H_{11})_3^{\oplus}Cl^{\ominus}$. In the presence of *(1)*,



(1)

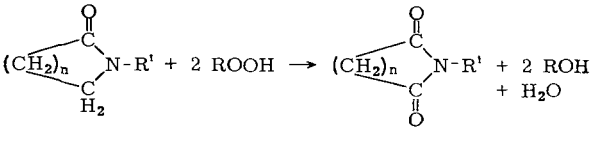


(2)

$CHCl_3$ containing 0.75% of ethanol evolves dichlorocarbene; the complex *(1)* is converted into the salt *(2)* in the reaction. The carbene can be trapped with olefins. Thus it reacts with cyclohexene to give dichloronorcarane along with isomeric products formed by insertion into the C—H bonds of C-2 and C-3. Conventionally generated $:CCl_2$ reacts differently. / Chem. Commun. *1970*, 932 / —Ee. [Rd 251 IE]

Anodically induced 1,3-cycloaddition of acetonitrile to 3,6-diisobutylpiperazine-2,5-dione *(1)* is reported by *L. A. Simonson* and *C. K. Mann*. In a particular experiment [in 0.5 M $NaClO_4/CH_3CN$, divided cell, anode potential + 2.2 V relative to $Ag/AgNO_3$(0.5 M)—CH_3CN] the only result expected was C—N cleavage, by analogy with the behavior of other amides. In fact the cycloadduct *(2)* is formed in 5 and 50% yield (relative to the amount of *(1)* used and the amount that undergoes electrochemical reaction, respectively). No monoadducts were found. / Tetrahedron Lett. *1970*, 3303 / —Ee. [Rd 252 IE]

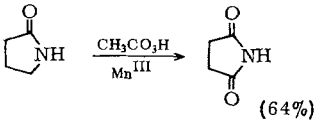
(1)



(2)

The conversion of bromo into chloro compounds with silver chlorodifluoroacetate is the subject of report by *J. A. Vida*. A mixture of the bromo compound and reagent in stoichiometric quantities is heated in a suitable solvent. Silver bromide precipitates out; the chloro compound can be isolated in good yields. For example: 1-chloroadamantane (85% yield); 1-chloro-1-phenylethane (95%); *N*-(2-chloroethyl)phthalimide (92%). / Tetrahedron Lett. *1970*, 3447 / —Kr. [Rd 254 IE]

The chlorine difluoride radical has been obtained by *G. Mamantov*, *D. G. Vickroy*, *E. J. Vasini*, *T. Maekawa*, and *M. C. Moulton* by photolysis (2800—4200 Å) of mixtures of $ClF/F_2/Ar$ or $ClF/F_2/N_2$ (molecular ratios of 1:10:100 or 1:5:300) on a CsI window cooled to 15 °K. Formation of the angular radical ClF_2 is recognized by bands at 575 cm^{-1} (N_2 matrix) and at 535 and 242 cm^{-1} in the IR spectrum which disappear completely on warming to ≈ 50 °K. The radicals either react with fluorine atoms to give ClF_3 or disproportionate to give ClF and ClF_3. / Inorg. Nucl. Chem. Lett. *6*, 701 (1970) / —Kr. [Rd 255 IE]



A new method for the synthesis of imides has been described by *A. R. Doumaux jr.* and *D. J. Trecker*. Hydroperoxides or peroxy acids in combination with catalytic amounts of a Mn(II) or Mn(III) salt oxidize lactams or *N*-alkylamides under very mild conditions (0 °C to room temperature, ethyl acetate) to imides (yields up to 84%). Cyclic amides and compounds bearing two substituents on the neighboring atom to the nitrogen do not react. Examples:

$CH_3-CO-NH-CO-CH_3 + CH_3CONH_2$

Grundlagen der analytischen Chemie (Principles of Analytical Chemistry). By *F. Seel.* Verlag Chemie, Weinheim/Bergstr. 1970. 5th Edit., 387 pp., 53 tables, plastic DM 36.—.

This is the fifth improved edition of the well-known textbook which first appeared in 1955 and which caters in particular for those chemistry students whose introductory laboratory work consists essentially of analytical inorganic chemistry, which is still the case at most universities. The author provides the reader with a detailed introduction to the principles of classical analytical chemistry, the methods of which are based on equilibria. Practical instructions are intentionally omitted. Other analytical methods like instrument techniques, which are becoming more and more important, are also purposely left out.

In the introductory chapters elementary concepts are explained and defined, and detailed treatment is given to the law of mass action. Finally, the principles of chemical reaction types are discussed in the following order with reference to the most important analytical methods: dissolution and precipitation, complex formation, acid-base reactions, and redox processes. Appropriate space has been allocated to the combination of these four types of reaction. Furthermore, special chapters have been included on the colloidal state and adsorption, ion exchangers, reactions in molten salts, potentiometric titration, electrolytic precipitation and, an important improvement on the last edition, the thermodynamic principles of analytical chemistry in aqueous solvents.

This book gives a very good introduction to the systematic treatment of the chemistry of aqueous systems.

Gerhard Geier [NB 911 IE]

Methodensammlung zur Rückstandsanalytik von Pflanzenschutzmitteln (Methods for the Analysis of Residues of Crop Protection Products). Ed. by the Abt. "Analytik" der Kommission für Pflanzenschutz-, Pflanzenbehandlungs- und Vorratsschutzmittel der Dtsch. Forschungsgemeinschaft, Bad Godesberg. Verlag Chemie, Weinheim/Bergstr. 1969. 1st Edit., 376 pp., loose-leaf DM 48.—.

This collection, which was compiled by a specialist commission of the Deutsche Forschungsgemeinschaft (German Research Association), is the first of its kind to be published in German. The methods discussed for determining residues of crop protection products in foods relate to agents selected on the basis of whether they are of "practical interest" in the Federal Republic of Germany.

An enormous number of analytical procedures for the determination of the residues of many important crop protection products have been described in the relevant literature in the last 20 years, which only goes to show that really "good" methods are rare. It should therefore be realized that the most important objective in selecting the material for the present collection was not to produce a complete survey of the literature but only to include those methods that are based on "experience gained in relevant university laboratories and in relevant Federal and industrial research institutes". Another advantage of the book is that it gives the source for each method so that in cases of doubt the author can be consulted or informed of improvements.

This highly commendable approach naturally also has disadvantages, particularly in cases where analytical techniques have undergone further development before the collection appeared. This was inevitable particularly in the case of gas chromatography which, with the development of new types of detectors, rapidly gained importance in the field of residue analysis. It is to be hoped that this collection, which is in loose-leaf form, will be suitably expanded (the first supplement is at present in preparation). Future supplements will in particular have to devote more attention, in the interests of public analysts' laboratories, to the simultaneous determination of several different residues, *i.e.* to group or "multi-residue" methods.

Particularly praise-worthy is the exemplary uniform, schematic presentation of the methods by the editors. Structural formulas and general physical data are also given for each active ingredient. The compounds are designated by their common names; trade names do not appear. In its present form the collection already provides a wealth of highly useful information, at a reasonable price, for all laboratories working on the problems of residues.

Helmut Frehse [NB 912 IE]

Handbuch der experimentellen Pharmakologie (Manual of Experimental Pharmacology). Edited by *H. Herken.* Vol. XXIV: Diuretics. Springer Verlag, Berlin-Heidelberg-New York 1969. 1st Edit., xix, 764 pp., 124 figures, bound, DM 248.—.

The editor of this volume has drawn on the services of ten prominent colleagues in the field of renal physiology and pharmacology, so that it should attract not only pharmacologists, physiologists, internists, chemists, and pharmacists but also students of medicine and the natural sciences. The fundamentals of renal physiology and diuretics are given detailed treatment in twelve chapters.

In the section "Fundamentals of Renal Physiology" the ultra-structure of the kidney is discussed lucidly with the aid of schematic diagrams and clear electron micrographs. Open questions are left open, as befits a manual of this type. The clear tables in the chemistry section of the chapter entitled "Mercurial Diuretics" have a pleasing and striking layout. Commercially available products are cited by their trivial, chemical, and trade names. [It might have been better, however, to take "Organic Chemical Drugs and their Synonyms" (*Negwer*, Berlin 1967) as a recent source book for trivial names, since it is more easily available here than *Marler* (1961); also not the possibility of confusing Diucardin and Diucardyn.] The fact that basic pharmacological investigations have been included is an asset for a handbook of experimental pharmacology.

The era of modern sulfonamide diuretics begins with the chapter "Renal Carbonic Anhydrase and the Pharmacology of Sulfonamide Inhibitors". The comprehensive data on the importance of carboanhydrase are reproduced completely, concisely, and clearly. Finally, the other diuretics having sulfonamide structures (sulfamoyl substitution) — "Thiazide Diuretics and Related Drugs" — are discussed. The table and the description of the relationships between structure and effect are very creditable. A few printing errorsi n the text and tables and in the references should be corrected.

The difference between "potency" and "efficacy" is justifiably emphasized. Perhaps it was these technical terms that induced the authors to submit their contributions in English since it is impossible to reproduce these concepts exactly in German without resorting to circumlocutions.

Furosemide and ethacrynic acid have been treated separately as diuretics with different modes of action. In the reviewer's opinion there is no justification for speaking of an ethacrynic acid type of saluretic action in both compounds, since it is well known that ethacrynic acid does not have the same effect on all animal species and it might lead to misunderstandings. The concepts of diuretic and natriuretic should, in my opinion, be supplemented by the concept of salidiuretic for diuretics with the action of furosemide or ethacrynic acid. The introductory sentences of the chapters

on furosemide and ethacrynic acid do not, on the basis of my own experience, entirely fit the real facts (for instance. notice the use of "accidentally"). The chapters on furosemide and ethacrynic acid are laid out in the same way and in clear manner. The references contain nothing later than 1967.

The mode of action and the clinical application of aldosterone antagonists (spironolactone) are explained lucidly and reference is made to the experimental procedure for the investigation of these substances. The pseudoantialdosterones which reduce K^+ elimination or retention by the kidneys are described with particular reference to the two main representatives of this group, triamterene and amiloride, whose clinical applicability has not yet been fully demonstrated (bibliography up to 1968). The diuretic uses of the glucocorticoids and the inhibitors of corticosteroid biosynthesis are described by *G. Senft* (deceased). Finally, the book deals with the use of cation exchangers as diuretics. The reviewer agrees with the editor on the important historical contribution of the chapter "Xanthine Derivatives as Diuretics".

The pleasing appearance of the printing is somewhat marred by the fact that art paper has been used only where histological illustrations are reproduced (production costs?). The editor and his colleagues have succeeded in producing a coherent and didactically well constructed book which, in addition to its uses as a handbook, will be of great value to both the student and the teacher of natural sciences.

Roman Muschaweck [NB 906 IE]

Organic Geochemistry. Methods and Results. Ed. by *G. Eglinton* and *M. T. J. Murphy*. Springer-Verlag, Berlin-Heidelberg-New York 1970. 1st Edit., xxiv, 828 pp., 246 figures, bound DM 178.—.

While biogeochemistry deals with the relation of sediments and minerals to plant and animal life, organic geochemistry concerns the characterization of organic substances as they occur in sediments and other natural environments.

The present book attempts for the first time to give comprehensive coverage to one of the youngest and most heterogeneous fields of knowledge on the fringes of organic chemistry, biology, and geology: 37 authors write about their own special fields in 31 chapters.

Chapters 2—6 present the organic chemist's approach and discuss the analytical possibilities for isolating and characterizing organic compounds: general methods, gas chromatography, mass spectrometry, isolation of kerogen and related substances from sediments and fossils.

Chapters 7—12 stress the biological and geological aspects: evolution, fossilization, sedimentology, organic substances in sediments, microbiological decomposition, and the biochemistry of the stable carbon isotopes. Chapters 13—19 give an account of the geological frequency of the classes of organic compounds most commonly occurring in sediments, hydrocarbons, fatty acids and alcohols, fossil carbohydrates, terpenoids, carotenoids, proteins, peptides and amino acids, and porphyrins.

Chapters 20—30 deal with the occurrence of certain compounds in specific geological situations: conchiolin in fossils and mussel shells, organic substances in gas occlusions in minerals, chemistry of the humic acids and related pigments, soil lipids, earth waxes, peat, Montan wax, fossil and recent kauri resins; kerogen from the Green River formation, crude oil, petroleum formation, carbon, importance of pre-paleozoic sediments in organic geochemistry.

Chapter 31 deals with the organic derivatives of clay minerals, zeolites, and related minerals.

In spite of the diverse nature of the material and the large number of authors this book provides a first survey of our knowledge of a field which in future will play an increasingly important role not only in science but also in practice.

German Muller [NB 914 IE]

Elektronenspinresonanz (Electron Spin Resonance). By *K. Scheffler* and *H. B. Stegmann*. Vol. 12 in the series Organic Chemistry Monographs. Ed. by *H. Bredereck, K. Hafner*, and *E. Müller*. Springer Verlag, Berlin-Heidelberg-New York 1970. 1st Edit., viii, 506 pp., 145 figures, bound, DM 120.—.

Electron spin resonance (ESR) spectroscopy has in recent years gained increasing importance as a physicochemical method of studying the paramagnetic properties of radicals. A monograph dealing with the use of this technique from the standpoint of the organic chemist is now available. ESR spectroscopy can be used to obtain information on the spin density distribution and the structure, as well as the dynamic behavior of radical molecules, *e.g.* in various solvents. However, the method has been used successfully for the detection of short-lived radical intermediates generated chemically or by electro-, photo-, or radiation-chemical processes.

The subdivision of the present book into two main sections is based on the realization that an introduction to the principles of ESR spectroscopy that is to be readily understandable whilst at the same time taking into account all the important recent developments in the technique should be separated from the detailed treatment of the most interesting classes of organic radicals. In adopting this subdivision it is of course necessary to reconcile oneself to repetition, since the theoretical treatment in the first part is elucidated by reference to numerous experimental results, which then appear again in the systematic section. In this way it may be possible to guide someone with limited experience, who turns to the book for the solution of practical problems, to the principles underlying the observed effects.

The chapters on dynamic effects and on electron-nucleus interactions are especially pleasing. As, indeed, in the rest of the book, extraordinary care has been taken here in citing the original literature. On the other hand, at many points opportunities have been missed for helping the reader who wishes to delve further into the subject, and who would have welcomed advice on more advanced textbooks and monographs.

The systematic section contains a chapter on organic radicals in solution, the relevant data appearing in valuable tables. Aids are given to the identification and interpretation of ESR spectra, as well as instructions for the preparation of standard radicals.

The book is well and clearly written and the general presentation is attractive. It will prove to be an essential tool not just to organic chemists but also to many others.

Klaus Eiben [NB 905 IE]

Physikalische Chemie. Teil I: Einführung in die Gastheorie, Quantentheorie, Thermodynamik (Physical Chemistry. Part I: Introduction to the Theory of Gases, Quantum Theory, Thermodynamics). By *G. M. Barrow*. Friedr. Vieweg u. Sohn, Braunschweig 1969. 1st Edit. 257 pp, 67 figures, 35 tables, paperback DM 19.80.

Gordon M. Barrow's textbook "Physical Chemistry" which is widely used in English-speaking countries, is to be published in German in three volumes. The first part, which was translated by *G. W. Herzog*, is now available. It contains an introduction to the theory of gases, the quantum theory, and thermodynamics.

The first half of the book (Chapters 1 to 4) presents an insight and an introduction into the actual principles of physical chemistry and its concepts. Some general properties and concepts are first presented with the empirical gas laws. This is followed by a discussion of the kinetic theory of gases and an introduction (confined to the barest essentials) to the constitution of matter and quantum mechanics and to classical and quantum statistics. The partition function is dealt with in rather more detail. However, it has been necessary here to

anticipate laws that are derived only in the volumes to be published later.

The second half of the book deals with thermodynamics. Though the layout differs only little from that of most textbooks on physical chemistry (first law, thermochemistry, second and third laws, equilibria), the preceding introduction to statistics is helpful, since the discussion of a thermodynamic quantity can be followed immediately by its statistical calculation.

The presentation of individual items of knowledge is deliberately avoided, and greater weight is placed instead on a detailed discussion of the laws of physical chemistry and the properties of the quantities described. This aim is reinforced by numerous examples of calculations in the text and in problems for practice at the end of each section.

The presentation and type are clear, and the illustrations are good. The book should make it easier for students to understand the thinking of physical chemistry.

Gerd Wedler [NB 899 IE]

Toxic Properties of Inorganic Fluorine Compounds. By *R. Y. Eagers*. Elsevier Publishing Company, Amsterdam-London-New York 1969. 1st Edit. x, 152 pp., bound, Dfl. 24.—.

This book differs fundamentally from the familiar Elsevier Monographs on Industrial Toxic Agents edited by *Ethel Browning* (e.g. *Pattison*: Toxic Aliphatic Fluorine Compounds, 1959). The difference is to be found not only in the external format of 6 × 9 in. as against the earlier 5 × 7½ in., but also in the approach to the subject. *Eagers* confines his attention essentially to cases of acute poisoning with inorganic fluorine compounds described in the literature, mass poisoning due to confusion between baking powder, *etc.* and fluorine compounds apparently being a subject of special preoccupation with him. An interest in history is evidenced in reports of cases of poisoning from the last century and the first half of the present one. Practically the only industrial poisonings described are those involving hydrogen fluoride. When dealing with their prevention and treatment the author also refers to more recent work. Regrettably, substances of such different toxicities as sulfur hexafluoride (MAC 1000 ppm) and sulfur pentafluoride (MAC 0.025 ppm) are referred to with merely the bare statement of these figures, whereas in the case of the latter a description should surely have been given of the fatal accidents that had occurred. Even the highly toxic boron trifluoride is no more than touched upon. Chronic and endemic fluorine poisoning (affecting the bones and teeth) is disposed of in 23 pages, and the effects on animals, insects, plants, enzymes, and bacteria in 28 pages, mainly in the form of tables. The book does have a bibliography with 730 entries (476 of them concerned with effects on animals, plants, enzymes, and bacteria!), but the authors are not arranged alphabetically and the titles of the works cited are not given. The Definition of Terms given on pages 2 and 3, which includes explanations of such items as acute, chronic, endemic, local, and systemic poisoning, makes one think that the book is intended primarily for laboratory workers, although the latter are hardly likely to be interested in the historical aspects. The industrial toxicologist will be disappointed, especially if, like the reviewer, he was expecting a continuation of the excellent Elsevier Monographs.

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABSOLUTE configuration, new method for determination of ~ of carboxylic acids (SC) 796 [G.E. *82*, 808 (1970)]

Aceheptylene, New synthesis (SC) 247 [G.E. *82*, 217 (1970)]

Acetone, Oligomeric molecules in ~, methanol, and formic acid vapors (LA) 745

Acetonitrile, Anodically induced 1,3-cycloaddition to 3,6-diisobutylpiperazine-2,5-dione (LA) 967

Acetylene, Dicyclopropyl- ~ by Fritsch-Buttenberg-Wiechell rearrangement (SC) 243 [G.E. *82*, 257 (1970)]

Reaction between oxygen atoms and ~ (LA) 250

Acids, Die Acidität der CH-Säuren (Book Review) 818

Acid halides, Behavior toward Lewis acids and Lewis bases (FP) 114 [G.E. *82*, 143 (1970)]

Acidity, of surface OH groups (LA) 252

Die Acidität der CH-Säuren (Book Review) 818

Acrylic esters, Preparation of glutamic acid derivatives from α-metalated ethyl isocyanoacetate and ~ (SC) 896 [G.E. *82*, 932 (1970)]

Actinides, The Halides of Lanthanides and Actinides (Book Review) 915

Actinoid complexes, Fluorine-bridged heteroadducts of organometallic lanthanoid complexes and ~ (SC) 957 [G.E. *82*, 956 (1970)]

Active transport, Some aspects of the ~ of amino acids (FP) 345 [G.E. *82*, 343 (1970)]

Acylium ions, Behavior of acid halides toward Lewis acids and Lewis bases (FP) 114 [G.E. *82*, 143 (1970)]

Adamantane, as a matrix for preparation and conservation of free radicals (LA) 471

Bis(adamantylidene)methane (LA) 814

Adenosine (3′-5′)-cyclophosphates, Synthesis of 5′-amido analogs (SC) 640 [G.E. *82*, 666 (1970)]

Adsorption, Inelastic interactions of slow electrons with adsorbed particles (FP) 255 [G.E. *82*, 263 (1970)]

Aldehydes, Catalytic cleavage to olefins, carbon monoxide, and hydrogen (SC) 169 [G.E. *82*, 181 (1970)]

Alkali atoms, Diffusion coefficient in flames (LA) 645

n-Alkanes, Homogeneous nucleation in supersaturated vapors of ~ (LA) 645

Alkali metals, Addition to 1,1-diphenyl-2-cyclopropylethylene (LA) 469

Alkaloid, Valerianine, a tertiary monoterpene ~ from valerian (SC) 891 [G.E. *82*, 875 (1970)]

Alkenes, Synthesis of γ-lactones from ~ (LA) 178

Alkenylamines, Addition of nitroacetylenes to ~ and ynamines (SC) 795 [G.E. *82*, 836 (1970)]

Enamines. Synthesis, structure, and reactions (Book Review) 747

Alkyl bromides, n-Ionization potentials (SC) 305 [G.E. *82*, 320 (1970)]

Alkyl-metal bond, Homolytic reactions (CR) 741 [G.E. *82*, 704 (1970)]

Alkynes, Simple new synthesis (SC) 464 [G.E. *82*, 484 (1970)]

Cycloaddition of halogenosulfonyl isocyanates to ~ (LA) 252

Alkynylamines, Addition of nitroacetylenes to enamines and ~ (SC) 795 [G.E. *82*, 836 (1970)]

Allene, New ~-s from 1-bromo-3,3-diphenylallenyllithium (SC) 524 [G.E. *82*, 548 (1970)]

Catalytic cyclodimerization (LA) 176

Allosteric enzymes, Biosynthesis of vitamins; ~ – recent results (CR) 384 [G.E. *82*, 398 (1970)]

π-Allylhydridonickel compounds (SC) 736 [G.E. *82*, 699 (1970)]

Aluminum compounds, The dipole moment of tris(2,4-pentanedionato)-aluminum (LA) 84

Amines, New degradation (SC) 892 [G.E. *82*, 876 (1970)]

Amino acids, Some aspects of the active transport of ~ (FP) 345 [G.E. *82*, 343 (1970)]

New route for asymmetric synthesis of α-~ (LA) 646

Synthesis of peptides from β-~ (LA) 745

Amino Acids Determination – Methods and Techniques (Book Review) 319

Amino-acid sequences, Automatic analysis of ~ in proteins and peptides (FP) 267 [G.E. *82*, 299 (1970)]

5′-Amino-5′-deoxyadenosine (3′-5′)-cyclophosphoramidate, Synthesis of 5′-amido analogs of adenosine (3′-5′)-cyclophosphates (SC) 640 [G.E. *82*, 666 (1970)]

Aminomethylation, Nucleophilic imino- and aminomethylation of ketones (SC) 163 [G.E. *82*, 138 (1970)]

Ammine complexes, The Thermal Properties of Transition Metal Ammine Complexes (Book Review) 387

Ammonia, Chemistry of the lanthanides in liquid ~ (CR) 383 [G.E. *82*, 397 (1970)]

Anaerobic organisms, Energy production in ~ (FP) 138 [G.E. *82*, 153 (1970)]

Analytical chemistry, Catalyzed reactions in ~ (CR) 910 [G.E. *82*, 886 (1970)]

Grundlagen der analytischen Chemie (Book Review) 968

Aniline, Conformations of ortho-disubstituted ~ and toluene derivatives. PMR and semiempirical energy calculation (SC) 806 [G.E. *82*, 840 (1970)]

Anionic polymerization of methacrylonitrile (CR) 538 [G.E. *82*, 560 (1970)]

[12]Annulene, Nitrogen-bridged ~ (LA) 815

Anthracene, Diffusion constant of mobile electrons in ~ (LA) 541

ana-Anthraquinone, Synthesis of an ~ (SC) 164 [G.E. *82*, 174 (1970)]

Anthraquinone-2-sulfonate, Chemiluminescence on oxidative formation of triplet states of anthrasemiquinone- and anthraquinone-2-sulfonate (SC) 307 [G.E. *82*, 321 (1970)]

Anthrasemiquinone, Chemiluminescence on oxidative formation of triplet states of anthrasemiquinone- and anthraquinone-2-sulfonate (SC) 307 [G.E. *82*, 321 (1970)]

Antibodies, Structure rule of ~ and the antibody problem (CR) 534 [G.E. *82*, 556 (1970)]

Antigens, Structure and immunogenicity of synthetic ~ (FP) 206 [G.E. *82*, 202 (1970)]

Antiinflammatory agents, Recent lines of development (CR) 315 [G.E. *82*, 296 (1970)]

Ants, Plant bioregulators in the metathoracic glands of myrmicine ~ (SC) 173 [G.E. *82*, 181 (1970)]

Aroxyl radical, Stable ~ of the heteroaromatic series (SC) 519 [G.E. *82*, 522 (1970)]

New aroxyls: mono-, di-, and triradicals, detection of a triplet state (SC) 520 [G.E. *82*, 521 (1970)]

Arsinate, Sodium dimethyldithio-~. A new complexing agent (SC) 811 [G.E. *82*, 842 (1970)]

Arylalkynes, Simple new synthesis (SC) 464 [G.E. *82*, 484 (1970)]

Asymmetric synthesis, New route for ~ of α-amino acids (LA) 646

Automerization, Synthesis and attempted ~ of [1-^{13}C]naphthalene (LA) 470

2-Azaallyllithium compounds, Anionic 3 + 2-cycloaddition to CN and NN double bonds (SC) 960 [G.E. *82*, 986 (1970)]

Azapeptides, Novel class of peptide analogs (CR) 813 [G.E. *82*, 817 (1970)]

Azepine, "Azepine ⇌ benzene imine" equilibrium (SC) 377 [G.E. *82*, 393 (1970)]

Structure of a tricarbonyl-1-isopropoxycarbonyl-1,2-diazepineiron complex (SC) 958 [G.E. *82*, 982 (1970)]

General synthesis of 1H-~ derivatives (LA) 176

1-Azetine, Reactions of azirines. Synthesis and properties of a ~ (SC) 731 [G.E. *82*, 772 (1970)]

Azide ion, Oxidative addition of ~ to olefins. A simple route to diamines (SC) 158 [G.E. *82*, 134 (1970)]

Azidinium salts, Heterocyclic ~ in preparative chemistry (CR) 80 [G.E. *82*, 86 (1970)]

Azido metal complexes as N_3 generators (SC) 735 [G.E. *82*, 701 (1970)]

Azimines, Amino-~ by addition of aminonitrenes to α-carbonylazo compounds (SC) 634 [G.E. *82*, 636 (1970)]

Aziridine, Stereospecific deaminations of some N-alkyl-~-s by m-chloroperbenzoic acid (SC) 374 [G.E. *82*, 395 (1970)]

$TiCl_4$-catalyzed addition to cyclic ketones (LA) 84

Vicinal halo(cyanoamines) and N-cyano-~-s (LA) 540

Aziridine imines (SC) 381 [G.E. *82*, 395 (1970)]

Aziridin-2-one, 1-tert-Butyl-3-(trifluoromethyl)-~ (LA) 912

Azirines, Reactions of ~. Synthesis and properties of a 1-azetine (SC) 731 [G.E. *82*, 772 (1970)]

Azo compounds, Liquid crystalline phases having particularly low freezing points (SC) 962 [G.E. *82*, 984 (1970)]

Azo groups, Radical 1,3-migration of aryl-~ – CIDNP effect with p-tolyl protons (SC) 804 [G.E. *82*, 813 (1970)]

Azomethine nitroxide, Unusual reaction of ~ radicals with carboxylic acids (SC) 636 [G.E. *82*, 634 (1970)]

Azoxy compounds, Liquid crystalline phases having particularly low freezing points (SC) 962 [G.E. *82*, 984 (1970)]

Azulene, Cycloadditions to the ~ system (SC) 159 [G.E. *82*, 135 (1970)]

New synthesis of 2H-benz-~ (SC) 248 [G.E. *82*, 218 (1970)]

BEETLES, Defensive chemistry of land and water ~ (FP) 1 [G.E. *82*, 17 (1970)]

2H-Benzazulenes, New synthesis (SC) 248 [G.E. *82*, 218 (1970)]

Benzenes, Distortions of the π-electron system in substituted ~ (FP) 87 [G.E. *82*, 106 (1970)]

Benzene imine, "Azepine ⇌ benzene imine" equilibrium (SC) 377 [G.E. *82*, 393 (1970)]

Benzene radical anion, Reinterpretation of the ESR spectrum ascribed to a non-degenerate state of ~ (SC) 73 [G.E. *82*, 45 (1970)]

Benz[c]isothiazole, New synthesis (LA) 177

Berkelium, Metallic ~, element 97 (LA) 386

Biallenyl, 1,2,4,5-Hexatetraene (~) (SC) 732 [G.E. *82*, 703 (1970)]

Bicyclo[6.1.0]nona-2,4,6-triene, Reactions with dienophiles (LA) 540

2,2'-Biimidazolidinylidenes, Stable dipoles from 1,1',3,3'-tetraaryl-~ and ketenes (SC) 375 [G.E. *82*, 394 (1970)]

Bile pigments, Recent chemistry and biochemistry (FP) 473 [G.E. *82*, 527 (1970)]

Biopolymers, Cooperative conformational transitions of linear ~ (FP) 389 [G.E. *82*, 468 (1970)]

Biphenylene, Single-step synthesis from 9-fluorenone in a discharge plasma (SC) 312 [G.E. *82*, 295 (1970)]

Bis(adamantylidene)methane (LA) 814

1,1'-Bisaziridyl, Conformational analysis of ~ by vibrational spectroscopy (SC) 245 [G.E. *82*, 258 (1970)]

Bishomo-o-quinodimethane, Dispiro-[2.0.2.4]deca-7,9-diene, a ~ (SC) 899 [G.E. *82*, 934 (1970)]

Bishomoquinone, Tricyclo[5.1.0.$0^{3,5}$]-octane-2,6-dione (LA) 176

anti-1,6:8,13-Bismethano[14]annulene (SC) 513 [G.E. *82*, 510 (1970)]

Bis(N-trimethylsilylimido)sulfur difluoride, Tris(N-trimethylsilylimido)sulfur and ~ (SC) 309 [G.E. *82*, 324 (1970)]

Bituminous coal, Dissolution of ~-s below 200 °C (CR) 81 [G.E. *82*, 87 (1970)]

Kinetics of fast thermal reactions in ~ (CR) 314 [G.E. *82*, 297 (1970)]

Butadiene, Novel effect of CO_2 on catalyst properties in the dimerization of ~ (LA) 250

1,6:8,13-Butanediylidene[14]annulene (SC) 516 [G.E. *82*, 513 (1970)]

n-Butyllithium, Cleaves carboxamides (LA) 316

3-Butynoate, Preparation of triethyl ortho-~ and its conversion into 5-oxo-3-alkynoate esters and into derivatives of 3,5-dioxoalkanoate esters (SC) 456 [G.E. *82*, 482 (1970)]

Bohr, From Planck to ~. The first fifteen years in the development of the quantum theory (FP) 34 [G.E. *82*, 1 (1970)]

Bonds, Polarity of covalent ~ (FP) 500 [G.E. *82*, 534 (1970)]

Bonding, Transition between metallic and ionic ~ in alkali and alkaline earth metal silicides (CR) 965 [G.E. *82*, 959 (1970)]

Bonding electrons, Distribution in decaborane-14 (SC) 524 [G.E. *82*, 519 (1970)]

Boranes, Cleavage of a carbon-sulfur bond by organodihalo-~ (SC) 738 [G.E. *82*, 774 (1970)]

Boron compounds, Metal-boron compounds – problems and perspectives (FP) 819 [G.E. *82*, 920 [1970)]

Compounds having the 1,2,4,3,5-trithiadiborolane skeleton (LA) 83

Boron heterocycle, Novel aromatic ~ as ligand in a transition metal π-complex (SC) 805 [G.E. *82*, 838 (1970)]

Bromine, Equilibrium of the system nitrosyl bromide/~/nitrogen monoxide (LA) 84

Bromo compounds, Conversion into chloro compounds (LA) 967

Bromo(pentafluorophenyl)silanes, Direct synthesis and reactions (SC) 467 [G.E. *82*, 483 (1970)]

Bullvalene, Stable complexes (SC) 800 [G.E. *82*, 810 (1970)]

Butadiene, Investigations on sequence length distribution of copolymers of α-methylstyrene and ~ (SC) 532 [G.E. *82*, 554 (1970)]

tert-Butylacetylene, Electrophilic cyclodimerization of ~ with hydrogen chloride (SC) 812 [G.E. *82*, 841 (1970)]

1-tert-Butylvinyl trifluoromethane sulfonate: solvolysis and rearrangement via a vinyl cation (SC) 302 [G.E. *82*, 323 (1970)]

CARBANION CHEMISTRY, Recent results (FP) 763 [G.E. *82*, 795 (1970)]

Carbene, Transfer of methoxyphenyl-~ ligands from molybdenum to iron and nickel (SC) 72 [G.E. *82*, 44 (1970)]

Cycloadditions of vinyl-~-s (CR) 526 [G.E. *82*, 549 (1970)]

Reaction of the ~ 2-methylpropylidene with olefins (LA) 84

α-Dimethylamino-α-methylthio-~ (LA) 912

New dichloro-~ generator (LA) 967

Carbene complexes, Ethoxydiethylaminocarbenepentacarbonylchromium(0) (SC) 309 [G.E. *82*, 325 (1970)]

$Ru_3(CO)_9H(C_6H_5CC_6H_4)$: A μ-hydridocarbonyl metal cluster derivative of diphenylcarbene (SC) 633 [G.E. *82*, 635 (1970)]

Carbohydrates, Determination of type of linkage in disaccharides by measurement of circular dichroism (SC) 964 [G.E. *82*, 985 (1970)]

Carbohydrate metabolism, Comprehensive Biochemistry (Book Review) 86

Carbon, New forms of ~ (FP) 414 [G.E. *82*, 401 (1970)]

MINDO/2 treatment of species present in ~ vapor (SC) 738 [G.E. *82*, 774 (1970)]

Insertion of atomic ~ (LA) 815

Carbon compounds, Silicon-carbon compounds with a carborundum structure ("carborundanes") (SC) 464 [G.E. *82*, 445 (1970)]

Carbon dioxide, Novel effect of ~ on catalyst properties in the dimerization of butadiene (LA) 250

Carbon disulfide, Cleavage of σ bonds between transition metals and carbon by ~ (SC) 639 [G.E. *82*, 639 (1970)]

Carbonic acid, Formation and decomposition in aqueous solution (LA) 177

Carbonic acid derivatives, Chlorosulfenylated ~ (FP) 54 [G.E. *82*, 63 (1970)]

Carbonium ions, Degenerate ~ (FP) 860 [G. E. *82*, 889 (1970)]

Carbon monoxide, Derivatives of tetrameric ~ (SC) 900 [G.E. *82*, 935 (1970)]

Carbon-sulfur bond, Cleavage of a ~ by organodihaloboranes (SC) 738 [G.E. *82*, 774 (1970)]

α-Carbonylazo compounds, Aminoazimines by addition of aminonitrenes to ~ (SC) 634 [G.E. *82*, 636 (1970)]

Carbonyl complexes, Hofmann- and Lossen-rearrangements (SC) 735 [G.E. *82*, 701 (1970)]

Carbonyl compounds, Ethyl 2-oxazoline-5-carboxylate from ethyl isocyanoacetate and ~ (SC) 300 [G.E. *82*, 290 (1970)]

Carborane, New ~ cage system (LA) 470

Naphtho[2,3-a]-o-~ (LA) 815

Carborundanes, Silicon-carbon compounds with a carborundum structure (~) (SC) 464 [G.E. *82*, 445 (1970)]

Carboxamides, n-Butyllithium cleaves ~ (LA) 316

Carboximide derivatives, Direct conversion of cyclic carboxylic acid anhydrides into ~ (SC) 68 [G.E. *82*, 81 (1970)]

Carboxylic acids, Unusual reaction of azomethine nitroxide radicals with ~ (SC) 636 [G.E. *82*, 634 (1970)]

New method for determination of absolute configuration of ~ (SC) 796 [G.E. *82*, 808 (1970)]

Carboxylic acid anhydrides, Direct conversion into carboximide derivatives (SC) 68 [G.E. *82*, 81 (1970)]

Carcinogens, Carcinogenic alkylating substances, chemical constitution and action (CR) 742 [G.E. *82*, 777 (1970)]

Catalysis, Transfer paths in heterogeneous ~ (CR) 966 [G. E. *82*, 959 (1970)]

Catalyst, Novel effect of CO_2 on ~ properties in the dimerization of butadiene (LA) 250

Catalytic oxidations, Configurational selectivity in ~ on platinum catalysts (CR) 383 [G.E. *82*, 363 (1970)]

Catalyzed reactions in analytical chemistry (CR) 910 [G.E. *82*, 886 (1970)]

Cation complexes, Cryptates, a new class of ~ (CR) 175 [G.E. *82*, 183 (1970)]

Cationic polymerization, Influence of electron donor-acceptor complexes on ~ (CR) 533 [G.E. *82*, 555 (1970)]

Investigations on the course of the cationic copolymerization of tetrahydrofuran with dicarboxylic anhydrides (CR) 536 [G.E. *82*, 558 (1970)]

Cell receptors, Structure and function (CR) 79 [G.E. *82*, 48 (1970)]

Cellulose derivatives, High-resolution NMR studies on ~ (CR) 533 [G.E. *82*, 555 (1970)]

Cell wall lipopolysaccharides, Recent results on the biochemistry of the ~ of Salmonella bacteria (FP) 649 [G.E. *82*, 708 (1970)]

Central nervous system, Biochemistry of ~. Some observations on mass transport (CR) 813 [G.E. *82*, 816 (1970)]

Cephalosporins, Synthesis and reactions of penicillin-like compounds (CR) 539 [G.E. *82*, 523 (1970)]

Charge distribution in ionic crystals (CR) 814 [G.E. *82*, 843 (1970)]

Charge-transfer triplet excited state,The problem of an intermolecular ~ (SC) 171 [G.E. *82*, 179 (1970)]

Chelates, New tetrachalcogenide ~ (SC) 801 [G.E. *82*, 814 (1970)]

α-Diimine-metal ~; cyclic delocalization of π-electrons and ^{13}C chemical shifts (SC) 963 [G.E. *82*, 957 (1970)]

Semiconductor properties of transition metal ~ (LA) 82

Chemiluminescence on oxidative formation of triplet states of anthrasemiquinone- and anthraquinone-2-sulfonate (SC) 307 [G.E. *82*, 321 (1970)]

Chiroids, Stereorelating syntheses of planar ~ (SC) 371 [G.E. *82*, 360 (1970)]

Chlorine difluoride radical (LA) 967

Chlorocarbonyl isocyanate, Isolation, properties, and reactions (LA) 470

Chloro compounds, Photochemical synthesis of aromatic ~ from aromatic iodo compounds (LA) 470

Conversion of bromo compounds into ~ (LA) 967

N-Chlorodifluoromethyleneamine (LA) 541

m-Chloroperbenzoic acid, Stereospecific deaminations of some N-alkylaziridines by ~ (SC) 374 [G.E. *82*, 395 (1970)]

Chromatography, Gas-liquid ~ and mass spectrometry in methylation analysis of polysaccharides (FP) 610 [G.E. *82*, 643 (1970)]

Chromophore, Crystal structure of the ~ from the yellow-green fluorescent peptide produced by iron-deficient Azotobacter vinelandii (LA) 317

Chromium complex, Tricyclo[4.3.1.$0^{1,6}$]-deca-2,4-dienetricarbonylchromium, a homoaromatic transition metal complex (SC) 303 [G.E. *82*, 292 (1970)]

Crystal structure of tricarbonyl complexes of chromium(0) and iron(0) with tricyclo[4.3.1.$0^{1,6}$]deca-2,4-diene (SC) 304 [G.E. *82*, 293 (1970)]

Ethoxydiethylaminocarbenepentacarbonylchromium(0) (SC) 309 [G.E. *82*, 325 (1970)]

Chromium compounds, Tetracarbonylbis(1,2-dimethyl-4-imidazolin-2-ylidene)chromium(0) (SC) 739 [G.E. *82*, 775 (1970)]

Chromosome damage in lead workers (LA) 815

Circular dichroism, Determination of type of linkage in disaccharides by measurement of ~ (SC) 964 [G.E. *82*, 985 (1970)]

Citric Acid Cycle (Book Review) 471

Claisen rearrangement, Extension of ~ (LA) 744

Coals, Dissolution of bituminous ~ below 200 °C (CR) 81 [G.E. *82*, 87 (1970)]

Cobaltates(V), Magnetic behavior of alkali-metal tetroxo-~ (SC) 519 [G.E. *82*, 519 (1970)]

Cobalt compounds, μ-Carbonyldi-μ-difluoromethylenebis(tricarbonyliron) (Fe–Fe) and di-μ-difluoromethylenebis(tricarbonylcobalt) (Co–Co) (SC) 166 [G.E. *82*, 182 (1970)]

Free radical additions to dicyclopentadienylcobalt (SC) 897 [G.E. *82*, 883 (1970)]

Tetrakis(trimethylphosphane)hydridocobalt(I) and -dihydridoiron(II) (SC) 904 [G.E. *82*, 885 (1970)]

Novel five-membered metal-metal-heterocycle (LA) 385

Cobalt complexes, Oxidation of the salicylaldehyde ligand in cobalt(II)- and nickel(II) complexes (SC) 640 [G.E. *82*, 640 (1970)]

Novel aromatic boron heterocycle as ligand in a transition metal π-complex (SC) 805 [G.E. *82*, 838 (1970)]

Solvolysis of σ-2-acetoxyalkylbis(biacetyldioximato)pyridinecobalt: Evidence for a novel intermediate olefinic complex (SC) 959 [G.E. *82*, 983 (1970)]

Collagen, Synthesis and conformation of ~ models (CR) 535 [G.E. *82*, 557 (1970)]

Color by action of mechanical forces on organic molecules (CR) 174 [G.E. *82*, 184 (1970)]

Communication, Present-day ~ in chemistry – problems and possibilities (FP) 545 [G.E. *82*, 563 (1970)]

Theoretical aspects of ~ in chemistry (FP) 555 [G.E. *82*, 574 (1970)]

Complexes, Magnetic resonance of paramagnetic ~ (FP) 196 [G.E. *82*, 227 (1970)]

NMR spectroscopy of paramagnetic ~ (FP) 946 [G.E. *82*, 975 (1970)]

Bis(trimethylstannyl)selenide and bis(trimethylstannyl)telluride as ligands in carbonyl ~ of transition metals (SC) 246 [G.E. *82*, 256 (1970)]

Cryptates, a new class of cation ~ (CR) 175 [G.E. *82*, 183 (1970)]

The influence of electron donor-acceptor ~ on cationic polymerization (CR) 533 [G.E. *82*, 555 (1970)]

Complexing agent, Sodium dimethyldithioarsinate a new ~ (SC) 811 [G.E. *82*, 842 (1970)]

Some polymeric complex formers (CR) 535 [G.E. *82*, 558 (1970)]

Configuration, Synthesis and determination of ~ of (3Z, 5E)-, (3Z, 5Z)-, and (3E, 5E)-N-cyclohexyl-6-phenyl-3,5-heptadienamide (SC) 239 [G.E. *82*, 220 (1970)]

Conformations of ortho-disubstituted aniline and toluene derivatives. PMR and semiempirical energy calculation (SC) 806 [G.E. *82*, 840 (1970)]

Conformational analysis of 1,1'-bisaziridyl by vibrational spectroscopy (SC) 245 [G.E. *82*, 258 (1970)]

Conformational isomerism of the eight-membered P–N ring in octaoxocyclotetraphosphazanates (SC) 78 [G.E. *82*, 85 (1970)]

Conformational transitions, Cooperative ~ of linear biopolymers (FP) 389 [G.E. *82*, 468 (1970)]

Cooperative conformational transitions of linear biopolymers (FP) 389 [G.E. *82*, 468 (1970)]

Coordination Chemistry in Nonaqueous Solutions (Book Review) 543

Coordination number, The ~ – an "inorganic chameleon" (FP) 25 [G.E. *82*, 7 (1970)]

Copolymerization, Problems of ~ in multicomponent systems (CR) 469 [G.E. *82*, 485 (1970)]

Copper, The reaction of N_2O with ~ surfaces (LA) 85

Copper compounds, Selective metalation of 1,2-bis-(6-methyl-2-pyridyl)ethane and its preparative uses (SC) 808 [G.E. *82*, 815 (1970)]

Copper sulfate, The fractionation of hydrogen isotopes during dehydration of $CuSO_4 \cdot 5\,H_2O$ (LA) 84

Coupling reaction, Photo-aryl ~ (LA) 744

Covalent bonds, Polarity (FP) 500 [G.E. *82*, 534 (1970)]

Covalent compounds,Ionization (heterolysis) of ~ as a coordination-chemical phenomenon (FP) 843 [G.E. *82*, 858 (1970)]

Crosslinking reactions in fibrous proteins under the action of monofunctional reagents (CR) 538 [G.E. *82*, 561 (1970)]

Cryptates, a new class of cation complexes (CR) 175 [G.E. *82*, 183 (1970)]

Crystals, Disorder in solids (ionic ~ and metals) (FP) 489 [G.E. *82*, 498 (1970)]

Radiation effects in NH_4HF_2 and $NaHF_2$ ~ (LA) 645

Crystal chemistry, Grundzüge der anorganischen Kristallchemie (Book Review) 746

Crystal growth from the vapor phase (CR) 78 [G.E. *82*, 48 (1970)]

Crystallization, Kristallisation. Grundlagen und Technik (Book Review) 85

Crystal structure, of tricarbonyl complexes of chromium(0) and iron(0) with tricyclo[4.3.1.$0^{1,6}$]deca-2,4-diene (SC) 304 [G.E. *82*, 293 (1970)]

X-Ray structure analysis of a 1,2,3,6,-7,8-hexathiecane (SC) 313 [G.E. *82*, 319 (1970)]

~ of cycloheptasulfur (SC) 379 [G.E. *82*, 390 (1970)]

~ of $TeCl_4$: Presence of tetramers in solid chalcogen(IV) halides (SC) 463 [G.E. *82*, 446 (1970)]

~ of 1,6:8,13-propanediylidene[14]-annulene (SC) 519 [G.E. *82*, 516 (1970)]

~ and molecular structure of $Zn_7O_8(CH_3)_{14}$ – a dicubane (SC) 905 [G.E. *82*, 931 (1970)]

~ of the chromophore from the yellow-green fluorescent peptide produced by iron-deficient Azotobacter vinelandii (LA) 317

Cumulenes, New synthesis (LA) 816

Cyanoacetaldehyde derivatives (LA) 251

Cyanoamines, Vicinal halo(~) and N-cyanoaziridines (LA) 540

N-Cyanoaziridines, Vicinal halo(cyanoamines) and ~ (LA) 540

Cycloaddition, to the azulene system (SC) 159 [G.E. *82*, 135 (1970)]

~ to homofulvenes (SC) 167 [G.E. *82*, 176 (1970)]

Osazone formation from α-haloketones. A novel 1,4-~ (SC) 242 [G.E. *82*, 254 (1970)]

Geometry of transition state in polar ~ (SC) 311 [G.E. *82*, 322 (1970)]

Anionic 3 + 2 ~ (SC) 380 [G.E. *82*, 396 (1970)]

Anionic 3+2 ~ of 2-azaallyllithium compounds to CN and NN double bonds (SC) 960 [G.E. *82*, 986 (1970)]

Anionic 3+2 ~ of a 1,2-diazaallyllithium compound (SC) 961 [G.E. *82*, 987 (1970)]

~-s of vinylcarbenes (CR) 526 [G.E. *82*, 549 (1970)]

~ of halogenosulfonyl isocyanates to alkynes (LA) 252

~ of cis,cis,cis-1,3,5,7-cyclononatetraene to 4-phenyl-1,2,4-triazoline-3,5-dione (LA) 469

Intramolecular nitrone-olefin ~-s leading to heterocycles (LA) 540

Anodically induced 1,3-~ of acetonitrile to 3,6-diisobutylpiperazine-2,5-dione (LA) 967

Cycloalk-2-ene-1,4-diones, Intramolecular cyclization of bis(α-diazoketones) to ~ (LA) 744

Cyclobutadienes, Alkyl-substituted ~ (SC) 529 [G.E. *82*, 551 (1970)]

Cyclobutane, Photoelectron spectrum (SC) 953 [G.E. *82*, 952 (1970)]

Fine structure of fundamental bands in the IR spectrum of ~ vapor (LA) 645

Cyclobutanone, New spiro-~ synthesis in the steroid series (SC) 237 [G.E. *82*, 219 (1970)]

Cyclobutenedione, Novel ring opening of hydroxyphenyl-~ (SC) 793 [G.E. *82*, 807 (1970)]

Cyclodimerization, Stereochemistry of catalyzed ~ of piperylene (SC) 528 [G.E. *82*, 550 (1970)]

Electrophilic ~ of tert-butylacetylene with hydrogen chloride (SC) 812 [G.E. *82*, 841 (1970)]

Catalytic ~ of allene (LA) 176

Cycloheptasulfur, Structure (SC) 379 [G.E. *82*, 390 (1970)]

1,2-Cyclohexadiene, Trapping of ~ (LA) 646

2,4-Cyclohexadienone, Photoacid derivatives of an achiral and a chiral ~ (SC) 238 [G.E. *82*, 219 (1970)]

Evidence of two configurational isomers of dienylketenes from 6-methyl-6-phenyl-~ by low temperature spectroscopy (SC) 240 [G.E. *82*, 221 (1970)]

The two configurational isomers of dienylketenes obtained as primary photoproducts from n,π*-excited 6-methyl-6-phenyl-~ (SC) 241 [G.E. *82*, 222 (1970)]

3-Cyclohexenyl Grignard compounds, Ring contraction on rearrangement (SC) 909 [G.E. *82*, 938 (1970)]

N-Cyclohexyl-6-phenyl-3,5-heptadienamide, Synthesis and determination of configuration of (3Z, 5E)-, (3Z, 5Z)-, and (3E, 5E)-~ (SC) 239 [G.E. *82*, 220 (1970)]

Cyclononatetraene, The cycloaddition of cis,cis,cis-1,3,5,7-~ to 4-phenyl-1,2,4-triazoline-3,5-dione (LA) 469

Cyclooctane, 1,2,5,6-Tetramethylene-~ (LA) 646

Cyclooctatetraene, Flattening of ~ systems by steric constraints (SC) 527 [G.E. *82*, 516 (1970)]

Unknown anti-3 + 2 dimer (LA) 386

1,3,5-Cyclooctatriene, 7,8-Dimethylene-~ (LA) 385

Cyclooctatriene complexes with fluctuating ligands (SC) 638 [G.E. *82*, 667 (1970)]

Cyclopentasulfur pentanitride, Preparation and structure of ~ cation (LA) 178

Cyclopeptides, Syntheses in the cyclopeptide series (CR) 315 [G.E. *82*, 327 (1970)]

Cyclopropane, Reaction of 1,1-diphenyl-~ with tetracyanoethylene (SC) 236 [G.E.*82*, 216 (1970)]

Dimethylene-~ (SC) 798 [G.E. *82*, 810 (1970)]

New route to phenyl-~-s (LA) 82

Cyclopropene, 3-Methyl-~ from 1-chloro-2-butenes (SC) 810 [G.E. *82*, 839 (1970)]

Cyclopropylethylene, Addition of alkali metals to 1,1-diphenyl-2-~ (LA) 469

Cyclotetraphosphazanates, Conformational isomerism of the eight-membered P–N ring in octaoxo-~ (SC) 78 [G.E. *82*, 85 (1970)]

3,7,11-Cyclotridecatrien-1-one and 11-vinyl-3,7-cycloundecadien-1-one (SC) 367 [G.E. *82*, 355 (1970)]

3,7-Cycloundecadien-1-one, 3,7,11-Cyclotridecatrien-1-one and 11-vinyl-~ (SC) 367 [G.E. *82*, 355 (1970)]

Cysteine, β-Substituted N-formyl-S-benzyl-~-s (SC) 236 [G.E. *82*, 253 (1970)]

Cysteine peptides, Fourier transform ^{13}C-NMR spectroscopy of biologically active ~ (SC) 894 [G.E. *82*, 882 (1970)]

Cytidine, Separation of nucleosides on ~-containing polymer gels in DMSO/$CHCl_3$ or water (SC) 465 [G.E. *82*, 448 (1970)]

β-Cytosine arabinoside, New simple synthesis (LA) 84

DEAMINATIONS, Stereospecific ~ of some N-alkylaziridines by m-chloroperbenzoic acid (SC) 374 [G.E. *82*, 395 (1970)]

Decaborane-14, Distribution of bonding electrons (SC) 524 [G.E. *82*, 519 (1970)]

Defensive substances, Defensive chemistry of land and water beetles (FP) 1 [G.E. *82*, 17 (1970)]

Degenerate carbonium ions (FP) 860 [G.E. *82*, 889 (1970)]

Dehydrobenzene from aromatic diazonium salts (SC) 522 [G.E. *82*, 547 (1970)]

Dehydrocyclopentadienyl anion (LA) 912.

Diamines, Oxidative addition of the azide ion to olefins. A simple route to ~ (SC) 158 [G.E. *82*, 134 (1970)]

2,4-Diaminopyridines, Simple synthesis (SC) 377 [G.E. *82*, 392 (1970)]

1,2-Diazaallyllithium compound, Anionic 3+2 cycloaddition of a ~ (SC) 961 [G.E. *82*, 987 (1970)]

1,3-Diazetidinediones, New preparation (SC) 372 [G.E. *82*, 362 (1970)]

Diazirine, Lone pair interaction in 3,3-dimethyl-~ (SC) 902 [G.E. *82*, 879 (1970)]

Diazoacetate, Ethyl lithio-~ (SC) 301 [G.E. *82*, 291 (1970)]

Diazo compounds, Recent investigations on the synthesis and reactivity of ~ (CR) 249 [G.E. *82*, 224 (1970)]

Diazoketones, Intramolecular cyclization of bis(α-~) to cycloalk-2-ene-1,4-diones (LA) 744

Diazonium salts, Dehydrobenzene from aromatic ~ (SC) 522 [G.E. *82*, 547 (1970)]

Substituted ethylene-~ (SC) 954 [G.E. *82*, 953 (1970)]

Dicyclopentadienylcobalt, Free radical additions to ~ (SC) 897 [G.E. *82*, 883 (1970)]

Dichlorocarbene, New ~ generator (LA) 967

Dichlorovinylene carbonate, Derivatives of tetrameric carbon monoxide (SC) 900 [G.E. *82*, 935 (1970)]

Dibenzo[a,o]perylene, Structure of the photo-oxide of ~ (LA) 177

(Dibenzoyldioxyiodo)benzenes, Synthesis and reactions of substituted ~; A new class of organic oxidants (SC) 797 [G.E. *82*, 834 (1970)]

Dibromostyrene, Pure cis- and trans-α,β-~ (LA) 744

Dicarboxylic anhydrides, Investigations on the course of the cationic copolymerization of tetrahydrofuran with ~ (CR) 536 [G.E. *82*, 558 (1970)]

Dichlorocarbene from trichloromethyllithium (SC) 169 [G.E. *82*, 177 (1970)]

8,8-Dichloro-1,2,3,4,5,6,7,8-heptathiatellur(IV)-ocane (SC) 463 [G.E. *82*, 447 (1970)]

Dictionary, Terminologie Chimique Franco-Anglaise. French-English Chemical Terminology (Book Review) 318

cis-1,2-Dicyano-1,2-ethylenedithiol, The "silver salt" of ~ (SC) 740 [G.E. *82*, 775 (1970)]

Dicyclopropylacetylene by Fritsch-Buttenberg-Wiechell rearrangement (SC) 243 [G.E. *82*, 257 (1970)]

Flames, Diffusion coefficient of alkali atoms in ~ (LA) 645

Flavoring substances, Volatile ~ in foodstuffs (FP) 917 [G.E. *82*, 965 (1970)]

Fluctuating ligands, Cyclooctatriene complexes with ~ (SC) 638 [G.E. *82*, 667 (1970)]

9-Fluorenone, Single-step synthesis of biphenylene from ~ in a discharge plasma (SC) 312 [G.E. *82*, 295 (1970)]

Fluorenone hydrazones, Unusual reaction (SC) 370 [G.E. *82*, 361 (1970)]

Fluoride donor, Xenon(II) fluoride pentafluoroorthotellurate as ~ (SC) 375 [G.E. *82*, 357 (1970)]

Fluorides, Radiation effects in NH_4HF_2 and $NaHF_2$ crystals (LA) 645

Fluorine, The Chemistry of Fluorine and its Compounds (Book Review) 817

Fluorine compounds, Hydrogen fluoride potassium hydrogen phosphite(1/1), an unusual lattice compound (SC) 459 [G.E. *82*, 443 (1970)]

Fluorine-bridged heteroadducts of organometallic lanthanoid and actinoid complexes (SC) 957 [G.E. *82*, 956 (1970)]

Syntheses involving perfluoroalkyl radicals from perfluoroalkyl iodides (LA) 83

Structure of IF_6^+ and IF_6^- (LA) 84

Toxic properties of inorganic fluorine compounds (Book Review) 970

Folic acid, Biochemistry of Folic Acid and Related Pteridines (Book Review) 748

Foods, Chemical changes in radiation-preserved ~ (CR) 539 [G.E. *82*, 522 (1970)]

Foodstuffs, Volatile flavoring substances in ~ (FP) 917 [G.E. *82*, 965 (1970)]

Formamide, All-electron calculations on lithium cyanide and ~ (CR) 911 [G.E. *82*, 939 (1970)]

~-s (LA) 317

Formic acid, Reactions with addition compounds containing activated ~ (FP) 50 [G.E. *82*, 73 (1970)]

Oligomeric molecules in acetone, methanol, and ~ vapors (LA) 745

N-Formyl-S-benzylcysteines, β-Substituted ~ (SC) 236 [G.E. *82*, 253 (1970)]

N-Formylphenylalanine ethyl esters by hydrogenolysis of ethyl 5-aryl-2-oxazoline-4-carboxylates (SC) 459 [G.E. *82*, 483 (1970)]

Fragmentation of a sydnone (LA) 912

Free radical additions to dicyclopentadienylcobalt (SC) 897 [G.E. *82*, 883 (1970)]

Free-radical chemistry, Relations between structure and reactivity in ~ (FP) 830 [G.E. *82*, 845 (1970)]

Methods in Free-Radical Chemistry (Book Review) 915

Fuel Cells, Electrochemical Processes in Fuel Cells (Book Review) 647

Fuel Cells and Fuel Batteries (Book Review) 747

GASES, The Virial Coefficients of Gases (Book Review) 746

Gas chromatography, Determination of halide ions (SC) 374 [G.E. *82*, 392 (1970)]

Practical Manual of Gas Chromatography (Book Review) 914

Gas molecules, A new separation method (LA) 317

Gel chromatography (FP) 689 [G.E. *82*, 675 (1970)]

Separation of nucleosides on polymer gels containing thymine or cytidine (SC) 68 [G.E. *82*, 82 (1970)]

Limits in the scope of ~ (CR) 538 [G.E. *82*, 560 (1970)]

Genetic analysis, Protein mapping in polyacrylamide and its application to ~ in plants (CR) 643 [G.E. *82*, 640 (1970)]

Geochemistry, Organic Geochemistry (Book Review) 969

Germanates, Hexathio-di-~ and -distannates. A new type of dimeric tetrahedral ion (SC) 897 [G.E. *82*, 884 (1970)]

Germanium compounds, A novel five-membered metal-metal heterocycle (LA) 385

Glass, Phototropic ~ (FP) 434 [G.E. *82*, 421 (1970)]

Glutamic acid derivatives, Preparation from α-metalated ethyl isocyanoacetate and acrylic esters (SC) 896 [G.E. *82*, 932 (1970)

Glutamine synthetase, Regulation by enzyme catalyzed structural modification (FP) 670 [G.E. *82*, 689 (1970)]

Glycosides, New preparation (SC) 455 [G.E. *82*, 480 (1970)]

Gold compounds, Organogold chemistry (FP) 101 [G.E. *82*, 120 (1970)]

Graphite, Evaporation (LA) 84

Grignard compounds, Ring contraction on rearrangement of 3-cyclohexenyl ~ (SC) 909 [G.E. *82*, 938 (1970)]

Group theory, Chemistry and logical structures (FP) 703 [G.E. *82*, 741 (1970)]

HALIDE ions, Determination by gas chromatography (SC) 374 [G.E. *82*, 392 (1970)]

Hall effect and electrical conductivity of lithium-ammonia solutions (LA) 745

Halo(cyanoamines), Vicinal ~ and N-cyanoaziridines (LA) 540

Halogens, Reactions of atomic and molecular ~ with silver (LA) 384

Halogen incandescent lamp, New contribution to the chemistry of the ~ (LA) 744

α-Haloketones, Osazone formation from ~. A novel 1,4-cycloaddition (SC) 242 [G.E. *82*, 254 (1970)]

Handbook, Handbook of Chemistry and Physics (Book Review) 85

Handbuch der analytischen Chemie (Book Review) 85

Gmelins Handbuch der anorganischen Chemie (Book Review) 913

Hard materials, Principles and latest developments in the field of metallic and nonmetallic ~ (FP) 926 [G.E. Chemie-Ing.-Techn. *42*, 589 (1970)]

3,5-Heptadienamide, Synthesis and determination of configuration of (3Z, 5E)-, (3Z, 5Z)-, and (3E, 5E)-N-cyclohexyl-6-phenyl-~ (SC) 239 [G.E. *82*, 220 (1970)]

Heptathiatellur(IV)-ocane, 8,8-Dichloro-1,2,3,4,5,6,7,8-~ (SC) 463 [G.E. *82*, 447 (1970)]

1,trans-3,trans-5-Heptatriene, Gas phase isomerization (LA) 385

cis,cis-1,4,6-Heptatrienoic acids, Cyclization of the 2,3-dihalo-4,5,6,7,7-pentachloro-~ (LA) 540

Heterocycles, Intramolecular nitrone-olefin cycloadditions leading to ~ (LA) 540

Chemie der Heterocyclen (Book Review) 179

Heterolysis, Ionization (~) of covalent compounds as a coordination-chemical phenomenon (FP) 843 [G.E. *82*, 850 (1970)]

Hexaammineiron(II) chloride, Mössbauer spectra (LA) 317

Hexachlorodisilane, Use as a reducing agent (LA) 251

1,2,4,5-Hexatetraene (biallenyl) (SC) 732 [G.E. *82*, 703 (1970)]

1,2,3,6,7,8-Hexathiecane, X-Ray structure analysis (SC) 313 [G.E. *82*, 319 (1970)]

Hofmann-rearrangement, Hofmann- and Lossen-rearrangements of carbonyl complexes (SC) 735 [G.E. *82*, 701 (1970)]

Homo-1H-azepine, Synthesis and photoisomerization of ~ derivatives (LA) 317

Homobenzenes, Monohetero derivatives of bis- and tris-~ (SC) 799 [G.E. *82*, 836 (1970)]

Homofulvenes, Cycloaddition to ~ (SC) 167 [G.E. *82*, 176 (1970)]

Homolytic reactions of the alkyl-metal bond (CR) 741 [G.E. *82*, 704 (1970)]

Homopentaprismane (LA) 316

Hot atoms, Chemie heisser Atome (Book Review) 471

Hydrazones, Unusual reaction of fluorenone ~ (SC) 370 [G.E. *82*, 361 (1970)]

Hydrocarbons, Novel photooxidation of ~ involving triplet oxygen (CR) 644 [G.E. *82*, 671 (1970)]

Hydrogen, Phase diagram of the niobium-~ system (LA) 250

Hydrogen bonds, in a Ni–Ni system (SC) 312 [G.E. *82*, 295 (1970)]

Neutron energy-loss spectrometry (LA) 384

Hydrogen fluoride-potassium hydrogen phosphite (1/1), an unusual lattice compound (SC) 459 [G.E. *82*, 443 (1970)]

Hydrogen ion, Spectroscopic evidence for the $H_5O_2^+$ ion (LA) 470

Hydrogen isotopes, Fractionation of ~ during dehydration of $CuSO_4 \cdot 5\ H_2O$ (LA) 84

Hydroxy steroids, New method for structure determination (SC) 75 [G.E. *82*, 82 (1970)]

IMIDAZOLE, Conductivity of ~ single crystals (LA) 471

Imides, New synthesis (LA) 967

Imido groups, Polymer-analogous formation of ~ in methacrylic acid/methacrylonitrile copolymers (CR) 537 [G.E. *82*, 559 (1970)]

Iminocarbonates, Spiroorthocarbonates and cyclic ~ (LA) 470

Iminomethylation, Nucleophilic imino- and aminomethylation of ketones (SC) 163 [G.E. *82*, 138 (1970)]

Iminosulfur oxydifluorides, Novel ~ (SC) 905 [G.E. *82*, 931 (1970)]

Immunogenicity, Structure and ~ of synthetic antigens (FP) 206 [G.E. *82*, 202 (1970)]

Incandescent lamp, New contribution to the chemistry of the halogen ~ (LA) 744

3-Indolylacetic acid, Plant bioregulators in the metathoracic glands of myrmicine ants (SC) 173 [G.E. *82*, 181 (1970)]

Inductive effect, CNDO calculation of ~ of the methyl group (SC) 462 [G.E. *82*, 444 (1970)]

Information services, Chemical ~ (FP) 550 [G.E. *82*, 559 (1970)]

Inorganic chemistry, Anorganische Chemie (Book Review) 818

Gmelins Handbuch der anorganischen Chemie (Book Review) 913

Interferons (FP) 480 [G.E. *82*, 489 (1970)]

Intermediates, Differential calorimetric study of the reactivity of unstable compounds (FP) 288 [G.E. *82*, 306 (1970)]

Kinetic evidence for reactive ~ (FP) 751 [G.E. *82*, 783 (1970)]

Inversion, Detection of hindered rotation and ~ by NMR spectroscopy (FP) 219 [G.E. *82*, 237 (1970)]

Pyramidal ~ (FP) 400 [G.E. *82*, 453 (1970)]

Iodine compounds, Structure of IF_6^+ and IF_6^- (LA) 84

The yellow adduct $(thiourea)_2 \cdot I_2$ (LA) 252

Iodo compounds, Synthesis and reactions of substituted (dibenzoyldioxyiodo)benzenes; a new class of organic oxidants (SC) 797 [G.E. *82*, 834 (1970)]

Photochemical synthesis of aromatic chloro compounds from aromatic ~ (LA) 470

Iodophosphanes PH_2I and PHI_2 (SC) 808 [G.E. *82*, 808 (1970)]

Ionic crystals, Charge distribution in ~ (CR) 814 [G.E. *82*, 843 (1970)]

Ionization (heterolysis) of covalent compounds as a coordination-chemical phenomenon (FP) 843 [G.E. *82*, 858 (1970)]

Ionization isomerism of sulfinato complexes of transition metals (SC) 308 [G.E. *82*, 322 (1970)]

n-Ionization potentials of alkyl bromides (SC) 305 [G.E. *82*, 320 (1970)]

Ionomers, Polyurethane ~, a new class of block polymers (FP) 40 [G.E. *82*, 53 (1970)]

Ion-selective sensors (FP) 445 [G.E. *82*, 433 (1970)]

Iron carbides, Oxidation (LA) 645

Iron complexes, Crystal structure of tricarbonyl complexes of chromium(0) and iron(0) with tricyclo[4.3.1.$0^{1,6}$]-deca-2,4-diene (SC) 304 [G.E. *82*, 293 (1970)]

Anomalous spin state of iron(II) in $[Fe(phen)_3]\,(ClO_4)_2 \cdot 2H_2O$ (SC) 637 [G.E. *82*, 638 (1970)]

Structure of a tricarbonyl-1-isopropoxycarbonyl-1,2-diazepineiron complex (SC) 958 [G.E. *82*, 982 (1970)]

Iron compounds, Transfer of methoxyphenylcarbene ligands from molybdenum to iron and nickel (SC) 72 [G.E. *82*, 44 (1970)]

μ-Carbonyldi-μ-difluoromethylenebis-(tricarbonyliron) (Fe–Fe) and di-μ-difluoromethylenebis (tricarbonylcobalt) (Co–Co) (SC) 166 [G.E. *82*, 182 (1970)]

Tetrakis(trimethylphosphane)hydridocobalt(I) and -dihydridoiron(II) (SC) 904 [G.E. *82*, 885 (1970)]

Mössbauer spectra of hexaammineiron(II) chloride (LA) 317

Novel five-membered metal-metal heterocycle (LA) 385

A tetrahedral metal cluster (LA) 541

Isocyanate, Investigation of the nitrile oxide-~ rearrangement (SC) 635 [G.E. *82*, 637 (1970)]

Cycloaddition of halogenosulfonyl ~-s to alkynes (LA) 252

Isocyanides, Recent results in carbanion chemistry (FP) 763 [G.E. *82*, 795 (1970)]

2-Isocyano-1-alkanols from carbonyl compounds and α-metalated ~ (SC) 458 [G.E. *82*, 482 (1970)]

Isocyanoacetate, Ethyl 2-oxazoline-5-carboxylate from ethyl ~ and carbonyl compounds (SC) 300 [G.E. *82*, 290 (1970)]

Preparation of glutamic acid derivatives from α-metalated ethyl ~ and acrylic esters (SC) 896 [G.E. *82*, 932 (1970)]

2-Isocyano-1-alkanols from carbonyl compounds and α-metalated isocyanides (SC) 458 [G.E. *82*, 482 (1970)]

Isomerism, syn-anti-~ at the carbon-sulfur double bond in isothiouronium salts (SC) 641 [G.E. *82*, 666 (1970)]

Isomerization, Gas phase ~ of 1,trans-3,trans-5-heptatriene (LA) 385

3-Isopropylidene-2,2-dimethyloxirane (tetramethylallene oxide) (SC) 71 [G.E. *82*, 43 (1970)]

2-Isopropyl-2-oxazoline, Addition of maleic anhydride to ~ (SC) 460 [G.E. *82*, 448 (1970)]

Isoquinoline, Mutual thermal interconversion of quinoline and ~ (LA) 540

Isothiathiophthene, Molecular structure of an "~" (LA) 384

Isothiocyanates, Thermal cyclization of o-chloraryl ~ (SC) 65 [G.E. *82*, 79 (1970)]

4-Isothiocyanatobenzenesulfonic acid as reagent for Edman peptide degradation (SC) 731 [G.E. *82*, 771 (1970)]

Isothiocyanato carboxylic acids and 2-thio-5-oxazolidones (SC) 526 [G.E. *82*, 550 (1970)]

Isothiouronium salts, syn-anti-isomerism at the carbon-sulfur double bond in ~ (SC) 641 [G.E. *82*, 666 (1970)]

KETENES, Evidence of two configurational isomers of dienyl-~ from 6-methyl-6-phenyl-2,4-cyclohexadienone by low temperature spectroscopy (SC) 240 [G.E. *82*, 221 (1970)]

The two configurational isomers of dienyl-~ obtained as primary photoproducts from n,π*-excited 6-methyl-6-phenyl-2,4-cyclohexadienone (SC) 241 [G.E. *82*, 222 (1970)]

Stable dipoles from 1,1′,3,3′-tetraaryl-2,2′-biimidazolidinylidenes and ~(SC) 375 [G.E. *82*, 394 (1970)]

Ketones, Nucleophilic imino- and aminomethylation of ~ (SC) 163 [G.E. *82*, 138 (1970)]

Reactions of 2,2-diethoxyvinylidenetriphenylphosphorane with ~. Synthesis of 1,3-dioxo-4-pentenes and their enol ethers (SC) 367 [G.E. *82*, 359 (1970)]

$TiCl_4$-catalyzed addition of aziridine to cyclic ~ (LA) 84

Kinetics, Kinetic evidence for reactive intermediates (FP) 751 [G.E. *82*, 783 (1970)]

~ of fast thermal reactions in bituminous coal (CR) 314 [G.E. *82*, 297 (1970)]

Comprehensive Chemical Kinetics (Book Review) 387

LABORATORIES, Chemische und biologische Laboratorien (Book Review) 541

γ-Lactones, A simple synthesis of α-methylene-~ (SC) 457 [G.E. *82*, 480 (1970)]

Synthesis from alkenes (LA) 178

Lanthanides, Chemistry of the ~ in liquid ammonia (CR) 383 [G.E. *82*, 397 (1970)]

The Halides of Lanthanides and Actinides (Book Review) 915

Lanthanoid complexes, Fluorine-bridged heteroadducts of organometallic ~ and actinoid complexes (SC) 957 [G.E. *82*, 956 (1970)]

Lasers, Chemical ~ (FP) 773 [G.E. Chemie-Ing.-Techn. *42*, 573 (1970)]

Laser Raman Spectroscopy (Book Review) 915

Laser technology, Organic dyes in ~ (FP) 9 [G.E. *82*, 25 (1970)]

Lead compounds, Crystalline π-radicals containing lead – isotropic ^{207}Pb-ESR hyperfine structure (SC) 456 [G.E. *82*, 481 (1970)]

Leed, Inelastic interactions of slow electrons with adsorbed particles (FP) 255 [G.E. *82*, 263 (1970)]

Leuchs anhydrides, Diketopiperazines from ~ (SC) 162 [G.E. *82*, 137 (1970)]

Lewis acids, The behavior of acid halides toward ~ and Lewis bases (FP) 114 [G.E. *82*, 143 (1970)]

Lewis bases, The behavior of acid halides toward Lewis acids and ~ (FP) 114 [G.E. *82*, 143 (1970)]

Light scattering, by branched systems (CR) 532 [G.E. *82*, 554 (1970)]

~ measurements on polymer solutions in the pressure range 1–1000 atm (CR) 534 [G.E. *82*, 557 (1970)]

Determination of the heterogeneity of the chemical composition of copolymers by the ~ method (CR) 535 [G.E. *82*, 557 (1970)]

Lipopolysaccharides, Recent results on the biochemistry of the cell wall ~ of Salmonella bacteria (FP) 649 [G.E. *82*, 708 (1970)]

Liquid crystals, Liquid crystalline phases having particularly low freezing points (SC) 962 [G.E. *82*, 984 (1970)]

Lithium cyanide, All-electron calculations on ~ and formamide (CR) 911 [G.E. *82*, 939 (1970)]

Literature, The Use of Chemical Literature (Book Review) 748

Lithiodiazoacetate, Ethyl ~ (SC) 301 [G.E. *82*, 291 (1970)]

Lithium, Hall effect and electrical conductivity of ~-ammonia solutions (LA) 745

Lithium compounds, Dichlorocarbene from trichloromethyllithium (SC) 169 [G.E. *82*, 177 (1970)]

New allenes from 1-bromo-3,3-diphenylallenyllithium (SC) 524 [G.E. *82*, 548 (1970)]

Anionic 3+2 cycloaddition of 2-azaallyllithium compounds to CN and NN double bonds (SC) 960 [G.E. *82*, 986 (1970)]

Anionic 3+2 cycloaddition of a 1,2-diazaallyllithium compound (SC) 961 [G.E. *82*, 987 (1970)]

Lossen-rearrangement, Hofmann- and Lossen-rearrangements of carbonyl complexes (SC) 735 [G.E. *82*, 701 (1970)]

2,6-Lutidine, NMR study of the ~-water system in the critical region (LA) 745

MACROMOLECULAR colloquium (CR) 531 [G.E. *82*, 553 (1970)]

Macromolecules, Macromolecular chemistry and medicine (FP) 332 [G.E. *82*, 367 (1970)]

Magnesium compounds, Ionization and rearrangement of diphenylphenoxymethylmagnesium chloride (SC) 163 [G.E. *82*, 136 (1970)]

Magnetochemistry, Magnetic behavior of alkali-metal tetroxocobaltates(V) (SC) 519 [G.E. *82*, 519 (1970)]

Magnetophotoselection (LA) 316

Maleic anhydride, Addition to 2-isopropyl-2-oxazoline (SC) 460 [G.E. *82*, 448 (1970)]

Malonic esters, Condensation of dialkyl sulfone diimines with ~ (SC) 373 [G.E. *82*, 391 (1970)]

Mass spectrometry, Gas-liquid chromatography and ~ in methylation analysis of polysaccharides (FP) 610 [G.E. *82*, 643 (1970)]

Zahlentafeln zur Massenspektrometrie und Elementaranalyse (Book Review) 914

Mathematics for quantum chemistry (Book Review) 320

Measurement, Messgrössenverarbeitung (Book Review) 252

Mechanochemistry, Color by the action of mechanical forces on organic molecules (CR) 174 [G.E. *82*, 184 (1970)]

Medicine, Macromolecular chemistry and ~ (FP) 332 [G.E. *82*, 367 (1970)]

Mercury compounds, The structure of ~ of 2,4-pentanediones (SC) 379 [G.E. *82*, 390 (1970)]

Tetrakis(acetatomercurio)methane (LA) 318

Mercury-nitrogen compounds, Development of and problems in the chemistry of ~ (FP) 357 [G.E. *82*, 379 (1970)]

Mesoionic triazole, Mesoionic 2-benzoyl-1-benzoylimino-4,5-dimethyl-1,2,3-triazole (SC) 67 [G.E. *82*, 81 (1970)]

Metabolism, Regulation of glutamine synthetase by enzyme catalyzed structural modification (FP) 670 [G.E. *82*, 689 (1970)]

Metals, Disorder in solids (ionic crystals and ~) (FP) 489 [G.E. *82*, 498 (1970)]

Electron Microscopy and Microanalysis of Metals (Book Review) 472

Metalation, Selective ~ of 1,2-bis-(6-methyl-2-pyridyl)ethane and its preparative uses (SC) 808 [G.E. *82*, 815 (1970)]

Metal cluster, A tetrahedral ~ (LA) 541

Methacrylic acid, Polymer-analogous formation of imido groups in ~-methacrylonitrile copolymers (CR) 537 [G.E. *82*, 559 (1970)]

Methacrylonitrile, Polymer-analogous formation of imido groups in methacrylic acid/~ copolymers (CR) 537 [G.E. *82*, 559 (1970)]

Anionic polymerization of ~ (CR) 538 [G.E. *82*, 560 (1970)]

Methanol, Reactions of silicon fluorides with ~ (LA) 251

Oligomeric molecules in acetone, ~, and formic acid vapors (LA) 745

syn-1,6-Methano-8,13-oxido[14]-annulene (SC) 517 [G.E. *82*, 514 (1970)]

Methoxyphenylcarbene, Transfer of ~ ligands from molybdenum to iron and nickel (SC) 72 [G.E. *82*, 44 (1970)]

Methylene, ESR spectrum of triplet ~ (LA) 814

Methylene chloride, Preparation of solutions of anhydrous perchloric acid in ~; a cautionary note (SC) 75 [G.E. *82*, 46 (1970)]

α-Methylene γ-lactones, A simple synthesis (SC) 457 [G.E. *82*, 480 (1970)]

Methyl group, CNDO calculation of inductive effect of ~ (SC) 462 [G.E. *82*, 444 (1970)]

4-Methyl-1-pentene, Polymerization of ~ with Ziegler catalysts (CR) 538 [G.E. *82*, 560 (1970)]

Methylphosphines, Simple preparation (LA) 82

2-Methylpropylidene, Reaction of the carbene ~ with olefins (LA) 84

α-Methylstyrene, Investigations on the sequence length distribution of copolymers of ~ and butadiene (SC) 532 [G.E. *82*, 554 (1970)]

Microanalysis, Electron Microscopy and Microanalysis of Metals (Book Review) 472

Microorganisms, Modern industrial microbiological fermentations and their effects on technical developments (FP) 936 [G.E. Chemie-Ing.-Techn. *42*, 580 (1970)]

Mineral oils, Mineralöle und verwandte Produkte (Book Review) 319

Mitochondrial proteins, Internal and external contributions to the biogenesis of ~ (CR) 174 [G.E. *82*, 139 (1970)]

MO calculations, Accurate ~ of chemical reactivity (CR) 966 [G.E. *82*, 960 (1970)]

Molecular Orbital Theory of Organic Chemistry (Book Review) 180

Molybdate, A new octa-~: $(NH_4)_6Mo_8O_{26}(OH)_2 \cdot 2H_2O$ (SC) 639 [G.E. *82*, 639 (1970)]

Molybdenum complexes, Dependence of solvatochromism on the ground state in 1,4-heterobutadienecarbonylmolybdenum complexes (SC) 793 [G.E. *82*, 805 (1970)]

[1,2,3,4-Tetrakis(methoxycarbonyl)-cyclobutadiene]tetracarbonylmolybdenum (SC) 810 [G.E. *82*, 835 (1970)]

Molybdenum compounds, Transfer of methoxyphenylcarbene ligands from molybdenum to iron and nickel (SC) 72 [G.E. *82*, 44 (1970)]

Nonaphenylcyclotrisilaphosphanetricarbonylmolybdenum (SC) 76 [G.E. *82*, 46 (1970)]

Mössbauer spectra of hexaammineiron(II) chloride (LA) 317

NAPHTHALENE, Synthesis and attempted automerization of [1-^{13}C]-~ (LA) 470

Naphtho[2,3-a]-o-carborane (LA) 815

Nematic phases, Liquid crystalline phases having particularly low freezing points (SC) 962 [G.E. *82*, 984 (1970)]

Nematogenic substances, Liquid crystalline phases having particularly low freezing points (SC) 962 [G.E. *82*, 984 (1970)]

Neptunium, Existence and oxidation potential of heptavalent ~ (LA) 316

Neutron energy-loss spectrometry (LA) 384

Nickel complexes, Oxidation of the salicylaldehyde ligand in cobalt(II)- and nickel(II) complexes (SC) 640 [G.E. *82*, 640 (1970)]

Isomeric ~ (LA) 469

Nickel compounds, Structure of the anion in solid $K_4[Ni_2(CN)_6]$ (SC) 71 [G.E. *82*, 43 (1970)]

Transfer of methoxyphenylcarbene ligands from molybdenum to iron and nickel (SC) 72 [G.E. *82*, 44 (1970)]

Hydrogen bonds in a Ni–Ni system (SC) 312 [G.E. *82*, 295 (1970)]

π-Allylhydridonickel compounds (SC) 736 [G.E. *82*, 699 (1970)]

Tetrakis(trimethylphosphane)nickel(0) (SC) 903 [G.E. *82*, 885 (1970)]

Niobium, Phase diagram of ~-hydrogen system (LA) 250

Nitrenes, Aminoazimines by addition of amino-~ to α-carbonylazo compounds (SC) 634 [G.E. *82*, 636 (1970)]

Nitrile oxide, Investigation of the ~-isocyanate rearrangement (SC) 635 [G.E. *82*, 637 (1970)]

Nitroacetylenes, Addition to enamines and ynamines (SC) 795 [G.E. *82*, 836 (1970)]

α-Nitro epoxides (nitrooxiranes) (LA)470

Nitrogen, Chemical behavior of active ~ (FP) 181 [G.E. *82*, 187 (1970)]

Nitrogen-nitrogen bonds, Preparation of sulfur-nitrogen rings containing ~ (SC) 956 [G.E. *82*, 954 (1970)]

Nitrogen-mercury compounds, Development of and problems in the chemistry of ~ (FP) 357 [G.E. *82*, 379 (1970)]

Nitrogen monoxide, Equilibrium of system nitrosyl bromide/bromine/~ (LA) 84

Nitro groups, The Chemistry of the Nitro and Nitroso Groups (Book Review) 180

Nitrone, Intramolecular ~-olefin cycloadditions leading to heterocycles (LA) 540

Phenyl ~-s (LA) 744

Nitrooxiranes, α-Nitro epoxides (~) (LA) 470

Nitroso groups, The Chemistry of the Nitro and Nitroso Groups (Book Review) 180

Nitrosyl bromide, Equilibrium of system ~/bromine/nitrogen monoxide (LA) 84

NMR spectroscopy, Magnetic resonance of paramagnetic complexes (FP) 196 [G.E. *82*, 227 (1970)]

Detection of hindered rotation and inversion by ~ (FP) 219 [G.E. *82*, 237 (1970)]

~ of paramagnetic complexes (FP) 946 [G.E. *82*, 975 (1970)]

New method for structure determination of hydroxy steroids (SC) 75 [G.E. *82*, 82 (1970)]

Fourier-transform ^{13}C-~ of polyols (SC) 803 [G.E. *82*, 812 (1970)]

Radical 1,3-migration of arylazo groups – CIDNP effect with p-tolyl protons (SC) 804 [G.E. *82*, 813 (1970)]

Conformations of ortho-disubstituted aniline and toluene derivatives. ^1H-~ and semiempirical energy calculation (SC) 806 [G.E. *82*, 840 (1970)]

Fourier transform ^{13}C-~ of biologically active cysteine peptides (SC) 894 [G.E. *82*, 882 (1970)]

α-Diimine-metal chelates; cyclic delocalization of π-electrons and ^{13}C chemical shifts (SC) 963 [G.E. *82*, 957 (1970)]

High-resolution NMR studies on cellulose derivatives (CR) 533 [G.E. *82*, 555 (1970)]

Study of the 2,6-lutidine-water system in the critical region (LA) 745

Noble-gas Chemistry (Book Review) 179

Norbornanes, Rearrangement of ~ to norpinanes (SC) 165 [G.E. *82*, 174 (1970)]

Norpinanes, Rearrangement of norbornanes to ~ (SC) 165 [G.E. *82*, 174 (1970)]

Nuclear chemistry, Einführung in die Kernchemie (Book Review) 253

Nucleation, Homogeneous ~ in supersaturated vapors of n-alkanes (LA) 645

Nucleic acids, Cooperative conformational transitions of linear biopolymers (FP) 389 [G.E. *82*, 468 (1970)]

The Biochemistry of Nucleic Acids (Book Review) 818

Nucleic acid chemistry, Synthetic Procedures in Nucleic Acid Chemistry. Vol. I: Preparations of Purines, Pyrimidines, Nucleosides, and Nucleotides (Book Review) 253

Nucleosides, and nucleotides as potential therapeutic agents (FP) 678 [G. E. *82*, 730 (1970)]

Separation of ~ on polymer gels containing thymine or cytidine (SC) 68 [G.E. *82*, 82 (1970)]

A general synthesis of pyrimidine ~ (SC) 461 [G.E. *82*, 449 (1970)]

Separation of ~ on cytidine containing polymer gels in DMSO/$CHCl_3$ or water (SC) 465 [G.E. *82*, 448 (1970)]

Nucleotides, Nucleosides and ~ as potential therapeutic agents (FP) 678 [G.E. *82*, 730 (1970)]

New protective groups for the phosphate residue on synthesis of deoxyribooligo-~ (LA) 646

Nucleotide 5′-phosphates, Synthesis of oligonucleotide 5′-phosphates on a polymeric carrier containing 2-pyridineethanol as functional group (SC) 368 [G.E. *82*, 358 (1970)]

OCTAMOLYBDATE, A new ~: $(NH_4)_6Mo_8O_{26}(OH)_2 \cdot 2H_2O$ (SC) 639 [G.E. *82*, 639 (1970)]

Olefins, Oxidative addition of the azide ion to ~. A simple route to diamines (SC) 158 [G.E. *82*, 134 (1970)]

Catalytic cleavage of aldehydes to ~, carbon monoxide, and hydrogen (SC) 169 [G.E. *82*, 181 (1970)]

α-~ from ethylene (SC) 243 [G.E. *82*, 255 (1970)]

Reaction of the carbene 2-methylpropylidene with ~ (LA) 84

Oligomeric molecules in acetone, methanol, and formic acid vapors (LA) 745

Oligonucleotide 5′-phosphates, Synthesis on a polymeric carrier containing 2-pyridineethanol as functional group (SC) 368 [G.E. *82*, 358 (1970)]

Organometallic compounds, Cleavage of σ bonds between transition metals and carbon by carbon disulfide (SC) 639 [G.E. *82*, 639 (1970)]

Binuclear ~ (CR) 910 [G.E. *82*, 940 (1970)]

Orthosulfite, Tetraphenyl ~ (SC) 73 [G.E. *82*, 45 (1970)]

Osazone formation from α-haloketones. A novel 1,4-cycloaddition (SC) 242 [G.E. *82*, 254 (1970)]

1,2,4-Oxadiazine, New synthesis of the ~ ring system (LA) 317

Oxastannadihydroanthracene, Unusual cleavage of Sn,Sn-disubstituted ~ by electron impact (SC) 161 [G.E. *82*, 182 (1970)]

1,3-Oxathiolane-2-thione, Two cyclic thiocarbonates, 1,3-dioxolane-2-thione and ~ (LA) 176

5-Oxazolidones, Isothiocyanato carboxylic acids and 2-thio-~ (SC) 526 [G.E. *82*, 550 (1970)]

Oxazoline, N-Formylphenylalanine ethyl esters by hydrogenolysis of ethyl 5-aryl-2-~-4-carboxylates (SC) 459 [G.E. *82*, 483 (1970)]

Addition of maleic anhydride to 2-isopropyl-2-~ (SC) 460 [G.E. *82*, 448 (1970)]

2-Oxazoline-5-carboxylate, Ethyl ~ from ethyl isocyanoacetate and carbonyl compounds (SC) 300 [G.E. *82*, 290 (1970)]

Oxidants, Synthesis and reactions of substituted (dibenzoyldioxyiodo)benzenes; A new class of organic ~ (SC) 797 [G.E. *82*, 834 (1970)]

Oxidation, Configurational and conformational selectivity in catalytic ~-s on platinum catalysts (CR) 383 [G.E. *82*, 363 (1970)]

Oxidation: Techniques and Applications in Organic Synthesis. Vol. I (Book Review) 254

Oxidation potential, Existence and ~ of heptavalent neptunium (LA) 316

Oxirane, 3-Isopropylidene-2,2-dimethyl-~ (tetramethylallene oxide) (SC) 71 [G.E. *82*, 43 (1970)]

α-Oxo N-sulfonyl carboxamides, Synthesis of disulfonimides, N-sulfonyl carboxamides, and ~ (SC) 66 [G.E. *82*, 80 (1970)]

Oxygen, Reaction of singlet ~ with thiophenes (LA) 385

Oxygenation of organic molecules in the solid state (LA) 386

Oxygen atoms, Reaction between ~ and acetylene (LA) 250

Oxygen compounds, Methoden der organischen Chemie (Houben-Weyl) (Book Review) 749

PALLADIUM(II)-CARBON σ-bonds, New compounds with ~ (LA) 912

[2.2]Paracyclophane, Specific heat (LA) 745

Penicillins, Synthesis and reactions of penicillin-like compounds (CR) 539 [G.E. *82*, 523 (1970)]

Pentalene, Simple synthesis of 1,2-dihydro-~ and its substitution products (SC) 892 [G.E. *82*, 877 (1970)]

2,4-Pentanediones, The structure of mercury compounds of ~ (SC) 379 [G.E. *82*, 390 (1970)]

4-Pentene-1,3-diones, Reactions of 2,2-diethoxyvinylidenetriphenylphosphorane with ketones. Synthesis of 1,3-dioxo-4-pentenes and their enol ethers (SC) 367 [G.E. *82*, 359 (1970)]

Peptides, Automatic analysis of amino-acid sequences in proteins and ~ (FP) 267 [G.E. *82*, 299 (1970)]

Gas chromatographic identification of the thiohydantoins of degradation products of ~ and proteins (SC) 893 [G.E. *82*, 880 (1970)]

Fourier transform ^{13}C-NMR spectroscopy of biologically active cysteine ~ (SC) 894 [G.E. *82*, 882 (1970)]

Separation of compounds with failure sequences in the solid-phase synthesis of ~ by means of the anhydride of 3-sulfopropionic acid (SC) 908 [G.E. *82*, 937 (1970)]

The crystal structure of the chromophore from the yellow-green fluorescent peptide produced by iron-deficient Azotobacter vinelandii (LA) 317

Synthesis from β-amino acids (LA) 745

A new amide protecting group (LA) 816

Trichloroacetylation (LA) 967

Peptide analogs, Azapeptides, a novel class of ~ (CR) 813 [G.E. *82*, 817 (1970)]

Peptide degradation, 4-Isothiocyanatobenzenesulfonic acid as reagent for Edman ~ (SC) 731 [G.E. *82*, 771 (1970)]

Perchloric acid, The preparation of solutions of anhydrous ~ in methylene chloride; a cautionary note (SC) 75 [G.E. *82*, 46 (1970)]

Perfluoroalkyl radicals, Syntheses involving ~ from perfluoroalkyl iodides (LA) 83

Perfluoropyridazines, Isomerization (LA) 177

Pharmacology, Handbuch der experimentellen Pharmakologie (Book Review) 968

Phase diagram of the niobium hydrogen system (LA) 250

α-Phenylaldehydes, Simple synthesis of ~ and α-phenylketones (LA) 251

Phenylcyclopropanes, New route to ~ (LA) 82

o-Phenylenediamines, New rearrangements of bis(organosilyl)-~ (LA) 385

p-Phenylenediamine, Primary photochemical processes of tetramethyl-~ (LA) 471

α-Phenylketones, Simple synthesis of α-phenylaldehydes and ~ (LA) 251

Phenyl nitrones (LA) 744

Phosphanes, "Single vessel reaction" for synthesis of various types of substituted ~ $PR^1R^2R^3$ (SC) 807 [G.E. *82*, 808 (1970)]

Iodo-~ PH_2I and PHI_2 (SC) 808 [G.E. *82*, 808 (1970)]

Tetrakis(trimethylphosphane)nickel(0) (SC) 903 [G.E. *82*, 885 (1970)]

Tetrakis(trimethylphosphane)hydridocobalt(I) and -dihydridoiron(II) (SC) 904 [G.E. *82*, 885 (1970)]

Phosphazanates, Conformational isomerism of the eight-membered P–N ring in octaoxocyclotetra-~ (SC) 78 [G.E. *82*, 85 (1970)]

Phosphazene compounds, Preparation of compounds of the type $R-(N=PX_2)_x-N=PCl_3$ (SC) 244 [G.E. *82*, 255 (1970)]

Phosphines, see also Phosphanes

Reactions of tritolyl-~ (SC) 308 [G.E. *82*, 326 (1970)]

Simple preparation of methyl-~ (LA) 82

μ-Oxodifluorophosphoryldifluorophosphine (LA) 176

Phospholes, Novel radicals from the reaction of ~ with potassium (SC) 310 [G.E. *82*, 325 (1970)]

Phosphonothioic dichlorides, Cycloalkane-~ by photochemical C–P linkage (SC) 458 [G.E. *82*, 444 (1970)]

Phosphorane, Reactions of 2,2-diethoxyvinylidenetriphenyl-~ with ketones. Synthesis of 1,3-dioxo-4-pentenes and their enol ethers (SC) 367 [G.E. *82*, 359 (1970)]

Phosphorin, Structure of 1,1-bis(dimethylamino)-2,4,6-triphenyl-~ (SC) 898 [G.E. *82*, 933 (1970)]

Phosphorofluoridous acid, Simple synthesis of ~ $H[PHO_2F]$ (SC) 733 [G.E. *82*, 702 (1970)]

Phosphorus complexes, ESR studies on vanadyl-phosphorus complexes (SC) 957 [G.E. *82*, 955 (1970)]

Phosphorus compounds, Nonaphenylcyclotrisilaphosphanetricarbonyl-molybdenum (SC) 76 [G.E. *82*, 46 (1970)]

Cycloalkanephosphonothioic dichlorides by photochemical C–P linkage (SC) 458 [G.E. *82*, 444 (1970)]

Hydrogen fluoride-potassium hydrogen phosphite (1/1), an unusual lattice compound (SC) 459 [G.E. *82*, 443 (1970)]

Phosphorus oxide fluorides of high molecular weight (LA) 82

Phosphorus ylides, Trans-silylation – a new method for the synthesis of silylated ~ (SC) 77 [G.E. *82*, 84 (1970)]

The Si–Si group as a structural unit in open-chain and cyclic ~ (SC) 737 [G.E. *82*, 773 (1970)]

Photoacid derivatives of an achiral and a chiral 2,4-cyclohexadienone (SC) 238 [G.E. *82*, 219 (1970)]

Photochemistry, Cycloalkanephosphonothioic dichlorides by photochemical C–P linkage (SC) 458 [G.E. *82*, 444 (1970)]

~ of the uranyl oxalate actinometer (LA) 645

Photochemical synthesis of aromatic chloro compounds from aromatic iodo compounds (LA) 470

The primary photochemical processes of tetramethyl-p-phenylenediamine (LA) 471

Photo-aryl coupling reaction (LA) 744

Simultaneous excitation of two absorbing centers by one photon (LA) 814

Photoelectron spectrum of cyclobutane (SC) 953 [G.E. *82*, 952 (1970)]

Photoisomerization, Synthesis and ~ of homo-1 H-azepine derivatives (LA) 317

Photooxidation, Novel ~ of hydrocarbons involving triplet oxygen (CR) 644 [G.E. *82*, 671 (1970)]

Photo-oxide, Structure of the ~ of dibenzo[a,o]perylene (LA) 177

Phototropic glass (FP) 434 [G.E. *82*, 421 (1970)]

Physical chemistry, Rechenseminar in physikalischer Chemie (Book Review) 914

Physikalische Chemie (Book Review) 969

Physical organic chemistry, An Introduction to Physical Organic Chemistry (Book Review) 746

Pigments, Recent investigations of plant ~ (CR) 249 [G.E. *82*, 259 (1970)]

Dispersion of Powders in Liquids, with Special Reference to Pigments (Book Review) 318

Piperazine-2,5-dione, Anodically induced 1,3-cycloaddition of acetonitrile to 3,6-diisobutyl-~ (LA) 967

Piperylene, Stereochemistry of the catalyzed cyclodimerization of ~ (SC) 528 [G.E. *82*, 550 (1970)]

Planck, From ~ to Bohr. The first fifteen years in the development of the quantum theory (FP) 34 [G.E. *82*, 1 (1970)]

Plant pigments, Recent investigations (CR) 249 [G.E. *82*, 259 (1970)]

Plasma, Single-step synthesis of biphenylene from 9-fluorenone in a discharge ~ (SC) 312 [G.E. *82*, 295 (1970)]

Solid state reactions with and without gas phase at high temperatures with special consideration of high-frequency ~ (CR) 174 [G.E. *82*, 139 (1970)]

Plasma chemistry, Developments in inorganic arc ~ (FP) 780 [G.E. Chemie-Ing.-Techn. *42*, 617 (1970)]

Plastics, Electroplating of ~ in theory and practice (FP) 425 [G.E. *82*, 412 (1970)]

Stabilisierung und Alterung von Plastwerkstoffen (Book Review) 542

Introduction to the Chemical Analysis of Plastics (Book Review) 816

Kunststoff-Handbuch (Book Review) 817

Platinum catalysts, Configurational and conformational selectivity in catalytic oxidations on ~ (CR) 383 [G.E. *82*, 363 (1970)]

Platinum chlorides, α-Platinum(II) chloride and platinum(III) chloride (SC) 158 [G.E. *82*, 135 (1970)]

Adamantane as a matrix for the preparation and conservation of free ~ (LA) 471

Chlorine difluoride ~ (LA) 967

Radical anions, ESR spectra of ~ of some 6a-thiathiophthene derivatives (SC) 306 [G.E. *82*, 294 (1970)]

Radioactive drugs (CR) 175 [G.E. *82*, 184 (1970)]

Raman spectroscopy, Laser Raman Spectroscopy (Book Review) 915

Reactivity, Accurate MO calculations of chemical ~ (CR) 966 [G.E. *82*, 960 (1970)]

Reagents for Organic Synthesis (Book Review) 817

Rearrangement, Ionization and ~ of diphenylphenoxymethylmagnesium chloride (SC) 163 [G.E. *82*, 136 (1970)]

~ of norbornanes to norpinanes (SC) 165 [G.E. *82*, 174 (1970)]

Investigation of the nitrile oxide-isocyanate ~ (SC) 635 [G.E. *82*, 637 (1970)]

A novel ~ (LA) 646

Reducing agents, Reactions with addition compounds containing activated formic acid (FP) 50 [G.E. *82*, 73 (1970)]

Use of hexachlorodisilane as a ~ (LA) 251

Refractory metallic compounds, Structural chemistry of ~ (CR) 173 [G.E. *82*, 139 (1970)]

Residues analysis, Methodensammlung zur Rückstandsanalytik von Pflanzenschutzmitteln (Book Review) 968

Rhodium compounds, The electrochemical reduction of rhodium(I)- to rhodium(0) compounds (LA) 83

A tetrahedral metal cluster (LA) 541

Riboflavin, The synthesis of succinate-dehydrogenase ~ (SC) 642 [G.E. *82*, 669 (1970)]

Ribonucleic acid, Structure of phenylalanine-specific transfer ~ from baker's yeast (CR) 533 [G.E. *82*, 555 (1970)]

Ribosome specificity, Biochemical and genetic aspects of ~ in protein synthesis (CR) 248 [G.E. *82*, 259 (1970)]

Ring contraction on rearrangement of 3-cyclohexenyl Grignard compounds (SC) 909 [G.E. *82*, 938 (1970)]

Ring opening, Novel ~ of hydroxyphenylcyclobutenedione (SC) 793 [G.E. *82*, 807 (1970)]

Rotation, Detection of hindered ~ and inversion by NMR spectroscopy (FP) 219 [G.E. *82*, 237 (1970)]

Ruthenium complexes, $Ru_3(CO)_9H(C_6H_5CC_6H_4)$: a μ-hydridocarbonyl metal cluster derivative of diphenylcarbene (SC) 633 [G.E. *82*, 635 (1970)]

SALICYLALDEHYDE, Oxidation of ~ ligand in cobalt(II)- and nickel(II) complexes (SC) 640 [G.E. *82*, 640 (1970)]

Salmonella bacteria, Recent results on the biochemistry of the cell wall lipopolysaccharides of Salmonella bacteria (FP) 649 [G.E. *82*, 708 (1970)]

Selenaheptathiocene, Synthesis (LA) 911

Selenium compounds, Bis(trimethylstannyl) selenide and bis(trimethylstannyl) telluride as ligands in carbonyl complexes of transition metals (SC) 246 [G.E. *82*, 256 (1970)]

α-Ag_3NSeO_3 (LA) 82

The structure of the Se_8^{2+} ion in $Se_8(AlCl_4)_2$ (LA) 177

Semiconductor properties of transition metal chelates (LA) 82

Separation method, New ~ for gas molecules (LA) 317

Sequence analysis, Automatic amino-acid ~ in proteins and peptides (FP) 267 [G.E. *82*, 299 (1970)]

Sequence length distribution, Investigations on ~ of copolymers of α-methylstyrene and butadiene (SC) 532 [G.E. *82*, 554 (1970)]

Sex attractants, Recent work on insect ~ (CR) 468 [G.E. *82*, 485 (1970)]

Silanes, Direct synthesis and reactions of bromo(pentafluorophenyl)-~ (SC) 467 [G.E. *82*, 483 (1970)]

N,N-Diethylaminooxy-~ (LA) 251

The use of hexachlorodisilane as a reducing agent (LA) 251

Silicides, Transition between metallic and ionic bonding in alkali and alkaline earth metal ~ (CR) 965 [G.E. *82*, 959 (1970)]

Silicon-carbon compounds with a carborundum structure ("carborundanes") (SC) 464 [G.E. *82*, 445 (1970)]

Silicon compounds, Nonaphenylcyclotrisilaphosphanetricarbonyl-molybdenum (SC) 76 [G.E. *82*, 46 (1970)]

The Si–Si group as a structural unit in open-chain and cyclic phosphorus ylides (SC) 737 [G.E. *82*, 773 (1970)]

Silicone chemistry, Problems of modern ~ (CR) 382 [G.E. *82*, 363 (1970)]

Silicon fluorides, Reactions with methanol (LA) 251

Silver, The reactions of atomic and molecular halogens with ~ (LA) 384

α-Ag_3NSeO_3 (LA) 82

Silver compounds, The "silver salt" of cis-1,2-dicyano-1,2-ethylenedithiol (SC) 740 [G.E. *82*, 775 (1970)]

Silver ketenide (LA) 541

Silyl compounds, The color of trimethylsilyl derivatives of diimine (SC) 69 [G.E. *82*, 42 (1970)]

1,1,4,4-Tetrakis(trimethylsilyl)tetrazene (SC) 70 [G.E. *82*, 47 (1970)]

Trans-silylation – a new method for the synthesis of silylated phosphorus ylides (SC) 77 [G.E. *82*, 84 (1970)]

New rearrangements of bis(organosilyl)-o-phenylenediamines (LA) 385

Sodium compounds, Preparation and properties of a crystalline compound $Na_4Sn_9 \cdot 6$–8 ethylenediamine (SC) 895 [G.E. *82*, 881 (1970)]

Solids, Disorder in ~ (ionic crystals and metals) (FP) 489 [G.E. *82*, 498 (1970)]

A method for analysis of the surface layer of ~ (LA) 316

Solid state reactions with and without gas phase at high temperatures with special consideration of high-frequency plasma (CR) 174 [G.E. *82*, 139 (1970)]

Solvation, Structure of the ~ shell of dissolved particles (FP) 124 [G.E. *82*, 91 (1970)]

Solvatochromism, Dependence of ~ on the ground state in 1,4-heterobutadienecarbonylmolybdenum complexes (SC) 793 [G.E. *82*, 805 (1970)]

Solvents, Electron transfer from solvent to a triplet excited acceptor molecule (SC) 369 [G.E. *82*, 356 (1970)]

Solute-solvent Interactions (Book Review) 253

Specific heat of [2.2]paracyclophane (LA) 745

Spin state, Anomalous of iron(II) in $[Fe(phen)_3](ClO_4)_2 \cdot 2H_2O$ (SC) 637 [G.E. *82*, 638 (1970)]

Spirocyclobutanone, New ~ synthesis in the steroid series (SC) 237 [G.E. *82*, 219 (1970)]

Spiroorthocarbonates and cyclic iminocarbonates (LA) 470

Stannane, Cyclopentadienyl(trifluoromethyl)-~ (LA) 913

Stannates, Hexathio-digermanates and -distannates. A new type of dimeric tetrahedral ion (SC) 897 [G.E. *82*, 884 (1970)]

Stereochemistry of the catalyzed cyclodimerization of piperylene (SC) 528 [G.E. *82*, 550 (1970)]

Steroids, Modern ~ problems (FP) 321 [G.E. *82*, 331 (1970)]

New method for structure determination of hydroxy ~ (SC) 75 [G.E. *82*, 82 (1970)]

A new spirocyclobutanone synthesis in the steroid series (SC) 237 [G.E. *82*, 219 (1970)]

Biogenesis of ~ in higher plants (CR) 742 [G.E. *82*, 704 (1970)]

Structure analysis, Structure of the anion in solid $K_4[Ni_2(CN)_6]$ (SC) 71 [G.E. *82*, 43 (1970)]

Styrene, Oligomer formation in the thermal polymerization of ~ (CR) 531 [G.E. *82*, 553 (1970)]

Styrene oligomers, Constitution of the ~ formed on thermal polymerization (CR) 537 [G.E. *82*, 560 (1970)]

Succinate-dehydrogenase riboflavin, Synthesis (SC) 642 [G.E. *82*, 669 (1970)]

Sulfanes, Haloformyl(perhaloalkyl)-~ and -di-~ (SC) 466 [G.E. *82*, 484 (1970)]

Sulfenic acid derivatives, Chlorosulfenylated carbonic acid derivatives (FP) 54 [G.E. *82*, 63 (1970)]

Sulfinato complexes, Metal-ligand bonding in ~ of transition metals (SC) 160 [G.E. *82*, 133 (1970)]

Ionization isomerism of ~ of transition metals (SC) 308 [G.E. *82*, 322 (1970)]

Sulfone diimines, Condensation of dialkyl ~ with malonic esters (SC) 373 [G.E. *82*, 391 (1970)]

N,N′-Sulfonylbis(sulfur difluoride diimide) (SC) 244 [G.E. *82*, 255 (1970)]

N-Sulfonyl carboxamides, Synthesis of disulfonimides, ~, and α-oxo ~ (SC) 66 [G.E. *82*, 80 (1970)]

3-Sulfopropionic acid, Separation of compounds with failure sequences in the solid-phase synthesis of peptides by means of the anhydride of ~ (SC) 908 [G.E. *82*, 937 (1970)]

Sulfur, Structure of cyclohepta-~ (SC) 379 [G.E. *82*, 390 (1970)]

Sulfur-carbon double bond, syn-anti-Isomerism at the ~ in isothiouronium salts (SC) 641 [G.E. *82*, 666 (1970)]

Sulfur cations, Compounds containing S_8^{2+} and S_{15}^{2+} (LA) 83

Sulfur compounds, N,N′-Sulfonylbis-(sulfur difluoride diimide) (SC) 244 [G.E. *82*, 255 (1970)]

Tris(N-trimethylsilylimido)sulfur and bis(N-trimethylsilylimido)sulfur difluoride (SC) 309 [G.E. *82*, 324 (1970)]

8,8-Dichloro-1,2,3,4,5,6,7,8-heptathiatellur(IV)-ocane (SC) 463 [G.E. *82*, 447 (1970)]

Cleavage of a carbon-sulfur bond by organodihaloboranes (SC) 738 [G.E. *82*, 774 (1970)]

Novel iminosulfur oxydifluorides (SC) 905 [G.E. *82*, 931 (1970)]

Preparation and structure of the cyclopentasulfur pentanitride cation (LA) 178

The cation S_4^{2+} in the compounds $S_4(SO_3F)_2$ and $S_4(SbF_6)_2$ (LA) 540

Sulfur hexafluoride, Relaxation of ~ (LA) 745

Sulfur-nitrogen rings, Preparation of ~ containing nitrogen-nitrogen bonds (SC) 956 [G.E. *82*, 954 (1970)]

Surface, Method for analysis of the ~ layer of solids (LA) 316

Surface OH groups, Acidity of ~ (LA) 252

Synthesis, Reagents for Organic Synthesis (Book Review) 817

Sydnone, Fragmentation of a sydnone (LA) 912

TECHNICAL chemistry, Ullmanns Encyclopädie der technischen Chemie (Book Review) 647

Tellurate, Xenon(II) fluoride pentafluoroortho-~ as fluoride donor: $[XeOTeF_5]\ [AsF_6]^-$ (SC) 375 [G.E. *82*, 357 (1970)]

Stereo- and polymerization chemistry of tellurites and ~s in the solid state (CR) 80 [G.E. *82*, 49 (1970)]

Tellurites, Stereo- and polymerization chemistry of ~ and tellurates in the solid state (CR) 80 [G.E. *82*, 49 (1970)]

Tellurium(IV) chloride, Crystal structure of $TeCl_4$: Presence of tetramers in solid chalcogen(IV) halides (SC) 463 [G.E. *82*, 446 (1970)]

Tellurium compounds, Bis(trimethylstannyl) selenide and bis(trimethylstannyl) telluride as ligands in carbonyl complexes of transition metals (SC) 246 [G.E. *82*, 256 (1970)]

8,8-Dichloro-1,2,3,4,5,6,7,8-heptathiatellur(IV)-ocane (SC) 463 [G.E. *82*, 447 (1970)]

Tellurium halide systems: Te_2Br and Te_3Cl_2 (SC) 802 [G.E. *82*, 811 (1970)]

Terpene, Valerianine, a tertiary mono-~ alkaloid from valerian (SC) 891 [G.E. *82*, 875 (1970)]

Terpene chemistry, Significance of monoterpene chemistry today (CR) 743 [G.E. *82*, 777 (1970)]

Tetracyanoethylene, Reaction of 1,1-diphenylcyclopropane with ~ (SC) 236 [G.E. *82*, 216 (1970)]

The adduct of tetramethoxyallene and ~ (SC) 733 [G.E. *82*, 700 (1970)]

Tetrahydrofuran, Investigations on the course of the cationic copolymerization of ~ with dicarboxylic anhydrides (CR) 536 [G.E. *82*, 558 (1970)]

Tetrakis(acetatomercurio)methane (LA) 318

1,1,4,4-Tetrakis(trimethylsilyl) tetrazene (SC) 70 [G.E. *82*, 47 (1970)]

Tetramethoxyallene, Adduct of ~ and tetracyanoethylene (SC) 733 [G.E. *82*, 700 (1970)]

Tetramethylallene oxide, 3-Isopropylidene-2,2-dimethyloxirane (SC) 71 [G.E. *82*, 43 (1970)]

1,2,5,6-Tetramethylenecyclooctane (LA) 646

Tetramethyl-p-phenylenediamine, Primary photochemical processes of ~ (LA) 471

Tetraphenyl orthosulfite (SC) 73 [G.E. *82*, 45 (1970)]

1,2,3,4-Tetrathiadecalin, X-Ray structure analysis (SC) 895 [G.E. *82*, 882 (1970)]

Tetrazene, 1,1,4,4-Tetrakis(trimethylsilyl)-~ (SC) 70 [G.E. *82*, 47 (1970)]

5-Tetrazolyl ylides (LA) 911

Tetroxocobaltates(V), Magnetic behavior of alkali-metal ~ (SC) 519 [G.E. *82*, 519 (1970)]

Thallium(III) trifluoroacetate, Synthesis of p-quinones with ~ (SC) 74 [G.E. *82*, 84 (1970)]

Thermal analysis, Device for ~ at temperatures up to 3000 °C (LA) 541

Thermodynamics, Chemische Thermodynamik (Book Review) 178

Thermogravimetric degradation, Problems in the kinetic evaluation of ~ of polymers (CR) 537 [G.E. *82*, 559 (1970)]

Thiohydantoins, Gas chromatographic identification of the ~ of degradation products of peptides and proteins (SC) 893 [G.E. *82*, 880 (1970)]

6a-Thiathiophthene, ESR spectra of radical anions of some ~ derivatives (SC) 306 [G.E. *82*, 294 (1970)]

Thiocarbonates, Two cyclic ~ 1,3-dioxolane-2-thione and 1,3-oxathiolane-2-thione (LA) 176

Thioethers, Synthesis of macrocyclic poly-~ (LA) 83

Thioformamides and dithiocarbamates (LA) 815

Thiols, Problems and possibilities of the free-radical addition of ~ to unsaturated compounds (FP) 273 [G.E. *82*, 276 (1970)]

Thiophenes, Reaction of singlet oxygen with ~ (LA) 385

Thiourea, The yellow adduct (thiourea)$_2$·I_2 (LA) 252

2-Thioxo-5-oxazolidones, Isothiocyanato carboxylic acids and ~ (SC) 526 [G.E. *82*, 550 (1970)]

Tin compounds, Unusual cleavage of Sn,Sn-disubstituted oxastannadihydroanthracene by electron impact (SC) 161 [G.E. *82*, 182 (1970)]

Bis(trimethylstannyl) selenide and bis-trimethylstannyl)telluride as ligands in carbonyl complexes of transition metals (SC) 246 [G.E. *82*, 256 (1970)]

Preparation and properties of a crystalline compound $Na_4Sn_9 \cdot 6$–8 ethylenediamine (SC) 895 [G.E. *82*, 881 (1970)]

Titanium tetrachloride, $TiCl_4$-catalyzed addition of aziridine to cyclic ketones (LA) 84

Toluene, Conformations of ortho-disubstituted aniline and ~ derivatives. PMR and semiempirical energy calculation (SC) 806 [G.E. *82*, 840 (1970)]

Tosylates of low stability (LA) 83

Transition state, Geometry of the ~ in polar cycloaddition (SC) 311 [G.E. *82*, 322 (1970)]

Transport, Some aspects of the active ~ of amino acids (FP) 345 [G.E. *82*, 343 (1970)]

Trans-silylation – a new method for the synthesis of silylated phosphorus ylides (SC) 77 [G.E. *82*, 84 (1970)]

1,2,3-Triazole, Mesoionic 2-benzoyl-1-benzoylimino-4,5-dimethyl-~ (SC) 67 [G.E. *82*, 81 (1970)]

1,2,4-Triazoline-3,5-dione, The cycloaddition of cis,cis,cis-1,3,5,7-cyclononatetraene to 4-phenyl-~ (LA) 469

Trichloroacetylation of peptides (LA) 967

Trichloromethyllithium, Dichlorocarbene from ~ (SC) 169 [G.E. *82*, 177 (1970)]

Tricyclo[4.3.1.0^{1,6}]deca-2,4-diene, Crystal structure of tricarbonyl complexes of chromium(0) and iron(0) with ~ (SC) 304 [G.E. *82*, 293 (1970)]

Tricyclo[4.3.1.0^{1,6}]deca-2,4-dienetricarbonyl chromium, a homoaromatic transition metal complex (SC) 303 [G.E. *82*, 292 (1970)]

Tricyclo[5.1.0.0^{3,5}]octane-2,6-dione, Bishomoquinone (LA) 176

Triplet excited acceptor molecule, Electron transfer from solvent to ~ (SC) 369 [G.E. *82*, 356 (1970)]

Triplet-excited state, The problem of an intermolecular charge-transfer ~ (SC) 171 [G.E. *82*, 179 (1970)]

Triplet ground state, Schlenk's biradical – A molecule in the ~ (SC) 906 [G.E. *82*, 935 (1970)]

Triplet methylene, ESR spectrum (LA) 814

Triplet oxygen, Novel photooxidation of hydrocarbons involving ~ (CR) 644 [G.E. *82*, 671 (1970)]

Triplet state, New aroxyls: mono-, di-, and triradicals, detection of a ~ (SC) 520 [G.E. *82*, 521 (1970)]

Chemiluminescence on oxidative ~ formation of anthrasemiquinone- and anthraquinone-2-sulfonate (SC) 307 [G.E. *82*, 321 (1970)]

Trishomobarrelene and trishomobullvalene (SC) 376 [G.E. *82*, 359 (1970)]

Trishomobullvalene, Trishomobarrelene and ~ (SC) 376 [G.E. *82*, 359 (1970)]

Tris(N-trimethylsilylimido)sulfur and bis(N-trimethylsilylimido)sulfur difluoride (SC) 309 [G.E. *82*, 324 (1970)]

1,2,4,3,5-Trithiadiborolane, Compounds having the ~ skeleton (LA) 83

Tritolylphosphines, Reactions (SC) 308 [G.E. *82*, 326 (1970)]

Tropylium triidophenylborate (SC) 734 [G.E. *82*, 699 (1970)]

URANIUM fission products, Internal electrolysis as an analytical method for ~ (LA) 646

Uranyl oxalate actinometer, Photochemistry of the ~ (LA) 645

Urethane elastomers, Physical structure of secondary valence crosslinking in ~ (CR) 531 [G.E. *82*, 553 (1970)]

VANADYL-PHOSPHORUS complexes, ESR studies (SC) 957 [G.E. *82*, 955 (1970)]

Vapor, Homogeneous nucleation in supersaturated ~-s of n-alkanes (LA) 645

Valerianine, a tertiary monoterpene alkaloid from valerian (SC) 891 [G.E. *82*, 875 (1970)]

Vibrational spectroscopy, Conformational analysis of 1,1'-bisaziridyl by ~ (SC) 245 [G.E. *82*, 258 (1970)]

Vinylcarbenes, Cycloadditions of ~ (CR) 526 [G.E. *82*, 549 (1970)]

Vinyl cation, 1-tert-butylvinyl trifluoromethanesulfonate: solvolysis and rearrangement via a ~ (SC) 302 [G.E. *82*, 323 (1970)]

11-Vinyl-3,7-cycloundecadien-1-one, 3,7,11-Cyclotridecatrien-1-one and ~ (SC) 367 [G.E. *82*, 355 (1970)]

Vinyl halides, New syntheses of ~ and vinylsilanes (LA) 815

Vinylsilanes, New syntheses of vinyl halides and ~ (LA) 815

Vinyl trifluoromethanesulfonates, Preparation of cyclic and acyclic ~ (SC) 521 [G.E. *82*, 517 (1970)]

Virial coefficients, The Virial Coefficients of Gases (Book Review) 746

Viruses, The Biochemistry of Viruses (Book Review) 388

Virus formation, Methods of ~ (FP) 663 [G.E. *82*, 723 (1970)]

Virus infections, Interferons (FP) 480 [G.E. *82*, 489 (1970)]

Vitamins, Biosynthesis of ~; Allosteric enzymes – recent results (CR) 384 [G.E. *82*, 398 (1970)]

Voltammetry, Inverse Polarographie und Voltammetry (Book Review) 318

WAVE mechanics The Wave Mechanics of Atoms, Molecules and Ions (Book Review) 648

Wittig reactions, Reverse ~ (LA) 911

Wittig rearrangement, Recent results in carbanion chemistry (FP) 763 [G.E. *82*, 795 (1970)]

XENON(II) fluoride pentafluoroorthotellurate as fluoride donor: [$XeOTeF_5$] [AsF_6]$^-$ (SC) 375 [G.E. *82*, 357 (1970)]

X-Ray structure analysis, of 1,2,3,4-tetrathiadecalin (SC) 895 [G.E. *82*, 882 (1970)]

Structure of 1,1-bis(dimethylamino)-2,4,6-triphenylphosphorin (SC) 898 [G.E. *82*, 933 (1970)]

YNAMINES, Addition of nitroacetylenes to enamines and ~ (SC) 795 [G.E. *82*, 836 (1970)]

ZIEGLER-NATTA catalysts, Determination and comparison of the number of active centers in the polymerization of ethylene, propylene, and 1-butene with ~ (CR) 536 [G.E. *82*, 559 (1970)]

Polymerization of 4-methyl-1-pentene with Ziegler catalysts (CR) 538 [G.E. *82*, 560 (1970)]

Zinc compounds, Crystal and molecular structure of $Zn_7O_8(CH_3)_{14}$ – a dicubane (SC) 905 [G.E. *82*, 931 (1970)]
