Complete substitution of the H atoms of the ammonium ion by Hg leads to derivatives of Millon's base, $NHg_2OH \cdot 2\,H_2O$. All compounds of this type have a bulky, three-dimensional coordination-polymeric, cationic skeleton ${}^3_\infty[NHg_{4/2}]^+$. The mutual arrangement of the NHg_4 tetrahedra, which are joined by their vertices, is influenced by the ability of the anions to coordinate with the Hg atoms of the skeleton; the symmetry of the three-dimensional cation thus depends on the anion. From observations made so far it appears that oxo anions with lower tendencies to coordinate, such as nitrate and chlorate(VII) [79,80], lead mainly to the development of cubic modifications, in whose cavities water can be reversibly accommodated with no change in structure. In the cubic $[NHg_2]HPO_4 \cdot H_2O$, however, thermal dehydration is accompanied by a transition to a tetragonal modification [80]. The existence of a cubic form of the dihydrate of Millon's base $[NHg_2]OH \cdot 2H_2O$ [2] is doubtful [11]. The oxo anions situated in the lattice passages can also be replaced, in some cases reversibly, particularly by halide ions. Though the cubic structure is retained, however, lattice imperfections are evidently produced [9,79]; under the action of heat, these distorted cubic forms change into denser, more stable, hexagonal modifications [11], which are also formed directly under suitable conditions. X-ray structure analyses of the hexagonal modifications [81,82] show that the Hg atoms effectively achieve a distorted octahedral coordination. The high coordinating power of the anions Cl^-, Br^-, I^-, and OH^- apparently plays an important part in the structure of the hexagonal lattice.

Weber has presented his views on the formation and degradation of Millon's base in several publications [83].

3.2.3. Comparison with Silicate Structures

The structural relationship of the Millon salts with the silicon dioxide modifications β-cristobalite (cubic) [79] (cf. Fig. 6) and β-tridymite (hexagonal) [81] (cf. Fig. 7) was quickly recognized. The two possibilities for the mutual orientation of two joined NHg_4 tetrahedra in the ${}^3_\infty[NHg_{4/2}]$ skeleton are also found in principle in the linkage of the SiO_4 groups in the three-dimensional ${}^3_\infty[SiO_{4/2}]$ network. Owing to the bond angle of 130 to 140 ° at the oxygen [84], the number of possibilities for the arrangement of the SiO_4 tetrahedra is greater (quartz modifications) than in the derivatives of Millon's base, in which the bonds at the mercury are collinear. Checks should be made to establish whether coesite-like high pressure modifications [85] can exist for Millon salts. Since the coordination number of nitrogen, unlike that of silicon, cannot exceed 4, no analogs of stishovite are to be expected.

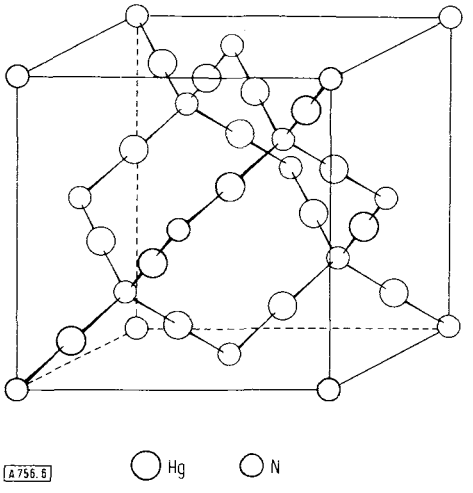

Fig. 6. Skeleton structure of the cation of cubic Millon salts ${}^3_\infty[NHg_{4/2}]^+X^-$ [79].

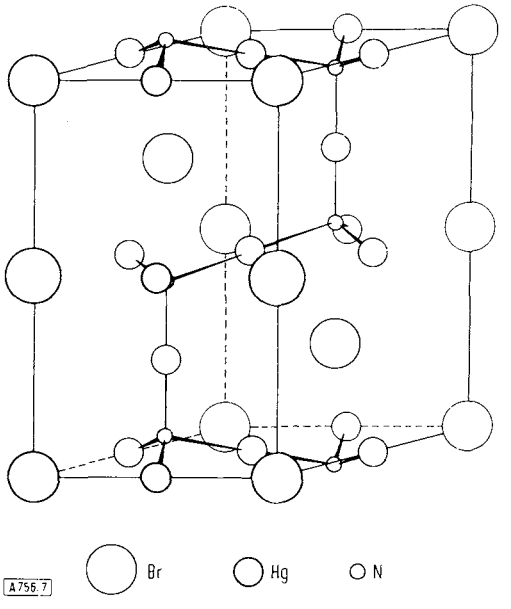

Fig. 7. Unit cell of hexagonal Millon salts [81].

The comparison of the structures of mercurioammonium salts and silicates may be carried still further. The relationships become clear on comparison of the general coordination formulas for mercurioammonium ions ${}^{n-1}_\infty[NH_{4-n}Hg_{n/2}]^+$ and for silicate ions ${}^{n-1}_\infty[SiO_{4-n}O_{n/2}]^{(4-n)-}$, with mercury corresponding to coordinately bidentate oxygen and protons to coordinately monodentate oxygen.

Silicate type	tecto-	phyllo-	ino-	soro-

While for $n = 4$, as described earlier, a correspondence exists between Millon salts and three-dimensional silicon dioxide modifications (tectosilicates), parallels can also be drawn between the layer structure of the polymeric cation in $NHHg_2Br_2$ and the two-dimensional phyllosilicates, the chain structure in NH_2HgX and one-dimensional inosilicates, and the group structure of $(NH_3)_2HgX_2$ and zero-dimensional sorosilicates.

Differences between mercurioammonium and silicate structures are due to the fact that in the Hg–N compounds, for $n \leq 3$, the anions can form N–H $\cdots$ X^- bridges, and also coordinate to the bridge Hg atoms. Silicates exhibit pronounced coordination of the cations M to terminal O atoms, which changes the strength of the Si–O(–M) bond, depending on the field strength of the cation, but also affects the bond parameters of the SiO(–Si) group, and hence the structure [86]. In layer silicates, this type of coordination leads to a cation-dependent infrastructure (layer folding) [87]. Such coordination effects undoubtedly determine the structure of Hg–N compounds, but still require systematic elucidation.

4. Comparison of the Parameters for Hg-C, Hg-N, and Hg-O Bonds

The bond system between mercury and hetero atoms is influenced by the positive charge acquired by the Hg atom, which depends in turn on the electronegativity of the bonding partner and its charge. If the Hg atom is strongly positive (formally treated as Hg^{2+}), a transition between the electronic configurations $5d^{10}$ and $5d^96s^1$ is possible with a relatively low energy requirement (5.3 eV), with subsequent $d_{z^2}s$ hybridization [88]; this explains the formation of two strong bonds along the z axis; weaker coordination of further ligands is possible in the xy plane, limited only by electrostatic and geometric factors. If the Hg is only weakly positive (formally treated as Hg^+ having the configuration $5d^{10}6s^1$), the energy required for the transition $5d^{10}6s^1 \rightarrow 5d^{10}6p^1$ is relatively large ($\approx$ 6eV). The most favorable economy occurs on formation of a linear sp hybrid system using only an energetically higher p state [89]. Owing to the weaker positive charge acquired by the Hg atom, little or no coordination tendency is now observed in a plane perpendicular to the direction of the sp hybrid.

An idea of the influence of the electronegativity of the bonding partner is provided by the Hg–C bond lengths found by microwave spectrometry for the methylmercury halides $H_3C-Hg-X$ (Table 2).

Table 2. Hg–C bond lengths in methylmercury halides.

X	Cl	Br	I
d(Hg–C) (Å)	2.061	2.074	2.087
Ref.	[90]	[90]	[91]

By contrast, equal Hg–C bond lengths are found for dimethylmercury (d(Hg–C) 2.094 Å [92]) and diphenylmercury (d(Hg–C) 2.092 Å [93]), despite the difference in the hybridization states of the carbons, which should lead to different electronegativities.

Finally, the influence of the ligands attached to the positively charged mercury in excess of the characteristic coordination number of 2 must also be taken into account.

It is against this background that the still problematic comparison of parameters for the Hg–C, Hg–N, and Hg–O bonds must be seen. The simplest solution appears to be a comparison of the isosteric groups $H_3C-Hg-CH_3$, $H_3\overset{+}{N}-Hg-\overset{+}{N}H_3$, and $H_2\overset{+}{O}-Hg-OH_2$, with the bond lengths d(Hg–C) = 2.094 Å [92] and d(Hg–N) = 2.05 (X = Cl) [7,66] or 2.11 Å (X = Br) [67] (coordination effect); in $HgSO_4 \cdot H_2O$ (highly distorted octahedral oxygen coordination), $d(Hg-\overset{+}{O}H_2)$ is 2.24 Å [94]. No structural data are available for diaquo complexes.

Let us compare the Hg–N distances in $(NH_3)_2HgCl_2$ (2.05 Å) and $(H_3CCONH)_2Hg$ (2.06 Å) [22], though the validity of such a comparison is questionable in view of the change in both the formal charge and hybridization state ($sp^3 \rightarrow sp^2$) of the nitrogen and the effective coordination number of the mercury. Without knowing the contribution due to each change individually, it can however be stated that the changes roughly balance each other out. A better comparison should be possible in the series $H_3C-Hg-CH_3$, $H_3C-Hg-\overset{+}{N}H_3$, $H_3C-Hg-\overset{+}{O}H_2$, since the positive

[94] *L. K. Templeton*, *D. H. Templeton*, and *A. Zalkin*, Acta crystallogr. *17*, 933 (1964).

charge on the Hg atom is smaller. The normal coordinate analysis for $H_3C-Hg-\overset{+}{N}H_3$, with d(Hg–N) = 2.07 Å and k(Hg–N) = 3.00 mdyne/Å in the general valence force field, gives good agreement between the calculated and the measured data [53]; though the $Hg-\overset{+}{O}H_2$ stretching vibration has been observed in the Raman spectrum, however, the Hg–O bond parameters have not yet been calculated [95].

Structural data are known for geminally dimercurated nitrogen and oxygen compounds, but not for carbon compounds of this type. For the polymeric cation $^1_\infty[NH_2Hg_{2/2}]^+$ in NH_2HgCl, d(Hg–N) is 2.05 Å [3], while for $^1_\infty[OHHg_{2/2}]^+$ in $OHHgXO_3$ (or $Hg(XO_3)_2 \cdot HgO \cdot H_2O$, X=Cl, Br), d(Hg–O) is 2.29 and 2.32 Å [96]. Both modifications of mercury(II) oxide have been found to have d(Hg–O) = 2.03 Å [97,98]. The weakening of the Hg–O bond by protonation of the oxide oxygen to oxonium oxygen can also be demonstrated in the pair $O(HgCH_3)_2$ (ν_s(Hg–O–Hg) = 487 cm^{-1}) and $[OH(HgCH_3)_2]^+$ (ν_s(Hg–O–Hg) = 415 cm^{-1}) [95].

Trimercurio onium groups are found in $NHHg_2Br_2$ and $O_2Hg_3SO_4$ ($HgSO_4 \cdot 2HgO$). For the nitrogen compound, it was deduced from IR data, using a simple mechanical model, that d(Hg–N) = 2.26 Å [11]; this value seems relatively high. Distances d(Hg–O) = 2.03 Å were found by X-ray studies for the cation $^2_\infty[OHg_{3/2}]^+$ [99]. Tris(chloromercurio)oxonium chloride $[O(HgCl)_3]^+Cl^-$ is found from neutron [100] and X-ray diffraction [101] to have Hg–O bond parameters of d(Hg–O) = 2.04 and 2.06 Å, Hg–O–Hg = 118.9 and 117.9 °, respectively.

The vibration spectra of the ion $[O(HgCH_3)_3]^+$ [102], which, unlike $[O(HgCl)_3]^+$, is evidently planar, have not yet been quantitatively evaluated. In view of the strength of the Hg–O and Hg–N bonds, it is interesting to note that the totally symmetrical stretching vibrations for the $[O(HgCH_3)_3]^+$ and $[N(HgCH_3)_4]^+$ groupings appear in the Raman spectrum with only slightly different frequencies (132 and 141 cm^{-1} respectively [53]).

Finally, mention should be made of the "mercarbides" having the idealized molecular formula $C_2Hg_6O_2X_2$, which, as apparently three-dimensional polymers, exhibit a certain similarity to Millon salts [103]. A distance d(Hg–N) = 2.07 Å has been reported for the cubic form of Millon's base and its salts, irrespective of the anion [79]; values ranging from 2.04 (dihydrate of the base) to 2.09 Å (Millon iodide), depending on the coordinating power of the anions, have been found, on the other hand, for the hexagonal forms [11,81]. The overall ranges of the bond lengths d(Hg–X) are thus

d(Hg–C): 2.06 – 2.10 Å
d(Hg–N): 2.05 – 2.11 (2.26) Å
d(Hg–O): 2.03 – 2.32 Å

5. Existence of Mercury(I)-Nitrogen Compounds

The supposed formation of mercury(I)-nitrogen compounds on reaction of Hg(I) salts with ammonia or amines of higher basicity has been definitely refuted [9, 79, 104, cf. 105]. The reaction leads by disproportionation to mercury and the mercury(II)-nitrogen compounds that are also formed from the corresponding Hg^{II} salts. Hg^I–N complexes can however be formed with amines of lower basicity, as has been shown for the system Hg_2^{2+}/aniline [56]. The potentiometrically and spectrometrically determined formation constant for the complex $[(C_6H_5NH_2)Hg_2]^{2+}$ ($\beta = 5.1 \times 10^3$ l $mole^{-1}$) is almost one order of magnitude lower than that of the Hg^{II} complex $[(C_6H_5NH_2)Hg]^{2+}$ ($\beta = 4.0 \times 10^4$ l $mole^{-1}$). It was assumed that the difference between $\beta_{Hg^{II}}$ and β_{Hg^I} would increase with increasing basicity; this would be compatible with the disproportionation of Hg^I and the formation of Hg^{II}–N compounds at higher basicities, but would also lead one to expect the existence of stable Hg^I–N compounds at lower basicities. This expectation is verified not only by the aniline complexes, which have been detected in solution [56] and isolated as $[(C_6H_5NH_2)_2Hg_2](NO_3)_2$ [106], but also by a few other Hg^I–N compounds. Shortly after it had been shown [27] that the products obtained in the reaction of mercury(II) acetate with NH-acid tetrasulfur tetraimide were probably Hg^I–N compounds, relatively stable mercury(I) derivatives of $(SNH)_4$ and S_7NH, *i.e.* the yellow $[(SN)Hg]_x$ and the light yellow $(S_7N)_2Hg_2$, were obtained [107], *e.g.*:

$$Hg_2(NO_3)_2 + 2\ S_7NH \xrightarrow{DMF,\ 20\,^\circ C} (S_7N)_2Hg_2 + 2\ HNO_3$$

Diacetohydrazide, which is also an NH-acid compound, reacts similarly in weakly acidic aqueous solution to give orange $(H_3CCO)_2N_2Hg_2$; the properties of this product and the Hg–Hg distance of 2.9 Å deduced from a calculated radial electron density distribution seem to establish conclusively that this is a Hg^I–N compound [108]. However, the Hg–Hg

vibration, which appears with high intensities for other Hg^I derivatives, could not be detected in the Raman spectrum of this compound [109].

In the meantime, further Hg^I derivatives of bis(fluorosulfonyl)amine, *N,N*-bis(fluorosulfonyl)urea, and fluorosulfonylcarbamates have been prepared [110] and investigated by vibrational spectrometric methods along with mercury(I) diacetohydrazide. All compounds exhibit intense Raman lines caused by Hg–Hg vibrations. From the observed frequencies Hg–Hg distances ranging from 2.44 to 2.47 Å have been calculated [111] using an appropiate Badger formula (cf. [109]).

However further preparative work and structural studies are necessary for a more profound understanding of the problem of Hg^I–N compounds.

We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support of our investigations.

3,7,11-Cyclotridecatrien-1-one and 11-Vinyl-3,7-cycloundecadien-1-one

By *Heinz Breil* and *Günther Wilke* [*]

Butadiene is cyclotrimerized to 1,5,9-cyclododecatriene *(1)* (at 20–100 °C) by "naked nickel" [1,2]. On refluxing (below 0 °C) with butadiene, bis(1,5-cyclooctadiene)nickel(0) *(2)* forms a complex $C_{12}H_{18} \cdot Ni$ *(3)*, which is isolable in crystalline form and in which a $C_{12}H_{18}$ chain is bonded to nickel by two terminal π allyl groups [1,2]. On reaction of compound *(3)* with electron donors such as phosphines (PR_3) in the molar ratio 1 : 1, C–C linkage occurs to give 1,5,9-cyclododecatrienephosphinenickel(0) *(4)*; reaction with an excess of phosphine affords *(1)* and $Ni(PR_3)_n$, $n = 2$–4 [1,2]. At –40 to –60 °C *(3)* undergoes an insertion reaction with carbon monoxide to give 11-vinyl-3,7-cycloundecadien-1-one [1,2] *(7a)*.

We have now found that reaction of compound *(3)* with isocyanides *(5)* proceeds *via* insertion to give the imines *(6a)* and *(6c)* of vinylcycloundecadienone *(7a)* and cyclotridecatrienone *(7c)*, and is accompanied by formation of tetrakis(isocyanide)nickel(0) complexes *(8)*.

R = C_6H_5, C_2H_5; R' = C_6H_5, C_6H_{11}, tert.-C_4H_9

The readily accessible [3] complex *(2)* is treated with liquid butadiene until all the crystals have disappeared. The deep red liquid reaction product is then allowed to react with isocyanide (Ni: *(5)* = 1 : 5) at 0 °C, precipitated *(8)* is filtered off, and the mixture of isomers *(6a)* and *(6c)* is isolated. The yields of *(6)* lie between 40 and 70% (based on *(2)*).

The isomers *(6)* can be hydrolyzed by 30% CH_3COOH/3.5 N H_2SO_4 (1 : 1) to yield the four ketones *(7a–d)* which were almost completely separated by distillation. We were able to identify *(7a)*, 11-ethylidene-3,7-cycloundecadien-1-one *(7b)*, and 3,7,11-cyclotridecatrien-1-one *(7c)* by their IR, ^{1}H-NMR, and mass spectra. Compound *(7b)* appears to be formed from *(7a)* on acid hydrolysis of *(6)*; *(7d)* is probably an isomer of *(7c)* having a *cis* double bond. The isomeric distribution (gas chromatography) varies according to the isocyanide used: *tert*-C_4H_9NC and $C_6H_{11}NC$ give *(7a)* : *(7b)* : *(7c)* : *(7d)* = 2 : 1 : 90 : 7 and 42 : 41 : 13 : 4, respectively — *i.e.* the bulky *tert*-butyl group causes preferential linkage of the terminal C atoms of *(3)* with the isocyanide C atom, while C-3 and C-12 of *(3)* react in the case of cyclohexyl isocyanide; the ratio C_{11}-ring/C_{13}-ring amounts to about 3 : 97 and 83 : 17, respectively.

Catalytic hydrogenation of *(7c)* yields cyclotridecanone, m.p. 32 °C (literature value).

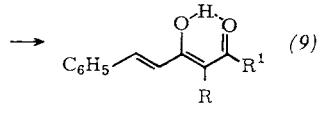
Reactions of 2,2-Diethoxyvinylidenetriphenylphosphorane with Ketones. Synthesis of 1,3-Dioxo-4-pentenes and Their Enol Ethers

By *Hans-Jürgen Bestmann* and *Rolf W. Saalfrank* [*]



2,2-Diethoxyvinylidenetriphenylphosphorane *(1)* [1] undergoes a Wittig reaction with fluorenone *(2)* to give the allene *(3)* which immediately dimerizes to *(4)* (m.p. 184 °C, yield 65 %). The structure of *(4)* was confirmed by degradation.

	R	R¹	(6) m.p. (°C)	(6) yield (%)	(7) m.p. (°C)	(7) yield (%)	(8) m.p. (°C)	(8) yield (%)
(a)	H	C_6H_5	174	65	85	57	111	95
(b)	H	CH_3	146	55	50	53	86	94
(c)	—$(CH_2)_4$—		177	69	51	51	93	81
(d)	H	OC_2H_5	166	74	55	66		

Reaction of *(1)* with ketones *(5)* having a methylene group α to the carbonyl is quite different: The stable ylides *(6)* are formed by Michael addition and subsequent loss of ethanol. The shift of the carbonyl band to 1582—1597 cm^{-1} in *(6a)*—*(6c)* and to 1645 cm^{-1} in *(6d)* indicates a large contribution by the resonance structure *(6')*. When R = H, this proton signal is split into a doublet by long-range coupling with the phosphorus ($^4J_{PH}$ = 6.5 Hz). Coupling between the phosphorus and the α-H atom is temperature dependent [2].

The alkylidenetriphenylphosphoranes *(6)* react with aldehydes, *e.g.* benzaldehyde, to give the enol ethers *(7)* of 1,3-dioxo-4-pentenes (C_6H_5—CH=CH: J_{HH} = 15.9 Hz), which can be cleaved by acids to give the free dicarbonyl compounds *(8)*. According to the ^{1}H—NMR spectra, compounds *(8)* are present almost exclusively as enols *(9)* [τ = —5.37 to —6.72 (OH/s)]. Scission of *(7d)* under the above conditions results in hydrolysis and decarboxylation to give benzylideneacetone.

Experimental:

An equivalent amount of ketone is added dropwise to a salt-free benzene solution of ylide [3] prepared from 2,2-diethoxyvinyltriphenylphosphonium tetrafluoroborate [1] by the sodium amide method. After 20 hours' stirring at room temperature the benzene is distilled off under vacuum and the residue recrystallized from ethyl acetate.

The resulting red-brown to yellow compound *(6)* is dissolved in anhydrous benzene, treated with an equivalent amount of benzaldehyde, and refluxed for 4 hours. The solvent is subsequently distilled off and the residue extracted with light petroleum; undissolved triphenylphosphine oxide is filtered off and the light petroleum is distilled off from the filtrate. Recrystallization of the residue from ethanol at —30 to —40 °C furnishes compound *(7)*. The enol ether *(7)* is stirred with hot 25% sulfuric acid for 30 min. The crystalline residue isolated by filtration is dissolved in methylene chloride, the solution dried over $MgSO_4$, and the solvent evaporated off. Compound *(8)* is then recrystallized from ether or ethanol at —60 °C.

Synthesis of Oligonucleotide 5′-Phosphates on a Polymeric Carrier Containing 2-Pyridineethanol as Functional Group

By *Wolfgang Freist* and *Friedrich Cramer* [*]

In syntheses of oligonucleotides on polymeric carriers the nucleotide is usually attached to the polymer by the 5′-OH group, so that removal from the carrier affords oligonucleotides with a free 5′-OH group [1]. Synthesis of oligonucleotide 5′-phosphates has been effected only on one carrier up to the trinucleotide [2].

We have prepared a new polymeric carrier for the synthesis of oligonucleotide 5′-phosphates, wherein the 2-pyridineethanol group is attached as "phosphate trap" (cf. [3]) to a 6% crosslinked, macroporous polystyrene. 23% benzoylated polystyrene *(1)* is first treated with a mixture of equivalent amounts of phenyllithium and 2,6-lutidine, whereupon lutidyllithium adds to the CO group, giving *(2)*. Then two equivalents of phenyllithium are added to this product, so

that not only the H atom of the hydroxyl group but also one hydrogen atom in the side chain of the pyridine ring is replaced by lithium. Finally formaldehyde is added to give product *(3)*[**]. About 20% of the phenyl groups of the carrier are thus converted into functional groups.

For synthesis of oligothymidylic acids the carrier was loaded with 0.2 mmole of nucleotide per g of polymer by reaction with 3′-*O*-acetyldeoxythymidine 5′-phosphate and dicyclohexylcarbodiimide (DCCD)[***], the 3′-*O*-acetyl group was removed by 2 N-NaOH and pyridine (1 : 1), and the product was condensed with 3′-*O*-acetyldeoxythymidine 5′-phosphate by means of 2,4,6-triisopropylbenzenesulfonyl chloride (TPSCl)[***]. The nucleotide was removed from the carrier by 2 N-$NaOCH_3$ in methanol/pyridine (1 : 1).

Oligothymidylic acids were thus synthesized up to the hexanucleotide.

Table 1. Yields in individual steps [a] based on the preceding step.

Electron Transfer from Solvent to a Triplet Excited Acceptor Molecule

By *Günther Briegleb* and *Helmut Schuster*[*]

We have studied the effect of electron donor-acceptor (EDA) complex formation on both the triplet-triplet (TT) absorption spectrum and the phosphorescence spectrum of the electron donor component in the complexes |DA| of the donors (D) naphthalene *(1)* and phenanthrene *(2)* with the acceptors (A) tetrachlorophthalic anhydride *(3)* and pyromellitic dianhydride *(4)* at $T = 96$ to 118 °K in solution in dipropyl ether (PE) glass[1].

After production of triplet (T) excited molecules of the donors *(1)* and *(2)* respectively in the complex $|D_T^* \cdots A|$ by flash excitation in the charge transfer (CT) absorption band of the dissolved complexes at $T \approx 100$ °K and at a concentration ratio $q = c_D/c_A = 1$ we recorded the TT absorption spectrum, the phosphorescence spectrum, and the mean lifetime τ of the T-excited state of complexed *(1)* and *(2)* respectively. Complex formation is seen to modify the spectra and τ[1].

At higher temperatures, T = 105—118 °K, and/or an excess of donor ($q = 100$) distinct changes were observed in the TT absorption, the phosphorescence spectrum, and the lifetime of the T-excited donor as a result of excimer formation $D \cdot D_T^* \cdots A$.

In addition, new relatively intense and broad unstructured absorption bands were observed between 12×10^3 and 20×10^3 cm^{-1} outside the typical spectral range of donor-TT

absorption of *(1)* (23—27 × 10^3 cm^{-1}) and of *(2)* (20—24 × 10^3 cm^{-1}). These new bands constitute the first evidence for CT* absorption bands of an electron transfer from a T-excited donor to an unoccupied energy level of an acceptor [2].

In the present communication we wish to report the results of studies on an electron transfer from the solvent dipropyl ether (PE) as n-donor to the dissolved T-excited acceptors *(3)* or *(4)* [3].

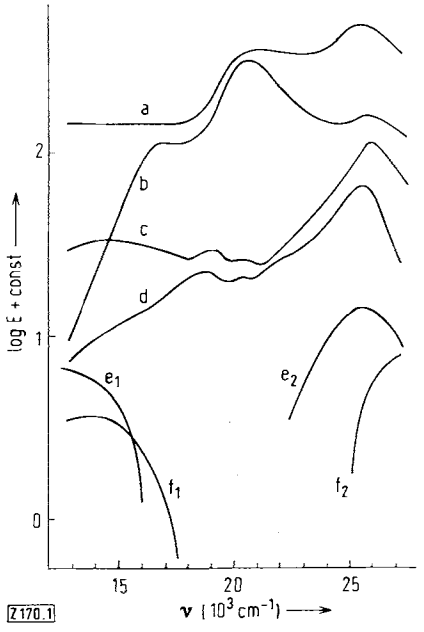

Fig. 1. Absorption spectra of triplet excited pyromellitic dianhydride *(4)* and tetrachlorophthalic anhydride *(3)* in solvent glass.

a) *(4)* in PE (3 × 10^{-5} M), T = 100 °K; b) *(4)* in BA (1.6 × 10^{-4} M), T = 115 °K; c) *(3)* in PE (6 × 10^{-5} M), T = 100 °K; d) *(3)* in BA (1.4 × 10^{-4} M), T = 115 °K. e) difference between the spectra of *(4)*, a—b; f) difference between the spectra of *(3)*, c—d. Band width: 70 (short wave region) to 200 cm^{-1} (long wave region).

We compared the TT absorption spectra of *(4)* and *(3)* in a solvent glass composed of 75 % butyl acetate, 19 % methylcyclohexane, and 6 % isopentane (BA) in the 12—27 × 10^3 cm^{-1} region (Fig. 1: b,d) with the corresponding spectra of solutions in (PE) glass (Fig. 1: a,c): The main difference is observed at $\tilde{\nu} < 17 \times 10^3$ cm^{-1} in a new, broad absorption band (Fig. 1: a,c). Assuming that the spectra a,b and c,d are equal, to a good approximation, in the TT absorption region 17—21 × 10^3 cm^{-1} of *(4)* and 18—25 × 10^3 cm^{-1} of *(3)* the subtraction of the spectra in (PE) and (BA) affords two broad unstructured absorption bands exhibiting no fine structure (Fig. 1: e,f). The red shift of the maxima of these new double bands in (PE) on going from *(3)* to *(4)* corresponds to an increase in the electron affinity of the acceptor from 0.55 to 0.85 eV [4].

If it is considered that the electron affinity of a T-excited acceptor molecule is higher than that in the ground state by an amount equal to the T-excitation energy [5], the longwave absorption band (Fig. 1, e_1, f_1) of T-excited *(3)* and *(4)* in (PE) can be interpreted as a CT* band of electron transfer from (PE) as electron donor to T-excited *(3)* and *(4)* respectively:

$$D + A_T^* \rightarrow |DA_T^*| \xrightarrow{h\nu_{CT^*}} |\dot{D}^+\dot{A}^-|$$

This would be the first observation of a CT absorption band due to an *electron transfer from a donor to a triplet excited acceptor molecule* [6].

The energy of the CT* absorption can be estimated from:

$$h\nu_{CT^*} \approx IE(D) - EA(A_T^*) - E_C \qquad (1)$$

where IE(D) is the ionization energy of the solvated donor; EA(A) and $EA(A_T^*)$ are the electron affinities of the solvated acceptor in the ground state and the triplet excited state respectively; E_C is the coulombic interaction energy in the ion pair $[\dot{D}^+ \cdots \dot{A}^-]_{solv}$; E_{00} ($S_0 \rightarrow T_1$) is the T-excitation energy of the acceptor; $EA(A_T^*) = EA(A) + E_{00}(S_0 \rightarrow T_1)$.

IE(PE) = 9.3 eV [7]; $EA(3)$ = 0.55 eV and $EA(4)$ = 0.85 eV [4]; $E_{00}(S_0 \rightarrow T_1)$ = 23 × 10^3 cm^{-1} = 2.85 eV for *(3)* and *(4)*; $EA(3)_T^*$ = 3.4 eV; $EA(4)_T^*$ = 3.7 eV.

With $\tilde{\nu}_{CT}$ = 29 × 10^3 cm^{-1} (3.6 eV) for the n,π complex (PE)-tetracyanoethylene *(5)*, the relationship $E_C \approx IE(PE) - EA(5) - h\nu_{CT}$ with $EA(5)$ = 2.0 eV [4] gives E_C = 3.7 eV. Insertion of these values into eq. (1) yields $\tilde{\nu}_{CT_1^*}(PE) \cdot (3)_T^* \approx$ 17.7 × 10^3 and $\tilde{\nu}_{CT_1^*}(PE) \cdot (4)_T^* \approx$ 15.3 × 10^3 cm^{-1}.

The $\tilde{\nu}_{CT_1^*}$ values calculated in this manner lie — within the limit of errors of such an estimation — in the range of the *long wave* CT* absorption band (Fig. 1: e_1, f_1).

The energy difference of the absorption bands (Fig. 1: e_1, e_2 and f_1, f_2) show good agreement with the excitation energy $E_{00}(T_1 \rightarrow T_2)$ of the acceptor (≈ 15 × 10^3 cm^{-1}). Thus it may be supposed that the second absorption band (Fig. 1: e_2, f_2) at shorter wavelength is also a CT* absorption band, which can be calculated from

$$h\nu_{CT_2^*} = h\nu_{CT_1^*} + E_{00}(T_1 \rightarrow T_2)$$

However, in view of the great errors of such rough estimations a further detailed experimental study (*e.g.* polarization measurements) will be necessary.

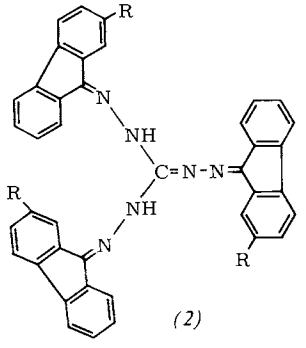
An Unusual Reaction of Fluorenone Hydrazones



By *Joachim Gante* and *Günther Mohr* [*]

Reaction of fluorenone hydrazone *(1a)* [1] and 2-chlorofluorenone hydrazone *(1b)* [2] with ethyl chlorocarbonate in anhydrous ethyl acetate in the presence of triethylamine (molar ratio 1 : 1 : 1) did not yield the expected carbazates but, instead, *N,N',N''*-tris(fluorenylidenamino)guanidine *(2a)* (yield 46%, decomp. pt. 300 °C, brownish red crystals) and *N,N',N''*-tris(2-chlorofluorenylidenamino)guanidine *(2b)* (yield 25%, decomp. pt. 340 °C, brownish red crystals).

(1)

(a), R = H
(b), R = Cl

(2)

(2a) and *(2b)* are insoluble in almost all the usual organic solvents. They may be recrystallized from dimethylformamide. The composition of *(2a)* and *(2b)* follows from analysis and the IR spectrum. Chemical evidence for the structure was obtained by heating triaminoguanidine hydrochloride[3] with fluorenone (molar ratio 1 : 3) in ethanol/conc. hydrochloric acid (7 : 1) to give a product that was identical with *(2a)* according to its IR spectrum and analysis.

Attempts to prepare compounds corresponding to *(2a)* and *(2b)* by the same route from other hydrazones, such as benzaldehyde-, *p*-nitrobenzaldehyde-, and benzophenone hydrazone, proved unsuccessful; complicated mixtures were obtained instead.

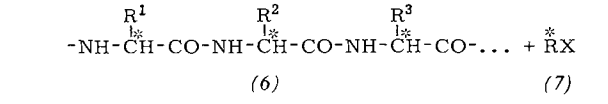
Stereorelating Syntheses of Planar Chiroids

By *Dieter Marquarding*, *Hans Klusacek*, *George Gokel*, *Peter Hoffmann*, and *Ivar Ugi*[*]

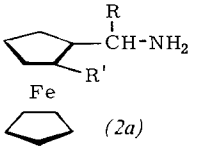


The success of asymmetrically induced four component peptide syntheses[1–3]

(1) *(2)* *(3)* *(4)*

(5)

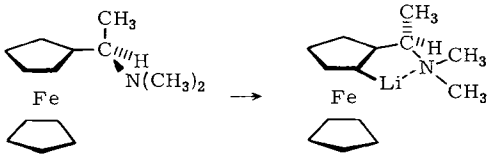
(6) *(7)*



depends appreciably upon the amine component *(2)*[3] which, in this context, has to meet the following requirements:

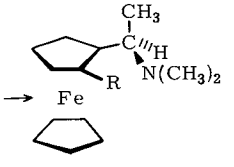
a) The condensation of *(2)* with *(1)*, *(3)*, and *(4)*, if necessary *via* the Schiff base of *(2)* and *(3)*, should take place rapidly and in high overall yield[2].

b) As a component of the condensation, *(2)* must also have the effect of an asymmetrically inducing steric matrix and provide for a highly stereoselective synthesis of the newly formed amino acid unit in the desired configuration.



c) The residue R* must be readily cleaved from *(5)* under mild conditions, *e.g.* in cold formic or trifluoroacetic acid, preferably in such a manner that *(2)* can be regenerated from *(7)*.

Of all previously tested[2] amines *(2)* only those of type *(2a)* meet all the specifications (a)–(c)[4,5].



(2a)

Optically pure chiral ferrocene derivatives[**] with planar and central chirality can be obtained *via* the *stereorelating*[6] metalation of chiral tertiary α-ferrocenylalkylamines, as is illustrated by the example of the synthesis of *(10a)*–*(10e)* from *(8)*. Both antipodes *(8)* can be readily obtained by resolution of the racemate by (*R*)-(+)-tartaric acid [*(8)*-(*S*)-(*R*)-tartrate from methanol, *(8)*-(*R*)(*R*)-tartrate from the residue of the mother liquor by crystallization from acetone-water (10 : 1)].

(8)-(*R*) *(9)*-(*R*)(*R*)

(10a)-*(10e)*

The metalation of *(8)*-(*R*)[5] by *n*-butyllithium in ether leads almost exclusively (Q_{pn} = 96 : 4[7], by quantitative chromatography) to *(9)*-(*R*)(*R*)[6]. The methyl group of the side chain has to point "downward" when the (*R*)(*S*)-diastereomer of *(9)* is formed by a chelate mechanism[8,9] with the consequence that an appreciable repulsive interaction with the ferrocene system is witnessed.

The reactions of *(9)*-(*R*)(*R*) with alkylating agents (methyl and ethyl iodide[9], trimethylsilyl chloride[6]) or carbonyl compounds (formaldehyde, benzophenone[6]) produce *(10a)* to *(10e)*.

(10a): R = CH_3 (after treatment of the reaction mixture with dimethylamine), yield 66%, chromatography on Al_2O_3-acetone/hexane (1 : 4), b.p. 104–105 °C/0.2 torr, $[\alpha]_D^{20}$ = +32.9 °, *c* = 2.4 (ethanol).

(10b): R = C_2H_5 (after treatment of the reaction mixture with dimethylamine), yield 47%, b.p. 106–107 °C/0.2 torr, $[\alpha]_D^{20}$ = –16.2 °, *c* = 1.7 (ethanol).

(10c): R = $(CH_3)_3Si$, yield 61%, R_f = 0.55 [NH_3-treated SiO_2-ligroin/isopropanol (20 : 1)] b.p. 103–104 °C/0.04 torr, $[\alpha]_D^{20}$ = +15.5 °, *c* = 1.5 (ethanol).

(10d): R = $HOCH_2$, yield 58%, m.p. 109–110 °C (cyclohexane), $[\alpha]_D^{20}$ = +121.5 °, *c* = 1.4 (chloroform).

(10e): R = $HO(C_6H_5)_2C$, yield 52%, m.p. 118–119 °C (methanol), $[\alpha]_D^{20}$ = –191.6 °, *c* = 0.5 (ethanol).

Since the amines of type *(10)* are easily transformed (*e.g.* by retentive S_N1[4,5] or eliminations[4,9]) into other ferrocene

derivatives with planar or planar and central chirality, the asymmetrically induced metalation of chiral tertiary α-ferrocenylalkylamines provides a general basis for sterically predesignated syntheses and configurational assignments for optically pure compounds of the above mentioned classes[10].

[**] In this and further papers by the present authors, the following procedure will be used with regard to the (*R*)(*S*)-nomenclature for the metallocenes [10, 11]: (a) The (*R*)(*S*)-nomenclature is confined to metallocenes with not more than two substituents per ring (*Ruch*'s class *a* [12]). Metallocenes with more than two substituents per ring represent chiroids of class *b* [12] and are therefore not subject to a right-left-classification like the (*R*)(*S*)-nomenclature (see also ref. [10]). (b) The observer looks upon the disubstituted ring along the main (C_5) axis of the metallocene framework. If the sequential priority [10] of the substituents decreases (or increases, respectively) on the shortest clockwise arc (*e.g.* 1→2 or 1→3), the configuration is termed an (*R*) (or an (*S*), respectively). (c) In the case of chiroids with several different types of classes of chirality elements, these are designated in the order: central axial, planar.

For example, in (*10c*)-(*R*)(*S*) the (*R*) refers to the side chain center of chirality and the (*S*) to the ligand sequence of the chirality plane of the ferrocene nucleus.

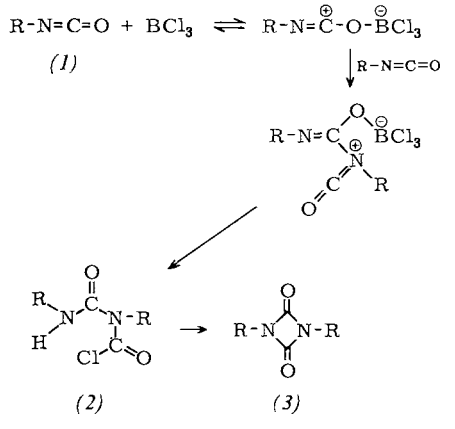
New Method for the Preparation of 1,3-Diazetidinediones[1]

By *Herbert Helfert* and *Egon Fahr*[*]

1,3-Diazetidinediones *(3)* have hitherto been prepared by dimerization of isocyanates *(1)*. We have now found that these industrially important compounds can also be synthesized by cyclization of allophanyl chlorides *(2)*. The



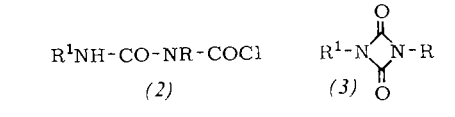


Table. Allophanyl chlorides *(2)* [4, 5] and diazetidinediones *(3)* [5].

(o)	CH_3	CH_3						

[a] *(2a)*–*(2g)* were prepared in toluene, *(2h)*–*(2m)* in $CHCl_3$.

[b] *(2c)* could not be crystallized and isolated in analytically pure state.

[c] A number of diazetidinediones *(3)* have already been described in the literature (prepared by "dimerization" of isocyanate), albeit with melting points deviating from our values. Since the isocyanate reaction, unlike allophanyl chloride cyclization, can lead, *e.g.*. to trimeric isocyanates, it may be assumed that the respective authors had obtained products of higher molecular weight or mixtures of such products with *(3)*.

[d] Optimum yields are most readily obtained by following the decrease in intensity of the allophanyl chloride band at *ca.* 1740 cm^{-1}.

[e] Reaction of 2.8 mmoles of *(2n)* in 50 ml of water- and alcohol-free $CHCl_3$ with 10 ml of 2,6-lutidine.

previously inaccessible allophanyl chlorides *(2)* bearing aromatic substituents[2] were obtained by reaction of *(1)* with BCl_3[3].

Allophanyl chlorides (2)

An excess of gaseous BCl_3 (N_2 stream) is passed into a solution of isocyanate *(1)* (100 mmoles) in anhydrous toluene (200 ml) or water- and alcohol-free $CHCl_3$ (200 ml) at −60 °C. After 4 hours' stirring at 0 °C the reaction mixture is treated with ice-water (100 ml) and filtered to remove boric acid[4]. The aqueous phase is repeatedly extracted with solvent (see Table).

Diazetidinediones (3)[6]

Pyridine (10 ml) is added to *(2a)*–*(2g)* (2.5 mmoles) in anhydrous toluene (60 ml) or *(2i)*–*(2m)* in water- and alcohol-free $CHCl_3$ (100 ml) and the reaction mixture is worked up by pouring into ice-water, acidifying with conc. HCl, and extracting the aqueous phase with $CHCl_3$ (2 × 30 ml). Reaction of allophanyl chlorides bearing aliphatic [*e.g. (2o)*] or aliphatic and aromatic substituents [*e.g. (2n)*[7]] with pyridine yields complex products[1]. If 2,6-lutidine, which is blocked in the *o*-position, is used in place of pyridine for reaction with *(2n)* then the diazetidinedione *(3n)* is formed; with *(2o)* no reaction occurs.

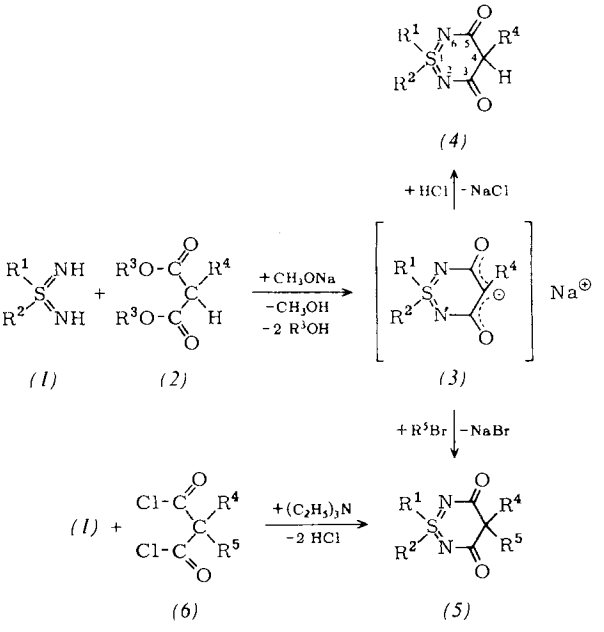
[4] In the case of *(2h)*–*(2j)* and *(2m)* a mixture of boric acid and *(2)* is precipitated; *(2)* is extracted with hot toluene.

[5] Satisfactory elemental analyses were obtained for the compounds.

[6] On cylization of *(2)*, isocyanates *(1)* are formed as by-products, both by monomerization of *(3)* and also directly from *(2)*. Compound *(2h)* gave only *(1h)*.

[7] Prepared from benzylphenylurea by a method based on that given in ref. [2] (yield 50%, m.p. 86–88 °C [5]).

Condensation of Dialkyl Sulfone Diimines with Malonic Esters



By *Manfred Haake*[*]

Dialkyl sulfone diimines *(1)*, which are accessible by chloroamination of thioethers[1], can be condensed with unsubstituted and monosubstituted malonic esters *(2)* in the presence of sodium methoxide to give novel 3,5-dioxo-3*H*-4,5-dihydro-1,2,6-thia$^{(IV)}$diazines *(4)*.

After dissolution of an equivalent amount of sodium in anhydrous methanol and addition of components *(1)* and *(2)* the reaction mixture was refluxed for one day. On prolonged standing, a portion of the sodium salt *(3)* crystallized from the cool solution. Compounds *(4)* were isolated by neutralization of the reaction mixture with dilute hydrochloric acid and extraction of the residue with boiling isopropanol, from which they crystallize on cooling.

Dialkyl malonates do not react with *(1)*. However, the 4,4-dialkylated compounds *(5)* can be prepared by alkylation of the salts *(3)*. Thus *(5a)* was obtained by reaction of ethyl methyl sulfone diimine[2] with ethyl malonate to give the salt *(3)* which was allowed to react with a slight excess of ethyl bromide.

Reaction of *(1)* with dialkylmalonyl dichloride *(6)* in the presence of triethylamine also yields compounds of type *(5)*. Thus *(5b)* was prepared by stirring equivalent amounts of dimethyl sulfone diimine and dimethylmalonyl dichloride with a five-fold excess of triethylamine in dry benzene for one day.

	R^1	R^2	R^3	R^4	R^5	M.p. (°C)	Yield (%)
(4a)	CH_3	CH_3	C_2H_5	C_2H_5	H	190	52
(4b)	CH_3	CH_3	CH_3	H	H	206	67
(4c)	CH_3	CH_3	C_2H_5	C_6H_5	H	245	34
(4d)	CH_3	C_2H_5	C_2H_5	C_2H_5	H	181	55
(5a)	CH_3	C_2H_5	C_2H_5	C_2H_5	C_2H_5	195	44
(5b)	CH_3	CH_3	–	CH_3	CH_3	215	42

(4) and *(5)* are colorless, hygroscopic substances that readily dissolve in water (with the exception of *(4a)*) and decompose at their melting points. Their structures were established by elemental analysis and spectroscopic data.

In addition to a strong band at 1640 cm^{-1} (ν_{CO}), the IR spectra (KBr) contain intense bands at 1330 and 1050 cm^{-1} (possibly due to ν_{NSN}[3]).

In the NMR spectra ([D_6]-DMSO, TMS as internal standard), all the *S*-methyl groups appear at δ = 3.6 (s) and the *S*-ethyl groups of *(4d)* and *(5a)* at 3.7 (q) and 1.3 (t) ppm, resp. The signals of the protons attached to C-4 are observed at 3.0 [(t) for *(4a)* and *(4d)*, (s) for *(4b)*] and 4.3 ppm [(s) for *(4c)*], those of the ethyl groups on C-4 in *(4a)* and *(4d)* and in *(5a)* at 2.0 (m) and 0.8 (m), resp., that of the phenyl group on C-4 in *(4c)* at 7.6 (s), and that of the methyl group on C-4 in *(5b)* at 1.3 (s) ppm.

On addition of D_2O, the protons on C-4 are seen to undergo rapid exchange; a gradual exchange of the *S*-alkyl protons in the α position may also be observed.

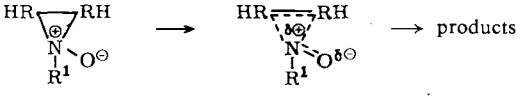
Stereospecific Deaminations of Some *N*-Alkylaziridines by *m*-Chloroperbenzoic Acid[1]

By *Harold W. Heine, Jay D. Myers*, and *Edward T. Peltzer III*[*]

When *cis*-1-benzyl- [*cis-(1a)*] or *cis*-1-cyclohexyl-2,3-dibenzoylaziridine [*cis-(1b)*][1a,2] was treated with an equivalent quantity of *m*-chloroperbenzoic acid in benzene in the dark at room temperature for 24 h and the reaction mixture worked up by extracting with aqueous sodium carbonate, drying the benzene layer over anhydrous magnesium sulfate, filtering, and evaporating the benzene in the dark, 85—90% yields of a mixture of the known *cis*-dibenzoylethylene [*cis-(2)*][3] and known nitroso dimer [either *(3a)* or *(3b)*, respectively][4] were obtained. Similar treatment of *trans-(1a)* and *trans-(1b)* gave 90% yields of *trans-(2)* and nitroso dimer.

cis-(1) *cis*-(2) (3)

(a), $R^1 = C_6H_5CH_2$



(b), R^1 = 

R = C_6H_5CO

The dimer of α-nitrosotoluene *(3a)* could be separated from *cis-(2)* or *trans-(2)* by dissolving the crude reaction products in a very small quantity of hot ethyl acetate, cooling, and filtering. Authentic samples of the *cis*- and the *trans*-dibenzoylethylenes[3] and the dimer of α-nitrosotoluene[4] were prepared by known procedures for purposes of comparison.

The deamination reaction and the work-up of the reaction mixture must be carried out in the dark to avoid extensive isomerization of *trans-(2)* to *cis-(2)*.

The stereospecific course of the reaction suggests a concerted mechanism for the deamination. The products probably arise *via* an intermediate such as *(4)*.

(4)

The results are to be compared with the reaction of 1,2,3-triphenylaziridine with *m*-chloroperbenzoic acid in methylene chloride. In this case, a non-stereospecific deamination occurred with the formation of 7% *cis*-stilbene, 7% *trans*-stilbene, 14% nitrosobenzene, 16% benzaldehyde, 8% benzylideneaniline, and 19% of a mixture of *cis*- and *trans*-stilbene oxides[5].

The reaction was also successfully extended to 3-benzyl-1,5-diphenyl-9,3-oxazatricyclo[3.3.1.$0^{2,4}$]nonan-7-one[6]. Treatment of the latter compound with at least a two-fold excess *m*-chloroperbenzoic acid afforded a 64% yield of 1,5-diphenyl-3,9-dioxatricyclo[3.3.1.$0^{2,4}$]nonan-7-one (m.p. 124 to 126 °C), which was characterized by elemental analyses and NMR and mass spectroscopy. Here the deamination reaction to the corresponding alkene was followed by an epoxidation.

Determination of Halide Ions by Gas Chromatography[1]

By *H. A. Rüssel*[*]

One method of converting hydrophilic, non-volatile halide ions in aqueous solution into readily volatile compounds lies in their reaction with 1,2-olefin oxides to give halogeno alcohols[2].

The reaction proceeds at a satisfactory rate, but leads to uniform products only with ethylene oxide. The reaction solution must be acidic; since addition of sulfuric or phosphoric acid promotes the already inevitable formation of glycol it is advisable to convert the halide ions into the hydrohalic acids in a strongly acidic ion exchanger. After passage of ethylene oxide and prolonged standing the sample is subjected to gas chromatography, whereupon the resulting compounds 2-chloro-, 2-bromo-, and 2-iodoethanol proved readily separable (Fig. 1). Conversions were practically quantitative; an interpretable signal was obtained at concentrations as low as 0.5×10^{-4} M hydrochloric acid.

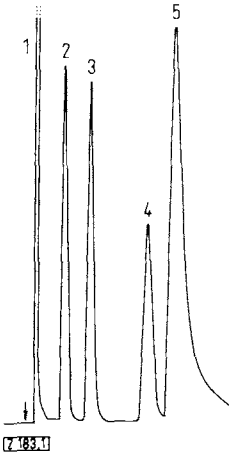

Fig. 1. Gas chromatogram: 1, ethylene oxide; 2, 2-chloroethanol; 3, 2-bromoethanol; 4, 2-iodoethanol; 5, ethylene glycol.

Experimental:

Solutions of the halides are converted into the corresponding acids by reaction with a strongly acidic ion exchanger. Ethylene oxide is passed (2 bubbles/s) into the ice-cooled acid (10.0 ml) for 15 min; alternatively, liquid ethylene oxide (1 ml) is added to the acid. After 1 hour, the volume is made up to 15.0 ml and 1 μl of the solution is injected into the gas chromatograph.

Conditions: 2 m column, 12% EGS on Gaschrom P, 100 °C (determination of very small amounts of chloride is best carried out at 80 °C), 60 ml N_2, FID; gas chromatograph: Packard 7839.

Example: A solution that was 0.1 N in hydrochloric, hydrobromic, and hydriodic acid was analyzed (cf. Fig. 1) and the

gas chromatogram compared with those of solutions containing known amounts of 2-chloro-, 2-bromo-, and 2-iodoethanol.

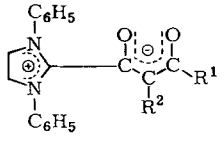
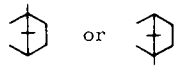
Stable Dipoles from 1,1',3,3'-Tetraaryl-2,2'-biimidazolidinylidenes and Ketenes[1] [**]

By *Manfred Regitz*, *Jürgen Hocker*, and *Bernd Weber* [*]



The exceptional reactivity of electron-rich olefins[2] is also evident in the reaction of the 1,1',3,3'-tetraaryl-2,2'-biimidazolidinylidenes *(1a)* and *(1b)* with diphenylketene, which proceeds *via* scission of the double bond to give the stable dipoles *(2a)* and *(2b)*. They are characterized by the extreme readiness with which they undergo (3 + 2)-cycloaddition with, *e.g.*, phenyl isothiocyanate and dibenzoylacetylene.



(1) *(2)*

(a), R = C_6H_5 *(b)*, R = p-$CH_3OC_6H_4$

Acylated ketenes, formed by Wolff rearrangement from 1,3-dioxo-2-diazo compounds, dimerize very rapidly. If the Wolff rearrangement is carried out in the presence of *(1a)*, however, the dipoles *(3a)*–*(3d)* derived from the monomeric

(3)

(a), $R^1 = R^2 = C_6H_5$
(b), $R^1 = OC_2H_5$, $R^2 = CH_3$
(c), R^1, R^2 = 
(d), R^1, R^2 = 

ketenes are obtained. As β-diketone enolates, they give a reddish-brown color on reaction with iron(III) chloride; a 1 : 1 complex (m.p. 210 °C) was isolated in the case of *(3a)*.

Owing to electron delocalization in the anionic part of the molecule, a long-wave CO absorption is observed in the IR spectrum of all the dipoles; compared with imidazolidines[3] the NMR signals of the CH_2 protons in the cationic part are shifted downfield as a result of decreased shielding (see Table).

Cpd.	Yield (%)	M.p. (°C)	NMR in $CDCl_3$ δCH_2 (ppm)

Xenon(II) Fluoride Pentafluoroorthotellurate as Fluoride Donor: $[XeOTeF_5]^+$ $[AsF_6]^-$

By *Friedrich Sladky* [*]

Xenon difluoride reacts with stoichiometric amounts of pentafluoroorthotelluric acid with loss of HF to give xenon(II) fluoride pentafluoroorthotellurate *(1)*[1] and xenon(II) bis(pentafluoroorthotellurate)[2]. With fluoride acceptors of type EIF_5 (*e.g.* El = As or noble metal), the salts $[XeF]^+$ $[EIF_6]^-$, $[XeF]^+$ $[El_2F_{11}]^-$, and $[Xe_2F_3]^+$ $[EIF_6]^-$ are formed[3].

Two routes are feasible for a reaction of *(1)* with equimolar amounts of EIF_5:

$$FXeOTeF_5 + EIF_5 \quad (1) \quad \begin{cases} \nearrow [XeF]^+ [F_5EIOTeF_5]^- \\ \searrow [XeOTeF_5]^+ [EIF_6]^- \end{cases}$$

The behavior of *(1)* towards BF_3, PF_5, and AsF_5 has been investigated; in the case of BF_3 or PF_5 no reaction takes place. Gentle warming of a mixture of *(1)* (which is a liquid at room temperature) and an excess of AsF_5 results in immediate formation of a bright yellow 1:1 adduct, m.p. 160 °C (in a glass capillary, partial decomposition), which can be sublimed very slowly and without decomposition in an oil-pump vacuum (10^{-3} torr).

The Raman spectrum of the product (He-Ne laser) is characteristic of a hexafluoroarsenate — AsF_6^- (O_h): ν_1 = 668 (vs), ν_2 = 596 (w), ν_5 = 385 (m) cm^{-1} — and in good agreement with the spectrum of the hexafluoroarsenate *(3)* (ν_1 = 683 (vs), ν_2 = 575 (w), ν_5 = 369 (m) cm^{-1})[3], whose structure has been confirmed by single crystal X-ray structure analysis[4]. The band ν_{Xe-F} that appears at 520 cm^{-1} in the Raman spectrum of *(1)* is absent. Consequently, the 1:1 adduct has to be formulated as the salt $[XeOTeF_5]^+$ $[AsF_6]^-$ *(2)*.

With increasing electronegativity of the second ligand in F_5TeO-substituted xenon(II) compounds, *i.e.* with increasing cationic character of the $XeOTeF_5$ group, a shift of the XeO

stretching vibration to higher wave numbers is observed [ν_{Xe-O} (cm^{-1}): $Xe(OTeF_5)_2$ 434; $FXeOTeF_5$ 457; $XeOTeF_5^+$ 477]. This tendency is already apparent to a greater extent in the transition $XeF_2 \rightarrow XeF^+$; the XeF valence force constant is about 30 % greater in the cation [3].

$Xe(OTeF_5)_2$ does not react with AsF_5, even above the melting point.

$$Xe(OTeF_5)_2 + AsF_5 \not\rightarrow [XeOTeF_5]^+ [F_5AsOTeF_5]^-$$

The fluoride donor strengths of *(1)* and XeF_2 appear to be similar. Both compounds donate F^- to AsF_5, but not the weaker acceptors BF_3 and PF_5. XeF_2, however, can displace *(1)*:

$$\underset{(2)}{} + 2\ XeF_2 \rightarrow \underset{(3)}{[Xe_2F_3]^+ [AsF_6]^-} + \underset{}{(1)}$$

The reaction is quantitative at 60 °C. Salt *(3)*, which crystallizes monoclinically, was identified from Debye-Scherrer photographs; compound *(2)*, on the other hand, is orthorhombic according to preliminary powder- and Buerger precession photographs.

Present results indicate the relative order of the fluoride donor strengths of xenon compounds to be:

$$XeF_4 \ll FXeOTeF_5 < XeF_2 < XeF_6$$ [5].

Experimental:

All reactions were followed tensimetrically in a Monel system and gravimetrically in easily weighable reaction vessels (Kel-F).

$FXeOTeF_5$ (2.319 g, 5.96 mmoles) was allowed to react with an excess of arsenic pentafluoride ($\approx$ 1400 torr) at 60 °C over a period of several hours. After pumping off the excess of AsF_5, 3.333 g of $[XeOTeF_5]^+ [AsF_6]^-$ could be isolated, yield 90 %.

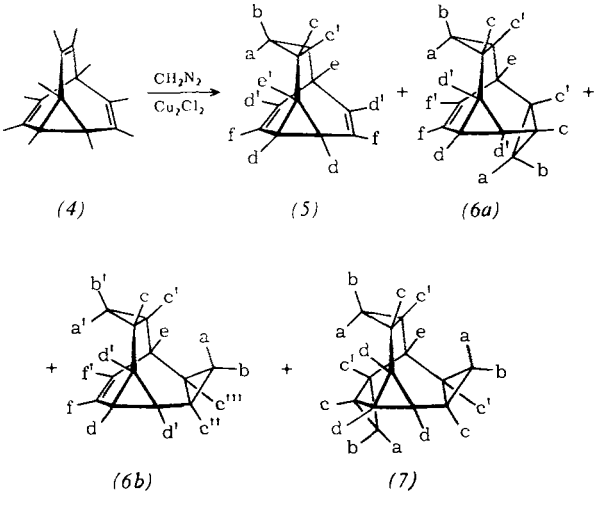
"Trishomobarrelene" and "Trishomobullvalene"

By *Armin de Meijere* and *Christian Weitemeyer* [*]

The stabilization of a carbonium ion by α-cyclopropyl groups has been verified in many cases [1]. In this connection the highly symmetric compounds "trishomobarrelene" *(3)* [2a] and "trishomobullvalene" *(7)* [2b] are of interest since they are rigid tricyclopropylmethyl ring systems [3]. Their bridgehead reactivities should, therefore, play a special role [4]. We wish to report here on the synthesis of these novel hydrocarbons [5].



"Homobarrelene" *(1)* [6] was treated with diazomethane in the presence of copper(I) chloride. The following products were isolated from the reaction mixture by preparative gas chromatography: the isomeric "bishomobarrelenes" *(2a)* (46 %) and *(2b)* (25 %), the "trishomobarrelene" *(3)* (27 %), and unreacted *(1)* (1 %).

(1) *(2a)* *(2b)* *(3)*

The analogous reaction of bullvalene *(4)* [7] with diazomethane in the presence of copper(I) chloride afforded a mixture of *(4)* (14 %), "homobullvalene" *(5)* (33 %), the two isomeric "bishomobullvalenes" *(6a)* (15 %) and *(6b)* (27 %), and "trishomobullvalene" *(7)* (10 %).

Assignment of structures was based mainly on spectroscopic findings. A distinction between *(2a)* and *(2b)* is possible by NMR spectroscopy because of the long range shielding effect of the cyclopropane rings on the olefinic protons [8]. In *(2a)* two cyclopropane rings act in this way on the olefinic protons; consequently their signal is shifted to $\tau = 4.73$ compared to $\tau = 4.06$ in the case of *(2b)* and $\tau = 3.54$ for the olefinic protons in *(1)* which are not additionally shielded [6].

(4) *(5)* *(6a)* *(6b)* *(7)*

"Homobullvalene" *(5)* [9], because of its homotropylidine system, is a molecule with fluctuating bonds; this is confirmed by the NMR spectrum. The isomers *(6a)* and *(6b)* can be distinguished in the same way as the isomers *(2a)* and *(2b)*. Compared to the barrelene system, the structure of these molecules is extended at one bridgehead and consequently the two cyclopropane rings in *(6a)* have a shielding effect on only one of the two olefinic protons ($\tau = 5.00$ for H^f and $\tau = 4.32$ for $H^{f'}$); this effect is less pronounced in the case of *(6b)* ($\tau = 4.32$—4.72 for H^f and $H^{f'}$).

The unidirectional arrangement of all three cyclopropane rings in *(3)* [9] and *(7)* [9] is suggested by an examination of molecular models. It is confirmed by the ratio of the NMR signal intensities [*(3)*: H^a:H^c:H^b = 3:6:3; *(7)*: H^a:(H^c+ H^d): H^b = 3:9:3] and also, in the case of *(3)*, by the relatively small number of absorptions in the IR spectrum, which is

consistent only with the highly symmetrical structure [point group C_{3h} for *(3)*].

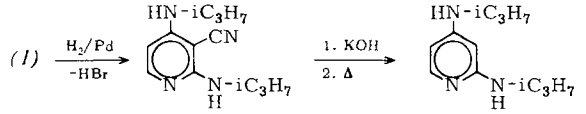
Simple Synthesis of 2,4-Diaminopyridines[1]

By *Peter Boldt*, *Wilfried Thielecke*, and *Jürgen Oberdörfer*[*]

Malononitrile can be *C-tert*-alkylated by tertiary alkyl halides in the presence of Lewis acid catalysts[2]. We have now tried to introduce secondary alkyl groups in the same way. Reaction of isopropyl bromide/aluminum chloride with malononitrile, however, did not yield the expected product but — as was shown by elemental and spectroscopic analyses — 2,4-bis(isopropylamino)-6-bromo-3-cyanopyridine *(1)*.



(5)

	R	Hal
(1)	*i*-propyl	Br
(2)	*i*-propyl	Cl
(3)	*cyclo*-C_6H_{11}	Cl
(4)	H	Br

The position of the substituents in *(1)* was established from the NMR spectra of the compounds *(6)* and *(7)*, which are accessible from *(1)* by hydrogenolytic removal of bromine (Pd-$BaSO_4$/H_2, 55 % yield) followed by hydrolysis of the nitrile group (10 %) and finally decarboxylation (100 %).

(6) *(7)*

Similarly, reaction of malononitrile/aluminum chloride with isopropyl chloride or cyclohexyl chloride affords pyridine derivatives, which, on the basis of analytical data and by analogy with *(1)*, could be assigned the structures *(2)* and *(3)*. Reaction of malononitrile with hydrogen bromide in benzene yields compound *(5)* (72%, as hydrobromide) and not *(4)*, as was assumed in earlier reports[3]: replacement of bromine by hydrogen (Pd-$BaSO_4$/H_2, 60 %) gives a product whose ring protons are, according to the NMR spectrum, *para* to each other, and which affords 2,4-diaminopyridine[4] after hydrolysis (60 %) and decarboxylation.

2,4-Bis(isopropylamino)-6-chloro-3-cyanopyridine (2)

An ice-cold solution of malononitrile (26.5 g, 0.4 mole) in nitromethane (80 ml) is treated successively with solutions of aluminum chloride (53.3 g, 0.4 mole) in nitromethane (80 ml) and isopropyl chloride (41 g, 0.52 mole) in nitromethane (20 ml), and, after 45 hours at +3 °C, with aqueous sodium bicarbonate (ice-cold). The reaction mixture is then filtered and the residue and filtrate are extracted with ether (Soxhlet in the case of the residue). Both extracts are combined, evaporated to dryness, and the resulting residue [17.5 g *(2)*, 35 % w. r. t. malononitrile] is purified by recrystallization from ethanol followed by sublimation (120 °C/12 torr); m.p. (after sublimation) 144—145 °C (corr.). [*(1)*: m.p. 161 to 161.5 °C, 20 %; *(3)*: m.p. 127—127.5 °C, 33 %].

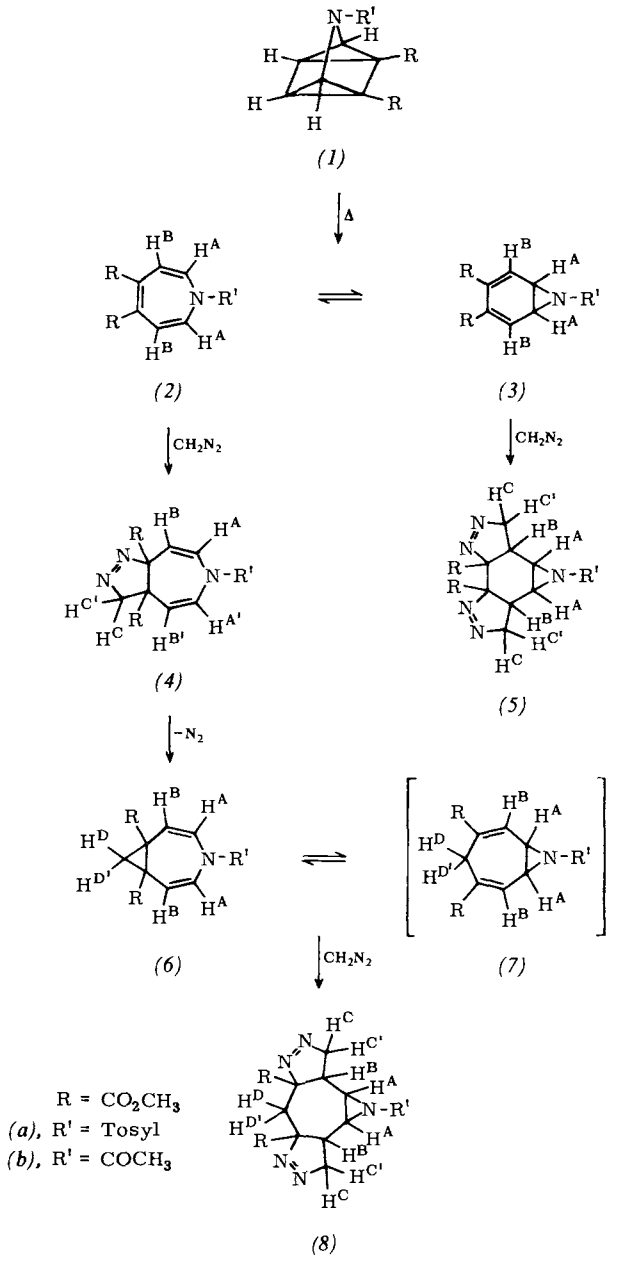
The Equilibrium "Azepine ⇌ Benzene Imine"[1][**]

By *Horst Prinzbach*, *Dieter Stusche*, and *Rainer Kitzing*[*]



Although existence of the equilibrium oxepin ⇌ benzene oxide has been confirmed on many occasions[2] by NMR measurements and adduct formation, a tautomerism azepine ⇌ benzene imine has not hitherto been established by the same criteria. Aromatization to aniline derivatives or aromatization with elimination of nitrogen have so far been the only indications of such a tautomerism[3].

We have now found evidence for the equilibrium azepine ⇌ benzene imine in that we have been able to isolate *(5a)* as a product of the reaction of *N*-tosyl-4,5-bis(methoxycarbonyl)-azepine *(2a)*[4] with diazomethane [1 g (2.8 mmoles) of *(1a)* or *(2a)*[5] and *ca.* 0.32 g (7.6 mmoles) of CH_2N_2 in CH_2Cl_2 (50 ml), 72 h, 20 °C; after concentration the pyrazoline is precipitated by addition of ether].

In our opinion, the way the diazomethane molecules are oriented in *(5a)* rules out an attack on *(2a)* and subsequent isomerization.

In addition to *(5a)* smaller yields of *(8a)* were isolated whose presence we explain as being due to competitive addition of CH_2N_2 to *(2a)* to give *(4a)* followed by loss of nitrogen to give the homoazepine *(6a)*, Cope rearrangement to give *(7a)*, and addition of CH_2N_2 to the CC double bonds, which are now activated by ester groups, to give *(8a)*.

Results in the *N*-acetyl series are in agreement with these hypotheses. Both *(1b)* and *(2b)* react with diazomethane [1 g (4.0 mmoles) of *(1b)* in ether (100 ml) and 0.64 g (15 mmoles) of CH_2N_2, 48 h, 20 °C] to give the labile monopyrazoline *(4b)*, which loses nitrogen on standing to give the homoazepine *(6b)*. At temperatures between +60 and —50 °C the NMR spectrum shows a temperature

R = CO_2CH_3
(a), R' = Tosyl
(b), R' = $COCH_3$

dependence for H^A and H^B (weak, acetyl rotation), but not for H^D. Reaction of *(6b)* with an excess of diazomethane, however, affords a bisadduct *(8b)* that is obviously derived from *(7b)*. Addition of a large excess of CH_2N_2 to *(2b)* (ratio *ca.* 4 : 1) results in direct formation of *(8b)*; *(5b)* could not be detected.

By analogy with the substitution-dependence of the equilibrium cycloheptatriene ⇌ norcaradiene[3] it can be reasoned that strongly electron attracting groups on the nitrogen favor the bicyclic form *(3)*. According to preliminary measurements, the NMR spectrum of *(2a)*, unlike that of *(2b)*, is temperature-dependent in the range +40 to −68 °C ($CDCl_3$).

The structures of the new compounds are established by elemental analyses and by UV-, IR-, and NMR spectra (see Table). The coupling constants of the methylene protons and the $n\rightarrow\pi^*$ transitions are typical of 1-pyrazolines. The *cis* configuration of the pyrazoline rings in the case of *(5a)*, *(8a)*, and *(8b)* follows from the NMR spectra; the structure of *(5a)* is further confirmed by the fact that azatrishomobenzene is formed on photolysis[6]. The coupling constant $J_{H^AH^B}$ of *ca.* 5 Hz determined for this compound by spectrum simulation[7] indicates the probability of an all-*cis* configuration of the pyrazoline and aziridine rings in *(5a)*.

Structure of Cycloheptasulfur

By *Isao Kawada* and *Erwin Hellner*[*]

We are engaged in the structural elucidation of the first sulfur ring known to contain an uneven number of atoms, *i.e.* cycloheptasulfur, which was recently prepared by *Max Schmidt et al.*[1,2].

The substance forms pale yellow needles that rapidly decompose at room temperature. It was therefore necessary to fit the Weissenberg camera with a low-temperature device[3] (cooling to −80 ± 1 °C with a stream of N_2) in order to carry out an X-ray study on a single crystal (length *ca.* 3 mm, thickness 0.2 mm). A photograph of the layers *hk*0 to *hk*5 with $Cu_{K\alpha}$ radiation afforded the following crystallographic data: a = 21.77 ± 0.04, b = 20.97 ± 0.04, c = 6.09 ± 0.01 Å; $\alpha = \beta = \gamma = 90°$; d_{exp} (20 °C) = 2.090, $d_{X\text{-ray}}$ (−80 °C) = 2.144 g cm^{-3}; Z = 16.

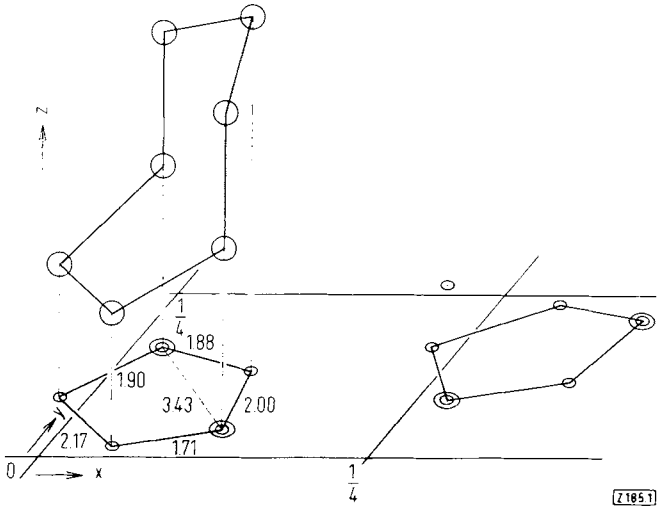

Figure. Perspective diagram of a cycloheptasulfur molecule and projection on the *xy* plane (distances given in Å).

C..a was found as extinction symbol; the space group could not, however, be determined unequivocally. The initially studied *xy* projection belongs to the planar pgg group with $a' = a/2$ and $b' = b/2$. The intensities of 137 independent *hk*0 reflections were estimated visually and the phases of the 40 strongest reflections ($E \geq 1.0$) determined unambiguously by the method of symbolic addition. A Fourier synthesis calculated with these values shows five maxima arranged in the form of a ring, two of which are doubly weighted, *i.e.* a projection of a seven-membered ring.

The x and y parameters were refined by the method of least squares. For the two double maxima we inserted twice the structure factor of sulfur. After six cycles the R factor was 20.9 % for all 137 reflections and 12.7 % for the observed reflections only.

The projection indicates a seven-membered ring in a chair configuration; in the projection on the *xy* plane two sets of atomic coordinates overlap (see Figure).

The Structure of Mercury Compounds of 2,4-Pentanediones[1]

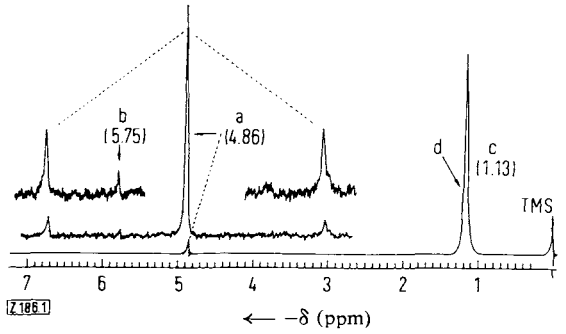
By *Karsten Flatau* and *Hans Musso*[*]

All metals so far investigated[2,3] react with 2,4-pentanedione to give soluble chelate complexes of type *(1)* in which the metal atom is equidistant from both oxygen atoms and the bonds are symmetrically delocalized. Since mercury tends to coordinate linearly with two organic ligands[4] an elucidation of the structure of Hg derivatives of 2,4-pentanedione appeared to be of interest. The chelates *(1)* show a characteristic broad long wavelength C—O band at 1580 cm^{-1} in the IR spectrum[5]. The mercury complex of 2,2,6,6-tetramethyl-3,5-heptanedione, however, exhibits a sharp C=O absorption band at 1678 cm^{-1}. *Nonhebel* has, therefore, suggested the open enolate structure *(2)* for this compound[6]. In this communication we present evidence that mercury is bonded to the central carbon atom of such β-ketones.

At room temperature the ^{1}H—NMR spectrum of the complex prepared according to the method given in ref.[6] consists of a sharp signal at −1.18 ppm (TMS, internal) for the two equivalent *tert*-butyl groups and a broad signal at −5.05 ppm for the proton on the central C atom. At −40 °C this latter signal splits into four sharper components. The most intense signal is at −4.86 ppm and is flanked by two symmetrical satellites whose intensities are about 10 % of the total, thus indicating a H—C—Hg coupling of J = 221 Hz (^{199}Hg is about 18 % abundant in natural mercury, and possesses a nuclear spin of $I = 1/2$). The weakest signal at −5.75 ppm is assigned to the olefinic protons of the

enolates *(2)* or *(3)*, which are present in about 3 % in equilibrium with *(4)*. A splitting is also visible on the downfield side of the *tert*-butyl singal (d in the Figure). On addition of 2,2,6,6-tetramethyl-3,5-heptanedione *(7)*, the intensities of the signals assigned to structure *(2)* and *(3)* increase. When mercuric chloride is added the H—C—Hg coupling vanishes and signals of the complex *(6)*, which can also be isolated, appear at −5.16 and −1.20 ppm, thus indicating the equilibrium *(4)* + $HgCl_2$ ⇌ 2 *(6)*. In the spectrum of the complex, no signals are observed in the region of the enol proton of *(7)* at −10.89 ppm.

The half-width and coalescense of the −5 ppm signal depends on the method of preparation of *(4)* and, of course, on the trace amounts of mercury salts present[7]. The best way to prepare *(4)* and *(5)* not contaminated by mercury salts is by



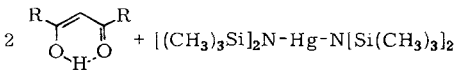


Figure. ^{1}H—NMR spectrum of bis(dipivaloylmethyl)mercury(II) *(4)* in $CDCl_3$ at −40 °C. a: HC (ketone); b: HC (enol); c: $(H_3C)_3C$ (ketone); d: $(H_3C)_3C$ (enol).

reaction of the β-diketones *(7)* and *(8)* with bis(hexamethyldisilylamido)mercury *(9)* [8,9] in dry ether. In this manner it was possible to prepare for the first time the sparingly soluble compound *(5)* in analytically pure form.

(7), R = $C(CH_3)_3$ *(9)*
(8), R = CH_3

(4) or *(5)* + 2 $HN[Si(CH_3)_3]_2$

The methods given in the literature [10,11] always lead to products which contain OH, acetate, or Cl as ligands, and which are *ca.* 3 % deficient in carbon, and exhibit several intense bands in the C=O region of the IR spectrum [12]. Since pure *(5)*, like *(4)* (in KBr), shows only one sharp C=O band at 1678 cm^{-1}, the metal in mercury(II) acetylacetonate *(5)* must also be bonded to the central C atom.

Bis(diacetylmethyl)mercury(II) (5)

A solution of acetylacetone *(8)* (12.02 g) in ether (50 ml) is added with stirring to a solution of *(9)* (3.24 g) in absolute ether (30 ml). A finely crystalline, colorless precipitate is formed immediately, yield 2.51 g (100 %). After recrystallization from acetylacetone, compound *(5)* decomposes at temperatures above 254 °C. The compound is very sparingly soluble in all common solvents.

Bis(dipivaloylmethyl)mercury(II) *(4)* has been prepared in the same way; yield 91 %, m.p. 195—197 °C (dec.). Its IR spectrum can be superimposed on that of the compound prepared from *(7)* and mercury(II) acetate according to the method given in ref. [6].

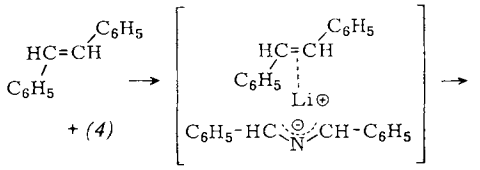
Anionic 3 + 2 Cycloaddition [1] [**]

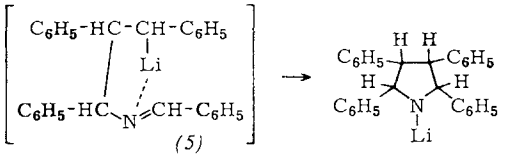
By *Thomas Kauffmann*, *Heike Berg*, and *Edgar Köppelmann* [*]

According to the principles of conservation of orbital symmetry the ionic one-stage $[_\pi4 + _\pi2]$ cycloadditions (A)—(C) are allowed [3]. Although there are examples for the two cationic types [3], no reaction is apparently yet described for anionic $[_\pi4 + _\pi2]$-cycloaddition (C) in accord with this principle [4].

We started from the consideration that cycloaddition of the general type (C) should be favored energetically and be accompanied by fewer undesired secondary reactions if an amide anion *(2)* were formed in place of a carbanion *(1)*, and we therefore treated the 2-azaallyllithium compounds *(3)* and *(4)* in tetrahydrofuran/ether (10 : 1) with unsaturated hydrocarbons that should be readily susceptible to nucleophilic attack. We obtained the azaallyl compounds by the action of one molar equivalent of lithium diisopropylamide in the same solvent mixture on, respectively, *N*-(diphenylmethylene)-methylamine and *N*-benzylidenebenzylamine at −60 °C (cf. [2]).

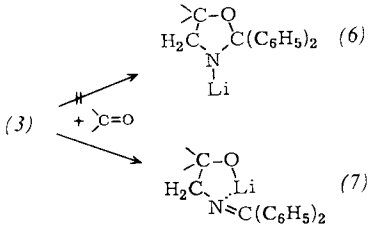


(3) *(4)*



Li cpd.	Alkene or alkyne	Temp. (°C)	Product	Yield (%) [a]	M.p. (°C)
(3)	Styrene	20 [b]	2,2,3-Triphenylpyrrolidine	85	86—87
(3)	Tolan	20 [b]	2,2,3,4-Tetraphenylpyrroline	43	138—139
(4)	Styrene	0	2,3,5-Triphenylpyrrolidine	75	68
(4)	*trans*-Stilbene	0	2,3,4,5-Tetraphenylpyrrolidine	39	110—111
(4)	Tolan	40 [c]	2,3,4,5-Tetraphenylpyrrole	73	215—217[d]

[a] Yields not optimized.
[b] The alkene or alkyne was added to a solution of the lithium compounds at −60 °C and the mixture was then warmed to +20 °C.
[c] No reaction at 0 °C.
[d] *G. Magnanini* and *A. Angeli*, Ber. dtsch. chem. Ges. *22*, 855 (1889), give m.p. 214.5 °C.



As shown in the Table, hydrolysis of the reaction mixtures usually gives the expected cycloaddition products. The 2,3,4,5-tetraphenylpyrrole produced is, however, a dehydrogenated cycloaddition product. The products isolated appear homogeneous on thin-layer chromatography and NMR spectroscopy, and their structures follow from analyses, molecular-weight determinations, NMR and mass spectra, and from the mode of preparation.

In these reactions the unsaturated hydrocarbon presumably forms a π-bond to the lithium ion. The question whether the subsequent 3 + 2 cycloaddition (*Huisgen*'s nomenclature[5]) occurs in one stage or in two stages [by way of an intermediate of type *(5)*] is under present study.

As expected, the electronegativity of the atoms participating in the multiple bonding plays a significant part in the course of addition of 2-azaallyllithium compounds. Thus reaction of *(3)* with carbonyl double bonds leads to open-chain compounds of type *(7)* and not to oxazole derivatives of type *(6)*.

Aziridine Imines[**]

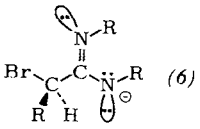
By *Helmut Quast* and *Edeltraud Schmitt*[*]

Although aziridones (α-lactams)[1] have already been known for some years, attempts to prepare aziridine imines have so far failed[2]. In connection with our investigations on the valence isomerization of heteromethylenecyclopropanes[3] we report here on a stereoselective synthesis of such compounds.

By treating the α-bromoamidines *(1)* and *(2)* (which can be prepared in the usual way from the corresponding *N*-methylamide) with potassium *tert*-butoxide in ether we were able to obtain compounds in 70—80% yield which, according to elemental analyses, molecular weight determinations (osmometric in benzene), mass spectra, and IR spectra [extremely high C=N frequency (see Table 2) and absence of NH bands], have an aziridine imine structure.

At low temperatures the 1,3 elimination of α-bromoamidines proceeds with both *high regio- and high stereo-selectivity;* at −40 °C, compound *(2)* yields predominantly *(4)* [(4) : (5) = 86 : 14], while at room temperature a mixture of about equal amounts of *(4)* and *(5)* is obtained. IR and NMR spectra permit unequivocal assignment of structure (see Table 2).

(3), b.p. <15 °C/0.001 torr *(5)*, m.p. −3 to −2.5 °C
(4), m.p. 19–20 °C (pentane) (pentane)



At −40 °C, both *(1)* and *(2)* yield almost exclusively the *trans* isomers (stereoselectivity > 90%), which are in equilibrium with their thermodynamically more stable *cis* isomers at room temperature.

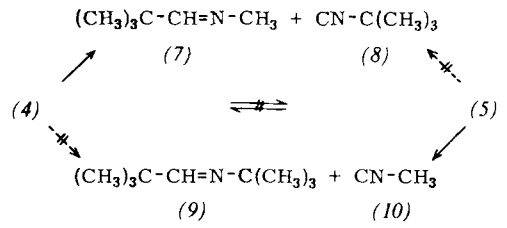
In order to distinguish between inversion of the ring nitrogen[4] and *syn-anti* isomerization of the imino group, the rate of this isomerization was followed by NMR spectroscopy. The data given in Table 1 are only consistent with a slow *syn-anti* isomerization of the imino group.

Table 1. Equilibrium and rate constants of the *syn-anti* isomerization of *(3)* and *(4)* at 36 ± 1 °C.

Starting compound	$K = k_t/k_c$ (±0.05)	$10^5 \times (k_t + k_c)$ (s^{-1})	$\Delta G^{\neq}$ (kcal/mole)
trans-(3)	2.33	5.95 ± 0.02	23.3
trans-(4)	4.49	138.0 ± 0.6	21.4

The configuration of *trans-(3)* and *trans-(4)* is proved by the observed coupling of the H on C-3 with the methyl group on the imino nitrogen[5]; *cis-(3)*, *(4)*, and *cis-(5)* show only singlets. The NMR spectra in benzene support the assignment of configuration: as expected, the upfield shift of the signals for all *cis* protons was larger than for those *trans* to the alkyl groups on the imino nitrogen[5].

(6)



The kinetically preferred formation of *trans*-aziridine imines in the intramolecular S_N reaction *via* a semi W-like transition state[6] can be explained by the greater stability of the configuration *(6)* of the intermediate amidine anion, in which mutual repulsion of the lone pairs is at its lowest[7].

Table 2. IR and NMR data of the aziridine imines.

Cpd.	IR, νC=N (cm^{-1})	NMR, δ (ppm) in CCl_4			
		C-3-*t*-Bu	C-3-H	N-1-R	=N—R

[a] Broad signal.
[b] Measured in the absence of solvent.

Compound *(4)* starts to decompose at 50 °C [→*(7)* + *(8)*, halflife about 17 h at 60 °C]; *(5)*, on the other hand, only decomposes above 120 °C [→*(9)* + *(10)*] to afford isocyanide and imine in quantitative yield (cf.[1–3]). This decomposition serves as independent proof of the structure of *(4)* and *(5)* and permits a simple preparation of pure *(5)* by fractional thermolysis of a mixture of *(4)* and *(5)* at 100 °C.

We have not yet been able to detect a valence isomerization *(4)*⇌*(5)* either directly or indirectly (by identification of isomeric thermolysis products).

CONFERENCE REPORTS

Problems of Modern Silicone Chemistry

By *Walter Noll*[*]

The diversity of this subject, particularly as regards industrial aspects, is illustrated by three selected topics.

1. *Synthesis of silanes*

Little use has been made of the many recommendations based on laboratory work in the technical development of the direct synthesis of methylchlorosilanes (use of η-phase Cu_3Si; other metallic catalysts in place of, or in addition to, copper; pretreatment of the silicon; *etc.*). The process has reached a high level of development owing to process-engineering measures and particularly to the use of fluidized beds. Apart from the usual addition reactions of the Si—H bond, substitution reactions of bromomethylsilanes (or siloxanes) have proved useful for the production of organo-functional silanes. Bromo-(sometimes also chloro-)methylsilanes have assumed a key role in the preparation of amino-, hydroxy-, mercapto-, or carboxy-substituted derivatives; they also permit ring-closure reactions (silamorpholine).

2. *Chain polymers*

Recent publications have paid detailed attention to mechanisms of "self crosslinking" of silicone rubber. Chain polymeric polydimethylsiloxanes having terminal OH groups are made into pastes with crosslinking agents of the type CH_3SiX_3, fillers, and other additives; these pastes may be stored unchanged in the absence of moisture. When exposed to the air, they react with the water vapor present to give crosslinked soft-elastic materials. Crosslinking agents having X = carboxy, amino, *N*-alkylacylamide, or ketoxime are of industrial interest. The products are used as sealants in the building industry.

The properties of polydimethylsiloxanes are modified considerably by anionic copolymerization with diphenylsiloxanes to give regular polymers of high crystallinity. Introduction of amino or hydroxymethyl groups or co-condensation with polyethers increases the hydrophilic character of the molecules; in both cases interesting surface activity results from the increase in polarity of the molecules.

3. *Surface chemistry*

This generally plays an important role in the uses of silicones. Force/area isotherms of monomolecular siloxane films, which were registered on a continuously operating, automatically recording film balance, show variations depending upon the nature of the substituents. The molecules of those siloxanes that are of industrial interest because of their surface activity lose their coil or helical form and are converted into "spreading chains" that are bonded to the water *via* their Si—O—Si bonds and can be converted into a two-dimensional close packing on compression (*e.g.* dimethyl-, methyl-*H*-, methyl-γ-trifluoropropylsiloxanes). Under such conditions, dimethylsiloxanes form surface layers in which only hydrocarbon groups are directed toward the gas phase. An increase in the size of the aliphatic groups, introduction of diphenylsiloxane

units, or presence of other bulky substituents results in loss of this orientation capacity; moreover, such siloxanes spread considerably more slowly than those mentioned above. Siloxanes bearing hydrophilic groups, *e.g.* hydroxymethyl or aminomethyl substituents, exhibit a capacity for orientation and a particularly high affinity for water. They are excellent agents for forming extremely thin, water-repellent, detergent-resistant, brilliant films on solid surfaces to which they are held by an adsorbed layer of water.

Chemistry of the Lanthanides in Liquid Ammonia

By *James C. Warf*[*]

Europium and ytterbium in liquid ammonia: Europium and ytterbium, *i.e.* the two lanthanides that most readily form doubly charged cations, dissolve in liquid ammonia to give deep blue solutions[1]. The enthalpy of the reaction

$$Eu_{(s)} \rightarrow (Eu^{2+})_{NH_3} + (2e)_{NH_3}$$

is found (Born-Haber cycle) to be approximately −26 kcal/mole: the change in free energy is −7 kcal/mole (240 °K). Europium is the only metal that dissolves in ammonia to give paramagnetic cations. Samarium is insoluble, as is also americium. Element 101, mendelevium, which readily forms Md^{2+} ions in aqueous solution, may also be soluble in liquid ammonia.

Magnetic properties of the hexammine compounds: The five compounds $Ca(NH_3)_6$, $Sr(NH_3)_6$, $Ba(NH_3)_6$, $Eu(NH_3)_6$, and $Yb(NH_3)_6$ form golden crystals that are excellent electronic conductors. $Eu(NH_3)_6$ fulfills all the prerequisites of ferromagnetic behavior. *Sienko et al.*[2] have found that it follows the Curie-Weiss law down to 47 °K. At this temperature the compound becomes ferromagnetic. Solid solutions of $Eu(NH_3)_6$ in diamagnetic $Yb(NH_3)_6$ or $Sr(NH_3)_6$ exhibit the same behavior and almost the same Weiss constant; thus the ferromagnetic behavior is not affected by the increase in the Eu—Eu distances. In $Eu_{0.085}\ Yb_{0.915}\ (NH_3)_6$, the Eu—Eu distance is 18.8 Å; nevertheless, coupling of the magnetic moments does occur, doubtless *via* the conductivity electrons.

Reactions of europium and ytterbium in liquid ammonia: Reaction with phosphine yields $Eu(PH_2)_2$ and $Yb(PH_2)_2$[3]. Benzene is reduced to cyclohexadiene and cyclohexene[4]. As expected, $Eu(C_5H_5)_2$ is obtained with cyclopentadiene in liquid ammonia. In contrast, ytterbium gives not only $Yb(C_5H_5)_2$ but also $Yb(C_5H_5)_3$ and the sublimable compound $Yb_2(C_5H_5)_3(NH_2)_2$ whose structure is unknown[5].

Amides of europium and ytterbium: Solutions of europium in liquid ammonia decompose to $Eu(NH_2)_2$[6] at 50 °C; on the other hand, ytterbium, whose ammonia solution is considerably less stable, gives a mixture of $Yb(NH_2)_2$ (≈ 30 %) and $Yb(NH_2)_3$ (≈ 70 %), as shown by IR spectra and magnetic measurements[7].

Formation of electrons solvated with ammonia: A remarkable reaction was observed during attempts to prepare $Yb(NH_2)_2$ from YbI_2 and KNH_2 in liquid NH_3[8]: The solution turns deep blue and a white precipitate appears. The spectrum of the solution is identical with that of a solution of electrons solvated with NH_3 (at 24 °C asymmetric curve, maximum at 5400 cm^{-1}) prepared by a different method. The reaction thus proceeds according to

$$(Yb^{2+})_{NH_3} + 3\ NH_2^- \xrightarrow[NH_3]{\text{liquid}} Yb(NH_2)_3 + (e^-)_{NH_3}$$

Yb^{2+} in liquid ammonia is therefore a stronger reducing agent than potassium. In fact, elemental potassium is found in the residue left on evaporation of the ammonia. The reductive power is further increased by the extreme insolubility of $Yb(NH_2)_3$ in liquid ammonia. The same reaction occurs with the iodides of Eu(II) and Sm(II). Within certain limits, $ZrBr_3$ behaves similarly to Eu^{II}, Yb^{II}, and Sm^{II}[9].

Recent experiments have shown that the equilibrium

$$Yb(NH_2)_2 + NH_2^- \underset{NH_3}{\overset{\text{liquid}}{\rightleftharpoons}} Yb(NH_2)_3 + (e^-)_{NH_3}$$

is shifted far to the right-hand side.

Configurational and Conformational Selectivity in Catalytic Oxidations on Platinum Catalysts

By *Kurt Heyns*[*]

The selective oxidations of polyhydroxy compounds, and of mono- and oligosaccharides in particular, with atmospheric oxygen on a platinum catalyst in solution — with conversion of primary hydroxyl groups into formyl and carboxy groups — have led to an efficient method for the preparation of uronic acids, aminouronic acids, uronosides, aldonic acids, and intermediates used in the synthesis of ascorbic acid. Further investigations on cyclitols of the inositol and conduritol type have shown that only secondary hydroxyl groups in axial positions are selectively dehydrogenated to keto groups. In the case of the 1H and H1 conformations of the half-chair structures of the six-membered ring the selectivity of dehydrogenation was found to decrease in the order: quasiaxial OH > quasiequatorial OH with vic. axial OH > quasiequatorial OH with vic. equatorial OH > axial OH > equatorial OH. These findings were successfully utilized in the preparation of keto sugars from the pyranosides of pentoses and hexoses.

Other substitution rules were obtained for the catalytic oxidation of secondary hydroxyl groups attached to cyclobutane, cyclopentane, cyclohexane, and tetrahydrofuran rings; different reaction rates could be ascribed to preferred conformations in which no eclipsing of neighboring ring members occurs. Specific selective dehydrogenations, *e.g.*, of the preferred *cis*-1,4-(a,e)-, *trans*-1,3-(a,e)-, and *cis*-1,2-(a,e)-conformations were possible in the case of the *cis*- and *trans*-1,2-, -1,3-, and -1,4-cyclohexanediols.

A similar series of decreasing rates could be established for the bicyclic [3.3.0], [3.2.1], and [2.2.1] ring systems. *Endo*

groups prove to be much more susceptible to dehydrogenation than do *exo* substituents. In the norbornanols the order is *endo* OH > *exo* OH > 7-OH. An *endo* OH in the presence of vicinal *exo* OH is dehydrogenated at a considerably slower rate than other *endo* groups. Furthermore, in the[2.2.1] system *exo* groups are dehydrogenated much faster in the presence of a 7-*syn* OH group than in the presence of a 7-*anti* OH group. The behavior of the isomeric bicyclo[2.2.2]-octane-2,6,7-triols illustrates unequivocally that intramolecular hydrogen bonds considerably increase the rate of catalytic oxidation.

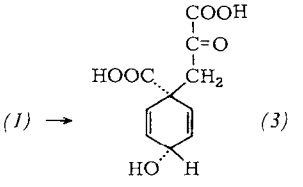
Biosynthesis of Vitamins; Allosteric Enzymes – Recent Results

By *Franz Lingens*[*]



Studies of vitamin biosynthesis in microorganisms employ deficiency mutants having genetic blocks in their biosynthetic pathways. *N*-Methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) has proved a particularly effective mutagen for the production of such mutants. Treatment of DNA with *N*-trideuteriomethyl-*N'*-nitro-*N*-nitrosoguanidine at pH 6 yields 7-trideuteriomethylguanine, thus ruling out exchange of deuteron with solvent proton and hence the intermediacy of diazomethane in the methylation.

Action of MNNG on a polyauxotrophic mutant of *Aerobacter aerogenes*, which produces large amounts of chorismic acid *(1)*, yielded a *p*-aminobenzoic acid$^-$-mutant. This latter mutant releases a nitrogen-containing intermediate into the medium which is readily converted by acids into *p*-aminobenzoic acid. Structure *(2)* (3-enolpyruvic acid ether of 2,3-dihydro-*p*-aminobenzoic acid) has been proposed for the intermediate. Chorismic acid *(1)* can be converted into *(2)* in the presence of glutamine by an enzyme extract from the mutant.

(1) *(2)*

Allosteric enzymes of the multiple-branched aromatic amino acid biosynthetic pathway have been enriched from the yeast *Saccharomyces cerevisiae* and from the fungus *Claviceps paspali*. Chorismate mutase from *C. paspali*, which converts *(1)* into prephenic acid *(3)*, is inhibited by phenylalanine and tyrosine, and is activated by tryptophan. This activation effect can be exploited for affinity chromatography of the enzyme. Sepharose was activated with cyanogen bromide and treated with tryptophan to give a carrier that absorbs chorismate mutase. The enzyme is eluted with tryptophan.

(1) → *(3)*

Activation of chorismate mutase with typtophan can be used as a sensitive analytical tool for the determination of this amino acid. It must, however, be borne in mind that tryptophan homologs and analogs also display an activating effect.

Lecture at Wuppertal on March 11, 1970 [VB 236 IE]

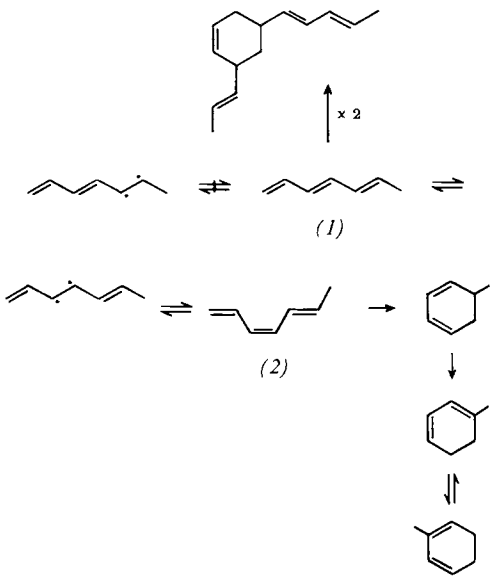
SELECTED ABSTRACTS

The reactions of atomic and molecular halogens with silver have been compared by *R. J. McIntyre* and *F. K. McTaggart*. Atomic chlorine, bromine, and iodine were produced in a flow system by an electric discharge; the walls of the apparatus were prepared with phosphoric acid to minimize early recombination of the halogen atoms. The rate of growth of silver halide film was followed by means of an interference method. The halide film was found to inhibit further attack of molecular halogens, whereas film thickness has no influence on the reaction rate with atomic halogens. Low activation energies (around 5 kcal mole^{-1}) and high reaction probabilities (0.73 for I, 0.52 for Br, 0.25 for Cl) were found for the halogen atom reactions. / J. physic. Chem. *74*, 866 (1970)/ —Hz. [Rd 164 IE]

The molecular structure of an "isothiathiophthene" *(1)* has been established X-ray crystallographically by *R. J. S. Beer* and *D. Frew*. The data support formulation of *(1)* as α-(4-*p*-bromophenyl-1,3-dithiol-2-ylidene)thioacetophenone rather than as a bicyclic system analogous to the thiathiophthene *(2)*. This is surprising since a number of isothiathiophthenes and thiathiophthenes resemble each other chemically and spectroscopically.

(1), m.p. 200–203 °C, crystallizes as purple triclinic needles, $a = 17.775$, $b = 7.190$, $c = 6.474$ Å, $\alpha = 90°55'$, $\beta = 110°1'$,

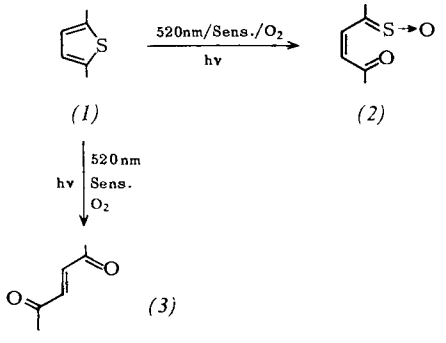


(1) *(2)*

$\gamma = 89°6'$, space group $P\bar{1}$. The exocyclic S—S distance is 2.91 Å. In the thiathiophthenes *(2)* the first and third of the almost linearly arranged S atoms are *ca.* 4.7 Å apart. / Chem. Commun. *1970*, 154 / —Kr. [Rd 173 IE]

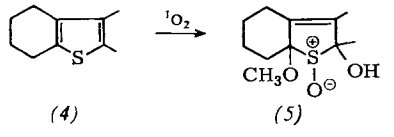
Neutron energy-loss spectrometry is used by *M. F. Collins*, *B. C. Haywood*, and *G. C. Stirling* for a study of the vibrational frequencies of hydrogen bonds. The instrument described allows the detection of resonances in the 400 to 1400 cm^{-1} range. Because of the mass similarity, the technique preferentially observes hydrogen motions, thus providing an advantage over IR and Raman spectroscopy. Coincidence of results with those of optical spectroscopy is demonstrated for KHF_2, $CsHCl_2$, and $CsDCl_2$. For $NaHCO_3$ and the acid potassium trifluoro- and trichloroacetates, the hitherto unknown bending modes of the hydrogen bridges are identified. / J. chem. Physics *52*, 1828 (1970). / —Hz. [Rd 170 IE]

The gas phase isomerization of 1,*trans*-3,*trans*-5-heptatriene *(1)* was followed by *K. W. Egger* and *T. L. James* at 247 to 332 °C and 1.6—22 torr with product analysis by gas chromatography. The primary product is 1,*cis*-3,*trans*-5-heptatriene *(2)*, which undergoes fast cyclization to 5-methyl-1,3-cyclohexadiene and further isomerization to 1- and 3-methyl-1,3-cyclohexadienes. The reaction is clean under the conditions used, only the Diels-Alder reaction contributing measurably to the overall conversion at lower temperatures and



(1)

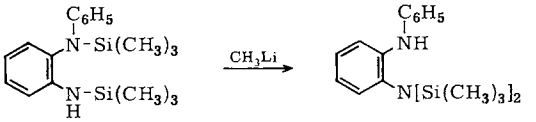
(2)



higher pressures. The observed rate parameters agree with those expected for a 3,4-biradical transition state, with the planes of the two radical ends perpendicular to each other. The isomerization about the 5,6-bond does not contribute to the reaction. / Trans. Faraday Soc. *66*, 410 (1970) / —Hz.

[Rd 168 IE]

The reaction of singlet oxygen with thiophenes has been studied by *C. N. Skold* and *R. H. Schlessinger* and by *H. H. Wasserman* and *W. Strehlow*. The first named authors irradiated 2,5-dimethylthiophene *(1)* in $CHCl_3$ and in CH_3OH in presence of methylene blue. The sulfine *(2)* and the diketone *(3)* were formed, obviously *via* different routes. Under similar conditions *Wasserman et al.* obtained the thiophene oxide *(5)*

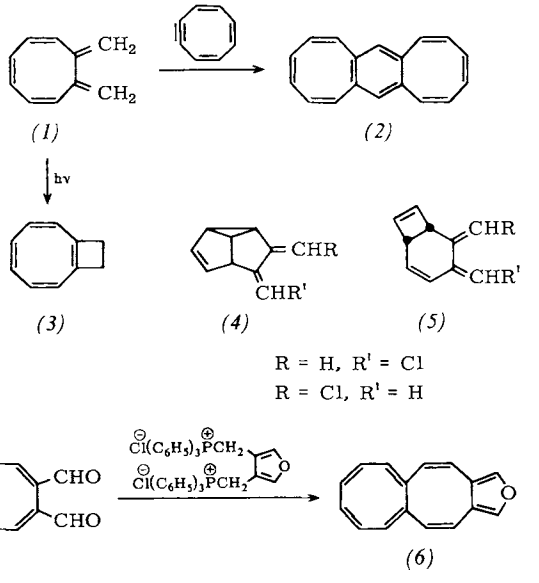


(1) *(2)* *(3)*

(4) *(5)*

from a solution of 2,3-dimethyl-4,5,6,7-tetrahydrobenzo[*b*]-thiophene *(4)* in CH_3OH with participation of the solvent. / Tetrahedron Letters *1970*, 791, 795 / —Kr. [Rd 174 IE]

New rearrangements of bis(organosilyl)-*o*-phenylenediamines have been described by *H. F. Stewart*, *D. G. Koepsell*, and *R. West*. In the presence of methyllithium, compounds such as *(1)* undergo anionic rearrangement in ether at room temperature to give *(2)*. Rearrangement appears to be intramolecular and to proceed *via* a planar transition state. Equilibrium is set up between compounds of type *(2)* and *(1)* as a



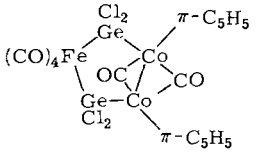
(1) *(2)*

result of the novel thermal intermolecular rearrangement occurring at 275 °C. / J. Amer. chem. Soc. *92*, 846 (1970) / —Kr.

[Rd 179 IE]

7,8-Dimethylene-1,3,5-cyclooctatriene *(1)* is, according to *J. A. Elix*, *M. V. Sargent*, and *F. Sondheimer*, a key substance for the synthesis of a great variety of novel polycyclic compounds. Compound *(1)*, which the authors obtained from 1,3,5,7-cyclooctatetraene-1,2-dimethanol *via* the dibromide, undergoes Diels-Alder reaction of its exocyclic double bonds. With dehydrocyclooctatetraene generated *in situ* it affords the pale yellow dicycloocta[*a*,*d*]benzene *(2)*, m.p. 179—181 °C, which is nonplanar and therefore unrelated to [18]annulene.

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

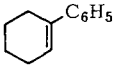


On UV irradiation, compound *(1)* is converted into dihydrocyclobutaoctene *(3)*, while in the reaction of α-chloro-*(1)* to give *(4)* and *(5)* the exocyclic double bonds are retained. The authors also obtained octalenofuran *(6)* by reaction of the dicarbaldehyde with a phosphonium salt of furan. The eight-membered rings in *(6)* have a tub-like configuration. / J. Amer. chem. Soc. *92*, 962, 969, 973 (1970) / —Kr.

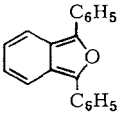
[Rd 180 IE]

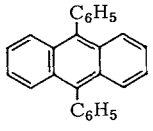
A novel five-membered metal-metal heterocycle *(2)* has been synthesized by *M. J. Bennett*, *W. Brooks*, *M. Elder*, *W. A. G. Graham*, *D. Hall*, and *R. Kummer*. The Ge-Co compound *(1)* was heated with $Fe(CO)_5$ under nitrogen for 2 h without solvent in a bath at 110 °C. On extraction of the residue with CH_2Cl_2, dark green crystals were obtained (yield 40 %) which were stable for many months to light and air; $[Cl_2GeFe(CO)_4]_2$ remains in solution. The spectroscopic data are consistent only with a cyclic structure; this has been confirmed by a

π-$C_5H_5(CO)Co(GeCl_3)_2 + Fe(CO)_5 \longrightarrow$



(1)





(2)

single-crystal X-ray structure determination. *(2)* crystallizes in the orthorhombic space group $P2_12_12_1$; the five-membered metal ring is almost planar. / J. Amer. chem. Soc. *92*, 208 (1970) / —Kr. [Rd 177 IE]

Oxygenation of organic molecules in the solid state by singlet oxygen produced in a microwave discharge has been accomplished on a preparative scale by *J. R. Scheffer* and *M. D. Ouchi*. The apparatus was based on that used by *Ogryzlo*[1]. The substrate was adsorbed on microcrystalline cellulose or silica gel and treated with the singlet oxygen at about 5 torr and room temperature in the dark. Examples: *(1)*→*(2)*, 33% yield; *(3)*→*(4)*, 91%; *(5)*→*(6)*, 79%. / Tetrahedron Letters *1970*, 223 / —Kr. [Rd 184 IE]

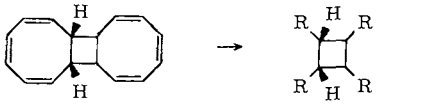
(3)  *(4)*



(5)  *(6)*

[1] *E. A. Ogryzlo*, Proc. New York Acad. Sci., in press.

The unknown *anti*-3+2 dimer of cyclooctatetraene *(3)* has been prepared by *A. G. Anastassiou* and *R. M. Lazarus*. Sensitized irradiation of 9-cyano-9-azabicyclo[4.2.1]nona-2,4,7-triene *(1)* in benzene in the presence of benzophenone at room temperature afforded the dimer *(2)*, m.p. 220—221 °C yield 70%. Treatment of *(2)* with hot methanolic KOH gave the diamine (65%) which was converted into a bis(nitroso) derivative (100%) by $NaNO_2$/dilute mineral acid. Reaction of this derivative with warm alkaline $Na_2S_2O_4$ was accompanied by evolution of N_2 and gave the dimer *(3)*, m.p. 98—99 °C. Ozonization of *(3)* followed by oxidative work-up and methylation with CH_2N_2 led to *(4)*. / Chem. Commun. *1970*, 373 / —Ma. [Rd 186 IE]

(1) *(2)*

(3) *(4)*, R = CO_2CH_3

Metallic berkelium, element 97, has been prepared by *J. R. Peterson*, *J. A. Fahey*, and *R. Baybarz* [a] and independently by *D. K. Fujita* [b]. 8—10 μg of berkelium(III) fluoride was reduced with lithium vapor at 10^{-6}—10^{-7} torr and 1025 to 1050 °C in a micro tungsten spiral which served as a crucible. The resulting metal was recrystallized by annealing for several minutes at 900 °C. Metallic berkelium is silver-white and malleable. It exists predominantly in a face-centered cubic modification with the lattice constant $a = 4.987 \pm 0.001$ Å [b] or 4.99 ± 0.01 Å [a] but there also appears to be a hexagonal modification having $a = 3.41 \pm 0.01$ Å and $c = 11.05 \pm 0.01$ Å [a]. The melting point of Bk is approx. 1000 °C. The atomic radius is calculated from the lattice constants to be 1.76 Å in the cubic phase and 1.74 Å in the hexagonal phase [b]. Susceptibility measurements by *Fujita* [b] yielded a magnetic moment of $\mu_{eff} = 8.23\ \mu_B$ for the cubic modification and $\mu_{eff} = 8.52\ \mu_B$ for the hexagonal modification. The cubic modification becomes ferromagnetic below 140 ± 15 K, and the hexagonal modification antiferromagnetic below 35 ± 3 K. The magnetic data indicate that more than three electrons per atom are in the bonding orbitals and that the metal valence is about 3.4. / [a] Oak Ridge National Laboratory Chemistry Division Progress Report for Period Ending May 20, 1969, ORNL-4437 (Sept. 1969); [b] Dissertation, Berkeley 1969, UCRL-19507 (Nov. 1969) / —FW. [Rd 187 IE]

BOOK REVIEWS

Lehrprogramm Chemie. (Programmed Learning: Chemistry.) By *J. Nentwig*, *K. Kreuder*, and *K. Morgenstern*. Verlag Chemie, Weinheim/Bergstr. 1969, Vol. 1, 29 Programs with 32 Ill., 1st Edit., xiii, 675 pp., paperback, DM 22.—.

In this book of programs the team of authors makes use of the experience they have themselves gained in training chemical laboratory assistants at Farbenfabriken Bayer. The material to be taught is divided into small "easily digestible bits" and is skilfully so arranged that the pupil reaches his objective in the optimal manner, which is an aim not achieved through a "search-and-find" book or through a formal lecture. "Programmed Learning: Chemistry" is characterized by its use of both the linear and the branched programming technique. In the linear method the pupil must formulate the answers himself; the questions are usually easy and the pupil sees at once from the next step whether he has answered correctly or not. Since his answer will usually be correct his success stimulates pleasure in active work; his confidence is strengthened and he is positively motivated for further problems. The disadvantage of the linear method is that when he gives the wrong answer the pupil does not learn why he went wrong. This and other didactic considerations induced the authors to build branches into the program. At each step in a branched program the student is faced with a large amount of information, but of a type that passes into associative memory; this material ends with a question for

which various, mutually exclusive answers are offered; if the pupil chooses the correct answer he is at once led further through the program as fast as his knowledge and intelligence allow; if he chooses the wrong answer he is led to an exposition especially designed to correct the error; and individual correction is thus achieved.

The first volume of "Programmed Learning: Chemistry" deals almost exclusively with the chemistry of materials. The contents are arranged according to the well tested principle of "from easy to difficult". An introductory program explains changes of phase as physical processes and changes of material as chemical processes; the differences between mixtures and chemical compounds are set out clearly. Then follow one chapter each on "Air", "Water", and "Hydrogen": they include descriptions of experiments that are already familiar to the laboratory assistants for whose use this book is primarily intended.

Among the programs dealing with materials are scattered six further program son "Theoretical Principles" such as the concept of an atom, valency, Avogadro's hypothesis, and quantitative analysis; the advantages of this procedure are obvious. Two programs on organic chemistry, on a purely practical basis, complete the volume.

The range of each program is restricted so that in general it can be worked through at one sitting without undue strain on the pupil.

Programs for chemistry are a rarity; indeed the 1968 bibliography, compiled by *J. Lorenz*, of programmed learning in German does not contain a single one. So the authors may be forgiven for occasionally faltering in their programming technique and for steps that, in the reviewer's opinion, are not of much use. Isolated steps such as the definition of a catalyst, and steps with too many gaps in the question or with implausible or trivial alternative answers at branch points should be avoided as far as possible.

The arrangement as a "scrambled textbook" explains the astonishingly low price but it also leads to diversions during the continuous cross-referencing; in a new edition it would be desirable to use a printing technique that leads to sharper separation of the individual programs since it is only too easy to turn to the wrong program during the forward- and back-referring.

In spite of these criticisms this book of programmed learning can be recommended for all those who want to build up a basic knowledge of chemistry quickly and effectively.

There is a companion volume to the programs, designed for the instructor, that explains in detail the connections between the various programs, isolating the main route and all the branches.

Siegfried Nöding [NB 871 IE]

The Thermal Properties of Transition Metal Ammine Complexes. By *W. W. Wendlandt* and *J. P. Smith*. Elsevier Publishing Company, Amsterdam-London-New York 1967, 1st Edit., x + 235 pp., numerous figures, bound, Dfl. 47.50.

This book deals with the results of the thermal decomposition of ammine complexes of the transition metals and also of gallium, indium, and thallium. It is principally concerned with kinetic methods.

First of all, the problem of thermodynamic stability is explained with some specific examples. This is followed by a comprehensive survey of kinetic breakdown techniques such as thermogravimetry, differential thermal analysis, mass spectrometry, thermomagnetic methods, and high-temperature reflectance spectroscopy, and of their applications. In a special section a systematic treatment is given of the thermal properties of the individual ammine complexes, taking full account of recent literature. Complexes with organic amines, and also aquo- and acido-ammine complexes are considered.

Only the results of the kinetic methods are given in detail, these methods having the advantage of being less time-consuming than the static methods (isothermal or isobaric tensiometric decomposition). They relate principally to differences in the rates of decomposition of the phases under consideration. This involves crystal formation, particle size, nucleation, growth, and diffusion processes. A very critical evaluation of the degradation curves is thus required, particularly where the number and the thermodynamic stability of the intermediates are concerned. The authors emphasize that one should never be satisfied with a single method. An X-ray study of the solids is absolutely indispensable, and yet it is performed all too rarely.

The value of this book lies predominantly in the following points: 1. All available kinetic methods and their uses are dealt with. 2. Comprehensive factual material is provided. 3. The book reveals the existing gaps in our knowledge which require further experimental treatment. We can also see that the theoretical treatment of the stability problem is still very much in arrears. For example, it is still not generally possible to say on theoretical grounds where the stability of ammine complexes will increase in the order chloride, bromide, iodine, and in which cases it will decrease. There are also still a number of gaps in the X-ray determination of the crystal structures of ammine complexes. Thus in many cases the proposed structures are still uncertain, and this is also true for the structural formulas given on pp. 170 and 172 for the adducts of *o*- and *p*-phenylenediamine with Cd salts. From the stereochemical viewpoint, these formulas are unsatisfactory.

The chemist working in the field of coordination chemistry will find this very clearly written book to be stimulating reading; its publication is therefore greatly welcomed.

Otto Schmitz-DuMont [NB 866 IE]

Comprehensive Chemical Kinetics. Edited by *C. H. Bamford* and *C. F. H. Tipper*. Vol. 1: The Practice of Kinetics. Elsevier Publishing Company, Amsterdam-London-New York 1969. 1st Edit., 450 pp., numerous figures, Dfl. 95

This is the first in a planned series of 25 volumes. It should be said at the outset that the authors have succeeded in collating and presenting in a thoroughly accessible form the widely scattered literature on the subject. This achievement is particularly welcome in the light of the explosive development in experimental techniques in certain branches of kinetics.

The chapters devoted to the experimental methods used in the study of slow (*L. Batt*), fast (*D. N. Hague*), and heterogeneous (*D. M. Shooter*) reactions, and the one on the detection of intermediates (*R. P. Wayne*), are well equipped with useful diagrams and descriptions of the apparatus used, including, where applicable, electronic instrumentation. The accent is placed on thermal, photochemical, and radiochemical systems, while biochemical and electrochemical systems have obviously been deliberately neglected.

Naturally, all classical and modern chemical and physical methods of studying chemical reactions are also discussed, though the treatment accorded to some of the modern methods is somewhat curtailed. The editors are to be complimented on the fact that overlapping between individual chapters has been reduced to a minimum. On the other hand, they have clearly failed to persuade the authors of the first three chapters to maintain uniformity of arrangement.

The concluding chapter on the treatment of experimental data (*D. Margerison*) is in particular of inestimable value to all those working in kinetics. It is illustrated with a number of examples and tables and constitutes an unsurpassed aid to the analysis of experimental results, even for the most complex systems.

This volume will provide invaluable help in planning, carrying out, and analyzing kinetic experiments, both to those who are occasionally concerned with kinetics and to those constantly dealing with this field.

Oskar Friedrich Olaj [NB 863 IE]

The Biochemistry of Viruses. Edited by *H. B. Levy*. Marcel Dekker, Inc., New York-London 1969, 1st Edit., xiv + 657 pp., numerous figures, bound $ 28.50.

The molecular biology of virus infections is currently receiving an increasing amount of attention. A large number of laboratories throughout the world are engaged in studying both the structure of viruses and the mode of replication of a number of types of virus, and also the effect of viral multiplication on the infected cell. In particular, it is known that a virus infection can lead not only to death of the infected cell but also to a malignant modification of the cell. This has resulted in the tumor viruses, thanks to the limited extent of their genetic information, becoming an excellent model for carcinogenesis. It is thus hardly surprising that the literature on the biochemistry of viruses has recently grown to such an extent that even the subject specialist finds it difficult to keep abreast of the latest developments.

It is therefore all the more gratifying to find that the present book, edited by *Levy* and written by a number of competent authors, provides a survey of the recent literature. The two opening chapters describe the chemical composition of animal viruses and the structure of viruses. After these general chapters, which contain a wealth of useful information, the biochemistry of the main virus groups is systematically discussed. Particular emphasis is placed on the mode of multiplication of the different types of viruses. In addition, one chapter deals with the genetic analysis of the polio virus. The final chapter is concerned with the biochemistry of interferon. In the introduction it is said that the work was intended as a textbook for advanced students and as a source of reference for the virologist. For this purpose it is certainly well equipped, particularly since the literature is covered up to 1968. It is a pity that the compilation of the chapters gives the impression of a certain degree of incompleteness. The value of the book would be increased if Arboviruses and Rhabdoviruses were also dealt with. The omission of any reference to RNA phages and DNA tumor viruses leaves the book incomplete.

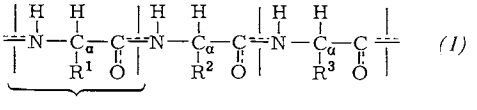
Cooperative Conformational Transitions of Linear Biopolymers



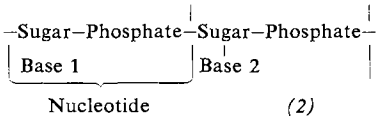
By Jürgen Engel and Gerhard Schwarz[*]

Conformational transitions in proteins, nucleic acids, and other biopolymers evidently play a decisive role in many biological processes, particularly in control processes. They often proceed cooperatively, i.e. the elementary process of the transition of an individual segment of these macromolecules is influenced by the state of other segments via intramolecular interactions. In general, the segments favor the same state as their neighbors. The resulting equilibrium properties of cooperative systems, e.g. the sharpness of the transitions and their dependence on the chain length, can be quantitatively explained for linear systems by the linear Ising model. The molecular causes of the cooperativity can be explained for simple model polymers.

1. Introduction

Macromolecules are important structural units of organisms, each by itself often exercising surprisingly complicated functions. These biological macromolecules consist chemically of chains built up from a relatively small number of types of monomer units. The most important of these macromolecules are the proteins, which include the enzymes that catalyze and regulate the metabolism, and the nucleic acids, which carry genetic information in the form of a control program for the biosynthesis of the proteins.

Proteins consist of polypeptide chains built up from a maximum of about 20 amino acids [see *(1)*].



(1)

Amino acid residue (= Segment of the chain)

R^1, R^2, R^3 .... = side chains, by which the amino acid residues differ from one another. The peptide linkage has partial double-bond character, which prevents free rotation.

(Switzerland)

Nucleic acids contain chains usually made up of at most four structural units, the nucleotides [see *(2)*].

(2)

Sugar = ribose in ribonucleic acid (RNA)
Sugar = deoxyribose in deoxyribonucleic acid (DNA)

The nucleotides differ essentially in their bases. In RNA these are cytosine (C), guanine (G), adenine (A), and uracil (U), while in DNA, U is replaced by thymine (T).

Biologically important chain molecules of this nature are referred to by the general term "biopolymers". The decisive difference between similar polymers lies in the sequence of the monomer units:

$$S_1S_2S_3 \ldots\ldots S_i \ldots\ldots S_N$$

where the N chain members are numbered from left to right and each S is a symbol for a monomer unit (*e.g.* C, G, A, or U in RNA chains).

Very simple sequences have been prepared synthetically, particularly polyamino acids, polypeptides with a periodically repeating sequence of a few amino acid residues, and analogous polynucleotides (*e.g.* poly-A). These synthetic biopolymers are useful as model substances, since the results of measurements are

easier to interpret than for the much more complicated natural biopolymers.

Under suitable conditions, most biopolymers have a specific steric structure (conformation), which is stabilized by noncovalent ("weak") interactions (such as van der Waals forces, hydrogen bonds, hydrophobic and electrostatic interactions) between the segments.

Native nucleic acids and synthetic polynucleotides frequently have relatively simple helical-linear conformations, the basic structure of which does not depend on the sequence of the segments. The best known is the double helix discovered by *Watson* and *Crick* (Fig. 1).

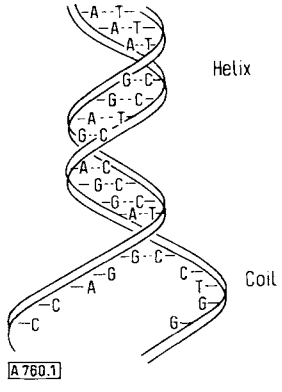

Fig. 1. Schematic representation of the DNA double helix after *Watson* and *Crick* [1]. The bands represent the sugar phosphate chains, which are joined in the helix *via* the bases A, C, G, T [see formula *(2)*] by hydrogen bonds (- -). A coil region is shown underneath.

Proteins generally have much more complicated, often globular arrangements of the polypeptide chains ("tertiary structure"), as might be expected from the great variety of possible sequences. A few basic structures ("secondary structures") are often found in limited regions of the protein; examples are the α-helix (Fig. 2), the pleated sheet (or β) structure, and the polyproline II helix (see Section 3.2). Since such structural types can be found in pure form in polyamino acids, these may be regarded as simple protein models.

The biological function of a biopolymer is usually confined to its structured (native) state. The enzymes are good examples of this. In their active sites, segments from different regions of the chains are brought close to one another by chain folding in such a way that they can cooperate in the catalysis of a metabolic reaction [3]. Even small changes in conformation generally lead to a large change in the enzymatic activity.

It has been found in a number of biological regulation phenomena that enzymes involved can assume conformations with different activities, between which reversible transitions occur. There is much to indicate that control processes of this nature are extremely

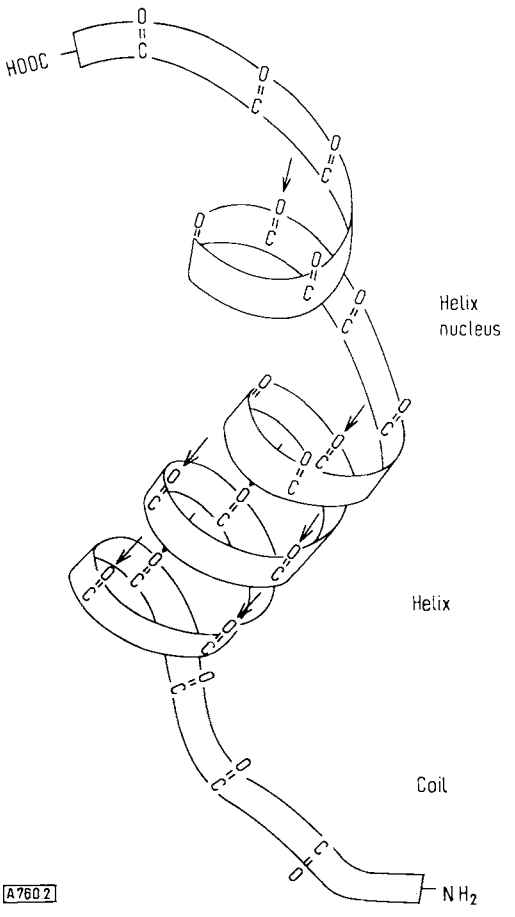

Fig. 2. Schematic representation of the α-helix after *Pauling* and *Corey* [2]. The band represents the polypeptide chain [see formula *(1)*], in which each amino acid residue is represented by its peptide CO group. In the helix, hydrogen bonds (arrows) connect the peptide NH group of each residue to the CO group of the third nearest residue. A helix nucleus (top) in a coil region has only one such hydrogen bond, but this fixes three residues in one turn of the helix.

important and widespread in molecular biology. An example is provided by the allosteric regulation process in enzymes consisting of several protein subunits ("protomers"). A regulating agent (substrate, activator, or inhibitor) becomes bound to an active site of the protein, as a result of which the activity of other sites in the same molecule are changed [4, 5].

This cooperative interaction is evidently due to induced conformational transitions of the protomers. Similar processes are postulated for the regulation of the function of repressors and biological membranes [6, 7]. There has been interesting speculation concerning its possible role in the short-term storage of information in the brain [8].

Nearly all biopolymers can change into a disordered (usually inactive) state of higher entropy. One example is the denaturation of proteins by changes in the

temperature, the pH, or the solvent. In transitions of this type, the weak stabilizing interactions and the associated blockage of free rotation about chemical bonds are largely eliminated. In solution, the chains (like other filamentous molecules) take the form of a random coil. This will be referred to briefly as the coil state. The transition in the opposite direction (coil → specific conformation) is a decisive step in the biosynthesis of proteins[3,9,10]. On the other hand, a process of the type double helix ⇌ coil must be assumed in the duplication of DNA with its genetic information.

Conformational transitions often proceed cooperatively, *i.e.* the elementary processes in the individual segments are influenced by the state of other chain segments. There is usually a strong tendency to assume the state of the neighboring segment. Consequently, even relatively small variations in the external parameters (*e.g.* temperature, pH, solvent composition) can lead to practically complete conformational transition. This property is of fundamental importance to the physiological control functions mentioned above.

A second characteristic of cooperative reactions is the dependence of the transition on the chain length. The sharpness of the transition generally increases with the size of the molecule. This effect was first observed on investigation of linear synthetic model substances, since it is only here that the size of the molecule can be systematically varied. Transitions that have been fairly extensively investigated and that can be described theoretically are α-helix ⇌ coil for polyamino acids, helix I ⇌ helix II for polyproline, and double

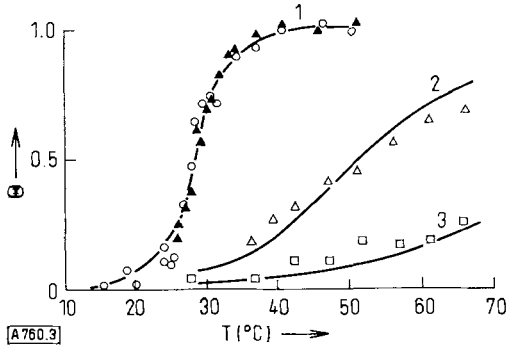

Fig. 3. Temperature-induced α-helix ⇌ coil transition of poly-γ-benzyl L-glutamate [R in formula *(1)* = $CH_2-CH_2-COO-CH_2C_6H_5$] in dichloroacetic acid/dichloroethane for various chain lengths, *N*. 1: $N = 1500$;, 2: $N = 46$; 3: $N = 26$. The degree of transition Θ was determined from the optical rotation α by means of the equation

$$\Theta = \frac{\text{Residues in the helix state}}{\text{Total number of residues}} = \frac{\alpha - \alpha_C}{\alpha_H - \alpha_C}$$

where α_H and α_C are the rotations of the pure helix form and of the pure coil form. The values indicated by circles were given by *Doty* and *Yang* [11], and all the other values by *Zimm*, *Doty*, and *Iso* [12]. The continuous curves were calculated [12, 13] (see Section 3.1).

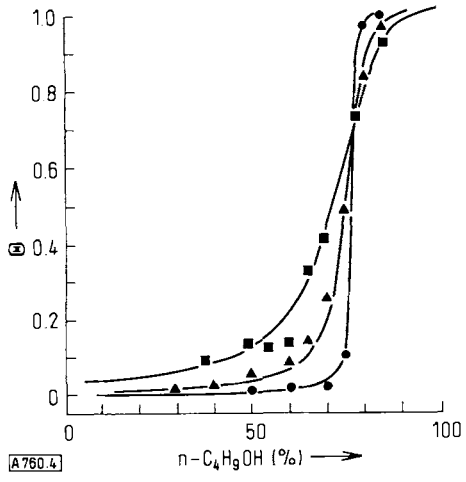

Fig. 4. Solvent-induced transition between two types of helix (I and II) of poly-L-proline [see formula *(3)*] having chain lengths $N = 12$ (●), $N = 30$ (▲), and $N = 132$ (■) [14]. The degree of transition Θ = number of residues in the I state/total number of residues was determined polarimetrically by a method similar to that used in the α-helix ⇌ coil transition (see caption of Fig. 3). The curves are calculated (see Section 3.2). Abscissa: *n*-butanol in trifluoroethanol, vol.-%.

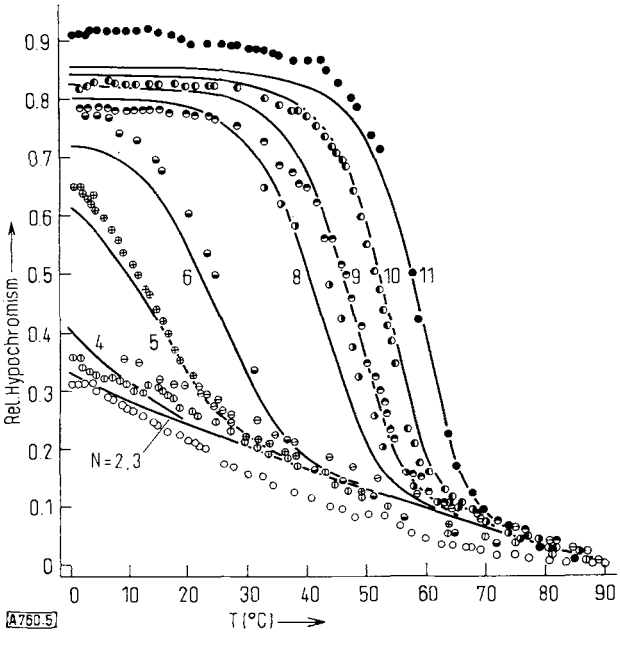

Fig. 5. Temperature-induced double helix ⇌ coil transition of polyadenylic acid [all bases = A in formula *(2)*] having various chain lengths *N* (after *Applequist* and *Damle* [15]). The hypochromism [16] (decrease in UV absorption on helix formation) used as the measured quantity does not give the degree of transition Θ directly, since it depends on the length of the helix section. This dependence was taken into account in the calculation of the curves shown [15].

○: $N = 2$; ⊖: $N = 3$; ⊙: $N = 4$; ⊕: $N = 5$; ◒: $N = 6$; ◑: $N = 8$; ◓: $N = 9$; ◐: $N = 10$; ●: $N = 11$.

helix ⇌ coil for polynucleotides (see Sections 3.1-3.3). At this stage we shall merely show a few typical transition curves (Figs. 3–5) based on optical measurements. The above-mentioned characteristics of cooperative transitions are clearly recognizable.

2. Theoretical Principles[17]

The representation of the sequence of a biopolymer chain as a sequence of symbols for the segments can be extended to a formal description of the conformation. We make use of the fact that the conformation is determined by interactions between the monomer units. Thus the i-th segment S_i can conceivably have the states A_i, B_i, C_i, *etc.* Each sequence of possible states then represents a certain conformational state of the entire chain. In general, there will be a very large number of such structural forms, but only those with minimal free energies will be really stable.

These forms can in principle be predicted from theory if the energy interactions of the segments are known. However, such calculations are usually possible only with powerful computers. Very successful investigations of this nature have been possible for simpler structures[18–20]. Further developments in this field should one day make calculation of the conformation of a given sequence feasible.

The stability of a conformation naturally depends on the external conditions (*e.g.* temperature, pressure, solvent). Conformational transitions may therefore occur when these conditions are changed.

We have found that interactions occur between various segments within the macromolecule. Thus it will be readily understood that the free energy of a segment often depends not only on the external conditions and its own internal structure, but also on the states of other parts of the chain. Consequently, the thermodynamic (and kinetic) properties of the elementary processes of the change in state are influenced by the situation prevailing at that time in more or less distant segments. This is the same as saying that the conformational transitions proceed cooperatively. If the process were non-cooperative, the transitions of single segments could be dealt with individually, and the complete transition would not depend on the molecular weight and would not exhibit abnormal sharpness.

It is convenient in theoretical studies to consider the simplest possible linear biopolymers first. Chains built up from only one type of monomer unit (*i.e.* in which all the S_i are the same) are particularly suitable. This is the case for the transitions illustrated in Figures 3–5. Another fact that can be used here is that each segment has only two possible states; let these be denoted by A and B [*e.g.* in polyproline, A = *trans* configuration of the peptide linkage, B = *cis* configuration (see Section 3.2)]. One extreme form of the conformation will then be described as a pure sequence of A states (in our example, this corresponds to the polyproline II helix) and the other as a pure B sequence (polyproline I helix). There are, in principle, also many mixed conformations, *e.g.*

$$\underset{1\ 2\ 3\ 4}{A\,A\,B\,B\,.....\ B\,A\,B\,B\,....\ A\,B\,B}\qquad\qquad\underset{N}{} \qquad (1)$$

the total number being 2^N. With only 100 chain segments, therefore, we must expect about 10^{30} different states.

With cooperative interactions, the properties of the elementary process

$$A \rightleftharpoons B \qquad (2)$$

become more or less complicated. A particularly simple situation evidently arises if cooperative interactions occur only between immediately adjacent segments. This corresponds to the model of a linear lattice discussed by *Ising* in 1925 in connection with a theory of ferromagnetism[21]. This author was able to show that all the thermodynamic properties could be calculated relatively simply in this case. The two-dimensional and three-dimensional models that were of interest for his own purposes, however, led to extreme mathematical difficulties, and further work in this field was suspended for a long time.

With the growth of interest in cooperative transitions of biopolymers, the linear Ising model acquired fundamental importance for the theory of such processes[13,22–30]. The quantitative relationships can be represented particularly elegantly by the matrix method (introduced by *Kramers* and *Wannier*[31]). This method was first applied to a conformation transition by *Zimm* and *Bragg*[13], the particular case being the helix ⇌ coil transition of polypeptides (see Section 3.1). In its simplified form, the theory can be extensively generalized. It describes the essential properties of cooperative transitions by means of the fundamental thermodynamic parameters s and σ.

The parameter s is the equilibrium constant for the process

$$A\,A\,B \rightleftharpoons A\,B\,B \qquad (3)$$

(or for BAA ⇌ BBA), which obviously represents the growth of existing sequences of B or A states, since the reacting (middle) segment is immediately adjacent both to an A state and to a B state.

In

$$A\,A\,A \rightleftharpoons A\,B\,A \qquad (4)$$

on the other hand, a new B sequence is started or an existing one disappears. Let the equilibrium constant of this "nucleation process" (for B) be σs.

The parameter σ defined in this way is a measure of the cooperativity of the transition. If $\sigma < 1$, the segments tend to assume the same state as their neighbors, *i.e.* pairs of the type AA or BB are more probable than pairs AB or BA (positive cooperativity). If $\sigma = 1$, there is no cooperativity, since the equilibrium constants of equations (3) and (4) are equal (*i.e.* they do not depend on the states of the neighbors). If $\sigma > 1$, adjacent segments tend to assume different states. This negative cooperativity or anticooperativity has not yet been detected with certainty in biopolymers.

On grounds of microscopic reversibility, the nucleation rate of an A state in a B sequence is described by the same σ. The equilibrium constant for

$$B\,B\,B \rightleftharpoons B\,A\,B \qquad (5)$$

is $\sigma \times 1/s$. The difficulty of nucleation can be different for A and B states only at the chain ends. The terminal segments (with the numbers 1 and N) are in fact characterized in that they have only one neighbor. *Zimm* and *Bragg* made the simplifying assumption that the formation of nuclei of the α-helix at the ends of a polypeptide chain is also described by the parameter σ. This can be easily justified for helix ⇌ coil

[17] The kinetics of cooperative transitions will be dealt with in a future paper.

transitions (see Section 3). We shall introduce this assumption for B first, and we can then describe the equilibrium properties of the transition completely by means of s and σ.

To demonstrate this, let us calculate the equilibrium concentrations of each chain state for the case $N = 4$. If we start with the pure A state, then *e.g.* the pure B state can be reached in four steps by the following processes:

$$\mathrm{A\,A\,A\,A} \rightleftharpoons \mathrm{B\,A\,A\,A} \rightleftharpoons \mathrm{B\,B\,A\,A} \rightleftharpoons \mathrm{B\,B\,B\,A} \rightleftharpoons \mathrm{B\,B\,B\,B}$$

The first step here is associated with nucleation, and this is followed by three growth steps. The equilibrium concentrations are accordingly given by

$$\bar{c}_{\mathrm{B\,B\,B\,B}} = \sigma s \cdot s \cdot s s \cdot \bar{c}_{\mathrm{A\,A\,A\,A}} \tag{6}$$

For $\sigma s^4 \approx 1$, therefore, the two extreme forms would be present in roughly equal quantities. If, moreover, the cooperativity is so strong that

$$1/\sigma^{0,25} \gg 1$$

we find that the concentrations of all the intermediate forms are small in comparison with those of the extreme forms (*e.g.* for $\sigma = 10^{-4}$: $\bar{c}_{\mathrm{BBBA}} = 0.1\ \bar{c}_{\mathrm{BBBB}}$; $\bar{c}_{\mathrm{BBAA}} = 0.01\ \bar{c}_{\mathrm{BBBB}}$, and $\bar{c}_{\mathrm{BAAA}} = 0.001\ \bar{c}_{\mathrm{BBBB}}$). In this case the transition in a given chain proceeds practically to completion or not at all.

This "all-or-nothing" behavior is evidently to be expected whenever the chains are very short and the cooperativity is sufficiently strong. The quantitative condition is found to be

$$N\sigma^{1/N} \ll 1 \quad \text{or} \quad N(1 + \log N) \lesssim -\log \sigma \tag{7}$$

The degree of transition Θ, *i.e.* the fraction of B states formed, is then

$$\Theta = \sigma s^N / 1 + \sigma s^N \tag{8}$$

The double helix $\rightleftharpoons$ coil transition of oligonucleotides has been very satisfactorily described in this way [15, 32].

As with very short chains, relatively simple behavior is also found in the limiting case of very long chains. The degree of transition then becomes

$$\Theta = \frac{1}{2}\left(1 + \frac{s-1}{\sqrt{(s-1)^2 + 4\,\sigma\,s}}\right) \tag{9}$$

so that the transition no longer depends on the chain length. As can readily be seen, the midpoint of the transition ($\Theta = 1/2$) for any σ always corresponds to $s = 1$. However, the sharpness of the transition will increase as the value of the cooperativity parameter σ decreases. This leads *inter alia* to a characteristic increase in the apparent molar enthalpy of transition. Thus using the "apparent equilibrium constant"

$$K = \Theta/(1-\Theta)$$

which can generally be readily obtained by experiment, the temperature coefficient (disregarding the temperature dependence of σ, which is permissible at least when the cooperativity is strong) becomes

$$\frac{\mathrm{d} \ln K}{\mathrm{d}T} = \frac{1}{\Theta\,(1-\Theta)} \cdot \frac{\mathrm{d}\,\Theta}{\mathrm{d} \ln s} \cdot \frac{\mathrm{d} \ln s}{\mathrm{d}T} \tag{10a}$$

In particular, at the midpoint of the transition

$$\left(\frac{\mathrm{d} \ln K}{\mathrm{d}T}\right)_m = N_0 \frac{\Delta H_u}{RT^2} \tag{10b}$$

where ΔH_u is the molar enthalpy of transition for the elementary growth process (3) and

$$N_0 = 1/\sigma^{1/2} \tag{11}$$

is the cooperative length. The name refers to the fact that for $\Theta = 1/2$ and $N \to \infty$, the average length of unbroken A or B sequences is exactly $N_0 + 1$. We now see from eq. (10b) that the apparent molar enthalpy of transition (after *van't Hoff*) is greater by the factor N_0 than the value found from the elementary process.

$N_0 \cdot \Delta H_u$ in eq. (10b) is often referred to as the van't Hoff enthalpy $\Delta H_{\text{van't Hoff}}$, since its value is obtained from a "van't Hoff plot" ($\ln K$ against $1/T$). It follows from equations (10b) and (11) that

$$N_0 = \Delta H_{\text{van't Hoff}} / \Delta H_u \tag{12a}$$

or

$$\sigma = (\Delta H_u / \Delta H_{\text{van't Hoff}})^2 \tag{12b}$$

This behavior of apparently infinitely long chains is found when

$$N \gg N_0 \tag{13}$$

Chains of medium length with

$$N_0 \gtrsim N \gg -\log \sigma \tag{14}$$

can generally be described only by fairly complicated expressions. Typical features are the dependence on chain length and the fact that each chain practically contains only one to two nuclei (suppressed nucleation). The special end effects, which are disregarded in the simplified Zimm-Bragg model discussed so far, play a decisive role here and in the "all-or-nothing" range. It is found that whereas the dependence of helix $\rightleftharpoons$ coil transitions on the chain length is described very satisfactorily by the Zimm-Bragg model the intersecting transition curves of polyproline (Fig. 4) cannot be explained on this basis. It has been shown that this phenomenon can be explained only if nucleation parameters for *each* of the two states are considered [33]. It is difficult to believe that nucleation at the chain ends is hindered in only one of the two helix forms of polyproline. These considerations have led to a general theory of cooperative transitions of linear biopolymers, in which the interactions are still restricted to immediate neighbors, but where no other special assumptions are necessary [34, 35]. Four independent thermodynamic parameters are required in this theory.

From the detailed presentation of the general theory [35], we find that if we introduce the nucleation parameters σ'_A, σ'_B (at one end of the chain) and σ''_A, σ''_B (at the other end),

$$\sigma = \sigma'_A \sigma'_B = \sigma''_A \sigma''_B \tag{15}$$

σ agrees with the Zimm-Bragg σ value. It is convenient to define two end effect parameters

$$\beta' = \sigma'_B/\sigma'_A\,;\ \beta'' = \sigma''_B/\sigma''_A \tag{16a, b}$$

β' and β'' can be expressed (though less concisely) in terms of the free energies of the cooperative interactions, as follows:

$$RT \ln \beta' = -(G_{BA} - G_{AB}) + (G_{BB} - G_{AA}) - 2(G'_B - G'_A) \tag{17a}$$

$$RT \ln \beta'' = (G_{BA} - G_{AB}) + (G_{BB} - G_{AA}) - 2(G''_B - G''_A) \tag{17b}$$

[32] *D. Pörschke*, Diplomarbeit, Universität Göttingen 1966; Dissertation, Techn. Hochschule Braunschweig 1968.

[33] *G. Schwarz*, Biopolymers *5*, 321 (1967).

[34] *J. Applequist*, Biopolymers *6*, 117 (1968).

[35] *G. Schwarz*, Biopolymers *6*, 873 (1968).

The terms G'_A, G'_B, G''_A, and G''_B denote any additional free energies of the end states that might be caused by the absence of the neighbor on one side, by the special chemical structure (end groups), and by special interactions with the solvent.

Similarly, σ can be expressed by

$$RT \ln \sigma = -(G_{BA} + G_{AB}) + (G_{AA} + G_{BB}) \quad (18)$$

Moreover,

$$RT \ln \sigma = RT \ln \sigma s - RT \ln s = -(\Delta G_K - \Delta G_W) \quad (19)$$

where ΔG_K and ΔG_W are the free energies of the nucleation step and of the growth step respectively.

Using the matrix method, the properties of the conformational equilibrium can now be calculated as a function of the chain length N, the Zimm-Bragg parameters s and σ, and the quantities β' and β''. The influence of β' and β'' decreases with increasing chain length. Finally, when $N \gg N_0$, the end effects can be completely ignored, so that irrespective of the particular β' and β'' values, the limiting case discussed in connection with the Zimm-Bragg model is realized. In general, therefore, the theory permits the representation of the transition curves in the form

$$\Theta = f(s, \sigma, \beta', \beta'', N) \quad (20)$$

where the four thermodynamic parameters must be regarded as a function of the variables of state. With stronger cooperativity and values of N that are not too small, however, the degree of transition Θ is influenced mainly by changes in s, since s, unlike σ, β', and β'', occurs in high powers (up to N) in eq. (20). Θ can then be regarded, to a first approximation, as a function of s alone (the other parameters being treated as constants). If the dependence of the latter on the experimental conditions (such as temperature, pressure, solvent) is known, the transition curves to be expected experimentally can be calculated from eq. (20). Since s is the equilibrium constant of the growth process, the required relations can often be deduced from known thermodynamic relations; for example, the temperature dependence can be given by the van't Hoff isochore

$$d \ln s / dT = \Delta H_u / RT^2 \quad (21)$$

as used earlier in eq. (10b). (For limitations see Section 3.2.)

The linear Ising model with interaction of nearest neighbors can in principle be extended *e.g.* to include cases where cooperative interactions extend beyond the nearest neighbors. However, this leads to much more complicated calculations, which are often not worth the trouble in any case, since if the cooperativity is strong and the chains are not too short, the actual interactions can be formally grouped together into interactions of nearest neighbors. For this reason, the theory discussed may be regarded as a useful basis, to a first approximation at least, for cooperative transitions of linear biopolymers that are of practical interest.

3. Experiments on Simple Linear Model Systems

Investigations on simple linear biopolymers are very important for an understanding of the principles of cooperative transitions. In these cases one can expect a theoretical description with few parameters and a molecular interpretation of the experimentally determined parameters to be possible.

A general comment is necessary concerning the number of these parameters. If the experimental transition data can be described to within the limits of error by a very small number of parameters (*e.g.* by s and σ), this does not necessarily mean that the theoretical model selected (in this example the Zimm-Bragg model) is strictly correct. It does, however, mean that additional parameters of a possibly more valid theory (*e.g.* β' and β'', or parameters that take long-range interactions and a complicated sequence into account) cannot be determined without further experiments. It is therefore also necessary in practice to apply the simplest possible theory that fits the main properties to the simplest possible systems.

For an understanding of the molecular causes of cooperativity, it has been found convenient to describe the experimental data by means of the theories discussed above, the parameters (*e.g.* σ) found by matching then being explained on the basis of the molecular facts of the case in question (*e.g.* σ by unfavorable interactions that arise in nucleation). A statistical thermodynamic treatment based directly on molecular data is less general and is also difficult, since the interatomic interactions in biopolymers and the polymer-solvent interactions are only approximately known.

3.1. The α-Helix ⇌ Coil Transition

Most of the investigations on this important transition have been carried out with poly-L-glutamic acid and its derivatives. A pioneering study was the theoretical description by *Zimm* and *Bragg*[13] of the temperature-induced rearrangement of poly-γ-benzyl L-glutamate [R in formula *(1)* = $CH_2-CH_2-COO-CH_2C_6H_5$] (Fig. 3). The transition is very sharp for long chains. The slope and position of the curves depend on the chain length.

For a quantitative description, *Zimm* and *Bragg* used their simple Ising model (see Section 2), which contains s and only one nucleation parameter σ. They defined an amino acid residue as being in the B state (helix) when its CO group is linked to the NH group of the third-nearest neighbor by a hydrogen bond of the type found in the α-helix (see Fig. 2). A residue is in the A state (coil) if its CO group is free. To fit the theoretical transition curves to the experimental values, it was assumed that s depends on the temperature exclusively in accordance with the van't Hoff isochore [eq. (21)]. The enthalpy of transition ΔH_u, which was unknown initially, was varied together with σ until the best fit was found for all the experimental values according to the criterion of least square deviations.

The values for the theoretical curves that describe the results well (see Fig. 3) are: $\sigma = 2 \times 10^{-4}$ and $\Delta H_u = 990$ cal/mole. The cooperative length N_0 is thus about 70 residues. The ΔH_u value has also been confirmed directly by calorimetric measurements. The most

reliable of the published results[36–39] is probably $\Delta H_u = 950 \pm 20$ cal/mole, which was obtained by a superior calorimetric method[36].

The surprising positive sign of ΔH_u (increase in the helix content with rising temperature) can be explained by the fact that the influence of the temperature on the stability of the α-helix is mainly indirect. In the solvent used (80 parts of dichloroacetic acid/20 parts of 1,2-dichloroethane), the dichloroacetic acid competes for the hydrogen bonds of the helix by adding to the free CO and/or NH groups of the residues in the coil state[40,41]. The temperature coefficient of this binding process determines the temperature dependence of the helix ⇌ coil transition[13,42]. This is supported by the fact that the transition can be induced by even a small increase in the dichloroacetic acid concentration.

If the calorimetric enthalpy of transition is known, σ values can be conveniently estimated by means of equations (10b) and (11) or (12) from the slope of a single transition curve. It is assumed in this method[38,43] that the Zimm-Bragg model is valid, that s depends in a simple manner on the temperature in accordance with the van't Hoff isochore, and that $N \gg N_0$. Whereas the last of these conditions can usually be satisfied by the synthesis of high molecular weight polyamino acids, the other assumptions need not be correct for every system (see Section 3.2).

For the molecular interpretation of σ, *Zimm* and *Bragg* assumed that the difficulty of nucleation is mainly due to entropy. In the growth step, *i.e.* in the addition of a residue to an existing helix section (see Fig. 2, bottom), the binding enthalpy ΔH_W of a NH···OC hydrogen bond is gained, and the energy $T\Delta S_W$ must be supplied. ΔS_W is essentially the entropy lost when an amino acid residue loses the free rotation about the HN–C_α and C_α–CO bonds [see formula *(1)*] on transition from the coil to the helix conformation. On formation of the first hydrogen bond corresponding to those in an α-helix (see Fig. 2, top), the same enthalpy is gained as in growth:

$$\Delta H_K = \Delta H_W \qquad (22)$$

(The subscripts refer to nucleation and growth.) However, the entropy loss ΔS_K is three times as large as for growth, since three residues are fixed in a helix conformation on nucleation. With eq. (22) it follows from eq. (19) that

$$\sigma = e^{-(\Delta S_K - \Delta S_W)/R} \qquad (23)$$

Since $\sigma \approx 10^{-4}$, $\Delta S_K - \Delta S_W \approx 18$ e. u., in agreement with the order of magnitude expected for the freezing-in of the degrees of freedom of two amino acid residues[13]. Though interactions other than hydrogen bonds (*e.g.* hydrophobic interactions of the side chains and binding of the solvent) and the change in entropy on solvation and desolvation are disregarded in this simplified picture, it undoubtedly shows the principal cause of the cooperativity of the α-helix ⇌ coil transition.

This picture also explains the validity of the simple Zimm-Bragg model with only one σ for the α-helix. The Zimm-Bragg theory may be regarded as a special case of the general theory with $\sigma = \sigma'_B = \sigma''_B$. According to eq. (15), therefore, $\sigma'_A = \sigma''_A = 1$. It is in fact to be expected that the formation of a helix (B) nucleus at the ends is at least as difficult as in the interior of the chain. The unfavorable entropy balance is the same in both cases, and a turn at the end of the helix lacks half of the stabilizing hydrogen bonds. In contrast, the formation of a coil (A) nucleus is much easier at the end than in the interior, since four hydrogen bonds have to be broken in the interior to form a coil nucleus, whereas only one hydrogen bond is broken at the end of the chain.

The validity of the simple entropy-based explanation of σ can be checked experimentally. Thus according to eq. (23), σ should be independent of the external conditions, whereas it must depend on the temperature whenever an interaction enthalpy is involved (as in poly-L-proline, see Section 3.2). It has unfortunately not yet been experimentally possible to separate the observed small dependences of σ on the temperature, the solvent concentration, and the polymer concentration from one another and from possible systematic errors in the determination of σ (see above and Section 3.2)[38,43]. A second conclusion from the simple entropy explanation is that σ should also be independent of the side chains of the polyamino acids forming the α-helix. Several interesting results have been obtained in this connection.

The solvent-induced helix ⇌ coil transition of another derivative of polyglutamic acid with uncharged side chains, *i.e.* poly-N^5-(3-hydroxypropyl)-L-glutamine [R in formula *(1)* = $(CH_2)_2$–CO–NH–$(CH_2)_3$–OH], in formic acid/water could be described by a σ value of 3×10^{-4}[44]. A similar σ value (1.5×10^{-4}) has also been found for poly-ε-benzoxycarbonyl-L-lysine [R = $(CH_2)_4$–NH–COO–$CH_2C_6H_5$][45]. The good agreement of the σ values indicates that the Zimm-Bragg hypothesis, according to which the cooperativity is independent of the side chains, is correct. The solvent evidently also has only a small effect on σ, since the polymers mentioned were examined in very different solvents.

On the other hand, a much lower cooperativity was found for polyglutamic acid [R = $(CH_2)_2$–COOH],

which contains free and therefore ionizable COOH groups: $\sigma = 3\times10^{-3}$, cooperative length $N_0 \approx 16$ [46,47]. At low pH values when the COOH groups are undissociated, the helix is stable. However, it is broken up at higher pH values by electrostatic repulsion between the $COO^{\ominus}$ groups. The entropy of the resulting more disordered state is nevertheless undoubtedly lower than that of the uncharged coil, since repulsion between the side chains greatly restricts the mobility of the residues. Since the difference between ΔS_K and ΔS_W is thus smaller, a lower cooperativity is to be expected, in agreement with the entropy-based explanation of σ [eq. (23)].

A high cooperativity of non-entropic origin is observed in a completely different type of transition between two ordered helical conformations of the polyamino acid poly-L-proline.

3.2. The Helix I ⇌ Helix II Transition of Poly-L-proline

Poly-L-proline *(3)* can exist in two forms, I and II (see Fig. 6), the conformations of which are known from X-ray structure analyses [48,49]. Form I is a

(3)

shallow right-handed helix with all the peptide bonds in the *cis* configuration. The CO groups in this compact helix are almost parallel to the axis of the helix,

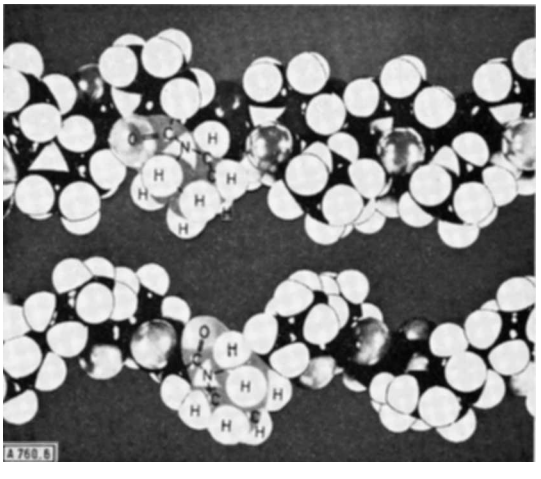

Fig. 6. Space-filling models of the I helix (top) and of the II helix (bottom) of poly-L-proline. The small white spheres and the large gray spheres are hydrogen and oxygen atoms respectively. The peptide nitrogen atoms appear as gray triangles. The carbon atoms are black [cf. *(3)*].

and are shielded to some extent by the proline rings. Form II is a steep left-handed helix with all the peptide linkages in the *trans* configuration. The CO groups are almost perpendicular to the axis, and are freely accessible to the solvent.

Both forms are sterically stabilized by the bulky rings. Intramolecular hydrogen bonds such as occur in the α-helix cannot occur here, owing to the absence of the peptide NH groups. Which of the two forms is more stable depends on the interactions with the solvent. Thus form I is more stable in *n*-butanol, and form II in benzyl alcohol or trifluoroethanol. It has been shown spectroscopically that all three alcohols form hydrogen bonds with the CO groups [50]. The relatively strong H-bond donors benzyl alcohol and trifluoroethanol prefer the open form II [51], and so displace the I ⇌ II equilibrium in favor of this form.

The reverse transition II → I can be induced by addition of *n*-butanol to benzyl alcohol or trifluoroethanol, and can easily be followed polarimetrically (Figs. 4 and 7). We again find the dependence of the transition on the chain length that characterizes cooperative transitions, but a new feature, which was not seen in the helix ⇌ coil transition, is an intersection of the curves (Fig. 4), which, as mentioned in Section 2, cannot be explained by the simple Zimm-Bragg model. There is no definite intersection in benzyl alcohol/*n*-butanol (Fig. 7), but the Zimm-Bragg theory does not lead to a satisfactory description even here.

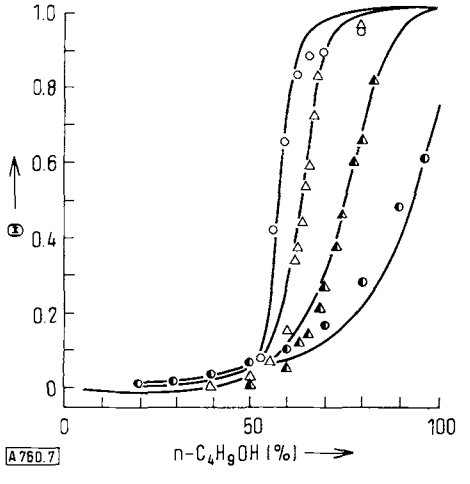

Fig. 7. Solvent-induced transition of poly-L-proline as in Fig. 4, but in benzyl alcohol/*n*-butanol (vol.-%). Experimental values for $N = 14$ (◐); $N = 33$ (▲), $N = 90$ (△), and $N = 217$ (○). The curves were calculated.

On the other hand, an attempt to describe the transition with the aid of the general equilibrium theory [35] (Section 2) was successful [14]. The I state of poly-L-proline was equated to the B state of the theory with no restriction of generality. To match the results, in contrast with the procedure described in Section 3.1, no definite function was given for the dependence of s on the composition of the solvent, but use was made

of the facts that σ, β', and β'' should be equal in one solvent system and that there is one s value for each solvent composition q.

Theoretical transition curves that best describe all the experimental values for a solvent system on the basis of the least square deviation criterion can be found by an electronic computer with variation of σ, β', and β'', using a special program (*Gaushaus* [52]). This method of fitting has the advantage that the s function not only may be unknown, but is actually obtained from the experimental transition data (Fig. 8). The

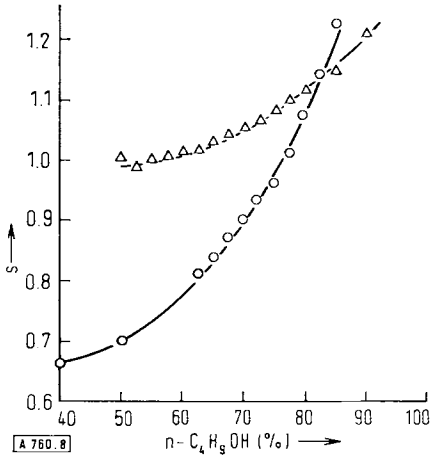

Fig. 8. Dependence of the equilibrium constant for the growth step of the I ⇌ II transition on the volume fraction of *n*-butanol in trifluoroethanol (○) and benzyl alcohol (△).

nucleation parameters determined by this method are unaffected by possible errors in the selection of an s function. The experimental results agree with theory to within the limits of error (see Figs. 4 and 7). The best values of σ, β', and β'' for the theoretical curves in Figures 4 and 7 are given in Table 1.

Table 1. Nucleation parameters for the helix I ⇌ helix II transition as found by fitting to the experimental values.

Solvent system	σ	β'	β''
Benzyl alcohol/ *n*-butanol	$(1.0 \pm 0.5)\ 10^{-5}$	0.05 ± 0.004	0.056 ± 0.004
Trifluoroethanol/ *n*-butanol	$(0.5 \pm 0.2)\ 10^{-5}$	$(9 \pm 4)\ 10^{-4}$	$(1.5 \pm 0.6)\ 10^{4}$

The very small values of σ point to a very high cooperativity. A nucleus is less probable by a factor of about 10^5 than an unbroken sequence having the same conformational states. The cooperative length is about 320. According to eq. (18), the unfavorable (positive) free energy that occurs in addition to the energy between the same states on nucleation is

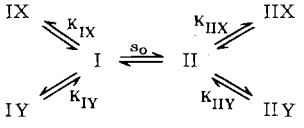
$$\Delta G_\sigma = G_{I,II} + G_{II,I} - G_{I,I} - G_{II,II} \approx 6.5 \text{ kcal/mole} \qquad (24)$$

Since σ is the same for both solvent systems (Table 1), the explanation of ΔG_σ must be sought in the internal properties of the polyproline chain. It may be assumed that the entropy component in ΔG_σ is very small, since the helices I and II and molecules containing both forms are very rigid and do not differ greatly in their degrees of freedom. Thus unlike in the helix ⇌ coil transition, $\Delta G_\sigma = \Delta H_\sigma$ must be interpreted here as the enthalpy of the interaction between the residues. A large part of ΔH_σ is due to repulsion between CO groups, which occupy unfavorable positions in relation to one another at the boundary ··II-I·· (the N-terminal end of the chain being written on the left). The bulky model of the I nucleus in a sequence of II states (Fig. 9) shows, in addition to other contacts, a very

Fig. 9. Polyproline II helix interrupted at the very top of the drawing by a single *cis* linkage. The imino end is on the left. On the left-hand side of the nucleus, *i.e.* at the ·· II—I ·· boundary, electrostatic repulsion occurs between two CO groups indicated by crosses.

close proximity of two carbonyl oxygen atoms having a negative charge of about 0.4 e. Calculation of the electrostatic [14, 53] and van der Waals interactions [14] at the boundary leads to a ΔH_σ value that agrees well with the value calculated from σ by means of eq. (18).

The electrostatic interactions make the larger contribution [14], and have a considerable range. The apparent conflict between this fact and the success of the theory, which takes into account only interactions between nearest neighbors, is resolved as follows. Owing to the high cooperativity the length of the unbroken sequences of the same state in a chain is generally much greater than the range of the interactions. The latter can therefore be formally described as interactions between the nearest neighbors at a boundary between two sequences.



In contrast with the difficulty of nucleation in the interior of a chain (expressed by σ), the ratio of the difficulties of nucleation for the two forms at the chain ends (β' and β'') is strongly dependent on the solvent (Table 1). A possible explanation of this is *e.g.* that binding that depends on the conformation of the terminal residue occurs between the solvent and the amino or carboxyl end groups. Binding of this type and any other interaction of the solvent with the terminal residues influences β' and β'' *via* the terms G'_A, G'_B, G''_A, and G''_B in eq. (17). The difference between the interaction energies at the ··I-II·· and ··II-I·· boundaries, which is also involved here, as well as the loss of stabilization energy in the terminal

residues as a result of the absence of neighbors, can be calculated from the molecular data for poly-L-proline [14,53,54].

However, since no detailed information about the influence of solvents is available, the β values cannot yet be calculated. On the other hand, the dependence of the s parameter on the composition of the solvent can be quantitatively described with the aid of the concept that the two forms are stabilized mainly by bonding of the solvent components X (benzyl alcohol

Scheme 1.

or trifluoroethanol) and Y (*n*-butanol) to the peptide CO groups of the proline residues. The complete binding system (Scheme 1) leads to the relation

$$s = s_0 \frac{1 + K_{IX}\, a_X + K_{IY}\, a_Y}{1 + K_{IIX}\, a_X + K_{IIY}\, a_Y} \qquad (25)$$

In this equation, s_0 is the equilibrium constant of the growth step of the free residues. This gives the ratio of I to II in the absence of interactions with the solvent, and has been estimated to be about 2 from calculations of the conformational energies of the I and II helices. K and a are the binding constants and the activities of the solvents. The dependence of the activities on the solvent composition and some of the binding constants have been determined experimentally. The experimental s functions can be satisfactorily described by eq. (25). Thus molecular interpretations have been found for all the theoretical parameters (σ, β', β'', and s) in the case of poly-L-proline [14].

It has already been mentioned that the use of a van't Hoff isochore for the temperature dependence of a transition can lead to errors in the determination of the nucleation parameters (see Section 3.1). Consideration of eq. (25) shows that for transitions involving binding processes (which also include the α-helix ⇌ coil transition), s_0 and all the binding constants may depend on the temperature, with the result that the dependence of s can no longer be represented by an equation of the type (21). Matching of the parameters without the use of assumptions is therefore also preferable in other cases.

The difference in the free energy that is required to convert poly-L-proline completely from one form into the other is also important. It can be seen from Figures 4 and 8 that for $N > 100$, a change of about 20 % in s is sufficient for about 95 % transition. This small change in the equilibrium constant corresponds to an energy change of about 0.1 kcal/mole. Thus this small energy difference is enough to stabilize one conformation or the other. In the case of poly-L-proline, it is supplied by the binding of the solvent. This strong dependence of the conformation on the free energy (over a small range of the external parameters) is a general property of cooperative systems. Consequently proteins and nucleic acids have a stable conformation even when the energy of their individual segments is only slightly more favorable than in the disordered state.

3.3. The Double Helix-Coil Transition of Nucleic Acids

The DNA double helix (Fig. 1) is stabilized by hydrogen bonds between bases of different strands and by the stacking energy $\Delta G_{st.}$ between the bases of each strand [55]. $\Delta G_{st.}$, which is particularly important in aqueous solution, consists of a large hydrophobic component and special interactions between the aromatic systems of the bases [56]. The double helix ⇌ coil transition (Fig. 5), which can be induced *e.g.* by a temperature rise and can be readily detected spectroscopically by means of hypochromism in the UV, has a chain length dependence that is qualitatively similar to that of the α-helix ⇌ coil transition.

A system that has been extensively studied is that of polyadenylic acid (poly-A) [15,16], the double helix of which is basically the same as the Watson-Crick double helix [57]. The theoretical description of the transition was possible for $N < 11$ by transfer of the Zimm-Bragg model with only one nucleation parameter to the double helix. The nucleation step, with the equilibrium constant $\sigma \cdot s$, is bimolecular in this "zipper model" (see Fig. 10). Even better results are obtained by the "staggering zipper model", in which states with mutually staggered chains are also taken into account. The partition function was obtained for this model by combinatorial analysis, in which particularly unlikely states were omitted from the very beginning for simplicity. By fitting the theoretical curves to the experimental transition curves for $N = 2$ to 11 [15,16], a σ value of 2×10^{-3} l/mole was obtained, taking into account the dependence of the hypochromism on the chain length [15]. In this system we again find a new molecular cause of the cooperativity.

The initial coming together of two bases of different strands (nucleation) is more difficult by $\Delta G_{st.}$ than the growth step, since the stacking energy appears only when a base pair is added to an existing base pair (see Fig. 10). The contribution of the hydrogen bonds is the same for the nucleation and the growth steps, since the number of bonds formed is always the same. The entropy loss probably also differs by only a small amount of the order of RT ln 2, this difference being due to the bimolecularity of the nucleation. It must otherwise be assumed that the number of confor-

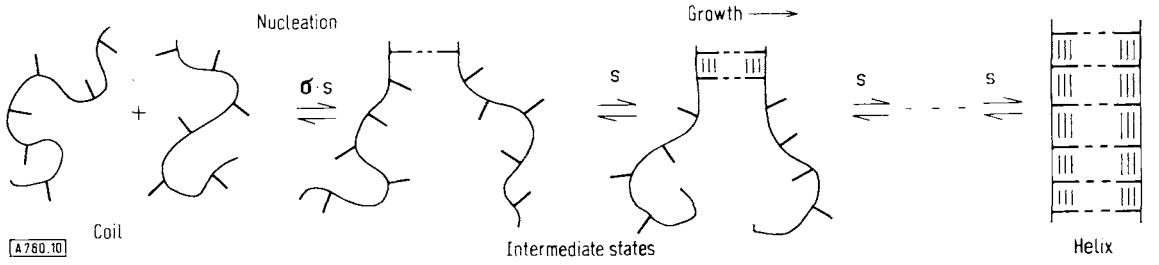

Fig. 10. Zipper model of the double helix ⇌ coil transition of nucleic acids having a short chain. —— = base; · · · = hydrogen bonds, ||| = stacking interactions.

mational degrees of freedom frozen in is similar in both elementary processes. Using these assumptions and eq. (19), a stacking energy of about − 4.5 kcal/mole can be estimated from the experimental σ value for the short-chain poly-A. Values of −5 to −7 kcal/mole were obtained from the transitions of high molecular weight polynucleotide systems[36] and of natural DNA[28].

At the large chain lengths of these last systems[28,36], as for multistrand helices in general[58,59], it is necessary to take into account a new type of statistical parameter that does not occur in single chains. If N becomes large, open rings of residues in the coil state inside closed helical regions can no longer be disregarded (Fig. 11). The difficulty of nucleation then depends essentially (apart from on the stacking energy) on the probability of meeting of the two ends of a ring

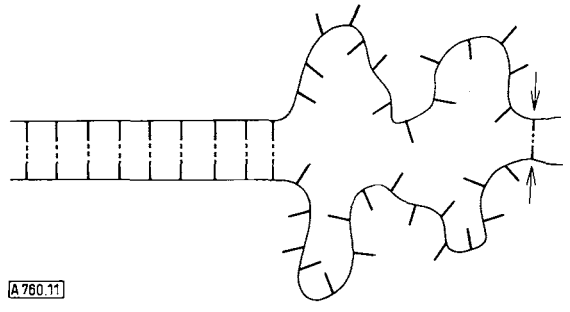

Fig. 11. Nucleation in a two-strand molecule having a long chain (see caption of Fig. 10 and text).

(arrows in the figure). This is inversely proportional to $(j+1)^{\alpha}$, where j is the number of segments in the ring (= number of unpaired residues in the two strands). The exponent α was found by computer simulation to be about 2[60]. If the probability of ring closure is taken into account, the theory predicts very sharp transition curves even at relatively small N, and true phase transitions of first and higher order occur for $\alpha \geq 2$[59–61].

Experimental evidence of phase transitions has actually been found for high molecular weight polynucleotides built up from chemically identical residues[61,62]. Natural DNA, which has extremely long chains, does not exhibit a phase transition, but gives a relatively flat melting profile. The reason for this lies in the inhomogeneity resulting from the sequence[63,64]. The double helix contains very stable as well as less stable base pairs. It must be expected in general that biopolymers in which different residues occur in rotation will give flatter melting curves than their conformational homologs built up from identical residues.

3.4. Outlook for Complicated Systems

An example of a more complicated system is the triple helix ⇌ coil transition of collagen[65]. Collagen is a relatively simple linear fibrous protein, in which three peptide chains are twisted into a three-stranded helix, for which simple model peptides with the same triple helix conformation have been synthesized. The dependence of the conformational transition on the chain length, which can never be determined in proteins, can be studied in these peptides[66,67]. The example of collagen is interesting, since here it is possible to explain the cooperativity in a real protein.

In general, a detailed understanding of the conformational transitions of proteins will be difficult even in cases where the steric structure in known. Since interactions occur in globular proteins in all directions between the residues, the linear Ising model can no longer be used, and the calculation of two-dimensional or three-dimensional models is possible only approximately and with a great deal of work.

A simplification results from the fact that most protein transitions appear to be "all-or-nothing" processes[68,69]. This conclusion was drawn in most cases from the observation that for each degree of transition, all the experimental quantities that are influenced by the transition consist additively of the

values for the two limiting structures (*e.g.* for the completely ordered and the completely coiled state). If intermediate states (*e.g.* semi-coiled molecules) were present, this additivity would not be expected for quantities that reflect complicated properties of the molecules (*e.g.* for the viscosity).

The all-or-nothing behavior of the large protein molecules points to a very high cooperativity. The transitions of the natural nucleic acids can be described better than those of proteins, since the nucleic acids usually have linear structures. Even here, however, their complicated and in most cases unknown sequence stands in the way of a quantitative understanding. On the other hand, the knowledge of the fundamental properties of simple cooperative transitions will suffice in most cases at least for a qualitative understanding of complicated systems.

Pyramidal Inversion

By Arvi Rauk, Leland C. Allen, and Kurt Mislow [*]

Pyramidal inversion is discussed from the point of view of recent theoretical and experimental investigations in an attempt to provide a unified description of this process. Quantum mechanical studies of pyramidal molecules indicate that the origin of the inversion barrier may be dependent on the degree of angular constraint. Effects due to the electronegativity of substituents on the inversion center, to the presence of adjacent lone pairs, and to inclusion of d-type functions in the basis set are discussed. The utility and limitations of molecular orbital calculations, vibrational spectroscopy, microwave spectroscopy, direct kinetic measurements, and dynamic nuclear magnetic resonance (DNMR) spectroscopy as means for determining barriers to pyramidal inversion are discussed in context with a review of the highlights of experimental observations on the subject. Ambiguities that arise in the interpretation of barriers determined by DNMR are explored in detail. Factors that affect the magnitude of inversion barriers are discussed separately in four broad categories: steric effects; effects of conjugation (including $(p-d)_\pi$ conjugation) and hyperconjugation; effects of angular constraint; and effects of heteroatomic substitution. In the last category, critical reference is made to the question of electronegativity vs. lone pair-lone pair repulsions, the problem of rotation vs. inversion, and the role of d orbitals.

1. Introduction

A molecule that contains a tricoordinate atom whose stable position is not in the plane defined by the three atoms directly bonded to it, may, in principle, exist in two conceptually distinct conformations which are related by a transposition of the tricoordinate atom from one side of the plane to the other. We describe such a molecule as being *pyramidal* and, without specifying mechanism, define *pyramidal inversion* as any process that effects the interconversion of the two conformations. The conformers shall also be referred to as *invertomers*.

We shall restrict discussion exclusively to those molecules in which pyramidal inversion occurs without bond formation or breaking, and which remain in their electronic ground state throughout the process. Two competitive modes occur. Classically, a vibrational mode leads to inversion through a coplanar or near coplanar arrangement of groups about the inversion center; the observed rate of inversion depends on the relative populations of vibrational energy levels above and below the top of the potential barrier to inversion. Non-classically, inversion can occur by quantum mechanical tunneling: a particle in a potential well penetrates the walls of the well and therefore, if the wall is of finite thickness, has a finite probability of existing on the other side of the wall. The rate of tunneling depends in a complex way on the mass of the particle, the shape of the potential well, the height and shape of the barrier and the energy of the particle [1,2]. In practice, however, tunneling is an important consideration only when at least one of the ligands bound to the central atom is hydrogen or deuterium, when the invertomers are not diastereomers, and at tem-

peratures at which vibrational levels within 5 or 6 kcal/mole of the top of the potential barrier are substantially populated.

The distinction between classical and non-classical inversion modes is unimportant for the discussion of *barriers* to pyramidal inversion, so long as it is remembered that the interpretation of *rates* of inversion, from which the barriers are obtained, is dependent on the relative importance of the two modes. Of the various possible methods for determining the magnitudes of inversion barriers (Section 3) only microwave spectroscopy depends explicitly on the observation of the quantum mechanical tunneling phenomenon which causes a splitting of the vibrational energy levels. The amount of splitting, and therefore the rate of inversion due to tunneling, can be computed from an analysis of the vibrational spectrum. Other methods, which ultimately depend on transition state theory to yield a value of the barrier, are valid only when the absence of quantum mechanical tunneling can reasonably be assumed.

In this review we attempt to provide a merging of theory and experiment. In Section 2 is discussed information on the inversion process that can only be derived theoretically, and in Section 3, non-empirical methods are incorporated along with empirical methods as means of determining the magnitude of barriers to pyramidal inversion. In Section 4 we discuss factors which affect the magnitude of the inversion barrier. We intend this as a critical review, with an emphasis on what we regard as salient features of current studies in this area, and no attempt has been made at presenting an exhaustive catalog of the vast literature.

2. Theoretical Investigation of Pyramidal Inversion

The investigation of a wide variety of pyramidal molecules by nonempirical (*ab initio*) molecular orbital calculations has yielded information on the intimate details of the inversion process that are not available from experimental research, and has provided theoretical support for *ad hoc* principles derived empirically. In this section, a description of the origin of the inversion barrier will not be accompanied by an analysis of the inversion process in terms of changes in overlap or atomic populations, since the usual (Mulliken) definition of these quantities is too sensitive to choice of basis set.

2.1. Inversion in Hydrides

Ammonia is thus far the only molecule for which it has been shown that the inversion barrier is quantitatively calculable within the molecular orbital (Hartree-Fock) approximation [3]. Consequently, some statements regarding the origin of the barrier may be made with considerable confidence. Except as indicated, the following results, as derived from the ammonia calculations, are consistent with calculations on CH_3^- [4], SiH_3^- [5], PH_3 [5,6], and SH_3^+ [5], and therefore may be general for simple unstrained pyramidal molecules.

The stable conformation of a molecule is determined by a subtle balance of attractive and repulsive forces [7]. A partitioning of the total energy of the molecule, E_T, into a sum of attractive and repulsive components [8] permits a determination of the difference in these terms between planar and pyramidal forms of the molecule:

$$E_T = V_{attr} + V_{rep} = (V_{ne}) + (V_{nn} + V_{ee} + T) \qquad (a)$$

where V_{attr} $(= V_{ne})$ is the attractive potential between electrons and nuclei, and V_{rep} is the sum of internuclear repulsions (V_{nn}), interelectronic repulsions (V_{ee}), and the kinetic energy of the electrons (T). Ammonia is more stable in the planar form with respect to the attractive term; the bond length is shorter, the bond overlap population is greater, and the bond stretching force constant is greater in the planar form. On the other hand, the pyramidal form is more stable with regard to the sum of the repulsive terms [9]. Since the net change in the repulsive terms is greater than the net change in the attractive term, the molecule is pyramidal and the barrier is said to be repulsive dominant. The well-known heuristic argument of *Gillespie* and *Nyholm* [10], that lone pair-bond pair repulsion results in a pyramidal geometry, is strengthened by this result.

Pyramidal structures for molecules isoelectronic with ammonia and phosphine have long been predicted by *Walsh*'s rules [11], which are an example of the empirical rule of stereochemical control by the highest occupied molecular orbitals.

2.2. Role of d Orbitals

The much discussed question of the role of d orbitals, especially where second or higher row atoms are involved, is relevant to the phenomenon of pyramidal

[7] For ammonia at its ground state equilibrium geometry, the attractive term of the total energy is 9.798484×10^4 kcal/mole while the sum of the repulsive terms is 6.269181×10^4 kcal/mole. Upon attaining a planar geometry, the attractive term increases by 164.41 kcal/mole and the sum of the repulsive terms increases by 169.48 kcl/mole. The difference in these changes, 5.07 kcal/mole, is the actual energy which is required to flatten the molecule.

[8] *L. C. Allen,* Chem. Phys. Letters *2,* 597 (1968).

[9] Both the interelectronic and the internuclear repulsions are greater in the planar form, overriding the much smaller variation in the opposite direction of the kinetic energy term.

inversion, when such atoms become the inverting centers. Inclusion of d-type functions[12] into the basis set has been shown[3] to be almost entirely responsible for the magnitude of the barrier in ammonia. The d-type functions play the role of polarization functions, allowing more freedom of movement for the electrons, rather than of d orbitals as they are usually understood. Although the data for PH_3 are not as definitive, it is highly probable that d-type functions are utilized only as polarization functions in this second row hydride also, as shown by a recent calculation[6]. Incorporation of d-type functions brings about virtually complete agreement between calculated and experimentally determined equilibrium geometries of both NH_3 and PH_3. The inversion barrier calculated[6] for PH_3 increases from 30.9 kcal/mole to 37.2 kcal/mole when polarization functions (p-type functions on H and d-type functions on P) are added to the basis set. In a comparative study[5] of SiH_3^-, PH_3, and SH_3^+, the calculated inversion barriers were found to increase from 36.0, 30.9, and 17.6 kcal/mole, respectively, to 39.6, 40.4, and 30.0 kcal/mole, respectively, upon the addition of d-type polarization functions to the basis set.

2.3. The Effects of Angular Constraint, Electronegativity, and Adjacent Lone Electron Pairs

It has long been anticipated[13], on the basis of valence force field arguments, that severe angular constraint, as occurs in three-membered rings, should have the effect of increasing the magnitude of the barrier to pyramidal inversion. Subsequent experimental work has confirmed this expectation (Section 4.3). Independent non-empirical calculations[14] of the inversion barrier of aziridine *(1)*, R = H, have yielded values of 18.3[15] kcal/mole and 15.5[16] kcal/mole.

(1)

(2)

The barrier has not been determined experimentally but is expected to be in this range (see Section 4.3). A component analysis of the data of *Lehn et al.*[15] shows that the barrier in aziridine is attractive dominant, in contrast to the results for unstrained systems (see Section 2.1). In the strained molecule, the pyramidal form is stable with regard to nuclear-electronic attraction but unstable with regard to the sum of the repulsive terms. Energy lost through decreased nuclear-electronic attraction is not compensated for by decreased repulsive interactions in the planar form. Component analyses of model systems, derived from fixing the HNH angle of NH_2F and one of the HNH angles of NH_3 at 80° during inversion, have yielded the same results[17].

The inversion barrier in oxaziridine *(2)* was computed[14,15] to be 32.4 kcal/mole and a component analysis of the data shows that, as in aziridine, the barrier is attractive dominant. The endocyclic oxygen appears to increase the absolute value of the changes in both attractive and repulsive terms. In a real system it is not possible to dissociate the role of the oxygen as an electronegative substituent, which influences the inversion barrier through an inductive withdrawal of electrons, from its role as an atom with lone pair electrons which interact with the lone pair of the nitrogen to a different extent in the pyramidal than in the planar form. The effect of electronegativity and angular constraint on inversion barriers has been simulated[17] in a model system, NH_2H', by altering the nuclear charge of H′ to values greater than and less than unity, and by varying the HNH angle. LCAO–MO–SCF calculations in this model system[17] suggest that the increase in the magnitude of the inversion barrier with increased electron withdrawal by the substituent on nitrogen may be sufficient to account for a large portion of the observed effect of heteroatomic substituents. To assess the relative magnitudes of the effect of electronegativity and lone pair repulsion in actual molecules, similar calculations were performed[17] on NH_2F', in which the nuclear charge of F′ was varied to values greater than and less than nine. The calculations[17] show that electronegativity has a much smaller effect on the barrier than does angular constraint or the presence of adjacent lone pairs, and that the effects of both electronegativity and adjacent lone pairs increase as angle constriction increases. A component analysis on both models indicates that, regardless of the electronegativity of H′ or F′, the barrier is repulsive dominant where angular constraint is absent or small, but becomes attractive dominant when the HNH angle is constricted to values approaching the internal bond angles of three-membered rings. This result is in complete accord with the detailed calculations on aziridine and oxaziridine[15]. The generality of this phenomenon, which suggests a different physical origin for the inversion barrier in strained than in unstrained systems, requires further examination.

3. Methods for the Determination of Barriers to Pyramidal Inversion

Any meaningful discussion of pyramidal inversion requires a knowledge of the amount of energy that must be put into a molecule to cause it to undergo an

inversion [18]. In the following subsections, brief descriptions are given of various methods that have been used to determine barriers to pyramidal inversion, with reference to the limitations of each method. A qualitative overview is required first to put these methods in the proper perspective. We consider on an equal footing such divers methods as rotation-vibration (microwave) and vibrational spectroscopy, dynamic nuclear magnetic resonance (DNMR) spectroscopy, kinetic methods, and molecular orbital (MO) calculations. There is seldom a decision to be made regarding the best method to use in determining the barrier for a particular system, since there is often little overlap in the range of applicability of the methods. The reliability of a method depends on the level of development of the theory supporting the method and the applicability of the theory to the problem at hand. For example, in MO theory, much of the formalism has been developed since the 1930's, but its practical application to even the simplest polyatomic systems has had to await the advent of large scale computers.

3.1. Molecular Orbital Methods for the Determination of Inversion Barriers

By these methods we mean theoretical methods that require no input of experimental data from the particular molecule whose inversion barrier is being determined, and which are based on the MO approach. Whereas in Section 2 we discussed information obtainable by nonempirical MO calculations regarding the *origin* of the inversion barrier, in this section we discuss the utility of MO calculations as means for deriving estimates of barrier *heights*. In principle, the MO methods have the widest applicability of any of the methods to be discussed. As indicated in Section 2.1, the nonempirical LCAO–MO–SCF method has yielded a quantitative value for the barrier of ammonia [3], and there is no reason to suppose that it cannot be extended to other inversion barriers. However, the inordinate amount of effort required to evaluate the properties of even the simplest invertible system precludes the investigation of most molecules of interest to the organic chemist. This difficulty can be partially surmounted in three ways:

a) Very high quality *ab initio* calculations may be performed on a simple model of the system of interest. The disadvantages of this approach, which arise because the numbers obtained for the model will not be strictly applicable to the actual system, are outweighed by the fact that a good deal of information can be obtained regarding the origin of the barrier and the effect on it of factors simulated by modifications to the model system, and by the reliability of the values so obtained.

b) Non-empirical calculations may be performed on actual systems if the basis sets are suitably chosen. Currently, a compromise must be reached with respect to size of systems to be studied, the size of the basis set (and hence the quality of the calculation); and the amount of computer time available. By this procedure, reasonably accurate barriers may be determined for systems involving, for example, three heavy atoms with their complement of hydrogen atoms.

c) For larger systems, recourse to semi-empirical schemes is necessary. Few reports of semi-empirical calculations of inversion barriers are on record [19].

The values of the barriers thus obtained are for the most part unreliable; however, *Dewar* and *Shanshal* [20] have recently shown that the reasonably sophisticated MINDO scheme can be parametrized to give qualitatively good inversion barriers for a variety of systems, including carbanions and radicals.

The calculated barrier is the difference in total energy of the pyramidal ground state (ideally at its calculated equilibrium geometry, but usually at the known experimental geometry) and the total energy of the planar transition state (ideally with calculated equilibrium bond lengths, but usually with the same bond length as in the pyramidal conformation) and refers to a molecule *in vacuo*, unperturbed by external forces. The number obtained is directly comparable to V_i which is determined by measurements in the gas phase by microwave or vibrational spectroscopy.

The chief advantage of the MO method is that barriers can be obtained for molecules which are too reactive or too unstable, or which have barriers that are too high or too low to be measured by empirical methods. In addition, many electronic properties of the molecule under study are obtained concurrently.

In approximate order of decreasing reliability, theoretical methods may be ranked as follows: LCAO–MO–SCF (Hartree-Fock) and LCAO–MO–SCF–CI, OCE–MO–SCF, two-electron semi-empirical schemes (MINDO, NDDO, CNDO/2), and one-electron semi-empirical schemes (EHMO).

3.2. Empirical Methods of Determining Inversion Barriers

The choice of the empirical method to be used in the determination of an inversion barrier hinges on the structure of the molecule and the magnitude of the barrier. Barriers in the range 0–5 kcal/mole are measurable by microwave spectroscopy, barriers in the range 10–20 kcal/mole by DNMR spectroscopy, barriers from 5–35 kcal/mole by infrared and Raman spectroscopy, and those in the range 20–40 by kinetic measurements. The ranges quoted are approximate and in some cases have been extended considerably by

[18] In the literature of this subject, the magnitude of the inversion barrier is generally expressed by $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, E_a, or V_i, depending on the method of determination and the preference of the authors.

[19] See, for example, a) *K. Issleib* and *W. Gründler*, Theoret. chim. Acta *6*, 64 (1966); b) *M. Jaro*, *P. Knowlton*, *J. E. Bissey*, *H. Goldwhite*, and *W. R. Carper*, Mol. Phys. *13*, 165 (1967); c) *T. P. Lewis*, Tetrahedron *25*, 4117 (1969); d) *M. S. Gordon* and *H. Fischer*, J. Amer. chem. Soc. *90*, 2471 (1968); e) reference [20].

[20] *M. J. S. Dewar* and *M. Shanshal*, J. Amer. chem. Soc. *91*, 3654 (1969).

special techniques. Except for kinetic measurements, the interpretation of the observations always requires an intermediate level of interpretation to relate the observed quantity to a kinetic quantity. A brief discussion of each method is given below. Results are given in Section 4, which deals with factors that influence barrier heights.

3.2.1. Measurement of Inversion Barriers by Microwave Spectroscopy

The influence of inversion on the rotational spectrum of a pyramidal molecule has been treated in detail by *Townes* and *Schawlow* [21] so that only a brief qualitative description need be given here. Inversion is detectable in the rotation-vibration spectrum by a splitting, ΔE, of the vibrational energy levels due to quantum mechanical tunneling, the frequency of inversion by tunneling being given by $\Delta E/h$. In its ground vibrational state, NH_3 inverts about 2.4×10^{10} times a second. The frequency of inversion, and hence the splitting of the vibrational energy levels, increases as the vibrational quantum number increases. In order to derive a number for the inversion barrier, an assumption is made regarding the shape of the potential function (force field) along some normal coordinate that leads to inversion, and the force field is parametrized to reproduce the observed microwave spectrum.

Microwave spectroscopy has been used to determine the barriers to inversion of the simple amines, NH_3 [21,22], CH_3NH_2 [23], and $(CH_3)_2NH$ [24]. In the last case the barrier was calculated by the Wentzel-Kramers-Brillouin method which assumes a double minimum potential function for inversion described by a cosine barrier connected by the Kramers connection formulas to increasing and decreasing exponentials.

Swalen and *Ibers* [22] have reviewed various types of potential functions that have been utilized to describe the inversion of ammonia and these will not be repeated here. Their own form of the potential function

$$V(q) = 1/2\, aq^2 + 1/2\, bq^4 + ve^{-(cq)^2} \qquad \text{(b)}$$

where a, b, c, and v are potential constants and q is the normal coordinate of the motion, has yielded the currently accepted value of the inversion barrier of ammonia. The quartic term does not markedly improve the agreement with experiment. The same form of the potential was used for determining the barrier in methylamine [23].

For all practical purposes, the applicability of microwave spectroscopy as a means for determining inversion barriers is limited to primary or secondary amines of relatively simple structure with barriers below 5 kcal/mole.

3.2.2. Barriers from Vibrational Spectroscopy

Vibrational spectroscopy is similar to rotational or microwave spectroscopy (Section 3.2.1) in that an assumption must be made regarding the shape of the potential function along some vibrational mode which leads to inversion. *Kincaid* and *Henriques* [13] used a parabolic potential function of the form

$$V = kh^2/2 \qquad \text{(c)}$$

where

$$k = 4\pi^2 \nu^2 \mu \qquad \text{(d)}$$

and h is the height of the pyramid, ν is the frequency of the vibration which leads to inversion, and μ is an expression for the reduced mass of the system. For a symmetric top molecule, XY_3, in which the Y–Y distances are invariant, this is given by

$$\mu = 3M_xM_y/(3M_y + M_x) \qquad \text{(e)}$$

where M_x and M_y are the masses of groups or atoms X and Y. This simple potential function tends to overestimate the value of V_i since the barrier is peaked rather than rounded.

The Costain-Sutherland [25] model [equation (f)] of a valence force field has had much greater success in the determination of barriers in symmetric top molecules [26]. The potential has the form

$$V = \frac{3}{2}\,(k_l\,(l-l_e)^2 + k_\delta\,(\alpha-\alpha_e)^2) \qquad \text{(f)}$$

where l_e and α_e are the equilibrium X–Y bond length and equilibrium YXY bond angles, respectively, and the force constants, k_l and k_δ, depend on the symmetric stretching frequency, ν_1, and symmetric bending frequency, ν_2, respectively. By symmetry, $(l-l_e)$ is related to $(\alpha-\alpha_e)$ so that equation (f) may be reduced to

$$V = K\,(\alpha-\alpha_e)^2 \qquad \text{(g)}$$

and the barrier is given by

$$V_i = K\,(2\pi/3-\alpha_e)^2 \qquad \text{(h)}$$

Other types of double-well potential functions, specifically applied to the ammonia molecule, have also been used [22,27].

Vibrational spectroscopy, as a method for determining barriers to inversion, differs from microwave spectroscopy in that the parameters of the assumed force field are obtained by fitting as many vibrational levels as can be observed, rather than by fitting the splittings of the first and second vibrational levels. Vibrational spectroscopy is therefore applicable to molecules where the splitting of energy levels is immeasurably small, such as hydrides with large barriers to inversion, *e.g.*, PH_3 or AsH_3, or molecules in which three heavy atoms or groups are bonded to the inverting center. For molecules with high barriers, a large extrapolation is necessary to obtain a value for the barrier height, and the value so obtained is usually quite sensitive to the equilibrium geometry of the molecule.

3.2.3. Direct Kinetic Measurements of Inversion Barriers

Inversion, which is a unimolecular reaction, obeys first order kinetics[28],

$$\ln \frac{(P_t - P_\infty)}{(P_0 - P_\infty)} = kt \qquad \text{(i)}$$

where P_t is an observable directly related to the concentration of the invertomers, such as specific rotation or absorbances (NMR, IR, UV) due to invertomers, at time t. Application of this direct method for determining the rate constant for inversion is limited to compounds whose invertomers are diastereomers or enantiomers with distinguishable physical properties, which can be obtained as a nonequilibrium mixture, and which invert at a convenient rate in an accessible temperature range.

Inversion barriers can be estimated from the rate constants by the following expressions. We can write

$$\frac{d\ln k}{dT} = E_a/RT^2 \qquad \text{(j)}$$

or

$$k = Ae^{-E_a/RT} \qquad \text{(k)}$$

where k is the unimolecular rate constant for inversion at temperature T, E_a is the Arrhenius activation energy, and A is the frequency factor. If the rate constant at a certain temperature is known, then the free energy difference, $\Delta G^{\ddagger}$, between ground and transition states can be calculated from the Eyring equation, assuming a transmission coefficient of unity,

$$k = \left(\frac{kT}{h}\right) e^{-\Delta G^{\ddagger}/RT} \qquad \text{(l)}$$

In solution, the enthalpy of activation, $\Delta H^{\ddagger}$, is related to the Arrhenius activation energy by the relation

$$\Delta H^{\ddagger} = E_a - RT \qquad \text{(m)}$$

The entropy of activation, $\Delta S^{\ddagger}$, a measure of the relative degree of disorder in the transition state, is defined by

$$\Delta S^{\ddagger} = \frac{\Delta H^{\ddagger} - \Delta G^{\ddagger}}{T} \qquad \text{(n)}$$

For the thermal inversion process, where no dissociation occurs in the excited state, $\Delta S^{\ddagger}$ and log A values are expected to be, and are usually found to be, close to zero and 13, respectively[29].

3.2.4. Determination of Inversion Barriers by Dynamic Nuclear Magnetic Resonance (DNMR) Spectroscopy

The DNMR method for determination of inversion barriers differs from direct kinetic methods solely in the manner in which the rate constant is obtained. In contrast to the direct methods, which involve a measurement of the rate of conversion of one invertomer to another under necessarily nonequilibrium conditions, the DNMR method depends on the interpretation of observed spectral changes in terms of the rate of exchange of the two invertomers only under equilibrium conditions.

The theory and application of NMR spectroscopy to the measurement of intramolecular exchange processes has been reviewed elsewhere[31–34]. Two approaches are in common use: that employing the coalescence phenomenon, and total line shape analysis. For the former, as the simplest example of many, equation (o) gives the rate of exchange, k_c, at the coalescence temperature, T_c, provided that the two exchanging groups

$$k_c = \left(\pi/\sqrt{2}\right) \Delta\nu_{AB} \qquad \text{(o)}$$

are uncoupled, that the signals (A and B) are of equal intensity, and that the limiting chemical shift difference, $\Delta\nu_{AB}$, is much greater than the linewidth of the signals in the absence of exchange[35]. Where conditions are optimum, this approximate and rapid procedure yields substantially the same value of $\Delta G^{\ddagger}$ as does the more laborious complete line shape analysis which is otherwise necessary to give rates of exchange from which activation parameters can be calculated.

Numerous computer programs exist for performing a complete line shape analysis[36]. It is therefore a

[28] *A. A. Frost* and *R. G. Pearson*: Kinetics and Mechanism, 2nd. Edit., Wiley, New York 1961.

[29] For a remarkable exception to this statement, see *Jautelat* and *Roberts* [30], who found that for *(3)*, R = CH_3, log A and $\Delta S^{\ddagger}$ ranged from 16.33 to 21.67, and from 14 e.u. to 38 e.u., respectively, depending on solvent.

trivial matter to convert a temperature-dependent NMR spectrum to the appropriate activation parameters. However, the interpretation of the origin of the barrier requires careful assessment of such extraneous factors as specific solvent effects, solute-solute interactions (dimerization and higher association), the constitutional integrity of the molecule in solution, and competitive intramolecular conformational processes, all of which may impart a temperature dependence to the observed spectrum that is not at all relevant to the barrier under investigation. The effects of the first three factors can usually be disclosed by standard procedures such as variation of solvent, dilution experiments, and observation of reversibility of spectral changes, among others. The fourth effect is far more difficult to identify, especially if, as will concern us in Section 4.4, the competing processes are intramolecular inversion of configuration and hindered rotation about one or more bonds to the tricoordinate center.

The magnitude of the barrier is determined from an analysis of the observed temperature-dependent spectral changes due to the effective averaging of the environments of diastereotopic groups in the molecule. If, in principle, both inversion at the tricoordinate center and rotation about some or all of the bonds to the tricoordinate center must be rapid on the NMR time scale in order to average out nonequivalent environments, two major assumptions have to be made in order to assign the origin of the rate-determining process:

a) The intrinsic chemical shift difference is sufficiently large so that, even under conditions of rapid rotation but slow inversion, a chemical shift difference in the diastereotopic groups is still detectable.

b) In the potential surface for rotation-inversion, discrete transition states occur for rotation and inversion, rather than a single transition state for both rotation and inversion.

Given these assumptions, a decision may be made regarding the origin of the barrier by considering changes that occur in the magnitude of the barrier as a function of substituents. However, this now requires further, albeit reasonable, assumptions concerning the probable effect of the substituents on the barrier, namely that bulky groups [37], and groups which can delocalize the lone pair of electrons on the central atom [38], lead to a lower inversion barrier and a higher barrier to rotation.

Assumption (b) could be resolved by determining the potential surface for rotation-inversion by detailed quantum mechanical calculation on the system in question. The complete surfaces for the model compounds $^{-}CH_2SH$ [45], $^{-}CH_2S(O)H$ [46], and $^{-}CH_2S(O_2)H$ [47] have been calculated by the nonempirical LCAO–MO–SCF method using a minimal Gaussian basis set. In every case, a single transition state for rotation-inversion was found. However, although gross conformational features are reasonably well obtained by this procedure, it is not known whether a single transition state for rotation and inversion would be obtained from more accurate calculations. Assumption (b) could also be verified by the observation of two discrete barrier processes, *i.e.*, two discrete coalescence phenomena.

Failure to observe more than one coalescence phenomenon where competitive processes can in principle occur means that one of the following three circumstances may obtain. First, assumption (b) may be invalid, *i.e.*, there may only be a single transition state to inversion-rotation. Second, two or more transition states may exist, but $\Delta G_c^{\neq}$ for only one lies within the explored range of measurements. Third, two transition states may exist, and both barriers may be in the explored range of measurements, but assumption (a) may not be valid, *i.e.*, the chemical shift difference in diastereotopic groups under conditions of rapid rotation but slow inversion may be too small to be detected at any temperature (accidental degeneracy) and any observed coalescence phenomenon is ascribable to the rotational mode; conversely, under conditions of rapid inversion but slow rotation, accidental degeneracy may lead to a single coalescence phenomenon ascribable to the inversional mode. Unfortunately, there is no way of predicting the magnitude of the chemical shift difference between diastereotopic groups, and as to precedent, numerous cases are on record of accidental NMR equivalence of such groups. The point cannot be overemphasized that, unless two distinct coalescence phenomena are observed, and in the absence of compelling supporting evidence, the identity and magnitude of the inversion barrier cannot be regarded as *rigorously* established. In the case of the inversion-rotation dichotomy under discussion, we know of no report on record in which both barriers (*i.e.* coalescence phenomena) have been observed.

4. Factors That Affect the Magnitude of the Inversion Barrier

It will be convenient to group major factors that influence the magnitude of the inversion barrier into four broad categories: steric effects; effects of con-

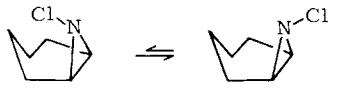
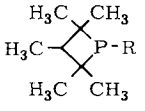
jugation or hyperconjugation; effects of angular constriction; and those due to heteroatomic substitution. The well-known increase of inversion barrier heights in a given group of the periodic table with increasing atomic numbers[26] (*e.g.*, $AsR_3 > PR_3 > NR_3$) will not be the subject of a detailed comparative analysis in the absence of a sound theoretical basis at this time. The less well defined effects of solvent on inversion barriers[48–51] and other special effects[52] will be considered outside the scope of this review.

4.1. Steric Effects on Inversion Barriers

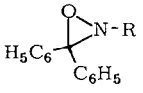


Steric size manifests itself as an electronic repulsion (due to the Pauli exclusion principle) between nonbonded groups. As the steric requirement of a substituent increases, the pyramidal ground state is destabilized relative to the less crowded transition state[53], with a resultant decrease in the barrier to inversion.

Steric acceleration of the rate of inversion in *N*-alkylaziridines has been confirmed by several studies[54–57]. For example, barriers of inversion of aziridines *(1)* decrease in the order of increasing steric requirement of R: $CH_3 < C_2H_5 < i\text{-}C_3H_7 \ll t\text{-}C_4H_9$[56,57]. Similarly, whereas simple *N*-haloaziridines are pyramidally



(1) *(3)*



stable at room temperature[58–60], the relatively facile *cis* → *trans* conversion of *(4)* has been attributed to steric crowding in the *cis* conformation[61]. Steric arguments also explain the different inversion rates in the 1-methylphosphetane *(5)*, R = CH_3, which shows

(4)

(5)

(6)

approximately 5% stereomutation after heating for four days at 162 °C, and the 1-*t*-butyl derivative *(5)*, R = $t\text{-}C_4H_9$, in which inversion is readily followed in the temperature range 118 to 157 °C[62]. The difference in steric requirements of a methyl group and a *t*-butyl group is also reflected in the barriers to inversion of diphenyloxaziridines[63]: the activation energy for pyramidal inversion of the methyl derivative *(6)*, R = CH_3, is 6.4 kcal/mole larger than the inversion barrier of the *t*-butyl derivative *(6)*, R = $t\text{-}C_4H_9$, (E_a = 28.4 kcal/mole).

4.2. Conjugative and Hyperconjugative Effects on Inversion Barriers

For reasons of ease in visualization, conjugation and hyperconjugation are often discussed in terms of changes in hybridization of atomic s, p, and d orbitals, rather than in terms of the more physically reasonable canonical Hartree-Fock molecular orbitals. The LCAO procedure is only one of many ways of arriving at an expansion of the one-electron wavefunctions (MO's), and the correspondence between MO's and AO's becomes increasingly indistinct as one passes from the occupied MO's of lowest energy to the higher occupied (valence) MO's. In this context, the question of the participation of atomic d orbitals is irrelevant. Within the valence bond framework, however, it is often desirable to invoke participation of "unoccupied d orbitals" to rationalize the accommodation of extra electrons in the vicinity of a nucleus. Thus, in this section, our use of the term "$(p-d)_\pi$ conjugation" is consistent with the useful and generally accepted *ad hoc* valence bond description of electronic structure, and is not to be regarded as a commentary on the controversial question of the participation of d orbitals in bonding to second row atoms.

During inversion, the hybridization of the bonding orbitals at the inverting center may be qualitatively regarded as changing from sp^3 to sp^2, and that of the lone pair of electrons from sp^3 to p. Any factor which favors the rehybridization process, such as π delocalization of the lone pair, tends to flatten the pyramid and thus to lower the barrier to inversion. Adjacent unsaturated systems lead to significantly lower barriers

[53] The transition state is closer to planarity than one or both of the ground states. It is not planar, however, when the invertomers are diastereomers, or when they are enantiomers in chiral media; *i.e.*, planarity obtains only in automerization reactions or in the interconversion of enantiomers under achiral conditions.

to inversion at nitrogen and phosphorus. The near planarity of the amide bond is well known [64]. Although the geometry at nitrogen in *(7)*, R = *p*-BrC_6H_4, is pyramidal [66] by reason of angle strain, as will be discussed in Section 4.3, slow inversion has not been detected in a variety of *N*-acylaziridines [*(7)*,

(7)

(3)

R = C_6H_5, *p*-$CH_3OC_6H_4$, *p*-$(CH_3)_2NC_6H_4$, *p*-$NO_2C_6H_4$ [67]; R = CH_3 [55]], suggesting that $\Delta G_c^{\neq} <$ 6 kcal/mole [67]. For *(7)*, R = OCH_3, and *(7)*, R = $N(CH_3)_2$, barrier values of $\Delta G_c^{\neq}$ = 7.6 and 10.8 kcal/mole, respectively, were observed [55].

The free energy of activation for inversion of *(3)*, R = CH_3, is in the range 17.7–18.8 kcal/mole [30] or 20.5 kcal/mole [59]. By contrast, *N*-arylaziridines have barriers which are less by 5 to 10 kcal/mole (Table 1) [34]. This effect provides evidence that an

[a] Calculated from the Eyring equation.

adjacent aryl group lowers the barrier to inversion at nitrogen, presumably by a conjugative mechanism.

In phosphines, the effect of aryl substitution is not as pronounced as in amines; a recent study [68] has shown that the free energy change, $\Delta G_{130}^{\neq}$, is roughly proportional to the number of aryl substituents, each aryl group decreasing the value of $\Delta G^{\neq}$ by approximately 2–3 kcal/mole (Table 2).

Table 2. Inversion barriers [68] for $R_1R_2PCH_3$.

Comparison of the data in Tables 1 and 2 further reveals that the magnitudes of the barriers to inversion in arylphosphines are far less sensitive to *p*-substitution than are barriers in arylaziridines. The same insensitivity was observed in a study of inversion in arylsulfoxides [69]. The conclusion is inescapable that the rate of inversion at an element from the second row is less sensitive to conjugation than that at an element from the first row. We note that, as the electron-withdrawing power of the *p*-substituent increases, the inversion barrier decreases, and that a Hammett-type linear free energy relationship correlates the rates for inversion at nitrogen [34], phosphorus [68], and sulfur [69].

A striking example of the lowering of the inversion barrier due to $(2p-3p)_\pi$ conjugation occurs in the phosphole system. A barrier of $\Delta G_{25}^{\neq}$ = 16 kcal/mole has been found [70] for *(8)*, which represents a reduction of about 25 kcal/mole from barriers in the analogous saturated systems. Conjugation of the lone pair of

(8)

electrons on phosphorus with the ring $2p_\pi$ electrons is probably facilitated by achievement of the favorable $4n+2$ ($n = 1$) π electron configuration in the planar (transition state) conformation. An assumption of coplanar geometry at nitrogen has been made to fit the observed microwave spectrum of the analogous nitrogen heterocycle, pyrrole [71]. The barrier of 35.1 kcal/mole calculated for 2-azirene [16] exemplifies the converse, a raising of the barrier by antiaromatic behavior ($4n$ π electron configuration) in the transition state.

Delocalization of the lone pair electrons into empty d orbitals by $(p-d)_\pi$ conjugation when the inversion center is directly bonded to a second row atom has been postulated to explain lowering of inversion barriers in systems such as 1-sulfenylaziridines [41,72], diphosphines [73,74], diarsines [74,75], and thiolsulfinates [76] (see also Sections 3.2.4 and 4.4). planar structure at nitrogen in *(9)* [77] and *(10)* [78] may also be explained by $(p-d)_\pi$ conjugation involving the lone pair on nitrogen and the d orbitals of

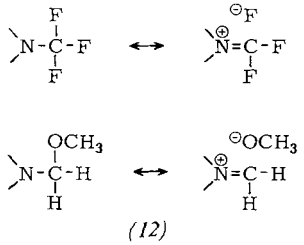
(9) *(10)*



silicon and phosphorus, respectively. A striking example of the lowering of the inversion barrier due to $(3p-3d)_\pi$ conjugation is encountered in *(11)*, where

(11)

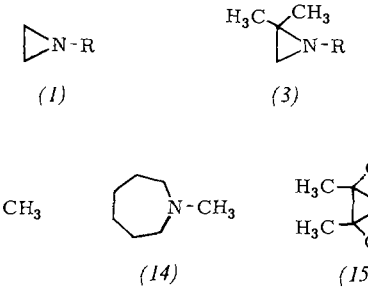
the inversion barrier is found [79] to be significantly lower than that of comparable non-silicon containing phosphines. Electronegativity effects undoubtedly contribute to the observed lowering of these barriers.

Electronegative groups *alpha* to the inversion center can also assist in π delocalization of the lone-pair electrons by hyperconjugation, as in *(12)*. Thus, trifluoromethyl-substituted aziridines [80] have substantially faster rates of inversion than alkyl-substituted aziridines, presumably because of C–F hyperconjugation. Similarly, in cyclic hydroxylamines [81] a

(12)

CH_2OCH_3 substituent on nitrogen has been found to lower the barrier relative to an *iso*-propyl substituent, presumably because of C–O hyperconjugation.

4.3. Effects of Angular Constraint



As a rule, simple amines undergo inversion at rates that are too fast to be measured by DNMR, and few measurements of barriers have been reported. Some of these are collected in Table 3. Values of the barrier lie in the range 4–8 kcal/mole.

Table 3. Inversion barriers in simple amines.

Amine	Barrier (kcal/mole)	Ref.
ammonia	V_i = 5.8 (mw) [a]	[22]
methylamine	V_i = 4.8 (mw)	[23]
dimethylamine	V_i = 4.4 (mw)	[24]
trimethylamine	V_i = 7.46 (vs) [b]	[26]
(13)	$\Delta G^{\ddagger}_{-100}$ = 8 (DNMR)	[82]
(14)	$\Delta G^{\ddagger}_{-125}$ = 7 (DNMR)	[82]

[a] Microwave spectroscopy. [b] Vibrational spectroscopy.

Early calculations led to the expectation [13,83] that severe angular constraint, as occurs in aziridines, should stabilize nitrogen pyramids at ordinary temperatures, and although the subsequently observed effect is not as dramatic as anticipated, angular constraint does lead to a substantial increase in the barrier to inversion. Thus, a lower limit of 11.6 kcal/mole has been estimated [84] for the inversion barrier of aziridine itself, and E_a = 10–12 kcal/mole has been measured [85] for *(15)*; the last value is also considered

(1) *(3)* *(13)* *(14)* *(15)*

a lower limit. *N*-Alkylaziridines apparently have considerably higher barriers, E_a = 19 kcal/mole [86] and $\Delta G_c^{\ddagger}$ = 17.7–20.5 kcal/mole [30,59] having been reported for *(1)*, R = CH_3, and *(3)*, R = CH_3, respectively.

The increased activation energy for inversion due to the angular constraint imposed by a three-membered ring is also apparent in cyclopropyl anions which are known to be capable of retaining configuration [87], and in cyclopropyl radicals which exist, at least transiently, as non-planar entities [88,89]. Inversion

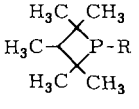
barriers of 20.85 kcal/mole [90] and 5.46 kcal/mole [4b] have been calculated for cyclopropyl and methyl anions, respectively. Theoretical [4b,91] studies of the methyl radical indicate that this species is planar, in agreement with experimental (ESR) data [92,93] on a variety of alkyl radicals, including the parent CH_3 [94].

Similarly, while theoretical [95] and experimental [96] evidence on H_3O^+ imply that unstrained oxonium ions are either planar or very shallow pyramids, an inversion barrier of 10 ± 2 kcal/mole has been reported [97] for *(16)*.

(16)



(17)

A rough estimate for the angle strain effect as a function of bond angle may be obtained by comparing the barriers in a series of cyclic tertiary amines, as given in Table 4. It is immediately apparent that, although the barrier for the azetidine derivative *(17)*, R = CH_3, may in part be lowered because of buttressing effects of the two methyl groups on C-3, the effect of angle strain on the barrier falls off rapidly as the CNC angle constriction is relaxed.

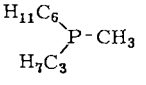


Table 4. Barrier height as a function of ring size.

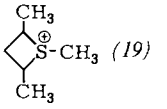
Compound	Ring size	Barrier height (kcal/mole)	Ref.
(1), R = CH_3	3	19	[86]
(17), R = CH_3	4	8.8	[59]
(13)	5	8.0	[82]
(14)	7	7.0	[82]
(5), R = CH_3	4	*ca.* 40	[62]
(18)	—	35.6	[68]

An indication that angle constraint is an important factor in stabilizing phosphorus pyramids is also seen from the last two entries in Table 4. The pyramid in the four-membered ring phosphorus system *(5)* is more stable than that in the acyclic phosphorus compounds *(18)*, even though buttressing effects in *(5)*,



(5)

(18)

R = CH_3, would tend in the direction of lowering the barrier. Similarly, racemization of unstrained sulfonium salts is conveniently followed [98,99] in the temperature range 50–70 °C, but isomers of *(19)* have been reported [100] not to undergo pyramidal inversion up to the temperature of decomposition, 80 °C.

(19)

4.4. Effects of Heteroatomic Substitution

The following attributes of heteroatoms adjacent to an inverting center have been invoked to explain the observed effects on the inversion barrier:

1. The inductive (electronegativity) effect of the substituent.
2. The effect of lone pair-lone pair interactions.
3. Use of substituent d orbitals for delocalization of the lone pair of electrons of the inverting center.
4. Delocalization of the lone pair of electrons of the substituent into d orbitals of the inverting center.

Both increasing electron withdrawal from the inverting center by a non-conjugative mechanism [101] (Section 2.3) as well as the presence of non-bonded electron pairs on the substituent [72,102] are expected to lead to increased inversion barriers. In no instance has it been possible to assess convincingly from empirical studies the relative importance of lone pair-lone pair repulsions and electronegativity of the heteroatom to the increased barrier height, although theoretical studies (Section 2.5) indicate that the former effect may be dominant in halides. The question of torsional angular dependence of the inversion barrier (in the case of axially non-symmetric heteroatomic substituents) remains unanswered. The effects due to use of d orbitals have been mentioned in Section 4.2 and are further discussed below.

A lively controversy exists with regard to the interpretation of the origin of barriers observed by DNMR (Section 3.2.4) in heteroatomically substituted pyramidal molecules. Due to the possible existence of substantial torsional barriers about some heteroatom-heteroatom bonds, an ambiguity arises in assigning the origin of the observed rate process to either rotation or inversion whenever the bond to the substituent containing the heteroatom is not axially symmetric.

The following discussion on heteroatomic effects is subdivided into two parts, the first dealing with in-

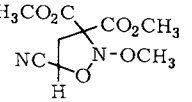
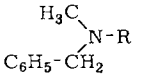
version at tricoordinate, first row atoms in which the main quantum number of the inverting atom is 2, the second dealing with inversion at second or higher row atoms (main quantum number greater than 2).



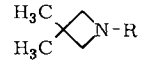
4.4.1. Inversion at First Row Atoms

Heteroatomic substitution slows inversion at nitrogen, as has been shown for five- or six-membered ring hydroxylamines [49,81,103] and hydrazines [104–109]. The effects on the barrier of heteroatomic substitution and angular constraint are compounded in *N*-haloaziridines [58–61], *N*-aminoaziridines [110,111], diaziridines [112], and oxaziridines [63,113–115]. In some cases invertomers have been separated [58b,61,63,103,112,114,115].

Multiple heteroatomic substitution leads to a marked increase in inversion barriers, even in unstrained systems. The powerful effect of fluorine on the stability of the pyramidal structure is seen in NF_3 and CF_3: a value of 42 kcal/mole [26], estimated from vibrational frequencies, for the inversion barrier of NF_3 has recently been revised [116] upward to 56–59 kcal/mole, and a barrier of 27.4 kcal/mole has been calculated [117] for inversion of CF_3 radical, which is known to be pyramidal from ESR data [118], in contrast to the unsubstituted methyl radical which is planar (Section 4.3). In addition, a recent study [119a] of some alkyldifluoroamines has yielded a lower limit of 18.0 kcal/mole for the barrier to inversion ($\Delta G^{\ddagger}$) at the nitrogen atom attached to the tertiary carbon atom in *(20)*, and barriers (E_a) in the range 29–30 kcal/mole have been found [103] for the interconversion of invertomers



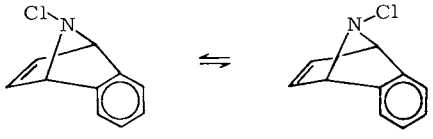
(20)



(21)

of *(21)*. The observed [119b] pyramidal stability of $-CFClBr$ in aqueous solution is a further example of this effect

In principle $(p-d)_\pi$ delocalization of the nitrogen lone pair is possible in *N*-haloaziridines and this effect was originally proposed to rationalize the apparent rapid inversion in *N*-chloroaziridines [120] (since shown to be slow [58,59,61]) and in *(22)*, R = Cl [102]. However, the low barrier (11.9 kcal/mole) of *(17)*, R = Cl [59], as measured by DNMR, is in sharp contrast to



(22)

(17)

the high inversion barrier ($\Delta G^{\ddagger}$ = 23.5 kcal/mole) [121] of *(23)*, as measured by direct kinetics, even though the internal bond angles at nitrogen are similar in the two compounds. Relatively high rates of inversion

(23)

have been reported [72] for aziridines *(1)* with sulfur and phosphorus centered groups attached to nitrogen, and are in the order [72]: $R = P(O)(C_6H_5)_2 \gg S(O_2)C_6H_5 > S[2,4\text{-}(NO_2)_2\text{-}C_6H_3] > SC_6H_5 > S(O)C_6H_5$. Once again, $(p-d)_\pi$ delocalization could here be invoked; unfortunately, in no case where a coalescence temperature was observed can slow rotation about the N–S or N–P bond be ruled out as the rate determining step, for reasons discussed below.

Barrier phenomena (10–20 kcal/mole) have been observed in *acyclic* hydroxylamines [40,102], hydrazines [43,44,122], sulfonamides [123,124], sulfinamides [125], sulfenamides [39,124,125,126], and aminophosphines [42,127,128]. The interpretation of the ori-

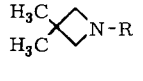
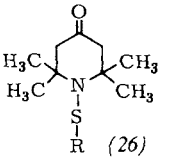
gin of the barrier in these molecules is ambiguous, as discussed in Section 3.2.4. Most of the barriers observed in acyclic molecules have been attributed to hindered rotation.

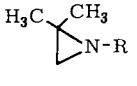
Assuming the validity of assumption (a) of Section 3.2.4, the values of $\Delta G^{\ddagger}$ obtained set upper limits on the barriers to pyramidal inversion in these compounds. However, in none of these systems has there been experimental verification of the validity of this assumption, and it follows that there is as et no unambiguous DNMR estimate of a barrier to inversion in acyclic heteroatom-substituted nitrogen compounds. The conformational interconversion of diastereomers of *(24)*, $\Delta G_c^{\ddagger}$ = 17.2 kcal/mole at 68 °C, ascribed to nitrogen inversion [123], may alternatively be a manifestation of rotational diastereoisomerism, as in *(25)* [124,126].



(24)



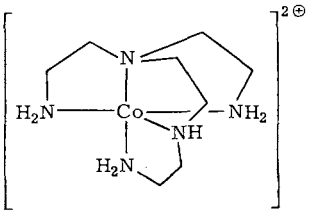
(25)



A similar ambiguity in interpretation exists for cyclic amines with an exocyclic heteroatomic substituent without axial symmetry. The stereomutations of sulfenamides *(17)*, R = $SCCl_3$ or SC_6H_5, and *(26)*, R = CCl_3, C_6H_5, or CH_3, were attributed [41] to rotation about the N–S bond. The observed steric effects in *(3)*, R = $SCCl_3$, $\Delta G_c^{\ddagger}$ = 9.1; *(3)*, R = S-*t*-C_4H_9, $\Delta G_c^{\ddagger}$ = 12.2; *(3)*, R = SC_6H_5, $\Delta G_c^{\ddagger}$ = 12.2; and *(3)*, R = S–CH_3, $\Delta G_c^{\ddagger}$ = 13.3 kcal/mole [41], are in the direction expected for an inversion process but small enough to render this interpretation uncertain. Similarly, low barriers observed [72] in the aziridines *(1)*, R = $P(O)(C_6H_5)_2$, $S(O_2)C_6H_5$, 2,4-$(NO_2)_2C_6H_3S$, SC_6H_5, $S(O)C_6H_5$, may be ascribed to rotational

(17)

(26)

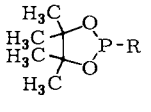


(3)

(1)

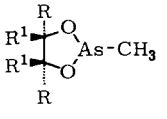
motions, with inversion being an invisible (by DNMR) process, possibly of much higher energy, in consonance with the high barriers found for 1-haloaziridines. In the single case *(1)*, R = $S(O)C_6H_5$, where chemical shifts due to diastereotopic protons were observed at room temperature, the magnetic nonequivalence was assumed [72] to be due to the asymmetric sulfoxide grouping.

Hydrogen exchange at nitrogen coordinated to transition metals has been found to proceed with a high degree of stereospecificity. For example, in *(27)*, hydrogen exchange occurs at a rate that is 2.3×10^6



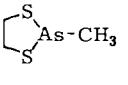
(27)

times faster than the rate of racemization [129]. Since nitrogen is the only center of asymmetry in the complex, the nitrogen pyramid formed after abstraction of the proton is remarkably stable to inversion. Similar, though less dramatic, results have been obtained in complexes of other transition metals [130,131].



4.4.2. Inversion at Second or Higher Row Atoms

Tricoordinate sulfur compounds such as sulfoxides [69,132], sulfinate esters [133], sulfinamides [134], sulfilimines [135], and sulfites [136] possess stable sulfur pyramids at ordinary temperatures. A study [69,132] of pyramidal inversion in sulfoxides yielded barriers ($\Delta H^{\ddagger}$) in the range 35–42 kcal/mole. Similarily, it has been assumed in studies involving these compounds that aminophosphines and chlorophosphines do not invert at phosphorus [42,127,128].



In view of the pyramidal stability of the majority of compounds containing tricoordinate second or higher row atoms, numerous reports in recent years of surprisingly labile P, As, and S pyramids must therefore be critically examined. Although no inversion was

(28)

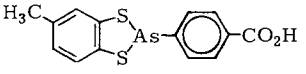
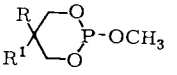
[135] For example: a) *J. Day* and *D. J. Cram,* J. Amer. chem. Soc. *87*, 4398 (1965); b) *D. R. Rayner, D. M. v. Schriltz, J. Day,* and *D. J. Cram, ibid. 90*, 2721 (1968).

[136] For example: a) *J. G. Pritchard* and *P. C. Lauterbur,* J. Amer. chem. Soc. *83*, 2105 (1961); b) *P. C. Lauterbur, J. G. Pritchard,* and *R. L. Vollmer,* J. chem. Soc. *1963*, 5307

observed [137] in *(28)*, R = OCH_3, $N(CH_3)_2$, OC_6H_5, C_6H_5, up to 150 °C, the structurally similar compounds *(29)*, R = R′ = H and R = R′ = CH_3, and *(30)* showed [138] chemical shift equivalence of the *cis* and *trans* groups at the 3 and 4 ring positions. However, accidental equivalence is more reasonable than the proffered [138] explanation of rapid inversion or coplanar geometry at arsenic, since invertomers of *(31)* (up to 110 °C) and *(32)* (at room temperature) can be

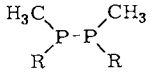


(31)

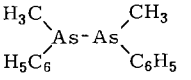


(32)

distinguished in the NMR spectrum [139], and since *(33)* has been resolved [140]. The ready equilibration [141,142] of isomers of *(34)*, R = *t*-C_4H_9, R′ = H; R = CH_3, R′ = CH_2Cl, may be ascribed to traces of methanol in the system [143].

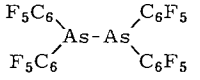


(33)

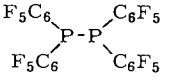


(34)

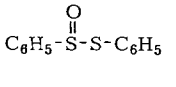
Barriers ($\Delta G^{\ddagger}_{150}$) of 22.5 to 24 kcal/mole have been measured [73,74] for a series of diphosphines *(35)*, R = *p*-$CH_3C_6H_5$, *p*-$CF_3C_6H_5$, C_6H_5, and $CH_2C_6H_5$, and a barrier (E_a) of 27 ± 1 kcal/mole for the diarsine *(36)* [74,75], all by DNMR. The spectral changes are



(35)

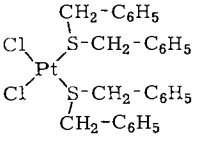


(36)



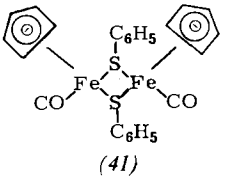
consistent with inversion at phosphorus and arsenic on the assumption that rotational barriers in these compounds are low. The separation of isomers of the diarsine *(37)* by sublimation *in vacuo* at 140 °C and 230 °C [144] suggests that a substantial barrier to inversion *and* rotation exists for this compound. In principle, the *gauche* isomer should display two sets of

(37)



(38)

(39)



pentafluorophenyl resonances, but this was not observed. The analogous diphosphine *(38)* showed only a single set of ^{19}F resonances, implying one stable isomer. The postulate [73,74,75] that $(3p-3d)_\pi$ or $(4p-4d)_\pi$ resonance is operative in lowering the barrier to inversion in the diphosphines and diarsines is strongly supported by the thermal racemization [76] of the analogous compound *(39)*, but not by the pyramidal stability of *(37)* [144].

Transition metal complexes where some of the ligands are organosulfides constitute another class of heteroatom-substituted tricoordinate centers that are capable of inversion of configuration. An activation energy of 18.0 kcal/mole was found [145] for the *cis*-bis(dibenzyl sulfide)platinum(II) complex *(40)* by NMR. Because of the low activation energy inversion was postulated [145] to proceed through a "partially dissociated transition state" in which both lone pairs of the sulfide are equally delocalized into the metal orbitals. The *trans*-complex *(40)* was found to invert more rapidly

(40)

than the *cis*-complex. A substantially higher activation energy barrier of 30.7–31.8 kcal/mole was measured [146] for inversion at sulfur in *(41)*.

(41)

The effect (magnitude and direction) on the inversion barrier of the fourth attribute of heteroatomic substituents mentioned at the beginning of this section, *i.e.*, delocalization of the lone pair(s) of electrons of the substituent into d orbitals of the inverting center, is uncertain. Although $(2p-3d)_\pi$ conjugation apparently contributes to the stabilization of carbanions adjacent to phosphorus and sulfur [147], no racemization of sulfoxides is observed [148,149] during base-catalyzed hydrogen exchange at attached carbon atoms, nor is racemization observed upon generation of the lithiated phosphine *(42)* [150]. The barrier to

pyramidal inversion in the sulfonium ylide *(43)*, $\Delta H^{\ddagger}$ = 23.3 kcal/mole [151], is somewhat lower than that for sulfonium salts ($\Delta H^{\ddagger}$ = 25–29 kcal/

(42) *(43)*

mole) [98,99], and much lower than barriers found in sulfoxides ($\Delta H^{\ddagger}$ = 35–42 kcal/mole) [69]. Although substantial $(2p-3d)_{\pi}$ bonding is postulated to occur in sulfoxides [152], and, by extension, in sulfilimines, it is not clear at present whether the pyramidal stability of these compounds should be attributed to the effect of the π bonding, rather than to the effect of the electronegativity of the oxygen and nitrogen substituent or to lone pair-lone pair interactions.

New Forms of Carbon

By Otto Vohler, Peter-Ludwig Reiser, Renato Martina, and Dieter Overhoff [*]

A number of novel carbon materials whose unique properties fit them for many uses have recently been developed. Pyrolytic graphites are excellent conductors of heat and electricity parallel to the surface, whereas they are semiconductors perpendicular to the surface. A similar anisotropy is found in graphite foils, which are impermeable, but also very flexible. Glasslike carbon, which is also impermeable, is, however, completely isotropic. Carbon foams and felts are extremely light and exhibit very good thermal insulation up to high temperatures. In addition to very high strength, carbon fibers have values of Young's modulus greater than that of any other fibers or wires. Carbon fiber/resin composites are therefore more rigid than any other known materials; their specific Young's modulus is five times that of steel.

1. Introduction

Up to the end of the 19th century, graphitic carbon was known practically only in the form of mined natural graphite. Though synthetic carbons had been prepared by heating mixtures of anthracite, coke, charcoal from wood and sugar, and retort carbons with carbonaceous binders such as sugar syrup, tar, and pitch, and the partial conversion of these synthetic carbons into synthetic graphite had repeatedly been observed, *e.g.* in an electric arc, the economic production of synthetic or artificial graphite was made possible only by the graphitizing process patented by *Acheson* [1] in 1896.

In this process, the material to be graphitized forms the thermally and electrically insulated heating core of an electric resistance furnace, as shown diagrammatically in Figure 1. The charge is heated to about 3000 °C by direct passage of current, *via* a resistor pack of granular coke. The graphitization that occurs at this temperature leads to extensive ordering within the crystallites of the coke grains and of the binder coke [2].

[2] *E. Dönges* and *O. Vohler* in *K. Winnacker* and *L. Küchler*: Chemische Technologie. Vol. I, 3rd. Edit., Hanser, München 1969.

As a result of its unique combination of chemical, electrical, mechanical, and high-temperature properties[3], artificial graphite has since become widely used in research and industry, *e.g.* as electrodes in arc furnaces for the production of electric steel, in carbide, reduction, and resistance furnaces, as anode material in aqueous and fused salt electrolysis, as casting molds and lining material, in the production of chemical equipment, as fuel element and moderator material in nuclear reactors, in rockets, and for small components, particularly in electrical engineering (cf. [2]).

In recent years, often as a result of extreme requirements for spacecraft, a series of novel carbons have been developed, not by additional treatment or transformation of classical artificial graphite, but by fundamentally different processes; examples are pyrolytic graphite by pyrolysis of gaseous carbon compounds, flexible graphite by explosive decomposition and subsequent compaction of graphite intercalation compounds, glasslike carbon and carbon foams by controlled carbonization of synthetic resins, and carbon fiber materials by crosslinkage and carbonization of suitable organic fibers.

These new carbon materials have unique properties, as a result of which they have found many uses. Some examples of extreme fields of application are electrical heating and thermal insulation, gaskets and porous filters, flexible parts and composites that are more rigid than any other material known.

2. Graphite Single Crystals

Some of these new carbons posses the typical graphite structure only in small regions, and their X-ray reflections are often considerably broadened because of the small crystallite size; in some cases, in fact, only two-dimensional order can be detected. It is nevertheless convenient to derive their properties from the crystal structure of graphite.

Graphite crystallizes mainly in a hexagonal layer lattice of space group D_{6h}^4 (Fig. 2). Each carbon atom within the layers is bonded to three neighboring atoms by very strong, covalent sp^2 bonds with a C–C distance of 1.415 Å. On the other hand, the π bonding between the layers is very weak; the distance between two neighboring *a,b* planes is 3.3539 Å.

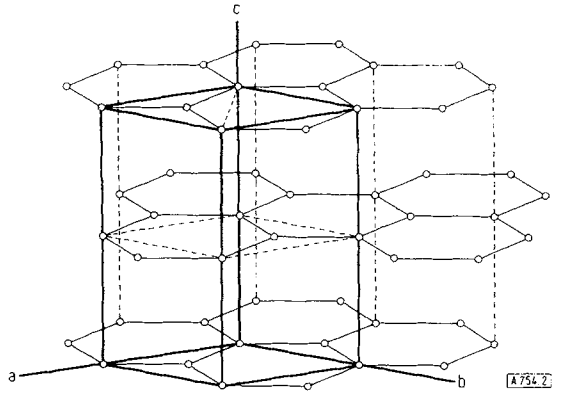

Fig. 2. Crystal lattice of graphite (hexagonal modification).

Because of this pronounced layer lattice, the properties of the graphite single crystal are strongly dependent on direction (Table 1); examples are the Young's modulus, the specific electrical resistance and the thermal conductivity, which is directly related to the nature and strength of the chemical bonding. Parallel to the *a,b* planes, the conductivity of the graphite single crystal is comparable with that of good metallic conductors such as aluminum or copper; perpendicular to the layers, on the other hand, it is a semiconductor. This anisotropy is particularly marked in the thermal expansion [3].

Table 1. Properties of graphite single crystals.

	parallel to *a,b* planes	perpendicular to *a,b* planes
Density (g/cm³)	2.266	
Young's modulus (kg/cm²)	$\approx 1 \times 10^7$	$\approx 3.5 \times 10^5$
Electrical resistance (ohm mm²/m)	≈0.5	$\approx 1 \times 10^4$
Thermal conductivity (kcal m⁻¹ h⁻¹ deg⁻¹)	>350	7
Coefficient of thermal expansion (20–200 °C) (deg⁻¹)	-1.5×10^{-6}	$+28.6 \times 10^{-6}$

This strong dependence on direction is found only for particularly well-formed natural graphite flakes, and is much less pronounced in the properties of the porous artifical graphite objects made by the classical methods for the production of synthetic carbon from solid fillers and pitch-like binders. In these artifacts, the anisotropy of the single crystal is greatly weakened by the various orientations of the crystallites, by microcracks and pores within the grains, and by the porous structure of the shaped article. However, the anisotropy is very pronounced in some new types of carbon, such as pyrolytic graphite, graphite foils, and the high-tensile or high-modulus carbon fibers.

3. Pyrolytic Carbon and Graphite

The formation of carbon by pyrolytic decomposition of gaseous or vaporized carbon compounds is not new; retort carbons were obtained in this way even before *Acheson* described his graphitizing process. It was only in the last decade, however, that suitable equipment has been developed for the production of pyrocarbon as coating and in the form of a compact, self-supporting body under controlled conditions, and hence with properties that could be varied as desired.

Pyrocarbon coatings and compacts are produced from gaseous or vaporized carbon compounds, which are decomposed pyrolytically on hot graphite supports (800–2800 °C) [4–6]. Examples of suitable carbon compounds are methane, ethane, propane, acetylene, benzene, and carbon tetrachloride.

3.1. Pyrocarbon Coatings

The structure and properties of the pyrocarbon layers obtained depend mainly on the temperature, pressure, residence time, and nature of the carbonaceous gas. The variability of pyrographite is extremely wide, and ranges from almost isotropic, *via* granular, to the highly anisotropic laminar structures.

These pyrocarbon structures have been examined in particular detail in connection with deposition in the fluidized bed reactor [7]. This deposition has gained considerable technological importance for the coating of fuel particles for nuclear reactors.

Multiple layers are used having various mechanical properties and irradiation behavior and exhibiting good fission product retention.

Another important application is the production of pyrocarbon coatings on artificial graphite bodies (see Fig. 3), the deposition then no longer taking place in a fluidized bed, but on fixed graphite objects. The pyrocarbon coating gives the artificial graphite a very smooth surface; it becomes substantially impermeable and its resistance to oxidation and erosion is greatly enhanced.

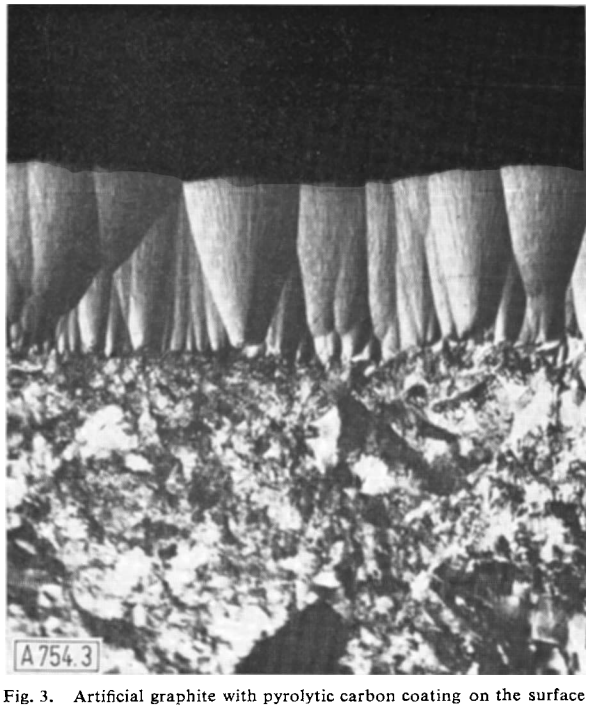

Fig. 3. Artificial graphite with pyrolytic carbon coating on the surface (magnification 1000 ×).

If the coating is applied only to the outer surface of the shaped body, it provides only incomplete protection against slow selective oxidation, such as occurs *e.g.* in graphite components in nuclear reactors. If the protective surface layer is damaged, the oxidizing gas can pass through the pores of the graphite body and so destroy the material. To prevent this, it is necessary to deposit the pyrocarbon within the pores (see Fig. 4). This is possible at slow deposition rates (low temperature, low partial pressure) [8]. Even after the surface of articles coated in this way has been attacked, the protective action of the pyrocarbon in the pores persists.

Fig. 4. Artificial graphite with pyrolytic carbon coating within the pores (magnification 1000 ×).

Graphites coated with pyrocarbon are used in particular where severe erosion and oxidation are likely to occur, *e.g.* as sleeves in CO_2-cooled nuclear reactors. They are also used for special purposes, such as vaporization dishes in the vapor-deposition of metals or as graphite molds for the sealing of terminals in tube bases. Owing to their high purity, graphites coated with pyrocarbons are being increasingly used in semiconductor technology as mold materials and as plates for epitaxy. Since blood has only a small tendency to clot in the presence of pyrocarbon layers, this could offer a new application in medicine, *e.g.* for artificial heart valves [9].

3.2. Compact Pyrolytic Graphite

Compact pyrolytic graphite bodies are produced at a constant temperature and a constant pressure at the lowest possible deposition rate. Crystalline order is obtained only within the layer planes; the material is turbostratic. Growth and ordering processes that lead also to extensive crystalline order in the *c* direction can be induced by additional heat treatment at temperatures up to 3000 °C.

The growth rate, density, and microstructure depend mainly on the deposition temperature [10]. Whereas pyrolytic carbons having a density of only 1.35 g/cm³ are obtained at 1600 °C, the bulk density of pyrographite deposited at about 2100 °C is between 2.20 and 2.23 g/cm³.

[10] *J. C. Bokros* and *R. J. Price*, Carbon *6*, 213 (1968).

Because of the good alignment of the layer planes, pyrolytic graphite bodies, like single crystals, are strongly anisotropic. Thus the ratio of anisotropy for the specific electrical resistance (perpendicular/parallel) is 1400; the parallel/perpendicular ratio for the thermal conductivity is about 440. As in the single crystal, the thermal expansion is negative parallel to the surface and strongly positive in the perpendicular direction (cf. Table 2).

Table 2. Properties of pyrolytic graphite.

	parallel to surface	perpendicular to surface
Bulk density (g/cm³)	2.20	
Young's modulus (kg/cm²)	2.5×10^5	—
Flexural strength (kg/cm²)	1×10^3	—
Compressive strength (kg/cm²)	1×10^3	4×10^3
Electrical resistance (ohm mm²/m)	5	7×10^3
Thermal conductivity (kcal m^{-1} h^{-1} deg^{-1})	350	0.8
Coefficient of thermal expansion (20–200 °C) (deg^{-1})	-0.8×10^{-6}	$+25 \times 10^{-6}$

A crystallographically almost ideal graphite has been obtained by uniaxial hot compression of pyrolytic graphite followed by annealing at a very high temperature and low pressure [11]. The ratio of anisotropy for the electrical resistance of this material at 300 °K was 4000, and increased to 90000 on cooling to 4.2 °K.

Owing to the high degree of alignment and the resulting strong anisotropy, pyrolytic graphite bodies can be produced only in limited thickness. The maximum thickness attainable for slab materials at present is about 10 mm. In the case of tubes it is proportional to the radius of curvature, *i.e.* maximum wall thickness/radius of curvature = 0.05. Bodies with sharp edges or thick walls can be produced by further machining or by combining thinner pyrographite plates.

The marked anisotropy of pyrolytic graphite and its increased resistance to erosion and oxidation, together with the high emission coefficient and high sublimation point of carbon, offer great advantages *e.g.* when used as rocket nozzles, as reentry cones of space vehicles, for the nose cones and wing leading edges of space gliders, or as protective shields. Owing to the excellent conductivity parallel to the *a,b* planes of the graphite crystal, the heat is well distributed over the surface, and both the radiation and the ablation take place over the entire surface. At the same time, underlying structural material is thermally protected by the insulating effect in the *c* direction. Compact pyrolytic graphite plates are often used when a very uniform distribution of heat over a surface is desired. Pyrolytic graphite is also used to advantage in electronic tubes [12].

Pyrographite alloys, *e.g.* with B, Si, Hf, and Co, are obtained when a vaporized organic compound of the alloying component is added to the gaseous carbon compound. A particularly well-known example is the pyrographite-boron alloy, which is characterized by higher elasticity, lower oxidizability, and greater insulation perpendicular to the layer planes and by an increase in the strength of the pyrographite, which is high even in the unalloyed state.

4. Carbon Foils and Membranes

It is well known that foreign atoms can be inserted between the layers of well-ordered graphite crystals to give intercalation compounds, such as potassium graphite, graphite hydrogen sulfate, and graphite oxide [13–16]. In graphite oxide, oxygen and hydroxyl groups are located between the carbon layers. *Luzi* found as early as about 1890 that graphite oxide can be thermally expanded to more than 100 times its original volume. A more recent process for the economical production of flexible graphite foils is based on the compression of this expanded material [17].

The starting material is generally coarsely crystalline, very pure natural graphite. The graphite is oxidized with fuming nitric acid or with a sulfuric acid/nitric acid mixture, and then hydrolyzed. If the graphite oxide, after drying, is heated in a fraction of a second to about 1000 °C, it decomposes explosively. The gases liberated expand the graphite lattice normal to the

[17] *J. H. Shane, R. J. J. Russel*, and *R. A. Bochman*, French Pat. 1395964 (1963), High Temperature Materials.

layer planes by a factor of more than 100. The separated carbon layers of the graphite lattice are then firmly bonded together by mechanical pressure; the resulting products are gas-tight, flexible, strongly anisotropic carbon foils having a density of about 1.1 g/cm³. An electron scan micrograph (Fig. 5) shows the pronounced layer structure of this material.

These foils are produced without binders; they consist of pure carbon, and can therefore be used up to temperatures above 3000 °C in inert and reducing atmospheres or under vacuum. The strong dependence of the properties on direction is again remarkable. The ratio of anisotropy for the specific electrical resistance is even higher than in pyrolytic graphite (cf. Table 3). The electrical conductivity parallel to the surface is comparable with that of well-ordered artificial graphite. Special emphasis must be placed on the impermeability of these foils to gases and liquids up to very high temperatures. Graphite foils are also much more resistant to oxidation than artificial graphites. Their surface is very smooth and resistant to abrasion.

Table 3. Properties of carbon foils.

	parallel to surface	perpendicular to surface
Bulk density (g/cm³)	0.9–1.1	
Electrical resistance (ohm mm²/m)	8	4×10^4
Thermal conductivity (kcal m⁻¹ h⁻¹ deg⁻¹)	150	3
Permeability (air) (cm²/s)	—	$<10^{-6}$

The flexible graphite is produced in the form of foils in thickness of 0.1 to 0.3 mm. These films are used directly or made into laminates several mm thick, the individual layers of which may be bonded together by carbonizable resin binders. Dense molded bodies can also be produced without binders. They are then equivalent to the foils in their resistance to corrosion and heat and in their thermal and electrical properties. Owing to their greater thickness, however, they no longer posses high flexibility.

Graphite foils and laminates have proved excellently suited for use in several fields:

a) as corrosion-resistant seals (gaskets and packings) for very low to very high temperatures: high thermal conductivity and hence good heat dissipation, self-lubricating, impermeable with and without cooling, long life, no maintenance, corrosion-resistant;

b) for the lining of press molds and casting molds: smooth surface, low friction, dense, abrasion-resistant;

c) as radiation shields in high-temperature furnaces: high reflection factor and good thermal conductivity parallel to the surface, combined with poor thermal conductivity normal to the surface;

d) in electrochemistry and electrical engineering, *e.g.* as a surface heater: high anisotropy of electrical and thermal conductivity;

e) as linings for chemical equipment: very flexible, corrosion-resistant, impermeable to gases and liquids;

f) as films for bursting disks: impermeable to gases and liquids, corrosion-resistant, heat-resistant.

Expanded graphite can also be made into porous foams (density 0.05–0.1 g/cm³) by compression under a lower pressure and without a binder. These foams may then be compressed further during use.

Self-adhesive or plastic-coated graphite foils are already on the market.

Carbon membranes only a few μm thick have now also been developed. Though thin enough to be translucent, these membranes are nevertheless impermeable to gases and liquids.

The membranes are again prepared from graphite oxide, which is made into a thixotropic gel in aqueous suspension. This gel is deposited on well-polished surfaces. Very careful drying gives a membrane of graphite oxide, which is reduced in a stream of hydrogen above 500 °C [18]. The resulting carbon membrane, which has a highly imperfect graphite crystal lattice, is graphitized above 2500 °C; during this process, the density increases to 1.8–2.2 g/cm³. Carbon membranes of this nature are used *e.g.* as dialysis membranes for the desalination of sea water.

5. Glasslike Carbon

The coking of coal-tar pitch or residues from the distillation of petroleum yields cokes that change into more or less well-ordered graphite on subsequent graphitizing treatment above 2500 °C. Three-dimensionally crosslinked synthetic resins, on the other hand, decompose without passing through a liquid phase; they therefore give poorly graphitizing carbons. The crystallites remain small even after heating at about 2800 °C (*e.g.* $L_a \approx 70$ Å, $L_c \approx 30$ Å) [19]. The distance between the layers is 3.44 Å, as compared with 3.354 Å in a well-ordered graphite.

The carbon obtained is very hard, and resembles glass in its impermeability and breaking behavior; it is therefore known as glasslike carbon.

The structure of this carbon contains small regions of graphite-like layers, which are joined by numerous crosslinks. The large proportion of crosslinking C atoms is the reason for the non-graphitizability of glasslike carbon and for its isotropy.

The density of glasslike carbon is very low (about 1.5 g/cm³). Its impermeability to gases is nevertheless excellent; the permeability as found mass-spectrometrically with helium is about 10^{-11} cm²/s, and is thus of the same order of magnitude as that of silicate glasses [20].

Table 4. Properties of glasslike carbon.

Bulk density (g/cm³)	1.45–1.50
Pore volume (vol.-%)	<1
Young's modulus (kg/cm²)	2.6×10^5
Flexural strength (kg/cm²)	700
Electrical resistance (ohm mm²/m)	50
Thermal conductivity (kcal m⁻¹ h⁻¹ deg⁻¹)	3
Coefficient of thermal expansion (deg⁻¹)	3×10^{-6}
Permeability (air) (cm²/s)	10^{-11}

[18] *J. Maire, H. Colas*, and *P. Maillard*, Carbon *6*, 555 (1968).
[19] *F. C. Cowlard* and *J. C. Lewis*, J. Materials Sci. *2*, 507 (1967).
[20] *S. Yamada* and *H. Sato*, Nature (London) *193*, 261 (1962).

Glasslike carbon is much stronger and stiffer than conventional carbons and graphites (Table 4). Its electrical and thermal conductivity are comparable with those of hard carbons.

Owing to the small number of accessible pores and its high impermeability, glasslike carbon is very corrosion-resistant. However, it is attacked by alkali metals with formation of intercalation compounds, as well as by carbide-forming metals [19].

To prepare glasslike carbon, partially precondensed phenolic or furan resins are mixed with catalysts, poured into molds with very smooth surfaces, and cured. The material is then removed from the molds and carbonized in accordance with a strictly defined heating schedule. The resulting shrinkage is pronounced, but quite definite and isotropic, so that moldings can be produced with a dimensional accuracy of $\pm 0.5\,\%$. Owing to its hardness, glasslike carbon can only be worked with diamond tools or by an ultrasonic technique. It is therefore preferable to work the cured resin before carbonizing, taking the amount of further shrinkage into account [21].

Glasslike carbon is produced as plates, tubes, crucibles, boats, *etc.* with wall thicknesses of about 3 mm. It has found a number of applications, particularly in laboratory work. The similarity of its coefficient of expansion to that of many borosilicate glasses makes it possible to bond the two materials permanently. Since glasslike carbon is not wetted by most molten metals, it can be used in metallurgy for melting crucibles, and also for pipes for passing corrosive gases into molten metals and as vaporization dishes for the evaporation of metals. Glasslike carbon has a high resistance to erosion, and is therefore also being tested as a rocket nozzle lining [22].

6. Highly Porous Carbon, Carbon Foam

Carbons in which up to 75 % of their volume is occupied by open pores of very uniform structure can be produced from microcrystalline cellulose without binders [23, 24].

These homoporous carbons are used mainly as electrode materials for the direct conversion of chemical into electrical energy in electrochemical fuel cells. Owing to the uniformity of their pores, such electrodes can accept very high loads.

Carbons with much greater pore volumes (carbon foams) are obtained by carbonizing foamed synthetic resins. The starting materials are open-pored rigid synthetic resin foams. There are two basic types:

a) A skeleton of a foam that gives only a low carbon yield on pyrolysis *e.g.* a foam based on polyurethane, which has been impregnated with a carbon-supplying synthetic resin, *e.g.* a phenolic resin [25].

b) A foam made from a synthetic resin that itself gives a relatively high coke yield, *e.g.* a phenolic resin foam [26, 27].

The carbon foams obtained by carbonization are extremely light, having densities of only about 0.05 g/cm³. The percentage decreases in volume and in weight are the same, so that the carbon foams have the same bulk density as the synthetic resin foam used. Carbon foam is composed of very thin carbon cell walls (cf. Fig. 6); it can be used up to temperatures higher than

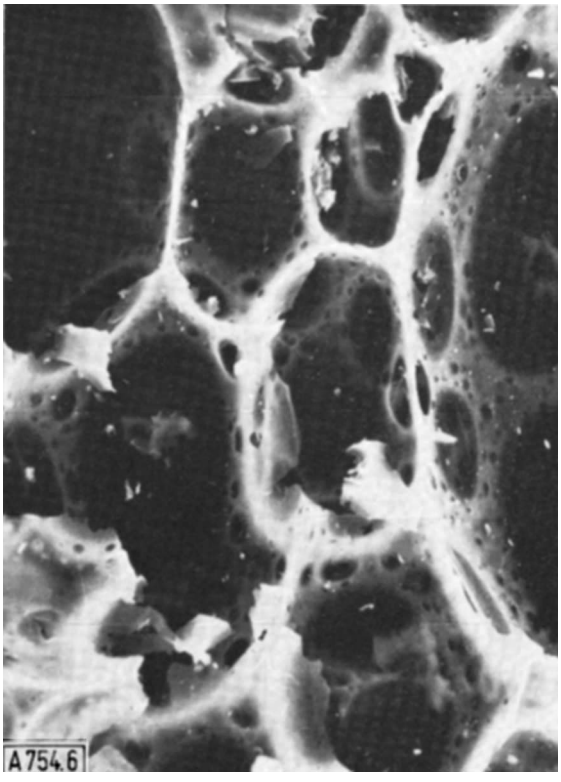

Fig. 6. Electron-scan micrograph of carbon foam (magnification 250 ×). The micrograph was prepared in the Labor für Raster-Elektronen-Mikroskopie Dr. *H. Klingele*, München.

3000 °C in an inert gas or under vacuum. Its thermal insulating qualities are outstanding (cf. Table 5); the thermal resistance of foamed synthetic resins is only slightly better (thermal conductivity about 0.03 kcal $m^{-1}\,h^{-1}\,°C^{-1}$). However, synthetic resin foams can only be used below their decomposition temperatures, *i.e.* below 180 °C.

Table 5. Properties of carbon foam.

Bulk density (g/cm³)	0.055–0.065
Pore volume (total (vol.-%))	97
Pore volume (open (vol.-%))	95
Young's modulus (kg/cm²)	1200
Compressive strength (kg/cm²)	4.8
Electrical resistance (ohm mm²/m)	5500
Thermal conductivity (kcal $m^{-1}\,h^{-1}\,deg^{-1}$)	0.04
Coefficient of thermal expansion (20–200 °C) (deg^{-1})	2.1×10^{-6}
(20–1000 °C) (deg^{-1})	2.5×10^{-6}
Permeability (cm²/s)	$\approx 10^{2}$

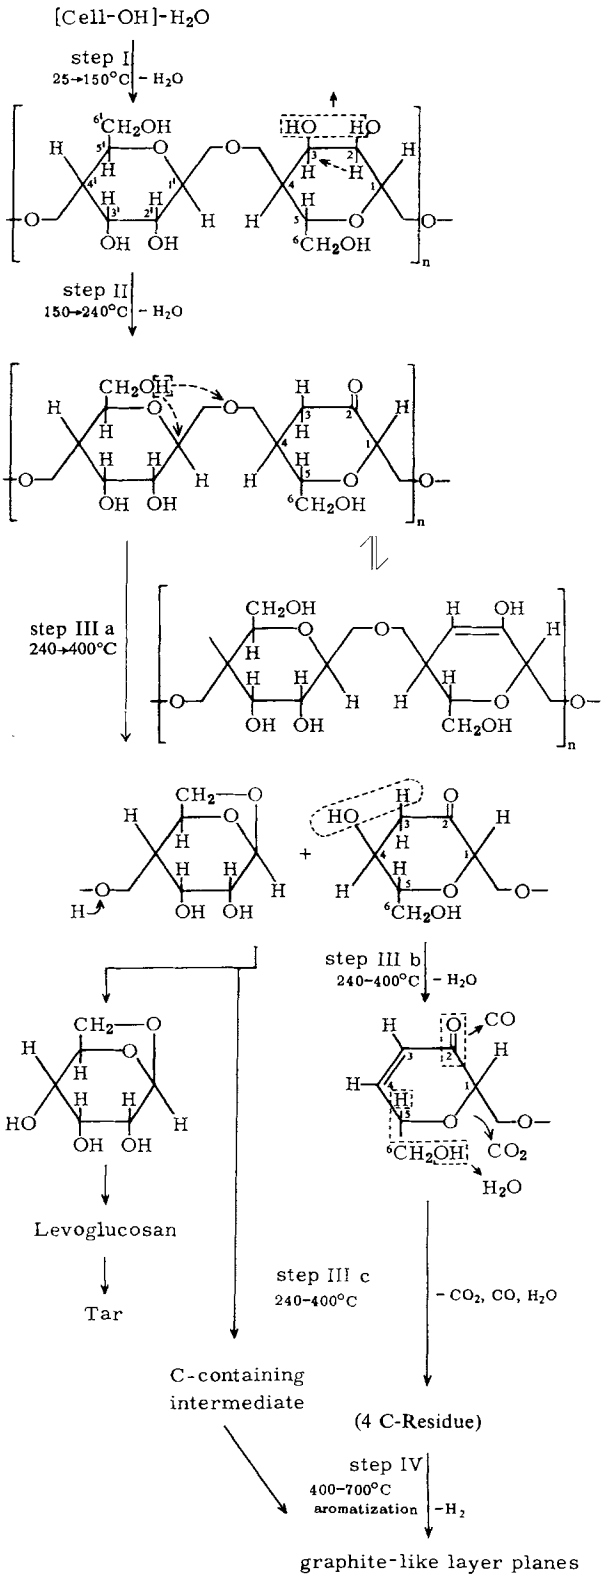
[27] *B. R. Atkins*, Brit. Pat. 1016449 (1963), Nobrac Carbon.

The thermal resistance of carbon foam is superior to that of refractory bricks by a factor of thirty, whereas its density is lower by a factor of about twenty. For the same weight of material, therefore, the thermal resistance is six hundred times as high.

The compressive strength of the highly porous carbon foam is relatively low. It can be increased merely by variation of the starting material or of the foaming; however, the thermal conductivity increases at the same time. The compressive strength can be increased to 1000–2500 kg/cm² by impregnation *e.g.* with pyrolytic carbon; this is accompanied by an increase in the thermal conductivity by a factor of about ten (approx. 0.35 kcal m^{-1} h^{-1} $°C^{-1}$) [28].



The most important application of carbon foam is insulation, in particular up to high and very high temperatures. It is also used as a filter for corrosive agents, for frits for the uniform distribution of gases in reaction mixtures, and as a support material for catalysts. Fire-resistant sandwich materials represent another application.

7. Carbon Fiber Materials

Edison (1880) was the first to carbonize cellulose filaments for the newly developed carbon filament lamp. The mechanical strength of these first carbon filaments was very low, and they were not very flexible. It was not until 1959 that flexible carbon fibers and fabrics, which were then available only on a laboratory scale, were first described in the technical literature [29, 30]. The starting material was again cellulose, now in the form of rayon.

In 1961, *Shindo* investigated the thermal degradation of polyacrylonitrile fibers and found that this material (particularly after preoxidation) leads to extremely strong carbon fibers with good carbon yields [31]. These investigations formed the main basis of the development of high-tensile and high-modulus carbon fibers at Farnborough [32].

The thermal degradation of other starting materials, *e.g.* animal fibers [33], polyvinyl acetate [34], polyvinyl alcohol [35], pyrolysis products of polyvinyl chloride [36], copolymers of vinyl chloride, vinyl esters, and vinyl alcohol [37], furfuryl alcohol condensates, and more recently phenol-formaldehyde condensates, has also been studied.

Scheme 1. Thermal degradation of cellulose [38, 39].

Step I: desorption of physically adsorbed H_2O. Step II: removal of chemically bound H_2O. Step III: depolymerization and chain cleavage with dehydration, decarbonylation, and decarboxylation. Step IV: dehydrogenation, demethanation.

In general, materials are suitable for the production of carbon fibers only if they satisfy the following basic requirements:

1. The fibrous form should be retained on pyrolysis, *i.e.* the material must not melt when heated, or it must

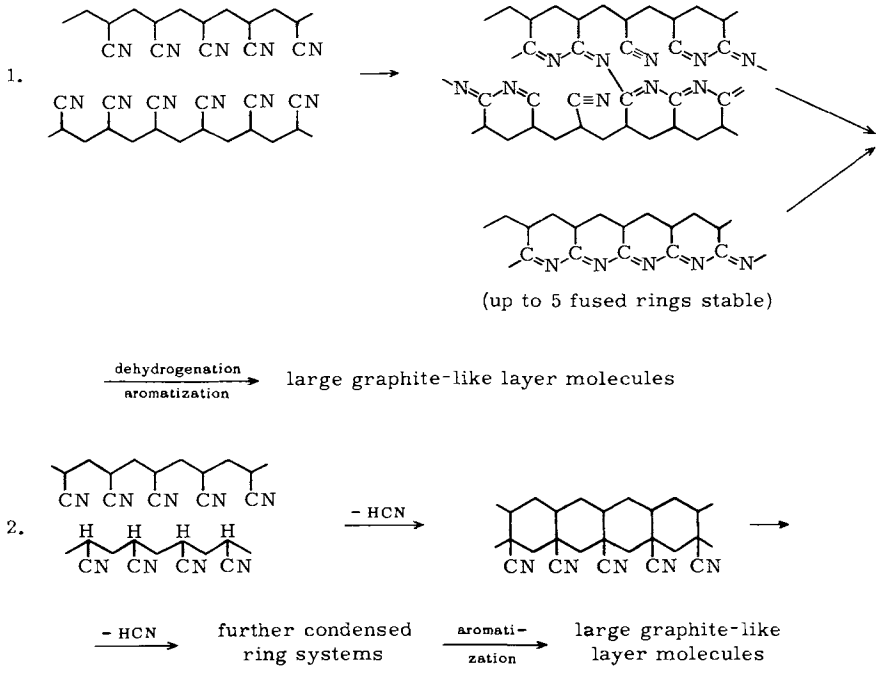
be capable of being pyrolytically decomposed below its melting point.



2. The carbon skeleton should be capable of being readily changed into a two-dimensional graphite structure.

3. The pyrolysis should take place without appreciable evaporation of carbon-containing volatile components.

These requirements are satisfied by cellulose and crosslinkable polymers such as polyacrylonitrile. According to *Tang* and *Bacon*, cellulose is decomposed as shown in Scheme 1 [38, 39].

The dehydration is assisted by treatment with phosphates, borates, vanadates, *etc.* Each cellulose unit ultimately contributes an average of four C atoms, which aromatize to form graphite layers.

When polyacrylonitrile is used as the starting material, it is treated with oxygen at 200 to 300 °C before thermal degradation. This leads to crosslinking and cyclization, with the result that a structure consisting of condensed dihydropyridine rings is formed. Above 350 °C, the nitrogen is removed as ammonia or hydrogen cyanide. Above 600 °C, further crosslinking takes place, with dehydrogenation, to give large graphite-like layer molecules. Reactions verified by IR spectroscopy are shown in Scheme 2.

Scheme 2. Thermal decomposition of polyacrylonitrile [40].

Because of their fibrous structure, the carbon fiber materials combine the characteristics of carbon (low vapor pressure up to very high temperatures, high sublimation point, chemical stability) with typical textile properties such as flexibility, elasticity, and lightness.

When textiles made of organic fibers are subjected to suitable heat treatment, the organic substances are ultimately converted entirely into carbon, while the textile form is retained. Carbon felts, wools, and fabrics can be made in this way [41]. Carbon fabrics are also made in special cases by weaving continous carbon fibers (see Section 7.2).

The starting materials are generally textiles made from cellulose fibers, though materials made from completely synthetic fibers, such as polyacrylonitrile, are used in some cases. However, only needled felts, which are relatively spongy, can be produced from these fibers. Suitable starting materials for the production of denser carbon felts are pressed felts of animal fibers, particularly sheeps' wool. As can be seen in Figure 7, the surface structure of the wool fibers with flat scale-like cells is retained even after carbonization.

The heat treatment of the textiles generally takes place in three steps:

First step (up to about 300 °C): precarbonizing.

Second step (up to about 1000 °C): carbonizing.

Third step (up to above 2500 °C): graphitizing.

In the first step the fiber material is decomposed into products that are already black. Crosslinking agents must be used in some cases to prevent softening or even melting before chemical degradation. In the case of polyacrylonitrile, for instance, atmospheric oxygen is used, while a special method has been developed for animal fibers [33]. The thermal decomposition may also be carried out in high-boiling liquids [42,43] or in at-

mospheres containing halogen or nitric oxide [44,45]. In the second step the precarbonized material is degraded to elementary carbon in the absence of air.

These carbon felts, wools, and fabrics can be used in this form for most purposes. For special applications the materials are heated in a third step to above 2500 °C (graphitization). The resulting products are known as graphite felts, wools, and fabrics, though there is crystallographically no pronounced graphitic structure.

Owing to the wide range of starting materials, it is possible to obtain products with various combinations of properties, as is shown by Table 6 for carbon and graphite felts.

Table 6. Properties of carbon and graphite felts.

	SIGRATHERM FA 5 G		SIGRATHERM F I/3		SIGRATHERM FD 400	
	Carbon	graphite	carbon	graphite	carbon	graphite
Weight per unit area (g/m²)	200	180	330	280	350	320
Bulk density (g/cm³)	0.05	0.05	0.20	0.17	0.08	0.08
Thermal conductivity (20 °C) (kcal m^{-1} h^{-1} deg^{-1})	0.05	0.10	0.08	0.15	0.05	0.30
Square resistance (ohm)	3.5	1.5	2	0.2	0.5	0.1
Tensile strength (kg/cm²)	0.5	0.3	4	1.5	1	0.5
Breaking strain (%)	25	20	15	5	10	5

The bulk density of these felts ranges from 0.05 to 0.20 g/cm³. The felts with the higher bulk densities, while having practically the same thermal insulating powers, are more stiff, and can therefore be used *e.g.* as self-supporting insulating shields. The insulating power of these carbon felts is illustrated in Figure 8.

Carbon and graphite felts are thus used mainly for thermal insulation up to very high temperatures both in resistance and in induction furnaces. They are cheaper and more effective than metal shields. Their insulating properties are superior to those of carbon black. Since the bulk density is

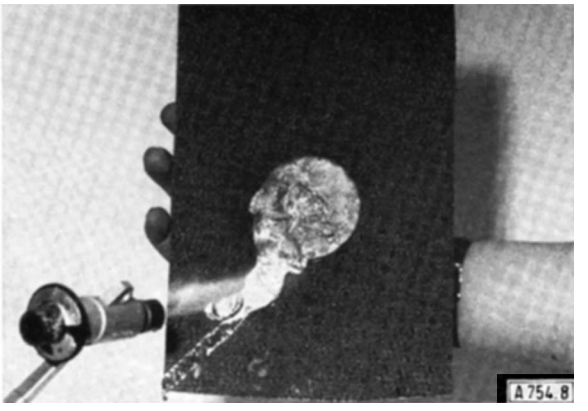

Fig. 8. Insulating power of carbon felt (melting of aluminum on a hand insulated with carbon felt).

only a fraction of that of carbon powder, suitably insulated furnaces can be heated and cooled more rapidly. Felt shields are also reasonably strong, and their strength increases with rising temperature. Since they can be cut with scissors or knives and stitched together with carbon yarn, insulators of any desired shape can be produced quickly and easily. Furthermore the material is so uniform that no hot spots occur, and uniform temperatures are obtained inside the furnace.

Their chemical corrosion resistance also offers other advantages, *e.g.* for use as a filter material for corrosive substances (gases, solutions, molten metals), as a support material for catalysts, as corrosion-resistant linings in chemical equipment, and (also in metalized form [46]) as "fiber-porous" electrodes in accumulators and fuel cells.

The electrical properties of the carbon and graphite felts provide unique and new methods of resistance heating (more flexible than the finest metal conductors, very good heat dissipation by black body radiation, high power densities, low heat capacity, fast heating and cooling).

Owing to their low neutron absorption cross section, carbon felts and wools are also used in nuclear engineering [47].

Carbon and graphite wools prepared from artificial cotton or similar starting materials are particularly suitable for use as packing materials for high-temperature insulation. Carbon and graphite fabrics are used basically for the same purposes as the felts, but not as insulating materials.

All carbon fiber materials have the disadvantage of restricted application in air above 300 °C, owing to their ease of oxidation. Their high-temperature properties are fully utilizable up to temperatures above 3000 °C only in inert or reducing atmospheres. The resistance to corrosion and erosion can however be increased by pyrolytic graphite, carbide, or silicide coatings.

7.2. Carbon Fibers

Carbon felt, wadding, wool, *etc.* generally do not possess high mechanical strength; the graphite single crystal, however, owing to its strong covalent bonds in the *a,b* direction, has an extremely high Young's modulus (about 1×10^7 kg/cm²) and a tensile strength of about 1×10^6 kg/cm².

In the production of continuous carbon fibers, the *a,b* planes can be extensively oriented parallel to the fiber axis if *e.g.* carbonized rayon filaments are stretched at about 2500 °C[48]. Stretching by a factor of 50% increases the Young's modulus *e.g.* from 1×10^6 to 4×10^6 kg/cm². The tensile strength simultaneously increases from 100 to 300 kg/mm².

With polyacrylonitrile fibers as the starting materials, stretching is carried out between 200 and 300 °C[32]. Carbon fibers from polyacrylonitrile attain their maximum strength after heat treatment at 1500 °C (cf. Table 7: high-tensile). As the treatment temperature is further raised, the Young's modulus rapidly increases; the high-modulus fibers of Table 7 were heated at 2500 °C. Additional high-temperature stretching above 2500 °C results in a further increase in the Young's modulus and tensile strength.

Table 7. Mechanical properties of carbon fibers, carbon fiber reinforced plastics, and other materials.

	Tensile strength (kg/cm²)	Young's modulus (10^3 kg/cm²)	Tension length (km)	Specific Young's modulus (km) [a]
Fibers and wires				
Graphite (high modulus)	21000	4200	110	22000
Graphite (high tensile)	30000	2300	170	13000
Boron (on tungsten)	30000	3800	115	14500

Steel	42000	2100	53	2650
Titanium	20000	1200	44	2600
Aluminum	1700	700	6	2600
Other materials				
Graphite fiber/ resin composite (V_f = 0.5) [b]	8400	2100	54	13600
Glass fiber/ resin composite (V_f = 0.5) [b]	9000	500	50	2800
Steel	14000	2100	18	2650

[a] Specific Young's modulus Σ Young's modulus/density.
[b] V_f = bulk factor (based on the volume fraction).

The tensile strength of high-tensile carbon fibers is exceeded only by those of asbestos fibers, steel wires, and of graphite whiskers.

The great advantage of carbon fibers over metals becomes all the more impressive when one considers the specific strengths and specific Young's moduli, *i.e.* those based on unit weight. The specific tensile strength corresponds to the tension length, *i.e.* the minimum length of a fiber or wire for which it breaks under its own weight. The high-tensile carbon fibers have a tension length of 170 km. As can be seen in Table 7, metal fibers have tension lengths of only a fraction of this value.

The decisive advantage of carbon fibers, however, lies in their extremely high stiffness, which is expressed by Young's modulus. Young's modulus of highly stretched carbon fibers is inferior only to that of graphite whiskers. The specific Young's modulus of high-modulus carbon fiber is eight times that of a metal wire.

The carbon fibers are produced in ropes containing 2000 to 1000 individual filaments. In the individual filaments, which have a diameter of about 8 μm, the two-dimensionally ordered graphite layer planes are aligned parallel to the fiber axis. As in textile fibers, large crystalline zones are combined to form supermolecular structures; under the electron microscope they exhibit a fibrillar structure in the form of strip-shaped zones arranged substantially parallel to the fiber axis.

Carbon fibers are used mainly for the production of high-tensile and high-modulus composite materials, which are discussed in Section 7.4.

7.3. Carbon Whiskers

Young's moduli and tensile strengths even higher than those of the carbon fibers described in the last section can be attained in carbon whiskers. These are hair-like crystals of carbon, a few centimeters long, whose diameter (about 0.5–5 μm) is appreciably smaller than that of carbon fibers. Since the strength of fibers in general increases rapidly with decreasing diameter, these carbon whiskers have the highest strength reached so far. *i.e.* a tensile strength of up to 2000 kg/mm² and Young's modulus of up to 7×10^6 kg/cm².

Graphite whiskers were first obtained in the mid-1950's by *Bacon* and *Bowman*[49]. They were prepared from graphite vapor by a high-energy electrical discharge. The methods used nowadays, however, make use of gaseous carbon compounds. Under very strictly limited deposition conditions, the pyrocarbon (cf. Section 3) formed on pyrolysis can be made to grow in the form of whiskers. This leads first to very thin primary whiskers having a diameter of about 0.01 μm[50], which then thicken as a result of secondary deposition of pyrolytic carbon. The main difficulties in the production of whiskers lie in the suppression of this secondary growth. Several methods have been used for this purpose, such as the addition of catalysts to the pyrolyzing gas[51,52]. The deposition of the

[52] *R. J. Diefendorf*, US-Pat. 3107180 (1961), General Electric Comp.

whiskers in steep temperature and concentration gradients has proved very favorable [53].

All these methods are being used only on a laboratory scale at present. Owing to their outstanding strength properties, carbon whiskers will undoubtedly be used in future for materials subject to extreme loads, though they will always be much more expensive than carbon fibers.

7.4. Carbon Fiber Reinforced Materials

All the common metals have roughly equal stiffness for equal weights; they have roughly equal specific Young's moduli. This is an inherent property of metals, and cannot be fundamentally altered by alloying or the like.

Because of the low defect concentration, wires, fibers, and above all whiskers always have higher tensile strength and Young's modulus than compact materials. In the development of new materials with extremely high specific stiffness, therefore, one starts with thin fibers or wires, which are combined with matrix substances to produce composite materials. The strength of these composites is roughly proportional to the volume fraction of the fibers that are arranged parallel to the direction of the stress.

Graphite whiskers are ten times as strong as carbon fibers. However, it is very difficult to embed them in a matrix material. Moreover, they do not differ so much from carbon fibers in their Young's modulus.

On the other hand, continuous carbon fibers, like glass fibers, can be easily embedded in a synthetic resin matrix in volume fractions of more than 50%, *e.g.* by the filament winding method. The matrix materials are generally epoxy resins, though polyester and phenolic resins are also used. Figure 9 shows an electron-scan micrograph of the point of fracture of a carbon fiber/synthetic resin composite. The good adhesion of the synthetic resin matrix to the surface of the fibers is obvious.

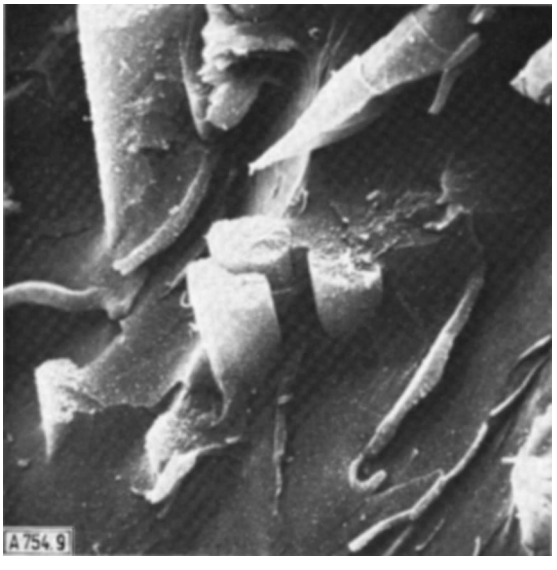

Fig. 9. Electron-scan micrograph of the fracture point of a carbon fiber-synthetic resin composite (magnification 1250 ×). The micrograph was prepared in the Labor für Raster-Elektronen-Mikroskopie Dr. *H. Klingele*, München.

As can be seen from Table 7, a composite of this type with a bulk factor of 0.5, *i.e.* consisting of 50 vol.-% of fibers and 50 vol.-% of synthetic resin, is as stiff as a steel body having the same dimensions; the specific Young's modulus, on the other hand, is five times that of steel. This means that a component made of carbon fiber reinforced plastic suffers only one fifth of the deformation under load exhibited by a comparable steel component.

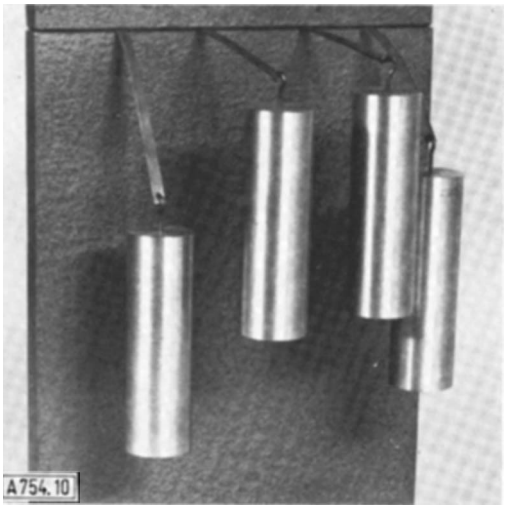

Fig. 10. Rigidity of materials, from left to right: aluminum, carbon fiber reinforced plastic, steel, glass fiber reinforced plastic.

The high rigidity of the carbon fiber reinforced plastics is illustrated by Figure 10. Strips of aluminum, glass fiber reinforced plastic, steel, and carbon fiber reinforced plastic having the same dimensions were loaded with equal weights. Bending is clearly least for the carbon fiber reinforced plastic and the steel. However, the steel strip is five times as heavy as the carbon fiber product.

Carbon fiber systems are unaffected by moisture. Their good electrical and thermal conductivity is also particularly advantageous.

These systems will be used in particular where high strength and high rigidity are required in conjunction with low weight, *i.e.* in rapidly rotating components and in aircraft and automobile construction. Examples are turbine blades in the Rolls-Royce RB 211 engine, heavy-duty jet housings, edges of aircraft wings, and floors of aircraft (in combination with honeycomb structures). There are also possible applications outside of aviation and space technology, *e.g.* for large centrifuges, spinning and weaving machines, sports cars, mountaineering equipment, and sailboat masts.

The application temperature of carbon fiber reinforced plastics is limited by the thermal stability of the plastic. Important advantages will result from the use of synthetic resins with high thermal stabilities, such as polyimides and polyimidazoles. The highest tem-

[53] *E. Fitzer* and *H. G. Schlesinger*, DAS 1269933 (1966), SIGRI.

peratures at which the composites may be used will be further raised by the use of glasses or metals as matrix materials [54, 55]. Carbon fiber reinforced carbons are stable up to 3000 °C in inert or reducing atmospheres. However, their production is still in the experimental stage.

The further development of these new fiber-reinforced high-temperature materials will open up wide fields of application for carbon fibers.

Electroplating of Plastics in Theory and Practice

By Kurt Heymann, Wolfgang Riedel, and Günter Woldt [*]

Electroplated plastics combine many advantages of plastics and of metals; they have the low weight and ease of shaping of plastics, together with the luster, hardness, and electrical conductivity of metals. An important part of any process for the electroplating of plastics is a pretreatment to ensure good adhesion of the metal film. Etch activation in the straight-through method requires only six steps for pretreatment.

1. Introduction

The rapid growth of the consumption of plastics in the last 20 years is primarily due to the ease with which they can be shaped to obtain useful objects. This was greatly appreciated by industrial users, who required versatility of types and shapes with no great increase in production costs, such as arises *e.g.* in the processing of metals.

For this reason the users accepted disadvantages in color matching, the attraction of dust by static electricity, and the relatively soft surface of injection molded thermoplastics.

These "made-to-measure materials" offer considerable scope for the work of the chemist. The polymers can be suited to a wide range of uses by modification of the nature of the monomers, the polymerization conditions, and pigmentation, and because of the possibility of reinforcement with glass fibers. Nevertheless, plastics have to compete with the traditional metal.

It seemed natural, therefore, to seek a good combination of plastic and metal, *i.e.* a genuine composite of plastic and metal.

An important factor here is undeniably the wish to give a plastic surface a metallic luster for decorative reasons, since large sections of the market like the glitter of metals. It is in fact impossible to tell by appearance whether a chromium-plated object is made of metal or plastic; the difference can be felt only by touch. Electroplated plastic feels warm and is much lighter. Because of its lightness, it is easier to transport and handle, and this is a further argument in favor of metalized plastics.

Plastics can be shaped more easily, more cheaply, and in greater variety than metals. To obtain shiny surfaces, the mold into which the plastic is injected is polished instead of each individual article. Without knowing the market, one might think that the electroplating of plastics is a passing fashion. However, this practice has many technical advantages, apart from its decorative value.

Many plastics are damaged by ultraviolet radiation. This damage is prevented by a film of metal. The flammability of plastics is also reduced by metalization.

Use is often made in the electrical industry of chassis having complicated shapes. To produce a metal chassis of this kind, several individual parts have to be fitted together and welded. It has been found in

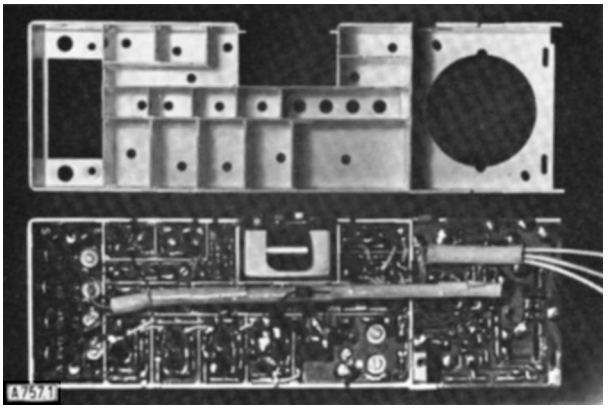

Fig. 1. Chassis of ABS plastic (Bosch Elektronik GmbH, Berlin).

[*] Dr. K. Heymann, Dipl.-Phys. W. Riedel, and Dr. G. Woldt
Schering AG, Galvanotechnik
1 Berlin 65, Postfach 59 (Germany)

practice that the same result can be achieved by injection molding of the chassis in one operation, followed by electroplating (Fig. 1). The metal deposit is electrically conductive. Contacts can be made as before if soldering is carried out quickly and without too much heat.

In other cases a metal deposit is desirable to prevent static build-up. Other uses are discussed in Section 4.

As long as there have been plastics, there have been efforts to electroplate them[1]. Plastics, like other nonconductors, clearly require petreatment to make them electrically conductive for the plating operation. The surface must first be made wettable and active, and then covered with a thin film of metal in electroless baths. Though promising methods were known[1,2], all efforts remained unsuccessful for years, since an adhesive bond could not be produced between the plastic and the electrochemically applied metal film. Conducting lacquers seemed for a time to offer a suitable bonding substance, but this plan failed because the conducting lacquer rounded the contours of the surfaces, and the metal pigments could not be uniformly exposed and built up by electrodeposition.

Around 1964, it was found by the work of *Narcus*[3], *Saubestre*[4], and investigators at Marbon Chemical[5,6] that ABS plastics (acrylonitrile-butadiene-styrene graft polymers) are excellently suited for electroplating. On this basis and with steady improvement of the pretreatment methods, the electroplating of plastics was developed in only five years into an industrially recognized process[7].

2. The Plating Processes

The sequences of operations involved in the electroplating of plastics are summarized in Table 1. For the first step of the pretreatment, *i.e.* etching, the ABS objects are mounted on jigs and immersed in chromosulfuric acid at 65 °C. This makes the surface of the plastic hydrophilic, and the butadiene units are oxidatively degraded. Cavities are formed at these points, and these later provide mechanical anchorage for the metal coating[8,9]. To make the plastic conductive, metal is deposited on it by electroless plating. However, deposition of metal on objects immersed in a copper or nickel reduction bath is possible only if electrons can be transferred from the reducing agent to the metal ions to be reduced *via* the solid phase. For this to happen, the solid phase must be a good electronic conductor and allow fast electron exchange. This condition is satisfied by many metals; however, noble metals are preferred since they can be deposited particularly readily in the cavities in the plastic by reduction of their ions. It is also possible to apply colloidal noble metals to the surface of the plastic.

Table 1. Sequence of operations in various methods for the electroplating of ABS and zinc die castings.

	ABS Conventional process	ABS Staight-through process	ABS Etch activation (straight-through process)	Zinc die castings Standard process

8.	Rinsing	Rinsing	Electroplating	
9.	Chem. deposition of Cu or Ni	Chem. deposition of Cu or Ni		
10.	Rinsing	Rinsing		
11.	Pickling	Pickling		
12.	Electroplating	Electroplating		

The production of the noble metal particles that catalyze the chemical deposition of metal is known in the plating industry as "activation of the plastic", or as "nucleation". This can be achieved by the following methods:

a) Immersion in stannous chloride solution and then, after rinsing with water, in silver nitrate, palladium(II) chloride, or gold(III) chloride solution.

b) Immersion in a solution of a palladium salt and then in hydrazine hydrate or sodium tetrahydroborate solution.

c) Immersion in a colloidal palladium solution.

d) Etch activation in chromosulfuric acid containing noble metal.

Method (a) was chemically dependable, but required too many workers for its execution. While the parts are being rinsed with water after activation with stannous chloride solution, hydrolysis leads to the formation of gel-like oxide chloride, which remains adsorbed not only on the ABS but also on the insulated jig. The result is that noble metal nuclei, and later copper or nickel, are deposited on the insulation of the jig. To confine the electrodeposition of metal to the ABS plastic, the parts are then transferred to different in-

sulated jigs that have not been in contact with the pretreatment baths. The efforts to overcome this disadvantage and to ensure selective deposition of the metal on the ABS led first to the introduction of activation methods (b) and (c).

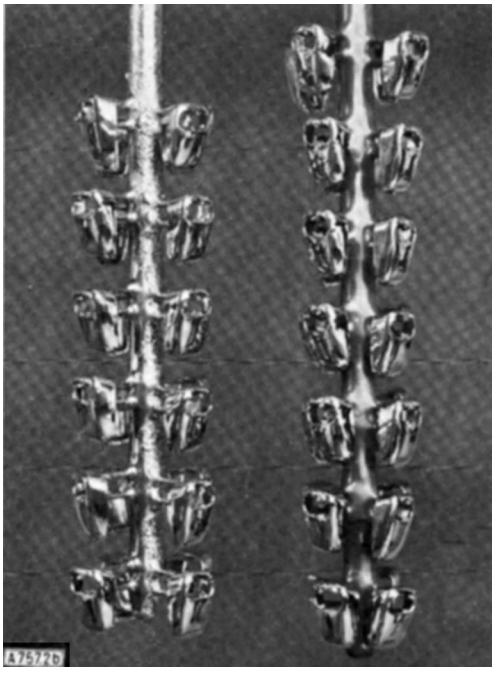

Fig. 2. Jigs with ABS components. Left: conventional process (deposition of metal on jig). Right: straight-through process (metal deposited on ABS only).

Processes involving no change of jig are known as "straight-through" processes, since the jig passes continuously through the plants from etching to plating with the object (Fig. 2).

Further rationalization of the pretreatment has recently been achieved by etch activation [7]. In this case some steps are no longer necessary, as can be seen in Table 1, so that the electroplating of plastics is now as simple as the electroplating of metals. Noble metals are added to the etching solution, and are carried into the plastic by the chromosulfuric acid.

It can be verified by experiments with radioactive isotopes that the noble metal is very firmly fixed to the plastic under these conditions, and is not washed out again. In these experiments, the noble metal compound was first activated by neutrons in a nuclear reactor, and then added to the etching solution. Several ABS samples were etched in the resulting activated etching acid for 4, 8, or 12 minutes at 65 °C, and were then vigorously rinsed for 1 or 10 minutes with introduction of air. After the samples had been dried, the radioactivity was monitored with a Geiger-Müller counter. Despite the vigorous rinsing, the activity of the samples decreased by only about 10%. This small decrease is of no importance to the subsequent chemical deposition of metal [7].

The next step after activation is the chemical deposition of metal from copper or nickel reduction baths. The principal components of these baths are the metal salts together with complexing agents and reducing agents. The reductions for copper-formaldehyde and nickel-hypophosphite solutions can be represented by the following simplified equations:

$$Cu^{2+} + HCOH + 3\,OH^- \rightarrow Cu^0 + HCOO^- + 2\,H_2O$$

$$Ni^{2+} + H_2PO_2^- + H_2O \rightarrow Ni^0 + H_2PO_3^- + 2\,H^+$$

Unlike the deposition of silver, which takes place spontaneously in silver salt-formaldehyde solutions, the deposition of copper and of nickel is strongly inhibited and occurs only in the presence of catalytically active nuclei.

The carry-over of small quantities of noble metal activator into a metalization bath was at first a great danger to practical operation, since these activators caused decomposition of the metalization bath. It was only with the development of efficient stabilizers, which prevent the spontaneous precipitation of copper or nickel (compounds of sulfur, selenium, and some heavy metals, as well as cyanides and oxygen, are suitable for use as stabilizers), that this danger was eliminated and the chemical deposition of metals became economical [10].

Once the plastic objects have been made conductive by the deposition of metal, the metal film can be built up by electrodeposition. The first step is the electrodeposition of copper from a sulfuric acid electrolyte. Any metal capable of being electrodeposited can then be applied. Electrolytes having a smoothing effect are preferred, since the deposition of the metal then proceeds in such a way that any depressions already present in the surface are preferentially filled up (Fig. 3).

Fig. 3. Smoothing of a rough base material by electroplating with copper.

A copper base about 20 µm thick ensures that the composite withstands thermal shocks between +80 and −40 °C despite the difference in the expansion coefficients of the plastic and of the metal.

The thermal shock test devised by the "Electroplated Plastics" work group of the German Standards Committee for quality control [11] specifies the following conditions:

105 min +80 °C
15 min room temperature
105 min −40 or −30 or −20 °C, as required
15 min room temperature

This cycle is repeated three times. The metal must not blister or crack. If the plastics processor and the electroplater have followed the correct procedures for injection molding and electroplating, the production parts will pass the test. If on the other hand highly strained plastics articles are electroplated without following the rule that the copper film should be twice as thick as the nickel-chrome film deposited on it, the quality standard will generally not be satisfied.

3. Theory of Adhesion

ABS plastics are thermoplastics prepared from acrylonitrile, butadiene, and styrene either by copolymerization or by graft polymerization. Chemically speaking, they are ternary materials, but they consist morphologically of two phases, *i.e.* the finely dispersed, soft butadiene rubber phase and the relatively rigid styrene-acrylonitrile copolymer phase [12]. Figure 4 shows a transmission electron micrograph of an ABS graft polymer [13]. The polybutadiene phase, which is in the form of globular particles, is visible as a result of material contrast. Depending on the type of plastic, the rubber particles have diameters of 10^{-5} to 10^{-4} cm.

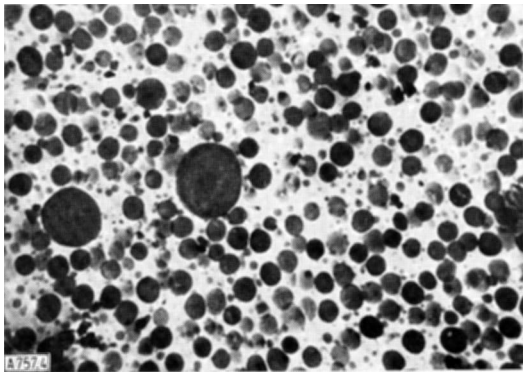

Fig. 4. Electron micrograph of ABS graft polymer (after [13], magnification 3700 ×).

During the etching of ABS plastics, the double bonds of the polybutadiene are oxidized, and this phase is selectively dissolved out of the ABS plastic. Figure 5 shows an ABS film that has been cast from solution, etched, and activated with silver nuclei [8]. The preparation of a film of this type from a solution naturally leads to relatively good homogenization of the macromolecular components. The etching has produced spherical holes wherever the polybutadiene component was present in the film.

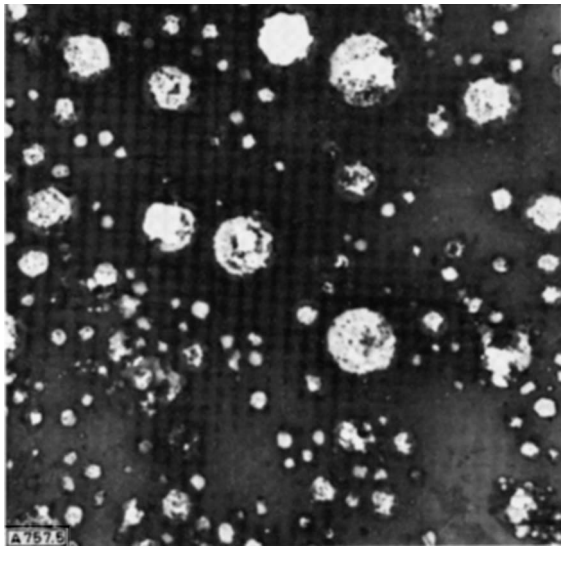

Fig. 5. Electron micrograph of cast, etched, and activated ABS plastic after *Wiesenberger* (from [8], magnification 6000 ×).

The activation and the chemical deposition of metal take place preferentially on the inside walls of the holes, as is shown by Figure 6, which was taken after a copper-plating time of 45 s. After 1.5 min, all the cavities have already been filled with copper.

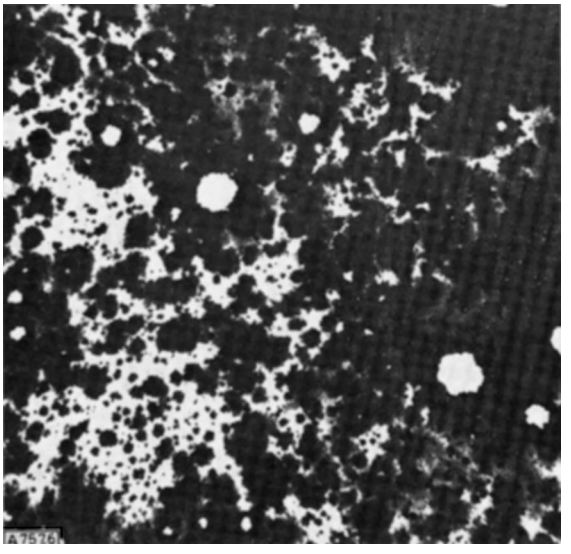

Fig. 6. Electron micrograph of an ABS film with incipient deposition of copper (after [8], magnification 6000 ×).

The chemical attack of the etching solution on the ABS graft polymer thus leads to dissolution of the elastomer out of the surface of the plastic, as was clearly recognizable. The resulting spherical cavities are more or less completely filled with metal during the chemical metalization. The good adhesion of the metal to the ABS plastic could thus be explained by mechanical anchoring of the metal in the ABS matrix polymer [8, 14]. Figure 7 shows a model of mechanical anchoring ("snap fastener theory" [17]).

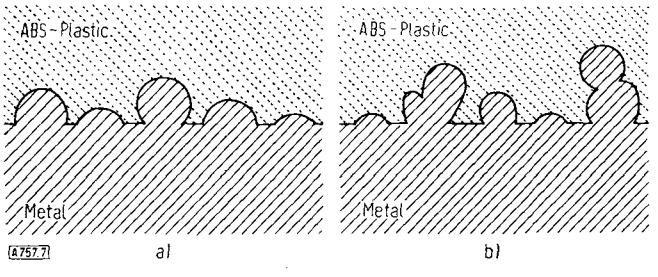

Fig. 7. Schematic diagram of the adhesion of metal to ABS plastic. a) Ideal model, b) real structure.

To check whether this hypothesis could explain adhesions of about 200 kg/cm² in a tensile test and peel strengths of about 4 kg/inch, an attempt was made to estimate the adhesion [8, 15].

[12] *K. Kato*, Kolloid-Z., Z. Polymere *220*, 24 (1967).

[13] *E. Zahn* and *K. Wiebusch*, Kunststoffe *56*, 773 (1966).

[14] *K. Heymann*, *W. Riedel*, *R. Blaschke*, and *G. Pfefferkorn*, Kunststoffe *58*, 309 (1968).

[15] *W. Riedel*, Galvanotechnik *57*, 579 (1966).

The force required to pull a metal sphere of radius r out of the matrix polymer AS when the center of the sphere is situated at a distance a under the surface ($a < r$) is:

$$K_L \approx 2\pi (r - \sqrt{r^2 - a^2}) S$$

S = tensile strength of the AS matrix.

For random variation of the depth a with $0 \leqslant a \leqslant r$, the force required to separate the bonded surfaces over an area of 1 cm² in the tensile test is:

$$K_S \approx \frac{2\pi r S}{e^2} \times \frac{1}{e} \int_0^{e/2} (r - \sqrt{r^2 - a^2})\, da \approx \frac{2\pi r^3}{e^3} \left(1 - \frac{\pi}{4}\right) \times S$$

If the butadiene spheres form a three-dimensional trivial lattice with a lattice constant e, then

$$e^3 = \frac{400\pi r^3}{3B}$$

B = volume fraction of butadiene in the ABS copolymer (%).

Thus the adhesion in the tensile test is

$$K_S \approx 3.22 \times 10^{-3} SB$$

Taking into account a number of second order factors such as the compressibility of the metal, the polydispersity and the shape factor of the holes, and the microroughness, we obtain K_S values of the order of 150 kg/cm² with $S \approx 750$ kg/cm² and $B \approx 25\%$. This almost agrees with the adhesions found experimentally [8, 16].

In practice, the adhesion is usually taken to be not the tensile strength but the peel strength in accordance with DIN 40802. The peel strength is defined as the force required to pull the coating away from a strip of plastic 1 inch wide with a pull parallel to the normal to the surface.

The peel strength P consists of two components, one taking the deformation of the metal into account (P_V), and the other the force needed to overcome the adhesion (P_H) [15]:

$$P = P_V + P_H = \frac{E\bar{a}\, b\, h^3}{4\, y^3} + \frac{K_L\, y\, b}{e^2}$$

E = elasticity modulus of the metal, $\bar{a}$ = average "immersion depth" of the snap fasteners, b = width of the metal film (2.5 cm), h = thickness of the metal film, y = contact length.

The unknown contact length y, *i.e.* the length of the zone in which stresses are acting to break the contact, can be eliminated by optimization:

$$y(h) = \left(\frac{3E\bar{a}\, h^3 d^2}{4 K_L}\right)^{1/4}$$

The peel strength is therefore:

$$P = 1.76 \left(\frac{E\bar{a}\, h^3 b^4 K_L^3}{4 d^6}\right)^{1/4}$$

$E = 1.3 \times 10^6$ kg/cm², $\bar{a} = 0.2 \times 10^{-4}$ cm, $K_L = 1.65 \times 10^{-6}$ kg, $d = 1.26 \times 10^{-4}$ cm, h (in cm) gives

$$P = 222 \times h^{3/4}$$

Thus the peel strength of a copper coating is theoretically strongly dependent on the thickness of the metal film. Figure 8 shows the measured and estimated dependence of the peel strength on the thickness of the copper coating. For a film thickness of 40 μm, one can expect a peel value of 3.5 ± 1.5 kg/inch if adhesion is assumed to be due to mechanical anchoring in accordance with the snap fastener theory. Good agreement is found between the experimental and the estimated values. It can thus be concluded that the bonding between the plastic and the metal may be of a mechanical-physical nature. There is therefore no need to postulate the existence of chemical, dipole, or van der Waals forces between the materials in contact, as was done by *Saubestre et al.* [4] and by *Logie* and *Rantell* [18].

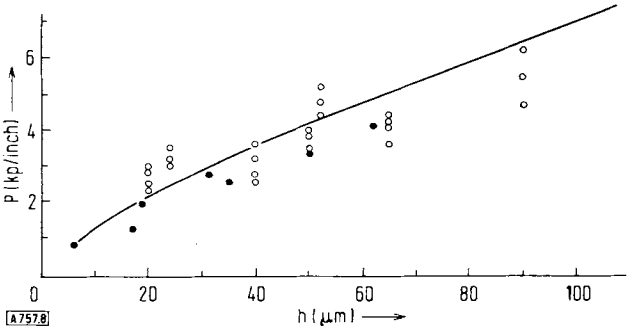

Fig. 8. Dependence of the peel strength P on the thickness h of the copper film (after [15]; — calculated. ● our experimental values, ○ *Saubestre*'s values).

The surfaces of bulk-injected or extruded ABS articles after etching naturally differ in morphology from the surfaces of cast ABS films. Figures 9–11 show electron-scan micrographs of an ABS plastic after etching for 2 min, 8 min, and 32 min, respectively. The morphological similarity of the specimen exhibiting optimum etching (Fig. 10) to that of Figure 5 is unmistakable.

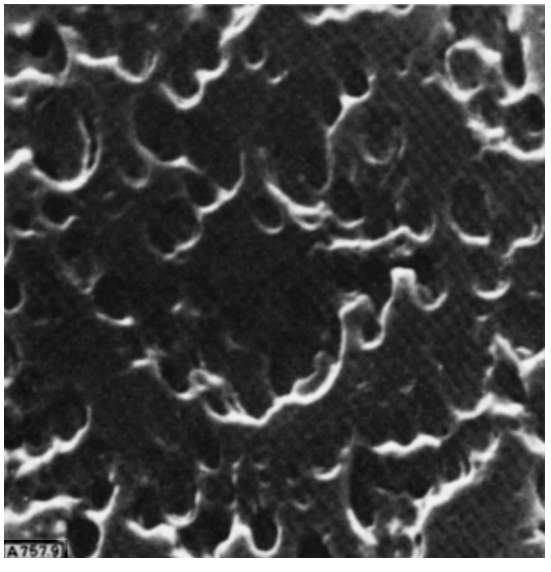

Fig. 9. Electron-scan micrograph of ABS plastic after etching for 2 min (magnification 6000 ×).

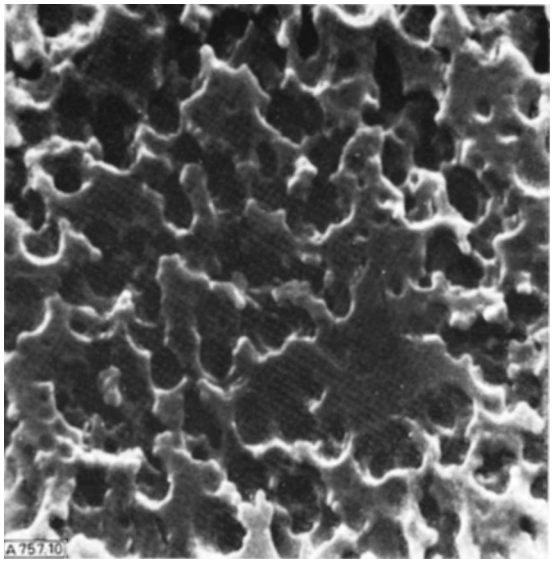

Fig. 10. Electron-scan micrograph of ABS plastic after etching for 8 min (magnification 6000 ×).

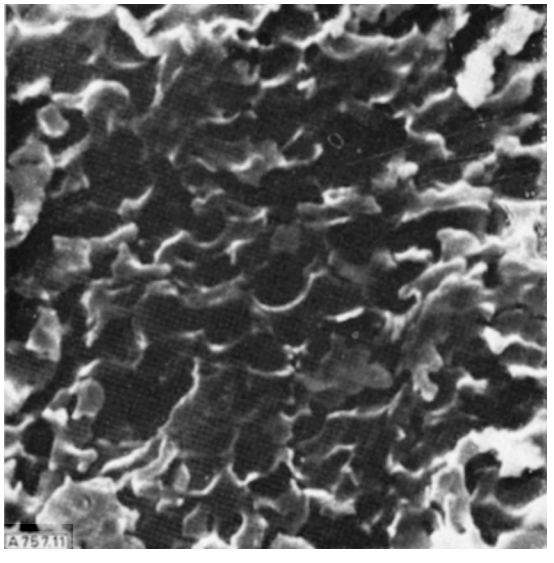

Fig. 11. Electron-scan micrograph of ABS plastic after etching for 32 min (magnification 6000 ×).

Figure 12 shows a cross section through the ABS-metal composite after *Zahn* and *Wiebusch*[13], in which the mechanical anchorage of the metal film in the plastic is visible.

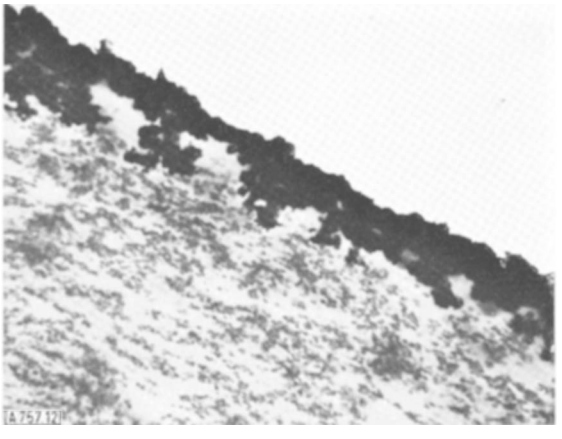

Fig. 12. Electron micrograph of a cross section of the ABS-metal interface (after [13], magnification 9250 ×).

A question of practical importance that now arises is whether plastics other than ABS can give strongly bonded composites on electroplating. On the basis of the theory of mechanical anchorage, it is possible to predict the composition required of a plastic if it is to be capable of being electroplated.

The plastic must consist of at least two phases, one of which must have a cotton-wool like structure with colloidal dimensions[14]. This phase must dissolve much more rapidly than the other phases in an etching medium. The phases that are less soluble in the etching solution must be coherent and mechanically stable. It must also be possible to deposit nuclei for chemical metalization on the etched surfaces, particularly in the holes.

Other plastics have in fact been electroplated; the peel values were similar to those found for ABS, and in some cases even higher. Figures 13 to 15 show three

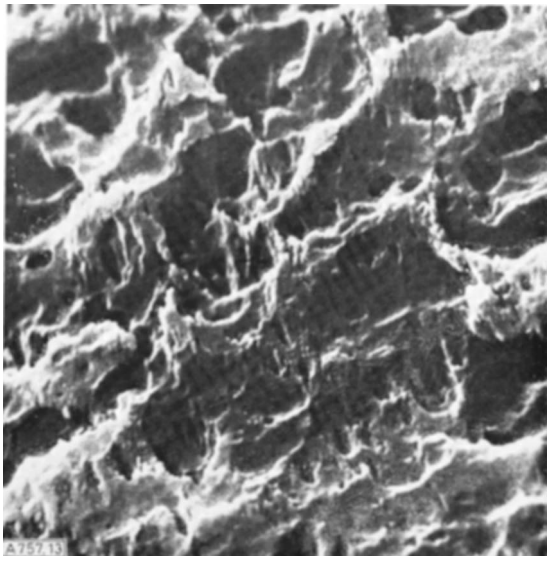

Fig. 13. Electron-scan micrograph of etched modified PPN (after [19], magnification 6000 ×).

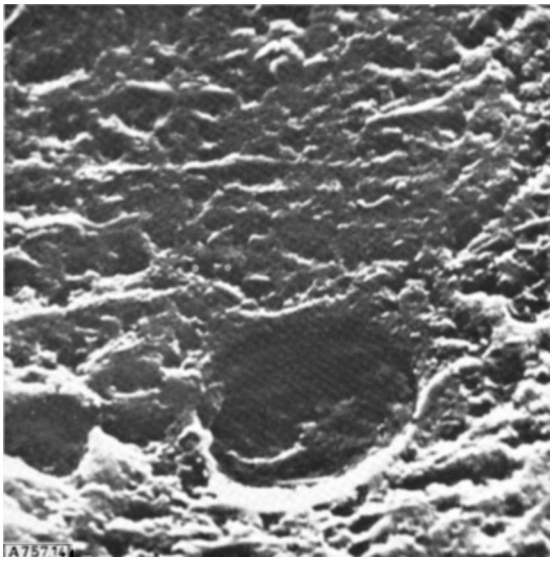

Fig. 14. Electron-scan micrograph of etched modified PPO (after [19], magnification 6000 ×).

[19] *G. Woldt*, Trans. Inst. Metal Finishing *47*, 236 (1969).

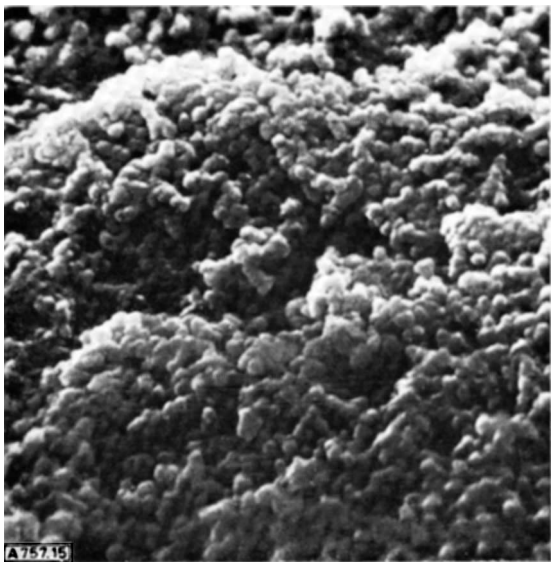

Fig. 15. Electron-scan micrograph of etched adhesive (after [20] magnification 6000 ×).

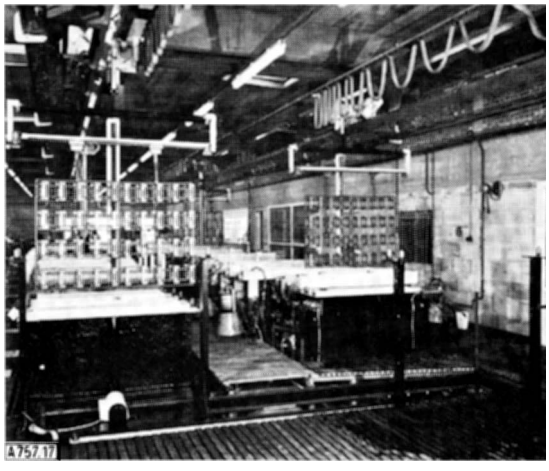
electron-scan micrographs of electroplatable plastics that have received optimum etching: modified polypropylene (PPN), modified polyphenylene oxide (PPO), and an adhesive for the production of printed circuits by an additive process [20]. These plastics were modified by copolymerization and by introduction of organic or inorganic fillers. The etched surfaces show a distinct similarity to that of optimally etched ABS; they are relatively uniformly roughened, and the light borders of the holes clearly show the presence of undercuts in which the metal can anchor.

Thus, on the basis of present knowledge, one can say that, to give good adhesion of electrodeposited films, a plastic must contain at least two phases, though the difference between the phases may be merely that one is crystalline while the other is not. In accordance with the mechanical adhesion model (snap fastener theory), the phase that can be dissolved out chemically must be uniformly distributed in the surface zones of the injection molded article.

If these requirements are satisfied, a number of further simple conditions must be observed in the injection molding process. The nature and number of gates must be such as to ensure that the articles produced will be as free as possible from strains and orientations. Care should be taken to follow the raw material producer's recommendations on predrying of the granulate, mass and mold temperatures, injection pressure, and injection rate. The article must be ejected from the mold without the aid of mold release agents. The objects must naturally be of a suitable design for electroplating [21].

4. Applications

The number of operations and tanks required is shown in Table 1. A large plant should have a fully automated transport system. The construction of the containers, which have capacities of up to 3000 l, depends on their contents. Lead-lined sheet steel tanks are used for strongly acidic etching solutions, PVC-polyester laminate tanks for the more dilute solutions, and glass fiber reinforced polyester tanks for rinsing water. The decontamination of the waste water is carried out separately. Accessories required are immersion heaters in some places, filter pumps, fume-extraction equipment, and (in the electroplating section) rectifiers. The jigs carrying the articles are passed in succession into the baths, where they remain for fixed times.



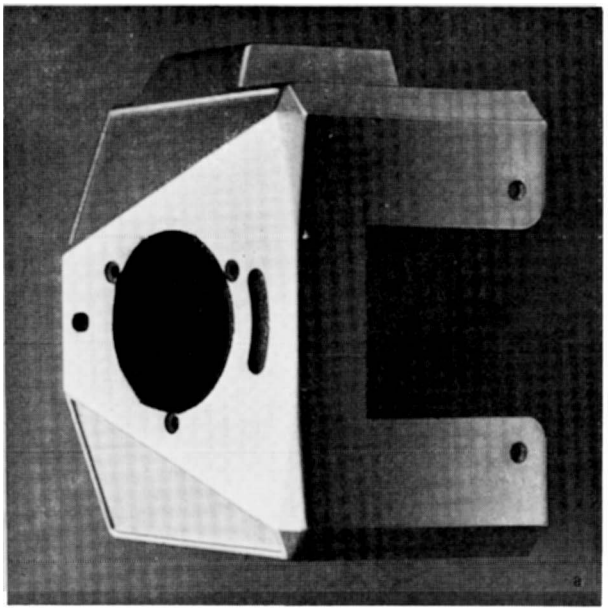


Fig. 16. Fully automated continuous plant for plating plastics with copper, nickel, and chromium located at the Overpelt-Plascobel S. A. Belgium.

The electroplating of plastics has already found applications in the automobile, audio, furniture, clock-making, photographic, household goods, fancy goods, and textile industries. We shall now describe a few examples selected from the many uses.

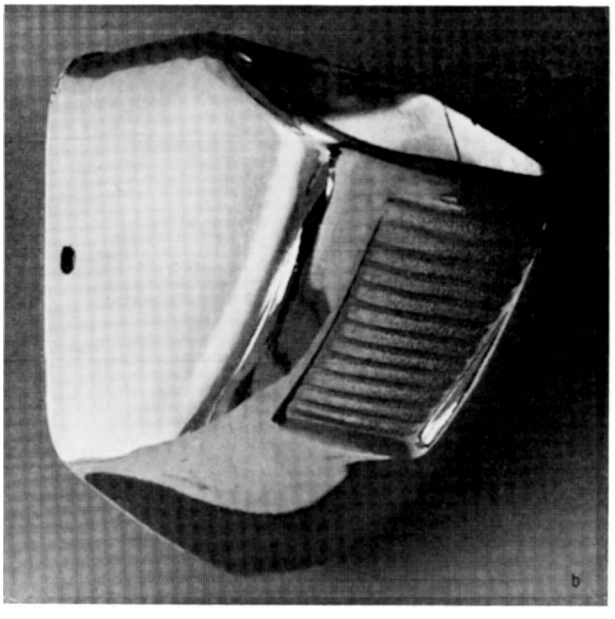

Figure 17c shows an outside mirror for an automobile. The mechanical polishing required when the part is made of metal is unnecessary when plastic is used; the same is true of the armrest fixture (Fig. 17b) and the miniature radio cover (Fig. 17h). The possibilities available to the mold designer are illustrated by the door knob (Fig. 17d) and the clock case (Fig. 17i). In this connection, there is greater variety in the design of clothes buttons (Fig. 17f). The camera front plate in Figure 17g is completely electroplated, though only the chromium plated edges are visible after the application of a black film and assembly. Since there is no need for polishing, this construction is cheaper than production of a front plate from zinc die castings or light metal. The exposure meter housing shown in Figure 17a can be injection molded cheaply in one piece. It is dull nickel plated and chromium plated. The processing of bathroom fittings made of plastic has also proved particularly economical (Fig. 17e). Other applications are navigation light housings for motor boats, radiator grills, automobile rear light housings, thermos flasks, perfume bottles, and mixing valves for bathroom fittings, to name but a few.

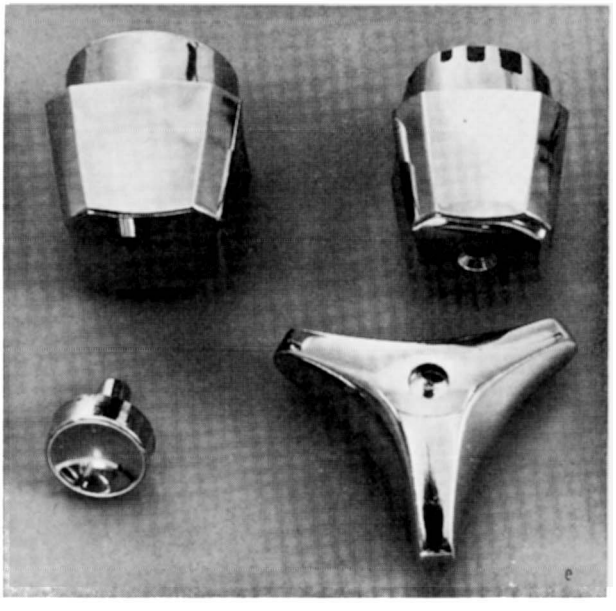
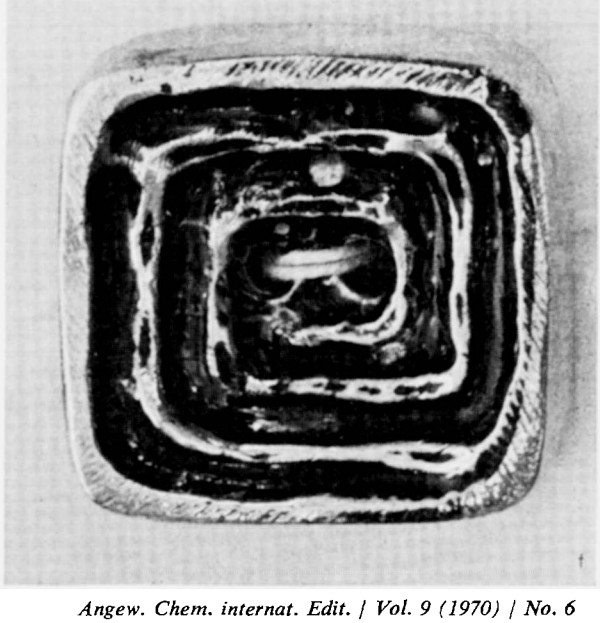
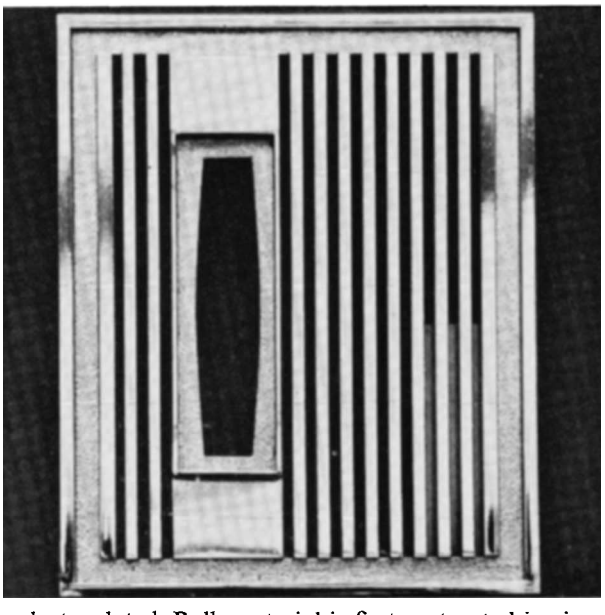


The applications are not confined to large objects, which must be fixed to jigs. Small articles can also be

[20] *H.-J. Ehrich*, Galvanotechnik *61*, 14 (1970).
[21] *P. Spiess*, Ingenieur Digest *7*, No. 9 (1968).





electroplated. Bulk material is first pretreated in sieve baskets. After being made conductive, the articles are copper plated, nickel plated, silver plated, or gold plated electrochemically in barrels. However, this requires a special barrel in which reliable current transfer is ensured by several cathode contacts. This

prevents the light plastic parts from floating away from the contacts.

These examples illustrate the magnitude to which the electroplating of plastics has grown within a few years. By rationalization of the process and improvement of reliability, even in the operation of the electroless metalizing baths, which has not until now been much used in industry, the confidence of the user was won, and a new field of application was opened up both for plastics processing and for electroplating.

As a readily obtainable and cheaply producible composite material, metalized plastic will be a material of the future, if only because of the rapidly expanding production of plastics. The continuous rapid growth of the plastics industry has now been in progress for 30 years. The consumption of plastics in the USA per head of population has increased by 413% since 1953. The consumption of plastics in the Federal German Republic is at present higher (34.1 kg/head of population) than in any other country. In 1980, German industry will process more than 5 million tonnes of plastics. We believe that the future will belong to the composite of plastic and metal.

Phototropic Glass

By Georg Gliemeroth and Karl-Heinz Mader[*]

Phototropic glass darkens on exposure to light and returns to its original state in the absence of light. The most extensively investigated of these glasses contain grains of silver halide having sizes > 50 Å. A discussion of theoretical principles is followed by a review of the very broad scope of the phenomenon.

1. Phototropy and Phototropic Materials

Phototropy is the reversible change between states having different absorptions that is induced by light (photons), or more generally by electromagnetic radiation. Photochromy is a special case of phototropy in which at least one of the states absorbs visible light.

Phototropy, as a photochemical phenomenon, obeys the Grothus-Draper law, *i.e.* only the light absorbed by the phototropic substance is effective. Under continuous exposure, the color changes until an equilibrium is reached between the forward and the reverse reactions.

Phototropy is reversible. When the light is switched off, the system returns to its original state:

$$\text{colorless} \underset{\text{absence of light}}{\overset{\text{exposure}}{\rightleftharpoons}} \text{colored}$$

The wavelength of the light causing a change in the light transmission and the rate at which the process takes place depend on the nature of the substance and on the temperature. A temperature rise displaces the absorption band to longer wavelengths. Higher temperatures also accelerate the regeneration reaction, which proceeds simultaneously with the color reaction and opposes the phototropic process.

Many inorganic compounds, of *e.g.*, mercury[1], copper[2], zinc, and chromium, molybdenum, and tungsten[3], exhibit phototropic behavior in the solid state or in solution. When the mineral sodalite $Na_8[Al_6Si_6O_{24}]Cl_2$ is exposed to X-rays it turns blue; the colorless state is regenerated on heating to 450 °C. (For reviews on organic and inorganic phototropic materials, see[4–7].)

Several authors have described inorganic glasses having phototropic properties. Phototropic glasses must not be confused with photosensitive glasses, in which irreversible images are produced as in photographic plates. Phototropic glasses are sometimes called "photochromic" in the American literature.

Cohen and *Smith*[8] studied the change in the transmission of sodium silicate glasses containing traces of europium.

A more comprehensive description of these processes in silicate glasses with variable transmissions is given by *Cohen*[9]. On exposure to light in the presence of titanium or iron, glasses containing cerium, europium, and other lanthanides exhibit color changes due to changes in valency. The variable transmission-absorption band in silicate glasses at 2.16 eV is attributed to the presence of traces of Ti^{3+} ions formed by reduction of Ti^{4+}. The required electron results from the photo-oxidation of Ce^{3+} or Eu^{2+}. This reaction is reversible.

Bishay and *Arafa*[10] observed a thermally reversible photochemical reaction in borate glasses containing arsenic or manganese on exposure to ^{60}Co radiation. *Sakka*[11] described the phototropy in alkaline earth metal tungstates sensitized with bismuth. *Stroud*[12] investigated the reversible formation of color centers in silicate glasses containing cerium.

Swarts and *Presseau*[13] reported the phototropy of reduced silicate glasses with a color center at 570 nm. Similar studies have been carried out by *Swarts* and *Cook*[14] on reduced silicate glasses containing iron. A phototropic effect has also been described for glasses containing germanium sulfide[15].

The first evidence of the existence of phototropic glasses of the type with which we are concerned here was obtained in 1964. *Stookey* and *Armistead*[16] described a borosilicate glass containing silver halides as phototropic components. The silver halides, which were present with a particle size of the order of > 50 Å and in a volume concentration of 500 ppm, decompose

on exposure to light in the same way as in the photographic process. *Garfinkel*[28] has used an ion-exchange process to introduce light sensitive silver halides into the surface of glass.

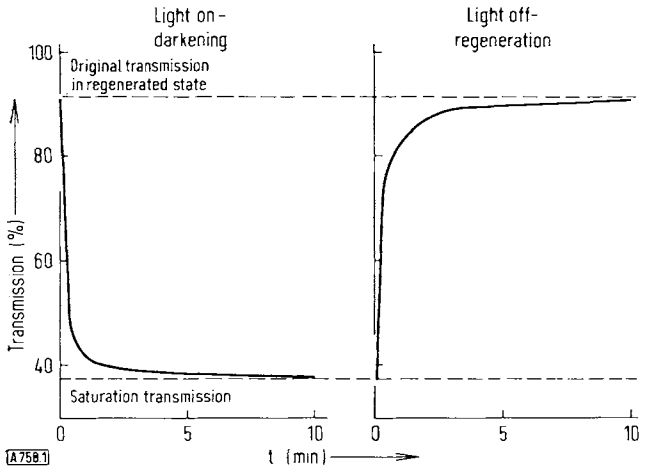

Fig. 1. Darkening and regeneration of a phototropic glass containing silver halides at 545 nm as a function of time (glass no. 7 in Table 1). Left: decrease in transmission during stimulation with xenon light (8000 lx); right: increase in transmission when the stimulation light is switched off. Temperature 20 °C, thickness 2 mm.

The phototropic process can be described with the aid of Figure 1, which shows the behavior of a phototropic glass as a function of time on constant illumination and after the stimulating light is switched off. The blackening process is shown on the left [*]. On exposure to light, the transmission decreases very rapidly to the saturation transmission value (*i.e.* the optical density or extinction or darkening increases). If the stimulating light is switched off after 10 min, the sample is regenerated, as shown on the right, until the original transmission of 92 % is restored.

2. Composition and Structure of Phototropic Silver Halide Glasses

The reversible darkening of pure silver halide crystals under the influence of stimulating radiation was described by *Pohl*[17] in 1938. *Armistead* and *Stookey*[16] discovered that the addition of silver salts and halides to a glass having melting temperatures between 1250 and 1450 °C gives a glass that has phototropic properties after subsequent heat treatment.

A wide range of phototropic glasses of various compositions based on silver halides have been reported since then, so that it is now hard to say what glasses *cannot* be made phototropic by addition of silver halides. The arbitrarily chosen list in Table 1 is based on the uses of the glasses, which impose different requirements as to transparency, chemical stability, melting behavior, and shaping. In glasses of this type, one can in general distinguish between the carriers of

[*] Unless otherwise specified, all experimental values in Tables and Figures refer to a glass thickness of 2 mm.

the phototropy, *i.e.* the silver halide components, and the glass matrix, whose composition and thermal history also influences the phototropic properties during the segregation of the silver halide-rich phase, but merely acts as a "solvent" for these segregates in the final annealed glass.

The segregates, which are formed by heat treatment of the initially homogeneous glass, determine the phototropic properties of the glass. Views differ on the structure of the segregate regions; their size is normally between 50 and 300 Å.

Smith[18] found segregate regions of different sizes on examination of electron micrographs of fracture surfaces of transparent and translucent phototropic glasses. For particles having a diameter of 100 Å separated by an average distance of 600 Å, there are 4×10^{15} particles per cm^3. *Smith* was able to identify crystalline silver chloride by X-ray diffraction.

Bereznoj and *Il'cenko*[19] studied phototropic lithium silicate glasses with an excitation maximum at 430 nm. For a constant excitation time, they observed a darkening that was proportional to the previous heat treatment, *i.e.* to the size of the segregate regions. With constant heat treatment, so that all the segregate regions are of the same size, the darkening varies with the number of segregate regions. The silver halide-rich phase separates out between 560 and 600 °C in this particular glass; the authors refer to silver halide crystals.

Robredo[20] has described crystals having a diameter of 50 Å that are responsible for the phototropic effect. *Krauth* and *Oel*[55] found values of between 100 and 400 Å by electron microscopy for the diameter of the silver halide regions.

Hammel and *McGary*[21] published electron micrographs of carbon replicas of freshly fractured and variously etched glass surfaces. These micrographs of

[18] *G. P. Smith*, J. Mater. Sci. *2*, 139 (1967).

[19] *A. I. Bereznoj* and *L. N. Il'cenko*, Izvest. Akad. Nauk SSSR, Neorgan. Mater *4*, 584 (1968).

[20] *J. Robredo*, Bull. Soc. franç. Céram. *65*, 51 (1964).

[21] *J. J. Hammel* and *T. E. McGary* in *J. M. Mitchell et al.*: Reactivity of Solids. Wiley, New York 1969, p. 695.

relatively highly tempered glasses containing silver chloride show that the segregates grow from 100 to 1000 Å with increasing annealing time at a constant temperature. The volumes of segregates and their percentage contributions in samples that had received different tempering treatments were deduced from the line broadening in X-ray diffraction.

The same authors observed an endothermic effect during the segregation of the phototropic regions, this effect occurring between 419 and 456 °C for glasses that contain only silver chloride, and between 392 and 429 °C for glasses that contain only silver bromide.

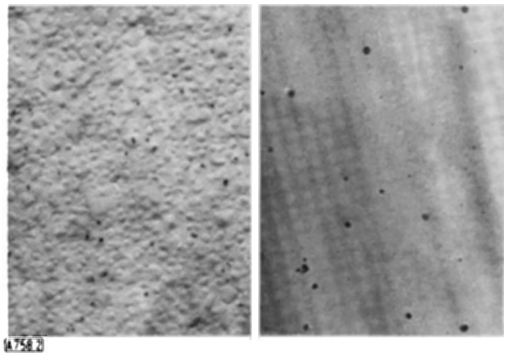

Fig. 2. Electron micrographs of phototropic glasses containing silver halide. Left: glass no. 2 in Table 1; annealed for 2 h at 610 °C, fracture surface etched for 60 sec in 2 % HF, carbon-platinum direct replica, magnification 12000×. Right: glass no. 7 in Table 1; annealed for 1 h at 570 °C, ion-etched, transmission photograph, magnification 48000×.

Figure 2 shows electron micrographs of phototropic glasses containing silver halides. Besides the phase separation in the glass itself, the silver halide-rich segregates (80–100 Å) are clearly recognizable owing to their silver content.

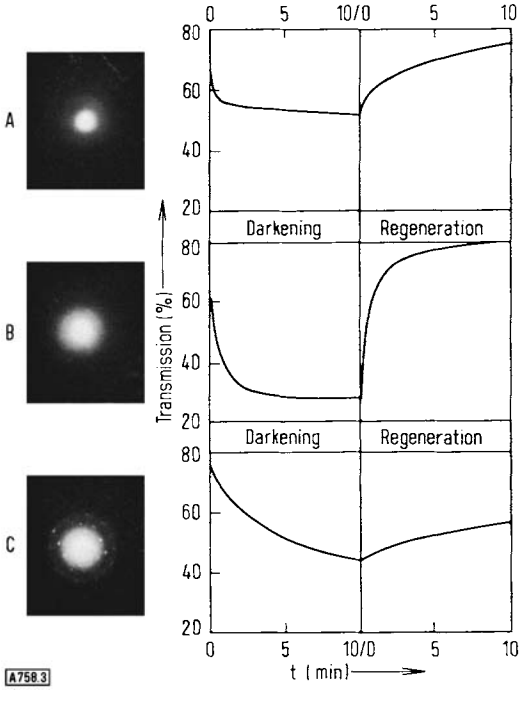

Fig. 3. Electron diffraction diagrams and kinetics of the phototropy of glass containing silver halide after different heat treatments. Glass no. 7 in Table 1. Sample A 40 min at 565 °C, sample B 180 min at 565 °C, sample C 900 min at 585 °C. Measurement of the phototropy at 545 nm and 20 °C during and after excitation with xenon light (8000 lx).

It can be shown in the case of glass no. 7 in Table 1 that the silver halide-rich segregates need not be macrocrystalline to ensure good phototropic properties in the glass. Electron diffraction diagrams for relatively large silver halide segregates and the darkening and regeneration behavior measured previously in the same samples are shown in Figure 3.

Electron diffraction diagram A, which shows no sign of a crystalline structure, but only weak diffractions due to the glass, is associated with medium darkening values and a medium regeneration rate. Tempering of this glass for a long time gives sample B, whose electron diffraction diagram again shows no clear sign of a crystalline structure. However, the phototropy is much better than in sample A. The saturation transmission is lower, *i.e.* the glass becomes darker for the same exposure, and it is regenerated much more rapidly. Sample C, whose electron diffraction diagram shows the first signs of a crystalline structure, is obtained when a glass of the same composition is tempered for a longer time and at a higher temperature. However, the phototropy is considerably poorer than in sample B.

Some of the processes involved in this thermal aftertreatment of the glass and the formation of the light-sensitive silver halide phase can also be deduced from the transmission curves.

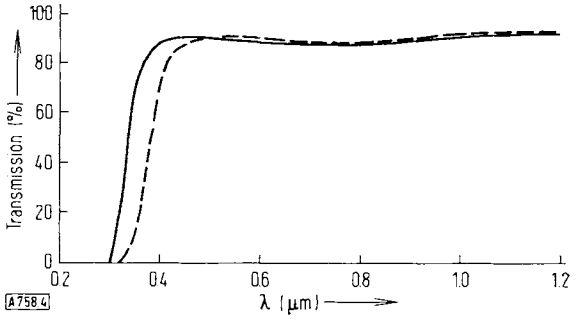

Fig. 4. Transmission curves of untempered glass containing silver halide (——) and of the same glass after tempering for 1 h at 603 °C (- - -) (glass no. 2 in Table 1).

Figure 4 shows a comparison of the transmission curve of the untempered non-photosensitive raw glass (glass no. 2 in Table 1) with that of the heat-treated phototropic final product. The raw glass has an absorption edge (50 % transmission) at 340 nm and an absorption maximum at 775 nm, which is responsible for the blue color of the glass and can be attributed to the Cu^{2+} ion.

After annealing, the color of the glass changes to green. The Cu^{2+} absorption at 775 nm remains unchanged, but the short-wave absorption edge is displaced by about 50 nm to longer wavelengths. This new absorption in the blue part of the visible region and the Cu^{2+} absorption in the red give the green color of the annealed glass. It is reasonable to suppose that the new absorption is due to the silver halide segregates formed during annealing of the glass.

Pure silver halide crystals are characterized by their UV absorption. The long-wave edge of the strong absorption of AgCl (measured for thin vacuum-deposited films at 293 °K) occurs at about 270 nm, and that of AgBr at 325 nm. Weak absorption tails extend far into the visible. The absorption is displaced to longer wavelengths with increasing particle size. The color of the AgBr itself shows a distinct change from white to yellowish with increasing grain size. The UV

absorption of the silver halides is explained by transitions of electrons from the valency band into the conduction band. Sharp bands superimposed on this absorption background can be attributed to exciton processes, in which the electron does not pass into the conduction band, but couples with a defect electron and migrates through the crystal lattice as an exciton.

In silver-free and halogen-free melts of the phototropic matrix glass, the absorption edge is not displaced by annealing, and the blue Cu^{2+} color accordingly persists on heat treatment. The same is true of a matrix glass containing silver and fluorine, of glasses that are free from bromine but contain silver and other halogens (F, Cl), and of phototropic glasses that do not contain silver. Glasses that contain all the components mentioned except chlorine, on the other hand, show the displacement of the absorption edge into the visible region, and the associated color change from blue to green, on annealing.

For a constant glass composition (*e.g.* glass no. 2 of Table 1), the position of the absorption edge depends on the annealing treatment. The edge is displaced to longer wavelengths with rising temperature and increasing annealing time. The same dependence is observed with increasing Ag(Br) concentration.

It thus appears to have been verified experimentally that no displacement of the absorption edge occurs without AgBr segregates in the phase separation during the heat treatment of the raw glass. The absorption of AgCl segregates lies in the region of the UV absorption of the glass itself, and so cannot influence the absorption edge and the color of the glass. The displacement of the absorption edge on heat treatment (annealing) can be explained by the increasing size of the segregate.

The detection of silver halide segregates in glass from the transmission curves agrees with the predictions based on electron microscope studies. According to *Armistead* and *Stookey* [16], *Smith* [22], and our own investigations, the segregates containing heavy metal can be detected in the electron micrographs only after heat treatment. If the silver halide segregates grow larger than 300 Å because of excessively high heat-treatment temperatures, they act as scattering centers (Rayleigh) for visible light. Phototropic glasses containing segregates larger than 2000 Å are distinctly cloudy.

In all phototropic glasses, in addition to the segregation of the silver halide-rich phase, phase separation is observed in the matrix glass. The silver halide segregates as a third phase. The fact that the segregation of the silver halide phase and the phase separation in the matrix glass often occur simultaneously may be attributed to the change in the solubility of the silver halides in the newly formed glass phases.

Evidence of this is provided by investigations by *Doremus* [23] on the diffusion of silver ions in a borosilicate glass with a tendency toward phase separation, the basic composition of which was very close to that of phototropic glasses. This glass consisted of a borosilicate phase containing about 95 % of the total sodium and a silicate phase containing 5 %. The measured diffusion rates show that the silver ions diffuse much more slowly in the silicate phase, *i.e.* they are bound more strongly in this phase. The solubility of the silver ions may therefore be assumed to be increased in this phase. The silver halide concentration is thus increased in this phase. A silver halide lattice that is strongly distorted by the components of the glass matrix can therefore be formed. The degree of microcrystalline order in the silver halide-richer phase cannot yet be stated precisely. The phototropic behavior of the light-sensitive segregates in the glass is described by most investigators in terms of models involving a more or less imperfect lattice.

It may be assumed that on slow segregation of these silver halide phases, not only does the size of the regions increase but the structure inside the segregation zones also changes on prolonged heating at high temperatures, after the manner of an aging process. It is not surprising, therefore, that signs of crystallinity are observed even in particles having a diameter of 1000 Å [21].

The compositions of the silver halide-rich segregation phases in two glasses are shown in Table 2. After annealing, the composition of the separated phase can be examined with the microprobe. The heat treatment in this case is such that the phase separation zones become much larger than 1000 Å. Whereas silver, the halogens, and the bivalent ions (mainly Ba^{2+}) are distinctly enriched, only components of the matrix glass that are also involved in phase separations in other glasses are found.

Table 2. Overall compositions of two glasses in wt-% and qualitative compositions of the segregated phases.

Sum (%)		Segregated phase	Sum (%)		Segregated phase

3. Models for the Kinetics of Phototropy

The phototropy of a glass is characterized by two properties of the material, *i.e.* the decrease in transmission (darkening) that can be achieved on exposure to light and the rate at which the glass lightens again on protection from light, *i.e.* the regeneration rate. The darkening on exposure is measured as the saturation transmission. This is the constant transmission value reached after the initial rapid decrease on prolonged exposure (cf. Fig. 1). Approximate values are used in practice to avoid excessively long measuring times.

A model has been developed by *Araujo* and *Stookey* [24] and by *Smith* [22] for the phototropic process. This model is capable of describing the darkening of phototropic glasses as a function of the light intensity. The rate of darkening, *i.e.* the change in the concentration of color carriers per unit time (dc/dt), is proportional to the intensity of the incident stimulating light I_d and to the number of light-sensitive silver halide centers A. While the glass is being darkened, the reverse reaction

[22] *G. P. Smith*, IEEE Spectrum *1965*, 39.

[23] *R. H. Doremus*, Physics Chem. Glasses *9*, 128 (1968).

[24] *R. J. Araujo* and *S. D. Stookey*, Glass Ind. *1967*, 687.

with formation of the silver halide is also taking place. This reverse reaction is proportional to the darkening c that has already occurred. Two effects must be distinguished in the reverse reaction; these are optical bleaching and thermal bleaching.

Pohl[17] described photochemical processes in silver halides and mentioned that light absorbed by the color centers, like elevated temperatures, has a regenerating action.

Optical bleaching is the removal of silver by absorption of visible light in the wavelength range 550–750 nm. The absorption of light quanta of this energy leads to the transfer of electrons from the silver into the conductivity band of the halide lattice. Optical bleaching may be compared to the Herschel effect in photography.

In the model proposed by *Araujo* and *Stookey*[24] and by *Smith*[22], the optical bleaching is also assumed to be proportional to the light intensity I_f in the above range of wavelengths. It is clear that the reverse reaction due to light absorption in the visible region increases with increasing darkening c. The absorption of this light is particularly effective in the fully exposed state, owing to the strong absorption band in this region. Thermal bleaching, *i.e.* the recombination of Ag and halogen to form the halide as a result of the thermal motion of the ions, electrons, and defect electrons, clearly plays an important part in deciding the equilibrium state, *i.e.* the saturation transmission. The overall darkening rate[24,22] is given by:

$$dc/dt = k_d I_d A - (k_f I_f + k_t) c \qquad (1)$$

where k_d, k_f, and k_t are the rate constants for darkening, optical bleaching, and thermal bleaching, respectively. In the equilibrium state, with $dc/dt = 0$, the saturation concentration c_s of the darkening silver centers (or the saturation transmission) is obtained from eq. (1)[22].

$$c_s = \frac{k_d I_d A}{k_f I_f + k_t} \qquad (2)$$

The values of the constants in the equation are determined by the structure, number, and size of the photosensitive silver halide regions.

For example, if the constant k_t for thermal bleaching tends toward zero, the color center concentration c_s in the equilibrium state becomes independent of the light intensity, since the ratio of stimulating light and optically bleaching light is constant. If the constant k_t is relatively large, on the other hand, it becomes rate-determining, and the color center concentration c_s is proportional to the stimulating intensity I_s (see Fig. 5).

The above model can be made to fit the experimental data by dividing the elementary phototropic process into surface or interfacial effects and volume effects.

A more advanced model has been proposed by *Araujo*[25], according to which the optical bleaching process

[25] *R. J. Araujo*, personal communication.

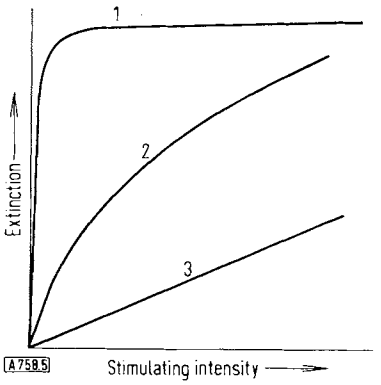

Fig. 5. Stimulating intensity *vs.* resulting darkening for glasses with different values of the constant k_t for thermal bleaching (schematic) after *Araujo* and *Stookey* [24].
Ordinate: Extinction reached in equilibrium state of saturation transmission.
1, very slow thermal bleaching, C_s = const.
2, phototropic glass $C_s = \frac{k_d I_d A}{k_f I_f k_t}$
3, very fast thermal bleaching, $C_s \approx I_s$.

can always be treated as a first order reaction. On the other hand, the thermal bleaching cannot be described by a simple first-order equation, and must be assumed to be of n-th order. In general, the rate constant k_t and the n-th order reaction can be attributed to a diffusion process. The dependence of the regeneration time on the exposure time as deduced from this model has been confirmed experimentally.

The time dependence of the transmission during recovery in the absence of light can be described surprisingly well by a simple diffusion model based on Tammann's rule for the growth of surface layers. Apart from the first increase (decrease) in the extinction on illumination (recovery), which is apparently determined by electronic processes[26], the time dependence of the extinction can be expressed in the form of straight lines as $\varepsilon = f(\ln t)$. According to this model[27], the time dependence of the recovery rate is explained by the increasing length of the diffusion paths of the silver atoms and ions. The small silver particles that are present after prolonged recovery recombine more slowly than the large silver regions that are still present shortly after screening from the light. The diffusion of the silver appears to be of great importance to the models discussed here. Since there is little diffusion of the halogen atoms and halide ions in the silver halide lattice, owing to their size, the key to the factor controlling the regeneration rate lies in the formation of a halide lattice that promotes the diffusion of silver.

The diffusion of silver in silver halide occurs mainly *via* Frenkel defects, *i.e. via* interstitial sites and lattice holes. Self-diffusion *via* interstitial silver ions predominates above 150 °C, and diffusion by means of holes in the silver lattice below this temperature. The number of holes is strongly dependent on doping with foreign materials.

An insight into the electronic process in the darkening can be gained by experiments in the microsecond range.

Figure 6 shows an arrangement for measurements with a powerful flashlight (1), which emits a measuring beam (2) and a reference beam (3). These beams proceed to the photodiodes (8) and (9) respectively. Photons reaching the photodiodes give the same optical signal when the samples (4 and 5) are alike. At the start of the experiment these samples consist of non-phototropic glass. The electrical signal from the photodiodes passes to a twin-beam oscillograph. Figure 7a shows a calibration plot with ordinary window glass in both beams. Both photodiodes, and hence both channels of the oscillograph, receive the same signal, and both curves coincide.

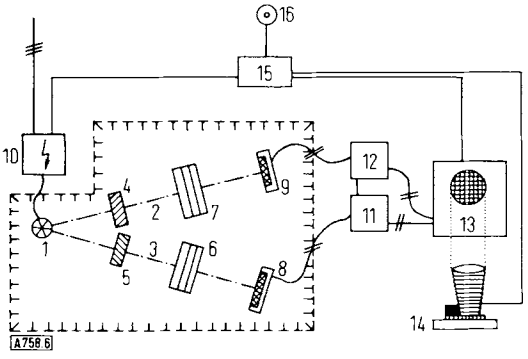

Fig. 6. Measuring arrangement for the determination of the intensity-time behavior of phototropic glass. 1. Flash tube, 2. measuring beam, 3. reference beam, 4. phototropic sample, 5. reference sample (window sheet glass), 6. + 7. filter system. 8. + 9. photodiodes. 10. high-tension unit. 11. + 12. adjusting systems. 13. oscillograph. 14. camera, 15. trigger system, 16. initiator for flash. The unit indicated (1 and 4—9) is thermostated.

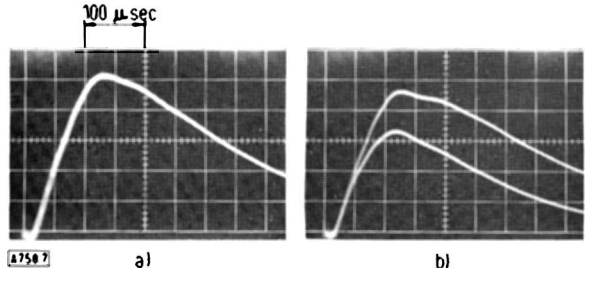

Fig. 7. Intensity-time diagram (photograph of the oscillograph screen) of the darkening at 545 nm of a glass containing silver halides under the action of a flash. a) Calibration measurement: window glass is placed in both beams, and the traces of the two oscillograph channels coincide. b) Glass no. 5 in Table 1 is placed in the measuring beam, and window glass in the reference beam.

Figure 7b shows the intensity-time diagram with a phototropic glass in the measuring beam and non-phototropic material in the reference beam. The light intensity passing through the phototropic glass per unit time decreases in proportion to the darkening effect in the phototropic glass.

If zero time is taken to be the moment when the intensity curve of the reference beam shows its first ascent, the intensity curve of the reference beam corresponds to the photon energy falling on the phototropic glass at any instant. The intensity of the light after passage through the phototropic glass is shown by the lower curve. It is thus possible by this twin-beam method to obtain comparable values even when the energy of the flash unit varies slightly. The difference between the two curves is the light energy absorbed by the phototropic glass.

Figure 8 shows the darkening intensity time functions for four phototropic glasses. Comparison of this darkening behavior in the short time range with the long-time plots for the same glasses (Fig. 9) shows that the rates of darkening of glasses a and b, which have the lowest saturation transmission in Figure 9, do not agree. This discrepancy can be explained by assuming that in the short-time experiments, the diffusion component of the rate constant k_t is of no importance at least in the part evaluated.

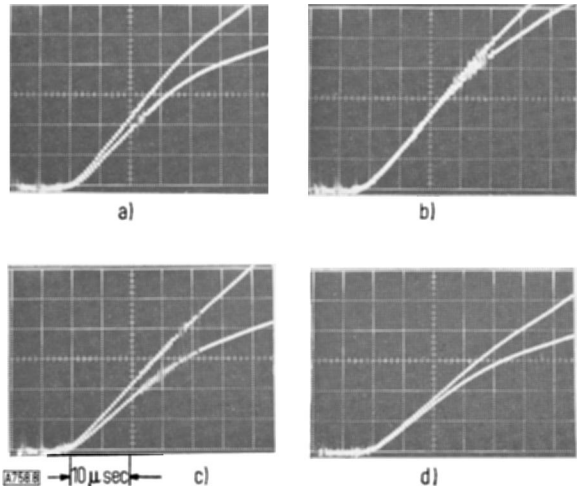

Fig. 8. Intensity-time diagram (photograph of the oscillograph screen) of the darkening at 545 nm of four phototropic glasses under the action of a flash at 20 °C. Horizontal scale 5 µs cm^{-1}. a) Glass 53—01—1989; b) glass 53-01-0491: c) glass 9416; d) glass C 16/4.

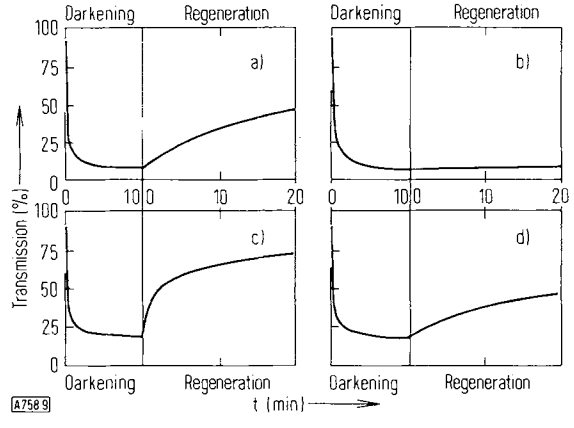

Fig. 9. Darkening and regeneration of phototropic glasses containing silver halides at 545 nm as a function of time on stimulation for 10 min with xenon light (8000 lx) and subsequent regeneration. Temperature 20 °C. For a—d see caption to Fig. 8.

It is only the rate constant k_t that causes any deviation from the reciprocity law governing the response of a photographic emulsion. According to this law, a constant density is obtained if the product of the time and the intensity is constant.

According to *Megla*[29] the rate constant k_t, *i.e.* the rate constant for thermal bleaching of phototropic

[29] *G. K. Megla*, Appl. Optics *5*, 945 (1966).

glasses, influences the darkening effect because the change in the optical density ΔD during the exposure can be described, not by a simple function

$$\Delta D = f(I \times t) \quad (3)$$

but by the equation

$$\Delta D = f(I \times t^p) \quad (4)$$

During the darkening process, the exponent p is smaller than 1; the thermal bleaching retards the increase in the optical density. On bleaching of the phototropic glass, p becomes greater than 1, since the thermal bleaching now accelerates the decrease in the optical density. Since the exponent, which represents the influence of the rate constant k_t on the thermal bleaching, is diffusion-controlled, it must be temperature-dependent.

4. Temperature Dependence

The temperature dependence, which results from that of the rate constant, is found in all the individual processes of the phototropic effect. The relationship between the saturation transmission and the temperature is particularly clear.

Strong darkening can be achieved at low temperatures, and the recovery is extremely slow. The recovery is strongly accelerated with rising temperature, and the saturation transmission at equilibrium simultaneously decreases. Most phototropic glasses no longer react above 80 °C.

Energy considerations connected with the fundamental photographic process (*Bodenstein* – silver seed theory 1941) showed that 30 to 60 kcal/mole would be required for the formation of atomic silver in the photodecomposition of silver bromide. On the other hand, the formation of crystalline silver aggregates on crystallization centers inside the silver bromide should be exothermic to the extent of 2 kcals/mole. This agrees qualitatively with thermodynamic data based on electrochemical measurements on the system Ag/Ag halide [30].

The exothermic character of the photolysis in phototropic glass is in agreement with the model of crystalline silver segregates. Activation energies of −2 to −10 kcal/mole are found by measurements between 0 and 80 °C. The strong temperature dependence (Fig. 10) of the phototropic process in glass is partly due to the decrease in the mobility of the silver ions and the decrease in the lattice vibrations.

A very important fact is that owing to the reduced thermal motion in the lattice, shallow energy troughs become active, and the finite probability of finding charge carriers in these troughs at normal temperature is very small. The time spent by the electrons and

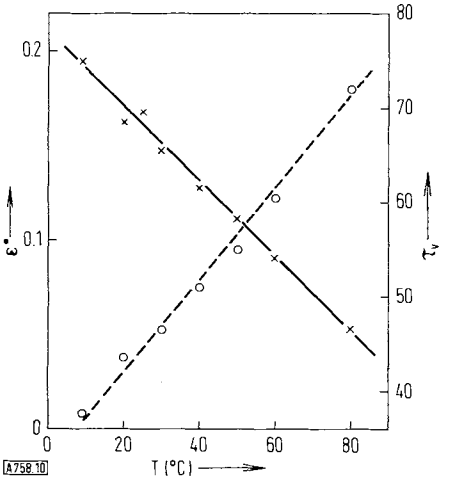

Fig. 10. Temperature dependence of the extinction ε^* and of the transmission τ_V of glass no. 2 in Table 1 at 545 nm. The experimental points were determined by stimulation with xenon light (8000 lx) until the saturation transmission was reached.

defect electrons in sites with shallow energy troughs generally increases with falling temperature. The higher photon yield measured at low temperatures contrasts with the reduced mobility of the interstitial silver ions Ag_i^+. The greater saturation absorption must therefore be explained by the greater probability of finding the electrons in deep energy troughs. Thus if the decrease in the rate of diffusion of the silver ions in the interstitial sites with falling temperature is faster than the increase in the time spent by the electrons in low-energy sites, the reaction between the electrons and the interstitial silver ions to form silver atoms is favored, while the recombination with defect electrons (*e.g.* in bromine atoms) is repressed. This factor is active in the pronounced retardation of the recovery process at low temperatures. These considerations are arguments from analogy that follow from experimental and theoretical studies on the fundamental photographic process.

5. The Phototropic Reaction

The process that occurs on exposure of a phototropic glass to light can be represented schematically, on the basis of the photosensitivity of silver halides, by the following equations:

$$Br^-(Cl^-) + h\nu \rightarrow Br^0(Cl^0) + e \quad (5)$$

$$Ag^+ + e \rightarrow Ag^0 \quad (6)$$

$$Cu^{2+} + e \rightarrow Cu^+ \quad (7)$$

$$Cu^+ + Ag^+ \rightarrow Ag^0 + Cu^{2+} \quad (8)$$

$$Cu^+ + Br^0 \rightarrow Cu^{2+} + Br^-$$

$$Ag^0 \rightarrow Ag^{\square} \quad (9)$$

Unexposed phototropic glass has a slight greenish color. This disappears on exposure to light, the im-

[30] *K. Meinig, G. Metz,* and *J. Teltow,* Physica Status solidi (Berlin) *2,* 1556 (1962).

[31] *J. Eggers, G. Haase,* and *R. Matejec*: Grundlagen der photographischen Processe mit Silberhalogeniden. Akad. Verlagsges., Frankfurt/M. 1968.

pression of color then being due to the silver segregates formed on decomposition of the light-sensitive silver halide segregates. The number and size of the silver segregates depends *inter alia* on the number, size, and structure of the silver halide segregates.

Silver atoms Ag^0 are deposited in accordance with equations (6) and (8), and grow together at the outer and inner grain boundaries of the halide phase to form larger aggregates, probably microcrystalline Ag□ [eq. (9)].

Figure 11 shows the transmission curves of an annealed phototropic glass (glass no. 2 in Table 1) in the unexposed and in the exposed state. The minima in the transmission curves at 1.45, 2.2 and 2.8 μm are bands due to the OH content of the glass, and are independent of the state of exposure of the phototropic glass. The broad absorption at 0.75 μm is due to the Cu^{2+} ion. It seems reasonable to attribute the strong absorption band with a maximum at 0.58 μm to the silver formed on exposure to light. Clear parallels would thus exist with the elementary photographic process, which has already been studied in detail.

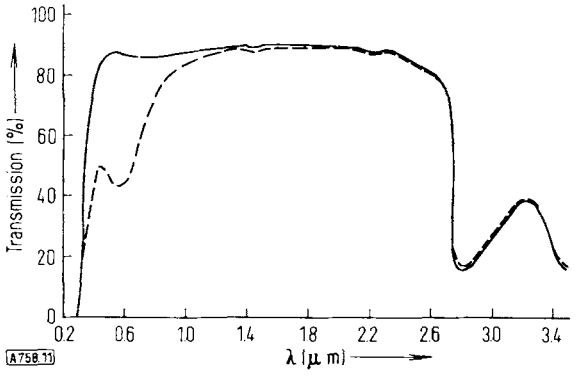

Fig. 11. Spectral transmission distribution for phototropic glass containing silver halide in the unexposed state (——) and after excitation for 20 min with xenon light (8000 lx) (- - -). Glass no. 2 in Table 1, temperature 20 °C.

6. Darkening Effect and Color in the Exposed State

In the photochemical decomposition of pure AgBr, *Hilsch* and *Pohl*[32] showed that exposure to light in the long-wave tails of the AgBr absorption leads to the development of a colloidal silver absorption band with a maximum between 0.6 and 0.8 μm. On the basis of *Rayleigh*'s views, *Mie*[33] calculated the dependence of the position of the maximum on the size of the colloidal silver particles for spherical silver particles in water.

Löhle[34] studied the shape and position of the absorption bands of silver colloids in AgCl crystals. With increasing exposure, the maxima become more intense and migrate from 520 toward 570 nm. Calculations and experiments on colloidal silver particles in gelatin and water have been reported by *Klein* and *Metz*[35]. The absorption curves calculated for the silver particles on the basis of *Mie*'s theory exhibit satisfactory agreement with the experimental curves. The absorption maxima are found to move to longer wavelengths with increasing particle size. Since the size of the silver particles is in the region of the wavelength of visible light, the colloidal "solutions" appear to be colored. On photolytic decomposition of silver compounds in gelatin, the color of the silver changes from yellow through red to blue with increasing particle size.

The silver formed on exposure of photographic layers to light is also colloidal, and exhibits absorptions that are proportional to the particle size between 600 and 800 nm.

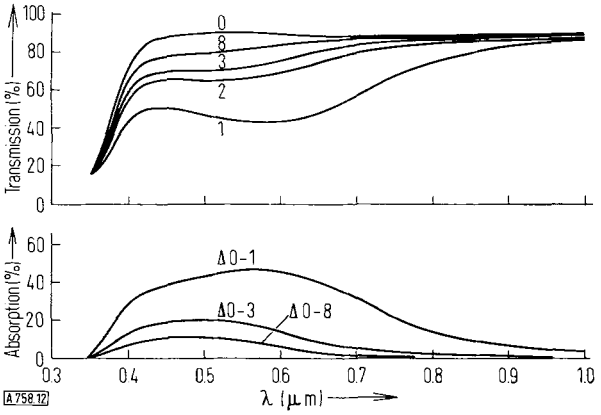

Fig. 12. Transmission curves of glass no. 2 in Table 1 for the excitation states 0 to 8 (top) and the absorption curves found from these by substraction (bottom), temperature 20 °C.

The above results cannot be freely applied to silver in phototropic glass, partly because the optical constants are different; nevertheless, substantial qualitative agreement is found. Figure 12 shows the transmission curves of a phototropic glass in the unexposed and in the exposed state. Subtraction of two curves gives the absorption curve (Δ curve) of the colloidal silver particles formed on exposure. The strong broadening of the absorption bands of the colloidal silver can be explained by the presence of a particle size distribution. As the glass becomes lighter again, the transmission minimum is displaced to shorter wavelengths and the extinction decreases. The color of the glass shown in Figure 12 changes from blue to red. As the glass becomes lighter, the size of the silver particles that have segregated in the glass must clearly decrease as a result of diffusion and recombination with halogen. The maximum of the size distribution moves toward smaller particles, and the integral absorption simultaneously decreases.

If the dependence on particle size found for colloidal silver in gelatin (refractive index $n_D = 1.5$) is assumed to be valid also for the silver particles in glass ($n_D = 1.523$), it can be estimated from the displacement of the absorption maxima on exposure to light and on recovery that the silver particles that separate out have a diameter of 40 to 100 Å. This roughly corresponds to the size of the silver halide regions as found from the electron micrographs. The requirements for quantitative agreement are not satisfied. Moreover, *Mie*'s theories and the absorption curves calculated from them are strictly valid only for spherical particles of uniform size, whereas we must expect a wide particle size distribution in phototropic glass.

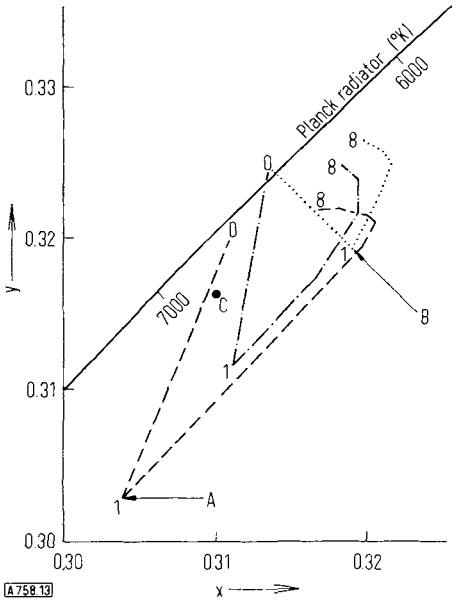

Fig. 13. Color shifts of a phototropic glass containing silver halide in the color chart representation in accordance with the German standard DIN 5033. Color in the unexposed state = 0, color at saturation transmission after exposure to xenon light (8000 lx) = 1. The differently shaded curves denote products obtained by various tempering treatments of glass no. 2 in Table 1. The numbers refer to the transmission curves of Fig. 12. For A, B and C, see text.

Figure 13 shows the color shifts occurring in phototropic glasses directly in a color chart representation in accordance with the German standard DIN 5033. The colors of the glasses are fixed by the x and y coordinates. The greater the change in the color of a glass during the darkening and recovery processes, the longer are the curves described in the color chart.

The colors of the unexposed phototropic glasses all lie in the white region of the color chart. The greatest color change occurs on exposure to light (curve segments 0-1); the glass moves away from the curve for the black body (Planck radiator). Depending on the size of the silver particles formed on exposure to light, the color changes *e.g.* toward blue (curve A) or purple (curve B). During regeneration, all colors move toward red (see curve segments 1–8). The visual transmission $\tau_{v,C}$, based on the nature of the light C, must be imagined to be plotted on the z axis above the plane of the paper. Between 0 and 1, the glasses are situated on the descending part of the curve in Figure 1 (exposure). The color (x and y coordinates) and the transmission (z coordinate) of the segment (1–8) correspond to the regeneration part of the curve in Figure 1.

It can also be seen from Figure 13 that the recovery is always associated with a color shift toward red. The magnitude of the shift increases with increasing blueness of the glass on full exposure. As was mentioned earlier, this behavior can be readily explained by the size of the colloidal silver particles that separate.

7. Wavelength of the Stimulating Radiation

The darkening of a glass is caused by a stimulating radiation. *Armistead* and *Stookey*[16] have published curves showing the relationship between the wavelengths that stimulate the darkening and the sensitivity of the glass. The theoretical excitation limits are about 390 nm for glasses containing silver chloride 500 nm for glasses containing silver bromide and silver chloride, and 580 nm for glasses containing silver chloride and silver iodide. Identical curves were published by *Araujo* and *Stookey*[24] and by *Justice* and *Leibold*[36]. However, all these curves appear to have been extrapolated from the properties of the pure crystalline silver halides.

Smith[18] published curves for the spectral sensitivity of the activation of glasses having different compositions. The glasses gave excitation maxima at 340 and 400 nm.

The light-sensitivity of the phototropic glass no. 2 of Table 1 with a high AgBr content is shown in Figure 14. The maximum darkening is obtained with stimulating light having a wavelength of 360 nm. With increasing transmission of the glass, the light-sensitivity falls off toward longer wavelengths.

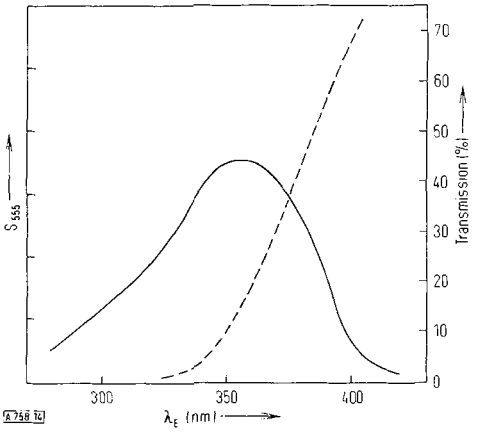

Fig. 14. Spectral position of the excitation maximum (——), determined by the darkening S_{555} at 555 nm resulting from excitation with the wavelengths λ_E, and position of the absorption edge (- - -) of phototropic glass no. 2 in Table 1, temperature 20 °C.

The position of the excitation maxima depends not only on the size and structure, but also on the composition of the silver halide-rich phase, and in fact only on its halide content; it appears to be independent of the type of matrix glass and of the phases that separate out from the matrix glass. Thus by choosing the halides used in the synthesis of the glass, it is possible to produce phototropic glasses with different excitation sensitivities in the short-wave visible and ultraviolet region of the spectrum.

The absorption by pure AgBr and AgCl extends far into the visible region; however, the absorption edge is smaller than 0.01 mm^{-1} above 400 nm at about 25 °C and at silver halide concentrations of less than 1 %. If the silver ions in the silver halide segregates in the phototropic glass are partly replaced by alkali metal, Cd^{2+}, or Pb^{2+} ions, the already low absorption in the long-wave region is displaced further toward shorter wavelengths[30]. Doping of the silver halide

[36] *B. Justice* and *F. B. Leibold*, Information Display, Nov./Dec. 1965, 23.

segregates formed in phototropic glass with components of the glass matrix (alkali metal, lead) is also very probable from what was said above. The reason for the shift of the absorption tails to shorter wavelengths lies in the increased energy difference between the valence band and the conduction band. The optical energy required for the transition from the valence band to the conducting band increases with the concentration of foreign substances in the silver halide lattice.

The fall-off of the darkening curve toward shorter wavelengths is not to be expected in this region because of the strong silver halide absorption. The reduced photosensitivity at wavelengths below 350 nm is due to absorption by the matrix glass itself. In addition to the light-sensitivity, Figure 14 shows the transmission of the phototropic glass as a function of the wavelength. The transmission is only 1 % at 325 nm, and at 290 nm it is less than 0.001 %. Since radiation from the sun begins only at 300 nm, the absorption region below 325 nm is of no interest *e.g.* for the use of phototropic glass in spectacles. Phototropic glasses can be stimulated by high-energy radiation of short wavelength. However, this excitation (X rays, electrons) is usually associated with more or less irreversible disturbance of the phototropic process.

The darkening produced at a constant light intensity also varies from glass to glass under otherwise identical conditions. This agrees with the observation [37] that the darkening in pure and doped silver halide crystals is also a function of the crystallite size, the degree of imperfection, and the concentration of foreign substances [38, 39].

Application of these ideas to the silver halide-rich segregates in phototropic glass provides a simple explanation of the fact that entirely different phototropic glasses can be obtained from the same matrix glass by different tempering. Short tempering times lead to segregates having high degrees of imperfection and high doping levels. Longer tempering times give silver halide segregates with better structures, but these have lower photosensitivities, *i.e.* poorer photon yields. Experiments have shown that for approximately equal crystallite sizes, the saturation transmission attainable on full exposure is strongly dependent on the degree of imperfection and the related doping of the silver halide phase with foreign substances.

8. Intensity of the Stimulating Radiation

Araujo and *Stookey* [24] described the influence of the intensity of the stimulating radiation on the darkening behavior of a phototropic glass. For an excitation wavelength of 400 nm, the intensity was between 10^{-3} and 10^{-5} W/cm². With a glass thickness of 6 mm and the highest intensity of 10^{-3} W/cm², they obtained an optical density of 1.5. Our own investigations have given an optical density of 1.7 at 20 °C with the same excitation intensity and wavelength for other glasses with a thickness of only 2 mm.

The dependence of the saturation transmission on the intensity of the stimulating radiation for a constant spectral composition is shown in Figure 15. The darkening process in a phototropic glass having given composition and structure ends with an equilibrium state that depends, for a constant number of possible color centers, on the number of photons that allow the darkening, as well as on the regeneration rate and the temperature.

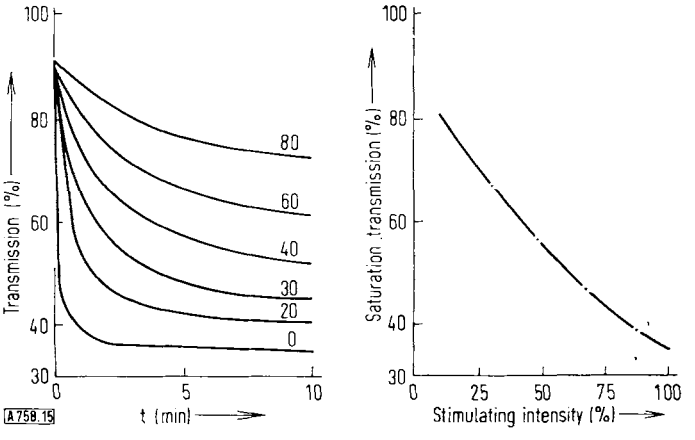

Fig. 15. Dependence of the darkening of a phototropic glass containing silver halide (glass no. 7 in Table 1) on the excitation intensity.
Left: decrease in transmission at 545 nm with time. The stimulation intensity of the xenon lamp (8000 lx) is reduced by rotating sector diaphragms. (The numbers by the curves denote the decrease, in %). Right: dependence of the equilibria of the saturation transmission on intensity, temperature 20 °C.

Figure 15 shows, on the left, the darkening behavior of a phototropic glass as the stimulating beam is stopped down (weakened). The numbers against the curves are the percentage decreases in the intensity of the stimulating light. It can be seen in the right-hand part of the figure that the darkening of a glass decreases with decreasing photon supply. As the number of photons falling on the glass decreases, the time taken to reach equilibrium between darkening and regeneration, *i.e.* the saturation transmission, becomes steadily longer.

Megla [29] determined the energy density of the light of optimum wavelength used. The results show that depending on the nature of the phototropic glass, 4 to 25 times as many photons are required for the bleaching of a previously exposed glass as for the darkening of an unexposed glass. Thus the glasses investigated by *Megla* are not sensitive enough for use *e.g.* as photographic materials in cameras.

A conventional photographic film is more than five times as sensitive as the phototropic glasses currently being produced. Further work is being aimed at much higher sensitivities, approaching the values for photographic films.

9. Sensitization of the Stimulation

A few investigations have been carried out on the possibility of sensitizing phototropic glasses. All attempts have been based on concepts regarding the silver halide lattice that have been obtained for pure silver halide crystals or for photographic emulsions [31,38,39]. *Fanderlik* [40], for example, studied the possibility of improving phototropic glasses containing only silver chloride by addition of small quantities of Ag_2S.

In silver halide crystals, disorder involving lattice vacancies and interstitial ions predominates [31]. This Frenkel disorder is confined to the silver part of the lattice ($Ag_{\ddot{o}}$ and $Ag_{\ddot{\square}}$), owing to the size of the halide ions. The imperfection concentration can be strongly influenced by the incorporation of bivalent ions having approximately the same ionic radius. Each bivalent ion incorporated into the silver halide lattice replaces two silver ions, *i.e.* in addition to the foreign ion in a silver lattice site ($Ag^{+}_{\square}$), a silver ion vacancy ($Ag_{\ddot{\square}}$) is also produced to maintain electroneutrality; at the same time, the number of silver atoms in interstitial sites ($Ag_{\ddot{o}}$) decreases.

Table 3. Ionic radii after *L. Pauling* (in Å).

Ag^+	1.26	Cd^{2+}	0.97
Cu^+	0.96	Pb^{2+}	1.21
Li^+	0.60	Ba^{2+}	1.35
Na^+	0.95	F^-	1.36
K^+	1.33	Cl^-	1.81
Ca^{2+}	0.99	Br^-	1.95

These considerations are valid in particular for the incorporation of Ca^{2+} and Cd^{2+} ions into the silver halide lattice, since the ionic radii of these ions favor their incorporation into the silver halide (Table 3). The compositions of the phototropic glasses (Table 1) should also be considered from this point of view. Monovalent foreign ions that replace the silver ions in the lattice ($Ag^{+}_{\square}$) do not displace the imperfection equilibria so much, since they do not introduce any excess charge into the host lattice.

An exception is the Cu^+ ion, which acts as a bivalent ion, and can occupy interstitial sites as well as silver lattice sites. These Cu^+ ions increase the photochemical sensitivity of the silver halide crystals, the increase in sensitivity, at least for low doping levels, being proportional to the Cu^+ concentration [37]. The Cu^+ ions reduce the defect electrons formed on exposure of the Cu^+-doped silver halide to light, and so prevent the reverse reaction of the silver with the halogen [*e.g.* in accordance with eq. (8)]. The resulting additional absorption in the long-wave absorption tails of the silver halides, on the other hand, appears to be less important. The Cu^{2+} ions formed by the capture of defect electrons revert to Cu^+ in the dark as a result of a "fading" process, the rate of which depends on the volume. It is not impossible that the reaction in accordance with eq. (7), *i.e.* the capture of electrons by the Cu^{2+}, explains the rapid bleaching of the absorption at 750 nm on exposure to light. The recovery of the phototropic glass in the dark leads back to the Cu^{2+} ion. The fading mentioned above appears to play only a minor part in the process as a whole. More detailed studies are still in progress.

The Cu^+ ions present in the glass as a result of the equilibrium between Cu^+ and Cu^{2+} must, however, be regarded as a necessary sensitizer for the phototropic process.

An observation corresponding to these discussions that can be used for the sensitization of phototropic glasses has been reported by *Belous* and *Ilmas* [41]. These authors observed a photoamplification effect in silver halide crystals and verified it with the aid of luminescence spectra.

10. Use of Phototropic Glasses

The phototropic effect in glass was first used ophthalmologically in spectacle glass that can vary its transmission for visible light in proportion to the sunlight falling on it [42,43]. The UV absorption of the matrix glass is particularly beneficial in this application, since it ensures that even when the thickness of the glass varies (correcting lenses), stimulation, and hence darkening, occurs mainly in a layer near the surface [44]. The darkening is therefore very uniform over the whole lens. Work in this field is being concentrated mainly on the color in the exposed state and the kinetics of the spectacle lenses [43,45].

Several studies have been carried out on the use of phototropic glasses in conjunction with lasers, which has led *inter alia* to the q switch [46]. In the improvement proposed by *Bojko* [47], the laser substance and the phototropic glass are in direct optical contact; this reduces disturbing reflections.

Another field of application is in image conversion [48,49], where *e.g.* UV light is passed through negatives. The UV light darkens a phototropic glass plate in accordance with the densities in the negative, and the image produced in the phototropic glass in this way can be read by means of an auxiliary light source.

The use of phototropic materials having an inorganic basis in holography and electrical engineering has been described by *Kiss* [50]. *Blue* and *Chen* [51] mentioned the use of phototropic glass for holography and in electronic data processing.

The phototropic properties of the glasses must be modified for this purpose[52].

A phototropic glass for use in holography[29,51,52] must have a high resolution. All phototropic glasses are better in this respect than the best photographic layer, which is tied to the photographic grain. A high writing rate (at least 10^6 bits/s) is required, and the hologram must exhibit good stability over long periods[29]; this requirement is linked with the regeneration time and the activation energy for regeneration[26]. Extinction must also be possible; lasers operating in the near IR region or heat may be used for this purpose[36]. *Baldwin*[53] has published information on the determination of the storage capacity of phototropic glasses for holography.

The use of a conducting film for accelerated regeneration, which is essential for holographic applications, has been described by *Justice* and *Leibold*[36]. The specimens are coated on both sides with a transparent, electrically conducting film of stannic oxide. The applied voltage was 120 V, and the power was approximately 48 W. Specimens with a half life of 500 s were completely regenerated in less than 10 s on application of the electric field.

The use of phototropic glasses in micrography has been described by *DeKing*[54].

Other applications are instrument panels that are controlled by computers and which write the data in the phototropic glass with UV beams[22]. Automobile windshields, window glass, *etc.* have been considered as a potential application of phototropic glass.

We thank Dr. H. Bach, Jenaer Glaswerk Schott & Gen., Mainz, for preparing[56] *and making all the electron micrographs shown in this article.*

Ion-Selective Sensors

By Wilhelm Simon, Hans-Rudolf Wuhrmann, Milan Vašák, Lavinia A. R. Pioda, René Dohner[*], and Zlata Štefanac[**]

Numerous advances have recently been made in the development of ion-selective (glass, solid, liquid) membrane electrode systems. The theoretical principles and practical requirements of such "sensors" are outlined in this article, and an attempt is made to review their possible applications.

1. Introduction

A number of reviews have been published on the selective detection of ions in aqueous and nonaqueous solutions by electrode systems[1–14,220,221,256]. The present position in this field is described below, with special emphasis on the discussion of various sensor systems. The associated membrane phenomena have already been discussed in detail in several publications[2,15–18,220–224].

The sensors to be considered here can be divided into three basic groups, according to the type of membrane:

1. glass membrane
2. solid-state membrane: a. homogeneous solid-state membrane
   b. heterogeneous solid-state membrane
3. liquid membrane: a. electrically charged ligand groups (ion exchangers) as membrane components

b. electrically neutral ligand groups as membrane components.

Figure 1 shows a diagram of a cell assembly for the detection of ions. The membrane, which responds selectively to ions, is normally combined in a unit with the internal filling solution and inner reference electrode (internal reference electrode). Such "sensors" are illustrated in Figure 2 for the membrane types mentioned.

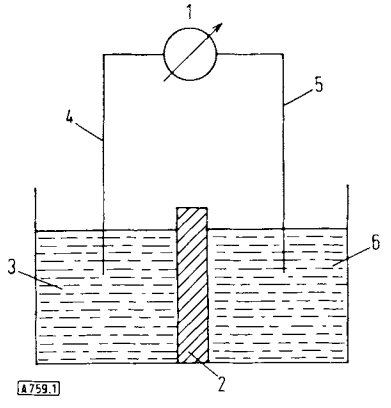

Fig. 1. Membrane electrode cell assembly (schematic).
1: EMF; 2: membrane; 3: internal filling solution; 4: inner reference electrode; 5: reference electrode (external); 6: solution to be measured.

Both the inner solution and the inner reference electrode may in principle be replaced by a direct electrical connection to the corresponding side of the membrane [19–21]. Such systems may occasionally be advantageous for membrane electrodes of types 2 and 3, but are not recommended for glass electrodes in view of the choice of the electrical zero of the cell assembly and the choice of the isopotential pH (intersection of isotherms) [19, 22, 23].

In the glass electrode (Fig. 2A), the ion-selective membrane is usually fused to an inert glass stem, while in solid-state membrane electrodes it is usually cemented to an inert membrane shaft (Fig. 2C,D). For heterogeneous solid-state membranes, *Pungor et al.* [7, 11, 221] use about 30 to 50 wt.-% of ion-selective membrane component (*e.g.* silver halide) having a grain size of 5–10 μm in a silicone rubber matrix. Other matrix materials that have been used are paraffin wax, acrylamides, and polyethylene [24–27].

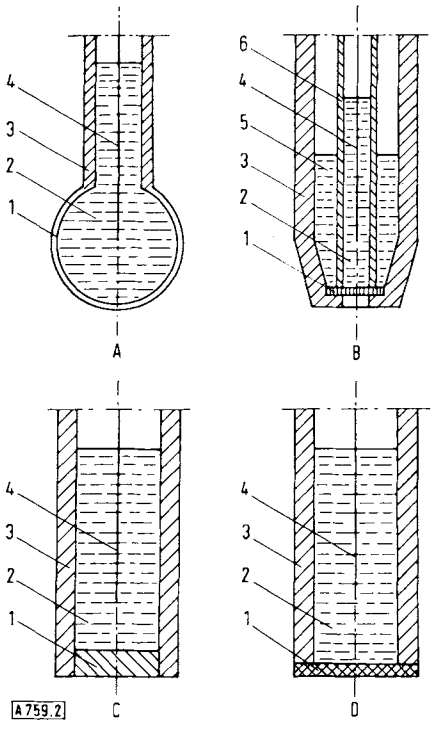

Fig. 2. Membrane electrodes (schematic).
A: *Glass electrode*: 1: glass membrane; 2: internal filling solution; 3: glass stem; 4: inner reference electrode.
B: *Liquid membrane electrode*: 1: filter paper impregnated with ion-selective ligand; 2: internal filling solution; 3: electrode shaft; 4: inner reference electrode; 5: ion-selective ligand; 6: tube to receive internal filling solution.
C: *Electrode with homogeneous solid-state membrane*: 1: homogeneous solid-state membrane; 2: internal filling solution; 3: electrode shaft; 4: inner reference electrode.
D: *Electrode with heterogeneous solid-state membrane*: 1: heterogeneous solid-state membrane; 2: internal filling solution; 3: electrode shaft; 4: inner reference electrode.

In the liquid membrane electrode of Figure 2B, a filter paper impregnated with ion selective ligand acts as the membrane. Any ion-selective component contaminating the solution being measured is replaced from the reservoir 5 (Fig. 2B); this should ensure a long electrode life of the membrane electrode system [28].

For ease of handling of the cell assembly and for working with small samples, it is advisable to combine the ion-selective membrane with the inner reference electrode, the internal filling solution, and the reference electrode that dips into the solution to be measured to form a single structural unit (single-rod cell assembly, combination electrode) [4, 12, 29].

2. Theoretical Considerations

Though liquid junction potentials that depend on the electrolyte of the reference electrode, the sample, the temperature, and other factors arise at the phase boundary between the reference electrode and the sample, it will always be assumed here that the poten-

tial of the reference electrode with respect to the sample is constant and independent of the nature of the sample solution (Fig. 1)[4,19,30–34].

2.1. Glass Membranes, Solid-State Membranes (Solid Ion-Exchange Membranes)

Relations based on investigations by *Nicolsky*[35] have been derived from experimental data for the EMF of a cell assembly with a liquid or solid ion-exchange membrane[15–17]. These relations can be formulated as follows for glass and pure solid ion-exchange membranes:

$$\mathrm{EMF}(T) = E_0^{\mathrm{A}}(T) + \frac{n \cdot R \cdot T}{F} \ln \frac{a_1^{1/n} + \left(K_{12}^{\mathrm{Pot}} \cdot a_2\right)^{1/n}}{a_1'^{1/n} + \left(K_{12}^{\mathrm{Pot}} \cdot a_2'\right)^{1/n}} \quad (1)$$

R = gas constant; T = absolute temperature; F = Faraday constant; a_i = ion activities in the sample solution (monovalent ions); a_i' = ion activities in the internal filling solution (monovalent ions); n = constant depending on the ions i and the membrane; K_{12}^{Pot} = selectivity constant (preference of sensor for ion 2 in relation to ion 1).

In sensors having a given inner reference electrode system (a_i' constant), we have

$$\mathrm{EMF}(T) = E_0^{\mathrm{B}}(T) + \frac{n \cdot R \cdot T}{F} \ln \left\{ a_1^{1/n} + \left(K_{12}^{\mathrm{Pot}} \cdot a_2\right)^{1/n} \right\} \quad (2)$$

Figure 3 shows functions of this nature for a glass electrode cell assembly with a high selectivity for sodium ions, one ion being H_3O^+ and the other an alkali metal cation in 0.1 M solution[36]. The selectivity constant $K_{\mathrm{Na^+H^+}}^{\mathrm{Pot}}$ is about 0.18[*] [36], so that for this sensor $(K_{\mathrm{Na^+H^+}}^{\mathrm{Pot}} \cdot a_{\mathrm{H^+}})^{1/n}$ is negligible in relation to $a_{\mathrm{Na^+}}{}^{1/n}$ in aqueous NaCl solutions of medium pH, and a linear relation should accordingly exist between the EMF of the cell assembly and the logarithm of the sodium ion activity of the sample. It can be seen from Figure 4 that this is largely so[36]. The linear regression of the experimental EMF values for the activity range 10^{-1} to 10^{-4} M gives a value of 59.8 mV/pNa$^+$ for the slope of the electrode function, in good agreement with the theoretical value of 59.2 mV/pNa$^+$.

From eq. (1) we obtain in general for a mixture of N monovalent ions with $n = 1$:

$$\mathrm{EMF}(T) = E_0^{\mathrm{C}}(T) + \frac{R \cdot T}{F} \ln \frac{\sum_{i=1}^{N} K_{1i}^{\mathrm{Pot}} \cdot a_i}{\sum_{i=1}^{N} K_{1i}^{\mathrm{Pot}} \cdot a_i'} \quad (3)$$

and

$$\mathrm{EMF}(T) = E_0^{\mathrm{D}}(T) + \frac{R \cdot T}{F} \ln \sum_{i=1}^{N} K_{1i}^{\mathrm{Pot}} \cdot a_i \quad (4)$$

for a given inner reference electrode system.

The selectivity constant K_{ij}^{Pot}, which characterizes the preference of the sensor for the ion j as compared with the ion i, is given by

$$K_{ij}^{\mathrm{Pot}} = \frac{u_j}{u_i} \cdot K_{ij} \quad (5)$$

where K_{ij} is the equilibrium constant of the exchange:

$$J_{\mathrm{solution}} + I_{\mathrm{membrane}} \rightleftharpoons J_{\mathrm{membrane}} + I_{\mathrm{solution}} \quad (6)$$

and u_i and u_j are the mobilities of the ions in the membrane. If the sensor responds to a bivalent ion (a_1) and a monovalent ion (a_2), eq. (3) becomes eq. (7):

$$\mathrm{EMF}(T) = E_0^{\mathrm{E}}(T) + \frac{R \cdot T}{2F} \ln \left(a_1 + K_{12}^{\mathrm{Pot}} \cdot a_2^2\right) \quad (7)$$

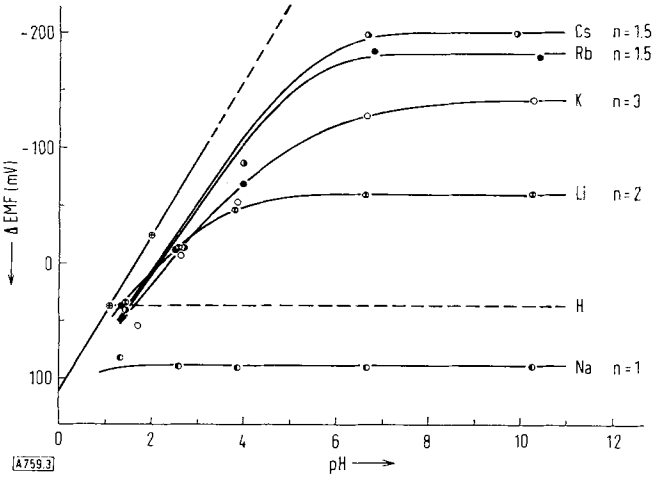

Fig. 3. EMF changes for a Na$^+$ responsive glass electrode in 0.1 M alkali metal ion solutions at various pH values [36].

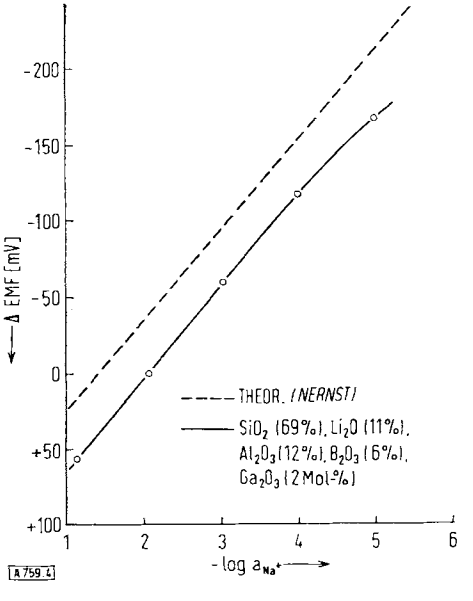

Fig. 4. Electrode function of a sodium-selective glass electrode assembly [aqueous NaCl solutions; cell assembly consisting of a glass electrode and a calomel reference electrode (KCl satd.) with electrolyte bridge (0.1 M NH_4NO_3)] [36].

[35] *B. P. Nicolsky*, Ž. fiz. Chim. *10*, 495 (1937).

[36] *Z. Štefanac* and *W. Simon*, Analyt. Letters *1*, No. 2, 1 (1967).

[*] If the indices are transposed in the logarithmic term of eq. (1) for $n = 1$, we obtain: $K_{ij}^{\mathrm{Pot}} = 1/K_{ji}^{\mathrm{Pot}}$

For a completely reversible cell assembly, K_{ij}^{Pot} can in principle be determined approximately by carrying out measurements in a solution of the ion i and in a solution of the ion j. If these are *e.g.* 0.1 M solutions of monovalent ions, it follows from eq. (4) (cf. also [37]) that:

$$0.1\ \text{M, Ion i: } EMF_1 = E_0^D(T) + \frac{R \cdot T}{F} \ln (0.1 + K_{ij}^{Pot} \cdot 0) \quad (8)$$

$$0.1\ \text{M, Ion j: } EMF_2 = E_0^D(T) + \frac{R \cdot T}{F} \ln (0 + K_{ij}^{Pot} \cdot 0.1) \quad (9)$$

$$EMF_2 - EMF_1 = \frac{R \cdot T}{F} \ln K_{ij}^{Pot} \quad (10)$$

$$\log K_{ij}^{Pot} = \frac{EMF_2 - EMF_1}{59.2\ \text{mV}} \quad (25\ ^\circ\text{C}) \quad (11)$$

Disturbances of the electromotive behavior of the sensor are to be expected when ions (interfering ions) form soluble products with membrane components (and so destroy the membrane) or give sparingly soluble compounds. In the second case, it is possible to calculate the maximum permissible activity $a_{1,max}$ of the interfering ion 1 from the solubility products $L_{2,3}$ (solubility product of the original membrane material) and $L_{2,1}$ (solubility product of the sparingly soluble compound formed) and the activity a_3 of the ion to be determined:

$$L_{2,1} = a_2 \cdot a_1 \quad (12)$$

$$L_{2,3} = a_2 \cdot a_3 \quad (13)$$

$$a_{1,max} = \frac{L_{2,1}}{L_{2,3}} a_{3,max} \quad (14)$$

Similarly, *Pungor* and *Tóth* [9] express the selectivity constant of heterogeneous solid-state membranes in terms of the solubility products L_{kj} and L_{ki} of the sparingly soluble membrane components:

$$K_{ij}^{Pot} = \frac{L_{ki}}{L_{kj}} \quad (15)$$

The arguments for ion-exchange membranes should be applicable only in part to solid membrane electrodes [15].

2.2. Liquid Membranes

2.2.1. Electrically Charged Ligands

Sandblom, Eisenman, and *Walker* [15–17] have derived a relation for the EMF of a cell assembly consisting of a liquid ion-exchange membrane electrode (Type 3a) and an external reference electrode.

$$EMF(T) = E_0^F(T) + \frac{R \cdot T}{F \cdot z_i} \left[\ln \frac{\Sigma u_i k_i a_i}{\Sigma u_i k_i a_i} - \int 1 - \int 2 \right] \quad (16)$$

$$k_i = \exp\left(- \frac{\mu_i^0 - \mu_i^0(m)}{R \cdot T} \right) \quad (17)$$

z_i = valency of the ion i; μ_i^0 = standard chemical potential of the ion i in solution; $\mu_i^0(m)$ = standard chemical potential of the ion i in the membrane phase.

[37] *K. Srinivasan* and *G. A. Rechnitz*, Analyt. Chem. *41*, 1203 (1969).

Eq. (16) is valid only under the following conditions:

1. the ligands are situated exclusively in the membrane;
2. there are no coions in the membrane;
3. equilibrium exists between the ion i and the ligand at all points in the membrane;
4. associates and ion aggregates of higher order do not occur;
5. the activities can be equated to the concentrations inside the membrane;
6. the system is at zero current.

For certain special cases, the integrals over the thickness of the membrane in eq. (16) can be neglected or can be easily calculated [17]. Thus in the steady state, $\int 2$ is equal to zero, owing to the disappearance of the entire ligand flow. If the concentration of the free ligand is negligible, $\int 1$ will also be zero, and eq. (16) reduces for a given internal electrode system of the sensor to

$$EMF(T) = E_0^G(T) + \frac{R \cdot T}{F \cdot z_i} \ln \sum_{i=1}^{N} u_i k_i a_i \quad (18)$$

in analogy with eq. (4). According to equation (18) the selectivity of the membrane is given mainly by the solvent used to dissolve the ligand. According to *Eisenman* [225] similar circumstances should hold for systems with completely dissociated ligands.

If on the other hand the ligand is mainly in the undissociated mobile form, eq. (16) can be replaced (cell assembly with a given internal electrode system) in the limiting case [*] by

$$EMF(T) = E_0^H(T) + \frac{R \cdot T}{F} \ln \left(a_1 + \frac{u_{2S}}{u_{1S}} K_{12} \cdot a_2 \right) \quad (19)$$

where u_{1S} and u_{2S} are the mobilities of the complexes of the ligand with ions 1 and 2 respectively. For this limiting case, therefore, the equilibrium constant K_{12} is a measure of the selectivity constant (cf. [37]).

In the ideal case, it is accordingly possible to produce liquid membrane sensors having widely different selectivities with components having suitable K_{ij} values [38]. The selectivity of glass and solid membrane electrodes, on the other hand, depends on the product of the exchange equilibrium constant K_{ij} and the mobility ratio of the ions in the membrane [eq. (5)]. In view of the low mobility of Ca^{2+} in glasses, therefore, it will be difficult to find glass electrodes with an extremely high preference for this ion over alkali metal ions [2].

2.2.2. Electrically Neutral Ligands

Eisenman, Ciani, and *Szabó* [220, 222–224] derived the following equation for the EMF of a liquid-membrane electrode of the electrically neutral ligand type and a given internal reference electrode system:

[*] In the limiting case in question, $u_{1S} \approx u_{2S}$.

[38] *C. J. Coetzee* and *H. Freiser*, Analytic. Chem. *41*, 1128 (1969).

$$E(T) = E_0^I(T) + \frac{R \cdot T}{F} \ln \left(a_1 + \frac{u_{2S} k_{2S} K_{2S}}{u_{1S} k_{1S} K_{2S}} a_2 \right) - \frac{R \cdot T}{F} \ln (1 + K_{1S}\, a_1 + K_{2S} a_2) \quad (20)$$

u_{1S}, u_{2S}: Mobilities of electrically charged complexes within the membrane;

k_{1S}, k_{2S}: Distribution coefficients of the complexes between sample solution and membranes;

K_{1S}, K_{2S}: Equilibrium constant of the interaction of the cations with ligand in the sample solution.

Equation (20) holds only under the following conditions:

1. Two monovalent cations with the activities a_1 and a_2 are in the sample solution;

2. The concentrations of all the electrically charged species within the membrane are so small as compared to the concentration of the complexed cations that only the flux of the complexes has to be considered to account for the electric current in the integration of the flux equation;

3. The activities of the complexed cations within the membrane as well as the complexed cations and the ligands in the sample solution are equal to the corresponding concentrations;

4. The fluxes of the complexes do not disturb the equilibrium at the membrane boundary;

5. The concentration of electrically neutral complexes and higher associates within the sample solution may be neglected;

6. The system is at zero current.

In equation (20) the second logarithmic term may be neglected relative to the first if the concentrations in the sample solution are so small that the complex formation in it may be neglected. Furthermore, the constants of the first logarithmic term in equation (20) can be expressed as a ratio of two equilibrium constants of the following salt extraction:

$$I^+_{(aqueous)} + X^-_{(aqueous)} + S_{(organic)} \overset{K_I}{\rightleftarrows} IS^+_{(organic)} + X^-_{(organic)} \quad (21)$$

$$\frac{u_{1S} k_{2S} K_{2S}}{u_{1S} k_{1S} K_{1S}} = \frac{u_{2S} K_2}{u_{1S} K_1} \quad (22)$$

Equation (20) therefore gives in analogy to equation (1)

$$EMF(T) = E_0^J(T) + \frac{R \cdot T}{F} \ln \left(a_1 + \frac{u_{2S} K_2}{u_{1S} K_1} a_2 \right) \quad (23)$$

Since in most cases $u_{1S} \approx u_{2S}$ [223] the selectivity constants of liquid-membrane sensors with electrically neutral ligands are mainly given by the ratios of the equilibrium constants K_1 and K_2 which again depend on the ligands and other possible components of the membrane.

3. Sensor Systems

Glass [39], solid [40,41], and liquid membrane electrode systems [39,42,43] have been known for some time, but apart from glass protodes, as can be seen from the literature (Table 1), they have for obvious reasons only recently come into wide use. Table 1 is the result of an attempt to make a list (by no means complete) of publications on the detection of individual ions by means of ion-selective sensors. The reader is referred in particular to some outstanding reviews in connection with glass electrodes [2–4, 31, 220].

Manufacturers often designate electrodes according to the ions for which they are supposed to be used. These designations should not be taken too seriously. So called "calcium electrodes" (liquid membrane electrodes) prefer Zn^{2+} [43] and "K^+ glass electrodes" are usually more sensitive to H^+ [2]. The most selective sensor available at present is undoubtedly the glass protode, which has $K^{Pot}_{H^+X^+}$ values of 10^{-13} (X^+ = alkali metal cation) [44].

It can be seen from Table 1 that the LaF_3 homogeneous solid-state membrane (single-crystal) sensor developed by *Frant* and *Ross* [45] has proved to be generally applicable for the detection of F^-. Its main limitations appear to be that OH^- ions interfere in most cases at high pH values (> about 8.5), owing to the selectivity constant $K^{Pot}_{F^-OH^-} = 10^{-1}$, and uncertainties can arise at low pH values (< about 5) as a result of the formation of HF and HF_2^-.

On the other hand, apart from the fundamental work of *Pungor et al.* [7–9, 11, 221], only relatively few publications on the use of heterogeneous solid-state membrane electrodes have appeared [46–48].

According to theoretical considerations, homogeneous and heterogeneous silver iodide membrane electrodes and Ag/AgI electrodes should respond similarly to I^-. This is in fact so, as is shown in Figure 5; the observed differences are due to the different histories of the electrodes and to differences in the liquid-junction potentials. The selectivities of adequately conditioned homogeneous and heterogeneous membrane electrodes and electrodes of the second kind with the same ion-selective components agree. Deviations are found only with redox systems. The main advantage of the silver halide solid-state membrane electrodes over the silver/silver halide electrodes is that the former is less sensitive to redox systems; difficulties are to be expected if strongly reducing components lead to the deposition of silver on the membrane. Homogeneous solid-state membrane electrodes appear to have a longer life, presumably because of the permeation in heterogeneous solid-state membrane electrodes (cf. [46]).

The homogeneous solid-state membrane electrodes with AgCl, AgBr, AgI, and Ag_2S membrane for the determination of Cl^-, Br^-, I^-, S^{2-} or Ag^+ and CN^- function mainly by the transport of silver ions in the membrane. By mixing these membrane components with components of larger solubility and a common ion, electrodes for further ions may be obtained. A mixed crystal electrode with $CuS-Ag_2S$ and $CdS-Ag_2S$ membrane for example responds to Cu^{2+} and Cd^{2+} respectively [201, 213, 226]. The electrode response for the divalent cation in these cases is coupled with the Ag^+ electrode function by the sulfide ion.

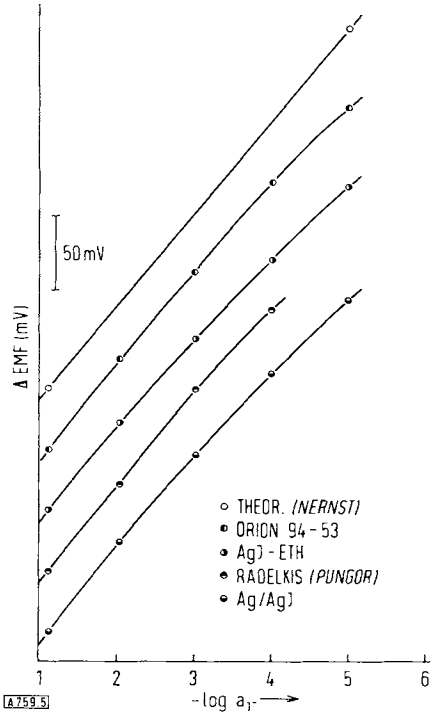

Fig. 5. Electrode function of iodide sensors [aqueous KI solutions; cell assembly consisting of ion-selective sensor and calomel reference electrode (KCl satd.)]. The membrane of the sensor AgI–ETH is a compressed membrane of purified AgI.

Though the nature of the inner solution of the electrode, according to eq. (1), (2), (18), and (20), should influence only the electrical zero point $E_0(T)$ of the cell assembly, it has been found that many sensors work best when the composition of their internal filling solution is similar to that of the sample solution (cf. also [49]). Sensor designs should accordingly allow easy adaptation of the electrode fillings to the measurement problem. Electrode systems with exchangeable membranes are illustrated in Figure 6. The arrangement of the membrane in the liquid membrane electrode prevents the inclusion of air bubbles at the lower end of the sensor (Fig. 6b). Sealing of the membrane is effected by pressure.

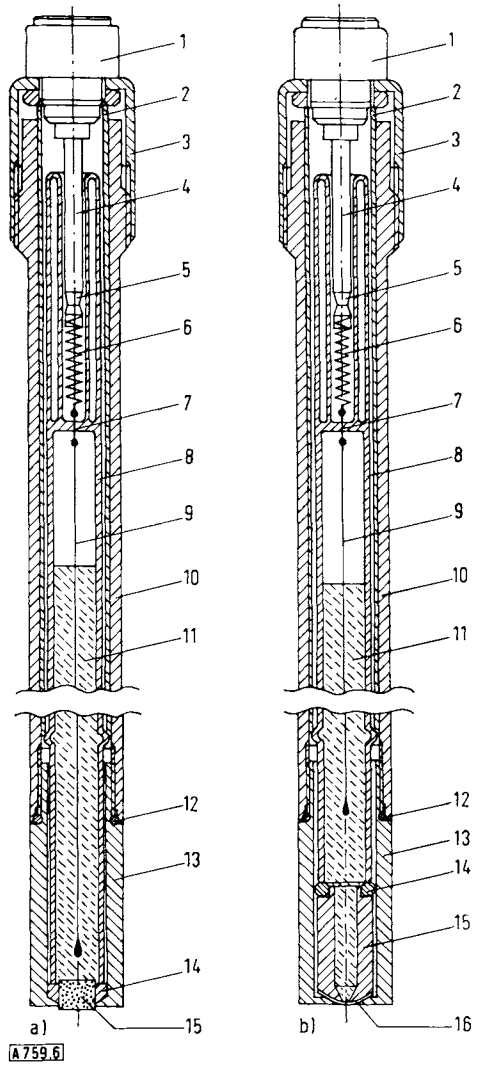

Fig. 6a.) Sensor with exchangeable solid-state membrane.

1: Plug for inner reference electrode system and electrical screening; 2: screening; 3: metal cap; 4: contact pin; 5: silver contact; 6: metal spring; 7: platinum duct; 8: glass insert; 9: inner reference electrode; 10: electrode shaft (plastic); 11: internal filling solution; 12: O ring; 13: membrane support (plastic); 14: silicone rubber sealing ring; 15: homogeneous solid-state membrane. The membrane 15 is held by sealing ring 14. This is done by screwing 3 firmly onto 10 by the screening 2 and the glass insert 8.

b) Liquid membrane sensor.

14: O ring; 15: hollow cylinder (plastic) pressing on membrane 16; 16: liquid membrane (filter paper impregnated with ion-selective ligand). The membrane 16 is fixed by the hollow cylinder 15 and the O ring 14. This is done by screwing 3 firmly onto 10 by the screening 2 and the glass insert 8.

Apart from their use in pH measurement, glass electrodes (mainly having the composition NAS_{11-18} or NAS_{27-4}) are also used for the determination of sodium and potassium ion activities [2, 3]. The glass electrodes for the measurement of Na^+ activities have

$K^{Pot}_{K^+Na^+}$ values of up to 10^4 [2, 36]; on the other hand, selectivities for K^+ over Na^+ of only about 10 can be obtained in glass electrodes for routine use [2, 3, 50]. Glass electrodes are therefore suitable for the determination of potassium ions *e.g.* in blood serum only if the influence of the sodium ions present in the sample on the EMF of the measuring cell is taken into account. Corrections of this nature are doubtful, in view of the dependence of the $K^{Pot}_{Na^+K^+}$ values on the ion concentration and on the pretreatment of the electrode [51, 52] (cf. [46]). However, liquid membrane electrodes of type 3b with considerably higher selectivities for K^+ over Na^+ than can be obtained with glass electrodes can be produced with the aid of certain antibiotics that selectively complex K^+ [53–56]. Thus valinomycin dissolved in diphenyl ether on Millipore filter [*] gives liquid membrane sensors (Fig. 6b) having a theoretical linear electrode function to potassium ions in the range 10^{-1} to 10^{-5} M (Fig. 7) with selectivities for K^+ over Na^+ of ≈4000 (cf. Table 2), and electrode resistances of about 1 MΩ [55, 56, 227]. With activity changes of one order of magnitude, the potentials generally approach in less than 30 sec to within ±0.5 mV of a steady value, and normally to within ±0.2 mV in one minute, this value being maintained to within an average of ±1.4 mV over 150 hours with routine use of the electrode in solutions of various KCl concentrations (10^{-1}–10^{-4} M).

Table 2. Selectivity constants $K^{Pot}_{M^+K^+}$ for the valinomycin membrane electrode (25 °C; diphenyl ether).

M^+	Rb^+	K^+	Cs^+	NH_4^+	Na^+	Li^+	H^+
$K^{Pot}_{M^+K^+}$	0.52	1	2.6	84	3800	4700	18000

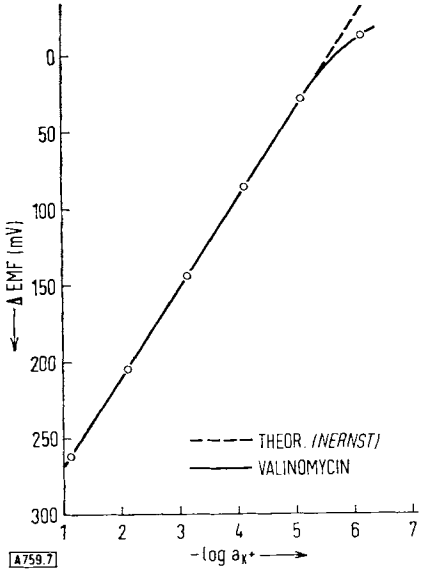

Fig. 7. Electrode function of the valinomycin liquid membrane electrode (25 °C). [Aqueous KCl solutions; cell assembly consisting of membrane electrode in accordance with Fig. 6b and calomel reference electrode (KCl satd.) with electrolyte bridge (0.1 M NH_4NO_3)].

[*] Type MF; Millipore Filter Corp., Bedford/Mass.

4. Error Considerations

A trivial error calculation shows that small uncertainties in the EMF measurement must lead to appreciable percentage errors in the determination of the ion activity or concentration (Table 3). Though short-term reproducibility to within 0.001 pH unit can in

Table 3. Errors Δa_i in the determination of the ion activity due to uncertainties ΔE in the EMF measurement (25 °C).

ΔE (mV)	$\frac{\Delta a_i}{a_i} = \frac{zF}{RT} \cdot \Delta E$ in % for ions having valency z =		
	1	2	3
10	38.92	77.85	116.77
1	3.89	7.79	11.68
0.1	0.39	0.78	1.17
0.01	0.04	0.08	0.12

principle be achieved with glass electrode cell assemblies [57], much larger deviations are found in practice. Uncertainties of 0.03 to 0.05 pH unit have been found in pH measurements on blood samples, presumably as a result of fluctuations of the liquid-junction potentials [32]. This corresponds to errors of 6.9 to 11.5 % in the determination of the hydrogen ion activity. Standard deviations of <1 % can be achieved in the determination of Na^+ concentrations [51]. Reproducibilities of this order can also be obtained with some liquid membrane electrodes (Fig. 7). At present the valinomycin liquid-membrane electrode makes determinations of K^+ in undiluted blood serum possible which are at least as reproducible as those performed by flame photometry [228, 229].

Heterogeneous solid-state membrane electrodes at least occasionally exhibit permeation of the membrane by components of the electrode filling solution or of the test solution [46], which is probably one cause of long-term changes in the electrode potential. In permeation experiments with ^3H and ^{131}I, homogeneous solid-state membrane electrodes (AgI–ETH) were found to have membrane permeabilities of the same order as that of a Teflon membrane with similar dimensions (zero current). The permeability of the membrane can thus be ruled out as a cause of long-term changes in the potentials of the electrodes examined. Silver halide electrodes occasionally exhibit large fluctuations of potential as a result of changes in the intensity of the light [218, 219].

5. Present Situation, New Directions

Although by now at least 37 ions and components (Table 1) may be selectively detected by membrane electrode systems, there are at present only few analytically valuable sensors commercially available. These may be used either for the direct potentiometric determination of the activity of a given ion in a mixture of ions or for the indirect determination by potentiometric titration.

Because of the restricted ion mobility in the membrane phase, glass as well as solid-state membrane electrodes have strict limitations in respect to selectivity (see Section 2). These limitations do not hold for liquid-membrane electrodes. This advantage, however, has its price in a relatively short life-time of the sensor and a sometimes disturbing contamination of the sample solution by membrane components. At present liquid-membrane electrodes for NO_3^-, Ca^{2+}, K^+ as well as $[Ca^{2+} + Mg^{2+}]$ (water hardness) seem to be finding acceptance in a wide range of analytical applications. Especially high selectivities are to be expected for liquid-membrane sensors with certain biologically active materials (antibiotics) as membrane components. Unfortunately our knowledge in connection with the correlation of the structure of organic compounds with their ion specificity is still relatively poor [56, 225].

Extremely high selectivities are obtained if an enzymatic degradation of the components to be determined can be used. The enzyme-carrying matrix is sandwiched between the sample solution and a sensor which detects one of the degradation products [83, 231–233]. There is no doubt that by now only a few possibilities for the production of ion selective sensors have been pointed out. There is therefore a real hope that research in this area will drastically influence analytical chemistry in the widest sense.

New Methods for Preparation of Glycosides [1] [**]

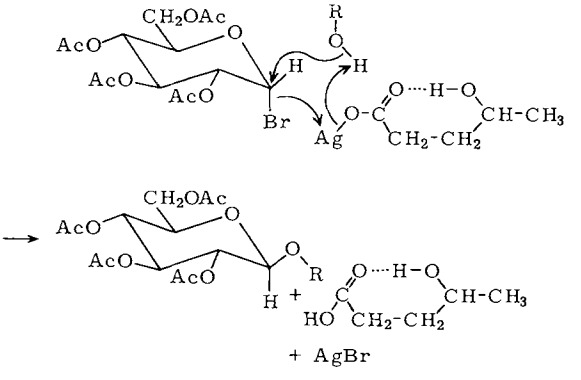
By *Günter Wulff, Gerhard Röhle,* and *Wolfgang Krüger* [*]

Dedicated to Professor R. Tschesche on the occasion of his 65th birthday

Reaction of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide with the silver salt of 4-hydroxyvaleric acid in benzene gives the glucosyloxy-acid *(2)* and the 1-*O*-(glycosyloxyacyl)glucose *(3)* as well as the very unstable 1-*O*-acylglucose *(1)*.

(1), R = -O-C(=O)-CH$_2$-CH$_2$-CH(OH)-CH$_3$

(2), R = -O-CH(CH$_3$)-CH$_2$-CH$_2$-COOH



(3), R = -O-CH(CH$_3$)-CH$_2$-CH$_2$-COO-

Silver salts of other 4- and of 5-hydroxyalkanoic acids give analogous products. Moreover, silver salts of 2-, 3-, and 6-hydroxyalkanoic acids afford corresponding products, but here the 1-*O*-acylglucoses are appreciably more stable.

Thus glucosylation of the alcoholic hydroxyl group of the hydroxyalkanoic acids occurs to a considerable extent in this reaction. We have therefore investigated the possibility of glucosylating added alcohols similarly. We found that, in the presence of silver salts of 2-, 3-, or 4-hydroxyalkanoic acids, or of 1,3- or 1,4-dicarboxylic acids, alcohols react with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide in ether to give good yields of 2,3,4,6-tetra-*O*-acetyl-β-D-glucosides. Silver 4-hydroxyvalerate proved particularly favorable for use in this reaction. Thus, for instance, we obtained cholesterol β-D-glucoside in 58 % yield (only 33 % [2] or 43 % [3] by the Königs-Knorr method and 45 % by *Kochetkov*'s method [4]) and a 65 % yield of tigogenin β-D-glucoside (45—50 % by the Königs-Knorr method).

The new method is extremely simple and mild: one merely stirs the readily available silver salt and, *e.g.*, 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide in dry diethyl ether for 30 min at room temperature or for 4 h at −10 °C; and since no water is produced there is none to remove. 4-Cholestenol, for example, gives almost wholly 3,5-cholestadiene by the usual methods, whereas we obtained the glucoside in 36 % yield. The reaction is clearly applicable also to alcohols of various types [5]; and other *cis*-halogenoses, *e.g.*, 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide and 2,3,4-tri-*O*-acetyl-β-D-arabinopyranosyl bromide, react analogously.

The reaction is highly solvent-specific; it occurs best in diethyl ether. Studies of anion-dependence, of the products, and of the kinetics are in accord with a trimolecular synchronous mechanism.

+ AgBr

This reaction occurs to any considerable extent only on the surface of solid bifunctional anions of specific structure. Such anions include those of 2-, 3-, and 4-hydroxyalkanoic acids and of certain dicarboxylic acids in which neighboring group effects limit the formation of 1-*O*-acylglycoses in favor of glycoside formation by way of a trimolecular transition

state. The Königs-Knorr synthesis in the presence of silver carbonate probably occurs analogously.

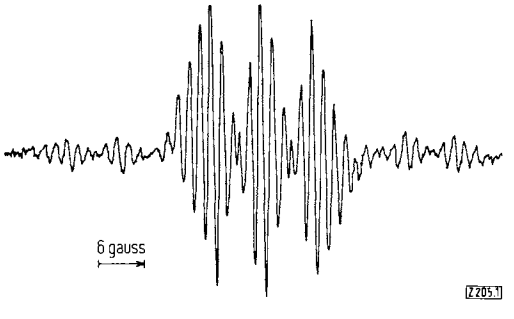
Crystalline π-Radicals Containing Lead – Isotropic ^{207}Pb-ESR Hyperfine Structure

By *Hartmut B. Stegmann*, *Klaus Scheffler*, and *Fritz Stöcker* [*]

Dedicated to Professor Eugen Müller on the occasion of his 65th birthday

Attempts to prepare solutions of paramagnetic organolead compounds — in particular by dissociation of hexaaryldiplumbanes [1] — have so far been unsuccessful. We have now been able to isolate lead-containing radicals as products of the reaction of 2-amino-4,6-di-*tert*-butylphenoxyl *(1)* with diaryllead dihalides. Reaction of the aminoaroxyl *(1)* with, *e.g.*, di-*p*-tolyllead dichloride in ethanol affords violet-brown crystals, m.p. 143—145 °C. Elemental analysis and mass spectrum suggest structure *(2)*. While solid *(2b)* gives an intense ESR signal exhibiting exchange narrowing, its solution in benzene gives a multicomponent spectrum.



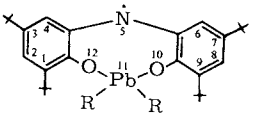


Figure: ESR spectrum of the di-*p*-tolyllead radical *(2b)* in benzene at room temperature.

The central section of the hyperfine structure (HFS) of this spectrum (see Figure) can be interpreted in terms of magnetic coupling of the free electron with two pairs of protons and one ^{14}N nucleus. The less intense components lying on the left- and right-hand sides can be attributed to further coupling with a ^{207}Pb nucleus. This isotope ($I = 1/2$) has an abundance of 22.62% in natural lead. The observed spectrum agrees very well with this figure, as is shown by the successful simulation (CDC 3300) of an enlarged spectrum.

The isotopic spectrum is masked by the main spectrum only in the central region, which corresponds to the 77.38% of nonmagnetic lead nuclei present; thus if both groups of satellites are taken into consideration, the whole ^{207}Pb HFS can be observed. Exact measurements show that the distances between the satellite centers and the center of gravity of the whole spectrum differ in the upfield and downfield directions. This asymmetry is attributable to a second order shift such as has already been detected quantitatively for radicals containing tin [2].

In agreement with other findings, the ESR spectra show the new organolead derivatives to be 11,11-disubstituted 1,3,7,9-tetra-*tert*-butyldibenzo[*d*,*g*]-[1,3,6,2]dioxazaplumbocin-5-yls. The coupling parameters were initially assigned by analogy with the corresponding tin compounds [2].

(2)

ESR data for the radicals *(2)* (gauss), recorded in benzene at room temperature; ΔH = line width.

(2)	$a^{(2)}_{H_{4,6}}$	$a^{(2)}_{H_{2,8}}$	$a^{(1)}_{N}$	$a_{^{207}Pb}$	g	ΔH
(a), R = C_6H_5	1.62	3.24	7.05	41.68	2.00081	0.76
(b), R = *p*-CH_3–C_6H_4	1.62	3.12	7.14	40.54	2.00093	0.70

As expected, the substituent R has only a limited effect on the coupling constants. The exceptional line broadening (≈ 0.7 gauss) is probably due either to an unresolved proton HFS or to unfavorable relaxation conditions. Since the spectra remain essentially unchanged between —70 and +120 °C, the line broadening cannot be due to mechanical movement. The *g* factors of compounds *(2a)* and *(2b)* are remarkably small, owing to interaction of the free electron and the Pb nuclei which has also been determined from the HFS spectra.

Preparation of Triethyl Ortho-3-butynoate and its Conversion into 5-Oxo-3-alkynoate Esters and into Derivatives of 3,5-Dioxoalkanoate Esters [1] [**]

By *Rolf Finding* and *Ulrich Schmidt* [*]

Dedicated to Professor Eugen Müller on the occasion of his 65th birthday

In triethyl ortho-3-butynoate (4,4,4-triethoxy-1-butyne) *(1)* (which we obtained from propargylmagnesium bromide and tetraethyl orthocarbonate) masking of the carboxyl group as orthoester protects it from attack by alkali-metal acetylides and prevents rearrangement of the acetylenic linkage to the α,β-position or to an allenic unit. The orthoester can thus be

metalated and then acylated to afford triethyl 5-oxoortho-3-alkynoates *(2)*, which can be converted into enol ethers of 3,5-dioxoalkanoic esters *(3)* by base-catalyzed addition of alcohols. Dimethylamine adds almost quantitatively to *(2)* giving triethyl 3-(dimethylamino)-5-oxoortho-3-alkenoates *(4)* which yield copper(II) complexes of the β-polycarbonyl compounds on treatment with a solution of copper(II) acetate in aqueous acetic acid. The reaction sequence *(1)* → *(2)* → *(3)* or *(4)* permits extension of a carboxylic acid chain by two acetyl units. The structures of compounds *(1)*—*(4)* are in agreement with their NMR spectra.

Triethyl 5-oxoortho-3-hexynoate (2a) from triethyl ortho-3-butynoate (1)

A solution of propargylmagnesium bromide[2] (43 g) in ether (160 ml) is dropped slowly under N_2 into a solution of tetraethyl orthocarbonate (48 g) in anhydrous ether (80 ml) at −30 °C (internal temperature). When the temperature is slowly raised, an exothermic reaction sets in at 25 °C; external cooling is applied to prevent the temperature rising above 30 °C; after 30 min the mixture is hydrolyzed by saturated NH_4Cl solution, whereafter working up gives *(1)* (17.3 g).

The orthoester *(1)* (6.9 g) is metalated in tetrahydrofuran (30 ml) and ether (60 ml) under nitrogen and at −60 °C by an equivalent amount of a 2 N solution of butyllithium in light petroleum. The mixture is allowed to warm to 0 °C and then dropped into a solution of acetic anhydride (5 g) in ether (50 ml) kept at −60 °C. Allowing the resulting mixture to warm to room temperature, shaking it with saturated NH_4Cl solution, and then distillation afford *(2a)* (4.0 g).

Triethyl 3-ethoxy-5-oxoortho-3-hexenoate (3a)

The product *(2a)* (2.3 g) in ethanol (2 ml) is dropped into a solution of Na (0.23 g) in ethanol (10 ml) cooled to 0 °C and after a few min is warmed to room temperature. After 30 min, addition of H_2O (50 ml), extraction with ether, and distillation afford *(3a)* (1.25 g).

A Simple Synthesis of α-Methylene γ-Lactones

By *Elisabeth Öhler, Klaus Reininger,* and *Ulrich Schmidt*[*]

Dedicated to Professor O. Hromatka on the occasion of his 65th birthday

Studies of syntheses in the lysergic acid series have revealed a simple route leading to the hitherto difficultly accessible α-methylene γ-lactones[1]. In tetrahydrofuran, α-(bromomethyl)acrylic esters *(1)*[2] readily form organozinc compounds which react with aldehydes and ketones to give methylene lactones *(2)* in very good yields. A single step technique in which the bromo ester is treated with zinc in the presence of the carbonyl compound has many advantages. Many higher and polycyclic ketones give almost quantitative yields [*e.g.* 1-benzoyl-5-oxo-1,2,2a,3,4,5-hexahydrobenz[*cd*]-indole gives *(3)*, m.p. 190—195 °C][3]. Formaldehyde affords a mixture of α-methylenebutyrolactone and γ-hydroxy-α-methylenebutyric ester in low yield.

(3)

General procedure:

A solution of bromomethylacrylic ester *(1)*[2] (50 mmoles) in anhydrous tetrahydrofuran (30 ml) is added dropwise with vigorous stirring under nitrogen to a mixture of granulated zinc (3.5 g, 53.5 mmoles, 20 mesh) and the carbonyl compound (45 mmoles) in anhydrous tetrahydrofuran (15 ml). Once the reaction has started, addition is adjusted such that the temperature does not rise above 40—50 °C. The reaction mixture is stirred for about an hour at 50 °C, cooled, and

poured onto ice-cold dilute hydrochloric acid. Depending on the solubility of the lactone *(2)*, the mixture is extracted with ether or methylene chloride, or the solid lactone is filtered off. The solution is washed with aqueous $NaHCO_3$ solution and with water, dried over Na_2SO_4, and finally distilled. Some methylene lactones, especially those bearing small substituents, polymerize very readily, often during distillation.

[3] *Note added in proof*: The corresponding reaction of β'-bromotiglic ester with ketones to give α-methylene-β-methylbutyrolactones has recently been reported by *A. Löffler, R. Pratt, J. Pucknat, G. Gelbard*, and *A. S. Dreiding* [Chimia *23*, 413 (1969)].

Cycloalkanephosphonothioic Dichlorides by Photochemical C–P Linkage

By *Ulrich Schmidt* and *Alfred Ecker* [*]

C—P linkage by irradiation of hydrocarbons and phosphorus compounds has hitherto only been accomplished in the reaction of phosphorochloridic diester, phosphonochloridic ester, and phosphinic chloride with cyclohexane[1]. Since compounds containing the O=P—Cl group absorb below 220 nm, irradiation must be carried out with deuterium lamps; reaction times of several weeks are therefore required, even for the preparation of mmole amounts.

We have now found that S=P—Cl derivatives are better suited for photochemical substitution since they absorb at about 260 nm, *i.e.* in the range of maximum intensity of low pressure Hg lamps. Irradiation of mixtures of cyclic hydrocarbons and phosphorothioic trichloride with such a lamp affords cycloalkanephosphonothioic dichlorides. Toluene reacts at the methyl group.

With cyclohexene and $PSCl_3$ *addition* occurs to give the cyclohexanephosphonothioic dichloride and three isomeric chlorocyclohexanephosphonothioic chlorides which were identified by a combination of gas chromatography and mass spectrometry; isolation of the chlorocyclohexanephosphonothioic dichlorides by preparative gas chromatography was precluded by rapid destruction of the column packing. No bicyclohexenyl was detected.

R—P(S)Cl_2 [a] R =	Irradiation duration (h)	Yield (%)	B.p. (°C/torr)	M.p. (°C)	n_D
Cyclopentyl	48	22	54/0.2		1.5590 (24 °C)
Cyclohexyl	96	44	70/0.6		1.5622
	48	21 (47 [b])			(20 °C)
Cyclooctyl	46	25	105/0.3	42–43	

[a] The structures of the phosphonothioic dichlorides follow from the mass spectra [*e.g.* $(CH_2)_5CHPSCl_2$: molecular ion at *m/e* 216 (18%). $(CH_2)_5C^+$ 82 (100)].

[b] Based on *reacted* $PSCl_3$.

Approximately 300 ml of a mixture of $PSCl_3$ and hydrocarbon (molar ratio 1 : 5) was irradiated under N_2 in a cylindrical quartz vessel (height 35 cm, diameter 4.5 cm) surrounded by a ring (diameter 8.5 cm) of seven low pressure Hg lamps (Type NN 15/44 VK produced by Quarzlampengesellschaft Hanau, each of 6 W emission at 250 nm). Deposition on the inner wall of the vessel was avoided by continuous brushing. The products were isolated by fractional distillation.

2-Isocyano-1-alkanols from Carbonyl Compounds and α-Metalated Isocyanides[1]

By *Walter A. Böll, Fritz Gerhart, Axel Nürrenbach*, and *Ulrich Schöllkopf* [*]

Reaction of α-isocyanoalkyllithium compounds *(1)* [2] with carbonyl compounds *(2)* followed after about 10 min by neutralization (—70 °C) with glacial acetic acid affords good yields of 2-isocyano-1-alkanols *(4)* (β-hydroxyisocyanides). The compounds *(4)* deserve attention because they can be converted into vinyl isocyanides [3], or hydrolyzed to 2-amino-1-alkanols, *i.e.* the above steps represent a route for the nucleophilic introduction of aminomethyl groups into carbonyl compounds [4].

(1) *(2)* *(3)*

(4)

(4)	R^1	R^2	R^3	Yield (%)
(a)	H	H	C_6H_5	80
(b)	H	CH_3	C_6H_5	75
(c)	$(CH_3)_2N—CH_2—CH_2$	CH_3	C_6H_5	75

The adducts *(3)* [2] occur as intermediates; if benzoyl chloride or acetic anhydride is added instead of glacial acetic acid, the benzoates or acetates of *(4)* [5] are obtained, *e.g.*, in the experiment with isocyanomethyllithium and benzaldehyde, the benzoate (m.p. 57 °C) or the acetate of *(4a)* (m.p. 85–86 °C) is isolated.

1-Isocyano-2-phenyl-2-propanol (4b)

A solution of methyl isocyanide (5.6 ml, 0.1 mole) in dry tetrahydrofuran (20 ml) was added dropwise to a stirred solution of butyllithium (0.105 mole, *i.e.* 66 ml of a 1.6 N solution in hexane) in dry tetrahydrofuran (100 ml) at —70 °C under nitrogen. After 10 min, acetophenone (12.0 g, 0.1 mole) in dry tetrahydrofuran (20 ml) was added to the suspension of isocyanomethyllithium at the same temperature, and after another 10 min the whole was neutralized with glacial acetic acid (6.3 g, 0.105 mole) in dry tetrahydrofuran (10 ml). The reaction mixture was poured into water (0.5 l), extracted

three times with benzene (3 × 50 ml), and concentrated under vacuum. On treatment of the residue with light petroleum (b.p. 50—70 °C), a crystalline precipitate of *(4b)* (9.4 g) appeared. Concentration of the light petroleum solution afforded a further crop of crystals (2.8 g) [m.p. 74—75 °C; IR spectrum (KBr): 2170 cm^{-1} (νNC), 3380 cm^{-1} (νOH)]. — A solution of *(4b)* (5 g) in dioxane (20 ml) was added dropwise (ice cooling) to a mixture of 2 N hydrochloric acid (50 ml) and dioxane (50 ml). After two hours' stirring, work-up at room temperature yielded 1-formylamino-2-phenyl-2-propanol (3.3 g).

N-Formylphenylalanine Ethyl Esters by Hydrogenolysis of Ethyl 5-Aryl-2-oxazoline-4-carboxylates [1]

By *Ulrich Schöllkopf* and *Dieter Hoppe* [*]

Phenylalanine and its derivatives (*e.g.* tyrosine, thyroxine, dopa, methyl-dopa, *etc.*) have attracted a great deal of attention because of their biological activity. We have found that *N*-formylphenylalanine ethyl esters *(2)*, R^1 = H, and the α-methyl compounds *(2)*, R^1 = CH_3, can be prepared by hydrogenolysis of 5-aryl-2-oxazoline-4-carboxylates *(1)* [2] with *e.g.* palladium/activated charcoal in ethanol. Compounds *(2)* can be converted into phenylalanines by heating with 20 % hydrochloric acid, while brief heating with potassium hydroxide in ethanol affords *N*-formylphenylalanines.

(1) *(2)*

	Ar	R^1	Hydrogenated [a] (h)	*(2)*, Yield (%)
(a)	C_6H_5	H	3	99
(b)	*p*-CH_3—C_6H_4	H	2	95
(c)	*p*-$CH_3OC_6H_4$	H	12	95
(d)	C_6H_5	CH_3	30	99

[a] With palladium/activated charcoal, room temperature, H_2 at atmospheric pressure.

Cleavage of the C—O bond in *(1)*, R^1 = CH_3, (20 °C, atmospheric pressure, proceeds ten times slower than in *(1)*, R^1 = H; furthermore, substitution in the nucleus, *e.g.* by methoxy groups, lowers the rate of hydrogenolysis. In these cases it is advisable to carry out the hydrogenation at higher temperatures or under pressure.

N-Formylphenylalanine ethyl ester (2a)

A solution of ethyl 5-phenyl-2-oxazoline-4-carboxylate [2, 3] (5.0 g, 23 mmoles) in dry ethanol (50 ml) is shaken at room temperature with 0.25 g of palladium/activated charcoal (10 % palladium, Merck) under hydrogen (normal pressure); in 3 hours 510 ml (22 mmoles) of hydrogen is taken up. After flushing with nitrogen, filtration, and evaporation of solvent there remains 5 g (99 %) of *(2a)* [NMR spectrum (CCl_4): CH_2, τ = 7.0 (*d*, *J* = 7 Hz); CH, τ = 5.2 (m). IR spectrum (film): 3320 cm^{-1} (νNH); 1740 and 1680 cm^{-1} (νCO)].

Hydrogen Fluoride-Potassium Hydrogen Phosphite (1/1), an Unusual Lattice Compound [**]

By *Hans Falius*, *Dietrich Mootz*, and *Horst Altenburg* [*]

Studies on phosphorofluoridous acid have led to the discovery of the adduct HF · KH[PHO_3] *(1)*, which is stable only in the solid state. It may be readily prepared by the following two methods:

$$\left.\begin{array}{l} HF + KH[PHO_3] \\ KF + H_2[PHO_3] \end{array}\right\rangle \rightarrow HF \cdot KH[PHO_3] \quad (1)$$

(1) is obtained as large colorless monoclinic crystals; d_4^{20} = 2.139 g cm^{-3}, m.p. 96 °C. Unit cell: *a* = 6.692, *b* = 11.040, *c* = 7.841 Å; β = 127.88 °; space group $P2_1/c$ with *Z* = 4.

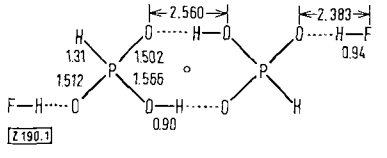
In the absence of moisture the crystals are stable at room temperature; when kept in glass vessels, however, local attack of the glass surface occurs. In aqueous solution, which shows a strong acid reaction, the compound exhibits only the reactions of its constituent ions; it cannot be reisolated from this solution. The NMR spectra (in methanol and in water) show only one fluorine signal alongside the resonances characteristic of phosphorous acid. The adduct is therefore not a hydrate of potassium phosphorofluoridite $K[PHO_2F] \cdot H_2O$, as was previously assumed. Its IR spectrum closely resembles that of KH[PHO_3].

The properties of "phosphorofluoridous hydrate" described by *Heinz* and *Röhner* [1] suggest that it is also an adduct of composition HF · $H_2[PHO_3]$, for phosphorofluoridous acid is stable and the νPF frequency (about 884 cm^{-1} in the acid) was not observed in the spectrum of this "acid hydrate".

Unlike phosphorofluoridous acid [2], compound *(1)* is immediately oxidized completely to phosphate by iodine in hydrogen carbonate solution. On alkalimetric titration it is neutralized by two equivalents of alkali in two stages. When *(1)* is heated in a vacuum it loses H_2O and HF, loss of weight setting in at 115 °C, to give a mixture containing a little $K[PHO_2F]$ and much $K_2[P_2H_2O_5]$.

Preparation:

1. Equimolar amounts of $H_2[PHO_3]$ and KF are vigorously ground together, the mixture first becoming sticky and then liquid. The syrupy liquid is extracted with hot methanol, filtered, and allowed to cool; yield 30 %.



2. A mixture of $KH[PHO_3]$ and 40% HF (molar ratio 1 : 1.5) is evaporated to dryness over P_4O_{10} and KOH in a vacuum desiccator. After a few days, the crystalline mass (or sometimes syrup) is extracted with methanol as above.

Method 1 is superior to the other. Elemental analysis (K, P, F) confirmed the composition of *(1)*; mol. wt. found by alkalimetric titration to be 139 (calc. 140).

The corresponding ammonium compound could not be prepared by the above method; attempted preparation of the sodium compound yielded only the known adduct $NaH[PHO_3] \cdot H_2[PHO_3]$.

X-ray analysis:

Three dimensional intensity data were measured with $Cu_{K\alpha}$ radiation on an automatic single crystal diffractometer[3] ($\Theta/2\Theta$ scan). Several sets of overlapping data had to be recorded for fresh crystals because *(1)* is sensitive to moisture and reacts with glass, as mentioned above. Data reduction resulted in 857 observed independent structure amplitudes which were used for determination of the structure by the usual technique and refinement to $R = 5.6\%$.

The Figure is a schematic representation of two equivalent formula units (without the potassium ions) arranged about a center of symmetry. The positions of the hydrogen atoms and the lengths of the PO bonds (two P—O bonds of 1.502 and 1.512 Å and one P—OH bond of 1.566 Å; standard deviation *ca.* 0.004 Å) provide conclusive proof of the formula $HF \cdot KH[PHO_3]$ (ruling out $KF \cdot H_2[PHO_3]$). Adjacent $H[PHO_3]^-$ ions are linked by equivalent hydrogen bonds O—H · · · O to form centrosymmetric dimers.

The short hydrogen bond F—H · · · O (F · · · O distance = 2.383 Å), which to our knowledge has not previously been reported, is the most interesting feature of the structure.

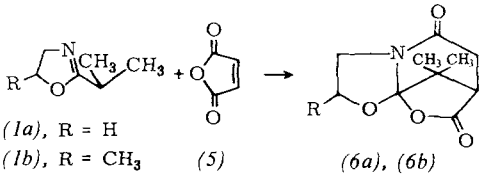
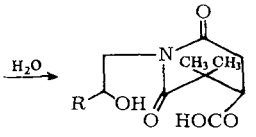
Addition of Maleic Anhydride to 2-Isopropyl-2-oxazoline

By *Rudolf Nehring* and *Wolfgang Seeliger* [*]



2-Oxazolines *(1)* add anhydrides and chlorides of monocarboxylic acids while undergoing ring scission to give 2-acyloxyethyl-[1] and 2-chloroethyl-*N*,*N*-diacylamines[2]. Reaction with cyclic anhydrides, such as those of phthalic and succinic acid *(2)*[3], affords *N*-(2-acyloxyethyl)-phthalimide and -succinimide *(4)*.



(1) *(2)* *(3)* *(4)*

It may be assumed that the reactive[4] double bond of *(1)* initially adds the anhydride group, which would give the intermediate *(3)* in the case of *(2)*. In this communication we wish to present a well-founded argument for the existence of an intermediate such as *(3)*.

Reaction of maleic anhydride *(5)* with 2-isopropyl- *(1a)* and 5-methyl-2-isopropyl-2-oxazoline *(1b)*, respectively, gave crystalline addition products which were assigned the structures *(6a)* and *(6b)*.

(1a), R = H
(1b), R = CH_3 *(5)* *(6a)*, *(6b)*

(7a)

Their IR spectra showed carbonyl absorption bands at 1780 and 1660 cm^{-1} which are typical of strained γ-lactones and six-membered lactams, respectively. The formulas are further supported by elemental analyses, molecular-weight determinations, and NMR spectra. The exceptional ease of hydrolysis of *(6a)* to *(7a)*, which is converted into α,α-dimethylcarballylic acid and ethanolamine by vigorous hydrolysis, deserves attention.

11,11-Dimethyl-2,10-dioxa-5-azatricyclo[6.2.1.$0^{1,5}$]*undecane-6,9-dione (6a)*

A solution of 2-isopropyl-2-oxazoline *(1a)* (0.8 mole) in dry 1,2-dichloroethane (200 g) was added dropwise to a stirred solution of maleic anhydride *(5)* (78.4 g, 0.8 mole) in dry 1,2-dichloroethane with exclusion of atmospheric moisture. The reaction mixture was boiled for 90 min and, after part of the solvent had been distilled off, allowed to cool, whereupon 119 g of *(6a)* crystallized; a further crop of 9 g was obtained on concentration of the mother liquor (total yield 77%). On washing with dry ethyl acetate, *(6a)* was obtained as colorless crystals (m.p. 178—191 °C, decomp.).

(6b), m.p. 137—139 °C, was prepared analogously in 48% yield.

A New Synthesis of Polyimides

By *Rudolf Nehring* and *Wolfgang Seeliger*[*]

11,11-Dimethyl-2,10-dioxa-5-azatricyclo[6.2.1.0^{1,5}]undecane-6,9-dione *(1)*[1], prepared by addition of 2-isopropyl-2-oxazoline to maleic anhydride, polymerizes when heated to 180 to 200 °C for about 20 min in the absence of moisture.

(1) *(2)*

The reaction affords poly[*N*-(2-hydroxyethyl) α,α-dimethyltricarballyl(α,γ-imid)ate] *(2)* as a transparent plastic of high molecular weight which is soluble in a number of solvents such as DMF, dioxane, DMSO, ethylene chloride, and pyridine. The relative viscosity of the solution was about 2.0 (1 g in 100 ml of chloroform at 25 °C).

During polymerization the γ-lactone carbonyl band of *(1)* (1780 cm^{-1}) disappears in favor of ester bands at 1720 and 1180 cm^{-1}.

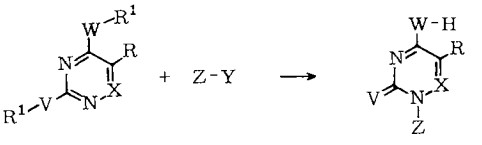
A General Synthesis of Pyrimidine Nucleosides[**]

By *U. Niedballa* and *Helmut Vorbrüggen*[*]

The most important method for the synthesis[1] of pyrimidine nucleosides is the Hilbert-Johnson reaction[1a], in which 2,4-dialkoxypyrimidines or the more readily accessible 2,4-bis-trimethylsilyl derivatives of uracils, cytosines[2], and their 2-thio analogs[3] react with protected 1-halo sugars to give predominantly the N^1-nucleosides. Up to now the reaction was usually conducted either by fusion, giving sometimes poor yields, or under milder conditions in boiling benzene in the presence of mercuric salts, which are often difficult to remove.

The Hilbert-Johnson reaction is basically a kind of Friedel-Crafts reaction with formation of a C—N bond. We therefore carried out the reaction in the presence of Friedel-Crafts catalysts and found, in contrast to earlier observations[4], that the above compounds react under mild conditions to give the N^1-nucleosides in good to very good yields.



Comparable results were obtained with the Friedel-Crafts catalysts $SnCl_4$, $ZnCl_2$, $TiCl_4$, BF_3—$(C_2H_5)_2O$, and $AlCl_3$ in 1,2-dichloroethane, benzene, acetonitrile, carbon disulfide, and dimethylformamide, but we preferred $SnCl_4$ in 1,2-dichloroethane for the sake of experimental simplicity. Under such conditions the 1-halo sugars can be replaced by the easily accessible and stable 1-alkoxy and 1-acyloxy derivatives of protected sugars. In the presence of a 2α-acyloxy substituent in the sugar component, only the β-anomers of the N^1-glycosides were isolated; the protected derivatives of 2-deoxy-D-ribose and D-arabinose yielded, as expected, mixtures of the α and β anomers. Use of a 10% excess of the pyrimidine component proved advantageous in that we then obtained not only a higher yield but also a purer end product, which in most cases crystallized spontaneously.

Because of the high yields and the simplicity of the procedure pyrimidine nucleosides have thus become readily accessible on an industrial scale.

Experimental:

2,3,5-Tri-*O*-benzoyl-1-acetyl-D-ribofuranose (Z—Y) (2.5 g, 5 mmoles) and the 2,4-bissilyl derivative of 6-azauracil (R = H, R^1 = $Si(CH_3)_3$, V = W = O, X = N) (1.42 g, 5.53 mmoles) in 1,2-dichloroethane (100 ml) were stirred for 4 h at 22 °C in the presence of $SnCl_4$ (0.42 ml, 3.6 mmoles). After addition of saturated aqueous $NaHCO_3$ solution (50 ml) the organic phase was filtered over Celite, dried with Na_2SO_4, and evaporated. The crystalline residue (2.7 g) gave 2.6 g (92%) of 2′,3′,5′,-tri-*O*-benzoyl-6-azauridine, m.p. 192 to 194 °C, after recrystallization from ethanol.

CNDO Calculation of the Inductive Effect of the Methyl Group

By *Herbert Kollmar* and *Harry O. Smith* [*]

MO calculations on hydrocarbons and carbonium ions predict [1,2] an increase in the positive charge at the α position by methyl substituents, a prediction apparently confirmed by ^{13}C-NMR [3]. This finding contradicts the usual assumption that the methyl group exerts an electron-releasing inductive effect.

Various CNDO calculations [4] by our own modified technique [5] have correctly reproduced properties of hydrocarbons and carbonium ions [6]. We have also been able to demonstrate the energetic stabilization of a positive charge by α-methyl substituents and, in particular, can show that, in terms of MO theory, the fact that methyl renders the α position positive is actually responsible for this stabilization.

Table 1 lists the relative heats of formation of a number of carbonium ions; the energies were calculated for complete minimization of the total energy with respect to the geometric parameters (bond lengths and angles).

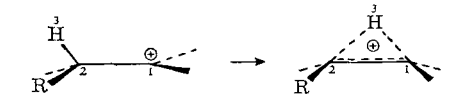

Table 1. Alkylcarbonium ions: Stability and charge distribution.

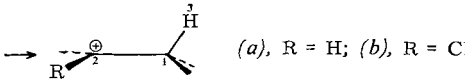
	Stabilization [a] exp.	calc.	Excess charge on the α-C atom
$C_2H_5^+$ *(1a)*		−13	+0.225
(2a)	− 2	− 3	−0.009
$C_3H_7^+$ *(1b)*	0	0	+0.190
(3b)	24	25	+0.250
(2b)		19	C-1 −0.049
			C-2 +0.066
t-$C_4H_9^+$	41	55	+0.273



[a] ΔH for the reaction: $R^+ + C_3H_8 \rightarrow n\text{-}C_3H_7^+ + RH$ (kcal/mole).

The tabulated data illustrate the reasonable energetic stabilization of the cation with increasing methyl substitution. The positive charge on the central C atom increases by about 0.02 of a unit charge per methyl group. The significance of the positive charge in the α position for the energetic stabilization of carbonium ions will be demonstrated in the present communication.

Let us consider the 2,1-hydrogen shift in the classical ethyl cation *(1a)* which proceeds *via* the nonclassical bridged ion *(2a)*. The three-center bond in *(2a)* can be formed by steady admixture of the empty p_z orbital on C-1 in *(1a)* with the orbital of the C-2—H-3 bond. The transition should therefore

(1) *(2)*

(3)

(a), R = H; *(b)*, R = CH_3

require negligible activation energy. Our CNDO calculations show structure *(2a)* to be about 10 kcal/mole more stable than *(1a)*, conversion of *(1a)* into *(2a)* entailing no activation energy.

The same process in the case of the 2-methylated ethyl cation (the *n*-propyl cation *(1b)*) leads to *i*-propyl cation *(3b)*. According to our calculations, the energy decreases monotonically during the transition: *(3b)* is 25 kcal/mole more stable than *(1b)*; thus the nonclassical structure *(2b)* is here less stable than the classical *i*-propyl cation. This state of affairs is reflected in the fact that the two C—H-3 bonds vary in strength in *(2b)*, where an H atom is situated above the middle of the C-1—C-2 bond: the H atom is drawn towards C-1. This asymmetry is caused by the methyl substituent on C-2.

In the CNDO formalism the total energy of a molecule can be allotted to bonds and atoms [4]:

$$E = \sum_{A} E_A + \sum_{A>B} E_{AB}$$

The term E_{AB} is a measure of the strength of the chemical bond A—B [7], and can be further resolved according to physical principles. It thus becomes clear (Table 2) that the bond 2—3 is weaker than 1—3 because the positive H atom 3 (charge + 0.205) is more strongly repelled by the more positive of the two C atoms, *i.e.* C-2. This is less obvious from the purely electrostatic bonding components E^S than from the resonance energy contributions (E_R = one-electron resonance energy; E^K = electron exchange energy [7]). However, more detailed analysis shows that the contributions of E^R and E^K to the bonds 1—3 and 2—3 differ only because the positive charge on C-2 is greater than that on C-1.

Table 2. Energy components of the bonds 1—3 and 2—3 in *(2b)*.

	1—3	2—3
E	−0.303	−0.262
E^R	−0.286	−0.271
E^K	−0.100	−0.082
E^S	+0.082	+0.092

Thus a relationship is established between the charge shift induced by the methyl group and the energetic stabilization of a positive charge by an α-methyl substituent: The CH_3 group increases the positive charge in the α position and is, in turn, bonded particularly strongly to a positive center. In alkylcarbonium ions, the methyl groups donate negative charge to the empty p orbital of the central C atom (hyperconjugation). This effect is overcompensated by electron withdrawal from the σ bonds by the methyl group [1]. In methyl substituted π systems, the appearance of a positive charge in the α position is accompanied by the occurrence of a corresponding negative charge in the β position. A methyl substituent therefore has a polarizing effect on a π system [2]. This is exemplified by propene [2], toluene, and also by the ion *(2b)* (see Table 1).

Crystal Structure of $TeCl_4$: Presence of Tetramers in Solid Chalcogen(IV) Halides

By *Bruno Buss* and *Bernt Krebs* [*]

On the basis of X-ray [1] and spectroscopic studies [2] of possible structures of Group VIB halides in the solid state and the steric effect of the lone pairs of chalcogen atoms, two structural models have been proposed for $SeCl_4$, $TeCl_4$, and $TeBr_4$: one model is ionic and contains $ElX_3^+X^-$ (the cations having C_{3v} symmetry) the other one being covalent and based on ElX_4 (C_{2v}; trigonal bipyramid) by analogy with the gaseous state. No unequivocal evidence in favor of either structure has hitherto been adduced. Relevant knowledge has been limited to the structure of TeF_4 [3].

We have determined the structure of solid tellurium(IV) chloride by a complete X-ray analysis of a twinned crystal. $TeCl_4$ forms monoclinic crystals of space group C2/c having $a = 17.076$ (8), $b = 10.404$ (5), $c = 15.252$ (8) Å; $\beta = 116.82°$; $Z = 16$; $d_{X\text{-ray}} = 2.959$, $d_{exp} = 3.01$ g cm^{-3}. The lattice constants are in good agreement with the known values [1b, 1d]. The structure was determined on the basis of about 3000 independent reflections (recorded with a four circle diffractometer and reduced to a single crystal). Refinement (isotropic) has so far reached $R = 0.09$.

The solid consists of isolated Te_4Cl_{16} units (Figure) with a cubane-like structure [4] and having only van der Waals contacts (Cl · · · Cl) with one another. Each of the Te atoms appears at the apex of an equilateral trigonal pyramid (mean TeCl distance 2.31 Å; σ for individual values 0.006 Å), three terminal Cl atoms forming the base. The coordination of the Te atom is made up to an octahedron by three much more remote bridging Cl atoms (mean TeCl distance 2.93 Å), the Te being displaced from the center parallel to the C_3 axis. The corners of the cubane-like skeleton are occupied alternately by Te and bridging Cl atoms. Mean bond angles are 94.8° for Cl(terminal)—Te—Cl(terminal), 85.1° for Cl(bridge)—Te—Cl(bridge), and 94.7° for Te—Cl(bridge)—Te. The Te_4Cl_{16} unit (exact symmetry C_2) has almost T_d symmetry. While the shorter Te—Cl bonds are ideal (covalent) single bonds, insofar as the bond length corresponds to the sum of the covalent radii, ionic bonding plays a dominant role in the much weaker Te—Cl bridging bonds. Thus the polar resonance structure can be fairly accurately described as an

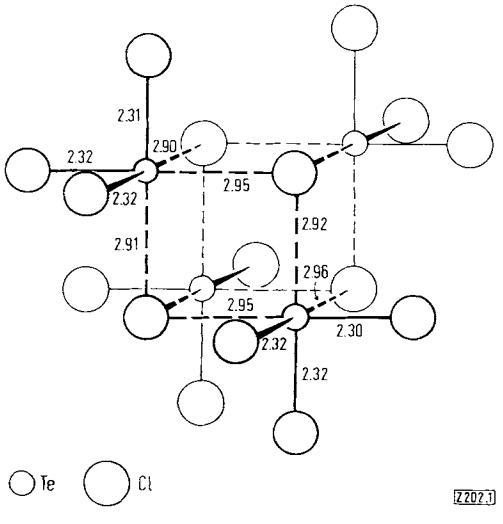

Figure: Te_4Cl_{16} structural unit in solid tellurium(IV) chloride

array of $TeCl_3^+$ ions, of approximate symmetry C_{3v}, and Cl^- ions. $TeCl_3^+$ ions have also been detected in $TeCl_3^+AlCl_4^-$ [2a, 2e], $TeCl_3^+AsF_6^-$ [2e, 5], and $TeCl_3^+SbCl_6^-$ [2e]. The shortest Te · · · Te distances in the tetramer are 4.30 Å, thus ruling out Te—Te bonding. The Cl atoms are approximately close packed (Cl · · · Cl distances 3.38 to 4.21 Å), Te filling 1/4 of the octahedral sites (cf. ref. [1c]).

Interestingly, the Te—Cl bond lengths in the $TeCl_3^+$ groups of $TeCl_4$ (2.31 Å) are much shorter than those found for Te^{IV}—Cl in, *e.g.*, $(CH_3)_2TeCl_2$ (2.51 Å) [6], $TeCl_6^{2-}$ (2.56 Å) [7], or *trans*-$TeCl_4(SC[N(CH_3)_2]_2)_2$ (2.53 Å) [8] (cf. also ref. [9]). A knowledge of the structure of solid $TeCl_4$ permits resolution of apparent contradictions in the properties of the compound, such as its electrical conductivity in the liquid state and its solubility in nonpolar solvents, *e.g.* benzene. A benzene solution of $TeCl_4$ is reported to contain trimers or tetramers [2b, 10]; this can readily be deduced from the structure. Under certain conditions, however, the possibility of an equilibrium with the monomer cannot be discounted [2c, 2e, 2f, 10]. Moreover, the vibrational spectra can now be unequivocally assigned, the twinning interpreted, and characteristic data such as the dipole moment, the high boiling point, the nuclear quadrupole resonance spectrum [11], *etc.* explained. $SeCl_4$ and $TeBr_4$ are isotypic with $TeCl_4$ (cf. also ref. [1c, 1d]).

8,8-Dichloro-1,2,3,4,5,6,7,8-heptathiatellur(IV)-ocane [**]

By *Johannes Weiss* and *Manfred Pupp* [*]

Reaction of $TeCl_4$ with polysulfanes affords a compound having the composition Cl_2TeS_7. We have been able to isolate this product as orange crystals that are stable in air and insoluble in the usual solvents; they are, however, slightly soluble in CS_2 (*ca.* 2 g/l). On heating, a black coloration is observed at 95 °C (m.p. 110–112 °C).

Cl_2TeS_7 forms orthorhombic crystals, space group D_{2h}^{16}—Pmnb, $a = 8.82$, $b = 9.01$, $c = 13.28$ Å; $Z = 4$; $d_{X\text{-ray}} = 2.65$ g/cm³.

Preliminary results from an X-ray structure analysis indicate the following structure:

The eight-membered ring has the same "crown shape" as the S_8 ring of the α-[1] and β-modification[2] of sulfur. The Te atom is coordinated as a distorted trigonal bipyramid: The Cl atoms occupy the apices of the pyramids, the lone pair taking up an equatorial position.

Procedure:

A solution of "crude sulfane"[3] (20 g) in CS_2 (0.5 l) is added dropwise to a stirred solution of $TeCl_4$ (20 g) in CH_2Cl_2 (1 l) and CS_2 (0.5 l) at room temperature over a period of 4—5 h. About 18 g of Cl_2TeS_7 is precipitated; concentration of the filtrate to a volume of 200 ml yields another 2 g of product. Purification is by recrystallization from CS_2.

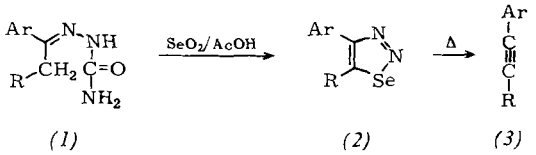
A Simple New Synthesis of Arylalkynes



By *Iradj Lalezari*, *Abbas Shafiee*, and *Mohamed Yalpani*[*]

In a previous communication we reported that selenium dioxide oxidation of aryl ketone semicarbazones *(1)* in acetic acid affords 1,2,3-selenadiazoles *(2)*[1]. We now describe experiments which show that compound *(2)* is an intermediate in a new synthesis of aryl derivatives of acetylene.

On attempted recrystallization of 4-phenyl-1,2,3-selenadiazole *(2a)* from water, the compound was found to decompose at elevated temperatures to a volatile substance having a pleasant odor and a red deposit of selenium. Steam distillation of compound *(2a)* gives an oily substance, the IR spectrum of which shows an absorption frequency at 2200 cm^{-1}. This substance reacts readily with aqueous silver nitrate to give a greyish precipitate from which phenylacetylene *(3a)* can be liberated.

A better yield of the arylalkyne *(3)* is obtained when the selenadiazole is mixed with five times its weight of sand, pyrolyzed, and vacuum distilled. Compounds of type *(3)* are also formed by exposing an alcoholic solution of *(2)* to sunlight over a long period of time.

The reaction represents a general method (see Table) for ready conversion of aryl ketones into arylalkynes. The course of reaction for aliphatic ketones is not yet clear.

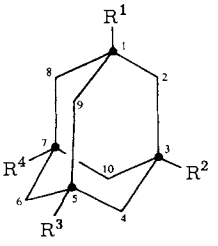
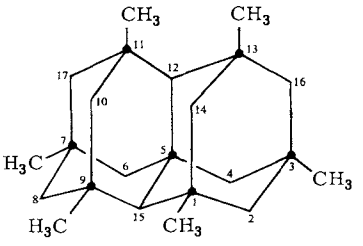
Silicon-Carbon Compounds with a Carborundum Structure ("Carborundanes"[**])

By *Gerhard Fritz*, *Fritz Diem*, *Helmut Köhler*, *Dieter Kummer*, and *Heinz Scheer*[*]



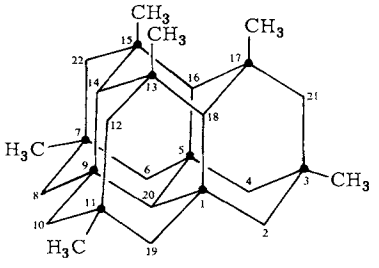
The chief products of pyrolysis of tetramethylsilane and of methylchlorosilanes are compounds having an —Si—C—Si— skeleton ("carbosilanes"); the structure of these readily distillable and sublimable compounds has already been the subject of many reports[1]. Thus, *(1a)* is formed from $Si(CH_3)_4$ and the derivatives *(1b)*—*(1e)* from $(CH_3)_3SiCl$; *(1f)* can be obtained by reaction of *(1b)* with $LiAlH_4$[2].



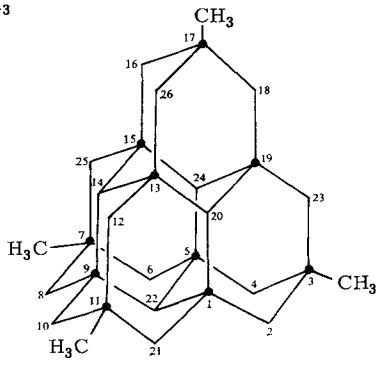
We have now been able to isolate by column chromatography (Al_2O_3, pentane) the compounds *(2)*, *(3)*, and *(4)*, which are present in low concentration in the viscous products of the gas-phase pyrolysis of $Si(CH_3)_4$ at 700 °C; their structures were established by ^{1}H-NMR- and mass spectrometry.

An accurate determination of the mass of *(2)* gave *m/e* = 424.121238 (calc. for $Si_7C_{16}H_{36}^+$ 424.120189). According to its IR spectrum and chemical properties the molecule does not contain Si—H or Si—Si groups; therefore, with the Si : C ratio under discussion, the presence of C—C groups can also be ruled out. This is also the case for *(3)* and *(4)*.

The six CH_3 groups in *(2)* can be differentiated according to their position: the methyl protons attached to the Si atoms 1, 9, 11, and 13 and to 3 and 7 are symmetrically equivalent. The ^{1}H-NMR spectrum (220 MHz) consists of two sharp $SiCH_3$ signals (τ = 9.80 and 9.81), a complex group of Si_2CH_2 signals (10.06 to 10.48) and an Si_3CH triplet (10.91), whose intensities are in the ratio 12 : 6 : 16 : 2. A more detailed analysis of the spectrum, supplemented by a double-resonance experiment, confirmed the structure *(2)*[3].



(3): *m/e* = 520.10496 (calc. for $Si_9C_{19}H_{40}^+$ 520.10534). ^{1}H-NMR: two sharp $SiCH_3$ signals (τ = 9.67 and 9.84), a group of Si_2CH_2 signals (10.20, 10.21, 10.28, 10.74), a doublet (10.74), and a quartet (10.84) due to the $SiCH_3$ protons; I_{rel} = 9 : 9 : 12 : 6 : 3 : 1. The 40 protons of *(3)* are distributed over six (3 + 3) $SiCH_3$, nine Si_2CH_2, and four Si_3CH groups. The CH_2 protons at positions 2, 4, 6, 8, 10, and 19



(1a), $R^1 = R^2 = R^3 = R^4 = CH_3$
(1b), $R^1 = R^2 = R^3 = R^4 = Cl$
(1c), $R^1 = R^3 = R^4 = Cl$; $R^2 = CH_3$
(1d), $R^1 = R^4 = Cl$; $R^2 = R^3 = CH_3$
(1e), $R^1 = Cl$; $R^2 = R^3 = R^4 = CH_3$
(1f), $R^1 = R^2 = R^3 = R^4 = H$

(2)

(3) *(4)*

• = Si

and those at 12, 21, and 22 are equivalent. Correspondingly, the Si_3CH protons at positions 14, 16, and 18 are symmetrically equivalent and can be differentiated from the proton on C-atom 20. W-coupling (spin-spin-splitting between protons in a planar $\begin{smallmatrix} H & & H \\ & \diagdown\ \diagup & \\ & Si & \\ C & & C \end{smallmatrix}$ arrangement) of C-20—H with C-14—H, C-16—H, and C-18—H causes splitting of the C-20—H signal into a quartet and conversely of the C-14—H, C-16—H, and C-18—H signal into a doublet; $J = 1.8$ Hz.

(4): *m/e* = 560.08118 (calc. for $Si_{10}C_{20}H_{40}^+$ 560.08227). ^{1}H-NMR: a sharp $SiCH_3$ signal ($\tau = 9.73$), an Si_2CH_2 signal (10.19), and an Si_3CH signal (10.87); $I_{rel} = 12 : 24 : 4$. The methyl protons at positions 3, 7, 11, and 17 are symmetrically equivalent; this is also true of the Si_2CH_2 protons at positions, 2, 4, 6, 8, 10, 12, 16, 18, 21, 23, 25, and 26 and of the Si_3CH protons at positions 14, 20, 22, 24.

These very stable and unreactive new compounds are crystalline, colorless, and sublime without decomposition in a Hg-vacuum [*(2)* at 140 °C; *(3)* at 200 °C; *(4)* at ≈ 200 °C]; they are only sparingly soluble in pentane, benzene, or carbon tetrachloride and moderately soluble in xylene (the solubility decreases with increasing molecular weight).

Nomenclature[**]: *(1a)*: 1,3,5,7-tetramethyl-1,3,5,7-tetrasilatricyclo[3.3.1.1^{3,7}]decane; *(2)*: 1,3,7,9,11,13-hexamethyl-1,3,5,7,9,11,13-heptasilahexacyclo[7.5.1.1^{3,13}.1^{7,11}.0^{5,12}.0^{5,15}]-heptadecane; *(3)*: 3,7,11,13,15,17-hexamethyl-1,3,5,7,9,11,13,-15,17-enneasilaenneacyclo [9.7.1.1^{1,5}.1^{3,17}.1^{7,15}.0^{5,16}.0^{9,14}.-0^{9,20}.0^{13,18}]docosane; *(4)*: 3,7,11,17-tetramethyl-1,3,5,7,9,11,-13,15,17,19-decasilaundecacyclo [9.9.1.1^{1,5}.1^{3,19}.1^{5,19}.1^{7,15}.-1^{13,17}.0^{9,14}.0^{9,22}.0^{13,20}.0^{15,24}]hexacosane.

Separation of Nucleosides on Cytidine-Containing Polymer Gels in DMSO/$CHCl_3$ or Water

By *Herbert Schott* and *Gerd Greber*[*]

The separation of nucleosides on thymine- or cytidine-containing gels in DMSO/$CHCl_3$ is possible by reason of Watson-Crick base pairing[1]. We have now synthesized cytidine gels that swell in both organic solvents and in water and which carry a cytidine residue in each structural unit. This was achieved by crosslinking copolymerization of *N*-benzoyl-$O^{x'}$,$O^{y'}$-bis(trimethylsilyl)$O^{z'}$-methacryloylcytidine with *N*-benzoyl-$O^{x'}$,$O^{y'}$-bis(methacryloyl)cytidine[2]. In contrast to the products crosslinked with tetramethylene dimethacrylate[3], in which some structural units do not contain a nucleoside residue, it was possible to separate mixtures consisting of two of the nucleosides adenosine (A), thymidine (T), cytidine (C), and guanosine (G), not only in DMSO/$CHCl_3$ but also in distilled water (Tables 1 and 2).

As shown in Table 1, when the separation of nucleosides is carried out on C-gel in DMSO/$CHCl_3$ the Watson-Crick complimentary guanosine is retarded the strongest and consequently can be separated almost quantitatively from the other nucleosides. This finding and the results of experiments on the separation of other pairs of nucleosides can be explained by the fact that the hydrogen bonds between the base pairs exhibit different degrees of stability[4]. It is already known[5] that pairing of nucleic acid bases in organic solvents takes place predominantly by hydrogen bonding whereas in water

Table 1. Separation of equimolar mixtures of nucleosides on a C-gel in DMSO/$CHCl_3$ (2 : 3) at room temperature. Diameter of column 1 cm.

TC	20	200	——		

[a] See footnote [a] in Table 1.

the base stacking effect makes the greater contribution. These different base pairing mechanisms are therefore responsible for the differing adsorption behavior of the same nucleoside mixture on the same gel in DMSO/$CHCl_3$ and in water.

For example, adenosine is so strongly adsorbed on C-gel from water that a separation of adenosine/guanosine in water is hardly quantitative but almost completely so in DMSO/$CHCl_3$. For the same reason the elution sequence of A and C is reversed on going from DMSO/$CHCl_3$ to water. Therefore, base pairing between cytidine and guanidine in our chromatographic system is only specific if it takes place predominantly *via* hydrogen bonding, as is the case in DMSO/$CHCl_3$.

Haloformyl(perhaloalkyl)-sulfanes and -disulfanes [**]

By *Alois Haas, Hartmut Reinke*, and *Jürgen Sommerhoff* [*]

Haloformyl(perhaloalkyl)-sulfanes *(1)* and -disulfanes *(2)* have not previously been described. Reactions of the haloformyl group, *e.g.* hydrolysis, alcoholysis, aminolysis, and thiolysis, should lead to derivatives of these compounds of interest both as herbicides and for further syntheses. Earlier attempts to obtain chloroformyl(trifluoromethyl)sulfane *(1b)* by irradiation of CF_3SCl and CO did not give unambiguous results [1].

We now report the desired synthesis and unequivocal characterization of *(1b)* and of related formyl chlorides and fluorides.

Chloro(fluoroformyl)sulfane reacts with silver trifluoroacetate in absence of a solvent, in a sealed tube at −10 °C, almost quantitatively according to the equation:

$$CF_3COOAg + ClSCOF \rightarrow CF_3COOSCOF + AgCl \quad (3)$$

Fluoroformyl(trifluoroacetoxy)sulfane *(3)* is a colorless liquid, stable if moisture is excluded and decomposing to CO_2 and fluoroformyl(trifluoromethyl)sulfane *(1a)* when irradiated by UV light [3]:

$$(3) \xrightarrow{h\nu} CF_3SCOF + CO_2 \quad (1a)$$

Aluminum chloride converts *(1a)* in a sealed tube at room temperature into *(1b)* with fluorine-chlorine exchange in the haloformyl group.

Photolytic reaction of thiocarbonyl halides with chloro(haloformyl)sulfanes in a sealed tube at 20 °C is particularly suitable for preparation of analogous compounds of type *(2)*, *e.g.*:

$$F_2CS + ClSCOCl \xrightarrow{h\nu} ClF_2CSSCOCl \quad (2c)$$

$$Cl_{2-n}F_nCS + ClSCOF \xrightarrow{h\nu} Cl_{3-n}F_nCSSCOF \quad (2d),\ n=2;\ (2e),\ n=1$$

$$CF_3SCSF + ClSCOF \xrightarrow{h\nu} CF_3SCClFSSCOF \quad (2f)$$

	B.p. (°C/torr)	M.p. (°C)	^{19}F-NMR δ (ppm) [a]	^{19}F-NMR J_{FF} (Hz)
(1a)	8/760	—	42.0 d (CF_3) −53.0 q (COF)	19.5
(1b)	46.8/760	—	43.1	—
(2a)	65/760	—	46.5 d (CF_3) −41.5 q (COF)	2.0
(2b)	103.9/760	—	46.2	—
(2c)	164/760	−44	34.7	—
(2d)	96.6/760	−76	33.3 d ($CClF_2$) −42.3 t (COF)	2.2
(2e)	143/760	—	26.4 d (CCl_2F) −45.0 d (COF)	2.4
(2f)	158/750	—	38.9 d (CF_3) −44.3 d (COF) 56.0 dq (CClF)	$J_1 = 9.6$ $J_2 = 2.0$
(3)	74/745	—	75.0 (CF_3) −20.0 (COF)	—

[a] CCl_3F as internal standard.

The time required for irradiation (15—40 hours) depends on the degree of fluorination of the reactants. These reactions, which proceed *via* radicals [4], afford complex mixtures of products which can be separated by distillation (1-m spinning band column) and purified by gas chromatography.

(Fluoroformyl)- *(2a)* and (chloroformyl)-(trifluoromethyl)-disulfane *(2b)* are formed from chloro(haloformyl)sulfane and mercury(II) trifluoromethanethiolate:

$$(CF_3S)_2Hg + 2\ ClSCOX \rightarrow 2\ CF_3SSCOX + HgCl_2$$
(2a), X = F
(2b), X = Cl

It is here seen that chloro(chloroformyl)sulfane reacts only monofunctionally. Attempts to replace also the Cl atom of the chloroformyl group by the trifluoromethyl group failed. This accords with findings by *Zumach* and *Kühle*[5] in which ClCOSCl was attacked by thiols only at the *S*-bonded Cl atom.

Compounds *(1)* and *(2)* are water-clear, mobile liquids which are stable in absence of moisture (see Table).

Direct Synthesis and Reactions of Bromo(pentafluorophenyl)silanes[1]

By *Manfred Weidenbruch* and *Nezam Wessal*[*]

Halo(pentafluorophenyl)silanes, which are of interest for the preparation of novel polysiloxanes, cannot be obtained by reaction of silicon tetrahalides with (pentafluorophenyl)-magnesium bromide or -lithium because, even with a large excess of the SiX_4 components, only tetrakis(pentafluorophenyl)silane is formed[2]. We have now found that a direct synthetic process[3] affords them easily and with a selectivity that is remarkable for perhalogenated compounds.

For instance, bromopentafluorobenzene reacts (optimum temperature: 600 °C) with a catalyst composed of silicon (85%) and copper (15%) to give 60% of dibromobis(pentafluorophenyl)silane *(1)*, b.p. 110 °C/0.6 torr, and 30% of tribromo(pentafluorophenyl)silane *(2)*, b.p. 205–208 °C, together with a little bromotris(pentafluorophenyl)silane, m.p. 83 °C:

$$C_6F_5Br + Si/Cu \xrightarrow{600\,^\circ C} \underset{(1)}{(C_6F_5)_2SiBr_2} + \underset{(2)}{C_6F_5SiBr_3}$$

Conversion of C_6F_5Br amounts to 10–30%, which indicates the advisability of a recycling technique in which the unused C_6F_5Br, b.p. 136 °C, is continuously distilled off fractionally from the less volatile products and returned to the heated catalyst. Decafluorobiphenyl *(3)*, m.p. 68 °C, b.p. 188 °C, is the only by-product formed in detectable amounts; the proportion of *(3)* formed depends on the copper content of the catalyst and produces difficulties if it exceeds 20%. On pure copper C_6F_5Br gives *(3)* quantitatively at 600 °C.

Chloropentafluorobenzene reacts analogously, giving chloro-(pentafluorophenyl)silanes, though the conversion is, as expected, lower because of the greater bond energy of R—Cl than of R—Br. Hexafluorobenzene does not react with the Si/Cu catalyst up to 600 °C.

Applicability of compounds *(1)* and *(2)* to synthesis of further pentafluorophenyl-substituted silanes and polysiloxanes is indicated by the annexed chart of some reactions of *(1)*:

$$\underset{(5)}{(C_6F_5)_2Si(OH)_2} \xrightarrow{120\,^\circ C} \underset{(6)}{[(C_6F_5)_2SiO]_n}$$

$$\underset{(4)}{(C_6F_5)_2SiF_2} \xleftarrow{SbF_3} \underset{(1)}{} \xrightarrow{C_2H_5MgBr} \underset{\text{b.p. 110 °C/0.4 torr}}{(C_6F_5)_2Si(C_2H_5)_2}$$

(H_2O: *(5)* ⇄ *(1)*; H_2O: *(1)* ⇄ *(4)*)

Heating *(1)* or *(2)* with antimony trifluoride leads to the fluorosilanes *(4)*, b.p. 207 °C, and $C_6F_5SiF_3$, b.p. 102 °C, respectively, which, like bromosilanes, react spontaneously with water. Hydrolysis of *(1)* and similarly of *(4)* proceeds *via* the stable silanediol *(5)*, m.p. 120–122 °C, which condenses at the melting point to give the resinous polysiloxane *(6)*, m.p. > 170 °C. On prolonged heating or on storage, *(6)* changes, without alteration in composition, to a silicone that is very resistant both thermally and chemically and has celluloid-like properties, melting at > 350 °C.

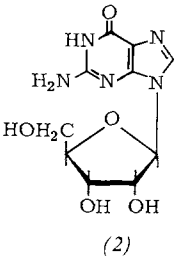
CONFERENCE REPORTS

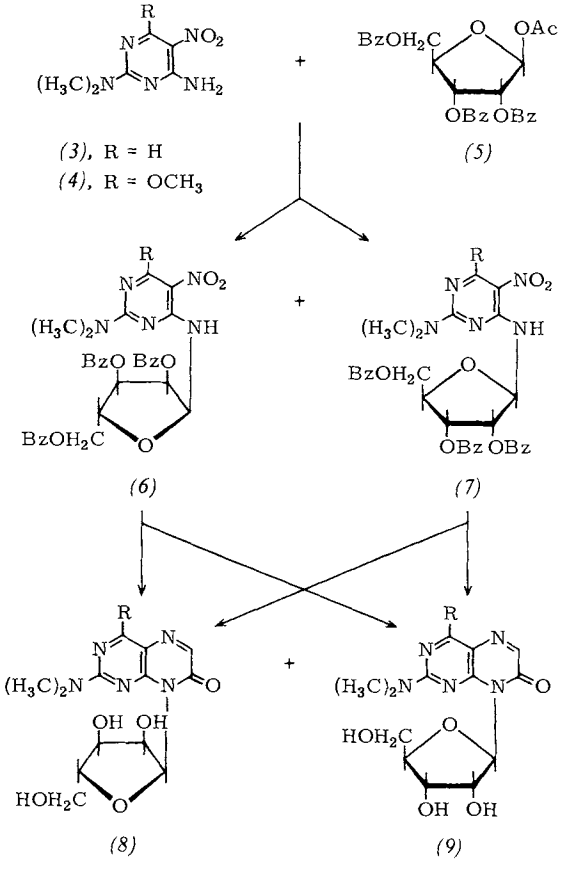
Synthesis of Pteridine 8-Ribosides



By *Wolfgang Pfleiderer*[*]

The synthesis of pteridine 8-ribosides *(1)*, the structural analogs of the purine nucleosides *(2)*, has been the focal point of our investigations in the field of pteridines for more than twelve years.

Previous investigations on the glycosidation of 7-oxo-7,8-dihydropteridines by the heavy-metal salt method have shown that 7-*O* glycosides are always formed and no *N*-8 glycosides[1]. The analogous behavior of the 2-oxodihydroquinoxalines[2] and of 2-pyrazinone[3] helped to clarify the complex nature of the reaction and showed that the observed selectivity in the direct glycosidation of the pteridine system



(1)

(2)

under such conditions is determined primarily by two factors steric hindrance and the particular electronic features of the pyrazine system — both of which oppose an $O \rightarrow N$ transglycosidation.

The first definite synthesis of a pteridine 8-glucoside was accomplished in 1964[4] using 4-amino-6-dimethylaminopyrimidine as starting material. The carbohydrate group was introduced into the molecule at the pyrimidine stage; amination at C-5 *via* the benzeneazo derivative followed by cyclization with α-oxo esters completed the synthesis. A further successful variant was found for the synthesis, namely the reaction of 4-chloro-5-nitropyrimidines with 1-aminohexoses to give 4-glycopyranosylamino derivatives which, on reduction and cyclization, afford the 7-oxo-7,8-didydropteridine 8-glycopyranosides[5]. Since attempts to use this method of synthesis in the ribofuranose series failed because of the instability of 1-amino-2,3,5-tribenzoylribofuranose, a new preparative route was developed on the basis of a fusion reaction. For instance, 4-amino-5-nitropyrimidines *(3)* and *(4)* react with fully acylated sugars such as 1-acetyl-2,3,5-tribenzoylribofuranose *(5)* on fusion in the presence of acid catalysts[6]. The 4-amino groups of *(3)* and *(4)* undergo ribosidation in good yield if the reactants are heated for 30 mins at 160 °C in the presence of $ZnCl_2$ as catalyst. Separation of the reaction mixture by layer chromatography showed that a mixture of anomers is formed under such vigorous reaction conditions and that the α-riboside *(6)* is the predominant product in each case. Assignment of the pure ribosides to the α- and β-series was established by analysis of the NMR spectra and by decoupling experiments. No definite conclusions could be drawn from the ORD spectra.

Surprisingly, it was found that the pure anomers *(6)* or *(7)* are partially anomerized to the pteridine-*N*-8-riboside during both the catalytic hydrogenation of the 5-nitro to the 5-amino group and the reaction with glyoxylate. Compounds *(8)* and *(9)* could be separated by preparative layer chromatography.

Recent Work on Insect Sex Attractants

By *Karl Eiter*[*]

The insect sex attractants found so far belong to one of the following classes: Singly or multiply unsaturated, straight-chain or slightly branched alcohols and their esters; olefinic carboxylic acids and their esters; heterocyclic and aliphatic substances resembling terpenes.

The sex attractant of the gypsy moth (*Porthetria = Lymantria dispar*), reported to be (+)-1-hexyl-10-hydroxy-3-*cis*-decenyl acetate and synthesized stereospecifically by *Jacobson et al.*[1] has been prepared by us[2] and by *Stefanovic et al.*[3] in a stereospecifically uniform synthesis and found to posses no biological activity. The explanation offered by the American authors[1], namely that the activity is inhibited by contamination with small amounts of the *trans* compound, was shown to lack any substance since mixtures of the synthetic material with active extracts exhibited a definite activity in an electroantennogram (EAG)[**]. *Jacobson et al.*[1] have further described the synthesis of 1-hexyl-12-hydroxy-3-*cis*-dodecenyl acetate, "gyplure", which is reported to be just as active as the gypsy moth attractant. We have also synthesized this substance stereospecifically and found it to be completely inactive. It follows that the structure given for the gypsy moth attractant cannot be correct.

Isolation and structural elucidation of the sex attractant of the American cockroach (*Periplaneta americana*) were also reported by *Jacobson et al.*; after publication of a total synthesis of this cyclopropane derivative by *Day* and *Whiting*[4], which yielded a biologically inactive product, they later retracted their claims.

The sex attractant of the pink bollworm moth (*Pectinophora gossypiella* S.) is given by *Jacobson et al.*[5] as 10-propyl-5-*trans*,9-tridecadien-1-ol, "propylure". On carrying out a sterically non-uniform synthesis we obtained a product completely lacking activity. *Jacobson*[6] repeated the synthesis and isolated the pure *trans* compound from the mixture of isomers. The presence of 15—20% of the *cis* compound was said to inactivate the attractant completely. This finding is the same as in the case of the gypsy moth attractant and rather unlikely, particularly in view of reports that the activity of propylure in field tests depends on the presence of activators (*N,N*-diethyl-*m*-toluamide : mosquito repellent Autan®)[7] and that 7-*cis*-hexadecenyl acetate, "hexalure", is considerably more active than propylure and is not inhibited by the *trans* compound[8].

In the present state of uncertainty regarding their mode of action, the pheromones of other insects, which are possibly only quantitatively definite mixtures of three or four synergically acting components, can hardly be used as models for studies on the problem whether insect pests can be attracted specifically to some central position. This paramount question of modern pest control still cannot be answered owing to the confusion present in this field of research.

Problems of Copolymerization in Multicomponent Systems

By *Wolfhart Ring* [*]

The rules governing copolymerization of multicomponent systems are based on simple kinetic premises. From them can be calculated the composition of a copolymer and the distribution of sequences of the same monomer unit as affected by monomer concentration and degree of conversion. Copolymerization parameters ("*r* values") are normally used for characterizing the polymerization behavior, these parameters being valid for a given monomer pair; they are available in tabular form.

The distribution of the sequences often have a great effect on the technological and physical properties of industrial copolymers, and this was discussed for two cases:

1. Ethylene-propane rubber. To repress the crystallization of the product as much as possible, it is desirable that there should be no long sequences (> 10—15) of the two components. The kinetic criterion for a suitable catalyst is as low a numerical value as possible for the product $r_{ethylene} \times r_{propene}$.

2. Styrene-butadiene copolymers — these are important as synthetic elastomers. On radical initiation, the copolymerization properties of styrene and butadiene present no problem in relation to distribution of sequences (short styrene sequences are desirable). However, on anionic initiation, the reactivities of the two monomers are generally so different that discontinuous copolymerization processes are excluded. Kinetiv calculations permit determination of suitable reaction conditions for a continuous process in a steady-state reactor [1].

Radical copolymerization can be discussed from the general standpoint of the relation between structure and reactivity, as shown, for example, in the work of *Bamford* and *Jenkins* [2].

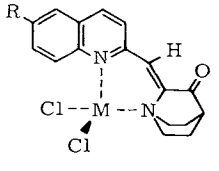
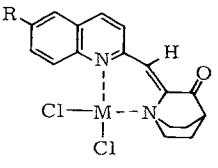
SELECTED ABSTRACTS

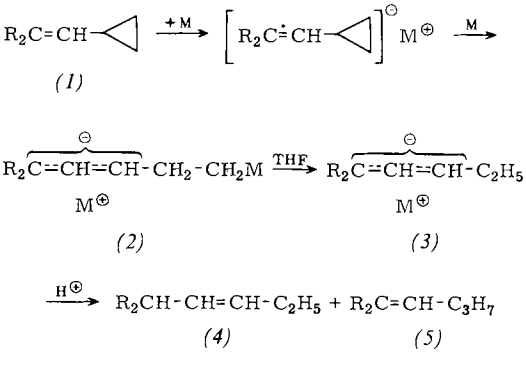


The cycloaddition of *cis,cis,cis*-1,3,5,7-cyclononatetraene to 4-phenyl-1,2,4-triazoline-3,5-dione has been studied by *A. G. Anastassiou* and *R. P. Cellura.* At —78 °C they obtained the adduct *(1)* (m.p. 181—183 °C, yield about 60%) as sole



(1)

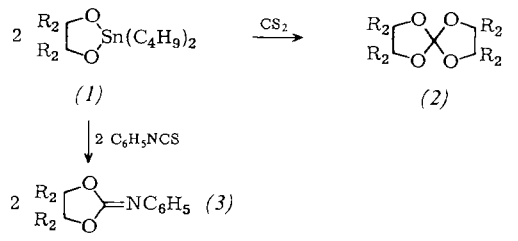
product. *(1)* could be distinguished from its conceivable isomers by NMR spectroscopy. / Tetrahedron Letters *1970,* 911 / —Kr. [Rd 181 IE]



Isomeric nickel complexes from *trans*-2-(2-quinolyl)methylene-3-quinuclidone and its 6-methoxy derivative have been obtained by *D. L. Coffen* and *T. E. McEntee jr.* On admixture of transition metal dichlorides in ethanol with the ligands the complexes *(1), (2), (5),* and *(6)* crystallize. On attempted recrystallization from methylene chloride/ethanol complex *(2)* was converted irreversibly into *(3).* The structures were assigned on the basis of the IR spectra and the fact that Co^{II} forms tetrahedral complexes and Cu^{II} planar ones. The magnetic moments for *(1), (6), (7),* and *(8)* confirm the structures assigned and also indicate contamination of *(8)* with *(6).* / J. Amer. chem. Soc. *92,* 503 (1970) / —Kr. [Rd 183 IE]

(1), M = Co, R = OCH_3 *(3)*, M = Cu, R = OCH_3
(2), M = Ni, R = OCH_3 *(4)*, M = Ni, R = OCH_3
(5), M = Co, R = H *(7)*, M = Cu, R = H
(6), M = Ni, R = H *(8)*, M = Ni, R = H

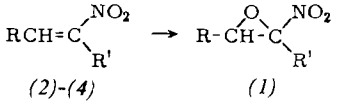
Addition of alkali metals to 1,1-diphenyl-2-cyclopropylethylene *(1)* has been studied by *A. Maercker.* The deep red THF solution obtained from *(1)* and Na/K alloy afforded a 3 : 2 mixture of the 1,1-diphenylpentenes *(4)* and *(5)* on hydrolysis. As shown by carboxylation of the reaction mixture to



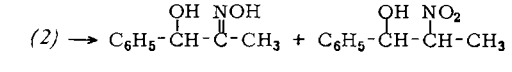
(1), *(2)*, *(3)*, *(4)*, *(5)*

R = C_6H_5

2,2-diphenyl-3-hexenoic acid and 2-ethyl-4,4-diphenyl-3-butenoic acid, *(4)* and *(5)* must arise from the monoanion *(3).* Reaction with lithium gave the same acids together with higher homologs (ethylene taken up from solvent). The Li—C bond in the dianion *(2)*, M = Li, could be detected directly. / Liebigs Ann. Chem. *732,* 151 (1970) / —Kr. [Rd 182 IE]



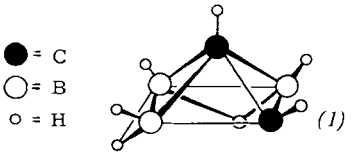
Spiroorthocarbonates *(2)* and cyclic iminocarbonates *(3)* have been obtained on a preparative scale by *S. Sakai, Y. Kobayashi*, and *Y. Ishii* on treatment of cyclic dibutyltin dialkoxides *(1)* with carbon disulfide and phenyl isothiocyanate, respectively. The organometal compound is removed as dibutyltin sulfide. Examples: *(1a)*, R = H, →*(2a)*, R = H,



(1) *(2)*

82% yield, b.p. 60—70 °C/0.5 torr; *(1b)*, R = CH_3, →*(3b)*, R = CH_3, b.p. 120—125 °C/0.4 torr (100%). / Chem. Commun. *1970*, 235 / — Kr. [Rd 185 IE]

α-Nitro epoxides (nitrooxiranes) *(1)*, a new group of compounds, were obtained by *H. Newmann* and *R. B. Angier* from nitro olefins and hydrogen peroxide in the presence of alkali. For example, (2-nitropropenyl)benzene *(2)*, R = C_6H_5, R′ = CH_3, *cis*-α-nitrostilbene *(3)*, R = R′ = C_6H_5, and (2-nitropropenyl)cyclohexane *(4)*, R = cyclohexyl, R′ = H, gave the nitro epoxides *(1)* in 67, 85, and 91% yield, respectively. However, for steric reasons *trans*-α-nitrostilbene did not react. The nitro epoxide from *(2)* (as example) behaves towards nucleophilic reagents like an α-halo ketone. With acids, *e.g.* dilute aqueous H_2SO_4, it gives 1-hydroxy-1-phenylacetone and a small amount of diketone. Reducing agents



(2)-(4) *(1)*

(5) *(6)*

such as Zn/aqueous acetic acid afford the oxime *(5)*; catalytic hydrogenation over PtO_2 leads to *(5)* and 2-nitro-1-phenyl-1-propanol *(6)*. / Tetrahedron *26*, 825 (1970) / —Ma. [Rd 188 IE]

A new carborane cage system, 1,2-$C_2B_3H_7$, is described by *D. A. Franz* and *R. N. Grimes*. The compound, 1,2-dicarba-*nido*-pentaborane *(1)*, a member of a new class of small carboranes, is isoelectronic and isostructural with pentaborane, B_5H_9. It was obtained in 3—4% yield by gas-phase reaction of tetraborane with an excess of acetylene at 50 °C and was purified by gas chromatography. Its structure was proved by IR, NMR, and mass spectra. It is stable in the vapor phase at 50 °C but in the liquid phase it polymerizes

(1)

rapidly at room temperature. It reacts rapidly with B_2H_6 at 50 °C but not with B_4H_{10}. / J. Amer. chem. Soc. *92*, 1438 (1970) / —Ma. [Rd 189 IE]

Photochemical synthesis of aromatic chloro compounds from aromatic iodo compounds that are readily accessible has been reported by *F. Kienzle* and *E. C. Taylor*. Dilute solutions of the iodo derivatives in CCl_4 were irradiated with light of wavelength 3000 Å, iodine exchange occurring without formation of impurities due to position isomerization. After reaction for 5 hours the conversion amounted to 70—75%; the reaction probably occurs in accord with the scheme:

$$ArI \rightarrow Ar^{\cdot} + I^{\cdot}$$
$$Ar^{\cdot} + CCl_4 \rightarrow ArCl + {}^{\cdot}CCl_3$$
$$2\,I^{\cdot} \rightarrow I_2$$
$$2\,{}^{\cdot}CCl_3 \rightarrow C_2Cl_6$$

Hexachloroethane was isolated in yields of up to 5%. Electron-donating substituents accelerate halogen exchange, electron-attracting substituents decelerate it. Examples are *p*-chloroanisole (96% yield), *o*-chlorophenol (80%), *o*-chlorobenzoic acid (51%). / J. org. Chemistry *35*, 528 (1970) / —Ma. [Rd 190 IE]

Isolation, properties, and reactions of chlorocarbonyl isocyanate *(1)* have been described by *W. Gottardi* and *D. Henn*. On photolysis of gaseous chlorine isocyanate *(2)* with light of > 280 nm in a vacuum, N_2, CO, and phosgene are formed together with an orange product *(1)* which after purification is obtained as a colorless liquid, m.p. —68 °C, b.p. 63 °C. Formation of *(1)* probably occurs by the primary radical-forming reactions:

$$2\,ClN{=}CO \rightarrow (Cl_2N{-}C(O){-}N{=}CO \rightarrow Cl_2N^{\cdot} + {}^{\cdot}C(O){-}NCO$$
$${}^{\cdot}C(O){-}NCO + ClN{=}CO \rightarrow ClC(O){-}NCO + {}^{\cdot}N{=}CO$$

(1) is both an isocyanate and an acid chloride and is thus sensitive to moisture. With less than the stoichiometric amount of water it affords, besides cyanic acid and CO_2, the previously unknown iminodiformyl dichloride, ClCO—NH—COCl, m.p. 88—89 °C. / Mh. Chem. *101*, 11 (1970) / —Ma. [Rd 191 IE]

Spectroscopic evidence for the $H_5O_2^+$ ion in the crystalline dihydrate of perchloric acid at —180 °C is presented by *A. C. Pavia* and *P. A. Giguère*. The absence of certain IR and Raman bands characteristic of H_3O^+ and H_2O confirms the existence of $H_5O_2^+$ ions in that crystal postulated previously on the basis of X-ray diffraction data. The spectra are consistent with a *trans* H_2O—H—OH_2 structure of approximate C_{2h} symmetry. In the deuterated compound IR spectra indicate the existence of $D_5O_2^+$ with the same structure. Unfortunately, the interference of strong ClO_4^- bands prevents identification of all the fundamentals of $H_5O_2^+$. / J. chem. Physics *52*, 3551 (1970) / —Hz. [Rd 193 IE]

Synthesis and attempted automerization of [1-^{13}C]naphthalene are reported by *H. A. Staab* and *M. Haenel*. The Grignard derivative from 1-bromo-3-phenylpropane was converted by $^{13}CO_2$ (from barium [^{13}C]carbonate) into 4-phenyl[1-^{13}C]-butyric acid. Ring closure of the acid chloride to give [1-^{13}C]-tetralone was followed by Clemmensen reduction and dehydrogenation (yield 55% based on barium [^{13}C]carbonate). The ^{13}C enrichment amounted to 50.6%. NMR spectra and the ESR spectrum of the radical anion showed selective α-labeling. No automerization could be detected under the conditions given by *Balaban* and *Fărcaşiu*[1] for [1-^{14}C]-naphthalene (heating with $AlCl_3$ in benzene at 60 °C). / Chem. Ber. *103*, 1095 (1970) / —Kr. [Rd 202 IE]

[1] *A. T. Balaban* and *D. Fărcaşiu*, J. Amer. chem. Soc. *89*, 1958 (1967); Tetrahedron Letters *1968*, 1273.

Adamantane as a matrix for the preparation and conservation of free radicals is recommended by *D. E. Wood* and *R. V. Lloyd*. Some radicals obtained by X-irradiation and found to be relatively stable (half-lives in the order of 10 h at room temperature) are *tert*-alkyl, benzyl, phenoxyl, semiquinone, and tropyl. As adamantane provides a nonpolar matrix with essentially spherical holes, the radicals can easily rotate, and their ESR spectra are normally isotropic at temperatures from −120 to +80 °C. A new class of free radicals was obtained by X-irradiation of aliphatic amines; they are formed by removal of a hydrogen atom *alpha* to the amine group. The average spin density on the trigonal carbon is estimated to be 0.63 in this class of radicals; thus about 1/3 of the spin density is delocalized, presumably on to nitrogen. / J. chem. Physics *52*, 3840 (1970) / —Hz. [Rd 192 IE]

The conductivity of imidazole single crystals was studied by *A. Kawada, A. R. McGhie*, and *M. M. Labes*. The conductivity in the crystallographic *c* direction, the direction of the hydrogen bonds, exceeds the conductivity along the *a* axis by a factor of about 10^3 provided that surface conduction is eliminated. After a sluggish start, electrolysis in *c* direction evolves up to 0.97/2 moles of H_2 per Faraday at the negative electrode. The conduction mechanism is thought to consist in injection of an "L-defect", a proton vacancy in a hydrogen bond. For further supply of charge carriers the imidazole molecules must reorient around an axis in the ring plane perpendicular to the *c* axis. This process accounts well for the relatively high activation energy of 1.7 eV. / J. chem. Physics *52*, 3121 (1970) / —Hz. [Rd 194 IE]

The primary photochemical processes of tetramethyl-*p*-phenylenediamine (TMPD) have been investigated by *J. T. Richards* and *J. K. Thomas* in cyclohexane, ethanol, and water. In cyclohexane, singlet fluorescence with 3.2 ns half-life and the triplet state absorption spectrum were observed; the triplet decays by triplet-triplet annihilation accompanied by delayed fluorescence. N_2O, SF_6, and CO_2 quench the excited singlet state; N_2O also reacts with triplet TMPD forming a charge transfer complex. In ethanol, the singlet fluorescence has a half-life of 5.1 ns; the triplet is also observed, but it decays over several 100 ns. Photolysis of TMPD in water produces, instead of fluorescence and triplet absorption, $TMPD^+$ (Wurster's blue) and hydrated electrons. The energy difference between exciting light (3.6 and 4.75 eV, corresponding to 3472 and 2650 Å) and the ionization potential of gaseous TMPD (about 7 eV) is supplied by the solvation energy of the ions produced. No biphotonic processes were observed with laser excitation. / Trans. Faraday Soc. *66*, 621 (1970) / —Hz. [Rd 195 IE]

BOOK REVIEWS

Chemie heisser Atome (Chemistry of Hot Atoms). By *G. Stöcklin*. Vol. 6 of the "Chemischen Taschenbücher", edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st ed., ix, 284 pp., 49 figures, 53 tables, paperback DM 18.—.

The reactions of "hot atoms", *i.e.* chemical reactions in the range 1—10 eV (0.025 eV corresponds to 300 °K) form a very heterogeneous field of investigation, which is full of controversies. Consequently, existing articles in scientific handbooks are mostly confined to collections of experimental facts and the reproduction of more or less speculative attempted interpretations. A "chemical pocket book" intended both as an introduction for students and as a review for the expert is therefore an undertaking that will undoubtedly be greeted with scepticism at first by the initiated. This merely adds to the respect one acquires for this book on reading it. The author has declined to discuss the pros and cons of the many hypotheses on high-energy reactions, which are so confusing to beginners in particular, but has confined his treatise largely to established facts, or else he expressly points out the hypothetical nature of statements cited. The author has also succeeded in presenting the numerous experimental facts clearly and understandably, despite their diversity.

The reader is first acquainted with the established physical facts concerning hot reactions. This is followed in the second part by experimental observations concerning numerous chemical systems and the most important theories on these observations. Out of a total of perhaps 2000 publications in this field, about 370 have been selected for illustration. Most of these are concerned with the reactions of tritium and of ^{14}C and ^{11}C. The other two topics, *i.e.* "Reactions of hot halogen atoms" and "Hot reactions in inorganic solids", are discussed in less detail, on the grounds (which are only partly valid) that these fields have not yet led to such definite results as the reactions of T and C.

Earlier models that have had an influence on developments are also briefly mentioned. It is gratifying to find that the priorities, which are often blurred in the literature, are correctly represented here (cf. p. 213).

On the whole, the present book can be described as a successful exposition of the "reactions of hot atoms", which lives up to the aims of the series of "pocket books". Physical chemists who are interested in high-energy reactions and organic chemists who are interested in labeled compounds may also find it useful.

Franz Baumgärtner [NB 873 IE]

Citric Acid Cycle. Control and Compartmentation. Edited by *J. M. Lowenstein*. Marcel Dekker, Inc., New York-London 1969. 1st ed., xxi, 366 pp., numerous figures, $ 17.75.

A reader who is not familiar with the trends in biochemistry will perhaps be surprised to find that the present monograph on the citric acid cycle tells him nothing about individual reactions, the coenzymes involved, *etc.*, and does not even contain the well-known diagram of the cycle. The book, which is not intended for beginners, presupposes such (by no means inconsiderable) biochemical knowledge. Details of reaction mechanisms are of no interest in any case in a book whose real theme is stated in the subtitle "Control and Compartmentation" (*i.e.* in the field of cell metabolism insofar as it is related to the citric acid cycle).

The first and longest article (by *G. D. Greville*) presents a sort of "topographical biochemistry" of the cell, in which the localization of the enzymes in the cell compartments, the displacements of the metabolites between these compartments, and the transport problems that arise are discussed. The interplay of these factors leads to a complicated network of interdependent reaction chains, which are separated as far as possible and examined with a view to establishing their importance. This treatment, which takes into account the situation in the intact cell, differs very considerably in some points from the "one-dimensional" picture of the metabolism as shown in essence by our textbooks.

The next two contributions (*D. E. Atkinson*; *P. B. Garland et al.*) try to draw a coherent picture of the control mechanisms that are involved in the synthesis and degradation of citric acid and that connect the citric acid cycle more inti-

mately with the fatty acid metabolism. The variety of the existing or assumed mutual influences is confusing, and imposes on the authors a need for a particularly critical view. Reference is repeatedly made to the difficulty of deducing the situation in the living cell from experiments *in vitro* ("Thus a postulated control mechanism may not in fact control *in vivo* nor may so called "regulatory enzymes" play a regulatory role").

Further contributions deal with the role of α-ketoglutaric acid (*J. M. Tager et al.*) and of the dicarboxylic acids (*M. F. Utter*) in metabolism. An enzyme-kinetic study of inhibition mechanisms of antimetabolites produced by the introduction of fluorine (*E. Kum*) provides the material for the final chapter.

The book is intended primarily for advanced biochemists and for biologists with corresponding interests, who will welcome a book by competent authors in this important field, which summarizes the results of various special lines of investigation (with more than 1000 references, extending up to 1968 in some cases).

To the chemist who possesses the knowledge mentioned above, this book, the title of which is really too modest, offers a source of information on the principal lines of research in modern biochemistry. While chemistry progresses toward a more detailed understanding of the properties of molecules, biochemistry is concentrating increasingly on combining the individual processes into one integrated picture. Since it is no longer concerned with the study of isolated reactions, or even cycles, but mainly with how they are linked and how they influence one another, it has taken an important step toward the true goal of its research.

Carl Martius [NB 876 IE]

Strahlen-Biochemie (Radiation Biochemistry). By *C. Streffer*. Vol. 59/60 of the "Heidelberger Taschenbücher". Springer-Verlag, Berlin-Heidelberg-New York 1969. 1st ed., xi, 196 pp., 69 figures, stitched DM 14.80.

In contrast with irradiation with UV light, in which a certain selectivity of the chemical reactions and biological effects induced by the radiation can be achieved by means of the wavelength used, the action of ionizing radiation on biological objects leads to many radiation-chemical reactions and biological phenomena. In the present pocket book the author has attempted to examine critically the voluminous, but in part very diffuse, material published so far on the basis of biochemistry and to present it in an orderly manner. As is stressed in the preface, research in the field of radiation biology is rapidly advancing, and it is not yet possible to glimpse the causal relationships in many cases. The blame for the rather confusing impression received by those who are not very familiar with the field on reading this book, as well as books on similar topics, cannot therefore be laid on the author, but is due rather to the present state of research.

After an introduction to the principles of radiation research, the changes suffered by the nucleic acids, proteins, and amino acids, carbohydrates, lipids, hormones, and vitamins (including their metabolism), as well as the respiratory chain, the metabolism of energy-rich phosphates, and the electrolyte balance on irradiation are described in a well-ordered manner. The bibliography includes 277 references, mainly to recent publications, with the aid of which earlier publications can be found.

The pocket book is recommended above all to chemists, biochemists, biologists, and physicians who wish to familiarize themselves with the problems of the irradiation of biological objects with ionizing radiations prior to their own scientific studies. *Egon Fahr* [NB 878 IE]

Electron Microscopy and Microanalysis of Metals. Edited by *J. A. Belk* and *A. L. Davies*. Elsevier Publishing Co. Ltd., Amsterdam-London-New York 1968. 1st ed., xiv, 254 pp., 80 figures, Dfl. 47.50.

The scope of the material sciences has recently been so greatly increased by the electron microscope and the microprobe that the use of these two instruments should be known to every materials engineer and metallographer, and to a certain extent also to metal and chemical technologists. The present book is excellently suited to provide a rapid survey of the construction and applications of these instruments. Following an introduction to electron optics by *W. James*, the editors and other well-known electron microscopists present the principles of electron diffraction and specimen preparation (thin films and replicas) and the use of the electron microscope in studies on deformations, strains, and precipitation processes. Further sections, also by renowned authorities, deal with the construction and operation of the microprobe, qualitative analysis using this instrument, and its industrial use.

Despite the large number of authors, the book still retains the character of an independent review of these two important methods for the investigation of solids. The concentrated text is relieved by numerous texture photographs, literature references at the end of each chapter offer an opportunity for further reading in this field, and a subject index facilitates searches and shows the relationships between the various chapters. Though the book is intended primarily for advanced students, it is also a valuable reference work for practising metallurgists, metallographers, and materials engineers. It can be stated quite positively that no previous knowledge of the subject is assumed, and that the practical aspect is stressed, while the theoretical principles are introduced only insofar as they are necessary for an understanding and for successful work. *Günter Petzow* [NB 880 IE]

Recent Chemistry and Biochemistry of Bile Pigments[**]

By Wolfhart Rüdiger[*]

Bile pigments are not merely waste products of the degradation of hemoglobin, but have specific functions in plants and lower animals, in which they occur in the form of chromoproteins (biliproteins). Chromic acid degradation under controlled conditions is particularly suitable for structural investigations. In the case of the phycobilins (bile pigments of red and blue algae), not only have the structures been established, but the linkages with the proteins have also been located.

1. Formation and Occurrence of Bile Pigments in Vertebrates

Hemoglobin *(1)*, the red blood pigment in man and the vertebrates, is continuously being synthesized and degraded [1,2]. Whereas the formerly complexed iron is retained in the organism and re-utilized for the synthesis of the blood pigment, the degradation products of the complexing agent (porphyrin) are excreted. The first isolable degradation product is bilirubin *(2)*, which occurs mainly in the bile and is the principal pigment of this body fluid. *(2)* is therefore referred to as "the bile pigment", and compounds having the same basic skeleton as *(2)*, irrespective of their occurrence, are known as "the bile pigments".

Bilirubin passes with the bile into the intestine, where it is hydrogenated by microorganisms to form urobilinogen *(3)* and stercobilinogen *(4)*. These are the principal excretion products, which partly change in air into urobilin *(5)* and stercobilin *(6)*; some mesobiliviolin *(7)* and mesobiliverdin [= glaucobilin, *(8)*] are also formed from *(3)*.

Bilirubin *(2)* is also present in small quantities (bound to albumin [3]) in the blood serum of healthy individuals. Under pathological conditions (icterus) its concentration here (and in the bile) is increased; it is then excreted in the urine and deposited particularly in elastin-rich tissues. The further transformation products *(3)*, *(4)*, *(5)*, and *(6)* are also formed in increased quantities under pathological conditions. The detection and the determination of bile pigments are therefore of clinical importance [4].

Instead of *(2)*, the bile of birds and of some reptiles contains the blue-green biliverdin *(9)*, which is readily obtainable *in vitro* by dehydrogenation of *(2)*, but is probably the precursor of *(2)* *in vivo* [5–7]. *(9)* is also found in the serum of some fish [8–10].

2. Occurrence of Bile Pigments in Other Organisms

Whereas the bile pigments of the vertebrates can be described as waste products of the degradation of the blood pigment, this description would be incorrect for most other organisms. Bile pigments frequently occur in plants and lower animals that do not contain hemoglobin or other heme or porphyrin components in corresponding amounts. The pigments are often bound

to proteins (biliproteins); some are known to have specific functions (protective coloring in insects, photosynthetic activity in algae, photoregulation of growth and development in higher plants).

Table 1 lists the occurrence of bile pigments (except in bile and serum). It can be seen that biliverdin IXα *(9)* is the most widespread; other bile pigments are found in only a few animals [biliverdin IXγ *(10)*, aplysioviolin *(11a)*] or plants [phycobilins *(11)* and *(12)* and phytochrome chromophore *(13)*]. Data on the occurrence of other pigments described as bile pigments (of unknown structure) are not included (confusion with carotenoids and ommochromes, see [11–13]).

Table 1. Occurrence of bile pigments outside bile and serum.

3. General Methods of Investigation

3.1. Chromic Acid and Chromate Degradation

Pyrrole pigments and some simple pyrrole derivatives, *e.g.* *(14)*, give maleimides on oxidation with chromium trioxide, the substituents in the β positions remaining intact [39].

(14) (15)

The rate of this reaction is pH-dependent [40]. It has been found that bile pigments can be distinguished from other pyrrole compounds (porphyrins, chlorophylls, vitamin B_{12}) by this reaction. This may be illustrated for protoporphyrin [*(1)* without Fe and globin] and biliverdin IXα *(9)*. At the same pH value (in this case pH = 1.7), the extinction of the bile pigment decreases almost 100 times as rapidly as that of the porphyrin ($t_{1/2}$ = 4.5 min and 420 min respectively).

The half lives of these decoloration reactions [40] under the conditions used here are between 0.5 and 20 min for bile pigments; pigments with unsaturated side chains [*e.g. (9)* with its vinyl groups] are decolorized more rapidly than those with saturated side chains [*e.g. (8)* with its ethyl groups]. Porphyrins, chlorins, and corrins are oxidized under the same conditions with half lives ranging from several hours to days.

Degradation with dichromate/hydrogen sulfate (pH ≈ 1.7), referred to below as "chromate degradation", and degradation with chromium trioxide in 2 N H_2SO_4, referred to below as "chromic acid degradation", both have proved suitable for the investigation of bile pigments. The chromic acid degradation is carried out at 20 °C ("non-hydrolytically") or at 100 °C ("hydrolytically").

A given bile pigment gives different degradation products, depending on the conditions used (Scheme 2). Thus the chromate degradation of *(9a)*, the dimethyl ester of *(9)*, yields the pyrroledicarbaldehyde *(18a)* as a new degradation product, together with methylvinylmaleimide *(16)* and hematinimide methyl ester *(17a)*, which is formed in small quantities. *(18a)* is an intermediate in the imide formation. On chromic acid degradation it is converted into the expected imide, *i.e. (17a)* at 20 °C and *(17)* at 100 °C. *(17a)* and *(17)* are also formed directly from the pigment *(9a)*.

Methylvinylmaleimide *(16)* is formed in roughly the same yield under all the conditions mentioned, but is destroyed by chromium trioxide in more strongly acidic media (*e.g.* 6 N H_2SO_4). Since 6—10 N H_2SO_4 had always been used in earlier chromic acid degradations of pyrrole pigments [42–44], *(16)* was not found in these investigations.

Pyrrole-2,5-dicarbaldehydes cannot be derived from the terminal (pyrrolone) rings (I and IV) of the original bile pigment, since they contain *two* of the former bridge C atoms. It has been shown [41] that with pigments of the biliverdin

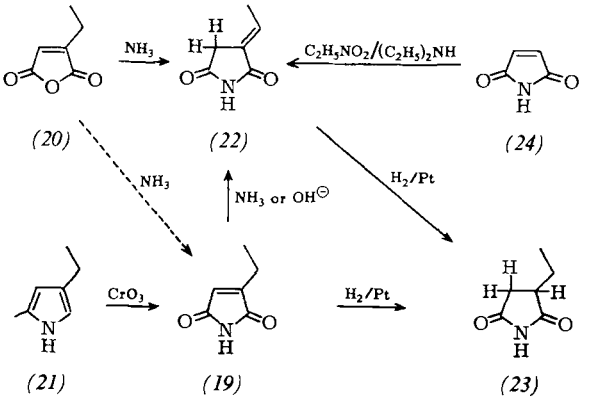
type the dialdehydes are derived from *both* inner rings (II and III), while with pigments of the mesobiliviolin *(7)* type they are derived almost exclusively from ring II.

Thus, by identification of the degradation products in the chromate degradation, it is possible to establish not only the nature but in some circumstances also the sequence of the β substituents of a bile pigment ("sequence analysis").

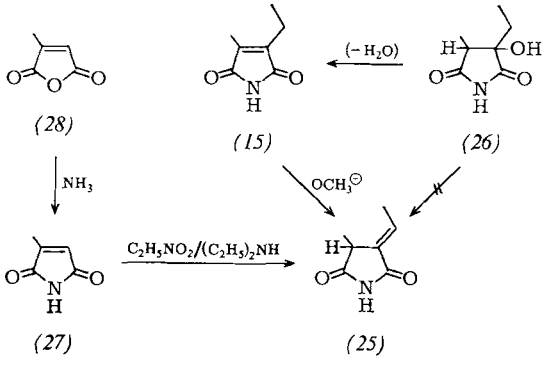
3.2. Separation and Identification

An effective separation method is important not only for the isolation and identification of the degradation products but also for the purification and characterization of the bile pigments. Thin layer chromatography has been found to be suitable, and is superior *e.g.* to column chromatography in the case of the pigments; these two methods are equally good for the degradation products.



The *bile pigments* are best separated from one another in the form of their dimethyl esters. In the standard developer (benzene/petrol/methanol 9 : 5 : 1)[33], the R_f value increases with the number of conjugated pyrrole rings [*e.g. (5)* < *(7)* < *(8)*]; the pigments containing vinyl groups migrate farther than their analogs with ethyl groups. Even very similar pigments (*e.g.* isomeric urobilins and mesobiliverdins[46]) can be separated by multiple development[45]. Finding the positions of the spots presents no problems, owing to their color; they are characterized by their color and the fluorescence colors of the zinc complexes in UV light[33]. Useful mass spectra can be obtained even with small quantities (approx. 0.1 mg) of the pigments isolated by thin layer chromatography[47].

In the standard developer for the *degradation products* (carbon tetrachloride/ethyl acetate/cyclohexane 5 : 3 : 1)[33,48], succinimides do not migrate so far as maleimides and pyrroledicarbaldehydes; the R_f values for all the degradation products increase with the chain length of the β-alkyl substituent. Difficult separations [*e.g. (15)* from *(16)*] can be effected by multiple development[40]. The color reaction of the imides with chlorine/benzidine[40,49] is sensitive, but not specific; it is advantageous to use the mass spectra of the imides isolated by thin layer chromatography for a sure identification[50]. Pyrroledicarbaldehydes can be detected by spraying with 2,4-dinitrophenylhydrazine[40].



3.3. Synthesis of Comparison Substances

Maleimides and succinimides can be obtained by reaction of the anhydrides with ammonia or urea, and have often been prepared as comparison substances for the degradation products of pyrrole pigments[43,44,51].

Conflicting data were found for ethylmaleimide *(19)*. *Anschütz*[52] had obtained a product having m.p. 141 °C from the anhydride *(20)* with ammonia, whereas the product *(19)* obtained by *Fischer et. al*[53] by chromic acid oxidation of 2-methyl-4-ethylpyrrole *(21)* melted at 80 °C. The product obtained by *Fischer*'s method was found to consist solely of *(19)*, whereas the mixture obtained by *Anschütz* consisted mainly of ethylidenesuccinimide *(22)*[48]. *(22)* was prepared independently from maleimide *(24)* and nitroethane[54].

When heated with alkali (*e.g.* even with ammonia), *(19)* is converted smoothly into *(22)*. A corresponding rearrangement also occurs with the methyl homolog *(15)*, but only when methoxide is used [maximum yield of *(25)* = 5%][54].

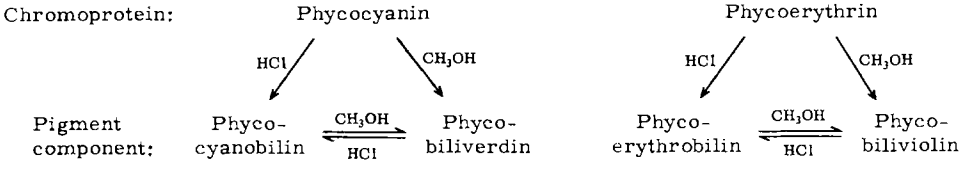
Scheme 4. Routes for the synthesis of 3-ethyl-4-methylpyrrole-2,5-dicarbaldehyde *(29)* and the propionic acid derivative *(29a)*.

Routes for the synthesis of this imide, which is a degradation product of aplysioviolin *(11a)* and of the phycobilins *(11)* and *(12)*, are summarized in Scheme 3 [40,41,55].



3-Ethyl-4-methylpyrrole-2,5-dicarbaldehyde *(29)* was chosen as a comparison substance for the chromate degradation [56]. The synthesis of this compound from cryptopyrrole *(30)* is shown in Scheme 4 [40,54,56,57]. Analogous reactions with propionic acid derivatives are also possible [54].

4. Chromoproteins of Red and Blue Algae

Red algae (Rhodophytae), blue algae (Cyanophytae), and Cryptophytae are distinguished from other algae by their red and blue pigments. Like the chlorophylls, these are light receptors for photosynthesis [58]. The red pigments are known as phycoerythrins and the blue pigments as phycocyanins. Depending on source and properties, we distinguish between R-, B-, C-, and cryptomonad phycoerythrins and R-, C-, allo-, and cryptomonad phycocyanins [59].

Numerous investigations have already been carried out on the structure of these pigments. *Kylin* [60] was able to crystallize the pigments and to confirm the assumed [61] protein nature by cleavage with pepsin; however, neither this author nor *Lemberg* [62] could obtain protein-free, colored groups with pepsin or with acid. *Lemberg* [63] managed to split off the protein-free bile pigment mesobiliverdin *(8)* from the phycoerythrin of red algae, and this was later [64] identified as mesobiliverdin IXα by X-ray investigations; owing to the color change that accompanies this cleavage, however, mesobiliviolin *(7)* has been considered to be the actual prosthetic group.

Two methods that lead to new bile pigments were described some time ago: 1. Cleavage of the phycobiliproteins with concentrated hydrochloric acid at room temperature yields pigments whose spectra agree with those of the denatured chromoproteins, and which are regarded as the native chromophores phycoerythrobilin and phycocyanobilin [65,66]. 2. Treatment with boiling methanol gives similar bile pigments, which were at first [67] thought to be the protein-free biological precursors of the chromoproteins and named "blue pigment" and "purple pigment", but were later [68] shown to be cleavage products of the chromoproteins. These pigments will be referred to as phycobiliviolin and phycobiliverdin. Phycoerythrobilin and

Scheme 5. Isolation and transformation of phycobilins. 12 N HCl, 30 min at 20 °C; CH_3OH, 24 h at 65 °C.

phycobiliviolin are interconvertible, as are phycocyanobilin and phycobiliverdin [68]. The formation of these bile pigments (phycobilins) from the chromoproteins (phycobiliproteins) is shown in Scheme 5.

4.1. Comparison of Phycobiliviolin with Aplysioviolin

Aplysioviolin *(11a)*, the principal pigment of the defensive secretion of sea hares (Aplysia), is presumably derived from phycoerythrin, which these molluscs

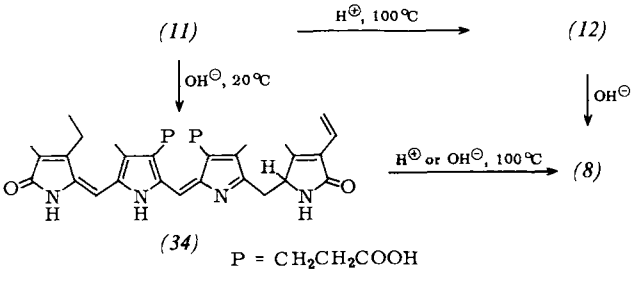
ingest with their food (which includes red algae)[69]. *(11a)* is more readily obtainable than the phycobilins, since it is only loosely bound (presumably by salt-like bonds) to the protein in the secretion, and can thus be obtained free from protein under mild conditions with no secondary changes. Its structure was therefore established at an early stage[33,34]. Aplysioviolin *(11a)* is a monomethyl ester; the phycobilins obtained by methanolysis, on the other hand, are unesterified dicarboxylic acids.

For comparison purposes, all the pigments were converted into the dimethyl esters. The dimethyl esters from phycobiliviolin and aplysioviolin are identical according to their chromatographic behavior (mixed chromatograms in several developers), the electronic spectra of the free bases, the hydrochlorides, and the zinc complexes, and the reactions with alkali and acid[70,71]. The algal pigment is thus the dicarboxylic acid *(11)* whose monomethyl ester is aplysioviolin *(11a)*. This supports the name "phycobiliviolin" introduced here (instead of "purple pigment").

4.2. Chromate and Chromic Acid Degradation of the Phycobilins

Aplysioviolin and phycobiliviolin are decolorized by chromate under standard conditions (cf. Section 3.1) with a half life of 0.5 min; they thus undergo this reaction faster than any other bile pigments[40]. The structural agreement of these two pigments was further confirmed by a comparison of their degradation products. Chromic acid degradation of *(11)* at 20 °C yields methylvinylmaleimide *(16)*, ethylidenemethylsuccinimide *(25)*, and hematinimide *(17)*, while *(11a)* also gives the ester *(17a)*. On chromate degradation, both pigments give the pyrroledicarbaldehyde *(29a)* as well as the imides. These results agree with the structure *(11)* assumed for phycobiliviolin.

Phycoerythrobilin also gives the imides *(16)*, *(17)*, and *(25)* on chromic acid degradation, while chromate degradation also yields the dialdehyde *(29a)*. This means that the substituents in the β positions in this pigment are the same as in phycobiliviolin; since the two pigments are interconvertible, the substituents must occupy the same positions. The differences in the spectra are thus due to differences in the α positions of the pyrrole rings, which have not yet been investigated in detail.



The pigments phycobiliverdin ("blue pigment") and phycocyanobilin obtainable from the phycocyanins give the imides *(15)*, *(17)*, and *(25)* as well as the pyrroledicarbaldehyde *(29a)* on chromic acid or chromate degradation. Thus the side chains in the β positions are again the same in both pigments. Since the first of these pigments ("blue pigment") is most like mesobiliverdin *(8)* in its spectral properties, it will be called phycobiliverdin. The structure *(12)* can be deduced from the degradation results and from the spectral behavior.

The structures *(11)* and *(12)* were proposed for the pigments obtained from the biliproteins with boiling methanol[72] in independent investigations on the basis of the mass and NMR spectra[73–76]. The dicarboxylic acid containing 2 hydrogens more than *(12)* at first supposed to be the native pigment[73] is possibly a product of disproportionation in the mass spectrometer[76].

4.3. Reactions of the Phycobilins with Alkali and Acid

The spectra of all phycobilins (and their chromoproteins) exhibit reversible bathochromic shifts in the alkaline range. The red bile pigments temporarily become blue, and the blue pigments turn colorless to light yellow at first, since the principal absorption band is displaced into the near infrared, and there is no longer a band in the visible region of the spectrum.

This shift can initially be reversed by neutralization of the solution but new pigments are formed (slowly in the cold, rapidly on heating) in alkaline solution. *(11)* first gives a pigment similar to mesobiliviolin, which has the structure *(34)* according to the results of the chromic acid degradation. It is converted by prolonged action of alkali into mesobiliverdin *(8)*, which is formed directly from *(12)*. Since the mesobiliverdin obtained by alkaline hydrolysis of the red chromoprotein had already been identified as the IXα isomer[64], it follows that all phycobilins have the IXα structure.

When *(11)* is heated with dilute hydrochloric acid, the principal product is *(12)*. In concentrated hydrochloric acid, on the other hand, the reaction leading to phycoerythrobilin[68] and further to a urobilin[77]

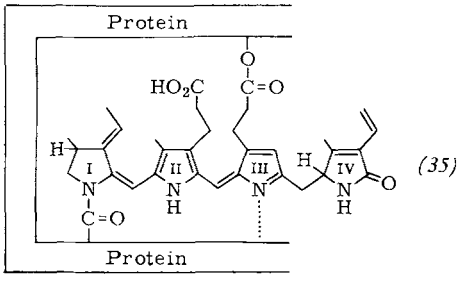
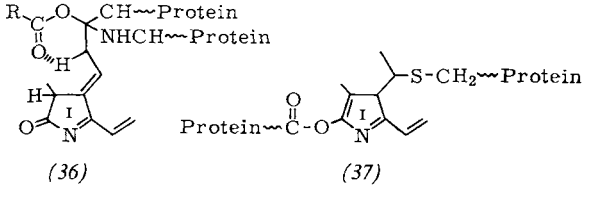
predominates. In contrast to the alkali reaction the ethylidene group is retained in all these reactions. The acid causes a prototropic rearrangement in which a vinyl group is converted into an ethyl group, with simultaneous conversion of a methylene bridge into a methine bridge. Rearrangements of this type are known in other bile pigments [78,79].

4.4. Linkage of the Phycobilins to the Protein



The chromic acid degradation of the native chromoproteins gives different results, depending on the conditions. This may be illustrated for C-phycocyanin. At 100 °C (hydrolytic degradation), the initially precipitated protein is hydrolyzed to peptides, which pass into solution; the same imides [*(15)*, *(17)*, and *(25)*] are obtained from the solution as from the free phycobilin *(12)*. If, on the other hand, the chromoprotein is degraded at 20 °C (non-hydrolytically), the protein precipitate remains intact; though the same quantity of *(15)* can be extracted from the suspension as on hydrolytic degradation, only half as much *(17)* is obtained, and no *(25)*. The missing imides [*(25)* and the second half of *(17)*] can be liberated by hydrolysis (without further oxidizing agent) from the separated and washed protein precipitate.

The same result is obtained with R-phycocyanin and in principle with R- and C-phycoerythrin, as well as with the chromopeptides obtainable from C-phycoerythrin with pancreatin, except that the red pigments give *(16)* instead of *(15)*.



According to these degradation experiments, only two of the four pyrrole nuclei of the phycobilins are free in the native chromoprotein, whereas the other two must be covalently linked to the protein. It is not yet known which functional group of the protein is involved in this linkage. In any case, the terminal ring I [which yields the imide *(25)*] and one of the inner rings [from which *(17)* is formed] must be bound, while the terminal ring IV [which gives *(15)* or *(16)*] and the other inner ring are free. Which of the inner rings is free and which is bound has been established for phycoerythrin. The pyrroledicarbaldehyde *(29a)* is liberated on chromate degradation at 20 °C, while the imide *(17)* is liberated only on hydrolysis of the protein precipitate. Since the pyrroledicarbaldehyde is formed from ring II in bile pigments of the biliviolin type (cf. Section 3.1), this ring must be free, while the ring III, which yields the imide, is bound.

The pyrrole nitrogen of ring III is probably masked by a hydrogen bond in the native chromoprotein, this hydrogen bond being broken on denaturation. For example, the nitrogen atom is accessible for the formation of a zinc complex in the denatured chromoprotein, but not in the native substance [66,80]. The nitrogen cannot be involved in the covalent bonding of ring III; linkage *via* the propionic acid side chain is most likely, and is certainly not an amide linkage, as was formerly [81] assumed, but presumably an ester linkage (but one that is relatively stable to alkali) [65,66]. We have shown the probable existence of an *N*-acyl linkage (*e.g.* aspartoyl or glutamoyl) between ring I and the protein [71]; this gives *(35)* as a partial formula of the biliprotein phycoerythrin.

Possibilities discussed for the linkage between ring I and the protein in C-phycocyanin are *(36)* [76] and *(37)* [82], in which the ethylidene group is not present as such in the chromoprotein, but is formed only when the phycobilin is split off. A decision between these (and other) possibilities will probably become possible only after the amino acid sequence of the phycobiliproteins has been established.

(35)

(36) *(37)*

5. Further Results and Possibilities

Of the other results obtained by the methods described here (cf. Table 1), mention should be made of the discovery of biliverdin IXγ *(10)* [31], the first natural bile pigment that does not belong to the IXα series. In the investigation of its biosynthesis [83], as in the classic studies on the biosynthesis of porphyrin [43,84], the specific incorporation of radioactively labeled glycine into the pigment was detected by a definite degradation (in this case chromate degradation). Attention should also be drawn to the cases in which bile pigments are linked *covalently* to the protein. This has been so far found only for Crenilabrus blue in the animal kingdom [22,23] and for the phycobiliproteins and the gene regulator phytochrome in the plant kingdom [37,38].

Chromic acid degradation has played an important part in the elucidation of the structures of numerous

pyrrole pigments [85]. Rapid progress may be expected in the investigation of new members of this class of compounds by the establishment of optimum degradation conditions for each type of pigment, operation on the micro scale, and combination of sensitive separation methods with modern analytical aids.

[85] A brief review of the most important works is given in [40].

My own investigations on the phycobilins were mainly carried out in collaboration with Dr. P. Ó Carra, Department of Biochemistry, University College, Galway (Eire). I am grateful to Professor C. Ó hEocha for his cooperation. Thanks are due to the Deutsche Forschungsgemeinschaft for generous support.

Interferons

By Y. K. S. Murthy and Hans-Peter Anders [*]

Interferons are proteins which bring about a nonspecific and nonimmunological defence reaction against virus infections in vertebrates. Interferon formation is induced in vivo and in vitro by viruses and other agents, e.g. endotoxins, nucleic acids, synthetic anionic copolymers, and phytohemagglutinins. All attempts to produce pure interferons have so far been unsuccessful. Interferons can only exert an antiviral action when the cellular RNA and protein synthesis is intact.

1. Introduction

It has long been known that the formation of antibodies is not the only defence an organism has to protect itself against a virus infection. One of these nonimmunological defences is "viral interference", *i.e.* the adverse effect that various viruses can produce on the multiplication of another virus when the two are present in the same host.

In 1937 *Findlay* and *MacCallum* [1] showed that treatment with Rift Valley fever virus protected monkeys against subsequent challenge with the immunologically unrelated yellow fever virus. Shortly after infection of rabbit skin with vaccinia virus, *Ørskov* and *Andersen* [2] observed the appearance of a "local" antibody, although no antibodies could yet be demonstrated in the serum. In 1962 the authors discussed this observation as a possible interferon effect. *Lenette* and *Koprowski* [3] were able to demonstrate a slight antiviral effect in infected chick- and mouse-embryo cultures even after the viruses had been removed. *Matumoto et al.* [4] showed that mice that had been infected with a neurotropic Rift Valley fever virus were protected against a virulent pantropic variant of the same virus. (For reviews of viral interference see [5–7].)

In 1957 *Isaacs* and *Lindenmann* [8] succeeded in clearly differentiating the principle of viral interference from that of specific immunity. These authors treated the chorioallantoic membrane of chick embryos with inactivated influenza virus incapable of multiplication. After three hours at 37 °C pieces of membrane with adsorbed virus were added to a buffer solution and incubated for 24 hours. After removal of the tissue a substance having an antiviral action was found in the buffer solution, which the authors called "interferon" Subsequently, it has been found that interferons or similar substances are formed in the cells of many vertebrates in response to viral infection.

The effect of these interferons also extends to Bedsonia organisms, bacteria, protozoa, and some oncogenic viruses, *e.g.* leukemia viruses [9, 10]. Today it is generally accepted that interferons play an essential role in the formation of a host's nonspecific resistance to superinfection with a second virus. It is difficult to decide whether the effects of viral interference described before the discovery of interferons were due to interferon action or to other causes, but it is certain that

there are other kinds of viral interference in addition to the interferon system [11–14]. (For the current position in interferon research see also [15–20].)

2. Biological Properties

One of the most interesting properties of interferons is the nonspecificity of their antiviral action. Interferon makes the host cell resistant to both RNA and DNA viruses, including some oncogenic viruses. In addition, its range of action also extends to bacteria, Bedsonia organisms, and protozoa. There are, however, considerable differences in the sensitivity of virus strains to interferon. *Ruiz-Gomez* and *Isaacs* [21] were able to show that 30 times the amount of interferon was necessary in chick embryo fibroblast cultures to inhibit Newcastle disease virus (NDV) [**] to the same degree as O'nyong-nyong virus. Other authors have also described differences in the sensitivity of viruses to interferons [22–24]. Such differences apparently also depend on the type of the host cell. Two strains of vesicular stomatitis virus (VSV), which are inhibited to different degrees in L cells (a stable mouse fibroblast cell line), show the same sensitivity in chick embryo cells [25].

It is very difficult to summarize the sensitivity of viruses to interferons, partly because of the contradictory results. The arbor viruses are among the most sensitive, whereas Newcastle disease, herpes, adeno, and Aujeszky's disease viruses appear to be relatively resistant. VSV has a moderate sensitivity. Most of the findings indicate that interferon sensitivity and the ability to induce interferon formation go in parallel. An interesting suggestion is that the virulence of viruses is closely connected with their interferon sensitivity and their ability to induce interferon formation [26, 27]. The interferon system is less effective against virulent than against nonvirulent strains.

Another important biological characteristic of interferons is shown by the observation that the inhibitory effect is much clearer if the cells used in the test come from homologous animal species. This "species specificity" was first observed by *Tyrell* [28] with interferon from calf and chick fibroblasts. Similar findings were made when chick and rabbit cells [29] or chick and duck cells were used [7, 30]. In all these cases the interferon had a weaker effect in heterologous tissue. Frequently no activity at all can be determined in such tissues. This "species specificity" of the antiviral effect – whether absolute or partial – is regarded as an important characteristic of the interferon system.

Recently, however, the general validity of this "species specificity" has been questioned. *Bucknall* [31] found that the interferon of *Macaca* monkeys exerted an antiviral activity in the cells of two other genera (*Cercopithecus* and *Erythrocebus*). Thus, this interferon not only did not show any "species specificity" but also no genus specificity. *Merigan* [32] observed a cross-reaction between human and rabbit interferons in cell cultures. *Bucknall* proposed that in future the "species specificity" of the antiviral effect should no longer be regarded as a typical interferon property.

The present account of important studies on interferon would be incomplete without any mention of the antigenicity of this substance. As interferons are proteins (see Section 4), attempts have been made to immunize animals with them, but the first experiments were unsuccessful [33–35].

Paucker et al. [36, 37] were the first to obtain an interferon antiserum. For this purpose guinea pigs and rabbits were injected intraperitoneally with highly purified interferon samples obtained from NDV-treated L cells. The treatment was repeated several times. An antiserum that inactivated up to 99 % of the interferon from L cells was thus obtained. Antibodies to mouse and chick interferon only neutralized the activity of the homologous preparations. The two interferons thus differed in their antigenic properties. *Paucker* considered it probable that all the earlier attempts to obtain an antiserum failed because too little interferon was given; interferon is obviously a substance with an extremely high biological activity, *i.e.* only relatively few interferon molecules are present

even in the highly active purified preparations (see Section 4).

An interesting and so far little-studied property of the interferon system is the occurrence of the refractory phase. *Cantell* and *Paucker* [38] established that the production of interferon ceased 24 hours after the treatment of L cells with inactivated NDV. No renewal of interferon production could be demonstrated after further treatment with NDV. *Ho* and *Kono* [39] and *Youngner* and *Stinebring* [40] made similar observations in experiments carried out *in vivo*. Rabbits were treated with Sindbis virus or endotoxin from *E. coli*, a very potent interferon inducer. When the treatment was repeated 24 hours later, no renewal of interferon production could be detected. In the serum of tolerant animals, *Ho et al.* [41] found a humoral factor which inactivated the interferon-inducing capacity of endotoxin.

3. Methods of Determining Interferons

All methods used to determine interferons are based on the fact that interferons inhibit virus multiplication. Of extreme importance in judging the results are the experimental conditions, such as the type of the host cell, the time of preincubation with interferon, the type and amount of the test virus, and the experimental temperature.

3.1. Reduction of Virus Hemagglutinin Titers

Many viruses, including influenza virus, can form hemagglutinins. The amount of hemagglutinin that can be measured is proportional to the quantity of the virus. Chorioallantoic membranes from chick embryos are incubated in an interferon-containing medium and are then infected with influenza virus. The decrease in the hemagglutinin titer parallels that in the interferon titer [8].

3.2. Decrease in Hemadsorption (Quantitative Hemadsorption Method)

The phenomenon of hemadsorption is based on the fact that many virus-infected cells can adsorb erythrocytes. The cells are incubated with the interferon preparation and infected, and erythrocytes are then added. After removing the unadsorbed erythrocytes, the adsorbed erythrocytes are lyzed; the hemoglobin released is measured spectrophotometrically. The method is simple and gives reliable results [42].

3.3. The Plaque Inhibition Method

The cells are incubated with the interferon sample and then infected with a definite amount of a plaque-forming virus. After adsorption of the virus the cells are covered with a layer of agar. The interferon titer is given as the reciprocal of the greatest dilution of the interferon sample that reduces the plaque count by 50 % compared with controls [43]. At the same time this shows that the interferon neither prevents virus adsorption nor inactivates extracellular viruses.

3.4. Indicator Test

Normal cells excrete acids into the incubation medium. Phenol red, a constituent of most cell culture media, thus changes to a yellow color. Infected cells do not excrete enough acid to produce a change in color, while interferon-treated cells behave in the same way as non-infected ones, *i.e.* the medium becomes yellow. *Paucker* [37] used this effect to develop a very reliable and sensitive method for the determination of interferons.

3.5. Reduction of the Cytopathic Effect

In certain tissues the multiplication of viruses leads to microscopically detectable cytopathic effects. The inhibition of these effects by pretreatment of the tissue with interferon preparations is also used for interferon determination.

3.6. Prevention of Incorporation of [^{14}C]-Thymidine into Virus DNA

Bodo [44] has described a biochemical method for the determination of interferons in which the decrease in the incorporation of [^{14}C]-thymidine into the acid-insoluble DNA fraction is taken as a measure of the amount of interferon (the cellular DNA was broken down with DNase in the presence of Triton X-100).

4. The Chemical and Physicochemical Properties of Interferons

Isaacs and *Lindenmann* [8] describe interferons as substances that are not dialyzable, not sedimented at 100000 × g, partly inactivated by trypsin, precipitated with a saturated ammonium sulfate solution, and not undergoing any loss of activity with DNase. They conclude from this that interferons or at least their essential components must consist of protein. Other research workers have confirmed this hypothesis [45]. Today, it is generally accepted that the operative part

of an interferon consists of protein with a small carbohydrate component. It is considered certain that it does not contain any RNA or DNA.

The well-known methods of protein chemistry have been used in experiments to isolate interferons. It must be recalled that the only way of demonstrating an interferon is by biological tests – a fact that makes isolation very difficult. Two of the best-known methods of purification are briefly described in the following paragraphs.

Lampson et al.[46] purified interferon in the following way from hen's eggs infected with influenza A virus:

1. The virus and inactive protein were precipitated with 0.15 N $HClO_4$.

2. The interferon was precipitated at pH 6 with zinc acetate. After centrifuging, the sediment was dissolved in 0.2 N HCl, dialyzed against 0.9% NaCl solution, and re-precipitated with zinc acetate.

3. The precipitate was dissolved in 0.01 M phosphate buffer (pH 6), chromatographed on a carboxymethylcellulose column, and eluted using a 0.01 M phosphate buffer (pH 8) with 0.1 M NaCl.

4. The biologically active fractions were again treated with zinc acetate.

5. This was followed by another chromatographic separation on carboxymethylcellulose, and

6. precipitation with zinc acetate.

7. The operation was finished by zone electrophoresis at pH 8.9 on Pevikon.

The specific activity of the interferon purified in this way was 236000 units/mg protein[47].

A product with a still higher specific activity (1.6×10^6 units/mg protein) was obtained by *Fantes et al.*[48,49] using the following procedure:

1. Adsorption of interferon at pH 5 on Doucil (a synthetic sodium aluminum silicate) and elution at pH 7.5 with potassium thiocyanate.

2. Precipitation of the inactive protein at pH 2.

3. Precipitation of further inert protein with 5 volumes of methyl alcohol.

4. Precipitation of interferon by neutralization of the solution.

5. Precipitation of interferon in 0.01 M phosphate buffer (pH 7.5) and filtration through DEAE cellulose.

6. Chromatography of the filtrate at pH 5.9 on a carboxymethyl-Sephadex column. The interferon-containing fraction was eluted with an increasing pH gradient.

20000-fold concentration was obtained with this method of purification. The overall recovery of the activity was 7%.

The use of polyacrylamide gel electrophoresis resulted in a substantial advance in the field of interferon purification. On the one hand this showed that all the highly purified products still contain many impurities, and on the other hand that interferon itself is not homogeneous[45,50,51]. In polyacrylamide gel electrophoresis the biological activity of a highly purified product is distributed over a broad zone. The biologically active constituents of the interferon preparation of *Fantes et al.*[52] differed both in molecular weight and in isoelectric point. Other authors too have concluded that there may be no "interferon" as such; instead, there are probably several substances with interferon-like properties which appear simultaneously in the same animal in response to the same stimulus[53,54]. Thus, it seems to be certain that different types of cell from the same organism form different interferons[55,56]. Their molecular weight was between 13000 and 160000[17].

There is as yet no explanation for these facts. So far it is not clear whether these substances are preliminary stages of interferon formation, interferon produced by different cells, interferon with different carrier proteins, or something quite different.

Since the only possible conclusion is that none of the biologically active substances so far isolated and investigated was a pure interferon, it seems advisable to treat with reservation some of the values and properties so far determined *e.g.* the amino-acid composition.

On the other hand, certain characteristics can be accepted as generally valid. In all cases the interferons were neutral or weakly basic proteins or protein-containing compounds. Their stability over a wide pH-range is particularly worth mentioning. *Lampson et al.*[57] observed that highly purified chick interferon was stable at 23 °C for over an hour in the pH range 1–10. These results have been confirmed several times. Today the stability at pH 2 is regarded as an important characteristic of all interferons. Most interferons are relatively heat resistant. *Lampson et al.* found that purified chick interferon remained fully active for one hour at 66 °C. Some inactivation only occurred after heating at 76 °C for one hour. The biological activity of interferon is destroyed by proteolytic enzymes such as trypsin, chymotrypsin, and pepsin, but not by DNase, RNase, lipase, peptidase, and α-amylase.

It has already been mentioned that the general current opinion is that interferon or at least its active part consists of protein. A Japanese research team[58,59] has described an interferon-like compound, which was isolated from rabbit skin infected with vaccinia virus. This compound was reported to be a protein-free polysaccharide (molecular weight 10000), which

was only active *in vivo* and had no "species specificity". Whether this substance is the active part of interferon, which is combined with a species-specific protein in the animal body and thus forms a "normal" interferon molecule, or whether it is an interferon-inducing compound, has not so far been elucidated.

5. Mode of Action of Interferon

Isaacs et al.[60,61] observed an increased rate of glycolysis in interferon-treated cells. In addition, it was found that there was a decline in the direct oxidation of glucose *via* the pentose phosphate cycle and that less inorganic phosphate was incorporated. As the same metabolic changes are produced by chemical uncoupling of oxidative phosphorylation, *Isaacs et al.* came to the conclusion that interferon likewise acts as an agent of uncoupling oxidative phosphorylation and that this uncoupling occurs not in the mitochondria but in the cell nucleus. However, *Lampson et al.*[62] were able to show later that the described effects failed to appear when the experiments were carried out with highly purified interferon preparations. It now appears certain that the uncoupling of oxidative phosphorylation and other effects on the uninfected cells were produced by impurities[63].

The following processes must occur before a virus can multiply within a host cell: Adsorption of the virus onto the cell surface; penetration of the cell; and liberation of the viral nucleic acids by removal of the protein coat.

Interferon has no effect on the adsorption of viruses[64,65]. From the fact that the multiplication of infectious RNA isolated from viruses is inhibited by interferon, it was concluded that interferon has no effect on the penetration of intact virus or the liberation of viral nucleic acids[66,67].

This conclusion does not seem to be absolutely correct, at least for certain DNA viruses, as the recent findings of *Magee et al.*[68] indicate that interferon probably inhibits the uncoating process in vaccinia virus. Since it is known that the uncoating enzymes of some DNA viruses are virus proteins[69], this effect can be attributed to an inhibition of virus-specific protein synthesis. It has also been possible to exclude a direct inactivating action of interferon on the complete virus particle[70,71] as well as on viral RNA[72]. From this it can be concluded that the action of interferon must be based on an inhibition of the synthesis of virus-specific proteins or viral nucleic acids.

RNA viruses multiply in the following way:

1. The "early" cistrons of the parental RNA molecule (plus strand) encode directly as m-RNA for the synthesis of "early" enzymes such as the RNA-dependent polymerase.
2. Through the RNA-dependent RNA polymerase is formed the "replicative" form of the virus, *i.e.* a second RNA strand (minus strand) is synthesized on the parental plus strand which then acts again as a matrix for the synthesis of plus strands.
3. Translation of the "late" cistrons and thus synthesis of the viral coat protein.
4. Combination of viral RNA (plus strand) with coat protein to form the intact virus.

The synthesis of viral RNA is inhibited in interferon-treated cells[73–75]. This means that either the synthesis or the activity of RNA-dependent RNA polymerase is interrupted by interferon. *Sonnabend, Martin*, and *Mécs*[75] have shown that interferon has no effect on the activity of the RNA-polymerase of Semliki Forest virus (SFV) in a cell-free system.

Miner, Ray, and *Simon*[76] studied the effect exerted by a homogenate of interferon-treated L cells on Mengo virus RNA polymerase, and established that the activity of the polymerase was not decreased. The same authors, however, found that pretreatment of L cells with interferon clearly decreased their content of virus-specific RNA polymerase after a Mengo virus infection. *Sonnabend et al.* also demonstrated a decrease in the extractable amount of SFV RNA polymerase when they pretreated L cells with interferon. This means it is not the action but the synthesis of viral RNA polymerase that is inhibited.

Marcus and *Salb*[77] were able to show that although Sindbis virus RNA and the ribosomes of interferon-treated chick embryo cells form a polysome complex, no amino acids are incorporated. The action of interferon on the multiplication of RNA viruses thus obviously consists in an inhibition of the translation of virus-specific m-RNA, and consequently in inhibition of the synthesis of virus proteins.

The multiplication of DNA viruses take place according to the following series of events:

1. "Early" transcription of the viral DNA molecule with the formation of "early" viral m-RNA.
2. Translation of the "early" m-RNA into "early" proteins.

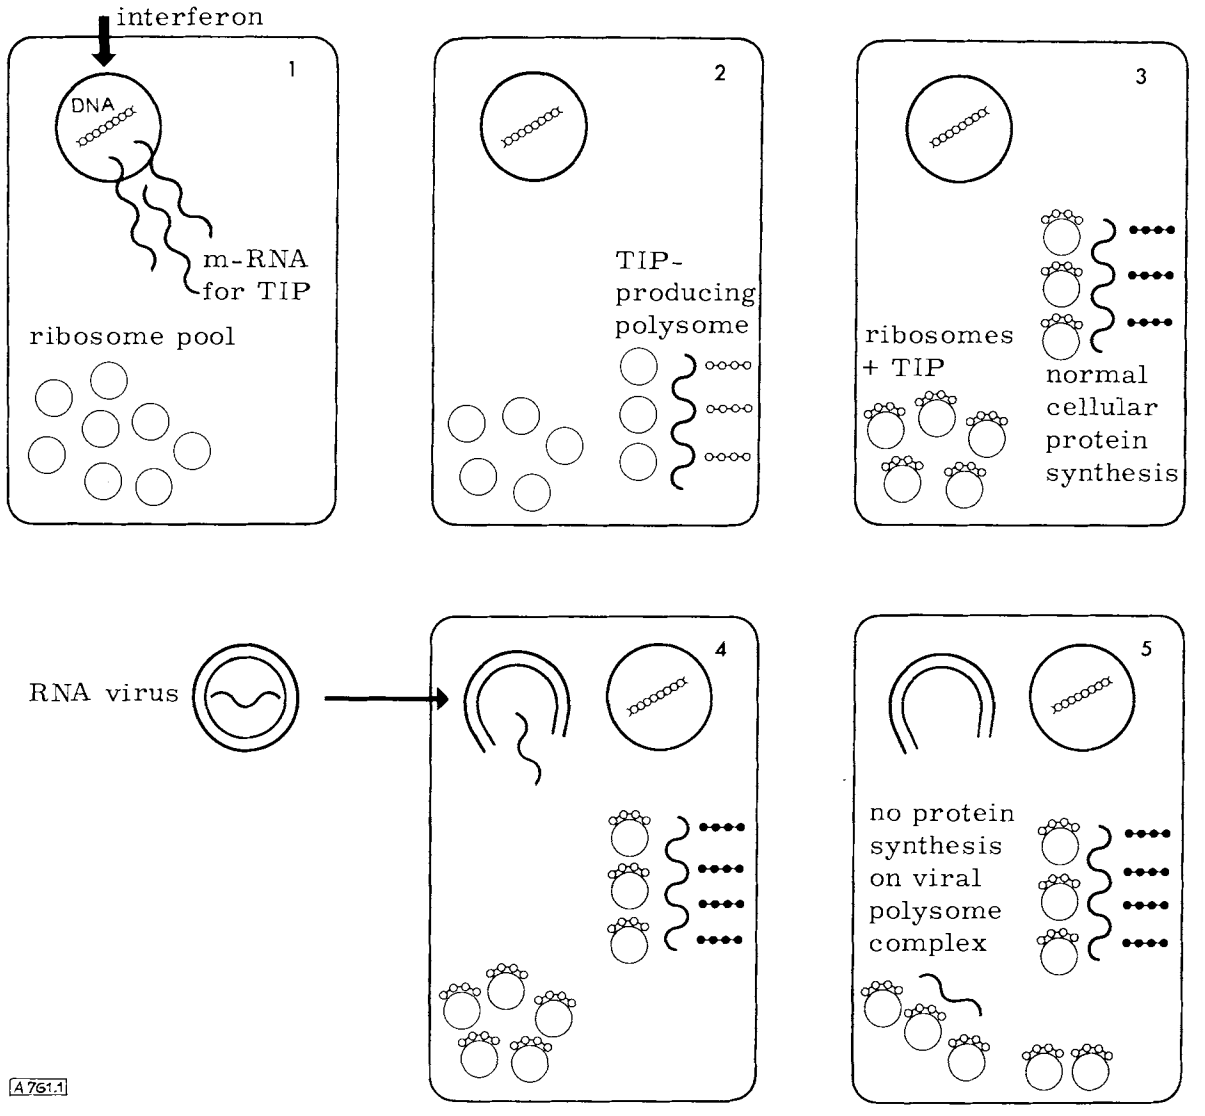

Figure 1. Mode of action of interferon according to *Marcus* and *Salb* [77] and *Hilleman* [19].

1. Interferon penetrates the uninfected cell and induces the synthesis of m-RNA for TIP. 2. With the help of this m-RNA the cell synthesizes TIP 3. TIP interacts with the ribosomes, but does not effect the cellular protein synthesis. 4. A virus penetrates the cell. 5. Although the viral RNA comes in contact with the TIP ribosome complex, no viral protein is synthesized.

3. Synthesis of viral DNA.

4. Formation of "late" m-RNA.

5. Translation of the "late" m-RNA into the viral coat proteins.

6. Combination of viral DNA and coat protein to form intact virus (maturation).

In several systems it has been possible to show that the synthesis of viral DNA is inhibited in interferon-treated cells [78,79].

Joklik and *Merigan* [80] showed that the synthesis of viral m-RNA is not affected by interferon in the L cells/vaccinia virus system. The virus infection produced a disintegration of the host's polyribosomes, which was followed by a formation of virus-specific polyribosomes with viral m-RNA. In the presence of interferon the formation of these polyribosomes fails to occur, with the result that no virus-specific proteins —and thus no DNA polymerase – are synthesized.

Looking for common factors in the inhibitory action of interferon on the multiplication of RNA and DNA viruses, it can be established that in both cases it is the "early" translation of virus-specific message, *i.e.* the formation of "early" virus-specific proteins, that is inhibited. Whether the inhibition is based on the prevention of reading of the m-RNA in the polyribosome, or whether the formation of the polyribosomes is suppressed, has not been finally resolved. It is even possible that both effects can occur. The problem of the site of action of interferon seems to be solved, but the mode of action at the molecular level remains an open question.

Taylor [81] established that actinomycin C, which is known to inhibit cellular DNA-dependent RNA synthesis, prevents the antiviral action of interferon. A similar effect is produced by many inhibitors of protein biosynthesis such as puromycin [82,83] and *p*-

fluorophenylalanine [84]. The cellular RNA and protein synthesis must therefore be intact for the development of the antiviral action of interferon. It was concluded that interferon induces the formation of a second protein, which is the substance with the true antiviral effect ["antiviral protein", "translation inhibitory protein (TIP)"] [77,85].

Using the model proposed by *Jacob* and *Monod* to explain these processes, the development of the antiviral effect of interferon can be supposed to proceed largely in accord with Figure 1. There has been no lack of attempts to provide direct experimental proof of the existence of TIP. Using a double labeling method, *Vilcek et al.* [86,87] were able to demonstrate that the ribosomal protein fraction of interferon-treated cells showed a different distribution of activity in polyacrylamide electrophoresis from that of normal cells. The authors found one completely new band and an increased amino-acid incorporation in two other protein bands. The identification of one or more of these proteins as TIP has still not yet been accomplished.

Marcus and *Salb* [88] allowed trypsin to react under mild conditions with the ribosomes of interferon-treated cells. At 0 °C the ribosomes could form a polysome complex with Sindbis virus RNA, which rapidly disintegrated again and took up amino acids at 37 °C. *Marcus* and *Salb* regarded this as an indication of normal translation, since the corresponding complex with interferon-treated nontrypsinized ribosomes was not broken down and did not take up any amino acids.

Surprisingly, *Dianzani*, *Buckler*, and *Baron* [89] found that cycloheximide – another inhibitor of protein biosynthesis – did not neutralize the antiviral action of interferon. The authors considered that it was possible that the m-RNA for TIP is formed in the presence of the inhibitor and remains relatively stable, and that the period after removal of the cycloheximide and before addition of the virus is sufficient for enough TIP to be formed with this m-RNA.

Summing up, it may be said that there is yet no definite proof of the existence of one or more antiviral proteins whose synthesis is induced by interferon, but that the majority of the experimental findings supports this hypothesis. It should also be added that, if this theory is confirmed, the formation of m-RNA and the synthesis of TIP would be the only effects of interferon on normal, *i.e.* uninfected cells.

6. Interferon Inducers

As already mentioned, both intact and inactivated viruses, *i.e.* viruses not capable of multiplying, can induce the formation of interferon. This ability to induce interferon formation is apparently a feature of all viruses, no matter to what class they belong. It has been known for some years that other agents besides viruses can stimulate interferon formation. Such agents include bacteria, rickettsiae, phytohemagglutinins, Toxoplasma, Mycoplasma, protozoa, cycloheximide, as well as some anionic copolymers and nucleic acids.

6.1. Bacteria and Bacterial Endotoxins

Even before the discovery of interferon it was recognized that bacteria have an inhibitory effect on the growth of some viruses. In 1938 *Armstrong* [90] observed that certain myxovirus infections of mice are prevented by bacteria. *Horsfall* and *McCarty* [91] established that the multiplication of viruses in the lungs of mice infected with pneumonia virus was decreased 10–100 fold if the animals were also treated with a nonhemolytic Streptococcus MG′ strain.

Youngner and *Stinebring* [92] were the first to show that bacteria can act as interferon-inducers. These authors infected hens with a virulent strain of *Brucella abortus* and found an antiviral activity in the birds' serum. The substance responsible for this showed the same physicochemical and biological properties as interferon. They also found an interferon-like substance after treating mice with purified *E. coli* endotoxin [93]. Thus bacterial multiplication is not a prerequisite for the induction of interferon. Similar results were obtained by *Ho* [94] with an endotoxin which he administered to rabbits. *Hopps et al.* [95] were also able to isolate an interferon-like substance from chick embryo cells inoculated with *Rickettsia tsutsugamuchi*. There are indications that endotoxin treatment does not induce the synthesis of interferon but only the release of preformed molecules. Endotoxin-induced interferon appears earlier in the serum of treated rabbits than virus-induced interferon, and, in addition, its formation is not inhibited by actinomycin D [96].

6.2. Phytohemagglutinin

Phytohemagglutinin is a substance contained in an extract of *Phaseolus vulgaris*. *Wheelock* [97] established that this plant product has an antiviral effect in human

leukocytes; the cytopathic effect of Sindbis virus was also decreased. Like interferon, the antiviral substance can be neither dialyzed nor sedimented.

6.3. Synthetic Anionic Copolymers

In 1966 *Regelson*[98] found that copolymers of maleic anhydride and divinyl ether (molecular weight 17000–450000) develop an antiviral activity after intraperitoneal administration to mice, and this appears in the serum 24 hours after the injection.

Merigan[99] was able to show that this antiviral substance had all the known properties of interferon. The same agent also inhibited virus-induced leukemia in mice, and in clinical trials it inhibited neoplasm formation in man[100]. An interferon-inducing effect could also be demonstrated with copolymers of maleic anhydride and vinyl methyl ether or vinyl acetate[101]. The corresponding styrene compounds were not such good inducers and were more toxic.

Some of these copolymers have been tested clinically. A maleic anhydride/divinyl ether copolymer with a molecular weight 17000 was tested in the USA as an antitumor drug. A definite disadvantage of this compound is that it is not broken down in the body but is stored in the reticulo-endothelial system[102]. So far there has been no success in inducing interferon formation *in vitro*. The exact mode of action of these polymers is not known. It has been argued that the antiviral action is based not only on the formation of interferon but also on a direct interaction with the cell due to the polyanionic structure of the molecule.

6.4. Nucleic Acids

In 1961 *Isaacs*[103] put forward the theory that the formation of interferon is a reaction of the cell to a "foreign" nucleic acid, in the same way that antibodies are formed by recognizing differences between foreign and the body's own proteins.

Rotem et al.[104] established that mouse liver RNA inhibits the growth of pox viruses in chicken cell cultures, exactly in the same way as chicken RNA inhibits it in mouse cell cultures. A much smaller inhibition occurred with the homologous RNA. *Isaacs*[105] continued these investigations and established that nucleic acids did not induce interferon formation in the homologous cells. The RNA could do this, however, after treatment with nitrous acid. *Isaacs* concluded that the RNA was so changed by deamination that it was taken for a foreign nucleic acid by the cells. Although some later findings supported this concept[106–108], *Isaacs*' theory did not find general recognition. In 1965 *Isaacs*[109] reported that he himself had also obtained "different results" in further studies.

The theory that the foreign nucleic acids induced interferon formation received further experimental support from *Hilleman*'s group. For some years this team had sought a potent interferon inducer that would be suitable for clinical use. *Hilleman* reported attempts to fractionate viruses into their constituent parts and to examine the individual fractions for their capacity to induce interferon formation[110]. These experiments were unsuccessful.

Braun and *Nakano* reported[111,112] that they had succeeded in stimulating antibody synthesis with some synthetic oligonucleotides. This prompted *Hilleman*'s group to test the interferon-inducing capacity of synthetic polynucleotides. These investigations were crowned with success: a few μg of a double-stranded complex of polyriboinosinic acid and polyribocytidylic acid (poly-I:C) induced interferon formation in mice[113]. This interferon protected the animals against a lethal dose of Columbia SK virus. A double-stranded complex of polyriboadenylic acid and polyribouridylic acid (poly-A:U) and a mixture of polyinosinic acid and cytidylcytidine (I + CpC) were also active, but to a lesser degree. No activity, however, was shown by single-stranded polynucleotides, and by some oligonucleotides, dinucleotides, nucleotides, and nucleosides. Interferon formation could also be demonstrated *in vitro* with poly-I:C.

These findings led to a search for other kinds of double-stranded RNA. *Hilleman* and his associates succeeded in isolating such a double-stranded RNA from helenine (an antiviral substance produced by *Penicillium funiculosum*)[114]. *Rytel*[115] was able to show that helenine can induce interferon formation *in vivo* and *in vitro*. The double-stranded RNA from helenine was also an excellent interferon inducer[116].

Subsequently it was established that the antiviral principle of statolon, an extract of *Penicillium staloniferum* is likewise a double-stranded ribonucleic

acid [117]. Another source of naturally occurring RNA is the replicative form of RNA viruses. The replicative form of the MS2 bacteriophage was isolated and shown to be an interferon inducer even in very small amounts [118]. A similar result was obtained with purified reovirus RNA [119]. Reovirus is one of the few viruses whose nucleic acid core consists of double-stranded RNA.

It is interesting to note that the ability of poly-I:C to induce interferon formation can be increased about 100-fold by the addition of DEAE-dextran [120]. This raises the question why double-stranded ribonucleic acids are some of the most powerful interferon inducers. The possibility of these nucleic acids conveying genetic information can be ruled out, since double-stranded homopolynucleotides such as poly-I:C cannot do this.

Two explanations have been suggested. *Hilleman* believes that the appearance of the double-stranded replicative form, one of the first steps in the multiplication of RNA viruses, is normally the starting signal for interferon synthesis. When double-stranded RNA is supplied, the cell reacts as if virus multiplication were occurring, and interferon synthesis begins. The weak point in this theory is that RNA viruses incapable of multiplication and also DNA viruses are good interferon inducers, although, according to present knowledge, there is no double-stranded RNA in either of these cases.

The surprising finding reported by *Colby* and *Duesberg* [121] is of special interest in this connection. These authors observed that chick embryo cells infected with vaccinia virus (a DNA virus) contained 10 times as much double-stranded RNA as did noninfected cells. According to the concepts generally accepted today concerning DNA virus multiplication, there is as yet no evidence of the presence of double-stranded RNA after vaccinia virus infection. Likewise, there is no explanation for the existence of double-stranded RNA in noninfected cells. However, it is also worth mentioning that *Montagnier* [122] was able to demonstrate double-stranded RNA in normal rat liver cells.

The second explanation for the good inducer properties of double-stranded RNA is the principle of "foreign" nucleic acid put forward by *Isaacs*. A well-known characteristic of double-stranded RNA is its relative stability in the presence of RNase; this gives it a greater chance of reaching the cell than all the other types of nucleic acids, which are very quickly broken down by nucleases.

7. Future Prospects

There has been no lack of ideas and experiments on the use of the interferon system for the control of virus diseases. Its broad antiviral spectrum of activity, its lack of toxicity, and its low antigenicity apparently make interferon especially suitable for this purpose. The virus diseases, for which only a limited number of serologically different types of viral agents are responsible and which in addition lead to prolonged immunity, are today largely kept in check by vaccination. This is the case with measles, pox virus diseases, yellow fever, poliomyelitis, *etc.* In addition to this, virus chemotherapy has been introduced with the use of iododeoxyuridine, adamantamine, and methylisatin-β-thiosemicarbazone in the treatment of herpes, influenza, and pox virus infections, respectively.

The hope that interferon could help in the effective control of virus diseases was recently strengthened when *Hilleman* reported in 1967 that some double-stranded ribonucleic acids were extremely potent interferon inducers. *Park* and *Baron* [123] as well as *Pollikoff* [124] were also able to establish that interferon is suitable for both prophylactic and therapeutic treatment. The above authors observed that rabbits recovered from herpetic conjunctivitis much quicker and better after treatment with poly-I:C than the control animals. This therapeutic effect was observed both with local and systemic administration. *Guerra et al.* [125] described the poly-I:C treatment of 22 patients suffering from herpetic keratitis. A good therapeutic effect was obtained in 17 cases.

The great difficulties which stand in the way of clinical use of interferon inducers are, in the first place, the already mentioned refractory phase and, secondly, the considerable toxicity of most of the inducers known at present.

The clinical application of interferon itself, *i.e.* exogenous interferon, is problematic, since it is very difficult to prepare sufficient quantities of human interferon.

Thirteen years have passed since the discovery of interferon by *Isaacs* and *Lindenmann*, and much new information has been acquired during this time. The process of interferon induction on the molecular level, and the mode of action of interferon are still obscure in many respects. Another task for the future is the further purification of interferon, so that its chemical composition can be investigated. Recently, *Vilcek* [126] discussed an interesting possibility: "Further studies may perhaps lead to the discovery of non-interferon inducers of TIP. Or would such agents be called interferons?"

Disorder in Solids (Ionic Crystals and Metals)

By Jens Nölting[*]

Important properties of crystalline solids are due to deviations from the ideal crystal structure. Lattice defects can be divided into structural defects (grain boundaries, dislocations, impurities) and intrinsic defects. The present article deals mainly with the problems and possibilities for the determination of intrinsic disorder. This disorder, which varies reversibly with temperature, plays an important role in many solid-state processes, such as diffusion, ionic conduction, and chemical reactions in the solid phase.

After an introduction to the usual physical and chemical descriptions of the state of disorder, the principal methods of investigation are discussed. Special emphasis is placed on methods of determining disorder data from "anomalous" specific heats.

1. General

1.1. Introduction

Ideally ordered crystalline solids, characterized by an absolutely regular and perfect arrangement of their atoms in a crystal lattice, do not occur in nature. Crystal growth itself depends on the presence of structural defects (at least one dislocation with a screw component). However, even a single crystal with a very small number of dislocations has lattice defects on the atomic scale, which increase in number with rising temperature, and which are known as intrinsic defects. They are characterized by their occurrence in a reversible, temperature-dependent equilibrium. The number of defects increases with rising temperature, and decreases again when the temperature is lowered; to each temperature there corresponds a precisely defined concentration of defects. Apart from the properties of the crystal, therefore, the temperature alone determines the concentration of such lattice defects.

These defects are all of the type known as point defects. The regions of non-ideality in the lattice are confined to one lattice point and its immediate surroundings. An example of a typical and commonly occurring point defect is a missing lattice atom; this is called a vacancy. Another type of point defect is an interstitial atom, which is an atom inserted in a normally unoccupied site in the lattice. In comparison with a regularly occupied lattice site, a defect always involves an increase in the energy requirement by an amount necessary to produce the defect[**]. The type of defect in a lattice is largely determined by the lattice geometry. Vacancies are nearly always favored in structures with close packing of atoms (*e.g.* face-centered atomic lattices), whereas more open structures (*e.g.* body-centered atomic lattices) may also allow interstitial atoms. In ionic crystals, on the other hand, either type of defect may be favored, depending on the relation between the sizes of the ions. In this case the condition of electroneutrality plays a special role. Each defect in an ionic lattice means the absence of one charge or the presence of an additional charge in comparison with the perfect lattice. At equilibrium, the state of disorder must be such that the sum of the charges of all the defects is zero.

Foreign atoms incorporated into the lattice in small numbers are also point defects in our scheme. They play an important role in disorder equilibria, since they can cause a marked difference in the state of disorder from that in the pure substance. Deviations from the stoichiometric composition, which are possible for many ionic compounds, also cause changes in the state of disorder. Thus a deficit of one type of ion means either vacancies in the lattice of these ions or the insertion of interstitial ions of the other type. The presence of foreign atoms and nonstoichiometry are often referred to collectively as chemical disorder, which is characterized by introduction of disorder with a change in the composition of the crystal. These additional defects are independent of temperature, but they influence the (temperature-dependent) equilibrium of the intrinsic disorder.

1.2. Statistics of the Disorder in Thermal Equilibrium

The reason for the presence of intrinsic defects in the crystal lattice of a pure solid of stoichiometric composition is the temperature-dependent vibration of the lattice atoms about the rest positions of their ideal lattice points[*]. The normal vibrations correspond to a Boltzmann energy distribution. At a finite temperature, there are always combinations of the individual normal vibrations that allow the deflection of a

[*] Priv.-Doz. Dr. J. Nölting
Institut für Physikalische Chemie der Universität
34 Göttingen, Bürgerstrasse 50 (Germany)

[**] It is naturally assumed here that the lattice is in thermodynamic equilibrium *i.e.* that its structural units have in fact assumed the arrangement that gives the minimum free energy for the temperature in question. This is always assumed to be so in the following discussion. It is shown in Section 1.2 that the free energy minimum is reached only when a certain number of defects are present (at a finite temperature).

[*] According to quantum theory, the lattice atoms cannot be definitely located even at absolute zero, since they have a finite zero-point energy.

lattice atom in a favorable direction to become so large that it can escape from the potential trough of its lattice point and reach other positions in the lattice (*e.g.* a neighboring interstitial site). The important question of the equilibrium defect concentration at a given temperature can be answered with the aid of statistical thermodynamics[1]. We begin with the requirement that the free energy of the disordered crystal at equilibrium must be a minimum. This minimum condition then gives the definite concentrations of the various types of defects.

It is clear even without explicit calculation that the completely ordered state cannot correspond to the minimum free energy $A = E - TS$[*] since the entropy S is a minimum in this state. As defects appear, S increases very rapidly at first, so that the increase in TS exceeds the increase in the internal energy E. The free energy minimum, *i.e.* equilibrium, is reached only when so many defects are present that the increases in the two terms are exactly equal. For low defect concentrations (<1 %), a simple expression for the entropy can be given with the aid of the Boltzmann formula $S = k \ln W$. The probability W is proportional to the number of distinguishable ways in which the state can be achieved with a certain number of defects in the lattice. Besides this "configuration entropy", other entropy changes in the vicinity of a defect are taken into account by an extra additive term.

1.3. Disorder Models

Let us first consider a crystal lattice that contains only one type of particle, such as the atomic lattice of a pure metal. Two possible types of defect are shown in Figures 1 and 2. In the Schottky type, atoms have migrated from the interior of the crystal to the surface, leaving behind a corresponding number of vacancies. However, the atoms generating the vacancies may also remain in interstitial sites in the interior of the crystal lattice (Frenkel type). A third possibility would be the migration of surface atoms to interstitial sites in the interior (anti-Schottky disorder); however, this type is less likely because of the unfavorable energy requirements.

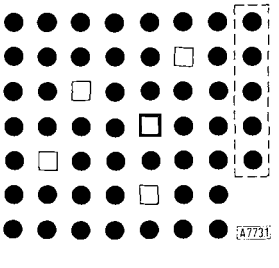

Fig. 1 (left). Atomic lattice with Schottky disorder.

Some atoms have left their lattice sites and migrated to the surface of the crystal. *One* disorder center (vacancy) is formed per misplaced lattice atom.

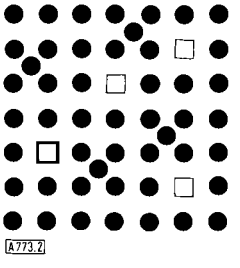

Fig. 2 (right). Atomic lattice with Frenkel disorder.

Some atoms have left their lattice sites and occupied interstitial sites in the interior of the crystal. *Two* disorder centers (vacancy and interstitial atom) are formed per misplaced lattice atom.

[1] *C. Wagner* and *W. Schottky*, Z. physik. Chem., Abt. B *11*, 163 (1930); *C. Wagner*, *ibid.*, Bodenstein-Festband, 177 (1931); Abt. B *22*, 181 (1933).

[*] We should really use the Gibbs function $G = E - TS + pV$ instead of the Helmholtz function A, but since all the cases discussed here relate to normal pressure, the term pV may be neglected for solids.

Basically the same types of defects occur in ionic crystals. Figure 3 shows Frenkel disorder of the cations[*] in the silver bromide lattice. The Br^- lattice shows negligible disorder in comparison with the Ag^+ lattice. On the basis of energy considerations, *Jost*[2] and *Schottky* found that Schottky disorder should be favored in alkali metal halides, and this has been confirmed experimentally (Figure 4).

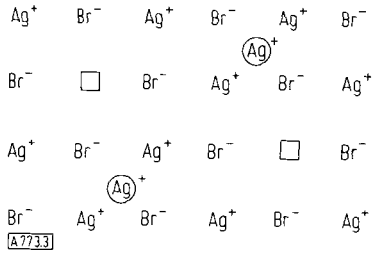

Fig. 3. Frenkel disorder in the Ag ion lattice of AgBr.

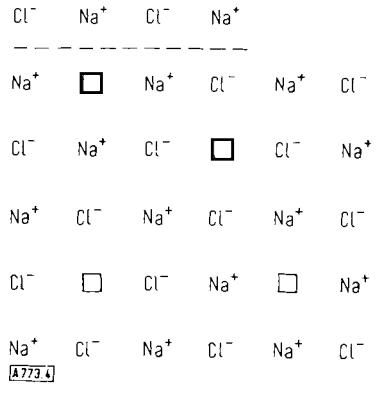

Fig. 4. Schottky disorder in the NaCl lattice.

The anion lattice and the cation lattice contain the same number of vacancies. *Two* vacancies are formed per defective NaCl unit. The missing NaCl unit is situated on the surface of the crystal.

1.4. Disorder Equilibria

The concept of the disorder equilibrium has a special significance in the case of compounds, particularly ionic crystals. The view of chemical equilibrium familiar to the chemist can be applied without difficulty to the state of disorder. The crystal is regarded as a reactive system in which the "reacting species" are regularly occupied, vacant, and incorrectly occupied lattice positions. These species can be interconverted in accordance with a certain reaction scheme and a "reaction equilibrium" will be set up between them. The equilibrium is characterized by the minimum free energy that the system then assumes.

[*] Frenkel disorder in the anion lattice, which is much less common, is known as anti-Frenkel disorder (example: SrF_2).

[2] *W. Jost*, J. chem. Physics *1*, 466 (1933); Physik. Z. *36*, 757 (1935); *W. Jost* and *G. Nehlep*, Z. physik. Chem., Abt. B *32*, 1 (1936).

Let us consider the case of Frenkel disorder, where vacancies and interstitial atoms are present in equal numbers. The reaction scheme can be written as follows:

$$\left.\begin{array}{l}\text{occupied lattice site A}\\ +\ \text{vacant interstitial site A}'\end{array}\right\} \rightleftharpoons \left\{\begin{array}{l}\text{vacant lattice site A } (\square)\\ +\ \text{occupied interstitial}\\ \text{site A } (\circ)\end{array}\right.$$

(the "energy of reaction" is E_f)

and the corresponding mass action expression, where c_A, $c_{A'}$, $c_\square$, and $c_\circ$ are the concentrations of occupied lattice sites, vacant interstitial sites, vacant lattice sites, and occupied interstitial sites respectively, is

$$\frac{c_\square \times c_\circ}{c_A \times c_{A'}} = K_f = \exp(S_f/R) \times \exp(-E_f/RT) \qquad (1)$$

The mass action constant K_f is a pure function of temperature, and is expressed in the usual manner as an exponential function with the free "energy of reaction" $E_f - TS_f$. S_f is the increase in entropy due to disturbance of the lattice in the vicinity of the defect.

In the pure, stoichiometric substance, the defects (vacancies and interstitial atoms) occur in equal numbers. Thus $c_\square = c_\circ$. If S_f and E_f are independent of temperature, for low defect concentrations ($c_\square \ll c_A$) and $c_A = c_{A'}$, we can deduce the degree of disorder γ from eq. (1)

$$\gamma = c_\square/c_A = c_\circ/c_A = \gamma_0 \exp(-E_f/2\,RT) \qquad (2)$$

As in chemical reactions, the equilibrium (1) can be displaced by addition of another component. For example, if pure silver bromide is doped with cadmium ions (Fig. 5), one additional vacancy must be produced in the cation lattice for each Cd^{2+} introduced, or else an interstitial cation must disappear from the equilibrium, in order to preserve electroneutrality. Since the product of the concentrations of vacancies and of interstitial lattice cations is constant according to eq. (1), the concentration of interstitial cations decreases to a degree that varies with the amount of Cd^{2+} added.

In the case of ionic compounds that can exhibit pronounced deviations from the stoichiometric composition (examples: Cu_2O, ZnO, TiO_2, FeS, Ag_2S),

Ag^+	Br^-	Ag^+	Br^-	Ag^+	Br^-
Br^-	$\square$	Br^-	$\square$	Br^-	Ag^+
Ag^+	Br^-	Ag^+	Br^-	$\underline{Cd}^{2+}$	Br^-
Br^-	$\underline{Cd}^{2+}$	Br^-	Ag^+	Br^-	Ag^+
Ag^+	Br^-	$\square$	Br^-	$\underline{Cd}^{2+}$	Br^-
Br^-	Ag^+	Br^-	Ag^+	Br^-	Ag^+

A773.5

Fig. 5. AgBr lattice with added $CdBr_2$.

Each Cd^{2+} ion incorporated in an Ag^+ lattice site requires an additional vacancy in the cation lattice. Interstitial ions are largely suppressed.

the number of defects can also vary widely. A metal deficit usually leads mainly to cation vacancies; with a deficit of non-metal, anion vacancies can occur as well as interstitial cations (example: TiO).

2. Processes in the Solid State Due to Lattice Defects

2.1. Diffusion

Though the degree of disorder γ of solids even in the vicinity of the melting point is usually only of the order of 10^{-3}, it has a decisive influence on mass transport within the lattice since only the defect centers can move in the lattice; a direct transposition of neighboring lattice atoms is unlikely on energy grounds.

The following transposition mechanisms involving disorder centers are important and have been verified experimentally:

1. Exchange of a vacancy with a neighboring lattice atom (vacancy migration).
2. Migration of an interstitial atom to a neighboring (equivalent) interstitial site (interstitial migration).
3. Displacement of a normal lattice atom to an interstitial site by a neighboring interstitial atom (*Wagner*'s displacement mechanism [11]).

All these elementary steps require a particular "threshold energy" U, which corresponds to the position of the saddle point between the initial and final states of the migrating particle. For the migrating step, therefore, an arbitrarily chosen particle requires the threshold energy U in addition to the disorder energy E_f. In the description of mass transport by a diffusion coefficient, therefore, we find an exponential expression of the form

$$D = D_0 \exp\left(-\frac{E_f + U}{RT}\right) \qquad (3)$$

for a monatomic substance with Schottky disorder, and a similar expression for an ionic compound A^+B^- [*].

$$D = D_0 \exp\left(-\frac{E_f/2 + U}{RT}\right) \qquad (4)$$

The energy relations for a lattice site and a neighboring interstitial site are shown schematically in Figure 6.

The factor D_0 in the diffusion coefficient involves the vibration frequency and the distance through which the defect jumps, as well as some quantity depending on the geometry of the lattice.

[*] $E_f/2$ occurs if two defects are formed per misplaced lattice atom, as is the case in Schottky or Frenkel disorder in an ionic compound A^+B^-. The simple expression (4) is sufficiently accurate only if the threshold energies U_1 and U_2 of the two defect centers are not very different. If $U_1 \gg U_2$, *e.g.* eq. (3) with $U = U_2$ is valid; if U_1 and U_2 are of the same order of magnitude, but differ appreciably, eq. (4) is replaced by an exponential expression containing two terms with different values of D_0 and U.

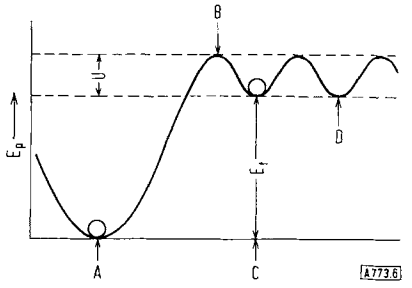

Fig. 6. Potential energy diagram of a particle in various lattice positions.

A: Occupied normal lattice site; B: Saddle point for transition into interstitial site; C: Occupied interstitial site; D: Vacant interstitial site.

Diffusion plays a decisive role in many solid state reactions, such as tarnishing and scaling processes. The rate-determining step is often not the reaction at the interface but the diffusion of the reactants through the solid layer formed. Thus the parabolic oxidation law discovered empirically by *Tammann* [3]

$$(\Delta\xi)^2 = 2\,k't \qquad (5)$$

($\Delta\xi$ = thickness of oxide layer, t = oxidation time, k' = tarnishing constant)

is readily explained if the diffusion of ions and electrons through the reaction layer is assumed to be rate-determining [4].

2.2. Ionic Conductivity

The random diffusion of atoms due to disorder proceeds by essentially the same mechanism in ionic crystals and in metals; in ionic crystals a preferred flow of ions can be superimposed on this random motion by application of an external electric field. The defect centers (vacancies, interstitial ions) move with or against the electric field, depending on their charge in relation to the neutral crystal.

The ionic conductivity can thus be described by an expression similar to that found for diffusion:

$$\sigma = \sigma_0 \exp\left(-\frac{E_f/2 + U}{RT}\right) \qquad (6)$$

This expression is valid if only one type of defect is present and the threshold energies for the defect centers are not very different.

Since diffusion and ionic conduction involve the same transport mechanism, a definite relation must exist between the two. This relation is given by the Nernst-Einstein equation

$$D = \frac{kT}{n\,(z \times e)^2}\,\sigma \qquad (7)$$

(k = Boltzmann's constant, T = absolute temperature; e = electronic charge; z = valency of ions; n = concentration of ions).

However, this equation is valid only if all the defect centers that contribute to diffusion also contribute to conduction. Thus there must be no neutral defect associations, which would diffuse, but would not exhibit a preferred migration direction in an electric field. Moreover, σ naturally must not contain any electronic conduction component. For very accurate comparisons of diffusion and conductivity, a "correlation factor" must be introduced into eq. (7) to take into account the differences in the migration of the defect centers and of the labeled ions observed in the diffusion experiment. The correlation factor has characteristic values for the various migration mechanisms. The correlation factor found by comparison of very accurate diffusion and conductivity measurements can thus serve as an indication of the nature of the defect migration mechanism [5].

2.3. Disorder in Nonstoichiometric Compounds

So far we have been dealing mainly with pure substances whose components are present in exactly the correct stoichiometric ratio; any atomic disorder in such cases must be thermal intrinsic disorder. Though the problems of substances with nonstoichiometric compositions can only be touched on lightly here, the principal aspects in connection with disorder cannot be completely ignored.

The disorder equilibria of binary nonstoichiometric ionic compounds depends not only on the temperature but also on the partial pressure of one of the components in the external gas phase; this pressure fixes the equilibrium ratio of metal to non-metal in the compound. Corresponding to the deviation from the stoichiometric composition, an equivalent number of ionic and electronic defects are produced, and these largely determine the properties of the compound. Owing to the very much greater mobility of electrons, substances of this nature are always predominantly electronic conductors. With an excess of metal, conduction is by electrons (n-type conduction), while with an excess of the non-metal, conduction is by defect electrons (p-type conduction).

Information about the equilibrium of disorder is provided above all by measurements of the conductivity as a function of the temperature and of the external gas phase. Many investigations of this nature have been carried out. They have made an important contribution to the elucidation of the complicated problems of tarnishing and scaling processes, particularly in the oxidation of metals [6, 7].

The characteristics of heterogeneous catalysts are undoubtedly also largely determined by the electronic properties due to disorder. This will probably also receive considerable attention in future fundamental

[7] *K. Hauffe*: Oxidation of Metals. Plenum Press, New York 1965.

research. Apart from the possibility of controlling chemical reactions, the processes involved in heterogeneous catalysis are of great interest in themselves. However, the problem is very complex, since in addition to the disorder phenomena, which are now relatively well known, many other factors such as chemisorption, electronic charge reversal processes, and boundary layer phenomena must also be considered [8].

3. Methods of Determining Disorder Data

3.1. Diffusion and Ionic Conductivity

The experimental methods most commonly used for testing disorder models and for the quantitative determination of disorder data are conductivity and diffusion measurements. The conductivity measurements must be supplemented by transport number measurements in order to separate the cationic, anionic, and electronic components of conductivity.

According to *Tubandt* [9], this can usually be done by measurements on several tablets of the material in question between two suitable electrodes (Fig. 7). After the passage of a certain quantity of electricity, which is measured with a coulometer, the transport numbers of the ions can be determined from the changes in the weights of the cathode and anode cylinders. If the ion equivalents transported are less than that indicated by the coulometer, the difference is due to an electronic conduction component. However, the simple arrangement shown in Figure 7 is often inadequate; it is frequently necessary to interpose "protective electrolytes" (*e.g.* AgI, $BaCl_2$), which prevent the growth of metal filaments and the liberation of components as a result of electronic conduction.

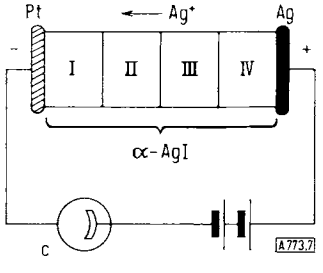

Fig. 7. *Tubandt*'s arrangement for the measurement of transport numbers in solids.

In the investigation of AgI, silver ions flow from the Ag anode to the Pt cathode. The quantity of electricity passed is determined with the coulometer C.

A similar arrangement is normally used to measure the total conductivity, but only a single tablet is placed between the electrodes in this case. For a sample of medium conductivity, one need only measure the current as a function of the voltage across the electrodes. For higher conductivities, the potential drop along the sample should be measured with probes and a compensating apparatus; this avoids the inclusion of contact resistances at the electrodes in the measurement. An arrangement of this type is shown in Figure 8. Alternating current is frequently also used (an AC bridge with an oscillograph as a zero indicator) to eliminate polarization processes at the electrodes.

[8] *K. Hauffe*, Angew. Chem. *67*, 189 (1955); *68*, 776 (1956).

[9] *C. Tubandt* in *W. Wien* and *F. Harms*: Handbuch der Experimentalphysik. Akademische Verlagsgesellschaft, Leipzig 1932, Vol. XII/1, p. 383.

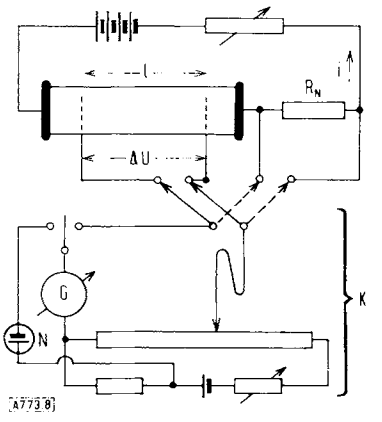

Fig. 8. Arrangement for conductivity measurement with probes.

Using the compensating apparatus, one measures: (a) the current i flowing through the sample as the potential drop across the standard resistance R_N; (b) the potential drop Δu over the length l of the specimen. The specific conductivity of the specimen is given by $\sigma = li/q\Delta u$ (q = cross section of specimen).

If eq. (6) is valid, the usual plot of the conductivity in an Arrhenius diagram (log σ against $1/T$) gives a straight line, the slope of which can be used to find the apparent [*] activation energy $[(E_f/2) + U]$ for the migration of the defect centers.

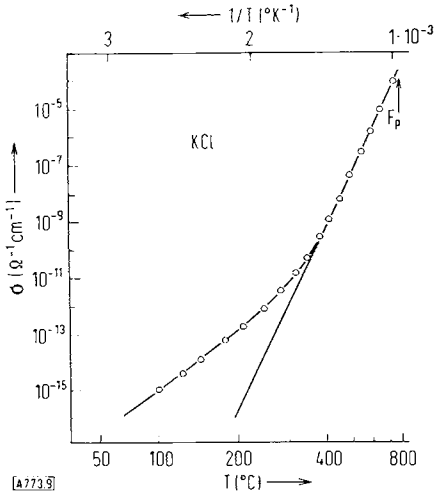

Fig. 9. Temperature dependence of the electrical conductivity of an ionic conductor, with KCl as example.

The intrinsic conduction range is seen above 400 °C. Below 200 °C the conductivity is determined by extraneous Ca^{2+} ions; the KCl specimen, which was purified by zone melting, had a Ca^{2+} content of 10^{-8}—10^{-9} (after [10]).

Figure 9 shows a typical diagram for an ionic conductor [10]. A particularly striking feature is the sharp change from the steeper linear section at high temperatures to a much shallower curve at low temperatures; this point separates the region of intrinsic conduction, in which the determining factor is the thermal

[*] The descriptions "apparent" and "formal" as applied to the activation energy refer to the fact that we are not usually concerned with a single elementary step of migration associated with an activation step that can be described precisely. Thus in ionic crystals, several transport processes usually take place simultaneously (*e.g.* vacancy migration and interstitial migration); the apparent activation energy found experimentally is then merely a formal expression obtained as the average of various processes. This correct designation is particularly important in reaction kinetics.

[10] *H. Gründig*, Z. Physik *158*, 577 (1960).

disorder [the apparent activation energy here is found from eq. (6)], from the region of impurity-dependent conduction in which the thermal disorder is so slight that the defects due to impurities predominate. The number of induced defects of the latter type is independent of the temperature, and the temperature dependence of the conductivity in this region depends only on the threshold energy U. It is therefore possible to find U alone, and hence also E_f. The purer the sample, the lower is the temperature at which the discontinuity in the conductivity curve appears. This temperature can be displaced within certain limits by specified additions of cations having a different valency. At the temperature of the discontinuity, the concentration of bivalent ions is roughly equal to the concentration of thermal defects. All disorder data can in principle be found from conductivity measurements on anomalous solid solutions [*], as has been shown by *Koch* and *Wagner* [11].

Self-diffusion measurements offer another method of obtaining information about the state of disorder. They fit in well with conductivity measurements, since the self-diffusion coefficient and the conductivity are related by the Nernst-Einstein equation [eq. (7)]. Since radioactive isotopes of most elements have become available, self-diffusion measurements essentially can be carried out without difficulty, but the experimental outlay is greater than for conductivity measurements.

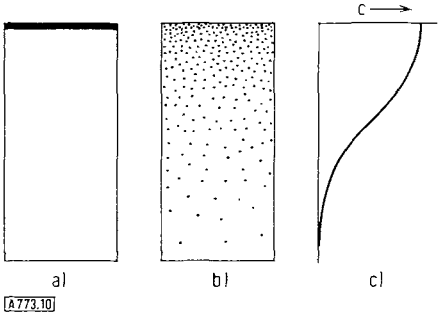

Fig. 10. Frequently used form of diffusion specimen for measurement with radioactive isotopes.

a: Before diffusion; a thin layer containing radioactive atoms is situated on the face of the specimen.

b: After diffusion; the radioactive atoms are distributed throughout the specimen.

c: Concentration profile of the radioactive atoms along the specimen.

The specimen normally used is as shown in section in Figure 10a. Radioactive isotopes of the atoms under investigation are applied to the polished face in the thinnest possible layer. Diffusion at high temperatures leads to distribution of the radioactive atoms in the interior of the specimen. If the dilution of the labeled atoms is sufficiently high, the diffusion coefficient is concentration independent and can be readily determined from the concentration profile. The most reliable method of finding the concentration profile (cf. Fig. 10c) is to cut the specimen into thin sections parallel to the surface. The activities of the various layers provide a relative measure of the concentration of radioactive atoms that have diffused in at the corresponding distance from the surface.

[*] This is the most usual term. *Wagner* refers to solid solutions in which additives with different valencies are incorporated into normal lattice sites as heterotypical mixed phases.

[11] *E. Koch* and *C. Wagner*, Z. physik. Chem., Abt. B *38*, 295 (1937).

It is sometimes very difficult to cut specimens of ionic crystals into such sections. In this case the absorption of the radiation of the tracer atoms that have diffused in is normally utilized. If the radioactivity above the surface is measured with a counter tube, a decrease in radiation is observed after diffusion as a result of absorption of the radiation of diffused atoms in layers nearer to the surface. If the linear absorption coefficient for the radiation in the medium in question is known, the diffusion coefficient can be calculated from the drop in intensity of the radiation.

Some methods involving the use of radioactive isotopes for diffusion measurements [12] are suitable for special problems, and particularly for the measurement of very small diffusion coefficients (between 10^{-14} and 10^{-19} cm^2/s). It is necessary to use diffusion measurements in such cases, since the partial conductivity of an ionic component is then less than $10^{-8}\,\Omega^{-1}$ cm^{-1}. Diffusion measurements are particularly important for metals, since there is no alternative method that allows the direct measurement of mass transport in the lattice, as there is in the case of ionic crystals.

3.2. Cubic Expansion Determined from Macroscopic and X-Ray Measurements

The accurate determination of the expansion of a lattice by X-ray diffraction gives smaller values than macroscopic measurement if appreciable Schottky disorder is present in the temperature range in question. In this case atoms migrate from the interior of the crystal to the surface as the temperature is raised (see Fig. 1), with the result that the expansion of the lattice is accompanied by an additional macroscopic increase in volume.

Disorder data have been obtained for some metals with the aid of this behavior. Figure 11 shows the result of such measurements on gold [13]. Table 1 shows some values obtained by this method and/or from the increase in the electrical resistance for quenched metal specimens as a result of "frozen-in" defects.

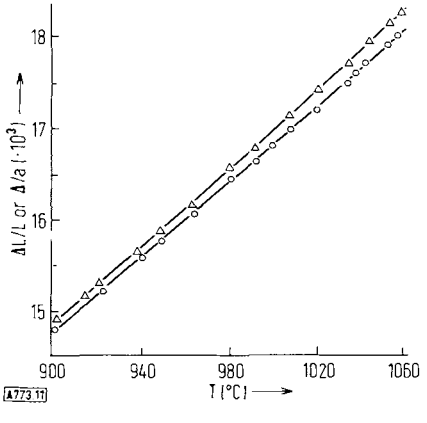

Fig. 11. Different linear expansions in gold.

△: $\Delta L/L$ = linear expansion found by macroscopic measurements.

○: $\Delta a/a$ = lattice expansion found by X-ray measurements.

The Schottky disorder that occurs preferentially in metals leads to an additional macroscopic expansion (after [13]).

[12] *R. Lindner*, Acta chem. scand. *5*, 735 (1951).

[13] *R. O. Simmons* and *R. W. Balluffi*, Physic. Rev. *125*, 862 (1962).

Owing to the low defect concentrations and the correspondingly small measurement effects, the accuracy of the measurements must be very high. For these reasons, measurements have so far been carried out only on a few metals with favorable mechanical and metallurgical properties.

In the case of ionic crystals, this method offers a possibility of distinguishing between Frenkel and Schottky disorder. Frenkel disorder does not lead to an additional macroscopic increase in volume since the atoms from the vacancies remain inside the crystal; this produces only a slight expansion of the lattice, which is practically undetectable at low degrees of disorder.

Table 1. Disorder data for some metals.

	Energy of disorder E_f (kcal/mole)	Degree of disorder at m.p. $\gamma_{m.p.} \times 10^3$	Ref.	Method
Au	21.7 ± 2	0.72 ± 0.06	[13]	[b]

[b] From density measurements.

4. Influence of Disorder on the Temperature Dependence of the Specific Heat

4.1. Specific Heats of Solids

The increase in the intrinsic disorder in the crystal lattice with rising temperature means that more energy is required, and this in turn increases the heat content of the crystal. The specific heat must therefore contain a component due to the change in disorder with temperature.

Before estimating the magnitude of this effect and deriving quantitative expressions for it on the basis of the disorder models, let us recall some basic facts about the specific heats of solids.

According to Dulong and Petit's law, the specific heats of most solid elements in the vicinity of normal temperatures are roughly equal to $3R$, where R is the molar gas constant. By extension of this rule we find that the molecular heats of many solid compounds can be calculated by summation of the atomic heats of the elements present (Kopp's law). Thus a diatomic solid compound would have a molar heat of $2 \times 3R$, and the values for polyatomic compounds, provided that they are not too complicated, should roughly be multiples of 6 kcal/mole °K $\approx$ 25 J/mole °K.

Above normal temperature, the specific heat slowly increases with rising temperature. This can be explained by slight anharmonicities of the lattice vibrations, and in the case of metals by a small contribution from the quasi-free electrons. The important point here is that both components lead to an approximately *linear* increase with rising temperature.

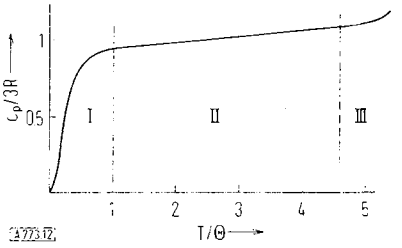

Fig. 12. Typical course of the specific heat of a solid.
Region I: Lattice vibrations not fully excited.
Region II: The lattice vibrations are fully excited; slight temperature dependence of c_p.
Region III: Stronger temperature dependence as a result of anharmonicities of the lattice vibrations.

Figure 12 shows a typical plot of the specific heat of a monatomic substance against temperature in units of the characteristic Debye temperature. We are interested here in the portion II above the Debye temperature, which corresponds to the range of validity of Dulong and Petit's law in the extended form mentioned above. In region III, the increase with rising temperature is faster than linear; this is due to a stronger influence of the anharmonicity of the lattice vibrations, and possibly to a greater contribution from the electrons at higher temperatures.

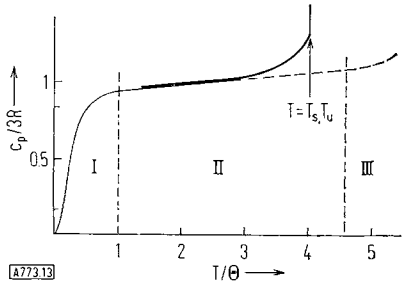

Fig. 13. Temperature dependence of the specific heat before melting and transition points.

Figure 13 illustrates the situation in which a melting point or transition point occurs in region II. It has been found that pronounced disorder is produced in the crystal even in a temperature range below this point, as can be seen from a marked increase in c_p some 100–150 °C before the transition point. The form of this increase can be predicted with the aid of the disorder models. It must be approximately exponential, since the degree of disorder also increases roughly exponentially according to eq. (2).

4.2. Estimation of the Component Due to Disorder

To illustrate the estimation of the additional specific heat due to disorder, let us consider the metal aluminum. Aluminum crystallizes in a simple close-packed, face-centered cubic atomic lattice, for which the degree

of disorder is not expected to be very large. It is known from a comparison of the densities as found by macroscopic and X-ray measurements (Table 1) that only about every thousandth lattice site in solid aluminum is unoccupied in the immediate vicinity of the melting point; approximately 20 kcal must be supplied in order to produce one gram atom of such defects.

Thus if one gram atom of aluminum is heated from a low temperature, where the disorder is still negligible, to a temperature very close to the melting point, an energy of $\gamma_{m.p.} \times E_f \approx 10^{-3} \times 20 \times 10^3 \approx 20$ cal must be supplied to the lattice for the disorder in addition to the heat of vibration. Owing to the exponential increase in the disorder with rising temperature, therefore, we obtain an additional specific heat of $\approx$1 cal/mole · °K in the vicinity of the melting point; this corresponds to more than 15% of the normal specific heat of aluminum.

Jost [19] deduced some considerable time ago for silver bromide that the effect can be very much greater for other solid substances whose structures are still relatively simple. Since conductivity measurements had given a degree of disorder of $\approx$2% and the disorder energy had been found to be 20 kcal/mole [11], the total heat effect at the melting point should be $\approx$400 cal/mole. Experiments have in fact given additional heats of this order of magnitude (cf. Section 4.5).

4.3. Experimental

Heat effects of this type are best measured with a continuous-operation adiabatic calorimeter (Isoperibol type); it should give high accuracy over the widest possible temperature range, since we require accurate determination not only of the additional heat effect at high temperatures, but also of the linear portion of the specific heat curve at low temperatures. A suitable apparatus is shown schematically in Figure 14.

The apparatus [20] used by our team in the investigations described in Section 4.5 has now been improved to such a degree that all adjustments and the recording of the measured values (temperature-time function) within a single run are carried out automatically. An individual series of measurements is reproducible to within ±0.2%. Comparisons with measurements carried out on aluminum by the National Bureau of Standards (USA) showed an agreement to within ±0.3% over the entire temperature range from −70 to 650 °C.

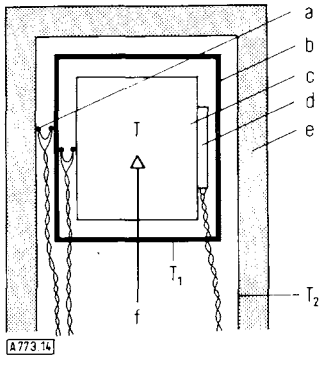

Fig. 14. Scheme of an adiabatic calorimeter.

a: Differential thermocouples; b: Adiabatic jacket; c: Sample container (cf. [21]); d: Pt resistance thermometer; e: Outer jacket and insulation; f: Heat input $u \times j$ = const.).

Adiabatic condition $T = T_1$; control condition $T_1 > T_2$. Energy is supplied continuously (under control) to the sample inside (constant heat supply) in such a way that its temperature rises steadily. The adiabatic jacket undergoes the same temperature rise and prevents heat exchange with the environment.

4.4. Evaluation of the Heat Effects

For a simple evaluation of this anomalous temperature dependence of the specific heats of solids, it is assumed that the deviation of the c_p values from linearity, as found at low temperatures, is due only to disorder in the lattice. The additional specific heat Δc_p can thus be obtained by taking the difference between the experimental curve and the linear extrapolation of the specific heat from the low temperature range. At low degrees of disorder ($\gamma < 10^{-2}$), the contributions of the individual defects are additive. For a temperature-independent disorder energy E_f, the total additional quantity of heat per mole that must be supplied for disorder up to the temperature T is

$$Q = E_f \times \gamma(T) = E_f \times \gamma_0 \exp(-E_f/RT)\ [*] \qquad (8)$$

The additional specific heat is obtained by differentiation of this expression with respect to temperature

$$\Delta c_p = \frac{dQ}{dT} = \frac{E_f^2 \gamma_0}{RT^2} \exp(-E_f/RT) \qquad (9)$$

or

$$\ln(\Delta c_p T^2) = \text{const.} - \frac{E_f}{RT} \qquad (10)$$

A plot of $\ln(\Delta c_p \cdot T^2)$ against $1/T$ should therefore give a straight line, from whose slope the disorder energy E_f can be obtained.

According to eq. (8), the degree of disorder is

$$\gamma(T) = Q(T)/E_f = \frac{1}{E_f} \int_0^T \Delta c_p \, dT' \qquad (11)$$

$Q(T)$ is usually found by graphical integration of the area between the measured c_p curve and the linear extrapolation.

4.5. Results of Measurements

Figure 15 shows the temperature dependence of the specific heat of silver bromide, for which the disorder effect was detected first [22, 23]. As expected, the curve shows a very pronounced, quasi-exponential increase, which begins 200 °C below the melting point. The total

anomalous heat effect is 776 cal/mole. This leads to the astonishing conclusion that 9% of the total heat content of AgBr at the melting point is due to Frenkel defects in the cation lattice. The disorder component of the specific heat at the melting point is almost 50%. Figure 16 shows a plot in accordance with eq. (10), which gives a straight line to a good approximation. The disorder data are given in Table 2, which also contains comparison values obtained by other methods However, the agreement is not expected to be particularly good in the extreme case of AgBr, since the simple idea of independent defects is undoubtedly only approximately valid at degrees of disorder $\gamma > 10^{-2}$ [*]

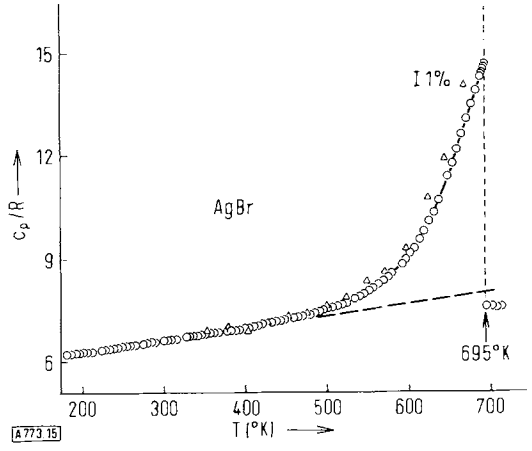

Fig. 15. Specific heat of AgBr.
△: Values according to [22]. ○: Values according to [23].

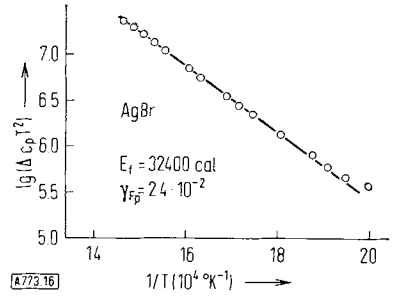

Fig. 16. Determination of the disorder energy E_f of the Frenkel disorder in AgBr from additional specific heats.

Figure 17 shows the results of measurements on AgI [24]. A distinct, though not very pronounced, ascent is found for the β phase (up to 147 °C). This can again be attributed to Frenkel disorder in the cation lattice (see Table 2). According to X-ray structure analysis [25] and conductivity measurements [26], the disorder in the cation lattice of α-AgI (147–558 °C) is practically complete; the disorder consequently cannot

[*] At a 1% degree of disorder, the average distance between a vacancy and an interstitial ion is only about three times the distance between cations in the lattice. Associations of defects, which can have a strong influence on the ionic conductivity in particular, must therefore be expected.

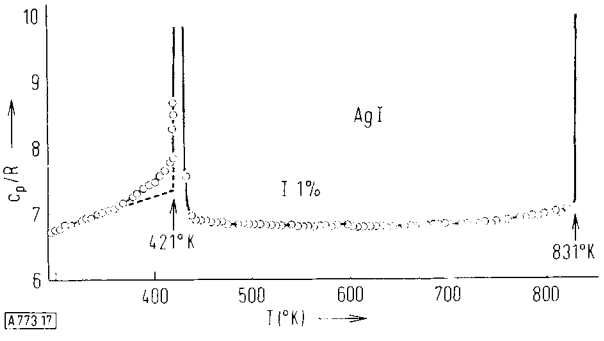

Fig. 17. Specific heat of AgI.

increase with rising temperature, and no additional specific heats appear. The slight fall of the curve can be attributed to residual short-range order in the cation lattice, the breakdown of which requires further small quantities of energy. According to self-diffusion measurements [27], the disorder in the anion lattice is very slight, and the absence or near-absence of disorder anomalies of the iodide ions at the melting point of AgI is quite understandable.

Further examples of pronounced anomalies in ionic crystals are shown in Figures 18 to 20 [23,28]. In addition to the characteristic increases in c_p in the low-temperature phases, which are very pronounced for CuI and CuBr, unusual downward trends are also observed. It can be seen that these occur only in phases that are almost completely disordered. One might therefore attribute it to a short-range order effect like that in α-AgI; however, the descent with temperature is about an order of magnitude too fast for this, as can be deduced from the theories of order-disorder transitions for metal alloys [28]. An attempt to explain it by the transition of a vibration into a quasi-free translation of the cation in the disordered lattice, corresponding to the treatment of the inhibited rotator [29], can also provide only a qualitative explanation of such a variation of the specific heat. For quantitative interpretations, it is necessary to take into account the

difference $c_p - c_v$ between the measured and the calculated values (on the basis of the formula $c_p - c_v = \alpha^2 TV/\varkappa$); measurements of the coefficients of linear expansion α and of the compressibilities $\varkappa$ of the substances mentioned are now in progress [30].

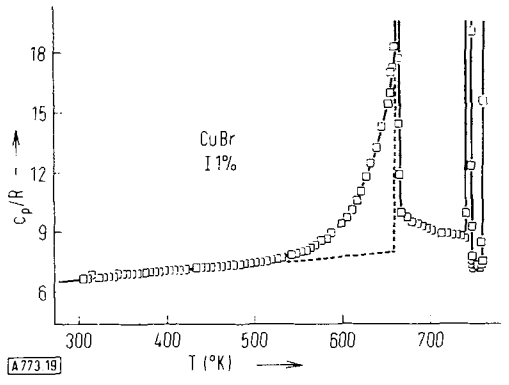

Fig. 19. Specific heat of CuBr.

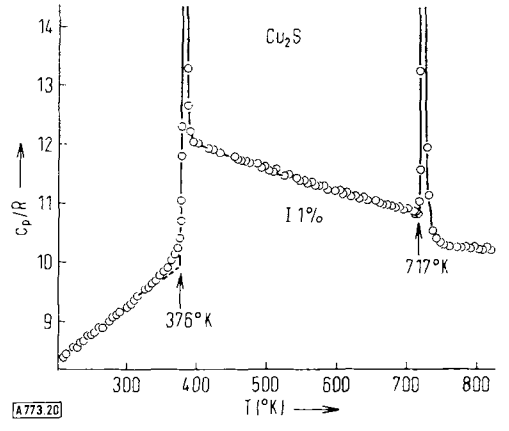

Fig. 20. Specific heat of Cu_2S.

The disorder data for alkali metal halides are particularly interesting. For example, Figures 21 and 22 show the results of c_p measurements on NaCl and NaBr [31]. The disorder data obtained from these assuming Schottky disorder are shown in Table 2. Comparison data from conductivity measurements agree well with these results. On the other hand, the degrees of disorder found in this way are higher by a factor of about 10 than the few known estimates [32, 33]. In connection with the results of measurements on metals, we must ask ourselves whether it is necessary to modify the simple evaluation method hitherto used for the anomalous specific heats.

It is very difficult to determine the intrinsic disorder for metals. Though the apparent activation energy ($E_f + U$) can be determined by diffusion measurements, U cannot be determined separately by a simple method similar to that used for ionic crystals. The only methods available are those based on density comparison and

on the increase in electrical resistance (cf. Section 3.2), which are not without complications.

Disorder data for metals can be obtained from anomalous specific heats. Some examples are shown in Figures 23 to 25. It can be seen from the diagrams, however, that the anomalous effect is about one order of magnitude smaller than for ionic crystals. The additional specific heats are only a few per cent of the total c_p. The measurements must therefore be accurate to within 1 promille if the additional component is to be determined to within a few per cent. It is also doubtful whether the extrapolation of the linear part is sufficiently accurate. We have found that the energy of disorder found for aluminum by the usual evaluation

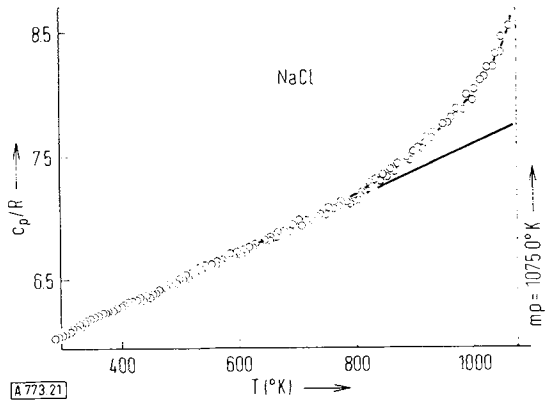

Fig. 21. Specific heat of NaCl.

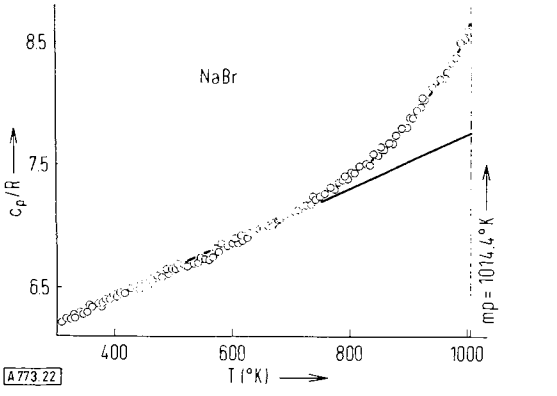

Fig. 22. Specific heat of NaBr.

agrees well with values obtained by other methods [15], whereas the degree of disorder is too large by a factor of 2. This deviation may be due to stronger anharmonicities of the lattice vibrations in the vicinity of the melting point. This difficulty may be overcome by conversion of the measured c_p values into c_v values. The specific heat at constant volume c_v should contain only very small components due to the anharmonicities of the lattice vibrations. This conversion and the corresponding evaluation [*] for aluminum gave agreement with the values reported by *Simmons* and *Baluffi* even in the degree of disorder (Table 2; in parentheses). The same evaluation method also seems to be called for in the case of the alkali metal halides. Unfortunately, however, the necessary coefficients of linear expansion and of compressibility are only very rarely known with sufficient accuracy for temperatures up to the melting point.

4.6. Outlook

In addition to the disorder properties, the temperature dependence of the specific heats of solids provides further important information which will not be discussed here. Apart from the surprising negative temperature coefficients, for which no conclusive explanation has yet been found, valuable information can be obtained from $c_p(T)$ measurements particularly on solid solutions. Phases in which temperature-dependent states of order occur exhibit a characteristic behavior. This has been known for a long time in the λ transitions of some metal alloys [52]. However, entropy considerations sometimes also provide a further insight into structural peculiarities in the case of ionic crystals [53]. Though thermal analysis is favored as a fairly economical method for the construction of phase diagrams, direct measurement of the specific heat may be prefer-

[*] In the conversion of c_p into c_v here it should be remembered that the macroscopic expansion coefficient contains the volume component of the Schottky disorder. To ensure that the defect component is retained in c_v, therefore, the expansion found from X-ray measurements must be used in the conversion formula [51].

able in complicated cases. For solid solutions, the absolute value of c_p and its variation with temperature often yield definite information about the nature of the phase present or of a phase transition.

Another group of problems surrounds the processes involved in delayed transitions. Here, particularly in connection with phenomena at critical phase separation points in the solid phase, we find difficult but extremely interesting applications of high-temperature calorimetry.

Polarity of Covalent Bonds

By Martin Klessinger [*]

The concept of "partial ionic character" has proved exceedingly valuable and fruitful as a qualitative description of the electronic structure of molecules; however, the theoretical ideas underlying the empirical relations for the determination of the ionic character of a bond do not bear critical examination. Even Mulliken's population analysis fails in many cases as a means of interpreting quantum-chemical calculations. On the other hand, a graphical representation of the spatial charge density distribution allows an intuitive interpretation even of complicated calculations, and (possibly in combination with an analysis of the forces acting on the atomic nuclei) yields very much farther-reaching information on the polarity of a bond than can be expressed by the values of some parameters on the basis of excessively simplified models.

"*I believe the chemical bond is not so simple as some people seem to think.*" *R. S. Mulliken* [1].

1. Introduction

A bond between two atoms A and B is described as polar if the distribution of the valence electrons shared by these two atoms is unsymmetrical, so that the centers of the negative electronic charge and of the positive nuclear charge do not coincide. Any bond between non-equivalent atoms is therefore more or less polar; nonpolar bonds occur only between identical atoms in identical environments, examples being the bonds in homonuclear diatomic molecules such as H_2 or N_2 and the C–C bond in ethane.

The concept of bond polarity is of great practical value for the qualitative understanding of the properties and reactions of chemical compounds. Thus the inductive effect exerted by a bond on its environment depends on its polarity, as does the reactivity or the mode of reaction of the bond.

It would be very useful if one could determine the polarity of a bond quantitatively, and so place any bond between the limiting cases of an ideal covalent bond with a symmetrical charge distribution and an ideal ionic bond with complete charge transfer. Numerous empirical equations have been established in order to attain this goal, and some of these will be described shortly. This will be followed by a brief discussion of the theoretical basis of the concept of bond polarity and a description of more recent results and views based on extensive quantum-chemical calculations. For the sake of simplicity, only diatomic molecules will be dealt with in Sections 2 to 5. It will finally be shown how the results obtained for diatomic molecules can be applied to polyatomic molecules.

2. Empirical Rules for the Determination of Bond Polarity

2.1. Partial Ionic Character

Pauling [2,3] introduced the concept of partial ionic character as a measure of the polarity of a bond. The partial ionic character I_{AB} of a two-electron bond A–B shows how much negative charge (in % of the charge of an electron) was transferred from one atom to the other as a result of bonding. For an ideal ionic bond, therefore, $I_{AB} = 100\%$, while for an ideal covalent bond with a symmetrical charge distribution, $I_{AB} = 0\%$. The partial ionic character cannot be

[3] *L. Pauling*: The Nature of the Chemical Bond. Cornell University Press, Ithaca, N.Y., 1939.

found experimentally, since even if charge distributions could be determined as accurately as one wished, it would still be necessary to make a more or less arbitrary division of the charge of a molecule into the components belonging to the individual atoms in order to be able to determine the partial ionic character. The ionic character of a bond must therefore be expressed by other quantities, which are better defined.

2.2. Bond Moments

Polar bonds have a dipole moment. It seems reasonable to correlate this bond moment with the partial ionic character. *Pauling* [3] determined the partial ionic characters of the hydrogen halides from the observed dipole moments μ and the internuclear distances R on the basis of the following argument. For a positive point charge and a negative point charge δe separated by a distance R, $\mu = \delta e \cdot R$; consequently, $100\,\mu/eR$ should give the charge transfer as a percentage of the charge e of an electron. From the experimental data for the dipole moments and internuclear distances (cf. Table 1), an ionic character of 17% is found in this way for HCl, 11% for HBr, and 5% for HI; *Pauling* estimated a value of 60% for the ionic character of HF.

The value of the partial ionic character found in this way must, however, seem questionable, since on the one hand the "theoretical" bond moment $\mu = eR$ (100% ionic character) is not reached even for an ideal ionic bond, owing to the mutual polarization of the charge distributions [4], and on the other the charge transfer is not the only factor that contributes to the bond moment. The dipole moment of a bond can be formally broken down into four components:

$$\mu = \mu_e + \mu_{at} + \mu_{hom} + \mu_{pol} \qquad (1)$$

The first term $\mu_e = \delta e \cdot R$ is the component of the dipole moment that results from the transfer of the charge δe from one atom to the other, and which alone is a measure of the polarity or partial ionic character of the bond. μ_{at} is the atomic dipole moment, which results from the asymmetry of the charge distribution in hybrid orbitals (Fig. 1a). μ_{hom} is the homopolar dipole moment due to the difference in the sizes of the orbitals (Fig. 1b), and μ_{pol} is due to the mutual polarization of the charge distributions as mentioned earlier. In practice, the individual contributions to the overall

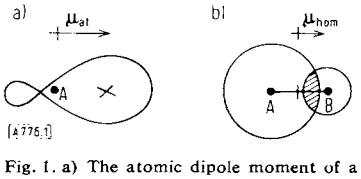

Fig. 1. a) The atomic dipole moment of a hybrid orbital. The atomic nucleus A is the center of positive charge and x is the center of negative charge.

b) The homopolar dipole moment. The accumulation of charge in the bond occurs in the shaded overlap region, which is not symmetrical with respect to the center of the line joining the nuclei.

dipole moment can only be isolated by calculation, and it is found that they often have different signs [5].

The following example illustrates how unsuitable the dipole moment of a bond is as a measure of its polarity. Since the C atom is more strongly electron attracting than the H atom, one should expect a transfer of charge δe from H to C in a C—H bond of methane; $\mu_e \approx 1$D when $\delta e = 0.2\,e$. The atomic moment can be estimated to be $\mu_{at} \approx 2$D [5], and is opposed to the moment μ_e due to the charge displacement. Despite the polarity C^-H^+, therefore, each bond of methane is found to have a bond moment whose direction is given by $\overset{+}{C}\!-\!\overset{-}{H}$, *i.e.* despite the charge transfer from H to C, the carbon forms the positive end of the dipole. These arguments are confirmed by quantum-chemical calculations for methane. The calculated values are $\delta e = 0.096\,e$ and $\mu_{CH} = 1.77$ D [6].

2.3. Nuclear Quadrupole Coupling Constants [7]

The nuclear quadrupole coupling constant eQq is the product of the quadrupole moment eQ of an atomic nucleus and the field gradient q, which gives the deviation of the potential V from spherical symmetry at the position of the nucleus. s electrons and complete inner shells have spherical charge distributions, and d and f electrons have practically no effect on the charge density in the vicinity of the nucleus; any asymmetry of the potential at the position of the nucleus is therefore mainly due to incompletely occupied p orbitals [8], so that to a good approximation, q is a measure of the occupancy of the p orbitals of an atom, and can thus be used for the estimation of the partial ionic character [8,9].

For the free Cl atom with one unoccupied p orbital, $eQq = -110$ MHz, while for the Cl^- ion with its spherically symmetrical charge distribution, $eQq = 0$. From the measured value $eQq = -75$ MHz [10] found for the Cl atom in CH_3–Cl, therefore, it follows that instead of one free p orbital as in the Cl atom, there is the fraction $(eQq)_{CH_3-Cl}/(eQq)_{Cl} = 0.68$ of an unoccupied p orbital.

$(eQq)_{AB}/(eQq)_B$ values for some diatomic molecules AB are given in Table 1. These values may be interpreted either in the sense that $[1-(eQq)_{AB}/(eQq)_B]$ electrons have been transferred from the atom A to the atom B in the molecule AB, or as indicating that the unoccupied orbital on the atom B is not a pure p orbital but a hybrid orbital with $100 \cdot [1-(eQq)_{AB}/(eQq)_B]$ % s character. Both the ionic character of a bond and the hybridization influence the value of the coupling constant, but both quantities cannot be determined from one measured value [11]. Information

R = internuclear distance (after [12]); μ = dipole moment (after [13]); $\Delta\chi_P$ and $\Delta\chi_M$ = differences $|\chi_A-\chi_B|$ in the Pauling and Mulliken electronegativities (after [14]); I_{AB} = ionic character, calculated from $\Delta\chi_P$ and from $\Delta\chi_M$ (values in parentheses); $(eQq)_{AB}/(eQq)_B$ = nuclear coupling constants (after [15]); I_{AB}(G) = ionic character after *Gordy* [10]. I_{AB}(DT) = ionic character after *Dailey* and *Townes* [15].
[a] Based on DBr; [b] based on DI; [c] after [17].

about the ionic character is consequently obtainable only if one can make plausible assumptions about the hybridization.

2.4. Electronegativity [18]

According to *Pauling* [3,19], the electronegativity χ_A is the ability of the atom A to attract electrons towards it in a molecule. It seems reasonable on the basis of this definition to assume the existence of a relation between the ionic character I_{AB} of a bond and the electronegativity difference $|\chi_A - \chi_B|$. *Pauling* [3] gave the relation

$$I_{AB} = 100\left[1-e^{-\frac{1}{4}(\chi_A-\chi_B)^2}\right] \quad (2)$$

while another formula was given by *Hannay* and *Smyth* [20]:

$$I_{AB} = 16\,|\chi_A-\chi_B| + 3.5\,|\chi_A-\chi_B|^2; \quad (3)$$

The latter is claimed to be more suitable for large values of $|\chi_A - \chi_B|$. *Gordy* [10,16] proposed a linear relation

$$I_{AB} = 50\,|\chi_A-\chi_B|, \quad (I_{AB} = 100 \text{ for } |\chi_A-\chi_B| \geqq 2) \quad (4)$$

whereas *Dailey* and *Townes* [15] reported an S-shaped relation between the partial ionic character and the electronegativity difference. These various relations are illustrated in Figure 2.

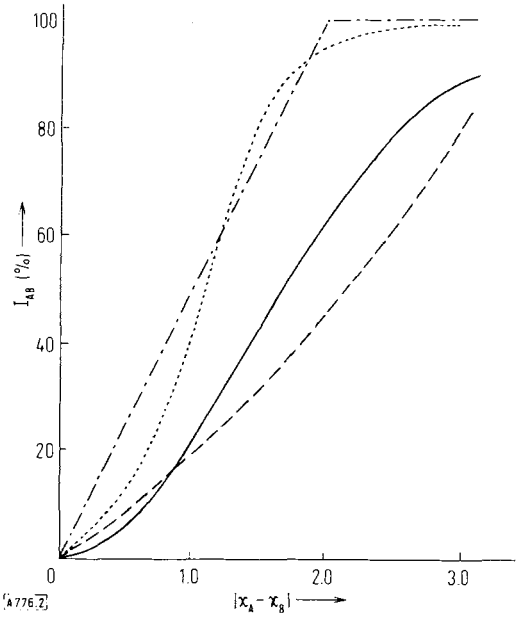

Fig. 2. Graphical representation of the relation between ionic character and electronegativity difference:
——— after *Pauling* [3], - - - - after *Hannay* and *Smyth* [20], — · — · — after *Gordy* [10, 16], · · · · after *Dailey* and *Townes* [15].

Equations (2) and (3) were derived on the basis of the values found for the partial ionic characters of the hydrogen halides from the dipole moments [21]. The ionic character values used by *Gordy* and by *Dailey* and *Townes*, on the other hand, were obtained from nuclear quadrupole coupling constants, but the hybridization was taken into account differently.

The four relations mentioned are clearly affected by all the inaccuracies that are associated with the determination of the polarity of a bond from the bond moments or the nuclear quadrupole coupling constants. Moreover, the electronegativity itself is not a measurable physical quantity which can be rigorously defined, but is an empirical quantity in certain greatly simplified models of the chemical bond. It is therefore pointless to try to determine electronegativity differences with great accuracy.

In Table 1, the differences in the electronegativity values determined by *Pauling* [3] from bond energies

[21] *Hannay* and *Smyth* based their equation on the dipole moment of HF, which was determined by them for the first time, and which corresponds to an ionic character $I_{HF} = 43\%$, whereas the value estimated by *Pauling* was $I_{HF} = 60\%$.

are given for some diatomic molecules under $\Delta\chi_P$, while $\Delta\chi_M$ are the differences in the absolute electronegativity values defined according to *Mulliken*[22] by the ionization potential I_A and the electron affinity E_A of the valence state as follows:

$$\chi_A = {}^1/_2 (I_A + E_A) \tag{5}$$

Columns 6 and 8 of Table 1 contain the values of the partial ionic character calculated from eq. (2), eq. (3), and eq. (4). It is clear from the data in this table and from earlier remarks that the concept of the partial ionic character (as it was defined here as an empirical quantity) can certainly be useful for qualitative treatments, but that the quantitative data found in many textbooks for ionic character (Be–F 79 %, Be–O 63 %, *etc.*) are probably of no great significance.

3. Theoretical Principles of the Determination of the Partial Ionic Character

3.1. VB Method

The concept of partial ionic character is closely linked historically with the VB (valence bond) expression for the wave function Ψ of a diatomic molecule A–B, which can be written in the form[23]

$$\Psi = C_1 \{\varphi_A(1)\varphi_B(2) + \varphi_B(1)\varphi_A(2)\} + C_2\varphi_A(1)\varphi_A(2) + C_3\varphi_B(1)\varphi_B(2) \tag{6}$$

where the constants C_1, C_2, and C_3 are determined according to the variation principle by minimizing the energy calculated using the wave function Ψ. The first term in eq. (6), the Heitler-London function[24], is described as the covalent part of the wave function, and expresses the situation that one of the two indistinguishable electrons 1 and 2 is situated on the atom A and the other on the atom B, and that they can be described by the atomic orbitals (AOs) φ_A and φ_B of these atoms. The second and third terms take into account the case in which both electrons are situated on the atom A or on the atom B, and so characterize the ionic component of the wave function.

If A is more strongly electron-attracting than B, the probability of finding both electrons on the atom B will be very small, so that the third term in eq. (6) may be neglected, and the wave function can be written in the form

$$\Psi = \psi_{cov} + \lambda\psi_{ion} \tag{7}$$

λ is then regarded as a measure of the polarity of the bond, and $100\,\lambda^2/(1+\lambda^2)$ as the definition of the percentage ionic character[2].

Clear as this theoretical model appears at first sight, however, its physical significance is doubtful[25,26]. To see this, one must remember that all physical states, as eigenstates of a Hamiltonian operator, are described by orthogonal wave functions. The covalent and ionic components ψ_{cov} and ψ_{ion} in eq. (7), on the other hand, are not orthogonal to each other, but are linearly dependent[27]. Thus ψ_{cov} and ψ_{ion} do not describe physically realizable states; they can be broken down in any number of ways into mutually orthogonal components, but it cannot be decided in the model used here which of these breakdowns is physically meaningful.

The linear dependence of ψ_{cov} and ψ_{ion} is best demonstrated geometrically for the extensively studied example of the H_2 molecule. A normalized[28] wave function ψ can be represented as a unit vector in function space. The scalar product of two such vectors ψ_1 and ψ_2 is given by $\int\psi_1^*\psi_2 d\tau = S_{12} = \cos\theta$, where θ is the angle between ψ_1 and ψ_2; if ψ_1 and ψ_2 are orthogonal, this means that $S_{12} = 0$ and $\theta = 90°$. The normalized wave functions for the covalent and ionic components of the bond in the H_2 molecule are

$$\psi_{cov} = \frac{1}{\sqrt{2\,(1+S^2)}}\,[\varphi_A(1)\varphi_B(2) + \varphi_B(1)\varphi_A(2)]$$

and (8)

$$\psi_{ion} = \frac{1}{\sqrt{2\,(1+S^2)}}\,[\varphi_A(1)\varphi_A(2) + \varphi_B(1)\varphi_B(2)]$$

since C_2 and C_3 in eq. (6) must be equal on symmetry grounds. $S = \int\varphi_A^*(1)\varphi_B(1)dv_1$ is the overlap integral of the AOs φ_A and φ_B, and

$$\int\psi_{cov}\psi_{ion}d\tau = \frac{2S}{1+S^2} \tag{9}$$

For the equilibrium distance, this corresponds roughly to an angle $\theta = 20°$. These relations are shown graphically in Figure 3, where the x axis corresponds to the correct wave function for the ground state of the H_2 molecule, which is purely covalent by definition, whereas the y axis defines the orthogonal, purely ionic state[29]. It can be seen from this

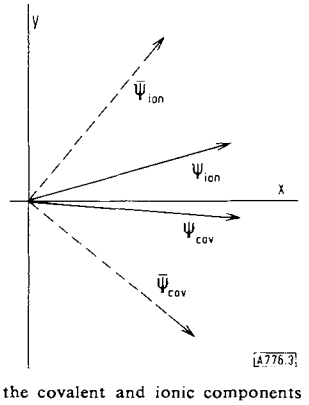

Fig. 3. Vector representation of the covalent and ionic components ψ_{cov} and ψ_{ion} (nonorthogonal AOs φ_A and φ_B in eq. (8)) and $\bar{\psi}_{cov}$ and $\bar{\psi}_{ion}$ (orthogonal AOs $\bar{\varphi}_A$ and $\bar{\varphi}_B$ in eq. (8)) of the wave function for the H_2 molecule (after [27]).

[28] A wave function ψ is said to be normalized if $\int\psi^*\psi\,d\tau = 1$, where $\int d\tau$ denotes the integration over the entire definition range of all variables.

[29] Only these two states can be obtained as the solution of the Schrödinger equation if a wave function with a covalent and an ionic component is used.

vector representation that while ψ_{cov} is a good approximation for the covalent ground state, ψ_{ion} is far from describing the ionic state.

One might assume that the intuitive model could be rescued if φ_A and φ_B in eq. (8) were replaced by orthogonal AOs $\bar{\varphi}_A$ and $\bar{\varphi}_B$, since S is then automatically zero, and $\bar{\psi}_{cov}$ and $\bar{\psi}_{ion}$ are orthogonal. However, $\bar{\psi}_{cov}$ describes a state that is shown by the calculation to be not bonding [27], and which is in no way suitable for the definition of the partial ionic character (cf. Fig. 3) [25].

3.2. Population Analysis

The polarity of a bond would be known if the electronic charges on the individual atoms could be determined. The spinless one-electron density function $P(1)$, which describes the electron distribution in a molecule, thus seems a more suitable starting point for a discussion of bond polarity than the very special VB expression chosen by *Pauling*. Irrespective of the quantum-chemical approximation, $P(1)$ is defined for any N-electron wave function $\Psi(1, \ldots N)$ by [25, 30]

$$P(1) = N \int |\Psi(1,\ldots N)|^2 ds_1 d\tau_2 \ldots d\tau_N \qquad (10)$$

$\int ds_1$ is the integration over the spin coordinates of electron 1, and $\int d\tau_2 \ldots d\tau_N$ is the integration over the (space and spin) coordinates of all the other electrons.

$P(1)dv_1$ is the probability of finding an electron with any spin, and irrespective of the positions and spins of the other electrons, in the volume element dv_1. Integration of $P(1)$ over a volume enclosing the atom A gives the number $\bar{N}_A$ of electrons in the vicinity of A. The number of electrons transferred from the vicinity of A to the vicinity of B is then equal to $1/2|\bar{N}_A - \bar{N}_B|$, so that the partial ionic character of a bond A–B is given by $I_{AB} = 50 \cdot |\bar{N}_A - \bar{N}_B|$. The methodical difficulty now lies entirely in defining the "vicinity of A".

The definition of the vicinity of an atom is the purpose of the population analysis introduced by *Mulliken* [31], which is based on the following idea. In nearly all quantum-chemical calculations one starts from a basis of atomic orbitals φ_μ, *i.e.* the total wave function of a molecule is expanded in terms of functions that are centered on the individual atoms, and which therefore differ appreciably from zero only in the neighborhood of an atom. The calculation of $P(1)$ then involves squared terms $|\varphi_\mu(1)|^2$ and mixed terms $\varphi_\mu^*(1)\varphi_\nu(1)$, which are known on suitable normalization as orbital and overlap densities [32]

$$\rho_\mu(1) = |\varphi_\mu(1)|^2 \quad \text{und} \quad \rho_{\mu\nu}(1) = \varphi_\mu(1)\varphi_\nu(1)/S_{\mu\nu} \qquad (11)$$

where $S_{\mu\nu} = \int \varphi_\mu^*(1)\varphi_\nu(1)dv_1$ is the overlap integral of the AOs φ_μ and φ_ν.

$\rho_\mu(1)$ describes the electron distribution in the orbital φ_μ (*i.e.* in the neighborhood of the atom A if φ_μ is centered on A), and $\rho_{\mu\nu}(2)$ describes the electron distribution in the region where φ_μ and φ_ν are both different from zero (*i.e.* between the atoms A and B if φ_μ is centered on A and φ_ν on B).

With the aid of these orbital and overlap densities, $P(1)$ can be written in the form

$$P(1) = \sum_\mu q_\mu \rho_\mu(1) + 1/2 \sum_{\substack{\mu\,\nu \\ (\mu \neq \nu)}} \sum q_{\mu\nu}\rho_{\mu\nu}(1) \qquad (12)$$

where, owing to the normalization of $\rho_\mu(1)$ and $\rho_{\mu\nu}(1)$, it follows from

$$N = \int P(1)dv_1 = \sum_\mu q_\mu \int \rho_\mu(1)dv_1 + 1/2 \sum_{\mu \neq \nu} \sum q_{\mu\nu} \int \rho_{\mu\nu}(1)dv_1$$

that

$$\sum_\mu q_\mu + 1/2 \sum_{\mu \neq \nu} \sum q_{\mu\nu} = \sum_\mu (q_\mu + 1/2 \sum_{\nu \neq \mu} q_{\mu\nu}) = N \qquad (13)$$

q_μ and $q_{\mu\nu}$ being the orbital and overlap charges (populations). If a formal charge p_μ of the orbital φ_μ is defined by

$$p_\mu = q_\mu + 1/2 \sum_{\nu \neq \mu} q_{\mu\nu} \qquad (14)$$

then $\sum_\mu p_\mu = N$, *i.e.* the sum of the formal charges is equal to the total number of electrons in the molecule [33]. Summation of the formal charges of all the AOs φ_μ centered on the atom A gives the formal atomic charge

$$p_A = \sum_{\mu(A)} p_\mu \qquad (15)$$

which allows the division of the overall charge density into components belonging to the individual atoms. The charge transferred from the atom A to the atom B is then equal to $1/2|p_A - p_B|$, and the partial ionic character is given by $I_{AB} = 50\,|p_A - p_B|$.

As an example, let us consider a molecule AB with the AOs φ_A and φ_B (μ = A or B). Let us calculate the density function $P(1)$, the orbital and overlap charges q_A, q_B, and q_{AB}, and the formal atomic charges p_A and p_B for a Heitler-London function

$$\psi(1,2) = 1/\sqrt{2(1+S^2)}\,\{\varphi_A(1)\varphi_B(2) + \varphi_B(1)\varphi_A(2)\}$$

and for a simple MO function

$$\Phi(1,2) = \{c_A\varphi_A(1) + c_B\varphi_B(1)\}\{c_A\varphi_A(2) + c_B\varphi_B(2)\}:$$

VB function:

$$P(1) = N\int\psi^2(1,2)dv_2$$

$$= \frac{2}{2(1+S^2)}\,[\int\varphi_A^2(1)\varphi_B^2(2)dv_2 + 2\int\varphi_A(1)\varphi_B(1)\varphi_B(2)\varphi_A(2)dv_2 + \int\varphi_B^2(1)\varphi_A^2(2)dv_2]$$

$$= \frac{1}{1+S^2}\,[\varphi_A^2(1) + 2S\varphi_A(1)\varphi_B(1) + \varphi_B^2(1)]$$

i. e. $q_A = q_B = \frac{1}{1+S^2}$, $q_{AB} = \frac{2S^2}{1+S^2}$ and

$$p_A = p_B = \frac{1}{1+S^2} + \frac{S^2}{1+S^2} = 1;$$

[30] *R. McWeeny*, Rev. mod. Physics *32*, 335 (1960).

[31] *R. S. Mulliken*, J. chem. Physics *23*, 1833 (1955).

[32] *R. McWeeny*, J. chem. Physics *19*, 1614 (1951).

[33] *Ruedenberg* [34] refers to the components q_μ and $1/2\sum q_{\mu\nu}$ in eq. (14) as the "valence inactive fraction" and the "valence active fraction", respectively, of the formal charge, since a chemical bond is produced by an accumulation of charge between the atoms.

[34] *K. Ruedenberg*, Rev. mod. Physics *34*, 326 (1962).

MO function:

$$P(1) = N\int\Phi^2(1,2)dv_2$$
$$= 2\int[c_A^2\varphi_A^2(1) + 2c_Ac_B\varphi_A(1)\varphi_B(1) + c_B^2\varphi_B^2(1)] \times$$
$$[c_A^2\varphi_A^2(2) + 2c_Ac_B\varphi_A(2)\varphi_B(2) + c_B^2\varphi_B^2(2)]dv_2$$
$$= 2\,[c_A^2\varphi_A^2(1) + 2c_Ac_B\varphi_A(1)\varphi_B(1) + c_B^2\varphi_B^2(1)]$$

i. e. $q_A = 2c_A^2$, $q_B = 2c_B^2$, $q_{AB} = 4\,Sc_Ac_B$ and

$$p_A = 2[c_A^2 + Sc_Ac_B],\ p_B = 2[c_B^2 + Sc_Ac_B]$$

For homonuclear diatomic molecules, $c_A = c_B = 1/\sqrt{2(1+S^2)}$ and it follows that $p_A = p_B = 1$, in agreement with the result of the VB calculation and the definition of the partial ionic character, which must be zero in this case.

In general, eq. (15) assumes the form

$$p_A = \sum_i \eta_i \sum_{\mu(A)} [c_{\mu i}^2 + \sum_\nu c_{\mu i}c_{\nu i}S_{\mu\nu}] \qquad (16)$$

in the LCAO–MO method [31], the sum over i extending over all MOs $\Phi_i = \sum_\mu c_{\mu i}\varphi_\mu$ with the occupation number η_i ($\eta_i = 2$, 1, or 0). Eq. (16) is the definition of *Mulliken*'s "gross atomic population", which is therefore identical with the formal charge that is defined rather more generally in equations (14) and (15). ($q_A = \sum_i \eta_i \sum_{\mu(A)} c_{\mu i}^2$ is referred to by *Mulliken* as the "net atomic population").

A relation can also be qualitatively derived within the MO method between the ionic character as defined by the formal charges and the electronegativity [35], but despite this apparently closed relation between formal charge, ionic character, and electronegativity difference, the definition of the partial ionic character on the basis of the population analysis is not yet entirely satisfactory. The results of the population analysis can depend very strongly on the choice of the AOs; physically meaningful results can be expected only if a sufficient number of AOs is used for each atom, corresponding to its electronic structure, and also only if AOs that can describe the polarization of the atomic charge distribution on molecule formation are used. Such a basis is described by *Mulliken* [36] as a formally balanced basis set [37].

The difficulty of deciding whether a basis is formally balanced is shown by the example of two very extended calculations for the HF molecule [39,40], both of which give almost the exact Hartree-Fock energy ($E = -100.0575$ and $E = -100.0571$ a.u.) and practically the same electron density function $P(1)$. However, the population analysis leads to the very different values $p_H = 0.52$ and $p_H = 0.77$ for the formal charge density on the H atom [41]. It must be concluded that a formally unbalanced basis of atomic orbitals was used in one calculation (or in both).

Thus the overall electron density in the molecule can in principle be broken down into the components belonging to the various atoms by *Mulliken*'s population analysis. However, the practical use of this method requires that a check be made in every case, *e.g.* by increasing the number of basis AOs in steps, to ensure that the basis is in fact formally balanced.

4. Graphical Representation of the Electron Distribution

4.1. The One-Electron Density Function $P(1)$

Whereas the result of the population analysis can depend on the choice of the AOs, the density function $P(1)$ is independent of this provided that sufficiently high accuracy of the calculation (the "Hartree-Fock approximation") has been achieved [42]. It seems reasonable, therefore, to use the density function $P(1)$ directly for the characterization of a bond, instead of trying to use it to derive simple numerical values such as the formal charge.

Figure 4 shows the density functions $P(1)$ for first row diatomic hydrides AH in the form of contour diagrams. These and the following diagrams were calculated by *Bader et al.* [44–46] and are based on molecular Hartree-Fock calculations by *Cade et al.* [47]; the accuracy of the diagrams is therefore sufficient to show all the essential features of the chemical bond.

The extent r_A and r_H of the density function $P(1)$ on the atoms A and H along the molecular axis away from the bond (measured to the last contour line shown here, which corresponds to $0.002\ e/a_0^3 \approx 0.01\ e/Å^3$; cf. Fig. 6) can be read off from Figure 4.

The differences Δr_A and Δr_H between these quantities for the molecules and for the isolated atoms are shown in Figure 5 for the diatomic hydrides of the first and second rows (the density diagrams of the hydrides of the second row [46] are so

[35] Cf. *e.g.* [14].

[36] *R. S. Mulliken*, J. chem. Physics *36*, 3428 (1962).

[37] The wave function of a molecule can be expanded in terms of any complete set of basis functions, *i.e.* also in terms of AOs that are all centered on the same atom A. One-center expansions of this kind have been successfully carried out for molecules with a heavy central atom, such as CH_4 or NH_3 [38]; results of any desired accuracy can in principle be obtained in this way for physical quantities such as energy and dipole moment, and also for the density function $P(1)$. The population analysis, on the other hand, gives the formal charge $p_A = N$ for the atom A and $p_R = 0$ for all other atoms R. According to *Mulliken*, therefore, a one-center expansion is a physically balanced but formally unbalanced basis.

[41] *C. W. Kern* and *M. Karplus*, J. chem. Physics *40*, 1374 (1964).

[42] Not only does this emerge from the example of the two Hartree-Fock calculations for the HF molecule (Section 3.2), but it can also be shown in general [41] that the Hartree-Fock density function differs from the true density function at most in terms of the second order of smallness. *Bader* and *Chandra* [43] have also shown explicity for the H_2 and Li_2 molecules how small the changes in $P(1)$ are when one goes beyond the Hartree-Fock approximation.

similar to those of the hydrides of the first row that they need not be reproduced here). In both series the r_A and r_H values as well as the Δr_A and Δr_H values decrease with increasing atomic number of A, *i.e.* the charge density is increasingly concentrated on the atomic nuclei. LiH and NaH at the beginning of the series appear to be exceptions as far as the charge on the Li or Na nucleus is concerned; this can be readily explained by the fact that Li and Na have only one valence electron, which is evidently transferred to the H atom in the hydride.

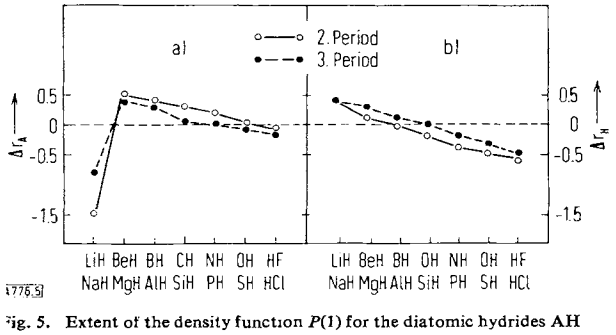

Fig. 5. Extent of the density function $P(1)$ for the diatomic hydrides AH of the first and second rows. a) Difference Δr_A between r_A in the molecule AH and in the isolated atom A, b) difference Δr_H between r_H in the molecule AH and in the isolated H atom [in Bohr radii a_0 ($1a_0$ = 0.52917 Å)] (after [46]).

The charge transfer from Li or Na to H is also seen in the "nonbonded charges" $\tilde{p}_A$ and $\tilde{p}_H$, where $\tilde{p}_A$ and $\tilde{p}_H$ are the fractions of the charge that are situated in the shaded region of the atom A and of the atom H respectively in Figure 6; $\tilde{p}_A$ for an isolated atom A is thus exactly equal to half of the nuclear charge Z_A.

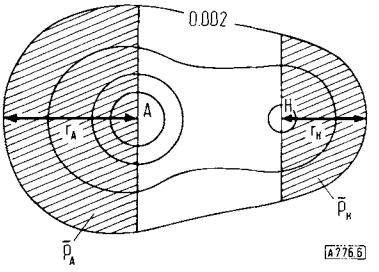

Fig. 6. Definition of the extent r_A and r_H of the density function $P(1)$ and of the nonbonded charge $\tilde{p}_A$ and $\tilde{p}_H$.

It can be seen from Figure 7 that the decrease $\Delta\tilde{p}_A$ in the nonbonded charge $\tilde{p}_A$ as compared with the isolated atom is approximately 0.5 *e* for LiH and NaH, as would be expected for an ideal ionic bond. $\Delta\tilde{p}_A$ is also negative for BeH and MgH; for the other hydrides of the first and second rows,

$\Delta\tilde{p}_A$ is positive, $\tilde{p}_A$ being almost constantly 0.22 and 0.1 *e*, respectively, higher than in the free atom. The difference $\Delta\tilde{p}_H$ between the nonbondet charge on the proton in the molecule and on the isolated H atom decreases from positive values for LiH and NaH to negative values for HF and HCl.

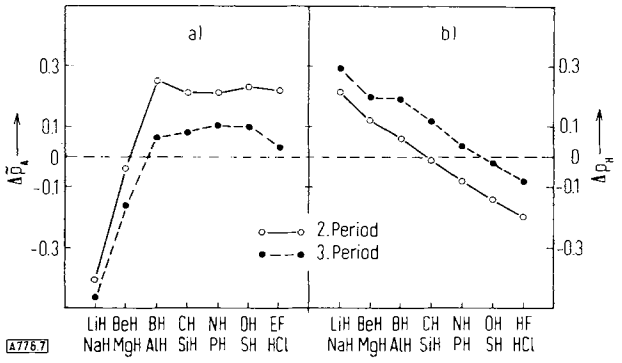

Fig. 7. Nonbonded charge for the diatomic hydrides of the first and second rows: a) Difference $\Delta\tilde{p}_A$ between $\tilde{p}_A$ in the molecule AH and in the isolated atom A, b) difference $\Delta\tilde{p}_H$ between $\tilde{p}_H$ in the molecule AH and in the isolated H atom [in electronic charge units *e*] (after [46]).

Both the extent of the density function and the nonbonded charges indicate that charge is transferred from the heavy atom to H in LiH and NaH, whereas charge transfer in the opposite direction, *i.e.* from the proton to the heavy atom, occurs to an increasing degree in the series BeH to HF; this is confirmed by the decrease in the number of contour lines that surround only the proton. The charge transfers are only slight in SiH to HCl.

4.2. Density Difference Diagrams

The density diagrams shown in Figure 4 give a good picture of the overall charge distribution in the molecule, but many details are not shown with sufficient prominence. A very much more detailed picture of the charge rearrangement associated with molecule formation is obtained by subtracting the density functions $P_R(1)$ of the isolated atoms R at the same internuclear distance from the density function $P(1)$ of the molecule [48]. Density difference diagrams of this type, *i.e.* contour diagrams of the function $\Delta P(1) = P(1) - \sum_R P_R(1)$, are shown in Figure 8 together with the profile of the charge density difference $\Delta P(1)$ for LiF and N_2 as typical examples of molecules having an ionic and a homonuclear covalent bond [44]. The difference in appearance of these diagrams for the two extreme types of bonds is obvious.

Any chemical bond, whether covalent or ionic, results from a charge accumulation between the atomic nuclei that is sufficient to counterbalance the forces of repulsion between the nuclei. In the purely covalent bond, the electrostatic equilibrium results from the removal of charge from the atoms and its symmetrical concentration between the nuclei; at the same time the charge remaining on the atoms experiences a strong polarization directed away from the bond (Fig. 8). In the ionic bond, on the other hand, the electrostatic equilibrium is achieved by a highly unsymmetrical rearrangement of the charge. The increase in charge is mainly concentrated on one nucleus, *i.e.* the zero contour of the region of increased charge encloses only one nucleus; polarization of the charge also occurs in the direction opposite to that of the charge transfer (cf. Section 5.2).

Figure 9 shows the density difference diagrams for the diatomic hydrides AH of the first row [45], which are substantially the same as the corresponding diagrams for the hydrides of the second row [46].

The diagrams for LiH and NaH, which differ markedly from those of the other molecules, are very similar to the corresponding diagram for LiF, and so point to ionic bonding of the type Li^+H^- and Na^+H^-. The characteristics of covalent bonding predominate in the series BeH to HF and MgH to HCl, though differences from the diagram of the first member of the series become increasingly noticeable, particularly in the hydrides of the first row. The main increase in charge still occurs between the nuclei; whereas it practically includes both nuclei in BH, it is clearly concentrated on the heavy atom in HF, corresponding to a polarity F^-H^+. At the same time an increasingly pronounced decrease in charge on the side of the proton away from the bond is observed in the series BH to HF. The ionic character of the A—H bond thus increases steadily from BH to HF. BeH as well as MgH and AlH occupy intermediate positions between the ionic bond in LiH and NaH and the covalent bond in BH and in SiH, PH, SH, and HCl, which is difficult to characterize.

5. The Hellmann-Feynman Theorem and the Forces Acting on the Atomic Nuclei

It can be seen from the density difference diagrams that in the discussion of the polarity of a bond, the size of the spatial regions of increased or decreased charge is equally important as the number of electrons on the individual atoms. Both the quantity of charge and its precise distribution are taken into account in the determination of the forces that hold the atomic nuclei of a molecule together.

5.1. The Hellmann-Feynman Theorem

According to the Hellmann-Feynman theorem [49,50], for two atoms A and B separated by a distance R, the force $F_A(R)$ acting on the nucleus A, which has a nuclear charge Z_A, is equal to the force calculated by classical electrostatics from the electron density distribution $P(1)$ and the point charge Z_B on the nucleus B:

$$F_A(R) = \frac{Z_A}{R^2}\left[Z_B - R^2 \int \frac{P(1)\cos\theta_A}{r_A^2}\, dv_1\right] \qquad (17)$$

r_A is the distance from the electron 1 to the nucleus A, and θ_A is the angle between the line joining the nuclei

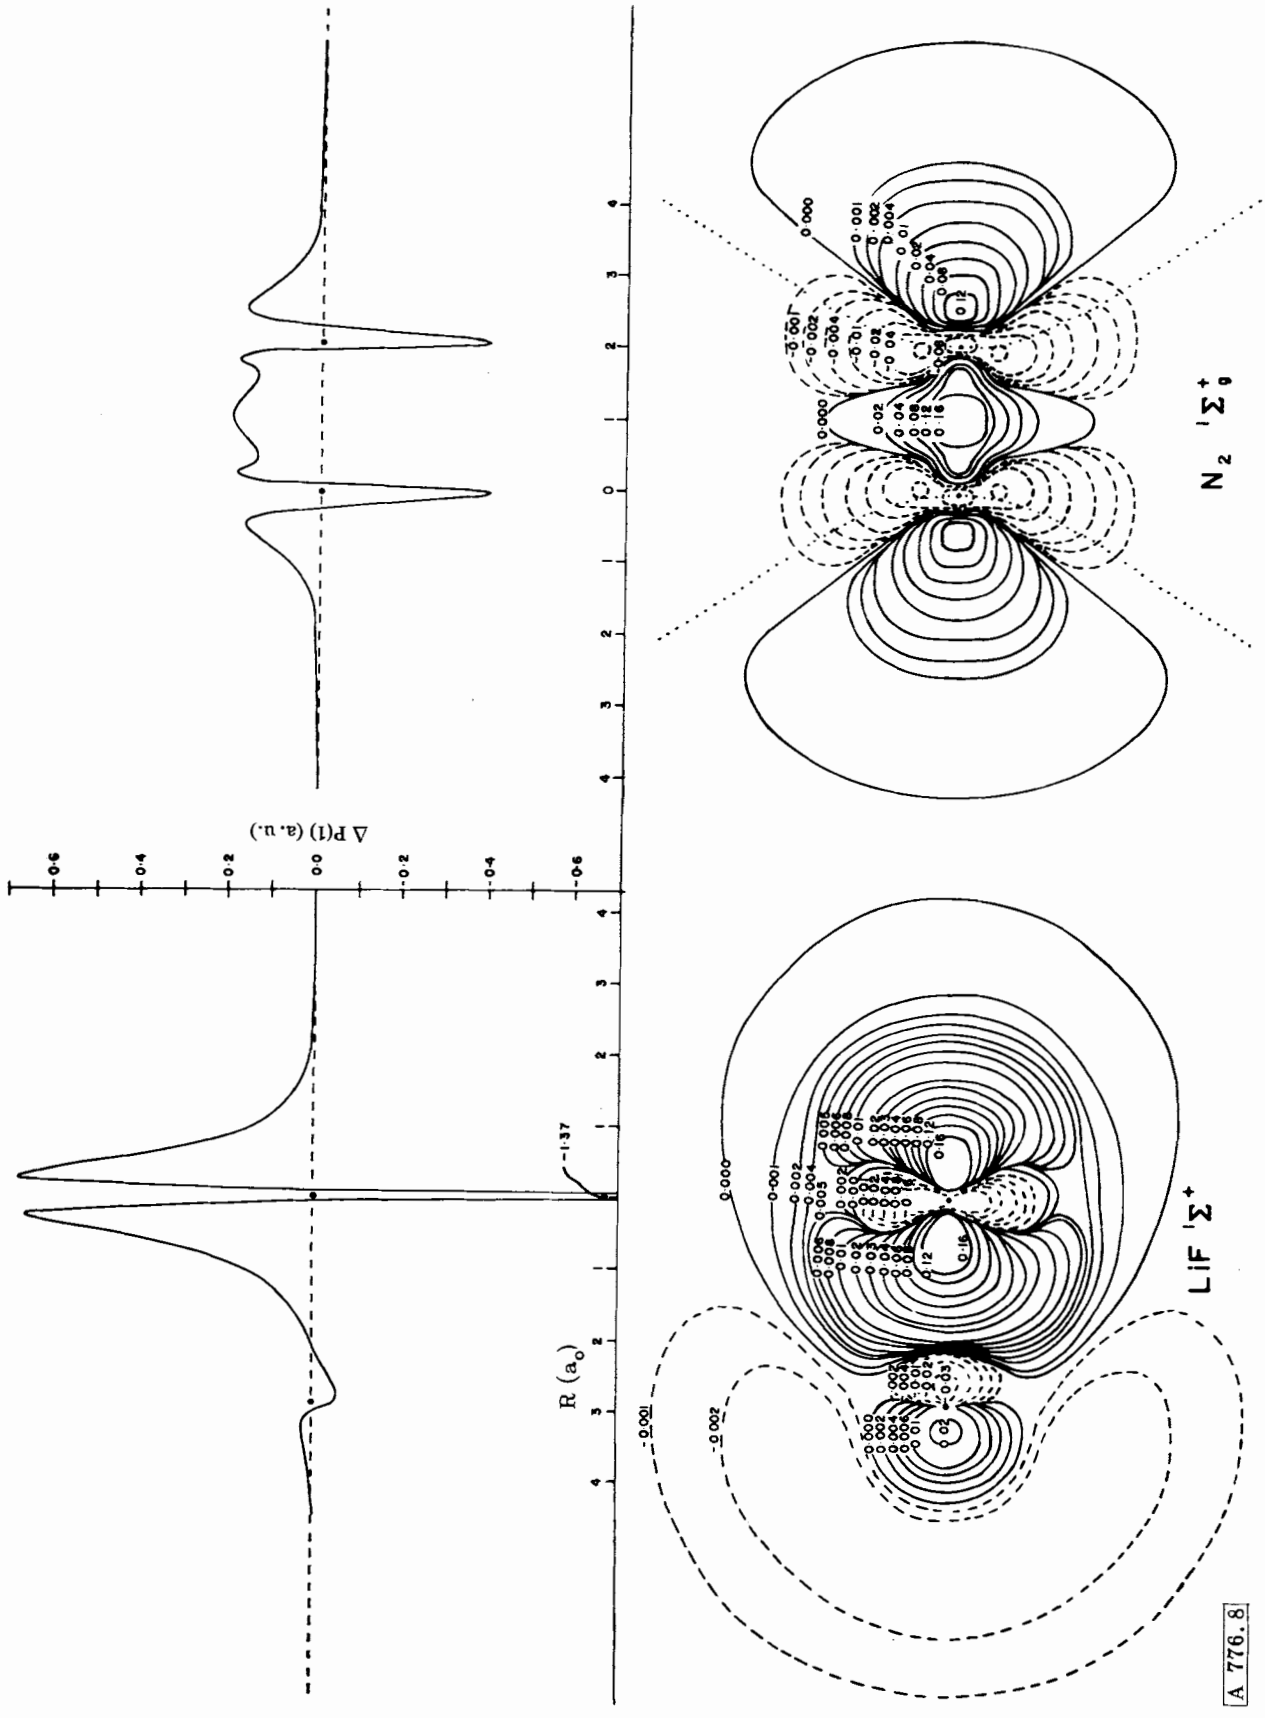

Fig. 8. Contour diagrams and profile of the density difference function $\Delta P(1)$ for LiF and N_2 as examples of an ionic and a covalent bond (after [44]).

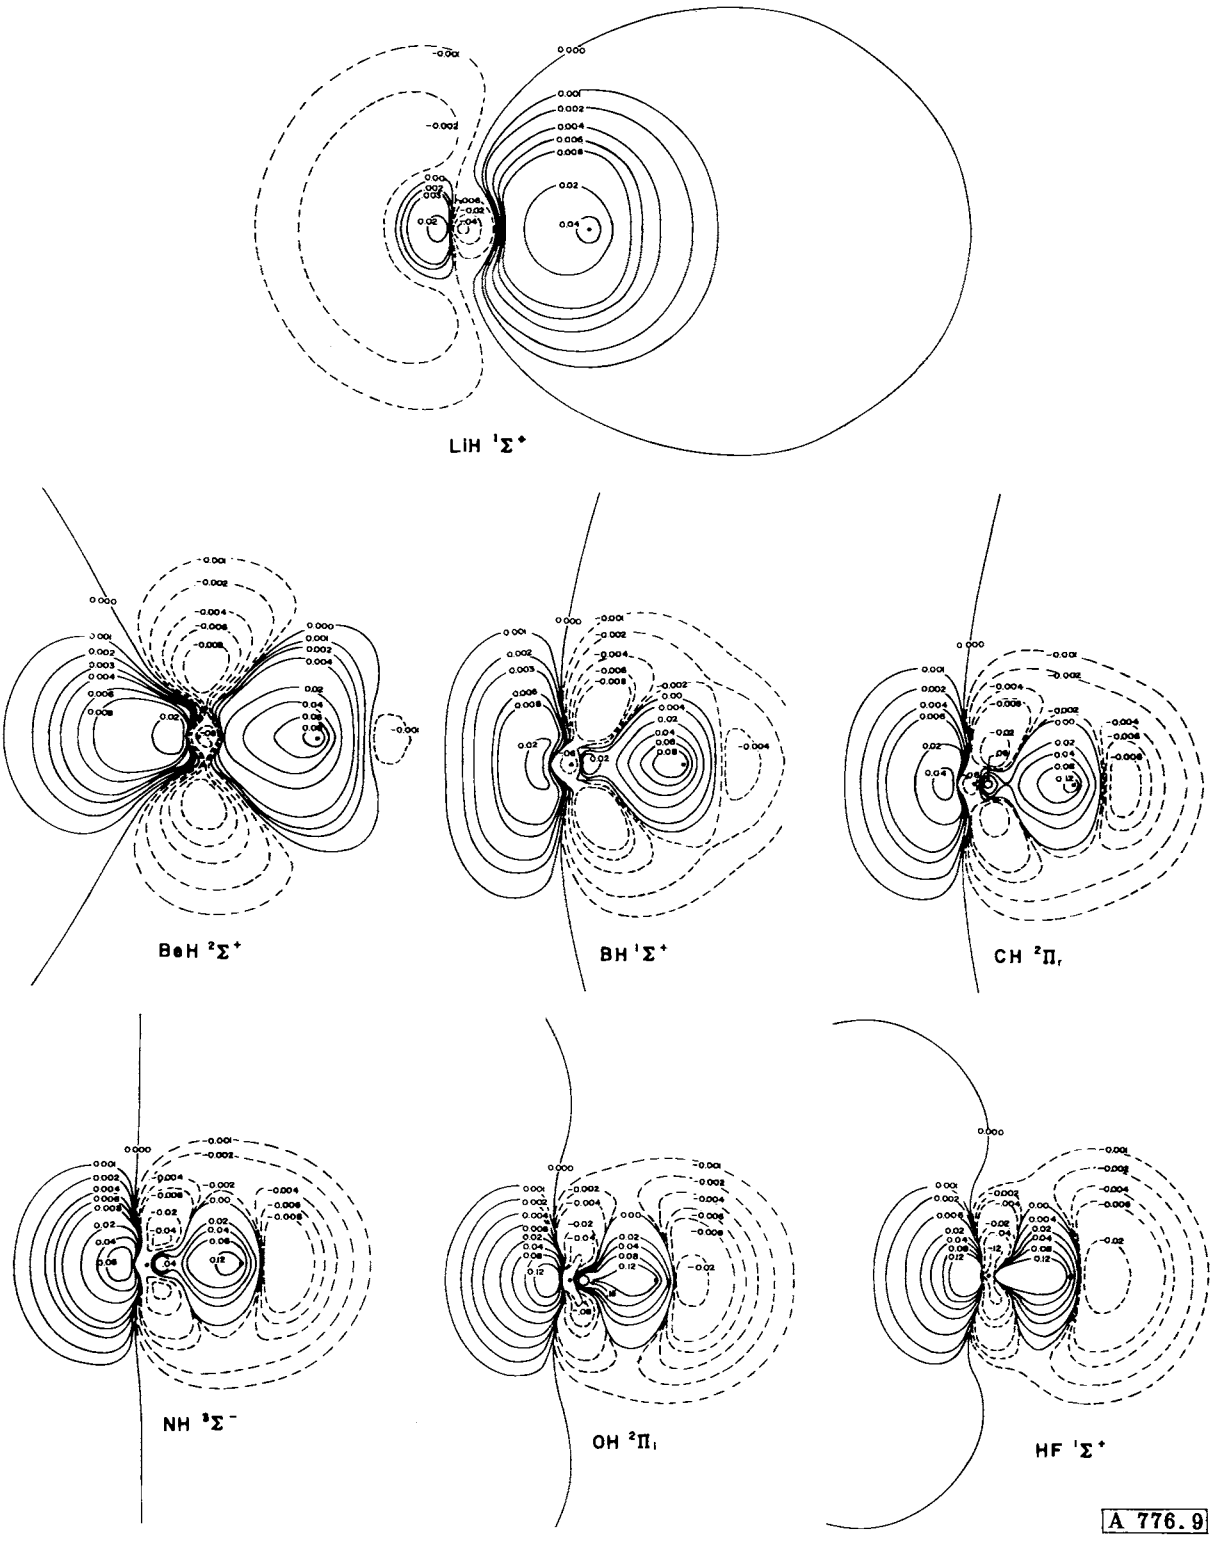

Fig. 9. Density difference diagrams for the diatomic hydrides AH of the first row (after [45]).

and the direction of r_A. By introduction of the abbreviation

$$f_A = R^2 \int \frac{P(1)\cos\theta_A}{r_A^2}\, dv_1 \qquad (18)$$

the force acting on the atom A can be written in the form [51]

$$F_A(R) = \frac{Z_A}{R^2}\,[Z_B - f_A] \qquad (19)$$

f_A/R^2 is the electrostatic force exerted by the charge density $P(1)$ on each unit of nuclear charge of the nucleus A. f_A has the dimensions of a charge, and is numerically equal to the point charge q_B on the nucleus B that would exert the same electrostatic force on A. f_A may therefore be described as the charge equivalent of the force acting on A.

[51] *R. W. F. Bader* and *G. A. Jones*, Canad. J. Chem. *39*, 1253 (1961).

For a diatomic molecule AB, the relation

$$F_A(R) = -F_B(R) \tag{20}$$

is valid for any internuclear distance R, *i.e.* the forces acting on the nuclei A and B are equal and opposite. The forces vanish for $R = \infty$ and for the equilibrium distance R_e, so that according to eq. (19) we have

$$f_A = Z_B;\ f_B = Z_A \quad (\text{for } R = R_e \text{ and } R = R_\infty) \tag{21}$$

5.2. Breakdown of the Charge Equivalents

If one assumes that a basis of AOs φ_μ were used in the calculation of $P(1)$, one obtains three additive contributions to f_A (and similarly to f_B) for a diatomic molecule A–B, corresponding to the breakdown of the charge density in accordance with eq. (12) [44]:

1. the atomic contribution $f_A^{(AA)}$, which is due to the charge density $\sum_{\mu(A)} q_\mu \rho_\mu(1)$ on the atom A,
2. the overlap contribution $f_A^{(AB)}$, which is due to the overlap density $^1/_2 \sum_{\mu \neq \nu} \sum q_{\mu\nu} \rho_{\mu\nu}(1)$, and
3. the screening contribution $f_A^{(BB)}$, which is due to the charge density $\sum_{\mu(B)} q_\mu \rho_\mu(1)$ on the atom B, and which indicates how many units of positive charge of the nucleus B are screened by this charge distribution [52].

A comparison of the atomic, overlap, and screening contributions of the charge equivalents for a molecule at the equilibrium distance R_e with the limiting values for the separated atoms ($R \rightarrow \infty$) shows clearly the changes in the charge distribution that are responsible for molecule formulation. The forces acting on the atomic nuclei and the charge rearrangement as illustrated by the $\Delta P(1)$ diagram are mutually complementary characterizations of a bond.

For the separated atoms ($R = \infty$) of a molecule A–B, the atomic contributions $f_A^{(AA)}$ and $f_B^{(BB)}$ and the overlap contributions $f_A^{(AB)}$ and $f_B^{(AB)}$ are zero, while the screening contributions are given by $f_A^{(BB)} = Z_B$ and $f_B^{(AA)} = Z_A$; the electric field of the electron distribution of an isolated neutral atom must therefore exactly balance the field of the nucleus.

In a covalent bond, both atomic nuclei are incompletely screened, and the resulting mutual repulsion of the nuclei is balanced by the forces due to the accumulation of charge between the nuclei. For the N_2 molecule, as an example of a pure covalent bond, the values obtained are as follows [44]. The screening contribution $f_A^{(BB)} = 5.136$ is considerably smaller than the nuclear charge number $Z_N = 7$, but the repulsion of the incompletely screened nuclei is more than compensated by the overlap contribution $f_A^{(AB)} = 3.853$. The atomic contribution ($f_A^{(AA)} = -1.943$) must therefore be negative, corresponding to polarization of the charge away from the bond, to satisfy $f_A \equiv f_A^{(AA)} + f_A^{(AB)} + f_A^{(BB)} = Z_B$ in accordance with eq. (21) [53] (cf. the $\Delta P(1)$ diagram in Fig. 8).

For an ideal ionic bond A^+B^-, the overlap contributions $f_A^{(AB)}$ and $f_B^{(AB)}$ should disappear, while the screening contributions of the anion and of the cation should be $f_A^{(BB)} = Z_B + 1$ and $f_B^{(AA)} = Z_A - 1$, owing to the charge transfer. To satisfy $f_A = Z_B$ and $f_B = Z_A$, therefore $f_A^{(AA)} = -1$ and $f_B^{(BB)} = +1$, *i.e.* the increased screening of the anion exerts an attraction on the nucleus of the cation, which is compensated by polarization of the charge on the cation away from the bond; conversely, the repulsion of the nucleus of the anion by the incompletely screened nucleus of the cation is compensated by polarization of the charge on the anion into the bond (cf. the $\Delta P(1)$ diagram in Fig. 8).

The f values to be expected on the basis of these arguments for a pure ionic bond in LiF are given in the first line of Table 2, while the values in the second line are found by calculation. It can be seen from the density difference diagram for LiF (Fig. 8) that the increase in charge in the region between the atoms is completely localized on the F atom.

Table 2. Contributions of the charge equivalents of the forces acting on the nuclei for LiF LiH, and NaH (after [44–46]).

AB	Forces acting on the cation A $f_A^{(AA)}$	$f_A^{(AB)}$	$f_A^{(BB)}$	Forces acting on the anion B $f_B^{(BB)}$	$f_B^{(AB)}$	$f_B^{(AA)}$	
LiF	−1.0	0.0	10.0 (=Z_F+1)	1.0	0.0	2.0 (=Z_{Li}−1)	[a]
	−0.710	0.346	9.511	0.068	0.985	2.041	[b]
	−0.71	—	9.86	1.05	—	2.04	[c]
LiH	−1.0	0.0	2.0 (=Z_H+1)	1.0	0.0	2.0 (=Z_{Li}−1)	[a]
	−0.616	0.732	0.890	0.225	0.573	2.226	[b]
	−0.62	—	1.62	0.80	—	2.23	[c]
NaH	−1.0	0.0	2.0 (=Z_H+1)	1.0	0.0	10.0 (=Z_{Na}−1)	[a]
	−0.392	0.105	1.354	0.528	0.410	10.059	[b]
	−0.39	—	1.46	0.94	—	10.06	[c]

[a] Ideal ionic bond. [b] Calculated; breakdown according to eq. (12). [c] Calculated; breakdown according to $\Delta P(1)$.

[52] $\sum_{\mu(A)}$ as in eq. (15) means that the summation is to be carried out over the μ that relate to AOs φ_μ centered on the atom A.

[53] The deviation from zero of the force F_A acting on the atomic nuclei A is a measure of how well a given wave function satisfies the Hellmann-Feynman theorem. Since the Hellmann-Feynman theorem is valid not only for the exact wave function but also for the Hartree-Fock function [50], the accuracy with which a given wave function satisfies the Hartree-Fock approximation can be established on the basis of the f_A and f_B values.

If this is taken into account by adding the overlap contributions $f_{Li}^{(LiF)}$ and $f_{F}^{(LiF)}$ to the contributions $f_{Li}^{(FF)}$ and $f_{F}^{(FF)}$ due to the charge density on the F atom, we obtain the f values given in the third line of Table 2, in very good agreement with the model of the pure ionic bond.

5.3. Diatomic Hydrides of the First and Second Rows

The f values and their individual contributions are given in Table 3 for the diatomic hydrides AH of the first and second rows [45,46].

The incomplete screening of the nucleus A (cf. the column $Z_A - f_H^{(AA)}$ in Table 3) is more pronounced in the second row than in the first; thus the unscreened nuclear charge of the F atom in HF is 0.88 charge unit, as compared with 2.05 for the Cl atom in HCl. Screening of the proton is also stronger in the hydrides of the second row than in those of the first; the effective charge on the proton in NaH, MgH, and AlH is increased by 0.35, 0.17, and 0.09 unit respectively.

Table 3. Contributions of the charge equivalents of the forces acting on the nuclei for the diatomic hydrides of the first and second rows (after [45, 46]).

AH	$f_H^{(HH)}$	$f_H^{(AH)}$	$f_H^{(AA)}$	$Z_A - f_H^{(AA)}$	F_H [a]	$f_A^{(AA)}$	$f_A^{(HA)}$	$f_A^{(HH)}$	$Z_H - f_A^{(HH)}$	F_A [a]

[a] Forces in a.u., $e^2/a_0^2 = 8.2378 \times 10^{-3}$ dyne.

The overlap contributions in the first row increase at first, pass through a maximum for BH, and then decrease again to HF. For the hydrides of the second row, the overlap contributions increase continuously from NaH to HCl, and unlike in the first row, the overlap density here does not exert a greater force on the proton than on the nucleus A.

BH and CH are typical examples of molecules with a covalent bond. Both nuclei are incompletely screened, and the overlap contributions of the forces acting on the two nuclei are large and approximately equal. The bond becomes increasingly polar from NH to HF, and the nucleus A increasingly determines the overall charge distribution. In the second row, on the other hand, the influence of the nucleus A on the charge distribution does not predominate, and distinctly polar bonds such as those in OH and HF are not observed; the molecules SiH to HCl all exhibit the characteristics of typical covalent bonds. In these molecules, however, the distribution of the valence electrons is much more strongly determined by the proton than in CH and BH.

The individual contributions of the f_A and f_H values for LiH and NaH, on the other hand, exhibit the characteristics seen in the case of the LiF molecule for an ionic bond. If one considers that on the basis of the density difference diagram, the increase in charge in the region between the nuclei in LiH and NaH is completely localized on the proton, one obtains the values given in the sixth and ninth lines of Table 2 for the atomic and screening contributions of f_A and f_H, which are not very different from the values to be expected for an ideal ionic bond [54]. The forces exerted on the proton by the Li and Na atoms correspond to a point charge distribution $Li^{+0.8}$ $H^{-0.8}$ and $Na^{+0.9}$ $H^{-0.9}$, which are close to the ionic limiting value found *e.g.* in $Li^{+1}F^{-1}$. Since the charge distribution on the anion is very diffuse while that on the cation is very compact (in comparison with the neutral atom in both cases), a molecular charge distribution appears more or less ionic according to whether it describes the electric field acting on the anion or that acting on the cation. Thus according to Table 3, the forces acting on the Li and Na nuclei in LiF, LiH, and NaH correspond to a point charge distribution $Li^{+0.9}F^{-0.9}$, $Li^{+0.6}H^{-0.6}$, and $Na^{+0.5}H^{-0.5}$. NaH is now less ionic than LiH, the reason being that the increase in charge on the proton is more diffuse in NaH than in LiH.

The values found from the dipole moments for the ionic character of the molecules LiH and HF are $I_{LiH} = 77\%$ and $I_{HF} = 39\%$, while those obtained from the electronegativity differences are $I_{LiH} = 26\%$ and $I_{HF} = 59\%$. The same arguments that have shown that the bond in LiH is essentially ionic while that in HF is essentially covalent also show why the dipole moment and the electronegativity difference lead to different results for the ionic character [55]. The overlap contributions $f_{Li}^{(LiH)}$ and $f_{H}^{(LiH)}$ in LiH differ less than the corresponding quantities in HF, and on this basis

[54] It is interesting to compare the bonding in LiH and in HF, which comes closest to the ionic limiting case A^-H^+. If as in the case of LiH the overlap component of the force acting on the cation is added to the corresponding screening contribution for HF, the resulting value (8.988) is smaller than the nuclear charge $Z_F = 9$, whereas one would expect $Z_F + 1 = 10$ for an ionic bond. While the bond in LiH may be described as ionic with a small covalent component, therefore, the bonds in the series NH, OH, and HF must be regarded as covalent with increasing ionic character.

[55] *R. W. F. Bader* and *W. H. Henneker*, J. Amer. chem. Soc. *88*, 280 (1960).

one would expect a stronger ionic character in HF than in LiH. Unlike in HF, however, the atomic contributions in LiH (as expected for an ionic bond) point to polarization of the charge in the direction opposite to that of the charge transfer, so that the dipole moment gives a very much stronger ionic character for LiH than the electronegativity difference.

It is clear from these last examples why all attempts to characterize the ionic character of a bond by a number or a percentage must be unsuccessful. The type of chemical bond is determined by the total molecular charge distribution, which cannot be described by a simple number.

6. Polyatomic Molecules

Some brief indication should now be given of how far the results described in the last few sections are applicable to polyatomic molecules, since it is clear that the concept of the polarity of a bond can be chemically useful only if its applicability is not restricted to diatomic molecules.

Density and density difference diagrams can be calculated for polyatomic molecules, but their interpretation involves new difficulties. If one wishes to discuss *e.g.* the properties of the bonds A–B and B–C of a triatomic molecule A–B–C, one must decide which of the two bonds was responsible for the characteristic charge rearrangement on the central atom. This will frequently not be immediately possible. (Similar arguments apply to the forces acting on the individual atomic nuclei.)

Before any discussion of the properties of individual bonds in a polyatomic molecule can be possible, therefore, the quantum-mechanical many-electron problem must be broken down into a series of two-electron problems. This allows a separate treatment of any bond, the influence of the inner electrons and of the electrons of other bonds being taken into account by an effective potential for the bonding electrons.

These ideas are in agreement with a suggestion by *Hurley*, *Lennard-Jones*, and *Pople*[56] that the wave function $\Psi(1, \ldots N)$ of a polyatomic molecule should be written as an antisymmetric product of localized two-electron functions $\Phi_R(1,2)$:

$$\Psi(1, \ldots N) = \mathcal{A}\,[\Phi_A(1,2)\Phi_B(3,4) \ldots \Phi_R(N-1, N)] \qquad (22)$$

This expression is the basis of the self-consistent group function (SCGF) method[57], which also enables many-electron groups to be taken into account, and which satisfies all the requirements for a discussion of the polarity of the bonds of polyatomic molecules in the manner described here for diatomic molecules.

SCGF calculations have so far been carried out only with a minimal basis of atomic orbitals, but even these calculations show that interesting results may be expected from a systematic analysis of the polarity of bonds in polyatomic molecules[58]. Thus a population analysis shows that the polarity of the CH bond in substituted methanes CH_3–X depends in a characteristic manner on the nature of the group X[59], or that in multiple bonds, the charge transfer in the σ-bond takes place in the direction to be expected from the electronegativity difference, whereas a smaller charge transfer in the opposite direction may occurs in the π-bonds[60].

Other methods for the interpretation of the charge distribution of a polyatomic molecule are based on the construction of orbitals localized in the bonds from a delocalized total wave function of the molecule[61]. However, these localized orbitals cannot be obtained without arbitrary additional assumptions, and different localization procedures sometimes yield different results.

7. Conclusion

Coulson[62] said in 1951: "It might humorously be said that there is a kind of uncertainty relation about our knowledge of molecular structure: the more closely we try to describe the molecule, the less clearcut becomes our description of its constituent bonds." However, it appears that studies of the type described here will be able to cast doubt on the validity of this "uncertainty relation", since as sufficiently accurate calculations are carried out on more and larger molecules, we shall also learn to read the information contained in the charge distribution that characterizes a molecule. The decisive factor that makes this possible is that the density function $P(1)$ is defined quite generally and independently of the quantum-chemical approximation used. The results of even the most complicated quantum-chemical calculations can therefore be represented graphically by density diagrams, which contain much farther-reaching, chemically important information than one can express by values of a few parameters on the basis of excessively simplified models.

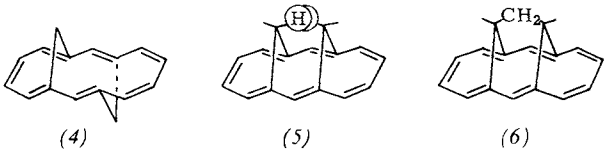
anti-1,6:8,13-Bismethano[14]annulene[1]

By *Emanuel Vogel*, *Ulrich Haberland*, and *Harald Günther*[*]

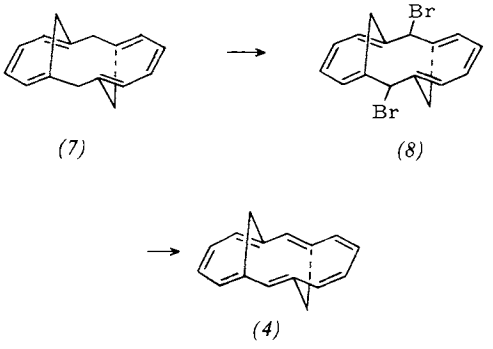


The synthesis and aromaticity of 1,6-methano[10]annulene [*(1)*, X = CH_2][2] and of its analogs with a hetero atom bridge [*(1)*, X = O or NH] suggested the existence of a homologous series of bridged annulenes *(1)*, *(2)*, *(3)*, *etc.*, whose members are formally derived from naphthalene, anthracene, naphthacene, *etc.*, by insertion of the bridges X into the bonds common to two rings and which, like the parent hydrocarbons, contain $(4n + 2)$ π-electrons. The "device of bridging" thus allows the well-known acene series to be converted into a series of $[4n + 2]$annulenes.

(1) *(2)* *(3)*

The presence of more than one bridge implies that there will be a *syn*- and an *anti*-form for the [14]annulenes *(2)* and three forms (*syn-syn*-, *syn-anti*-, and *anti-anti*-) for the [18]-annulenes *(3)*. Since the Hückel rule can be considered valid up to the 22 π-electron system[3], it depends essentially on the geometry of the annulene ring whether the aromaticity established for *(1)* extends to the higher homologs.

Inspection of Dreiding and space-filling models of the bridged [14]- *(2)* and [18]-annulenes *(3)* leads to the following conclusions: 1. In the *syn*-configuration of the [14]annulenes the annulene ring can assume an approximately planar conformation provided that no steric interaction occurs between the bridges. 2. In the *anti*-configuration of the [14]annulenes the $2p_z$ orbitals of the C_3 segments consisting of neighboring bridgehead atoms and the C atom (of the annulene ring) between them are considerably skewed with respect to one another. 3. For the *syn-syn*-configuration of the [18]annulenes the steric conditions resemble those in the *syn*-configuration of the [14]annulenes. 4. Extension of the annulene ring from 10 to 14 or 18 C atoms eases the restraint on the bridge angle and allows the ring for the *syn*- and *syn-syn*-configurations of the bridged [14]- and [18]-annulenes to approach planarity more closely than *(1)*.



(4) *(5)* *(6)*

These conclusions have recently been substantiated for the *syn*-[14]annulenes (in absence of appreciable steric interference of the bridges) by preparation of the carmine-red *syn*-1,6 : 8,13-bisoxido[14]annulene[4].

We have now synthesized the *anti*-1,6 : 8,13-bismethano[14]-annulene *(4)*, and its properties also verify our ideas regarding the *anti*-configurations of the [14]annulenes. *syn*-1,6 : 8,13-Bismethano[14]annulene *(5)*, on the other hand, has so far defied all attempts at synthesis. It seems questionable whether *(5)* would possess aromatic character since the inner H atoms of the bridge will most probably force the annulene ring to be bent. If, however, these hydrogen atoms are replaced by a CH_2 group one obtains 1,6 : 8,13-propanediylidene[14]-annulene *(6)*[5, 2d] in which the annulene ring is approximately planar, as in *syn*-1,6 : 8,13-bisoxido[14]annulene; *(6)* is thus to be regarded as the actual *syn*-analog of *(4)*.

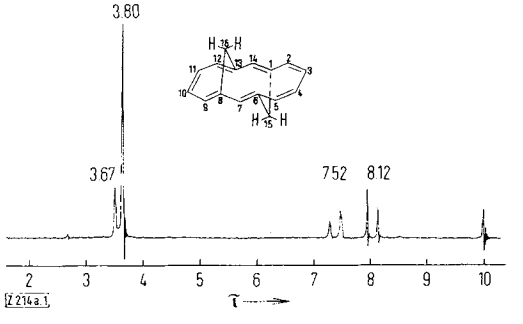
Synthesis of *(4)* was accomplished by reaction of 7,14-dihydro-*anti*-1,6 : 8,13-bismethano[14]annulene *(7)*[6] with 2 moles of *N*-bromosuccinimide and treatment of the resulting dibromide *(8)* (presumably a mixture of *cis-trans*-isomers) with sodium iodide in acetone under nitrogen. The hydrocarbon *(4)* produced forms lemon-yellow crystals of m.p. 41—42 °C [yield 58%, based on *(7)*] and, in striking contrast to *syn*-1,6 : 8,13-bisoxido[14]annulene and 1,6 : 8,13-propanediylidene[14]annulene, has a sensitivity to oxygen reminiscent of polyenes such as vitamin A, though it can be stored for months under nitrogen.

(7) *(8)*

(4)

The [14]annulene structure of the hydrocarbon and the nature of its π-electron system follow unambiguously from the NMR spectral findings:

In the room-temperature NMR spectrum (Fig. 1) the annulene protons are observed as two singlets at τ = 3.67 (2 H) and 3.80 (8 H), while the bridge protons are found as an AB system at τ = 7.52 and 8.12 with J = 11.0 Hz (4 H). The position of the proton resonances excludes an aromatic structure with a delocalized 14π electron system *(9)*, and yet a polyene



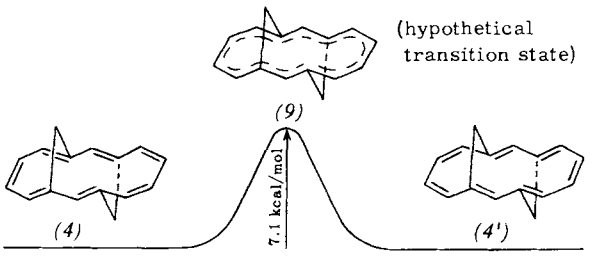


Fig. 1. NMR spectrum of *anti*-1,6:8,13-bismethano[14]annulene *(4)* at room temperature (in $CDCl_3$; 60 MHz, tetramethylsilane as internal standard).

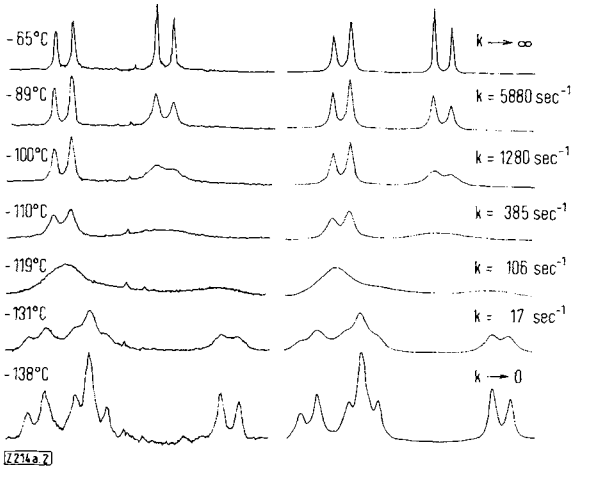
structure with fixed double bonds *(4)*, containing not less than nine different types of protons, cannot be reconciled with the paucity of lines actually observed. Low-temperature NMR measurements cast light upon the structural question: The simplicity of the spectrum is due to a dynamic process which on the NMR time scale confers C_{2h} symmetry on the molecule above −60 °C and, in addition, to an accidental equivalence of the mean values $(\tau_{2,5} + \tau_{9,12})/2$ and $(\tau_{3,4} + \tau_{10,11})/2$ (see below). Between −70 and −120 °C all the signals except the singlet at τ = 3.67 show considerable exchange broadening. The changes in the line shape of the signals cease at about −130 °C, where a spectrum is observed corresponding to the polyene structure *(4)*. This consists of two AA'BB' systems at τ = 3.43 (H-10, H-11) and 3.93 (H-9, H-12), and 3.66 (H-2, H-5) and 4.26 (H-3, H-4), the unchanged singlet at τ = 3.67 (H-7, H-14), and two AB systems at τ = 7.33 and 7.71, as well as 7.61 and 8.53, each with coupling of 11.0 Hz.

The nature of the changes in the line shape of the NMR spectrum of *(4)* caused by lowering the temperature (Fig. 2) leads to the conclusion that the dynamic process is a double-bond migration, *i.e.*, a valence tautomerism [*(4)* ⇄ *(4')*].

To determine the kinetic parameters of the double-bond migration the line shape of the bridge-proton resonances between —70 and —138 °C was simulated by standard techniques[7]. The excellent agreement obtained between the calculated and the experimental spectra is shown in Figure 2. Insertion of the rate constants measured between —84 and —131 °C into the Arrhenius equation gave an activation energy of 7.1 kcal/mole and a frequency factor of $10^{12.2}$.



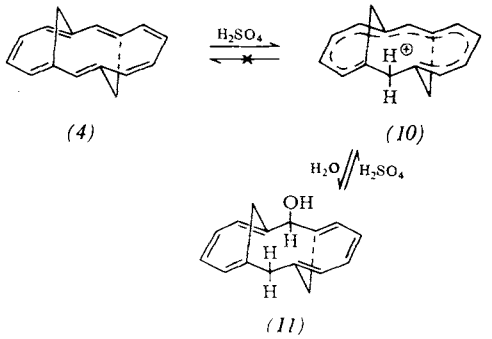


Fig. 2. Absorption of the bridge protons of *(4)* in dependence on temperature [in COS/CS_2 (80 : 20); 100 MHz]; on the left the experimental, on the right the calculated spectra together with the respective rate constants.

The double-bond migration is most plausibly explained by assuming that the resonance hybrid *(9)* constitutes the transition state. An alternative to this would be a series of electrocyclic reactions with the (hitherto unobserved) norcaradiene valence isomer of *(4)* as an intermediate.

anti-1,6 : 8,13-Bismethano[14]annulene satisfies the Hückel rule with respect to the number of π-electrons, yet the hydrocarbon obviously deviates so far from planarity that the delocalization energy is insufficient for equalization of the C—C bonds. Thus in *(4)* the structure with localized bonds is lower in energy than the resonance hybrid.

The UV spectrum of *(4)* can be interpreted in terms of a polyene system [maxima at 217 (ε = 33600), 272 (7800), and 350 nm (4350) (in cyclohexane)].

The olefinic nature of *anti*-1,6 : 8,13-bismethano[14]annulene *(4)* is manifested also in its chemical properties. *(4)* is protonated selectively at C-7 by concentrated sulfuric acid, with formation of the remarkably stable carbonium ion *(10)*. If the dark red solution of *(4)* in H_2SO_4 is added to water, the alcohol *(11)* (m.p. 146—147 °C) is obtained. Analogously, with bromine in methylene chloride at —70 °C *(4)* gives the dibromide *(8)* (steric homogeneity not confirmed) which shows no tendency to form the 7-bromo derivative of *(4)* by elimination of hydrogen bromide.

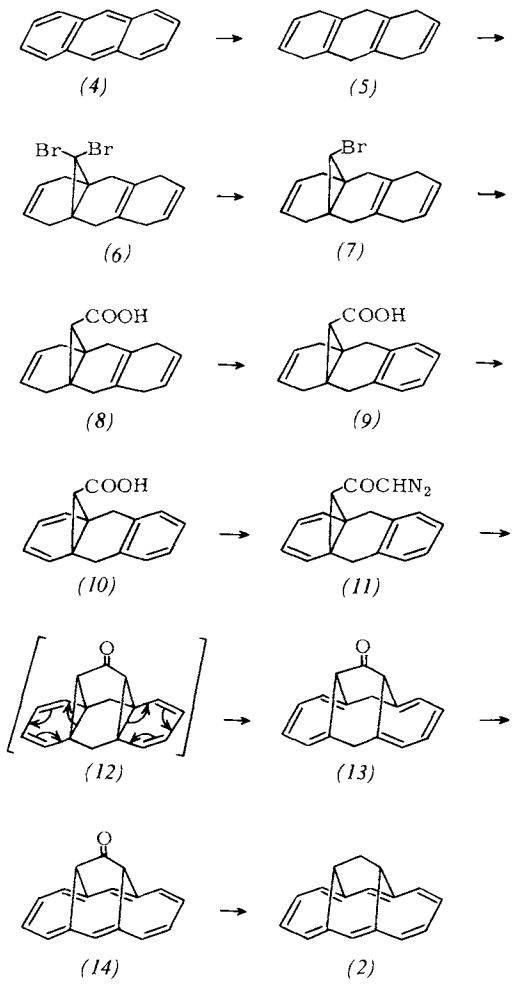
1,6:8,13-Propanediylidene[14]annulene[1,2]

By *Emanuel Vogel, Axel Vogel, Hans-Klaus Kübbeler*, and *Wolfgang Sturm*[*]



For comparative studies of [4*n* + 2]annulenes it would be desirable to have an annulene series available whose members molecules closely agree in those geometrical properties that are relevant to π-electron delocalization — configuration[3], conformation, and rigidity. In the series of monocyclic [4*n* + 2]annulenes there are considerable differences in this respect[4], so that correlations are possible only to a limited extent.

(1) *(2)* *(3)*

Inspection of models drew our attention to the series 1,6-methano[10]annulene *(1)*[5], 1,6 : 8,13-propanediylidene-[14]annulene *(2)*, and 1,6 : 8,17 : 10,15-pentane-1′,3′,5′-triylidene[18]annulene *(3)*. Since the members of this series show a wealth of common features — they have the same symmetry (acene configuration), have an approximately planar annulene ring, and are completely rigid — they should be particularly suitable for comparison. The synthesis and properties of 1,6 : 8,13-propanediylidene[14]annulene *(2)* justify the expectations placed upon the [4*n* + 2]annulene series *(1)*, *(2)*, and *(3)*.

The synthesis of 1,6 : 8,13-propanediylidene[14]annulene[6] started from 1,4,5,8,9,10-hexahydroanthracene *(5)*[7] which is readily obtained from anthracene *(4)* by way of 9,10-dihydroanthracene. The tetraene *(5)* was treated in tetrahydrofuran with three-molar amounts of bromoform and potassium *tert*-butoxide, thus giving a 20% yield of the 1 : 1 dibromocarbene adduct *(6)*, m.p. 121—122 °C. Reducing *(6)* with tri-*n*-butyltin hydride afforded a product that, according to its NMR spectrum, consisted of the required *endo*-bromide *(7)* (*endo* with respect to the central six-membered ring) and its *exo*-isomer in the ratio 1 : 1. The monobromide mixture was treated at −80 °C with butyllithium, and the resulting organolithium compounds were subsequently allowed to react with solid carbon dioxide at the same temperature. There resulted a 2 : 1 mixture of the *endo*-acid *(8)* [22% based on *(6)*; m.p. 186—188 °C] and the *exo*-acid [m.p. ≈ 200 °C (dec.)], which could be separated by chromatography on silica gel. The configurations of these acids could not be deduced unequivocally from the spectra but follow from bromination studies on the dehydrogenation products [*(9)* and its *exo*-isomer] obtained by means of palladium-charcoal; the dehydrogenated acid [*(9)*; m.p. 180—182 °C] formed in 47% yield from the acid of m.p. 186—188 °C reacted with bromine to give a normal dibromo adduct [m.p. 213—214 °C (dec.)], whereas the isomeric dehydrogenated acid afforded a bromo lactone.

The intention to build the bridge at the *endo*-acid stage *(8)*[8] met with difficulties, for reaction of *(8)* with thionyl or oxalyl chloride gave a β-chloro ketone instead of the expected acid chloride. It was therefore proposed to form the bridge starting from either the acid *(9)* or *(10)*. The dibromo adduct of acid *(9)* was readily dehydrohalogenated by methanolic potassium hydroxide to the acid *(10)* which contained the norcaradiene skeleton [yield 51% based on *(9)*; m.p. 215—217 °C (dec.); NMR ($CDCl_3$), τ = 2.92 (s, 4 arom. CH), 3.7—4.2 (AA'BB' system with a N value of 10.5 Hz, 4 C=CH), 6.45 and 7.09 (AB system with J = 16 Hz, 2 CH_2), 8.92 (s, 1 cyclopropyl-CH); UV (methanol), λ_{max} = 267 (ε = 2700), 272 nm (2770)], and this acid *(10)* was accordingly introduced into the synthesis. Reaction of *(10)* with thionyl chloride was normal, producing the acid chloride, which was next converted by diazomethane into the diazo ketone *(11)* [86% based on *(10)*; m.p. ≈ 100 °C (dec.); IR (CCl_4), CN_2 2120 cm^{-1}]. Copper-catalyzed thermolysis of the diazo ketone resulted in the intended bridge formation to give the ketone *(12)*, which, as anticipated, underwent a spontaneous double norcaradiene-cycloheptatriene valence isomerization to yield *(13)* as the product actually isolated [80%; m.p. 182—183 °C; NMR ($CDCl_3$), τ = 3.5—4.2 (AA'XX' system, 8 C=CH), 6.52 and 6.92 (AB system with J = 15 Hz, 2 CH_2), 7.60 (s, 2 bridge-CH); UV (cyclohexane), λ_{max} = 220 (ε = 39700), 262 nm (7310); IR (KBr), C=O 1730 cm^{-1}]. The dihydro compound *(13)* was dehydrogenated by 2,3-dichloro-5,6-dicyano-*p*-benzoquinone even at room temperature, affording the brilliant orange ketone *(14)* [90%; m.p. 220—221 °C; NMR ($CDCl_3$), τ = 2.09 (s, 2 arom. CH), 1.9—2.6 (AA'BB' system, 8 arom. CH), 10.87 (s, 2 bridge-CH); UV (cyclohexane), λ_{max} = 275 (ε = 21400), 308 (106400), 333 (18200, sh), 365 (8880), 486 (480, sh), 492 (530), 498 (560), 505 (515, sh), 513 (450), 520 nm (360); IR (KBr), C=O 1730 cm^{-1} [9]], and reduction of this ketone by the Huang-Minlon modification of the Wolff-Kishner method gave the desired 1,6:8,13-propanediylidene[14]annulene *(2)* as a stable yellow-orange compound of m.p. 180—181 °C (75%).

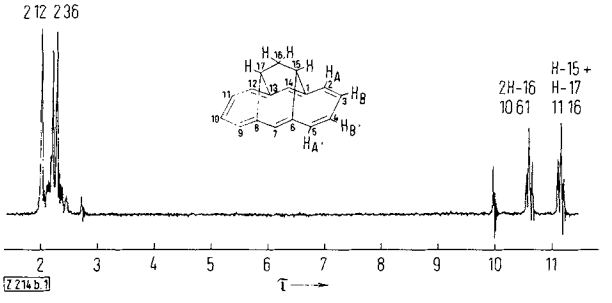


Fig. 1. NMR spectrum of 1,6:8,13-propanediylidene[14]annulene *(2)* (in $CDCl_3$; 60 MHz; tetramethylsilane as internal standard).

The nature of the 14π-electron system in *(2)* is proved above all by the NMR spectrum ($CDCl_3$) (Fig. 1)[10]. The annulene protons appear as a singlet at τ = 2.12 (H-7, H-14) and as an AA'BB' system with τ_A = 2.26 and τ_B = 2.45 (H-2 to H-5, and H-9 to H-12), whilst the bridge protons give rise to two triplets at τ = 10.61 (2 H-16) and 11.16 (H-15, H-17) with J = 2.8 Hz. From the spectrum of the 16,16-dideuterated compound [obtained from *(14)* and tetradeuteriohydrazine] it follows that the triplet at higher field is due to the two outer bridge protons. The absorptions of the annulene protons at relatively low field, together with the strong shielding of the bridge protons, indicate a ring current in the π-electron system and thus show the molecule to be aromatic. The coupling constants of the protons of the AA'BB' system can be interpreted in the same sense (J_{AB} = 9.15 Hz, $J_{BB'}$ = 9.50 Hz, $J_{AB'}$ = 0.41 Hz, $J_{AA'}$ = 1.37 Hz). The annulene protons of *(2)* exhibit approximately the same shifts and coupling parameters as are found for *syn*-1,6 : 8,13-bisoxido-[14]annulene[11], whence it can be concluded that the geometrical and electronic conditions in the C_{14} rings of the two compounds correspond very closely.

The UV spectrum of *(2)* also indicates aromatic character: λ_{max} = 303 (ε = 165000), 322 (23100, sh), 362 (6620), 374 (6560), 480 (410), 486 (435), 492 (440), 498 (385, sh), 506 (300), 513 nm (230) (in cyclohexane).

An X-ray structure analysis of *(2)* proved the approximately planar conformation of the C_{14} ring and the presence of aromatic C—C bonds[12].

Chemically, the aromatic character of *(2)* manifests itself in the formation of substitution products upon treatment of the compound with electrophilic reagents. As in *syn*-1,6 : 8,13 bisoxido[14]annulene[5b], the first substituent preferentially enters at position 2.

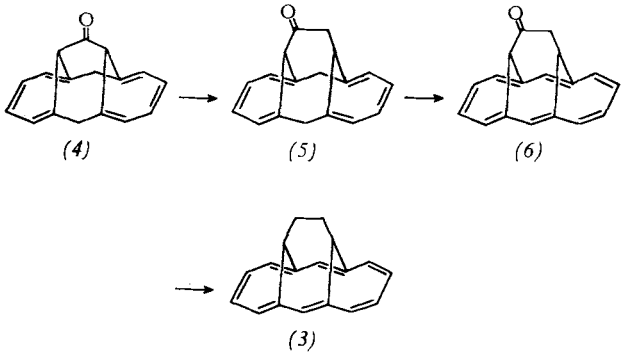
1,6:8,13-Butanediylidene[14]annulene[1]

By *Emanuel Vogel, Wolfgang Sturm*, and *Hans-Dieter Cremer*[*]



Replacement of the two inner bridge-protons in the as yet unknown syn-1,6 : 8,13-bismethano[14]annulene by one or more CH_2 groups – and, in the simplest case, direct linkage of the two bridging C atoms – leads to the series *(1)*, *(2)*, *(3)*, *etc.* of bridged [14]annulenes, of which one member, 1,6 : 8,13-propanediylidene[14]annulene *(2)*[2], has already been described.

(1) *(2)* *(3)*

From consideration of molecular models it can be predicted that *(2)* has an approximately planar annulene ring[3], whereas for the higher analogs of *(2)* the $(CH_2)_n$ intermediate bridges will compel progressive bending and/or zig-zagging of the peripheral C_{14} skeleton. According to the models it is probable that the lower homolog of *(2)*, *i.e.* 1,6 : 8,13-ethanediylidene[14]annulene *(1)*, will fulfill the steric requirements for delocalization of the π-electrons even better than *(2)* itself. Thus the [14]annulene series *(1)*, *(2)*, *(3)*, *etc.*, opens up the possibility of studying the properties of a cyclic conjugated system in relation to the geometry of the ring skeleton.

The starting point for the synthesis of 1,6 : 8,13-butanediylidene[14]annulene *(3)* was the dihydro[14]annulene ketone *(4)*[2]. Treatment of a solution of the ketone *(4)* in methanol-methylene dichloride (1 : 1) with ethereal diazomethane led to, amongst other products, the required homologous ketone *(5)* [m.p. 131–132 °C; NMR ($CDCl_3$), τ = 3.5–4.2 (multiplet consisting of two partially superimposed AA'XX' systems, 8 C=CH), 6.41 and 7.01 (AB system with J = 13 Hz, 2 allylic CH_2), 6.87 (d with J = 3.5 Hz, bridge-CH_2), 7.22 (s, 1 bridge-CH), 7.80 (t with J = 3.5 Hz, 1 bridge-CH); UV (cyclohexane), λ_{max} = 224 (ε = 30300), 261 nm (7100)], which could be isolated in 7% yield by chromatography on silica gel with methylene dichloride-hexane (2 : 1). 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone dehydrogenated *(5)* in boiling anisole (24 h) to *(6)* [m.p. 164–165 °C; yield 60%; NMR (CCl_4), τ = 2.05 (s, 2 arom. CH), 2.25–2.95 (multiplet consisting of two partially superimposed AA'BB' systems, 8 arom. CH), 8.78 (d with J = 4.0 Hz, bridge-CH), 9.87 (s, 1 bridge-CH), 10.87 (t with J = 4.0 Hz, 1 bridge-CH_2); UV (cyclohexane), λ_{max} = 272 (ε = 8570, sh), 305 (121000), 333 (12900, sh), 360 (7780), 478 (195), 484 (205), 490 (205), 498 nm (170, sh); IR (KBr), C=O 1708 cm^{-1}]. Finally, reducing *(6)* by the Huang-Minlon modification of the Wolff-Kishner reaction afforded the stable yellow hydrocarbon *(3)*, m.p. 175–176 °C, in 66% yield.

(4) *(5)* *(6)* *(3)*

The spectra of *(3)* all indicate the presence of an aromatic compound. The NMR spectrum (CCl_4) (Fig. 1) shows the annulene protons as a singlet at τ = 2.14 (H-7, H-14) and as an AA'BB' system with τ_A = 2.43 and τ_B = 2.88 (H-2 to H-5, and H-9 to H-12), and the bridge protons as two groups of signals at τ = 9.48 (2 H-16, 2 H-17) and 10.96 (H-15, H-18) which, to a first approximation, can be regarded as a triplet and a quintuplet (^3J = 2.4 Hz and ^4J = 1.9 Hz), respectively (relative intensities 2 : 8 : 4 : 2). The coupling constants of the annulene protons H-2 to H-5 (and of H-9 to H-12) are J_{AB} = 9.24 Hz, $J_{BB'}$ = 9.31 Hz, $J_{AB'}$ = 0.21 Hz, $J_{AA'}$ = 1.53 Hz. The absorptions of the annulene- and the bridge-protons at relatively low and relatively high field, respectively, together with the symmetry of the spectrum, indicate that the

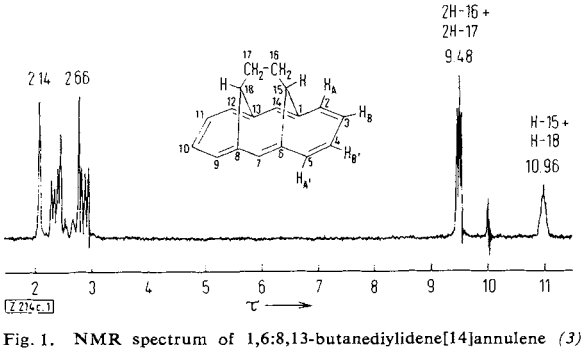


Fig. 1. NMR spectrum of 1,6:8,13-butanediylidene[14]annulene *(3)* (in CCl_4; 60 MHz; tetramethylsilane as internal standard).

π-electron system of the hydrocarbon is delocalized. The UV spectrum of *(3)* can be interpreted in the same terms [λ_{max} = 302 (ε = 145000), 320 (25800, sh), 360 (7450), 373 (7220, sh), 467 (270, sh), 473 (295), 480 (285), 486 (275), 492 nm (215, sh) (in cyclohexane)].

An X-ray structure analysis of 1,6 : 8,13-butanediylidene[14]-annulene *(3)* is not yet available[4], but the geometry of the molecule is already evident from a comparison of its NMR spectrum with that of *(2)*[2,5]. The two compounds have almost identical chemical shifts for the annulene and CH-bridge protons; furthermore, they have virtually the same coupling constants for the annulene protons. However, for *(3)* the signals of the CH_2-bridge protons lie approximately 1.1 ppm farther downfield than for *(2)*. Thence it follows that the annulene ring of *(3)* has almost the same, nearly planar conformation as in *(2)*, and that — contrary to the predictions based on models — it is rather the bridge moiety than the annulene ring that experiences deformation. In the spectrum of *(3)* the absorption of the CH_2 protons is at comparatively low field, indicating that the intermediate CH_2—CH_2 bridge is largely forced out of the space between C atoms 15 and 18. That the conformations of the annulene rings of *(3)* and *(2)* are very similar also follows from the close agreement of the UV spectra of the two hydrocarbons. As far as can be seen, considering the small quantity of *(3)* available up to the present, *(3)* corresponds to its homolog *(2)* also in its chemical behavior.

The spectra of *(3)* show that the tendency of the 14π-electron system for maximal p-orbital overlap determines the geometry of the molecule to a much greater extent than was assumed from consideration of models. Thus, intermediate bridges that are appreciably more rigid and more space-filling than a CH_2—CH_2 grouping will be required to enforce the intended bending of the annulene ring of bridged [14]-annulenes of the present type.

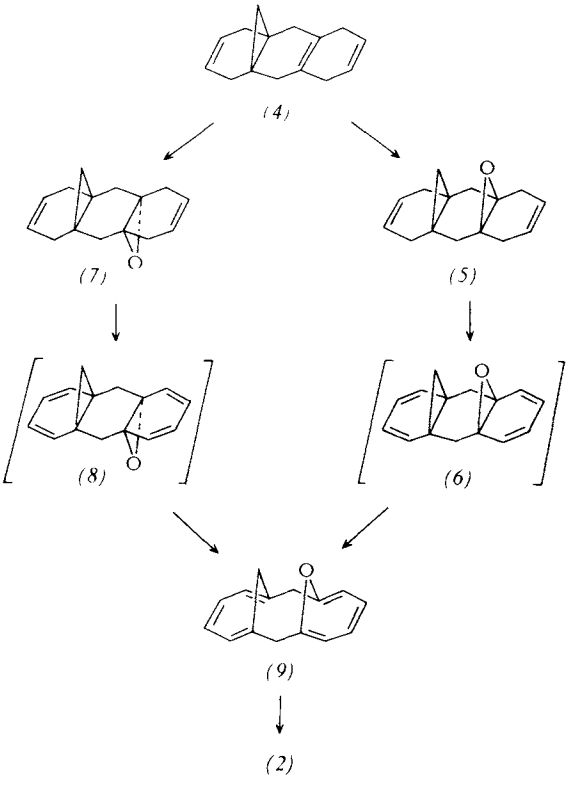
syn-1,6-Methano-8,13-oxido[14]annulene[1]

By *Emanuel Vogel, Ulrich Haberland*, and *Jürgen Ick*[*]

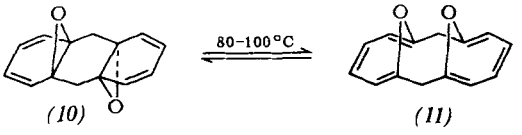


For the aromatic *syn*-1,6 : 8,13-bisoxido[14]annulene *(1)*[2] it was shown by X-ray structure analysis[3] that the annulene ring is approximately planar, that the C—C bonds are of equal length within experimental error, and that the bond lengths (mean 1.392 Å) are almost identical with the C—C distance in benzene. If the two oxygen bridges of *(1)* are replaced successively by the more space-filling CH_2 groups, steric interaction between the bridges increases appreciably. The annulene rings in *syn*-1,6-methano-8,13-oxido[14]annulene *(2)* and *syn*-1,6 : 8,13-bismethano[14]annulene *(3)* should thus experience progressive bending. It seemed interesting to investigate what effects the geometrical changes on going from

(1) *(2)* *(3)*

(1) to *(3)* will have on the physical and chemical behavior of the molecules in question.

This communication concerns the stereoisomeric 1,6-methano-8,13-oxido[14]annulenes [*(2)* and its *anti*-isomer], which were to be synthesized from 1,4,5,8,9,10-hexahydroanthracene[5] in analogy to the preparation of *(1)* and *anti*-1,6 : 8,13-bismethano[14]annulene[2b,4]. It therefore seemed advisable to introduce the bridge functions by cyclopropanation with Simmons-Smith reagent and subsequent peracetic acid epoxidation. When the hexahydroanthracene was treated with a three-fold excess of methylene diiodide and a zinc-copper couple a moderately selective attack at the central double bonds occurred to give the cyclopropane hydrocarbon *(4)* which had to be isolated by chromatography [m.p. 56 °C; yield 23%; NMR (CCl_4), τ = 4.3—4.6 (2 broad singlets, 4 C=CH), 7.5—7.8 (m, 6 CH_2), 9.47 and 9.58 (AB system with J = 3.5 Hz, cyclopropyl-CH_2)]. When *(4)* was treated with one mole of peracetic acid, epoxidation of the residual central double bond was highly selective and there resulted a mixture of the *syn*-epoxide *(5)* [m.p. 79—80 °C; yield 8%;

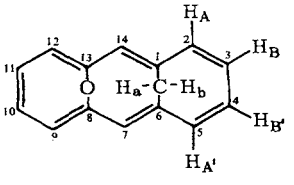


(4) *(7)* *(5)* *(8)* *(6)* *(9)* *(2)*

NMR ($CDCl_3$): τ = 4.5 (s, 4 C=CH), 7.5—8.3 (multiplet, in which an AB system at 7.68 and 8.20 with J = 15.5 Hz can be discerned, 6 CH_2), 8.78 and 9.60 (AB system with J = 3.0 Hz, cyclopropyl-CH_2)] and the *anti*-epoxide *(7)* [m.p. 55—56 °C; yield 66%; NMR (CCl_4): τ = 4.4—4.7 (m, 4 C=CH), 7.5—8.0 (m, 4 CH_2), 8.1 (s, 2 CH_2), 9.25 and 10.01 (AB system with J = 4.2 Hz, cyclopropyl-CH_2)]; these isomers were separated by chromatography on alumina. Structural assignment was based on the assumption that in the *syn*-epoxide the inner cyclopropane proton will absorb at relatively low field since it is certainly subject to deshielding by the oxygen atom.

The *syn*- and *anti*-epoxides [*(5)* and *(7)*] were separately treated in methylene dichloride at —70 °C with 2 moles of bromine, and the resulting tetrabromides [m.p. 140 °C (dec.) and 144—146 °C (dec.), respectively; yield about 50% in each

case] then subjected to dehydrohalogenation by 1,5-diazabicyclo[4.3.0]non-5-ene[6]. Surprisingly, both tetrabromides gave one and the same pale yellow compound [m.p. 80—81 °C, yield 50% in each case; NMR (C_6D_6), τ = 3.7 and 4.2 (AA'XX' system, 4 C=CH of the cycloheptatriene portion), 4.3 and 4.9 (AA'XX' system, 4 C=CH of the oxepin portion), 6.41 and 8.24 (AB system with J = 11.0 Hz, CH_2-bridge protons), 6.80 and 7.35 (AB system with J = 12.5 Hz, 2 CH_2); UV (cyclohexane), λ_{max} = 223 (ε = 26500), 267 (5350), 310 nm (630, sh)], which is shown by spectral data to have the structure of a 7,14-dihydro-1,6-methano-8,13-oxido[14]annulene [*(9)* or its isomer]. Evidently, one is dealing with the *syn*-compound *(9)* since one of the bridge protons absorbs at relatively low field indicating that this proton is close to the oxygen bridge.



The change of configuration on dehydrohalogenation of the tetrabromide derived from *(7)* can best be explained by assuming that 7,14-dihydro-*anti*-1,6-methano-8,13-oxido[14]-annulene is formed as intermediate and that this compound subsequently isomerizes by flipping of the oxygen bridge (or less probably the CH_2-bridge) through the annulene ring. This interpretation is supported by the reversible isomerization of the *anti*-bis-arene-oxide *(10)*[2b] to the *syn*-bisoxepin *(11)*[2b] observed at 80—100 °C, in which the *anti*-bisoxepin is believed to be an intermediate.

(10) *(11)*

The compound taken as 7,14-dihydro-*syn*-1,6-methano-8,13-oxido[14]annulene *(9)* is dehydrogenated by 2,3-dichloro-5,6-dicyano-*p*-benzoquinone to the orange-red, aromatic *syn*-1,6-methano-8,13-oxido[14]annulene *(2)*, m.p. 118—119 °C (yield 40%).

Taking the reduced molecular symmetry (C_s as against C_{2v}) into account, the NMR spectrum of *(2)* (Fig. 1) corresponds fully to that of the known *syn*-bridged [14]annulenes *(1)* and 1,6 : 8,13-propanediylidene[14]annulene[7]. The absorptions of the annulene protons consist of a singlet at τ = 2.25 (H-7, H-14) and a complex multiplet at τ = 2.2—2.7 composed of two partly superimposed AA'BB' systems (H-2 to H-5, and H-9 to H-12). The calculated chemical shifts and coupling constants for the annulene protons are shown in the Table[8].

	τ_A	τ_B	J_{AB}	$J_{BB'}$
H-2 to H-5:	2.35	2.66	8.8 Hz	9.3 Hz
H-9 to H-12:	2.36	2.57	9.4 Hz	9.1 Hz

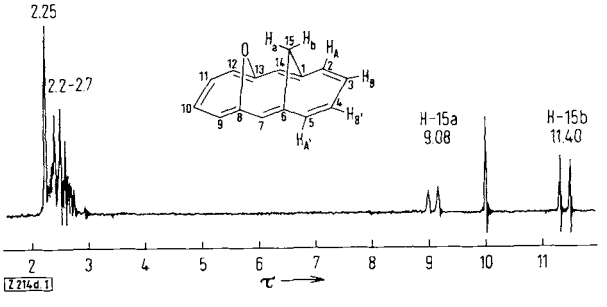


Fig. 1. NMR spectrum of *syn*-1,6-methano-8,13-oxido[14]annulene *(2)* (in $CDCl_3$; 60 MHz; tetramethylsilane as internal standard).

The signals of H-2 to H-5 could be assigned on the basis of a long-range coupling (M mechanism) between H-15a and H-2 and H-5 (J = 1.1 Hz), which was established by a double resonance experiment. As expected from the aromatic character of *(2)* which is indicated by the NMR parameters of the annulene protons, the resonances of the CH_2 bridge protons [the AB system at τ = 9.08 (H-15a) and 11.40 (H-15b) with J = 10.6 Hz[9]] are at relatively high field. The 2.3 ppm difference in the chemical shifts of these CH_2 protons, due mainly to deshielding of H-15a by the oxygen atom, not only proves the *syn*-configuration of *(2)* but also, because of its magnitude, shows appreciable steric interaction between the bridges[10]. From the NMR data for both the annulene and the bridge protons it follows that the molecule rather tolerates a compression of the bridges than a bending of the ring[11].

The UV spectrum of *(2)* has the same shape as that of *(1)* [λ_{max} = 300 (ε = 141700), 330 (17500, sh), 372 (8170), 518 nm (510) (in cyclohexane).

In analogy to *(1)*, *(2)* gives substitution products with electrophilic reagents. As a typical example, Friedel-Crafts acylation with acetic anhydride in the presence of boron trifluoride-ether affords three red monoacetyl derivatives (total yield 66%) which are readily separable by chromatography on aluminum oxide: 2-acetyl- (m.p. 159—160 °C; yield 14%), 9-acetyl- (m.p. 107—108 °C; yield 40%), and 10-acetyl-*syn*-1,6-methano-8,13-oxido[14]annulene (m.p. 117—118 °C; yield 12%). The positions of the substituents are determined by NMR spectroscopy.

An X-ray structure analysis of *(2)* is not yet available, but it is evident from the spectral data alone that the annulene ring of *(2)* has a geometry very similar to that of *(1)*. This result suggests that the steric interference of the two inner bridge-hydrogen atoms in the still unknown *syn*-1,6 : 8,13-bismethano[14]annulene will cause less bending of the annulene ring than is implied by the models.

The Crystal Structure of 1,6:8,13-Propanediylidene-[14]annulene

By *Gianluigi Casalone, Angelo Gavezzotti, Angelo Mugnoli,* and *Massimo Simonetta*[*]

The relationship between the aromatic character and the form of the bridged annulene ring in 1,6 : 8,13-propanediylidene-[14]annulene[1] is of considerable interest.

1,6:8,13-propanediylidene[14]annulene, m.p. 180—181 °C, crystallizes in the orthorhombic space group Fdd2 (C_{2v}^{19}) with 16 molecules in the unit cell, $a = 19.47$, $b = 36.37$, $c = 6.58$ Å, $d_{X\text{-ray}} = 1.244$, $d_{exp} = 1.248$ g cm^{-3}. The intensities of about 1300 independent reflections were recorded on a linear automatic diffractometer using $Mo_{K\alpha}$ radiation.

The orientation of one molecule in the unit cell was determined by an automatic comparison between the experimental three-dimensional sharpened Patterson synthesis calculated near the origin and the intramolecular vector distributions calculated for a plausible molecular model rotating about three mutually perpendicular axes[2]. The position of the reference molecule in the unit cell was then determined by systematic comparison between observed and calculated structure factors, while shifting the oriented model along x and y (z being a polar axis). Some cycles of full-matrix isotropic least-squares refinement on the 826 reflections having $I \geq 2\,\sigma(I)$ led to an R index of 11.5%. Further refinement is in progress taking into account the anisotropy of the thermal vibration.

The molecular conformation (Fig. 1) is very close to the mm2 symmetry, the differences being of the order of the estimated standard deviations as calculated at this point of the refinement. The geometrical features along the annulene perimeter are similar to those previously found for 1,6 : 8,13-bisoxido[14]annulene[3].

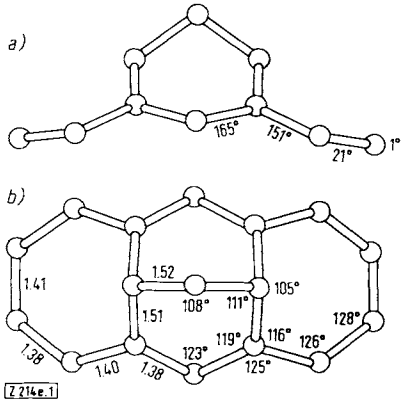

Fig. 1. Crystal structure of 1,6:8,13-propanediylidene[14]annulene. a) Absolute values of torsion angles in the annulene perimeter. b) Mean values of symmetrically equivalent bond lengths and angles.

Magnetic Behavior of Alkali-Metal Tetroxocobaltates(v)

By *Claus Brendel* and *Wilhelm Klemm*[*]

Dedicated to Professor Eugen Müller on the occasion of his 65th birthday

A few years ago we reported on potassium tetroxocobaltate(v)[1]. Although a magnetic moment of $\geq 4.9\,\mu_B$ expected for Co^V having the 3d electron configuration $(e)^2(t_2)^2$ with tetrahedral coordination was found for solid solutions of K_3CoO_4 with K_3PO_4, considerably lower values were observed for pure K_3CoO_4, possibly because of interactions between the CoO^{3-} groups.

Since such interactions should be less effective in rubidium and cesium tetroxocobaltate(v) we have now studied the magnetic behavior of these compounds. They were prepared by heating 3 : 1 mixtures of $RbO_{0.7}$ and $CoO_{1.5}$ at 350 °C for 4 h or at 280 °C for 46 h, and 3 : 1 mixtures of $CsO_{0.5}$ and $CoO_{1.5}$ at 300 °C for 2—3 h, respectively, under approx. 0.5 atm of O_2 in a sealed tube. The black products of uniform appearance resulting on quenching to room temperature react with water in the same way as K_3CoO_4. The change in weight incurred during reaction also corresponds to the formation of Rb_3CoO_4 and Cs_3CoO_4. The molar volumes of 97 and 112 cm^3 calculated from the densities of 3.9_0 and 4.6_5 g cm^{-3} are consistent with the molar volume of K_3CoO_4 ($d = 2.7_4$ g cm^{-3}, $v_M = 88$ cm^3). The debyeogram permits no conclusion whether the three compounds are isotypic.

The magnetic behavior of the new tetroxocobaltates(v) is similar to that of K_3CoO_4, as can be seen from the tabulated effective moments:

	μ_{eff} (in μ_B)		
	90 °K	195 °K	293 °K
K_3CoO_4	1.1_8	1.7_0	2.0_8
Rb_3CoO_4	1.3_5	1.7_4	2.0_7
Cs_3CoO_4	1.8_2	2.0_3	2.3_3

As expected, the μ_{eff} values increase on going from the K compound to the Cs compound, *i.e.* the anionic interactions decrease in magnitude. However, the value of μ_{eff} recorded for the Cs compound at room temperature is still far removed from the moment predicted for Co^V.

A Stable Aroxyl Radical of the Heteroaromatic Series

By *Hans-Joachim Teuber, Günther Schütz,* and *Hans-Joachim Gross*[*]

Dedicated to Professor Eugen Müller on the occasion of his 65th birthday

Of the isomeric hydroxypyridines, the 3-hydroxy compound shows the closest resemblance to phenol. The phenolic character has now been effectively established by the successful dehydrogenation of its 2,4,6-triphenyl derivative *(2)* to a stable radical *(3)*. This is the first radical of its kind in the heteroaromatic series.

We have synthesized *(2)* from methoxychalcone and phenacylpyridinium bromide *via* the methyl ether *(1)*.

(3)

Isolation of the chalcone is unnecessary if methoxyacetophenone and benzaldehyde are used as starting materials[1]. The pyridine *(1)* can also be prepared by *Weiss*'s modification of the Chichibabin synthesis[2].

The methyl ether *(1)* (colorless needles from ligroin, m.p. 130—131 °C) is cleaved by pyridinium chloride or hydrobromic acid/glacial acetic acid to give the 3-hydroxypyridine *(2)* (yellow needles, m.p. 138—139 °C). Dehydrogenation of *(2)* with potassium hexacyanoferrate(III) or potassium nitrosobissulfate in sodium hydroxide/carbon tetrachloride affords a violet-brown solution of the radical 2,4,6-triphenyl-3-pyridyloxyl *(3)*. Concentration of the carbon tetrachloride solution yields *(3)* as a crystalline yellow dimer (containing 1 molecule of CCl_4) which we formulate as the quinol.

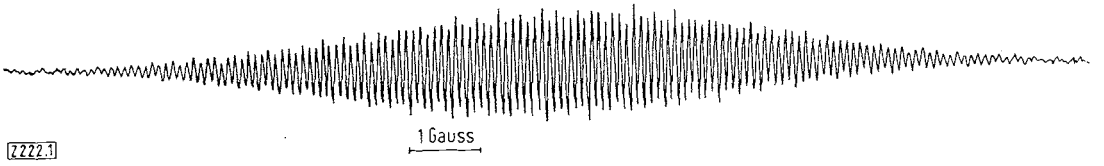

Figure. High resolution ESR spectrum of the radical 2,4,6-triphenyl-3-pyridyloxyl *(3)* in benzene.

In organic solvents the dimer dissociates to the free radical and shows the expected temperature-dependent equilibrium (color deepening on warming). Characteristic quinol absorption bands are present in the IR spectrum of the solid (1707, 1623; 1210 cm^{-1}). The free pyridyloxyl *(3)* gives a UV spectrum containing more bands than the spectrum of triphenylphenoxyl[3] (λ_{max} = 665, 550, 415, 358, 318 nm, in chloroform). The radical, which, unlike 2,4,6-tri-*tert*-butylphenoxyl[4], is completely stable towards oxygen, reacts preferentially as a dehydrogenating agent; it slowly attacks such solvents as acetone, methanol, and chloroform. It obviously has a higher oxidation potential than triphenylphenoxyl. The comparatively low symmetry of *(3)* can be deduced from the ncreased number of lines in the ESR spectrum (see Figure)[5].

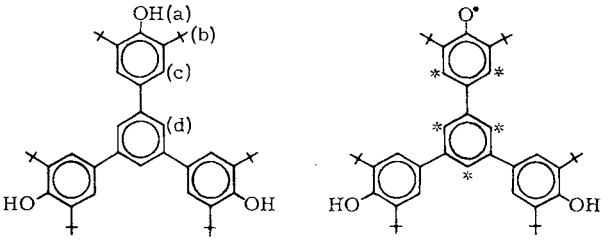
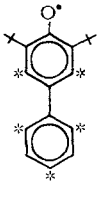
New Aroxyls : Mono-, Di-, and Triradicals. Detection of a Triplet State



By *Gerd Kothe, Claudia Nowak, Karl-Heinz Denkel, Ernst Ohmes, and Herbert Zimmermann*[*]

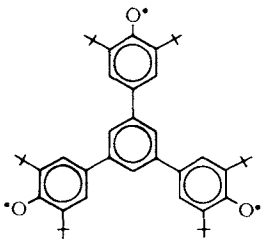
Dedicated to Professor Eugen Müller on the occasion of his 65th birthday



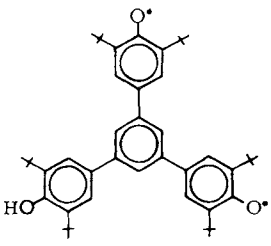
HCl condensation of 4-acetyl-2,6-di-*tert*-butylphenol[1] in dry ethanol at room temperature leads to a small yield of the new triphenol 1,3,5-tris(3,5-di-*tert*-butyl-4-hydroxyphenyl)-benzene *(1)* [colorless crystals, m.p. 313—314 °C (uncorrected); λ_{max} = 271 nm, log ε = 4.74 (ethanol)], from which a number of radicals of the aroxyl series can be derived. The structure of *(1)* follows from elemental analysis, the molecular weight, IR spectrum [ν_{OH} = 3639 cm^{-1} (sharp)], and NMR spectrum [H^a δ = 5.27 ppm (3), H^b 1.49 (54), H^c 7.46 (6), H^d 7.57 (3); δ in $CDCl_3$ with TMS as internal standard].

Dehydrogenation of the triphenol *(1)* with a deficit of lead dioxide in benzene or toluene yields the violet monoradical *(2)*, λ_{max} = 529 nm (in benzene). The color of *(2)* closely resembles that of the radical *(3)*, λ_{max} = 491 nm (in benzene)[2], which was isolated pure by *Eugen Müller et al.*[3].

At low resolution the ESR spectrum of *(2)* in toluene shows six equidistant lines at g = 2 in the intensity ratio 1 : 5 : 10 : 10 : 5 : 1, coupling constant a_H = 1.71 G. The splitting pattern of the signal can be attributed to coupling of the radical electron with five equivalent protons [asterisked aromatic positions in *(2)*]. Similar observations were made in the case of *(3)*[4,5].



(1) *(2)*



(3)

If the triphenol is dehydrogenated with an excess of lead dioxide in benzene or toluene the orange-brown radical *(4)* is formed whose chemical behavior is consistent with a triradical [λ_{max} = 478 nm with a shoulder at 577 nm (in benzene)].

On iodometric titration[6] of *(4)*, 2.4 to 2.5 equivalents of iodine are liberated. After titration, 96% of the triphenol can be recovered, thus indicating the absence of fragmentation

(4)

(5)

during dehydrogenation. Osmometric molecular-weight determinations in benzene show the triradical *(4)* to be monomeric in solution.

The ESR spectrum of *(4)* in toluene (—70 °C) contains 16 lines at $g = 2$ (Fig 1a). The spectrum can be simulated with two sets of three and six equivalent protons (Fig. 1b) [$a_{H^1} = 1.75$ (3), $a_{H^2} = 0.60$ G (6); half-width of the absorption curve $\Delta H = 0.50$ G; 100% Gaussian curve].

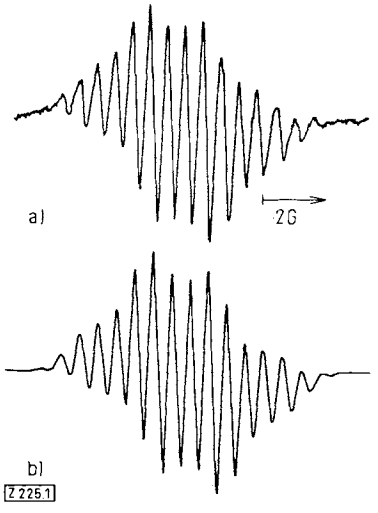


Fig. 1. ESR spectrum of 4,4',4''-(1,3,5-benzenetriyl)tri(2,6-di-*tert*-butylphenoxyl) *(4)* in toluene at —70 °C.
a) Experimental. b) Simulated.

Combination of toluene solutions of the triphenol *(1)* and the triradical *(4)* in the molar ratio 1 : 2 affords a radical solution containing not only *(2)* and *(4)* but also the diradical *(5)* which is present in the triplet state. The triplet state of *(5)* can be deduced from its half-field transition ($\Delta m = 2$) at 1621 G and the corresponding $\Delta m = 1$ lines in the ESR spectrum of a toluene solution frozen to a rigid glass. The high-field ESR spectrum of this glass contains a number of $\Delta m = 1$ lines arranged almost symmetrically with respect to the $g = 2$ transition of *(2)* and *(4)* at 3246 G (Fig. 2).

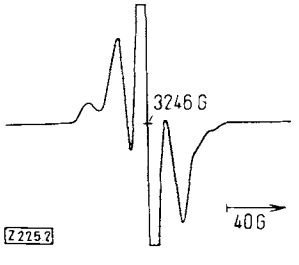

Fig. 2. ESR spectrum of 4,4'-[5-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-1,3-phenylene]bis(2,6-di-*tert*-butylphenoxyl) *(5)* in toluene glass at approx. —180 °C.

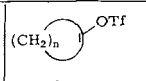
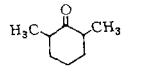
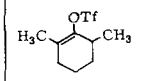
Preparation of Cyclic and Acyclic Vinyl Trifluoromethanesulfonates[**]

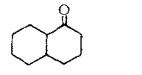
By *Thomas E. Dueber*, *Peter J. Stang*, *Wolf D. Pfeifer*, *Richard H. Summerville*, *Michael A. Imhoff*, *Paul v. Ragué Schleyer*, *Klaus Hummel*, *Siegfried Bocher*, *Charles E. Harding*, and *Michael Hanack*[*]

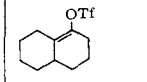
We have found that cyclic vinyl trifluoromethanesulfonates (Table) can be prepared in a simple manner by treating cycloalkanones with trifluoromethanesulfonic anhydride.

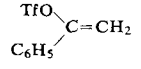


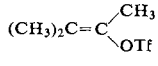


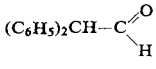


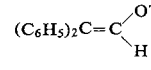












Method 1 (without solvent): Trifluoromethanesulfonic anhydride[1] and an equimolar amount of the cycloalkanone are mixed with stirring at a temperature of —15 to 0 °C. The temperature of the reaction mixture is kept at —5 °C for 2 h and then at 0 °C for 2 to 14 days (Table). For work-up, the reaction mixture is poured on to ice, neutralized with aqueous sodium bicarbonate, and extracted with ether. The ether solution is washed with water, dried, and after removal of the ether the residue is vacuum distilled. The trifluoromethanesulfonate can easily be separated from the distillate by preparative gas chromatography (3 m column, diethylene glycol succinate, 110—140 °C).

Method 2 (with methylene chloride or pentane as solvent): Trifluoromethanesulfonic anhydride (15 mmoles) in methylene chloride (15 ml) is added dropwise within 30 min to a stirred, cold solution (—70 °C) of the ketone (or aldehyde, see Table) (15 mmoles) in methylene chloride (or pentane). Anhydrous sodium carbonate (8 mmoles) is added simultaneously in small portions. During addition of the anhydride a slight increase in temperature is observed. When the reaction mixture has warmed to —10 °C it is yellow or red in color. After one day to three weeks the solution is filtered, washed with water, and dried. The methylene chloride is removed by means of a rotary evaporator and the residue is vacuum distilled. Pure trifluoromethanesulfonate can be obtained from the distillate by preparative gas chromatography, fractional distillation, or chromatography on silica gel (pentane solvent).

Acyclic trifluoromethanesulfonates can be prepared in like manner from acyclic aldehydes or ketones (Table). In addition to the compounds listed in the Table, the corresponding vinyl trifluoromethanesulfonates were prepared from 2,5-dimethylcyclopentanone, *p*-chloroacetophenone, adamantyl methyl ketone, and 1,1-diphenylacetone.

Alkyl trifluoromethanesulfonates solvolyze about 10^4—10^5 times faster than the corresponding alkyl arylsulfonates[2]. Using another method *Stang* and *Summerville*[3] as well as *Jones* and *Maness*[4] prepared for the first time acyclic vinyl trifluoromethanesulfonates. While the acyclic derivatives which they prepared can form the energetically favorable linear vinyl cations[5] on solvolysis[6], it may be possible to generate nonlinear vinyl cations by the solvolysis of the cyclic vinyl trifluoromethanesulfonates described above[7].

Vinyl trifluoromethanesulfonates, prepared by methods 1 and 2.

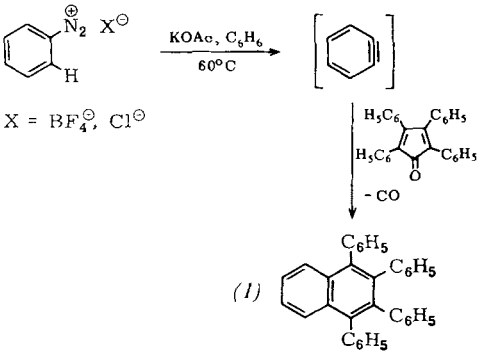
Dehydrobenzene from Aromatic Diazonium Salts [1]



By *Christoph Rüchardt* and *C. C. Tan* [*]

Not long ago we showed that benzenediazonium *p*-chlorobenzoate, which is prepared by isomerization of *p*-chloro-*N*-nitrosobenzanilide in CCl_4, reacts with tetracyclone in CCl_4 at 70 °C to give tetraphenylnaphthalene *(1)* in 46% yield [2].

Compound *(1)* may be synthesized more readily and in better yields by portionwise addition of crystalline benzenediazonium tetrafluoroborate or chloride (10 mmoles) to a vigorously stirred mixture of tetracyclone (1.92 g, 5.0 mmoles), glacial acetic acid (0.1 g), and anhydrous potassium acetate in benzene at 60 °C. Evolution of nitrogen ceases within 2.5 h. After the product had been washed neutral and chromatographed on acidic Al_2O_3, 1.52 g (3.52 mmoles, 70%) or 1.60 g (3.70 mmoles, 74%) of tetraphenylnaphthalene *(1)* could be detected by gas chromatography. The compound was isolated in good yield by concentration and crystallization from dioxane/ethanol. The structure was confirmed by comparison of melting points [197 °C ([3]: 197 °C) and 202 °C ([4]: 204 °C)] and IR spectra, and by C, H analysis.

The analogous reactions of anthracene were found to give 9% and 41% (36% isolated) of triptycene [m.p. 249–251 °C ([3]: 254 °C)].

We interpret this synthesis in terms of formation of dehydrobenzene in an E_2 elimination which is initiated even by the weak base acetate ion owing to the favorable leaving group properties of N_2.

The success of the above reaction suggested that the synthesis of *(1)* (17–34%) and triptycene (1–3%) from *N*-nitrosoacetanilide described by *Cadogan et al.* proceeds not *via* an "arynoid intermediate", as was originally suspected, but rather *via* dehydrobenzene [5]. However, its precursor, benzenediazonium acetate, undergoes rapid, competitive decomposition by a chain reaction in the presence of *N*-nitrosoacetanilide [2b, 6]. If this decomposition is suppressed by slow, dropwise addition of an ice-cold benzene solution of *N*-nitrosoacetanilide (10 mmoles/30 ml or 15 ml, respectively) to a solution of tetracyclone (5 mmoles/30 ml)

or anthracene (5 mmoles 15 ml), to which solid potassium acetate has been added, at 60 °C over a period of 20 min, then 88% of *(1)* (96% found by gas chromatography) or 14–18% of triptycene (according to gas chromatography) may be isolated.

One-Step Synthesis of 2-Substituted *N*-Ethoxycarbonyl-1,2-dihydropyridines[**]

By *Gideon Fraenkel, J. W. Cooper,* and *C. M. Fink*[*]

Pyridine derivatives react only slowly with Grignard compounds to give poor product yields[1]. The same applies to *N*-acylpyridinium salts[2].

We have now found that pyridine derivatives *(1)* react with ethyl chloroformate and Grignard compounds to give 2-alkyl-1-ethoxycarbonyl-1,2-dihydropyridines *(3)*, the reaction presumably proceeding *via* the pyridinium chloride *(2)*.

(1) *(2)* *(3)*

	R^1	R^2
(a)	CH_3	n-C_4H_9
(b)	$(CH_3)_3C$	$(CH_3)_3H$
(c)	CH_3	C_6H_5
(d)	C_2H_5	n-C_4H_9
(e)	H	n-C_4H_9

Treatment of *(3b)* with *n*-butyllithium in hexane gave a red solution which was found to contain 2,4-di-*tert*-butyl-1,2-dihydropyridyl-1-lithium by NMR spectroscopy[3]. It is converted into 2,4-di-*tert*-butylpyridine when the solution is heated. The low-temperature NMR spectrum of *(3b)* indicates the presence of two rotational isomers.

1-Ethoxycarbonyl-2,4-di-tert-butyl-1,2-dihydropyridine (3b):

To a mixture of 4-*tert*-butylpyridine (1.01 g, 7.5 mmoles) and 20 ml of a 0.75 M solution of *tert*-butylmagnesium chloride in tetrahydrofuran (15 mmoles) is added ethyl chloroformate (0.81 g, 7.5 mmoles) at 0 °C over a period of 10 min. The reaction mixture is hydrolyzed with 1 ml of water at 0 °C, filtered, and the white precipitate is washed with tetrahydrofuran. The washings are added to the filtrate which is then dried with $MgSO_4$ and vacuum distilled. UV: λ_{max} = 2921 Å; IR: $\tilde{\nu}$ = 3000, 1700, 1365, 1300–1275 cm^{-1}: NMR: τ = 5.43, 5.70, 4.70, 3.27, (H-2, H-3, H-5, and H-6, respectively), $J_{2,3}$ = 6.0, $J_{5,6}$ = 7.0 Hz, b.p. 110 °C/0.0014 torr, yield 55%.

A New Synthesis of the Quinazoline System

By *Gerhard Simchen, Günther Entenmann,* and *Rolf Zondler*[*]

We recently reported on the synthesis of aza and 1,3-thiaza heterocyclic compounds by cyclizing acylation of ω-cyano and ω-thiocyanato carbonyl halides[1]. We have now found that 1,3-diaza heterocyclic compounds are also accessible by this method. Reaction of *o*-cyanophenyl isocyanates *(1)*, Z = O, and *o*-cyanophenyl isothiocyanates *(1)*, Z = S, with hydrogen halide at room temperature in di-*n*-butyl ether initially affords carbamoyl and thiocarbamoyl halides *(2)*, Z = O and Z = S, resp.[2], which cyclize at about 70 °C in the presence of an excess of hydrogen halide to the hitherto undescribed 4-halogeno-2-quinazolones *(3a)–(3c)* and 4-halogeno-2-quinazolinethiones *(3d)*, respectively.

(1) *(2)* *(3)* *(4)*

	R	X	Z	M.p. (°C)	Yield (%)
(3a)	H	Cl	O	213	87
(3b)	H	Br	O	348–350	78
(3c)	Br	Cl	O	> 350	77
(3d)	H	Cl	S	295–296	70

Ring closure proceeds by nucleophilic attack of the intermediate nitrile-hydrogen halide adducts on the carbamoyl or thiocarbamoyl halide *(2)*. The 4-chloro-2-quinazolines *(3a)* to *(3c)* can also be synthesized without isolation of intermediates by successive passage of phosgene (*ca.* 1 h) and hydrogen chloride (*ca.* 7 h) through a suspension of 2-cyanoanilinium chloride *(4)* in di-*n*-butyl ether at 120 °C and at 80 °C respectively. Nucleophilic substitution of the halogen atoms attached to C-4 of *(3)* proceeds readily.

General procedure:

Compound *(1)*, Z = O or S, (0.01 mole) is suspended in di-*n*-butyl ether (50 ml). HCl or HBr is passed into the suspension at 80 °C for 7 hours. The resulting precipitate is

filtered off, dried at 100 °C in a vacuum for 3 hours, and recrystallized from bromo- or chlorobenzene.

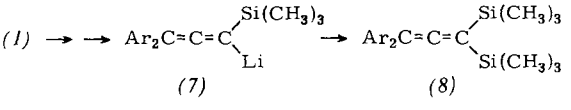
New Allenes from 1-Bromo-3,3-diphenylallenyllithium [1]

By *Gert Köbrich* and *Ernst Wagner* [*]



Except for carboxylation, the reactions of the deep violet trichloroallenyllithium — the first metalated haloallene to be prepared [1a] — are very complex. We have now prepared the structurally related and still more thermolabile reddish-black 1-bromo-3,3-diphenylallenyllithium *(2)*, which is found to react in a more comprehensible manner, by exothermal Br—Li exchange between equivalent amounts of 1,1-dibromo-3,3-diphenylallene *(1)* [2] and *n*-butyllithium in 2-methyltetrahydrofuran at —125 °C. *(1)* is characterized by its reaction with methyl chloroformate to give a good yield of the quite stable ester *(4)*, m.p. 125—126 °C, together with 15—25% of unchanged *(1)* [3].

Ar = C_6H_5; R = n-C_4H_9

Carboxylation of *(2)* gives the expected carboxylic acid *(3)*, m.p. 143—145 °C [with which diazomethane gives the ester *(4)*], but also surprisingly the hydroxypropiolic acid *(5)*, $\nu_{C\equiv C}$ = 2200 cm^{-1}. According to control experiments, *(5)* is probably formed during work-up from *(3)*, which thus must be very easily solvolyzed [4]. *(3)* and *(5)* were converted into a common product: 1 mole of *(3)* and 2 moles of butyllithium at —110 °C form a greenish-black organolithium compound [5,6], which is changed to the butyric acid derivative *(6)* [7] on protolysis, catalytic hydrogenation, and esterification with diazomethane. A comparison sample, dec. p. 79—81 °C, identical with *(5)*, was prepared from α-ethynyl benzhydrol by treatment with butyllithium (molar ratio 1 : 2) and subsequent carboxylation; it was converted by catalytic hydrogenation into 4,4-diphenylbutyrolactone [8] and thence by partial hydrogenolysis and esterification into *(6)*.

The disilane *(8)*, b.p. 124—127 °C/0.2 torr (dec.), is formed on treatment of 1 mol. equiv. of *(2)* with 2 mol. equiv. of butyllithium and then 2 mol. equiv. of (chloro)trimethylsilane; the α-metalated silane *(7)* must occur as intermediate.

Like the reaction of *(1)* with butyllithium in ether at +20 °C [2], thermolysis of *(2)* affords approx. 10% of tetraphenylhexapentaene alongside resins.

Methyl 2-bromo-4,4-diphenyl-2,3-butadienoate (4)

The dibromide *(1)* (1.75 g, 5.0 mmoles) in dry 2-methyltetrahydrofuran (60 ml) and light petroleum (10 ml; b.p. up to 40 °C) is treated at —125 °C with butyllithium (5.0 mmoles) for 40—50 min with strict exclusion of moisture. The mixture is stirred for a further 2 hours at the same temperature, and the resulting reddish-black *(2)* is treated dropwise with methyl chloroformate (4.0 g) in light petroleum (15 ml). The whole is kept for a further 3 hours at —105 °C, after which the cooling-bath is removed. The usual work-up gives a red oil (2.04 g), which, when mixed with small portions of ethanol (finally at —20 °C) leaves a total of 52% (0.85 g) of *(4)*, m.p. 125—126 °C (after recrystallization from ethanol).

Distribution of the Bonding Electrons in Decaborane-14

By *Rudolf Brill, Hans Dietrich*, and *Hinrich Dierks* [*]

The structure of the compound decaborane-14, $B_{10}H_{14}$, is given in Fig. 1 [1]. It contains B—H bonds as well as B—B bonds and hydrogen bridges between two boron atoms. This

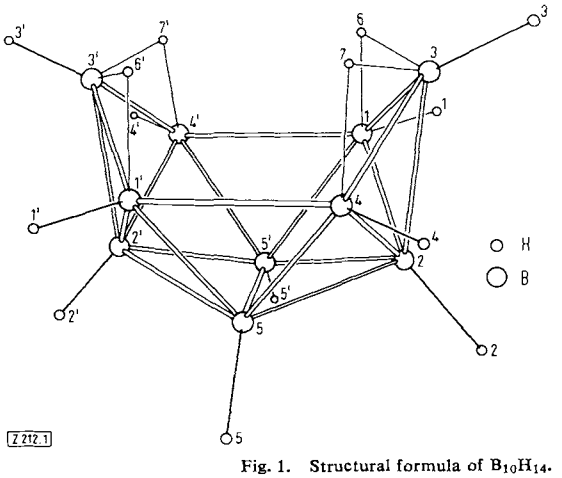

Fig. 1. Structural formula of $B_{10}H_{14}$.

compound, therefore, is especially suited for studies of the electron distribution corresponding to these bond types. In order to achieve the greatest possible accuracy it was necessary to determine the precise nuclear positions and vibrational parameters by means of neutron diffraction. For this purpose the compound consisting of the isotopes ^{11}B and ^{2}H had to be prepared[2]. To keep the thermal vibrations as small as possible the crystals were kept at −160 °C[3,4,5] during the measurement of the neutron- and X-ray diffraction.

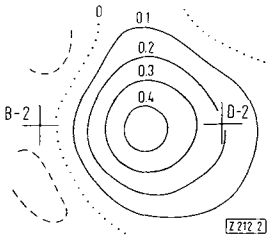

Fig. 2. Longitudinal section through a terminal B—H bond in the difference synthesis (contours at intervals of 0.1 e/A³).

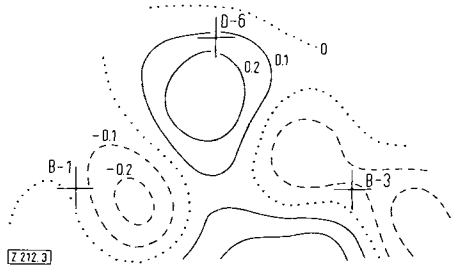

Fig. 3. Section through a three-center bond B—H—B in the difference synthesis (contours at intervals of 0.1 e/A³).

The first difference synthesis of the X-ray data was based on the parameters of the atomic positions as determined by neutron diffraction and also based on atomic scattering factors for neutral atoms[6] (first approximation). In the second approximation the atomic scattering factors were adapted to the charge transfer caused by the chemical bond between boron and hydrogen atoms[7]. In this way a further refinement of the distribution of the remaining bonding electrons was achieved.

The salient results are given in Figs. 2—4. Fig. 2 shows the strong local accumulations of bonding electrons in normal covalent terminal B—H bonds. Fig. 3 shows — also in the first approximation — a maximum of electron density close to the H-atom in the three-center bonds B—H—B. Unlike the minima of equal magnitude in Fig. 3, the maximum is supposed to be real because it appears at the same position in all of the B—H—B bridges of the asymmetric unit.

The distribution of electrons bonding the atoms of the B-skeleton is revealed in the second approximation only. These electrons are smeared over the planes formed by the B-atoms of the skeleton. Fig. 4 shows the cross-section at about the middle between the bottom and the rim of the basket-shaped molecule. The density of these bonding electrons is only of the same magnitude as in the background of a metal. It remains to be seen whether or not a relation exists between the arrangement of the B atoms in $B_{10}H_{14}$ and that in metallic boron. In both cases the atomic arrangement is icosahedral with the same atomic distances. Accumulations of the electrons of the skeleton appear outside the cross-section of Fig. 4, especially on the line B-2 to B-3 (closer to B-3 than to B-2) and, a little weaker, in the middle of the triangle B-2—B-5—B-5′. They are again found uniformly on all chemically equivalent locations of the asymmetric unit and correspond approximately to the electron distribution postulated by *Lipscomb*[8]. We find, however, slight evidence only for a "central" three-center bond in the triangle

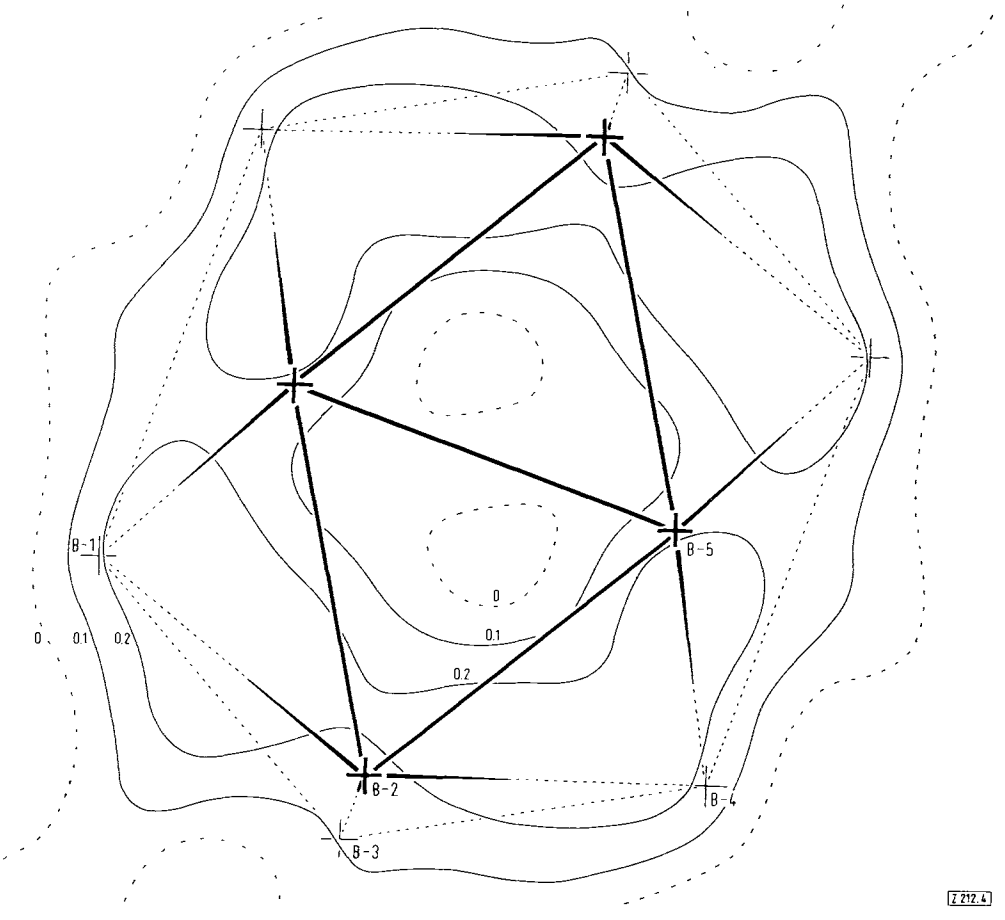

Fig. 4. Section through the boron skeleton of a molecule in the difference synthesis (contours at intervals of 0.1 e/A³).

B-1′—B-4—B-5 and its chemical equivalent in the asymmetric unit of the molecule. Likewise, the B—H—B bonds are not characteristic open three-center bonds. In such a case the bonding electrons are supposed to be concentrated on the lines connecting the atoms B—H—B. Fig. 3 clearly shows that this is not so.

Isothiocyanato Carboxylic Acids and 2-Thioxo-5-oxazolidones

By *Hans R. Kricheldorf*[*]

Isothiocyanato carboxylic acids *(3)* and 2-thioxo-5-oxazolidones *(4)* can be polymerized with loss of COS to give polyamides or peptides.

The hitherto unknown trimethylsilyl isothiocyanato carboxylates *(2)*, which proved accessible by silylation of *N*-dithiocarboxy amino acid derivatives *(1)*, appeared suitable as starting materials for the preparation of *(3)* and *(4)* (R^1 = $CO—OC_2H_5$[1], C_2H_5[2], $CH_2—C_6H_5$[3]; for R and *n*, see Table).

g	H	5	95–98/10^{-3}	32–34	

[a] D,L form. [b] L form.

The carboxylic acids *(3)* can be liberated in 85–95% yield from the silyl esters *(2)* by treatment with ethanol at 0 °C.

(4)

The α-compounds *(2a)* to *(2d)* gave only the 2-thioxo-5-oxazolidones *(4)*. These compounds have a low thermal stability; for example, *(4a)* and *(4b)* decompose within a few hours at room temperature, and, although slower, also at temperatures as low as about −20 °C. Those bearing larger substituents, *e.g.*, *(4c)* and *(4d)*, exhibit a definite melting point and can be kept at −20 °C for several weeks. Decomposition involves loss of COS to give peptides; a concurrent isomerization gives the more stable thiazolidin-2,5-diones, but in far smaller yield.

β-Isothiocyanatopropionic acid *(3e)* also polymerizes in the course of a week at +25 °C to give oligo-β-alanine. In contrast, γ-isothiocyanatobutyric acid *(3f)* and ε-isothiocyanatohexanoic acid *(3g)* (which has already been prepared by another method[4]) are stable at room temperature. The compounds polymerize readily only above about 150 °C or, in the presence of triethylamine (not pyridine!), above 50 °C. Copolymers can be isolated from mixtures of monomers[5].

All the new compounds listed were characterized by C, H, N elemental analysis and IR spectra, and some of them by NMR spectra.

Isocyanato carboxylic acids (3) and 2-thioxo-5-oxazolidones(4)

Triethylamine (2.1 moles) is added dropwise to a warm mixture of *(1)* (1 mole), having R^1 = $CO—OC_2H_5$, C_2H_5, or $CH_2—C_6H_5$, and trimethylchlorosilane (2 moles) in dry toluene (*ca.* 1.5 l) and the reaction mixture is heated to boiling for 2 h. Precipitated triethylammonium chloride is filtered off and the esters *(2)* are isolated in 70–90% yield by fractional distillation.

A solution of *(2)* (0.1 mole) in light petroleum (100–150 ml) is treated at 0 °C with dry ethanol (0.1 mole) and a catalytic amount of dry hydrogen halide, and the solution is stirred at 0 °C until the product [*(3)* or *(4)*] has precipitated (5–30 min). The 2-thioxo-5-oxazolidones *(4)* must be filtered off, dried in a high vacuum, and used immediately. At 20 °C compound *(4b)* yields a solid foam of poly-D,L-alanine within about 20 min of isolation.

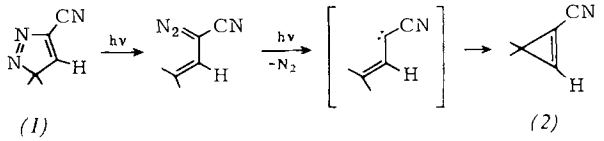
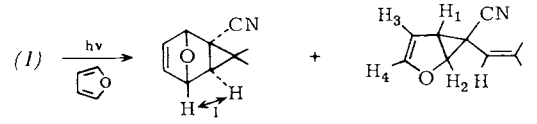
[5] The β-, γ-, and ε-isothiocyanato carboxylic acids and their silyl esters have an extremely powerful urticating action and give rise to painful blisters and wounds, even in high dilution.

Cycloadditions of Vinylcarbenes



By *Michel Franck-Neumann* and *Christiane Buchecker*[*]

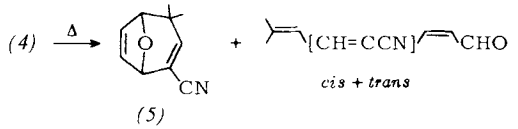
Carbenes that can undergo intramolecular stabilization generally react very reluctantly with other molecules[1]. This appears to be the case, for example, with vinylcarbenes which can give cyclopropenes by intramolecular addition[2,3] and which, to our knowledge, exhibit no intermolecular additions providing proof of carbenoid structure[4].



We have now been able to intercept the vinylcarbenes supposed to give rise to cyclopropenes *via* diazoalkenes[3] on photolysis of 5-cyano-3*H*-pyrazoles[5]. This was accomplished by intermolecular cycloaddition to alkenes, alkynes, and dienes to give vinylcyclopropanes, vinylcyclopropenes, and divinylcyclopropanes, respectively.

Two special cases will serve as illustrations: (i) Stereospecific addition to furan and (ii) addition to benzene, which gives a new stable norcaradiene derivative.

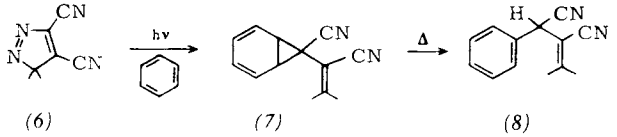
If irradiation of 5-cyano-3*H*-pyrazole *(1)*, which gives only the highly unstable 3,3-dimethyl-1-cyanocyclopropene *(2)* [ν (C=C) = 1720 cm^{-1}] when performed in ethereal solution, is carried out in furan, the resulting Diels-Alder adduct *(3)* of cyclopropene (m.p. 52 °C, $J < 0.4$ Hz) is accompanied solely by the 1,2-divinylcyclopropane derivative *(4)* (*cis* or *trans*).



(1) *(2)*

(3) 1:2.5 *(4)*

6-Cyano-6-(2-methyl-1-propenyl)-2-oxabicyclo[3.1.0]hex-3-ene *(4)*, ν (C=C) (vinyl ether) = 1685 cm^{-1}; δ = 1.67 ppm (3 H/d), J = 1.4 Hz; 1.78 (3 H/d), J = 1.2 Hz; 4.54 (1 vinyl H/heptuplet); 3.04 (H^1/dd), J = 2.8 and 5.5 Hz; 4.94 (H^2/d), J = 5.5 Hz; 5.16 (H^3/t), J = 2.8 Hz; 6.24 (H^4/d), J = 2.8 Hz[6].



(4) is sufficiently stable to be isolated in pure form (yield 42%), although it gradually rearranges at room temperature to three new substances (halflife 65 min at 50 °C and 23 min at 60 °C). Divinylcyclopropane rearrangement[7] gives 2-cyano-4,4-dimethyl-8-oxabicyclo[3.2.1]octa-2,6-diene *(5)*, δ = 0.88 (3 H); 1.28 (3 H); 4.52 (1 bridgehead H/t), J = 2 Hz; 4.68 (1 bridgehead H/m); 5.95—6.70 (3 vinyl H/m), and furanocyclopropane rearrangement[8] affords a *cis-trans* mixture (1 : 3.4) of two trienealdehydes, ν (C=O) = 1680 cm^{-1}; ν (C=C) = 1600 and 1640 cm^{-1}; λ_{max} (CH_3OH) = 330 nm (ε = 8050); δ (*o*-dichlorobenzene) = 9.60 ppm (aldehyde H/d), J = 7.4 Hz; 10.10 (aldehyde H/d), J = 6.4 Hz.

(5) *cis + trans*

The ready divinylcyclopropane rearrangement cannot be regarded as proof of the *cis* structure of *(4)* in this case (cyano substituent, concomitant isomerization).

Photolysis of 4,5-dicyano-3H-pyrazole *(6)* gives a much more reactive vinylcarbene which even undergoes a C—H insertion reaction with ether. Unlike the carbenes generated from *(1)*, it reacts with benzene to give both the cyclopropene [δ (CH_3) = 1.53], which was not isolated, and the stable norcaradiene derivative *(7)* (one isomer, pure yield 45%), which isomerizes mainly to *(8)* only at elevated temperatures (halflife at 160 °C about 60 min).

(6) *(7)* *(8)*

7-Cyano-7-(1-cyano-2-methyl-1-propenyl)norcaradiene *(7)*, colorless crystals, m.p. 91 °C (from dimethoxyethane), spectroscopic properties similar to those of 7,7-dicyanonorcaradiene[9]: ν (C=C) = 1630 cm^{-1}; λ_{max} (CH_3OH) = 265 nm (ε = 3320); δ = 2.07 ppm (3 H); 2.12 (3 H), 2.93 (2 cyclopropane H/m); 6.20 (4 vinyl H/m).

1,2-Dicyano-3-methyl-1-phenyl-2-butene *(8)*, δ = 2.03 ppm (3 H), 2.15 (3 H); 4.95 (1 allyl H), 7.36 (5 arom. H).

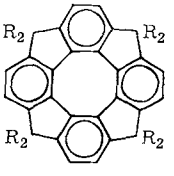
Cyclooctatetraene Systems Flattened by Steric Constraints[**]

By *Dieter Hellwinkel* and *Günther Reiff*[*]

Cyclooctatetraene[1] is a tub-shaped molecule which can assume a planar conformation with predominantly localized double bonds (symmetry D_{4h}) only in a relatively energy-rich transition state (12—15 kcal/mole) during a ring inversion[2]. Flattening of the cyclooctatetraene ring can also be achieved by alteration of the π-electron skeleton (*i.e.* by addition of two electrons[2] and formation of transition metal complexes[3]) the dianion then being structure determining. The same is true for the symmetrical dibenzocyclooctene[4].

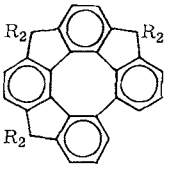
The ESR data of the radical anions of the cyclooctatetraene derivatives mentioned above and of the tub-shaped tetrabenzocyclooctene (*o*-tetraphenylene), on the other hand, do not afford definite information about the structure[4,5].

In order to force tetraphenylene, and hence the inherent cyclooctatetraene skeleton, to assume a planar conformation by purely steric means we used as starting materials the tetra-



(1) *(2)*

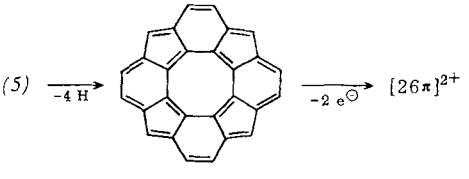
(a), R = CH_3; *(b)*, R = COOH; *(c)*, R = $COOCH_3$



methyltetraphenylenes *(1a)* (m.p. 274 °C) and *(2a)* (m.p. 208 °C), which are accessible in very low yield *via* a multistep synthesis[6]. Oxidation of *(1a)* and *(2a)* with $KMnO_4$ gives the tetracarboxylic acids *(1b)* (dec. pt. 450 °C) and *(2b)* (dec. pt. 380 °C), which react smoothly with diazomethane to give the esters *(1c)* (m.p. 260 °C) and *(2c)* (m.p. 240 °C) respectively.

Treatment of *(1c)* and *(2c)* with polyphosphoric acid (*ca.* 240 °C) yields the orange cyclic ketones *(3)* (subl. > 500 °C, νC=O = 1720 cm^{-1}) and *(4)* (subl. ≈ 380 °C, νC=O = 1720 cm^{-1}) whose monomeric structures have been established by mass spectrometry[7]. Interestingly, in the IR spectrum of *(3)* the characteristic strong γCH bands for 1,4-di- and 1,2,3,4-tetrasubstituted benzene derivatives are shifted to 740 cm^{-1}. The IR spectrum of *(4)* contains a very intense multiply-split band in this region having a maximum at 739 cm^{-1}.

Reduction of the ketones *(3)* and *(4)* with hydrazine hydrate/sodium diethylene glycolate[8] affords 1,16;4,5;8,9;12,13-tetramethano-*o*-tetraphenylene *(5)* (subl. 380 °C) and 4,5;8,9;12,13-trimethano-*o*-tetraphenylene *(6)* (m.p. 240 °C) in good yields; the molecular weights of *(5)* and *(6)* have been determined by mass spectrometry[7]. The IR spectrum of *(5)* exhibits very few lines and shows an unusually large shift of the intense γCH bands (775 cm^{-1}) towards longer wavelengths.



(3), R_2 = O
(5), R_2 = 2 H

(4), R_2 = O
(6), R_2 = 2 H

The UV spectra of *(5)* and *(6)* ($HCCl_3$) resemble very closely those of fluorene and indeno[2,1-*c*]fluorene, yet all maxima, and in particular the two at the longest wavelength, show increased intensity and considerable bathochromic shifts as a result of the greatly extended conjugated system. [*(5)* λ_{max} (log ε): 262 (4.63); 275 (4.67); 285 (4.70); 343 (4.24); 358 (4.50); (6): 275 (4.84); 285 (4.80); 335 (4.25); 348 (4.32).]

The mass spectrum of *(5)* affords an indication of the stability of the potential dehydrogenation products of *(5)*, *i.e.* of the tetramethinotetraphenylene *(7)*[7]. [M^+ = 352, 100%; $(M-1)^+$, 35%; $(M-2)^+$ 25%; $(M-3)^+$, 27%; $(M-4)^+$ = $(7)^+$, 25%; M^{2+}, 36%; $(M-1)^{2+}$, 27%; $(M-2)^{2+}$, 51%; $(M-3)^{2+}$, 48%.] A relative intensity of 100% is observed for $(M-4)^{2+}$ = $(7)^{2+}$; this is four times greater than the intensity of the accompanying singly charged fragment ion $(M-4)^+$!

(7), 28π

This behavior seems to indicate the tendency of the non-Hückel 28π electron system *(7)* to be transferred, following the loss of two electrons, into a 26π electron system obeying the Hückel rule[9].

Stereochemistry of the Catalyzed Cyclodimerization of Piperylene

By *Paul Heimbach* and *Hansjörg Hey*[*]

The cyclodimerization of butadiene in presence of nickel-ligand catalysts affords *cis*-1,2-divinylcyclobutane in yields of up to 40% together with *cis,cis*-cycloocta-1,5-diene if the reaction is carried out to 85% conversion of butadiene[1,2]. We have now investigated the stereochemical course of this catalyzed synthesis of four- and eight-membered rings, using as example the cyclodimerization of the piperylenes (1,3-pentadienes)[3].

In addition to the eight-membered rings *(6)*—*(9)*, five of the ten possible isomeric dimethyl derivatives of *cis*-1,2-divinylcyclobutane are formed stereospecifically in yields of 16—92%.

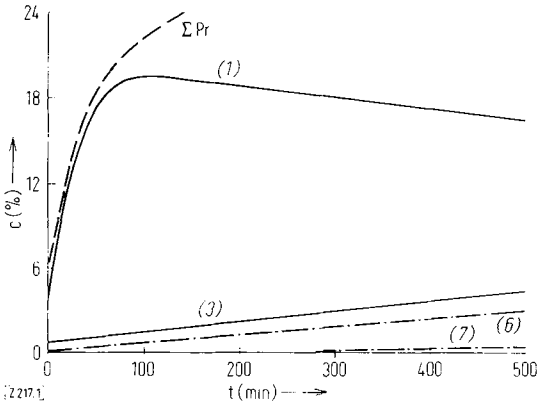
Two molecules of *trans*-piperylene give the four-membered rings *(1)* and *(3)*, whereas two molecules of *cis*-piperylene give the four-membered rings *(1)* and *(2)*, and one molecule each of *cis*- and *trans*-piperylene afford the four-membered rings *(4)* and *(5)*.

The yields are dependent on the type of ligand (phosphines or phosphites) in the nickel catalyst, on the composition of the piperylene, and on the conversion of the 1,3-diene.

The structures and the configurations of the isolated four-membered ring derivatives were determined by IR- and ^{1}H-NMR spectroscopy; they are in agreement with the behavior of the compounds *(1)*—*(5)* in the thermal Cope rearrangement[4].

In the course of these investigations a *thermodynamic equilibrium between 1,3-dienes and cis-1,2-divinylcyclobutanes* was observed for the first time.

Thus, *e.g.* the shape of the concentration-time curve for the four-membered ring *(1)* (see Fig. 1) obtained on reaction of *trans*-piperylene in presence of nickel-tricyclohexylphosphine catalyst can only be explained by an equilibrium between the 1,3-diene and the corresponding *cis*-1,2-divinylcyclobutane.



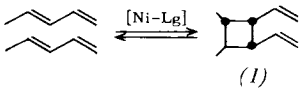


Fig. 1. Concentration-time curves for the four- and eight-membered rings obtained from *trans*-piperylene in presence of nickel-tricyclohexylphosphine catalyst. Temperature. 30 °C; Ni:diene = 1 : 48. ———: four-membered rings, — · · —: eight-membered rings.

(1)

$$K = \frac{[\text{four-membered ring } (1)]}{[\textit{trans}\text{-piperylene}]^2}$$

The equilibrium constant K has a value of $(2.3 \pm 0.3) \times 10^{-2}$ l/mole at 30 °C irrespective of the type of ligand in the nickel catalyst. At lower temperatures the equilibrium shifts in favor of the four-membered ring *(1)*.

The catalysts give rise not only to addition but also to an *isomerization of cis- to trans-piperylene via the four-membered ring (1)*. This novel type of isomerization is apparent in particular from the kinetics of the cyclodimerization of pure *cis*-piperylene.

Reaction of two molecules of *cis*-piperylene in presence of nickel-tricyclohexylphosphine catalyst leads, in the first instance, to slow formation of the four-membered ring *(1)*. Reaction of one molecule each of *cis*- and *trans*-piperylene proceeds about three times as fast, but with a distinct incubation period, to give the four-membered ring *(4)*. The *trans*-piperylene necessary for the formation of *(4)* is available only after cleavage of *(1)*.

The catalyzed retrocleavage of the pure four-membered rings *(2)—(4)* also proceeds stereospecifically. The above mentioned stereospecific formation of the four-membered rings is therefore confirmed. Unambiguous results are obtained, however, only if the 1,3-diene formed is immediately withdrawn from the reaction mixture at 30 torr. In addition, the corresponding eight-membered rings *(6)—(8)* are formed stereospecifically by a catalyzed Cope rearrangement [5].

Mango suggests that the *cis*-1,2-divinylcyclobutane is formed in a suprafacial concerted process [6]. The stereospecificity found for formation of the four-membered rings from piperylene is not in agreement with this hypothesis.

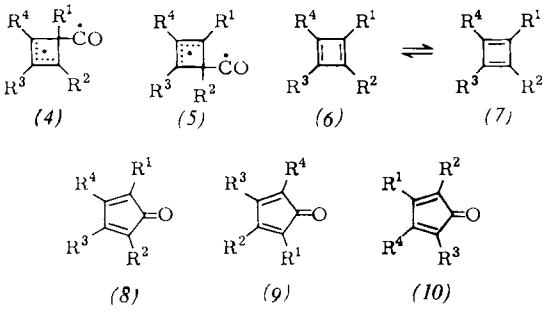
Alkyl-Substituted Cyclobutadienes[1][**]

By *Günther Maier, Giselher Fritschi*, and *Bernd Hoppe*[*]

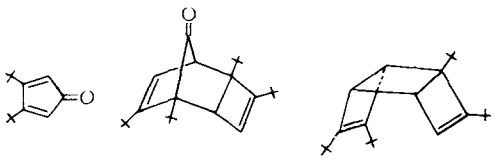
The photofragmentation of cyclobutenedicarboxylic anhydrides at room temperature leads to products whose formation can readily be interpreted in terms of the intermediacy of cyclopentadienones and cyclobutadienes [1b, 1c].



When the anhydrides *(1a)—(1c)* are irradiated in a tetrahydrofuran matrix at —196 °C a deep yellow color appears; this disappears immediately when the matrix melts, or, more

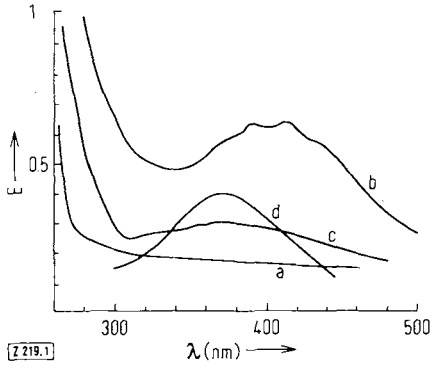
	(a)	(b)	(c)	(d)
R^1	CH_3	H	H	H
R^2	CH_3	CH_3	H	H
R^3	CH_3	CH_3	CH_3	$C(CH_3)_3$
R^4	CH_3	CH_3	CH_3	$C(CH_3)_3$

exactly, at a temperature when the organic glass just becomes mobile. The cyclobutadiene-cyclopentadienone adducts *(2)* and the dimers *(3)* of the cyclopentadienones are the sole products that can be isolated from the low-temperature photolysis.



This is not only true for the anhydrides *(1a)* and *(1c)* [1a] but also for the trimethyl derivative *(1b)*. The distribution of the methyl groups in the products suggests that, in the irradiation of the anhydrides, CO_2 is first eliminated and the diradical fragments *(4)* and *(5)* formed subsequently lose CO to give

the cyclobutadienes *(6)* and *(7)* — in the case of singlet cyclobutadienes, two valence isomers come into consideration — or cyclize to give the isomeric bicyclo[2.1.0]pentenones, which can isomerize *via* ring opening to the cyclopentadienones *(8)*, *(9)*, and *(10)*. The fact that the isolated adducts *(2)* and *(3)* are formed by a Diels-Alder type reaction and have an *endo* configuration suggests that the cyclobutadienes and cyclopentadienones have singlet character and are stable as monomers when frozen into a matrix at —196 °C.



Supporting evidence for this concept can be gained from spectroscopic investigations: In the IR spectra recorded during the low-temperature irradiation, the anhydride bands disappear and a carbonyl stretching vibration characteristic for cyclopentadienones appears at 1700—1710 cm^{-1}. This is an indication that the yellow glasses probably do not contain any compounds having a carbonyl group other than starting anhydrides and cyclopentadienones.

In the case of the anhydride *(1d)* [2], it is of particular importance for the spectroscopic detection of the cyclobutadienes that the 3,4-di-*tert*-butylcyclopentadienone *(8d)* [m.p. 47.5—48.5 °C; IR(CCl_4): 1708 cm^{-1}; UV(ether):

(8d) (11) (12)

λ_{max} = 365 nm, ε = 80; NMR(CCl_4): τ = 4.65 (2 H/S); 8.64 (18 H/S)] can be isolated. It is therefore possible to compare the UV spectrum of the dienone *(8d)* with the total absorption of the primary products occurring in the photofragmentation of the anhydride. The Figure shows quite clearly that the

Low-temperature irradiation of 3,4-di-*tert*-butylcyclobutenedicarboxylic anhydride (1d) in 2-methyltetrahydrofuran (3.7×10^{-2} mole/l); a) before irradiation: b) irradiated two hours (low-pressure Hg lamp, Vycor); c) after warming to room temperature; d) isolated 3,4-di-*tert*-butylcyclopentadienone *(8d)*.

yellow color observed in the low-temperature irradiation of *(1d)* not only stems from *(8d)* — and consequently not from *(9d)* — but must originate predominantly from another species having a structured absorption band in the visible region (maximum at 410 nm). In the case of the anhydrides *(1a)*—*(1c)*, spectra of the same type are found under analogous conditions; only the position of the maxima is bathochromically shifted with increasing number of methyl groups.

We ascribe these absorptions to the cyclobutadienes and believe that this is the first successful direct spectroscopic detection of simple substituted cyclobutadienes.

The low-temperature photolysis of *(1d)* affords *(8d)* and two further products: the monoketone *(11)* [m.p. 140 °C; IR(CCl_4): 1765 cm^{-1}; NMR(CCl_4): τ = 3.53 (1 H/D) (J = 4.5 Hz); 4.45 (1 H/S); 7.15 (1 H/S); 7.27 (1 H/D) (J = 4.5 Hz); 8.67 (18 H/S); 8.94 (9 H/S); 8.97 (9 H/S)] and the hydrocarbon *(12)* [NMR(CCl_4): τ = 4.18 (1 H/S); 7.0—7.7 (3 H, ABX system); 8.85 (18 H/S); 8.90 (9 H/S); 9.01 (9 H/S)]. Apparently the 3,4-di-*tert*-butylcyclopentadienone *(8d)* does not dimerize, even at room temperature, because of steric hindrance in the transition state of the Diels-Alder reaction. It does not even add di-*tert*-butylcyclobutadiene; only 2,3-di-*tert*-butylcyclopentadienone *(9d)* can react with the 1,2-di-*tert*-butylcyclobutadiene. The unconsumed cyclobutadiene dimerizes to the tricyclic compound *(12)*. The formation of *(11)* and *(12)* indicates that the equilibrium *(6d)* $\rightleftharpoons$ *(7d)* lies on the side of the valence isomer *(7d)*, in which the bulky groups are further removed from one another.

In the series of methyl-substituted anhydrides, the C=O band belonging to the cyclopentadienones is rapidly lost on thawing out, and the signals expected for the adducts *(2)* and *(3)* are formed. Similarly, the UV absorption in the region > 350 nm disappears as soon as the matrix begins to melt. On the other hand, in the case of the anhydride *(1d)* a residual yellow color remains even on warming because of the dienone that is still present; the maximum at 410 nm, however, vanishes completely. At the same time, the carbonyl absorption in the IR spectrum decreases only slightly and a weak band, which can be ascribed to the adduct *(11)*, appears at 1765 cm^{-1}.

In the ESR spectrum[3] — irradiation of the anhydride *(1a)* and recording of the spectrum were carried out at the temperature of liquid nitrogen — there are no signals to be seen other than a septet, which can be ascribed to the radical[4] occurring by cleavage of hydrogen from 2-methyltetrahydrofuran. It is almost certain, therefore, that neither triplet molecules nor any other sufficiently long-lived diradical intermediates are present in the yellow matrix.

The chemical and spectroscopic[5] findings can, in our opinion, be interpreted as follows: alkyl-substituted cyclobutadienes are highly reactive substances which are detectable only under extreme conditions *e.g.* when frozen into a matrix at the temperature of liquid nitrogen. They have a singlet ground state for which theory demands a rectangular geometry and alternating single and double bonds. They are to all appearances[6] yellow owing to a characteristic absorption between 400 and 430 nm.

[2] *R. E. K. Winter*, St. Louis, Missouri (USA), first prepared this anhydride and found that *o*-di-*tert*-butylbenzene is formed when it is irradiated at room temperature (private communication).

[3] We are indebted to Dr. *K. Eiben*, Karlsruhe, for the recording of the spectrum.

[4] *F. S. Dainton* and *G. A. Salmon*, Proc. Roy. Soc. (London) Ser. *A 285*, 319 (1965).

[5] *N. L. Allinger*, *C. Gilardeau*, and *L. W. Chow*, Tetrahedron *24*, 2401 (1968), have calculated the UV spectra of triplet- and singlet-cyclobutadiene. The latter cannot give rise to an absorption in the region 200—400 nm; however, two forbidden transitions ought to be observed at 439 and 487 nm. The maxima > 400 nm observed by us, as well as the relatively small extinction coefficients (crudely estimated as a few hundred at most), are in agreement with these calculations.

[6] The longwave absorption could possibly be due to a charge-transfer complex between a cyclopentadienone and a cyclobutadiene molecule. An orientation of the anhydride molecule would then have to take place in the matrix before the irradiation. Furthermore, if this were the case it would be difficult to explain why the two closely neighboring, highly reactive partners are not converted into the adducts *(2)* before the thawing-out.

Macromolecular Colloquium

The Macromolecular Colloquium was held at Freiburg/Br. (Germany), February 26–28, 1970.

From the lectures:

Preparation of Monodisperse Polyethylene Oxides by Gel-Chromatographic Separation of Discontinuous Polymer-Homologous Series

By *Bruno Bömer* (lecturer), *Walter Heitz*, and *Werner Kern*[*]

We have been able to prepare monodisperse polyethylene oxides HO–[CH_2–CH_2–O–]$_n$–H having molecular weights of up to 2000, corresponding to degrees of polymerization $n \leq 45$, by the triplication process on a preparative scale.

In this process, both condensation components are derived from the same oligomer, so that the condensation gives a mixture of the members of a discontinuous polymer-homologous series.

The polyethylene oxides are synthesized from di-*p*-toluenesulfonates and sodium alkoxides of the same diols at room temperature, *e.g.*

$$\begin{aligned} &HO\text{–}[\text{–}CH_2\text{–}CH_2\text{–}O\text{–}]_3\text{–}Na + \\ &TsO\text{–}[\text{–}CH_2\text{–}CH_2\text{–}O\text{–}]_3Ts + NaO\text{–}[\text{–}CH_2\text{–}CH_2\text{–}O\text{–}]_3\text{–}H \\ &\qquad\downarrow \\ &HO\text{–}[\text{–}CH_2\text{–}CH_2\text{–}O\text{–}]_{3n}\text{–}H \\ &n = 2, 3, 4, 5, \ldots \end{aligned}$$

The purity of the triethylene glycol was verified by gas chromatography of the bis(trimethylsilyl) ethers. The gel-chromatographically uniform compounds nonaethylene glycol ($n = 9$, molecular weight = 414) and pentadecaethylene glycol ($n = 15$, molecular weight = 678) were obtained from the reaction mixture of the first triplication step by molecular distillation.

The nonaethylene glycol was used as the starting material for the second triplication stage. The resulting polymer homologs of nonaethylene glycol were separated by preparative gel chromatography on a polystyrene gel crosslinked with 2% of divinylbenzene, the pure monodisperse hepteikosaethylene glycol ($n = 27$, molecular weight = 1207) and pentatetrakontaethylene glycol ($n = 45$, molecular weight = 2000) being obtained on the preparative scale. Samples of up to 5 g in 50 ml of THF could be separated on a 200 × 5 cm column.

In the separation of industrial polyethylene oxides prepared by polymerization, it was found that the resolving power of the separation arrangement used extended up to $n \approx 27$.

Physical Structure of Secondary-Valence Crosslinking in Urethane Elastomers

By *R. Bonart*[*]

Elastomers crosslinked by secondary valences are generally block copolymers of "hard" and "soft" segments, which must be substantially insoluble in each other. Owing to the weakness of secondary-valence interactions technologically satisfactory crosslinking is obtainable only if a large number of interactions contribute simultaneously and cooperatively to each crosslink, *i.e.* if the "crosslinks" are formed by crosslinking regions that are spread out in space. Elastomers crosslinked by secondary valences are therefore always two-phase systems of hard and soft segment regions. The soft segments are in the molten state at the service temperature and make the material extensible, whereas the hard segments are vitreous, crystalline, or paracrystalline, and in addition to effecting the crosslinking, they also have a certain filler character. This should be remembered in particular in the discussion of stress softening, which is often wrongly attributed to a fundamental weakness of secondary-valence crosslinking, whereas it is really due to the filler action of the hard segments. Attempts to optimize the technological properties of elastomers crosslinked by secondary valences by additional principal-valence crosslinking have therefore often been unsuccessful.

In the urethane elastomers, polyethers or polyesters having an average chain length of about 150–200 Å are generally used as the soft segments. The hard segments, on the other hand, generally result from the reaction of diisocyanates with diamines or diols as chain extenders. They contain urethane or urea groupings, and are therefore capable of forming hydrogen bonds. Information about the phase separation of the hard and soft segments is obtained by X-ray small angle scattering, while the mutual arrangement of the hard segments in space within the crosslinking regions is shown by special wide angle reflections. According to these reflections, the segregated hard segments are generally not crystalline in the conventional sense, but form paracrystals in Hosemann's sense, the statistical structural principle (referred to by *Hosemann* as the coordination statistic) of which depends on the chain extender, *i.e.* on the steric conditions for the formation of hydrogen bonds between adjacent hard segments. Even with a constant concentration of urethane or urea groupings, the conditions for the formation of hydrogen bonds are sometimes favorable and sometimes less favorable, depending on the steric structure of the chain extender. This leads to differences in the stability of the crosslinking regions and to differences in the solubility or phase separation of the hard and soft segments, and hence to differences in the number of crosslinking regions despite the constant ratio of the components. Both factors affect the mechanical behavior and the softening by heat.

Oligomer Formation in the Thermal Polymerization of Styrene

By *K. Kirchner* and *K. Buchholz* (lecturer)[*]

In the thermal polymerization of styrene, small quantities of oligomers are formed as undesirable by-products[1,2]. 0.023% of dimer and 0.082% of trimer are formed in pure styrene at 137 °C and 10% total conversion. These oligomers consist mainly of cyclic compounds with no olefinic double bonds. Kinetic measurements showed that there are essentially two independent reactions taking place. Firstly, a cycloaddition with the Flory diradical as an intermediate leads to *cis*- and *trans*-1,2-diphenylcyclobutane, and secondly, two styrene molecules from the unstable Diels-Alder adduct formulated by *Mayo*, which can enter into three secondary reactions: 1. Addition of a further molecule of styrene leads

to trimers. This reaction predominates at high monomer concentrations. 2. By migration of a H atom, the adduct is stabilized as 1-phenyltetralin. 3. A H atom is transferred to a third styrene molecule so that two monoradicals are formed. This reaction occurs to a relatively small extent [5].

The results of the kinetic measurements on oligomer formation agree with the investigations on the thermal polymerization [3]. *Brown*'s arguments [4] are discussed.

Light Scattering by Branched Systems

By *Walter Burchard* (lecturer), *Kanji Kajiwara*, and *Beate Pfannemüller* [*]

The interpretation of solution properties of branched macromolecules meets with difficulties for two reasons. Because of the formation conditions, products are formed having

a) extremely broad molecular weight distributions (M_n/M_w about 200–1000) and

b) a large number of isomers.

Owing to these difficulties, investigations have recently been carried out on the chemistry and theory of uniform macromolecules having specific branching, *i.e.* star and comb polymers. According to *Good* [1] and *Gordon* [2], however, the properties of randomly branched chains can also be calculated by means of "generating functions". These functions themselves generate the required broad molecular weight distributions with the corresponding isomer distributions. To set up the functions, one need only know the probabilities with which the reactive groups of a polyfunctional fundamental unit may have reacted. In this way, *Gordon* was able to calculate various average values of the molecular weight and of the mean square radius of gyration.

After generalization of the generating functions, it was possible to derive an expression that allows the calculation of the scattering functions for light and small-angle X-ray scattering in addition to the average values already known; the rigidity of the chains can be taken into account in this calculation [3].

Four examples were discussed:

1. Polyfunctional homopolycondensations.

2. Cocondensation of trifunctional with bifunctional monomer units of the types A—$\langle^{A}_{A}$ and A—A (Stockmayer model).

3. Condensation of trifunctional monomer units of the type A—$\langle^{B}_{C}$, where A can react with B and C, but B cannot react with C and like groups cannot react with one another (French-Erlander model).

4. Condensation of A—$\langle^{B}_{C}$ with A—B, where A can again react with B and C, while all other combinations are impossible.

Examples 1 and 2 give straight lines in the Zimm plot and indicate the same angle dependence as for linear chains. Type 3, however, gives plots with a strong upward curvature, while type 4 can exhibit all intermediate forms between the Stockmayer and French-Erlander models, depending on the reaction conditions.

Models 2 to 4 are applied to light scattering measurements on amylopectin tricarbanilate. The results are best described by model 4.

Segment Mobility in Polyethylene Terephthalate According to NMR Measurements

By *Uwe Eichhoff* (lecturer) and *Hans Gerhard Zachmann* [*]

The thawing of segment mobility can be seen in the NMR spectrum of semicrystalline polymers from a pronounced decrease in line width and in the second moment in the region of the glass transition temperature, as well as in the appearance of a narrow component.

For polyethylene terephthalate, irrespective of prior and subsequent heat treatment, a maximum of the transition temperature is found at crystallization temperatures of 200 and 220 °C. It can be shown on the basis of X-ray measurements that a large number of very small crystallites is formed at these temperatures. The strains in the small crystallites are responsible for the maximum of the transition temperature.

A process has been reported for the separation of the components of the spectrum, which permits the determination of the correct absolute value of the mobile component, free from experimental effects. By subtracting the mobile component from the noncrystalline fraction found by density measurements, one obtains the immobile noncrystalline component. This has a maximum at crystallization temperatures of 200–220 °C. In agreement with the interpretation of the maximum of the transition temperature, it must be assumed that at these temperatures the crystallization gives rise to strains that hinder the thawing of the segment mobility in these regions, even at high temperatures. If the samples are swollen in deuterated acetone after crystallization, this maximum disappears.

It can be shown by calculation of the line form of the spectra and comparison with the measurements that hindered rotation already exists for all the CH_2 groups up to the start of the glass transition. Above the glass transition, rotation of the benzene rings in the noncrystalline regions begins, and this changes into a microbrownian movement of the chain segments as the temperature is further raised.

Investigations on the Sequence Length Distribution of Copolymers of α-Methylstyrene and Butadiene

By *K. F. Elgert* (lecturer), *E. Seiler*, and *Horst Friebolin* [*]

The butyllithium-initiated copolymerization of α-methylstyrene (A) and butadiene (B) in THF at −75 °C is described by the copolymerization parameters $r_A = 0.017$ and $r_B = 2.8$. The sequence length distribution was investigated by 220 MHz NMR measurements. Analysis of the in part strongly overlapping band systems with a curve simulator allowed the quantitative determination of the frequencies of the AAA, BBB, BBA, and ABA triads as a function of composition and conversion. The experimentally determined triad frequencies agree well with those calculated from the *r* parameters.

High-Resolution NMR Studies on Cellulose Derivatives

By *Horst Friebolin* (lecturer), *Gunda Keilich*, and *Egon Siefert*[*]

Tests were carried out to determine whether the proton magnetic resonance method (measuring frequency 220 MHz) can be used to elucidate the structure of polysaccharides. Acetyl and benzoyl derivatives of cellulose were used as model substances, since in addition to their better solubility in organic solvents (*e.g.* $CDCl_3$), these compounds also exhibit spreading of the ^{1}H-NMR signals of the seven ring protons.

For the cellulose derivatives with molecular weights of several hundred thousand, all seven ring protons are separately visible in the spectra. However, the coupling constants, which are important for the determination of the configuration and conformation, cannot be determined because of the large line width.

The spectra of the cellulose derivatives with degrees of polymerization between about 50 and 100, on the other hand, exhibit such sharp lines that it has been possible to assign all the ring proton signals by means of the coupling constants. The chair conformation of the monomer units, glucose, and their β-glucosidic linkage were definitely confirmed. The 1,4-linkage of the glucose units is conclusively demonstrated by comparison of the chemical shifts of the protons in the 1 and 4 positions with those of the corresponding glucose and cellobiose derivatives; the structure that has been assumed for cellulose until now is thus confirmed.

The ^{1}H-NMR signals of the three acetyl groups of cellulose triacetates give three separate lines in the 220-MHz spectrum, which can be assigned to the acetyl substituents in positions 2, 3, and 6.

Structure of Phenylalanine-Specific Transfer Ribonucleic Acid from Baker's Yeast

By *Friedrich von der Haar*[*]

Transfer ribonucleic acid (tRNA) has a dual function in protein biosynthesis. Firstly, a specific tRNA binds, and hence activates, only the corresponding amino acid (acceptor function), and secondly the resulting activated amino acid is introduced into the ribosomal apparatus and built into the growing protein chain (transfer function). Whereas very detailed views exist on the second step (codon-anticodon interaction), the details of the course of the specific aminoacylation are unknown. In particular, there is no explanation at present for the very high specificity of the reaction, which must proceed with an error rate of less than 10^{-4}. In this connection it is important to clarify the three-dimensional structure of tRNA, which must be a globular molecule[1].

We therefore investigated tRNA by oxidation with monoperoxyphthalic acid. Under strictly defined conditions, this reagent specifically oxidizes non-base-paired adenines to adenine 1-*N*-oxide, which can be readily detected analytically. All the tRNAs that have been sequenced so far can be folded back by optimum base pairing in the Watson-Crick sense to give a planar clover-leaf structure, as was first suggested by *Holley* for $tRNA^{Ala}$[2]. In such a structure, nine adenines should be oxidizable in $tRNA^{Phe}_{Yeast}$. We found that only four of these bases are oxidized; the other five must therefore be protected by hydrogen bonds. Three of the oxidizable adenines are situated in the anticodon loop, while the fourth is at the 3′-terminal end of the $tRNA^{Phe}_{Yeast}$.

This result can be readily explained by folding of the dihydro-U-loop and of the T—Ψ—C loop to the 3′-terminal end. New interloop base pairs are then formed by proximity in space, the stability of these base pairs arising from optimum stacking.

Investigations by *Litt* on the guanosine-specific reagent ketoxal[3] and biochemical[4] and physicochemical[5] measurements confirm these views, which can be applied to all other tRNAs.

We have now succeeded in crystallizing $tRNA^{Phe}_{Yeast}$[6], and there is thus a possibility that its structure can be elucidated by X-ray analysis.

The Influence of Electron Donor-Acceptor Complexes on Cationic Polymerization

By *Manfred L. Hallensleben*[*]

We have investigated the cationic polymerization of styrene and α-methylstyrene in solution in the presence of organic electron acceptors that form an electron donor-acceptor complex with the monomer (monomer-acceptor complex, MA complex). In inert solvents such as carbon tetrachloride, the MA complex decomposes at low acceptor concentrations after initiation *e.g.* with $BF_3 \cdot O(C_2H_5)_2$, and a new electron donor-acceptor complex is formed with the negatively charged ion (anion-acceptor complex, AA complex). The separation of the ion pair by this AA complex increases the polymerization rate. Its increase is a linear function of the acceptor strength. At high electron acceptor concentrations, the MA complex causes retardation or even inhibition of polymerization.

In aromatic solvents such as benzene or toluene, which can compete with the monomer as electron donors, the influence of the electron acceptor on the polymerization is small.

Influence of Polymer and Copolymer Microstructure on the Chemical Reactivity of Polymers

By *H. James Harwood* (lecturer), *Edwin Thall*, and *Arthur B. Robertson*[*]

Investigations of the kinetics of reactions involving functional groups attached to polymer chains and studies of the limiting conversions obtained in such reactions suggest that polymers may contain groups with considerably different reactivities, depending on their environment in the polymer chain. These studies suggest that information about the stereoregularity of homopolymers and the distribution of monomer sequences in copolymers can be obtained from studies of their chemical reactivity.

The reactivity of polymers is influenced by many factors other than microstructure, however, and the influence of

these other factors changes with the extent of reaction. For this reason, kinetic and limiting conversion data should not be used for the characterization of microstructure.

A radiotracer procedure has been developed for detecting groups present in polymers which have different reactivity. The procedure provides information about the relative amounts of the various groups present and their relative reactivity.

When this procedure was used to study the reactivity of MMA units in styrene-methyl methacrylate copolymers, all the MMA units were found to have the same reactivity. Similarly, all the units in conventional poly(methyl methacrylate) were found to have the same reactivity.

The Structure Rule of Antibodies and the Antibody Problem

By *Norbert Hilschmann* (lecturer), *Herwig Ponstingl*, *Maxime Hess*, *Ludwig Suter*, *Heinz Ulrich Barnikol*, *Knut Bazcko*, *Shitsu Watanabe*, and *Dietmar Braun* [*]

Comparative structure analysis of monoclonal, *i.e.* chemically uniform, immune serum globulins have shown that

1. antibodies with different antigen specificities have different amino acid sequences, and

2. these structural differences are confined to the variable part of the immune globulin chains.

In the light (L) chains (molecular weight 24000), this variable part corresponds to the N-terminal half, while in the heavy (H) chains, which are approximately twice as long (molecular weight 50000), it is the N-terminal quarter of the molecule. The variable parts are thus of the same size in both chains, and contain 110 to 120 amino acid residues. The structural differences in the variable part involve several exchanges of amino acids and a few deletions.

To gain an insight into the causes of this antibody variability, we have studied other variable parts of immune globulin L chains over the past few years. We found that the amino acid exchanges in the variable part that determine the specificity follow an ordering principle. The ordering principle is the number of amino acids exchanged.

Several "subgroups" of chemically related proteins occur, in which at most 25% of the amino acids are exchanged. Proteins of various subgroups differ in an exchange of 50% of the amino acids. We have found three such subgroups in the $\varkappa$ chains and four in the λ chains.

This degree of order is understandable only if one assumes that the antibody variability has arisen by evolution and that the chains are derived from a common basic form after the fashion of a phylogenetic family tree. If this "variability rule" is confirmed by further investigations, particularly for proteins within the subgroups, this would mean that the information for the specificity of the antibodies is genetically fixed, and is thus not an acquired property, but an inherited one.

Mosaic Structure, Grain Boundaries, and Paracrystalline Distortions in Polyethylene Single Crystals

By *Rolf Hosemann* [*]

Some interesting properties of polyethylene single crystals can be deduced from the X-ray small angle and wide angle interferences.

If X-rays pass through a bundle of parallel oriented single crystals of this type, the small angle scattering appearing on the meridian points to a "long period" of 100 to 300 Å or more, depending on annealing, and gives the distance between neighboring crystal platelets (from center of gravity to center of gravity). The widths of the first layer line wide angle reflections, on the other hand, give direct information about the thickness of the crystallites [1]. The thickness of the "amorphous" intermediate layer in the single crystals of linear polyethylene (Lupolen 6011 H, BASF) studied here can then be calculated and is only a few Å. The crystals were prepared isothermally from 0.01% xylene solution at 85 °C, filtered and washed in acetone for 24 hours at the same temperature, and finally dried for 3 days under vacuum.

The width of the equatorial wide angle reflection gives the dimension of the lattice regions perpendicular to the chain direction. Careful consideration of the *h*00 and *hk*0 reflections showed that the structure probably consists of mosaic blocks whose grain boundaries are often formed by (310) planes, the diameters in the *h*00 and 0*k*0 directions being about 340 and 840 Å respectively [2]. On annealing at 125 °C, both quantities and the crystallite thickness increase to approximately the same degree, after 10^4 min, for instance, by about 30%. It is therefore permissible to speak of a type of equilibrium form, and to apply the Wulff equation. From the surface energy of the frontal faces (≈ 39 erg/cm^2), the surface energy within the lateral grain boundaries was found to be 68 ± 7 erg/cm^3. Since the intramolecular energy of a 2*g*1 kink, according to ref. [3], is about 38×10^{-14} erg, we find a two-dimensional kink concentration of 0.77×10^{14} cm^{-2} if these kinks are alone responsible for the distortions at the grain boundaries.

Comparing this quantity with the number of chain units $(CH_2)_3$ immediately adjacent to or lying in the (310) plane one obtains a kink concentration of about 24%. This agrees very well with the picture reported by *Pechhold et al.* for the concentrations of "jogs" in the grain boundaries. We find a different situation for the kink concentration inside the mosaic blocks; these can be calculated from the widths of the *hk*0 and *h*00 wide angle reflections with the aid of the paracrystal theory. The so called *g* value of the paracrystals, which characterizes the relative fluid-like statistical fluctuations of the distances between the planes, is found by X-ray studies to be 1.4 and 1.8% respectively for the (110) and (200) planes. A rough calculation on this basis gives a three-dimensional kink concentration of a least 0.14% inside the mosaic blocks.

Light Scattering Measurements on Polymer Solutions in the Pressure Range 1–1000 atm

By *M. Lechner* (lecturer) and *G. V. Schulz* [*]

Very extensive data exist on light scattering measurements on solutions of macromolecules as a function of composition and of temperature, the pressure generally being kept constant. For a complete knowledge of such systems, it is necessary to abandon the accidental external condition of atmospheric pressure and to introduce pressure as an available independent variable. We have therefore constructed a photometer that allows the measurement of the scattering intensity at a scattering angle of 90° up to pressures of about 1000 atm [1]. To determine the dimensions of the dissolved molecules, the dependence of the scattered light on the wavelength was measured instead of its angle dependence.

In this way we have measured the second virial coefficient of the osmotic pressure A_2 and the radius of gyration $\bar{r}$ as a function of pressure between 15 and 50 °C for the following systems[2–4]: the two endothermic systems polystyrene/*trans*-decalin (Θ = 20 °C at 1 atm) and polystyrene/cyclohexane (Θ = 36 °C at 1 atm); the athermic system polystyrene/toluene; and the exothermic system polystyrene/chloroform.

We have obtained the following results:

1. All the solvents examined become thermodynamically poorer with increasing pressure, *i.e.* the Θ temperature (A_2 = 0) increases, and all the systems examined become more endothermic.

2. The radius of gyration, which was measured for the systems polystyrene/*trans*-decalin and polystyrene/toluene, decreases continuously with increasing pressure for both systems between 15 and 40 °C.

3. The excluded volume model satisfactorily represents the observed behavior of the systems in the vicinity of the Θ temperature. At greater distances from the Θ temperature, the deviations become greater, *i.e.* agreement with the experiments can be obtained only if the unperturbed dimensions decrease with increasing pressure.

4. The free volume theory fairly accurately reproduces the temperature and pressure dependence of the thermodynamic properties even for athermic and exothermic systems.

Notes on the Determination of the Heterogeneity of the Chemical Composition of Copolymers by the Light Scattering Method

By *Pavel Kratochvíl* and *Zdeněk Tuzar*[*]

The molecular weight (M_w) and the parameters Q and P characterizing the chemical heterogeneity of binary copolymers can be determined by measurement of the scattered light intensity in at least three solvents having different refractive indices[1]. The refractive indices of the components A and B of the copolymer should differ as much as possible.

We have investigated the question of the optimum conditions for the determination of M_w, P, and Q. It was found that the three solvents should satisfy the following conditions. First solvent: both refractive index increments (ν_A, ν_B) should have large absolute values and the same sign; second solvent: $|\nu_A|$ large, $\nu_B = 0$; third solvent: $\nu_A = 0$, $|\nu_B|$ large.

It is generally difficult to achieve the optimum conditions with single-component solvents. If ν_A and ν_B are virtually equal, analysis is impossible. However, it is possible to obtain mixed solvents[2] with differing values of ν_A and ν_B, provided that they are measured after establishment of the dialysis equilibrium between solvent and solution. This effect is based on the different selective sorption of the components of the mixed solvent on the components A and B of the copolymer. It should accordingly be possible, in principle, to determine the chemical heterogeneity even of copolymers whose components have very similar refractive indices.

Our investigations on the light scattering from solutions of copolymers in mixed solvents have shown that the classic relations derived for single solvents by *Bushuk* and *Benoît*[1] are also valid for systems of this type; however, it is necessary to use the ν values determined after dialysis, in order to take into account the optical effect of the selective sorption.

These views have been tested for model mixtures of polymethyl methacrylate, polyethylene glycol monomethacrylate, and their copolymers in methyl cellosolve/α-bromonaphthalene. The copolymer components have very similar refractive indices in this case. The satisfactory agreement of the calculated and experimental M_w, P, and Q values confirms the importance of mixed solvents in the determination of the chemical heterogeneity of the copolymers.

Synthesis and Conformation of Collagen Models

By *Manfred Rothe* (lecturer), *Rainer Theyson*, *Klaus-Dieter Steffen*, *Hans-Jürgen Schneider*, *Mohammed Zamani*, *Michael Kostrzewa*, and *Wolfgang Schindler*[*]

In its nonpolar regions, collagen has an ordered structure with the regularly repeating tripeptide unit –glycine-proline-X–. Polytripeptides having this sequence with different X can help, as models, to elucidate the molecular basis of the biological function of collagen.

Since the polytripeptides investigated so far have not always been suitable, because of low molecular weights in most cases, partial incorporation of the condensing agent, and broad molecular weight distributions, pure, defined oligotripeptides having the sequence H(Pro-Gly-Gly)$_n$OH *(1)* up to $n \approx 8$ were synthesized in a chromatographically pure state after *Merrifield*.

Conformation studies by CD measurements showed that ordered structures as in the polymer occur at least beginning with the heptamer *(1)*, n = 7, in trifluoroethanol [three Cotton effects at 203–205 (weakly positive), 223 (weakly negative), and just below 185 nm (strongly negative), polytripeptide: 206, 230, <185 nm]. However, the first effects already occur with the tetramer *(1)*, n = 4. In hexafluoroacetone, on the other hand, the CD curves point to the absence of secondary structure.

In the stiff-chained oligoprolines H(Pro)$_n$OH, which were obtained by the same route in an electrophoretically uniform state up to n = 17, helices are found even for shorter chains. As in the case of polyproline, two conformations with *cis*- or *trans*-peptide linkages, different helical sense, and different residue translations, depending on the solvent, occur beginning with the tripeptide. This is shown by the molar rotations, the UV, NMR, and CD spectra in solution, and the IR spectra in the solid state. Interconversion of the two helices is possible by changing the solvent, as is shown by remarkable changes in the optical rotation (mutarotation).

Further models for the polymers are cyclopeptides with a rigid arrangement of the amino acids, *e.g.* cyclotri-L-prolyl and cyclo-L-prolyl-ε-aminocaproyl, as is shown by the optical data.

Some Polymeric Complex Formers

By *Georg Manecke*, *Hans-Uwe Schenck* (lecturer), and *Hans-Peter Aurich*[*]

The coordination behavior of 3(5)-pyrazolecarboxylic acid, 3(5),4-pyrazoledicarboxylic acid, their esters, 3(5)-pyrazolyl alkyl(aryl) ketones and 3(5)-pyrazolecarbaldehyde oxime was

investigated. 1 : 1 or 1 : 2 (M^{2+} : pyrazole derivative) complexes were obtained with Cu^{2+} and other transition metal ions.

3(5)-Vinylpyrazole derivatives have been obtained in good yields by 1,3-dipolar addition of vinyldiazomethane to sufficiently activated acetylene derivatives such as propiolic esters and ethynyl alkyl(aryl) ketones. Where these vinyl compounds were readily soluble in dimethylformamide, they could be homopolymerized in this solvent by a free-radical mechanism.

Both the copolymer of ethyl 3(5)-vinyl-5(3)-pyrazolecarboxylate with 2.5 mole-% of bis[3(5)-vinyl-5(3)-pyrazolyl] ketone and that of 3(5)-vinyl-5(3)-pyrazolyl methyl ketone were prepared. In both cases, crosslinked products exhibiting only limited swelling were formed. Alkaline hydrolysis of the polymeric vinylpyrazolecarboxylate gave a chelate-forming ion exchanger having a high capacity.

Polymerizable 5-vinyl derivatives were obtained from 5-acetyl-8-alkoxyquinoline and 5-acetyl-8-alkoxyquinaldine by reduction of the acetyl group to form the alcohols followed by dehydration with Al_2O_3. The 8-hydroxy-5-vinylquinoline obtained on hydrolysis of the phenol ester did not polymerize. Copolymers of 8-benzyloxy-5-vinylquinoline and 8-benzyloxy-5-vinylquinaldine with divinylbenzene lost the benzyl residue quantitatively on treatment with 5 N HCl. Peptides could be synthesized on the quinaldine resin.

The quinaldine and quinoline resins, as well as the C-7-brominated resins, were examined for complex formation with Cu, Ni, and Zn. The resins had higher capacities than one would have expected from the heterocycle content on the basis of the formation of 2 : 1 (ligand : metal) complexes. It is assumed that 1 : 1 complexes are formed. The copolymer of 8-ethoxy-5-vinylquinaldine (8-ethoxy-5-vinylquinoline does not polymerize well) with divinylbenzene takes up bromine as an adduct from aqueous solution.

Investigations on the Course of the Cationic Copolymerization of Tetrahydrofuran with Dicarboxylic Anhydrides

By *Waldemar Öchsner* (lecturer) and *Karl-Heinz Reichert* [*]

The cationically initiated reaction of tetrahydrofuran with dicarboxylic anhydrides leads *via* a ring-opening copolymerization to polyesters with ether units in the polymer chain [1]. The reaction was investigated in the system tetrahydrofuran (THF)/succinic anhydride (SA) and in the low molecular weight model system THF/acetic anhydride (AA), in most cases with PF_5 as the initiator. The induction period observed in the homopolymerization of THF with Lewis acids in the absence of cocatalysts could be avoided by prepolymerization of THF and addition of the comonomer after depolymerization of the polytetrahydrofuran formed.

Kinetic studies with various initial monomer concentrations in dichloroethane at 80 °C showed that the rate-determining step involves only THF, and not the anhydride monomer. By comparison of the overall rates of the copolymerization and the model reaction, this slowest step was identified as a nucleophilic attack by THF on the anhydride oxonium ion. The relative reactivities of the anhydride oxonium ions *(1)* and *(2)* towards THF were determined from the ratio of the overall polymerization rates. The results agree favorably with those obtained on sterically hindered acid hydrolysis of butyrolactone and on similar reactions of five-membered rings compared with reactions of unstrained systems [2].

(1) > *(2)*

For a detailed structure analysis, the alkaline hydrolysis products of the copolymer were acetylated to the same oligoether diacetates $CH_3CO-[O(CH_2)_4-]_nOCOCH_3$, which are formed directly in the model reaction. As expected from the polymerization equilibrium of THF, the diacetate distribution showed that above the ceiling temperature of THF (84 °C) the reaction leads mainly to the diacetate with $n = 2$ (BEDA) together with that having $n = 1$ (BDA). Considerable amounts of diacetates with longer ether sequences ($n \geqslant 3$) are formed only below this temperature.

Conclusions as to the relative reactivities of the two monomers (THF and anhydride) in a competitive addition to the oxonium ion *(3)* can be drawn from the molar ratio BEDA/BDA above the ceiling temperature, taking the initial monomer ratio into account. Structural unit analysis of the oligomeric diacetates of a copolymerization product and of a model reaction product, prepared in dichloroethane at 80 °C, gave higher values for BEDA/BDA in the model system THF/AA than in the copolymerization of THF/SA. The results indicate that succinic anhydride is more reactive than acetic anhydride in attacking the oxonium ion *(3)*, as was also to be expected from the carbonyl absorption frequencies of 1865 and 1782 cm^{-1} (SA) and 1825 and 1748 cm^{-1} (AA).

Determination and Comparison of the Number of Active Centers in the Polymerization of Ethylene, Propylene, and 1-Butene with Ziegler-Natta Catalysts

By *Karl A. Jung* and *Hans W. Schnecko* (lecturer) [*]

The reaction constants for the polymerization of the three monomers mentioned in the title can be determined from the initial polymerization rate, the viscosimetric molecular weights, and the complete chain termination at given times. The ^3H method is much more suitable than *e.g.* reaction with iodine for the measurement of the last process; though iodine can be quantitatively determined both by microtitration and by activation analysis, the termination reaction is not quantitative.

In view of the strong transfer reaction at the beginning of polymerization, it is necessary to extrapolate the number of active centers to the start of polymerization. This gives the following values for the three monomers: $C^* = 6.9 \times 10^{-3}$ mmole/mmole of $TiCl_3$ for ethylene, 5.3×10^{-3} for propylene, and 3.5×10^{-3} for 1-butene.

Moreover, these monomers behave quite differently during the polymerization, as can be seen in the different rate and molecular weight curves, as well as in the values of the polymerization and transfer rates and of the lifetime of growing chains. It may be assumed that the differences are due to the differences in the structures of active centers for the various monomers.

Optically Active Poly-β-amides

By *Erwin Schmidt*[*]

Optically active β-lactams with one and with two centers of asymmetry in the lactam ring have been polymerized alone and as mixtures of enantiomers of various optical purities. The properties of the polymers, their solubility and behavior in solution, as well as structural features, were described.

The optically active poly-β-amides have higher melting points and are less readily soluble than the corresponding optically inactive polymers. The optically active poly-β-aminobutyric acids, which can be made into fibers and films, have been studied in most detail. The textile properties do not differ appreciably from those of poly(+)-β-aminobutyric acid.

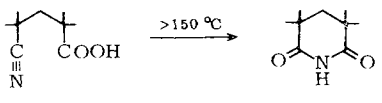
Problems in the Kinetic Evaluation of the Thermogravimetric Degradation of Polymers

By *Ion Adam Schneider*[*]

Thermogravimetric measurements on the stability of polymers have frequently been evaluated kinetically during the last decade. However, these methods can hardly be described as absolute, since the kinetic parameters obtained may depend both on the conversion and on the heating rate. The reason for these peculiarities is that observations based on the isothermal degradation kinetics were applied uncritically to complicated degradation reactions occurring under conditions of rising temperature. The thermal degradation reactions are heterogeneous, and so probably also may depend on transport phenomena. Moreover, it must be noted that the degradation process of polymers is not a simple reaction. Even if *e.g.* the polymer is degraded by a simple chain mechanism comprising at least the three phases initiation, depolymerization, and termination, it cannot be assumed that quasi-steady states are formed under conditions of steadily rising temperature, since, in particular, the rate of the initiation reaction, and hence the concentration of the chain carrier, increases exponentially according to the Arrhenius equation, until the influence of the decreasing concentration of the polymer becomes noticeable.

It can thus be readily shown that under thermally dynamic conditions, the activation energy of chain reactions must decrease with the conversion. According to the Flynn-Wall equation

$$\frac{d \log \beta}{d(1/T)} = -(0.457/R)E_a$$



where β is the constant heating rate, it can be seen indirectly that the heating rate also influences the activation energy. In our opinion, therefore, thermogravimetry is kinetically only a relative method.

Polymer-Analogous Formation of Imido Groups in Methacrylic Acid/Methacrylonitrile Copolymers

By *G. Schröder* (lecturer), *W. Gänzler*, *P. Huch*, and *W. Metzger*[*]

When copolymers of (meth)acrylonitrile and (meth)acrylic acid are heated, adjacent nitrile and acid groups react above about 150 °C to form glutarimide units.

Reactions of this type have been known in low molecular weight chemistry since 1868 through the work of *Gautier*. In macromolecular chemistry they provide a simple route for the preparation of polymers with cyclic di(meth)acrylimide units. The number of imido groups formed depends on the composition of the initial copolymer, its sequence length distribution, the heating temperature, and the heating time. If there are long nitrile sequences, more or less pronounced discoloration is observed as a result of the well-known polymerization of the nitrile groups. Glutaric anhydride units can be formed from adjacent acid groups by elimination of water. The glutaric anhydride units can react with urea, in accordance with the following equation

When suitable (meth)acrylonitrile/(meth)acrylic acid copolymers (which can be prepared by bulk polymerization) containing urea are heated, therefore, they give foams containing imides, the pores of which are filled with CO_2. In the absence of urea and other foaming agents, yellowish, clear plastics are formed. All polymers containing (meth)acrylimide are characterized by high softening points, high mechanical strength, and resistance to most organic solvents.

Poly(dioxyarylene)diphenylsilanes

By *Klaus-Dieter Steffen*[*]

High molecular weight thermoplastic poly(dioxyarylene)-diorganosilanes (also known as polyorganosilicic esters) can be prepared by polycondensation of bis(anilino)diorganosilanes with diphenols[1].

In another process known from the preparation of simple organosilicon compounds, high molecular weight poly(dioxyarylene)diphenylsilanes are obtained from diphenylsilane and diphenols by elimination of hydrogen.

The polycondensation can be carried out in solution or in the melt after the addition of catalysts.

Twelve poly(dioxyarylene)diphenylsilanes were prepared by polycondensation of bis(anilino)diphenylsilane or diphenylsilane with diphenols. The glass transition and Vicat temperatures (43—208 °C), viscosities [$\eta_{sp/c}$ = 0.4—1.5 dl/g (0.5% in THF)], and molecular weights (20×10^3 — 200×10^3) of the twelve polymers were determined. Thermal stability measurements were carried out on the polymers by determining the loss of weight and the decrease in viscosity as a function of time.

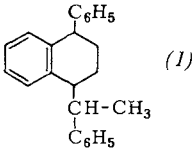
Constitution of the Styrene Oligomers Formed on Thermal Polymerization



By *Joachim Kurze, Dieter J. Stein* (lecturer), *Petr Šimák*, and *Rudolf Kaiser*[*]

In the thermal polymerization of styrene, oligomers are formed in a side reaction. According to *Mayo*[1], these are saturated and unsaturated dimers and trimers of styrene; this

author assumes a close relation between oligomer formation and the initiation reaction of the thermal polymerization of styrene. Later investigations by other authors on the structure of the dimers led to contradictions.

By independent synthesis of the oligomers, we have largely confirmed the assignment suggested recently by *Brown*[2]: the principal components of the dimer fraction are *trans*- and *cis*-1,2-diphenylcyclobutane in a ratio of about 3 : 1; 2,4-diphenyl-1-butene and 1-phenyltetralin were also detected in smaller quantities.

The principal object of this work was to elucidate the structure of trimeric styrenes. We were able to verify the assumed presence[3] of 2,4,6-triphenyl-1-hexene by synthesis; this compound forms about 30% of the trimer fraction. We also showed that the trimeric styrenes without olefinic double bonds (about 65% of the trimer fraction) are the four isomeric optically inactive 1-phenyl-4-(1-phenylethyl)-1,2,3,4-tetrahydronaphthalenes *(1)*. The structure was demonstrated by dehydrogenation to obtain the optically inactive 1-phenyl-4-(1-phenylethyl)naphthalene, which was compared with an authentic sample.

(1)

We believe that the tetrahydronaphthalenes are formed by recombination, in the solvent cage, of the initiating radicals that are responsible for the thermal polymerization.

Polymerization of 4-Methyl-1-pentene with Ziegler Catalysts

By *Heinrich Weber* (lecturer), *Günther Kiessling*, and *Eberhard Blanck*[*]

The polymerization of 4-methyl-1-pentene with the catalyst α-titanium trichloride/diethylaluminum chloride yields crystalline, isotactic poly-4-methyl-1-pentene. With titanium tetrachloride/triethylaluminum, depending on the temperature (−20 to +60 °C) and Al/Ti ratio (0.2 : 1 to 2 : 1), the reaction yields low molecular weight hydrocarbons (olefins and paraffins), atactic poly-4-methyl-1-pentene, and isotactic poly-4-methyl-1-pentene. The composition of the reaction products changes considerably when the catalyst is aged, *i.e.* the components of the catalysts can react at 60 °C/30 min in toluene. No low molecular weight reaction products but only alkylated toluenes are formed in this case.

It was found that the low molecular weight olefins and paraffins do not consist only of dimers, trimers, and higher oligomers of 4-methyl-1-pentene, but that *trans*-olefins and paraffins containing two C atoms more than oligomers are also formed. These two C atoms come from the ethyl groups of the triethylaluminum. The ratio of *trans*-olefins to paraffins depends strongly on the nature of the solvent used; the amount of paraffin is higher in aromatic than in aliphatic solvents.

Experiments in which tris(ethylphenyl)aluminum was used instead of triethylaluminum and others that were terminated with H_3COD support the view that the ethyl groups are derived from organotitanium groups as reaction products from the catalyst components. The proposed reaction course also explains the formation of *trans*-olefins and paraffins.

Anionic Polymerization of Methacrylonitrile

By *H. Vankerckhoven*, *M. Van Beylen* (lecturer), and *G. Smets*[*]

The anionic polymerization of methacrylonitrile was studied kinetically in toluene at low temperature (approx. −75 °C). 1,1-Diphenylhexyllithium and *n*-butyllithium were used as initiators. The reaction was found to be second order with respect to the initiator in both cases.

In the polymerization with butyllithium as the initiator, induction periods occur at low initiator concentrations. To obtain more information about the initiation stage, the decrease in the butyllithium concentration was followed as a function of time by gas chromatography. Only a small part of the initiator is consumed in the polymerization, and the greater part remains unchanged. The efficiency of the initiators was calculated from the molecular weights of the polymers (about 2000–8000), and it was found that the growing chains are "living".

Limits in the Scope of Gel Chromatography

By *Wolfram Gerlich*, *Helmut Determann*, and *Theodor Wieland* (lecturer)[*]

Regenerated cellulose gels in bead form (obtained from tetramminecopper(II) hydroxide or from xanthate solution at various concentrations) were calibrated as media for gel chromatography with a total of 21 substances having radii of 1–1000 nm by recording the elution parameter K_{av} as a function of the particle radius.

The bead gels obtained from xanthate by precipitation with acetic acid are comparable in their separation range and separation efficiency with the well-known weakly crosslinked dextran or agarose gels, but are superior in their mechanical stability. Very large particles such as bacteriophages, mitochondria, and even bacteria can be chromatographically separated on particularly wide-pored gel beads precipitated from the solution containing copper. However, the use of gel chromatography for particle radii greater than 200 nm is restricted by substantial irreversible adsorption.

Crosslinking Reactions in Fibrous Proteins under the Action of Monofunctional Reagents

By *Helmut Zahn* (lecturer) and *Dietrich Brandenburg*[*]

After exposure to the action of monocarboxylic acid chlorides in dimethyl sulfoxide and pyridine (2–24 hours, 20–65 °C), wool[1], silk, and collagen gave the analytical data for the crosslinked protein. Only a small proportion of the carboxylic

acid residues is firmly bound by the proteins (*e.g.* by *N*-acylation). The principal reaction is the formation of N_ε (γ-glutamyl- or β-aspartyl)-lysine bridges. It is assumed that these carboxamide bridges are formed *via* mixed anhydrides from the carboxylic acids and the free carboxyl groups of the glutamyl or aspartyl residues.

Self-crosslinking has also been observed, though only as a side reaction, on reaction of wool with *p*-nitrophenyl esters. Fluorodinitrobenzene causes crosslinking on reaction with wool in the presence of acetate buffer at pH values below 7. Self-crosslinking of insulin has been observed on reaction with active esters of Boc-amino acids and with *tert*-butyl trichlorophenyl carbonate; monomeric and dimeric insulin derivatives with additional carboxamide bridges have been isolated.

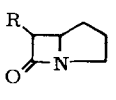
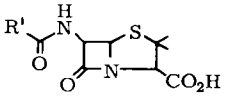
Synthesis and Reactions of Penicillin-Like Compounds

By *Friedrich Moll*[*]



Penicillins and cephalosporins contain, as essential structural component, a β-lactam ring (azetidinone ring), which is fused to a five-membered ring and an unsaturated six-membered ring, respectively. The high reactivity of this fused azetidinone ring towards nucleophiles plays a decisive role in the blocking of bacterial cell-wall synthesis by β-lactam antibiotics. In the case of penicillin, *Woodward* has offered two possible explanations for this marked reactivity: a) Linkage of the azetidinone ring with a second ring increases the ring strain (increased energy content of the bicyclic ring system and change of the amide resonance); b) neighboring group participation of the acylamino side chain enhances the reactivity of the azetidinone ring to the observed level.

The neighboring group effect has received detailed attention in the production of semisynthetic penicillins. In contrast, the extent of the "ring-strain effect" was hardly known until recent syntheses and reactivity studies on penicillin-like compounds bearing no side chains permitted an assessment of its significance.



Carbocyclic analogs of the penicillin and cephalosporin skeletons can be synthesized by cycloaddition or by acid cyclization. [2 + 2] Cycloaddition of ketenes and cycloimines only gave the desired bicyclic compounds when the ring member β to the nitrogen was geminally substituted. Acid cyclization, however, proved generally applicable. It was possible to prepare the azabicyclo[4.2.0]octanones *(1)* (R = H, C_6H_5, NH_2) and the azabicyclo[3.2.0]heptanones *(2)* by synthesis and cyclization of correspondingly substituted 2-piperidyl- and 2-pyrrolidinylacetic acids.

(1)

(2)

(3)

Comparison of the reactivity of the new bicyclic compounds towards nucleophiles on the basis of the rate constants of alkaline hydrolysis led to an interesting result: The reactivity of the azetidinone ring increases by about 10^2 on fusion with a five-membered ring instead of a six-membered ring. Whereas the rate constant for azabicyclo[4.2.0]octanone *(1)*, R = H[1], is similar to the corresponding constants for monocyclic azetidinones, that for azabicyclo[3.2.0]heptanone *(2)*, R = H[2], is of the same order of magnitude as for the penicillins *(3)*.

Since neighboring group effects cannot operate in the case of *(1)* or *(2)*, it follows for the structure-activity relationships in β-lactam antibiotics that the enhanced reactivity of penicillins and cephalosporins must be due to a ring strain set up when the azetidinone ring is fused to another ring that is already strained. The neighboring-group effect, which can be controlled by variation of the side chains, plays a modifying role.

Chemical Changes in Radiation-Preserved Foods

By *J. F. Diehl*[*]

Since treatment of foods with ionizing radiation is forbidden in the Federal Republic of Germany and exceptions are likely to be made only for specific foodstuffs, methods must be devised whereby a previous irradiation can be detected. In our laboratory we have found that deoxy sugars are formed on irradiation of carbohydrate-rich foodstuffs and that this can be detected very sensitively as malondialdehyde formed on oxidation by periodic acid[1]; in protein-rich foodstuffs, protein aggregates are produced that can be detected by electrophoresis and by thin-layer gel chromatography[2]. In dry foods a content of free radicals can be demonstrated by ESR measurements months after the irradiation[3].

The extent of changes induced by radiation depends on the dose given. In the region required for sterilization, *i.e.* for killing of all microorganisms, the requisite dosage (1--5 Mrad) can be demonstrated for most foods by the above methods. In the region 0.1—1 Mrad (radiation-pasteurization) the chemical changes are so small that detection is still uncertain. For the region below 0.1 Mrad (pest control in grain, prevention of sprouting of potatoes) there is still no usable method of detection.

It is also of interest how far the radiation destroys essential ingredients. The effect on vitamins has been the subject of numerous studies[4], which, however, have been confined to determination of the vitamin contents before and immediately after irradiation. However, the important matter is the vitamin content at the time of consumption. The finding that vitamins E and B_1 are strongly degraded further, even after irradiation, during storage and preparation of the food[5], leads to the question, still unanswered, whether radicals, traces of peroxides, or other radiation-produced compounds, are responsible for this. The matter is our particular present interest. In respect to the sensitivity of essential amino acids to irradiation it has been repeatedly determined that no loss worth mentioning occurs even with the dosage of about 5 Mrad[6].

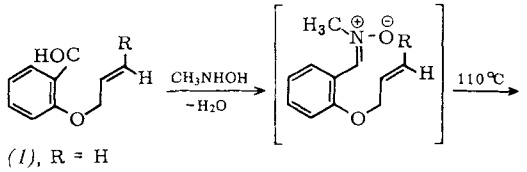
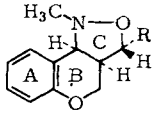
Reactions of bicyclo[6.1.0]nona-2,4,6-triene with dienophiles have been studied by *W. H. Okamura* and *T. W. Osborn* and by *C. S. Baxter* and *P. J. Garratt*. According to the conditions, the reaction with tetracyanoethylene gives *(1)* or *(2)*.



(1) *(2)*



With maleic anhydride the bicyclic compound gives products that, like *(2)*, are derived from tricyclo[4.3.0.0^{7,9}]nona-2,4-diene. No product retaining the original bicyclic skeleton was obtained in reactions with these or other dienophiles. / J. Amer. chem. Soc. *92*, 1061, 1062 (1970) / —Kr.

[Rd 196 IE]

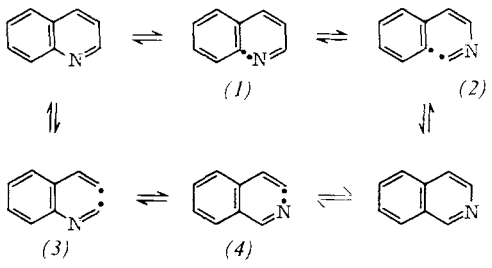
Intramolecular nitrone-olefin cycloadditions leading to heterocycles have been discovered by *W. Oppolzer* and *K. Keller*. For example, these workers obtained benzopyrano[4,3-*c*]isoxazole *(2)* (yield 80%, m.p. 184—185 °C) from *o*-(allyloxy)-benzaldehyde *(1)* and *N*-methylhydroxylamine by way of a nitrone intermediate. This type of synthesis can be effected

(1), R = H
(3), R = CH_2Cl

(2), R = H
(4), R = CH_2Cl

with numerous derivatives of *(1)* and with, *e.g.*, the naphthalene derivative and with *o*-(*N*-allylformylamino)-, *o*-(3-butenyloxy)-, and *o*-(vinyloxy)benzaldehyde. *W. Oppolzer* and *H. P. Weber* determined the X-ray structure of the product *(4)* from *(3)* and *N*-methylhydroxylamine and this showed that rings B and C are always *cis*-fused independently of the conformation of the olefinic compound. The conformation at C-3 and C-3a corresponds to the conformation of the starting material. / Tetrahedron Letters *1970*, 1117, 1121 / —Kr.

[Rd 197 IE]

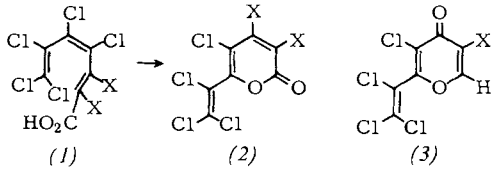


Vicinal halo(cyanoamines) and *N*-cyanoaziridines were obtained by *K. Ponsold* and *W. Ihn* by simultaneous addition of cyanamide and compounds containing positive halogen to olefins. The stable chloro cyano amines can be converted by alkali into the aziridine derivatives. Bromo cyano amines

readily react further to give the aziridines. Examples (cyanamide added in all cases): *trans*-stilbene + *N*-bromosuccinimide → 1-bromo-2-(cyanoamino)-1,2-diphenylethane (21% yield); cholesterol + dichlorourethane → 5α-chloro-6β-(cyanoamino)cholestan-3β-ol (21%); cholesteryl acetate + *N*-bromosuccinimide → 3β-acetoxy-5,6β-(cyanoimino)cholestane (62%). / Tetrahedron Letters *1970*, 1125 / —Kr.

[Rd 198 IE]

Mutual thermal interconversion of quinoline and isoquinoline was investigated by *J. M. Patterson*, *C. H. Issidorides*, *E. P. Papadopoulos*, and *W. T. Smith jr.* At 850 °C quinoline is converted into isoquinoline to the extent of 0.7%, and isoquinoline affords 2.3% of quinoline. Only hydrogen cyanide



(1) *(2)* *(3)* *(4)*

and acetylene are formed as gases. The mass spectra of quinoline and isoquinoline, and of the by-products of the pyrolysis, make it probable that reaction occurs by way of *(1)* and *(2)* and/or *(3)* and *(4)*. / Tetrahedron Letters *1970*, 1247 / —Kr.

[Rd 199 IE]

Cyclization of the 2,3-dihalo-4,5,6,7,7-pentachloro-*cis*,*cis*-2,4,6-heptatrienoic acids *(1)* was studied by *A. Roedig*, *G. Märkl*, and *H. Schaller*. On thermal decomposition, *(1)* (prepared from perchloro-*cis*-2,4-pentadienal by chain elongation) affords the α-pyrone derivative *(2)*, together with a small amount of the hexahalobenzene. However, amides and anilides of the trienoic acids *(1)* cannot be cyclized. Aldehydes corresponding to *(1)* are converted into γ-pyrone

(1) *(2)* *(3)*

(a), X = Cl *(b)*, X = Br

derivatives *(3)* by proton catalysis. Thus these authors did not find the 1,7-heptatriene-oxygen shift expected from analogy with the 1,5-pentadiene-oxygen shift of perchloro-*cis*-2,4-pentadienal. / Chem. Ber. *103*, 1011 (1970) / —Kr.

[Rd 200 IE]

The cation S_4^{2+}, in the form of the compounds $S_4(SO_3F)_2$ and $S_4(SbF_6)_2$, was obtained by *J. Barr*, *R. J. Gillespie*, and *P. K. Ummat* on oxidation of sulfur. On treatment of sulfur with a solution of $S_2O_6F_2$ in fluorosulfuric acid there were formed first S_{16}^{2+} and S_8^{2+} (detected spectroscopically) and finally, with an excess of $S_2O_6F_2$, a colorless solution of S_4^{2+} (λ_{max} = 330 nm). When an excess of $S_2O_6F_2$ is condensed on powdered sulfur in liquid SO_2 at −196 °C and the mixture is allowed to warm slowly to −23 °C a solid, pale yellow, diamagnetic compound $S_4(SO_3F)_2$ is obtained. $S_4(SbF_6)_2$ is formed as a white powder from sulfur and SbF_5 in liquid SO_2 after several days' heating at 140 °C. / Chem. Commun. *1970*, 264 / —Kr.

[Rd 201 IE]

N-Chlorodifluoromethylenamine *(2)*, the simplest *N*-chloroperfluoroalkylenamine, was prepared by *D. E. Young*, *L. R. Anderson*, and *W. B. Fox* by thermolysis of *N,N,C*-trichlorodifluoromethylamine *(1)*. Compound *(1)* was obtained from cyanogen chloride and chlorine fluoride.

$$ClC{\equiv}N + 2\,ClF \xrightarrow{25\,^{\circ}C} CF_2Cl{-}NCl_2$$
(1), >90%

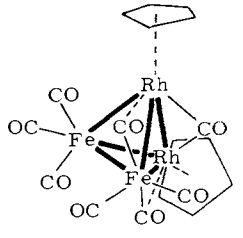
$$CF_2Cl{-}NCl_2 \xrightarrow[4\,h]{100-150\,^{\circ}C} CF_2{=}NCl + Cl_2$$
(1) *(2)*, ≈80%

(2) was freed from chlorine by means of mercury and was purified by gas chromatography. Azo and azino compounds RN=NR and R=N—N=R were not among the thermolysis products. *(2)*, b.p. ≈5 °C, has a very simple IR spectrum and gives almost all the possible ions in the mass spectrum. / Chem. Commun. *1970*, 395 / —Kr. [Rd 203 IE]

The diffusion constant of mobile electrons in anthracene was measured by *N. Karl*, *E. Schmid*, and *M. Seeger*. Plane-parallel crystal plates of the highest purity available are silver-coated on both sides by evaporation. If by a short flash of UV light a certain number of electron-hole pairs are generated on one side of the crystal, and an electric field is applied across the crystal, current carriers will drift through the crystal in the direction of the field. With increasing distance from the starting area, the current pulse corresponding to the moving carriers will be broadened by, among other factors, the diffusion of carriers. Quality criteria for the crystals to be used in these measurements are given together with experimental conditions that render carrier diffusion the major factor of current pulse broadening. The diffusion constant (in the crystallographic *a* direction) of 0.06 $cm^2\,s^{-1}$ is in good agreement with the independent value derived from drift mobility. As shallow traps would decrease the mobility, but increase the apparent diffusion constant, the agreement is a good argument that the electrons are actually free. / Z. Naturforsch. *25a*, 382 (1970) / —Hz. [Rd 205 IE]

A device for thermal analysis at temperatures up to 3000 °C is described by *N. L. Baldwin*, *S. Langer*, *F. L. Kester*, and *C. Hancock*. The samples (10—30 g) are heated in a high vacuum induction furnace. The radiation emitted from the sample impinges on a lead sulfide photoconductive cell placed in one leg of a bridge circuit. The imbalance signal is processed so that the sample temperature or its first time derivative can be recorded. A chopper system is provided allowing radiation from sample and standard to impinge alternately on the detector for differential thermal analysis. The lead sulfide photoconductive cell is especially well suited for this purpose because of its spectral sensitivity from 0.25 to 3.5 μm allowing the detection of black-body radiation at 100 to 3000 °C. Investigations of the phase transitions in the system

$$a\mathrm{U(liquid)} + \mathrm{UO_{2-}}_x\mathrm{(solid)} = \mathrm{U_{1+}}_a\mathrm{O_{2-}}_x\mathrm{(solid)}$$



as functions of temperature and O : U ratio showed that isothermal enthalpy changes down to 7 cal can be detected if the derivative of the sample temperature is recorded. / Rev. Sci. Instruments *41*, 200 (1970) / —Hz. [Rd 206 IE]

Silver ketenide *(1)* has been synthesized by *E. T. Blues*, *D. Bryce-Smith*, *H. Hirsch*, and *M. J. Simons* by reaction of Ag salts with ketene or acetic anhydride in pyridine at room temperature:

$$2\,AgOCO{-}CH_3 + (CH_3CO)_2O \xrightarrow{(py)} Ag_2C{=}C{=}O(py) + 3\,CH_3COOH$$

(1) and its pyridine adduct are yellow, non-melting, explosive substances. *(1)* reacts with HCl gas (diluted with N_2) to give acetyl chloride, and with Br_2 in CCl_4 at room temperature to give tribromoacetyl bromide (>90%), and with CH_3I in octane at 90 °C to yield tetramethylcyclobutane-1,3-dione. Both Ag atoms of *(1)* are bonded covalently to the terminal C atom. The rapid thermal decomposition of *(1)* at 150 °C under argon affords carbon suboxide almost quantitatively. X-ray and electron-diffraction studies show *(1)* to have a layer structure in which the Ag atoms of a layer are separated by 2.84 Å and the interlayer distance amounts to 5.846 Å. / Chem. Commun. *1970*, 699 / —Ma. [Rd 215 IE]

A tetrahedral metal cluster is present in the center of the compound $(\pi\text{-}C_5H_5)_2Rh_2Fe_2(CO)_8$ *(1)*, which *J. Knight* and *M. J. Mays* obtained along with other compounds of the same type by reaction of $(\pi\text{-}C_5H_5)Rh(CO)_2$ with $Fe_2(CO)_9$ and which has now been subjected to X-ray structural analysis

(1)

by *M. R. Churchill* and *M. V. Veidis*. *(1)*, a = 17.979, b = 12.079, c = 9.386 Å, has space group Pnma (D_{2h}^{16}, No. 62) and C_s symmetry. The two unsymmetrical carbonyl bridges are particularly noteworthy. / Chem. Commun. *1970*, 529 / —Kr. [Rd 217 IE]

BOOK REVIEWS

Einführung in die Strahlenchemie (Introduction to Radiation Chemistry). By *A. Henglein*, *W. Schnabel*, and *J. Wedenburg*. Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., x, 400 pp., 124 figures, 29 tables, plastic cover DM 45.—.

Radiation chemistry in its present state appears in very many guises. This is partly due to the fact that chemical reactions can be induced by high-energy radiation in nearly all substances, whether they are inorganic, organic, or macromolecular, and irrespective of their aggregation state. This last point leads to fundamentally new possibilities for investigations in solid phases, and in the form of the matrix isolation technique it has greatly increased our knowledge of the properties and behavior of highly reactive intermediates such as free electrons, radical-ions, and free radicals. The pulse radiolysis technique, which allows the direct investigation of the kinetic behavior of the short-lived intermediates mentioned by ESR- and absorption-spectroscopic and electrochemical methods of analysis, is also important to general chemistry.

This diversity of radiation chemistry is clear from a shortened list of topics dealt with in 23 chapters of roughly equal length in *Henglein*'s book: types of radiation, radiation sources,

chemical dosimetry, specific energy losses of charged particles, elementary processes, formation and reactions of excited molecules, free radicals, and carbons, the technique of pulse radiolysis and its use, and electrons and ions in solids. In addition to these chapters, which are concerned with the fundamentals of radiation chemistry, the application of radiation in a number of fringe fields is also discussed. Topics represented include chemical aspects of radiation biology, the action of radiation on polymeric systems, and industrial radiation chemistry.

It is obviously not easy to present these many facets in an easily understood manner in a book of 400 pages. However, this enterprise has been successful for two reasons. First, the book is intended mainly for students and learners, including chemists, physicists, biologists, and physicians who wish to acquire a knowledge of the fundamentals and the present state of radiation chemistry. The book does not aim to replace textbooks by means of the many special chapters that it contains. This has made it possible to keep the various chapters short and concise, and this has greatly benefitted understandability and educational requirements. Another factor that undoubtedly helps in this respect is the fact that the book is made up from lectures that have been in use over a long period at the Berliner Technische Universität. Secondly, the authors have gone to some trouble to ensure clarity and simplicity. This has made it possible for the reader to obtain a rapid grasp of radiation chemistry, though this is generally regarded as a difficult field. Further assistance is provided by the references that are added to each chapter, and which are consequently arranged in a clear manner. The reader is also led up to the latest position of knowledge in this field and introduced to the problems on which research is currently being carried out. A great help to those who wish to learn about radiation-chemical methods will be the mathematical and experimental problems given at the end of most chapters, which are taken directly from radiation-chemical practice.

On the whole this book, when judged in relation to its aims, is very successful. It can be recommended to anyone who wishes to gain an insight into modern radiation chemistry and its problems.

Dietrich Schulte-Frohlinde [NB 874 IE]

Stabilisierung und Alterung von Plastwerkstoffen. (Stabilization and Aging of Plastics). Vol. 1. Stabilisierung und Stabilisatoren von Plastwerkstoffen (Stabilization and Stabilizers for Plastics). By *K. Thinius*. Verlag Chemie GmbH, Weinheim Bergstr. 1969. 1st Edit., 720 pp., 80 figures, 58 tables, linen DM 84.—.

The systematic review of literature on the stabilization of plastics started only a few years ago, and involves the difficult tasks of critically examining a practically endless and constantly growing mass of empirical results, deriving general rules that can be applied in practice, and explaining the observed effects as consistently as possible. The present book is particularly remarkable in that it is based on work carried out by the author over decades, and thus provides a valuable presentation of the results of research by an outstanding authority on the problem of the stability of plastics.

The book is divided into eight chapters, which differ considerably in size. The first chapter explains the concepts stability, stabilization, stabilizers, and aging. The second chapter is rather vaguely entitled "Measures for the stabilization of plastics", and deals with the modification of the intrinsic stability of the polymeric raw material by impurities in the starting materials, by the production process (only in the case of nitrocellulose), and by the isolation process. Stabilization by chemical modification, *e.g.* the blockage of end groups, which is important in polyacetal technology, is also discussed here. Details of geat practical interest are to be found in the third chapter ("Interrelations between the stability of the plastic and the parameters of its processing to form a molding composition"). The fourth chapter, again under a very general title "Stabilizers for plastics and their efficiency", provides information about the mode of addition of stabilizers to plastics and a collection of methods for testing their efficiencies. This collection is very detailed with respect to thermal and thermooxidative aging, and is particularly recommended to those who are interested in testing techniques.

The principal chapter of the book, which comprises more than 70 % of its volume, is the fifth chapter ("The effectiveness of the various groups of stabilizers"). All types of stabilizers are described here, together with investigations on their effectiveness, the stabilizers being arranged according to their chemical constitution, which experience has shown to be the most suitable basis for classification. In the description of the stabilizers, in addition to a relatively complete coverage of patent and journal literature, the author devotes considerable space to his own results, some of which are of great importance. Special mention should be made of the extensive studies on the stabilization of PVC. Unfortunately, too little emphasis is placed on the stabilizer systems that are important in modern industrial practice, the specific importance of which cannot be guessed by the reader from the comprehensive material. Thus the great importance of the benzotriazole UV absorbers and their structural variants reported by Geigy is allotted too little space, apart from the mention of Tinuvin P (though the structural formula given is wrong, and the text might give the impression that it resulted from the work of Japanese authors). The same is true of the phenol esters of carboxylic acids, which currently hold a considerable share of the market in commercial antioxidants for polyolefins. On the other hand, from the space given to the stabilization of polyolefins with amines, the reader might be led to wrongly assume that this is currently of considerable industrial importance. In a field as closely linked with practice as this, more attention should have been paid to the additives that have proved themselves in industry and that are commercially available.

In the sixth chapter the author discusses "Theoretical views and experimental results on the mechanism of action of stabilizers", dealing separately with purely thermal degradation, thermooxidative degradation, photooxidative degradation, and synergism. In view of the far-reaching, more or less speculative theories on degradation and stabilization mechanisms, particularly in the fields of autoxidation processes and the decomposition of PVC, this chapter has been kept relatively short. The mechanisms are mainly indicated qualitatively, and reaction formulas are usually not given; kinetic equations are totally avoided. However, this is not a disadvantage, if one considers the very arbitrary character of most current theories of stabilization and the fact that their prognostic value is small. Certain fundamental physicochemical concepts, such as the criteria of autocatalytic reactions, the stability period, and the critical stabilizer concentration, should however have been defined clearly at a suitable point.

The seventh chapter is devoted to the "Analysis of stabilizers". This chapter is too short to present more than very general considerations, together with brief notes on the methods for a few selected analyses, with references to the original literature. The discussion of the "Toxicity of stabilizers" in the eight chapter is thorough and careful. The ninth part of the book, which is headed "Index", is an alphabetic index of keywords. This is the only index in the book, apart from the list of contents. The absence of a general bibliography or author index is regrettable. Since the references are scattered throughout the book, it is practically impossible to obtain information about a given publication or patent without considerable search. The references to literature and patents attached to each sub-chapter, which can only be found from the text, cover the journal literature up to 1965, and in a few cases up to 1966, and patent applications up to about 1963, again with occasional exceptions of more recent date. Literature from the German Democratic Republic and Eastern European countries is generally covered up to later

dates. The references are accurate, but more care should have been taken in spelling the authors' names.

On the whole, the book will be an excellent source of knowledge for the reader who is particularly interested in obtaining a general picture of the field, and will provide him with a good knowledge of the fundamental relationships and of the author's results. The practical worker, on the other hand, will have difficulty in finding information on methods of stabilizing a given plastic or on a processing or application problem. A short chapter showing the present position with regard to the stabilization of certain types of plastics, with reference to particular technical requirements, would greatly enhance the usefulness of a book of this type.

The presentation is excellent.

Joachim Voigt [NB 875 IE]

Chemische und biologische Laboratorien. Planung-Bau-Einrichtung (Chemical and Biological Laboratories. Planning-Building-Equipment). By *W. Schramm*. Verlag Chemie GmbH., Weinheim/Bergstr. 1969. 3rd Edit., 412 pp., 1200 figures, linen DM 98.—.

This standard work, which is important because of its comprehensive details and examples of plans for the construction of chemical and biological laboratories that have already been executed, has been out of print for several years, and is now available in a fully revised and enlarged 3rd edition[1].

The arrangement of the subject matter follows the same successful pattern as earlier editions, but a great improvement results from the use of the decimal classification system.

The material in the 20 chapters is based on the latest experience and technical developments in laboratory construction. Some of these chapters are considerably longer than in the 2nd edition, and a number of topics also appear in the book for the first time; in particular, these are Part 2 "General planning principles", Part 3, "Principles of the dimensioning and furnishing of laboratory rooms and buildings", and Part 4 "Guide to space requirements and floor layout in laboratories" Reference is made in Chapter 2 to the questions of flexibility, prefabrication, execution by general contractors, and the formulation and programming of the problem and of the design principles, which is essential for planning ahead.

With the aid of instructive drawings, the author deals with suitable dimensions for the laboratory, widths of passages, furnishing schemes of single and large rooms, and laboratory boxes. A noteworthy feature is a table giving the room, and bench dimensions of 50 laboratory buildings for predominantly chemical and biological fields of specialization; because of the numerous examples, this makes it easier both for the owner of the building and for the planner to visualize the space requirements.

The guiding values given in the fourth chapter for space requirements and outlay also provide pointers and possibilities of comparison for the assessment of designs.

In later sections, the advantages and disadvantages of the various types of buildings (low buildings and multistorey buildings are critically weighed). A distinction is drawn in the construction of buildings between conventional and industrialized building methods; as is shown by the photographs and drawings, increasing use is being made of prefabricated constructions in laboratory buildings.

As might be expected on grounds of importance in the laboratory, the book devotes considerable space to Chapter 7 "Technical supply equipment and installations". In addition to the two basic pipe arrangements, *e.g.* vertical and horizontal installation systems, good summaries are given for the first time of the possible combinations for the arrangement of the entire supply systems; the problems of drying, aeration and deaeration, and air conditioning of laboratories are also discussed in detail.

The questions of sound and vibration damping, protection against corrosion and acids, safety appliances, fire prevention, and protection against radiation, which are usually treated very cursorily, are discussed in great detail in Chapters 8 to 10.

The consumption figures, connected loads, and isochronism factors, which are important for the determination of the power requirements, are summarized in another chapter, making more accurate calculation of the requirements possible.

The discussions on the wide and many-layered field of laboratory fittings make it easier for the reader to judge and select from the designs that are currently available.

The chapters on "Laboratory rooms", "Subsidiary rooms", and "Animal rooms" have also been revised in the present edition, and contain an abundance of information, recommendations, and hints for arrangement, installation, and fitting; the information on climatic conditions for research animals, the space required by the animals, and cage dimensions and axis dimensions of animal rooms is extremely useful to the designer. The "open system" and the "closed system" described for SPF plants for animal rooms also provide useful hints for the less common special stalls.

Another new inclusion is Chapter 19 "Greenhouses".

The example part is greatly enlarged; it shows many laboratory buildings for a wide range of specialized fields and tasks. The new examples are all of buildings erected since 1960, and are therefore very up-to-date. The fact that they are confined to Central European installations is no disadvantage to the designer.

The present 3rd edition has not only been revised and enlarged by more than 60 pages as compared with the last edition, but has also been given a new, clear, and pleasing make-up. In this volume the author has provided a good, comprehensive source of advice on questions of laboratory construction. The interested reader should use and consider the copious factual information and the many suggestions and examples in this book as valuable aids in his future planning.

Oskar Grüneis [NB 872 IE]

Coordination Chemistry in Non-Aqueous Solutions. By *V. Gutmann*. Springer-Verlag, Vienna-New York 1968. 1st Edit., viii, 174 pp., 10 figures, bound DM 48.—.

The present book is remarkable in two respects. 1. It was written in English by an Austrian. Though some linguistic weaknesses must be taken into account, it is pleasing to find English gaining ground as a language for chemical communication in the German-speaking countries. 2. It classifies a large number of non-aqueous solvents (mainly covalent oxides, halides, oxide halides, and organic solvents containing functional groups, and less comprehensively the "water-like", ionizing solvents) and their chemistry purely on the basis of coordination chemistry, instead of according to the usual approach.

The discussion is based on the Lewis acid (acceptor)-base (donor) concept (Chapter I). Donor solvents (which preferentially solvate cations) and acceptor solvents (which preferentially solvate anions) are distinguished, and each of these types is divided into aprotic and protonic solvents (Chapter II). The Brønsted concept is also used for the protonic solvents; in general, however, the acid-base reaction is regarded only as part of the coordination chemistry, which is classified by the Lewis theory. The donor strength of an aprotic solvent is measured by the donor number DN (Chapter II), which is defined as the negative enthalpy of formation of $SbCl_5$·Donor in dichloroethane.

The acceptor solvents discussed are the hydrogen halides, HCN, H_2SO_4, HNO_3, H_3PO_4, HSO_3F, HSO_3Cl, HPO_2F_2,

[1] Cf. Angew. Chem. *74*, 334 (1962).

$H_2S_2O_7$ (Chapter IV), SO_2, ClF_3, N_2O_4, BrF_3, IF_5, AsF_3, and covalent chlorides, bromides, and iodine (Chapter V). This is followed by the discussion of the donor solvents (DN in parentheses) NH_3 (a more detailed treatment of the ammines passing beyond the qualitative would have been desirable in a book on coordination chemistry), N_2H_4, H_2S, $HC(O)NH_2$, $CH_3C(O)NH_2$, HCOOH, CH_3COOH, alcohols (Chapter III), and oxide halides (particularly $POCl_3$ (11.7), which has been investigated by *Gutmann*, originally on the basis of the solvent concept and his concept of ionotropy; he defends his results in detail against American workers) (Chapter VI). A series of solvents with increasing DN from ClH_2CCH_2Cl (0.1) *via e.g.* CH_3NO_2 (2.7), CH_3CN (14.1), $(C_4H_9O)_3PO$ (23.7), $HC(O)[N(CH_3)_2]$ ($\approx$ 27) to $[(CH_3)_2N]_3PO$ (38.8) follows (Chapter VII).

The coordination chemistry of the transition metal halides in donor solvents, which is discussed particularly fully and summarized in many tables (Chapters II, VI, VII, VIII) essentially involves three equilibrium reactions: 1. Formation of a complex anion by addition of an anion donor, 2. autocomplexing, and 3. ionization. Which reaction predominates depends on the relative donor strengths of the halide ion and of the donor solvent. The donor strength of the solvent C_6H_5COCl (2.3), for example, cannot compete with that of the chloride ion, so that the formation constant for $[FeCl_4]^-$ from $FeCl_3$ and Cl^- is greater than 10^{-4}. The donor competition of the solvent $(CH_3O)_3PO$ (23), on the other hand, leads to autocomplexing:

$$2\ FeCl_3(TMP) \rightarrow [FeCl_2(TMP)_2]^+ + [FeCl_4]^-$$

Finally, $FeCl_3$ is completely ionized in the strong donor solvent $(CH_3)_2SO$ (29.8):

$$FeCl_3 + 6\ DMSO \rightarrow [Fe(DMSO)_6]^{3+} + 3\ Cl^-$$

It follows *e.g.* that a solvent with a low DN should be used for the preparation of complex compounds, and a solvent with a high DN to eliminate unwanted hydrates.

This is a useful book, from which not only students, but also trained chemists can learn, and not least because of the plentiful references to the original literature.

Present-Day Communication in Chemistry – Problems and Possibilities

By Günter Kresze [*]

This article deals with the problems and possibilities in the present-day communication of chemical results and opinions. Personal communications as well as primary and secondary literature have to be supplemented in the future by documentation and information services which use modern electronic data processing equipment.

1. Classical Methods for the Communication of Information in the Field of Chemistry

The problem of communication in all branches of science is closely connected with the development of our thinking. People everywhere are challenging the validity of concepts and objectives that date from a period when the world was scientifically naive by today's standards; methods which were formerly adequate for solving problems are now proving inadequate. In the field of communication, especially in the natural sciences, these problems were recognized at a relatively early stage. An attempt will be made in this article to survey some of the basic problems and to give an idea of the main possibilities in this field.

The first category of problem is that of large numbers. According to the National Science Foundation's estimates there are 500000–700000 chemists and chemical engineers working in the world today. How does this number affect communication in chemistry? The "most natural" means of communication in any field is speech (Fig. 1), the direct communication of a result or an opinion. Speech plays an essential role even today.

The many conferences, for example, are proof of the importance accorded to oral communication. Direct oral or written discussion can meet the information needs of the chemist who receives it only if he knows all the people working in the same field. In individual fields of intensive research, *e.g.* biochemistry, where the research is directed toward a specific end, this requirement is still approximately satisfied. In most fields, however, the large numbers of chemists involved make this situation impossible.

Fig. 1. The "most natural" method of communication: speech (illustration: Daumier).

In general, therefore, communication is only possible through the intermediary of "exchanges". The classical medium for such communication is the primary chemical literature: journals, patents, monographs (Fig. 2). Communication thus becomes more indirect

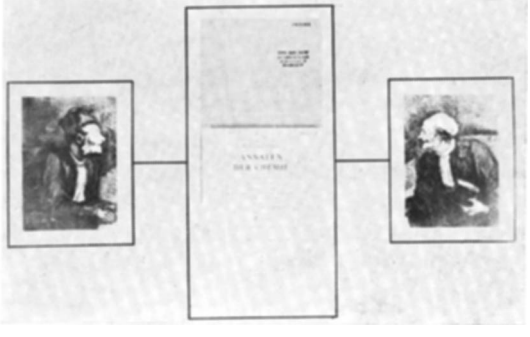

Fig. 2. The primary chemical literature as a communication medium.

[*] Prof. Dr.-Ing. G. Kresze
Organisch-chemisches Institut der Technischen Hochschule
8 München, Arcisstrasse 21 (Germany)

and more impersonal, but it is only in this way that it is possible at all. Let us consider the wishes of those involved in this type of communication and examine how far the primary literature is capable of fulfilling its tasks. First and foremost every author's wish is to communicate his results to all interested parties; he wants a target-oriented form of communication. The wish of every reader must be to find *all* the material that interests him in response to a specific inquiry. These wishes should be taken particularly seriously in the field of chemistry: the results of others are a considerable help to the chemist in his own work, and frequently have a decisive influence on the further course of this work.

How far are today's journals capable of acting as communication "exchanges"? According to the National Science Foundation's "Overview of World Wide Chemical Information Facilities and Resources" the total number of journals in the field of chemistry is at present 12000; about 300000 articles and 50000 patents appear every year. An estimated 25% of publications in the field of chemistry are contained in only 50 journals, 50% in about 250 journals and 75% in about 1300 journals. Furthermore, it is obvious that the individual chemist does not have to read all – or even the majority of – chemical journals to get the fullest information possible on his particular sphere of interest. The number is limited by the mere fact that many of these journals carry mostly articles from narrowly specialized fields, and this trend has recently been increasing. Nevertheless, one only has to compare the number of journals in existence with the number which, according to the 1967/68 questionnaire [*] sent out by the Gesellschaft Deutscher Chemiker (GDCh), the average chemist reads (eight) to see that the "comprehensive information" requirements cannot be even approximately met by the reading of journals alone.

For a long time, therefore, a further means of communication has been used in addition to journals, *i.e.* secondary chemical literature, lists of titles, or abstracting journals (Fig. 3). This means that there is another relay station in communication and hence a further depersonalization, as well as a further time lag. Even more stringent checks must be made on how far the introduction of a secondary service at least meets the requirement of specific and comprehensive information. Here we immediately encounter the second problem of communication in chemistry: information retrieval *i.e.* chemical *documentation.* Chemical results keep their value for a long time. Methods of preparation, data on the properties of compounds, and reactions can often still be used for one's own work even if they were first reported a hundred years ago.

Fig. 3. The secondary chemical literature as a communication medium.

The fullest possible retrieval of all earlier results, together with that of up-to-date information, is therefore an aim which the chemical communications services must achieve. This was the original objective of the abstracting journals which, like the handbooks, were intended to facilitate comprehensive and summary searches for compounds and factual data by means of their indexes. To ensure that *every* later search will bring to light all the available information, all relevant data must be extracted from a publication and reproduced by the abstractor. There is, however, much doubt as to whether this is necessary at all, and such an analysis in depth takes considerable time. The attempt to meet *documentation* requirements, despite the ever-increasing number of publications (nowadays the volume of chemical literature doubles every eight to ten years) and despite the fact that the number of processors is not increasing at the same rate, has led to the abstracting journals being behindhand in their work, something which has often been criticized in the past, and therefore to their being ineffective as vehicles of up-to-date information.

One way of using the secondary literature effectively as an exchange for communication in chemistry is to dispense with the task of documentation [1].

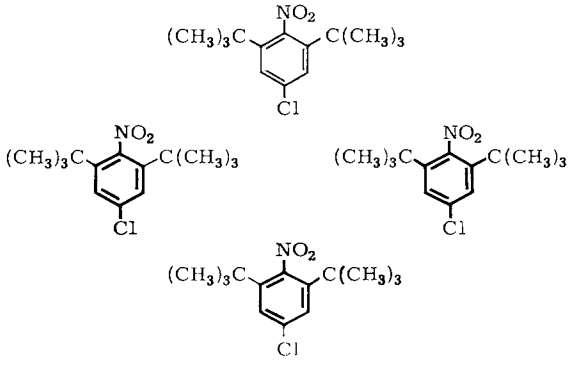
Briefly, we have seen that the increase in the amount of material to be communicated not only reduces the comprehensiveness of communication but also makes the communication aids used *qualitatively* incapable of fulfilling their function in the field of up-to-date information. Moreover, we are still faced with the fundamental problem that as the number of intermediaries involved in communication increases, so also does the possibility of falsification and delay.

The obvious conclusion is that traditional customs must be abandoned in the search for new ways of conveying up-to-date information which, although even more depersonalized than those used hitherto, will nevertheless probably be able to meet the main demands for the speedy dissemination of specific and comprehensive information. Such methods will be described in Section 4.

2. Requirements for a Communication System in Chemistry

While the welter of material has an adverse effect particularly on the speed and comprehensiveness of its communication, the second category of problems, the

[*] Summarized by *Ch. Weiske*, Nachr. Chem. Techn. *18*, 250 (1970).



[1] For current work, see *Ch. Weiske*, Angew. Chem. *82*, 569 (1970); Angew. Chem. internat. Edit. *9*, 550 (1970).

change in the nature of inquiries, affects particularly the specificity and completeness of information. In the field of chemistry inquiries have been and are being received relating to substances, structures, and properties both in respect of up-to-date information and in respect of retrieval (retrospective search). The significance of these categories has, however, changed in recent years as a result of the development of chemistry from an empirical to a deductive science. This can be seen from a glance at the results of the GDCh's questionnaire (Table 1).

Table 1. Subjects of chemical documentation searches. (Evaluation of the Gesellschaft Deutscher Chemiker questionnaire.)

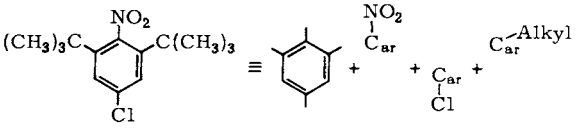
Searches for:	Answers (%)
1. Individual compounds	25
2. Partial structures	23
3. Reactions	22
4. Properties	7
5. Applications	5
6. Combinations of 1–5	17

Almost the same number of requests are received for information on *classes* of compounds with a common structural element, *i.e.* for "partial structures", as for information on individual compounds. Properties or applications alone, however important the search for them might be, are requested much more rarely than, for example, the combination of properties and structural characteristics. Searches for reactions (relation between the structures of the starting material and the end product) should also be regarded as combination inquiries of this type. A modern chemical documentation system must be capable of answering such inquiries. One way to achieve this is to arrange its contents in a systematic manner. A principle of arrangement is the basis of every documentation system. Arrangement systems which are still valid today have been created for chemical compounds in the handbooks. These allow compounds with common structural elements to be grouped together insofar as these correspond to the arrangement system used. When one realizes, however, how many groupings and how many partial structures could be of interest in later searches in the case of a relatively simple compound, *e.g.* 1,3-di-*tert*-butyl-5-chloro-2-nitrobenzene (chloronitrobenzene derivatives for the person interested in the S_N reactions of the aromatic nucleus; 1,2,3,5-tetrasubstituted benzenes for the molecular spectroscopist; *o*-*tert*-butylnitrobenzenes for the chemist working on

sweetening agents), it becomes clear that no linear arrangement system, however perfect, will allow a search for *all* conceivable groupings in a handbook or index. Every arrangement system must of necessity be *mono*dimensional, while present day inquiries demand *multi*dimensional search possibilities.

The situation is even worse when it comes to factual content; the indexes of monographs are mostly still in the form of compilations of words that are considered to be important and that have been extracted from the text, arranged solely on the alphabetic principle. The user is expected to find *the* word that has been used in the text for the concept he is looking for or to be able to think of words of a similar or the same meaning. There is a certain standardization for the indexes of abstracting journals: references are given for synonyms, *i.e.* words of the same meaning. They consist of collections of designations of facts (a "thesaurus"). Nevertheless, in searches for factual content – a property or an application – there is always the risk that some information will be missed if the traditional documentation aids, particularly indexes, are used. Furthermore, a desire for general information is often concealed behind the special formulation of enquiries relating to factual content. For example, an inquiry may be received that relates specifically to the antipyretic action of a substance, while, in the wider sense, information on other pharmaceutical applications may also be of interest. As with chemical structures, the documentation system must allow facts to be grouped together. Systems for the arrangement of the designations of facts, *i.e.* classifications, that make it possible to use more general or more specific concepts, as desired, in the formulation of an inquiry, have been under development for only a relatively short time in the field of chemistry. Such systems of classification, however, are essential for a specific and comprehensive search. Moreover, such systems must be constructed on a multidimensional basis; the traditional methods of documentation cannot meet this requirement.

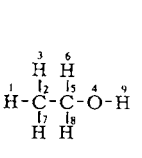
Finally, conventional methods do not solve the problem of answering combination inquiries. In this case, as in searches for partial structures, the problem cannot be solved with a monodimensional register.



To sum up, conventional methods of chemical documentation enable one to find answers only to some of the questions which are important today. These shortcomings have come to be recognized during the past twenty years. This has led to severe criticism of the existing organs of communication, but it has also led to attempts to develop an adequate information and documentation system in the field of chemistry. Generally speaking it is certain that the systems of classification will have to be reconsidered before the problems described can be solved [2]. This specialist task can be performed only with the use of new *technical* methods.

[2] For re-examination of the objects and methods of communication in chemistry, see *R. Fugmann*, Angew. Chem. *82*, 574 (1970); Angew. Chem. internat. Edit. *9*, 555 (1970).

3. Computer Oriented Description of the Structures of Organic Compounds



Electronic data processing machines, which offered a solution both to the problem of the welter of material and to that of polydimensional searches, fortunately appeared on the scene just when the communication problem was becoming acute in the field of chemistry, with the result that the technical means of solving the problem was on hand. However, the information to be communicated clearly could not be simply fed into a computer in the usual way in the hope that an inquiry will then meet with success. The information had to be transformed in such a way that it could later be found by computer. This means that a new *language* had to be created for describing chemical structures and factual data, and that arrangement systems had to be devised for chemical structures and factual data which allow full use to be made of the ability of electronic data processing machines to deal with combination inquiries; in short, that there had to be a reappraisal of chemical expressions. Taking the example of the description of the structures of organic compounds, the ways in which such descriptions are arrived at will now be briefly described.

One of the ways is based on the idea of characterizing the conceivable fragments in a structural formula by code symbols and using the sum of these code symbols as a description of the compound. In such fragment codes, for instance, we would indicate that the compound in our example contains a benzene ring substituted in the 1,2,3,5-positions, has a nitro group bound to an aromatic C atom and a chlorine atom similarly bound, and has one or more alkyl groups on the aromatic nucleus.

Many suggestions have been made for such fragment codes in recent years; within the range of fragments in the code they allow searches for partial structures. One of the most advanced codes of this type, the GREMAS system, is used by a European industrial chemical documentation enterprise, the IDC (Internationale Dokumentationsgesellschaft für Chemie mbH, Frankfurt) [3]. The advantage of such a fragment code lies in a structural description which is familiar to the chemist; this allows the clear formulation of inquiries that can be answered quickly and therefore cheaply with the aid of data processing machines, even when there is a large amount of material. The disadvantage lies in the fact that the translation of a structural formula into such a description, *i.e.* the coding, is an intellectual exercise which must be performed by specialists with a thorough knowledge of the often very complicated coding rules, and is a very arduous and expensive process where large amounts of material are concerned.

The second fundamental possibility for the description of chemical structures is the abstract summation of the atoms of the molecule in their relation to one another, *i.e.* topology. Figure 4 shows the principle of this technique.

a)

1	4	2	000
2	1	1	357
3	4	2	000
4	2	5	900
5	1	8	264
6	4	5	000
7	4	2	000
8	4	5	000
9	4	4	000

b)

Fig. 4. The instructions are as follows:

a) Draw the structural formula and number the atoms in any order (example: ethanol).

b) Write the numbers allocated to the atoms underneath each other, together with the element symbols (in the example, the figures 1 for carbon, 2 for oxygen, and 4 for hydrogen) and also the numbers allocated to the ligand atoms that are bound to the atom concerned.

The result is a sequence of numbers known as a matrix. This description is quasi-mathematically equivalent to a "graph", *i.e.* a system of straight lines (the bonds) and nodes (the atoms). This equivalence makes it particularly easy to process the description on an electronic computer. No knowledge of complicated coding rules is necessary for the topological description of structures [4], and it is even possible nowadays to automate the process to a large extent by using formula-reading machines. When the topological system is used, therefore, input is very simple and cheap, even where large quantities of material are involved. However, the retrieval of information is often very complicated. The partial structures, *i.e.* the groups of compounds, constituting the content of the inquiry have to be assembled in the data processing machine from many individual records. Searching is more arduous and more expensive than with fragment codes. The IDC has now succeeded in combining the two systems.

Topological input is followed by nonrecurring machine conversion into the well-developed fragment code, the GREMAS system. In the majority of searches, only this code is consulted. Thus, even when there are large quantities of data (more than 800000 structures are stored at present), rapid and cheap retrieval is possible.

The development in the description of the structure of a chemical compound, from the name through the fragment data to the topology, is an abstraction process and also a development of the ideas of chemistry. An analogous abstraction process, again using mathematical methods based on graph theory, can be seen in the preparation of factual content codes for processing in electronic computers. In this case the

[3] For the IDC System, see *M. A. Lobeck*, Angew. Chem. *82*, 598 (1970); Angew. Chem. internat. Edit. *9*, 576 (1970).

[4] For the topological description of structures, see *E. Meyer*, Angew. Chem. *82*, 605 (1970); Angew. Chem. internat. Edit. *9*, 583 (1970).

task was even more difficult; many, frequently inadequate or variously defined concepts, which furthermore vary in meaning over a period of time, had to be incorporated into a logical system [5].

To sum up, it is technically possible to overcome the difficulties described at the beginning of this article by the use of electronic data processing machines in conjunction with arrangement and description systems for chemical structures and factual data. The relevant information can be retrieved speedily and reliably from large quantities of material; it is possible to answer inquiries that are now comparable in importance with the so-called "classical inquiries", *i.e.* for groups of compounds of any type, or for combinations of structures and factual data.

Special mention should be made of one possibility in particular. Searches of this type can be formulated in such a way as to cover the entire field of interest of an individual worker, *i.e.* his "interest profile". If all the publications in one field are fed into a data processing machine as soon as they appear, then, by immediate searches for the topics of interest to the various participants, up-to-date information can be supplied by a communication system of this nature; furthermore, only the relevant information is supplied to individuals on a selective and specific basis. This is the principle of the "selective dissemination of information" (SDI) which is already used in many centers of industrial chemical documentation.

4. Information and Documentation Services of the Present and Future

The new technical scope for communication makes reconsideration necessary from another point of view. In this connection brief mention should be made of a problem concerned not primarily with communication itself but rather with the apparatus used in the conveyance of information. The diversity of the fields of interest and the different tasks involved in modern information and documentation, among other things, have led to the situation where at present many general or specialized information and documentation services exist *side by side*. Each of these centers evaluates the primary literature and analyzes it; for many publications this intellectual work is carried out twice, three times, or even more often. This has the advantage, particularly in the case of the specialized services, that they can to a large extent be adapted to suit the needs of their subscribers. On the whole, however, it means that both labor and money are wasted. If the traditional mode of communicating information proves to be inadequate, at all events when it is subjected to a thorough critical appraisal, then the information services must sooner or later go over to using methods which allow rapid selective dissemination of comprehensive information; *i.e.* they must operate a computerized documentation system. This means greater costs for the running of information and documentation services, and this increase in cost is intensified if many services are being operated side by side and if the same material is processed many times. If the very necessary conversion to modern working methods is not to be hindered by financial considerations, the mode of communication *must* be organized differently.

This reorganization has been a moot point for a fairly long time. Two concepts that regularly arise are the information *center* and the information *network*. Fundamentally one can imagine all primary chemical literature being evaluated in a single center. This center then operates information services, ideally for *all* chemists, or, by means of searches conducted on the collections of material stored immediately after evaluation, publishes target-oriented information in the form of notes relating only to the sphere of interest of the individual chemist, *i.e.* it operates an SDI.

The material stored at the center also serves for later comprehensive searches; it is the foundation stone of the documentation system. A center of this nature on a worldwide scale has come to be accepted as a near impossibility. In its place many centers concerned with the problem of the organization of documentation in the natural sciences, in technology, and especially in chemistry recommend a merger of the existing services. Such a merger would also be made technically much easier by the use of machine methods; an exchange of information based on computer tapes involves the use of very little language (or language that is easy to translate) and entails less difficulty than, for example, the exchange of abstracts, provided that a *uniform* system is used. Such collaboration has already been realized many times on a small scale. Thus, large European companies have come together in the IDC in order jointly to run a machine documentation system primarily in the field of low molecular weight organic chemistry. A similar system of collaboration is also getting under way in those services available to the chemical public. A first step toward such collaboration was the arrangement between the American Chemical Society and the British Chemical Society whereby agreements were reached on the joint processing of the primary literature and the creation of national centers to undertake machine searches. A similar agreement was reached in 1969 between the American Chemical Society and the Gesellschaft Deutscher Chemiker. It is to be hoped that this is the beginning of a modern worldwide chemical documentation system that is capable of meeting today's requirements.

A future chemical information network of this type might, for example, take the following form. Communication by means of lectures, conferences, and journals is supplemented by the dissemination of information by special high-speed abstracting services which, relieved of the documentation tasks that have hitherto fallen to the abstracting services, provide fast and specific reports on the primary literature in specific fields. By the use of machine aids in producing these

[5] For the graphical method of representing relations between concepts in mechanized chemical documentation, see *R. Fugmann, H. Nickelsen, I. Nickelsen*, and *J. Winter*, Angew. Chem. *82*, 611 (1970); Angew. Chem. internat. Edit. *9*, 589 (1970).

services it would be possible to produce indexes for abstracting journals and to keep the individual chemist up to date on the work of special interest to him with the aid of standing inquiries, *i.e.* to offer an SDI.

Apart from the up-to-date information, there will probably be only *one* general chemical documentation service, which will be operated on an international cooperation basis. It will be possible to search these documents by means of a computer; area centers will be set-up for such searches. The Gesellschaft Deutscher Chemiker, in collaboration with other German scientific societies and documentation enterprises, is planning to set up such a center with governmental support.

For the individual chemist this will definitely mean a wider scope for obtaining information and, to some extent, a change in his information habits. Up-to-date briefing will in the future be obtained through the intermediary of an SDI, as well as through reading journals and through special information services. Comprehensive literature searches in the library will frequently be replaced by machine searches in the documentation center.

The success of such a reorganization depends primarily on us all. Even the best, technically perfect system is useless if people fail to use it or do not use it enough; this is a sad observation that has often been made in the field of documentation. However, so that the individual can also make satisfactory use of the information services, he must see that, within reason, they will meet his requirements. This is also a problem of communication, of the contact between those who operate the information and documentation services and those who use them.

This active interest is also important from another point of view. A prerequisite for the use of a method is knowledge of it. The young chemist going into industry should know what possibilities are open to him for obtaining information. Not everyone has to know the details of the machine process, since this task is taken over by experts in practice. However, recruits must be available in relatively large numbers to take over from these experts. This does not mean that there should be special chairs for documentation in the universities. In the USA there are courses for the propagation of knowledge relating to information methods and the principles of machine methods. Such courses are also being planned in Germany.

Chemical Information Services

By Christian Weiske [*]

The definition of information services derives from the demarcation between documentation and information. The main criteria for information services are up-to-dateness, clarity, manageability, relevance, and flexibility. In addition to the printed information media (tables of contents, lists of titles, abstract journals) services have been offered in recent years which are prepared with the aid of data processing machines and which operate on the basis of data tapes (SDI, profile searches).

1. Introduction: Information – Information Service

While documentation is generally understood to be a method for storing information or the systematic collection of published research results which can be consulted on specific subjects, information is variously defined as the end product of documentation [1], as the communication of news coupled with a literature-processing procedure [2], or in general as the reduction of uncertainty [3]. In this article the word will be interpreted as "apprizal" or "instruction" in accordance with the Late Latin meaning of the word "informare".

Taking this definition, the information services are media for the propagation of information. The media may differ, but they all have a common aim, namely to show scientists a way out of the dilemma of having to keep continually up to date but not being able to do so because of the large number of publications [4].

It is very necessary to have information so that one can press on with one's own scientific work, keep abreast of developments in one's own particular field,

build foundations for theories and ideas, guard against avoidable financial losses, *etc.* [5–7].

Thus, according to the survey by the Gesellschaft Deutscher Chemiker in 1967 [8], chemists spend 6 hours a week on keeping up to date with current developments; this amounts to 15% of their working time for a 40-hour week. It is therefore extremely important that the information should be prepared and presented in such a way that the recipient can use the time available to him as effectively as possible.

If they are to be of use to the research chemist, information services, whatever their form, must be suited to the needs of the users and must therefore fulfill a number of conditions. The survey shows how few people recognize or take notice of this fact. About a third of the chemists consulted were dissatisfied with the information services available to them.

2. The Requirements of a Chemical Information Service

2.1. Up-to-dateness

One of the most important prerequisites of an information service is that the information it supplies must be fully up to date. Because of the very rapid development in almost all fields of chemistry (about 30–35 new publications are registered every hour) it is essential that information be the very latest. Although the time taken for publications to become outdated is a few years on average, it can be as little as a few months in special fields *e.g.* biochemistry. Another benefit to be gained from up-to-date information is the reduction of the delay between a new discovery and its use. *Voigt* [9] coined the term "technertia" to describe this phenomenon.

The basic problem is thus to minimize the time lag between the publication of a scientific document and the publication of the information. Since the information services are consequential upon the primary publications (journals, patents, reports, *etc.*) their up-to-dateness depends on the nature and depth of the evaluation of the primary publications and on how the results are produced (photochemical reproduction, offset printing, letterpress). Collections of tables of contents (*e.g.* Current Contents, Isotope Titles) require relatively little intellectual work, the depth of evaluation is not very great, and technical production is possible with very little loss of time. Collections of titles, *e.g.* Chemical Titles, the Signal Information from the All-Union Institute for Scientific and Technical Information, Moscow, Current Chemical Papers, and Chemical Biological Activites (with keywords), are certainly more demanding, but because their evaluation is not very deep and because of the low production costs they can be more up to date than information services based on abstracts. However, they can only be used as an aid to orientation. This is also echoed in the survey [8], according to which 73.5% of those consulted used abstracting services to keep up to date, while only 24.5% used lists of titles. This is partly because of other features demanded of the information services and partly because of the steady improvement of up-to-dateness that has been possible in the abstracting services. Thus only two months are required for the scientific and technical production of the Chemischer Informationsdienst, which first appeared in 1970, as compared with the three months required for the Schnellreferatedienst of the Chemisches Zentralblatt published until 1969.

2.2. Clarity

Another important factor for an information medium is good readability and clarity both in the organization of the information and in its arrangement. Thus *Erbersdobler* [7] claims that information work is facilitated by a layout with visual impact. General mention is made of typographically emphasized titles (*e.g.* by using semi-bold type faces). If the texts of the abstracts are supplemented with structural formulas, the readability of the abstracts is further improved for the chemist, and therefore the amount of time spent in sifting through the information is considerably reduced. Structural formulas are the lingua franca of the chemist. Examples are the Fortschrittsbericht of the Farbenfabriken Bayer AG, the Index Chemicus and the Chemischer Informationsdienst published jointly since 1970 by the Gesellschaft Deutscher Chemiker and Farbenfabriken Bayer AG.

The short abstract as defined by *Harbeck* and *Lutterbeck* [10], which should tell the reader whether it is worth his while to read the original itself, is normally sufficient for information purposes. The abstracts should be concise, indicative, and to the point, *i.e.* they should contain no superfluous material [11]. The reading speed can be further increased if the abstracts are introduced by a heading indicating the main content of the work. Abstracts of this type may be thought of as position abstracts [12]. An example is given in Figure 1.

The individual pieces of information in the information media can be arranged according to journals, *e.g.* collections of tables of contents (Current Contents *etc.*), or according to subjects, *e.g.* collections of titles and abstracting services, the arrangement by subject naturally being more useful for the reader. Fig. 1. Example of an easily readable abstract.

almost all information services use classification systems (UDC, DK [*], or their own) for the classification of the abstracts or titles they publish. According to its main content the information is filed in conformity with the system in the information service. The disadvantage of such a procedure is that articles containing several major points can be found only in one place. The abstract in Figure 1, for example, has several headings (S 7142 = organoiron compounds, isocyclic complexes, Q 0051 = seven-membered cycloaliphatic rings). Repetition of the same abstract is not possible on the grounds of cost. This shortcoming can be avoided by insertion of cross references in the other possible filing positions (*e.g.* in Chemical Abstracts) or by appending indexes, *e.g.* KWIC (Keyword in Context), keyword and compound indexes, to the journal issues. Keyword indexes with data relating to subject matter (properties, applications, *etc.*) as well as substance and compound classes, such as are found in the Chemischer Informationsdienst, are advantageous because the entries in the indexes come not only from the titles, as is the case with keyword indexes, but also from the text of the publication. With their alphabetically arranged keywords and additional context they are a valuable aid to finding specific information in the abstracts section [14]. In other words, the indexes are another form of information filed according to different principles.

To facilitate the use of the journal indexes "standardized" keywords [13], *i.e.* words taken from a concept list, are used instead of "free" keywords in the Chemi-

Fig. 2. Section from the keyword list of the Chemischer Informationsdienst.

scher Informationsdienst (see Fig. 2). The author index is a further aid for those wishing to follow the progress of research teams. The indexes are produced by means of data processing machines at the same time as the abstract part of the journal. The advantage of this is that, once produced, the data tapes can be used in the development of further services (see Section 3.2).

2.3. Manageability (Format, Size)

The material issued by an information service should never be regarded as material for circulation. If it were it might either be passed on without being carefully looked at because of lack of time or it might fall into the hands of someone who keeps it to himself for a few months. In the first case the service would have failed in its aim to inform and stimulate, in the second it would no longer be up to date. For this reason the Chemischer Informationsdienst is intended to provide information for the individual chemist. The scientist should be free to mark the data he considers important, cut it out, and file it in his own card index.

This means, however, that care had to be taken over seemingly superficial things such as format when planning the new service since the material published by an information service, unlike a comprehensive documentation organ, has to be manageable if it is going to be read and used. In this respect, information services are like news magazines, which are also read anywhere and not merely at the desk. Not only to keep up to date but also to achieve a manageable size, therefore, it was decided that the Chemischer Informationsdienst should appear weekly; the result is a weekly output of 250–300 abstracts in the inorganic section and 350–400 in the organic section. Moreover, this system meets the demands of the users, the majority of whom prefer a weekly or fortnightly publication [8].

2.4. Relevance and Flexibility

Information services must be related to practice and hence also be flexible to the changing needs of their users. However, this is easier said than done. Because of their size, as well as on price grounds, the subscribers to the larger chemical abstracting journals, which are used both for searches and for keeping track of current developments, are establishments such as libraries, institutes, and companies. Most users have no direct access to the editorial staff of the abstracting journals, whereas this is important for the introduction of improvements into the abstracting service. Questionnaires distributed to determine the needs of the users unfortunately usually reach only the subscribers, who cannot be compared with the users. Therefore the Gesellschaft Deutscher Chemiker sent out questionnaires to its members. A successful move in the USA has been to call consumer forums which give rise to lively exchanges of ideas between the consumers and the information chemists.

It is particularly important for information service publications, whose circulations depend on the number of individual subscribers, to be relevant to current practice and to be tailored to meet the needs of the users. Hence when the Chemischer Informationsdienst was still in the planning stage its organizers profited by the industrial experience gained from the Fortschrittsbericht of Farbenfabriken Bayer AG and established the main policy for the new service in "hearings". One of the major outcomes of these planning conferences was that the users of an up-to-date chemical information service do not demand the kind of completeness necessary for a documentation system. On the contrary it is desirable, for the purposes of current awareness and for keeping an overall view of the stage knowledge has reached in the main branches of chemistry, that the less relevant publications should not be taken into account. *Bischoff*[14a] arrives at the same conclusion. He maintains that qualitative selection is necessary to cope with the avalanche of information. In his opinion the selective dissemination of information is a valuable help.

However, the introduction of the selection principle is certainly not without problems. A constant watch must be kept on its correct application by the readers of the Chemischer Informationsdienst. The scientists who make the selections bear a great responsibility. For this reason articles from fringe journals, the novelty value of which it is often difficult to judge, must be selected by experts from industry and research outside of the editorial teams.

Major journals which are well-known because of the quality of their articles and which fall within the field covered by the service are, however, fully evaluated. This is an additional aid to the subscriber because he no longer needs to look through these journals. An advisory board made up of university teachers and industrial chemists from various fields of research selects and classifies the journals in conjunction with the editorial staff. The members of this committee should be regarded as representatives of the users. They pass on to the board of the Chemischer Informationsdienst recommendations relating to the fields to be covered and the execution of the abstracts, the depth of analysis, *etc.* This ensures that the new service is relevant to current practice.

[14a] See ref. [2], p. 166.

3. Other Types of Information Services

3.1. Card Indexes, Microfilms

In addition to the type of service published in book form there are also services which take the form of microfilms or card indexes. Card indexes are the classic search medium. Both information and documentation are involved. The cards are filed according to salient features. If an article contains several salient points, the information is usually filed in several places. Since card index issues are being offered for the Chemischer Informationsdienst if the demand is sufficiently great, provisions were made to incorporate this feature of card indexes from the very beginning. Abstracts having several salient points receive a corresponding number of classification numbers. The subscriber can use this as a guide when building up his card index. The classification system with the classification numbers and their meanings is thus at his disposal. The services that offer their information on punched cards (edge-punched, notched, peephole cards), *e.g.* Documentation for Molecular Spectroscopy (DMS) are a modification of the classical card-index services. These services, however, are no longer pure information services.

Microfilm also fall outside the definition of information services given at the beginning of this article since they appear only after the journals of abstracts have been delivered and are used mainly for searches. It should be mentioned, however, that information services prepared with data processing machines (see Section 3.2) also use microfilm stores to supplement their computer answers (distribution of copies of abstracts instead of references)[15]. The microfilm service of the Chemischer Informationsdienst could also in principle meet such a requirement.

3.2. Selective Dissemination of Information

The user must himself sort out the information relevant to him from all the material supplied by the information services in printed or microfilm form. By so doing he is protected from becoming overspecialized and is from time to time stimulated by work in other fields, but it takes up more of his time. It is therefore understandable that information should be required that is tailored to meet the needs of the user[16]. There has recently been some discussion on whether field-oriented or mission-oriented information should be offered[17]. Suppliers of special services and special

card indexes have sought out and exploited this market (see Section 3.1, DMS). In this case too, however, economic factors set a lower limit for the number of subscribers.

There will therefore be no printed services that go any further toward meeting the needs of a few or just one individual, but such needs can be met by modern data processing techniques. The information meeting the requirements of the interested parties can be retrieved from magnetic tapes containing all kinds of data by means of data processing machines with suitable programs. The selective dissemination of information (SDI) by means of magnetic tapes has been discussed in the literature and has been successfully applied for some time. In the opinion of *Sage*, *Anderson*, and *Fitzwater* the selective dissemination of information is one of the most promising developments in the field of information [18] and *Brown* [19] believes that this method of communicating information will meet with increasing success.

In practice the magnetic tapes containing up-to-date information are checked against the user's search profile. As soon as the search term agrees with an entry on the information carrier, a high-speed printer types out the data. The information may consist merely of a reference number (*e.g.* abstract number) or of the literature reference for the appropriate work. The reference may be supplemented by the title of the work, keywords, *etc.* The answers are obtained by word analysis of the clear, uncoded text (*e.g.* titles) or by calling for keywords. Little work is involved in data input in the free word searches but the search programs are more arduous. On the other hand "structured" data, *i.e.* information that is arranged and categorized on input, has the advantage that it is easier to handle.

The data tape produced for the Chemischer Informationsdienst belongs to the second group. On it are stored the abstract particulars (year, part, issue, abstract number), the classification numbers given alongside the abstract, the title of the publication, the journal reference, the names of the authors, and the keywords with accompanying text in that order. The keywords are given in alphanumerical notation (letter + five-digit number) (see Fig. 2). The content of the accompanying text is roughly coded (*e.g.* 21 = preparation). As was mentioned earlier the keywords may be facts or classes of compounds. The issue indexes are also produced from this data tape. As will be obvious, however, it contains many more data, which are available for answering the inquiries of the participants in an SDI.

4. Cooperation in the Field of Information

The Chemischer Informationsdienst's data tape cannot give answers to inquiries for groups of compounds, partial structures, and reactions because of the way it is made up. This is a shortcoming that can be made good only by using the "structure tape" of the Internationale Dokumentationsgesellschaft für Chemie mbH (IDC). The IDC encodes the structural formulas and reaction schemes contained in the abstracts of the Chemischer Informationsdienst in accordance with the GREMAS system, and recently to a certain extent on a topological basis [20].

Originally, the structure tapes produced from these data were accessible only to the members of the IDC, but since April 1970 they have also been open to inquiries from university workers [21].

This is another step toward a national information system such as has been suggested by *Mathers*, *King*, and *Rea* [6] for the USA. These authors view the improvement of the existing information services and cooperation between them as the most practical solution. The cooperation between the editorial staff of the Farbenfabriken Bayer AG Fortschrittsbericht and the West-Berlin editors of the Chemischer Informationsdienst may be considered as the beginning of cooperation at a national level. Further signs of this can be seen in the existence of a working group for chemical documentation (Arbeitsgemeinschaft Chemie-Dokumentation) [22]. This working group deliberates on common development problems and thus helps to avoid unnecessary duplication and overlapping of work.

Even if such a national information system is set up it will in no way detract from the importance of cooperation with outside information or documentation systems. Furthermore, the work cited above [6] does not at all exclude the possibility of international cooperation. Indeed the superabundance of material makes such a thing urgently necessary.

With a view to the future, the Gesellschaft Deutscher Chemiker (GDCh) came to an agreement with the American Chemical Society in 1969. The terms of this agreement were that the GDCh should have at its disposal all the data tapes of the Chemical Abstracts Service (CAS) and that it should be empowered to use these tapes to develop special services [23].

Tapes from the following services are available for evaluation: Chemical Titles (CT), Chemical Biological Activities (CBAC), CA-Condensates (CAC), Polymer Science and Technology (POST), Basic Journal Abstracts (BJA), and other tapes which the CAS has not so far been distributing. Chemical Titles covers 130000 titles from 650 journals per year, and CBAC contains about 17000 abstracts from 550—600 journals per year. The compound numbers are contained on the data tape as well as the titles. CAC covers 250000 titles with keywords per year (the service therefore has the same coverage as the Chemical Abstracts Service), POST covers the work in the field of polymer chemistry (about 460 journals and appropriate patents), and BJA puts on tape the abstracts from 35 main journals. In this last case searches can be made for facts, compound names, and molecular formulas. Unlike the Chemischer Informationsdienst data tape, the CAS tapes are not structured. Tests on the CAS tapes have already been in progress for some years [24].

Investigations are being carried out at present on a CA-Condensates test tape in the Development Division of Chemie-Information und -Dokumentation Berlin.

The evaluation of data tapes from foreign information services for information purposes in national centers has the advantage that it is easier to make contact with the users, and their requirements can be covered better. Furthermore, the experience they have accumulated in using the tapes is communicated to the producers of the data tapes *via* the national centers. The producers for their part take the suggestions into account in planning and development, so that the information services can be continually improved. The setting up of such a system should be advantageous to all chemists.

Theoretical Aspects of Communication in Chemistry

By Robert Fugmann[*]

Nothing is more practical than theory
Ludwig Boltzman

Successful searching for publications on the basis of subject obeys rules whose relations to thermodynamics are unmistakable. As a collection of literature grows, the degree of order required increases, since the patience, time, and memory used by man to compensate for lack of order cannot keep pace. The high degrees of order that are necessary nowadays in scientific literature cannot be attained by traditional documentation methods. If modern techniques are used to improve communication, the conceptual basis of such a documentation method must be revised and adapted to suit the new possibilities. The conditions in chemistry are relatively favorable for the effective use of modern technical and conceptual methods, since the terminology has been developed further than in most other sciences.

1. Introduction

A factor essential to the progress of any piece of research is the closeness of communication with the scientific environment of the present and of the past. This communication is of direct practical value to any scientist or engineer if it provides him with experimental results that he no longer has to establish by his own time-consuming and costly experiments. Special investigations frequently even prove to be unnecessary, since the problem in hand has already been solved or brought close to solution.

Equally important is the heuristic role that has always been played by communication in science. In investigating unexplained phenomena observations by colleagues are as valuable as one's own findings, and the soundness of a hypothesis increases with the number of observations on which it is based. Furthermore, the more fully all subsequent experimental results are checked against this hypothesis (again largely a question of effective communication), the more rapidly and more reliably does the hypothesis develop into the final theory, *i.e.* the sooner one can form a new hypothesis with a greater explanatory value.

If one wished to obtain the epistemological raw material purely by one's own experiments and without the aid of communication, many generations would not be enough to complete the task in many cases. It is also not certain that the creative idea would emerge in any case after immersion in such an ocean of detailed work.

Communication is also involved when one more or less accidentally encounters new methods and results in other fields, after which these frequently prove to be extremely useful in one's own field. Many fields on the borderlines between physics, biology, and chemistry owe their relatively rapid development largely to interdisciplinary communication. It will be to the disadvantage of any research worker in the long run if he does not participate, or participates insufficiently, in this mutual give and take in science.

This is occasionally due to an individual way of working and a lack of willingness to communicate. However, other factors are always also involved, and they paradoxically result from the scientific work itself and the publication of its results. They become increasingly predominant with increasing intensity of

[*] Dr. R. Fugmann
Farbwerke Hoechst AG
6230 Frankfurt/M. 80, Postfach 800320 (Germany)

the scientific work. It is obviously not enough that cognition and experience merely *exist*, printed in an exotic journal or presented at an exclusive lecture meeting. They must also be readily accessible to those who wish to advance knowledge or who require the published results for their own studies. Only then can they be useful in the heuristic or practical sense.

It is an accepted fact that people differ considerably in the extent to which they are inclined to consciously search for knowledge gained by others in order to utilize it, together with justified criticism, in their own situation. Thus, the efforts made by the individual scientist to look out for knowledge gained by others will vary between wide limits. Published knowledge is therefore all the less used the more troublesome the search for it is. This is all the more true in that the prospects of success in a search are often uncertain, whereas a result will undoubtedly be obtained in a reasonable time by one's own experiments.

A considerable discrepancy already exists between the actual outlay on research and development and the outlay that would be sufficient in case of effective communication. The resignation that is occasionally encountered in this connection is evident from the recommendation that a preliminary literature study may be dispensed with if the anticipated cost of a research project does not exceed 100000 dollars[1].

Various estimates have been made of the amount of unintentional duplication of work that results from lack of information about existing knowledge. The most reliable values for chemistry are probably around 30 %[2,3]. However, no one can guess how often new cognition in natural science has already failed to be reached merely because someone missed the vital link in the mosaic of facts, although it had already been published.

The present situation encountered in science is comparable with that of a manufacturing company which, while holding large stocks of its products, is faced with so much trouble in locating a specific article when an order is received that they rather repeat production than search through the existing stock. Eventual bankruptcy of such a company is by no means ascribable to faults in manufacturing techniques, for that is just the sector showing a tremendous productivity. Instead, the reason for failure is obviously to be sought in an entirely different sector that is nevertheless of equally vital importance.

The aim of the present article is to show the kind of obstacles that have stood in the way of fluent communication in science, and particularly in chemistry, and how these obstacles can be overcome with the greatest possible prospect of lasting success.

It is of secondary importance to these considerations whether the published knowledge is from journals or patent literature, has been published in a book, or was initially communicated orally. On the other hand, it makes a decisive difference whether or not one can *define* his information requirements, since only in the first case can the desired information be retrieved by a *directed* search. Otherwise it can be found only by *undirected* literature studies.

[1] *G. M. Corney*, Steel *152*, 20 (1963).
[2] *L. H. Flett*, Chem. Week *1960*, 75.
[3] *A. Neelameghan*, Library Sci. *5*, 264 (1968).

2. The Undirected Literature Study

It is inherent to science that no one can predict its progress in detail. Consequently, no one can specify in advance which future discoveries will be of particular interest to him. Only *after* hitting upon an innovation, *i.e. a posteriori*, can he decide from case to case and purely subjectively whether or not this is of interest to him. The discovery of penicillin or of the compounds of inert gases, the bonding of molecular nitrogen to organic molecules under physiological conditions, the surprising ability of saturated hydrocarbons to be protonated, and the accumulation of pure neutron matter in certain celestial bodies are only a few examples of subjects that might have interested any chemist. However, practically no one could have defined his interest in this direction *a priori*, *i.e.* before these phenomena were observed. It is only by regular undirected reading in the literature and by personal contact or by browsing in a library that one can keep abreast.

"What are the most favorable conditions for reaction A?" "What are the economic prospects for product B?" "What substituents reduce the toxicity of substance C?" These are also questions to which no documentation system can provide the answers. The questioner would be unable to decide *in advance* which of two reaction courses is the more favorable, if the apparatus requirements, the accessibility of auxiliary substances, the desired purity of the product, *etc.* have to be taken into account as well as the yield. Documentation can only help to uncover publications on these topics, and the questioner must then make a subjective judgement for himself.

3. The Directed Literature Study

The scientist's undirected literature study will provide him with information on a given topic at best from a certain time onward. The earlier literature had previously been disregarded by him. To include this literature in the search, reading must be confined to a very small part of all the previous literature, and this part must be selected in a *directed* manner.

The literature in its original state, *i.e.* in purely chronological order, is unsuitable for this purpose, since information relating to a topic is scattered in an almost completely random manner. One must therefore refer to literature prepared in some way in which the material of interest is more or less *localized*, either as itself or in the form of its representatives, *i.e.* the references. This prepared form of the literature may consist of monographs, handbooks, a well ordered library catalog, or an index. Alternatively, it is sufficient to localize the material of interest only when it is required, *e.g.* by selection procedures on a card index, a magnetic tape, *etc.* The preparation of literature in

this manner so that material on many subjects is localized or becomes localizable is the object of scientific documentation.

3.1. Terminological Requirements

Whatever the final form resulting from the preparation of literature in this manner, this preparation has usually been carried out by scientists *other* than those who will later use this aid for their directed literature studies. This is why the prospects of success in any directed literature study are strongly dependent on how far the terminology of a field has developed. They depend on how far it is terminologically possible for an author to express his ideas and experiences in the technical language, and how far the author's intended meaning can be grasped from this linguistic form of expression by a second expert. Terminological vagueness cannot be overcome even by an excessive employment of scientific personnel and technical aids in documentation.

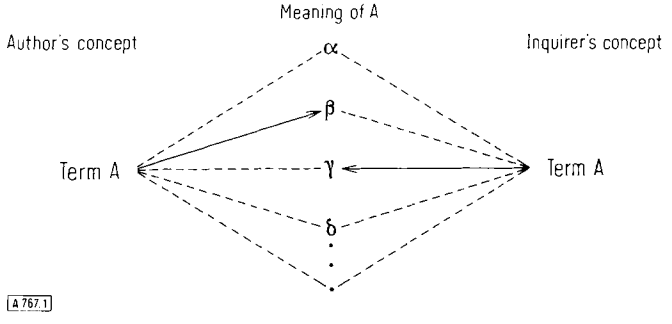

Fig. 1. Multiplicity of meanings of a term A.

To illustrate this, let us consider the unfortunate case of a term A with many different meanings α, β, γ, δ, *etc.* in common use. Two experts, *e.g.* the author and the inquirer, will therefore associate different concepts with the term A (Fig. 1).

One can *e.g.* easily encounter a dozen widely differing definitions for the term "corrosion", even when the medical and geological connotations are disregarded.

As an inquirer, the expert with the idea γ expects that the literature on the topic γ can be retrieved by means of the term A, *i.e.* in the simplest case under the subject heading A in an index. The word or words accidentally chosen by an author to describe this topic should not exert any influence on the assignment of the subject heading. However, the same requirement is valid for experts with the ideas α, β, δ, *etc.* They all expect the literature on their (different) ideas to be localized under the search term A.

The most that can be expected from a documentalist in this situation is that he will include *all* the concepts α, β, γ, δ, associated with a term A when they are recognizable in the text of a publication, and that he will make them all retrievable by the same search term A. Any inquirer, whichever idea he accepts, will then find literature references, many of which he will regard as ballast, since they correspond not to his own individual idea of the term A (*e.g.* γ), but to the other ideas α, β, δ, *etc.* This ballast inevitably increases in size with increasing heterogeneity of present and past terminology.

The situation in practice is less favorable still. It is impossible to establish all the ideas for each and every one of the numerous subject headings and to memorize them continually during literature analysis. Thus perhaps only the meanings α and β for the topic A will be considered, while all other meanings γ, δ, *etc.* are ignored. If these ideas occur in a publication, therefore, they will not be designated by the term A. This has a much more serious, though less obvious, consequence for many literature searchers than ballast, namely loss of relevant information.

If the *majority* of the terms in a certain field are terminologically vague, the maintenance of an intersubjective literature documentation based on joint work is an unrewarding task that can never be satisfactorily fulfilled. The only answer is for each worker to build up his own card index, in which he can use his own interpretations of the terms. Necessarily, he is then cut off from extensive communication with the literature in his field, since he can record at most only those publications that he has read himself.

The core of any chemical documentation system, *i.e.* substance concepts, is largely free from terminological difficulties of the type described. On the other hand, considerable vagueness exists in the terminology of reaction types. Even greater difficulties arise in borderline fields with engineering, biological, and other property concepts. A great deal of terminological work is required if communication in these fields is to be effective[*].

3.2. The Second Law of Thermodynamics in Documentation

In any directed literature study one expects the material on the topic of interest, at least insofar as it is definable, to be *localized* as well as possible in the part of the collection of publications to which the inquiry is addressed. For example, if the problem is to list the original literature on herbicidally active ureas, the collection should, so to speak, break down into two parts, in one of which the relevant material should be localized as completely as possible; this part should also be as free as possible from irrelevant material. The more complete this localization is, the surer the searcher can be that he will miss nothing relevant if he merely scans the localized part, and the less time it will take him to find the relevant material in this part (cf. Scheme 3 in Section 5.1).

The greater his uncertainty in this respect, the more he must rely on his memory – insofar as his time allows – in order to retrieve at least those cases which he himself has previously encountered in unforeseeable places.

Localization in this manner means nothing else but establishing order if order is defined as "meaningful proximity of the parts of a whole". The number of documentation systems that have been developed for this purpose is bewilderingly large. If on the other hand we accept the thermodynamic definition of order, it is relatively easy to obtain a general overview of these systems, and in particular to assess more reliably the very pronounced differences in their capabilities as well as their prospects for the future. *All these systems*

[*] Some terms from the documentation field are listed in Section 5.1, together with the meanings with which they are used here.

can be characterized by the degree of order that they can establish in the literature and by the extent to which they can be developed to obtain still higher degrees of order.

A collection of documents or references can exist in states with very different entropies[*], the state of least entropy and greatest order having the greatest working capability (*Erich Meyer*)[4]. Such a collection is productive in a very real sense, and performs useful work, so to speak, when this order provides an inquirer with practical or heuristic assistance in the form of an ordered collection of literature. Thus a documentation system with a high working capability will save much search time and effort of memory, both of which are always of only limited availability for a literature search. Moreover, a documentation of this kind will stimulate many scientists to undertake extensive literature studies.

3.2.1. Requirements as to the Degree of Order

Let us consider a case in which a medium degree of order prevails in or can be established in a collection of literature. Let us assume that 20 % of the references localized or capable of being localized for a given topic are relevant to the inquiry. It then makes an important difference whether there are two relevant references out of ten or 200 out of 1000. Purely because of lack of time, it will be necessary in the second case to content oneself with a few publications selected at random, and to tolerate loss of information.

If the references localized are to be scanned on the inquirer's behalf for relevant material by the documentalist, he will soon be overloaded by the amount of work that converges on him. This is true in particular if the collection is steadily growing. The number of searches with which the documentalist can cope steadily decreases, and he will be grateful for each search from which he is *exempted.* He is soon forced to sacrifice quality, and more and more often he has to restrict his search to *parts* of the collection ("the last few years are the most important").

If this work is left to the inquirer himself, on the other hand, the number of searches carried out will gradually dwindle to nothing, since this is, according to Mooers' law[6], the simplest way for the inquirer to avoid being overloaded by search work.

The result in either case is that the system will ultimately be discontinued, since the intellectual and technical outlay that would be required to keep it working would no longer be justifiable. Its working capability would thus have decreased in a very real sense, and would finally have fallen to zero.

If on the other hand *a higher degree of order* could have been established in the larger collection mentioned above, so that the 200 relevant references were localized among *e.g.* 300 instead of 1000, the information offered would be much easier to utilize, since it would generally be possible to read these 300 references instead of 1000 and "process" them intellectually.

It follows that the requirements as to order in a collection of literature increase with the growth of the collection. This is due to the limited and constant time available to man, the user of the system. Thus, if the growth of a collection of literature is regarded as a natural and even very desirable process, one must also recognize the need for a continuous increase in the order that prevails in this collection or that can be established in it.

It is even better to establish, as early as possible, such a degree of order that will be adequate to maintain the working capability of the collection for as long as possible in the future. For, to any given degree of order there corresponds a certain method of literature preparation and of localization in this collection (see Section 4). If this method were repeatedly changed to achieve increased order and to increase the working capability, the collection would become so heterogeneous over the years that it would no longer be possible to search through it reliably as a whole, since a different variant of the localization method would be required for each past period of literature processing.

Another factor that increases the demands as to order is the *frequency with which the collection is used to obtain information.* An ordered collection of literature naturally becomes more attractive to the inquirer as it grows. However, the time available to man for searching can be used up not only because of the increase in the time taken for each single search, but also because of the increase in the number of searches. This would lead to the same overloading even if the time required for each single search remained unchanged. Thus, as searches must be carried out with greater frequency, it becomes more important to counteract the increasing search work by a corresponding increase in order.

The degree to which the future of a literature documentation is assured is seen when the tendency toward specialization in science begins to affect the kind of inquiries addressed to the collection. In the example given above, we had to find 200 references that were relevant to a given topic. If this inquiry were repeated in the same form 20 years later, the result might be 2000 relevant references. A topic on which the literature volume is moderate today may grow extensively in only a few years. For instance, the needs of the steroid chemist in earlier times would have been satisfied if every relevant publication had been posted under the subject heading "steroid". Nowadays, on the other hand, it is normal that inquiries in the steroid field specify the precise positions of certain substituents on the ring skeleton, the exact positions of double bonds, the configurations and conformations at carbon atoms, *etc.* These inquiries can now be answered only if the documentalists of many years ago had the foresight to devise, test, and use sufficiently detailed methods in literature processing. Similarly, it is still necessary today to make *provisions for future*

[*] In this discussion "entropy" is always to be understood in the thermodynamic sense, and not in the sense in which it is used in information theory[5].

[4] *Erich Meyer*: Grundfragen der Patentdokumentation. VDI-Verlag, Düsseldorf 1960, p. 207.

[5] Cf. *W. Meyer-Eppler*: Grundlagen und Anwendung der Informationstheorie. Springer-Verlag, Berlin 1969, p. 78.

[6] *C. N. Mooers*, Amer. Documentation *11*, 204 (1960).

specializations and to record such details *now* that will be used as search conditions only in the distant future.

Thus it is an essential criterion for the future usefulness of a literature and patent documentation system that it should at any time possess a remarkable reserve of inquiry specificity. In other words, provision must always be made for degrees of order that will be utilized only in the future, and which would always appear excessive when measured against present-day requirements.

3.2.2. The Price of Order

Any increase in the degree of order such as is necessitated by the three factors mentioned (growth of the store, increasing frequency of searches, tendency toward higher specificity) is inseparably bound with an increase in cost. As a postulate of thermodynamics, increases in order never occur spontaneously, but must be enforced by a supply of energy. Otherwise we would have a perpetual motion of the second kind. The amount of energy that must be supplied inevitably increases with the degree of order that is desired.

In documentation, the energy that must be supplied to establish order is mainly intellectual work. Those concepts and connections of concepts on the basis of which the literature is later to be ordered must be selected from the publications to be stored. These facts must then be brought into a form that can be predicted in future searches, to ensure that the inquiry can be phrased adequately.

In addition to this work, it is often necessary to write an abstract that presents the essentials of a publication lucidly, and to this are often added programming costs and the cost of the machines used.

The higher the degree of order that is desired in a collection of literature the greater is, for thermodynamic reasons, the cost of these operations. For example, if it is desirable to be able to localize literature not only on specific compounds, but also on certain methods for the preparation of these compounds, possibly under certain operating conditions, then all concepts relating to synthetic chemistry and to chemical engineering must also be selected from the respective literature, translated into a suitable form, and stored.

In the short-term view, therefore, it will always appear that a very pronounced decrease in the cost of literature processing could be achieved by a small decrease in order, although such a measure is necessarily accompanied by an increase in the work of searching. In doing so, however, the future prospects of the system would be reduced, since the result would be a lower degree of order and hence a cut in the reserves on which the system will very soon have to call. However, one should not bemoan the surprisingly high cost of a documentation system with a guaranteed future, since the steadily increasing use of a growing system will more than justify the cost, provided that the system retains its working capability.

One of the peculiarities in the documentation field is that the working capability of a literature collection can be very easily decreased, and that the consequences of such a change are extremely serious. By merely continuing a procedure that was initially entirely satisfactory one can steadily devalue the whole outcome of the procedure. This decrease in value even affects the work that was done earlier by this procedure and that adequately satisfied the requirements at that time, since the collection was then much smaller, since search frequency was low, and since inquiries of the more general kind still predominated.

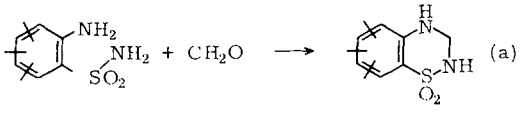
If the decrease in the working capability finally brings the documentation system to a halt, the fruits of all the documentation work carried out in past years must be written off as valueless. Apart from the system's use in former years the situation is then the same as if no literature documentation had been carried out at all. This means a serious loss of time, work, and results.

The requirements as to order, and hence the minimum cost, are much smaller for systems that will always remain small. This situation is found in fields in which the literature quickly becomes obsolete or uninteresting for some other reason.

A similar situation prevails when it is intended to select from current publications only those in which the user is most likely to find material of interest. Facilities of this kind have been available for a long time for journal and patent literature. Rough grouping is adequate for this purpose, since the part of the collection that is to be scanned by the user is, relatively speaking, very small. It includes only the recent publications from the last issue of an information bulletin of the "current awareness" type.

It would be wrong, however, to think that groupings or indexes based on such very general topics need only be cumulated mechanically in order to establish cheaply a large collection of literature for retrospective retrieval purposes. Since such a cumulation process is not associated with a second and deeper analysis of the literature, the degree of order in the cumulated collection is no greater than that in the original collections. Such a collection would very soon lose its working capability, and would thus become valueless for searches of the retrospective type.

A method that is often considered for the wide field of patent documentation is also merely cumulative. It involves the separate development of viable special documentations for the various fields, which is not excessively difficult or expensive. It has been suggested that a comprehensive documentation for the field as a whole could then be obtained by purely assembling these subsidiary systems. Again, the order in this cumulated system can never be greater than that of the individual parts. However, the order requirements for any one of these parts would be much less rigorous; the order in the cumulated system will also be correspondingly low, whereas the requirements here are very much higher. Accordingly, cumulation in this manner leads not to an integrated system for the field as a whole, but to chaos.



3.3. The Nature of the Order that Can Be Required

We have considered in an abstract manner the degree of order that is desirable or necessary if a literature collection is to remain capable of working. The degree of order is a measure of the extent to which irrelevant publications will be found in the localized part of the ordered literature collection (ballast), and of how many relevant publications of the collection are absent from this part (loss of relevant information). We have not yet considered the question of the conditions that a publication must satisfy in order to rank as relevant to the inquirer's topic.

The inquirer can expect to find the literature in an ordered state such as he has in mind only on one condition: He must be able to define the nature of this order. It has already been shown in Section 2 that those literature problems that cannot be adequately defined fall entirely in the field of the undirected literature study.

Experience has shown, however, that most chemical searches in practice fall in a broad border area between directed and undirected literature studies. The inquirer is entirely unaware of this problem if he is accustomed to carrying out the search himself. With the modest means available to him (usually conventional indexes) he cannot narrow his particular field of interest adequately. He therefore has to scan much more literature than is relevant to his problem. After having digested the scanned publications, it is easy for him to decide intuitively and subjectively whether the additional concepts, for which he had no suitable subject headings in his search, are also satisfied. To do this, there is no need to decide on the nature of these additional concepts *a priori*.

If a literature study of this nature is delegated, it is an essential part of the documentalist's duty to clarify, by discussion with the inquirer, which parts of his inquiry are to be regarded as defining the problem and which are intended merely as examples. In an inquiry for literature on the reaction (a), for example, it could emerge from such a

(a)

discussion that the inquirer is interested not only in formaldehyde itself, but also in its derivatives (acetals, 1,1-halogeno ethers, *etc.*) and in formaldehyde generators (hexamethylenetetramine, methanol-dichromate, formic acid by disproportionation, oxalic acid likewise, *etc.*). Even reactions involving "low aliphatic aldehydes" in general, as well as their generators and derivatives (enols, epoxides, *etc.*), may be of possible interest. The formulation given by the inquirer could even be open to objection in respect of the starting material indicated. It would fail to retrieve *e.g.* the ring closure reactions of the acylated amino compound or of acylamino sulfonyl chlorides, in which replacement of halogen by an amino group and ring closure take place in a single step. The definable object of the search would thus merely be "ring closure to form the 1,2,4-thiadiazine derivative", and the documents found in this way would then have to be checked *a posteriori*, preferably by the inquirer himself, to see whether they satisfy the entire aim of his search.

Even when everything that cannot be defined *a priori* has been eliminated from an inquiry, the decision regarding the relevance of localized references is still occasionally problematic. Judgement of relevance is at present a highly controversial topic in documentation literature, and several criteria have already been proposed [7], in some cases even with graded evaluations. However, a rough division into relevant and non-relevant publications is sufficient for our purposes. To illustrate this, let us consider the inquiry: "Obtaining α-amino acids by fermentative processes with microorganisms".

An inquirer can expect a documentation system to localize all the publications, as far as they are contained in the collection, in which

a) the desired concepts occur with equal or higher specificity,

b) the concepts are connected in the desired manner, so that they occur in the desired context.

[7] Cf. *S. E. Robertson*, J. Documentation *25*, 93 (1969).

The words that an author happened to choose to express his results or ideas should be of no influence. Moreover, the subject of interest need not even have been referred to expressly by the author. For example, in a process that proceeds "aerobically", it is unnecessary to mention that microorganisms are involved. If amino acids are obtained in a "fermenter", a common type of apparatus for this process, the participation of microorganisms is again implied with sufficient clarity. The formation of amino acids is indicated by a report on the total hydrolysis of proteins or on the determination of the hydrolysis products with the aid of typical amino acid reagents, *etc.*

On the basis of all these criteria, the following topics would be relevant:

1. "Treatment of filtrates from the cultures of *Acetobacter suboxidans* to isolate L-glutamic acid as the sodium salt".

2. "A sugar-decomposing microorganism is grown in a culture medium with a source of nitrogen, and the amino acids formed are isolated with the aid of ion exchangers".

3. "Biotechnical production of diaminopimelic acid by *E. coli* in submersed and aerobic cultures".

4. "Increased formation of free amino acids, particularly glutamic acid, in the aerobic degradation of wheat straw".

5. "Production of L-amino acids from keto acids in the presence of L-glutamic acid as a catalyst with the aid of a multienzyme system from *Cl. butylicum* with the addition of extracts from *E. coli*".

The following topics would not be relevant according to the above criteria:

6. "Formation of α-ketoglutaric acid by *Aerobacter aerogenes* in a culture medium containing glutamic acid".

7. "Formation of acids in sausage fillings after infection with the microorganism *Lactobacillus plantarum*".

8. "Determination of amino acids, particularly glutamic acid, by cultivation of a *Pseudomonas* mutant that requires glutamic acid on a deficient culture medium".

Should a general topic of the type 7 be of interest as well as the specific topic, the inquiry would have to be formulated in a more general manner at the outset. However, the inquirer must be protected in some way against excessive generality, and the best solution is to draw the line where the stored publication becomes more general than the inquiry. Otherwise the position of the dividing line with respect to non-relevant responses could not at all be defined reliably.

In special patent searches, however, the situation may be completely reversed. In a search to establish the patent situation regarding a certain subject, for which an application is intended, one is interested in all more general claims that cover this subject. Subjects that are more specific than the subject of the intended application, on the other hand, are of minor interest. They must be covered primarily in a search for novelty.

3.4. Distortion of an Inquiry

Every user of a documentation system should realize that localizing all relevant publications in a collection, approximately without loss and without ballast, is an ideal case of extremely high order. A documentation system can approximate to this ideal case only insofar as the means are available in the form of adequately qualified personnel and technical aids. However, the user must also accept that some of his expectations could prove to be generally incapable of fulfillment, since he is unable to define these expectations.

On the other hand, the documentalist is well advised to pay the greatest conceivable attention to the requirements that *can* be satisfied. The surest way of taking practical requirements into account is to carry out an extended analysis of the needs of future users and to try to ensure the localization or localizability of the literature relevant to inquiries of the types recognized, in accordance with the above criteria.

In particular, it would be a serious misunderstanding of the task of documentation if the inquirer's expectations regarding his general inquiry concepts were not fulfilled. To find literature on "amino acids" in a certain context, it should not be necessary for the inquirer to list all conceivable *specific* members of this group, or to enumerate all (!) conceivable species of microorganisms that might occur in the desired context. It must be left to the documentalist and his system to include these concepts unasked, so that an inquiry for a generic concept will be satisfied not only by a stored concept on the same specificity level, but also by all more specific subconcepts of this generic concept. If a system does not allow the localization on this basis so that the inquirer or documentalist is forced to list all more specific concepts as alternatives, the result is usually *falsification* or *distortion* of the original topic, since the selection of the more specific concepts to which one is forced to commit oneself will usually be incomplete. In no circumstances can he then expect the satisfactory localization of the literature in which he is interested. The best result that can be obtained after such a distortion of the topic by the enforced specificity is precise localization on the basis of the distorted topic, and this will necessarily be associated with loss in respect to the original form of the inquiry.

If forced to use more specific concepts, one will naturally include mainly those for which the probability of being found in the literature is greatest. They may, for example, still be remembered from earlier literature studies. Glutamic acid will thus be favored in comparison with an aminostearic acid, *etc.* The frequently given advice, however, that the inquiry should be confined to the "correct" subconcepts is worthless in this general form, since it presupposes knowledge of what one wishes to learn, *i.e.* of the existing literature on this topic and of the contents of the store. A listing of subconcepts for retrieval would be easy to make *a posteriori*, *i.e.* after examination of the entire store. In retrieval, however, the same judgement must be made *a priori*.

Distortion of the original inquiry again occurs if instead of a concept of the inquiry such as "amino acid" or "microorganisms" only a more *generic* term ("aliphatic carboxylic acids", "primary aliphatic amines" or "plant life forms", "organisms") is available for localization, the distortion in this case being due to enforced generalization. The inevitable result is that the publications localized will include ballast in an amount that depends on the degree of distortion. The causes are again purely conceptual in nature, and even the most effective mechanized localization technique can do nothing to alter the situation.

The above discussion leads us to the postulate that for substantially every scientific inquiry topic, insofar as it is definable, there should be an extremely precise formulation under which the relevant literature is localized (index) or can be localized (mechanized systems). To fulfill this postulate these undistorted formulations should be able to be chosen just as specifically and generically as the inquiry topic itself. This means that a very great number of these "inquiry terms", as we shall now call them, should be available in a documentation system. The greater the number of meaningful inquiry terms and the greater their differentiation, the greater is the likelihood of finding an inquiry term that corresponds exactly to the inquiry topic; this is a fundamental necessity for localization with the minimum loss and ballast.

It sometimes becomes necessary to resort to concepts bearing no systematic relationship at all to the theme of the inquirer. If a search is made, *e.g.* for production routes for a particular class of compounds, a search for supposed authors of relevant documents means a considerable distortion of the original search idea. Ballast and loss will be correspondingly large. — Similar conditions apply when one bases his literature search on the citations given by authors. These citations naturally refer to conceptually highly diverse publications which rarely form a meaningful class with regard to the specific idea of the inquirer, since the work of any one author is mostly made up of diverse statements that are the subjects of his citations. Nor can any author even approach completeness in his citation of all the pertinent previous work conducted by other chemists that is likely to be of interest to an inquirer with his own individual viewpoint.

As to the number of inquiry terms available, and in general the extent to which distortion of the inquiry topic can be avoided, great differences are found in the present-day methods of practical chemical documentation. These methods therefore differ greatly in the degree of order that can be brought into the literature with their help.

4. Practical Methods for Directed Literature Studies

The discussion of these documentation methods is easiest if they are divided into three groups:

1. purely intellectual localization,
2. purely mechanized localization,
3. combined intellectual and mechanized localization.

Intellectual and purely mechanized localization methods are distinct opposites in scientific documentation, with characteristic advantages and shortcomings. Neither of these methods can lead to high degrees of order if used in isolation. Their specific defects can, however, be overcome by a suitable combination of the two methods, and combinations of this type form the basis of the most successful documentation systems today.

4.1. Purely Intellectual Localization

In the purely intellectual localization of literature, any publication that falls in the respective subject field is usually examined by a documentalist to establish

which important concepts and topics are expressed or implied.

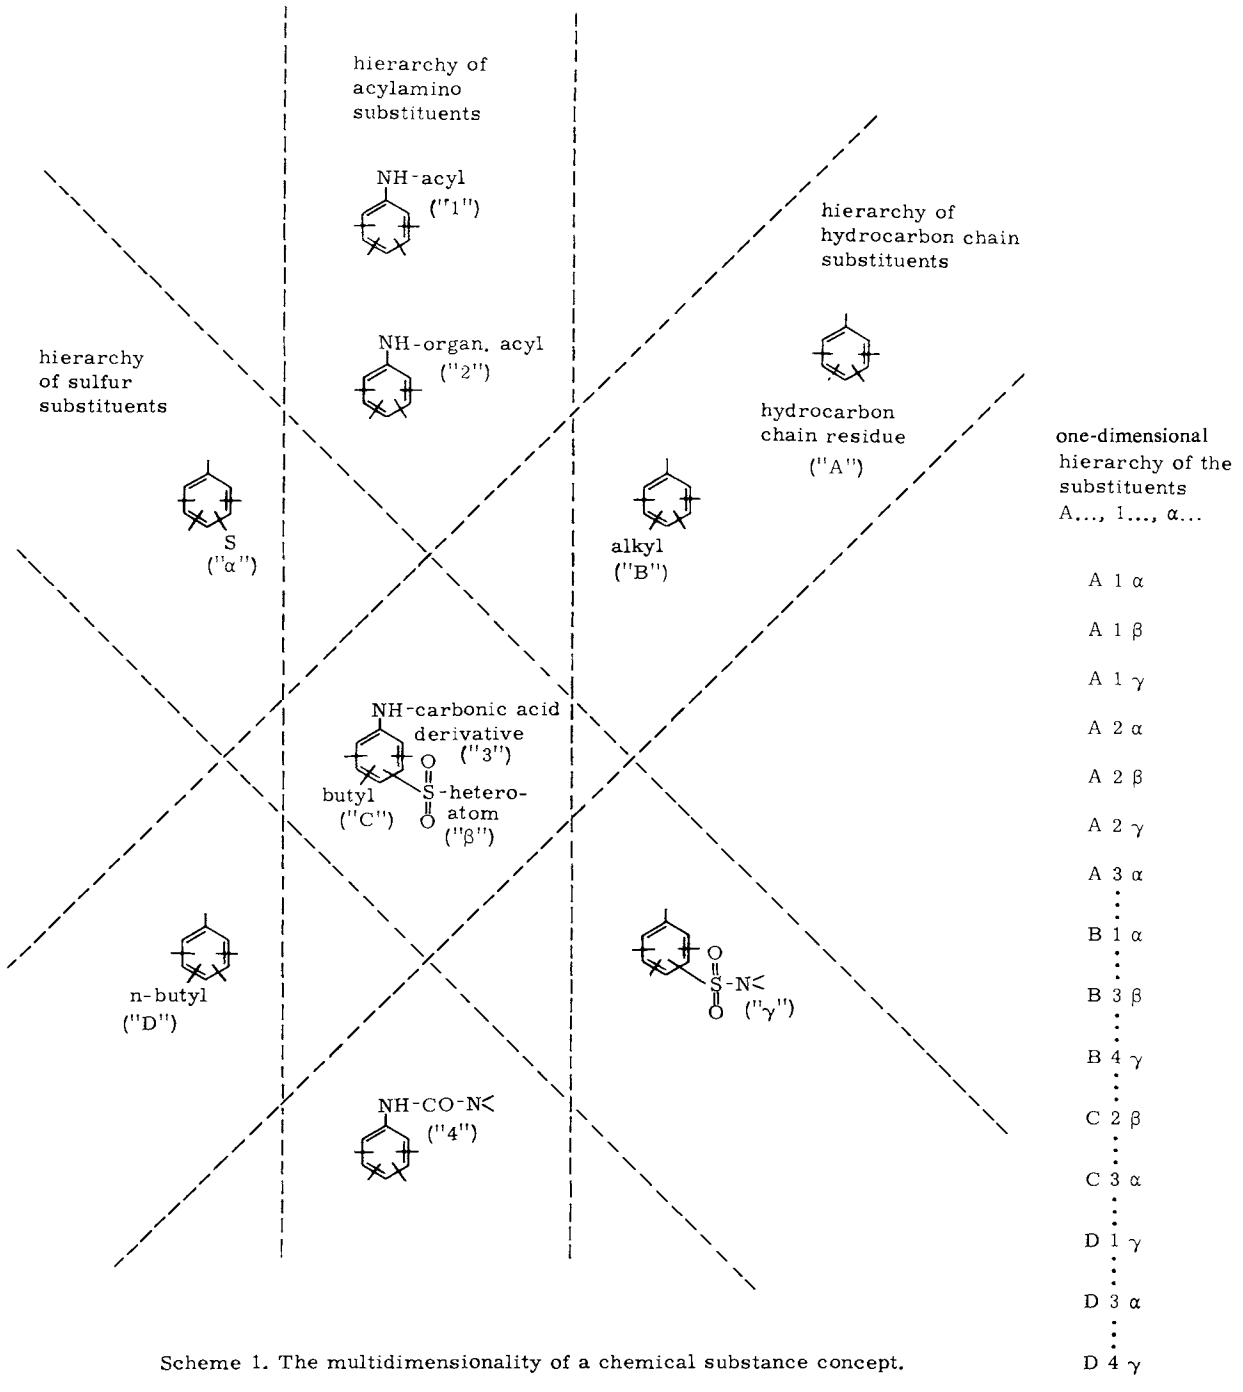
To do this a publication need not satisfy any special conditions or standards, except that it must be easily understandable to any expert. It is no obstacle in intellectual localization if the publication is in a common foreign language, nor does it present any serious difficulties if the author uses trade names, scientific nomenclature, or names chosen by himself and not agreeing with any standards for structures and reactions. When the documentalist encounters unfamiliar terms or novel concepts, he turns to a reference work, or confers with colleagues. Concepts that are merely implied are also recognized and denoted by appropriate subject headings. Thus, irrespective of the formulations that the author happened to choose, in intellectual localization a very pertinent picture of the author's ideas is obtained. This is in sharp contrast to the purely mechanized localization discussed later. This picture, however, is an essential prerequisite for reliable localization of the literature on a topic in question.

The documentalist also bears in mind a substantially preset vocabulary of inquiry terms for generic concepts and topics of which it can be said that there is some probability of their being used in inquiries. In the simplest case this is the vocabulary of subject headings for generic concepts that is characteristic of subject indexes.

If it is found that a publication is relevant to one or more of these subject headings, they are assigned to this publication[8]. This completes the most important step for the intellectual localization of the literature, *e.g.*, under the subject headings of an index or of a conventional card index or on the concept cards of a peek-a-boo card index.

4.1.1. Lack of Order in the Vocabulary of Inquiry Terms

The difficulties inherent in this technique are illustrated by the structure shown in Scheme 1. Let us assume that literature regarding the carbonic acid derivatives of aminobutylbenzenesulfonic acids is being searched for. In order to find the pertinent subject heading, or at least approximately pertinent subject headings, in an index, one has to have a complete overview of the whole vocabulary; for, an appropriate subject heading may occur in almost any alphabetical position in the vocabulary. Frequently, an approximately pertinent term will not be found at all. When it is to be memorized as reliably as is required in a search, a vocabulary should contain no more than one to two thousand subject headings. If this limit is exceeded it becomes unlikely that the documentalist will reliably remember the appropriate term and actually use it both during literature analysis and during searching.



[8] *C. L. Bernier*, Amer. Documentation *16*, 323 (1965); cf. *J. Koblitz*: Schlagwortgebung in Information und Dokumentation. VEB Bibliographisches Institut, Leipzig 1968.

Many present-day subject indexes give the impression of an extremely large and highly differentiated vocabulary for generic concepts. The fact that *e.g.* no more than a dozen articles are cited under the subject heading "diene synthesis" in an annual index of world literature, however, shows just how unreliable intellectual localization with such a vocabulary is in practice.

Thus, the problem of order is met on another level: If order is to prevail in a collection of publications, then an order should be established before in the vocabulary of subject headings. One should not have to rely on memory and patient searching if an optimum choice of subject headings is to be made. Instead, the subject headings that come into question for this choice must be brought together at a predictable place in this vocabulary, as completely as possible and mixed with only a minimum number of nonpertinent subject headings. If this order is not established the vocabulary must be restricted to far too small a size if it is to be capable of functioning. This is a serious obstacle to the localization of the literature with the aid of this vocabulary for an undistorted representation of an inquiry theme will only rarely be possible. Thus a high degree of disorder, *i.e.* ballast and loss, will mostly remain after purely intellectual localization, owing to the lack of order in the vocabulary.

The basic reason for the lack of order in the literature after purely intellectual localization lies in the impossibility of achieving a sufficiently high order of technical terms with the aid of the conventional kind of index, which is usually the outcome of this kind of localization. The aim to express hierarchical relationships between terms by spatial proximity can only be accomplished for a single dimension. Hierarchical relationships between terms, however, normally extend over many dimensions. For instance, it is possible to proceed from the central concept in Scheme 1 in a variety of dimensions and to arrive at a related concept, depending upon whether one moves in the hierarchy of the hydrocarbon chain, of the acylamino group, or of the sulfur substituent. Just this simple example gives $3\times4\times4 = 48$ substance concepts if the vacancies in this scheme are considered occupied by further dimensional intersections.

If one were forced to arrange these interrelated substance concepts as a linear series, as indicated in abbreviated form on the right-hand side of the scheme, it would be possible to base such an arrangement on only one dimension as a primary ordering principle, *e.g.* the dimension of the hydrocarbon chain. Such a list would begin with all representatives having the generic concept "hydrocarbon chain" ("A"), combined with variants from the other dimensions. Then would follow all representatives bearing an "alkyl" ("B") substituent. The list would close with all substance concepts containing the *n*-butyl substituent. No objections could be raised regarding the order in the dimension of the hydrocarbon chain. However, the concepts from the acylamino (*e.g.* "1") and the sulfur dimension are scattered throughout the list. In practice they are scattered much more randomly than in the

Scheme 1. The multidimensionality of a chemical substance concept.

example, which has only three, equally short and completely occupied, dimensions.

Whichever of the many possible dimensions is chosen, relationships existing in the remaining neglected dimensions will always be hidden. If a question is then aimed at a concept from one of the neglected dimensions, the inquirer is faced with an almost completely chaotic vocabulary.

One-dimensional arrangement of concepts not only impairs the overview of the vocabulary but is also responsible for the complete lack of any natural filing position for a large number of concepts. For, if neither the author nor the inquirer makes any statement in the preferred dimension ("ring-substituted carbamylamino sulfonamides" — no mention of alkyl substituents) it is always necessary arbitrarily to choose a statement in the preferred dimension in order to be able to express the respective concept with the aid of the one-dimensional vocabulary. This amounts to distortion of the original concept.

4.1.2. Localization in a Single Dimension

The immediate consequence of a linearly ordered vocabulary is that the literature itself can also be ordered only in a single preferred dimension. This need not be detrimental so long as only literature for a single subject heading is searched for, *e.g.* only for "ureas", for "sulfonamides", or for "herbicides". In a search for a combination of subject headings however, such as "ureas containing sulfonamide groups as herbicides", all the more specific subject headings given under "ureas" must be examined to see whether they contain any that refer to a herbicidal effect, or an analogous search is to be made under "herbicides".

If this process proves too time-consuming, the documentalist can introduce a new subject heading into the vocabulary, corresponding to the "compounded" concept ("urea herbicides"). In such a subject heading the constituent elementary concepts are contained in a "precoordinated" form. During literature analysis the documentalist must always remember these compounded concepts and assign the respective subject headings to any relevant literature that he may encounter.

This possibility is subject to natural limits from two sides. Firstly, the formation of a highly precoordinated subject heading is justifiable only if it is already in common use. Otherwise hardly any requester will use this subject heading in his literature searches. It would therefore be pointless to coin an artificial subject heading "urea herbicide" and introduce it into the vocabulary. It would also be asking too much of the documentalist to expect him to keep such unusual terms constantly in mind during his analysis of the literature.

Even if common terms already exist for such highly compounded concepts, however, there still remains the inherent disadvantage of practically any vocabulary of precoordinated subject headings. Even when it is as large as is still acceptable from the working psychological point of view it can never approach the desired comprehensiveness. For example, if one formed precoordinated subject headings merely for all practically important binary combinations of the substance-property type, the resulting vocabulary would already be much too large to be reliably memorized for the practical analysis of the literature. — An equally serious disadvantage is that the relations between the subject headings remain latent. Thus one would also have "pyrimidine herbicides", "carbamate herbicides", *etc.*, and with an inquiry for "herbicides in general" in a certain context, one would be faced with an almost completely unordered vocabulary.

The one-dimensional character of the subject index is however not only the cause of an incomplete vocabulary of inquiry terms, but also of an incomplete localization of documents under each subject heading, even though this is not very obvious. This leads to loss, for it is unreasonable and also impracticable to post *all* relevant documents under the pertinent subject heading. For example, there would be so many structures to be listed under "ureas" that a (linear!) list of this kind would no longer permit a specific inquiry, *e.g.* for "sulfonated phenylureas", because of its size and inherent disorder. It is therefore necessary, in order to preserve the practical usefulness in the case of such a broad subject heading, to drastically reduce the number of relevant citations. It is therefore usual in a subject index to make a selection from among the references for most of the subject headings and to cite only the most typical publications for a subject heading. For example, in a common annual index of world chemical literature, it has been found that as many as 30 % of all publications on phenothiazines were not listed under the appropriate subject heading [9]. However, this type of loss in subject indexes is not immediately obvious, and is therefore not widely known.

Thus, the documentalist responsible for compiling a subject heading vocabulary for a conventional index has the choice of using mainly elementary concepts or giving preference to compounded concepts. Subject headings for elementary concepts allow localization for a greater number of very general topics, but lead to large quantities of ballast in more specific inquiries. With a preponderance of precoordinated inquiry terms, on the other hand, no localization will be possible for many topics, owing to the necessarily large proportion of gaps in such a vocabulary.

[9] *B. Loev*, J. chem. Documentation *1*, 27 (1961).

4.1.3. Subdivision of Concepts According to the Kind of Index

The subject index is characterized by its subject headings for generic concepts, *i.e.* for concepts that can be further specified by the addition of a further conceptual characteristic. "Carbamylaminoalkylbenzenesulfonic acids", for example, can be further specified by the length of the alkyl chain, its branching, its configuration, *etc.* Depending on the kind of characteristics that are added to a generic concept of this nature, the sequence in which they are added, and their number involved, a generic concept can be the origin of many hierarchies of various lengths for more specific concepts.

These characteristics for further subdivision must be chosen with great care. It would be of little value, for instance, to subdivide the phenylureas according to their heats of combustion, their diffusion rates under standard conditions, or the structure of their crystal lattices. The resulting substance class concepts would be totally unsuitable for the documentation needs of a synthetic chemist. Molecular weight and elemental composition are also of minor importance from this point of view, since these characteristics can differ very widely within a meaningful class of substances. In a search for a generic concept, no inquirer from the field of synthetic organic chemistry would be inclined to commit himself in respect of such unimportant characteristics. Thus, if it is desired to store generic concepts (particularly classes of compounds) and to use them in searching, the respective *essential* characteristics of the objects must be determined and chosen for subdivision ("canon of relevance" [10]).

The situation is entirely different for the individual concepts, in which the progressive specification of the generic concepts has reached a limit. Every conceivable characteristic of the concept, whether important or unimportant has been evolved and determined [11]. 2-Carbamylamino-5-*n*-butylbenzenesulfonamide cannot be specified further by any substance characteristic. Even its heat of combustion, molecular weight, and elemental composition are fixed, both for storage and for inquiry. In these circumstances one has complete freedom in the choice of a characteristic for the arrangement of the individual concepts, be it essential or purely formal. Given this freedom of choice, it is preferable to select a characteristic that is as simple as possible to handle, *e.g.* the elemental composition in the form of the molecular formula. Applying these characteristics stepwise in an arbitrarily established sequence (carbon, hydrogen, nitrogen content, *etc.*) one always arrives at only one hierarchy in which each individual concept necessarily finds its place.

Whenever it is necessary to display a single hierarchy of concepts such as would result from subdivision on

[10] *S. R. Ranganathan*: Prolegomena to Library Classification. Asia Publishing House, London 1967, p. 146.

[11] *v. Freytag-Löringhoff*: Logik – ihr System und ihr Verhältnis zur Logistik. Kohlhammer-Verlag, Stuttgart 1955, p. 27.

the basis of a single characteristic, the linear structure of a conventional index is an entirely adequate medium. For individual concepts, there is accordingly no need to use multidimensional techniques, which are much more expensive, and whose capabilities would not be even approximately fully utilized.

Authors may also be looked upon as individual concepts. A single characteristic of the person, *e.g.* his name or the instant of his birth, is again satisfactory as an ordering principle both for filing and for retrieval.

In our experience, however, the individual concept plays a very much smaller part in the literature interests of the scientist than would appear from the use of author and formula indexes. In most cases where a literature search is carried out on the basis of an individual structural formula or an author's name, distortion of the actual topic of the inquiry has already occurred. Really, the inquirer is interested in a whole class of substances, in which, *e.g.*, the length of the alkyl chain can vary, and not in one single individual compound. The structural formula with which the literature search is started is usually intended as an example rather than as a definition of the topic of the inquiry. The factors that lead the inquirer to use the individual concept are the ease of use of formula and author indices, as well as the difficulty and uncertainty of finding a generic subject heading in the subject index that fits the topic of the inquiry. This is why too much value is often placed on documentation systems and notations that are only designed for individual compounds.

Though indexes, because of their one-dimensionality, can only present the literature in very modest degrees of order, they are nevertheless of great value to the chemist. They allow undirected literature studies in which there is no need to specify the object of the search in too much detail, and the chemist can decide subjectively and *a posteriori* what is of interest to him. If the index is used for this purpose, the lower order will not prove a serious disadvantage. The information available in this way covers a much wider area in any case than when one reads only a few special journals. Indexes will therefore still hold their place in the future alongside the large mechanized stores.

4.2. Purely Mechanized Localization

The deficiencies inherent in the purely intellectual localization method result in the necessity of having to separate relevant from non-relevant literature by (renewed) expert surveillance. Time and cost required for this has steadily increased with the volume of literature and with the number of references under a given subject heading. On the other hand, the time available to each scientist for literature work has by no means increased. The possibility of compensating intellectually for the disorder that remains after purely intellectual localization has therefore steadily decreased, relatively speaking. For this reason, all mechanized methods that allow the localization of literature *without* intellectual examination of many publications merit great interest.

The general practice in every sphere today is to try to use machines whenever demands on time or reliability are beyond human capabilities. Computers have found wide-spread use even for those processes that were formerly left entirely to the human mind. The credit for the occasionally astonishing results has been given almost exclusively to the machines, though man who gave the machine its instructions can claim at least an equal share of success. The programmer must first analyze the process in a depth that is otherwise rarely necessary, and this is sometimes a high-ranking scientific task. If despite this analysis the machine encounters a situation that the programmer failed to foresee, it finds no instruction, and is unable to solve the problem at hand. *It is important to our discussion, though seemingly trivial, that processes can be programmed and left to the computer only if the parameters which exert an influence on this process are foreseeable by man.*

4.2.1. Poor Predictability of Storage Terms

In documentation, the retrieval of publications from a store also involves a large number of operations, which one wishes to execute as rapidly and as reliably as possible. It has been found in purely intellectual localization that the need for a human expert to read every publication to be stored creates a serious bottleneck. One is therefore inclined to try the use of machines for this purpose. In a typical example of purely mechanized localization, the texts are transferred letter by letter into the memory of a computer without prior standardization or interpretation by man. In such a store the machine can also find any desired word or part of a word in any part of the text, purely mechanically.

The problem that faces scientific documentation, however, is not the retrieval of publications in which the inquirer's *verbal formulation* occurs, but of those publications whose *subjects are sufficiently closely related* to the topic of the inquiry [12]. If this search is to be carried out by a computer, it must be given precise instructions as to which particular formulations in the stored publications are to be regarded as relevant to the topic of the inquiry. These instructions must be continuously effective as the machine searches through the store and compares the stored formulations with the inquiry term. If exact or sufficiently close agreement is found between the "storage term" of a publication and the inquiry term, the publication is regarded as pertinent. Its text or bibliographical data are then printed out in a list or fixed in some other way. This completes the purely mechanized localization.

We shall use the expression "storage term" for any formulation of a stored topic, provided that this formulation serves for the mechanized localization of publications. It is of no importance whether it is in clear text or in a code of some kind.

It is always easy for an expert to recognize which concepts are expressed or implied by an author, including their context, in a given text. This is the process always involved in purely intellectual localiza-

[12] *C. L. Bernier*, J. chem. Documentation *2*, 117 (1962).

tion and intelligent reading. The judgment required here may be described as *a posteriori*, *i.e.* the decision as to the meaning of a formulation is taken only *after* this formulation has been presented.

The main task to be fulfilled in using our common language is to represent scientific facts in as lively and precise a manner as possible. It provides us with much freedom for choice of expression and development of personal style. However, such a language is extremely unsuitable as a basis for the purely mechanized retrieval of relevant literature, since here the relation between a particular mode of expression and what is meant by this expression cannot be decided *a posteriori*, as it normally is in scientific communication. On the contrary, concepts and their context are given and it is necessary to judge *a priori*, without seeing relevant publications, what modes of expression could conceivably have been used for this concept. All these formulations must be assumed to occur in the store, and must therefore be specified in the inquiry term, since this is part of the instructions that the machine requires in order to check the stored publications for pertinence.

As is well known, it is far easier to describe an event with hindsight than to predict it. Any rational and valid prediction requires that the course of the event follows a known pattern. The event of phrasing scientific concepts in the words of our colloquial and technical language is no exception to this rule. However, we know of no set of principles which are strictly obeyed by man in expressing ideas in his language and which would therefore permit the prediction of the words used. Indeed, should there be such a set of principles then we are at present still very far from knowing them. Purely statistical regularities in the use of language by authors have been established, but their shortcomings are apparent[13], for they are invalid for the isolated case of an individual publication and give no guidance, for example, of how an author might have expressed himself when formulating his first patent application. In scientific documentation, however, we always have to deal with the isolated case.

The *a priori* character of such a determination of an inquiry term is not altered by the fact that publications already exist which could give guidance about the storage terms that have already occurred for the concept of the inquiry and consequently are to be taken into consideration in establishing the inquiry term. The main point is that these publications are unknown to the inquirer and that he does not know of anyone whom he can or will ask about them.

If however an inquirer has previously read the publications which he is now searching and can remember in detail the linguistic formulation then the *a posteriori* route to the formulation of the inquiry term is open to him. One must remember, however, that the fraction of the literature which the scientist happens to cover today in the course of his own reading is becoming smaller and smaller. Still much smaller is the fraction which he remembers so precisely in all details as is demanded in the purely mechanized localization. Consequently, only a very small fraction of documents relevant to his inquiry can be retrieved reliably in this way.

The conceptual problems involved in purely mechanized localization can be readily imagined from the list of topics given earlier for the "production of α-amino acids by fermentative processes with microorganisms". There is no general rule according to which a search mechanism that operates purely formally could recognize which of the stored topics listed there are relevant to the inquiry topic and which are not. It will always be easy to devise examples, or to find them in the literature, for which such a rule fails, however many refinements one makes to it.

The situation is not much better even in inquiries for structures alone, though the names are easier to deduce here because of the rules of nomenclature. An attempt has been made, for example, to find literature on Schiff bases that are mentioned in a certain context[14]. For the structural part of the inquiry it was thought sufficient to search for the character sequence "imin" or "Schiff base" or "azomethin". It is indeed difficult to add appreciably to this search instruction by mere prediction of other possible names.

Such an *a priori* definition of the inquiry term inevitably means that a number of names of compounds will be omitted, partly because though perfectly familiar, they can never be completely memorized, and partly because they are quite unforeseeable (*e.g.* "anil", "hydrobenzamide", "benzylidene...amine", "azallyl compounds", *etc.*). This results in a loss of relevant information. Practically the only way in which this loss can be discovered is by parallel searches with more effective systems and tedious comparison of the results. However, this has been done only in very rare cases. Thus the shortcomings remain unrecognized for a long time, and the first assessment of the effectiveness of a fully mechanized system is usually much too high.

It is much easier to assess the ballast in this method, since this becomes evident in every localization operation[15]. In this case it results from words such as "*imino* ether", "e*limin*ation reaction", "ketone *imines*", and "ethylen*imine*", as well as from trivial names such as "capaur*imine*". Equally unwanted is the retrieval of all imines that are not substituted on the nitrogen by carbon.

A literature search based exclusively on *names* of structures and partial structures will often be unsuccessful simply because no names are given for many published structural formulas. This holds *e.g.* for all patent claims that are formulated in a general fashion.

The root of these failures is that in purely mechanized localization no distinction is made between a word and its meaning. When one wishes to find a *concept*, one merely searches in the stored publications for the *words* that might have been used by chance to express this concept. In this respect the same confusion that arose in the early literature of logic, before a distinction was made between object language and metalanguage, now recurs in documentation[16]. If on the other hand we try to compensate for this by means of the requirement that all other conceivable formulations should be sought, in addition to that chosen by the inquirer, we are again presupposing what we wish to know. We are presupposing the knowledge of the relevant publications in the store with all the details of their formulation.

The tacit postulate of the predictability of the storage terms, which is the ultimate basis of purely mechanized localization, is thus illfounded. It is not surprising

[13] Cf. *M. E. Lesk*, Amer. Documentation *20*, 27 (1969).

[14] *Kallner*, Lecture on May 21, 1969 at the University of Köln.

[16] Cf. *W. Stegmüller*: Wissenschaftliche Erklärung und Begründung. Springer-Verlag, Berlin 1969, p. 30.

that the degrees of order attainable in this way have so far always been rather poor, *i.e.* localization has always been subject to considerable loss and ballast. However, even this can represent an improvement on the prevailing situation. Moreover, it cannot be denied that intellectual localization is sometimes far from perfect, particularly when hindered by the limited possibilities of a one-dimensional method. In such cases purely mechanized localization is sometimes quite capable of competing. This is so in particular if the machine search is based on an extremely careful language analysis [17, 18].

What are the prospects of further development of the mechanized method to such a point that man can adequately be replaced by the computer in literature analysis? The above arguments have shown the utopian demands that would have to be made on the machine (and on the people that must program it!) to achieve this. The computer would have to make a skilled assessment of any text in the store, in order to decide whether or not it is relevant to the inquiry. But is it really possible to *foresee* all the many situations, and to cover them in a machine algorithm, in which the human agent must interpret an author's implications? It is only thus, for example, that one will be able to find the starting materials if an author has merely given the final product and the respective preparation reaction. Only thus can one find a method of control for a pathogenic parasite if the author has described only the control of a typical intermediate host for this parasite because he could leave the reader to draw the obvious conclusion from this.

It would be of little value to science if the effectiveness of scientific documentation was decreased as a result of the uncritical adoption of purely mechanized documentation methods. Efforts are being made everywhere to provide research with increasingly effective tools, and with good reason. Should these principles not apply in scientific documentation?

Anyone who is very well aware of the drawbacks of purely mechanized localization, but nevertheless recommends its use in the practical large-scale documentation of chemical journal and patent literature, must have underestimated the degree of order that must be attainable in such a store now or in the near future if it is to remain capable of working. This route inevitably leads to a dead end [19, 20].

Thus if high demands are made on the order in a literature collection, special efforts must be made to render the storage terms predictable. We shall see in Section 4.3.1 what form these measures can take.

4.2.2. Multidimensional Localization

As one drawback of the purely intellectual localization we recognized that the subject index is always in a one-dimensional order only and that accordingly the literature is localized in only a single dimension. Should one wish to display the multidimensional conceptual relationships given in Scheme 1 without distortion then one obviously must avail oneself of a likewise multidimensional method of representation.

In most chemical substance concepts one can distinguish – on grounds of definition alone – a series of conceptual units which should be available to the inquirer either as an *isolated* unit or in *combination* with any other unit. Frequently, these units also occur as isolated generic concepts in the literature to be stored ("ureas", "sulfonamides", *etc.*). Many of these units are so closely interrelated that they can be placed in one and the same hierarchy of concepts. Each hierarchy now corresponds to one of the dimensions into which a compounded concept has to be split if it is to be represented in all its dimensions. The example from Scheme 1 would result in a picture of the following type (Scheme 2).

Scheme 2. Hierarchically arranged three-dimensional list of elementary concepts for the example from Scheme 1.

The most appropriate inquiry term for a given topic is then found very reliably and easily by selecting the appropriate elementary concept from the respective hierarchy, and combining it with an elementary concept that can be freely selected from another hierarchy. Scheme 2, for example, shows the representation of carbamylaminobutylbenzenesulfonamide by "postcoordination" of the respective elementary concepts (by connecting lines). Very many inquiry terms can be formed by this postcoordination of elementary concepts.

From this scheme the inquiry terms for any combination which is compounded of a smaller number of dimensions can also be taken. The *storage* of compounded concepts is similarly facilitated if one splits them into the same dimensions.

In spite of the large volume of inquiry terms covered such a vocabulary always remains comprehensible. The number of elementary concepts from which the most complicated inquiry terms can be compounded, remains small and easily memorizable.

The analysis of compounded concepts into simpler concepts is a well-known and well-established philosophical principle. Any scientific system is ultimately founded on this analytical approach. A procedure of this type can, furthermore, be based on axioms and on fundamental principles of classification theory. One then speaks of an analytic-synthetic

classification, the development of which has been mainly due to *Ranganathan* and his Indian school[21,22].

This resolution of a compounded concept into its constituent elementary concepts affords the prerequisites for the localization according to each single elementary concept and particularly according to every desired coordination of them. To this end, each of these concepts is represented on a suitable carrier, *e.g.* on a concept card of a peek-a-boo card index, by a typical pattern of holes or magnetic spots on punched cards or on magnetic tape *etc.* Then, by means of a suitable technique, those publications can purely mechanically be localized, which fulfill *all* dimensions of the inquiry. For instance, all documents in a store can be localized, which contain the desired concepts "urea" *and* "alkylbenzene" *and* "halogenobenzene" *and* "herbicidal activity". Publications in which only one of these concepts or only up to three of them are contained are excluded, contrary to the one-dimensional localization. Hence, in the mechanized multidimensional localization a much higher degree of order is achievable.

4.3. Combined Intellectual and Mechanized Localization

If we draw up a balance of the specific advantages and weaknesses of the two localization methods, we find the picture shown in Table 1.

Table 1. Capabilities of three localization methods. The superiority of a method is indicated by +.

Feature / Localization method	Recognition of what is meant	Possibility of obtaining suitable inquiry terms by coordination	Reading time required after localization	Predictability of the storage terms
Purely intellectual	+	–	– [a]	+ [b]
Purely mechanized	–	+ [c]	+	–
Combined	+	+ [c]	+	+

[a] Much time is required to sort out the relevant material among the ballast.

[b] The predictability is achieved by the translation into a preestablished vocabulary of subject headings.

[c] By postcoordination.

It is clear that the two methods complement each other well, and should be capable of being combined in such a way that their advantages are retained while their specific disadvantages are cancelled out. In such a combined conception (line 3 in Table 1), the purely intellectual method would have to be used in the analysis of the publications to be stored. The author's ideas are now recognized, irrespective of whether they have been expressed explicitly in words or in pictures or whether they are merely implied. Everything that might be the subject of a later inquiry is selected for storage, as far as the technical and economic possibilities allow.

A further important intellectual contribution is that the form of these facts in the store is made predictable. This can be done by the use of subject headings in clear text, either formed particularly for this purpose or even taken from the original text under certain conditions, to represent the essential concepts and their context. These designations are stored in the most suitable form depending on the technical facilities available. These storage terms must be recognizable in this form by the respective mechanical aids, and can therefore be used for mechanized localization of the publications characterized in this way, either singly or in postcoordination.

Several attempts have also been made to arrive at a combined intellectual-mechanized method of localization by transferring the subject headings of a conventional index onto mechanically searchable carriers. However, one must always consider how many concessions had to be made regarding the conceptual soundness of the subject headings when they were intended for an index and how unreliable their assignment to publications is. This is particularly true with regard to the high degree of precoordination which materializes in these subject headings. If they are incorporated uncritically into a technique which is completely capable of conceptual postcoordination the efficiency of the mechanized technique would be far from fully exploited. *There is no subject heading vocabulary that is equally suitable for working both with a conventional index and with a mechanized system.*

4.3.1. Methods of Making the Storage Terms Predictable

From the methodical viewpoint of documentation, one can differentiate between achieving predictability of the storage terms for concepts themselves or of the particular connections in which the concepts occur in the context of a publication.

There are often good arguments both for treating a given idea as a single compounded concept ("urea herbicide") and for regarding it as being compounded of separate elementary concepts ("urea derivative", "herbicidal activity"). Once it has been decided for a given field which categories of concepts are to be capable of being used for the localization of literature ("substances", "reactions", "properties", *etc.*), this at the same time provides a guide as to what is to be regarded as a compounded concept and how far compounded concepts must be broken down. According to this guide all those concepts must be resolved which contain concepts from more than one category or dimension. Otherwise one would tolerate that a certain concept from one category would be scattered throughout the system of concepts, depending on the other concepts with which it happened to be compounded. — To combine the elementary concepts to form the compounded concepts required by inquirers is then the task of postcoordination.

4.3.2. Predictability of Storage Terms for Concepts

In order to make the storage term for an elementary concept predictable the original text of the publication can no longer be fed directly into the computer without supervision, as it is in the fully mechanized

[21] Cf. *S. R. Ranganathan*, Library Sci. *6*, 193 (1969).

[22] Cf. *A. Neelameghan*, Herald Library Sci. *8*, 96 (1969).

method. Instead, a "thesaurus"[23] is compiled and kept up to date to show the various expressions that have already occurred for a given concept in the stored publications. Before phrasing an inquiry term, one ascertains beforehand which expressions for the inquiry concepts have so far been incorporated into the store. These are all formulated as alternative search conditions in an appropriately comprehensive inquiry term ("manipulated grouping"[24]).

The effectiveness of this method is greatest when the store is still relatively small, *i.e.* when the number of different terms that have occurred for a given concept and related concepts is not yet too large. However, in the course of time more and more storage terms will have to be taken into consideration for an inquiry term. Furthermore, owing to the tendency that soon arises to make inquiries more and more specific, the number of concepts for which this step is necessary in each inquiry also increases. The work of establishing and handling all these alternatives can easily grow to a magnitude that is unacceptable both for man and for machine.

The problem cannot be solved in the long run by fixing all the alternatives for an inquiry concept once and for all and giving them to the machine in advance as a fixed instruction, so that all the alternatives for a given inquiry concept are automatically considered. Taking into account and searching for a very large number of alternatives can mean an excessive cost in machine time, particularly when the number of alternative terms per inquiry concept reaches orders of magnitude of more than a thousand.

On the other hand, this method has the advantage that a store suitable for searches is available very quickly, and there is no need to wait for the tedious construction of a system of concepts, since this system can be built up independently of and parallel to the storage. In doing so one can thus be guided by the practical requirements encountered in current storage and in searching.

A further step toward improved predictability of the storage terms is to use only one single term for the storage of a given concept, all other expressions with the same meaning (synonyms) being replaced by this standard term[25].

For this purpose, all texts may be scanned mechanically before final storage to establish whether they contain any synonyms that must be eliminated. The machine is instructed to replace such terms by the standard form. If it encounters terms for which it has no instructions, a corresponding message is printed out, and the documentalist can then provide the appropriate further instructions. – Difficulties arise in this method from the fact that there are terms that can have entirely different meanings, depending on the context in which they occur; examples of such terms are cell, oil, and plasma ("homonyms"). These would therefore have to be converted into *different* standard terms, depending on the context.

Furthermore, there is always some doubt regarding the reliable recognition of the author's ideas, since intellectual analysis of the text, particularly regarding context, is carried out only in the emergency cases notified by the machine. Many an implication that could be readily gleaned by reading between the lines is thus lost.

The only escape from this difficulty is that one entirely dispenses with feeding an original text into the store word for word without any intellectual interpretation. Instead, an expert must be introduced into the documentation process at this point. Only he can decide everything that is stated and implied in the author's words and pictures, so that the implied concepts can also be expressly added to a publication and thus made retrievable. – On this occasion he could easily standardize the expressions for concepts to be stored. This conversion of the expressions encountered into a pre-established, controlled, and hence predictable form is nothing other than the traditional "coding", which is still the most widely used method of preparing scientific publications for storage, and is by no means an antiquated procedure, but is an extremely important step if one wishes to attain high degrees of order[26].

The amount of work involved in coding can be reduced considerably by employing machines. One need only write out a clear text word and put it on tape. Then the machine replaces this (or other words having the same meaning) by a notation according to previous instructions[25,27,28]. The progress that is always associated with such a standardization of storage terms, whether carried out purely mechanically or intellectually, is unmistakable. It means that only one storage term for each concept need be taken into consideration in phrasing the inquiry term, at least as far as *individual concepts* are concerned, such as a single compound or one specific reaction.

The special position of individual concepts becomes clear if one recalls the relevance rule of Section 3.3. For an inquiry containing the concept α, all publications are relevant in which α itself or any more specific concept occurs for which α is a generic concept. The reason for the simplicity of the situation with an individual concept is that it has no more specific concept below it in the hierarchy concepts, which would have to be considered in a search. If on the other hand an inquiry is made for a generic concept *e.g.* for "herbicide", provision must be made for the localization of literature on more specific concepts such as "selective herbicide", "contact herbicide", and "soil herbicide". All these more specific concepts, that fall under this generic concept must therefore be used as alternative search conditions in the inquiry term. The fact that after standardization only one storage term is required for each of these more specific concepts (*e.g.* only "soil herbicide" and not also the synonym "root herbicide") already greatly simplifies the phrasing of the inquiry term. Considerable problems can nevertheless arise if the number of more specific concepts to be considered is large.

[28] *H. Behmenburg* and *M. Glos*, Nachr. Dokumentation *12*, 146 (1961).

In a situation such as that prevailing in chemistry, where one generic concept ("urea derivative") has an immense number of more specific concepts ("halogenophenylurea", "halogenoalkylphenylurea", "polyhalogenodialkylsulfaminocarbanilide", *etc.*), any attempt to make even an approximately complete list of all such specific concepts and to handle them by machine at a reasonable cost as alternative search conditions is doomed to failure. There is only one reliable way to achieve order of the kind and degree that are expected by the inquirer: the hierarchical relationships between the concepts must be expressed so clearly in their controlled storage terms that these relationships are recognizable even by a machine when it encounters these terms as it scans the store. This can readily be achieved by storing all urea derivatives with a term in which a certain character sequence, *e.g.* "PD" always occurs, irrespective of the other details of the structure of the molecule. In other words, "PD" is fixed as a mandatory notation of *all* urea derivatives.

If all structures have been stored in the form of "systematic notations" of this type, it is easy to formulate an inquiry term for "urea derivatives" (*e.g.* in conjunction with a certain herbicidal activity). The machine is instructed to search the stored molecular structure notations for the character sequence "PD". The relevant publications are localized without ballast and without loss. With this method it is no longer necessary to know or to guess which specific urea structures are present in the store.

This principle can be made even more effective if it is agreed that all "carbonic acid derivatives", which as a generic concept includes all urea derivatives, will be denoted by the fixed character "P". An inquiry containing this generic concept will then necessarily result in the retrieval of all stored guanidines, carbodiimides, isocyanates, ureas, isoureas, *etc.* if the character sequences "PA", "PB", "PC", "PD", "PE", *etc.* have been assigned to these types of compounds ("mechanized group formation [24, 29]).

The changeover to systematic notations is also necessary in the case of biological concepts as soon as a significant number of these concepts has been collected in the store [25, 30].

4.3.3. Predictability of Storage Terms for Connections Between Concepts

The measures described so far are still not enough to satisfy the requirements of very large literature collections in which searches are frequent. It is certainly possible with their help at least to make the storage terms for a concept and for a family of concepts predictable, so that a search instruction can now be reliably phrased for these concepts.

[29] Cf. also *R. Fugmann, W. Braun,* and *W. Vaupel,* Angew. Chem. *73,* 745 (1961).

[30] Cf. Chemical-Biological Coordination Center, National Research Council, Washington, D. C. (1950): A Method of Coding Chemicals for Correlation and Classification, Biology Code.

However, they do not help us to predict the many ways of expressing the *particular context* in which the concepts occur in the stored publication. Accordingly, mechanized searching for concepts in a particular context still remains unsatisfactory. If the problem of an inquirer is actually concerned with the context of concepts, he must therefore tolerate a great deal of loss and ballast. Much research has recently been undertaken on this topic [31].

The techniques of mechanized localization differ extremely widely in their ability to express context in storage and to include contextual search conditions in the inquiry term. With simple manual punched cards, one cannot expect much more than a single level of concept coordination and a very simple connection logic of concepts. Computers, on the other hand, together with highly advanced programming, enable many details of context and connection logic to be represented during storage, and to be used in the inquiry term [32–37].

4.3.4. Distinguishing Different Levels of Concept Coordination

It is interesting to examine more closely the publications that could be localized by the simple post-coordination of the inquiry concepts "urea derivative", "alkylbenzene", "halogenobenzene", and "herbicidal activity". Though all the publications localized would satisfy the condition that they contain all the concepts mentioned, there is no guarantee that it is in fact the urea derivative that has the desired herbicidal activity. A publication may be concerned with herbicidally active pyrimidines that have been synthesized from ureas, and the other structural conditions may be satisfied in another context, *e.g.* in the solvent, in the structures of precursors, in the substances of a peripheral reaction *etc.* These publications then formally satisfy the search conditions in the inquiry term, though they are not relevant in the true sense. This can only be avoided if the storage term shows the various *levels of coordination* as they occur in a publication. At least, structural concepts relating to one and the same compound must be presented very closely coordinated in the storage term. Otherwise, the degree of order in the localized literature cannot be very high. For the same reason, it is desirable not

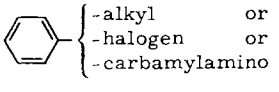
[37] *R. Fugmann, H. Nickelsen, I. Nickelsen,* and *J. H. Winter,* Angew. Chem. *82,* 611 (1970); Angew. Chem. internat. Edit. *9,* 589 (1970).

merely to mention *properties of substances* in the storage term but also to assign them exactly to the respective substances.

The particularly close coordination that exists between the *components of a mixture* should also be shown. An inquirer will occasionally be interested only in publications that expressly describe the use of two substances *as a mixture*, *e.g.* in a pharmaceutical preparation. Publications in which these substances are mentioned only in other connections, *e.g.* in a comparison of their activities, are then of no interest. In many cases a substance is of interest only in connection with a certain other component as a stabilizer, solubilizing agent, additive to increase activity or to decrease side effects, *etc.*

If one wishes information on the preparation of a class of substances from a certain other class by successive reaction steps, then it is desirable to preserve the close coordination of all substances that *belong to the same sequence of reactions* but not to different, mutually independent reactions, which may all be described in the same publication. It is also desirable to show the time sequence of the reaction steps and substances, and to be able to specify this in the inquiry term. Ballast must otherwise be expected in the form of publications in which the reverse reaction sequence is described.



If the preparation of a certain *class of substances by a certain type of reaction* is wanted, then simple coordination can lead to ballast in which the class of substances and the reaction type are certainly described, but independently of each other and in different context.

Different coordination levels can even be recognized within a molecular structure. They are reflected in the requirement that the alkyl, halogeno, and carbamylamino groups be *substituents on the same benzene ring*, and not on different benzene rings that might be present in a stored molecular structure. Furthermore, this one benzene ring should carry only one of each of the substituents named, and there should be no other substituents on this ring, *etc.*

4.3.5. Connection Logic of Concepts

To find literature on the therapeutic use of a particular combination preparation, an inquiry might specify *e.g.* the concepts "penicillin" and "tetracycline" in the logical relation of conjunction. All publications in which only *either* penicillin *or* tetracycline is described, *i.e.* in which they both occur in disjunction, are then of no interest.

Similarly, a formula of the type

such as often occurs in patent literature should not be localized in response to an inquiry according to which *all three* substituents are to be present on the same benzene ring.

There are also much more complicated cases of multi-level logic, particularly in the patent literature of the macromolecular field. Copolymerization of substance A may be required, together with the substance B or with a mixture that consists either of the components C and D or of the substance E, to which either F or G may be added. If the details of the connection logic were ignored here, one would have to expect literature to be localized along with an immense proportion of ballast. The simple condition that the substances A, B, *etc.* should merely occur in a publication is not sufficient for a precise enough localization, since the literature in this field is rather monotonous with regard to the substances used, and the emphasis is placed on their typical coordination in the documents.

It was mentioned in Section 3.2.1 that as a literature store grows and as the proliferation of knowledge progresses, the inquiries to the store become increasingly specific. This specification of the inquiry is effected by the addition of further, restricting search concepts, which may be of a positive or *negative kind.*

It is quite meaningful to submit an inquiry for herbicides that are *not* of the urea or pyrimidine types. Herbicidally active arylated ureas having any substituents on the phenyl residue except sulfonic acid or alkyl substituents, may be of interest, *e.g.* because this group has already been exhaustively studied.

Publications in which the "forbidden" concepts occur in any other, possibly purely peripheral context should naturally not be rejected with an inquiry of this type. A publication in which the forbidden urea or pyrimidine structure in fact occurs may nevertheless be relevant to the first of the above inquiries, if these structures are mentioned only incidentally, *e.g.* as standard preparations for comparison of action.

Similarly, generally excluding any alkyl groups attached to rings in the structure would be a serious distortion of the inquiry if one wished to exclude only alkyl groups bound to *one particular* phenyl residue. It is also important that a negation in the inquiry should not lead to the rejection of stored publications in which a forbidden concept indeed occurs, but belongs to a group of alternative concepts. For, this alternative concept can be thought of as being replaced by another alternative concept, "innocuous" for the requirements of the inquirer.

It is thus permissible to express negations in an inquiry term only if their effect can be restricted precisely to those parts of a publication at which the inquiry is aimed. This again calls for a rigorous distinction between various coordinative levels and appropriate indication of disjunctive connections in the storage term. Otherwise concealed distortion of the subject to be stored will result. If these precautions are not taken in compiling the store, there may later be a serious limitation of the possibilities for the phrasing of highly specific inquiries, with the result that the future usefulness of the documentation system is endangered.

With the introduction of multidimensional techniques (punched cards, computer systems) conceptual post-coordination has found a wide field of application. Despite all its advantages (see Section 4.2.2), however, its success has for the most part remained far behind expectation. In the mere resolution of *several* compounded concepts of a publication or inquiry into their constituent elementary concepts, a completely structureless conglomerate of elementary concepts arises. Every desired coordination of elementary concepts can now be read out from such a conglomerate, and not only just those which correspond exactly to the original compounded concepts. Hence, if the manner in which elementary concepts are connected is not represented by a special method in

the storage and inquiry term considerable distortion of the original information occurs.

Strictly speaking, complete predictability of the storage terms for concepts and for concept connections can be achieved only by translation of the author's ideas into a new, *artificial language*. This language must be tailored to suit primarily the needs of retrieval, and not so much those of conveyance of ideas and experience, like a natural language. To serve that purpose the artificial language must have a large vocabulary, and this must have an extremely systematic structure, so that the choice of an appropriate term does not make excessive demands on memory and patience in searching for it. The artificial language, for the sake of high fidelity, must also have a very expressive "grammar" to enable the connections of concepts to be displayed as they occur in the document or as they are required in the inquiry [38].

If one considers scientific documentation from this angle, it is easy to estimate whether a documentation system can meet the requirements in a large-scale documentation scheme. If it does not involve any kind of artificial language and if no provisions are taken to ensure predictability of the storage terms, the future prospects of the system must be rated as poor. The same is true of a documentation system based on a kind of artificial language that is not sufficiently expressive. A vocabulary of only a few thousand terms, possibly with no highly developed possibility of representing relationships and connections between concepts is not an adequate basis. Many plans for large-scale documentation schemes in science are being discussed and even started at present before it has been ascertained that the method envisaged will be adequate from a conceptual viewpoint to cope with the requirements that will soon arise. The mere provision of computers is no guarantee by itself that a method will be effective.

4.4. Topological Documentation Methods

Let us turn again to the statement that rigorous post-coordination leads to extremely high demands with regard to fidelity of representation of the connections between concepts. This is the basic reason why an almost self-evident treatment of chemical structural formulas is only now being belatedly introduced. Chemical substance concepts are more suitable for an analytical treatment than any other scientific concepts. They are built up not only in a figurative sense but also materially from elementary concepts, *i.e.* the atoms themselves.

However, the consistent breakdown into atomic elementary concepts has so far been hindered by the lack of a method of preserving the connections of the atoms in a structure, and in particular of a method that can also be used in the inquiry term for a class of substances, and which is therefore effective during localization. Without such a tool a thorough analysis of compounded concepts would have been useless, as was pointed out in Section 4.3.

What is needed is an inquiry term that covers not only the atoms themselves *but also their connections* as desired by the inquirer. For lack of sufficiently effective methods, it has been necessary in the past to be content with a rather superficial analysis of the structural concepts which ceases at highly precoordinated concepts such as "ureas", "pyrimidines", *etc.*

A structural formula may be regarded mathematically as a "graph", *i.e.* as an abstract system of "nodes" and "edges". The nodes may be taken to denote atoms, and the edges are interpreted as bonds between the atoms. The mathematical laws that govern such topological systems can now be used to allow the complete description and storage of a structural formula as a graph, and also to retrieve it by using a graph as the inquiry term. In particular, any partial structure consisting of atoms and their connections, *e.g.* the urea or the pyrimidine grouping, can be detected mechanically in a topologically stored structure [39–41].

Since topological storage in principle preserves all the details of a structural formula, it is possible, if necessary, to search even for partial structures that have never before been thought important, for which no suitable inquiry term would be available in any other system, and for which no suitable name has even been given as yet. For example, there are no difficulties in a topological system for the reliable localization of biuret or triuret structures, or of any other urea derivative still more compounded and irrespective of how this structure is built into a larger molecule.

In the literature and in inquiries, one occasionally also encounters substance concepts that cannot be represented by a certain sequence of atoms and bonds ("unsaturated aliphatic amino acid derivatives", "alicyclic diketones", *etc.*) without distortion. A structure concept of this type cannot be treated purely topologically. A solution to this problem can be achieved by parallel use of a second, non-topological system specifically designed for the storing and searching of such generic concepts. Both systems interact in such a way that all topologically encoded structural formulas are transformed mechanically into the generalized representation of the second system [39]. There they are then available for a non-topological search together with those generic concepts which had to be entered by a direct route into the second system. Such a search can be carried out in a most economical manner. Only those few publications which had responded to the preceding search in the second system need now be subjected to the expensive topological search.

In inquiries for molecular structures such a combined system works practically without loss or ballast. It is

[38] Cf. *S. R. Ranganathan*, Library Sci. *5*, 296 (1968).

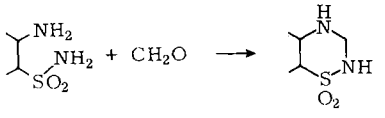
[39] *Ernst Meyer*, Angew. Chem. *82*, 605 (1970); Angew. Chem. internat. Edit. *9*, 583 (1970).

[40] *D. P. Leiter, H. L. Morgan*, and *R. E. Stobough*, J. chem. Documentation *5*, 238 (1965).

[41] *D. J. Gluck*, J. chem. Documentation *5*, 43 (1965).

largely unaffected by the growth of the store, the increase in the frequency of searches, and increased specificity of the inquiries. Accordingly, it can work unchanged for many years, and so leads to a homogeneous store in which searches are easy. It is not surprising however, in view of the thermodynamic arguments presented earlier, that the cost of such advanced ordering facilities is considerable.

In the topological documentation of structural formulas, we meet the analytic-synthetic principle in an extremely advanced form. The concept analysis has been pursued down to the ultimate meaningful units, the atomic elementary concepts. The manner in which these concepts are (literally "synthetically") connected to one another in the molecule is represented exactly. Using an extremely small and hence easily memorizable vocabulary of about a hundred elementary concepts, the chemical elements themselves, we have available an unlimited number of (predictable) storage terms and an equally large number of inquiry terms. Despite this large number, there is no difficulty in finding the appropriate term in every case, since there is no need to look it up in a large index. It is simply formed by postcoordination in accordance with each particular case of storage or inquiry.



4.5. Documentation of Reaction Types

Other concepts in which the ground is equally well prepared for the analytic-synthetic documentation principles are reaction types. The common names for reaction types ("Hofmann degradation", "diene synthesis" ,"beta oxidation", "Krebs cycle", *etc.*) appear from this standpoint as terms for highly compounded concepts. As long as the only documentation techniques available were printed indexes and reference works, the only route open was *via* highly precoordinated terms. The usefulness of such aids, within their natural limits, is undeniable, as is the case with the likewise one-dimensional subject and formula indexes.

As in the case of pure structural chemical concepts, however, a nonanalytic approach of this type does not display the relationships between concepts. This is a serious obstacle to a generic inquiry for reaction types. For example, ring closures that were carried out with a certain component are scattered randomly over such a vocabulary of precoordinated reaction concepts, and it is practically impossible to bring them all together, however much memory and patience one can devote to the task. Moreover, storage by a method of this kind must also be very incomplete. Not only is such a vocabulary too large and too difficult to memorize, but it is also incomplete insofar as no generally accepted names exist for the vast majority of reaction types, and particularly for all new reaction types. Furthermore, names of this type are mostly quite insufficiently defined.

Ideas differ widely *e.g.* as to which synthetic variants should be included under Friedel-Crafts reactions. While one chemist believes that the use of the typical catalysts in a reaction is enough to make it a Friedel-Crafts reaction, another imposes conditions with respect to the reactants *etc.*

On the other hand, this difficulty can be overcome by resolving reaction concepts in the same way as the structural-chemical concepts[29,34,42,43]. To do this one establishes certain criteria according to which it is decided which parts of a molecule are actually involved in a reaction. Each of these parts is described in its states before and after the reaction, and in this way one obtains elementary concepts of the reaction-chemical type. In the reaction

for example, the carbon of the formaldehyde would be considered to be involved in the reaction. Another characteristic of this reaction would be the thiadiazine ring formed. This reaction could therefore be written as follows:

1. Formaldehyde → CH_2 of heterocycle
2. – → thiadiazine ring formed
3. $C-NH_2$ → C–NH as members of a heterocycle.

The same vocabulary as is used in structure documentation can be used to name the parts of molecules that are involved in the reaction. The only difference is that the parts of the molecule encoded are to be interpreted as participants in a reaction, and that the particular kind of connection between these elementary concepts must be represented.

All types of reactions can be completely described for storage and inquiry by enumerating the constituent reaction-chemical elementary concepts and by representing their connections with one another. As in the case of structure documentation, a relatively small vocabulary of elementary concepts is sufficient for this purpose.

It is easy to see that the complete specification of all starting materials, intermediates, and final products can by no means replace reaction documentation of the kind described. For example, if one tried to find alkylations of aromatic systems by reaction with the olefinic double bond of another component, it is not sufficient merely to demand both classes of compounds to be mentioned as reactants in a publication. For, these conditions are already fulfilled if the reactants did not react *with each other* but *with any other reactant* also mentioned in the same document. Even if they reacted with each other, the desired attachment of the carbon chain to the aromatic ring need not necessarily have taken place. According to the inquiry, other reactive groups present in the reactants must not be excluded, and just these may have reacted with each other in various ways. All this would lead to immense ballast.

Success in the documentation of other fields similar to that achieved in pure chemistry will be possible only by abandoning the present precoordinating thinking in favor of the analytic-synthetic approach,

[42] *H. J. Ziegler*, J. chem. Documentation *6*, 81 (1966).

[43] *G. E. Vleduts*, Information Storage and Retrieval *1*, 117 (1963).

with the simultaneous use of a highly advanced technique for the representation of the relationships and contextual and logical connections between concepts in storage and in inquiries.

If this approach is not yet very widespread in the field of reaction chemistry, it is even less so for concepts from neighboring fields such as "corrosion", "zone melting", "fluidized bed drying", *etc.* Chemists in these fields must come to accept that the creation of a new technical or scientific expression carries with it a duty to define the concept meant, or at least to describe it in detail.

5. Concluding Remarks

No efforts and costs have been spared in the attempts to improve our experimental capabilities in chemistry and in the natural sciences. The most effective techniques imaginable have been developed and used, partly even to a degree that is beyond the powers of single countries and has led to international alliances. For centuries it has been a matter of course that man need not content himself with the effectiveness of his natural sense organs for the *observation* of phenomena. In all our attempts to *interpret* and understand these phenomena, however, we are still seriously handicapped by the lack of methods that have been developed to a comparable degree of perfection and that have a similar superiority over the natural *mental* aids that man has available for research work.

Cognition in natural science means ingeniously ordered experience. To trace out a hitherto hidden law of nature, one gathers together as much published material as possible that might be related to this topic. Today this is still largely a matter of patience and memory, as well as luck in finding relevant material. This information, supplemented by our own experiments, is scanned for analogies in order to find clues to the conjectured relations. Imagination and scientific intuition must tell us what can be hypothetically postulated as analogy, *i.e.* as conformity in the essentials. However, the facts must then be reordered in the light of the new hypothesis in order to separate those that support the hypothesis from those that oppose it and to weight the two sides against each other. Any falsification of the hypothesis leads to a new modification that explains the facts better, and new material has then to be collected once more and ordered in accordance with new ideas. Since the possibilities for the ordering of scientific facts in accordance with any point of view are still at such a backward stage of development, we are constantly operating at the limits of our patience and memory. Thus we are still far from having exhausted the possibilities offered by effective communication with contemporary and with long-established knowledge.

It is important to realize that the freezing of communication is *not* fundamentally due to the mere mass of published knowledge and its continuous growth. If this were so, there would be no remedy. The true cause is the lack of order that science has tolerated among its own results from the very beginning. The effects of this disorder have become increasingly disturbing with the continuous growth of our knowledge, since they cannot be counteracted by a continuous increase in the patience and memory devoted to searches.

Any resignation to the communication problem, such as is sometimes encountered nowadays, is therefore unjustified. On the contrary, this problem presents science itself a task of paramount importance [44]. The efficiency of research and development work must be prevented from lagging even further behind the expectations to which we are entitled in view of the outlay in labor and in experimental aids.

However, this is a problem that cannot be solved by natural scientific thinking alone. If one wishes to achieve more than a provisional result of limited working capability, important principles from philosophy must be followed. Close contacts exist in particular with mathematics, logic, and epistemology, and extensive studies have been carried out on this aspect in recent years. It is fortunate that the technical aids that are necessary to satisfy the requirements of theory have now become available in the form of computers. Thus the time seems mature, from both the theoretical and the technical standpoints, for a breakthrough to fundamentally new, more effective communication methods.

We look forward to the time when the results of philosophy for the first time begin to exert a direct influence on the efficiency of research in natural science, and first of all in chemistry, since the basic conditions for fluent communication are best satisfied here as far as terminology and concept formation are concerned.

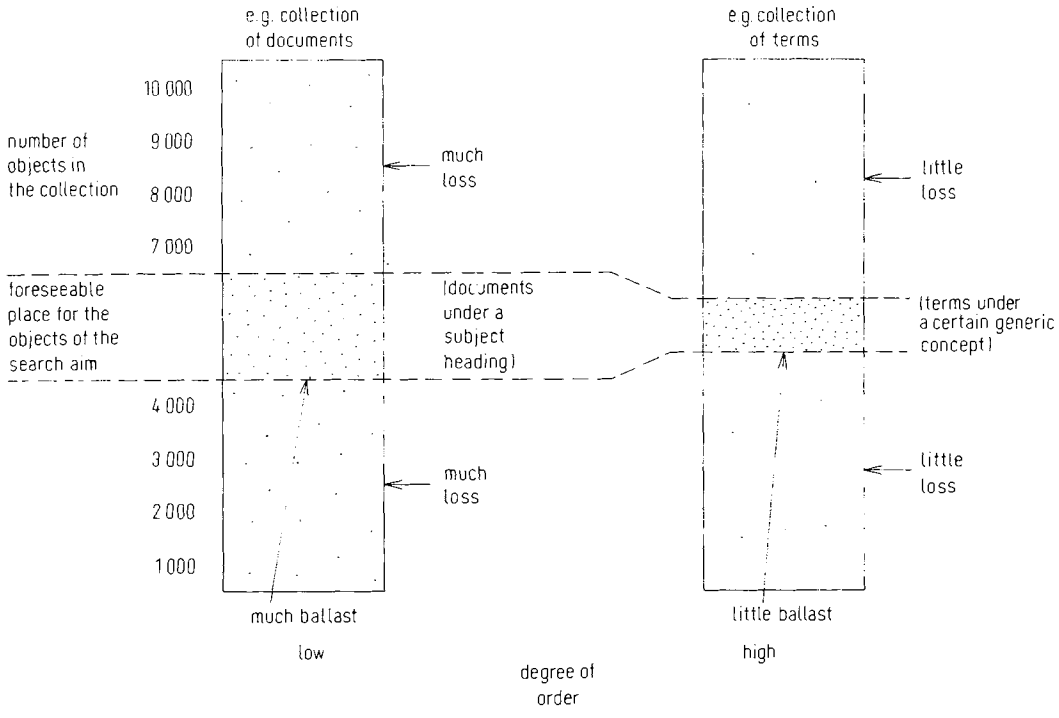
5.1. Meanings of the Terms Used

Order:

State characterized by the meaningful proximity of the parts of a whole.

If the "whole" is a collection of publications or their representatives (abstracts, references, referred to in the following as "documents") or a collection of terms for concepts, the user of such a collection must specify what type of arrangement of these objects is "meaningful" for his present search or future searches.

In this case "proximity" means



a) that a maximum number of objects corresponding to the search aim should be collected at a foreseeable place and

b) that a minimum number of objects not corresponding to the search aim should be collected at the foreseeable place.

Ballast:

Documents or terms that are found at the foreseeable place after localization, though they do not correspond to the search aim.

[44] Cf. Report of The Presidents' Science Advisory Committee USA, The White House, Jan. 1963: Science, Government and Information. Supplement No. 12 to the Nachr. Dokumentation.

Scheme 3. The rectangles represent the size of a collection of objects. Each point denotes an object corresponding to the search aim. The space between the points represents a complementary number of objects not corresponding to the search aim.

Loss:

Documents or terms that are not found at the foreseeable place after localization, though they do correspond to the search aim.

Degree of order:

Measure of the extent to which a meaningful proximity has been established by localization, *i.e.* the extent to which ballast and loss have been avoided at the foreseeable place.

Relevance:

A document is relevant ("corresponding to the search aim")

a) if it contains all the concepts of the search aim in the same or higher specificity, and

b) if it contains the concepts of the search aim in the desired connection with the tolerance indicated in (a).

The occurrence of the required concepts and connections in the document must be capable of being clearly recognized by an expert in this field, irrespective of the mode of expression chosen by the author.

Inquiry term:

The entire formulation of an inquiry that is used for the localization of documents.

Storage term:

The entire formulation of a stored document with which the inquiry term is mechanically compared, and which can be used in the mechanized localization of this document.

Subject heading:

Inquiry term assigned mentally or physically to a document to be stored during the intellectual relevance check, irrespective of whether or not it occurs in the document itself. A subject heading characterizes the place at which the relevant documents are localized.

Localize, localization:

Establishing order in a collection of objects. — The foreseeable place where *e.g.* the documents corresponding to the search aim (relevant documents) are collected may be a place for the physical collection of the documents themselves, a place for listing the representatives of the publications (*e.g.* under the subject heading in an index), or a collection of documents prepared on particular demand and corresponding to a user's search aim.

Intellectual localization of documents:

Localizing of documents purely by expert examination.

Intellectual localization results in the assignment of characterizing subject headings to the documents or in the assignment of documents to their characterizing subject headings.

Purely mechanized localization of documents:

Localization of documents without any expert examination of these documents, purely on the basis of search instructions established in advance.

Combined intellectual and mechanized localization of documents:

Intellectual localization followed by localization purely on the basis of search instructions established in advance, without further expert examination of the documents that have already been localized intellectually.

Search:

Localization of documents relevant to an *a priori* stated search aim or relevant to a search aim which the inquirer has modified *a posteriori*, *i.e.* after examination of documents.

Category:

Most generic concept, for which there is no broader concept in the subject field that would be meaningful in an inquiry.

Elementary concept:

Concept formed by logical subdivision of a single category.

Compounded concept:

Concept formed by synthesis from several elementary concepts. It contains the sum of the characteristics of the elementary concepts.

Precoordination:

Coordination of at least two elementary concepts to form a compounded concept *before* the localization is carried out.

Localization is carried out only for those compounded concepts for which these coordinations have been formed in advance.

Postcoordination:

Coordination of at least two elementary concepts to form a compounded concept *after* the localization for the elementary concepts has been carried out.

Postcoordination allows localization of relevant documents with regard to all concepts that can be formed by coordination of elementary concepts, without (further) expert examination of the respective documents.

Part of the work involved in gaining the experience described was supported by the Internationale Dokumentationsgesellschaft für Chemie mbH.

Use of the IDC System

By Martin A. Lobeck [*]

The documentation system operated by the IDC Internationale Dokumentationsgesellschaft für Chemie mbH uses electronic data processing methods. It allows the storage and retrieval of structures, reactions, and nonstructural keyword information. Structures and reactions are coded as terms of a faceted classification, while keywords are stored in clear text. 900000 formulas from patent and journal publications, including many Markush formulas, have now been stored on magnetic tape. Searches in this store are carried out with IDC programs, which require an average computer time of less than 1 minute per inquiry (CPU time). The structure terms can be produced by computer from topological records. The field covered at present is low molecular weight organic chemistry, though extension to macromolecular chemistry is feasible, and is in fact planned.

1. Introduction

The IDC (Internationale Dokumentationsgesellschaft für Chemie mbH, Frankfurt) has undertaken to encode chemical publications (journals and patents) to make them amenable to searches by the methods of electronic data processing. The first field chosen for attack was low molecular weight organic chemistry, since this is the field in which it is most difficult to answer the kind of questions about partial structures that are frequently asked in practice. In the IDC system, therefore, structural formulas of organic substances are stored in such a way as to allow searches for partial structures, as well as for reactions of organic substances with organic and inorganic reactants and for other keywords.

2. Development of the IDC System

2.1. Coding of Structures

The development of the system started in the 1950's at Farbwerke Hoechst. *Fugmann* and his coworkers found that the methods of structure coding in existence at that time were unsatisfactory for searches in large files. The system conceived and used at Hoechst was soon adopted by the Farbenfabriken Bayer and by the Badische Anilin- und Soda-Fabrik, who also introduced improvements and new ideas. The IDC was founded only in 1967, and its membership now consists of 13 chemical companies.

When the society was founded, there were already more than 400000 records stored on magnetic tape, and this number has now more than doubled. To each record there corresponds one or more related structural formulas coded by the GREMAS method [1].

2.1.1. Triplet Terms

The GREMAS system is based on a faceted classification. Each carbon atom in an organic compound is described by at least one term consisting of three letters and known as a triplet term.

The first letter of the triplet term, which is called the generic letter, tells us something about the number of hetero bonds in which the C atom in question is involved, and usually also with what atoms. Any bond that does not lead to a hydrogen atom or to another C atom is regarded as a hetero bond.

It can be seen from Figure 1 that *e.g.* the generic letter for amines is B, that for halogeno compounds is H, and the first

[*] Dr. M. A. Lobeck

[1] Generic REtrieval with MAgnetic tape Storage.

Genus B:	Amines	*e.g.*
BA.	primary	CH_3-NH_2
BB.	secondary	$(CH_3)_2NH$
BC.	tertiary	$(CH_3)_3N$
BD.	quaternary	$(CH_3)_4N^{\oplus}$

Genus H:	halogen compounds	*e.g.*
HA.	fluorine	C_6H_5-F
HB.	chlorine	C_6H_5-Cl
HC.	bromine	C_6H_5-Br
HD.	iodine	C_6H_5-I

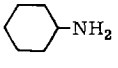
Genus R:	unsubstituted chain C atoms	*e.g.*
RA.	saturated	CH_3-CH_3
RB.	olefinic	$CH_2=CH_2$
RC.	acetylenic	$CH\equiv CH$

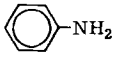
Fig. 1. Examples of genus and species.

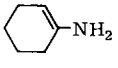
letter of the triplet term when the C atom is not linked to a hetero atom is R.

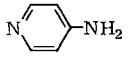
The second letter of the term, *i.e.* the species, qualifies the information embodied in the first term. Thus in the genus B, the letter A in the second place denotes a primary amine, B a secondary amine, C a tertiary amine, and so on. In the genus H, the second letters A, B, C, *etc.* denote fluorine, chlorine, bromine, *etc.*, and in the genus R they indicate whether or not the C atom is involved in double or triple bonds.

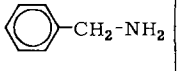
The last letter of the triplet term, the subspecies, indicates the environment of the C atom in question, *e.g.* whether it is situated in or on a heterocycle, an aromatic compound, or a chain with or without double bonds (Fig. 2).

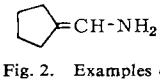












BA.	Primary amines
$CH_3-CH_2-NH_2$	BAA
$CH_2=CH-NH_2$	BAF
$CH\equiv C-NH_2$	BAM
	BAQ
	BAR
	BAT
	BAS
	BAD
	BAH

Fig. 2. Examples of subspecies.

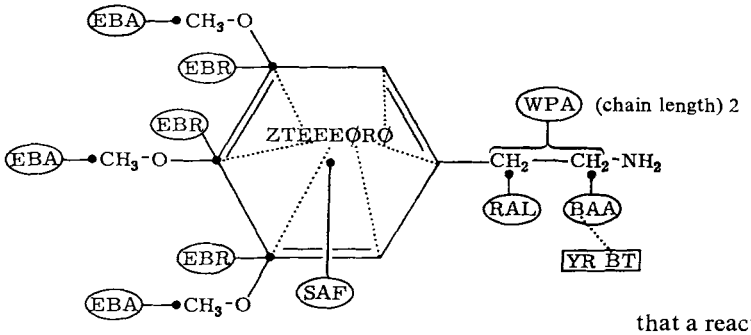
Well over 3000 triplet terms are defined by combination of letters; the result is a very fine network, which should represent the structure very satisfactorily. These terms were in fact accepted as a complete structure at first, but it was soon found that the percentage of false drops in many inquiries was still quite considerable.

2.1.2. Zone Terms

Zone terms of variable length (Y terms) were therefore introduced to show *e.g.* what substituents are present on a ring or chain, whether there are double or triple bonds present and how many, and in the case of aromatic compounds, whether substitution is *ortho*, *meta*, or *para*.

	Triplet terms	Zone terms
	SFA EAR	YT E---
	SAF EAR	YT EE2–
	SAF EAR	YT EE3–
	SFA EAR	YT EE4–
	SAF EAR	YT EE1–
	SAF EAR	ZT EEEEEE----
	SAF EAR	ZT EEEØTØ----- and ZT ETEØEØ---

Fig. 3. Zone terms can distinguish structures having the same triplet terms.



For aromatic compounds with more than two substituents, it was even made possible to specify how all six positions were occupied (Z terms). In the zone terms, the substituents are indicated merely by the generic letter, *i.e.* not very precisely.

As can be seen in Figure 3, different zone terms are obtained for compounds having exactly the same triplet terms, and the structures can therefore be distinguished.

2.2. Example of Structure Coding

This example of the complete coding of a compound will also be used later to illustrate retrieval.

It can be seen that a triplet term has been assigned to each C atom in Figure 4. In the final listing, terms that occur more than once are listed only once. The ether linkage is considered on the one hand from the alkyl side and on the other from the phenyl side, and gives

BAA EBA EBR RAL SAF WPA
YRBT --
ZTEEEØRØ ----

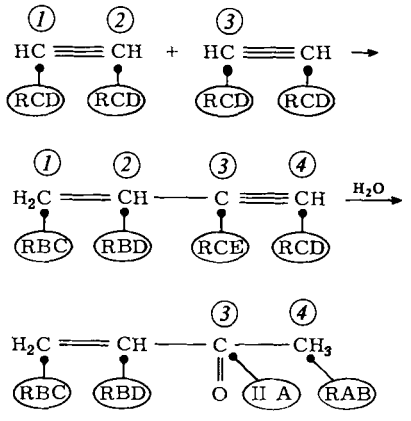


Fig. 4. Complete coding of a structural formula.

the terms EBA and EBR. SAF denotes the benzene ring, or more precisely, each of its C atoms. RAL indicates the aromatically substituted CH_2 with no hetero ligands, and BAA the NH_2-substituted CH_2.

A term WPA is added for a chain length of two C atoms, and it also shows that there are many triplet terms that have not been discussed here, including terms for substitution and condensation data in heterocycles and carbocycles, terms that indicate pharmacological or microbiological activity of the structure in question, and others that contain information about spectroscopic or analytical properties.

2.3. Reaction Coding

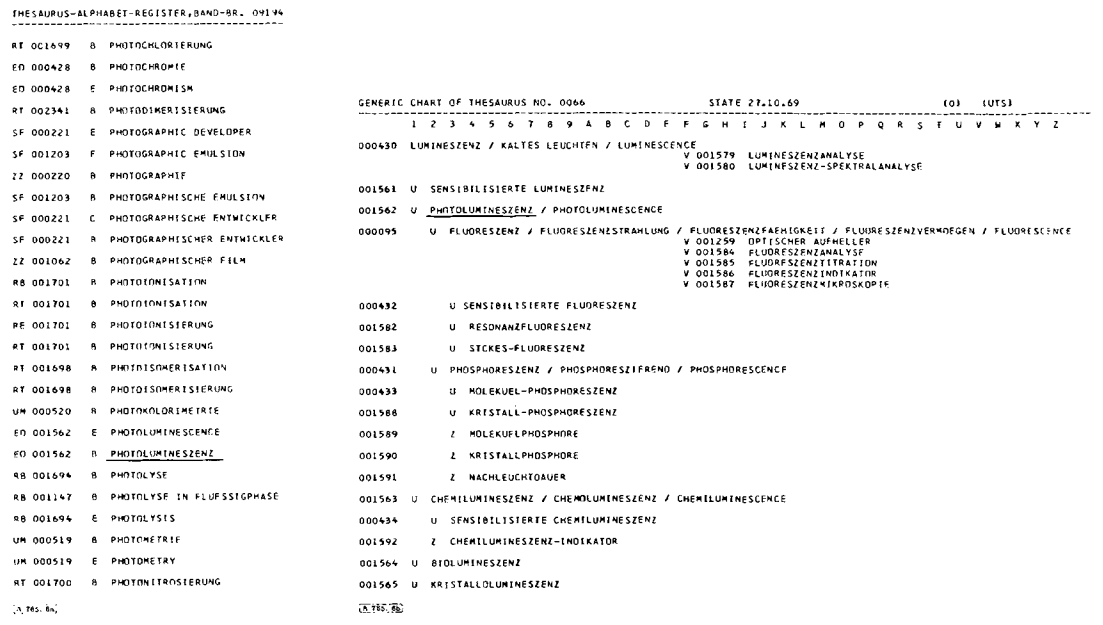
Reactions are coded with the aid of the triplet terms of each reacting carbon atom. The first three places of a twelve-place term are occupied by @ DR to indicate

@ DR RCD RBC - - 1
/ DR RCD RBD Z L 2
/ DR RCD RCE Z L 3
1 2 3 4 5 6 7 8 9 10 11 12 *1st step*

@ DR RCE I I A - - 3
/ DR RCD R A B - - 4
1 2 3 4 5 6 7 8 9 10 11 12 *2nd step*

Fig. 5. Coding a reaction with prefix (1—3), initial term (4—6), final term (7—9), reaction conditions (10—11), and numbering of the C atoms (12).

that a reaction code will follow. The triplet term of the C atom *before* the reaction is then given followed by that *after* the reaction. Special features, such as ring closure or cleavage, or chain lengthening (ZL), are coded in places 10 to 11, and the carbon atom may be numbered in place 12 so that it can be recognized again if further reaction steps are described in the same article. The search can then be carried out over several steps in retrieval.



Since the reaction terms must be sought with special programs, "short reaction terms" are always formed. These are a simplified coding of the reaction, which is stored at the same time during the coding of the end products, and which is 2RB, 2RC, and 3ZL, or 2II and 2RA here. These reaction terms can then be retrieved like any other triplet terms. In many cases these are sufficient, and they often make it unnecessary to use the actual reaction retrieval program.

2.4. Nonstructural Concepts

Frequently occurring keywords are given triplet terms of their own, as was mentioned earlier, while other concepts are stored in clear text, as are inorganic reactants. The coder has been given a completely free choice of words in the case of concepts, so that new ones need not be expressed in terms laid down before these concepts existed. Because of this, however, very intensive checking is necessary, since each new concept must be examined, and relations with other concepts, *e.g.* belonging, part-to-whole relation, hierarchic relations (wider concepts, narrower concepts), or synonymity, are established. A definition or explanation of the concept is formulated, and the collection of terms is periodically printed out as a thesaurus, in which all the concepts (Fig. 6a) are transferred from an alphabetic register to the appropriate concept fields, from which all the relations can be seen (Fig. 6b).

2.5. Storage

In the IDC system, all the formulas to be stored are encoded, and the terms are recorded, together with the facts, on punched cards or tapes. Facts and inorganic reactants, as well as the reaction terms, are given different prefixes, which are checked during subsequent searches and prevent searching in locations that definitely do not contain information of the desired nature. The structures are not all encoded by human operators; this is necessary only for structures that

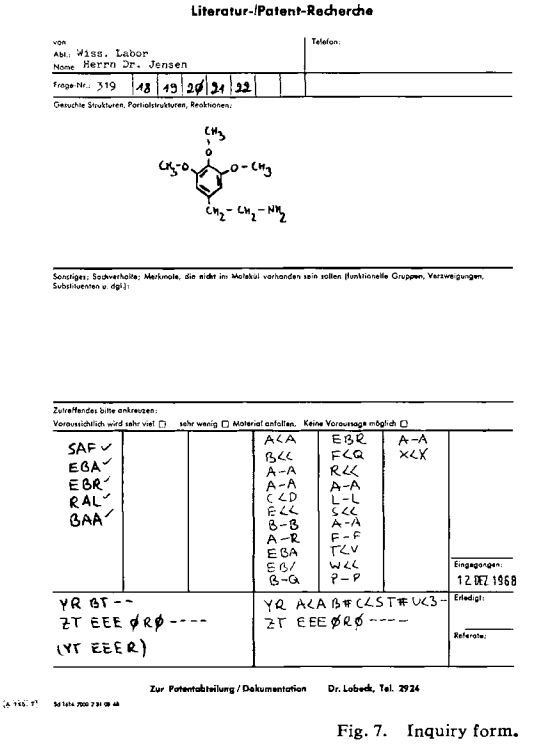
exceed the capacity of the formula reading machine, which records the formulas mechanically and topologically. The structure terms are then formed from the topological record by a computer program [2].

After repeated checking, the information recorded on punched cards or tapes is stored on a supplementary tape that is separate from the "structure tape". Each structure has a separate record, which contains all the necessary bibliographical data, *e.g.* a document number of the publication in question. Separate searches in the structure tape and in the supplementary tape can then be correlated by means of the record number and the document number.

For each document the coder adds one or more field letters, by which the publication is roughly classified; for example, B denotes organic chemistry in general, D is pharmaceutical chemistry, and E is pest control.

This field letter can be included in the inquiry to reduce the number of answers in the case of substances that occur with a high frequency.

These notes on storage are not complete, but should be sufficient to enable the reader to understand the following inquiry formulations.



3. Retrieval

3.1. Organization

On entering our company, each chemist receives inquiry forms as shown in Figure 7. The main points about retrieval possibilities are presented in a brief note. The forms give the chemist's department and name, as well as a three-place inquirer number. The chemist draws the required structure and notes any further conditions, and the form is submitted to the Documentation Section.

[2] *E. Meyer*, Angew. Chem. *82*, 605 (1970); Angew. Chem. internat. Edit. *9*, 583 (1970).

Following the three-place inquirer number, a running tally of the inquiries by this chemist is indicated in the input by a two-place number. Consequently, all inquiries, computer lists, *etc.* for a given chemist will be found together on the storage shelves.

Fig. 7. Inquiry form.

3.2. Coding of Inquiries

For each inquiry, the structure in question is coded on the form as outlined above, together with other encodable criteria, such as particular preparation methods.

At first sight it appears a good idea to use the same terms as search conditions as were used for the storage of the compound. This is in fact possible, and yields

all records involving the formula in question; unfortunately, however, a very large proportion of false drops is usually also obtained. The search principle corresponds exactly to the procedure used with peek-a-boo cards. It is clear, therefore, that with this method only minimal requirements can be queried in a record; all required terms *must* be present, but there may be others too. One therefore obtains not only the desired structures, but also more complicated ones. Matters can be improved only if it is possible to forbid all unwanted terms. Obvious as this may seem, it is rare for such a facility to be provided in documentation systems unless they use electronic data processing equipment.

In view of the large number of triplet terms, all the terms to be forbidden cannot be listed individually. The usual method of formulation in the IDC system will be illustrated by a model search for the structure encoded in Figure 4.

If we start with the structure terms entered at the bottom left of the inquiry form (Fig. 7), these must be arranged in strict alphabetical order in formulating the inquiry. This need for alphanumerical arrangement could be avoided by the use of a simple sorting program. Such a program is in fact used in the storage of structures, but not in the inquiry. The reason for this is that the forbidden terms are also included here, and it is logical to run through the possible genera (first letter of the term) to see whether any term in this genus is required. If the answer *e.g.* for genus A is no, this genus can be forbidden by the simple formulation A < A. The program allows the extension of this system to entire ranges; thus H < L means that the record must not contain a triplet term with the genus H, I, J, K, or L.

The requirement that a given term must be present in the record is formulated by giving the term itself, *e.g.* BAS for a primary amino group attached to a heterocycle. If the requirement is more general, one may specify a range from which at least one term must be present. The "any" symbol *, for which any character in the record may stand, is used.

Thus the requirement H**, which means that there must be at least one halogen atom somewhere in the molecule, will result in the retrieval of all stored terms that begin with H. The "any" symbol may be qualified, *i.e.* restricted. Thus in H** B—C R—S, the second term B—C qualifies the first asterisk, and R—S qualifies the second; the inquiry calls for halogen (H) which must be either chlorine (B) or bromine (C), and which must be attached to an aromatic (R) or heterocyclic (S) ring. Other compounds containing halogen, such as iodobenzene (HDR) or chloroethane (HBA) do not fall within the required range, and are not retrieved. Fluorochlorobenzenes (HAR HBR), on the other hand, are retrieved, since HBR is called for.

If it is desired to prevent this, both requirements and exclusions must be specified within a genus. This leads to an "only" condition; H << B—C R—S is the same requirement as before, except that all H terms outside the specified range are expressly excluded. There are also pure exclusion terms. H // B—C R—S is the exact negation of the corresponding term with**. A < C means that all terms begining with A, B, or C are excluded. If we now consider the example in Figure 4, we see that the genus A must not be present, but B is required in BAA (and only there). The formulation is therefore A < A B << A—A A—A. The other formulations are read in the same manner. To make it easier to understand, the search has been carried out in various versions in part of the IDC file (Figure 8). If only the triplet terms required by the structure are

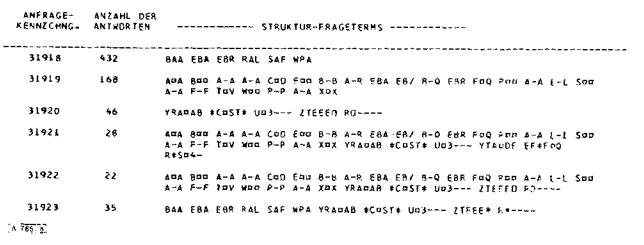

Fig. 8. Number of answers for various formulations of an inquiry. (□ is equivalent to <)

used, the search yields more than 400 answers. If we now add the exclusion of all other triplet terms, the number of answers is reduced to less than half. Using Y and Z terms alone, without triplet terms, one obtains 46 answers. The usual formulation is shown in inquiries 31921 and 31922. In these cases the Y or Z terms are called for in addition to the triplet terms, and 28 or 22 answers are obtained.

We have assumed so far that the structure being sought is given in full. This is by no means the most common type of inquiry, since it is easy to find such a compound from indexes. The problem assumes a different complexion if only partial structures are specified in the inquiry. If in our model case, for example, *any* further substitution of the benzene ring is allowed, no terms can now be excluded. We are therefore left with the triplet terms required and the appropriately modified zone terms. This leads to 34 answers.

Between these two extremes (*i.e.* complete data on the one hand and a partial structure with unrestricted substitution on the other), there are many intermediate stages that can be taken into account in various ways during formulation. Since the system was designed by chemists, chemically similar groups also have similar triplet terms, which can be easily requested together in an abbreviated notation, and which can equally well be excluded.

During the coding of patent claims, it is common to encounter Markush formulas, *i.e.* structures in which a parent structure may be substituted in one or more positions with various and often numerous alternative substituents. In the storage of such formulas, the alternative fragments are stored in specially labeled locations, so that the structure is not blocked by exclusions in the inquiry. Thus if a compound may have either a chlorine or a hydroxyl substituent in one position, this compound should be retrieved in a search for the chlorinated compound, even if OH is forbidden. Alternative groups may also be indicated by a special symbol in the inquiry, and several alternatives are again possible. The ability to include alternatives in the inquiry is not essential for a successful search. A structure in which one position can have three alternative substituents can be found by three individual inquiries. On the other hand, if it has three positions with six possible substituents on each, it is much easier to formulate a single inquiry instead of $6^3 = 216$. In many other systems, however, searches for Markush formulas are very tiresome tasks.

In searches for reactions, the inquiries may again be very special, or they may be general; structural conditions will usually also be known and included in the inquiry. Though the programs for structure searches and reaction searches are executed separately, the results can be correlated afterwards.

Bibliographic data on the encoded publication itself cannot be retrieved directly, since they are not included in the record. For example, one cannot carry out a search for authors. However, there are concordance volumes in the patent field that give the patent number against the abstract. With the aid of these volumes and other data sources that give more detailed information against the patent numbers, it is possible, *e.g.* to prevent one's own patents from being retrieved in the search.

The inquiries coded on the inquiry forms are recorded on punched cards, and the search is carried out with an IBM/360-50 computer.

3.3. Checks for Errors

All inquiries are first checked for formal errors by a diagnostic routine. The inquiries are listed with their number and the codes, and if a discrepancy is found, such as failure to follow the alphabetic sequence, an appropriate error description is printed out.

Punched cards having an inquiry number for which an error description has been received are removed from the batch by the operator, and the diagnostic routine is repeated for the remaining cards. The list of these inquiries, which is now free from errors, is used for this machine run. The computer time required for the diagnostic routine is about 2 to 5 seconds.

3.4. Sequential Scanning

The actual search begins immediately after the diagnostic routine. The entire file is scanned sequentially. At first sight, this procedure seems time consuming. It is even more surprising to find that the time taken for a single inquiry is only about 90 seconds, and that the time is usually reduced by about half, and often to as little as 20 seconds, when several searches are carried out simultaneously. The time given here is the CPU time, *i.e.* the time during which the central processing unit is in use, which is the basis of cost calculations.

3.5. Screening

High searching speed would, however, be impossible if every term of every record were actually checked. It is made possible by "screening" a technique introduced by *Ernst Mayer*, as a result of which the formerly very time-consuming and hence expensive mechanical search has become a relatively cheap routine.

In screening, each record is preceded in the store by a machine word of 32 bits. One bit in this word is reserved for each possible generic letter from A to X; thus if *e.g.* the genus C occurs in the record, an entry is made in the third bit in the screen word, which is reserved for C, by a special program during the storage operation. In the preparation of the inquiry, a bit is inserted in an inquiry screen word (also mechanically) for each *forbidden* genus. The screen words in the inquiry and in the store are then compared at the beginning of the search in a very fast machine operation (Fig. 9).

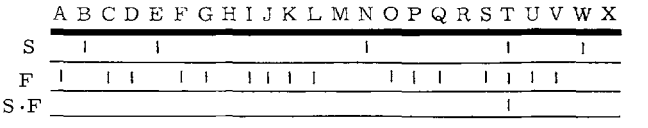

Fig. 9. Screening. In the first screen word, the genus letter of the record S (*i.e.* B, E, N, T, W, in this case) is compared with the genera that are *forbidden* in the inquiry (*i.e.* A, C, D, F, G, I—L, O—Q, S, T, U, V). The logic product S · F of the two sets must be zero. This is not so in the example, since the record contains T, which is forbidden in the inquiry.

If any place is occupied in both, the record contains a genus that is expressly forbidden. This record consequently need not be checked further; the computer jumps over it and tests the screen word of the next record. In addition to this screen word there are also four others, which check combinations of the first and second or of the second and third letters of required triplet terms. Even with the first screen word alone, however, an average of 99% of all the records in the store can be rejected without further checking.

3.6. Output

The answers found by the computer are temporarily stored on a magnetic tape, sorted according to inquiry numbers, and then printed out in a list. Assistants in the Documentation Section then find the corresponding abstracts, and copy them or enlarge them from microfilm. The copied abstracts are examined by documentation officers and sorted into relevant and false drops. The requesting chemist receives both, mainly because even irrelevant compounds are structurally similar to one another and to the compound sought, and *could* therefore be of interest. The computer list remains in the Documentation Section, and is shelved, as are the inquiry punched cards.

If the number of answers is greater than 200, it is usual to ask the requester whether he wants so many answers, or whether he can narrow the inquiry. It is possible, but not very meaningful, to give an average number of answers. This is clear when one considers that there are many searches for structures that are to be claimed as new in patents. In such cases the requester hopes for, and usually receives, the answer "No records". On the other hand, the Documentation Section tries to avoid very large numbers of answers, so that the majority of inquiries yield 0–100 abstracts.

3.7. Updating of Files, Standing Queries

Roughly every three weeks, the IDC supplies new material for filing on magnetic tape, which is simply appended to the existing file, owing to the sequential arrangement. However, the new material is first submitted to all the standing queries in hand.

This type of standing instruction may be regarded as a form of selective dissemination of information. A standing query is frequently made broader than the original query to the existing material. We always have about 60–70 standing queries in hand.

4. Critical Data for a Documentation System

Besides a knowledge of coding, the course of searches, and the search possibilities in a system, other points of great interest are:

1. Coverage (what publications are encoded?)
2. Depth of analysis (how precise? Is every compound named encoded?)
3. Proportion of false drops and the closely related question of the danger of missing relevant documents
4. Frequency of error in encoding
5. Time taken (a) for storage, (b) for encoding inquiries, (c) for machine searches
6. Costs of (a) storage, (b) searches.

These points will be briefly discussed below.

4.1. Coverage and Depth of Analysis

It is common knowledge that all documentation systems yield too little relevant material. The IDC has encoded practically no material earlier than 1959. Moreover, the sources used for coding do not cover the relevant literature fully, though coverage of patents is better.

The sources used at present are:

a) The Farbenfabriken Bayer Progress Report ("Fortschrittsbericht"), which covers about 600 journals.

b) The Chemical Information Service ("Chemischer Informationsdienst"); prior to 1970 the rapid abstracts service of Chemisches Zentralblatt ("Schnellreferate des Chemischen Zentralblatts") was used.

c) The patent report (Patentschnellbericht) published by the Badische Anilin- und Soda-Fabrik, Farbwerke Hoechst, and Farbenfabriken Bayer.

This contains abstracts by the Patent Documentation Group (PDG) of new chemical patents from Belgium, France, the United Kingdom, the Netherlands, Austria, the German Federal Republic, the German Democratic Republic, the Soviet Union, the USA, and Japan. Corresponding patents published later in other countries are not reabstracted but can be searched with special lists.

In the case of the Chemical Information Service, the coding is based on the original publication instead of on the abstract. All compounds named are encoded for all sources (with a few exceptions, such as very common solvents, which no one wishes as an answer to a search).

4.2. False Drops

The proportion of false drops in the IDC system is strongly dependent on the compound being sought. Only a few reasonably dependable rules can be given:

1. The more complicated the structure, the smaller will be the absolute number of false drops.
2. The more general the formulation of the structure, the greater will be the number of false drops, since the number of terms that can be forbidden decreases.

Systematic false drops are sometimes unavoidable. For example, it is often impossible to separate isomers; thus 3-octanol cannot be distinguished from 1-, 2-, or 4-octanol. Moreover, when chain lengths are given, it is not possible to indicate which of several chains is meant. The degree of saturation cannot be given precisely for many heterocycles. An immediate improvement results if topological searching is possible.

Since nearly all formulas will in future be filed by IDC in form of a topological matrix, from which triplet and zone terms can be produced by computer, topological searching will be available in these cases as a means of fine selection. This mutual complementation of the two methods is a decisive factor to us for future planning in the Documentation Section, since it means that earlier and future files can both be questioned by the same methods. The future usefulness of the file is assured by the possibility of topological searching, and despite the enormous data files to be expected, the Documentation Section need neither give up nor start from the beginning again.

4.3. Misses and Error Frequency

The reverse of the false drop problem, *i.e.* the loss of items that have been filed, is found with any ordinary card index arranged according to subject. The loss rate usually increases at first with the size of the index and then falls off again to zero, since the card index has become so large that it is no longer used. This danger is small in the IDC system. Misses result almost exclusively from errors in coding and punching. Punching errors are usually detected at an early stage by quadruple punching. Many typing errors and coding errors can be detected by specific error inquiries (*e.g.* for non-existent terms or combinations of terms). The residual error is not accurately known, but is probably less than 1% of the *terms*. This does not mean, however, that the corresponding *compounds* are untraceable.

Coding and punching errors can also occur in the inquiry. Moreover, the information officer has to know

all the formulations that were used in the system at earlier stages. Some coding possibilities did not exist during the first few years, and many questions must therefore be asked differently in different parts of the file.

4.4. Time Taken

Delays in *storage* were formerly quite appreciable at times. However, the backlog has now been almost completely cleared. For 1970, IDC expects a delay of 8–10 weeks between receipt of the abstracts and delivery of the magnetic tape with the coding to members.

The time taken to *encode an inquiry* varies. It may be a matter of minutes, but it may also be half an hour if the inquiry is difficult to reconcile with the faceted classifications. Inquiries involving substitution data of the type "0 to 2 OH groups and 0 to 3 halogen atoms in the molecule" are nearly always time-consuming.

The *search time* per inquiry has already been reported as 20–90 seconds. The programs written in assembler language require core storage for 54 K bytes. Since only 12 K of these are occupied by the actual search program, smaller core memories may be used, though the operation is then not quite so fast.

The time taken for subsequent treatment naturally depends on the number of answers. In general, however, the chemist receives copies of the abstracts within 24 hours of submitting the inquiry.

Thorough familiarization is necessary in order to acquire a precise knowledge of the sophisticated search technique. However, the system is logical and well thought out, so that an intelligent technician can master it with 4 to 8 weeks' training.

4.5. Costs

The search costs depend on the computer used and on the accounting system of the computer center. The CPU times given should provide an adequate indication to anyone interested; however, the search costs are small in relation to the membership subscription to the IDC. Each member at present pays about 1000 DM per annum per chemist, this subscription being based on a minimum of 50 chemists. Subscription fees are reduced if a member desires searches of the literature or the patents section only, and naturally also decrease as the membership increases. Members with no computer of their own can have searches carried out at the IDC.

5. Outlook

The IDC system provides a search method that, though not very cheap, is reliable and has an assured future. Coding of inquiries is convenient and flexible. The scope will be extended in the near future to include macromolecular chemistry, a further step toward the still distant goal of complete and rapid documentation of the chemical literature of the world.

Versatile Computer Techniques for Searching by Structural Formulas, Partial Structures, and Classes of Compounds[1]

By Ernst Meyer[*]

The principles of the topological encoding of formulas and machine searching are briefly described. These methods have been developed to the point where it is now possible to carry out a computer search for a given structural fragment without the risk of false drops. It is also possible to carry out searches whose requirements, while well-defined and readily used by chemists, cannot be represented exclusively by element symbols and chemical bonds.

1. Introduction

One of the most important tasks of any information system for organic chemistry is the retrieval of structural formulas and of classes of substances characterized by a common structural unit. Up to now this has generally involved the use of fragmentation codes, in which a selection of structural characteristics is encoded as predetermined code symbols, which can then be searched for singly or in combination. The principal advantage of such systems is the ease of searching. The disadvantages are the intellectual effort required for indexing and above all the restriction to a limited number of predetermined characteristics. If a search is to be run on substances with structural fragments for which there is no actual code symbol, it is necessary to

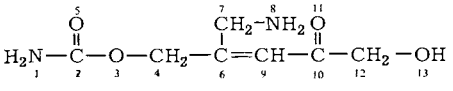
der Badischen Anilin- & Soda-Fabrik AG
67 Ludwigshafen, C 6 (Germany)

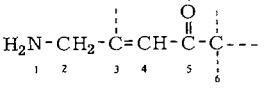


[1] The work was supported in part by the IDC Internationale Dokumentationsgesellschaft für Chemie mbH, Frankfurt.

falsify the question and run the risk of false drops in the answer. This can often be very tedious, and renders pointless many searches that would otherwise be of interest.

2. The Topological Method

The topological method is a new procedure made possible by the introduction of computers. It was suggested by *Mooers* [2] in 1951 for the documentation of structural formulas, and has the advantage that under this system it is possible to search for any structural fragment without the risk of false drops, even if the significance of such a fragment was not appreciated at the time of indexing. The following example shows the basic principles (Fig. 1): To index a compound, its



File structure:

1	N	1–2.
2	C	1–1, 1–3, ②–5.

7	O	②–5.

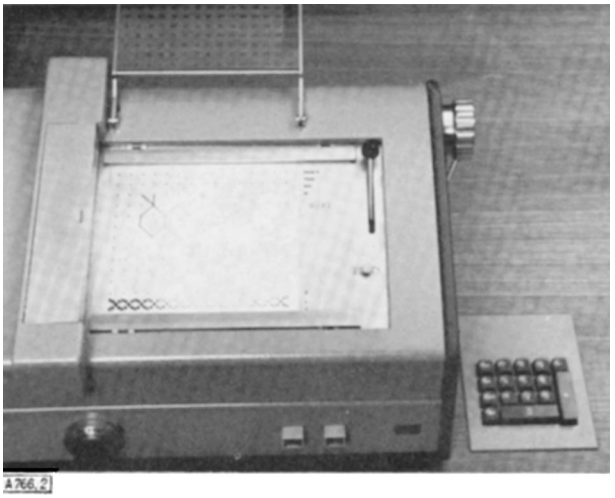
Match: search structure: 1 2 3 4 5 6 7
file structure: 8 7 6 9 10 12 11

Fig. 1. Topological structural formula coding (simplified example). Above is a stored formula, and below is shown the required structural fragment both as formula and code.

formula is encoded by assigning a number to each atom other than hydrogen; the order in which these numbers are assigned does not matter. Each atom is then coded (on a separate line), the code consisting of the symbol for the element and the numbers of its "ligands" (neighboring atoms). Each ligand number is prefixed by a code number for the type of bond with which the ligand is connected to the atom in question. In this way we derive a connectivity matrix that may appear at first glance to be heavily influenced by the chance sequence in which the atoms were numbered, but which nevertheless can be used to reconstruct uniquely the original structural formula.

The structure for which a search is being run can be encoded in similar fashion. It is highly unlikely that the numbers assigned to the atoms in the search structure will coincide with those in the corresponding stored structure which answers the question, but the computer can "recognize" equivalent structures. In Figure 1, this is done as follows: Atom No. 1 in the search structure is nitrogen, and the first nitrogen atom in the file structure is also numbered 1. Both have only one ligand, attached by a single bond, and in both cases this is carbon. If we continue the comparison, however, a difference appears: Atom No. 2 of the search structure should have only two single bonded ligands, but No. 2 of the file structure has three. No. 2 (and consequently also No. 1) thus does not meet the requirements of the question. The computer therefore supposes that the next nitrogen atom of the stored structure (No. 8) might correspond to No. 1 of the search structure. For this to be so, its ligand (No. 7) must correspond to No. 2 of the search structure. Both are carbon atoms with two singly-bonded ligands. The next atom of the search structure (No. 3) would then have to correspond to the (still unchecked) ligand of atom No. 7 of the file structure, *i.e.* No. 6. Both are carbons, and the atom of the file structure – as required – has at least one singly and one doubly-bonded ligand. The latter, No. 9, would then have to correspond to atom No. 4 of the search structure (see the comparison in Fig. 1). This process is continued to give a list of possibly matching assigned atom numbers. At branching points it is possible that several atoms of the file structure will have to be considered as possible matches for one atom of the search structure, and these are carefully noted. If the further search shows discrepancies, the computer program jumps back to the last branching point and follows an alternative path. This is repeated until the required structure (or structural fragment) has been found, or until all possible paths have been exhausted.

The Chemical Abstracts Service [3] programmed a similar topological search system [4] at about the same time as ours. It should be mentioned that there are other methods for topological structure comparisons [5], but the iterative search described has the advantage of simulating largely the thought process of a chemist comparing structures, and for this reason it could be extended to meet more complex requirements. Thus, from the beginning we have provided for the indexing of Markush formulas (*i.e.* formulas with one or more positions capable of having several alternative substituents), and have devised a search program that will retrieve these formulas without the need for them to be resolved into all their possible individual compounds; otherwise, in patent documentation too much storage space would be required. We were also able to take into consideration defined rings with substituents at undefined locations.



The topological method has two disadvantages: firstly, the indexing would involve a lot of writing and there would be a high risk of error if the connectivity matrices were to be

[2] *C. N. Mooers*, Zator techn. Bull. *59*, 1 (1951).

Fig. 2. Formula reader. The structure is drawn on a transparent grid sheet, which is placed in a slide and scanned by twelve photocells; a punched paper tape is produced which can be processed further by the computer.

prepared manually; secondly, it would take far too much machine time to check all the structural formulas of a large file in this way. We have described elsewhere[6] how we overcame these difficulties. For encoding we built a special the computer, the topological formulation also generates a coding by *Fugmann*'s GREMAS system[9] (an approved and extremely efficient fragmentation code), and this is further processed to give a particularly machine-oriented (and therefore quickly searchable) superimposition code[10]. Only the formulas that pass these two preselection stages — and they represent only a very small portion of the file — need be subjected to a topological search, assuming that the GREMAS search was not sufficient. The machine costs for this are rarely significant.

The topological method has yet another limitation; it does not make it possible to search for structural fragments which, although clearly defined, cannot be represented as structures consisting of a definite number of atoms and bonds, for example "carboxylic acid derivatives" or "alkyl", "alkynyl", "cycloalkyl", "heterocyclic" or "aryl" fragments. This type of question occurs relatively frequently, because the chemist is accustomed to think in these terms and because, for example, he formulates his patent claims in this manner. For this reason we have built into our search programs the possibility of searching for a large number of such fragments, and also of connecting them with well-defined partial structures. We attacked this problem in two ways: In the first place, we used

atom[11] (from now on we shall refer to both these concepts by the more generalized term "parameter"). For each parameter we retained a number of characteristic data in our "main matrix", *i.e.* in the expanded connectivity matrix (Fig. 3). For this we made use of concepts like "ring value", "bonding value", "degree of hetero orientation", and also the number of ring members, the attached hydrogen atoms or other ligands, the charges, *etc*; we entered these into the main matrix, thus making them rapidly accessible for searching.

For example, the ring value indicates the type of ring to which an atom belongs (heterocyclic, aromatic, or other carbocyclic). The bond value shows the number of double and/or triple bonds in which the atom is involved, irrespective of the neighboring atoms to which they lead; this information is particularly valuable in cases of tautomerism. The degree of hetero orientation, which is based on the GREMAS coding, indicates the number of bonds that are not part of a ring and lead to hetero atoms. Special columns are used to record the numbers of the rings to which the atom concerned belongs or with which the ring concerned is condensed. In addition to this, in ring parameters a reference address leads to a counting up of the ring members. Furthermore, we may distinguish eight types of bonds: single, sesqui, double, and triple bonds, either in chains or in rings.

Code	Significance	
$A	Anything, not *H*	
$B	Hetero atom	
$C	Nonmetallic hetero atom	
$D	Metallic hetero atom	
$I	Nonaromatic ring	in store "Position undetermined"
$J	Aromatic ring	in store "Position undetermined"
$K	Hydrocarbon residue, general	
$L	Alkyl	unsubstituted
$M	Cycloalkyl	unsubstituted
$N	Aryl residue	unsubstituted
$O	Isocyclic residue	unsubstituted
$P	Alkenyl (position of double bond unimportant)	
$Q	Alkynyl (position of triple bond unimportant)	
$R	Unsaturated hydrocarbon chain (position unimportant)	
$S	Hetero- or ring-substituted alkyl	
$Z	Ring closure	
HL	Any halogen	

Bond values (completely additive)

0	Only single bonds
1	One (possibly delocalized) double bond
2	Two double bonds (etc. additive)
6	One triple bond

Fig. 4. List of pseudo-element symbols and bond values used in topological searches. The computer follows this direction and checks whether any fragments other than those given occupy this position.

Secondly, in addition to this, we introduced a number of pseudo-element symbols (Fig. 4), for coding questions; their effect in searching is to call up the appropriate subroutines, which test for definite requirements laid down in the program. For example, the subroutine for "alkenyl" will search in the direction given and will check whether the structure stored there has only carbon (and hydrogen) atoms and has (at least) one double bond in a chain together with single bonds in a chain. By building in further such subroutines we can, if required, introduce any other search concept that is well-defined but not structurally describable.

[11] This enables general questions to be put concerning ring structures, such as the number of members, number and type of multiple bonds, number of substituents and/or condensed rings, *etc*.

3. Examples of Applications

A high flexibility in asking questions inevitably complicates the coding of the enquiry. We have used a set schedule in an attempt to keep the question input as simple as possible, reducing the risk of error and simplifying checking; apart from this, the computer checks the question for formal errors and internal inconsistencies. In order to demonstrate just how many ways there are of putting a question to the system, we are going to describe the process of encoding the question in more detail. It begins, as in the case of formula input, with the drawing of the structural fragments required to be present (or absent) and a numbering of atoms (except for hydrogen) and rings (Figs. 5 and 6).

The sequence of numbering is quite arbitrary, but it is possible to save much computer time by following certain rules; for example, it is preferable to start with the least common hetero atom and then to number in the direction of some other uncommon characteristic. As has already been indicated, it is possible to put a number of partial structure requirements linked by the logical operators AND, OR, and NOT to the same formula on the same question form (Fig. 7); for this it is possible to ask for the identity (overlapping) or nonidentity of individual atoms in different subquestions (col. 20–22) and also to require or prohibit that individual atoms should belong to given ring parameters (col. 23–25). In addition to this, several inquiries can be combined into one (col. 5); it is then required that the inquiry structures should occur in the same document, *e.g.* in a starting material and in an end product.

The question form is filled in by first placing a "1" in column 11 (logic operator); further subquestions start in this column with a number corresponding to their logic. In columns 12 and 13 is entered the number of the atom or ring to be described, in this case "01", and in columns 15–16 the symbol for the element or pseudoelement. Further characteristics for this parameter are entered into the appropriate columns of the same line.

The last four double columns cannot be used for the moment, since up to the present our program has not taken these characteristics (complex bondings, reactions, chirality, and mass) into account. Most of the columns describing properties of the parameter have a logic (L) column prefixed to them; this indicates whether the property in question is required or prohibited, or whether it is to be greater than, less than, or equal to a given value.

In the case of the following atoms it is assumed – provided that there is no entry in column 11 – that they are bonded to the atom immediately preceding them, and the type of bond is indicated in columns 17–19. If more than one type of bond is permitted, then their code numbers are added together and the sum is en-

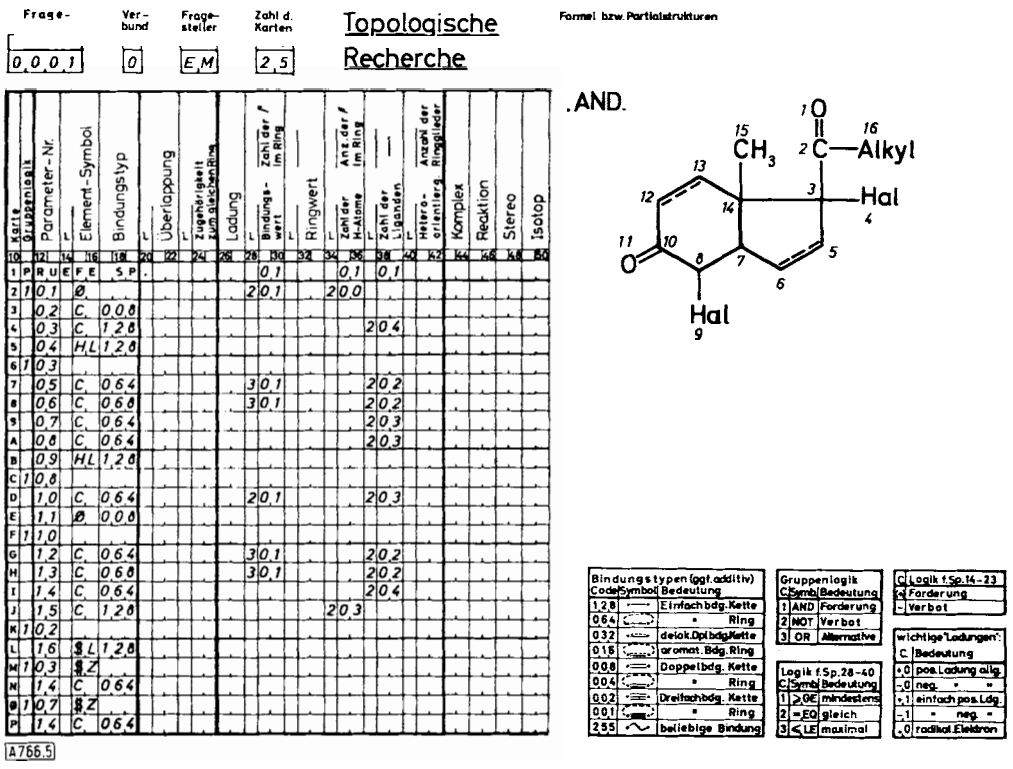

Fig. 5. **Sample question: the type of compound required is shown in the formula.** At the points marked the ring may have double bonds but no substituents, and no further rings may be condensed with it.

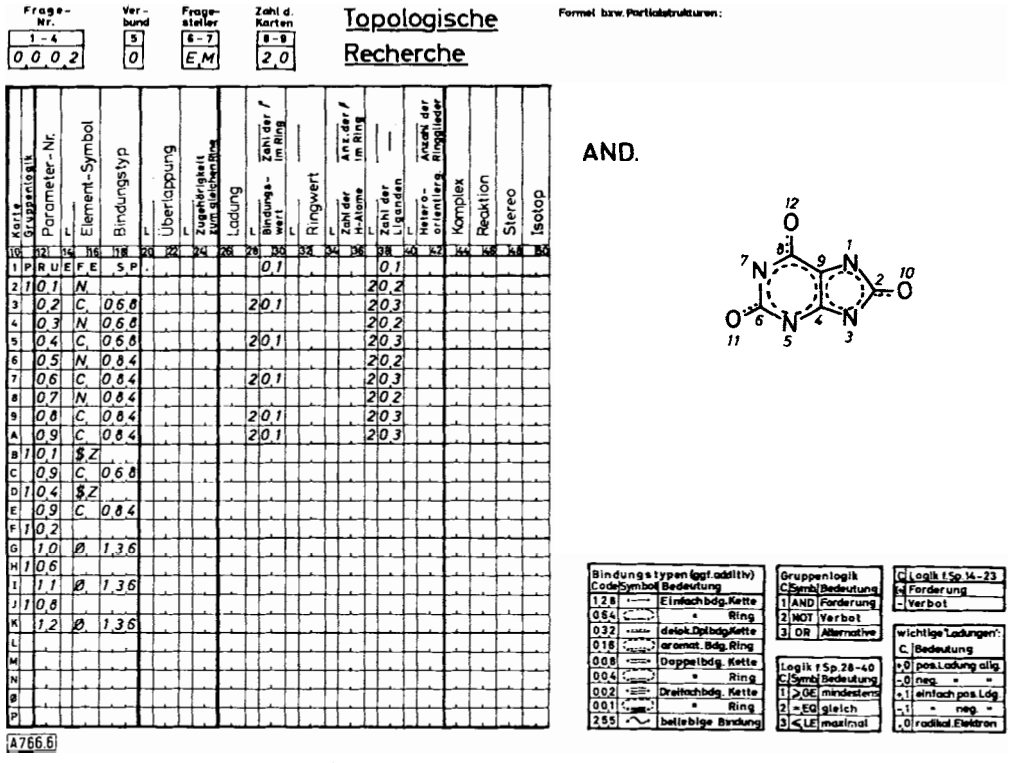

Fig. 6. Sample question: search for all the tautomeric formulas of uric acid and its esters.

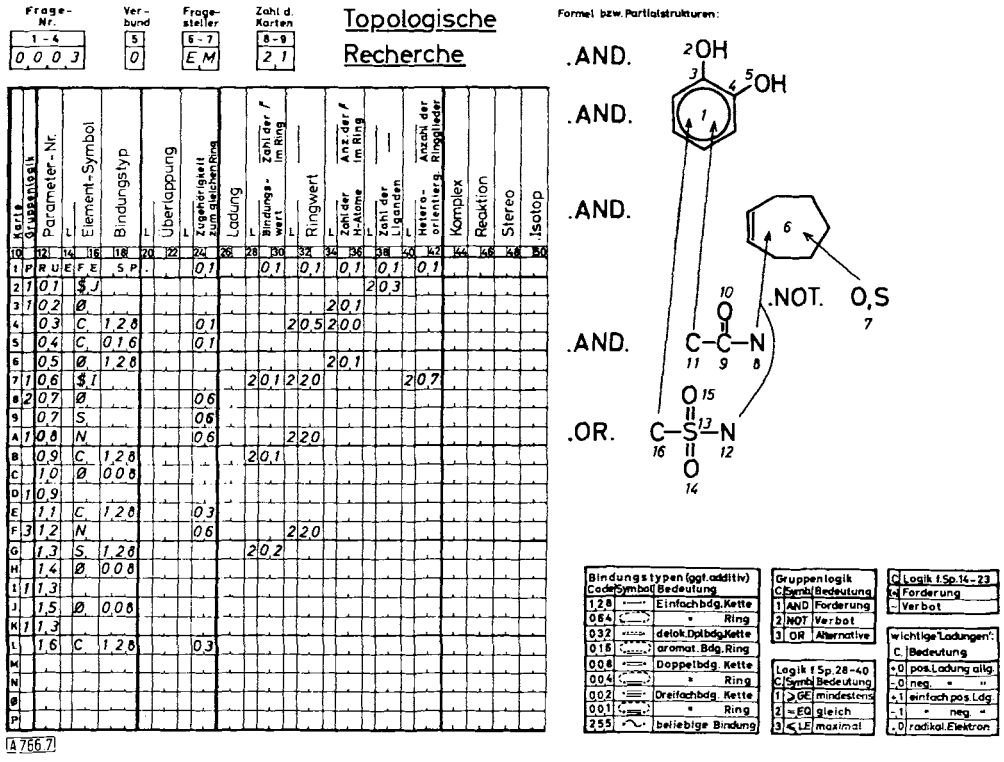
tered into the computer memory. (The fact that the code numbers are all in powers of two will make it at once obvious to the expert that we are working with bit strings and masks, and thus the use of alternatives does not require any additional machine time.) If a continuous chain of atoms has been coded in this way and we then want to jump back to a branching point from which a side chain is next to be encoded, then we must first of all enter a "1" in column 11 of a new line and then repeat the number of the branching point in columns 12–13; the rest of this line is empty. Ring closures are coded in a similar way, but here the symbol "$Z" is entered in the element symbol column, and in the following line are given the atom number of the ring closure partner, its element symbol, and the type of bond required for ring closure.



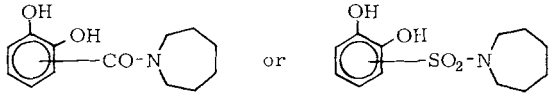


Fig. 7. Sample question: a search for all compounds having the formula

in which the pyrocatechol ring has no other substituents or rings condensed with it, and the seven-membered heterocycle has one double bond but does not contain either oxygen or sulfur.

The "overlap" column is used when a parameter of a given partial structure is to be identical (or nonidentical) with a parameter from a previous partial structure; the number of the earlier one is entered here (in the second partial structure the atom or ring would be given a new number). In the same way, the number of a previously quoted ring or ring atom is entered into columns 24–25 if the atom which is being encoded is to belong (or not to belong) to the same ring. Some of the columns have different significances when ring parameters and not atom parameters are involved; if required, it is possible to enter the number of double bonds in the "bonding value" column, the number of triple bonds in the ring in place of the number of hydrogen atoms, and the number of ring members in place of the hetero orientation. This permits question formulations of the type "Heterocycle with at least seven members and not more than two double bonds". (The maximal ring that can be stored as a ring parameter is a nine-membered one; larger rings can only be searched for as chains with ring closure.)

As already mentioned, alternative formulations can be coded as partial structures in their own right with the appropriate logic operators. If the only alternative requirements are individual atoms or pseudoelements the coding is even simpler; they are given the same atom number and are thus entered in successive lines of the question form (Fig. 7, rows 8 and 9).

Redundant data, *i.e.* those that can be derived from the rest of the question coding, do not need to be entered. Nevertheless, it is often expedient to do so, since then under certain circumstances the computer will discover more quickly that it is on a false track; this can save computer time but it should be remembered that an increase in the number of redundant data also leads to an increase in the danger of erroneous question coding.

For the simpler type of enquiry there is no need for all the columns of the question form to be used. In order to exclude these requirements from the question and thus to save computer time, we have introduced a "column vector". In the first line of the form an "01" is entered into each column to be used; the others are not checked. If one form is not sufficient for a question, others can be attached to it; in each continuation sheet the first line is struck out. Figures 5–7 show the coding for three sample questions, which illustrates some important search requirements and the way in which they are encoded. There is no space in the present article to describe further possibilities or details.

Once the form has been filled out and checked, the information it contains is transferred to punched cards, each line of the form being punched on a separate card. These cards, together with a list (on tape or disk) of the formula numbers that have passed the preselection steps, are fed into the computer with the search program and are then compared by the machine with the tape of topological data. In order to save reading time, the latter tape contains the main matrices in a greatly abbreviated form. The redundant data are still

explicity given, but the overwhelming number of zero elements of the matrices are suppressed by simple routines; it does not require a great deal of computing time to blow them up again in the core storage. The computer prints out the answers either in the form of literature references or as abstract numbers; in most cases we copy the abstracts and send them to the inquirer. If required, the structural formula can also be reconstructed from the main matrix by computer, and can be printed out. This may be done even during input for checking purposes; however, the commercial high-speed printers currently used are not very good at printing out formulas.

4. Conclusions

The computer programs for the searches described have been written for the IBM 360 (OS) and have been tested out [12] – with the exception of the four question modes mentioned previously. These too are being written. "Complex" is intended for searches for co-ordinate bonds and also for significant hydrogen bridges. "Reaction" will be used when studying a series of reactions to specify an atom that has reacted or will react. "Stereo" will use a system suggested by *Petrarca, Lynch,* and *Rush* [13] to check whether a given atom has the required chirality or *cis/trans* position. (The real prerequisite for the practical application of the technique is an economic method of input; programs for achieving this with the aid of our formula reader have already been written for the IBM 7090, but they have not yet been rewritten for use on the 360.) Finally, "Isotope" will be used for compounds labeled in certain positions.

We hope that this documentation system will be a useful tool, particularly for the preparative chemist. Not only will he be able to get answers to his questions from chemical data banks more rapidly and certainly than before, but also the possibility of putting questions in a large variety of new ways should enrich and stimulate chemical research, provided that these possibilities are recognized and put to use. This should make it possible to plan the work more logically, and above all it should reduce the danger of unwittingly duplicating previous work.

TOSAR – A Topological Method for the Representation of Synthetic and Analytical Relations of Concepts

By Robert Fugmann, Herbert Nickelsen, Ingeborg Nickelsen, and Jakob H. Winter [*]

In mechanized systems used for searching in literature stores there is a steadily growing necessity not only to be able to formulate concepts as a search condition but also the characteristic connections under which these concepts appear in the inquiry. In this way the precision of the mechanized literature search is considerably increased. TOSAR has been developed in order to improve computerized literature searching in this respect.

1. Introduction

With the steady growth of chemical literature, increasing importance is being attached to all methods that allow the retrieval of relevant publications in response to a scientific or technical inquiry. Conventional indexes are quite helpful only if the inquiry is confined to a single concept, and only if the index contains a keyword for this topic. With increasing specialization in science and technology, however, it becomes increasingly difficult to express the subject of a question by a single concept, *e.g.* by a structural formula. A search for terephthalic acid derivatives or for propylene alone would nowadays result in the retrieval of more literature than anyone could afford to examine, unless he intended to write a monograph on this subject and was prepared to spend several months on the task, including the literature searches.

Normally the requester would be much more interested in being directed to literature on *e.g.* processes for the

oligomerization of propylene to form hexenes and higher olefins with a certain organoaluminum catalyst, with re-utilization of unreacted propylene for the continuous elimination of continuously formed impurities from the catalyst, with the result that the latter is continuously reactivated. The subject of the inquiry is thus much too specific to be sought under the concept "propylene" alone. This concept is "coordinated" with a number of others, and the requester is interested in only those publications in which these other concepts also occur and in which the relation between the concepts is the desired one.

To provide keywords suitable for inquiries as specific as that in the above example, in order to be able to narrow the literature selected, these keywords would have to be in the form of complete sentences. This would require many billions of highly "compounded" keywords of this type. No documentalist could memorize a keyword vocabulary of this size to ensure the assignment of the most appropriate keyword(s) to each publication in his literature analysis, since he would be unable to visualize all the relationships between these keywords. This, however, is a necessary condition for the selection of the most appropriate of a group of keywords. Moreover, the cost of compiling such an index would be prohibitive, as would the insuperable difficulties in its technical handling. Even with a much smaller vocabulary of such "precoordinated" keywords, as used *e.g.* in conventional subject indexes, the completeness of the references under each keyword leaves much to be desired. This is a necessary consequence of the size of the vocabulary from which a choice must be made during literature analysis and of the limited possibilities in the conventional, strictly one-dimensional index. There is thus no advantage to be gained from a further expansion of such keyword vocabularies in order to allow more specific inquiries.

A highly precoordinated vocabulary of keywords would also be unsuccessful for another reason. It is quite common for an author's statements to be so general and to embrace so many cases that it would take much too long to file each case individually with its own keyword. For example, the starting material for an oligomerization process may be given as ethylene, propylene, 1-butene, 2-butene, isobutylene, 1,3-butadiene, or a certain pentene. A separate keyword would have to be used for each of these processes to prevent the mistaken idea that several of these substances take part in the reaction simultaneously. If the monomers in a copolymerization process are given as A and (B or C or (D and E)) and F and/or G, one cannot expect to be able to represent such a complex logic by a single precoordinated keyword.

It has occasionally been suggested that these difficulties could be overcome by feeding the entire original text of a publication into a computer memory and providing the possibility of retrieving any word or any sequence of characters, *e.g.* "propylene" or "oligomerization", from such a text. It may appear from a superficial examination that this satisfies all the requirements for a reliable search, since all the information supplied has apparently entered the memory in a retrievable form. Before the machine can carry out the search, however, it needs a precise order indicating which particular sequences of characters and words are to be retrieved from the stored texts. It is however a fundamental error to believe that it is easy to formulate such an order, or even that it is a task with which the scientist is familiar from his own literature searches. Recognizing the intended meaning of a given text, which is an operation that is always carried out by the expert reader, is quite different from guessing the words in which an author might have described the subject in question. But just that is required in phrasing an inquiry for a mechanized search in the original texts. The first case involves *a posteriori* judgment, while the second requires *a priori* judgment.

Reliable predictions of this nature are possible only if some law governing the event in question is known. No such law is known at present for the words chosen by an author to describe a given subject. One is therefore reduced to guesswork when one wishes to carry out a mechanical search for propylene in the original text ("C_3H_6"?, "propene"?, "C_2 to C_4 olefins"?, "olefinic cracking gases, with a boiling range of 50–60 °C at 20–22 atm?, "... the gaseous reaction products from the dehydration of isopropanol"?, *etc.*). Moreover, how can one allow for the possibility that only the structural formula is given? Lucky finds can undoubtedly be made by these methods, but the procedure could never be described as reliable.

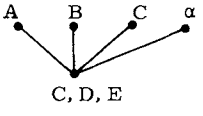
A first step toward the solution of this problem is to bring all the concepts named or implied by the author into a form that is *foreseeable* for future searches. To do this one must either keep a continuous record of all the words that have already been used for a given concept in the stored documents or else translate all the important concepts into a controlled, standardized vocabulary. Morever, in case of an inquiry, instead of using a highly compounded, precoordinated keyword for the concept or for a combination of concepts (*e.g.* "continuous oligomerization of propylene to give hexene and nonene with continuous regeneration of the trialkylaluminum catalyst", *etc.*), one uses a number of "elementary" keywords, which serve merely as conceptual building units. Thus the keywords assigned to a patent might be "catalyst", "continuous process", "cracking", "dimerization", "fractional distillation", "hexene", "isoprene", "nonene", "propylene", "recovery", "regeneration", "trialkylaluminum", and "trimerization". For an inquiry of this kind, the highly compounded keyword under which the relevant literature is to be listed is formed only at the time of the inquiry, *i.e.* by "postcoordination". A special multidimensional search technique must then ensure that only publications in which all the keywords of the inquiry occur in coordination are retrieved from the literature store. A vocabularly of these elementary keywords can be kept much smaller and is easier to memorize than a corresponding vocabulary for all anticipated precoordinated keywords that can be built up from them. This is a principle common to all present-day mechanized documentation methods, such as manual and mechanical punched card systems, magnetic tape files, *etc.*

Mechanized literature searches based on this principle can still be disappointing. Though all the elementary concepts of the inquiry will be contained in the references retrieved, they will often occur in a context quite different from the one desired. For example, a publication may describe the oligomerization of hexene, the cracking reaction may lead to propylene, and

the recovery may apply to excess hexene instead of to propylene. The number of irrelevant publications retrieved in this way will increase with the volume of literature in the subject field in question. If *e.g.* only ten to twenty relevant references are present among one thousand references retrieved in a mechanical search, the subsequent intellectual separation of the relevant from the irrelevant will be tedious in view of the large proportion of the latter, and the usefulness of the documentation system will accordingly be doubtful.

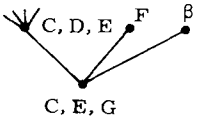
In the long term, therefore, we cannot be content with breaking down highly compounded concepts into their elementary concepts and posting the respective documents under these concepts. In addition, it is necessary to show how these elementary concepts fit together to give the meaning of the original publication. Only then are the author's statements satisfactorily represented, and only then can relations among concepts be used as a condition for the mechanical search.

The documentation literature contains many suggestions and reports on the representation of relations between concepts in storage and in inquiries. A survey of the present position in this field was provided by a symposium devoted to this topic[1]. In one method that is relatively widely used, for example, a syntactic indicator (role indicator, functor, relator) is attached to each concept. This shows more or less clearly the function of a concept in relation to the accompanying concepts in a publication. Examples for these indicators are "starting material", "reaction product", "isolated substance freed from impurities", and "auxiliary material in syntheses". The failure however to specify the particular synthesis in which the substance is a starting or auxiliary material, which impurities in particular have been eliminated from a substance, *etc.*, inevitably leads to irrelevant documents among the ones selected.



In another method, concepts that occur in the same sentence of a text or in the same paragraph are regarded as being particularly closely related. All the concepts in such a formal section of the document are denoted by a common character ("link"), by means of which they can be distinguished from the concepts in a different section. However, since the boundaries of the conceptual relations frequently do not coincide with these formal sections of the document, inaccuracies and distortions again occur.

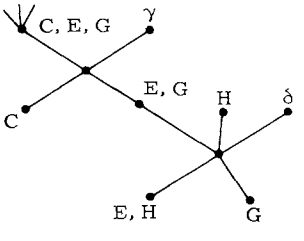
Methods based on graph theory have also been used for the mechanical handling of relations between concepts[2]. However, the graphs have always been built up entirely automatically, and not constructed intellectually by an expert after analysis of the publication to be stored.



In this article we shall describe a new graphical model for the representation of these relations between concepts, for which we chose the acronym "TOSAR"[*]. In this model a graph is drawn by the documentalist, displaying the relations of the concepts of the documents to be stored or of the inquiry. Since certain principles must be followed in the construction of such a graph, the relations between the concepts assume a form that is forseeable in later searches. All the concepts in this graph and the relations between them are coded and introduced into the memory of a computer. These graphs can then be retrieved by any relevant inquiry with the aid of suitable machine programs.

2. Principles of the Graphical Model

A graph is an abstract system of lines and points, the mathematical rules of which are described by graph theory, a subsidiary field of topology. Concepts whose relations with other concepts are to be represented are assigned to the points. The relations between the concepts are represented in the usual manner by lines joining the points. Each process that is carried out experimentally (or that is thought of as being carried out) is represented by a series of levels. The principal concepts *before* the process in question (α, β, γ, δ, *etc.*) are arranged in a level of their own, and the resulting concepts *after* the process are united in one point on a lower level. All the initial concept points are connected to the result point by lines.



"The substances A, B, and C undergo the reaction α, which leads to the new substances D and E, while the substance C (*e.g.* a solvent) is still present" The fact that A, B, and C are substance concepts whereas α is a reaction concept is also expressed but the details will not be discussed here.

The mixture of substances C, D, and E can undergo a further reaction β on addition of the substance F, as a result of which the substance G is formed from D and F. C and E are still present unchanged in the mixture.

The solvent C is then removed from the mixture of C, E, and G by distillation γ, and E and G in the resi-

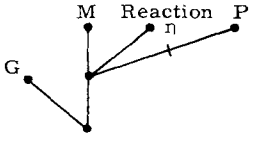
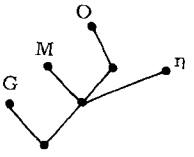
[*] *T*opological Representation of *S*ynthetic and *A*nalytical *R*elations of Concepts.

due are separated (δ) with a solvent H in which only E is soluble.

Just as the figure  is characteristic of the combination of substances, so its inversion denotes any separation of the components of a mixture. If the separation yields several fractions, the topological figure assumes a form such as



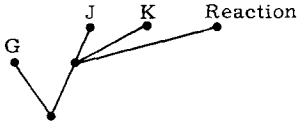
The substance G is now allowed to undergo the reaction ε either with a mixture of I and J or with the product obtained from K and L by the reaction ζ. However, the reaction ε with G may also be carried out using a product obtained from M and N by the reaction η, which is carried out in the presence of O and/or P.



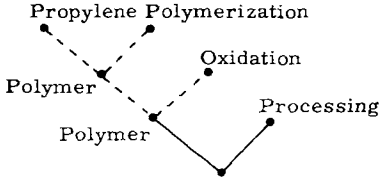
The reaction leads to the class of substances Q, *e.g.* to the individual compound R, S, or T, depending on the reactant used with G.

If two concepts are mutually exclusive, such as the mixture I and J on the one hand and the reaction product of K and L on the other, they are connected to a point indicated by an unshaded circle. If this exclusion occurs at a result point, the alternatives are written inside a circular figure, like the concepts Q, R, S, and T. The mutual exclusiveness of the concepts Q, R, S, T exists insofar as only one concept at a time must be mechanically detectable at that point but never a combination of these concepts. If on the other hand the exclusion is merely potential, a double circle is used, as for the concepts O and P. This logic can be extended over any number of levels, and the relationships can always be clearly recognized by the reader.

For our documentation purposes, it was necessary to be able to store this representation of the relations between concepts and to compare them by computer with the respective representation of an inquiry. An inquiry containing any combination of the concepts α to T should yield a stored graph as an answer if and only if its concepts are connected in exactly the desired manner. For example, the above figure is clearly relevant to an inquiry expressed as follows:



"G is to have reacted with a reaction product of M. Any other substance except P may be present during the reaction of M". (The cancelled line leading to P in the inquiry graph means that P is negated in the connection indicated.) Obviously, the graph in the file contains the partial statement: "G is allowed to react with the reaction product of M, which is formed in the presence of O (and not necessarily of P)":



Apparently, a certain concept can be negated in an inquiry only if this exclusion can be precisely restricted to the context intended. No conclusion can be drawn from the mere occurrence of a negated concept in a publication, since the negated concept may be mentioned in a purely incidental, "innocuous" context, *e.g.* as a substance for comparison of properties, as an auxiliary substance for the synthesis of secondary products that are of no interest to the requester, *etc.* However, negations in the inquiry inevitably result in the loss of relevant information if the context of the concepts in the stored documents is not preserved, as frequently occurs in modern mechanized documentation.

The stored figure is not relevant to an inquiry: "Reaction of G with a reaction product of J and K":

It is of no importance in this model whether or not the structure of a substance is known, and indeed whether there is any valid designation for the substance. Its identity *e.g.* as the reaction product obtained from certain starting materials, as an extract from certain organs or plant parts, *etc.*, is unequivocally fixed by the topologically defined position in the graph. The substance concept can thus be reliably retrieved.

Processes for which the experimental procedure was not expressly described, but was merely implied, in the publication or patent to be stored are represented by broken lines. For example, if the processing of a partly oxidized polypropylene is described without a detailed description of the preparation of the polymer itself, the corresponding figure is:

In an inquiry for a particular process, one can choose whether the answer will include only publications in which the process is *expressly described*, or whether *implied* processes are also of interest.

A surprisingly large number of property and process concepts prove on closer examination to be highly compounded. Conceptual analysis to determine the elementary concepts from which they are built up would make them easier to handle in documentation. The elementary concepts, together with the relations between them, would be the ideal replacements for compounded concepts of this nature. Examples of such compounded concepts are "fungistatic thiocarbamic esters", "insecticides that are harmless to bees", "zone melting methods", and "halogenated hydrocarbons having only limited miscibility with glycerin above 60 °C". The analytical approach has been seriously hindered in the past by the fact that while the constituent elementary concepts can be represented with sufficient accuracy, their characteristic mutual relations cannot. Consequently, an essential part of the information contained in the compounded concept would be lost in the analytical treatment of these concepts. This would inevitably lead to the inaccuracies that have already been mentioned. A method of representing relations between concepts precisely and clearly smooths the road to a consistent analytical treatment even of concepts that are not concerned with structural chemistry.

2.1. Example of the Use of the Graphical Model

Let us now take an example from chemical processing (abstract of French Patent 1356225) and consider some of the many types of inquiries that can already be answered by this model using our existing programs:

In the oligomerization of olefins, such as propylene, to obtain unsaturated oligomers, *e.g.* hexenes and nonenes, the activity of the catalyst steadily decreases as a result of the catalyst being loaded with the oligomers formed. A reusable catalyst is regenerated from the oligomerization mixture as follows.

Propylene and the oligomerization products are distilled off from the catalyst in a fractionation column A under pressure. In a second column B in series with the first, propylene is separated from the oligomer mixture, which consists mainly of hexene and nonene, by fractional distillation. The propylene is partly returned to the oligomerization reactor, while the remainder is introduced into the lower part of the column A to free the catalyst collecting there from the last traces of oligomer. This operation is carried out at a temperature below the decomposition range of the catalyst and below the boiling point of the contaminating oligomers.

The purified trialkylaluminum catalyst is continuously removed from the base of the column A and returned to the oligomerization reactor. The hexene fraction formed can be used for the production of isoprene by cracking.

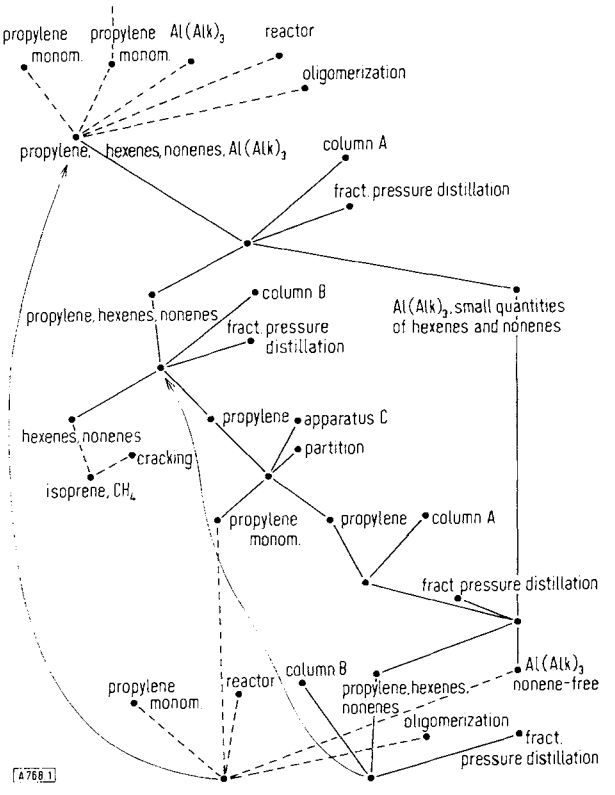
These processes can be represented graphically *e.g.* as shown in Figure 1.

It should be mentioned that it is often impossible to write an abstract of a patent until the relations have been represented graphically in some way.

The partition or separation of a system of substances and the subsequent recombination of the substance flows is evident from the presence of a cycle in a graph of this process.

If a substance or a mixture of substances is recycled, this is also shown in the graph in a characteristic manner. If one follows the purely chronological flow of such a substance, the substance will be found in the same apparatus twice, having left it once in between, and on both occasions it will be associated in this apparatus with exactly the same other substance and reaction concepts. The points at which the same set of concepts is found at different times are joined in the above graph by nonlinear arrows.

It is also possible to see whether a substance is introduced into a reaction as fresh material, or whether it is recovered from the reaction products and returned to the reaction. For example, only part of the propylene used in the oligomerization is fresh feed, while the remainder has been recovered from the process. The point representing freshly introduced



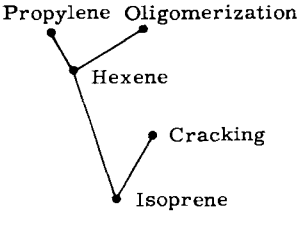


Fig. 1. Relations between the concepts in French Patent 1356225.

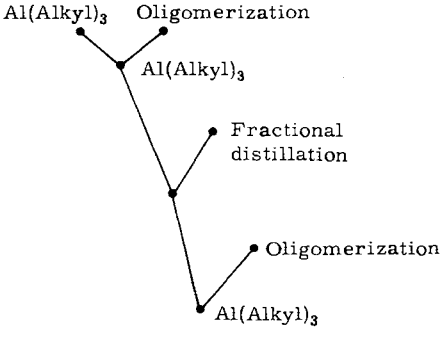
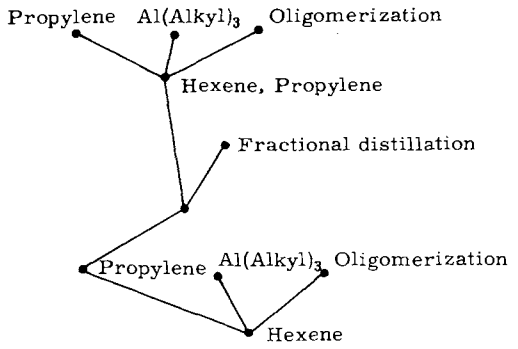
propylene has no connecting line from above. However, this is not covered by our coding method at present, and therefore cannot be specified in an inquiry.

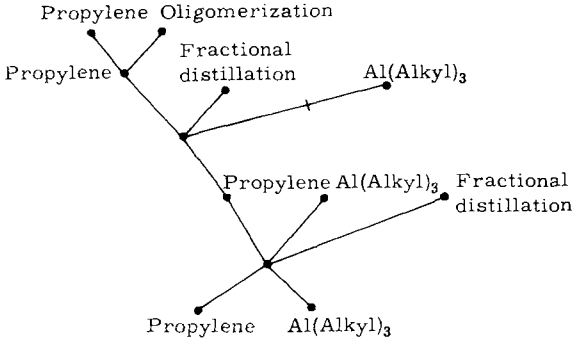


We now consider a series of relevant inquiries from this field, and describe their formulation in accordance with our model, as well as the result of the mechanized comparison of the inquiries with the stored graph.

1. "Production of isoprene by cracking of hexene obtained by oligomerization of propylene".

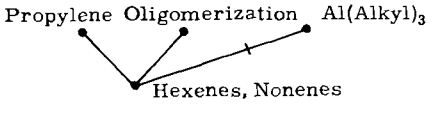


The inquiry can be formulated graphically as follows:



2. "Use of an Al(alkyl)$_3$ catalyst for an oligomerization and its reuse for the same process after purification by fractional distillation".

3. "Oligomerization of propylene with the aid of Al(alkyl)$_3$ to obtain hexene, and separation and purification of the excess propylene by fractional distillation and recycling of the propylene".

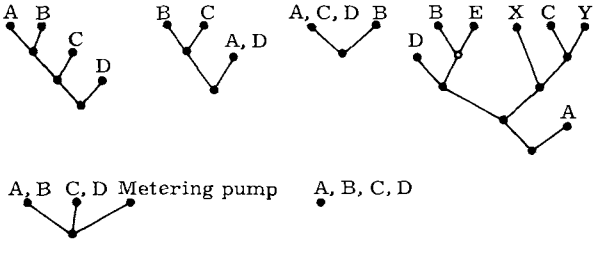


4. "Fractional distillation of $Al(alkyl)_3$ with the aid of added $Al(alkyl)_3$-free propylene that has previously been fractionally distilled and recovered from an oligomerization process".

Topological comparison of the inquiry graph with the stored graph shows that agreement exists in all these cases, *i.e.* the bibliographical data for the stored graph are retrieved in response to these inquiries.

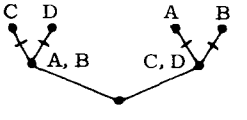
On the other hand, this patent would rightly not be selected as an answer to an inquiry of the type: "Oligomerization of propylene with catalysts other than $Al(alkyl)_3$ with formation of hexenes and nonenes".

3. Principles of the Comparison of the Inquiry Graph and the Stored Graph



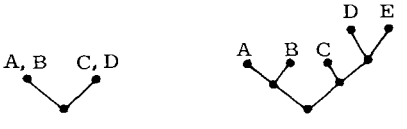
As can be seen from the examples, the mechanized check to establish whether a stored graph is relevant to an inquiry graph cannot be a simple process. For example, a process can never be satisfactory which merely aims at finding those stored graphs of which the inquiry graph is a congruent part. More exactly, one cannot simply try to recognize the inquiry graph homeomorphically and simplicially in the stored graph and regard stored graphs for which this is possible as being relevant to the inquiry.

Such a simple process would fail even for the first of our examples, since the stored graph showing the treatment of the oligomerization products of propylene contains no direct connection between the hexene formed and the isoprene produced from it, whereas such a connection is present in the inquiry graph. On the contrary, the hexene passes through a series of separation and purification steps in the stored graph before being subjected to cracking. However, these are processes whose occurrence or non-occurrence may be purely incidental to the requester and in respect of which he consciously does not wish to commit himself. Moreover, the publication could be of interest to the requester even if the hexene were combined with other substances before reacting further. The hexene may have formed inclusion compounds, been distributed in two-phase systems, *etc.* to allow the separation of impurities. If the requester was always forced to commit himself with regard to details of this nature, which are of no interest or of no importance to him, and whose occurrence in the interesting publications is unforeseeable, the documentation system would be of no help to him. By making a decision about restrictive details of this type, he would be cutting himself off from valuable sources of information. His position would be similar to that of someone looking for a *group* of substances in a molecular formula index; in looking for a basic structure he is compelled to specify the nature and number of the substituents, which are of no importance to him.



For the same reason, it must not be necessary, *e.g.* in an inquiry for a certain multicomponent system, to specify the order in which the components are brought together, whether *e.g.* two of them are premixed before being combined with another component (or with a mixture of other components), *etc.* If these requirements are satisfied, an inquiry graph having the structure

A, B, C, D



will yield as responses graphs of the following types:

If on the other hand a condition of the inquiry is that a mixture of A and B be combined with a preformed mixture of C and D, the inquiry graph

should produce as a response only the stored graphs of the types:

The mathematical theories now in existence offer no help for the comparison of two graphs in the system described above. Thus graph theory, *i.e.* one-dimen-

sional combinatorial topology, describes in detail the general properties of graphs, and the inquiry and stored graphs described here are no exceptions in this respect. However, graph theory provides no solution for the special procedure according to which the comparison of an inquiry graph with a stored graph must be performed in order to satisfy the requirements of chemical documentation.

Symbolic logic, on the other hand, shows how logical expressions can be transformed in various ways, but does not deal with the logic described above on the basis of which the relevance of a stored graph to an inquiry graph must be judged.

These mathematical disciplines merely suggest certain machine-processable forms for the representation of the publication and of the inquiry in the memory. The principles in accordance with which the two graphs must be compared in a practical literature search, on the other hand, had to be constructed by us specially for this purpose, on the basis of numerous individual pragmatic considerations. The outcome of these considerations has been a very comprehensive computer program. This program is still being improved to increase convenience of storage, as well as precision of retrieval and flexibility in the inquiry.

To enable such a machine program to be advantageously used in chemical documentation, it must be combined with another program whose purpose is to find the *desired concepts themselves*, irrespective of their mutual relations. For, until it has been established that the concepts of the inquiry do indeed occur in a stored document, it is pointless to instruct the machine to search for the desired relation between these concepts. We are currently engaged in bringing about the successive execution of two such machine programs. The preselection on the basis of the concepts themselves is being carried out by the method already being used by the IDC in searches for chemical concepts [3].

4. Outlook

If one considers the familiar structural formula from this angle, it may also be regarded as a graph, though one with special properties. Here, each point is occupied by an atom. The bonds between the atoms form the lines of the graph. The structural formula may in fact be regarded as a highly compounded concept built up from many elementary concepts, *i.e.* the atoms themselves. Experience spanning more than a hundred years has shown that this analytical consideration and representation of the structural formula is incomparably clearer than the complex nomenclature or any arbitrarily fixed trivial name for a substance. This approach is also much more fruitful heuristically, since it clearly displays the relations between substance concepts.

In this light, the graphs described are nothing but the application of the idea of the structural formula to the whole context of a publication. The gain in clarity becomes obvious if one compares the graph drawn above with the original patent. We are therefore watching very carefully the reactions of our colleagues engaged in research and production to graphs of this nature which serve them purely as a rapid information medium, possibly in conjunction with an abstract or with the original text.

This work was supported by the Bundesministerium für Bildung und Wissenschaft. We are grateful to the member companies of the macromolecular chemistry documentation study group for stimulating discussions.

The "Dokumentationsring der chemisch-pharmazeutischen Industrie"; Aims and Methods

By Wolfgang Nübling and Walter Steidle [*]

The members of the Documentation Ring have chosen the "punched picture" method for coding of chemical and pharmaceutical literature. Chemical, biochemical, and medical facts gleaned from a publication are broken down into basic concepts, each of which is allocated a certain position on the punched card. This system has proved to be reliable over a period of twelve years.

1. Introduction

The "Dokumentationsring der chemisch-pharmazeutischen Industrie" was founded in 1958 [1] to provide, by improving present methods and developing new ones, a more thorough collecting of chemical and related literature, thereby allowing better use to be made of this material. The Documentation Ring enables the individual member to make use of the Society's large total store of material at reasonable cost. Each member processes an essentially equal part of the whole of the sources (journals, patents, or other literature), this division of labor permitting even small and medium sized institutions to operate an extensive documentation system with punched card machines nowadays accessible almost everywhere.

In particular, the pharmaceutical, biochemical, and medical range covered by the Documentation Ring allows the members to supply universities and clinics with literature which is normally not available to them in such diversity. A desirable by-product of this development was the possibility of processing, on the same principles, the results of research carried out by the members themselves, and thus of collating published and unpublished material.

2. Organization of the Documentation Ring

Fifteen members [2] have now come together to find economical and quickly realizable solutions to the problems of documentation. The development of suitable codes for data processing plays a very important part in this work.

Collecting and processing literature from the field of pharmaceutical chemistry involves special difficulties. The subjects concerned cover a particularly wide field, including medicine, chemistry, and pharmacy. Data relating to all of these fields must be collected from the publications and stored in suitable filing systems, since only then is it possible to retrieve the required data later at reasonable cost. At all times it must be possible to establish the relationship between a chemical substance and its application or effect.

The numerous users [3] employ widely different computer systems; punched cards, however, constitute a suitable input medium for almost all of them. In addition there are no problems involved in exchanging punched cards at short intervals, *i.e.* when their numbers are small. This ensures that all members can quickly be supplied with up-to-date material. Our aim originally was to make sure that the system could be used with simple punched card machines. In spite of the fact that the majority of users in the meantime are making use of magnetic tapes and disk units for retrieval even today some members are still coping with the material assembled up to now [4] with the aid of simple sorters *etc.*

Furthermore, punched cards allow special card indexes to be set up which cover separate fields only or which are presorted on specific principles. If decentralized, these special card indexes can considerably facilitate the work of individual centers, or in conjunction with very simple sorting machines, they can solve certain problems with a minimum of time and expense. Finally, other interested people can acquire and use such subindexes, thus solving their special problems with a reasonable expenditure of effort.

[3] Since 1964 Derwent Publications Ltd., London, have been evaluating the literature on the basis of the system developed by the Documentation Ring for processing "pharmaceutical" literature in the widest sense. Since then this literature service has been available in an extended form to more than 100 subscribers under the names Ringdoc (literature on pharmaceutical chemistry), Pestdoc (pest control literature), and Vetdoc (veterinarian literature).

[4] Since the Documentation Ring was founded, about 500000 articles *etc.* have been abstracted. Their content is recorded on more than 1.5 million punched cards.

We prefer a decentralized retrieval system to a centralized one. It takes less time to process data within one's own organization. The best result is assured only by a permanent dialogue between the inquirer and the file. This implies good collaboration between the inquirer and the documentation center, since only the documentation specialist is able to put the inquirer's question into the form which suits the storage method best.

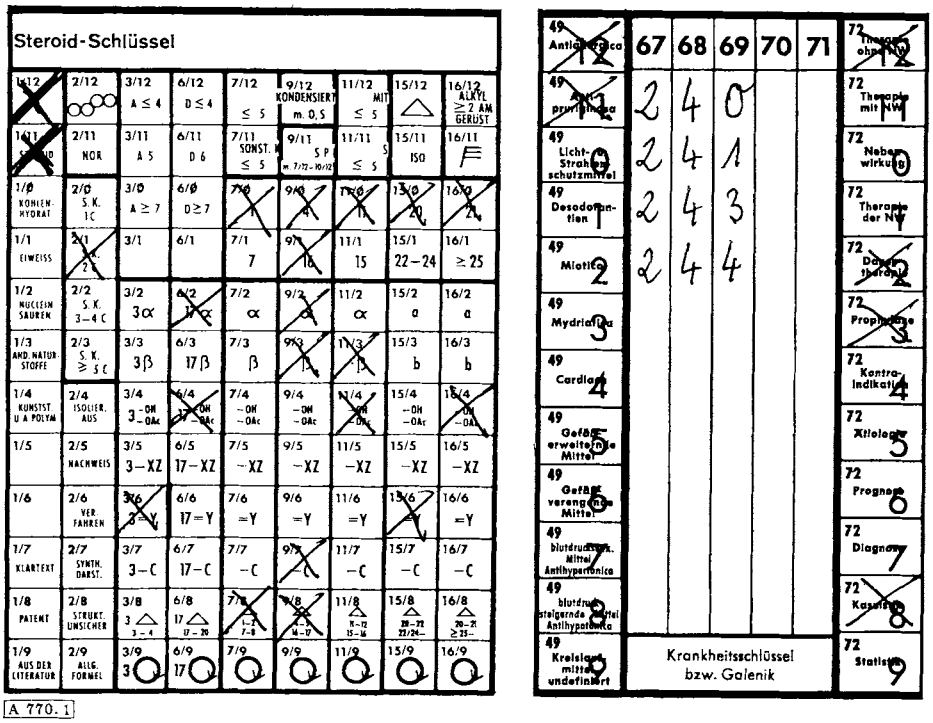
The ever-increasing costs for the machinery of a modern documentation center, however, will sooner or later necessitate a central storage unit which is at the disposal of all members by means of suitable terminals. Moreover, only such a solution will allow optimal use to be made of the material stored by provision of suitable computer programs. This optimal use naturally involves not only the usual information concerning sources but also answers to unusual inquiries which, for example, give an early indication of development trends or automatically draw attention to advantageous combinations of methods in such fields as analytical or preparative chemistry.

3. The Documentation Ring's Coding Methods

In our choice of coding system we were governed by the desire to find a simple code that would as far as possible accord with the habits and thought processes of the specialists concerned with coding. It should be possible to encode quickly and without errors. The more complicated and unusual the coding system is, however, the more numerous become the errors. The filing of the material, *i.e.* the coding, should not take too long, since any system is acceptable only if the given volume of work can be dealt with in the time available. The coding time determines when the material stored is available for searches. Furthermore, the system should be easy to learn so that it can be used by the largest possible number of members. Only then can the costs be kept within acceptable limits.

These considerations led us to choose simpler and cheaper methods than the topological system for chemistry. These, however, do not always supply clear-cut results; in addition to the correct answers there is often a proportion of false drops, the number of which varies according to the inquiry. The documentation specialist, therefore, sometimes has to sift through the material supplied by the machine before he hands it over to the inquirer. In fact, since according to experience only a fraction of the total material stored is ever required again, the cost of input plays a very important role. Moreover, excessively narrow coding frequently leads to incomplete retrieval and loss of data that might be relevant or even necessary for a particular topic. To avoid this disadvantage all necessary concepts must initially be thought out at length. In the majority of cases, however, the specialist whose job is the correct formulation of such precise inquiries for the computer comes up against considerable difficulties.

A carefully constructed fragmentation system eliminates these difficulties at source; the very act of selecting the fragments that have to be taken into account for a special question makes it possible to increase or reduce the number of relevant answers as desired. By separating the interconnecting characteristics from the fragments, the search often reveals combinations which neither the inquirer nor the documentation specialist has thought of, but which may be of great value for the inquirer's work.



The punched picture system has proved to be a particularly good way of recording the chemical, biochemical, and medical facts of a publication on a single punched card. Each fact to be included is broken down into basic concepts, and every basic concept is allocated a certain position on the punched card. In this way it is possible to request each basic concept alone or in any combination with other basic concepts. Each of the 960 punching positions, *i.e.* every bit, thus has a definite meaning. This holds good not only for chemistry, where the fragment code is nowadays already in general use but also for medicine, biochemistry, and biology, where organisms, organs, pharmaceutical activities, metabolism, and physiology are covered on the same principle.

The coding of a publication usually involves the preparation of several punched cards. Superposition rules show which compounds and facts can be overcoded on the same card. These rules prevent the store from becoming too large but on the other hand may lead to false drops being obtained during searches.

In this way the use of keywords is avoided even for non-chemical facts. We believe that, because of the linguistic nonuniformity, because of the possibility that different keywords will be used by different workers, and because of their one-dimensional nature, keywords are not an ideal medium for the documentation of facts. Furthermore, they take up a relatively large amount of space on the magnetic tape or in the store, which, in view of the large and ever-increasing volume of literature, should be used sparingly, despite the enormous capacity of modern machines. It is naturally possible to avoid these difficulties to some extent by standardizing the terms and compiling thesauri in which the permitted terms are collected and the unacceptable expressions are referred back to the acceptable ones. This activity, however, entails a lot of work, must necessarily be spread out over a number of years, and is practically never-ending.

Bitwise classification, however, which means that there is a fixed address for every basic concept, allows unequivocal storage with very few aids. At the same time very rapid access is possible. By combining building blocks and by using numerical and alphanumerical codes in partial fields one can satisfactorily reproduce all required data. Figure 1 shows an example for coding the treatment of diseases.

A further major advantage of our method lies in the fact that, because they are attached to punched cards, forms can be used as coding sheets on which the positions provided for chemical and biochemical data and

reaction steps are printed so that it is easy for the coder to do the work correctly. The necessity for coding on preprinted coding sheet ensures that the encoder is always aware of the possibilities that exist and also causes him to use these. Coding errors and the omission of codable concepts are thus reduced to a minimum. The use of document readers nowadays saves manual input with its scope for error.

We know no other system with such an ideal relationship between input and output costs, especially since the percentage of punched cards retrieved in one search averaged out over a fairly long period, is only 0.02% of those consulted. Because the indexes are presorted, only a fraction of the store is generally searched through. Furthermore, since normally several punched cards lead to the same abstract, the number of literature sources obtained as a result is extremely small, despite the false drops described above. We therefore came to the conclusion that more expensive systems would be uneconomical.

After laying the foundations for documentation in pharmaceutical chemistry [5], the Documentation Ring now turns its attention to other problems. We wish to mention here only the documentation of chemical reactions [6], and the coding of carbohydrates, pharmaceutical specialities, and Markush formulas. All these projects rely on the same basic principles, thus building up one integrated system of documentation.

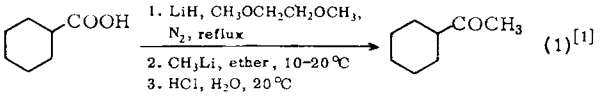
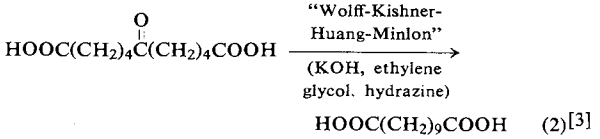
A System for the Documentation of Chemical Reactions



By Oswald Schier, Wolfgang Nübling, Walter Steidle, and Jacques Valls[*]

The Documentation Ring of the chemical and pharmaceutical industries uses a punched card system to record chemical reactions. The starting materials and the end products are encoded with a fragmentation code, and the bonds that change during the reaction are recorded in the same way. Reaction modifiers and physical data can also be stored. In the case of multistage reactions, both the individual stages and various groups of stages are recorded.

1. Introduction



It is basically more difficult to record chemical reactions than it is to record chemical substances. A substance is an independent concept, generally defined by formula or name, if not by both. On the other hand, in a reaction we usually have several substances reacting with one another under defined conditions to form new substances.

A chemical reaction involves a large number of data: The starting materials; the end products; the bonds that react; the reagents used; and the reaction conditions. Even the simple reaction shown in eq. (1) comprises a considerable number of concepts which must be taken into consideration when it is recorded.

(1)[1]

Such reactions are not only difficult to record, they are often even difficult to name. In many cases this problem is solved by naming the reaction after its discoverers[2] rather than after the structural change that it brings about [eq. (2)].

[3] *L. J. Durham, D. J. McLeod*, and *J. Cason*, Org. Syntheses, Coll. Vol. IV, 510 (1963).

These difficulties in the documentation of reactions are one of the reasons why it is not merely the chemist's experience and intuition that are put to the test when he is trying to devise a new synthetic route. The decisive factor may often be his ability to find the appropriate individual reactions in the literature.

Conventional methods of recording facts fail when it comes to the complex network of data represented by a chemical reaction. Only modern documentation techniques can achieve this. Some years ago *Ziegler*[4], among others, described a method for recording chemical reactions on field-punched cards.

Having solved problems in medicinal chemistry documentation[5], the Documentation Ring of the chemical and pharmaceutical industries turned to the task of developing a card system for chemical reactions. The present article reports the results of this work. After extensive tests, the system is to be made generally available with a data base of 25000 abstracts.

2. Method of Documentation with the Reaction Card File

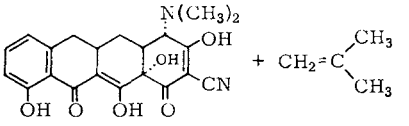
The choice of a documentation system is determined by the amount of material to be recorded and the number of concepts occurring together or in conjunction with one another. In the case of a card system for reactions, the minimum number of individual reactions to be recorded is of the order of 20000; for example, the 24 volumes of *Theilheimer*'s "Synthetic Methods of Organic Chemistry"[6] which have appeared up to now contain in themselves more than 22000 examples of reactions, with many additional literature references. We must also reckon that our card file is going to grow at the rate of at least 2000 references per year.

A file of this size would be difficult to operate as an ordinary card index and would not work well with peephole cards or with edge- or field-punched cards. It would be unable to cope with the multiplicity of

[4] *H. J. Ziegler*, J. chem. Documentation *6*, 81 (1966).

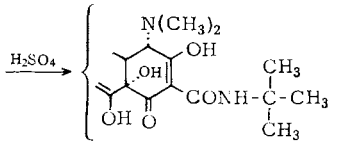
[5] a) Cf., *e.g.*, *M. Scheublein, W. Steidle, W. Germann, W. Nübling*, and *R. Wilhelmi*, Naturwissenschaften *55*, 362 (1968); b) *W. Nübling* and *W. Steidle*, Angew. Chem. *82*, 618 (1970); Angew. Chem. internat. Edit. *9*, 596 (1970).

[6] *W. Theilheimer*: Synthetic Methods of Organic Chemistry – Synthetische Methoden der Organischen Chemie. S. Karger, Basel, New York, Volumes 1–24 (1946–1970).

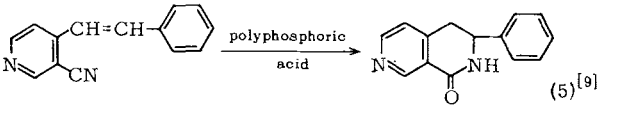


concepts to be considered for each reaction. Peephole cards can only represent one concept per card, and are limited in the number of items that can be handled. In the case of edge- and field-punched cards there are mechanical limitations, since the sorters have a maximum capacity of 250–500 cards and would thus need to be reloaded an impracticable number of times for an extensive collection.

We therefore asked ourselves whether the code for our reaction file should also be suitable for machine-sortable punched cards, or only for a computer. The normal punched card contains 960 punch positions, which is sufficient for a reaction card file. Modern punched card sorters are well able to cope with the number of cards expected; for example, an IBM 108 sorter can sort about 60000 cards per hour for up to 12 questions.



For the Documentation Ring's reaction card file a code suitable both for machine sorters and for computers was developed. We knew that this would deny us certain advantages that a system intended purely for computer can frequently offer. However, the deciding factor was the thought that a reaction card file should benefit the widest possible circle of potential users. Users with access to a computer can of course transfer the contents of the cards to tape, disk, or drum.

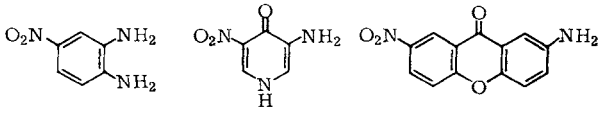


(3)[7]

(4)[8]

(5)[9]

3. Data Recorded in the Reaction Card File



At the start of any documentation system it is necessary to decide which data are to be recorded. It goes without saying that all the important data should be retained and all the unimportant data eliminated. These general considerations determine the code to be used.

3.1. Starting Materials and End Products

3.1.1. General Considerations

How important is the detailed recording of the starting materials and end products in a reaction card file? On this point we may note that when a chemist wants to make use of a reaction he is often looking for substances that have structural characteristics in common with the materials treated by him. For example, a synthesis described in the literature for a substituted amide from a nitrile can also be valuable in the preparation of an amide or a lactam of a completely different class of substances [eq. (3)–(5)].

In reactions (3) to (5) the sole search requirement was the reacting and the final functional groups. Often, however, it is necessary to search for parts of the molecule that do not take part in the reaction. For example, in the search for a selective reduction of dinitro compounds to nitroamines a second, nonreacting nitro group is assumed to be present. The nitroamines which are obtained from dinitro compounds by the same method (action of ammonium sulfide) can belong to completely different groups of substances [examples (6) to (8)].

(6)[10] (7)[11] (8)[12]

The previously mentioned search for "Amides from nitriles" could also be narrowed down by specifying that they should be aliphatic or heterocyclic nitriles, as in (3) and (5), or a nitrile of the tetracycline series, as in (4).

These requirements relate to parts of the molecule that react and also those that do not. The reaction card file should therefore contain the fullest possible record of the structures of the substances. However, the essential features are not the overall structures but rather those general formulas and partial structures which permit questions of the kind described.

3.1.2. Encoding the Data

The starting materials and the end products are encoded by means of the code developed by the Documentation Ring in 1958–1960 (see[5b]). In this code the substance concerned is broken down into partial structures, giving just the type of fundamental units

[10] *K. P. Griffin* and *W. D. Peterson,* Org. Syntheses, Coll. Vol. III, 242 (1955).

[11] *W. H. Crowe,* J. chem. Soc. (London) *127,* 2028 (1925).

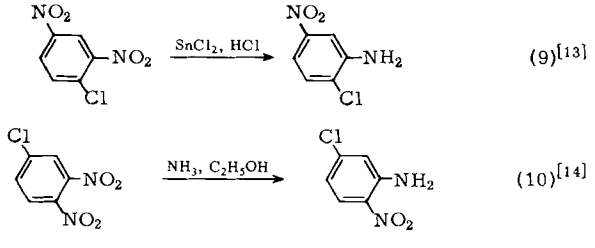
[12] *S. Dhar,* J. chem. Soc. (London) *109,* 744 (1916).

that are important in a reaction card file. For example, β-naphthylamine is encoded to give the fragments 1–4:

where

1. is a system of two condensed rings
2. is two condensed benzene rings
3. is a β-substitution in a condensed benzene ring
4. is a primary amine group at a double bond.

These data correspond to six holes in a punched card. Other naphthylamines with different substitutions would give the same punching (with the exception of the hole for the β-substitution) together with other holes for the appropriate additional concepts.

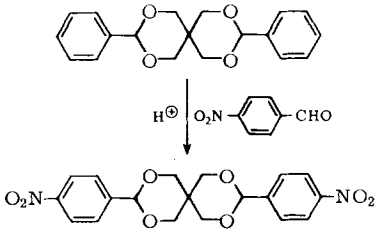


The coding and searching operations are simple. In breaking the substance down into its structural fragments, the code uses the same basic units to which the chemist himself is accustomed, and requires neither code numbers nor letter combinations.

The starting materials and the reaction products each require 27 columns of a machine-sortable punched card (324 hole positions each).

3.2. Modified Bonds

3.2.1. General



In general, the encoding of the starting materials and end products is not a sufficient record of a reaction. Even in simple cases it is often hardly possible to recognize the type of reaction if only the structures and no data on the reagents are given. Thus, in eq. (9) the nitro group is being reduced to an amino group, whereas in (10) it is being replaced by the amino group, which is a completely different reaction.

(9)[13]

(10)[14]

In the transacetalization in eq. (11), a comparison based on structures alone could lead to the assumption that it was a nitration[*].

(11)[16]

In any case, data on bond changes are also required for other reasons; for example, they permit a classification of reactions. Conversions of the type ester → amide, ester → lactam, ester → hydrazide, ester → acylurea, *etc.* can be summarized as

Bond change data are here independent of whether the reaction occurs in an acyclic structure or in a ring.

3.2.2. Encoding the Data

The bonds which are broken down in the starting material and formed in the end product are easily recorded. Thus, the reaction H–N → C–N (*e.g.* the alkylation of an amine) is recorded by the code as the two punch positions "H–N broken" and "C–N formed".

In many cases the environment of the modified bond is also of interest. For this reason it is possible to distinguish in the code whether, in the case of a C–H cleavage, the C–H is present in the structure $>C=\overset{|}{C}-H$ (*e.g.* in benzene), $>C=\overset{|}{C}-\overset{|}{C}-H$ (*e.g.* allyl), $-C(=Y)-\overset{|}{C}-H$ (*e.g.* the α-position in ketones, acids, *etc.*), or in some other structure.

The code enables the bond data to be amplified by providing further positions for the formation, cleavage, decrease or increase in the size of rings, and further reactions such as rearrangements, the conversion of a racemate into optically active compounds, stereospecific and asymmetric syntheses, and many more.

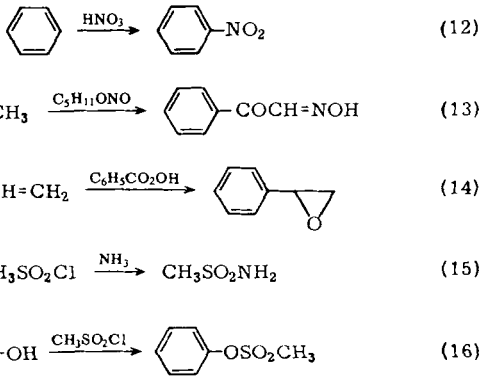
Eight columns (96 punch positions) are allowed for these data in the punched card used in our system.

3.3. Reaction Modifiers

3.3.1. General

Any organic chemical reaction usually involves a number of substances that are described as "starting materials", "reagents", "solvents", and other terms. In many cases the distinction between "starting material" and "reagent" is merely a reflection of the availability and frequent use of one substance as opposed to the other. For example, in eq. (12) to (16) the reagent is the substance above the arrow.

In the last two examples, the same substance is the "starting material" in one case and "reagent" in the other.



[13] *A. Claus* and *A. Stiebel*, Ber. dtsch. chem. Ges. *20*, 1379 (1887).

[14] *A. Laubenheimer*, Ber. dtsch. chem. Ges. *9*, 1826 (1876).

[*] Attempts have been described [15] to record chemical reactions by a computer analysis of the structural changes. Our own studies show that the computer requires considerably more data for such an analysis if it is not to yield false results; cf. eqs. (10) and (11).

[15] *J. E. Armitage, J. E. Crowe, P. N. Evans, M. F. Lynch*, and *J. A. McGuirk*, J. chem. Documentation *7*, 209 (1967).

[16] *E. Bograchov*, J. Amer. chem. Soc. *72*, 2268 (1950).

(12)

(13)

(14)

(15)

(16)

In order to avoid errors, a documentation system should define its concepts in the way normally used by chemists. The best way to achieve this is to describe the following substances as "reaction modifiers" (reagents, solvents, *etc.*):

inorganic substances (cf. eqs. (12), (15));

organic substances that do not provide any of the carbon atoms in the end product (cf. eqs. (13), (14));

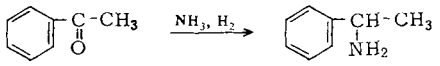
some 30 other organic substances such as methyl iodide, methanol, acetic anhydride, or mesyl chloride, which count as reaction modifiers if they react with an organic substance [cf. eq. (16)].

The separation into starting materials and reagents is justified from the point of view of the reaction. In a reaction card file for organic chemistry it would be pointless to record reagents like hydrochloric acid, nitric acid, *etc.* time after time as starting materials whose bonds were broken in the reaction.

3.3.2. Encoding the Data

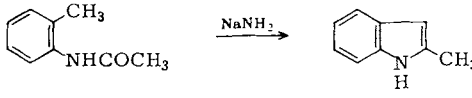
The reaction modifiers are recorded in our system in ten columns of the punched card (120 hole positions). In order to permit general questions, broad concepts such as oxidizing, reducing, and condensing agents, catalysts, inhibitors, biological agents, and others are included. The code also permits the recording of whether the reaction occurs in an acid, basic, or buffered medium.

The encoding of the reaction modifiers is simple. Frequently occurring substances like alcohol, acetone, pyridine, $LiAlH_4$, HCl, and iron are coded directly, and the others are coded by combinations of partial structures, *e.g.* lead acetate as metal acetate + lead.



3.4. Physical Data and Other Information

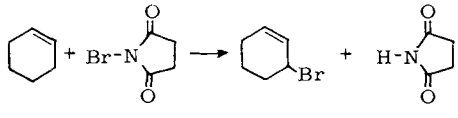
In addition to the substances reacting and present in the reaction medium, the physical data of the reaction are also of interest since they can have a decisive influence on the course of the reaction. These data include temperature, pressure, effect of light, *etc.*, and are given explicitly in one column of the punched card.



In addition, the code can indicate whether the article is a review and also whether it deals in some detail with the reaction mechanism.

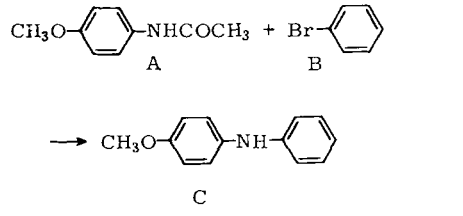
3.5.1. General

When we talk of a synthesis we are generally considering a single starting material which is to give a single end product.



(17)[17]

(18)[18]



This corresponds to the previously mentioned division into starting material, reaction modifier, and end product. Even where two organic substances are reacting to give two end products, it is often only one of the four possible combinations that is of interest. Thus, in eq. (19) we are only interested in recording the conversion of cyclohexene into the 3-bromocyclohexene which can be isolated from the preparation (A → C). It is certainly necessary to record the reagent bromosuccinimide, but its reactions to give succinimide (B → D) or even to give 3-bromocyclohexene (B → C) are of little interest. The conversion of cyclohexene into succinimide (A → D), which is the fourth possible combination, is of no interest.

A B C D

(19)[19]

This is not the case with reactions of the type shown in eq. (20). Here both the conversions A → C and B → C are of interest and must be recorded.

(20)[20]

A is the starting material in (19) and A and B are the starting materials in (20); the bromosuccinimide in (19) is, however, a reaction modifier in the sense of the definition given previously. In both reactions it is only the substance C, isolated from the preparation, that is of

[17] *J. C. Robinson jr.* and *H. R. Snyder*, Org. Syntheses, Coll. Vol. III, 717 (1955).

[18] *C. F. H. Allen* and *J. VanAllan*, Org. Syntheses, Coll. Vol. III, 597 (1955).

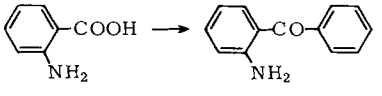
[19] *K. Ziegler, A. Späth, E. Schaaf, W. Schumann*, and *E. Winkelmann*, Liebigs Ann. Chem. *551*, 80 (1942).

[20] *F. E. King, T. J. King*, and *J. H. M. Muir*, J. chem. Soc. (London) *1946*, 5.

interest as the reaction product. This defines the range of reactions to be recorded: any conversion of a starting material into a reaction product which is isolated from the preparation is to be recorded.

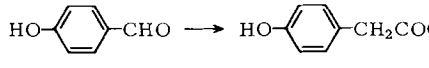
3.5.2. Encoding the Data

Each punched card is used to record the reaction of *one* starting material (punched in columns 1–27) to form *one* end product (columns 28–54). If several such combinations are possible, as for example in (20), then two or more punched cards are used, related to one another by the use of the same abstract number which also enables them to be searched in common.



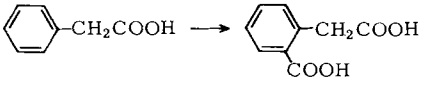
The bonds that are modified and certain other data are punched in columns 55–62. After column 63, which is left blank for the purposes of the individual user, the reagents and solvents (reaction modifiers) are punched in columns 64–73. The operating conditions are given in column 74.

Columns 75–80 contain the abstract number, which relates the card to the abstract.



3.6. Multistage Reactions

3.6.1. General



The reactions shown in eqs. (21) to (23) are syntheses requiring two or more steps and giving good yields and, as such, of considerable interest.

(21)[21]

(22)[22]

(23)[23]

Despite this fact, if they are recorded in the usual way they will usually not be found in the form given, since generally it is not the overall reaction but rather the individual stages as such that are recorded. A reaction card file should not fall into this error.

3.6.2. Encoding the Data

In our reaction card file, multistage reactions are recorded not only as the individual stages but also as combinations of two or more stages. The reaction sequence A → B → C → D, is encoded as a number of punched cards, which contain the individual reactions A → B, B → C, C → D, but also A → C, A → D, and B → D. In this way it is possible to encode and search for reactions that would have been lost by the single-stage approach. The amount of trouble that our system can save the chemist involved in synthesis work can easily be estimated.

4. Practical Applications of the Reaction Card File

4.1. Methods of Searching

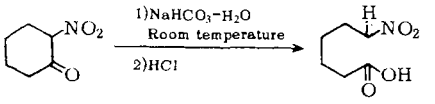
Figure 1 shows the way in which the concepts for reaction (24) (chosen at random from Vol. 23 of *Theilheimer*'s "Synthetic Methods of Organic Chemistry") are encoded. The 24 concepts given appear on the punched card as 24 holes. For example, the nitro group shown in box 7 is punched in column 17, line 4 of the card; the same is true of any nitro group in any starting material.

Questions may be formulated using any desired combination of punch positions ("multidimensional searching"). The searches may range from specific to quite general inquiries. For example, the specific search for reactions of 2-nitrocyclohexane would match on positions 1 to 9. A specific search for the synthesis of 6-nitrocaproic acid would match on positions 17 to 22.

The code does contain a certain degree of ambiguity. The same positions 17 to 22 are also used to encode the closely related compounds 5-nitro-*n*-valeric acid and 7-nitroheptanoic acid.

Apart from these specific questions, a large variety of general questions can also be put. The combination of structure and reagent, *e.g.* the effect of bases on oxo compounds (positions 8 + 9 + 12 for reaction (24)), provides information on the reactions that a structure can undergo when treated with a given reagent. Among other things, this is important in the prediction of side reactions.

More general questions on the stability of compounds are, of course, possible. Reaction (24) as encoded will match the following search requests: cleavage of alicyclic rings (positions 3 + 11); stability of nitro groups at an active methylene group (6 + 7); reactions of cyclohexanones (2 + 3 + 8 + 9); and the influence of α-substituents on the stability of oxo compounds (6 + 8 + 9).



Again, if one is carrying out a synthesis with sensitive materials which will not permit the use of high temperatures, one can use the concept "Room temperature", and, for example, search for reactions of α-nitro ketones at room temperature (positions 6–9, and 16 for reaction (24)).

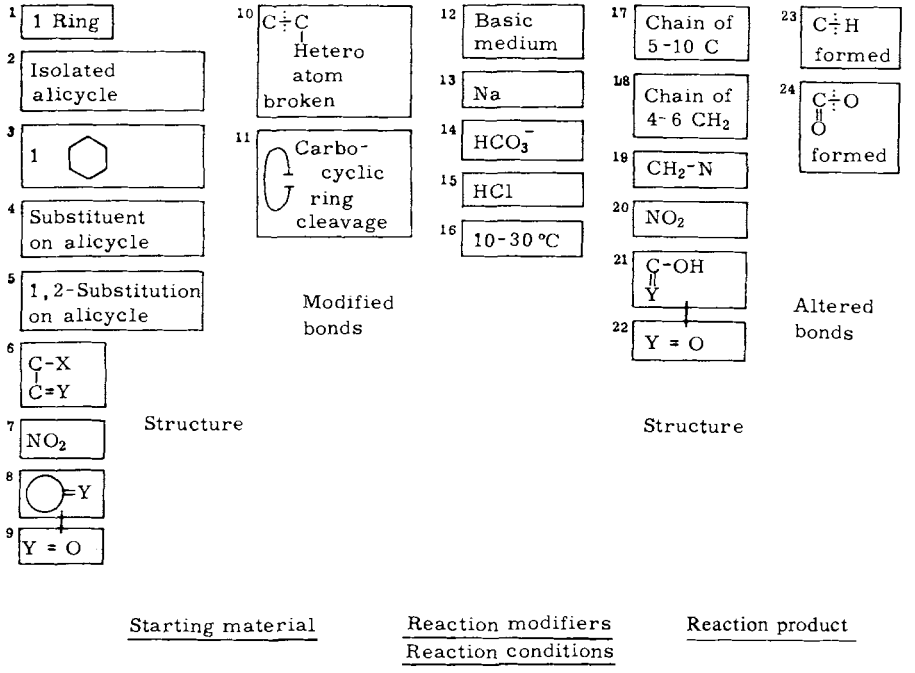
General questions on the end products can also be put in a number of ways. On the punched card for reaction (24), the positions given will answer the following questions: synthesis of ω-nitro carboxylic acids from other nitro compounds (positions 19–22 and 7); synthesis of nitro carboxylic acids (positions 20–22); synthesis of carboxylic acids (positions 21 and 22).

[21] *H. J. Scheifele jr.* and *D. F. DeTar*, Org. Syntheses, Coll. Vol. IV, 34 (1963).

[22] *G. Billek*, Org. Syntheses *43*, 49 (1963).

[23] *P. A. S. Smith* and *R. O. Kan*, Org. Syntheses *44*, 62, 91 (1964).

(24)[24]



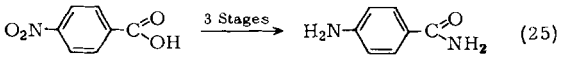


Figure 1.

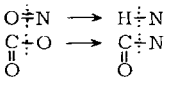
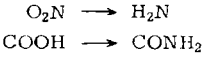
4.2. Quality of the Answers

The described code uses the simplest possible concepts familiar to any chemist. This makes the cost of coding relatively low (about 8 DM per abstract). The searching is also quite a simple process. Does this also mean that we must expect a high number of false drops?

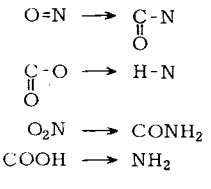


A structural fragmentation code does not normally give a unique and unambiguous coding for every single substance. In the case of reaction (24) it was mentioned that the coding of the end product could also apply to two closely related nitro carboxylic acids. This, however, is no drawback, since a highly detailed structural coding is generally not required in a reaction card file.

Substances and bonding are encoded together, and they supplement one another to give a high degree of selectivity. Even in cases like (25), where there are parallel reactions of several groups in the same molecule, so that false combinations of punch positions could give rise to wrong answers, a simultaneous search for structures and bonds generally excludes the irrelevant answers. For this reason, the punched card for reaction (25) would not match the incorrect combinations shown.



(25)



Modified bonds:

Modified structures:

Combinations giving false drops

A fundamental refinement of the code could enable the very small proportion of irrelevant material to be reduced still further. However, this would complicate the code and make the encoding process more tedious; hardly any user would then be in the position to supplement the card file by encoding his own material. In addition to this, in the case of parallel reactions like (25) the independent reactions would be encoded separately, which would make it impossible to search for such reactions [*e.g.* amino carboxylic acid amides from nitro carboxylic acids as in (25)].

The reaction card file described represents the joint efforts of 14 firms in the Documentation Ring of the chemical and pharmaceutical industries. We should like to express our particular thanks to the following: O. Dold (Boehringer Mannheim, Mannheim/Germany), G. Hallermann (CIBA A.G., Basel/Switzerland), R. Payer (Chemie Grünenthal, Stolberg/Germany), H. Lebrecht and M. Scheublein (Knoll A.G., Ludwigshafen/Germany), K.-H. Bork (Merck, Darmstadt/Germany), U. de la Vaissiere (Roussel-Uclaf S.A., Romainville/France), H. Seidel (Schering A.G., Berlin/Germany), I. Schuler (Thomae GmbH, Biberach/Germany), and H. Lehwald (Troponwerke, Köln-Mülheim/Germany).

CCBF – A System for the Computer Processing of Chemical and Biological Facts[**]

By Gerhard Ohnacker and Werner Kalbfleisch[*]

A computer-based system for the documentation of company research results in drug research is described. The system stores the numerous results of standardized biological tests and processes chemical formulas by topological techniques. The stored material is processed to provide computer-printed card indexes and lists on chemical and/or biological topics. The programs enable searches to be made for any desired substructure and for pharmacophoric groups, thus providing highly effective assistance in the search for structure-activity relationships.

1. Introduction

The development of a new, biologically active substance to the point where it can be introduced as a drug takes at present an average of six to eight years. As a rule it requires the synthesis of a few thousand new chemical substances, which must be tested by a wide variety of biological test methods. The requirements for proof of biological activity, medical usefulness, and the relative degree of safety are continually refined and made more stringent, and we must give serious consideration to the predictions[1] that in future the time required to develop a new drug resulting from a large research project might increase to as much as 15 to 20 years.

During this long period scientists in many disciplines will be working simultaneously or successively on a large number of promising groups of substances, and as the project progresses the number of data that must be evaluated will increase. In such a case individual results are only meaningful when confirmed by other similar results. Thus for a given substance large numbers of results, obtained either simultaneously or at different times, have to be compared with other individual values or with the activity profiles of other substances.

Such comparisons can assist the scientists efforts in optimizing biological activity by variation of both substance groups and substituents. The usefulness of these comparisons increases with:

– the size of the cooperating team, *i.e.* with the number and range of the tests from which the given individual results are derived;

– the degree of certainty of the biological results, *i.e.* with the number of standardized tests that can be used, the results of which remain comparable over long periods and are largely unaffected by external influences;

– the extent and accuracy of the physicochemical data that can be used for regression and correlation analyses.

Today the ever-increasing mass of data can be stored and processed efficiently by large computers. The usefulness of computers depends on the speed and certainty with which access is offered to the collection of formulas and results, and on the clearness and readability of the answer. In an effort to meet these requirements as closely as possible, a system for the documentation of company research results can use different approaches and more specific techniques than those used by a documentation system for published material in the same field which is of interest to numerous people.

Every documentation system of published material has to strive for completeness. It aims to cover every publication in a given field and all publications in the marginal fields. In addition, it must try to ensure that each document is indexed to the same depth. Often this is only partly achieved, because it is determined not only by the actual content of the publication but also by a more or less detailed thesaurus which lists the terms considered worth indexing, and also by the subjective on-the-spot decisions of the abstractor. Contrariwise, company research results can be deliberately indexed at different levels and depths, because the subsequent use of the system can be planned very exactly to match the needs of a team of limited size.

If the documentation system is to give effective support to the research effort, the best system for a given case will depend not only on the nature and extent of the data to be stored and processed but also on the specific scientific requirements. For this reason we need the collaboration of the scientists themselves in the design of the means for data recording, in the establishment of SDI (Selective Dissemination of Information) profiles, and in the continuous enlargement of the system.

This is the basis upon which the CCBF system for the computer processing of chemical and biological research results was developed. As in all documentation

[**] CCBF = Computer processing of Chemical and Biological Facts.

[1] Medicine in 1990 – a technical forecast by the Office of Health Economics, London, Med. Pharm. Studienges. e.V., Frankfurt, 1969.

systems, data recording is the bottleneck. Therefore, particular care was taken that the various possibilities of the system can be offered with a minimum expenditure of data recording.

2. Functions of the CCBF System

The system is required to:

- store chemical structures and biological results;
- provide information in the search for structure-activity relationships;
- supply the scientist, either in a current awareness or at special request, with computer-produced card indexes and lists of results;
- prepare statistical data for management.

To meet these requirements the programs enable the chemical file to be searched for individual compounds, substructures, and general formulas. The biological file can be searched for individual results or activity profiles. The computer prints out the appropriate formulas and data. To a large extent the printouts can be arranged to suit the inquirer's wishes. Table 1 shows examples of some of the types of questions that can be put, together with the types of printouts. In addition to these specifically requested searches, the CCBF system also offers a continuing service in the form of chemical (Fig. 1) and biological (Fig. 2) card index systems. These subsystems are continually updated and distributed to the scientific workers.

Table 1. Summary of types of questions and answers in the CCBF system.

Type of question	Format of search result
Chemical questions:	
Search for a definite structure	Printout of structural formula
Search for a definite class of compounds Search for a general formula Search for any given substructure	Printout of the structural formulas of all the compounds found. The list can be arranged by code names or by substituents
Combined questions:	
Search for the biological action of a definite substance	Printout of all biological data stored for this substance
Search for compounds which are effective in one or more tests; dosage limits can be set	Printout of the code names and/or formulas of the substances found together with the pharmacological data. The substances can also be arranged in order of effectiveness
Search for compounds with one or more given side effects	Printout of code names and/or formulas of the compounds found, arranged by dose, animal, and mode of application
Statistical questions:	
Summary of all new compounds synthesized in a given period	List of code names and/or formulas, arranged by classes of substances
Summary of all biological results reported in a given period	List arranged by test number and/or customer

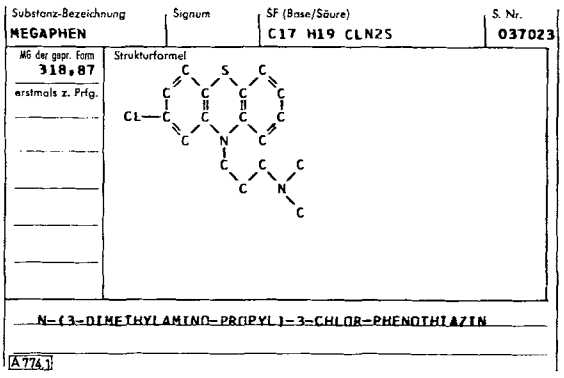

Fig. 1. CCBF chemical index card. (Original format 6" × 4".)

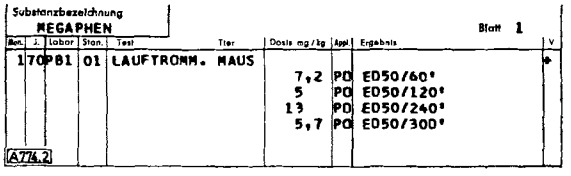

Fig. 2. CCBF biological index card. (Original format 6" × 4".)

3. Scope of the CCBF Store

3.1. Biological Facts

All results obtained on screening with standardized biological test methods in pharmacology, biochemistry, and microbiology are stored numerically. Results from special studies of individual substances are also stored, but they are not indexed in such depth since they have no significance in the search for structure-activity relationships. These can only be detected with standardized tests on a series of structurally related compounds. However, the individual results are important in searching for activity profiles of individual substances. But in these cases it is usually sufficient to find indications of the dates, authorships, and locations of the reports on the results of special biological tests.

3.2. Chemical Facts

The file contains the structures of all new compounds synthesized within the company for biological testing. It also includes the formulas of published compounds that have been used for biological testing within the company.

4. Documentation Techniques

4.1. Biological Results

The indirect coding of biological information with numerical codes or thesauri [2] is certainly of universal application, but it also involves considerable ex-

[2] For example the Biology Code of the Chemical Biological Coordination Center, ed. by *P. G. Seitner, G. A. Livingston,* and *A. S. Williams,* National Academy of Sciences, National Research Council, Washington D.C., 1960.

penditure. Conversion of the information into combinations of numbers or keywords, and also the continual amplification of the codes and thesauri, can only be performed with the necessary degree of accuracy by well trained experts. The same applies to direct codings with coding forms on which the relevant information must be marked.

The great majority of the biological results stored in the CCBF system is derived from tests performed by standardized methods. For this reason the format of all the results from a given test is always the same; therefore, a data sheet suitable for direct data recording has been developed for each test method. All the data sheets can be filled in while experiments are going on. The data on these forms are transferred to the biological file either in text form or as numerical values. For example, Fig. 3 shows the data sheet for the motility test with the revolving drum. The entry of data becomes still simpler in the case of tests whose results are calculated using biometrical methods by computer. In these cases the results form (Fig. 4) is also produced by computer; it is first sent to the scientist so that he can eliminate any useless results. Only the data worth recording are transferred from the results tape to the CCBF store. All the data are first checked by the computer for formal errors and plausibility. Formal errors are indicated, for example, if the substance tested has not yet been entered in the chemical file, or if the sequence of results (card sequence) is incorrect. Testing for plausibility shows whether the data supplied make good sense; the program will give a warning if, for example, the results are illogical or the doses are nonsensical.

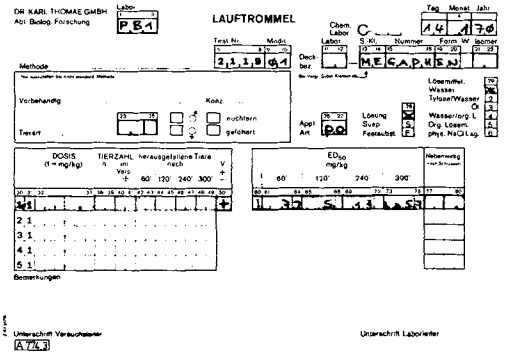

Fig. 3. Data sheet for the input of biological data into the CCBF system. Code symbols are only used in the "Test No." and "Modif." fields for the method of test, in the "Type of animal" field, and in the "Side effects" field. Anything that the scientist has entered in the "Remarks" section will be stored as text. Such remarks cannot be searched for but they can be printed out together with biological search results. (Original format 8'' × 6''.)

Fig. 4. Computer-produced results form for biometrically calculated biological data.

The data record of all the results relating to an individual substance in the biological file begins with the key data of the compound, which also provide the link to the chemical file. The test results follow in the order of their entry. For each test there are the characteristic data (test number, type of animal, mode of application, *etc.*), the dosages, the numerical results, and finally any remarks made by the investigator, in clear text.

4.2. Chemical Structures

Only substances of clearly defined structure are entered into the chemical file of the CCBF system; Markush formulas do not occur [*]. Thus it is possible to process the chemical formulas topologically. In this method, the fundamentals of which were first described by *Mooers* [3], the structures are stored unambiguously and searches may be carried out for any desired substructure. In developing our coding system for formulas we took advantage of the experience of *Horowitz* and *Crane* [4], *Waldo* [5], and *Meyer* [6]. The formulas are entered manually onto a grid sheet (Fig. 5). Certain rules have to be observed mainly with regard to the data recording equipment.

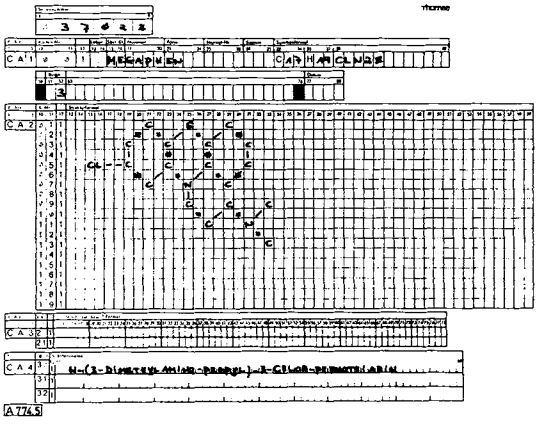

Fig. 5. Coding sheet for recording chemical formulas in the CCBF system. (Original format 12'' × 8''.)

For printing formulas by computer we use a high-speed IBM 1403/N 1 line-printer with additional characters to print some chemical symbols not included in the normal character-set. These are: ⟍, for this one single bond, ⫴, ⫽, and ⟍, for the double bonds, ≡ and ⫼ for the triple bonds, and the symbol □ to characterize an aromatic ring. In order to get a

[*] A Markush formula is a general formula such as $R'NH_2$, in which R' might for example stand for any alkyl group from C_1 to C_{10}.

[3] *C. N. Mooers*, Zator Techn. Bull. *59*, 1 (1951).

[4] *P. Horowitz* and *E. M. Crane*: Hecsagon: A System for Computer Storage and Retrieval of Chemical Structure. Eastman Kodak Company, Rochester, N.Y., 1961.

[5] *W. H. Waldo*, J. chem. Documentation *2*, 1 (1962).

[6] *E. Meyer*, Angew. Chem. *77*, 240 (1965); Angew. Chem. internat. Edit. *4*, 347 (1965).

suitable printed formula, the line density is altered to eight lines per inch. Since these symbols do not appear on a normal key punch, the aromatic ring is coded as @, the single bond \ as ×, the double bond in any direction as #, and the triple bond as ∏. The coding program ensures that the correct symbols are filed. For the bonds of six-membered aromatic systems the program generates the "aromatic" bond type. With regard to a suitable printed formula it is also possible to draw dotted bonds to indicate ionic bondings or steric positions; furthermore, signs of charges can be drawn. A special code relates these and other data (*e.g.* radioactive labeling) to the corresponding atoms. This code gives the grid coordinates (row and column number of the atom in the grid-sheet) together with a keyword for the special fact.

Topological coding is concerned solely with atoms other than hydrogen. Hydrogen atoms are therefore not drawn on the grid-sheet, unless they are required for the improvement of the formula printout. Not only the descriptive data, such as key-data of the compound, month of its synthesis, and the chemical name or bibliographical data, but also for test purposes the empirical formula and the number of rings present in the molecule are given.

One technician is able to fill in the grid-sheets for an average of 40 formulas per hour. The coding is easy to check visually and does not involve any worries about future eventualities; for instance, later on they might be processed by optical scanners [7]. Moreover, this kind of input provides the information for computer printing of the formulas without any additional manual operation. The input data are checked by the computer for formal validity. Error messages are produced for invalid atom or bonding symbols, missing lines of the formula matrix, and similar formal errors.

In order to produce the topological connectivity table, the computer numbers the atoms of each formula. The program also ascertains the quantity and type of the bonds from each atom. No attention is paid to hydrogens, unless they are specially coded. The computer then produces a compact list [8] by removing the redundant information from the connectivity table. In order to achieve higher speed in searching by higher selectivity we have deviated from the topological methods described by *Gluck* [8] and *Morgan* [9], insofar as the CCBF encoding program calculates further information about the individual atoms and includes it in the compact list. This information records whether or not the atom is a ring member, and also the number of hydrogen atoms attached to it (this can shorten the search time if it is required that hydrogen atoms should be present at definite places in the structure or substructure that is searched for).

In the computer file, each atom of a structure is described by:

– the code for the type of atom;

– the information "Ring member or not ring member";

– the information "Bond from atom No. ...";

– the code for the type of bond;

– the code for the number of hydrogens connected with the atom;

– the codes for any special data.

Some of these codes are bit chains, thus Boolean logic operators (AND, OR, NOT) can be used in searches.

The computer calculates the empirical formula and the number of rings and compares them with the values given. Erroneous codings are rejected.

Since even third generation computers still require too much time for the iterative atom by atom comparison described by *Ray* and *Kirsch* [10], the CCBF system also employs some preliminary checks. These screens are produced by the computer. At present the system uses:

– an empirical formula screen;

– a two-atom fragment screen, which indicates how often multiple bonds occur between two carbon atoms or single and multiple bonds between carbon and hetero atoms or between two hetero atoms; single, double, aromatic, and triple bonds are counted separately;

– a ring screen, in which every basic ring in the molecule is described. This ring screen corresponds approximately to the ring fragments of the Ring Code [11].

These preliminary checks eliminate at least 90 %, and in many cases over 99 %, of the stored compounds very quickly as "not relevant". Only those remaining need to be subjected to a topological comparison.

The entire data record for a structural formula thus comprises:

– the key data (for company-produced substances the company code, for compounds known in the literature the name in clear text);

– the computer-generated screens:

– the computer-generated compact list;

– the information for the printing of the formula (a computer condensed form of the input data);

– the chemical name and/or bibliographic details.

On average such a data record occupies 330 bytes, so that one magnetic tape can hold about 120000 formulas. The CCBF encoding program processes an average of 150 formulas per minute.

5. Search Program

Not only does the CCBF system perform the continuing service of producing card index subsystems (Figs. 1 and 2) but it also enables searches to be made on chemical or biological topics or on structure-activity relationships (Table 1).

5.1. Coding of Biological Questions

In biological searches every field of the biological data record can be searched. Logical connections are possible within similar parts of different records. All

[7] *W. E. Cossum, M. E. Hardenbrook*, and *R. N. Wolfe*, Proc. Amer. Documentation Inst. *1964*, 269.

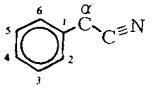
[8] *D. J. Gluck*, J. chem. Documentation *5*, 43 (1965).

[9] *H. L. Morgan*, J. chem. Documentation *5*, 107 (1965).

[10] *L. C. Ray* and *R. A. Kirsch*, Science (Washington) *126*, 814 (1957).

[11] *W. Steidle*, Pharm. Ind. *19*, 88 (1957).

questions about dosages and results must be connected with the appropriate test code. It is also possible to put an overall request for certain data, *e.g.* toxicity data (percentage of animals that died during the test) and side effects. Biological questions are generally coded in free form in the order keyword – operator – search requirements. The keywords name the data fields in the biological record that are to be checked in the search. The operators and search requirements define all the conditions that must be fulfilled or items that must be excluded in order to answer the question. The permitted operators are "equal to", "not equal to", "greater than", "lower than". The search requirements can also include ranges of values, *e.g.* ED-50 "between 10 and 50 mg/kg".



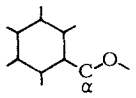
5.2. Coding of Chemical Questions

The formula file can be searched for definite structures, for general formulas, and for substructures of any desired type and size. Substructures are sets of connected atoms within complete structures, and may contain straight chain, branched, and ring elements or ring fragments in any desired combination.

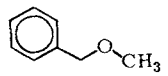
A chemical search starts with manual coding of the connectivity table of the required structure or substructure. The search time can be shortened by choosing numbers as low as possible for those elements of the structure that are "rare" in relation to all the stored formulas [12]. In addition, all the screens relevant for the required structure or substructure are coded. In topological searches for definite compounds the number of H atoms with which every non-H atom in the formula is to be connected is given. This means that in fact only the formula explicitly requested would be retrieved.

In topological searches for substructures and general formulas it is possible to replace one or more atoms by dummy symbols, *e.g.* "Any halogen", "Any hetero atom", "N or O or P or S", and "C or O or N or S". In this way it is possible to search for groups of isosteric compounds in a single question. In coding of the bond type it is possible to choose for each bond OR or NOT combinations, *e.g.* "Single or double bond", "Single or aromatic or double bond (=NOT triple bond)" and "Any bond".

By specifying the number of hydrogen atoms that are to be attached to a non-H atom of a given substructure or general formula it is possible to request that, for example, in substructure *(1)* the α-carbon shall have two hydrogens, and each of the carbon atoms 3, 4, 5, and 6 of the phenyl group shall carry one hydrogen.

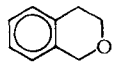


(1)



[12] *W. E. Cossum, M. L. Krakiwsky,* and *M. F. Lynch,* J. chem. Documentation *5,* 33 (1965).

Thus, in this example only phenylacetonitrile and those mono-*ortho* derivatives which are not substituted in the α-position are retrieved.



By specifying that an atom should or should not be a ring member, we can, for example, request for substructure *(2)* that the α-carbon be a ring member; then only formula *(4)* will give a match. Without this restriction, the question would also retrieve structure *(3)*.

(2)

(3)

(4)

5.3. Searching

The search program first converts the coding of the biological and/or chemical questions from punched cards to an internal format. It is checked for formal and logical errors analogous to the input checking. In combined searches it is possible to select whether the chemical or the biological file shall be searched first. If, for example, the question refers to a rare biological test, then the biological file is searched first. If, on the other hand, the structures required do not occur frequently, then the chemical file is searched first.

The search program transfers the data records of all the substances retrieved to an intermediate file. From this file the editing program selects all the parts for the desired printout (Table 1). Printout instructions are given at the same time as the initial question. Provision is also made for printout instructions to be given even after the search has been completed, so that the whole of the information for all the substances retrieved can be used repeatedly and for different purposes.

6. Experience Gained

In 1968, after two years of development, the CCBF system was installed to modernize a research documentation system which for the previous eight years had been recording chemical formulas with the Ring Code [11] and biological information by direct coding. Our experience with these documentation systems enables us to make the following statements:

– a research documentation system which is to be an effective aid both now and in the future must continually be adjusting its techniques to keep up with developments in the field of data processing and with progress in the documentation methods for the particular subject concerned;

– in a documentation system concerned with chemical formulas in drug research, the selectivity of pure fragmentation codes is insufficient and, particularly for substructure searching, only topological methods meet all the requirements;

– the only expedient way to run a biological documentation system is to keep the data recording so simple that no specialists are required for encoding;

– a research documentation system will only be attractive to the scientist if it provides both the opportunity to carry out individual searches and also a continuing service in the form of SDI;

– a research documentation will only remain up-to-date if the system is controlled by the research department, and if the scientist whose research results are documented continually collaborates in its extension and maintenance.

In cooperation with the department Zentrale Datenverarbeitung der Firma C. H. Boehringer Sohn, Ingelheim, the programs for the CCBF system were written partly in Assembler and partly in PL/I for an IBM 360/40. Dr. B. Braun, Ingelheim, coordinated the programs for the various sections of the system and made many valuable suggestions for the system analysis, the system maintenance, and the continual extensions to the system. Fräulein U. Zech helped considerably in the extensive planning for the computer processing of biological information and supplied numerous practical ideas. Herr J. Becker in his writing of the encoding program for chemical formulas contributed very useful details. Herr J. Gruber programmed the biological section; his shrewd suggestions helped considerably in the development of the system. The updating and editing programs were written by Herr P. Oppitz with many fruitful ideas.

Gas-Liquid Chromatography and Mass Spectrometry in Methylation Analysis of Polysaccharides

By Håkan Björndal, Carl Gustaf Hellerqvist, Bengt Lindberg, and Sigfrid Svensson[*]

New methylation procedures and the combined application of gas-liquid chromatography and mass spectrometry for the qualitative and quantitative analysis of mixtures of methylated sugars permit methylation analysis of polysaccharides to be performed more accurately, faster, and with less material than previously.

1. Introduction

Methylation analysis is an important method in structural polysaccharide chemistry. It involves exhaustive methylation of the polysaccharide and hydrolysis to a mixture of monomeric methylated sugars, which are then separated, identified, and quantitatively estimated. The positions of glycosidic linkages in the polysaccharide correspond to the positions of unsubstituted hydroxyl groups in these methylated monosaccharides. The method gives no information on the relative order of the sugar residues or on their anomeric nature.

Determination of the complete structure of a polysaccharide also requires complementary analyses, the most important of which are graded hydrolysis, by acids or enzymes, followed by isolation and identification of the oligosaccharides formed, and various modifications of periodate oxidation. Unlike most other methods used in structural polysaccharide chemistry, methylation analysis provides quantitative information [1].

2. Methylation of Polysaccharides

2.1. Haworth and Purdie Methylation

The aim of methylation is to achieve etherification of all the free hydroxyl groups in the polysaccharide. In the original procedure, used by *Denham* and *Woodhouse* [2] and by *Haworth* [3], this was achieved by repeated reaction with dimethyl sulfate and sodium hydroxide. Often, only a partially methylated product was obtained which was then fully methylated by repeated treatment with silver oxide in boiling methyl iodide, according to *Purdie* and *Irvine* [4].

Purdie's technique was considerably improved by *Kuhn* and co-workers [5], who carried out the reaction in the polar solvent *N,N*-dimethylformamide. Polysaccharides which dissolve or swell in this solvent may be

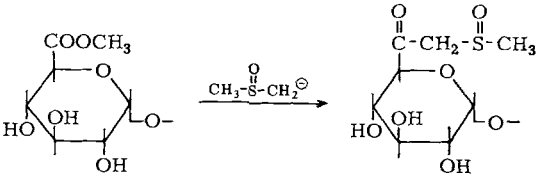
methylated directly. Silver oxide, however, causes oxidative degradation of free or partially methylated polysaccharides; more recent modifications using barium hydroxide[6] or sodium hydroxide[7] are therefore preferred. With these bases, reaction can be performed in dimethyl sulfoxide, which is a better solvent for polysaccharides.

2.2. Hakomori Methylation

The simplest and most convenient method for methylation of polysaccharides and other carbohydrates is probably that recently developed by *Hakomori*[8]. The polysaccharide is treated with the strong base methylsulfinylmethylsodium in dimethyl sulfoxide; the hydroxyl functions are thus ionized to give the corresponding polyalkoxide ions which then react readily with methyl iodide. Complete methylation may be accomplished in one step; isolation of the methylated polysaccharide is simple and the procedure is suitable for work both on a macro and on a micro scale.

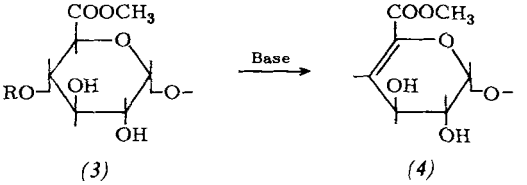
The base is prepared by adding sodium hydride to dimethyl sulfoxide[9]. Solutions of methylsulfinylmethylsodium may be prepared in advance (they are stable for several weeks in the frozen state), or sodium hydride may be added directly to a solution of the polysaccharide in dimethyl sulfoxide[10]. In either procedure, ultrasonic treatment facilitates reaction between sodium hydride and dimethyl sulfoxide[11]. Ultrasonic treatment also assists dissolution of the polysaccharide and seems to facilitate the final reaction with methyl iodide. It is essential that the solution of methylsulfinylmethylsodium is protected from contact with air. When methylation is complete, the reaction mixture is poured into water and the fully methylated polysaccharide isolated by dialysis or by extraction. Polysaccharides that do not dissolve or swell in dimethyl sulfoxide cannot be methylated by this technique; they may *e.g.* first be partially methylated by the Haworth[3] method and the process then completed by the Hakomori procedure.



The ionization of the hydroxyl groups in the polysaccharide is a comparatively slow reaction[8] and the polysaccharide is therefore left in contact with the base for several hours before the methyl iodide is added. Reaction of alkoxide ions with methyl iodide is presumably much faster. Methyl iodide is also consumed by the base.

Price and *Whiting*[12] studied the reaction of glycerol with methylsulfinylmethylsodium and found that only 1.5 equivalents of the base were consumed. Since it is well established that carbohydrates containing several adjacent hydroxyl groups are completely methylated by the Hakomori procedure, ionization of hydroxyl groups probably occurs also during the methylation stage, *i.e.* after methyl iodide has been added to the system.

Estimation of the completeness of the methylation is difficult. Methylated polysaccharides are hygroscopic and the last traces of dimethyl sulfoxide or other solvents are difficult to remove. Methoxyl analyses therefore often give erroneously low values, and are impractical when only a few mg of polysaccharide are available. The absence of OH absorption in the 3400 to 3600 cm^{-1} region of the infrared spectrum is a better criterion, but the presence of traces of water will obscure the result.



In practice, estimation of the degree of methylation is unnecessary since undermethylation reveals itself when the relative proportions of methylated sugars are determined. A reasonably good agreement between terminal residues and branching points should be obtained. The presence of sugars bearing more than two unmethylated hydroxyl groups, even in traces, indicates severe undermethylation. A perfect agreement and quantitative recovery of methylated sugars is seldom attained since some demethylation during the hydrolysis and some losses of the more volatile methylated sugars during concentration are unavoidable.

The presence of uronic acid residues in the polysaccharide may cause complications during the methylation. An esterified uronic acid residue *(1)* may react with the methylsulfinylmethyl anion, yielding a methylsulfinylmethyl ketone *(2)*, a reaction of preparative interest[13].

(1) *(2)*

An esterified uronic acid residue *(3)* may also undergo β-elimination in the strongly basic medium, yielding an unsaturated residue *(4)*, and this reaction will become particularly important when C-4 of the original uronic acid residue *(3)* is substituted.

(3) *(4)*

When methyl iodide is added to the alkoxide ion of a polysaccharide containing uronic acid residues its etherification and esterification and also the reaction of the excess base with methyl iodide are probably fast reactions; the ester formed is therefore exposed to the strong base only for a short time. If, however, the carboxyl groups are esterified (either naturally or as a result of a previous methylation) the uronic esters will be in contact with the base for several hours, and the side

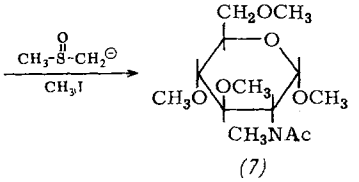
[13] *E. J. Corey* and *M. Chaykovsky,* J. Amer. chem. Soc. *87,* 1345 (1965).

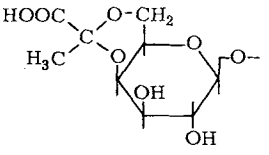
reactions mentioned above may become important. Studies by *Andersson et al.*[14], on acidic polysaccharides, which were subjected to repeated methylations, show that these expected side reactions (β-eliminations) are severe only if the uronic acid residues are substituted on C-4. The reason why the ester groups did not react more extensively with the methylsulfinylmethyl anion, *e.g.* to give ketones such as *(2)*, is obscure; possibly the solution contained enough sodium hydroxide to hydrolyze the ester groups before *(2)* could be formed.



Despite the fact that successful results have been reported in methylation of acidic polysaccharides by the Hakomori procedure, it would seem advisable not to remethylate an undermethylated sample but to start anew and attempt to attain a complete methylation in one step. If this cannot be achieved, it would seem safer to perform any remethylations by other procedures, *e.g.* with methyl iodide-silver oxide, according to *Kuhn et al.*[5].

Most of the *O*-acetyl groups present in an acetylated polysaccharide survive during a Kuhn methylation[15], but acetyl migration is promoted under these reaction conditions. On Hakomori methylation, *O*-acetyl groups are completely replaced by *O*-methyl groups; other *O*-acyl groups may be expected to react in the same manner. The Hakomori methylation of polysaccharides containing sulfonate or phosphate ester groups, or of simple model substances in which these groups are present, has not been investigated.

Aminodeoxy sugars, generally *N*-acetylated, are common components of polysaccharides. When polysaccharides or other carbohydrates containing such residues, *e.g.* methyl 2-acetamido-2-deoxy-α-D-glucopyranoside *(5)*, are methylated by the Haworth or Kuhn procedures, the acetamido group remains intact *(6)*[16]. When *(5)* was methylated by the Hakomori procedure, the fully *O*-methylated *N*-methylacetamido derivative



(6) *(5)*

(7)

(7) was obtained[17]. This important difference between the methylation procedures, which is probably of general validity, reflects the much stronger basic conditions under which the Hakomori methylation is performed.

Some polysaccharides contain pyruvic acid residues, linked as ketals to sugar residues [*e.g. (8)*][18]. Acetalization of polysaccharides has been applied for the

(8)

localization of ester groups[19]. As expected, the ketal and acetal groups are stable during the Hakomori methylation.

3. Hydrolysis of Fully Methylated Polysaccharides

Fully methylated polysaccharides are often not soluble in hot aqueous solutions. For this reason methanolysis (with methanolic hydrogen chloride at the boiling point or higher), formolysis (with 90 % formic acid at 100 °C), or treatment with 72 % sulfuric acid (at room temperature) is usually performed before the hydrolysis with hot dilute acid. In this manner degradation and demethylation are kept as low as possible. Treatment with hydrochloric acid in water or in methanol causes more demethylation than either formolysis or treatment with 72 % sulfuric acid followed by hydrolysis in dilute sulfuric acid[20].

Some methylated sugars, *e.g.* a tri-*O*-methylpentose, are rather volatile and are partially lost on concentration of the hydrolyzate. Such losses are avoided if the polysaccharide is subjected to methanolysis, and the mixture of methyl glycosides obtained is analyzed by GLC without preceding neutralization or concentration of the methanolyzate[21].

Certain glycosidic linkages are fairly resistant to acid hydrolysis; complete hydrolysis may then be accompanied by sugar degradation. One example is the uronosyl linkage. To facilitate hydrolysis, uronic acid residues may be first reduced to neutral sugar residues. 2-Acetamido-2-deoxyglycosides are not particularly resistant to acid hydrolysis but concurrent hydrolysis of the amidic linkage gives rise to 2-amino-2-deoxyglycosides, which are extremely resistant to acid hydrolysis. No systematic studies on the hydrolysis of methylated polysaccharides containing 2-acetamido-2-deoxy sugar residues seems to have been carried out. Presumably complete fragmentation into monomers could be achieved by acetolysis.

4. Separation of Mixtures of Methylated Sugars

4.1. Methyl Glycosides of Methylated Sugars

The separation of the different methylated sugars obtained on hydrolysis of a methylated polysaccharide was accomplished originally by fractional distillation and later by paper, cellulose column, or carbon column chromatography. These chromatographic methods are still in use for the isolation of sufficient material for an unambiguous identification. For analytical separation GLC is presently the preferred method. The methylated sugars cannot be separated directly by GLC but have to be transformed into more stable derivatives, usually the methyl glycosides.

Each methylated sugar gives one or two anomeric pairs of glycosides, depending upon whether one or both of C-4 and C-5 are unsubstituted. This fact may facilitate the identification of components in simple mixtures. In more complex mixtures the multiplicity of peaks becomes a disadvantage, as the quantitative evaluation becomes more difficult. The best GLC separations are obtained on polar columns such as butanediol succinate and polyphenyl ether. Retention times relative to methyl 2,3,4,6-tetra-*O*-methyl-β-D-glucoside (*T*-values) for methyl glycosides of a number of methylated sugars have been determined by *Aspinall*[21].

4.2. Alditol Acetates of Methylated Sugars

By reduction of the methylated sugars to alditols a single derivative is obtained from each sugar. The separation of isomeric alditol derivatives (*e.g.* acetates) was, however, inferior to that obtained for isomeric methyl glycoside derivatives. It was only after the introduction of a new phase for GLC, ECNSS–M (a nitrile silicone-polyester copolymer[*]), that good separation of partially methylated alditol acetates became feasible. This procedure has been used in the authors' laboratory for some years[22]; some representative results are shown in Table 1. The few components that are not well separated on ECNSS–M may be separated on other columns (Table 2). Recently ECNSS–M SCOT-columns have become available which provide much better separation than the packed columns.

Table 1. Retention times (*T*-values) of partially methylated sugars, in the form of their alditol acetates, relative to 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol. Generally, 2-m glass columns of 4-mm internal diameter containing 3 % ECNSS–M on chromosorb Q, 100–120 mesh were used.

Position of CH_3	Parent sugar [a]

[a] OS 138 consists of polyphenyl ether.

Manufacturer: Applied Science Laboratories Inc., P.O. Box 140, State College, Pa. (USA).

The reproducibility of a *T*-value is good, generally 1 % or better, provided that *two* internal standards with considerably different retention times are used and that the values are determined by interpolation. This is also true for different columns and at different temperatures. Partially methylated alditol acetates are preferably separated at 160–200 °C, fully acetylated

[*] Manufacturer: Applied Science Laboratories Inc., P.O. Box 140, State College, Pa. (USA).

[22] *H. Björndal, B. Lindberg,* and *S. Svensson,* Acta chem. scand. *21*, 1801 (1967).

alditols at 200–220 °C. The optimum temperature range depends on the percentage of ECNSS–M phase on the support. Since this phase leaks out on usage the temperature range should be decreased accordingly. SCOT columns are used at somewhat lower temperatures.

Alditol acetates containing any number of *O*-methyl groups, or none at all, can be separated on the same column. Undermethylation (see above) is therefore easily detected.

The partially methylated alditol acetates deriving from aminodeoxyhexoses have high retention times on ECNSS–M columns but no systematic study of these substances has been made.

Although it is usually necessary to determine response factors for the different components in quantitative GLC, this does not seem to be essential for the partially methylated alditol acetates when glass columns and flame ionization detector are used. The assumption that the molar response is the same for all components is probably true within ± 5 % or better, as demonstrated by the results of several methylation analyses of oligosaccharides and polysaccharides. Errors introduced by this assumption are probably less severe than those due to degradation during hydrolysis and to losses during concentration of solutions of methylated sugars.

5. Characterization of Methylated Sugars

5.1. Crystalline Derivatives

An enormous amount of ingenious and time-consuming work has been devoted to the synthesis of different methyl ethers of natural sugars required for identification purposes in methylation analysis. (For tables listing crystalline derivatives of methyl ethers of the natural sugars see ref. [23].) In classical methylation analyses, each methylated sugar is isolated in pure state, transformed into one or more crystalline derivatives, and compared whenever possible with authentic samples.

5.2. Characterization by GLC

For simple polysaccharides it may suffice to identify the methylated sugars obtained on methylation analysis by GLC. This identification, which may be confirmed by GLC on other columns, by other chromatographic procedures, or by electrophoresis, is of course only tentative. For complex polysaccharides, it may be impossible, or too risky, to identify the components from the methylation analysis by chromatographic methods only.

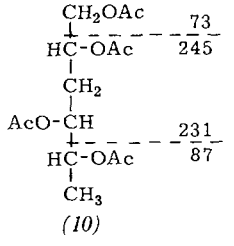
5.3. Characterization by Mass Spectrometry

5.3.1. Glycosides



Recently, mass spectrometry has become an important tool in organic chemistry and several groups have studied the mass spectra of various carbohydrates [24]. *Heyns et al.* investigated the mass spectra of fully methylated glycosides [25], and *Kochetkov et al.* [26] and *Samuelson et al.* [27] examined the mass spectra of the trimethylsilyl derivatives of partially methylated glycosides. These studies, and the use of combined GLC-mass spectrometry, in which the components from the chromatographic column are introduced directly into the ionization chamber of the mass spectrometer, have led to new methods for the qualitative and quantitative analysis of the mixtures of methylated sugars.

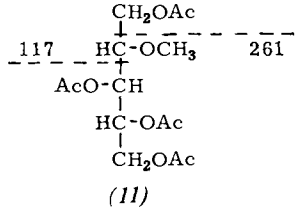
5.3.2. Alditol Acetates of Methylated Sugars

Mass spectrometry of partially methylated alditol acetates has been studied in the authors' laboratory [28]. The fragmentation of alditol acetates, *e.g.* D-glucitol hexaacetate *(9)*, is easily interpreted, as demonstrated by *Chizhov et al.* [29]. The main peaks of the mass spectrum correspond to ions formed by primary fission between two adjacent carbon atoms in the chain and to those arising by elimination of acetic acid (*m/e* 60) or ketene (*m/e* 42) from these primary fragments. The intensities of the fragments decrease with increasing molecular weight. A deoxy group inhibits the cleavage of the neighboring bonds, as exemplified by abequitol tetraacetate *(10)*, derived from the natural sugar abequose (3,6-dideoxy-D-*xylo*-hexose). Mass spectra of isomeric alditol acetates having the same structure but different configurations are practically indistinguishable. The same has been found for various glycosides [24] and other stereoisomeric substances.

(9)

(10)

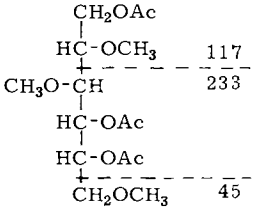
A systematic investigation of mass spectra of partially methylated alditol acetates has led to the following generalizations:



1. Derivatives with the same substitution pattern (*e.g.* 2,3,4,6-*O*-methyl derivatives of hexitols) give very similar mass spectra, typical of that substitution pattern. The small differences that may be observed in the relative intensities of peaks for stereoisomers are insufficient for unambiguous identification.

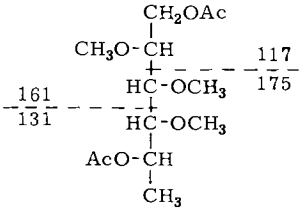
[28] *H. Björndal*, *B. Lindberg*, and *S. Svensson*, Carbohydrate Res. *5*, 43 (1967).

[29] *O. S. Chizhov*, *L. S. Golovkina*, and *N. S. Wulfson*, Izvest. Akad. Nauk SSSR, Otd. chim. Nauk *1966*, 1915.

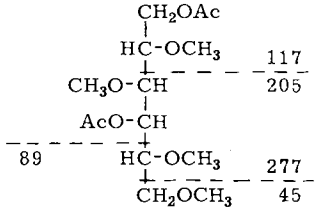


2. The base peak of the spectrum is generally *m/e* 43 ($CH_3C\overset{\oplus}{\equiv}O$).

3. Primary fragments are formed by fission between carbon atoms in the chain. Fission between a methoxylated and an acetoxylated carbon is preferred over fission between two acetoxylated carbons. The fragment with the methoxyl group carries the positive charge. The alditol acetate derived from 2-*O*-methyl-D-xylose *(11)* therefore only gives two main primary fragments.

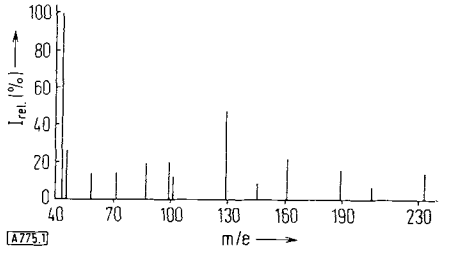


(11)

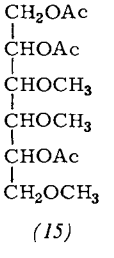


4. When the molecule contains two adjacent methoxylated carbons, *e.g.* the alditol acetates derived from 2,3,6-tri-*O*-methyl-D-glucose *(12)* and 2,3,4-tri-*O*-methyl-L-fucose *(13)*, fission between them is preferred over fission between one of these and a neighboring acetoxylated carbon. Both fragments from this fission

(12)



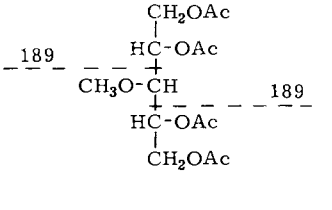
(13)



(14)

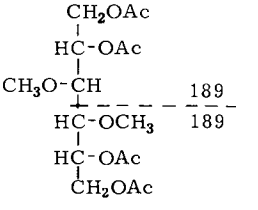
are found as positive ions. An important exception to this rule are the 1,2-di-*O*-methylalditol derivatives which, like the alditol acetate derived from 2,3,5,6-tetra-*O*-methyl-D-galactose *(14)*, always give the primary fragment *m/e* 89 as a strong peak.

5. Secondary fragments are formed from the primary fragments by single or consecutive loss of acetic acid



(15)

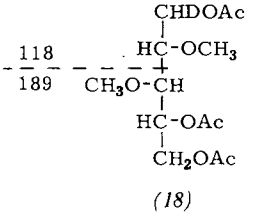
Fig. 1. Mass spectrum of a 1,2,5-tri-*O*-acetyl-3,4,6-tri-*O*-methylhexitol.



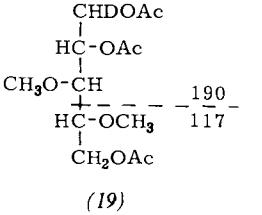
(*m/e* 60), ketene (*m/e* 42), methanol (*m/e* 32), or formaldehyde (*m/e* 30). A typical mass spectrum of a 1,2,5-tri-*O*-acetyl-3,4,6-tri-*O*-methylhexitol *(15)*, is given in Fig. 1.

The mass spectra of a number of partially methylated alditol acetates are listed in Table 3. It is thus possible, by mass spectrometry, to determine the substitution pattern in a partially methylated alditol acetate, either by comparing the spectrum with previously determined spectra or by analyzing it according to the principles outlined above.

There are two alditol acetates which, in spite of their different structures, give similar mass spectra, namely those derived from 3-*O*-methyl-pentoses [*e.g. (16)*] and 3,4-di-*O*-methyl-hexoses [*e.g. (17)*]. This is to be expected since both give one and the same main primary fragment (*m/e* 189). The acetates of mono-*O*-methylpentitols and di-*O*-methylhexitols have very different *T*-values and therefore this similarity in mass spectra need not cause any confusion.

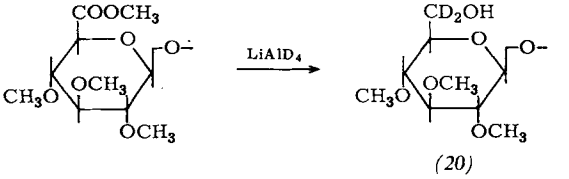


(16)



(17)

On reduction some pairs of methylated sugars, *e.g.* a 2-*O*-methyl- and a 4-*O*-methyl-pentose or a 3-*O*-methyl- and a 4-*O*-methyl-hexose, give alditols with the same substitution pattern, as indicated in Table 3. These may even be identical, as in mannose derivatives, or enantiomorphs, as in galactose derivatives, and thus inseparable by GLC. The information lost when the sugars are reduced to alditols can be readily compensated if the reduction is performed with sodium deuterioborate. This is exemplified by the alditol acetates derived from 2,3- and 3,4-di-*O*-methyl-D-xylose *(18)* and *(19)* respectively, which, although not separable by GLC, give different mass spectra.



(18)

(19)

The uronic acid residues of polysaccharides are reduced to neutral sugar residues, either before or after methylation. If this reduction is performed with a deuterium compound the neutral sugar residue obtained [*e.g. (20)*] is readily distinguished by mass spectrometry

(20)

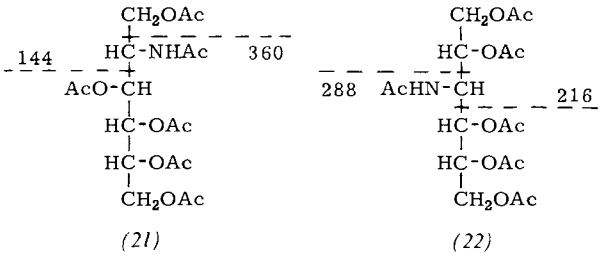
[a] Primary fragments having mass numbers higher than *m/e* 261, which are formed by fission between a methoxyl and an acetoxyl group, are of low intensity and are not included in the Table.

from other sugar residues present in the same polysaccharide.

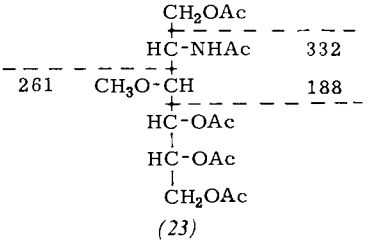


This labeling technique was used during methylation analysis on a fungal glucuronoglucan [30]. Mass spectrometry revealed that one of the sugars obtained, 2,3,4-tri-*O*-methyl-D-glucose, was derived from both the glucose and the glucuronic acid residues. From the intensities of pertinent peaks in the mass spectrum it was also possible to estimate their approximate proportions.

When a heteropolysaccharide contains only one sugar of each class (*e.g.* one pentose and one hexose), the methylated sugars obtained can be unambiguously identified by mass spectrometry. If, however, the polysaccharide contains different sugars of the same class (*e.g.* two or more different hexoses) an unambiguous identification of the different methylated sugars can be accomplished only if the *T*-values of the relevant alditol acetates are sufficiently different. It is generally possible to find chromatographic columns that fulfil such requirements. When the *T*-value for a presumed component of the mixture is not available, it can be readily determined by subjecting a suitable sugar derivative to partial methylation, converting the reaction product into alditol acetates, and characterizing the various methyl ethers by GLC-mass spectrometry. Components with different substitution patterns which are not resolved on the chromatographic column would necessarily give a mixed mass spectrum. If separation of these components cannot be achieved on other columns, or at different temperatures, it is still possible to make a semiquantitative estimate of the relative proportion of these components from the mass spectrum.

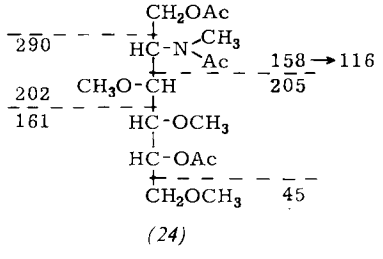
5.3.3. Alditol Acetates of Amino Sugars

No systematic study on GLC-mass spectrometry of alditol acetates derived from acetamidodeoxy sugars has been made. Preliminary studies show that they have much higher retention times than the corresponding neutral sugars. In the unmethylated compounds, *e.g. (21)* and *(22)*, fragmentation is governed by the acetamido group. Secondary fragments are formed from



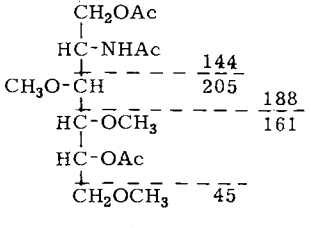
[30] *H. Björndal* and *B. Lindberg*, Carbohydrate Res. *12*, 29 (1970).

(21) (22)



the primary ones by elimination of acetic acid (*m/e* 60), acetamide (*m/e* 59), and ketene (*m/e* 42).

When a methoxyl and an acetamido group are adjacent, as in *(23)*, fission between these groups is preferred and the positive charge is carried almost exclusively by the fragment containing the methoxyl group. Fission between C-1 and C-2 and between C-3 and C-4 is however also observed.



(23)

As mentioned in Section 2, acetamido groups are methylated by the Hakomori procedure [*e.g.* to *(24)*] but not by other methylation procedures [see *(25)*]. The resulting alditol acetates have similar mass spectra.

(24)

(25)

One important difference is that for *(25)* the primary fragment (*m/e* 144) containing C-1 and C-2 is insignificant but for *(24)* it becomes the strongest primary fragment (*m/e* 158). The secondary fragment of *m/e* 116, derived from *m/e* 158 by loss of ketene, is the base peak of the spectrum, and is even stronger than $CH_3C\overset{\oplus}{\equiv}O$ (*m/e* 43).

These preliminary studies indicate that GLC-mass spectrometry may also become a valuable tool in methylation analysis of polysaccharides containing aminodeoxy sugar residues.

6. Examples

6.1. Methylation Analysis of a Fungal Fucoxylomannan[31]

Acid hydrolysis of a fungal fucoxylomannan from *Polyporus pinicola* (Fr.) yielded L-fucose, D-xylose, and D-mannose in the relative proportions 0.8:0.7:1. The polysaccharide was methylated, hydrolyzed, and the mixture of methylated sugars converted into their alditol acetates and analyzed by GLC-mass spectrometry (Table 4, I). Part of the polysaccharide was also subjected to a mild acid hydrolysis, with 0.05 M sulfuric acid at 100 °C for 1.5 h. Nearly all the L-fucosidic linkages were cleaved by this treatment. The residual, polymeric material was subjected to methylation analysis (Table 4, II).

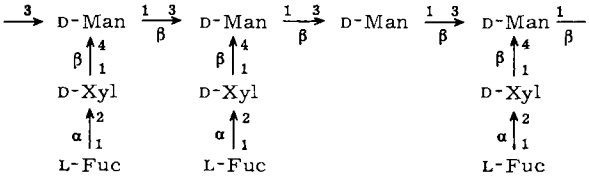


Table 4. Retention times (*T*-values) of partially methylated sugars in the form of their alditol acetates from the hydrolyzate of the methylated fucoxylomannan (I) and of the previously partially degraded and subsequently methylated fucoxylomannan (II). The *T*-values were measured at 175 °C; standard and column as in Table 1.

Alditol acetate of	*T*	I (mole-%)	II (mole-%)
2,3,4-Tri-*O*-methyl-L-fucose	0.65	30.2	–
2,3,4-Tri-*O*-methyl-D-xylose	0.68	–	38.8 [a]
3,4-Di-*O*-methyl-D-xylose	1.54	29.5	3.4
2,4,6-Tri-*O*-methyl-D-mannose	2.10	9.7	19.4
2,6-Di-*O*-methyl-D-mannose	3.35	30.6	38.4

[a] Including traces of 2,3,4-tri-*O*-methyl-L-fucose.

The almost complete disappearance of 3,4-di-*O*-methylxylose and the concomitant appearance of 2,3,4-tri-*O*-methylxylose show that the L-fucose residues are linked to C-2 of the D-xylose residues.

As a result of these and other studies structure *(26)* was proposed for the polysaccharide.

(26)

6.2. Methylation Analysis of the Lipopolysaccharide from *Salmonella typhi*[32]

Lipopolysaccharides from gram-negative bacteria consist of a lipid part, of the "O-specific" side chains, composed of repeating oligosaccharide units, and of a "basal core" linking the lipid to the "O-specific" side chains.

The lipopolysaccharide from *Salmonella typhi* contains D-glucose, D-galactose, D-mannose, L-rhamnose, and tyvelose (3,6-dideoxy-D-*arabino*-hexose) in the side chains and D-glucose, D-galactose, 2-acetamido-2-deoxy-D-glucose, and a heptose in the core. Some sugar residues also contain *O*-acetyl groups.

GLC of the alditol acetates of methylated sugars obtained from the fully methylated lipopolysaccharide gave a complicated picture. Mass spectra were determined at the beginning, maximum, and end of each major peak, and at the maxima of minor peaks. Peaks B and D were found to contain two components. Those in peak B were later separated on a polyphenyl ether column (OS-138), those in peak D on an ECNSS—M column at a lower temperature. From mass spectra and *T*-values it was possible to identify and determine

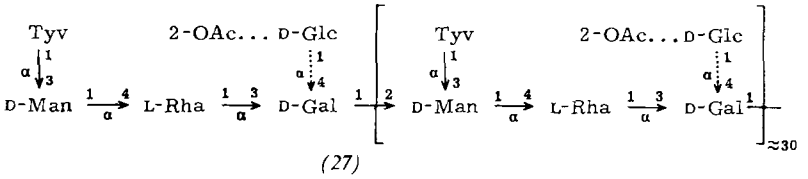
[31] *K. Axelsson, H. Björndal,* and *B. Lindberg,* Acta chem. scand. *23,* 1597 (1969).

[32] *C. G. Hellerqvist, B. Lindberg, S. Svensson, T. Holme,* and *A. A. Lindberg,* Acta chem. scand. *23,* 1588 (1969).

the relative proportions of 12 methylated sugars in the mixture (Table 5, I). Small amounts of methylated heptoses, which should have been present, escaped detection. Methylated derivatives of 2-acetamido-2-deoxyglucose, which have high *T*-values, were not looked for.

Table 5. Retention times (*T*-values) of partially methylated sugars in the form of their alditol acetates from the hydrolyzate of the methylated lipopolysaccharide (I) and the previously partially degraded and subsequently methylated lipopolysaccharide from *Salmonella typhi* (II). Standard and column as in Table 1.

Aldol acetate of	Peak	*T*	I (mole-%) [a]	II (mole-%) [a]
2,4-Di-*O*-methyltyvelose	A	0.29	8.0	
2,3-Di-*O*-methyl-L-rhamnose	B	0.98	20.0	20.0
2,3,4,6-Tetra-*O*-methyl-D-glucose	B[1]	1.00	13.5	10.4
2,3,4,6-Tetra-*O*-methyl-D-galactose	C	1.25	0.8	2.0
3,4,6-Tri-*O*-methyl-D-mannose		1.95		22.6
2,4,6-Tri-*O*-methyl-D-mannose	D	2.08	0.8	
3,4,6-Tri-*O*-methyl-D-glucose	D	2.11	2.1	
2,4,6-Tri-*O*-methyl-D-galactose	E	2.28	8.2	7.0
2,3,6-Tri-*O*-methyl-D-galactose		2.42		
3,4,6-Tri-*O*-methyl-D-galactose	F	2.50	0.5	
4,6-Di-*O*-methyl-D-mannose	G	3.29	24.5	
2,6-Di-*O*-methyl-D-galactose	H	3.62	16.5	10.5
3,6-Di-*O*-methyl-D-galactose	I	4.30	0.8	
2,4-Di-*O*-methyl-D-glucose	K	5.10	1.0	
2,4-Di-*O*-methyl-D-galactose	L	6.35	–	



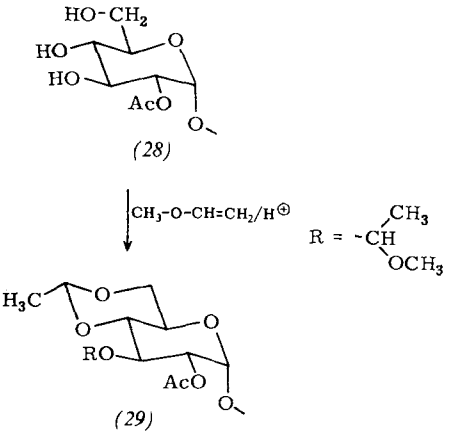
[a] Since a considerable amount of 2,4-di-*O*-methyltyvelose was lost during the methylation analysis the amounts of the methylated sugars are given relative to that of 2,3-di-*O*-methyl-L-rhamnose which is assumed to represent the amount of L-rhamnose in the original lipopolysaccharide.

There is a good agreement between the sugar analysis and the methylation analysis, except for tyvelose. It is reasonable to assume that a considerable amount of 2,4-di-*O*-methyltyvelose and derivatives was lost during concentration of solutions.

Part of the lipopolysaccharide was subjected to a mild acid hydrolysis, which cleaved all tyvelosidic and part of the L-rhamnosidic linkages, and a methylation analysis was performed on the polymeric and oligomeric material recovered (Table 5, II). The finding that 4,6-di-*O*-methyl-D-mannose was completely replaced by 3,4,6-tri-*O*-methyl-D-mannose shows that the tyvelose residues are linked to the 3-position of D-mannose. Likewise, it became evident that the L-rhamnose residues are linked to the C-3 of D-galactose.

All the minor components obtained in the methylation analysis of the original lipopolysaccharide, except 2,4,6-trimethyl-D-mannose, derive from the core polysaccharide. The presence of this sugar and of a considerably higher percentage of 4,6-di-*O*-methyl-D-mannose demonstrates that the non-reducing terminal of the "O-specific" side-chains is a 3-*O*-tyvelosyl-D-mannose residue and also allows an approximate estimation of the average number of repeating units in the chain.

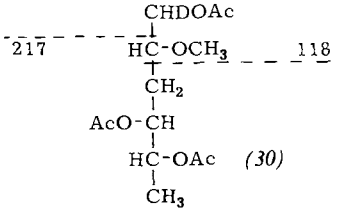
From these and other studies, structure *(27)* was proposed for the O-specific side-chains of the lipopolysaccharide (a dotted line indicates that only part of the residues are substituted).



(27)

6.3. Localization of *O*-Acetyl Groups in Polysaccharides

Several polysaccharides contain *O*-acetyl groups, and the localization of such groups previously proved difficult. The problem can be solved by a modified methylation analysis, according to *de Belder* and *Norrman*[19]. All free hydroxyls are converted into acetals by reaction with methyl vinyl ether and an acidic catalyst in dimethyl sulfoxide. The polymer is best recovered by gel filtration on Sephadex LH 20 in acetone. It could then be methylated either directly by the Hakomori procedure, with automatic loss of the *O*-acetyl groups, or first deacetylated and subsequently methylated. Acid hydrolysis gives a mixture of sugars and partially methylated sugars. The original points of acetylation correspond to the positions of methoxyl groups.



The reaction between carbohydrates and methyl vinyl ether gives acyclic acetals and, when the stereochemistry is favorable, cyclic acetals[33] as well, *e.g. (28)* → *(29)*.

(28) *(29)*

(28) is the terminal *O*-acetylated α-D-glucopyranose residue found in the lipopolysaccharide from *S. typhi (27)*.

The lipopolysaccharide from *S. typhimurium* 395 MS contains abequose (3,6-dideoxy-D-*xylo*-hexose) instead of tyvelose, but otherwise the same sugar components as the lipopolysaccharide from *S. typhi*. It also contains immunologically significant *O*-acetyl groups. After acetalization, methylation, and hydrolysis the sugars were reduced with sodium tetradeuterioborate and acetylated[34]. GLC of this mixture showed that abequose was virtually absent; the only new component not present in the mixture of alditol acetates from

(30)

the original lipopolysaccharide had a lower retention time than abequitol acetate. Although *T*-values of methylated derivatives of abequose were not available, the unknown was readily identified as the alditol acetate of 2-*O*-methylabequose *(30)* from its mass spectrum. These results demonstrate that only C-2 of abequose residues, and no other position in the side chain sugars was acetylated.

7. Conclusions

Methylation analyses of polysaccharides from wood [35,36], fungi [30,31,37–40], lichens [41], and bacteria [32,34,42] have recently been performed in the authors' laboratory using the Hakomori procedure for methylation and GLC-mass spectrometry for the qualitative and quantitative analysis of the methylated sugars. This technique has the following advantages:

1. It is more accurate and sensitive than previous procedures. It is thus possible to identify and determine the relative proportions of minor components, which may be structurally significant.

2. Only small amounts of material are required. Two to ten mg of polysaccharide can be handled conveniently, but a complete methylation analysis has been done with as little as 0.5 mg. This may be a decisive factor for biologically active materials.

3. It is faster than previous methods. A complete methylation analysis can be accomplished in one week.

4. Access to a great number of methylated sugars as reference standards is not essential. When a new methylated sugar is obtained, its identification is far simpler than previously.

5. The ease and accuracy of the method should prompt research workers to perform additional methylation analyses of chemically modified polysaccharides, and thus obtain complementary structural information.

These advantages are considerable and the methods described above, or related methods based upon GLC-mass spectrometry, will probably largely replace classical methods used for methylation analysis of polysaccharides and other carbohydrates.

Solvated and Stabilized Electrons in Radiation-Chemical Processes

By Klaus Eiben[*]

The electrons solvated in metal-ammonia solutions are relatively stable; by contrast, hydrated electrons are very unstable and have been discovered only recently during radiolysis of water. They can be regarded as the simplest radicals. Radiation chemical production of solvated electrons has proved to be a particularly elegant method for the qualitative and quantitative investigation of the reactions between these electrons and numerous compounds, whose rates are partly controlled by diffusion. It has been possible in some cases to identify optically and ESR-spectroscopically the resulting short-lived products (radical-anions). The similarity between the physical and chemical properties of electrons solvated in solutions and those of electrons stabilized in the solid phase suggests that the two species are identical.

1. Introduction

It was first suggested in 1952 that hydrated electrons are formed as short-lived intermediates in the radiolysis of water [1]. Shortly afterward, *Platzman* [2] outlined the expected properties of such electrons on the basis of data for the deep blue metal-ammonia solutions [3], known for the past hundred years or so. Several indirect proofs for the existence of hydrated electrons were published in the following years [4–7]. The first direct proof was obtained in 1962 when an intense blue color was observed after the irradiation of glasses formed by NaOH solutions [8,9], and when – shortly

afterward – the same color was observed in liquid water [10]. It was found in the subsequent rapid development of this field that *solvated* electrons and electrons *stabilized* in the solid phase are formed quite generally in the radiolysis of polar and nonpolar compounds [11]. These electrons, which can be regarded as the simplest radicals, are currently under detailed investigation, and in fact few free radical reactions have been investigated more than theirs [11–21].

2. Radiation Induced Formation of Solvated and Stabilized Electrons

2.1. Absorption of Energy and Thermalization [15, 16]

When corpuscular or electromagnetic radiation is absorbed in gaseous, liquid, and solid matter, high-energy electrons, called primary and secondary electrons, are liberated by the Compton effect and the photoelectric effect (Table 1). These electrons enter into Coulombic interactions with molecules, thereby ionizing or exciting the latter.

Table 1. Time scale for radiation-chemical formation of solvated and stabilized electrons.

Primary ionization	10^{-18}s	
Secondary ionization	10^{-18}s e_c^-	High-energy electrons (10^4–10^6 eV)
	e_{sec}^-	Secondary electrons (10–10^4 eV)
	10^{-16}s e_n^-	Low-energy electrons (< 10 eV)
	10^{-13}s e_m^-	Thermalized but not yet solvated electrons ($E = 3/2\,kT$)
Chemical reactions	10^{-11}s e_t^- e_{solv}^-	Stable electrons in solid phase: e_s^- Solvated electrons in liquid phase: e_{solv}^-, e_{aq}^-
	$\approx 10^{-11}$s	Shortest resolution time so far achieved in pulse radiolysis studies [29]
	$\approx 10^{-8}$s	Homogeneous distribution of primary radicals produced by radiation-chemical techniques in solution [17]

The resulting, mainly low-energy electrons (< 10 eV) give up most of their energy in exciting electronic transitions and vibrational states. When their energy reaches or drops below 0.5 eV, the electrons, now called subexcitation electrons, are thermalized which means that they are slowed down to about 10^7 cm/s (at room temperature), and their energy is reduced to about 0.03 eV.

During this stepwise loss of energy by the electrons (Fig. 1), the distance between the cations and the electrons (ion pairs) increases, and the thermalized electrons (e_m^-) may leave the track and possibly also the Coulombic field of the cations. However, they can recombine, with charge neutralization, this process being known as geminate combination.

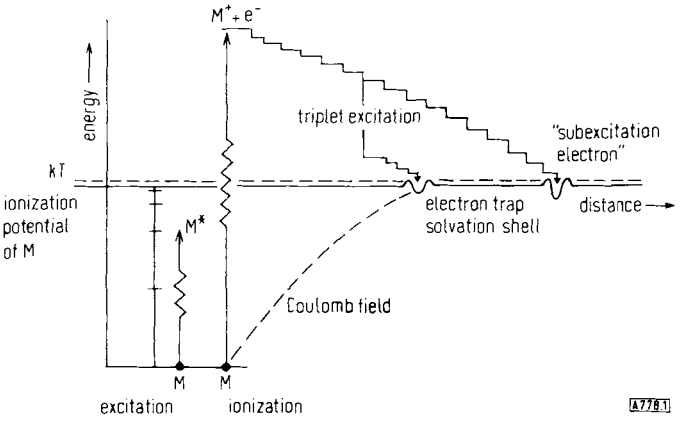

Fig. 1. Thermalization of electrons. Schematic representation after *Dainton* [16].

The probability that thermalized electrons will escape from the Coulombic field depends on the system's polarity, degree of order (crystalline or glassy amorphous state), and temperature (viscosity). For example, the charge neutralization is about five times as intense in nonpolar media, in which the Coulombic field is strong because of the low dielectric constant. In water, by contrast, more than half of the thermalized electrons recombine [16].

The thermal equilibrium of the irradiated system, which is perturbed by the rapid absorption of energy, is reorganized in various simultaneous processes, which will not be discussed here in detail. It should be noted, however, that unlike the energy of light quanta in the first step of photochemical processes, the energy of the ionizing radiation is not absorbed selectively. Therefore the solvent molecules are decomposed in the radiolysis first, while the solutes are attacked only in the subsequent reactions of the primary radicals. The initial distribution of the latter is inhomogeneous (in tracks and spurs), and calls for a distinction between *spur reactions* (recombination and molecular rearrangement) and *radical reactions* (initiated by diffusion).

2.2. Solvation and Stabilization

A previous article [22] dealt with the theory of the formation and the structure of the solvation shells of electrons in polar solvents, this theory having been

developed mainly for the metal-ammonia solutions. In this connection, the electrons solvated in liquids and the electrons stabilized in glasses are described mostly on the basis of *Jortner*'s continuum model [23].

According to this, the thermalized electrons e_m^- induce electronic polarization in the medium, which is followed by a much slower orientation polarization of the solvent molecules in polar liquids, leading to the solvation of the electrons. The solvents under consideration (*e.g.* water and alcohols) have a negative electron affinity, which means that they have no accessible orbitals for the incorporation of additional electrons. *Onsager* [24] assumes that the excess electrons are accommodated in cavities formed by the positive ends of a number of polar molecules.

Several authors have examined whether the thermalized electrons can bring about a solvation shell by self-induced dipole orientation [23] (*i.e.* whether they "dig themselves a hole"), or whether they are captured on anionic defect sites [25] (positive holes), produced by irradiation, or in cavities formed accidentally [26]. As regards solvation in liquids, no clear answer has yet emerged in this connection. *Schiller* [27] estimates that the rate of solvation of electrons *e.g.* in water is thirty times as high (10^{-13} s) as the dipole relaxation time of water. On this basis, the electrons must accelerate the dipole orientation of the solvated molecules, or they must be captured by pre-oriented water molecules. It is not possible to decide experimentally which of these two mechanisms of formation is valid, because not even the fastest method of detection (pulse radiolysis in the picosecond range; cf. Section 3) can resolve the electron solvation period [28].

In the case of frozen solutions, on the other hand, the electrons are assumed to be captured and stabilized in partially or wholly preformed traps [26, 29–31]. Glassy or amorphous systems, which lack short-range order, are characterized by a much higher concentration of preformed electron traps compared to crystals, where short-range order dominates. Thus, no electrons are detected in irradiated $NaOH \cdot 7\,H_2O$ and $NaOH \cdot 3.5\,H_2O$ [32], but electrons are stabilized in high yields [*] in frozen glassy solutions of the same compositions (6.5 N and 13.5 N NaOH) [8, 26, 33, 34] (Tables 2 and 4). The same difference has been found in the case of crystalline aliphatic alcohols and their corresponding glassy forms, obtained by rapid freezing [32].

Electrons solvated in liquids reach a homogeneous distribution through diffusion about 10^{-8} s after formation (Table 1), while electrons in glasses are stabilized in the immediate vicinity of the spur produced by the irradiation. As found from ESR relaxation data [36], the mean distance from the spur center increases with decreasing polarity of the medium, being 40, 59, and 72 Å in 7 N NaOH [35], methanol, and methyltetrahydrofuran [36], respectively. Accordingly, the density of preformed electron traps is greater, and the range of thermalized electrons is smaller, in polar glasses than in nonpolar ones.

2.3. Properties

Solvation reduces the mobility of electrons in polarized dielectrics. Paramagnetism and intense absorption in the red-infrared region are the most conspicuous and – as far as detection is concerned – the most valuable properties of electrons (Table 2).

The light absorption is attributed to a 1s → 2p transition of the electron localized in the cavity [23]. The absorption maximum shifts toward shorter wavelengths in any solvent as the temperature is lowered, which means that the depth of the potential well of the solvation shell increases. In *Jortner*'s semi-empirical

continuum model[59] this is explained by the temperature-dependence of the cavity radius (R_0)[*] and of the dielectric constant of the solvent. In the case of alcohols the absorption maximum shows a red shift and the band-width of the ESR singlet decreases as the dielectric constant decreases[51]. As the polarity decreases, R_0 increases and the interaction between the electrons and the protons of the solvate molecules become weaker. The absorption maximum in heavy water lies at shorter wavelengths than that in ordinary water[44]. An increase in the pressure by 1000 atm similarly causes λ_{max} of the hydrated electrons to shift toward shorter wavelengths by 200 ± 50 Å[49]. This indicates that the volume of hydrated electrons is less than 20 ml/mole, the corresponding value in the case of ammonia being 60–90 ml/mole[49].

The band-width of the ESR singlet is smaller in D_2O than in H_2O[43] which is explained by the smaller nuclear magnetic moment of deuterium. The isotope effect, which is observed also with deuterated alco-

The absorption maxima of electrons stabilized in some glassy hydrocarbons (Table 4) lie in the infrared region. The yield and the thermal stability of the electrons are clearly lower here than in polar glasses, but they can be raised by adding unreactive but polar substances such as triethylamine (TEA)[65, 66]. Mixtures of polar and nonpolar solvents show a similar behavior, but they give two absorption maxima in the visible and the infrared region[51, 67]. This is explained by an association of the polar molecules in the nonpolar solvent, and by preferential stabilization of the electrons near the polar molecules.

Table 4. Absorption and ESR spectra of stabilized electrons in nonpolar glasses [63].

2.4. Structure of the Hydration Shell

The Natori-Watanabe model[68] of hydrated electrons is based on the concept that the molecules of liquid water have an ice-like tetrahedral arrangement. According to this model, the electrons occupy the position of an accidentally missing H_2O molecule at the center of the tetrahedron. The tetrahedral structure is slightly widened, and in addition, it is assumed that polarization of the surrounding H_2O molecules leads to the binding of the electron.

Like *Jortner*'s empirical cavity radius[59] ($R_0 = 1.45$ Å for water), however, this model gives only a mean value for the size of the hydration shell of the electrons. However, to account for the large half-widths observed in the absorption spectrum, it must be assumed that electrons populate traps of different depths (Table 2)[15]. One of the experimental proofs of this is seen in the blue shift of the absorption maximum, observed when the blue color of stabilized electrons of irradiated glasses is photobleached with light whose wavelength exceeds λ_{max}[30] [this process remobilizes only those electrons that are stabilized in the shallow traps (cf. Section 4.3)]. The other experimental proof is that glasses formed from a mixture of polar sol vents give only a broadened absorption band whose maximum is shifted according to the proportion of the components of the mixture[30]. The distribution of the electron traps is obviously influenced by the size of the substituents acting as functional groups for the solvation (OH and NH_2).

By contrast, the half-width of the absorption bands is smaller in crystalline systems [hexagonal ice (Table 2) and F-centers in ionic crystals[69]], where the dimensions of the electron traps differ only slightly.

The participation of a certain number of water molecules (*e.g.* four in the Natori-Watanabe model[68]) in the formation of the hydration shell of electrons should also be manifested in the hyperfine structure of the ESR spectra, but this has not yet been detected either in the liquid or in the solid phase[25, 26, 33, 34]. The ESR singlet of irradiated glasses can be described by a Gauss function, and therefore it points to an unresolved hyperfine structure. An observation[70] frequently quoted is that the ESR singlet obtained for condensates of alkali metals and water and assigned to electrons stabilized at −196 °C shows binomial hyperfine splitting into five to seven lines when the sample is warmed to −140 °C. However, this is probably due to a phase transition of ice from the amorphous to the cubic state, occurring under special conditions, and thus leads to a preferred orientation of the solvation shell. Furthermore, one cannot exclude the possibility that the alkali metal cations are involved in this phenomenon, since the annealing of condensates prepared without any alkali metals is not accompanied by hyperfine splitting. In these condensates the electrons are formed by irradiation in the vapor phase and stabilization in the ice matrix occurs 15 μs later[43]. The lack of hyperfine splitting of the ESR singlet in liquid water[41] is probably due to the fast exchange interaction with protons of the hydration shell.

3. Experimental Methods

The detection of electrons formed during radiolytic processes is hampered by their short lifetime. Two main methods are employed. The technique of *matrix stabilization* is used to accumulate radicals and electrons in the frozen matrix during irradiation *e.g.* with ^{60}Co γ-rays [26,71]. Their properties can be studied by optical and ESR-spectroscopic methods using instruments specially equipped for low temperatures. Kinetic investigations can be carried out while the frozen solutions are warmed until the stabilized electrons become diffusive. Photochemical remobilization of the stabilized electrons can initiate reactions in the irradiated glasses. The matrix isolation method first proposed by *Lewis et al.* [72] is used to stabilize radicals and electrons produced during irradiation in the vapor phase. The reactive radicals are frozen on to a cold-finger at −196 °C about 15 μs after their formation [43,73].

In the second method, the light absorption [10], the paramagnetic properties [41], or the changes in the conductivity [61] of a system are investigated by rapid techniques directly after the formation of the solvated electrons. In pulse radiolysis [20,28,74], the most favored technique to date, the sample is irradiated with 1–10-MeV electron pulses of 10^{-5} to 10^{-11} s duration, the decrease in the optical absorption of the solvated electrons is measured, and the formation of new absorbing species is observed. Only recently has it become possible to use ESR spectroscopy for direct investigation of solvated electrons and their short-lived products in irradiated solutions [41,75]. In this technique the polar solution flows through a flat cell in the resonator of the ESR spectroscope, and a focused beam of highly accelerated electrons (2.8 MeV) is used to maintain a stationary concentration of radicals in the solution while the ESR spectrum is being recorded (Fig. 2).

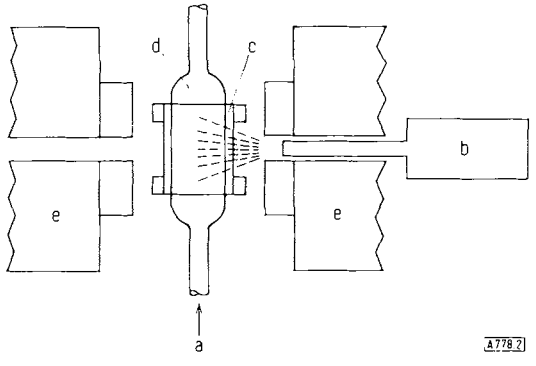

Fig. 2. Schematic representation of the ESR-spectroscopic investigation of short-lived radicals in polar solutions. a, solution; b, electron accelerator; c, ESR resonator; d, flat cell; e, magnet.

4. Reactions of Solvated and Stabilized Electrons

Owing to their high reduction potential, solvated electrons can react with numerous compounds, these reactions involving either *electron addition* or *dissociative electron attachment*.

Electron addition to an acceptor molecule produces either a radical-anion

$$e^-_{solv} + A \rightarrow A^- \qquad (1)$$

or reduces a metal cation (M^{n+}) by one valence stage.

$$e^-_{solv} + M^{n+} \rightarrow M^{(n-1)+} \qquad (2)$$

Dissociative electron attachment by an acceptor molecule leads to stable anions and radicals.

$$e^-_{solv} + RX \rightarrow R^{\bullet} + X^- \qquad (3)$$

We now know from pulse-radiolytic measurements the bimolecular rate constants for the reactions between solvated electrons and well over 500 organic and inorganic compounds in aqueous and other polar solutions [76], but do not yet have a clear picture of the structure and the properties of all these short-lived intermediates. *Habersbergerova et al.* [77] have published a survey on the optical absorption spectra of unstable radicals generated by photochemical and radiolytic reactions.

4.1. Reactions of Solvated Electrons in Solutions

Hydrated electrons and their reactions in aqueous solutions have been investigated most extensively. Essentially the same behavior is exhibited by solvated electrons in irradiated alcohols [78,79]. The following primary radicals and products are formed in the radiolysis of water:

$$H_2O \rightsquigarrow e^-_{aq}\ (2.8);\ OH\ (2.4);\ H\ (0.6);\ H_2\ (0.45);\ H_2O_2\ (0.7);\ H_3O^+\ (2.8) \qquad (4)$$

The figures in brackets give the yields of primary radicals, which have been detected indirectly by the addition of suitable radical scavengers, and in some cases by analysis of the products [80]. Hydrogen atoms [81] and electrons [41] are detected directly by ESR measurements. The molecular prod-

ucts H_2 and H_2O_2 are formed in the spur by radical reactions, and their yield is affected only slightly by the addition of radical scavengers [82].

The following reactions are responsible for the disappearance of hydrated electrons in irradiated pure water:

a) Reactions with the primary radicals of water:

$$e^-_{aq} + H \rightarrow H_2 + OH^-; \quad k_5 = 2.5 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (5)$$

$$e^-_{aq} + OH \rightarrow OH^-; \quad k_6 = 3.0 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (6)$$

$$e^-_{aq} + O^- \rightarrow 2\,OH^-; \quad k_7 = 2.2 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (7)$$

$$e^-_{aq} + e^-_{aq} \rightarrow H_2 + 2\,OH^-; \quad k_8 = 0.5 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (8)$$

b) Reactions with the radiolysis products of water:

$$e^-_{aq} + H_2O_2 \rightarrow OH + OH^-; \quad k_9 = 1.2 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (9)$$

$$e^-_{aq} + H_3O^+ \rightarrow H + H_2O; \quad k_{10} = 2.0 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (10)$$

c) Reaction with water molecules:

$$e^-_{aq} + H_2O \rightarrow H + OH^-; \quad k_{11} = 8.9 \times 10^2\ \text{s}^{-1} \quad (11)$$

Reactions (5–10) are very fast and in part diffusion-controlled. In the case of reaction (10), *Sworski* [83] has assumed the formation of H_3O or H_9O_4 as an intermediate, since – according to *Debye* [84] – diffusion-controlled charge neutralization should be about twice as fast.

By contrast, the pseudo-first order reaction (11) between the hydrated electrons and the solvent is very slow. This reaction has been investigated very carefully, since it is decisive for the lifetime of hydrated electrons in pure water and for the determination of thermodynamic constants [85]. To investigate reaction (11), the water must be very pure: substances capturing electrons (*e.g.* oxygen [12] and CO_2 [13]) interfere even in very low concentrations ($> 10^{-8}$ mole/l).

$$e^-_{aq} + O_2 \rightarrow O_2^- \quad k_{12} = 2.2 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (12)$$

$$e^-_{aq} + CO_2 \rightarrow CO_2^- \quad k_{13} = 2.7 \times 10^{10}\ \text{lmole}^{-1}\text{s}^{-1} \quad (13)$$

A lifetime of 780 μs has been found for hydrated electrons at very low e^-_{aq} concentrations, but it may be assumed that even longer lifetimes will become possible when the technique is improved [85].

The corresponding reaction between solvated electrons and aliphatic alcohols [86] is very much faster:

$$e^-_{solv} + ROH \rightarrow RO^- + H \quad (11a)$$

The rate constants k_{11a} are 4.6×10^5, 10^5, 5×10^5, and $3 \times 10^5\ \text{s}^{-1}$ in the case of methanol, ethanol, 1-propanol, and 2-propanol, respectively. Thus the solvated electrons have a shorter lifetime (*ca.* 5 μs) in alcohols than in water; *Freeman* [86] has attributed this to a difference between the activation energy for reorientation of the solvent molecules from the solvation shell of electrons to the OH^- and RO^- anions respectively.

4.1.1. Acid-Base Equilibrium and the Difference between Hydrogen Atoms and Solvated Electrons

Hydrogen atoms and hydrated electrons form acid-base pairs in water, the corresponding equilibrium being dependent on the pH.

$$e^-_{aq} + H_3O^+ \rightleftharpoons H + H_2O; \quad pK = 9.6\ [62] \quad (14)$$

Pulse-radiolysis investigations [87] have shown that the transformation of hydrated electrons into hydrogen atoms (10) is faster than the reverse reaction (15) by three orders of magnitude.

$$H + OH^- \rightarrow e^-_{aq}; \quad k_{15} = 2.2 \times 10^7\ \text{lmole}^{-1}\text{s}^{-1} \quad (15)$$

The transformation of hydrogen atoms into solvated electrons (15) has also been demonstrated [88] in a reaction in which hydrogen atoms formed in a discharge tube were introduced into an alkaline aqueous chloroacetate solution (pH 13.5). Reaction (15) then took place on account of the high basicity, and the resulting solvated electrons reacted with the chloroacetate to yield Cl^- ions.

$$e^-_{aq} + ClCH_2COO^- \rightarrow Cl^- + {\cdot}CH_2COO^-; \quad k_{16} = 1.2 \times 10^9\ \text{lmole}^{-1}\text{s}^{-1} \quad (16)$$

By contrast, hydrogen atoms react with chloroacetic acid in an acidic solution (17) comparatively slowly to yield hydrogen [76]:

$$H + ClCH_2COOH \rightarrow H_2 + {\cdot}CHClCOO^-; \quad k_{17} = 2.6 \times 10^6\ \text{lmole}^{-1}\text{s}^{-1} \quad (17)$$

The historical significance of reactions (16) and (17) is that it was through the pH-dependent formation of Cl^- and H_2 that *Hayon* and *Weiss* [4] first detected in 1958 the acid-base equilibrium of "two reducing species obtained during radiolysis of water", thereby proving indirectly the existence of hydrated electrons (polarons) as intermediates.

The conversion of hydrated electrons into hydroxyl radicals with N_2O is another reaction (18) where hydrated electrons and hydrogen atoms behave differently; this reaction was first investigated by *Dainton* and *Peterson* [89].

$$e^-_{aq} + N_2O \rightarrow [N_2O^-] \xrightarrow{H_2O} N_2 + OH^- + OH; \quad k_{18} = 5.6 \times 10^9\ \text{lmole}^{-1}\text{s}^{-1} \quad (18)$$

[89] *F. S. Dainton* and *D. B. Peterson*, Nature *186*, 878 (1960).

The corresponding reaction in alcohols leads to O^- radical anions [90].

$$e^-_{solv} + N_2O \rightarrow N_2 + O^-; \quad k_{CH_3OH} = 1.4 \times 10^{10}\ l\,mole^{-1}s^{-1} \qquad (18a)$$

The existence of transient electrons during radiolysis of N_2O-saturated hydrocarbons is established by the production of nitrogen [91]. The reaction between hydrogen atoms and N_2O in water is slower by a factor of 10^5 [76].

Reaction (9) between H_2O_2 and hydrated electrons is 145 times as fast as the reaction between H_2O_2 and hydrogen atoms. This difference was noticed by *Barr* and *Allen* [5] in the radiolysis of aqueous solutions of H_2O_2, and was attributed already in 1959 to the coexistence of two different reducing radical species. Similarly, the formation of the trinitromethyl anion from tetranitromethane is 100 times faster in the presence of hydrated electrons [reaction (19)] than in the presence of hydrogen atoms [92]

$$e^-_{aq} + C(NO_2)_4 \rightarrow C(NO_2)_3^- + NO_2; \quad k_{19} = 4.6 \times 10^{10}\ l\,mole^{-1}s^{-1} \qquad (19)$$

Since the formation of trinitromethyl anion can be detected optically, this reaction offers a possibility of determining the molar extinction coefficient of hydrated electrons (ε = 15800 l mole^{-1} cm^{-1} at G_{e^-} = 2.6) [92].

Solvated electrons also differ from hydrogen atoms in their optical absorption spectrum (H atoms absorb below 200 nm [93]), ESR spectrum (H atoms show a characteristic 503-gauss doublet [81]), electric conductivity [61, 94], and the kinetic salt effect [6, 7] (this effect has an influence only on the reactions of electrons and not on the reactions of H atoms, which are electrically neutral).

4.1.2. Reactions between Solvated Electrons and Organic Compounds

The reductions brought about by solvated electrons in irradiated solutions can be compared to those occurring in metal-ammonia solutions [95]. Simple and dissociative electron attachment [reactions (1) and (3)] have been shown to be the first steps in electron transfer.

Table 5. Rate constants of bimolecular reactions of organic compounds with hydrated electrons (after [76]).

k (l mole^{-1} s^{-1})	Amino acids (pH)	Heterocycles (pH)	Aliphatic compounds (pH)
↑		adenosine (5) purine (7) thymine (6)	tetranitromethane carbon tetrachloride chloroform, nitromethane 1-iodoethane
10^{10}	cystine (6)	uracil (7)	1-iodobutane
↑	cysteine (6)	uric acid adenine (7)	butadiene chloroacetic acid (1) acetone

↑	hydroxyproline (7) tryptophan (7) phenylalanine (7)	indole uracil (11) guanine (6)	1-chloropropane 2-chlorobutane 1-chlorobutane maleic acid (6)
10^8	arginine (8)	imidazole (8.7)	formic acid (5)
↑	methionine (8) lysine (7)	thiophene (7) imidazole (9.1)	cyanoacetic acid (11) acetonitrile
10^7	serine (7)		
$< 10^7$	glycine; alanine; valine; leucine; isoleucine; threonine; formaldehyde; fluoroacetic acid; diethyl ether		

Aliphatic Compounds [18, 76]

Solvated electrons react very slowly ($k < 10^7$ l mole^{-1} s^{-1}) with aliphatic compounds having stable C–C, C–O–C, COOH, OH, and NH_2 groups, *i.e.* compounds without low-lying orbitals accessible to electrons. Halogen substituents enhance the reactivity of aliphatic compounds in the order F $\ll$ Cl $<$ Br $<$ I, which can be attributed to dissociative electron attachment (3) at the halogen substituents [96].

Electrophilic groups next to halogen substituents reduce the reactivity toward solvated electrons. *Anbar* and *Hart* [98] found a linear relationship between the

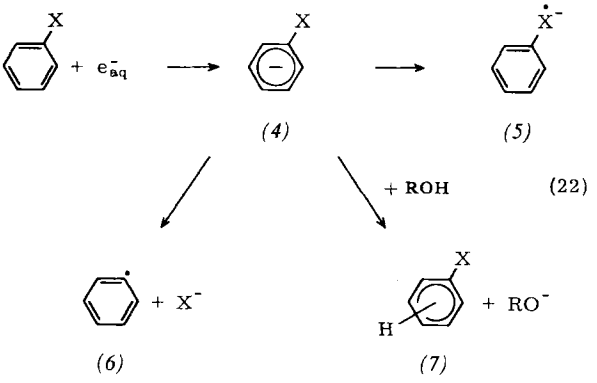
experimental rate constants of halogen-containing aliphatic compounds and *Taft*'s σ* values [97] for these electrophilic substituents. Polychlorinated hydrocarbons, *e.g.* CCl_4 and $CHCl_3$, are among the organic compounds with the highest reactivity toward electrons. Nitromethane and tetranitromethane (19) [100] are also good electron acceptors. The absorption spectra and the kinetic behavior of the nitroalkane radical anion *(3)*, formed as an intermediate, have been investigated [99], and the structure of this radical anion has been confirmed by the *in-situ* ESR-spectroscopic technique [75]. According to the findings, hydrated electrons react both with nitromethane *(1)* and with its *aci*-form *(2)* to give the radical anion *(3)*.

$$\begin{array}{ccc} CH_3NO_2\ (1) & \underset{H_2O}{\overset{OH^-}{\rightleftharpoons}} & CH_2{=}NO_2^-\ (2) \\ \downarrow + e_{aq}^- & & \downarrow + e_{aq}^- \\ CH_3\dot{N}O_2^-\ (3) & \underset{OH^-}{\overset{H_2O}{\rightleftharpoons}} & CH_2{=}\dot{N}O_2^{2-} \end{array} \qquad (20)$$

Carbonyl compounds such as aldehydes and ketones [101,102] give hydroxyalkyl radicals *via* the formation and protonation of an electron adduct.



$$R_2CO + e_{aq}^- \rightarrow R_2\dot{C}O^- \underset{}{\overset{H^+}{\rightleftharpoons}} R_2\dot{C}OH \qquad (21)$$

The ketyl radical formed during the irradiation of aqueous acetone has been identified as an intermediate at pH > 12 by use of the *in-situ* ESR technique (at lower pH values the protonated form, *i.e.* the hydroxyisopropyl radical, is observed) [103]. Enols react slowly, and so does also formaldehyde, in the case of which the electron affinity of the carbonyl group is reduced by hydrate formation.

Double bonds in aliphatic compounds enhance the reactivity to electrons only when they are conjugated or are adjacent to CN and CS groups. The addition of an electron is generally followed by rapid protonation, giving hydrogenated products [101]. The case of chloroacetic acid in Table 5 illustrates the observation that aliphatic acid anions react with electrons more slowly than do the undissociated acids.

Aromatic Compounds

As in the nucleophilic substitution of aromatic compounds by the S_N2 mechanism, the reactions of hydrated electrons with monosubstituted benzenes (22) first give a carbanion radical *(4)*, but the existence of this species can be detected only in certain cases (X = NO_2, NO, COOH) in which resonance stabilization involving *(5)* is possible [85, 98, 104].

R = H, CH_3, C_2H_5, $(CH_3)_2CH$

In the case of halogen-substituted aromatic compounds it has not yet been demonstrated that the dissociative electron attachment (3) proceeds *via* the intermediate formation of carbanions. Phenyl radicals *(6)* have been found as transient products.

Protonation of the aromatic carbanion *(4)* gives products of the cyclohexadienyl type *(7)*. The protonation of the carbanions of *e.g.* biphenyl, naphthalene, and anthracene in alcohols [105] is slower by a factor of about 10^5 to 10^6 with the solvent molecules

$$A^- + ROH \rightarrow RO^- + {}^{\cdot}AH \qquad (23)$$

than with alkoxonium ions.

$$A^- + ROH_2^+ \rightarrow ROH + {}^{\cdot}AH \qquad (24)$$

As in the case of nucleophilic substitutions, the effect of substituents on the reactivity of the aromatic ring can be deduced from the rate constants and can be expressed by *Hammett*'s σ function [106] (Fig. 3). The

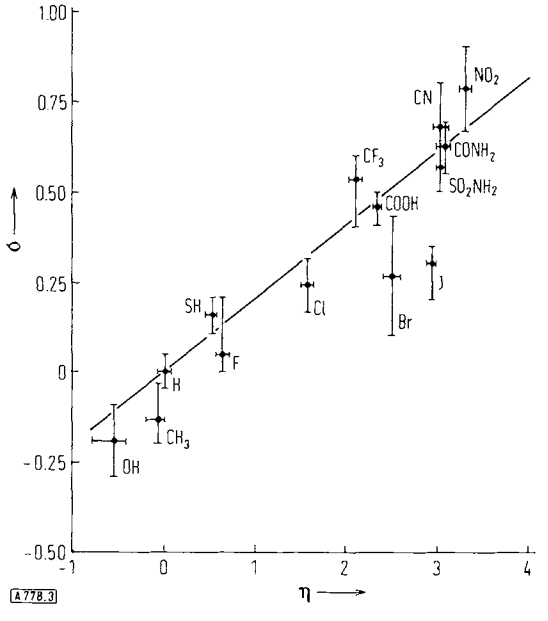


Fig. 3. Variation of *Hammett*'s σ function with $\eta = \log (k_{C_6H_5X} + e_{aq}^-)/(k_{C_6H_6} + e_{aq}^-)$ [106].

reactivity is greater in the presence of *meta*-directing substituents than in the presence of *ortho*- and *para*-directing ones.

Bromine- and iodine-substituted aromatic compounds are exceptions: they react faster with hydrated electrons than with other nucleophilic species. This is ascribed to the possibility of bromine and iodine "transferring" electrons to the aromatic ring, or to the possibility of direct attachment to halogen (3) occurring besides the ring addition [106]. Transfer by halogen ligands has also been observed in the reduction of transition metal complexes by hydrated electrons (Table 6) [107].

The reactions between disubstituted aromatic compounds (Fig. 4) and hydrated electrons are complex.

Sherman [108] has investigated the rate of the reactions between solvated electrons and substituted aromatic compounds in methanol and isopropanol in comparison with the reaction with N_2O (18a). *Dainton et al.* [90] have obtained by pulse radiolysis the value $k_{18a} = 1.4 \times 10^{10}$ l mole^{-1} s^{-1} for the absolute rate constant of the reaction with N_2O in methanol. If the relative rates are taken into account the reactions are generally found to be about 2–3 times as fast in methanol as in water.

Substances of Biological Importance [109, 110]

Physiological reactions mainly take place in aqueous systems, in which – as we have seen – irradiation produces hydrated electrons. Investigations of the reactions of these electrons in radiobiological processes are therefore of great interest. However, the investigations are complicated by the simultaneous presence of other primary radicals (OH and H), and so they have been mainly confined to simple systems such as the aqueous solutions of amino acids, peptides, compounds of nucleic acid, and sugars. The mechanisms of the electron transfer and the reactive centers in the acceptor molecules are still hardly known. The reactions between electrons and simple amino acids containing only C, H, O, and N atoms proceeding with the loss of NH_3 or CO_2, are relatively slow ($k < 10^7$ l mole^{-1} s^{-1}), whereas the reactions between electrons and amino acids containing aromatic substituents or sulfur are very much faster (Table 5). This is explained by the increase in the electron affinity, caused by the

Table 6. Rate constants of bimolecular reactions of inorganic compounds with hydrated electrons.

k (l mole^{-1} s^{-1})	Nonmetallic compounds	Oxo anions	Metal cations	Lanthanide ions	Metal complexes
↑	I_2		Cd^{2+}; Cr^{3+}	Eu^{3+}	$Co(NH_3)_6^{3+}$
	CS_2; OH	MnO_4^-	Cr^{2+}; Ag^+	Yb^{3+}	$[CoO(NH_3)_5]_2^{5+}$
	H; H_3O^+	$Cr_2O_7^{2-}$	Cu^{2+}; Ni^{2+}		$Cr(H_2O)_6^{3+}$
	O_2; SF_6	BrO^-		Sm^{3+}	$[CoO(CN)_5]_2^{5-}$
	Br_2; H_2S				$Fe(CN)_5NO^{2-}$
10^{10}	H_2O_2	IO_4^-; NO_3^-	Pb^{2+}; Co^{2+}		$Cu(NH_3)_4^{2+}$
					$Cr(CN)_6^{3-}$
↑	CO_2	NO_2^-; BrO_3^-			$PdCl_4^{2-}$
	NO_2	$S_2O_8^{2-}$; IO_3^-			$Zn(NH_3)_4^{2+}$
	e_{aq}^-				$Fe(CN)_6^{3-}$
				Tm^{3+}	$Co(CN)_6^{3-}$
				Ho^{3+}	
			Al^{3+}		FeF_6^{3-}
10^9	CO		Zn^{2+}		$Zn(CN)_4^{2-}$
↑		$S_2O_3^{2-}$		Nd^{3+}; Gd^{3+}	
				Dy^{3+}; Tb^{3+}	
				$[La^{3+}]$; Pr^{3+}	$Cu(CN)_2^-$
		ClO_3^-		Lu^{3+}; $[Y^{3+}]$	
					$Hg(CN)_4^{2-}$
10^8			Fe^{2+}		$Cd(CN)_4^{2-}$
$< 10^8$	H_2F_2		Mn^{2+}	Er^{3+}	

The differences in the reaction rates are due to the effects exerted by the substituents on the electron density distribution in the aromatic molecule [106].

substituents or the sulfur atom. *Fessenden* and *Neta* [110c] have shown that protonated amino groups are readily deaminated by hydrated electrons.

$$^{+}NH_3-CH_2-CO_2^- + e_{aq}^- \rightarrow NH_3 + {}^{\cdot}CH_2-CO_2^- \quad (25)$$

The resulting carboxylatoalkyl radicals have been detected with the aid of ESR spectroscopy [110c].

Peptides react with electrons faster than their constituent amino acids. On the other hand, the rate of the reactions between electrons and proteins is determined by the partial reactivities of their various components [110b]. All these examples clearly show that several reactive centers in the molecules must be considered for the attack by hydrated electrons. The purine and pyrimidine bases involved in nucleic acids are highly reactive with respect to hydrated electrons. The pH-dependence of the reactivity of pyrimidines (Table 5) points to a preferential addition of electrons to the carbonyl group (keto-enol tautomerism). It is not yet clear whether the absorption spectra observed in pulse-radiolytic investigations are to be attributed to radical anions of substituted pyrimidines or to the protonated products of these [109c]. Probably the C=N and the C=O groups are responsible for the preferential electron addition in purines.

4.1.3. Reactions between Solvated Electrons and Inorganic Compounds

Investigations of the reactivity of hydrated electrons toward a few hundred inorganic compounds have revealed a great variety in this respect, the rate constant varying from $k > 10^{10}$ l mole^{-1} s^{-1} for diffusion-controlled cases to $k_{11} = 16$ l mole^{-1} s^{-1} for the "slow" reaction with water. It has not yet been possible to classify these reactions as systematically as in the case of organic reactants. The product formed by electron transfer (2) is often thermodynamically unstable and reacts further, by protonation, dissociation, disproportionation, or charge transfer.

Neutral Molecules (Table 6)

The reactions with oxygen (12), CO_2 (13), and I_2 (26) [112] lead to the relatively stable electron addition products O_2^-, CO_2^-, and I_2^-. The absorption spectra and the chemical properties of these radical anions have been studied.

$$e_{aq}^- + I_2 \rightarrow I_2^-; \quad k_{26} = 5.1 \times 10^{10} \text{ l mole}^{-1} \text{ s}^{-1} \quad (26)$$

The reaction between electrons and hydrogen sulfide (27) leads to SH^- and S^- in a ratio of 1.9:1 *via* an intermediate that has not yet been intercepted [113].

$$e_{aq}^- + H_2S \rightarrow (H_2S)^- \begin{cases} \rightarrow SH^- + H \\ \rightarrow S^- + H_2 \end{cases} ; k_{27} = 1.35 \times 10^{10} \text{ l mole}^{-1} \text{ s}^{-1} \quad (27)$$

The high electron affinity of sulfur hexafluoride, which is otherwise chemically stable, has recently been utilized to capture electrons in solutions, as has been done with N_2O (28) [39].

$$e_{aq}^- + SF_6 \rightarrow SF_6^-; \quad k_{28} = 1.65 \times 10^{10} \text{ l mole}^{-1} \text{ s}^{-1} \quad (28)$$

The radical anion SF_6^- decomposes into SO_4^{2-}, H_3O^+, and F^- anions *via* a number of oxidizing intermediates. A value of $G_{e_{aq}^-} = 2.76$ has been obtained for reaction (28) by the determination of the fluoride formed [39].

Ions (Table 6)

Hydrated electrons react relatively slowly ($k \leqslant 10^7$ l mole^{-1} s^{-1}) or not at all with anions having a noble gas configuration (F^-, Cl^-, Br^-, I^-, CN^-, CNO^-, N_3^-, and OH^-), and with the oxygen-containing anions of nonmetallic elements in their highest oxidation state ($B_4O_7^{2-}$, CO_3^{2-}, HCO_3^-, ClO_4^-, PO_4^{3-}, HPO_4^{2-}, and SO_4^{2-}). Alkali metal phosphates and borates can be used as buffer additives to adjust the pH, owing to their lack of reactivity toward hydrated electrons. By contrast, the strongly oxidizing oxygen-containing anions of metals (MnO_4^- and CrO_4^{2-}) are very reactive. The anions NO_2^- and NO_3^- and the oxygen-containing anions of halogens also give fast and practically diffusion-controlled reactions with hydrated electrons. However, little is known as yet of the properties of the products formed in these reactions.

Hydrated electrons do not react with alkali metal and alkaline earth metal cations, but – as expected on the basis of their negative reduction potential (Table 3) – they do react with a number of metal ions that can be reduced by one valence state according to reaction (2) [114]. Some cations are thus reduced to the metallic state ($Ag^+ \rightarrow Ag^\circ$ [114]; $Au^+ \rightarrow Au^\circ$ [115]), while others are reduced to unstable oxidation states. Thus radiolytic reduction of the divalent cations of Cr, Mn, Fe, Co, Ni, Cu, Zn, and Cd yields the corresponding monovalent cations with a very short lifetime [114]. The monovalent cations of Mn, Co, Ni, Zn, and Cd give an absorption maximum at 310 nm, indicating that these cations are loose electron addition products (*e.g.* $Mn^{2+} \cdot e_{aq}^-$) [114].

There is a connection between the redox potential of trivalent lanthanide cations and their reactivities toward hydrated electrons [112]; Eu^{3+}, Yb^{3+}, Sm^{3+}, and – to a smaller extent – Tm^{3+} give stable divalent cations, and their reduction by hydrated electrons is faster by one order of magnitude than the corresponding reduction of the other lanthanide ions. Pr^{3+}, Tb^{3+}, and Dy^{3+}, which are relatively easily oxidized, react with

hydrated electrons particularly slowly. Since the 4f orbital in La^{3+}, Gd^{3+}, and Lu^{3+} is not half- or fully occupied, these cations have a relatively stable electron configuration, and therefore show a low electron affinity [112].

Rates of Reactions between Hydrated Electrons and Metal Complexes

Many inorganic compounds are reduced by electrons in a practically diffusion-controlled reaction [111]. This holds particularly for some metal complexes [107], in the case of which the ability of the ligand to transfer electrons to the central atom follows the order $OH^- < CN^- < NH_3 < H_2O < F^- < Cl^- < I^-$ (Table 6). The electron density distribution at the central atom is so modified by some ligands that orbitals accessible to electrons appear. An attempt has recently been made [107] to compare the experimental results with the values calculated from the Debye equation (29) for diffusion-controlled ionic reactions [84].

$$k_{diff} = \frac{4\pi N_A (D_{e^-_{aq}} + D_X)(r_{e^-_{aq}} + r_X) Q}{e^Q - 1} \qquad (29)$$

$$Q = \frac{-Z_X e^2}{\varepsilon kT (r_{e^-_{aq}} + r_X)}$$

The rate constant k_{diff} is expressed here in terms of the summed diffusion coefficients of the ions ($D_{e^-_{aq}} + D_X$), the summed effective ionic radii ($r_{e^-_{aq}} + r_X$), and the product of the ionic charges (Z_X and e^-). (ε is the dielectric constant, N is Avogadro's number, k is Boltzmann's constant, and T is the absolute temperature.)

The experimental rate constants and the values calculated from eq. (29) agree well for a series of complexes of divalent and trivalent cobalt and chromium [107]. The calculations were carried out with the $D_{e^-_{aq}}$ values [61] found from independent measurements, and with the effective ionic radius ($r_{e^-_{aq}}$) [23] of the hydrated electrons (Table 1). In a series of metal complexes, the reaction rates were faster (for $[CoO(CN)_5]_2^{5-}$, FeF_6^{3-}, and $Cr(CN)_6^{3-}$) or slower (for $[CoO(NH_3)_5]_2^{5+}$) than the corresponding calculated value. It must be assumed in these cases that not all the gegenions of the complex salts are dissociated, and therefore a smaller or a greater effective total charge must be taken for the complex.

4.2. Activation Energy and the Mechanism of Electron Transfer

The activation energy E_a involved in the reactions with hydrated electrons has been determined pulse-radiolytically [116] and by the method of competition kinetics [117]; it has been found to be 3.5 ± 0.4 kcal/mole for about 20 reactions differing in their reduction rate constants by 10^4. This suggests that the observed activation energy must be ascribed to the diffusion of the hydrated electrons, which is feasible in view of the energy needed for the dipole orientation of water (4 kcal/mole) [117].

The first product formed in the electron transfer is not yet known, but it is assumed to be the radical anion in an excited vibrational or electronic state, whose transition into a stable state is associated with a gain in free energy. There is yet no experimental proof to support the concept that this energy gain and the energy requirement for the orientation of the donor and the acceptor species into the electron transfer complex [*] (Frank-Condon condition) are a measure of the probability of a reaction [117].

4.3. Reactions of Electrons in Glasses Formed from Polar and Nonpolar Solutions [21, 119–123]

Optically transparent glasses are obtained by the rapid cooling of highly concentrated aqueous solutions, alcohols, and some hydrocarbons. The solutes are assumed to be uniformly distributed in the resulting glasses (except for polar and readily associating molecules in nonpolar hydrocarbons [51]). The reactions of electrons in these glasses can be described as follows. The localization of thermalized electrons e^-_m in electron traps T according to reaction (30) competes with the reactions with acceptors (1–3).

$$e^-_m + T \rightarrow e^-_t \qquad (30)$$

Thermally or photochemically delocalized electrons can react similarly

$$e^-_t \xrightarrow{\Delta, h\nu} e^-_m + T \qquad (31)$$

Apart from a few cases where resonance stabilization must be assumed, the radical anion intermediate A^- formed in (1) is not stable in protonic glasses, on account of the rapid protonation (23) that proceeds even at low temperatures. The secondary radicals R· can be detected in reactions (3) between electrons and halogen-substituted organic substances. It is characteristic of these reactions in glasses that the intensity of the optical absorption spectra and the ESR spectra of stabilized electrons decreases with increasing concentration of added electron acceptors (10^{-3} to 10^{-1}

[116] *B. Cercek* and *M. Ebert*, J. Phys. Chem. *72*, 766 (1968).

[117] *M. Anbar*, *Z. B. Alfassi*, and *H. Bregman-Reisler*, J. Am. Chem. Soc. *89*, 1263 (1967).

[*] The reactions of hydrated electrons differ from the classical electron transfer between a donor and an acceptor in two points:

1) the electron wave-function, which extends over several molecules and even outside the solvation shell, is very sensitive to changes in the orientations in the liquid; and

2) the number of reactants is decreased by one when the hydrated electron is captured by the acceptor [118].

mole/l), and that the absorption and the ESR spectra contain new bands, attributable to the radicals A^-, AH, or $M^{(n-1)+}$. The course of the competing reactions (1)–(3) and (30)–(31) is determined by the range of the thermalized electrons in the medium and by the electron affinities of the acceptors A, M^{n+}, and RX. The concentration which decreases the yield of stabilized electrons to one half can be taken as a measure of the relative reactivity of electron acceptors. In glassy NaOH this concentration is 10^{-1} and 10^{-2} mole/l for chloroacetic acid [124] and for sodium nitrate [119], respectively.

4.3.1. Pure Ice and Neutral Aqueous Glasses

In comparison with the yield of OH radicals (G_{OH} = 0.8 [126]), the yield of detectable electrons in crystalline ice [42, 125] at −196 °C is very low ($G_{e_s^-} = 5\times10^{-4}$). Pulse-radiolytic measurements on ice [29, 127, 128] between −2 and −160 °C have shown that, as the temperature decreases, the yield of optically detectable electrons decreases (from $G_{e_s^-}$ 0.5 at −5 °C to 10^{-3} at −160 °C), and the lifetime increases by several orders of magnitude ($t_{1/2}$ is 2×10^{-5} s at −5 °C and 10^{-1} s at −130 °C) [29].

The disappearance of the light absorption is a kinetically complex process due probably to the inhomogeneous distribution of electrons in the crystal. The decrease in the electron yield with a decrease in the temperature is explained by the combination of charge carriers according to (32) or (33) [29].

$$e_m^- + H_3O^+ \rightarrow H + H_2O \quad (32)$$

$$e_m^- + H_2O^+ \rightarrow H_2O \quad (33)$$

Owing to the high mobility of the excess protons formed in ice [*] in accordance with reaction (34), and the low concentration of suitable electron traps T, reaction (32) is so much preferred that most of the thermalized electrons react before they are stabilized [29].

$$H_2O^+ + H_2O \xrightarrow{\approx 10^{-14}\,s} H_3O^+ + OH \quad (34)$$

Doping of ice crystals with H_2F_2, which increases the H_3O^+ concentration, leads to a further decrease in the electron yield [127].

Unlike the ice crystals, to which electrons impart only a pale blue color [42], the condensates of water irradiated in the vapor phase [43] show a deep blue color and strong ESR singlet signals. The electrons produced can presumably influence the orientation of the water molecules into the ice structure during condensation, for no electrons can be stabilized on subsequent irradiation of condensates produced from pure water vapor. The addition of electron scavengers $C(NO_2)_4$ and $(CD_3)_2SO$ to the gaseous mixture attenuates the blue color of the condensates, while the ESR spectra point to the formation of the radicals NO_2 and CH_3 [43].

The above-mentioned influence of the structure is particularly conspicuous in the glasses formed from highly concentrated salt solutions (> 5 mole/l), in which electrons can be stabilized in differing yields [119] ($G_{e_t^-}$ is 0.5, 0.6, and 2.0 for $NaClO_4$, LiCl, and K_2CO_3 respectively). Aqueous solutions of glycerol, ethylene glycol, and some hydrocarbons also form glasses in which electrons can be stabilized by irradiation [119, 120]. The absorption maximum exhibits a blue shift with respect to that of pure ice, indicating that the distribution of the electron traps is influenced by solvated ions.

4.3.2. Acid Glasses [122, 123]

Rapid cooling of aqueous solutions of phosphoric acid, sulfuric acid, perchloric acid, and sodium hydrogen sulfate (in a concentration of more than 5 mole/l) leads to the formation of glasses. Although the ESR spectroscopic examination of these "acid glasses" after irradiation at −196 °C reveals not electrons but hydrogen atoms [129], electrons should be regarded as the precursors of these hydrogen atoms in accordance with reaction (32). A direct proof is afforded by the formation of reduced metal cations, which occurs by reaction (3) when *e.g.* Mn^{2+}, Co^{2+}, or Cd^{2+} is added. This process is accompanied by a drop in the yield of hydrogen atoms [25].

4.3.3. Alkali Metal Hydroxide Glasses

Much work has been done on stabilized electrons in glasses formed by freezing of alkali hydroxide solutions with a concentration of over 5 mole/l [26, 119]. According to the absorption spectra and the ESR signals (Table 2), the alkali metal exerts no particular effect, but the solvent does, and this excludes the possibility that the electrons are stabilized in the immediate vicinity of the alkali metal cations [9]. The yield of stabilized electrons depends on the alkali concentration, and is $G_{e_t^-} = 2.0 \pm 0.2$ for a glass obtained from 10 N NaOH [26, 119]. By capturing the electrons with a nitrate, *Ershov* and *Pikaev* [121] have found $G_{e_t^-} = 3.0$. The acceptor-free glass evidently stabilized only two-thirds of the thermalized electrons according to reaction (30).

Kevan et al. [130a] have measured a photoelectric current in the bleaching of stabilized electrons, and have thus demonstrated that the optical transition from the

ground state is to a nonbonding conduction-band-like state.

According to recent work, dielectrons can be stabilized in alkali metal hydroxide glasses, similarly to the F'-centers in ionic crystals [130b]. These dielectrons arise in the photochemical bleaching of the blue color, or in irradiation with very high doses (> 10 Mrad), when the electrons e_m^- react with stabilized electrons as shown below:

$$e_m^- + e_t^- \rightarrow e_t^{2-} \xrightarrow{h\nu'} e_m^- + e_t^- \qquad (35)$$

Dielectrons, which are characterized by spin coupling, diamagnetism, and a broad absorption band ($\lambda_{max} \approx 900$ nm), can dissociate into singly occupied centers on annealing or photo-bleaching in the IR region [second step of reaction (35)] [130c].

Among the electron acceptors dissolved in alkali glasses [119], chloroacetic acid and chloroform react in accordance with (3) to yield chloride ions. Acetone [25], acrylamide [131], and aromatic carboxylic acids [135] form radical anions A^-, which are identified by their absorption spectra and sometimes also by their ESR spectra. The transfer of the photochemically remobilized electrons (31) onto aromatic carboxylic acids in accordance with reaction (1) is reversible. When the sample is exposed to monochromatic light, the absorption band of the radical-anion formed decreases, and the absorption band of the stabilized electrons increases [135].

4.3.4. Organic Glasses [21, 71]

The transfer of electrons induced by ionizing radiation has been studied in glasses formed from alcohols, methyltetrahydrofuran, or simple hydrocarbons, the electron acceptors being olefins, aliphatic and aromatic ketones, alkyl-substituted and vinyl-substituted aromatic compounds, aryl halides [71a], alkyl halides [71], and sulfur compounds [132]. In methyltetrahydrofuran and hydrocarbons such as pentane and 3-methylpentane, electron transfer (1) yields stabilized radical-anions, which can be detected optically and by ESR spectroscopy [71]. They are identical with the radical anions formed in ammoniacal and ethereal solutions of sodium [133].

Only the radical-anions of biphenyl [71] and of some aromatic carboxylic acids [135] have been identified in alcohol glasses. The electron adducts of benzene and naphthalene rapidly react further with the solvent (23) or with alkoxonium ions (24) [134].

Like the excess protons in water and ice [reaction (33)], the alkoxonium ions are produced in the transfer of protons to the alcohol cations *(8)*.

$$\begin{aligned} &R{-}CH_2{-}OH^+ + R{-}CH_2{-}OH \rightarrow \\ &\qquad R{-}CH_2{-}OH^+ + R{-}CH_2{-}O^\bullet \\ &R{-}CH_2{-}OH^+ + R{-}CH_2{-}OH \rightarrow \\ &\qquad R{-}CH_2{-}OH^+ + R{-}\dot{C}H{-}OH \end{aligned} \qquad (36)$$

They represent the gegenions to the solvated electrons, and are presumably also mobile in alcohol glasses, on account of proton migration.

Thermal and photochemical generation of electrons give different reactions in irradiated alcohol glasses [120]. Electrons remobilized by warming undergo reaction (24) [*] with alkoxonium ions, and can also be scavenged by the electron acceptors according to reactions (1)–(3). In the case of photochemically delocalized electrons, on the other hand, these reactions have not been observed; instead, the pseudo-first order photochemical reaction (37) leads quantitatively to hydroxyalkyl radicals with a quantum yield of 0.06.

$$e_t^- + CH_3OH_2^+ \xrightarrow[(\lambda = 540\ nm)]{h\nu} {}^\bullet CH_2OH + H_2 \qquad (37)$$

The formation of dielectrons, involved in reaction (35), has not been observed in alcohol glasses.

The author wishes to thank Prof. Dr. D. Schulte-Frohlinde, Prof. Dr. U. Schindewolf, and Dr. K. W. Böddeker for stimulating and valuable discussions.

$Ru_3(CO)_9H(C_6H_5CC_6H_4)$: A μ-Hydridocarbonyl Metal Cluster Derivative of Diphenylcarbene[1]

By *A. W. Parkins, E. O. Fischer, Gottfried Huttner*, and *Dieter Regler*[*]

During our studies on the formation of carbene complexes of trinuclear metal carbonyl complexes we treated dodecacarbonyl-*triangulo*-triruthenium with one equivalent of phenyllithium in tetrahydrofuran at low temperatures. Chromatography of the products gave a very low yield of red crystals, m.p. 139–142 °C, total analysis of which gave the composition $Ru_3C_{22}H_{10}O_9$:

$$Ru_3(CO)_{12} \xrightarrow[2.\ H_3PO_4/CH_3OH]{1.\ LiC_6H_5/THF} Ru_3C_{22}H_{10}O_9$$

In accord with this composition the mass spectrum (50 eV; Atlas CH4) showed a peak for the molecular ion at $m/e = 730$ (referred to ^{104}Ru)[2]. The osmometric molecular weight in benzene was determined as 726. The mass-spectral fragmentation of the compound indicated the presence of nine CO ligands, which appeared in the IR spectrum (cyclohexane solution) as seven ν_{CO} absorptions — at 2097 m, 2071 s, 2041 vs, 2032 vs, 2018 s, 2006 s, and 1990 m cm^{-1}, which indicated terminal positions for these ligands; further, for KBr disks there were four strong C—C deformation vibrations of aromatic rings — at 767, 757, 723, and 703 cm^{-1}, which could indicate the presence of two differently bound phenyl groups. The ^1H-NMR spectrum (CS_2 solution) showed a strongly split group of signals for phenyl protons at $\tau = 2.5$–3.0 and a very sharp signal at $\tau = 30.2$ with relative intensities $\approx 10 : 1$, which, together with the diamagnetism of the compound, indicated a bridging H atom bound to metal.

These findings do not suffice to prove a structure, which was finally established (see Figure) by X-ray analysis.

The compound crystallizes in the triclinic system, space group $P\bar{1}$ with cell constants: $a = 9.38 \pm 0.01$, $b = 13.51 \pm 0.02$, $c = 9.75 \pm 0.01$ Å, $\alpha = 95.50 \pm 0.08$, $\beta = 90.02 \pm 0.08$, $\gamma = 110.70 \pm 0.06°$, $V = 1150 \pm 6$ Å^3, $d_{calc} = 2.08 \pm 0.01$, $d_{obs} = 2.06 \pm 0.02$ g · cm^{-3}, $Z = 2$.

4962 independent non-zero diffraction intensities in the range $0 < \sin\theta/\lambda \leq 0.845$ were collected for two crystals on a Weissenberg diffractometer (manufactured by Stoè) using $Mo_{K\alpha}$ radiation ($\lambda Mo_{K\alpha} = 0.71069$ Å). The structure was solved by Patterson, Fourier, and least-squares methods, the present value of R_1 being 0.071[3].

The ruthenium atoms form a three-membered ring. The bond distances Ru¹—Ru² and Ru²—Ru³ are equal within experimental error and appreciably shorter than the distance between Ru¹ and Ru³ which are joined by a H bridge (Table, Fig.). Three carbonyl groups are bonded to each ruthenium atom, two of which are approximately equatorial with respect to the plane formed by the metal atoms. The three remaining carbonyls occupy approximately axial positions on one side of the Ru ring.

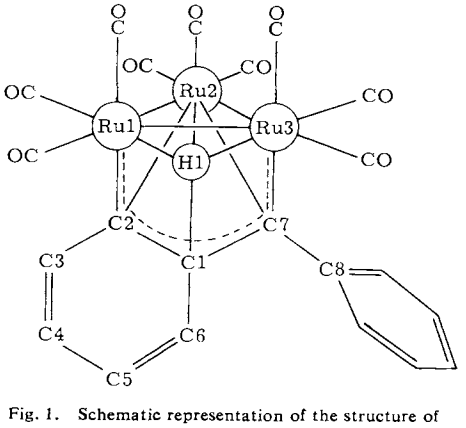

Fig. 1. Schematic representation of the structure of $Ru_3(CO)_9H(C_6H_5CC_6H_4)$.

Bond distances (in Å).

Ru¹—Ru²	2.776 ± 0.004	C¹—C²	1.46 ± 0.01
Ru¹—Ru³	2.914 ± 0.004	C²—C³	1.42 ± 0.01
Ru²—Ru³	2.773 ± 0.004	C³—C⁴	1.36 ± 0.02
Ru¹—C²	2.10 ± 0.01	C⁴—C⁵	1.42 ± 0.01
Ru³—C⁷	2.08 ± 0.01	C⁵—C⁶	1.36 ± 0.02
Ru²—C¹	2.36 ± 0.01	C⁶—C¹	1.43 ± 0.01
Ru²—C²	2.32 ± 0.01	C¹—C⁷	1.43 ± 0.01
Ru²—C⁷	2.26 ± 0.01		

The other side of the three-membered metal ring is occupied by the organic ligand system. This system can be derived formally from diphenylcarbene; it is, however, coordinated to all three metal atoms of the cluster in a quite unusual way. The average length of the bonds Ru¹—C² and Ru³—C⁷ (2.09 ± 0.01 Å) is only 0.18 Å greater than the mean Ru—C_{CO} bond length (1.91 ± 0.01 Å), so the former appear to have marked double-bond character. A double-bond contribution to these bonds is in line with the coplanarity of the atoms Ru¹, Ru³, C¹···⁶, and C⁷ which provide the skeleton of an extended mesomeric heterocyclic system that is stabilized by the π-bonding of the allyl fragment C²—C¹—C⁷ to Ru². The C—C bonds of the phenyl ring C¹···⁶ that is involved in the mesomeric system show clear alternation in length in accordance with the valence scheme illustrated in the Figure (cf. Table). The carbon atom C⁸ of the second phenyl group is in the plane of the heterocyclic system, but the ring itself does not take part in complex formation and lies perpendicular to that plane.

Experimental

LiC_6H_5 (0.85 mmole) is added rapidly to a suspension of $Ru_3(CO)_{12}$ (500 mg, 0.78 mmole) in tetrahydrofuran (100 ml) at −30 °C. The deep red mixture is evaporated to dryness in a vacuum at −30 °C and the red residue is taken up in 20% aqueous methanol precooled to −30 °C. The resulting red solution is acidified with 85% H_3PO_4 (0.75 ml) and at once extracted with pentane at −30 °C. This extract is dried over Na_2SO_4, filtered, and concentrated to 20 ml. The product is chromatographed at 10 °C on a silica gel (Merck) column (2 × 55 cm) prepared in pentane. Elution with 2.5–5% benzene/pentane gives unchanged $Ru_3(CO)_{12}$; then elution with 7.5–10% benzene/pentane gives a yellow oil that has not yet been examined; a third fraction, obtained by using 12.5–15% benzene/pentane, contains the new complex. The third fractions of four batches are collected and chromatographed once again by the same procedure. On recrystallization from pentane we obtained the product in 1% yield (25 mg).

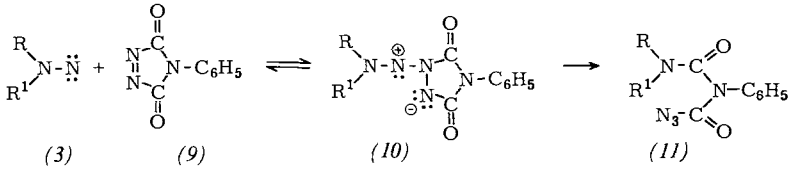
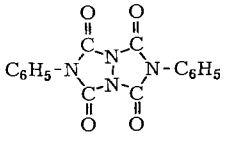
Aminoazimines by Addition of Aminonitrenes to α-Carbonylazo Compounds[1,2]

By *Karl-Heinz Koch* and *Egon Fahr* [*]



Reaction of the unsymmetrically substituted hydrazines *(1a)* to *(1c)* [3] with diethyl azodicarboxylate *(2)* leads to the formation of the aminonitrenes *(3)* and hydrazodicarboxylate. The aminonitrenes *(3)* add a second molecule of *(2)* to give the aminoazimines *(4)* [4], which then decompose — presumably *via* compound *(5)* — into the urethanes *(6)* and ethyl azidoformate *(7)*. The intermediary formation of the aminonitrenes *(3)* is supported by the following findings:

a) In the reaction, as in other reactions of aminonitrenes [5], some tetrazene *(8)* is formed.



b) When compound *(1) is added to (2)*, the aminonitrene *(3)* is intercepted by *(2)* with formation of much *(6)* and *(7)*, the yield of tetrazene *(8)* being low [*(1a)*:*(6a)* 80 %, *(7)* 80 %, *(8a)* 5 %; *(1b)*: *(6b)* 70 %, *(7)* 70 %, *(8b)* < 2 %; *(1c)*: *(6c)* 75 %, *(7)* 80 %, *(8c)* < 2 % [6]]. If, however, *(2) is added to (1)* under the same conditions then the yield of tetrazene increases considerably and the yields of *(6)* and *(7)* are lower [*(1a)*: *(6a)* 30 %, *(7)* 30 %, *(8a)* 20 %; *(1c)*: *(6c)* 30 %, *(7)* 30 %, *(8c)* 50 % [6]].

(1) *(2)* *(3)* *(8)* *(4)* *(5)* *(6)* *(7)*

(3) *(9)* *(10)* *(11)*

[b] Region 380—450 nm. toluene.

If the cyclic α-carbonylazo compound *(9)* is used instead of *(2)*, the reaction sequence *(4)* → *(5)* → *(6)*/*(7)* is so hindered by the rigidity of the C=O group in *(9)* that the aminoazimines can be isolated. Their structure is based, in addition to elemental analysis and molecular weight determination, on the following findings:

a) Their absorption maximum between 387 and 435 nm (see Table) excludes unequivocally a triaziridine structure [corresponding to the formulation *(5)*].

b) On reduction with dithionite four H atomes are taken up per molecule with formation of *(1)* and phenylurazole.

c) On warming in an apolar solvent, cleavage into the azo compound *(9)* [identified as the thermal decomposition product *(12)* [7]] and the aminonitrene *(3)* [trapped with *(2)* as *(6)*/*(7)*] takes place alongside the rearrangement to *(11)*.

d) The "element list" [carried out for *(10a)* [8]] determined for the molecular ion and 12 fragments by mass spectrometry also proves the suggested formulation.

e) The aminoazimines *(10)*, like triazenes [9], exhibit a hindered rotation of the R_2N grouping that can be studied by NMR spectroscopy; *e.g. (10d)*: $\Delta G_c^{\ddagger} \approx 14.5$ kcal/mole, $T_c \approx 25\,^{\circ}C$ [10].

f) Gentle warming in ethanol results in rearrangement to *(11)*, which corresponds to the formation of *(6)*/*(7)* from *(2)* and *(1)* [*(11a)*: m.p. 58—60 °C, yield 40 %].

General preparation of aminoazimines (10)

A solution of compound *(9)* (10 mmoles) in anhydrous toluene (250 ml) is added at room temperature to a solution of *(1)* (5 mmoles) in anhydrous toluene (20 ml) and the mixture is allowed to stand for 12 hours. The phenylurazole formed is then removed from the reaction mixture by suction and the filtrate, in the case of *(10b)*—*(10d)*, is concentrated to 10—15 ml; in the case of *(10a)* and of *(10e)* the filtrate is evaporated to dryness. The aminoazimines are precipitated from the filtrates of *(10b)*—*(10d)* when the latter are allowed to stand with ice-cooling. *(10a)*, *(10d)*, and *(10e)* can be recrystallized from alcohol-free glacial acetic acid, and *(10b)* and *(10c)* from toluene (take care: tendency to decompose).

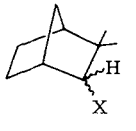
An Investigation of the Nitrile Oxide-Isocyanate Rearrangement[1] [**]

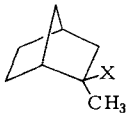
By *Christoph Grundmann* and *Peter Kochs* [*]

The thermal isomerization of nitrile oxides to isocyanates has been known for more than sixty years [1a].



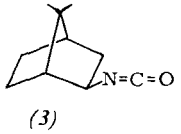
$$R-C\equiv\overset{\oplus}{N}-O^{\ominus} \rightarrow R-N=C=O$$

A recent INDO-calculation of the fulminate-cyanate rearrangement [2] indicates an oxazirinyl anion as cyclic transition state (or intermediate).

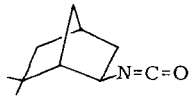


If the nitrile oxide-isocyanate rearrangement proceeds *via* separated ions, and if R in R—CNO is a group of demonstrated propensity toward carbon skeleton rearrangement

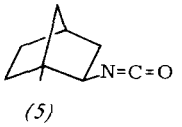
$$R-C\equiv\overset{\oplus}{N}-\overset{\ominus}{O} \rightarrow R^{\oplus} + C\equiv\overset{\ominus}{\underset{}{O}}\!\!\rightarrow N \rightarrow R-N=C=O$$



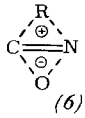
under conditions in which cationic carbon is thought to be involved, then the ionic mechanism should lead to carbon skeleton rearrangement. Such systems R are, *e.g.*, the camphenilyl group *(1)* and the *endo*-2-methyl-2-norbornyl group



(1a), X = CH=N⁓OH
(1b), X = CNO
(1c), X = N=C=O



(2a), X = CH=N⁓OH
(2b), X = CNO
(2c), X = N=C=O
(2d), X = CO_2H

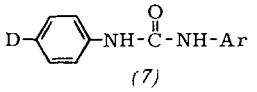


(3) + 

(4)

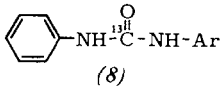
(5)

(6)



(2), which were chosen since the precursors for the required nitrile oxides were easily accessible.

The dehydrogenation of a mixture of *endo-* and *exo-(1a)* [3,4] yielded the unstable nitrile oxide *(1b)* which partly rearranged to the isocyanate *(1c)* on being heated to 110 °C in xylene solution, while most of the material dimerized to the corresponding furoxane.



The isocyanate, isolated as the symmetrical urea derivative, showed a mass-spectrographic disintegration pattern compatible only with the unrearranged carbon skeleton structure *(1c)*; structures *(3)* and *(4)* are definitely ruled out [5]. Furthermore, we were not able to detect a rearrangement of *endo-(1b)* to *exo-(1b)*.

We investigated then the nitrile oxide *(2b)*, easily available from *(2a)* [6], and also found no products derived from a Wagner-Meerwein rearrangement, *e.g. (5)*, such as are formed in carbonium ion reactions [7]. The isocyanate *(2c)* was also synthesized independently by Curtius degradation of the known acid *(2d)* [8], and found identical with that obtained from the nitrile oxide. Both compounds were compared as the corresponding symmetrical urea derivatives.

To support the evidence for an intramolecular, rather than an intermolecular, mechanism we rearranged *p*-deuteriobenzonitrile oxide in the presence of [α-^{13}C]benzonitrile oxide. These compounds should rearrange at approximately the same rate, so that, if the reaction were to any extent intermolecular, the product should contain some *p*-deuterio-[α-^{13}C]phenyl isocyanate. We isolated the phenyl isocyanate as the unsymmetrical urea by reaction with *o*-toluidine. Only the singly labeled products *(7)* and *(8)* could be detected by mass spectrometry [9].

(7)

(8)

Ar = *o*-CH_3-C_6H_4

This intramolecular rearrangement [10], in which bond breaking and bond making are essentially synchronous, can be visualized as proceeding *via* an activated transition complex *(6)*. A consequence of such a mechanism is that the group R migrating from carbon to nitrogen should do so with retention of configuration when the point of attachment is a center of optical asymmetry.

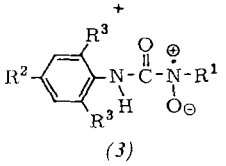
An Unusual Reaction of Azomethine Nitroxide Radicals with Carboxylic Acids[**]

By *Hans Günter Aurich* and *Klaus Kabs*[*]



Dedicated to Professor K. Dimroth on the occasion of his 60th birthday

We have found that *N*-alkyl-*N*-aryliminomethyl nitroxides *(1)* are converted into *N*-alkyl-*N*-benzoxazolyl nitroxides *(2)* and *N*-alkyl-*N*-arylcarbamoyl nitroxides *(3)*, with retention of the nitroxide group, by treatment with carboxylic acids.

If small amounts of glacial acetic acid are added, in the absence of oxygen, to the violet solutions of the radicals *(1a)* to *(1f)*[1] in benzene, which are then frozen, pale red radicals *(2)* are formed immediately; their ESR spectra differ significantly from those of the initial radicals *(1)*. Analysis of the ESR spectra showed that the H atom attached to the central C atom and one of the two *o*-H atoms of the phenyl had been replaced during the reaction. Treatment of 2-chlorobenzoxazole with *N*-*tert*-butylhydroxylamine and *N*-isopropylhydroxylamine, respectively, and subsequent oxidation of the reaction solution yielded radicals whose ESR spectra were identical with those obtained on reaction of *(1a)* and *(1b)*.

(1) *(2)*

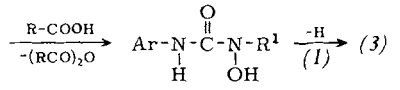
(3)

	R^1	R^2	R^3
(a)	$C(CH_3)_3$	H	H
(b)	$CH(CH_3)_2$	H	H
(c)	$C(CH_3)_3$	$C(CH_3)_3$	H
(d)	$CH(CH_3)_2$	$C(CH_3)_3$	H
(e)	$C(CH_3)_3$	$C(CH_3)_3$	D
(f)	$CH(CH_3)_2$	$C(CH_3)_3$	D

Coupling constants of the radicals *(1)* and *(2)* (in gauss):

	$a_{N(NO)}$	$a_{N(-N=C)}$	$a_{H(H-C^{\diagup})}$	$a_{H(R^1)}$	$a_{H(R^2)}$	$a_{H(R^3)}$	$a_{H(meta)}$
(1a)	8.3	3.5	1.4	–	0.9	0.9	0.45
(1b)	7.85	3.8	not assigned				
(1c)	8.3	3.6	1.5	–	–	1.0	0.45
(1d)	7.8	3.9	not assigned				
(1e)	8.3	3.6	1.5	–	–	–	<0.5
(1f)	8.1	3.9	1.9	2.5	–	–	<0.5

	$a_{N(NO)}$	$a_{N(-N=C)}$	$a_{H(R^1)}$	$a_{H(R^2)}$	$a_{H(R^3)}$	$a_{H(5\text{ and }7)}$
(2a)	8.85	2.55	–	0.95	0.95	<0.5
(2b)	8.3	2.7	2.5	1.1	1.1	<0.5
(2c)	8.75	2.6	–	–	0.9	0.3 (1 H) <0.3 (1 H)
(2d)	8.4	2.75	2.75	–	1.2	<0.5
(2e)	8.75	2.6	–	–	–	<0.5
(2f)	8.3	2.75	2.6	–	–	<0.5



Surprisingly, the radicals *(1)* react with acetic acid much more slowly at room temperature (solution not frozen). Under such conditions the radicals *(2a)* and *(2b)* can no longer be detected; only after several hours do *(1c)*–*(1f)* afford *(2c)*–*(2f)* and *(3c)*–*(3f)* [superposed ESR spectra: *(3c)* and *(3e)*: triplet $a_{N(NO)}$ = 10.25 G; *(3d)* and *(3f)*: six-line spectra, $a_{N(NO)}$ = 9.9 G, $a_{H(R^1)}$ = 3.3 G. The C=O group in such radicals[2] imposes a barrier to delocalization of the unpaired electron and the Ar–NH group consequently has practically no effect on the spectrum].

We prepared the radicals *(3)* independently by oxidation of *N*-hydroxy-*N*-*tert*-butyl-*N'*-arylureas and *N*-hydroxy-*N*-isopropyl-*N'*-arylureas *(6)*, respectively. Mixtures of solutions of these radicals with solutions of *(2)* gave the same superposed ESR spectra as were obtained during the slow radical reaction at room temperature.

From experiments with substituted phenylacetic acids and substituted benzoic acids we have found that the rate of conversion at 25 °C increases with the strength of the carboxylic acid. We therefore assume that the first step of the highly complex reaction involves addition of the carboxylic acid to the C=N double bond. The fact that intermediates of the radical conversion are dehydrogenated by unreacted *(1)* suggests the following reaction route for the formation of *(3)*:

(4) *(5)*

(6)

The mode of formation of the benzoxazolyl nitroxides *(2)* is not yet clear. Since *(6)* is not converted into *(2)* under the reaction conditions, formation of *(2)* from *(4)* or *(5)* in several reaction steps appears likely.

If the conversion of *(1c)* by acetic acid is followed by means of the decrease in concentration, the reaction occurring on freezing is seen to be accelerated by a factor of 300 to 1700, depending on the concentration of acetic acid, compared with that at 25 °C. Experiments with other solvents and solvent mixtures indicate that this acceleration is caused by a freezing out of the solvent and concentration of the reactants in the liquid regions[3].

Anomalous Spin States of Iron(II) in $[Fe(phen)_3](ClO_4)_2 \cdot 2H_2O$ [**] [1]

By *J. Ensling, B. W. Fitzsimmons, Philipp Gütlich*, and *K. M. Hasselbach* [*]

The Mössbauer spectrum of the complex $[^{57}Co^{II}(phen)_3](ClO_4)_2 \cdot 2H_2O$ [1,2] (symmetry D_3; as source) is temperature dependent (absorber: ^{57}Fe-enriched $K_4[Fe(CN)_6] \cdot 3H_2O$ at room temperature); in the range 4.2—296 °K, only iron(II) was observed in the decay product of the labeled cobalt compound.

The spectrum recorded at 296 °K gave the same values for the isomer shift (δ = 0.40 ± 0.02 mm/s) and the quadrupole splitting (ΔE_Q = 0.30—0.04 mm/s) of the resonance lines as Mössbauer measurements on the synthesized complex $[Fe^{II}(phen)_3](ClO_4)_2 \cdot 2H_2O$ as absorber (δ = 0.38 mm/s relative to $K_4[Fe(CN)_6] \cdot 3H_2O$ and ΔE_Q = 0.27 mm/s) [3–5]. Accordingly, the magnetic properties of the iron, occurring in the lattice of the strongly paramagnetic cobalt compound (μ_{eff} = 4.70 μ_B at 300 °K [2]) by nuclear disintegration (K capture), are not influenced by the high-spin (hs) character of the surrounding Co^{II} ions (S = 3/2); the iron exhibits the same magnetic behavior, *i.e.* low-spin (ls) character, as in the corresponding synthesized Fe^{II} complex (S = 0).

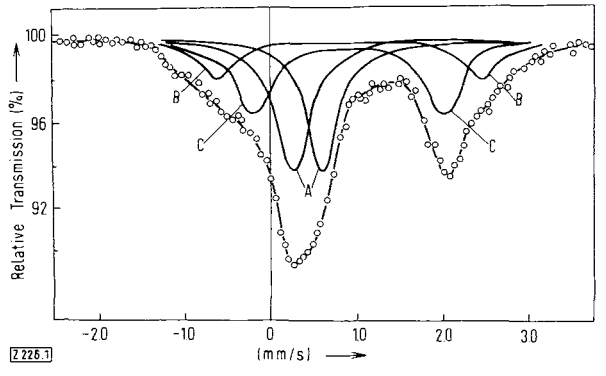

Fig. Mössbauer spectrum of $[^{57}Co(phen)_3](ClO_4)_2 \cdot 2H_2O$ at 4.2 °K relative to $K_4[Fe(CN)_6] \cdot 3H_2O$ (296 °K).

The spectra recorded at or below 223 °K, however, contain alongside the quadrupole doublet of the ls form of $[Fe(phen)_3](ClO_4) \cdot 2H_2O$, new resonance lines whose intensity increases with decreasing temperature. The Figure shows *e.g.* the spectrum at 4.2 °K; least-squares analysis using an appropriate computer fit program yields a superposition of three quadrupole doublets (A, B, C). The values for the Mössbauer parameters of all measured spectra are given in the Table.

The doublets B and C occurring at low temperature differ in magnitude of splitting by a factor of about 2 and in this respect are very different from A. As the lattice surroundings of the iron originating from ^{57}Co disintegration may be assumed to be the same in each case the different magnitudes of quadrupole splitting for A, B, and C must be chiefly ascribed to different arrangements of valence electrons. This would result in different valence electron contributions to the electric field gradient at the Fe^{II} nucleus in the species corresponding to A, B, and C. The valence electron contribution to the field gradient in the case of the ls form A is known to be zero, since the d electron configuration about the nucleus is spherically symmetrical. (The small quadrupole splitting of 0.3 mm/s is due to the trigonal distortion of the octahedron; this is also true for the species B and C.) On the basis of ligand field theory (splitting of the d orbitals [6] and occupation of the three most stable $3d^6$ electron configurations in a ligand field of D_3 symmetry according to the strong field approximation) we suggest the excited electron configurations $a_1^2 e_2^3 e_1^1$ with S = 1 for the doublet C, $a_1^2 e_2^2 e_1^2$ with S = 2 for the doublet B, and configuration $a_1^2 e_2^4$ with S = 0 for the stable ls form (A). The observed value of δ = 1.08 ± 0.06 mm/s for the isomer shift of the species B and C is in agreement with this suggestion; it is characteristic of paramagnetic Fe^{II} compounds.

A further indication of the occurrence of the "anomalous" spin states S = 1 (C) and S = 2 (B) follows from the valence electron contributions to the field gradient calculated according to *Ingalls* [7]: the factor of 2 between the values of $-2/7 \langle r^{-3} \rangle$ and $-4/7 \langle r^{-3} \rangle$ for C and B is in good agreement with the observed difference in the quadrupole splittings for C and B.

From the average lifetime of the 14.4 keV level of the ^{57}Fe nucleus and the lifetime of excited electron states along with the consideration of permitted and forbidden d—d transitions there follows an average lifetime for the "anomalous" spin states B and C of $10^{-9} < \tau \lesssim 10^{-8}$ s at room temperature and $\tau \gtrsim 10^{-8}$ s at $T \leq 223$ °K. The temperature dependence of τ can readily be understood on the grounds of the (likewise temperature dependent) spin lattice relaxation.

Table. Chemical isomer shift (δ), quadrupole splitting (ΔE_Q), intensity (I), and half-width (Γ_{exp}) of the resonance lines of $[^{57}Co(phen)_3](ClO_4)_2 \cdot H_2O$ as a function of temperature (A, B, and C refer to various spin states of Fe^{II}).

T (°K)	δ(A) (mm/s)	ΔE_Q(A) (mm/s)	δ(B) = δ(C) [a] (mm/s)	ΔE_Q(B) (mm/s)	ΔE_Q(C) (mm/s)	I(A)	I(B)	I(C)	Γ_{exp} (mm/s)
296	0.40 ± 0.02	0.30 ± 0.04	—	—	—	1.00 ± 0.05	0	0	0.56 ± 0.04
223	0.44 ± 0.02	0.28 ± 0.04	1.05 ± 0.06	3.0 ± 0.1	1.70 ± 0.08	0.86 ± 0.05	0.08 ± 0.05	0.06 ± 0.05	0.53 ± 0.04
78	0.46 ± 0.02	0.27 ± 0.04	1.10 ± 0.06	3.0 ± 0.1	1.68 ± 0.08	0.65 ± 0.05	0.15 ± 0.05	0.20 ± 0.05	0.56 ± 0.04
4.2	0.44 ± 0.02	0.26 ± 0.04	1.08 ± 0.06	3.0 ± 0.1	1.86 ± 0.08	0.49 ± 0.05	0.16 ± 0.05	0.35 ± 0.05	0.56 ± 0.04

[a] The isomer shifts of species B and C are, within the limit of error, equal.

The above observations indicate the "anomalous" spin states as resulting from various kinds of processes in the highly excited electron shell immediately following the nuclear transformation.

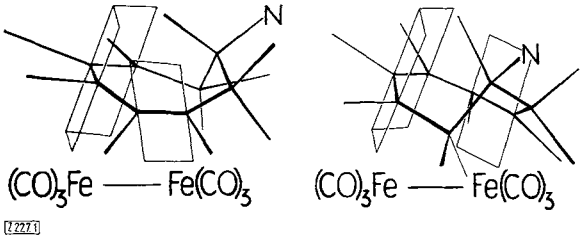
Cyclooctatriene Complexes with Fluctuating Ligands

By *Rudolf Aumann*[*] and *Saul Winstein* (deceased)

Reaction of $C_8H_9Fe_2(CO)_6^+BF_4^-$ [1] with nucleophiles N was found to give specifically substituted 1,3,5-cyclooctatriene complexes $C_8H_9NFe_2(CO)_6^+BF_4^-$ *(1)* [N = pyridine *(1a)*, $P(C_6H_5)_3$ *(1b)*] and $C_8H_9NFe_2(CO)_6$ *(2)* [N = N_3^- *(2a)*, CN^- *(2b)*, H^- *(2c)*, D^- *(2d)*]. In the complexes *(1)* and *(2)* the π-electron system of cyclooctatriene is distorted to such an extent that an isolated double bond, a π-allyl system, and a two-center bond between a C atom and an Fe atom can be distinguished as new structural features [2] (Fig. 1).



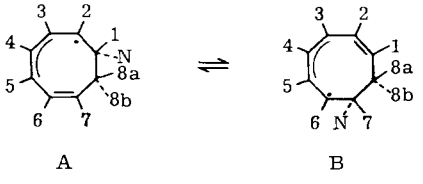


Fig. 1. Enantiomers A and B of the complexes *(1)* and *(2)*.

Both *(1)* and *(2)* were obtained as racemates. On the basis of ^{1}H-NMR measurements, we were able to demonstrate for *(1)* a mutual rearrangement of the enantiomers A and B *via* a 1,3 shift of the substituent N and a simultaneous migration of the vinyl system from 6,7 to 1,2; the allyl system $H^{3,4,5}$ remains fixed during the process.

The NMR spectrum of the pyridine adduct *(1a)* at 37 °C shows three sharp groups of signals for H^4, H^{8a}, and H^{8b}, and a broad signal (with little structure at a field of 60 MHz) for the other protons which undergo an exchange of magnetic environment and whose resonance frequencies are therefore averaged in pairs $H^1 \rightleftharpoons H^7$, $H^2 \rightleftharpoons H^6$, $H^3 \rightleftharpoons H^5$. At −20 °C the lifetime of the enantiomers is sufficiently high to give a non-averaged spectrum corresponding to the racemate *(1a)*.

The triphenylphosphine adduct *(1b)* is considerably more rigid than *(1a)* and shows a non-averaged spectrum at 37 °C. However, in this case we were able to demonstrate interconversion of the enantiomers ($t_{1/2}$ = 1.7 at 37 °C) using the double resonance- (relaxation-) method developed by *Hoffman* and *Forsén* [3].

Like *(2c)* and *(2d)*, the neutral azide- and carbonitrile complexes *(2a)* and *(2b)* are configurationally stable on the NMR time scale up to 50 °C; however, in *(2c)* and *(2d)* rapid isomerization of the valence tautomers C and D (Fig. 2) occurs; they are the only members of the series to exhibit such behavior.

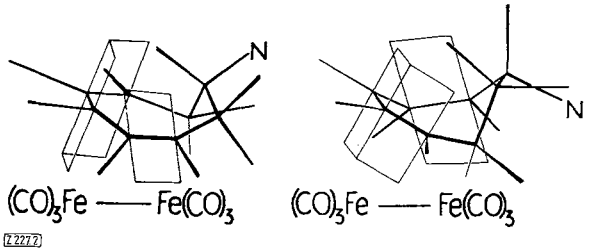

Fig. 2. Valence tautomers C and D of the complexes *(1)* and *(2)*.

C and D differ in the position of the allyl system and the isolated double bond on the one hand, and in the relative arrangements of the substituents N (in C pseudoequatorial, in D pseudoaxial) on the other. At −90 °C the spectrum of *(2c)* corresponds to structure C or D [2]; on stepwise increase in the temperature, averaged resonance frequencies are observed as a result of increasingly rapid interconversion of the valence tautomers (Fig. 3). In contrast to the rearrangement of the enantiomers described above, exchange of the magnetic environments of $H^4 \rightleftharpoons H^5$, $H^3 \rightleftharpoons H^6$, $H^2 \rightleftharpoons H^7$, $H^{1a} \rightleftharpoons H^{8a}$, $H^{1b} \rightleftharpoons H^{8b}$ occurs (cf. Table).

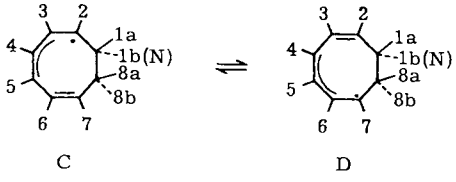

Table: ^{1}H-NMR spectrum of *hexahapto*-1,3,5-cyclooctatrienehexacarbonyldiiron(Fe—Fe) *(2c)* in $CHCl_2F$ (TMS as internal standard; 100 MHz). Comparison of the resonance frequencies (τ values) measured at 37 °C with values calculated by averaging the relevant resonance frequencies observed at −90 °C.

	measured	calculated

$H^{3,6}$	6.13	6.15
$H^{2,7}$	7.37	7.32
$H^{1a,8a}$	8.08	8.12
$H^{1b,8b}$	8.52	8.50

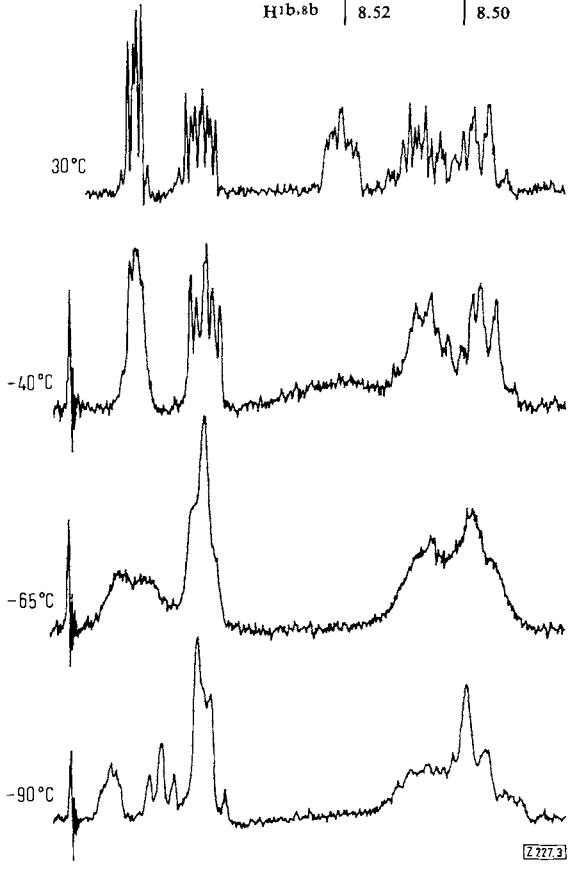

Fig. 3. ^{1}H-NMR spectrum of *(2c)* at various temperatures (10% $CHCl_2F$ solution; reference signal CH_2Cl_2 = 4.70 τ; 60 MHz).

A common feature of the complex NMR spectra of the compounds *(1)* and *(2)* is the H^3—H^4—H^5 allyl system (protons numbered as in C) with $J_{3,4} \approx J_{4,5}$ = 6—7 Hz, as is also the isolated vinyl system of the protons H^6 and H^7 with a vicinal coupling constant of 8—9 Hz; as expected, the signal of H^2 always appears at high field (τ = 7.9—8.5).

The coupling constants $J_{1a,2}$, $J_{1a,8a}$, $J_{1a,8b}$, $J_{7,8a}$, $J_{7,8b}$ of *(2a)* and *(2b)* can be explained by the Karplus equation[4], paying attention to the group electronegativity[5] of the substituents N[6], and the allyl coupling can be interpreted satisfactorily in terms of a relationship given by *Garbisch*[7]. It can be assumed with a high degree of certainty that N is fixed exclusively *cis* to the $Fe_2(CO)_6$ group, thus suggesting that the attacking nucleophile is transferred onto the ring by the agency of the metal.

A New Octamolybdate: $(NH_4)_6Mo_8O_{26}(OH)_2 \cdot 2\,H_2O$

By *Oskar Glemser*, *Gebhard Wagner*, and *Bernt Krebs*[*]

If an almost saturated aqueous solution of ammonium heptamolybdate (0.20 to 0.25 M) is allowed to stand for several weeks slow formation of almost colorless needle-like crystals occurs; they may be filtered off and dried in air without undergoing any change in composition. Analysis showed the crystals to have the composition $(NH_4)_6Mo_8O_{27} \cdot 3\,H_2O$; the IR and Raman spectra differ markedly from those of solid ammonium heptamolybdate $(NH_4)_6Mo_7O_{24} \cdot 4\,H_2O$ and ammonium octamolybdate $(NH_4)_4Mo_8O_{26} \cdot 4\,H_2O$.

IR (cm^{-1}): 480w, 570w, 670w, 700w, 790m, 845vs, 865m, 885vs, 900sh, 912m, 935vs, 1405vs, 1625m, 3020m.

Raman (cm^{-1}): 45m, 78m, 106w, 123w, 136m, 154w, 185m, 208m, 307w, 338m, 360m, 393w, 706m, 826w, 857s, 875s, 886s, 918s, 945vs.

Weissenberg and precession photographs recorded for a single crystal of about 0.1 mm in length show the compound to crystallize in the space group $P2_1/c$ with lattice constants $a = 9.50 \pm 0.03$, $b = 11.30 \pm 0.03$, $c = 15.00 \pm 0.04$ Å; $\beta = 109.5 \pm 0.5°$. Assuming $Z = 2$, the value $d_{pyk} = 3.01 \pm 0.05$ g cm^{-3} determined in benzene and in carbon tetrachloride gives a molecular weight of 1376 (value calculated for $(NH_4)_6Mo_8O_{27} \cdot 3\,H_2O = 1362$).

Since the general point distribution is fourfold in the space group $P2_1/c$, the octameric structural unit must possess a center of inversion. According to the rules for aggregation of polywolframates and polymolybdates[1], a centrosymmetric octamolybdate containing an odd number of oxygens, *i.e.* having one oxygen at the center, cannot consist entirely of MoO_6 octahedra. The structure of the compound must therefore contain an even number of oxygen atoms which may not exceed 28[1]. Moreover, the symmetry of the space group permits only an even number of molecules of water of crystallization. The new octamolybdate with two OH groups should therefore be formulated $(NH_4)_6Mo_8O_{26}(OH)_2 \cdot 2\,H_2O$. In order to distinguish between the two octamolybdates we designate the known compound "octamolybdate A" and the new one "octamolybdate B".

The Z^* value[2] of octamolybdate B (1.25) is higher than that of heptamolybdate (1.14), but lower than that of octamolybdate A (1.50). We also found that formation of solid octamolybdate B ceases when 60—70 % of the heptamolybdate has reacted; NH_3 is liberated in the process.

$$48\,NH_4^+ + 8\,Mo_7O_{24}^{6-} + 18\,H_2O \rightarrow 7\,(NH_4)_6Mo_8O_{26}(OH)_2 \cdot 2\,H_2O + 6\,NH_3$$

The new isopolymolybdate can form a solid ammonium salt only as a result of its lower solubility. Formation of an alkali-metal salt of this type would yield OH^- ions, which would effect immediate disaggregation.

Ammonium octamolybdate B dissolves slowly in water with hydrolysis

$$10\,(NH_4)_6Mo_8O_{26}(OH)_2 \cdot 2\,H_2O \rightarrow 8\,Mo_7O_{24}^{6-} + 3\,Mo_8O_{26}^{4-} + 60\,NH_4^+ + 30\,H_2O$$

to form heptamolybdate and octamolybdate A. X-ray structure analysis of octamolybdate B is in progress.

Cleavage of σ Bonds between Transition Metals and Carbon by Carbon Disulfide

By *Ekkehard Lindner*, *Rudolf Grimmer*, and *Helmut Weber*[*]

CS_2-insertion reactions of organometallic compounds leading to dithiocarboxylato derivatives have so far been encountered only with main group metals[1–3]. We have now observed the first cleavage of σ bonds between the transition metal and carbon in organometal carbonyls of Group VII A elements, a reaction requiring a great deal of energy, under pressure at 90—150 °C.

$$R{-}M(CO)_5 + CS_2 \xrightarrow{CS_2} RC(S)SM(CO)_4 + CO$$

M \ R	CH_3	C_6H_5	p-$CH_3C_6H_4$	p-ClC_6H_4	$C_6H_5CH_2$	$(C_6H_5)_3C$
Mn	*(1a)*	*(1b)*	*(1c)*			
Re	*(2a)*	*(2b)*	*(2c)*	*(2d)*	*(2e)*	*(2f)*

The reaction, in which CS_2 also functions as solvent, is of a general nature, the only exceptions being perfluorinated organometal carbonyls. The diamagnetic products *(1a)–(2f)*, whose colors vary between yellow and deep red depending on the substituent R, can be sublimed and are soluble in almost all organic solvents. The rhenium derivatives *(2)*, unlike those of manganese *(1)*, are stable towards oxygen and heat.

Composition and structure of *(1a)–(2f)* result from elemental analyses, molecular-weight determinations, IR, Raman, ^1H–NMR, and mass spectra, as well as from X-ray studies[4]. In the terminal CO region the IR spectra show four sharp absorption bands of irreducible representation $2\,A_1 + B_1 + B_2$ (*e.g.* for *(2a)* in *n*-hexane: 2110m, 2011vs, 2000s, 1963 cm^{-1} s-vs). The ν_{as} and ν_s (CS_2) vibrations observed in the Raman spectrum lie in the ranges 1270—1140 and 620—600 cm^{-1} re-

pectively (*e.g.* for *(2a)* in CCl_4: $\nu_{as}(CS_2)$ = 1146vw, $\nu_s(CS_2)$ = 619 cm^{-1} vs). Spectroscopic and X-ray data indicate pseudo-octahedral environment of the metal in *(1a)*–*(2f)* with (pseudo)-C_{2v} symmetry. The ^1H–NMR spectra indicate in particular that an isomeric mixture containing *(2e)* and a tolyldithiocarboxylato derivative is only formed on reaction of $C_6H_5CH_2Re(CO)_5$ with CS_2.

The dithiocarboxylato complexes described above are reactive. For instance, *(2b)* loses CO on reaction with $P(C_6H_5)_3$ at 80 °C in benzene to give the stable orange compound *cis*-$C_6H_5C(S)SRe(CO)_3P(C_6H_5)_3$ (dec. pt. 190 °C).

Oxidation of the Salicylaldehyde Ligand in Cobalt(II)- and Nickel(II) Complexes[**]

By *Hans G. Biedermann* and *Karl E. Schwarzhans* [*]

Bis(salicylaldehydato)diaquocobalt(II) *(1a)* reacts with pyridine[1] and several other unsaturated heterocycles[2] with substitution of the two *trans* water molecules in the pseudo-octahedral complex.

(1a), M = Co^{II}
(1b), M = Ni^{II}

In the corresponding reaction with an excess of morpholine under an inert gas atmosphere (N_2) the neutral ligands are likewise exchanged and a deep-red 1:2 adduct is formed. If, however, the reaction is not carried out under inert gas the color of the reaction solution changes from deep-red to red-brown; this change of color takes place much more rapidly when the reaction mixture is heated to about 120 °C in air, and when only morpholine is present as solvent. An examination of the susceptibility of such a solution by *Evans*' method[3] shows, however, that no oxidation of the central metal ion takes place. The magnetic moment of the starting complex and of the isolated end product was determined as μ_{eff} = 4.8 μ_B. If the reaction of *(1a)* with morpholine is carried out in $CHCl_3$ solution at room temperature in an open vessel 3.4 moles of water are liberated (H_2O determination by K. Fischer method) and 0.7–0.8 mole oxygen is taken up per mole of *(1a)* over a period of 48 hours (oxygen uptake measured volumetrically). Decomposition of the oxidation product with 6 N HCl yields salicylic acid morpholide; hydrolysis with 6 N KOH followed by cleavage with 6 N HCl gives salicylic acid in yields of up to 40 % [referred to *(1a)*]. The product complex bis(salicylmorpholidato)bis(morpholine)cobalt(II) was identified, as was the secondary product arising from its degradation, by elemental analysis, determination of melting point or decomposition point, and by ^1H–NMR and IR spectra.

The remarkable ease of oxidation of the aldehyde function in complex *(1a)* by atmospheric oxygen can be explained by the fact that a very high spin density is present even on the aldehyde group as a result of delocalization of the unpaired electrons of the central metal ion in the ligand. The ^1H-NMR spectrum of bis(salicylaldehydato)bis(pyridine)cobalt(II) shows *e.g.* the C(O)H signal at −365 ppm relative to TMS[4]. If an excess of morpholine is added to a solution of this complex and the mixture shaken in presence of air, the signal of the proton is no longer detectable in the NMR spectrum. NMR spectroscopy, therefore, can give information about reactive centers in such complexes. Analogous compounds having similar NMR parameters ought to show the same reaction. We have already been able to confirm this in the case of bis(salicylaldehydato)diaquonickel(II) *(1b)*.

Synthesis of 5′-Amido Analogs of Adenosine (3′-5′)-Cyclophosphates

By *Akira Murayama*, *Bernd Jastorff*, and *Hans Hettler* [*]

Adenosine (3′-5′)-cyclophosphate plays a key regulatory role at various levels of organization, *e.g.* it acts as "chemical messenger" in the production of blood sugar by the liver, as aggregation initiator of slime fungi, and as a kind of "second messenger" for more than a dozen hormones found in mammals, including humans[1,2]. Here we report on the synthesis of its 5′-amido analogs, 5′-amino- *(5a)* and 5′-*N*-methylamino-5′-deoxyadenosine (3′-5′)-cyclophosphoramidate *(5b)*.

5′-Amino- *(1a)*[3] and 5′-*N*-methylamino-5′-deoxyadenosine *(1b)*[4] are converted into the diester amides *(2a)* and *(2b)*,

(1) *(2)* *(3)* *(4)*

A =

(a), R = H
(b), R = CH_3

(5)

respectively, in about 50 % yield by reaction with di(*p*-nitrophenyl) phosphorochloridate[5].

Whereas *(5b)* is obtained directly (55 % yield) on treatment of *(2b)* with 1 N NaOH/methanol (1:1) in 100 h at room temperature, *(5a)* can only be synthesized stepwise. As first step, one *p*-nitrophenol group is removed by ammonia/pyridine/water (5:2:1); *(3)* is isolated in 80 % yield by preparative layer chromatography and cyclized according to *Borden*[6] by treatment with 1 M potassium *tert*-butoxide/*tert*-butanol in dimethyl sulfoxide (15 min, 10 °C) to give the cyclophosphate analog *(5a)* which is isolated in 65 % yield after separation on a DEAE cellulose column. Ring closure of *(2b)* to *(5b)* proceeds *via* the unusual cyclic diester amide: after 1 h it was possible to isolate compound *(4)*.

All the compounds gave correct analyses and spectroscopic data. Compounds *(5a)* and *(5b)* are currently being tested in conjunction with other research teams for biological activity.

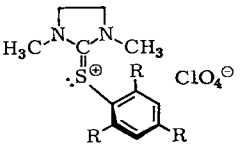
syn-anti-Isomerism at the Carbon-Sulfur Double Bond in Isothiouronium Salts [1] [**]

By *Horst Kessler* and *Hans-Otto Kalinowski*[*]



While the *syn-anti* isomerism at the C=N double bond in imines is well known, the possibility of *syn-anti* isomerism (A, B) at the isoelectronic C=S double bond in thioketonium ions *(1)* has not yet been reported on. In an NMR spectroscopic examination of the isothiouronium salt *(1)* (X=X' = $N(CH_3)_2$; Z = aryl, alkyl) at low temperature, we have been able to detect and "freeze" the equilibrium A ⇌ B[2]. The isomerization could be effected by rotation about the partial CS double bond (transition state C) or by inversion at the sulfur (transition state D)[3]. A differentiation is possible by studying the influence of *ortho* substituents on the isomerization of the *S*-aryl substituted compounds *(2)* and *(3)*.

(1)

(2)

(3)

The rotation is hindered[4,5] by large groups R, which must rotate past X. In contrast the steric hindrance in the transition state of the inversion (D) is less than in the ground state — hence, the rate of inversion ought to increase with increasing size of R[3].

The free enthalpies of activation determined in the case of isothiouronium perchlorates *(2)* and *(3)* are given in the following table.

Table. NMR parameters for the *syn-anti* isomerization of *S*-aryliso-thiouronium perchlorates *(2)* and *(3)*. T_c = coalescence temperature. The coalescence of the methyl signal is used for the evaluation [4].

	R	Solvent	Δν (Hz)	T_c (°C)	$\Delta G_c^{\neq}$ (kcal/mole)
(2a)	H	CH_2Cl_2	57	− 83	9.1 [a]
			10	− 92	9.3 [a]
(2b)	CH_3	CH_2Cl_2	67	− 64	10.0 [a]
			13	− 73	10.2 [a]
(2c)	*i*-C_3H_7	CH_2Cl_2	40	− 29	12.0 [b]
(2d)	*t*-C_4H_9	$(CD_3)_2SO$	50	+ 89	17.9 [b,d]
(3a)	H	CH_2Cl_2	—	<−115	<7.6 [c]
(3b)	CH_3	CH_2Cl_2	46	−107	8.0 [d]
(3c)	*i*-C_3H_7	CH_2Cl_2	55	− 80	9.3 [d]
(3d)	*t*-C_4H_9	TCB [e]	75	+106	18.5 [d]

[a] The error is ± 1 kcal/mole because the simultaneous "freezing-in" of the CN rotation interferes with the evaluation; the first results are w. r. t. the coalescence of the outer singlets, the second to the two inner singlets.
[b] Splitting to a doublet; the CN rotations are only "frozen-in" at lower temperature. [c] Calculated for an assumed splitting of 40 Hz. [d] Error ± 0.2 kcal/mole. [e] 1,2,4-Trichlorobenzene.

The distinct increase of the $\Delta G^{\neq}$ values on going from the phenyl compounds *(2a)* and *(3a)* to the sterically much hindered tri-*tert*-butylphenyl compounds *(2d)* and *(3d)* proves that the *syn-anti* isomerization at the partial CS double bond is *via* rotation (transition state C) and not by inversion, as in the corresponding process in the guanidines[3]. A minimum value of the activation barrier for the inversion at doubly bonded sulfur is obtained at the same time: it must be greater than 18.5 kcal/mole [= the value for *(3d)*]. In compounds with less strongly electron repelling groups X on the thiocarbonyl system, inversion at the sulfur atom ought — according to findings in the imine system[3] — to be very much less probable. The high barrier to inversion should make a separation of such *syn-anti* isomers at room temperature possible. This is at present under investigation.

The compounds *(2a)*—*(2c)* and *(3a)*—*(3c)* can be prepared from chloroformamidinium chloride and thiophenols[6]. *(2d)* and *(3d)* were not prepared *via* thiophenol but *via* the lead or thallium salt.

1,1,3,3-Tetramethyl-2-(2,4,6-tri-tert-butylphenyl)-isothiouronium perchlorate (2d)

Thallium 2,4,6-tri-*tert*-butylthiophenolate (4.5 g) was added with stirring to a solution of tetramethylchloroformamidinium chloride[7] (1.5 g) in anhydrous acetonitrile (50 ml). After three hours' stirring the reaction mixture was filtered and the filtrate treated with a solution of $NaClO_4$ (1.15 g) in aceto-

nitrile (20 ml). After refiltration the solvent was evaporated off and the residue recrystallized from ethanol [yield of *(2d)*, 25 g (64 %); m.p. 214–215 °C].

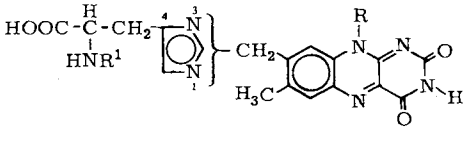
The Synthesis of Succinate-Dehydrogenase Riboflavin

By *Sandro Ghisla, Ursula Hartmann*, and *Peter Hemmerich* [*]



Singer and *Kearney* [1], in their early studies, recognized that the flavocoenzyme of mitochondrial succinate dehydrogenase ("SD-flavin") [**] was a derivative of flavin-adenine-dinucleotide which was covalently bound to the protein. In cooperation with Dr. *Singer*'s team [***], we have attempted to elucidate the structure of this coenzyme. In the first preliminary communication [2], we concluded from the hyperfine structure of electron spin resonance (ESR) spectra of partially purified SD-riboflavin (obtained from SD-FAD-peptide mixtures by total hydrolysis in 6 N HCl) that

a) SD-riboflavin is irreversibly converted into riboflavin *(1a)* by reduction and

b) the bond between the leaving group "X" [cf. *(1)*] and the heteroaromatic flavin nucleus is connected through position 8α.

(1a), X = H, R = Ribityl
(1b), X = Morpholino, R = CH_3
(1c), X = Br, R = Tetraacetyl-ribityl

(2a), R = Tetraacetyl-ribityl, R^1 = C_6H_5CO
(2b), R = Ribityl; R^1 = H

The light absorption of neutral SD-riboflavin is hardly different from that of riboflavin *(1a)* (λ_{max} 445 nm), but the near UV spectrum of the oxidized cation differs more drastically (Fig. 1, λ_{max} shifted from 395 [2] to 373 nm). Most characteristic is the pH-dependence of the fluorescence obtained with SD-riboflavin (Fig. 2) and, as mentioned above, the ESR hyperfine structure of the red radical cation (Fig. 3). Since these ESR results could be interpreted unequivocally [2] in terms of 8α-substitution of the flavin nucleus, we have synthesized 8α-substituted flavin derivatives [3], *e.g. (1b)*, which mimic the light absorption as well as the fluorescence properties of SD-riboflavin closely. This work enabled us to predict that the characteristic quenching of SD-riboflavin fluorescence with p*K* 4.4 (Fig. 2) originates from a secondary or tertiary nitrogen function in position 8α. Subsequently, *Walker* and *Singer* [4] succeeded in identifying the X-fragment obtained from reductive cleavage of the flavin-X-bond as *histidine*.

We have now synthesized SD-riboflavin *(2b)* as follows: Riboflavin *(1a)* is peracetylated in pyridine-acetic anhydride and then monobrominated in position 8α with an 80 % yield by refluxing 40 min with an 1.3-fold excess of Br_2 and catalytic amounts of dibenzoyl peroxide in dioxane. The yield is estimated from the decrease of the C(8)CH_3-peak in the NMR spectrum (δ = 2.45 ppm).

In addition to the C(8)CH_2Br-signal (δ = 4.7 ppm), the product of bromination *(1c)* shows only a trace of C(8)$CHBr_2$-signal (δ = 7.0 ppm [6]), indicating the presence of dibrominated analog [6]. The dibrominated product is obtained quantitatively upon heating with a larger excess of bromine in

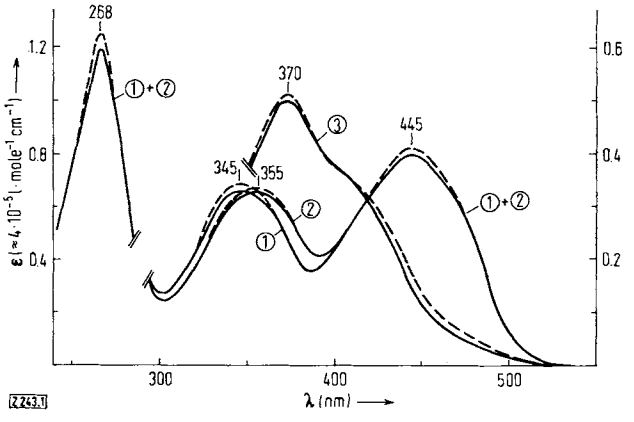


Fig. 1. Electronic spectra of native (---) and synthetic (—) SD-riboflavin.
① Neutral SD-riboflavin, pH 7, λ_{max} = 445, 355, 268, 221 nm.

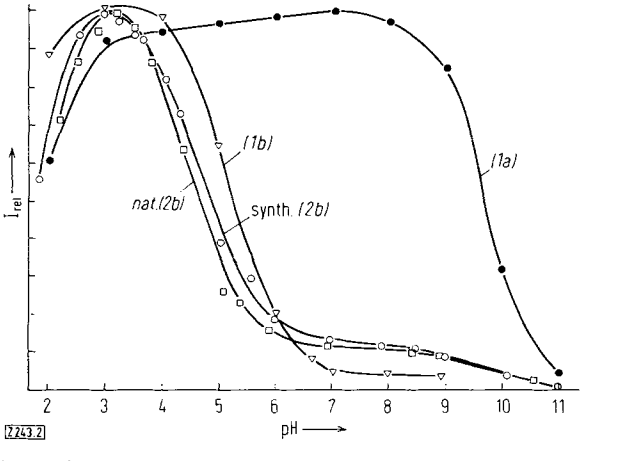

Fig. 2. Dependence of the relative intensity of fluorescence I_{rel} on the pH of unbuffered solutions of native and synthetic SD-riboflavin *(2b)*, riboflavin *(1a)*, and the model compound *(1b)*.

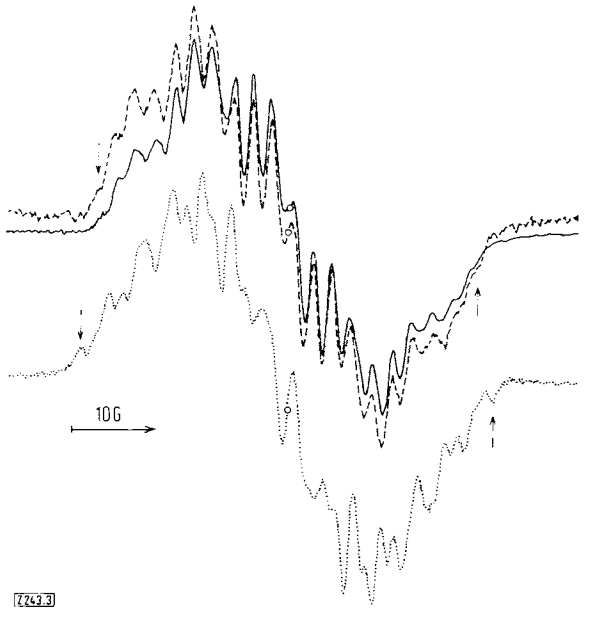

Fig. 3. Hyperfine structure of the ESR of SD-riboflavosemiquinone cation in 6 N HCl obtained by reduction with $TiCl_3$. The arrows indicate the outermost lines of the spectrum. Riboflavin *(1a)* shown for comparison, exhibits 2 more ESR active 8α-protons than SD-riboflavin *(2b)* since. in contrast to the 8-methyl group in riboflavin *(1a)*, the bulky histidyl-CH_2 group in *(2b)* is not free to rotate. (An analogous situation, for instance, exists with 5-methyl- and 5-benzylflavosemiquinone [5].) All ESR spectra have been recorded at a modulation amplitude of 0.5 gauss and 25 mW power in an anaerobic flat cell with a Varian E3 spectrometer. ———: native SD-riboflavin, —: synthetic SD-riboflavin, ····: riboflavin.

presence of pyridine[6]. The monobromide *(1c)* was heated for 15 hours at 90 °C in absolute dimethylformamide (without addition of a basic catalyst) with a 2.5-fold excess of N_α-benzoylhistidine. The resulting flavin mixture was shaken in aqueous buffer of pH 7. The aqueous phase contains the 8α-histidyl flavin *(2a)* which can be separated from the unreacted histidine by extraction with chloroform at pH 3 after saturation of the aqueous phase with ammonium sulfate. Finally, *(2a)* is hydrolyzed to *(2b)* by refluxing in 6 N HCl for 2 hours (overall yield 35 %).

The ESR and light absorption spectra of the resulting 8α-(*N*-histidyl)riboflavin are identical with those of authentic native material[4] (Figs. 1, 3). The pH derived from quenching of fluorescence (Fig. 2) of the synthetic product is slightly less clear cut than that of the native material. We conclude from this that the synthesis leads to a mixture of isomers because the imidazole nitrogens are chemically not equivalent. The native and synthetic products appear homogeneous and identical in thin layer chromatography on silica gel. The chromatographic separation of the presumed isomers and their structural assignment is presently under investigation.

CONFERENCE REPORTS

Protein Mapping in Polyacrylamide and its Application to Genetic Analysis in Plants

By *Hermann Stegemann*[*]

At present, the best separations of charged macromolecules are accomplished in gels of crosslinked polyacrylamide (PAA) as carrier. In PAA electrophoresis the migration is determined by both the charge and the size of the molecule; the extent of migration is a function of time.

In an electrofocusing run (in PAA gel with ampholines®) the site of the focused ampholyte is constant after equilibration of the pH gradient (in practice, a slight cationic migration of the ampholines® is observed); the proteins, nucleic acids *etc.* separate according to their isoelectric values.

If proteins are focused in a PAA rod, which is then placed horizontally on the 3 mm front edge of a 13 cm×18 cm PAA plate, proteins having the same charge start to migrate in the gel matrix and separate according to molecular size. This technique of separation, which is called "mapping", for it provides a "map" of protein spots, is probably the most rapid and efficient method for the separation and characterization of such mixtures. The lower limit of detection is 0.5 μg protein or fractions of a nanogram phosphorylase. In an apparatus designed for PAA layers between 1 and 16 mm, which will soon be available commercially, sample mixtures of up to 1 g can be analyzed. The molecular weight of proteins in PAA are determined according to *Maizel*'s method, and loading with dodecyl sulfate is carried out in a new continuously operating microdialysis apparatus.

The main proteins in potato tubers have molecular weights between 20000 and 25000, the distribution of charge and molecular weight is genetically fixed (thus permitting a diagnosis of type). The mapping method also affords a means of differentiating very closely related hybrids.

Use of Pulse Radiolysis in Elucidation of the Mechanisms of Complex Organic and Inorganic Reactions

By *Arnim Henglein*[*]

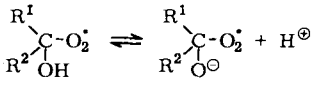
Free OH radicals and hydrated electrons in known concentration can be generated in aqueous solution by passage of a microsecond pulse of high-energy ionizing radiation. Reac-

tions of these species with dissolved organic and inorganic substances can be followed by electronic registration of optical absorption and electrical conductivity as a function of time. Some typical applications are described below.

Hydrates of aromatic nitroso compounds: These compounds were hitherto unknown. They are formed by reduction of a nitro compound by the hydrated electron; in acid solution the anion formed then picks up a proton and disproportionates:

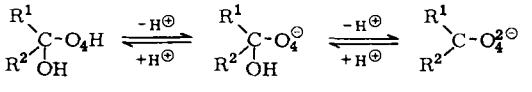
$$2\,XC_6H_4NO_2H \rightarrow XC_6H_4N(OH)_2 + XC_6H_4NO_2$$

The hydrates, whose spectra were recorded in a number of cases, give up water within 10^{-4} to 10^{-2} s, depending upon the nature of the substituent X and the pH of the solution. The dehydration proceeds in two steps:



$$XC_6H_4N(OH)_2 + H^{\oplus} \underset{K}{\rightleftarrows} XC_6H_4N(OH)_2H^{\oplus} \xrightarrow[k_1]{-H_2O}$$

$$XC_6H_4\overset{\oplus}{N}OH \xrightarrow[k_2]{} XC_6H_4NO + H^{\oplus}$$



($k_2 \gg k_1$). The dissociation constants and the Hammet constants of the substituents X are related according to:

$$\log K/K_0 = 2.3 \times \sigma \quad (K_0 \text{ for } X = H).$$

Charged intermediates of autoxidation: Oxidation of many organic substances in aqueous solution (alcohols, ethers, olefins) in presence of O_2 proceeds *via* intermediate acids that can be detected by their conductivity. α-Hydroxyperoxyl radicals dissociate according to

The spectra of the acid and basic forms were recorded. The pK is 7.1 for the radical formed from methanol, 8.3 for that from ethanol, and 8.5 for that from isopropanol. Two hydroxyperoxyl radicals form a dibasic acid that disappears in accord with first order kinetics. The results can be quantitatively interpreted if a hydroxyhydrotetroxide structure is assigned to the acid:

The first pK value is about 4.5, the second is about 8 (for R^1 and R^2 = alkyl or H). Decomposition is attributed to the loss of O_2.

Unstable oxides and acids of nitrogen: Short-lived compounds of nitrogen in abnormal valence states are obtained by the action of OH radicals and hydrated electrons on dissolved nitrate- and nitrite ions and nitrogen monoxide. The absorption spectra of the unstable compounds were recorded and the rate constants of their reactions were determined.

The species H_2NO_3, $HNO_3^{\ominus}$, and $NO_3^{2\ominus}$, and also H_2NO_2, $HNO_2^{\ominus}$, and $NO_3^{2\ominus}$ are in protolytic equilibrium. All pK values were determined and the decomposition of the various species to give NO_2 or NO was studied. It also proved possible to determine the equilibrium constants for

$$N_2O_4 \rightleftarrows 2\,NO_2$$

and

$$N_2O_3 \rightleftarrows NO_2 + NO$$

and the rate constants of hydrolysis of N_2O_4 and N_2O_3. The reaction of NO_2 and OH leads to pernitrous acid whose pK and rate constant for isomerization to HNO_3 were measured. Reduction of NO by the hydrated electron gives the species $NO^{\ominus}$, NOH, $N_2O_2^{\ominus}$, N_2O_2H, N_3O_3H, and $N_3O_3^{\ominus}$, of which the last two subsequently yield $(H)NO_2^{\ominus}$ and N_2O by spontaneous decomposition.

A Novel Photooxidation of Hydrocarbons Involving Triplet Oxygen

By *R. C. Petterson* [*]

A photooxidation of certain olefins has been discovered which is unusual in that reaction of a vibrationally excited ground state or twisted form of the hydrocarbon with triplet (ground state) oxygen appears to be involved, and the products are epoxides. 1,1-Diphenylpropene, *cis*- and *trans*-phenylpropenes *(1a)* and *(1b)*, and *trans*-stilbene undergo the reaction when irradiated (in contact with air) with light of wavelength 3000–4000 Å (16-8 W lamps) in 0.1 M benzene or heptane solution at 35 °C for 72 hours. Neat 1,1-diphenylpropene also is thermally oxidized (110 °C) to 1,1-diphenylacetone, undoubtedly *via* the epoxide; in this case a vibrationally excited ground state or twisted state must be involved.

The *cis* and *trans* forms of olefin *(1)* rapidly interconvert photochemically, but the epoxide isomers *(2a)* and *(2b)* do not, and the predominance (*ca.* 30/1) of *trans* epoxide *(2a)* over the *cis* form *(2b)* in the products suggests the existence of an intermediate which can rotate to give the thermodynamically more stable epoxide isomer.

The photooxidation of *(1)* can be sensitized with triphenylene and thus may go through a triplet state, but whether directly or only after crossing to a vibrationally excited ground state or twisted state is not clear.

By-products from oxidative cleavage, *e.g.* benzaldehyde from *(1)*, are always found in small amounts. While these may have been products of reaction of singlet oxygen, it was shown that singlet oxygen, produced *in situ* by irradiation of photo-

sensitizers such as rose bengal with visible light, does not oxidize these olefins to epoxides. It is interesting that singlet oxygen type by-products were not increased in the triphenylene sensitization experiment.

A mechanism is tentatively proposed in which the excited olefin collides with a triplet oxygen molecule forming a dioxy diradical molecule or a complex *(3)* of the type previously postulated by *G. O. Schenck*[1]. *(3)* then attacks a further olefin molecule to give the diradical *(4)*, which could give either 2 molecules of epoxide or one epoxide plus an oxy radical.

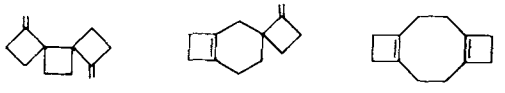
SELECTED ABSTRACTS

The oxidation kinetics of iron carbides have been studied by *J. Freel*, *B. R. Wheeler*, and *A. K. Galway*. Starting materials were a) a cementite with low surface area and small carbon excess, prepared by treatment of reduced magnetite with hydrocarbon vapor at 350 °C; b) a cementite with high surface area and large carbon excess from pyrolysis of basic iron mellitate; c) the reaction product of iron with CO and H_2 consisting of 76% Fe_5C_2, 8% Fe_3O_4, and 9% "free" carbon, besides catalyst residues. The reaction rates were monitored by observation of CO_2 evolution; the activation energies of oxidation of all three preparations were equal within the limits of error (102 kJ mole^{-1} at 240—500 °C). Both free and carbidic carbon were oxidized to CO_2, the primary solid product was always Fe_3O_4; Fe_2O_3 appears only in an advanced period of the reaction. It is concluded that the oxidation proceeds in the same manner as that of metallic iron: the rate determining step is diffusion of cations across the boundary between metallic phase (metal or carbide) and the primary product Fe_3O_4. / Trans. Faraday Soc. *66*, 1015 (1970) / —Hz. [Rd 204 IE]

Diffusion coefficients of alkali atoms in flames are measured by *A. F. Ashton* and *A. N. Hayhurst* by a new technique. A metal atom "point-source" is realized as follows: the gas mixture for the flame ($H_2 + O_2 + N_2$ under atmospheric pressure) flows through an array of 270 thin tubes and a metal salt solution is supplied in aerosol form *via* a single central tube. The intensity of the resonance emission of the metal measured at different points of the flame is used as a measure of concentration. The diffusion coefficients of sodium atoms were measured with an accuracy of ±7% in the temperature range 1920—2520 °K. They are in the range 10^{-3} m^{2}s^{-1}, are proportional to T^n with $n = 2.1$—2.2, and are larger in fuel-rich than in stoichiometric flames. In addition, the rate of thermal ionization of sodium atoms was determined in the hottest flames: in a stoichiometric flame at 2520 °K it was 105 s^{-1}, in a flame with $H_2 : O_2 = 2.5 : 1$ at 2480 °K, 58 s^{-1}. / Trans. Faraday Soc. *66*, 824, 833 (1970) / —Hz. [Rd 207 IE]

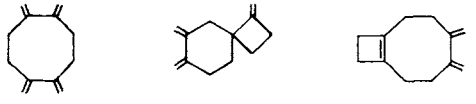
The photochemistry of the well-known uranyl oxalate actinometer has been thoroughly investigated by *L. J. Heidt*, *G. W. Tregay*, and *F. A. Middleton, jr.* For solutions with an uranyl ion concentration not less than 10^{-3} M and with an oxalate: uranyl ratio of 2 or greater the quantum yield of oxalate decomposition is 0.6 (±3%) at 208 to 436 nm. This value is constant for initial pH values between 1 and 5; outside this range it decreases. The photolysis always consumes acid. For each mole of oxalate consumed, approximately 1 mole of CO_2 is formed, which, depending on the pH, partly remains in solution. The quantum yield of CO formation amounts to nearly unity at pH 0; it drops rapidly with increasing pH. At pH 6 no CO was detected. The uranium(IV) yield increases with pH to a maximum of 10% of the oxalate consumed. The following mechanism is proposed for interpretation of the results: an electron is transferred from oxalate to uranium by light absorption; the primary products are U(V) and 1 mole of CO_2. With a proton from water, the U(V) intermediate is converted to a "hot" uranyl formate complex. At low pH CO is evolved from this complex, at higher pH formate is conserved. As a side reaction, the U(V) intermediate can disproportionate to U(VI) and U(IV). / J. physic. Chem. *74*, 1876 (1970) / —Hz. [Rd 208 IE]

Homogeneous nucleation in supersaturated vapors of *n*-alkanes was studied by *J. L. Katz*. A cloud chamber was used for measurement of critical supersaturation ratios. A thin layer of liquid hydrocarbon is spread on a horizontal thermostated metal plate and its vapor diffuses upward through a light carrier gas (H_2, He, Ne) to a second, cooler metal plate. The pressure and the temperature gradient between the two plates are chosen so that condensation will take place at about 80% of the chamber height. Condensation is determined visually by scattering of light. Results on *n*-alkanes from hexane to nonane at 225—330 °K are in good agreement with predictions from a simple theory used for calculating the equilibrium distribution of nuclei in the vapor with the assumption that the free energy of a nucleus equals the free energy of the same number of molecules in the bulk of liquid plus the surface free energy of the nucleus considered to be a sphere and to have the density of the liquid. The size of the critical nucleus lies between 24 and 87 molecules, depending on molecular weight and temperature. / J. chem. Physics *52*, 4733 (1970) / —Hz. [Rd 209 IE]



Radiation effects in NH_4HF_2 and $NaHF_2$ crystals following 1 MeV electron irradiation at 77 °K were studied by *L. J. Vande Kieft* and *O. R. Gilliam* by means of ESR and optical spectra. The crystals turn blue-green on irradiation, and the paramagnetic resonances developing can be interpreted to result from F_2^- ions in anion sites. Such defects arise from displacement of H atoms from their normal positions in the linear HF_2^- ions; however, only in NH_4HF_2 could the displacedH atoms themselves be detected. Annealing kinetics of the F_2^- ions in both crystals are of second order, as is to be expected for a recombination process. In certain sites of NH_4HF_2, the F_2^- ions appear to be tilted from the orientation of the original HF_2^- ion. This is interpreted as resulting from weaker N · · H · · F bonding to the F_2^- ions, since these are shorter and the N—H—F distance consequently larger than in the intact crystal. / Physic. Rev. [3] *B 1*, 2015 (1970) / —Hz. [Rd 210 IE]

Fine structure of fundamental bands in the IR spectrum of cyclobutane vapor at low pressures is interpreted by *J. M. R. Stone* and *I. M. Mills* as being due to the puckering motion of the C_4H_8 ring. The most conclusive results were derived

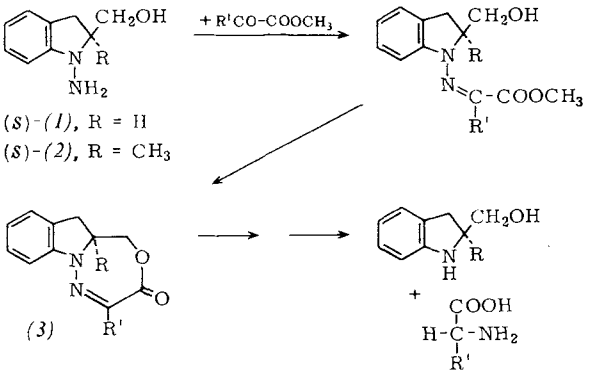


from sidebands on the 1453 cm^{-1} CH_2 scissoring mode: the side bands could be analyzed in terms of two slightly different puckering potential functions of the ground and the excited vibrational states. Barriers of inversion of 503 cm^{-1} ≙ 1.44 kcal $mole^{-1}$ in the ground state and 491 cm^{-1} in the excited state were calculated. The equilibrium dihedral angle of the C_4 ring is estimated to be about 35 °, in good agreement with electron diffraction data. A similar puckering structure of other IR and also Raman bands of C_4H_8 and C_4D_8 was observed; all observations are consistent with the same ground state puckering potential function. / Molecular Physics *18*, 631 (1970) / —Hz. [Rd 211 IE]

Internal electrolysis as an analytical method for uranium fission products was investigated by *F. Van Kote* and *J.-C. Catonne*. The electrolysis cell consists of a gold or platinum gauze cathode and a copper or zinc anode separated by a semipermeable cellulose diaphragm. If the cell is short-circuited across a suitable load resistance (*ca.* 1 ohm), the metals with more positive standard potentials than that of the anode metal are deposited on the cathode. With suitably selected anode materials and compositions of the electrolyte separations are feasible. The deposition of a few milligrams of Ag, Cd, and Te, alone and in the presence of each other from 5 M NaCl solution was followed with the aid of radioactive tracers, and the optimum conditions for electrolysis were established. Ag, Pd, Cd, and Sb were then deposited selectively by this method from a 5 M NaCl solution of fission products. Complete radiochemical purification, however, requires in addition conventional chemical methods. / Radiochim. Acta *13*, 139, 145 (1970) / —Hz. [Rd 212 IE]

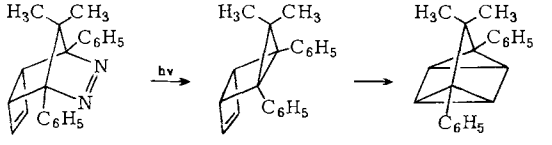
1,2,5,6-Tetramethylenecyclooctane *(4)*, which is of interest as a model substance for the formation of polycyclic hydrocarbons by transannular photochemical ring closure, has been synthesized in a two-step process by *W. T. Borden, L. Sharpe*, and *I. L. Reich*. Benzophenone-sensitized photodimerization of 1,2-dimethylenecyclobutane in benzene afforded *(1)*—*(3)* as major products. Pyrolysis of the crude photoproduct at 330 °C affords a 3 : 2 mixture of *(4)* and *(5)* (85% yield based

(1) *(2)* *(3)*



(4) *(5)* *(6)*

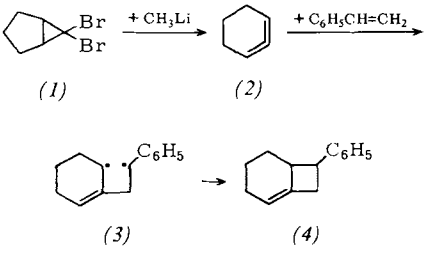
on 1,2-dimethylenecyclobutane), which can be separated on a preparative scale by gas chromatography. Direct photolysis of *(3)* leads solely to *(4)*; at 270 °C *(6)* is also detected. / Chem. Commun. *1970*, 461 / —Ma. [Rd 213 IE]



New protective groups for the phosphate residue on synthesis of deoxyribo oligonucleotides of defined sequence, namely 3-*p*-methoxyanilino-3-oxopropyl, 3-anilino-3-oxopropyl, benzylideneamino, and 3-benzylamino-3-oxopropyl groups, have been suggested by *S. A. Narang, O. S. Bhanot, J. Goodchild*, and *J. Michniewicz*. They can be removed by mild treatment with alkalis at room temperature — without simultaneous deamination. The protected di- and trinucleotides are isolated by chromatography on benzoylated DEAE cellulose and by Sephadex gel filtration. / Chem. Commun. *1970*, 516 / —Ma. [Rd 216 IE]

A new route for the asymmetric synthesis of α-amino acids with the chiral *N*-amino-2-hydroxymethylindolines *(S)-(1)* and *(S)-(2)* has been described by *E. J. Corey, R. J. McCaully*, and *H. S. Sachdev*. *(1)* and *(2)* are condensed with α-keto acids to give the chiral tricyclic compounds *(3)*. After reduction of the C=N group of *(3)* and hydrolysis of the N—N

bond and ester hydrolysis, the optically active amino acids can be isolated. D-Alanine and D-α-aminobutyric acid were prepared from pyruvic acid and α-ketobutyric acid in 80 and 90% purity respectively. / J. Amer. chem. Soc. *92*, 2476 (1970) / —Ma. [Rd 214 IE]



A novel rearrangement has successfully been employed by *L. A. Paquette* and *L. M. Leichter* to prepare a quadricyclane derivative *(3)* of the *trans*-tricyclo[4.1.0.$0^{2,5}$]hept-3-ene system *(2)*. The reaction can be regarded as an intramolecular capture of a 1,3-diradical by a cyclobutene ring. In the reaction of cyclobutadiene (liberated *in situ* from its tricarbonyl-iron complex) with 4,4-dimethyl-3,5-diphenyl-4*H*-pyrazole

(1) *(2)* *(3)*

the adduct *(1)* is formed which, on irradiation, is converted quantitatively into *(2)*. Compound *(3)* is obtained in quantitative yield when *(2)* is heated at 100 °C in tetrachloroethylene for four hours. This reaction can only proceed *via* a diradical. At 130 °C, *(3)* can be obtained directly from *(1)*. / J. Amer. chem. Soc. *92*, 1765 (1970) / —Kr. [Rd 218 IE]

Trapping of 1,2-cyclohexadiene *(2)* by styrene is reported on by *W. R. Moore* and *W. R. Moser*. *(2)*, which occurs as intermediate in the reaction of 6,6-dibromobicyclo[3.1.0]hexane *(1)* with methyllithium, reacts with the styrene to give *exo*- and *endo*-7-phenylbicyclo[4.2.0]oct-1-ene *(4)* (total yield

(1) *(2)*

(3) *(4)*

76%). The authors assume that the reaction of *(2)* with styrene proceeds in two steps *via* a diradical *(3)*. / J. org. Chemistry *35*, 908 (1970) / —Kr. [Rd 220 IE]

Electrochemical Processes in Fuel Cells. By *M. W. Breiter.* Vol. IX of the series "Anorganische und Allgemeine Chemie in Einzeldarstellungen". Springer-Verlag, Berlin-Heidelberg-New York 1969. 1st Edit., xi, 247p p., 98 figures, bound DM 48.—.

The present monograph deals exclusively with electrode processes in fuel cells; technological aspects are not discussed.

The material is presented concisely, and is more like a series of reviews than a textbook. The contents are therefore rather heavy, and not always easy for the non-expert to understand. For example, pages 39 to 59 of *Levich*'s book[1] have been condensed to only three pages. The problems on which the author has worked are discussed rather more fully. The depth in which the various questions are dealt with appears arbitrary. Thus the oxidation of ammonia is not even mentioned, and the reactions of hydrazine are touched on only briefly. The classification of fuel cells (p.3) includes a group b "organic electrolytes". This evidently refers to the biochemical fuel cells. However, these are not discussed further by the author.

After introductory chapters (definitions, thermodynamics, mass transfer, and electrode kinetics, 47 pp.), the adsorption of hydrogen on platinum metals and their alloys is discussed (37 pp.). This is followed by a very brief discussion of the anodic oxidation of hydrogen (11 pp.). Some results from investigations on oxygen surface films are described for platinum, nickel, silver, and carbon. The adsorption of hydrocarbons and the mode of action of the oxygen electrode in aqueous electrolytes and carbonate melts are dealt with in considerable length.

In Chapter X, on the anodic oxidation of fuels, the emphasis is placed on the study of methanol and formic acid. The book closes with some results on the properties of porous electrodes and their model treatment (30 pp.).

The present work provides a maximum of information for the number of pages available. References to the literature are very copious, though not complete. An author index would have been welcome in this respect.

The volume provides the electrochemist with a very valuable summary of a large number of investigations in a compact form. The printing and presentation of the book are excellent.

Wolf Vielstich [NB 881 IE]

Ullmanns Encyclopädie der technischen Chemie (Ullmann's Encyclopedia of Technical Chemistry). Chief editor: *W. Foerst.* Editor: *Hertha Buchholz-Meisenheimer.* Urban und Schwarzenberg, Munich-Berlin-Vienna.

Vol. 19: Zement bis Zwischenprodukte (Cement to Intermediates). 1969. 66 illustrations 418 pp., DM 120.—.

Complete Index for Vols. 1, 2/I, 2/II and 3 to 19 with references to the supplementary volume. 1969. 354 pp., DM 80.— price of the two volumes together DM 190.—.

Supplementary Volume: New Processes, New Products, Economic Developments. 1970, 175 illustrations + 846 pp., DM 198.—

19 years after work on the project began, the publication of these three volumes[*] completes the encyclopedia, which has a total of 16243 pages and 808 articles, with contributions from more than 1000 authors. The individual fields dealt with are as follows: organic intermediates and chemicals 16.2%, inorganic chemistry 11.2%, metals 8.7%, drugs, natural products (alkaloids, vitamins, hormones), cosmetics, and perfumes 8%, plastics, lacquers, and rubber 7.1%, physical methods in the laboratory 6.2%, construction of apparatus and process technology 6.1%, fuels and petrochemistry 6%, fibers, wood, cellulose 5%, food, fats, and foodstuffs 4.6%, dyes and dyeing 4.4%, production supervision 4.2%, ceramics, silicate chemistry, cement, other building materials, glass, enamels 2.9%, and miscellaneous (including fertilizers, pest control, nuclear energy, isotopes, and atomic structure) 9.4%. The work contains a unique assortment of material, giving a coherent picture of the whole field of technological chemistry including the economic principles of this branch of science, manifestly an enormous and bold undertaking in view of the rapid development of science and technology in the postwar period, which is clearly mirrored in the 22 volumes.

Volume 19 contains sections on intermediate products (147 pp.), zinc, zinc alloys, and zinc compounds (107 pp.), sugar and confectionery (62 pp.), cement (34 pp.), tin, alloys of tin, and tin compounds (31 pp.), zirconium and zirconium compounds (24 pp.), and flammables (9 pp.), with contributions from 22 authors, of whom 20 work in industry and 2 in universities. *H. Morchel*'s (Farbenfabriken Bayer) article on "Intermediates" deserves special attention. He concentrates on aromatic and heterocyclic intermediate products, tabulating in twenty subdivided synopses the methods of preparation for 1400 compounds arranged in order of precedence on the basis of the introduction of functional groups. The article gives detailed references to the original literature and to relevant sections in the encyclopedia. Dye chemists in particular will find this section useful, with its comprehensive coverage and novel way of classifying the material.

The index volume is of considerable importance to the complete work, and the editors have therefore devoted particular attention to it. Chemical technology is developing so rapidly that it is difficult to classify it on a systematic basis. Nor has it been possible to avoid overlapping in the case of this encyclopedia, where a lexical arrangement has been chosen for the articles which are of varying length and are in some cases presented in monographic form. Moreover, the later volumes have to take into account and incorporate progress made in the fields dealt with earlier. This means that any system for the classification of material of this type is far from perfectly practicable, and a comprehensive and reliable keyword index becomes all the more important. The present index volume contains 354 pages and about 30000 keywords, covering the whole field of technological chemistry. Important keywords are provided with comprehensive and subdivided textual references. For example, the keyword "rubber", is accompanied by 150 references covering such topics as recovery, use, grades, processes, and economic considerations. To facilitate the search for subjects the index also contains a number of titles arranged both as independent keywords and as subdivisions under main entries. Normal and bold type is used for quoting page references, the difference showing where more detailed treatments of the relevant topic can be found. It is easy to see that all the material contained in this encyclopedia can quickly be found by means of the index.

The supplementary volume is a useful and interesting addition to the complete work. This volume contains articles on organic intermediate products (131 pp.), plastics and plastics products (85 pp.), drugs (81 pp.), economic development and its importance in the chemical industry (78 pp.), petrochemical bases (53 pp.), fertilizers (41 pp.), metals (34 pp.), rubber (31 pp.), dyes and optical brighteners (28 pp.), fibers (25 pp.), nuclear energy (25 pp.), petroleum (21 pp.), and a number of shorter sections, with contributions from 177 authors. The subject matter of the book is varied and stimulating since the editors with the experience of the previous 21 volumes behind them and suitable contacts with specialists have gathered together new and interesting material from all fields. This volume can also be bought singly, and makes worthwhile reading independent of the encyclopedia. New fields like lasers, holography, and nuclear energy are described with

maximum clarity, but it has also been necessary to include reports on the revolutionary progress made in classic processes. We find, for example, that the ammonia process has changed fundamentally in the last decade. Petrochemical synthesis gas production has become established, new catalysts allow almost complete CO conversion at low temperatures, and with the development of the turbocompressor there has been a transition to a single-line plants with capacities of 1000 t/day.

In addition to the varied scientific and technical developments reported in this volume, particular mention should be made of the article on the development of science, which gives an impressive picture of the dynamics and importance of technological chemistry. The global chemical production has quintupled in the last twenty years, and will continue to increase at this exponential rate. The pipeline network for oil and petrochemical products amounts to 40 times the circumference of the earth and is increased by 15000 to 20000 km a year. Between the years 1958 and 1968 the world production of synthetic fibers increased ninefold. In contrast to other large industries, the chemical industry deals at the same time with the production of basic substances, intermediates, and consumer articles. Unlike any other industry, it acts both as a supplier and as a purchaser in all fields of the economy, and is thus perpetually involved in the development of human relationships and social life. With its abundant key figures, this article gives a clear survey of development trends.

In view of this dynamism one may well wonder to what extent a field subject to such far-reaching changes can be covered by an encyclopedia. In fact, the achievements and difficulties of our scientific and technological development are mirrored in the achievements and problems of the present Ullmann Encyclopedia. A characteristic of our time is that the quantity of information increases more quickly than it can be arranged and classified. New documentation systems are being developed so that we can remain masters of this situation and store information in readily available form. Electronic information services, however necessary and important they are, can only store material; they cannot sift through it, evaluate it or select what is important — they cannot process (reduce and compress) the information. The more quickly a field changes and grows the more important the condensation of material becomes, so that a survey of trends and developments is available. If there is no overall survey, contact and understanding between allied branches are lost and hence also the possibility of fruitful cooperation.

Furthermore, difficulties will be created if this welter of material is handed down in disorder to the next generation. There is little point in supplying students with the newest and most up-to-date information — it will be out of date by the time they are ready to use it — but there must be a comparative penetration of the material so that the essential principles, which will play a decisive role in development, can be worked out. A large number of our educational difficulties arise because we neglect the didactic processing and condensation of knowledge in the process of searching out new material. In the case of many students this leads not only to difficulties in understanding but also to misconceptions and highly undesirable attitudes to this complex of modern chemical practice which is so important for our very existence.

Ullmann can be considered as a comprehensive personal interpretation of chemical technology and the chemical industry; it is an example of the fact that abstract modern theory can successfully be shown to have relevance to the accepted for mulas already used in practice. It is written in such a way that anyone can obtain information on the main aspects of a related field in which he is not at home. Finally, therefore, we must thank the authors who have taken the time, for the most part in spite of pressing practical duties, to describe their work to a wider circle of colleagues, and in particular the management and editors who have managed to coordinate all this work and produce an encyclopedia which, as its name implies, deals coherently with the whole sphere of chemical and technological knowledge.

Hans Sachsse [NB 889 IE]

The Wave Mechanics of Atoms, Molecules and Ions. By *C. J. H. Schutte*, Edward Arnold (Publishers) Ltd., London 1968. 1st Edit., xiii + 502 pp., numerous figures, bound, 84 s.

Many of the modern textbooks devoted to the subject of wave mechanics and molecules suffer from the disadvantage, in particular as regards the chemistry student, of assuming either a very extensive or a very meager knowledge of mathematics on the part of the reader. Consequently, the understanding of the chemical bond is often inadequate.

The present book attempts to tread the middle path, and in fact the author does succeed in striking a happy medium between the two extremes.

The book consists of three main parts, the first of which deals with the principles of wave mechanics. Numerous examples are given starting with classical mechanics. Perhaps it was not entirely necessary to include *Bohr*'s postulates, which have now passed into history and which have been extended by wave mechanics. On the other hand, the reviewer finds it it highly sensible to present the fundamentals with the aid of operator algebra. The perturbation method is discussed at length.

The second part consists of a total of 11 sections in which the individual methods of quantum chemistry are dealt with: First of all a particle in simple potential fields, then the harmonic oscillator in its application to spectroscopy. Rotational and vibrational states are considered next. The 5th section deals with the hydrogen atom, and the 6th with polyelectronic atoms. Sections 7 and 8 are devoted to group theory and, finally, the last three sections are concerned with di- and polyatomic molecules and with a number of applications of the Hückel theory.

The third part of the book deals exclusively with spectroscopy. An introduction to the principles of spectroscopy is followed by a discussion of the spectroscopic behavior of rotational states, vibrational states, and finally, of complex compounds, including magnetic effects.

Exercises are given with each section, the solutions being collected at the end of the book. There is also an appendix on symmetry groups.

The book is clearly written, well illustrated, and provided with a very detailed subject index. It can be emphatically recommended to every student of chemistry. Even those who merely want to acquaint themselves with the field will find it to be an excellent introduction.

Recent Results on the Biochemistry of the Cell Wall Lipopolysaccharides of *Salmonella* Bacteria[**]

By Otto Lüderitz[*]

Lipopolysaccharides, which are located in the cell wall of gram-negative bacteria, are characterized by their biological versatility. They represent the O antigens of the bacteria, they are potent endotoxins, and they often function as the receptor sites for bacteriophages. The study of the mode of action of lipopolysaccharides and the search for structures in the macromolecules that are responsible for biological activity became promising when principles of the chemical fine structure of lipopolysaccharides were identified. The following review summarizes the results of recent investigations regarding the structure of lipopolysaccharides, their biosynthesis and its genetic determination.

1. Introduction[***]

The great achievement of *Fritz Kauffmann* is the Kauffmann-White scheme[1,2], in which hundreds of bacterial species belonging to the genus *Salmonella* are classified according to their serological and biochemical properties. This classification provided the starting point and has since served as a basis for all chemical and biochemical work on *Salmonella* lipopolysaccharides. This is illustrated in Table 1, which summarizes the results we obtained about ten years ago, together with *Kauffmann*, when we subjected a first series of *Salmonella* species to immunological and chemical study. At that time, our efforts were directed to the correlation of the serological classification of these species with the sugar composition of their surface antigens. The fourteen *Salmonella* species listed in Table 1 are representative of the groups A–E of the Kauffmann-White scheme, and it was at this point that it first became clear that the lipopolysaccharides of species belonging to the *same* serogroup contain identical sugar units. There exists a close relationship between the *serotype* of a species and the *chemotype*

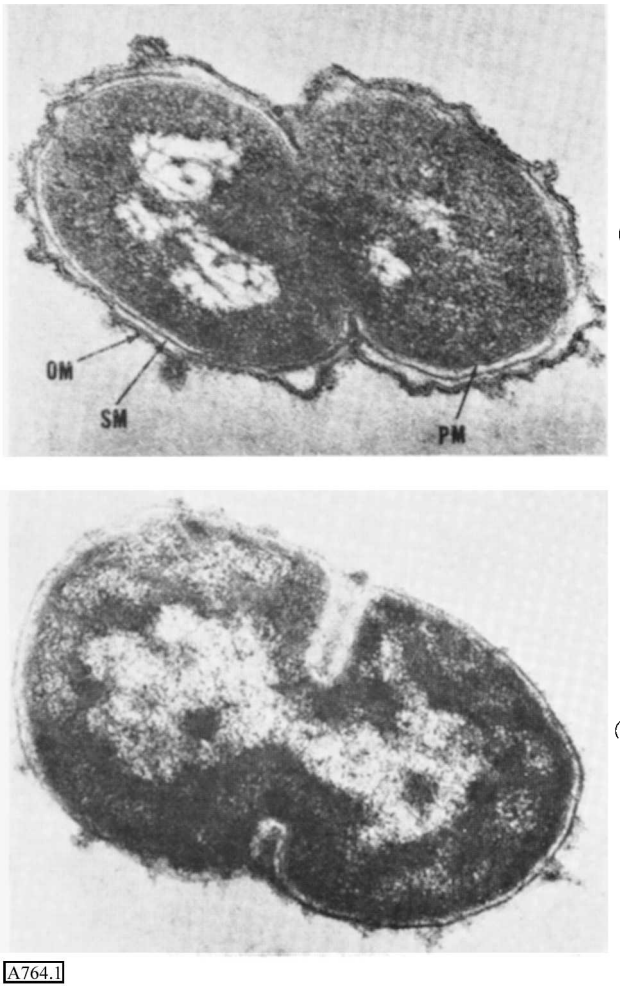
of its lipopolysaccharide. This was later shown to be true for the species of all *Salmonella* groups of the Kauffmann-White scheme [3].

Groups A–E contain approximately 500 species and the Kauffmann-White scheme includes about 45 groups. Each *Salmonella* species is characterized by the serological specificities of the heat-stable O antigen (lipopolysaccharide), and the heat-labile H (flagellar) antigen. By analogy, *E.coli* [4], *Shigella* [5], and other genera were classified later in a similar way. The designation of antigens as O and H has an historical origin and refers to flagellated and non-flagellated proteus strains. H comes from the German "mit *H*auch". O comes from "*o*hne Hauch", and both terms were meant to describe the morphological appearance of the cultures.



2. Isolation and Biological Properties of Lipopolysaccharides

Since the introduction of the classical extraction methods of *Boivin* and *Mesrobeanu* [6], *Morgan* [7], and *Goebel et al.* [8], a series of further methods has been developed for the isolation of lipopolysaccharides from gram-negative bacteria. Among these procedures the phenol/water method [9] has been widely adopted because of its wide range of applicability, and has been used in our laboratory for routine isolation of lipopolysaccharides.

Dried bacteria are heated at 68 °C for a short time in a mixture of phenol and water (45 : 55, v/v), whereupon the protein/lipid/lipopolysaccharide complexes of the cell wall dissociate and the components are released into the solution. The mixture which is monophasic at this temperature separates into two layers on cooling and centrifugation. The extracted cell residues appear at the bottom; the lower phenol phase contains lipids and proteins and the upper aqueous phase contains the desired lipopolysaccharide alongside nucleic acids and polysaccharides. After high speed ultracentrifugation (100000 g), the lipopolysaccharide is obtained as a sediment, and is finally lyophilized (1–4 % of the dry bacterial weight). The lipopolysaccharide thus extracted dissolves in water to give an opalescent solution.

Recently, a very mild extraction procedure has been worked out (PCP method) [10], which enables the isolation of exclusively R form lipopolysaccharides.

Electron-microscope studies carried out by *Bladen* and *Mergenhagen* [11] (Fig. 1) provide impressive evidence of the morphological changes on the bacterial cells after phenol/water extraction. Only the outer, plastic layer

A764.1

Fig. 1. Electron micrograph (approx. 75000× magnification) of *Veillonella* bacteria a) before and b) after extraction with phenol/water [11] OM = outer membrane, SM = solid membrane, PM = plasma membrane.

of the cell, the cell wall (OM, outer membrane), is dissolved away; the cell itself, surrounded by the plasma membrane (PM) and the rigid layer (SM, solid membrane), remains intact. These pictures show that lipopolysaccharides (complexed with proteins and lipids) are located on the surface of the bacterial cell, and it is likely that in this exposed state they play a special role in the interactions between bacterial cell and host organism in the course of an infection. The validity of this statement is supported by the fact that many of the endotoxic manifestations appearing during an infection can also be simulated when purified lipopolysaccharides are injected into animals.

Among the manifold endotoxic activities of lipopolysaccharides, their pyrogenicity is most remarkable (Fig. 2). Injection of 1 μg in man (and correspondingly smaller amounts in experimental animals) results, after a short latent period, in the development of fever, with body temperatures reaching up to 40 °C. Simultaneously, drastic changes occur in the white blood picture, *i.e.* leucopenia, followed by a pronounced leucocytosis. Many other biological manifestations of endotoxins can be observed, such as changes in blood pressure, fibrinolytic activity, complement activation, changes of resistance to infection, Shwartzman-activi-

ty, adjuvant-activity and, with larger amounts of lipopolysaccharide, lethal toxicity [12–14].

In addition to these non-specific endotoxic reactions, which are more or less common to all lipopolysaccharides, highly specific processes are also stimulated. Lipopolysaccharides constitute the O antigens of bacteria, and their introduction into the organism induces production of specific antibodies that are directed against specific structures in the lipopolysaccharide molecule used for immunization.

Lipopolysaccharides frequently exhibit a further distinct activity. They function as the specific receptor sites on the cell for a number of phages [15,16]. Fig. 3a shows an electron micrograph by *Lindberg* [17] which was obtained after incubation of Felix O1-phages with lipopolysaccharide from an *S.minnesota* Ra mutant (see Table 6). It can be seen that the phages are fixed by their tails to the chains of aggregated lipopolysaccharide. The phages that have released their contents on contact are present as ghosts. The high degree of specificity underlying this interaction is demonstrated in Fig. 3b where the same phage has been incubated with lipopolysaccharide isolated from a different, but closely related, strain. This (Rb) lipopolysaccharide

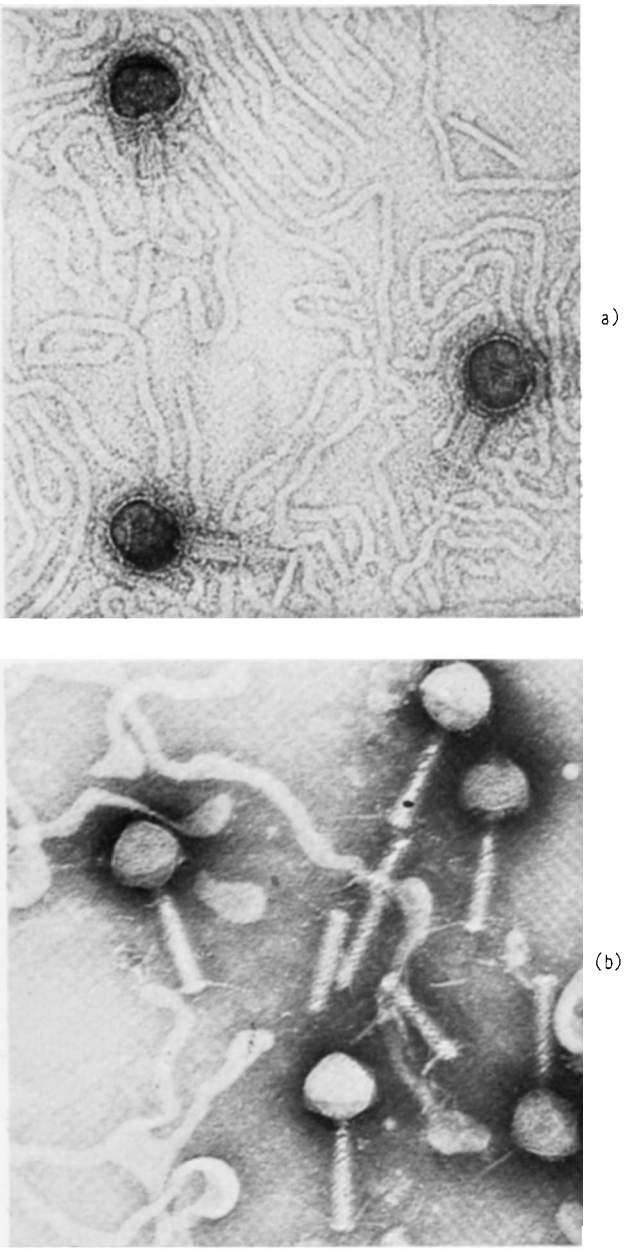

Fig. 3. Electron micrograph (approx. 400000 × magnification) of Felix 01 phages in admixture with lipopolysaccharides from a) *S. minnesota* Ra and b) *S. minnesota* Rb bacteria. The phages have reacted only with the Ra lipopolysaccharide [17].

differs from the preceding one only by the absence of *one terminal* sugar constituent, namely *N*-acetylglucosamine (see Table 6). This minor alteration in structure, however, causes a dramatic change in the specificity of the receptor, so that fixation of this phage, and its consequent inactivation, are no longer possible.

All the properties so far mentioned show clearly that the lipopolysaccharides of gram-negative bacteria represent a unique group of natural polymers, endowed with a great number of distinct biological activities. Inevitably a series of questions arises, regarding the structure of these substances, the mechanism of their action *in vivo*, as well as the question of the presence, in these macromolecules, of structural groupings or configurations which make it possible for them to act as antigens, endotoxins [12–14], or as phage receptors.

3. General Principles of Lipopolysaccharide Structure

As early as 1960, before structural chemical investigations had been undertaken, a series of analytical and biochemical results led to the assumption that lipopolysaccharides are built up according to a common general principle, and contain three regions of dissimilar structure. This concept (Fig. 4) has since proved to be correct.

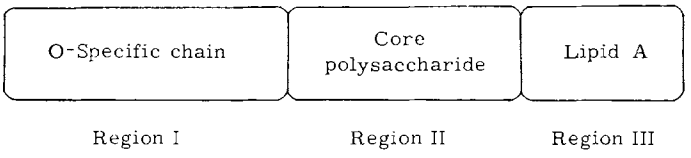

Fig. 4. The three structural regions and their sequence in lipopolysaccharides.

All lipopolysaccharides contain a lipid component, the so-called *lipid A* (region III), to which the *core polysaccharide* (region II) is bound. In closely related lipopolysaccharides, such as those of *Salmonella*, the structure of this core is identical or very similar. To region II are linked the *O-specific chains* (region I). It is by this part of the molecule that the lipopolysaccharides of different species are differentiated from one another. The type, sequence, as well as the nature of the linkages of the sugars in region I are specific for each individual lipopolysaccharide. Region I, which carries the serological specificity of each lipopolysaccharide, provides the close correlation that exists between the serological classification into serotypes and the chemical classification into chemotypes.

It should be emphasized that innumerable gram-negative species (serotypes) exist in nature, of which thousands have already been identified and characterized. Accordingly, thousands of serologically distinct lipopolysaccharides are in principle available, and in fact several hundreds have already been isolated in recent years. All lipopolysaccharides possess the general structure shown in Fig. 4. This large unique class of macromolecules constitutes an ideal subject for comparative investigations.

4. The Sugar Composition of *Salmonella* Lipopolysaccharides

The sugar units that have been identified in *Salmonella* lipopolysaccharides are shown in Table 2 [18,19]. The complexity of their structures is illustrated by the fact that they contain at least five, and some as many as nine, different sugar units. The 18 monosaccharides that have been found can be divided into two groups: the five "*basal sugars*" are common to all lipopolysac-

[18] *O. Lüderitz, A. M. Staub,* and *O. Westphal,* Bacteriological Reviews *30*, 192 (1966).

[19] *O. Lüderitz, K. Jann,* and *R. Wheat* in *M. Florkin* and *E. H. Stotz*: Comprehensive Biochemistry. Vol. 26 A, Elsevier, Amsterdam 1968, p. 105.

charides; they constitute the core polysaccharide (region II) and will be discussed in Section 6. The "*specific sugars*" of the second group occur in various combinations. Each individual sugar combination denotes the chemotype of a lipopolysaccharide for which it is specific. While some sugars are widely distributed in natural products, others, such as those belonging to the stereoisomeric 3,6-dideoxyhexoses or the 2- and 3-amino-6-deoxyhexoses, were first found in lipopolysaccharides. The list of chemotypes is probably still incomplete and new sugars may yet be found in the various *Salmonella* lipopolysaccharides.

In lipopolysaccharides obtained from other genera additional sugars were found: 4-amino-6-deoxy-D-glucose and -D-galactose; 2-amino-6-deoxy-D-glucose, -D- and -L-galactose, -L-mannose; D-glycero-D-manno- and -D-galacto-heptose; 2-amino-D-glyceroheptose; 6-deoxy-L-talose; D-rhamnose; ascarylose; glucuronic acid; galacturonic acid (see [19,20]).

5. The O-Specific Chains (Region I)

5.1. The Structure of the O-Specific Chains in Some Lipopolysaccharides

The realization that the role of the specific sugars is concerned exclusively with the building up of the O-specific chains (region I) has considerably advanced research on this part of the lipopolysaccharides, and in some cases has led to complete elucidation of the structure. Credit for these results goes mainly to *Staub et al.* [18–20] and *Robbins et al.* [21], who were able to reconstruct the complete structure of region I by studying fragments from partial hydrolyzates of the lipopolysaccharides with the aid of immunochemical methods. Recently, the suggested structures were confirmed and supplemented by *Lindberg et al.*, who applied the latest methods of methylation analysis [22–24].

Partially methylated sugars obtained by hydrolysis of fully methylated polysaccharides are converted to the *O*-acetyl-*O*-methylalditols. They are then identified by a combination of GLC and mass spectrometry. Methods have been worked out for the localization of acetyl groups. These have the advantage of being independent of individually synthesized, partially methylated sugar standards. By undermethylation, all theoretically possible partially methylated derivatives can be obtained. After reduction and acetylation the components of such mixtures can be characterized by gas chromatography and mass spectrometry (retention times).

The results of these investigations showed that O-specific chains are made up of a series of identical oligosaccharides, the *repeating units*. As an example, the lipopolysaccharide of *S.newington* (3, 15) is shown in Fig. 5. In this case, the specific chains (region I) contain 10 to 20 trisaccharide units of mannose, rhamnose, and galactose. They are linked to the lipid A, *via* the core polysaccharide, to form the complete lipopolysaccharide.

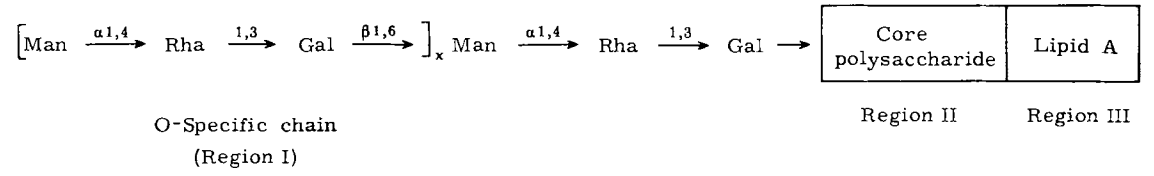

Fig. 5. Structure of the O-specific chains (region I) in the lipopolysaccharide of *S.newington* (3, 15) [21].

Table 3 shows the repeating units which constitute the O-specific chains of *Salmonella* serotypes belonging to groups B, D, and E [19–21,24]. They all contain a trisaccharide of mannose, rhamnose, and galactose, but are different with respect to their linkages and substituents.

Table 3. The "repeating units" of the O-specific chains in the lipopolysaccharides of *Salmonella* groups B, D, and E [18,21,23,24,24a].

Serogroup	O Factors	Repeating units
E_1	3, 10	6 → Man α1,4 → Rha 1,3 → Ac Gal α1 →
E_2	3, 15	6 → Man α1,4 → Rha 1,3 → Gal β1 →

saccharides are considerably different in their sugar composition and structure from the structurally related oligosaccharides of Table 3.

The oligosaccharide units shown in Fig. 5 and Tables 3 and 4 not only provide some evidence of the great variety of possible lipopolysaccharide structures that are present in bacteria, but also contribute to the recognition of one fundamental principle, *i.e.*, that identical repeating units form the structural units of the O-specific chains.

The results described so far lead to a series of questions, which will be discussed in the subsequent Sections. The O-specific chains carry the serological specificities of the lipopolysaccharides: which chemical structures correspond to the serological determinants, *i.e.* the antigen factors of the Kauffmann-White scheme? How are the side chains synthesized in the cell and how is their biosynthesis genetically determined? We have seen that the building up of the side chains in lipopolysaccharides of different species can be very similar (Table 3); are there any genetic relationships present within these species? The answer to these questions has been an essential target in recent research.

5.2. Localization of Determinant Groups (O-Antigen Factors) in O-Specific Chains

Immunochemical investigations led *Staub* [18, 20] and *Robbins* [26] to the identification of concrete structures in the O-specific chains, the serological determinants, which carry the specificity of the O factors of the Kauffmann-White scheme. By precipitation inhibition tests the monosaccharide is determined which gives the highest inhibition of a factor/anti-factor system. The monosaccharide that possesses the highest affinity for the anti-factor antibody is called the *immunodominant sugar* [18] (abequose in the 4 anti-4 system, mannose in the 3 anti-3 system, and so on). Oligosaccharide fragments containing the immunodominant sugar are then similarly tested for precipitation inhibition. The oligosaccharide displaying the highest inhibition activity has the same structure as the O factor under test. Figure 6 features the structures of determinant groups and their location in the O-specific chains [18, 20].

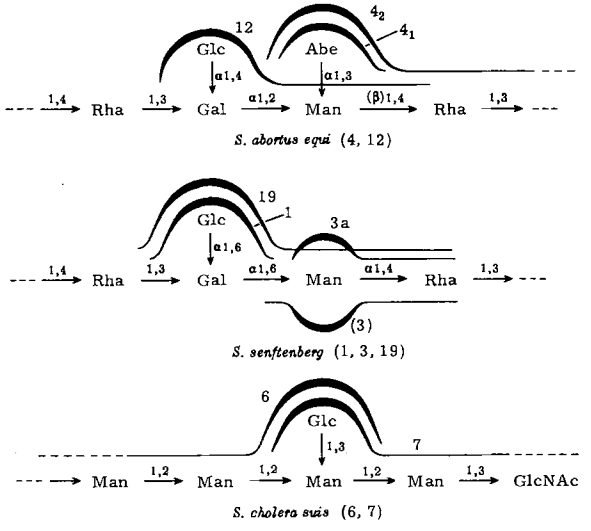

Fig. 6. Distribution of serologically determinant groups along the O-specific chains of lipopolysaccharides [18, 20, 24a].

These investigations have led to the following results [20]:

a) In theory, *each sugar unit* can function as immunodominant sugar.

b) The determinant structures *overlap* along the O-specific chain (*i.e.* factors 12 and 4, 19 and 3a).

c) *A family of antibodies* is produced against a single immunodominant sugar. These antibodies are directed against larger or smaller areas of the determinant groups. (*i.e.* factors 4$_1$, 4$_2$, and 1,19).

d) A determinant group commences with the immunodominant sugar and can extend to the right or to the left or in both directions to *neighboring sugars* (*i.e.* factors 6 and 7).

e) The Kauffmann-White scheme is an intentionally simplified one: many O factors can actually be differentiated into *subfactors* (*e.g.* factor 4 in 4$_1$, 4$_2$; factor 3 in (3), 3a).

5.3. Biosynthesis of the O-Specific Chains (Region I)

The reaction steps involved in biosynthesis of the O-specific chains are represented in Fig. 7 for *S.newington* (3, 15) as an example [27–30]. Throughout the biosynthetic pathway, the intermediate products are attached *via* a pyrophosphate bridge to the "Antigen Carrier Lipid" (ACL), a polyisoprenoid alcohol with 55 C atoms. In the first step the sugar residues, from the form of their activated derivatives (in the case of *S.newington* UDP-galactose, TDP-rhamnose, and GDP-mannose), are combined into a repeating unit by the

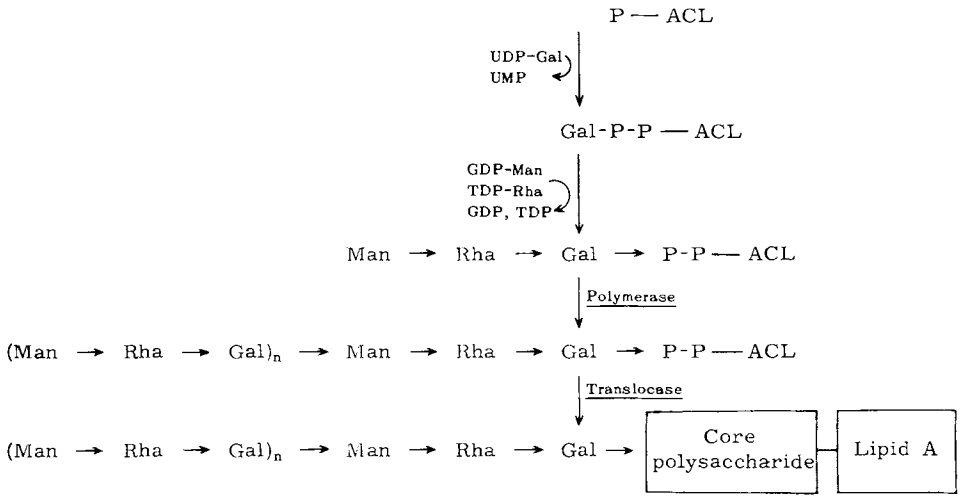

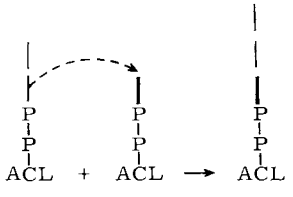

Fig. 7. Biosynthesis of the O-specific chains of the lipopolysaccharide of *S.newington* (3 15) [30] (see also [27]). ACL (antigen carrier lipid) = $H(CH_2-C(CH_3)=CH-CH_2)_{11}-O$.

action of specific transferases. These units are then polymerized by the enzyme polymerase, the side chain (which is attached to the antigen carrier lipid) being lengthened by one repeating unit in each growth step. Each freshly polymerized chain piece (– –) is transferred onto a new repeating unit (—), the chain thus growing at its reducing end [31].

In a final step the completed O-specific chain is transferred by the action of the enzyme translocase onto the core polysaccharide of the prefabricated lipid A-core polysaccharide unit. The individual steps of this biosynthesis have been studied *in vitro*. It was found that substituents such as glucosyl residues or acetyl groups (but not abequose or tyvelose) are transferred onto the O-specific chain *after* the lipopolysaccharide is completed [30].

It is believed that the ACL functions as an anchor to the cell membrane where biosynthesis of the specific chains proceeds, and that it serves as a transporting agent for the polysaccharides through the membrane. An analogous role could be attributed to lipid A during the synthesis of the core polysaccharide. The last step, the linkage of both polymers (region I and region II, III), probably takes place outside the cell membrane. Lipid carriers also play a role in the synthesis of other polysaccharides (*e.g.* murein synthesis [32]).

5.4. Genetic Determination of Biosynthesis of the Specific Side Chains: SR Mutants

The elucidation of the biosynthetic pathway of region I was accompanied by genetic investigations in the laboratories of *Stocker*, *Mäkelä*, and *Nikaido*. It was found that all the enzymes participating in the side chain synthesis are determined by a cluster of genes on the *Salmonella* chromosome near the *his* locus [33, 34, 34a]. This area of the chromosome, the O locus, is designated *rfb* (Fig. 8). Mutational changes in the *rfb* locus

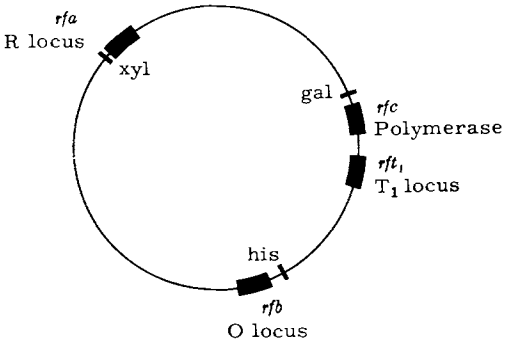

Fig. 8. The chromosome of *S.typhimurium* with the gene-regions of lipopolysaccharide biosynthesis [33].

and their effects on lipopolysaccharide synthesis will be discussed later (Section 6.3).

One exception, however, has been found. It concerns the enzyme polymerase (see Fig. 7), which maps at the *rfc* locus near the *gal* locus [35]. Mutations affecting the *rfc* locus lead to a defect in the synthesis of polymerase, resulting in the polymerization of the repeating units being blocked. In such mutants the sugar residues are assembled into *single* repeating units which are then transferred directly onto the core polysaccharide. The structure of an *rfc*⁻ lipopolysaccharide is shown in Fig. 9. In their bacteriological and serological proper-

ties, this class of mutants occupies an intermediate position between S forms and R mutants (see Section 6.1) and is, accordingly, termed semi-rough (SR).

5.5. Genetic Basis for Structural Relationships between Lipopolysaccharides of Different Species: Lysogenic Conversions

It has already been shown in Table 3 that different *Salmonella* species may show similarities with respect to the structure of their lipopolysaccharides, although they are not serologically related to one another (*e.g.* groups B and E). In many cases, the reason for such similarities may be traced back to a frequently occurring phenomenon: The so-called lysogenic conversion of *Salmonella* species brought about by the action of temperate (nonvirulent) phages. The credit for the elucidation of the chemical and biochemical principles underlying lysogenic conversions goes to *Staub* [18,20] and *Robbins* [26,30,36].

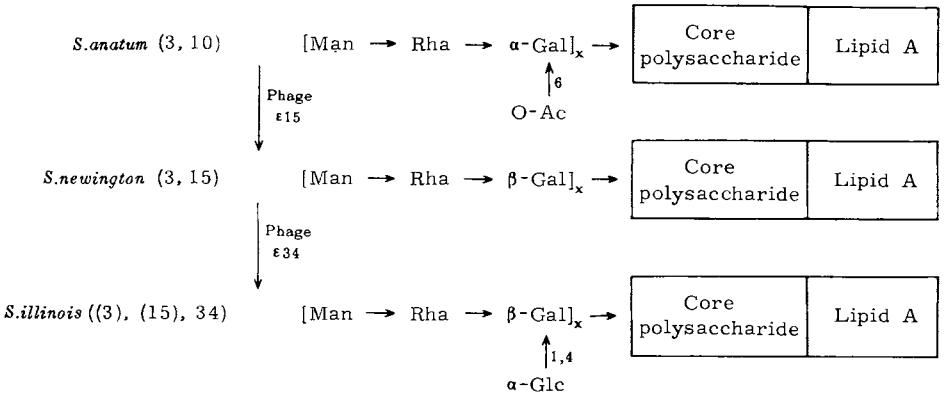

Fig. 10. Lysogenic conversions in *Salmonella* group E [26, 30].

An example of lysogenic conversions is given in Fig. 10 [30]: If *S.anatum* (3, 10) is infected with phage ε 15, it is converted into *S.newington* (3, 15). After superinfection of this species with phage ε 34, *S.illinois* ((3), (15), 34) is obtained. The serological changes (10 → 15 → 34) are paralleled by specific modifications in the structure of the O-specific chains of the respective lipopolysaccharides (Fig. 10). *S.anatum* contains α-linked acetylated galactosyl residues; in *S.newington*, galactose is β-linked but not acetylated, and in *S.illinois* the β-galactosyl residues carry a glucosyl side chain in position 4.

Although the complex mechanisms underlying lysogenic conversions are not fully understood, it is evident that the phage genome (phage nucleic acid), which is integrated into the chromosome of the host, influences and dictates new distinct steps of lipopolysaccharide biosynthesis. Thus, in the above example, some of the enzyme activities of the host are suppressed (acetylation and α-linking of galactose [37]), and new activities are introduced into the host (β-linking of galactose, and introduction of a glucosyl side chain). All cases of lysogenic conversion so far studied concern substituents of the O-specific chains or changes in the specificity of polymerases.

In the Kauffmann-White scheme (Table 1), factors 3 and 15 of *S.illinois* are placed in brackets ((3), (15)). This is to show that they cross-react with factors 3 and 15 of *S.newington*, but are not identical with them. In *S.illinois* the specificity of factor 34 is determined by glucose. At the same time glucose alters the specificity of the β-galactose to which it is bound. In contrast to the unsubstituted galactose with specificity 15, the substituted galactose determines the specificity (15), *i.e.* not all antibodies against the unsubstituted galactose "fit" onto the substituted galactose. Similarly, the mannose-determined specificity of factor 3 is influenced by the presence of glucose.

The constant unveiling of new conversion systems shows that many *Salmonella* species are genetically related. Inevitably, the question arises of the extent to which *Salmonella* serotypes are interrelated through lysogenic conversion, or, in other words, how many of the genes of the chromosome of a *Salmonella* are really its own or derive from prophages which were integrated during the course of evolution.

5.6. *Salmonella* Mutants with Atypical Specific Chains: T Forms

In 1956, two *Salmonella* strains that could not be typed with any of the known O sera were isolated in different hospitals in Europe. *Kauffmann* [1,2], to whom these two strongly cross-reacting strains were sent, hesitated to place them in a new *Salmonella* group. Further investigation revealed that, with respect to their flagellar antigens and their fermentative properties, the two strains were identical with *S.paratyphi* and *S.typhimurium*, respectively. From this, *Kauffmann* concluded that the new strains were mutants of the above mentioned species, in which the O antigens had been replaced by a new one which he termed T 1 antigen (T = transient, because T forms are relatively unstable and frequently undergo mutation into R forms). Later

[36] *R. Losick* and *P. W. Robbins*, J. molecular Biol. *30*, 445 (1967).

[37] *R. Losick*, J. molecular Biol. *42*, 237 (1969).

Schlosshardt found that many and perhaps all *Salmonella* species could in principle be converted into T1 forms [38]. However, T1 forms appear very seldom in nature.

In 1957, *Kauffmann* identified a T mutant derived from *S.bareilly* that was different from T1 and which he termed T2 [1,2]. Extraction of T1 and T2 forms with phenol/water yielded T1 and T2 lipopolysaccharides, which, like all *Salmonella* species, also contained the five basal sugars (Table 2). In addition, the T1 lipopolysaccharide also contained ribose and galactose in large quantities. Further examination showed that the O-specific chains, which are present in the wild forms, are replaced in the T1 lipopolysaccharide by T1-specific chains, which are also attached to the basal core polysaccharide in a similar way. These T1-specific chains are composed of ribose and galactose units. It was found that both sugars are present in the furanosidic form, *i.e.* in the five-ring structure [39,40]. A polysaccharide structure of this kind, which is rather rare in nature, is very acid-labile. For this reason it could not be established up to now whether T1 side chains are also made up of repeating units.

Mutation from the wild type into the T1 form proceeds in two steps (Fig. 11, see also Fig. 8): One mutation affects the O locus (leading to a block in the synthesis of the O-specific chains). A second mutation concerns the T1 locus, which determines the synthesis of

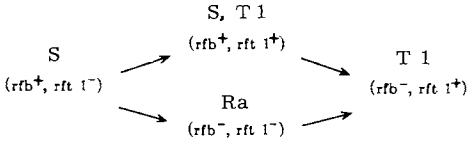

Fig. 11. The mutation steps leading from wild types to T1 mutants [41].

T1 chains [41]. Recently *rft1*+ mutants have been isolated with an intact *rfb* locus. As expected they synthesize simultaneously both O-specific and T1-specific lipopolysaccharides [42].

The biological significance of T1 mutants in nature (*e.g.* in pathogenicity) is not known. It is unlikely that *Salmonella* species possess a gene, *rft1*, which is never or very rarely brought into function.

6. The Core Polysaccharide (Region II)

6.1. The S → R Mutation

While the studies of O-specific chains (region I) could be performed with lipopolysaccharides of *Salmonella* wild forms (S forms), work on the basal core polysaccharide (region II) proved to be rather difficult, because in this case only a small internal region of the macromolecule was concerned. This difficulty was overcome by extending the studies to mutant strains, the so-called R forms. These mutants, which have been known for a long time [1,2], suddenly became of critical importance for biological and genetical studies on lipopolysaccharides when it was found that certain steps in their lipopolysaccharide biosynthesis are blocked.

Since R mutants occur spontaneously, they are frequently found in old cultures, from which their isolation is facilitated by their morphological properties. In contrast to the smooth-growing wild strains, the R mutants form rough colonies (hence *s*mooth = *S* form, *r*ough = *R* form). Parallel to these morphological changes, drastic serological changes take place: the O specificity of the parent strain is lost and new, R specificities become manifest.

6.2. Classification of R Mutants

It is possible to obtain a large number of R mutants from a single *Salmonella* species. The investigations discussed below were performed mainly with *S.minnesota* R mutants isolated by *Schlosshardt* [43]. Analogous series of R mutants were obtained from *S.typhimurium*, *S.ruiru*, and other *Salmonella* species.

Although R mutants do synthesize lipopolysaccharides, their sugar composition shows characteristic differences from that of the corresponding wild type lipopolysaccharides. All O-specific sugars are missing, and only all or some of the five basal sugars (see Table 2), which are also found in the wild form in addition to the specific sugars [18], are present. R (lipo)polysaccharides contain, besides ethanolamine and phosphate, *N*-acetyl-D-glucosamine, D-glucose, D-galactose, and two sugars that until now have been found exclusively in bacterial lipopolysaccharides: L-glycero-D-manno-heptose (first identified in *Shigella* [44]) and 2-keto-3-deoxy-D-mannooctonic acid (KDO) (first identified in *E.coli* [45]). Recently, a further sugar, 4-amino-L-arabinose, was found in R lipopolysaccharide preparations [45a]. It is not yet known whether it is a constituent of the lipopolysaccharide itself or of a contaminant.

In analogy to the chemotypes of the S forms (Table 2), comparative analysis of *S.minnesota* R forms led to a classification into R chemotypes (Ra, Rb, Rc, *etc.*) that is also based on the difference in sugar composition of the R lipopolysaccharides (Table 5, left-hand side) [43]. Ra mutants contain all five basal sugars. In Rb mutants, glucosamine is absent as a constituent of

the core polysaccharide (glucosamine is present in all *lipo*polysaccharides as a constituent of lipid A). In Rc mutants the only hexose present is glucose, while in Rd mutants no hexose at all is present. In the last group, Re, hexoses as well as heptose are absent, leaving KDO as the only sugar bound to lipid A (region III). The various R classes differ from one another also with respect to their R specificity (Table 5, right-hand side) [43]. Finally, each R class is characterized by an individual phage pattern [46]. Hence the classification of the R mutants into R chemotypes corresponds to a classification into R serotypes and R phage types.

6.3. Ra-Mutants: Defects and Genetics

Ra mutants hold a key position in the class of R mutants and their study has contributed extensively to the understanding of the mechanisms which underly S → R mutation [18, 27, 29].

Ra lipopolysaccharides contain the five basal sugars but are devoid of all O-specific sugars of the parent strain. These findings led to the conclusion that in Ra mutants the synthesis of the O-specific chains (region I) is blocked. Analysis of Ra mutants actually showed that whenever a defect was identified it was always associated with an enzyme that participates in the biosynthesis of region I. Thus an Ra mutant of *S.minnesota* has lost the capacity of the parent strain to synthesize *N*-acetylgalactosamine (UDPGlcNAc —|→ UDPGalNAc). Similarly, *S.typhimurium* R mutants have been identified defective in the synthesis of rhamnose (TDPGlc —|→ TDPRha), abequose (CDPGlc —|→ CDP Abe), or mannose (Glc-6-P —|→ Man-6-P). The block of a *single step* in the biosynthesis of region I renders the cell incapable of synthesizing specific chains (see Fig. 7). Lipopolysaccharide synthesis in Ra mutants therefore stops at that point where the specific side chains are normally transferred onto the core polysaccharide-lipid A unit. Consequently, Ra mutants synthesize a lipopolysaccharide composed merely of regions II and III.

Genetic investigations by *Stocker* on Ra mutants have shown that the defect concerns the O locus (*rfb* region) [34] whose genes govern the synthesis of the enzymes necessary for the biosynthesis of the specific chains. Ra mutants may differ with regard to their genotype, *i.e.* according to the genetic defects of their O locus. Phenotypically, however, they are identical: they synthesize the intact core polysaccharide (region II), bound to lipid A (region III).

6.4. Rb to Re Mutants: Defects and Genetics

While in Ra mutants the synthesis of the O-specific chains is blocked, in Rb to Re mutants defects are present which lead to a more or less incomplete core structure. As seen in Table 5, remarkable differences in sugar composition are found in lipopolysaccharides synthesized by mutants of the various R classes. The synthesis of the core polysaccharide in these mutants proceeds normally up to the point of defect, and there the synthesis is interrupted [in contrast to the usual "all or nothing" principle underlying the synthesis of the specific chains (see Fig. 7)]. Defects in Rb to Re mutants may be concerned with the synthesis of the sugar units and/or their transfer.

Genetic studies by *Stocker*, *Mäkelä*, and *Nikaido* have led to the identification of the R locus [27, 34]. This part of the chromosome, which is designated *rfa*, controls many enzymes that catalyze the synthesis of the core polysaccharide. It is far removed from the O locus (Fig. 8).

Besides R-specific lipopolysaccharides, the majority of Rb to Re mutants synthesize a polysaccharide containing the O-specific sugars of the parent strain but none of the core-specific sugars (heptose, KDO) and no lipid

[46] *G. Schmidt* and *O. Lüderitz*, Zbl. Bakteriol., Parasitenkunde, Infektionskrankh. Hyg., I. Abt., Orig. *210*, 381 (1969).

A[47]. This so-called "specific hapten" consists of free O-specific chains (region I). Since the *rfb* locus in *rfa*-defective mutants is intact, the synthesis of the specific chains can proceed unimpeded also after mutation. Because of the high acceptor specificity of the translocase (see Fig. 7), the chains are not transferred onto the incomplete core polysaccharide. They accumulate in the R cells, probably bound to the antigen carrier lipid. The extremely labile pyrophosphate bridges are broken down during phenol/water extraction and the specific hapten is found in the supernatant after ultracentrifugation, whereas the R lipopolysaccharide sediments.

6.5. Chemical Structure of the Core Polysaccharide

Fig. 12 shows the structure of the *S.minnesota* core polysaccharide (region II) as obtained by combining the part-structures identified in Ra to Re lipopolysaccharides. It consists of two oligosaccharides, one of which contains hexoses and the other heptose and KDO.

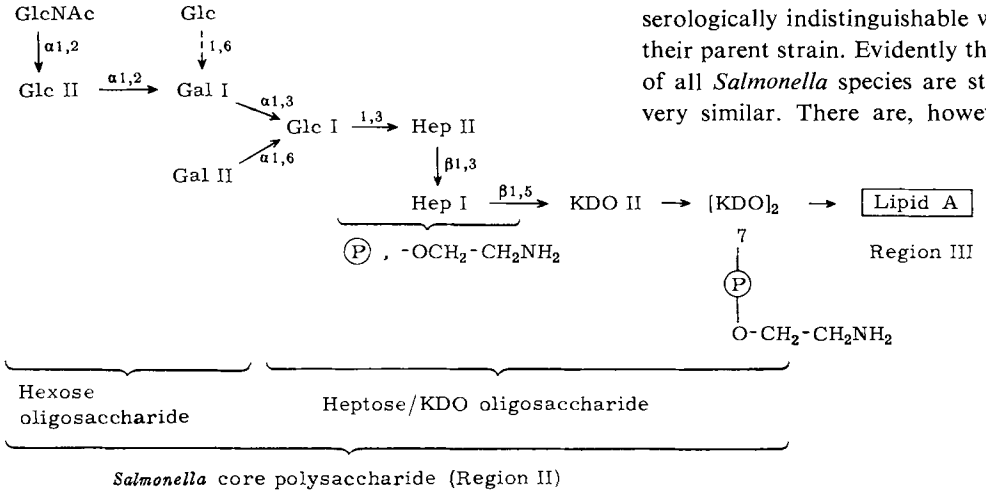

Fig. 12. Structure of *Salmonella* Ra lipopolysaccharides: The core polysaccharide (region II) [18, 29].

The structure of the hexose oligosaccharide resulted from analysis of fragments obtained by partial hydrolysis of Ra and Rb lipopolysaccharides[18,29]. According to more recent findings by *Nikaido*[48] and *Hämmerling et al.*[56], the O-specific chains are linked to the glucose II residue in wild type lipopolysaccharides.

In the heptose/KDO pentasaccharide, whose structure has been elucidated by analysis of Rc to Re lipopolysaccharides[49,49a], the three ketosidically-linked KDO residues are present as a branched trisaccharide, with the reducing end bound ketosidically to lipid A[54]. In the core polysaccharide, therefore, two KDO units are present in the main chain, while the third KDO unit forms a branch, carrying a phosphorylethanolamine group in position 7[49a]. One of the heptose residues[49b], probably heptose I[49c], is substituted in position 4 by a pyrophosphorylethanolamine group.

From the formula of Fig. 12, a molecular weight of about 2000 can be calculated for the core polysaccharide chain. The type of linkage of the phosphate groups, which are obtained as heptose phosphate after hydrolysis, is not known. The clarification of this matter could be of importance for the entire architecture of the lipopolysaccharide molecule. It is presumed that some of the phosphate groups form diester bridges to the neighboring chains. This would lead to a considerable enlargement of the molecule. A further question arises as to how many of the core polysaccharide units in an S form lipopolysaccharide are occupied by O-specific chains: Do all, a few, or just one core unit carry a specific chain?

Salmonella Ra lipopolysaccharides are chemically and serologically indistinguishable whatever the species of their parent strain. Evidently the core polysaccharides of all *Salmonella* species are structurally identical or very similar. There are, however, many indications that the lipopolysaccharides of other genera possess very different core structures. Thus, *Simmons* has isolated a pentasaccharide from a *Shigella flexneri* Ra lipopolysaccharide[50], which, although it has certain similarities to the pentasaccharide isolated from *Salmonella* (glucosamine as the non-reducing and glucose as the reducing end groups), is different with respect to the sequence of sugars and their substituents (Fig. 13). Even more contrasting differences are apparent in *Xanthomonas* species, whose lipopolysaccharides, according to *Volk*, contain KDO and galacturonic acid phosphate, but no heptose or galactose[50a,50b,50c].

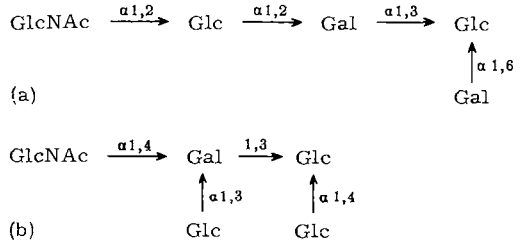

Fig. 13. Comparison of the hexose oligosaccharides in the core polysaccharides of a) *Salmonella* [18] and b) *Shigella flexneri* [50].

The elucidation of the detailed structure of core polysaccharides from as many bacterial groups as possible is of utmost importance for questions of evolution and taxonomy.

6.6. Structure of Core Defective Lipopolysaccharides: Possible Biosynthesis of the Core Polysaccharide

The entire structure of the core polysaccharide of *Salmonella* has been reconstructed from partial structures appearing in core-defective liposaccharides of the R classes Rb to Re. The structures ascribed to these lipopolysaccharides are summarized in Table 6 [19].

Table 6. Structure of the lipopolysaccharides of core-defective mutants: The biosynthetic pathway of *Salmonella* core polysaccharide [18].

Chemotype	Lipopolysaccharide
Re	$(KDO)_3 \rightarrow$ lipid A
Rd_2	Hep → $(KDO)_3 \rightarrow$ lipid A
Rd_1P^-	Hep → Hep → $(KDO)_3 \rightarrow$ lipid A
Rd_1P^+	Hep → Hep → $(KDO)_3 \rightarrow$ lipid A; Ⓟ, EtN
RcP^-	Glc → Hep → Hep → $(KDO)_3 \rightarrow$ lipid A
RcP^+	Glc → Hep → Hep → $(KDO)_3 \rightarrow$ lipid A; Ⓟ, EtN
Rb	Glc → Gal → Glc → Hep → Hep → $(KDO)_3 \rightarrow$ lipid A; Gal; Ⓟ, EtN
Ra	GlcNAc → Glc → Gal → Glc → Hep → Hep → $(KDO)_3$ → lipid A; Gal; Ⓟ, EtN

While the majority of the isolated mutants show a defect in sugar *synthesis* or in sugar *transfer*, some (P^-) mutants have been obtained whose defect concerns the transfer of phosphate groups to heptose. Biosynthetic experiments *in vitro* showed that ATP functions as a phosphate donor for the transfer of phosphate and it could be demonstrated that the presence of these heptose phosphate groups is necessary for the later transfer of galactose [51, 52].

The incompleteness of lipopolysaccharides from core defective mutants is the result of failure in certain biosynthetic steps. On the grounds of this concept the structures shown in Table 6 may be looked upon as intermediate products in the biosynthesis of lipopolysaccharides. Accordingly, two heptose residues are sequentially added to the Re lipopolysaccharide (which is now often termed glycolipid since it is rather a lipo-"oligosaccharide" than a lipo-"polysaccharide"). These heptose residues are then phosphorylated in a subsequent biosynthetic step. The incorporation of ethanolamine also takes place at this stage. *In vitro* transfer of heptose could not yet be carried out because the activated precursor of heptose (as well as its biosynthesis) is still unknown. However, *Osborn* and *Rothfield* and their co-workers have been successful in the *in vitro* synthesis of Ra from RdP^+ lipopolysaccharide by sequential incorporation of glucose, galactose, glucose, and finally *N*-acetylglucosamine [28, 29]. The sequence of incorporation of these sugars is determined by the high specificity of the transferases for acceptor and nucleotide sugars. The results from these biosynthetic studies are in good agreement with the results of structural investigations on the hexose oligosaccharide. They also show that the biosynthesis of the core polysaccharide and of the O-specific chains are based on fundamentally different principles.

6.7. Biological Properties of R Mutants

The mutants of all R classes are immunogenic and induce production of antibodies. The terminal nonreducing sugar residues of defective lipopolysaccharides act as immunodominant sugars, as was shown in precipitation inhibition studies (see Table 5). The corresponding homologous systems are thus inhibited by *N*-acetylglucosamine, glucose, heptose, and KDO, respectively.

R lipopolysaccharides also represent specific receptors for a series of phages. The phage Felix 01 reacts only with lipopolysaccharides which contain *N*-acetylglucosamine in the core polysaccharide (from S and Ra strains), but not with lipopolysaccharides of other R classes (*e.g.* from Rb strains) (see Fig. 3) [17].

Many *Salmonella* species are pathogenic. They are capable of entering the organism where they can multiply, thus flooding the system with endotoxin. *S.typhi*, *S.paratyphi*, and *S.enteritidis* are some of the well known pathogens. Although R lipopolysaccharides are also toxic, R forms are not pathogenic This is due to the action of macrophages which phagocytize R mutants and render them harmless. The S forms, on the other hand, are protected from this fate because of the presence of the long O-specific polysaccharide chains on their cell surface which prevent the contact between bacterial cell and macrophage that is necessary for subsequent phagocytosis. It can be demonstrated also *in vitro* that the hydrophilic specific chains of the S forms protect the cell against lytic enzymes, antibiotics, and adverse environmental conditions such as heat, a protection which the R forms lack [53a].

7. Lipid A (Region III)

7.1. Structure of Lipid A

By mild acid hydrolysis of (S and R) lipopolysaccharides the labile ketosidic linkage of the KDO residue, which links the core polysaccharide to lipid A, is broken down and lipid A is liberated in the form of a water-insoluble precipitate. Lipid A is a phospholipid with an uncommon structure. Instead of glycerol phosphate (lecithine, cephaline) it contains D-glucosamine-phosphate as the hydrophilic polyhydroxy compound. The amino groups of the glucosamine residues are occupied by D-β-hydroxymyristic acid, while the available OH groups are esterified with long-chain fatty acids, mainly lauric, myristic, palmitic, and β-hydroxymyristic acids [53].

For the elucidation of the glucosamine "backbone" of lipid A, the glycolipid from *Salmonella* Re mutants has proved to be most suitable as starting material because it contains only KDO and lipid A. On cleavage of the long-chain fatty acids by hydrazinolysis and subsequent partial hydrolysis, four main fractions (besides free KDO) could be identified by electrophoresis [54]. Their isolation and analysis led to the structures shown in Fig. 14. Fraction −5, glucosaminyl-β-1,6-glucosamine, represents the basic structure whose derivatives

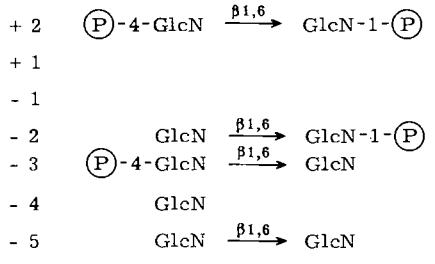

Fig. 14. Electropherogram of the partial hydrolyzate of a Re glycolipid after hydrazinolysis [54]. 40 V/cm, 150 mA, pH = 5.3.

carry one (fractions −3 and −2) and two (fraction +2) phosphate residues in positions 1 and, probably, 4′. When the product of hydrazinolysis was analyzed directly the corresponding phosphorylated derivatives of a KDO-containing pentasaccharide could be obtained. These derivatives could then be transformed into the (KDO)$_3$-glucosaminyl-β-1,6-glucosamine by phosphatase treatment or into the disaccharide glucosaminyl-β-1,6-glucosamine (and free KDO) by partial hydrolysis.

Lipid A therefore consists of phosphorylated β-1,6-linked glucosamine disaccharide units, whose hydroxyl and amino groups are acylated (Fig. 15). A KDO oligosaccharide which is linked to one of the hydroxyl groups of the non-reducing glucosamine residue effects the linkage of core polysaccharide and lipid A in S and R lipopolysaccharides.

It is quite probable that several glucosamine disaccharide units are linked together by phosphate bridges

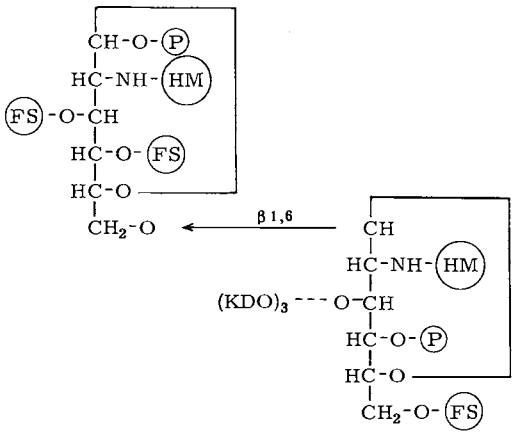

Fig. 15. Structure of a lipid A unit with a KDO oligosaccharide [54]. FS = long-chain fatty acids; HM = β-hydroxymyristic acid.

(1–4′) in the intact lipid A. This would mean a substantial increase in the size of the lipopolysaccharide molecule and could be of importance to the general design and organization of the cell wall.

7.2. The Endotoxic Region in the Lipopolysaccharide Molecule

The isolation and identification of a series of R classes and the study of their lipopolysaccharides and glycolipids has opened up new possibilities for the identification of regions in the lipopolysaccharide that are responsible for endotoxic activity. What has been postulated for a long time could now be confirmed, *i.e.* that the O-specific chains and the hexoses and heptoses of the core polysaccharide do not contribute to the toxic effects of the molecule and are, in this respect, non-essential. In many laboratories it has been shown that the glycolipids of Re mutants, which contain only KDO and lipid A, are just as active endotoxins as the lipopolysaccharides of the corresponding wild types [13, 14]. Lipopolysaccharides in which the lipid A component has been deacylated by either specific amoeba enzymes or by treatment with alkali are no longer toxic [55]. This and other results show that lipid A is responsible for the endotoxic activity of lipopolysaccharides.

8. Summary and Discussion

Fig. 16 shows the complete structure of the lipopolysaccharide from *S.typhimurium* [18, 23, 54, 56]. It is made up of the three regions shown in Fig. 4: the O-specific polysaccharide chains; the core polysaccharide; and lipid A.

The physicochemical properties of lipopolysaccharides are determined by the simultaneous presence of hydrophilic, strongly polar polysaccharidic regions, on one

[54] *J. Gmeiner, O. Lüderitz,* and *O. Westphal,* European Biochem. *7,* 370 (1969).

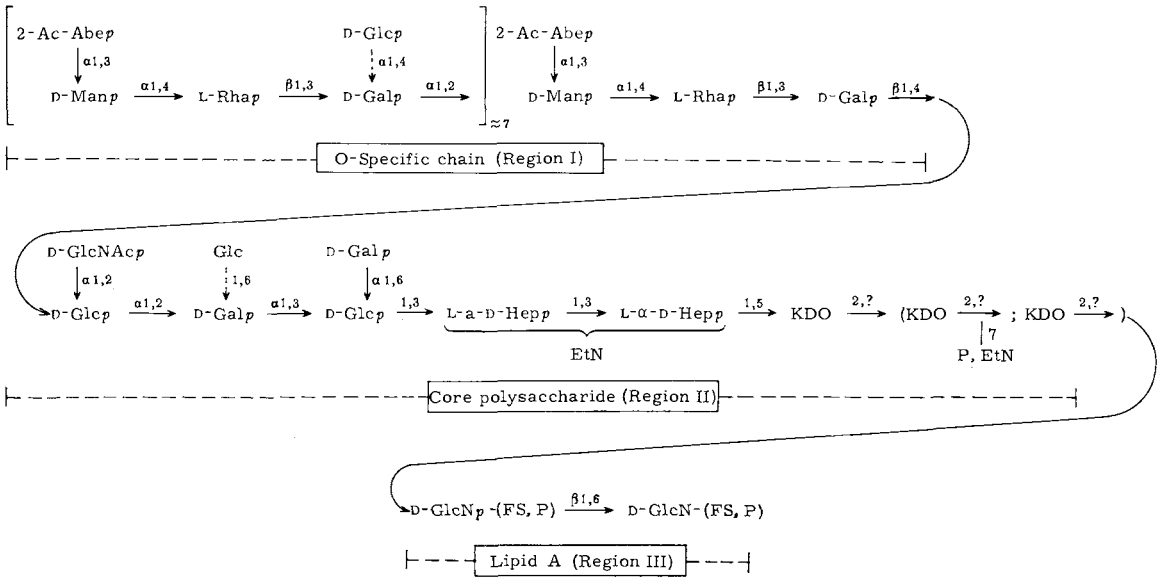

Fig. 16. Structure of the lipopolysaccharide of *S. typhimurium* according to our present knowledge [18, 23, 49a, 49b, 54, 56]. *p* = pyranoside linkage; L-α-D-Hep is equivalent to β-Hep of the preceding figures. EtN = ethanolamine; FS = long-chain (hydroxy) fatty acids.

hand, and lipid A on the other. This combination of hydrophilic and hydrophobic regions leads, in aqueous solutions, to the formation of micellar structures with a high degree of aggregation (see Fig. 3), thus making direct determination of the true molecular weight of lipopolysaccharides impossible. Also the formula of Fig. 16 provides no information about the molecular magnitude, since we do not know whether the phosphate groups bound to heptose or those present in lipid A act as bridges to neighboring chains to form a three-dimensional network. The inner region of the core polysaccharide, the heptose/KDO oligosaccharide, contains a bundle of polar groups (carbonyl groups of KDO, phosphate groups, amino groups of ethanolamine) whose physiological significance is not yet known. It is conceivable that they participate in the binding of other components in the bacterial cell wall. Another function of the ionic groups in the core polysaccharide could be, in analogy to the teichoic acids [56a], that they regulate the flow of ions to the cell membrane, thus maintaining an optimal concentration of bivalent ions necessary for many enzymes.

Biochemical and genetic investigations of recent years have shown that O-specific chains, on the one hand, and core polysaccharide-lipid A, on the other, are synthesized independently by different mechanisms. Their synthesis is determined primarily by the (species-specific) O locus and by the R locus (common to all *Salmonella*), respectively, which are situated far away from each other on the ring-shaped *Salmonella* chromosome.

In general, each defect in the synthesis of the O-specific chains leads to the complete absence of the O-specific chains in the lipopolysaccharide, no matter which biosynthetic step is concerned. O Locus-defective mutants therefore form a phenotypically uniform class, the Ra mutants, whose lipopolysaccharides contain the complete core polysaccharide.

On the other hand, core-defective (R locus-defective) mutants belonging to different genotypes are often phenotypically different. They synthesize the core polysaccharide up to the defective biosynthetic step and belong to the classes Rb to Re. As expected, these mutants also synthesize O-specific chains, which are, however, not transferred onto the incomplete core polysaccharide, but may remain linked to the antigen carrier lipid. After phenol/water extraction they are obtained as a soluble polysaccharide ("specific hapten"). It is obvious that the sequence of the sugar residues in lipopolysaccharides is not determined by a template mechanism but by the substrate specificity of many enzymes which participate in the polysaccharide synthesis. The sequence of the biosynthetic steps is thereby laid down and so also is the polysaccharide structure. There is evidence that in some lipopolysacharides the O-specific chains are not built up of repeating units [25, 40].

Present results indicate that in *Salmonella* species the core polysaccharide and the lipid A component are of identical structure. In other groups of bacteria, however, the core structure may be different [18, 20, 50, 50a–c]. It has been shown that occasionally different core structures carry identical O-specific chains [50b]. Similarly, structural differences exist in the lipid A component of other genera with respect to the glucosamine disaccharide [58] as well as to the fatty acids [59–62].

So far, no mutants have been described with a defect in the synthesis of KDO or lipid A. It is possible that

the usual methods of selection are not suitable for the isolation of such mutants, or that they are not able to grow under the usual cultivation conditions. The identification of substances which would inhibit early stages of lipopolysaccharide biosynthesis in the cell (as do some antibiotics in the synthesis of murein) would be of great theoretical and practical value. Such substances would convert the pathogenic wild types into non-pathogenic R forms which are known to be readily eliminated in the organism by macrophages.

Although the biosynthetic pathway of lipopolysaccharides has been extensively elucidated, very little is known about their degradation in nature. It is surprising that no enzymes have so far been described which degrade lipopolysaccharides specifically, since this would be of extreme value for structural analyses or for the identification of biologically active regions in the molecule. We have recently found that amoebae of *Dictyostelium discoideum* contain an enzyme system which degrades specifically the lipid A component of lipopolysaccharides [55]. After phagocytosis, lysis, and digestion of the fed bacteria, these amoebae egest degraded lipopolysaccharide into the culture medium. This lipopolysaccharide contains intact O-specific chains and core polysaccharide. The lipid A component, however, is quantitatively deacylated. Ester- as well as amide-bound fatty acids are cleaved off and the degraded lipopolysaccharide contains nonacylated glucosamine disaccharide. Amoebae-degraded lipopolysaccharide is *non-toxic*. It is possible that the inactivation (detoxification) of lipopolysaccharides, which is observed after incubation with serum, is based on an analogous reaction with acylases.

Immunochemical and serological studies on lipopolysaccharides have shown that O specificity is determined by defined structures in the O-specific chains; determinant groups, di- to hexasaccharides, determine the individual factors of the Kauffmann-White scheme. In each determinant group one sugar plays the role of the immunodominant sugar. In R mutants, which lack specific chains, the terminal sugars of the various incomplete core polysaccharides function as the immunodominant sugars. R mutants exhibit R specificities. Very recent studies by *Rank* [57] indicate that under certain conditions antibodies against lipid A are detectable which, as expected, can cross-react with nonrelated lipopolysaccharides.

All lipopolysaccharides are highly active endotoxins, irrespective of whether they are derived from S or R forms. The region responsible for this activity is located in the (KDO)-lipid A part of the molecule. The polysaccharide part is non-essential.

Methods of Virus Formation

By Gerhard Sauer[*]

Viruses occur in a great variety of shapes and sizes, but for all their diversity in appearance they possess certain characteristics in common: all viruses contain a single nucleic acid molecule – deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) – surrounded by a protective protein coat. Among other things, the protein coat enables the genetic information stored in the nucleic acid to enter a host cell in a usable state, where it can initiate the reproduction of identical virus particles. After penetration of the cell the foreign genetic material of the virus particle first induces the synthesis of macromolecules not normally present in the cell: the viral nucleic acid undergoes replication and very many copies are produced, the protein of the virus coat is synthesized, and then these components are assembled to form a new generation of infectious virus particles. Most viruses also exhibit certain common structural features: their protein coat is built up from subunits arranged in helical or icosahedral fashion around the genetic material.

1. Conversion of the Virus Genome into a Functional State

As most viruses consist of nothing but nucleic acid and a protein coat, they lack the prerequisites to carry out elementary life processes, *i.e.* to make constant use of their genetic information. Outside a cell, the virus particle is only a complex but biologically inert structure. For their multiplication the viruses require auxiliary agents that are only available in living cells, consisting of various enzymes, ribosomes, and transfer-RNA molecules. The viral nucleic acid only becomes functional when it penetrates the cell and is freed from its protein coat.

The cycle of infection, *i.e.* the period between the time when a virus particle comes into contact with a

[*] Priv.-Doz. Dr. G. Sauer
Institut für Virusforschung,
Deutsches Krebsforschungszentrum
69 Heidelberg, Thibautstrasse 3 (Germany)

cell and the time when its new infectious progeny are complete, can be divided into several phases. Adsorption of the virus particles onto the cell is followed by their penetration of the cell wall and liberation of the genetic information. When the protective protein coat is lost from the viral nucleic acid, the virus particle loses its morphological identity. It is now in the "eclipse" phase. During this phase occur the transcription and translation stages, which lead to the accumulation of virus components within the cell. This is followed by maturation of the virus and the release of a new generation of infectious virus particles.

If cells are infected with a definite amount of virus, and the infectivity of the nutrient medium surrounding the cells is determined, the characteristic virus growth curves are obtained as shown in Figure 1.

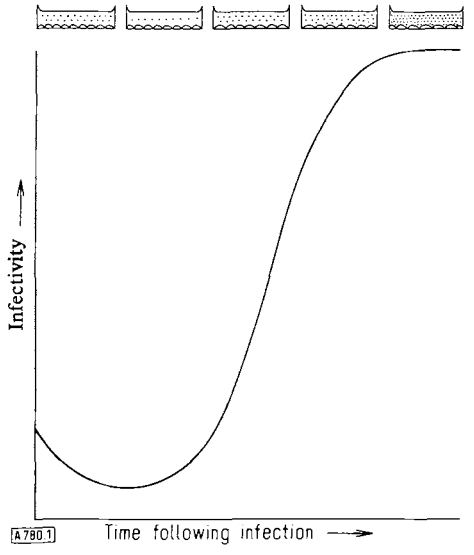

Fig. 1. Virus growth curve. The upper part of the figure shows cross-sections of vessels containing tissue culture cells covered with virus-containing nutrient medium. The amount of infectious virus is indicated by dots. The graph shows the amount of infectious virus during the course of a virus growth cycle.

Shortly after the addition of the virus suspension to the cells, the infectivity of the medium gradually decreases and rises again until finally a plateau is reached, when the synthesizing ability of the cells is exhausted. This is frequently associated with death of the host cells. The initial decrease in the infectivity of the supernatant is caused by adsorption of the viruses onto the cells, whereas the subsequent increase is attributed to the liberation of newly synthesized virus progeny. We shall first consider the initial part of the curve, *i.e.* the phase of adsorption of the virus particles onto the cell and their penetration of the cell interior.

The first cell-virus contact occurs as a result of molecular brownian motion. The number of irreversibly adsorbed virus particles per cell is considerably smaller than that expected from theoretical estimations, since not every collision between a virus and a cell leads to a stable contact. The forces binding the virus particles to the cell membrane are apparently electrostatic in nature. It is natural to ask whether there are any specific receptors on the cell membrane responsible for binding the virus particles, and this conjecture gains some support when it is considered how exacting many kinds of viruses are in their choice of host and even in their choice of the tissue in which they multiply.

One could assume that this selectivity is based on special processes at the site of contact. Here, however, the first complications arise: the members of the large poxvirus group are adsorbed at the same rate by the very many different cells, even by those in which they cannot multiply [1]. In this case the adsorption is obviously not based on any specificity. A very different situation is encountered in the classical example of the myxovirus group, which includes the influenza virus, where specific adsorption processes can be observed. Following its addition to a suspension of erythrocytes, the influenza virus is adsorbed on the erythrocyte surface. Binding of the myxoviruses to the periphery of the erythrocytes gives rise to bridging, as a result of which the erythrocytes form conglomerations, a process that is visible macroscopically and has been termed hemagglutination. By raising the temperature the virus can be displaced from the erythrocytes. An interesting point is that erythrocytes agglutinated once in this way cannot be agglutinated again by the addition of new virus; this obviously means that their surface has been changed by contact with the virus. Fragments possessing hemagglutinating activity – called hemagglutinins – can be isolated from the virus surface [2]. In addition, the myxoviruses contain in their coat an enzyme known as neuraminidase [3,4]. The substrate on which this enzyme acts occurs on the surface of erythrocytes, as well as in many biological fluids and on the surface of the natural host cells of influenza viruses. All these observations indicate that the contact between myxoviruses and host cells is brought about as a result of a special enzyme-substrate relationship. The above remarks show that the processes responsible for the adsorption of viruses onto cells can vary from one virus group to another [4].

The next step in the cell-virus encounter is penetration. Certain bacteriophages (bacterial viruses) infect their hosts by transferring their nucleic acid into the bacterium through an "injection apparatus". The protein coat of the bacteriophage does not in this case penetrate the bacterium but is left behind outside the membrane [5]. Such bacteriophages have been studied very thoroughly and have become a classical example of how a foreign nucleic acid can be transferred into a cell.

Electron microscopy has shown that the viruses of animals behave in quite a different way. They lack such injection apparatus and, in addition, empty virus coats have never been observed on cell surfaces. Everything indicates that animal viruses enter the cells

in a morphologically intact condition. The cell membrane surrounds the adsorbed virus particle, a vacuole is formed which moves to the interior of the cell, and the outer membrane of the cell closes again. In biology this process is termed phagocytosis. Basically, there is nothing specific about it, since cells absorb a wide range of particulate substances, for example metal salts and latex droplets, in the same way. When the walls of the vacuole containing the virus particles break down, these enclosed particles also begin to disintegrate.

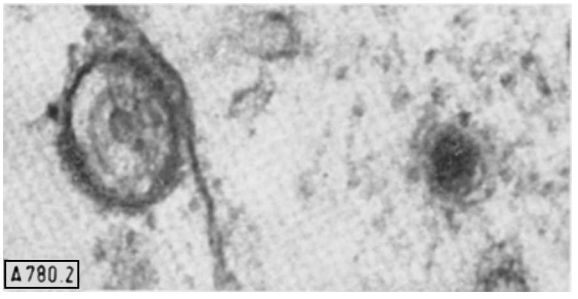

Fig. 2. Penetration of viruses into the cell. This electron micrograph shows the cross-section of a cell infected with herpesviruses. Outside the cell membrane (left) there is an infectious herpes virus particle characterized by an outer membrane, a virus coat, and a core. The identity of the virus particle that has entered the cell (right) is only revealed by the presence of its core. (This photograph was kindly made available by Prof. *K. Munk* and Frau *C. Waldeck*; magnification: 200 000 ×.)

Figure 2 shows the morphological changes a herpesvirus particle undergoes after penetration into a cell. The electron micrograph shows a herpesvirus particle on the outside of the cell and one within the cell. The intact herpesvirus particle adsorbed onto the cell surface consists of an outer membrane-like coat shown in section in the photograph; this coat can be partly of cellular origin. In the interior of the cell is the true virus coat, which surrounds the central structure of the virus particle. The latter consists of a particular protein and the viral nucleic acid closely associated with it; in herpesviruses this is DNA. This inner complex is called the core. Such a core, which has lost its outer membrane and its coat, is found in the interior of a cell. This is the first step in the breakdown of the virus particle leading to liberation of the viral nucleic acid. The virological term for this process is "uncoating". It includes two phases, each of which has been very carefully investigated using DNA-containing poxviruses [6]. The poxviruses consist of a double-stranded DNA, the virus coat protein, and phospholipids. The fate of these three components in uncoating can be traced precisely in radioactively labeled virus preparations. The first part of the uncoating process occurs very rapidly and immediately after adsorption of the virus onto the cell. The phospholipid of the outer virus coat is broken down into acid-soluble degeneration products, which results in particles that are about half the size of the true virus particles and consist only of DNA and protein. These are the cores of the virus particles.

The first stage in the uncoating process is carried out by the cells. As has been shown by the use of inhibitors (substances inhibiting protein or RNA synthesis), this does not require new synthesis of particular proteins or even of RNA. Apparently the cells are equipped with enzymes capable of breaking down the virus particles to reveal the core, *i.e.* of removing the outer virus coat. It is only in the second stage that the viral DNA is liberated from the core and can then be broken down by deoxyribonuclease (DNase) into acid-soluble fragments. This sensitization of the viral DNA to the action of DNase can be used experimentally to determine the degree and the rate of uncoating [6]. The principle of such experiments is relatively simple. Purified virus preparations whose DNA is radioactively labeled for this purpose are used. In order to analyze the rate and extent of the uncoating process the cells are disintegrated by ultrasound treatment at various times after infection and the cell lyzate is treated with DNase. Provided the viral nucleic acid is within the core it cannot be attacked by deoxyribonuclease, as it is still protected by its protein coat. Thus the radioactive components that are degraded by DNase and broken down into acid-soluble fragments must consist of viral DNA released from its inner protein coat (Fig. 3).

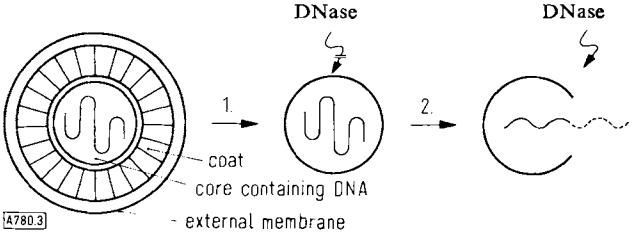

Fig. 3. Intracellular liberation of viral DNA from the enclosing protein coat (uncoating). The figure shows the process in diagrammatic form. The outer membrane, which can be missing in many kinds of viruses, is first removed, followed by the true virus coat. The core is left as a result of this step. The arrangement of viral DNA within the core is here represented very schematically. At this stage the DNA is still protected against DNase. It is only in the second stage, that of the true uncoating, that the DNA is freed from the core and exposed to the action of DNase.

When the process of uncoating is studied with the aid of radioactively labeled simian virus (SV 40) [7], it is found that in the course of a day only about 20 % of the viruses entering the cells liberate their DNA (the virus reproduction cycle does not last longer than two days). This observation shows the inefficiency of virus infection. It is absolutely untrue that every virus particle penetrating a cell can initiate an infectious cycle. Only some of the viruses give rise to infectious progeny.

2. The Phase of Information Transfer

When does the viral genome start to function, and how can this be determined? In discussing this question we have to distinguish between DNA and RNA viruses. In the former the commencement of function

[6] *W. K. Joklik*, J. molecular Biol. *8*, 263 (1964).

[7] *G. Sauer* and *E. C. Hahn*, Z. Krebsforsch. *74*, 40 (1970).

is synonymous with synthesis of messenger RNA on the DNA molecule. The genetic information contained in the DNA is transcribed onto the messenger RNA, and it is only after this that the virus-specific proteins can be synthesized in the cell ribosomes in accordance with the information contained in the messenger RNA. Thus, in DNA viruses the transfer of information initially occurs at the transcription stage (synthesis of messenger RNA on the virus DNA) and then at the translation stage (production of virus-specific proteins in the messenger RNA-ribosome complex). The RNA-containing viruses behave quite differently: there is no need for a transcription stage as their RNA acts directly as messenger RNA. In this case the commencement of function of the virus genome is identical with the production of virus-specific proteins.

The question on the commencement of virus genome function can be answered most easily by experiments using DNA viruses, as in this case one only has to demonstrate the appearance of virus-specific messenger RNA within the cell. With RNA viruses this can only be achieved by demonstrating the appearance of virus-specific protein in the cell, and this presents certain difficulties. Use of the DNA-RNA hybridization technique can demonstrate the presence of even a very small amount of virus-specific messenger RNA in an infected cell. As the sequence of bases in the viral messenger RNA is an exact mirror image of, and complementary to, the viral DNA, under suitable conditions the latter can be bound selectively to the messenger RNA among all the many other kinds of RNA present in a cell.

The synthesis of virus-specific messenger RNA requires the presence of an enzyme, a DNA-dependent RNA-polymerase. This enzyme catalyzes the synthesis of the messenger RNA molecule. It has recently been found that many DNA poxviruses carry this enzyme [8]. They are thus able to actuate their own transcription. It is not yet known, however, whether this enzyme occurs in other DNA viruses.

When does the transcription of the viral DNA begin? For a long time it was believed that this occurred when the viral DNA was completely freed from its protein coat by the uncoating process, but here too some surprising facts emerged from studies of members of the poxvirus group. It was shown that messenger RNA is synthesized if just the outer virus coat is removed, and not the inner protein coat around the virus DNA [9].

Is all the information in the virus DNA transcribed at the same time, or does this happen gradually in a certain order? In the viruses in which this has been investigated, the transcription is gradual. Thus, for example, in simian virus 40, only a quarter of the virus genome is copied as messenger RNA in the early phase of the infectious cycle. This transcription of the "early" messenger RNA is made from the viral DNA after the latter's penetration of the cell, but before replication of the DNA [10]. "Late" messenger RNA is only transcribed after the initiation of viral DNA replication (Fig. 4).

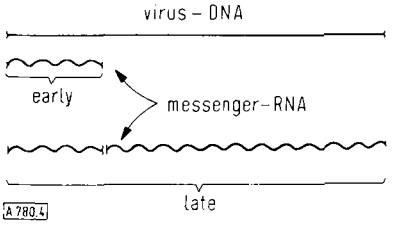

Fig. 4. Synthesis of virus-specific messenger RNA on the viral DNA. The information stored in the virus genome is transcribed in stages. First only one part of the DNA is translated into "early" messenger RNA. The remaining sequences of the DNA can only be transcribed at an advanced stage of the virus infectious cycle when the viral DNA has replicated. Such "late" messenger RNA contains "early" messenger RNA and new base sequences.

Obviously replication of the viral DNA is required before the whole virus genome and not only its early sequences can be transcribed. If one administers inhibitors of DNA replication and thus prevents multiplication of the viral DNA in the infected cell, only early messenger RNA is found and the late virus messenger RNA sequences are missing altogether. In such artificially inhibited cells one can only detect the presence of the "early" gene functions of the virus. For most DNA viruses these early gene functions are expressed by the stimulation of a series of enzymes concerned with DNA metabolism. Thus, in the affected cells the activity of the enzyme thymidine kinase is increased severalfold after infection with most DNA viruses [11]. "Late" virus functions require the presence of "late" virus-specific messenger RNA in the cells, which, as already mentioned, is dependent on replication of the viral DNA. Late viral functions are the synthesis of the virus protein coat and finally, as the last decisive step in the infectious cycle, assembly of the virus particle from its components present in the cell, *i.e.* virus maturation.

It follows from these remarks that the genetic information stored in the viral genome is transcribed sequentially and that this transcription is subordinate to a special control mechanism. It has not yet been explained what factors control the progressive promulgation of the genetic information, and why the viral DNA must undergo replication before being fully transcribed by late virus-specific messenger RNA.

What happens in the promulgation of the genetic information of RNA viruses? The question is somewhat more difficult to answer experimentally than in the case of DNA viruses. As regards the enteroviruses, in which this has been investigated, another set of rules seems to apply. In this case the viral RNA which also serves here as messenger RNA is translated not gradually but all at once, in its entirety, into a single very large protein. This protein is subsequently

[11] *S. Kit* and *D. R. Dubbs*: Monographs in Virology. Vol. 2. S. Karger, Basel and New York 1969.

broken down into several small proteins with different functions [12, 13]. Whether this principle is valid for all RNA viruses requires further demonstration.

Accumulation of the viral gene products in the infected cell is a function of the virus genome and is not dependent on whether it is a DNA or an RNA molecule. The amount of these products only increases strikingly after the initiation of the virus DNA or RNA replication, as shown by Figure 5. As already mentioned, it is not only the quantity but also the quality of the virus-specific proteins present in the cell that changes.

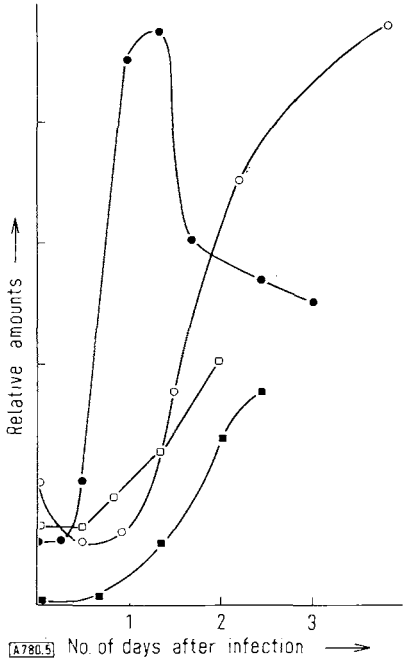

Fig. 5. Synthesis of specific virus products during a virus growth cycle, taking simian virus 40 as an example. In monkey kidney cell culture the replication cycle takes a little less than two days. The initiation of the replication of the viral DNA can be divided into two phases. In the early phase of the infection, even before the start of DNA replication (□), there is an increase in the activity of the enzyme thymidine kinase (●)[*]. The activity of this enzyme is subject to regulation, as may be seen from the fall in the curve toward the end of the infectious cycle. In the late phase of infection at the start of viral DNA synthesis (□), the amount of the virus-specific messenger RNA (■) in the cell increases strikingly. Mature virus particles are formed a few hours later (○).

Large numbers of copies of the virus nucleic acid are produced in the infected cells, and a great quantity of structural protein for the virus coat is synthesized. These are the precursors, the components of the newly maturing generation of virus particles, and their assembly to form infectious virus particles constitutes the end of the virus replication cycle.

3. The Architecture of Viruses

Are there any general principles underlying the structure of virus particles? The possible shape that most virus particles can assume is limited by the fact that only a limited space is available to contain the requisite genetic information. Thus, viruses must be satisfied with a fairly simple structure, since if this were complicated it would require many different kinds of structural proteins; the small amount of genetic information carried by viruses would certainly not be sufficient for this purpose.

Just how few opportunities there are for variation in the shape of virus particles was made clear more than 10 years ago in a review by *Crick* and *Watson* at the symposium on the nature of viruses [14]. *Crick* and *Watson* assumed that the nucleic acid of a small virus particle has a molecular weight of about two million, which corresponds closely with reality. Such a nucleic acid is composed of about 6000 nucleotides. As every three nucleotides determine one amino acid, not more than 2000 amino acids can be formed altogether and be united in one protein. Such a protein, however, is much too small to form a coat around the nucleic acid of the virus particle. To fulfill this purpose, it can be calculated that a protein must be at least 15 times as large. All the genetic information of the virus particle would then have to be used just for the formation of the protein coat. We know, however, that the virus nucleic acid has other functions to fulfil as well.

For this reason *Crick* and *Watson* concluded that the coat of a virus particle cannot consist of a single large protein molecule, but must be formed from many identical but small protein molecules, as only a minor section of the nucleic acid is required for the encoding of small protein molecules. In this way the limited genetic information is used economically. For the same reasons *Crick* and *Watson* concluded even at that time that it seemed unlikely that many small protein molecules of different kinds could participate in the construction of the virus coat: each different protein would require a section of the nucleic acid for its specification, and we would end up with the same difficulty. These possibilities are shown schematically in Figure 6.

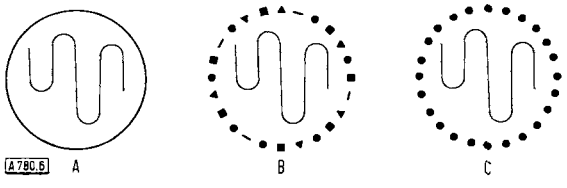

Fig. 6. Possible ways of assembling a virus coat. The diagram shows possible ways in which protein molecules can coat the viral nucleic acid, shown here by wavy lines. Case A, in which a single large protein molecule surrounds the nucleic acid, is not found. Case C is frequently found to occur in small viruses. Here many small, identical, protein molecules form a coat around the nucleic acid. The coat is only constructed of several different proteins in the larger viruses whose nucleic acid has a higher information content (case B).

According to our present knowledge the above views of *Crick* and *Watson* have proved to be thoroughly sound. They do, however, need some modification. It is clear that the structural complexity of the virus coat

is directly related to the information present in the nucleic acid. There are, for example, small viruses, such as the F2 phages, whose RNA has a molecular weight of only 1×10^6. This phage cannot encode more than three proteins, one of which is that of the protein coat of the virus particle [15]. In contrast, poxvirus, for example, has a more complicated structure. Its DNA has a molecular weight of 1.5×10^7, and so it is not surprising that the poxviruses have a very complex architecture, whose subunits are composed not of one but of several different proteins [16].

These proteins encoded by the virus genome are not joined in simple fashion to give a membrane-like envelope, but form small aggregates, as it were the bricks of the virus coat. After appropriate staining these bricks or subunits of the coat appear in the electron microscope as small cylinders or tubes, pentagonal or hexagonal in cross-section. These are termed capsomeres [17]. The structure formed by all the capsomeres is called the capsid, which surrounds the nucleic acid in the form of a protective coat. Thus, the virus coat consists of large numbers of radially arranged capsomeres or tube-like structures. Some viruses are in addition surrounded by a membrane-like structure, as already described in the previous section. The mature infectious virus particle is formed when all these different morphological structures are assembled together.

The question now arises as to the configuration in which the morphological subunits and thus the capsomeres are arranged, and we can further inquire as to whether there are certain basic forms of particle symmetry that are followed by the most dissimilar viruses. X-ray crystallography and electron microscopy have shown that most viruses are in fact constructed in one of two ways. They either form helical tubes or rods or are spherical capsules with cubic symmetry (Fig. 7).

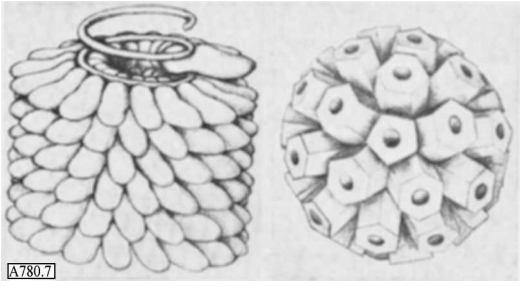

Fig. 7. Models of viruses possessing helical and cubic symmetry. The figure on the left shows a tobacco mosaic virus with a helical arrangement of its monomer proteins; the latter are also the morphological subunits of its coat. These proteins have been removed from the upper part to show the spiral configuration of the RNA. The internal axis of the rod-like particle is hollow [*]. The figure on the right is a model of a cubic (icosahedral) virus particle. The coat is formed of radially arranged morphological subunits, the capsomeres. The viral nucleic acid is in the center of the particle [**].

We shall first consider the group containing the smaller number of viruses, *i.e.* the rod-shaped or helical viruses. The most studied and most prominent member of this group is the tobacco mosaic virus (TMV). This is an elongated rod whose distinctly demarcated subunits have a coil-like configuration. The structure of this virus has been extensively analyzed in work extending over many years [18]. TMV is composed of 2650 chemically identical morphological subunits. Not only is the total number of these subunits known, but also their molecular weight – about 17500. The amino acid sequence of the monomer proteins and thus of these subunits has been analyzed exactly: they are composed of 158 amino acid residues. The ribonucleic acid, with a molecular weight of 2×10^6, has a coil-like configuration and lies between coils formed by the subunits. This arrangement implies that the inner axis of the particle is hollow. Such a virus rod is remarkably stable, and its RNA is very well protected against the action of destructive enzymes such as RNase. The stability of the virus particle is based primarily on the specific binding forces between the protein molecules. Although the nature of these binding forces is still not precisely known, it is suspected that they are essentially hydrogen bonds. In addition to the tobacco mosaic virus there are other plant viruses characterized by helical symmetry. Among the animal viruses a helical structure is shown in particular by the myxoviruses; as already mentioned, this group includes the influenza viruses.

Most kinds of viruses have coats with cubic symmetry. Several regularly constructed bodies with cubic symmetry are distinguished; incidentally, these regular solids were already described by *Pythagoras*. The simplest body is the tetrahedron with four sides, and the next more complicated body is the hexahedron or cube. In order of increasing complexity, then come the octahedron, the dodecahedron, and finally the complicated icosahedron. Of all these bodies the icosahedron is favored by most viruses as the basis of their construction [19]. It is natural to ask why the virus particles are not constructed according to a more simple pattern. In the evolution of organisms it is generally the most economical principle that is preferred, and this in fact is true for the complicated icosahedron, a regular polyhedron with 20 surfaces and 12 vertices. With its many sides the icosahedron approaches the shape of a sphere, and it is precisely because of its many sides that it can be composed of many bricks or subunits. Consequently, these subunits and thus the proteins of the virus coat are also very small. This is a very economical principle, which brings us back to the idea put forward at the beginning, for such protein molecules also only require a small part of the genetic information of the virus particle for

their encoding. As we have already seen, the genetic information in viruses is generally strictly limited.

It is not altogether easy to furnish proof that a virus particle is constructed according to the rules of icosahedral symmetry. An icosahedron is composed of a definite number of structural elements. Thus, in the analysis of viruses by electron microscopy one attempts to determine whether the total number of capsomeres corresponds to this rule [20]. It is not only the total number of capsomeres that must conform to certain crystallographic rules, but the arrangement of the capsomeres must also be in agreement with such principles. An icosahedron has several axes of symmetry. Figure 8 shows schematically an icosahedron from the aspect of a twofold, a threefold, and finally a fivefold symmetry axis. If one rotates the icosahedron body around these axes through 180, 120, or 72° it will assume the same orientation as at the beginning. The same must apply to the configuration of the capsomeres in the virus coat for icosahedral symmetry to be allotted to a virus. As an example of an icosahedron Figure 8 gives in diagrammatic form the capsomere arrangement of bacteriophage φX174. This phage is a very small virus particle; it consists of a total of 12 capsomeres [21].

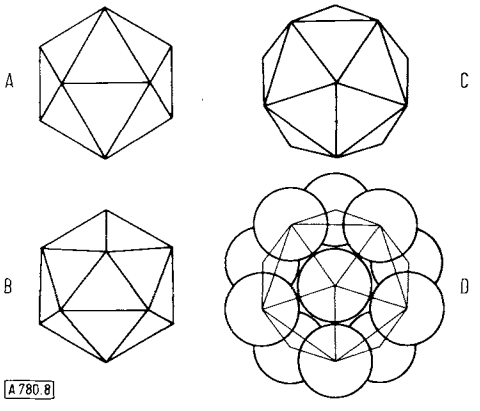

Fig. 8. Symmetry properties of an icosahedron. Most cubic viruses are constructed on the principle of an icosahedron, a polyhedron with 12 vertices and 20 surfaces, *i.e.* the arrangement and the number of its capsomeres (cf. Fig. 7) follow the rules of icosahedral symmetry. A, B, and C show two-, three-, and fivefold symmetry axes, respectively. D shows the capsomere arrangement of a small virus with 12 capsomeres, indicated simply by circles, and superimposed on this is the fivefold symmetry axis of the icosahedron.

Not all kinds of viruses have a helical or icosahedral shape. There are also viruses which cannot be allotted to any definite symmetry class. Thus, there is the complicated T4 phage with its hexagonal head containing the nucleic acid. Attached to this head is an elaborate apparatus whose purpose is to inject the nucleic acid into the host cell. Here we have a highly differentiated morphological structure.

Finally, mention should be made of a problem which has special relevance to general biology. This is the question whether the assembly of a virus particle from its constituent subunits is a self-organizing process, which occurs automatically and does not depend on anything other than the binding forces between the protein subunits. Or does it require a special protein, which controls the temporal and spatial pattern of the formative processes – in somewhat the same way as the organizer protein, which is known from the differentiation processes of higher organisms?

For some years now it has been possible to break down the tobacco mosaic virus into its monomer protein subunits and ribonucleic acid, and then to reassemble these components purely by mixing them in a test-tube, *i.e. in vitro* [22, 23]. The virus particles produced in this way do not differ in any way from those developed normally in a cell, and they prove to be fully infectious. Even in the absence of the ribonucleic acid the monomer protein subunits are united by their binding forces to produce a helical structure, which is very similar to the mature virus particle. No external influence is necessary for the assembly of a tobacco mosaic virus particle, and for this reason the process is said to be one of "self-assembly".

Recently, however, papers have been published which indicate that certain RNA phages require another kind of protein, in addition to their coating protein and their RNA, in order to be able to assemble an infectious particle. This protein has been called maturation protein, as it seems to exert a regulating function on the assembly of the virus coat. During the *in vitro* reconstruction of such phages from their components the presence of this protein seems to be necessary to ensure combination of the RNA and the coat protein to form infectious phages. It has been shown that only a few molecules of this maturation protein are necessary for one phage particle [24]. This observation throws an interesting light on the morphogenesis of such simply formed structures as viruses.

It is just because of the narrow limitations of their genetic information that viruses offer such excellent models for the analysis of many processes which are very difficult to study in higher organisms.

Regulation of Glutamine Synthetase by Enzyme Catalyzed Structural Modification[**]

By Bennett M. Shapiro[*]

A highly sophisticated mechanism for the regulation of glutamine metabolism in Escherichia coli involves the modification of the enzyme glutamine synthetase by the covalent attachment and release of adenylyl residues. Separate enzymes catalyze the adenylylation and deadenylylation reactions, and these enzymes are reciprocally controlled by the state of nitrogen nutrition of the cell. The resultant structural alterations in glutamine synthetase enable it to change its catalytic potential greatly in response to varying cellular demands, in order to maintain nitrogen homeostasis.

1. Introduction

Glutamine serves as the nitrogen donor for a great many metabolites in microorganisms, and thus occupies a central role in cellular physiology. The amide group of glutamine is the preferred source of nitrogen in the biosynthesis of tryptophan (Trp), histidine (His), cytidine 5'-triphosphate (CTP), adenosine 5'-monophosphate (AMP), glucosamine 6-phosphate (GA-6-P), and carbamyl phosphate (CP) (Figure 1). The α-amino group of glutamine may be used in the syntheses of other amino acids by glutamine-specific transaminative reactions (for review see [1]).

[1] *E. R. Stadtman, B. M. Shapiro, H. S. Kingdon, C. A. Woolfolk,* and *J. S. Hubbard,* Advan. Enzyme Regulation *6*, 257 (1968).

Glutamine synthetase, the enzyme which catalyzes the synthesis of glutamine (Gln) from glutamate (Glu), ammonia, and ATP (Fig. 1) is at the head of a highly branched metabolic pathway, and as such should be a strategic center of cellular regulation. A study of the regulation of the glutamine synthetase from *Escherichia coli* has led to the discovery that the bacterial enzyme is subject to control by at least four different mechanisms. Firstly, there is repression and derepression of enzyme biosynthesis in response to the nature and quantity of the nitrogen source given to *E. coli* for its growth. Secondly, glutamine synthetase is subject to cumulative feedback inhibition by the multiple end products of glutamine metabolism shown in Fig. 1.

Thirdly, the activity of glutamine synthetase is modulated by the relative concentrations of ATP, divalent cation, and other nucleotide tri- and diphosphates. These three mechanisms of regulation have been discussed in an earlier review [1] and will not be dealt with here.

The present article concerns a novel control mechanism effective on glutamine biosynthesis: regulation of the catalytic potential of glutamine synthetase by the covalent attachment and release of adenylyl residues.

2. Multiple Forms of Glutamine Synthetase

A comparison of the properties of glutamine synthetase preparations which had been highly purified from different batches of cells showed that the apparently homogeneous preparations differed markedly in their susceptibility to feedback inhibition by the compounds shown in Fig. 1, as shown in Fig. 2. The

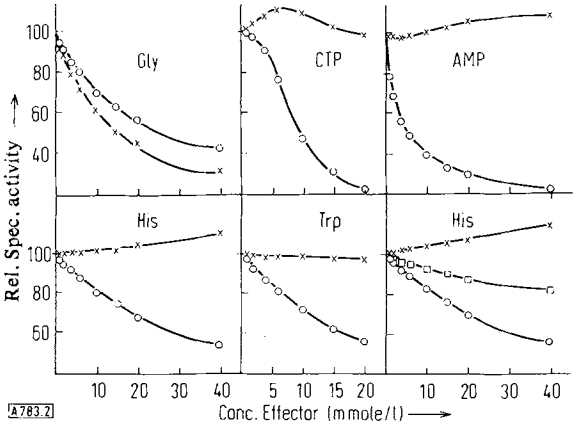

Fig. 2. Effect of products of glutamine metabolism on the activity of two purified preparations of glutamine synthetase. Preparation I (×—×) was purified from cells grown on limiting quantities of NH_4^+; Preparation II (o—o) was purified from cells grown on relatively high amounts of glutamate. Enzyme activity was measured by the γ-glutamyl transfer reaction catalyzed by glutamine synthetase (for details, see [3]).

different behavior of the preparations could not be attributed to structural modifications during the purification procedure, nor to differences in storage or handling of the enzyme preparations. In addition, all attempts to convert one form of the enzyme into another by treatments known to modify the tertiary and quaternary structure were unsuccessful.

The two preparations were made from cells grown under different conditions, and a detailed examination of the relationship between the conditions of growth of *E. coli* and the properties of the glutamine synthetase purified from it led to the discovery that different molecular forms of glutamine synthetase are produced depending upon the state of nitrogen nutrition of *E. coli* during growth [2, 3]. As shown in Table 1,

Table 1. Effect of nitrogen source (limiting NH_4^+ or glutamate) and age of culture on the response of γ-glutamyl transferase activity to various effectors (from [3]).

Effector (mmole/l)	Relative activity [a]			
	Log phase cells		Stationary phase cells	
	Limiting NH_4^+	Glutamate	Limiting NH_4^+	Glutamate
None	100	100	100	100
AMP, 40	131	131	115	20
L-tryptophan, 20	101	102	92	50
L-histidine, 40	115	113	107	53
CTP, 8	83	105	97	51
Glycine, 40	36	32	34	47

[a] Relative specific activities in the transferase reaction, catalyzed by glutamine synthetase, compared to activity without effector = 100. *E. coli* W was grown in medium containing 11 mmole/l glucose and either 6 mmole/l NH_4Cl or 19 mmole/l glutamate, as indicated. Cells were harvested 24 h after inoculating (stationary phase cells) or in late log phase (with NH_4^+, 5.5 h after inoculation; with glutamate 11 h after inoculation).

when *E. coli* was in the logarithmic growth phase, the quantity or nature of the nitrogen source for growth made little difference in the nature of the glutamine synthetase obtained. However, when the organism reached the stationary phase there was a significant difference in the enzyme activity of cell extracts, depending upon whether the nitrogen source was NH_4Cl in growth-limiting quantities or glutamate [3].

The enzyme from glutamate-grown, cells was very sensitive to inhibition by AMP, CTP, L-tryptophan and L-histidine, whereas the enzyme from NH_4-grown cells was insensitive to inhibition by these compounds, but was more susceptible to inhibition by glycine and alanine. Neither the carbon source used (glycerol or glucose) nor the extent of aeration of the culture made any difference in the type of glutamine synthetase obtained.

The results showed that the growth conditions were important in determining the character of the glutamine synthetase found in the cells, but a precise nutritional basis for the observed effects is still not apparent since the onset of the stationary phase in the two types of growth media might be due to different metabolic events. In the NH_4^+ medium the cessation of growth is clearly due to depletion of the available nitrogen source; in the glutamate medium, however, the stationary phase might be initiated by

[2] *B. M. Shapiro, H. S. Kingdon,* and *E. R. Stadtman,* Proc. Natl. Acad. Sci. U.S. *58,* 642 (1967).

[3] *H. S. Kingdon* and *E. R. Stadtman,* Biochem. Biophys. Res. Commun. *27,* 470 (1967); *H. S. Kingdon* and *E. R. Stadtman,* J. Bacteriol. *94,* 949 (1967).

either depletion of the energy supply or other unknown factors. It has been recently shown [5] that in the stationary phase attained after growth on NH_4^+ there is no free ammonia in the medium, but after growth on glutamate there is a fairly high ammonia concentration during the stationary growth phase. Thus, the availability of nitrogen for growth appears to be the decisive factor in determining the nature of the glutamine synthetase produced by *E. coli*.

To determine the structural basis for the different catalytic properties seen in enzyme preparations elaborated by cells grown under different conditions, a comparison was made between glutamine synthetase from cells grown on limiting quantities of NH_4^+ (Preparation I) and from those grown on glutamate (Preparation II).

The differences between the enzyme forms are preserved upon purification. Thus preparation I is more active in glutamine biosynthesis when Mg^{2+} is the activator used (Table 2) whereas Preparation II is

Table 2. Some properties of preparations I and II (from [7]).

Enzyme preparation	Specific activity		Effect of AMP on transferase activity [b]
	Mg^{++}	Mn^{++}	
I	60.1	2.0	10 % activation
II	12.8	8.1	74 % inhibition

[a] Specific activity in biosynthetic assay = μmoles P_i min^{-1} mg^{-1}, which is equivalent to the number of μmoles of glutamine synthesized (Fig. 1).

[b] AMP = 40 mmoles/l.

more active with Mn^{2+}. Moreover, the total biosynthetic activity seen with Preparation I (+ Mg^{2+}) is greater than that seen with Preparation II (+ Mn^{2+}). Thirdly, as shown in Table 2 and Fig. 2, Preparation II is more sensitive to feedback inhibition by the products of glutamine metabolism than is Preparation I.

3. Structural Basis for the Enzyme Multiplicity

Preparations I and II were purified by the same method [2], had the same molecular weight [4], and each migrated as a single molecular species when examined either in the ultracentrifuge or by disk gel electrophoresis [2,4,5]. Additionally, there were no remarkable differences in the amino acid compositions of the two enzyme preparations [2] and each was found to have the same characteristic double hexagon structure when examined by electron microscopy [6] (Fig. 3). However, a distinct difference between the two forms was seen when the ultraviolet spectra of the enzymes were compared (Fig. 4). Preparation II absorbs more ultraviolet light in the region below 280 nm than does Preparation I, and the difference

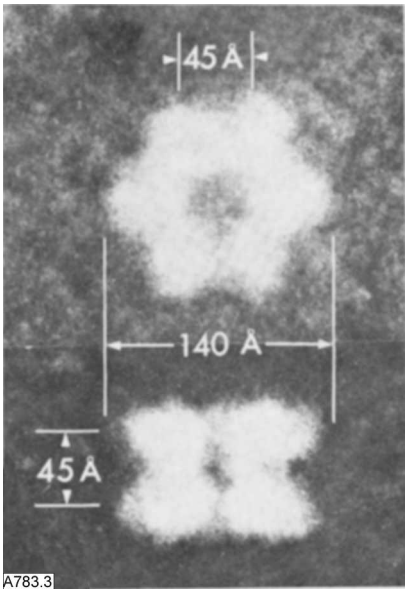

Fig. 3. Electron micrograph of the *E. coli* glutamine synthetase (by *R. Valentine*) showing full (above) and side views (below) of the enzyme molecule. The 12 subunits of the enzyme are arranged in two superimposed hexagons; from this micrograph we were able to calculate the molecular weight of the subunit (48 500) which was found to be in good agreement with that from hydrodynamic measurements. (Data of *Valentine et al.* [6]).

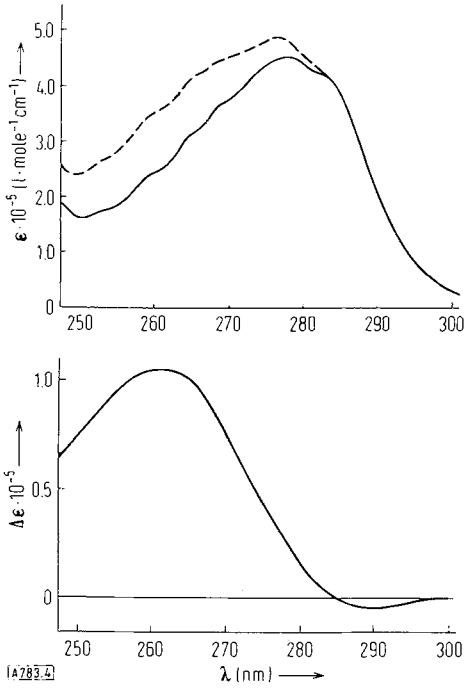

Fig. 4. Above: Ultraviolet spectra of Preparations I (—) and II (— — —). Below: Difference spectrum between the two forms (from [2]).

spectrum is characteristic of nucleotide derivatives. By isolation and chemical analysis of the nucleotide bound to preparation II, it was established that the two preparations differed in their content of AMP.

As is shown in Table 3, Preparation I contained about 1.2 equivalents of bound AMP, whereas Preparation II contained about 9.0 equivalents [2]. The covalent nature of the binding was indicated by the fact that the AMP could not be removed by treatment with charcoal, with acid ammonium sulfate, or by digestion with dilute acid or alkali [2]. On the other hand,

[b] Calculated from absorbancy at 260 nm for the solution after precipitation of protein with perchloric acid [2]. The product was also characterized by reaction with the specific enzymes, 5'-adenylic acid deaminase and adenosine deaminase.

the nucleotide is readily removed by digestion with snake venom phosphodiesterase, indicating that the linkage is a phosphodiester bond, and the product of this digestion is AMP, as determined by enzymic analysis [2].

4. Adenylylation of Glutamine Synthetase *in vitro*

The existence of preparations of glutamine synthetase which differ in their catalytic properties according to the number of adenylyl groups bound to them could constitute a powerful mechanism for regulating glutamine metabolism *in vivo*. That this type of regulation exists is indicated by the fact that during exponential growth on glutamine as a nitrogen source a relatively unadenylylated enzyme preparation is formed (Preparation I), whereas during the stationary phase the enzyme becomes adenylylated (Preparation II). This observation suggests that *E. coli* can elaborate an enzyme which will catalyze the adenylylation of glutamine synthetase. Such an enzyme has been found in extracts of *E. coli*; it catalyzes the transfer of the adenylyl moiety of ATP to glutamine synthetase [eq. (1)]:

$$\text{glutamine synthetase} + \text{ATP} \xrightarrow[\text{adenylyltransferase}]{M^{2+}} \text{adenylyl glutamine synthetase} + PP_i \quad (1)$$

The reaction is stimulated by glutamine and inhibited by glutamate and α-ketoglutarate [7]. The enzyme activity can be detected either by measuring the incorporation of radioactivity from ^{14}C-labeled ATP into glutamine synthetase, or by re-isolating the glutamine synthetase after adenylylation and determining the number of equivalents of AMP bound by measuring the absorbancy of the enzyme at 260 nm compared to that at 290 nm [7,8]. Both methods yield the same result: glutamine synthetase may be adenylylated to the extent of twelve equivalents of AMP per mole of enzyme (MW = 600000), or one equivalent of AMP per subunit (MW = 50000) [9]. The enzyme that catalyzes this covalent attachment of adenylate to glutamine synthetase has been named ATP: glutamine synthetase adenylyltransferase [7].

If the number of adenylyl groups present on glutamine synthetase were the only structural alteration responsible for the catalytic differences between Preparations I and II, then adenylylation of Preparation I should be accompanied by the following changes in its catalytic properties:

1) a decrease in biosynthetic activity when Mg^{2+} is the activating cation;

2) an increase in the biosynthetic activity with Mn^{2+} as the activating cation;

3) an increase in the sensitivity to feedback inhibition by any one of several products of glutamine metabolism.

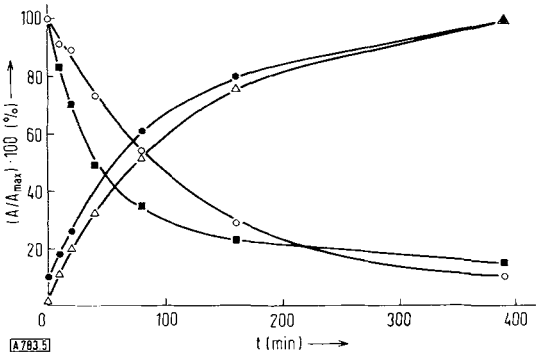

Fig. 5. Changes in several catalytic parameters of glutamine synthetase during adenylylation. Values are expressed as percentages of the maximal change seen as a function of the duration of the adenylylation reaction. △—△ covalent linkage of adenylyl residues; ○—○ Mg^{2+}-specific biosynthetic activity; ●—● Mn^{2+}-specific biosynthetic activity; ■—■ specific activity in the presence of 40 mmoles/l AMP (indicating change in the ability of the enzyme to be inhibited by AMP) (from [7]).

Figure 5 shows the changes seen in these parameters as a result of increasing numbers of adenylyl residues being attached to glutamine synthetase during the adenylylation reaction. The expected changes in the divalent cation specificity are seen to occur, as is the increased sensitivity to inhibition by AMP, as reflected by a decrease in enzyme activity in the presence of high concentrations of AMP. It has similarly been shown [7] that removal of the adenylyl residues, catalyzed by snake venom phosphodiesterase, leads to a conversion of glutamine synthetase from an enzyme with the properties of Preparation II into one with the properties of Preparation I. Thus, it seems that the different amounts of covalently bound AMP present on Preparations I and II of glutamine synthetase is the factor responsible for their different catalytic properties.

Holzer, Mecke, and their co-workers had previously described the presence of an enzyme in cell extracts of *E. coli* which catalyzed the ATP-dependent, glutamine-stimulated inactivation of glutamine synthetase [10]. They had studied the inactivation of glutamine synthetase by observing that the biosynthetic activity of the enzyme decreased when activity was measured in the presence of Mg^{2+} as divalent cation. Since this change in activity is one of several

associated with the adenylylation of glutamine synthetase, it occurred to us that this inactivation phenomenon might be the same as the adenylylation reaction [7]; the identity of the two phenomena was almost simultaneously demonstrated by *Wulff et al.* [11] when they showed that their "inactivating enzyme" catalyzed a concurrent attachment of the adenylyl moiety of ATP to glutamine synthetase. We prefer the name "ATP:glutamine synthetase adenylyltransferase" to "glutamine synthetase inactivating enzyme", because the loss of Mg^{2+}-dependent catalytic activity is only one of several changes affected by the covalent attachment of adenylyl residues.

5. Properties of the ATP:Glutamine Synthetase Adenylyltransferase

The adenylyltransferase has been purified some 200-fold by a combination of ammonium sulfate precipitation and chromatography on DEAE cellulose and on hydroxylapatite [12]. The enzyme as purified in this fashion is only partly pure, as shown by agar gel electrophoresis [12]. The adenylylating enzyme is stabilized by thiols, glutamate, glutamine, and phosphate [13]. Sucrose density gradient centrifugation showed it to have a molecular weight of 120000 [12].

ATP is the only nucleotide which can serve as a nucleotidyl donor in the modification reaction [eq. (1)] [7,14]. Other nucleoside triphosphates are inhibitory: CTP is a competitive inhibitor [14] and UTP is noncompetitive with ATP [13]. The adenylylation reaction requires divalent cation, Mg^{2+} being most effective; Mn^{2+} has only 30% of the activity of Mg^{2+} [14].

The adenylyltransferase catalyzes an exchange reaction as shown in eq. (2); that is, in the presence of glutamate and Mg^{2+}, the enzyme catalyzes the exchange of ^{32}P between pyrophosphate and ATP [15].

$$ATP^* + \text{enzyme} \xrightarrow{\text{glutamate, } Mg^{2+}} \text{enzyme (AMP)} + {}^*PP_i \quad (2)$$

In fact, the adenylyltransferase is able to complex with ATP (at 25 °C in the presence of Mg^{2+}) and this complex may be isolated from free ATP by rapid gel filtration at 4 °C [13]. By comparing the nature of the complex formed with either ^{14}C-ATP or with γ-^{32}P-ATP, it was found that 50–70% of the nucleotide in the complex exists as intact ATP [13]. The pyrophosphoryl moiety of ATP is then discharged from the complex by subsequent incubation with either unadenylylated glutamine synthetase or with L-glutamate; when glutamine synthetase is used to discharge the pyrophosphate, a concomitant adenylylation of the glutamine synthetase occurs [13]. The nature of the adenylyltransferase-nucleotide bond is still unknown.

The adenylyltransferase exhibits specificity with regard to its enzymic substrate, glutamine synthetase, as well as to its nucleotide substrate, ATP. Thus, although the glutamine synthetase from *Bacillus subtilis* is structurally very similar to that from *E. coli* it cannot act as substrate for the *E. coli* adenylyltransferase, nor does it inhibit the adenylylation of *E. Coli* glutamine synthetase [16].

6. The Nature of the Adenylyl-Glutamine Synthetase Bond

The adenylyl-glutamine synthetase linkage is very stable, resisting cleavage by either 0.3 M HCl or 0.3 M NaOH at 37 °C for several hours [2]. This stability to both acidic and basic cleavage is unusual for the well known serine or threonine linkages which occur in glycoproteins or phosphoproteins. To determine which amino acid residue is responsible for the stable bond, we subjected ^{14}C-adenylyl-labeled glutamine synthetase to proteolytic digestion and isolated the peptide derivative which contained the adenylyl group. A decapeptide was isolated in high yield after exhaustive digestion with pepsin and pronase [17]. Of particular interest in the composition of this peptide is the absence of serine, threonine, or basic amino acids. In fact, tyrosine is the only amino acid present in the peptide that would be expected to form a phosphodiester bond of the required stability. The peptide-adenylyl bond resisted cleavage in 1 N NH_4OH for 5 hours at 105 °C; 50% of the peptide was recovered intact after this treatment [17]. Acid hydrolysis was complicated by the fact that the adenine-ribose linkage was cleaved before the peptide-phosphoribose bond. Tyrosine phosphate esters have been shown to have the required stability to acid and base [18]; *O*-phosphotyrosine releases negligible amounts of inorganic phosphate when heated at 37 °C for 48 hours in either 1 N HCl or 1 N NaOH.

Tyrosine, when present free or in peptide linkage, exhibits a characteristic ultraviolet absorption spectrum at alkaline pH that is due to ionization of the phenolic group; this is absent when the phenolic group is blocked and unable to ionize. To examine whether the adenylyl moiety is indeed linked to the peptide by a phosphodiester bond with tyrosine, we compared the absorption spectra of the peptide in alkaline solution before and after removal of AMP with snake venom phosphodiesterase. Fig. 6 shows the difference spectrum obtained when the deadenylylated peptide

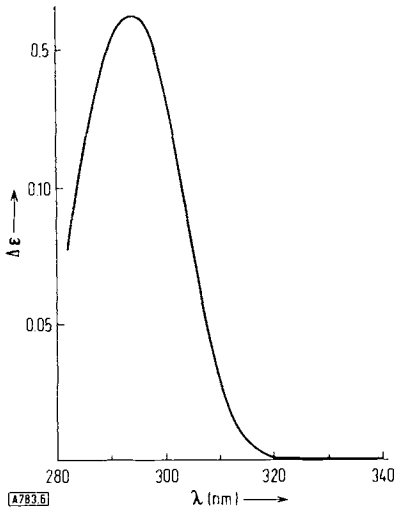

Fig. 6. Difference spectrum between adenylylated and unadenylylated peptide preparations. An adenylylpeptide was isolated after pepsin and pronase digestion of glutamine synthetase [17]. One portion of the peptide was treated with snake venom phosphodiesterase to release the adenylyl residue from covalent linkage; the other portion of peptide served as a spectral control. Both samples were adjusted to pH 13 and their spectra were compared. The phosphodiesterase cleavage resulted in the freeing of a tyrosyl hydroxyl group, which ionized in alkaline solution and gave the spectrum shown above (from [17]).

absorbancy is compared with that of the adenylylated peptide at pH 13. The peak at 292 nm is characteristic of an ionized phenolic hydroxyl group. One can calculate that it is present in equivalent amounts to that of the adenylyl moiety removed by the phosphodiesterase [17]. Thus, from the stability and spectral characteristics of the AMP binding peptide, it appears that the tyrosine residue present is responsible for this novel type of protein-effector covalent bond.

The decapeptide has a rather high proline content (2–3 residues per decapeptide). This may account for the difficulties encountered when we tried to digest the peptide to a smaller unit with other proteolytic enzymes [17]. One might additionally surmise that the high proline content provides a region of the glutamine synthetase molecule of minimal secondary structure. Such a region would be suitable for positioning the reactive tyrosyl residue such that the adenylyl group could be readily bound or removed.

7. Effect of Adenylylation on Subunit Interactions

As mentioned above, completely adenylylated glutamine synthetase contains twelve equivalents of AMP bound per mole of enzyme, or one equivalent per subunit. Therefore, species containing zero to twelve adenylyl residues per mole of enzyme are possible; with two or more adenylyl groups present per mole there exists the possibility of having multiple forms, each being unique with respect to the mutual arrangement of adenylyl residues. In fact, one can calculate [19] that 384 unique forms of glutamine synthetase are possible.

[19] *M. S. Raff*, personal communication.

Do hybrid forms containing a mixture of adenylylated and unadenylylated subunits in any one molecule of enzyme really exist? If they do, the question also arises whether subunit interactions in the hybrid molecules influence the stability and catalytic behavior of the enzyme. Toward this end, enzymes of different states of adenylylation (from 0–12 adenylyl residues per mole) were prepared and studied.

Enzymes exhibiting different states of adenylylation were prepared in one of the following three fashions:

1) Isolation from cells grown under different conditions of nitrogen nutrition;

2) incubation of unadenylylated enzyme preparations with the ATP:glutamine synthetase adenylyltransferase and ATP, to achieve progressive adenylylation of glutamine synthetase;

3) incubation of adenylylated glutamine synthetase with snake venom phosphodiesterase, to achieve progressive deadenylylation.

The partially adenylylated enzyme forms thus prepared were compared with mixtures of fully adenylylated and fully deadenylylated glutamine synthetase preparations which were mixed to have the same average content of adenylyl residues per mole of enzyme.

Two independent pieces of evidence have led to the conclusion that subunit interactions do indeed exist and that they may be of significance in the regulation of glutamine synthetase. The first of these [20] was a careful analysis of the Mg^{2+} and Mn^{2+} biosynthetic activities of hybrid glutamine synthetase forms under saturating substrate conditions. With optimal assay conditions, unadenylylated subunits were specifically activated by Mg^{2+} (pH optimum = 7.5–7.6) while the adenylylated subunits had an absolute requirement for Mn^{2+} (pH optimum = 6.5–6.6). This divalent ion specificity is that found by *Kingdon et al.* [7]. However, under optimal assay conditions, the relationship of divalent ion specificity to state of adenylylation is not a linear one but follows a sigmoidal distribution. Thus, the addition or removal of adenylyl residues at either extreme of adenylylation produces a relatively profound change in the Mg^{2+} or Mn^{2+} dependent catalytic activities, but at intermediate states of adenylylation (between three and eight moles AMP per mole glutamine synthetase) a change in the number of AMP residues covalently bound leads to a less marked alteration of catalytic properties. This non-linear behavior of the enzyme leads to the conclusion [20] that heterologous subunit interactions (between adenylylated and unadenylylated units) must have an effect on the catalytic activity of the enzyme.

The second set of experimental data leading to the conclusion that hybrid forms do exist concerns differential inactivation of adenylylated and unadenylylated enzyme forms in the presence of urea, under carefully defined conditions of temperature and pH [21]. *Ciardi* and *Stadtman* [21] found conditions in which only the adenylylated enzyme preparation was

[20] *A. Ginsburg, J. Yeh, S. B. Hennig*, and *M. D. Denton*, Biochemistry *9*, 633 (1970).

[21] *J. Ciardi* and *E. R. Stadtman*, personal communication.

inactivated, while the unadenylylated preparation was stable. Mixtures of adenylylated and unadenylylated enzyme preparations behaved as one might predict: all of the adenylylated enzyme was inactivated, leaving only unadenylylated enzyme still in the catalytically active form. Naturally occurring potential hybrid forms, on the other hand, are inactivated to a different extent than mixtures with the same average content of adenylyl groups, lending further support to the idea of interaction between subunits in hybrid molecules causing an alteration in the physical properties of the glutamine synthetase molecule. The extent and significance of the hybrid enzyme problem is presently under study [21].

8. The Glutamine Synthetase Deadenylylating Enzyme

In the growth studies cited above (Section 2) it was found that during the course of growth of *E. coli* with glutamate as the nitrogen source, the glutamine synthetase becomes adenylylated as the organism goes into the stationary phase of growth. Similarly, it was found [3,22] that when *E. coli* is changed from a medium containing glutamate to one containing low concentrations of NH_4^+, the glutamine synthetase changes the adenylylated to the unadenylylated enzyme. This led us to suspect the existence of a deadenylylating enzyme in *E. coli* which could remove adenylyl groups from glutamine synthetase in response to changes in growth conditions. To detect this enzyme, we used as substrate ^{14}C-AMP-labeled adenylylated glutamine synthetase, made with the adenylyltransferase as mentioned above (Section 4), and monitored the release of radioactivity [23], as shown in eq. (3):

$$^{14}\text{C-adenylylglutamine synthetase} \xrightarrow{\text{deadenylylating enzyme}} \text{glutamine synthetase} + {}^{14}\text{C-AMP} \quad (3)$$

We found such an enzyme activity in *E. coli* cell extracts and it had the quite interesting feature, from the point of view of cellular regulation (Section 9), that it was stimulated some twenty-fold by α-ketoglutarate and inhibited by glutamine. During the course of removal of adenylyl residues from glutamine synthetase, the enzyme changes from a form with characteristics of Preparation II (Section 2) to one with characteristics of Preparation I [23]. Thus, the removal of adenylyl residues by an *E. coli* glutamine synthetase deadenylylating enzyme leads to the changes in catalytic activity of glutamine synthetase which would be expected from what has been previously discussed. The presence of this enzyme has subsequently been confirmed by *Battig et al.* [24].

The glutamine synthetase deadenylylating enzyme has been purified twenty-fold by a combination of protamine sulfate fractionation, ammonium sulfate fractionation, and adsorption onto and elution from alumina C-γ gel [25]. When this partially purified preparation was chromatographed on a resin which separates macromolecules according to their size, it was resolved into two components, both of which are needed for enzyme activity [25]. *Anderson* [26] has found that component P_I has an approximate molecular weight of 150000 and P_{II} has a molecular weight of about 50000. The smaller component, P_{II}, is fairly stable; P_I is quite unstable and has resisted efforts at further purification [26].

There is a rather complex set of effectors which is required for stimulation of the deadenylylation of glutamine synthetase [25]. Thus, as shown in Table 4, omission of α-ketoglutarate from the reaction mixture decreases the reaction rate fifteen-fold. There is also a requirement for nucleotides; the synergistic effects of ATP and UTP lead to a fifty-fold stimulation of the reaction. Divalent cation is also required for deadenylylation. The most effective cation is Mn^{2+}; Mg^{2+} is needed at ten times as high a concentration to be as effective, and Ca^{2+}, Cd^{2+}, Zn^{2+}, and Ba^{2+} were without effect. Stimulation of the reaction by divalent anions is also observed; hydrogen phosphate and -arsenate were equally effective, and activated the reaction two-fold.

Table 4. Requirements for *E. coli* deadenylylation reaction. Enzyme used was 40-fold purified mixture of components P_I and P_{II}. (See ref. [25] for precise conditions of experiment.)

Reaction mixture	Activity (units)
Complete system	4.6
Complete system without α-ketoglutarate	0.3
Complete system without UTP	0.7
Complete system without ATP	3.5
Complete system without UTP and ATP	0.1
Complete system without $MnCl_2$	0.0
Complete system without phosphate	2.0
Complete system without dithiothreitol	4.1

The stimulation by α-ketoglutarate occurred at relatively low concentrations (K_m = 2.0 mM). Neither glutamate nor other α-keto acids could replace α-ketoglutarate in its stimulatory role. Conversely, 50 % inhibition occurs with glutamine [25] at 0.35 mM.

Thus, the deadenylylating enzyme is stimulated by α-ketoglutarate and inhibited by glutamine, whereas the ATP:glutamine synthetase adenylyltransferase was stimulated by glutamine and inhibited by α-ketoglutarate. The possible significance of these reciprocal effector responses is discussed in Section 9.

One of the most interesting features of the deadenylylation reaction is that it is specifically activated by nucleotide fractions [25], the most active of which are a combination of UTP and ATP (Table 4). This requirement was discovered during purification of the enzyme, when removal of nucleic acids from the

[26] *W. Anderson,* personal communication.

enzyme preparation led to a loss of deadenylylating activity. Subsequently it was shown that several polynucleotide fractions could stimulate the twenty-fold purified deadenylylating enzyme preparation, with ribosomal RNA preparations being the most effective, and these only when employed synergistically with UTP[24]. When RNA is added to the maximally stimulated UTP-ATP activated deadenylylating reaction, it leads to inhibition of the reaction[25]. In all cases the stimulatory effects of RNA preparations was removed by treatment with ribonuclease. Of the mononucleotides tested, ATP and UTP were certainly the most effective, and behaved synergistically, as shown in Figure 7. Thus, UTP activates the deadenylylating reaction by itself in a sigmoidal fashion. In the presence of a saturating concentration of ATP, however, the shape of the saturation curve for UTP changes considerably, and UTP is now effective at much lower concentrations[24]. It is the ATP effect on the UTP-stimulated deadenylylating reaction that can be replaced by polynucleotide preparations, as mentioned above. Nucleoside di- and mono-phosphates had little effect either alone or in concert with ATP or UTP. Stimulation of deadenylylating enzyme activity in crude cell extracts by nucleoside triphosphates has also been noted by *Heilmeyer et al.*[27].

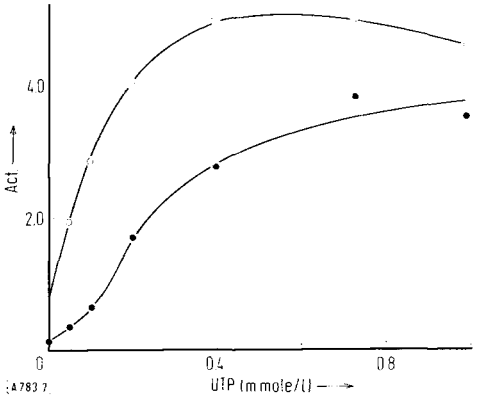

Fig. 7. Stimulation of deadenylylation by UTP alone (●—●) and by UTP in the presence of ATP (o—o) (from [25]).

The complexity of the requirements for deadenylylating enzyme activity in *E. coli* is rather puzzling. This complexity does not appear to reflect the necessity of exposing the adenylyl moiety prior to cleavage, a process which might be thought of as requiring energy (in the form of UTP and ATP) as well as structural effectors of the glutamine synthetase molecule (divalent cations and possibly α-ketoglutarate and phosphate), since the hydrolysis of the adenylylglutamine synthetase bond may be effected by a snake venom phosphodiesterase preparation which requires only divalent cation for activity. Thus the complex *E. coli* deadenylylation system, involving two macromolecular components and several other cofactors, most likely reflects a powerful means of control of the deadenylylation of glutamine synthetase in response to demands imposed by the need to maintain rigorous regulation of the synthesis of glutamine, and thus of other nitrogenous metabolites, during the growth and development of the organism. Although the physiological role of several of these effectors, notably the nucleotides, remains obscure, one can readily imagine the utility of having controls imposed by α-ketoglutarate and glutamine.

[27] *L. Heilmeyer, F. Battig,* and *H. Holzer,* Europ. J. Biochem. *9,* 259 (1969).

9. The Physiological Regulation of Nitrogen Metabolism by Adenylylation

The demand for intermediary metabolites of nitrogen probably fluctuates with the life cycle of the cell depending upon the need for specific biopolymer synthesis (*e.g.*, protein, nucleic acid, cell wall, membrane, *etc.*). In addition a variation in supply of nitrogen may occur with environmental change. To achieve maximal growth under all conditions, the cell would need to adapt itself efficiently to such alterations in the supply of and demand for nitrogen.

For an analysis of the possibilities for control of nitrogen metabolism, it is probably most graphic to consider the extremes of nitrogen nutrition, nitrogen starvation and nitrogen excess. In nitrogen starvation, there would be a relative decrease in nitrogen-containing metabolites in the cell. Among the most important of these are glutamine and its metabolic products (Fig. 1) because these are critical intermediates in nitrogen utilization. Along with this, there should be a reciprocal increase in the relative concentration of α-ketoglutarate, the carbohydrate skeleton of glutamine. Thus, it is postulated that the nitrogen saturation ratio, defined as (glutamine + glutamine products)/α-ketoglutarate, would be low.

On the other hand, with nitrogen excess, there should be a plethora of nitrogenous metabolites. If present in excess, these intermediates would decrease their own production, by means of the many feedback controls operative in biosynthetic reactions (for review, see [28]), leading to an increase in the relative concentration of glutamine. The increase in the concentration of glutamine and its metabolic products would lead to a relative increase in the nitrogen saturation ratio defined above. Although it is difficult to assess the absolute change expected in any one intermediate as a result of a simple perturbation in the multiply branched pathways of metabolism, a consideration of the nitrogen saturation ratio is helpful, since it stresses the importance of relative concentrations of several metabolic intermediates in reflecting alterations in nitrogen supply and demand.

In fact, *E. coli* has evolved a system for the regulation of its nitrogen metabolism that is very sensitive to alterations in the nitrogen saturation ratio. This system is composed of three enzymes which regulate the biosynthesis of glutamine: 1) glutamine synthetase; 2) the ATP:glutamine synthetase adenylyltransferase;

[28] *E. R. Stadtman,* Advan. Enzymology *28,* 41 (1966).

and, 3) the glutamine synthetase deadenylylating enzyme. Equation 4 shows the adenylylated and unadenylylated forms of glutamine synthetase, with their respective properties, as well as the enzymes which interconvert the two forms, and their effectors.

Activated by glutamine. Inhibited by α-ketoglutarate and UTP

Unadenylylated glutamine synthetase $\underset{\text{Deadenylylating enzyme}}{\overset{\text{Adenylyltransferase}}{\rightleftharpoons}}$ Adenylylated glutamine synthetase (4)

Activated by α-ketoglutarate and UTP. Inhibited by glutamine and glutamate

More active form
Resistant to feedback inhibition
Mg^{2+} specific

Less active form
More sensitive to feedback inhibition
Mn^{2+} specific

It is clear from this scheme that conditions of nitrogen starvation, with a correspondingly low nitrogen saturation ratio, lead to activation of the deadenylylating enzyme as well as to an inhibition of the adenylyltransferase, owing to the alterations in the relative levels of glutamine and α-ketoglutarate. This results in the formation of relatively unadenylylated glutamine synthetase, the form of the enzyme which is intrinsically more active and less sensitive to feedback inhibition. In this condition, ammonia will be converted into nitrogenous metabolites with high efficiency.

On the other hand, with high levels of the nitrogen saturation ratio, as might be expected with a surfeit of nitrogen-containing compounds, the deadenylylating enzyme would be inhibited and the adenylyltransferase activated. The result of this reciprocal enzyme control would be to convert the glutamine synthetase to the adenylylated form, which is less active and additionally more susceptible to inhibition by several of the products of glutamine metabolism. In this form glutamine synthetase activity is thus further diminished by the accumulated nitrogenous metabolites, which has as its result the lowering of the level of glutamine in the cell.

The three-enzyme nitrogen regulatory system has as its most obvious role the preservation of homeostasis in cellular nitrogen metabolism; any shift away from the "normal" nitrogen saturation ratio is accompanied by adjustments in the three enzymes which tend to restore the ratio toward the preexisting level. These intricate controls have as an ancillary effect the preservation of cellular ATP, since both glutamine synthesis and adenylylation of glutamine synthetase consume ATP; in fact, the adenylylation-deadenylylation system without reciprocal control would be a wasteful ATPase activity. The reason for the nucleotide controls in the adenylylation and deadenylylation phenomena is as yet obscure; a possible link between glutamine synthesis and polynucleotide metabolism is suggested by the effects of ribonucleic acid species on the deadenylylating system.

Nucleosides and Nucleotides as Potential Therapeutic Agents

By T. Y. Shen[*]

The present article summarizes recent progress in the study of nucleoside derivatives as antiviral and immunosuppressive agents. A number of 5'-substituted 5'-deoxy nucleosides have been found to be permeable and nonincorporable antimetabolites of 5'-nucleotides. N^6-isopentenyladenosine and analogs show certain promising immunosuppressive activities. Encouraged by the antibody-stimulating effect of oligonucleotides, we have developed a convenient synthesis of oligonucleotides using fully protected phosphorylated intermediates. A group of tetradeoxyribonucleotides, dApdApdApdX, was prepared for biological and physical evaluations. Nucleotide derivatives may prove valuable in the treatment of several immunological disorders.

1. Introduction

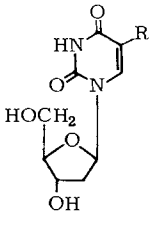
A brief review of some recent studies of nucleosides and nucleotides in the field of chemotherapy and immunology is presented below. The purpose of this discussion is to highlight several biomedical targets of interest to medicinal chemists and to indicate the therapeutic potentials of nucleosides and nucleotides [1].

[*] Dr. T. Y. Shen
Merck Sharp and Dohme Research Laboratories
Rahway, New Jersey 07065 (USA)

[1] Adapted from presentations at the Symposium on Recent Advances in Nucleoside Chemistry. 156th American Chemical Society Meeting, Atlantic City, New Jersey, Sept. 11, 1968, and at the Gordon Conference on Carbohydrate Chemistry, New Hampshire, June 1969.

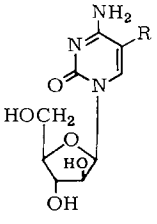
During the past fifteen years, extensive chemical and biological studies of nucleosides and some nucleotide analogs have been stimulated mainly by their antitumor and antibiotic properties. The cytotoxic or bactericidal activities of these antimetabolites are often attributable to the inhibition of enzyme systems involved in the biosynthesis of nucleic acids, such as nucleotide reductases, kinases, and polymerases, or to the formation of fraudulent nucleic acids through incorporation [2]. Several nucleoside antibiotics such as puromycin, blasticidins, and gugerotin inhibit protein synthesis, either by chain termination or by interference with the normal function of peptide synthetase or ribosomes [3]. However, since these components are also essential in the biosynthesis of protein and nucleic acids in normal cells, the therapeutic value of nucleoside antimetabolites are frequently diminished by their potential toxicity.

The need for a better therapeutic index is particularly important in the application of nucleoside analogs to viral chemotherapy [4] or metabolic diseases. Lack of incorporation into normal cells (*i.e.*, lack of mutagenic effect) and a high degree of selectivity toxicity are almost mandatory for any useful agent.



2. Inhibitors of DNA Viruses

2.1. 2′-Deoxyribo- and Arabinonucleoside Analogs



The first clinical application of a nucleoside as antiviral agent with an adequate therapeutic index was demonstrated by a well-known thymidine analog, 5-iodo-2′-deoxyuridine *(1)* (idoxuridine), in the treatment of an eye infection, herpes keratitis [5]. The apparent safety in this case was accomplished by a unique physiological phenomenon, namely, ophthalmic infections are topical and not unlike an *in vitro* system. Since then several more potent DNA-synthesis inhibitors or thymidine antimetabolites, such as trifluorothymidine *(2)* [6], cytosine arabinoside (cytarabine) *(3)* [7], and its 5-fluoro analog *(4)* [8], have also shown similar efficacy. A homolog of thymidine, 5-ethyl-2′-deoxyuridine *(5a)*, was also reported to have antiherpes activity [8a].

In our laboratory another analog, 5-methylamino-2′-deoxyuridine (MADU) *(5)*, was investigated [9]. As found by *Visser* and his co-workers, MADU is only poorly active as a thymidine antagonist in the bacterial system [10]. Surprisingly, in tissue culture and rabbit-eye systems MADU is as effective as idoxuridine against herpes simplex [11]. The high degree of selective toxicity against herpes virus was further dramatized by its lack of inhibition against other DNA and RNA viruses. It was suggested that the phosphorylated derivatives of MADU block the utilization of thymidine 5′-triphosphate for DNA synthesis. The selectivity of MADU is thus the consequence of an enhanced phosphorylating capacity of infected cells [12]. Unfortunately the activity of MADU against systemic herpes infections proved to be a disappointment.

The *in vivo* activity of nucleosides is often limited by their unfavorable distribution or metabolic characteristics [13]. It was observed recently that the *in vivo* immunosuppressive activity of 5′-adamantoyl cytarabine *(6)* is more potent and longer lasting than that of the parent nucleoside *(3)* [14]. Selective localization, sustained hydrolysis, and resistance to enzymatic degradation were suggested as possible explanations. It would seem that similar derivatization of active nucleosides with an *in vivo* cleavable group, a technique well studied in the production of other drugs, may well expand the potential application of other nucleoside analogs.

R = I (Idoxuridine) *(1)*
CF_3 *(2)*
$NHCH_3$ *(5)*
CH_2CH_3 *(5a)*

R = H (Cytarabine) *(3)*
F *(4)*

More recently a purine nucleoside, adenine arabinoside *(7)* [15], was described as a broad-spectrum anti-DNA viral agent *in vitro* and *in vivo* [16]. It is probably superior to idoxuridine in the treatment of herpes keratitis but its utility in systemic viral infections remains to be established. In view of the recent impli-

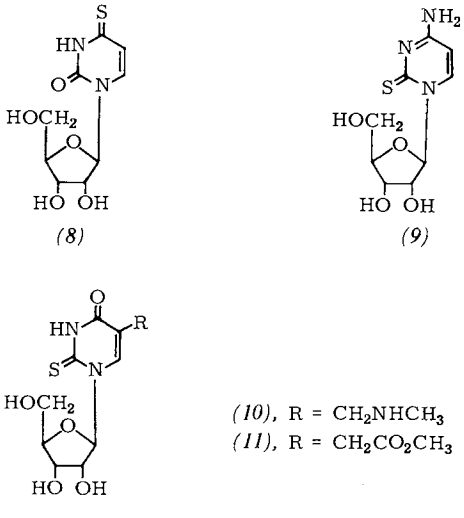
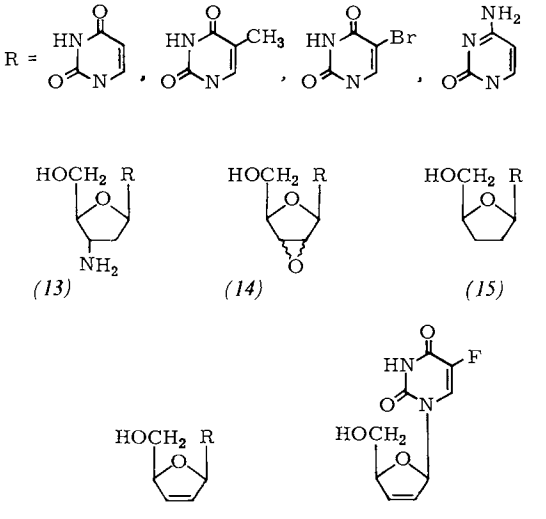
2.2. Search for Novel Structures



The potential role of soluble RNAs as regulators of nucleic acid metabolism has often been discussed [19]. The significance of various minor or abnormal nucleotides present is particularly intriguing. In our study of pyrimidine nucleosides as novel antimetabolites it was noted that several thiopyrimidine nucleosides, such as 4-thiouridine *(8)* [20], 2-thiocytidine *(9)*, and the 5-substituted derivatives *(10)* [21] and *(11)* [22], have been detected in t-RNA. Alteration of ^{35}S incorporation into t-RNA has also been observed after a phage infection [23].

2-Thiocytosine arabinoside *(12)* was synthesized in our laboratory by the ring-opening of a cyclonucleoside [24], but to our disappointment it does not possess any significant antiviral properties.



(12)

So far, anti-DNA viral activity seems to be mostly associated with pyrimidine analogs with 2′-deoxy-D-ribose and D-arabinose moieties. A group of compounds with pyrimidine bases such as uracil, thymine, 5-bromouracil, and cytosine attached to modified pentofuranoses such as 3-amino-2-3-dideoxyribose *(13)*, 2,3-anhydroribose *(14)*, 2,3-dideoxyribose *(15)*, or its 2,3-didehydro analog *(16)*, and several hexopyranoses are all inactive [25]. Recently, the 2′,3′-didehydro analog of 5-fluorouridine was found to be an anti-tumor agent [26], but its antiviral activity has not been described.

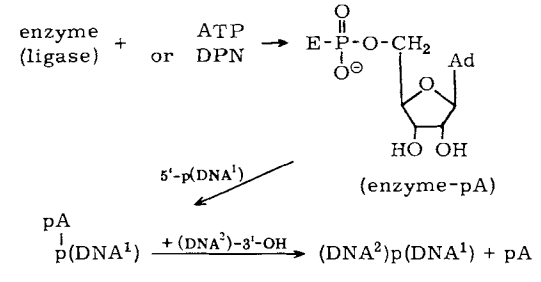
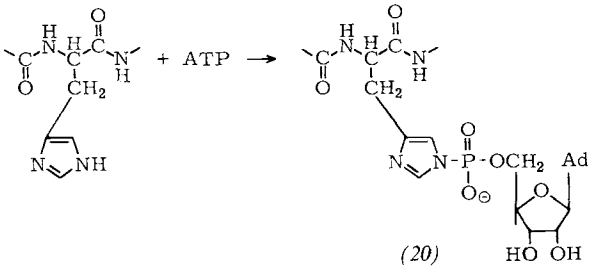
with 3′-deoxyadenosine (cordycepin), both 3′-*C*-methyladenosine *(18)* and 3′-*C*-methylcytidine *(19)* are much less toxic to cell cultures [29]. However, both showed interesting activity against vaccinia infection in mice when administered at doses of 1–2 mg and are superior to the standard drug, Marboran. The corresponding 2′-*C*-methyl analogs are much less active [28].



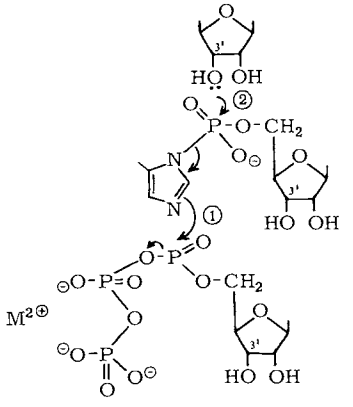
(18) *(19)*

3. Search for Inhibitors of RNA Viruses



3.1. Structure Information of RNA Polymerase

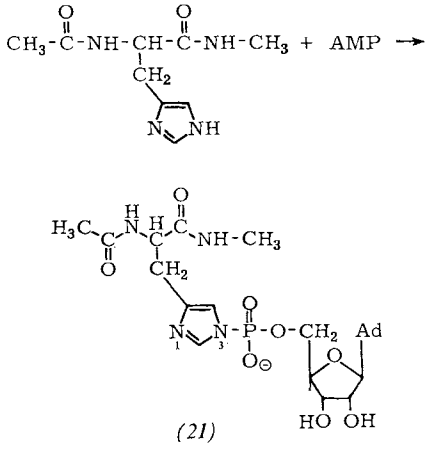
In the search for anti-RNA viral agents, our attention was directed to the unique synthesis of viral RNA, which involves a single-stranded RNA template, a double-stranded replicative intermediate, and a viral specific polymerase. The complexity of viral replication has generated much speculation and many hypotheses [30]. It would seem that novel reversible or irreversible inhibitors derived from nucleosides, in addition to their therapeutic value, might also be useful as molecular probes of the active site in polymerase and help to elucidate its mechanism. Current studies of RNA polymerases indicate that the incoming nucleoside triphosphate may interact first with the active site to form a reactive nucleoside-5′-phosphoryl-enzyme intermediate which then participates in coupling with the 3′-hydroxy group of the growing polymer. The sequence of reaction is similar to that in polynucleotide ligase [31] (an enzyme whose activity is changed significantly after viral infection and which may turn out to be a chemotherapeutic target also) [32].



(DNA-adenylate)

The active site of RNA polymerase contains a histidyl residue [33] which is essential for chain elongation. Analogous to the active site in nucleoside diphosphokinases [34], the histidyl group may form a phosphoryl-imidazole intermediate *(20)*, with the nucleoside triphosphate.

(20)



Speculatively, a concerted activation (step 1) and transfer (step 2) sequence may be visualized as shown in Scheme 1.

Scheme 1.

3.2. Models of the Enzyme Intermediate

As a model of this active intermediate we have synthesized the crystalline compound *(21)* [35]. The site of phosphorylation is tentatively assigned as N-3, based on the observation that the N-3-phosphoryl derivatives

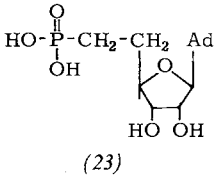
of histidine are generally more stable than those phosphorylated at N-1 [36].

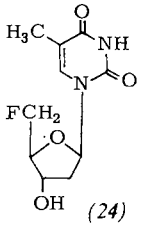
Unlike many adenylic acid derivatives, which have ORD spectra similar to that of 5′-AMP with a negative Cotton effect at 277 nm, compound *(21)* gave an anomalous ORD spectrum with a positive Cotton effect near 270 nm. Whether the reversal of Cotton effect is indicative of a conformational change due to the intramolecular interaction of the imidazole moiety and adenine chromophore remains speculative, but any correlation of the physicochemical properties with those of the active intermediate of polymerase would certainly be worth investigating. A similar reversal of the Cotton effect is found for the 5′-adenylyl derivative of imidazole, pyrazole, and 2-hydroxypyridine [35].



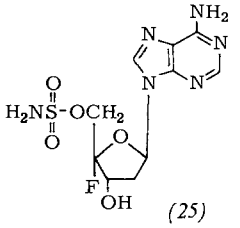
The possibility of using these analogs of an active intermediate to interfere with the enzyme action are still being investigated. It is assumed that in the normal course of polymerization the formation of the active intermediate (imidazole-p-A) is followed by transfer of p-A to the growing chain of the polynucleotide. This would require either a conformational change of the active site, *e.g.*, prompted by the elimination of the charged pyrophosphate group, or a translocation of the active intermediate itself. One could imagine that these analogs may well interfere with the transfer step. Classical antimetabolites of the substrate ATP, with their charged triphosphate-like side chain, will probably interfere only with the activation step and the formation of the active intermediate.

3.3. 5′-Substituted Nucleoside Analogs as Nucleotide Equivalents

The best known classical antimetabolites of nucleotides are their methylene phosphonate isosteres, *e.g.*, compounds *(22)* [37] and *(23)* [38]. In both cases an oxygen linkage is replaced by a methylene group that is noncleavable under physiological conditions.

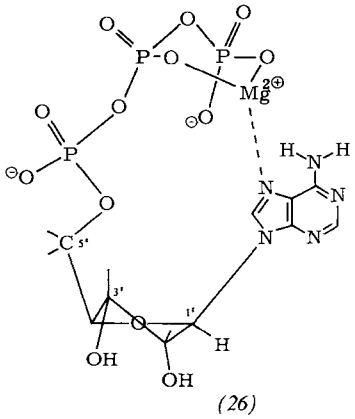


(22)



(23)

Depending on which oxygen atom is replaced by the methylene group, these analogs are either substrates or inhibitors [37]. However, their practical applications are obviously restricted by their poor permeability properties. To circumvent this barrier, we decided to investigate a group of nucleoside derivatives bearing a polar organic moiety at the 5′-position which might mimic the triphosphate-Mg^{2+} side chain of the polymerase substrate [39]. These 5′-substituted nucleosides probably permeate easily into cells. In addition, they are attractive for several important reasons. Firstly, with their 5′-hydroxyl group replaced by a substituent they are totally nonincorporable, thus fulfilling our safety requirement mentioned above. Secondly, unlike most nucleoside antimetabolites, any inhibitory action of a 5′-substituted nucleoside should not depend upon its prior enzymatic conversion into a nucleotide, and resistance development is therefore less likely [40]. Furthermore, as recently shown by 5′-deoxy-5′-methylthioadenosine [41], 5′-substituted adenosine derivatives might be more resistant to catabolic enzymes such as adenosine deaminase and purine nucleoside phosphorylase. Although unknown at the beginning of our study, the feasibility of using a 5′-substituted nucleoside as kinase or polymerase inhibitors was strongly indicated by the recent disclosure of 5′-deoxy-5′-fluorothymidine *(24)* as a competitive inhibitor, not of thymidine to its kinase, but of thymidylic acid to thymidylate kinase [42]. Another example of a 5′-substituted nucleoside analog is the naturally occurring antibiotic nucleocidin *(25)* [43] whose structure was elucidated recently.



(24)

(25)

Our endeavor to construct an organic equivalent of the 5′-triphosphate-Mg^{2+} complex was much hampered by the uncertainty on the configuration of nucleotides such as the ATP-Mg^{2+} complex. In general, a cyclic chelating structure formed by the β and γ phosphates and Mg^{2+} is favored, but the possible

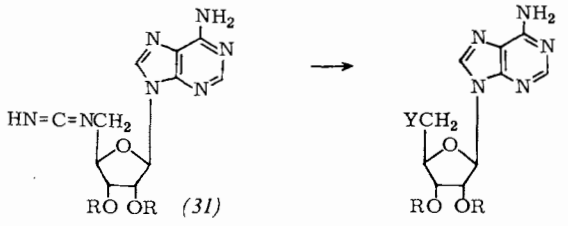
involvement of a ring nitrogen in the coordination remains to be established. Very recently structures *(26)* involving the participation of N^7, instead of the 6-amino group, have been suggested on the basis of relevant X-ray data [44]. The three-dimensional structure of ATP in the hydrated disodium salt, with the phosphate chain folded back towards the purine base, was reported by another group [45].

3.4. Derivatives of 5'-Amino-5'-deoxy Nucleosides

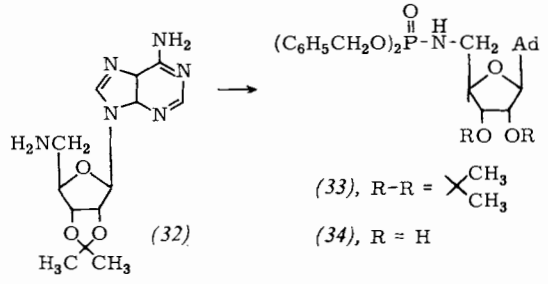
Our initial plan was to explore various nucleoside derivatives which have a cyclic or chelating structure at the 5'-position to mimic the triphosphate side chain, and the 5'-amino-5'-deoxy and 5'azido-5'-deoxy derivatives of adenosine *(27)* and *(28)*, respectively [46], were chosen as key intermediates for their synthesis. These selections turned out to be particularly fortuitous since both compounds exhibited antiviral activity *per se*; inhibition of parainfluenza III was demonstrated [47] at 8–30 μg/ml in tissue cultures with therapeutic indices ranging from 16 to 128, depending upon the severity of the infection. Encouraged by these findings, we synthesized a number of simple derivatives from the versatile 5'-tosylate *(29)* by similar nucleophilic displacement reactions. To minimize formation of the cyclonucleoside *(30)*, the N^6-formyl and 6-methylthio derivatives were employed in some cases.



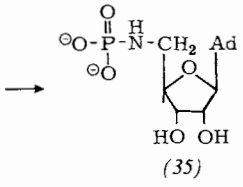
(29) *(30)* *(27)*, R = NH_2, X = NH_2; *(28)*, R = NH_2, X = N_3

R = CH_3S, HCNH, (Cl, NH_2, SH)

$X^- = N_3$, NH_2, CH_3NH, $(CH_3)_2N$, CH_3–C(O)S, –N=C=NH, –SC≡N



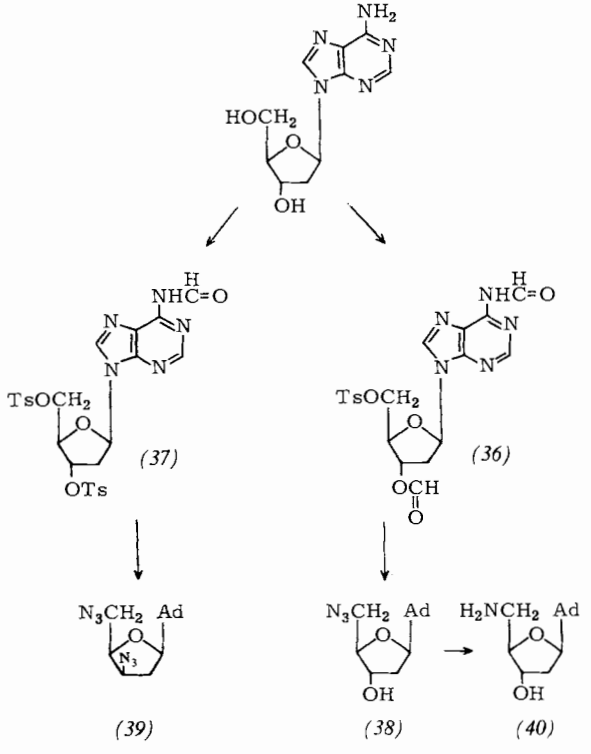
Several guanidine and urea derivatives were readily prepared from the cyanamide precursor *(31)*.



(31)

R = H or Y = NH–CO–NH_2, NH–C(NH)–NH_2,
R–R = isopropylidene NH–CS–NH_2, NH–C(NH)–NHC_4H_9

The protected 5'-amino-5'-deoxyadenosine *(32)* was phosphorylated with dibenzyl phosphite and *N*-chlorosuccinimide in methylene chloride to the phosphoramidate *(33)*. The isopropylidene group was first removed by dilute formic acid to give *(34)*, which, on



(32) *(33)*, R–R = *(34)*, R = H

(35)

hydrogenolysis in the presence of sodium hydroxide afforded a product, believed to be the desired 5'-aza AMP, that was too unstable for cyclization to the

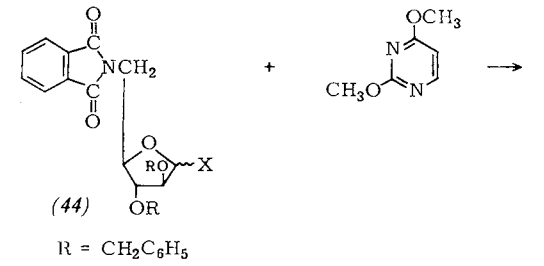
[47] *M. M. Nemes*, unpublished observations.

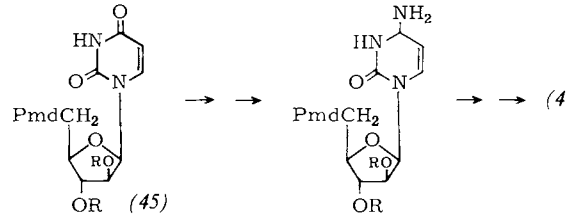
desired 5′-aza-3′,5′-cyclic AMP. A similar observation regarding the stability of *(35)* was reported recently [48].

In the 2′-deoxyribonucleoside series, 2′-deoxyadenosine, a known antimetabolite, was sulfonated to give a mixture of mono- and di-tosylates. Treatment of their formyl derivatives *(36)* and *(37)*, respectively, with sodium azide gave the corresponding azido derivatives *(38)* and *(39)*. The former was reduced to 5′-amino-2′-5′-dideoxyadenosine *(40)* [49].

3.5. 5′-Substituted Arabinosyl Nucleosides



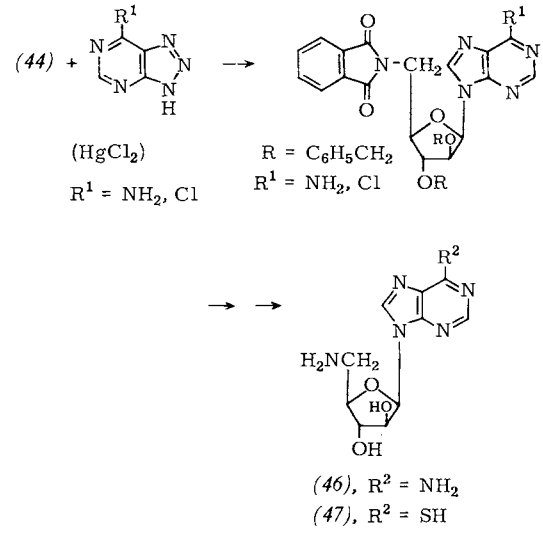
The importance of arabinosyl nucleosides in the therapeutic field has been amply demonstrated by cytosine-, adenine- and 6-methylthiopurine arabinosides. Cytosine arabinoside was readily transformed to its 5′-amino analog *(41)*.



(42), R = $CH_2C_6H_5$ *(43)*

In order to develop a versatile route to study 5′-substituted arabinosyl nucleosides, we first synthesized methyl 5′-azidoarabinofuranoside *(42)* as a potential intermediate. Unexpectedly, attempted mild acid hydrolysis yielded a new crystalline compound which was found to be the piperidone *(43)* [50].

On the other hand, when a phthalimido group was placed at the 5′-position, the protected arabinosyl halide *(44)* could be prepared readily from the corresponding arabinosyl *p*-nitrobenzoate and used in the standard Hilbert-Johnson reaction. The β-nucleoside *(45)* was formed as the predominant product from the α-chloride. The stereospecificity is reminiscent of our earlier experience with 2,3,5-tri-*O*-benzylarabinosyl halide in the synthesis of cytosine arabinoside



(44) R = $CH_2C_6H_5$

itself [51]. The 4-keto group in *(45)* was converted to the 4-amino *via* the methylthio intermediate, and the protecting groups were removed to give *(41)*.

The arabinosyl halide *(44)* was condensed with adenine and then deblocked to give 5′-amino-5′-deoxyadenine arabinoside *(46)*. The 6-mercaptopurine analog *(47)* was obtained in a small yield from the protected 6-chloropurine precursor by treatment with thiourea. In this case the removal of protecting groups was complicated by the formation of disulfide and other decomposition products.

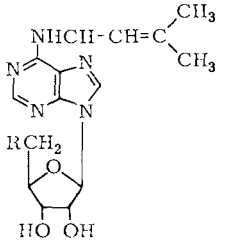
(46), $R^2 = NH_2$
(47), $R^2 = SH$

The β-configuration of these purine arabinosides was corroborated by the similarity of their ORD spectra with that of adenosine. Previous workers have shown that the configuration of the 2′-hydroxyl group has no significant effect on the ORD of these nucleosides.

3.6. Biological Properties of 5′-Substituted Nucleosides

The new analogs exhibited moderate to good cytotoxicity *vs.* HeLa cells at concentrations of 1 millimole/l [29]. The 5′-azido-5′-deoxy derivatives of both

[48] *B. Jastorff* and *H. Hettler*, Tetrahedron Letters *1969*, 2543.



[49] An independent synthesis of this compound was recently reported: *M. G. Stout*, *M. J. Robins*, *R. K. Olsen*, and *R. K. Robins*, J. med. Chem. *12*, 658 (1969).

[50] *W. V. Ruyle*, unpublished observations.

[51] *T. Y. Shen*, *H. M. Lewis*, and *W. V. Ruyle*, J. org. Chemistry *30*, 835 (1965).

adenosine and 6-methylthiopurine riboside are highly toxic at this level. Several analogs, *e.g.*, the 5′-amino, 5′-azido, 5′-ureido, and 5′-ethoxycarbamyl derivatives of adenosine, were shown to inhibit the conversion of adenosine to its phosphorylated derivatives in ascites cells to *ca.* 60 % at concentrations of 0.9 mmole/l [29]; however, no significant antiviral activity was uncovered. The inhibition of adenosine utilization by these compounds is reminiscent of the inhibition of thymidine utilization by 5′-deoxy-5′-fluorothymidine *(24)* mentioned earlier.

As part of our systematic structure modifications, the 5′-azido derivative *(49)* of 6-isopentenyladenosine *(48)* (6-IPA) [52] was also synthesized. This derivative is again a nonincorporable antimetabolite. Yet, like 6-IPA, it inhibited HeLa cells to almost 100 % at a concentration of 1 mmole/l, although its potency was somewhat less at lower concentrations.

(48), R = OH (6-IPA)
(49), R = N_3

4. Immunological Effects of Nucleosides and Nucleotides

4.1. Immunosuppressive Nucleosides

Our interest in 6-IPA analogs was further stimulated by their potential application as immunosuppressive agents. Nucleoside antimetabolites such as 6-mercaptopurine, imuran, and cytarabine *(3)* have been used in clinical treatment of various immunological disorders. 6-Mercaptopurine arabinoside *(50)* and 6-methylthiopurine riboside *(51)* and its periodate oxidation product have also been studied in the laboratory [53]. Using the hemagglutinin response to sheep erythrocytes as a model for humoral antibody production and graft *versus* host reactions as representative cell-mediated immune reactions, the mechanism of action of these immunosuppressants is gradually being elucidated [53]. It is instructive to realize that these DNA synthesis inhibitors are very effective in suppressing the proliferation of sensitized lymphocytes and cell-mediated immunity, but the biochemical blockades imposed are easily overcome. Humoral antibody response is generally not inhibited by these compounds [54].

4.2. Properties of Cytokinin Derivatives

Kinetin riboside *(52)*, 6-IPA, and other cytokinin derivatives represent a new group of immunosuppressants. The primary effect of 6-IPA was suggested as interference with RNA and protein synthesis [55]. It has recently been observed that, depending on the concentration and on the particular stage of the cell cycle, 6-IPA has a biphasic effect on the transformation and mitosis of human lymphocytes treated with phytohemagglutinin. This biphasic response is reminiscent of the antibody stimulating or inhibitory effect of another RNA synthesis inbibitor, 6-MP, in several *in vivo* systems [56].

6-IPA and cytokinins also exert an indirect influence on certain humoral immune responses mediated by nucleic acids. The participation of two or more cell types, macrophages and lymphocytes, in the primary response has been demonstrated [57, 58]. In the case of certain soluble antigens, a 4 S RNA or a RNA-protein complex is released by macrophage after phagocytosis of the antigen. This RNA-containing material, the nature of which is still being elucidated, is possibly involved in the sensitization of lymphocytes [59].

Coincidentally, nucleic acid digests or oligonucleotides have been shown to have an adjuvant effect in enhancing the phagocytosis of antigen by macrophage and in stimulating the production of antibodies by sensitized lymphocytes (Fig. 1) [60]. For reasons not yet understood, the antibody stimulating effect is inhibited by 6-IPA, kinetin riboside *(52)*, and other analogs [61].

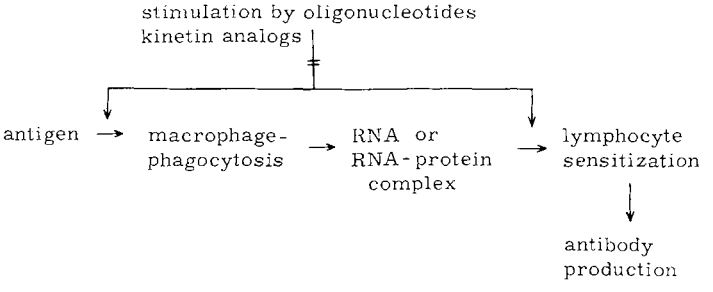

Fig. 1. Effect of cytokinin on antibody production.

Cytokinins are usually alkylated purine derivatives [62], but a pyrimidine cytokinin, 6-methyluracil (pseudothymine) *(53)*, was described recently [63]. It would be of interest to compare the immunosuppressive activity of pseudothymine nucleosides [64].

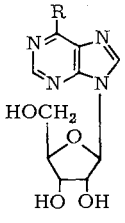
[64] *M. W. Winkley* and *R. K. Robins*, J. org. Chemistry *33*, 2822 (1968).



Another alkylated purine, 1-methyladenine *(54)*, is a potent meiosis inducer which stimulates ovulation in star fish at a concentration of 0.02 μg/ml [65]. The corresponding 1-ethyl homolog is much less active. We have noted that 1-isopentenyl adenine *(55)*, an intermediate in the synthesis of N^6-isopentenyladenine, inhibits thymidine incorporation in the HeLa cells at 1 mmole/l but increases thymidine and uridine incorporation in phytohemagglutinin-stimulated rat spleen cells at 10 μg/ml [66].

Both 6-IPA *(48)* and its 2-methylthio derivative have been found to occupy positions adjacent to certain anticodon regions in t-RNA [67,68]. The special location of these bases and the effectiveness of hydrophobic N^6 side chains have led to the suggestion that the cytokinin in t-RNA functions in the codon-anticodon interaction, possibly with an increasing ribosomal binding by the N^6-substituents. Whether the regulatory effect of exogenous cytokinins is achieved by the incorporation into t-RNA *per se* or by an indirect influence on the "pool" of cytokinin-containing t-RNA species remains to be elucidated. The asymmetric N^6-alkyl side chains in several cytokinins preferentially adopt the (*S*)-configuration [69].

The effects of these nucleoside analogs on mammalian cells have received much attention recently. Differential toxicity to certain leukemic cells and normal lymphocytes has been observed with a group of N^6-alkylated adenosines [70–72]. Obviously an extension of this kind of inhibitory action to immunological disorders would be of considerable interest.

5. Oligonucleotides

5.1. Adjuvant Effect of Oligonucleotides

In our laboratory we were also intrigued by the enhancement of host resistance to infection by oligonucleotides [60]. In the original immunological experiments an antibody-stimulation effect was observed with a gross mixture of DNA digest and the optimal size of the oligomers from DNA digest was estimated to be tri- to hexanucleotides. Our aim then was to delineate the active structural features of oligomers, and, if possible, to shed further light on the mechanism of this stimulating effect. Base sequence, charge distribution, molecular conformation, nature of backbone, and stability to nuclease cleavage were some of the parameters to be evaluated. The cellular uptake of oligonucleotides and the site of action, whether membrane or cytoplasmic, also required clarification (see Fig. 2).

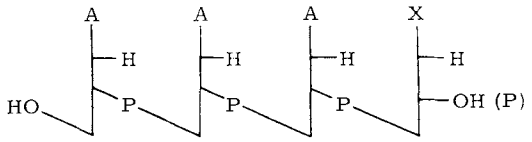
5.2. Synthesis of Oligo(2′-deoxynucleotides)

As an initial step, a group of tetradeoxynucleotides of the general type dApdApdApdX *(56)* with dX = dA, dG, dI, T, and dC were synthesized by a modified procedure which incorporates the advantages of several well known techniques [73,74a,74b].



N^6-Benzoyl-5′-*O*-monomethoxytrityl-2′-deoxyadenosine *(57)* was used as starting material. Treatment with trichloroethyl phosphate and mesitylenesulfonyl chloride in pyridine gives the 3′-phosphorylated derivative *(58)*. Condensation with the 5′-hydroxyl of N^6-benzoyl-2′-deoxyadenosine was also carried out in pyridine in the presence of triisopropylbenzenesulfonyl chloride to give the dinucleotide *(59)*. The sequence of 3′-phosphorylation and 5′-condensation was repeated to give the trinucleotide *(60)* and this in turn was condensed with appropriately protected deoxyadenosine, deoxyguanoside, and deoxycytidine. 2′-Deoxyinosine and thymidine were used directly. The use of fully protected intermediates enabled us to employ silica gel column chromatography for their isolation and to obtain 10–20 mg of products without

(60)

(61)

too much difficulty. The protecting groups in the tetranucleotide *(61)* were removed sequentially by treatment with Zn/Cu couple, dilute ammonia, and aqueous acetic acid. The selection of trichloroethyl as our phosphate-protecting group also conferred versatility to this approach for further structure modifications. The scope of this synthetic sequence was recently extended to the oligoribonucleotide series in which the 2′-tetrahydropyranyl was used as protected intermediate [75]. Conversion of our oligodeoxyribonucleotides to cyclic (circular) analogs in order to increase their resistance to nucleases and to enhance cellular uptake is still under study; we are particularly interested in the physicochemical properties of the products.

5.3. Potential Applications of Oligonucleotides

Another potential application of nucleotide derivatives lies in the area of autoimmune diseases, such as systemic lupus erythmatosus (SLE) and other chronic degenerative disorders, which are characterized by the production of anti-nuclear antibodies directed against nucleic acids and nucleoproteins. A variety of antibodies to native DNA, single-stranded DNA, and even double-stranded RNA are found in patients with SLE [76, 77]. These antibodies react with nucleic acids to form antigen-antibody complexes which cause inflammation along the basement membrane of renal glomerulus leading to the development of glomerular lesions. On considering the formation of pathogenic antigen-antibody complexes one is reminded of the fact that the binding of antigen with antibody is analogous to enzyme-substrate interactions. It is well established that the interaction of polysaccharide and its antibody can be inhibited by chemical analogs of the determinant group, such as oligosaccharides [78]. Similarly, a partial inhibition of SLE sera by tetra- or pentanucleotides was demonstrated several years ago [79]. With more precise information on the nature of binding involved it is conceivable that one may find oligonucleotide derivatives not only with higher affinity but also capable of cross-reacting with a large group of SLE sera. The formation of soluble antigen-antibody complexes between oligonucleotide analogs and anti-DNA antibodies would presumably minimize immunological lesions and possibly facilitate the induction of tolerance (see Fig. 3) [80].

The concept of using derivatives of oligonucleotides or much simplified "structure equivalents" to mimic or to compete with biologically active polynucleotides should be applicable to other important problems of

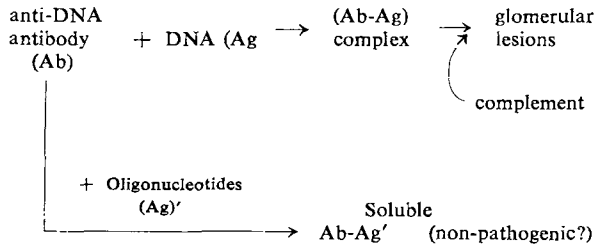

Fig. 3. Pathogenesis in systemic lupus erythmatosus.

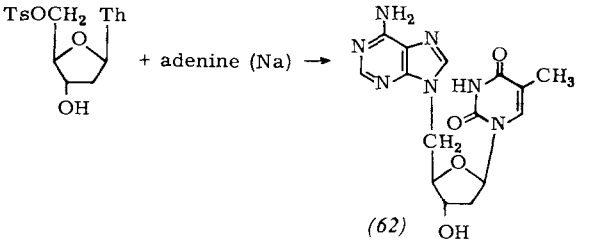
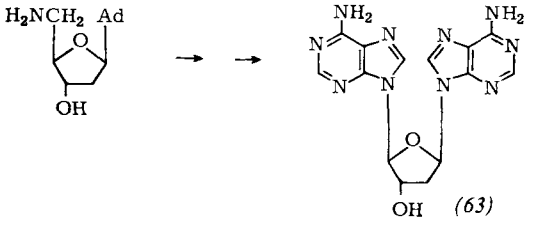


medicinal interest such as interferon induction, viral RNA polymerase inhibition, specific t-RNA inhibition, and episome transfer. In each case one may assume that the interaction of nucleic acid with a protein molecule or a receptor involves only one region or several regions of oligonucleotides and that the specificity is determined by the base sequence and secondary structure of those regions. The feasibility of this kind of approach is clearly indicated by recent sequence determinations of Qβ and R17 phage RNA. The base sequence of Qβ phage was determined from both the 3'-[81,82] and 5'-terminals[83], and no less than 175 nucleotides from the 5'-terminus with a well-defined loop-like secondary structure have been elucidated[83]. The identification of a specific binding region should enable us to design chemical structures either to compete for the protein binding site or to interact with the oligonucleotide region itself by means of intercalation, base pairing, or formation of other hydrogen bonds.

6. Novel Nucleoside Derivatives



6.1. "Double-Headed" Nucleosides

To explore nucleoside analogs which might show a selectivity for certain base-sequences on interaction with nucleic acid, we have utilized the versatile 5'-*O*-tosyl and 5'-amino-5'-deoxy derivatives of nucleosides described above to synthesize novel ribonucleosides and 2'-deoxyribonucleosides which possess a second purine or pyrimidine moiety at the 5'-carbon[84,85].

It is hoped that with the proper selection and spacing of the two bases, one may utilize one base for Watson-Crick type pairing and the other to intercalate between the next two adjacent nucleotides in a polynucleotide.

(62)

(63)

The specificity of these interactions will be the basis for selective binding of three nucleotides by one double-headed unit. The nucleoside *(63)* gave an unusual CD spectrum[84], presumably due to intramolecular interactions between the two proximate bases. These compounds are useful models for the study of base-base interactions. The pronounced Cotton effect may also serve as a convenient marker in following the intermolecular interactions between these compounds and polynucleotides.

7. Conclusion

The medical applications of nucleotide derivatives have not received much attention in the past partly because of the difficulties in chemical synthesis and partly because of their poor absorption and cellular permeability characteristics. However, recent developments in synthetic methods and isolation techniques have brought oligomers within the sphere of medicinal chemical explorations. New discoveries, such as the use of double-stranded polynucleotides as interferon-inducers in viral chemotherapy[86,87], have broadened the traditional concept of using only monomeric drugs. The growing knowledge of membrane receptor sites and membrane enzymes such as ATPase in the regulation of cellular activities also provides new extracellular targets for drug action. With the structure elucidation of nucleic acids and the understanding of their interaction with protein receptors, further advances in the application of nucleoside and nucleotide derivatives as novel therapeutic agents are certainly to be expected.

Gel Chromatography

By Walter Heitz[*]

Gel chromatography can be regarded as a network-limited partitioning of substances. The theory of this method and the preparation and properties of various gel systems are reviewed. Optimization of the method is illustrated for the separation of oligomers.

1. Introduction

Gel chromatography, also known as gel permeation chromatography [1] and gel filtration [2] has become a valuable laboratory method for separating mixtures according to the molecular weight of their components.

As in other chromatographic methods, a mobile phase capable of mass exchange is made to migrate through a stationary phase. The mobile phase is a liquid that can readily dissolve the sample mixture to be separated. The stationary phase is a porous material whose pore size is about as large as the molecules to be separated. Such porous structures can be obtained with inorganic polymers (glass [3] and silica gel [4–7]), but cross-linked organic polymers having the required structure at least in the swollen state are mostly used. The present article deals with the main advances made in this field in the past four years (for earlier surveys, see [8–14]).

2. Experimental Arrangement

In the simplest case a column is packed with swollen gel, the sample solution is poured in, the eluate is collected in fractions, and the fractions are investigated.

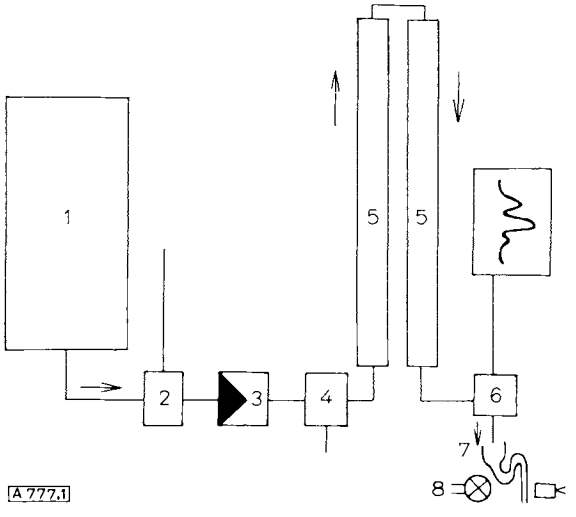

Fig. 1. Experimental arrangement in gel chromatography.
1 = solvent reservoir; 2 = degassing device; 3 = pump; 4 = sample inlet; 5 = column; 6 = recorder; 7 = siphon; 8 = light barrier.

The best experimental arrangement is shown schematically in Fig. 1.

The solvent flows from a reservoir (1) through a sintered glass plate into a degassing device(2); this is an electrically heated metal block with an upright tube or a Liebig condenser heated by a thermostated liquid. When the eluent is water, peristaltic pumps can be used, but piston pumps are preferred in the case of organic eluents. The piston strokes must be damped with the aid of a harmonica joint, particularly when a soft gel is used. As in gas chromatography, the sample in an aqueous system may be injected through an elastomer packing; for samples in organic systems, on the other hand, ball valves are used [15], or a sample loop is inserted in the solvent stream *via* a multiway valve. Having traversed the column, the eluent enters an indicator device (6). Differential refractometers have proved particularly suitable in this capacity, besides UV and IR apparatus [16, 17]. Owing to the high noise level, flame ionization detectors are used only in isolated cases in this field [18]. The volume of eluate is measured by a siphon (7) with a light barrier (8) or by a drop counter, and is recorded directly on the recorder.

3. Theory of Gel Chromatography

3.1. Principle of Separation

In the elution of a mixture down a column filled with swollen gel particles, the first component of the mixture appears in the eluate when a volume of liquid equal to the volume of solution (V_0) between the gel particles has left the column. This component comprises all the compounds whose molecules are too large to penetrate the gel pores. If interaction with the gel matrix is ignored, one may say that the last component of the sample leaves the column when a further volume of liquid equal to the volume of solution inside the gel particles (V_I) has emerged. The entire separation takes place between the eluent volumes V_0 and (V_0 + V_I) (Fig. 2). This indicates that the separating efficiency is considerably lower here than in other chromatographic methods, *e.g.* in gas chromatography.

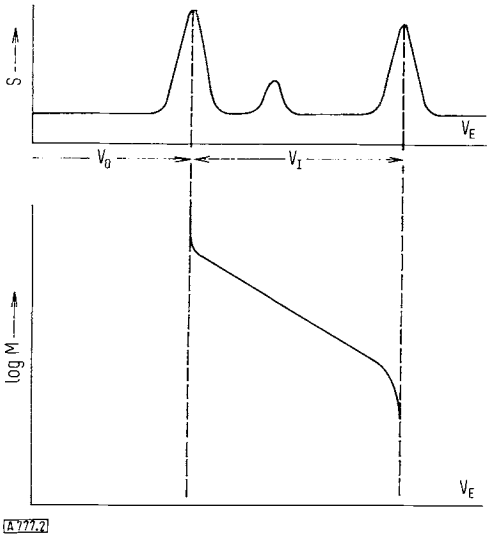

Fig. 2. Schematic gel-chromatographic elution pattern. For explanation see text. S = recorder deflection; V_E = elution volume.

The smaller the molecules the larger the proportion α of the total pore volume that is at their disposal. Molecules of different sizes therefore migrate at different speeds, the largest molecules leaving the column first, and the smallest leaving it last. The interactions between the solute and the gel phase (gel matrix and the trapped solvent) are not necessarily identical with those between the solute and the pure solvent, which leads to a substance-specific distribution between the external volume V_0 and the part α of the pore volume V_I that is available to the molecules on the basis of their size, this distribution being characterized by a partition coefficient K. Migration through the column is determined by a partition index G:

$$G = K \frac{V_0}{\alpha V_I} \qquad (1)$$

The polymeric network of the gel phase restricts the latter to the occupation by molecules of appropriate size, and so gel chromatography can be described as a form of network-limited partitioning.

On the assumption of multistage distribution, the following expression is obtained for the maximum of the elution curve V_{max}, analogously with other chromatographic techniques[19]

$$V_{max} = V_E = \frac{n-1}{n} V_0 \left(1 + \frac{1}{G}\right) \qquad (2)$$

where n is the number of equivalent distribution steps, *i.e.* the number of theoretical plates. Insertion of Eq. (1) into (2) gives

$$V_E = \frac{n-1}{n} \left(V_0 + \frac{\alpha}{K} V_I\right) \qquad (3)$$

For large values of n,

$$V_E = V_0 + \frac{\alpha}{K} V_I \qquad (4)$$

The following expression gives the mean deviation σ, which represents the distance between the point of inflection on the curve and a vertical line drawn from the saddle point of the peak (cf. Fig. 2):

$$\sigma = \frac{\sqrt{n-1}}{n} V_0 \left(1 + \frac{1}{G}\right) \qquad (5)$$

This can be simplified as follows with the aid of Eq. (3):

$$\sigma = \frac{1}{\sqrt{n-1}} V_E \qquad (6)$$

The number of theoretical plates is thus

$$n = (V_E^2/\sigma^2) + 1 \approx (V_E/\sigma)^2 \qquad (7)$$

We have that $b = 4\sigma$, where b is the peak width, *i.e.* the distance b along the base line between the tangents to the two points of inflection. It follows that

$$n = 16 (V_E/b)^2 \qquad (8)$$

This is the general equation for the number of theoretical plates in gel chromatographic columns, and it is usually checked with low-molecular compounds such as benzene, chlorobenzene, ethyl acetate, and octane, the resulting value depending on the substance used (cf. Section 3.3).

Furthermore, $\alpha/K = K_D$, where K_D is the apparent partition coefficient of *Flodin* and *Granath*[20]. Gel-chromatographic separation is essentially a function of the pore size and of the pore-size distribution, but the assumption of substance-specific interactions leads to a better understanding of the separation. The partition can be demonstrated experimentally in the separation of oligomers[21]. The assumption of network-based partitioning also explains why α/K is sometimes greater than unity[22,23], although the elution curves are symmetric.

Determann has pointed out that the gels have a large internal surface[14], and the adsorption isotherms are therefore linear over a fairly wide range. This assumption too could explain the experimental observations, but a number of gels are composed of individual solvated polymer

chains, crosslinked to form network units, and in such cases it is better to explain the concentration difference between the mobile and the accessible stationary phase by partitioning.

3.2. Calibration Equation

Gel chromatography permits the separation of mixtures of substances having different molecular dimensions, but it is not an absolute method and it requires calibration. *Determann* and *Michel*[24] have surveyed the systematic investigations of the relation between the elution volume and the molecular weight. In practice, use is generally made of the linear relationship between the elution volume and the logarithm of the molecular weight:

$$\log M = A - BV_E \tag{9}$$

where A and B are constants. There is a calibration plot for each homologous polymer series, so the interpretation of the experimental results by this technique is possible only if appropriate authentic samples are available. Whereas in the case of proteins one generally has at one's disposal well-characterized samples that are homogeneous in their molecular weight, synthetic polymers always show a certain molecular-weight distribution. However, the inhomogeneity in this respect ($\overline{M}_w/\overline{M}_n$) is often sufficiently low in the case of polymers made by anionic polymerization. Thus, it is possible to obtain polystyrenes[*] and polypropylene oxides[**] with a narrow molecular-weight distribution. Furthermore, polymers with a wide molecular-weight distribution may also be used for calibration if a correction is effected to eliminate perturbations due to concentration effects (cf. Section 3.3)[25]. However, well-characterized polymers are not available in all cases, and hence the need for a universal calibration equation. The latter also affords a better insight into the method, since it shows which factors determine the separation.

To find a universal calibration equation containing only parameters that are fixed by the compounds to be separated, the specific interactions between these compounds and the gel matrix must be negligible, *i.e.* K must be 1.

The experimental demonstration of specific interactions in the case of oligomers indicates that there is no universal calibration equation in this molecular weight range. However, gels used with oligomers differ greatly in their structure from gels used with polymers (cf. Section 4), and so there is no contradiction in finding a universal calibration equation for polymers that is at least approximately valid.

A calibration plot is obtained by plotting the elution volume against the logarithm of the length of the stretched molecular chains, account being taken of the bond angles and the bond lengths (stretched zigzag chains). This calibration plot should enable one to read off the molecular weight of any polymer after multiplication by the molecular weight per unit length[1,26,27]. However, several authors have shown that this relationship does not have a general validity[28–34]. The viscosity index $[\eta]$ and the diffusion coefficient D similarly cannot be used as calibrating parameters[29,30].

The size of polymer chains, which are coiled up in solutions, certainly has a great influence on the separation, but – as *Meyerhoff*[29,30] has shown – one cannot obtain a universal calibration equation by using the radius of gyration r_G and thus the mean distance between the chain ends. However, the following functions do represent approximately such a correlation.

$$M^{1/2} r_G = f(V_E) \tag{10a}$$

$$M^{1/2} [\eta]^{1/3} = g(V_E) \tag{10b}$$

According to *Benoit et al.*[35], the radius of equivalent hydrodynamic spheres r_{eq} can be used to devise a universal calibration equation. *Einstein*[36] showed that the macroscopic viscosity of a suspension of spheres depends on the volume fraction φ of the suspended spheres. If the polymer molecules in solution are regarded as such suspended spheres, the following relationship holds:

$$\varphi = (Nc/M)V_{eq} \tag{11}$$

where N is Avogadro's number, c is the concentration (in g/ml), and V_{eq} is the equivalent hydrodynamic volume of the polymer molecules. The bracketed ratio gives the number of polymer molecules per unit volume. Insertion of Eq. (11) into Einstein's equation gives

$$M[\eta] = kV_{eq} = k' r_{eq}^3 \tag{12}$$

where k and k' are constants and $[\eta]$ is the Staudinger index

$$[\eta] = \lim_{c \to 0} \frac{\eta - \eta_0}{\eta_0 c}$$

According to Eq. (12), a plot of log $M[\eta]$ against the elution volume V_E gives a universal calibration line within the experimental error (cf. Fig. 3). The validity of this relationship has been checked by several

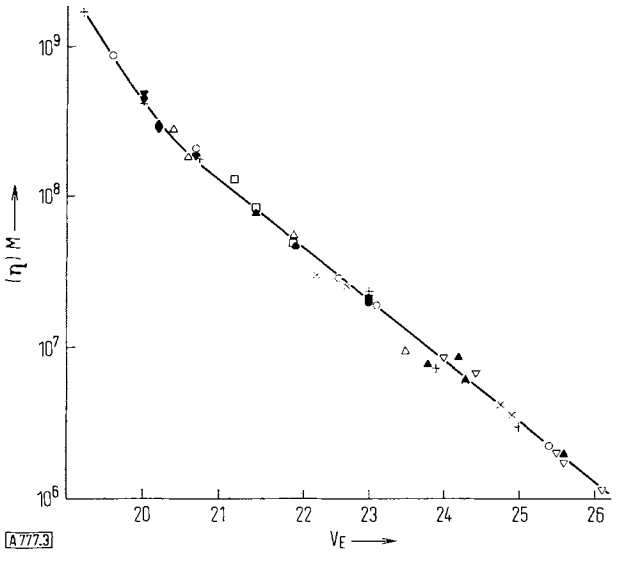

Fig. 3. Relationship between log $[\eta]$ M and V_E according to *Benoit* [42]. $[\eta]$ is given in cm³/g. and V_E in arbitrary units (siphons). ○ linear polystyrene; △ linear polymethyl methacrylate; ▽ linear polyvinyl chloride; □ linear polybutadiene; + comb-shaped polystyrene; × star-shaped polystyrene; ● comb-shaped graft copolymer of polystyrene and polymethyl methacrylate; ▲ graft copolymer of polystyrene and polymethyl methacrylate; ▼ polyphenylsiloxane; ■ linear statistical copolymer of polystyrene and polymethyl methacrylate.

authors [35, 37–42]. In particular, a calibration line obtained for linear polymers can also be used for branched ones, and so it is possible to obtain from the calibration line $M_{branched}$ for a polymer with a known viscosity $[\eta]_{branched}$, and to calculate $[\eta]_{linear}$ for the same M value [43]. The average number of branching points in the polymer molecule can be estimated from the $[\eta]_{branched}/[\eta]_{linear}$ ratio [44–47]. The molecular weight of an unknown sample (I) can be found from the calibration line obtained for polystyrene, provided that the constants appearing in Eq. (13) are known.

$$[\eta] = FM^s \tag{13}$$

According to Eq. (12), we then have that

$$F_I M_I^{s_I+1} = F_{II} M_{II}^{s_{II}+1} \tag{14}$$

or

$$\log M_I = \frac{1}{s_I+1} \log F_{II}/F_I + \frac{s_{II}+1}{s_I+1} \log M_{II} \tag{15}$$

Benoit et al. have shown that the specific interactions between a solute and the gel matrix can be neglected in the gel-chromatographic separation of polymers, but other authors [48–51] have found that log $M[\eta]$ does not always permit normalizing representation.

3.3. Separation Efficiency

Only a limited volume is available for the separation in gel chromatography, and the peak width for each substance determines how many substances can be separated within this limited volume. The following expression gives the resolution R, *i.e.* the extent of separation of two adjacent peaks [52]:

$$R = \Delta V_E/4\,\sigma \tag{16}$$

where ΔV_E is the difference between the two elution volumes, and the two peaks are assumed to have the same mean deviation σ.

Several authors have investigated the influence of experimental factors on the width of gel-chromatographic peaks [15, 50, 53–57], and have concluded that the relationships deduced for other chromatographic methods [58, 59] apply in gel chromatography as well.

The elementary processes i in the column make for a probability distribution of substances about the center of gravity of peaks whose variance σ_i^2 is additive:

$$\sigma^2 = \sigma_1^2 + \sigma_2^2 + \ldots\ldots \tag{17}$$

The height equivalent to a theoretical plate H is given by

$$H = l/n = \sigma^2/l \tag{18}$$

where l is the length of the column. The additivity of the contributions thus holds also for H:

$$H = H_1 + H_2 + \ldots \tag{19}$$

The particle size of the stationary phase is obviously decisive for the efficiency of the separation, but its influence can be eliminated by introducing reduced quantities [15, 58, 59]:

$$h = H/d_p;\ \nu = u\,d_p/D \qquad (20)$$

where h is the reduced plate height, ν the reduced velocity, d_p the diameter of the gel particles in the swollen state, u the linear elution velocity of the mobile phase, and D the diffusion coefficient of the solute in the mobile phase. When these reduced quantities are used, the van Deemter equation becomes

$$h = a + b/\nu + c\nu \qquad (21)$$

The three terms on the right-hand side are due to the irregular solvent flow, the diffusive broadening of the solute zone, and the exchange process. The quantity a describes the regularity of the packing: for good packing, its value is 2–3. The particle size distribution has a strong influence on packing regularity, and for good packing the standard deviation should not exceed 5 % of the mean particle diameter. However, fairly small particles can be separated only with difficulty in such narrow limits. Even when the particle size is uniform, one obtains a statistical packing of spheres ($V_0 \approx 0.37 \times$ total column volume) instead of a close packing of spheres ($V_0 = 0.26 \times$ total column volume) [60].

The quantity b is due to the diffusive broadening of the zones. The greater the elution velocity the less significant is the effect of b, whose value varies between 0.8 and 1.8 [61]. Since in the usual gel-chromatographic experiments ν is greater than 10, and mostly even greater than 100, the effect of the longitudinal diffusion can be neglected.

Only the exchange process is responsible for c. This must be investigated with substances that do not participate in partitioning, since in this case c is zero. For reduced velocities $\nu > 10$, the reduced plate height must then be constant, *i.e.* independent of the elution velocity.

According to *Giddings* [62], the terms contributing to the irregularity of the packing and the irregularity of the zone profile in the mobile phase are not independent quantities, and their variance σ^2 is not additive but coupled.

$$h = B/\nu + C_s\nu + \sum_i \frac{1}{1/A_i + 1/C_{m_i}\nu} \qquad (22)$$

where B, C_S, and A_i correspond respectively to b, c, and a in the van Deemter equation; C_{mi} represents the substance exchange in the mobile phase.

Giddings differentiates between five perturbing effects ($i = 5$), but only four of these are significant for gel chromatography (cf. Fig. 4). The theoretical estimation of the magnitude of these effects is uncertain. The magnitude of the perturbations that are responsible for the sum term in Eq. (22) varies closely with the experimental conditions and mainly with the quality of the packing. The trans-column effect should increase with the column cross-section, but experiments show that it can be kept negligibly small even when the column diameter d is 5 cm ($d/d_p \approx 10^3$) [63, 64].

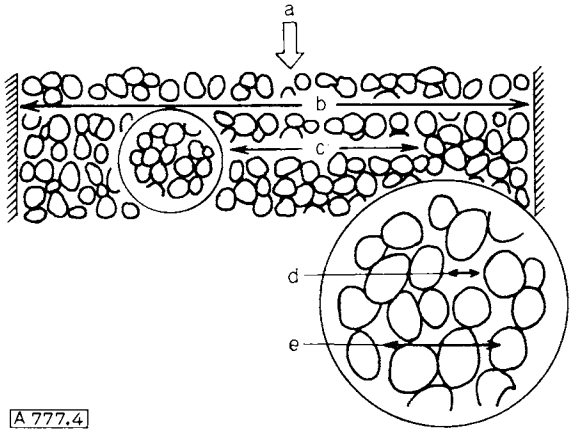

Fig. 4. Magnified cross-section of a chromatographic column. Region of various exchange processes (after *Giddings* [62]).
a = direction of flow; b = trans-column effect; c = long-distance interchannel effect; d = intrachannel effect; e = short-distance interchannel effect.

Fig. 5 shows the variation of the reduced plate height $h = H/d_p$ with the reduced velocity $\nu = ud_p/D$ for two polyvinyl acetate gels having different particle sizes (the same type of graph is obtained for polystyrene gels). The use of reduced quantities leads to a normalized representation of the separating efficiency, this representation being independent of the chemical nature of the gel and the sample, the particle size of the gel, and the flow velocity. Deviations from this state of affairs occur in the case of homogeneously cross-linked gels (cf. Section 4.1) in which the amount of the cross-linking agent exceeds about 5 %: here the graph varies with the substance, though not with the particle size of the gel [56, 57]. In the case of substances that are excluded from the gel and that thus do not participate in the separation the width of the peaks is independent of the elution velocity, as predicted by theory [15, 57].

The gels used always have more than one particle size, and generally the arithmetical mean of these particle sizes is used for Eqs. (21) and (22). Since $H \sim d_p^2$ for fairly large reduced velocities, we have the following approximate equality on the assumption that Eq. (19) can be used:

$$\bar{d}_p \approx \sqrt{\Sigma m_i d_{pi}^2}$$

where m_i is the fraction with a particle diameter i. The approximation is within the limits of error when the particle size distribution is very narrow, but otherwise

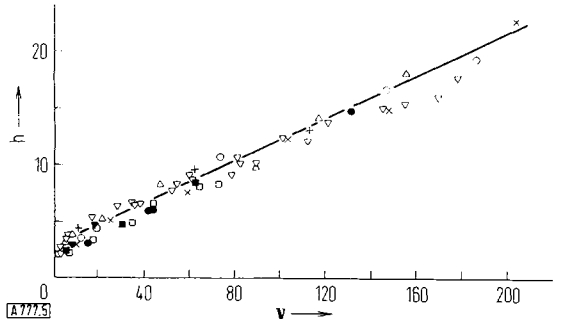

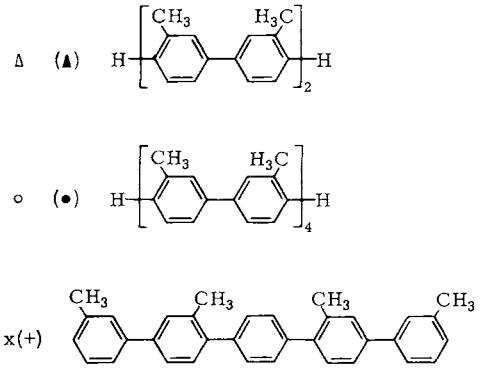

Fig. 5. Reduced separating efficiency of polyvinyl acetate gel cross-linked with 5 mole-% of butanediol divinyl ether; THF; methyl-substituted *p*-oligophenylenes [15]; $\bar{d}_p$ = 0.0191 cm (0.0382 cm). □ (■) benzene; ▽ (▼) *m*-bitolyl.

a considerably greater value is obtained for d_p. In a comparison of gels having the same mean particle size (arithmetical mean) but different particle size distributions, the gel that has a broader particle size distribution is found to give the less efficient separation.

In gel chromatography substances emerge from the column in decreasing order to molecular weight. Since the diffusion coefficient increases with decreasing molecular weight, the reduced velocity decreases as the elution proceeds at a constant linear elution velocity. As a result, the reduced plate height decreases and the efficiency of the separation increases. This explains the well-known observation that assuming a constant number of plates the bands of the last compounds to emerge are too narrow compared to the compounds emerging first from the gel column.

The separation of polymers is accompanied by perturbations that are absent in the elution of low-molecular compounds. When the molecular weight is high, the elution volume varies linearly with the amount of the sample [65, 66], and this effect becomes more conspicuous as the molecular weight increases.

3.4. Evaluation

With substances having a single molecular weight, the latter can be determined from the elution curve maximum and the appropriate calibration plot (cf. Fig. 2). When a differential refractometer is used, the absolute or relative quantities are found by integrating the recorded curve, since the response is proportional to the concentration. At high molecular weights the dependence of the refractive index on the molecular weight can be neglected, provided that there is a sufficient difference between the refractive index of the solute and that of the solvent. When a usual single-beam UV apparatus is used, the error in the determination of the quantities is somewhat greater, owing to the logarithmic concentration dependence and the necessary subtraction. Polymers give a broad band that can be regarded as a close succession of superimposed Gaussian distribution curves. In the simplest case the mean molecular weight is found from the maximum of the peak and the calibration curve. However, this mean is correct only when the molecular weight distribution is narrow, otherwise it is between $\overline{M}_w$ and $\overline{M}_n$ [67]. For polymers with a Schultz-type distribution [68], the peak maximum gives $\overline{M}_w$ [67,69].

The polymer is further characterized by its inhomogeneity U (= $\overline{M}_w/\overline{M}_n$), and *Bly* [70,71] has shown experimentally that the peak width b of a polymer is proportional to the inhomogeneity, *i.e.*

$$U_1/b_1 = U_2/b_2 \qquad (23)$$

This means that the inhomogeneity of an unknown sample can be found from that of a known one. The validity of Eq. (23) has been checked for U = 1.3–3.6, and the maximum error for U/b has been found to be 10 %. A better approximation is obtained by taking into account the ordinate values in a diagram of b against U (cf. Fig. 6). The peak width of polymers is

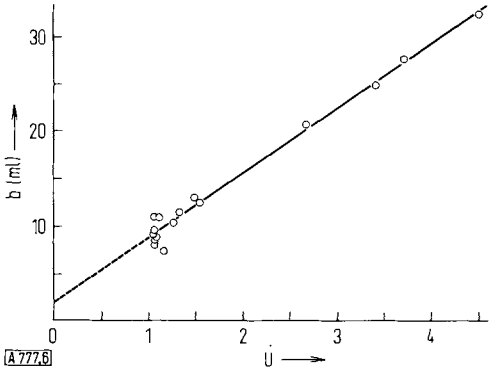

Fig. 6. Variation of the peak width b with the inhomogeneity U of polymers on the basis of *Bly*'s values [71].

determined by two factors: that of a polymer with U = 1 (ordinate value for U = 1) and the molecular weight distribution. Eq. (23) can be used if a) the polymer has a normal distribution; b) the chemical constitution is uniform; c) the peak lies in the linear part of the semilogarithmic calibration curve; and d) the column has a high separating efficiency.

[71] *D. Bly,* Analytic. Chem. *41,* 477 (1969).

The inhomogeneity can also be determined if the polymer sample and the reference sample have different calibration curves [70,71].

The molecular weight distribution can be calculated from the recorded curve by stepwise integration [28,30,72] provided that the resolution [Eq. (16)] is very good. As a result of the finite peak widths, however, the recorder deflection is a function not only of a substance with a given molecular weight, but also of the adjacent Gaussian curves. The finite peak width has been taken into account in the methods of *Tung* [73–75], *Hess* and *Kratz* [76], and *Pierce* and *Armonas* [77] with the aid of a computer programme [78,79]. By determining the moments of the corrected chromatogram, the mathematical oscillations in the latter can be eliminated [80].

4. The Stationary Phase

4.1. Preparation

Spherical particles give a good packing. The crosslinked copolymers used as stationary phases are usually prepared by bead polymerization. For this purpose, the monomer is dispersed mechanically in droplet form in water, and the resulting suspension is stabilized with a protective colloid during the polymerization [81]. The effects of the conditions on the particle size of the polymer have been investigated by *Hopff et al.* [82,83].

When a monovinyl compound is polymerized in the presence of a divinyl compound, the amount of the cross-linking agent determines the mesh size of the cross-linked copolymer. In the dry state the latter is not porous, but it can be swollen, as a result of which the molecular chains are solvated and form a loose, statistical network. The porosity is therefore present only in the swollen state (swelling porosity).

The order of magnitude of the mean range in which these gels are used is determined by the mean pore size, which in turn is a function of the amount of the crosslinking agent incorporated. It follows that these gels are in the statistical sense homogeneously crosslinked. The exclusion limit, *i.e.* the excluded molecular weight [*] increases as the amount of the crosslinking agent is decreased. However, such gels are only suitable for the separation of oligomers. As the amount of the crosslinking agent is decreased, the extent of swelling increases, and the mechanical strength of the gel falls off. Similar problems arise in the preparation of ion exchangers for large ions.

This led to polymerization techniques giving polymers with a heterogeneous structure and a high mechanical strength [10,84,85]. In these techniques, a crosslinkable monomer mixture is polymerized in the presence of inert and soluble components that can be removed from the end product. The inert components must not polymerize or be incorporated in the network, but they must be miscible with or soluble in the monomer. In the case of bead polymerization, the inert component is advantageously insoluble or only sparingly soluble in water. These conditions are fulfilled by numerous organic substances. Organic liquids that act as swelling agents or precipitants for the resulting crosslinked polymer are generally used. Polymers can also be used as the inert component [84,86].

When a mixture of a monovinyl compound and a divinyl compound is polymerized and a certain conversion is reached, gelling sets in at the gel point, where the viscosity and the molecular weight ($\overline{M}_w$) tend to infinity. Each molecular chain has here on average one crosslinking site. The resulting crosslinked polymer has a limited ability to absorb solvents. Therefore, when the amount of the inert component exceeds the absorption capacity of the polymer, phase separation should occur (on the assumption that the system is in thermodynamic equilibrium).

The type of phase separation depends essentially on when gelling sets in. When the polymerizing droplets form a loose network and the crosslinking becomes gradually more and more pronounced, the network may contract, expelling all the inert component (syneresis). The phase separation may occur before the gel point is reached. As in precipitation polymerization, the crosslinked copolymers (microgels) separate out and then coalesce into a porous polymer during further polymerization. In bead polymerization this process occurs in each monomer droplet. The inert component can be removed from the crosslinked polymer *e.g.* by steam distillation after the polymerization. The polymer thus obtained is often porous

even in the unswollen state (permanent porosity), and it possesses in addition swelling porosity. Owing to the heterogeneous constitution of the product, this technique is called heterogeneously crosslinking polymerization. The amount of the crosslinking agent and the nature and amount of the inert component determine mainly the heterogeneity of the product.

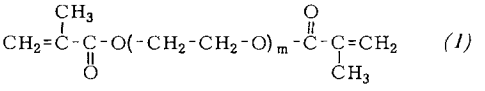
However, the particle size distribution of the bead polymerized products obtained by these two methods is too wide for gel-chromatographic purposes. When the particle size exceeds 50 μ, the gel is prepared by wet screening, while smaller particles are separated by sedimentation. According to Stokes' law, the sedimentation velocity v is given by

$$v = \frac{2\,\Delta\rho\, r^2\, g_n}{9\eta} \qquad (24)$$

where $\Delta\rho$ is the difference between the density of the polymer and that of the medium, r is the radius of the polymer beads, g_n is the acceleration due to gravity, and η is the viscosity of the medium.

When a constant liquid stream is produced with a piston pump or a peristaltic pump, the linear flow velocity decreases as the square of the diameter of the vessel. The sedimentation is generally carried out in water. In the case of copolymers having a permanent porosity, the surface tension of water is reduced with the aid of surfactants. Gels with a particle size of 40—80 μ are used for most separations.

4.2. Hydrophilic Gels



The rapid development of gel chromatography owes much to commercial crosslinked dextrans [86a]. Dextrans dissolved in water are crosslinked with epichlorohydrin in the presence of alkali. The crosslinked structure varies with the amount and the molecular weight of the starting dextran and the amount of the crosslinking agent. The commercial products permit a separation of proteins with molecular weights of up to about 5×10^5.

There are also several commercial types of acrylamide crosslinked with *N,N'*-methylenebis(acrylamide) [86b]. These too permit the separation of samples with molecular weights of up to about 5×10^5.

The porous structure may also be brought about by crosslinking with the aid of secondary valences, and such gels can be made from agarose [86a,86b]. *Determann* has described the preparation of cellulose gels by regenerating viscose [87]. Both gels can be made with exclusion limits of over 10^6.

Except for *Determann*'s cellulose gel, the hydrophilic gels described here have a large gel bed volume and thus a low mechanical strength at high exclusion limits, which hampers separation under pressure.

Hydrophilic gels with a high mechanical strength, obtained by heterogeneously crosslinking polymerization, can be prepared by subjecting polyethylene oxide dimethacrylate *(1)* to bead polymerization in the presence of inert components [88]. Substances capable

(1)

of crosslinking are formed in the reaction between methacryl chloride and the terminal OH groups of polyethylene oxide, which is soluble in water up to a high molecular weight. The exclusion limit can be varied over a wide range by varying the molecular weight of the polyethylene oxide and the nature and the amount of the inert component (cf. Table 1). Crosslinked polyethylene oxides can be used in water and organic solvents. Table 1 also shows for comparison the exclusion limits for polystyrene, as determined in THF.

Fig. 7 shows the superimposed elution curves for dextrans. The shape of curve 4, obtained for dextran

Table 1. Gel-chromatographic data for gels prepared from dimethacrylates of polyethylene glycols and polyethylene oxides [88]. V_{Sch} = bulk volume; V_G = specific gel bed volume; M_{lim} = exclusion limit (molecular weights).

Monomer (weight ratio)	Inert components (Part by volume in the total organic phase)		V_{Sch} (ml/g)	V_G (ml/g)		M_{lim}

S = recorder deflection.

with $\overline{M}_w \approx 2\times10^6$, is due to a wide molecular weight distribution. (Hydrophilic gels are summarized in [2,8,14].)

4.3. Organophilic Gels

It was logical to utilize the experience gained with crosslinked dextrans and to convert these hydrophilic gels into gels that swell in organic solvents. This has been done by reacting the OH groups, and the preparation and the use of acetyl [8], methoxy [89], and urethane derivatives [5] have been described. A hydroxypropyloxy derivative is known commercially as Sephadex LH 20® [*]. However, these reactions can be carried out easily only in the case of gels with a low exclusion limit (Sephadex G 25® and Sephadex G 50®).

The homogeneously crosslinking copolymerization of styrene with divinylbenzene [5,90], of methyl methacrylate with glycol dimethacrylate [5,88,91], and of vinyl acetate with divinyl adipate [92] gives gels that are suitable for the separation of oligomers. Fig. 8 shows the elution data obtained with polyvinyl acetate gels of different degrees of crosslinking; the straight lines run almost parallel to one another, which means that the elution-volume difference is roughly the same in all the gels at a given difference in the molecular weights. Therefore, the resolution at low molecular weights cannot be improved considerably by increasing the degree of crosslinking. Owing to the less intense swelling, the amount of the crosslinked copolymer needed for packing the column increases with the concentration of the crosslinking agent. This reduces the volume that is available for the separation.

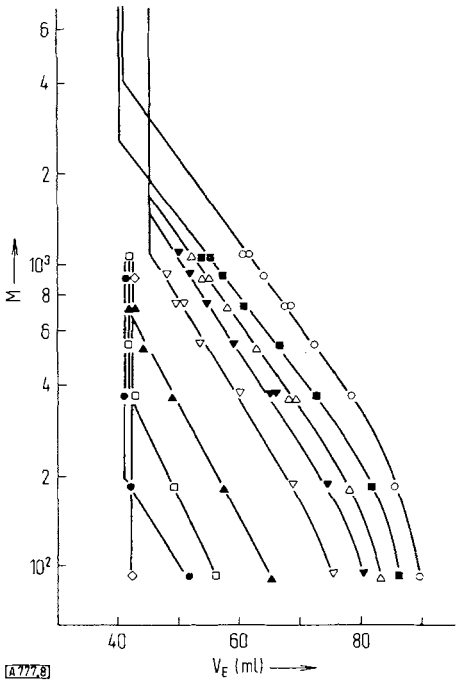

Fig. 8. Elution pattern of homogeneously crosslinked copolymeric vinyl acetates [92] in THF. Amount of divinyl adipate (in wt-%): ○ 0.5; ■ 1; △ 2; ▼ 3; ▽ 5; ▲ 10; □ 20; ● 30; ◇ 63. Samples: methyl-substituted *p*-oligophenylenes.

The exclusion limit is proportional to the specific gel bed volume, irrespective of the chemical nature of the gel. This indicates that the structure of all these gels is similar. The chain segments are pushed apart roughly to the same distance in swelling to a certain degree, so that similar pore size distributions are obtained.

The mechanical strength determines the range of applications of these gels. Gels with a very low degree of crosslinking swell heavily, and the column tends to clog even under a low pressure. However, gels with an exclusion limit of about 4000 can still be used without considerable difficulty.

Moore's use of heterogeneously cross-linked polystyrene gels constituted a great advancement [1], and these gels are now available commercially [*]. Gels suitable for practically any purpose can be obtained by an appropriate choice of the polymerization conditions. Polymethyl methacrylate gels [88,93,94] and polyvinyl acetate gels [92] can be prepared with a similarly wide range of modifications. Polyvinyl acetate gels are also on the market [**].

The copolymerization of styrene with divinylbenzene in the presence of a good solvent such as toluene and diethylbenzene gives gels with exclusion limits of up to about 2×10^3 (cf. Table 2). If the solvent power is reduced by adding a nonpolar precipitant, the exclusion limit first increases and then decreases. This phenomenon has not been observed with polar precipitants; in this case, one obtains very high exclusion limits, which should sometimes be regarded only as a

formal quantity on account of the size of the corresponding molecular coil. The elution volume V_0 can then be determined with a crosslinked polymer obtained by emulsion polymerization [92]. Electron micrographs reveal the heterogeneity of such copolymers; thus, Figs. 9a and 9b show clearly the different structures obtained by the use of a good solvent and a precipitant [95,96].

Polystyrene gels containing 55 % of a crosslinking agent still possess a little swelling porosity. The internal surface area of these gels is sometimes over 500 m^2/g [97].

A777.9a

A777.9b

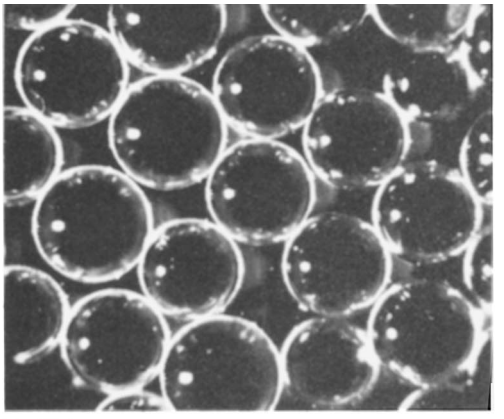

Fig. 9. Electron micrographs of heterogeneously crosslinked styrene-divinylbenzene copolymers, prepared in the presence of toluene (Fig. 9a) and heptane (Fig. 9b), according to *Millar* [95,96]. Magnification *ca.* 80000 ×.

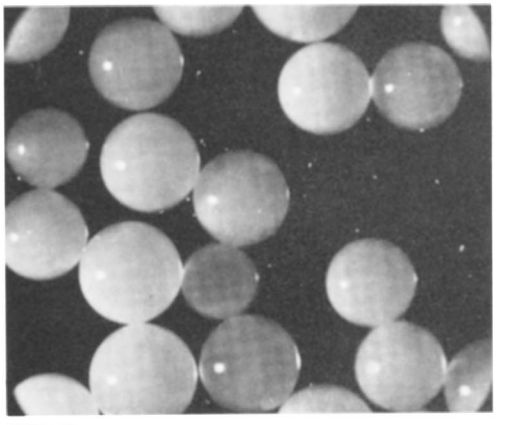
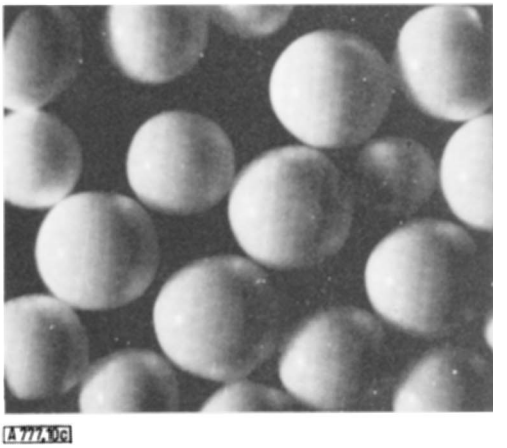
[95] *J. R. Millar, D. G. Smith, W. E. Marr,* and *T. R. E. Kressman,* J. chem. Soc. (London) *1963,* 218.



[96] *J. R. Millar, D. G. Smith,* and *T. R. E. Kressman,* J. chem. Soc. (London) *1965,* 304.

[97] *W. Heitz,* Angew. makromolekulare Chem. *10,* 115 (1970).



Heterogeneously crosslinking polymerization leads to gels with high exclusion limits in the case of vinyl acetate gels as well, and the heterogeneity of such networks can be seen even under an ordinary microscope (cf. Fig. 10). As the heterogeneity increases, the crosslinked copolymers at first become opaque, though retaining a certain surface gloss, and finally assume a chalky appearance.

A777.10a

A777.10b

A777.10c

Fig. 10. Micrographs of polyvinyl acetate gels with homogeneous cross-linking (Fig. 10a), and polyvinyl acetate gels crosslinked heterogeneously with 20 vol-% (Fig. 10b) and with 30 vol-% (Fig. 10c) of *n*-octane. Magnification 175 ×.

In the case of vinyl acetate gels and a good solvent (*e.g.* butyl acetate) as the inert component, there is no permanent porosity even when 40 % of divinyl adipate crosslinking agent is used. The apparent density ρ_0, which is the density of the polymer matrix and of the air enclosed in the pores,

is not affected by the addition of butyl acetate, *i.e.* no pores are present in the dry state. If *n*-octane is added, however, the apparent density greatly decreases within relatively narrow limits. The fact that the addition of butyl acetate does not alter the apparent density does not mean that the network is not heterogeneous. Between 40 and 50 vol-% of butyl acetate there is a pronounced jump in the exclusion limit, indicating that the gels are heterogeneous. However, this heterogeneity cannot be demonstrated either under the light microscope or through the apparent density.

The permanent porosity of crosslinked copolymers does not mean that the exclusion limit is high (Fig. 11). Although the greatest change in density occurs between 30 and 40 vol-% of added octane, the exclusion limit once more decreases. These gels, which lie to the right of the maximum in Fig. 11, all show a similar behavior. They are very brittle and can be readily made into a powder. Their gel-chromatographic behavior affords an insight into their structure (Fig. 12).

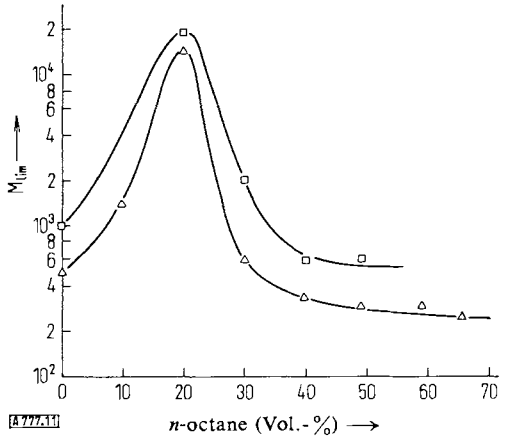


Fig. 11. Exclusion limit M_{lim} of heterogeneously crosslinked copolymers of vinyl acetate and divinyl adipate as a function of the *n*-octane concentration (on the total organic phase). Concentration of crosslinking agent: □ 10 wt-%; △ 20 wt-% (on the monomer mixture).

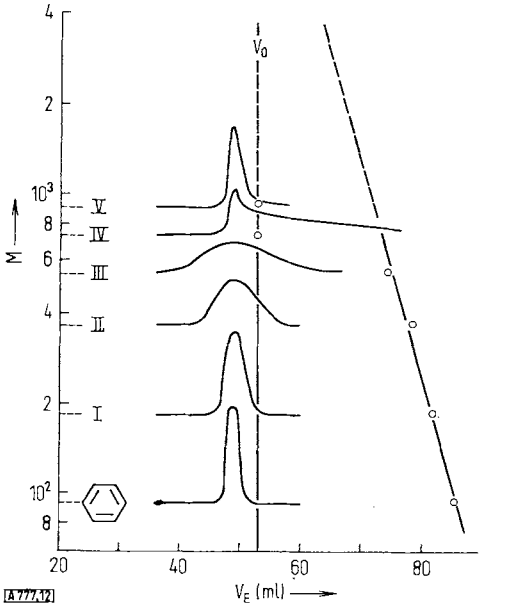

Fig. 12. Elution behavior of a heterogeneously crosslinked copolymeric vinyl acetate prepared with 40 vol-% of *n*-octane (on the total organic phase) and 10 wt-% of divinyl adipate (on the monomer mixture). The shape of the peaks is given in the middle.

While an exclusion limit of 10^4 would be extrapolated from the elution volume of the low-molecular compound, all the compounds beyond a molecular weight of about 800 appear at V_0. The shape of the elution curves is particularly informative: only compounds with very small or very large molecules give symmetric peaks, while compounds with intermediate molecular dimensions have peaks that at first broaden and then become unsymmetric as the molecular weight increases. This phenomenon is to be expected when the establishment of the equilibrium is greatly perturbed [98,99].

To explain these characteristics, one can assume that the gel particles have a heavily crosslinked surface. Such a surface is formed when the microparticles arising in the polymerization have a greater affinity for water than the inert component, and when they consequently accumulate at the phase boundary. These phenomena have not been observed with polar inert components.

5. Optimization of the Method

Chromatographic methods can be optimized with respect to the resolution or the time of the analysis. The resolution R [Eq. (16)] may be adjusted *via* the difference in the elution volumes and the peak width of the substances. According to Eq. (9), the following relationship holds for the linear part of the log M *vs.* V_E function:

$$\frac{d\,V_E}{d\,M} = -\frac{1}{BM} \qquad (25)$$

On the basis of Eq. (16), we obtain

$$\Delta\,M/M = -\,R\,4\,\sigma\,B \qquad (26)$$

When a homologous polymer series is separated into fully resolved peaks ($R = 1$), the limit is given by

$$P = -1/(4\,\sigma\,B)$$

where P is the degree of polymerization. The experimental peak width is approximately constant in the case of a homologous polymer series. The usual experimental arrangements should give a complete separation up to about the octamer. However, a satisfactory quantitative determination is possible even at $R = 1/2$, and the oligomers can still be isolated in the pure state if an appropriate fraction is chosen. For the separation of oligomers, the exclusion limit should be about 2000.

Polymers have small diffusion coefficients; the reduced velocities are therefore high, so that $H \sim d_p^2 u$. When the linear elution velocity is doubled, a certain separating efficiency can be maintained only by

[98] *H. Vink*, J. Chromatogr. *18*, 25 (1965).

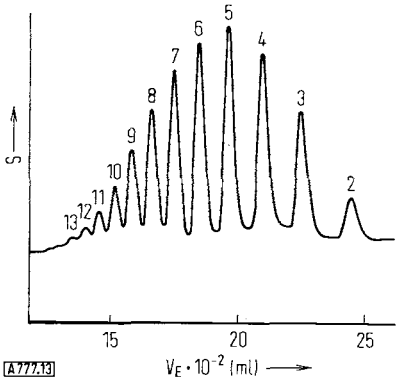
[99] *T. C. Laurent* and *E. P. Laurent*, J. Chromatogr. *16*, 89 (1964).

doubling the length of the column. This means that when using a constant total volume of the columns only the total time of analysis – and not the number of columns – is important for the separation of polymers. Optimization with respect to the time of the analysis is possible here by a reduction of the gel particle size. Thus, a twofold reduction in the latter permits a fourfold reduction in the length of the column l at the same linear elution rate and separating efficiency. The working pressure is the same in the two cases, since the pressure drop along the column is given by $\Delta p \sim l/d_p^2$.

6. Examples of Separation

6.1. Oligomers

The separation of oligomers [63,64] is both of scientific and of technical importance. Single molecular-weight oligomer samples are ideal model substances for numerous investigations. As regards technical polymers, it is important to know the oligomer content; some technical products (epoxy resins and surfactants) consist almost entirely of oligomers.



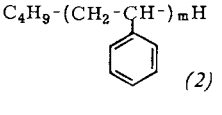


Fig. 13. Gel-chromatographic separation of oligostyrenes $C_4H_9(CH_2CHC_6H_5)_mH$ [64]. The numbers by the peaks give the degree of polymerization m. Column: 200×5 cm; eluent: THF; polystyrene gel (2 % of divinylbenzene), $\bar{d}_p$ = 74 μ; $\overline{M}_n$ = 583; S = recorder deflection.

Fig. 13 shows the separation of a polystyrene with $\overline{M}_n$ = 583 (determined by vapor pressure osmometry). The polymerization was initiated with the aid of butyllithium, and the oligomers had structure *(2)*. The indicated assignment of the peaks was confirmed by isolating the oligomers and

(2)

determining their molecular weights, as well as by the admixture of hexylbenzene (n = 1). When the indicator sensitivity was adjusted to the same value for all the oligomers, integration of the peak areas gave $\overline{M}_n$ = 580. In the case of a polystyrene with $\overline{M}_n$ = 1050, obtained analogously, the higher-molecular fraction was not resolved in the chromatogram, although it was still well below the exclusion limit of the gel.

The separation of technical polyethylene oxides is another interesting example. Monodisperse oligomeric ethylene oxides are available up to a degree of polymerization of 45 [100], and so the peaks can be identified with certainty. Technical polyethylene oxides were separated into their oligomers in the molecular-weight region between 300 and 400 (Fig. 14a). The molecular weight distribution, obtained for the oligomers by taking into account the different indicator sensitivities, was narrower than calculated by *Flory*'s method in the case of a Poisson distribution [101]. This agrees with *Törnquist*'s [102] gas-chromatographic findings and with results obtained by countercurrent

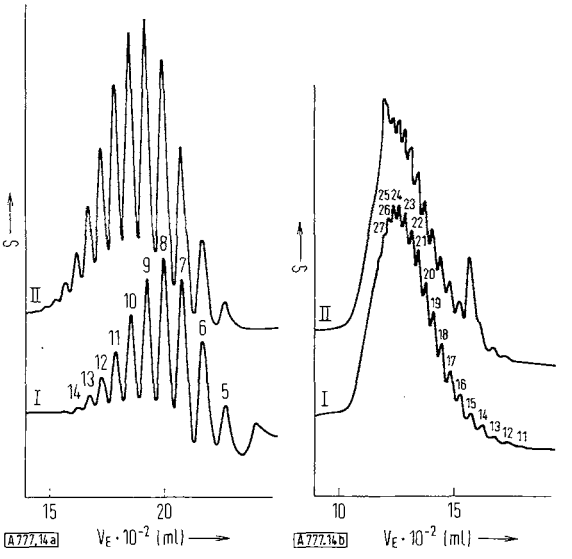

Fig. 14. Gel-chromatographic separation of oligomeric ethylene oxides. For the experimental details, see Fig. 13. Fig. 14a: $\overline{M}_n \approx 300$ (curve I); $\overline{M}_n$ = 430 (curve II). Fig. 14b: $\overline{M}_n \approx 1000$ (curve I); $\overline{M}_n \approx 1000$ admixed: terms with degrees of polymerization 15 and 27 (curve II)

distribution [103]. The condition for the use of *Flory*'s equation, namely that all the end groups should have the same reactivity, is evidently not fulfilled by polyethylene oxides in this range of molecular weights. The molecular weight distribution obtained would be explained by a higher reactivity of the low-molecular oligomers of the homologous series.

The unresolved background increases with the molecular weight (Fig. 14b). The peaks that can be assigned to these oligomers can be increased by mixing these oligomers in the pure state. Polyethylene oxides with $\overline{M}_n \approx 1000$ are no longer resolved into isolated peaks at the high-molecular end.

The gel-chromatographic separation of surfactants permits conclusions to be drawn about the molecular structure. Fig. 15a shows the separation of a technical fatty alcohol polyglycol ether that was prepared by the addition of ethylene oxide to a higher alcohol. This can be easily seen from the sharp termination of the chromatographic curve. The elution of several higher alcohols indicates that this last peak has the same elution volume as dodecyl alcohol. Fig. 15b shows the separation of a technical alkylphenol polyglycol ether, the alkylphenol moiety carrying on average about ten ethylene oxide units. The relatively poor resolution indicates that the starting phenol was not homogeneous.

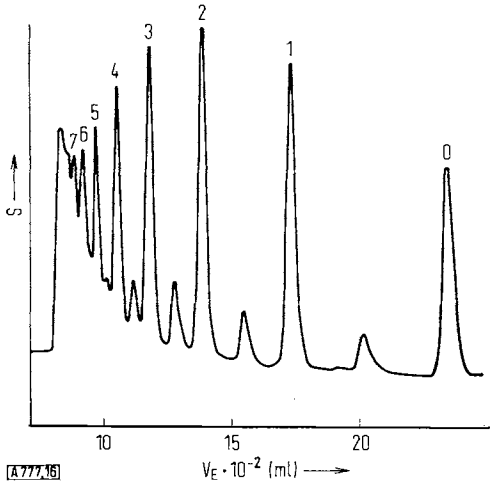
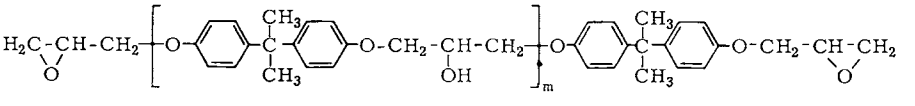
Technical polyepoxides often have a low molecular weight and can be separated into their constituent oligomers. Fig. 16 shows the chromatogram for a polyepoxide pre-





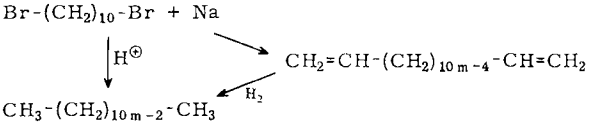


Fig. 16. Gel-chromatographic separation of a polyepoxide made from biphenol A and epichlorohydrin. For the experimental details see Fig. 13. The numbers by the peaks give the value of m in the homologous series of polymers.

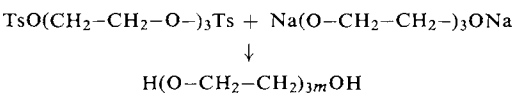
pared from bisphenol A and epichlorohydrin[104]. The alternation of small and large peaks indicates the presence of two series of oligomers, the main series corresponding to compounds with two epoxy end groups.



[104] *D. Braun, H. Cherdron*, and *W. Kern*: Praktikum der makromolekularen organischen Chemie. Hüthig, Heidelberg 1966.

The above examples show that it is not possible to isolate gel-chromatographically a compound with a degree of polymerization of *e.g.* 50 from a continuous homologous series of polymers. However, such monodisperse polymers can be obtained by separating a discontinuous homologous series of polymers, *i.e.* a series comprising only terms with certain multiples of the degree of polymerization. Such a molecular weight distribution should be ensured by appropriate synthesis. The first example of this is due to *Carothers*[105], who condensed 1,10-dibromodecane and thus obtained a mixture of alkanes in each of which the number of carbon atoms could be only a multiple of 10. A side reaction led to products with terminal

double bonds, which could be catalytically hydrogenated into alkanes[106]. The alkanes could be separated up to $C_{90}H_{182}$. The use of 1,20-diiodoeicosane gave a mixture of alkanes which could be identified in the chromatogram up to $C_{120}H_{242}$[107].

By *Williamson*'s ether synthesis, triethylene glycol can be converted into a mixture of polyethylene oxides whose degrees of polymerization are all multiples of 3.

The nonaethylene glycol can be separated from this mixture by molecular distillation. A second ether synthesis gives a mixture of components whose degrees of polymerization are all multiples of 9[100]. Preparative gel chromatography of this mixture permits the oligomers to be isolated up to $m = 45$.

6.2. Polymers

Polymers can be separated gel chromatographically when the polymer has a suitable solvent in which the stationary phase swells to a sufficient extent. Gels with a permanent porosity contain pores even in precipitants, but adsorption-induced perturbations are then obtained fairly often. Table 3 shows the working conditions for some polymers.

Chemistry and Logical Structures

By Ivar Ugi, Dieter Marquarding, Hans Klusacek, George Gokel, and Paul Gillespie[*]

The utility of the basic structures of modern mathematics for chemistry is discussed; general set theory, topology, and group theory are shown to pervade almost all static and dynamic aspects of chemistry. Chemical analogy, the systematic classification of molecules and a corresponding nomenclature system, conformational transformations, polyhedral rearrangements, and the relations between starting materials, transition complexes, and final products of chemical reactions are examples of where we apply the elements of modern mathematics to the solution of chemical problems.

"Die Moral dieser Geschichte ist offenkundig: man nehme solche vorläufigen kombinatorischen Schemata wie die Valenzdiagramme nicht zu wörtlich, so nützlich sie auch als erste Führung in einer scheinbar zusammenhanglosen Masse von Tatsachen sind. Von einem mit ein paar scharfen Strichen entworfenen Bild der Wirklichkeit kann nicht erwartet werden, daß es der Vielfalt all ihrer Schattierungen adäquat sei. Gleichwohl muß gerade der Zeichner den Mut haben, die Linien kräftig zu ziehen." – Hermann Weyl, on the chemical bond[1]

1. Introduction and General Considerations

1.1. Chemistry and Mathematics

Mathematics has recently undergone substantial reforms. A Paris group of mathematicians formalized the new approach to mathematics (see Section 1.3.1.) in their book "Eléments de Mathématique" published under the pseudonym *Nicolaus Bourbaki*[2i]. The organization of classical mathematics, which was strongly influenced by its applications, is now being oriented towards generating mathematics from the "basic structures", *i.e.* the *algebraic structures*, the *ordered sets*, and the *topological spaces*. The ideas of the Bourbaki group can be considered a consequential extension of the formalistic approach initiated by *Hilbert*.

Pure mathematics, from the contemporary viewpoint, is a general, hypothetical, deductive formalism of relations. This formalism, which may serve an objective, is created without any consideration of the objective. It provides us with a theory of logical structures which can be used as models for some characteristic properties of reality. It is our intention to develop a mathematical concept of molecules, confined and prejudiced as little as possible by our experience.

The relations between objects, rather than the objects themselves, are the primary concern of science. Usually, spatial relations are *prima facie* defined on the basis of the Euclidean space of our experience. It is, however, as physics illustrates, often advantageous for the solution of certain problems to use purely mathematical concepts of space, which have in common with Euclidean space only some formalistic characteristics.

The question of whether or not a certain mathematical concept provides the basis for the most suitable model of a phenomenon is consciously asked in physics. In chemistry, however, three-dimensional Euclidean space and classical mathematics have been so strongly favored by tradition that the use of the more abstract mathematical structures was confined to those who considered chemistry an extremely complicated special case of physics, and accordingly treated chemical problems with the advanced and sophisticated methods of theoretical physics. The use of mathematics in chemistry has been oriented almost exclusively towards generating numerical data in order to test the validity of some mathematical model of an experimentally observed phenomenon. Little use has generally been made of the fact that mathematics is formalized logical thought and can be used directly to gain insight into the intrinsic logical structure behind chemical problems.

The coming generation of scientists will have grown up with modern mathematics and it is safe to predict that this generation will use these fundamental concepts to an extent which we cannot even imagine. The present paper attempts to outline some aspects of chemistry where structure-oriented mathematics offers a promising approach.

1.2. Chemical Topology

Among the mathematical structures, the group and topological space have the greatest potential for chemistry. The striking success of group theory in solving problems which are related to symmetry is well documented. Group theory is also a powerful mathematical tool for dealing with such deviations from geometrical symmetry which can be represented by algebraic symmetry [7, 15].

Topology has not found extensive application to the solution of chemical problems. It was pointed out during various pertinent discussions [3] that stereochemistry ought to be discussed in terms of topology, because some of the metric features of molecules are not essential for stereochemistry.

Prelog [4] proposed the term "chemical topology" to be used for the description of stereochemical entities in topological terms:

"Chemical topology deals with properties of geometrical figures that are either isomorphous or homomorphous with the momentary or time average topography of chemical particles."

"When I use a word", Humpty Dumpty said in rather a scornful tone, "it means just what I choose it to mean – neither more nor less". *Lewis Carroll*, Through the Looking-Glass [5].

It is difficult to predict whether this concept of chemical topology will ever provide a basis for an operational formalism in chemistry or lead to new insights.

Nonetheless, *Prelog*'s definition of chemical topology has initiated and stimulated the use of mathematical structures in chemistry, as discussed in the present paper.

The main difficulty in generating a topological theory of stereochemistry arises from chirality; it is not possible to distinguish between a geometrical system and its non-superimposable mirror image by the representation of molecules as topological spaces. Yet, it is possible to generate a framework of thought for the treatment of chemical problems by a combined application of basic concepts from topology and group theory.

1.3. Elements of Modern Mathematics [2, 6] [*]

1.3.1. Sets [2c, f–h]

A fundamental concept in all branches is that of a set. A set is any well defined collection or class of distinguishable objects of our experience or thought. These objects are called elements or members of the set. The theory of sets contains only one basic relation, usually denoted by $\in$ and expressed as *belongs to*. Examples pertinent to our discussion include not only sets of individual elements, numbers, and points, but sets (classes, families) of sets. A set A is a *subset* of a set B, or conversely B is a *superset* of A;

$$A \subset B \quad \text{or} \quad B \supset A$$

if each element in A also belongs to B.

Sets are specified by giving them a property P which can be used to test the claim of membership to a set by any object in the universe, the set of all objects having the property P is defined by $\{x|x \text{ has the property } P\}$. In the following specific applications of set theory, all sets under investigation are subsets of a fixed set. We call this set the *universal set*, U. The *empty* or *null set*, $\emptyset$, is the set which contains no elements; it is a subset of every other set. Important additional concepts are *intersections* and *unions*. The *intersection* of two sets A and B, symbolized $A \cap B$, is the set of elements which belong to both A *and* B, *i.e.*

$$A \cap B = \{x|x \in A \text{ and } x \in B\}$$

The *union* of two sets A and B, symbolized $A \cup B$, is the set of elements which belong to at least one, A *or* B, *i.e.*,

$$A \cup B = \{x|x \in A \text{ or } x \in B\}$$

Here, "or" is used in the sense of "and/or".

Two more important set operations are best introduced at this point. The *complement* of set B with respect to set A or simply the *difference* between A and B, denoted by $A \setminus B$, is the set of elements which belong to A but not to B, *i.e.*,

$$A \setminus B = \{x|x \in A, x \notin B\}$$

The *absolute complement* of set A, symbolized by A^c, is the set of elements which do not belong to A, *i.e.*,

$$A^c = \{x|x \in U, x \notin A\}$$

Or, A^c is the difference between the universal set U and the set A.

These four set operations can be further illustrated with the use of Venn-Euler diagrams. Here, the sets A and B are symbolized by circles and the universal set U shown as a rectangle. The indicated operations are shaded.

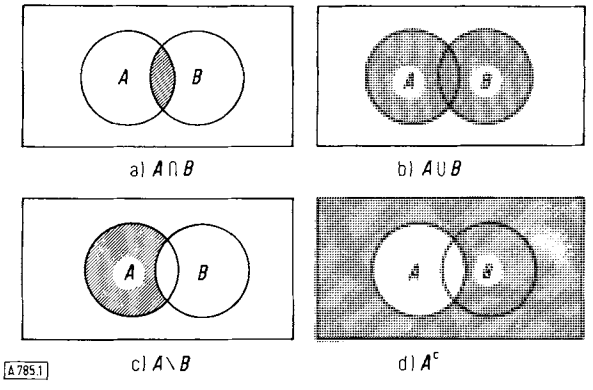

Fig. 1. Venn-Euler diagrams of set operations.

To each two objects, a and b, there corresponds a new object $\langle a,b\rangle$ called their *ordered pair*. Ordered pairs are required to satisfy:

$$\langle a,b\rangle = \langle c,d\rangle \text{ if and only if } a = c \text{ and } b = d.$$

The product set in set theory, written $A \times B$ and called the Cartesian product, is the set whose members are all ordered pairs $\langle a,b\rangle$ where $a \in A$ and $b \in B$, *i.e.*,

$$A \times B = \{\langle a,b\rangle | a \in A, b \in B\}$$

The product of a set with itself, *i.e.*, $A \times A$ is symbolized by A^2 and plays an important part in the definition of group structure (see Section 1.3.3.).

A rule f that assigns to each element of a set A a unique element of a set B is called a *mapping* f of A into B: $A \rightarrow B$ (or $A \xrightarrow{f} B$). The specific element $b \in B$ assigned to $a \in A$ by f is called the image $f(a)$ of a under f (or the value of f at a). Figure 2 illustrates the various types of mapping.

[*] We suggest that readers familiar with elementary topology and group theory omit Section 1.3.

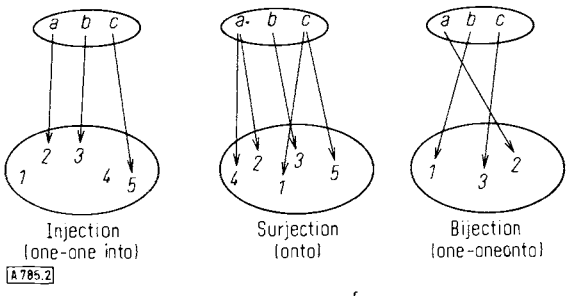

Fig. 2. Various types of mapping of sets $A \xrightarrow{f} B$.

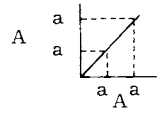
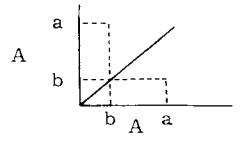
A propositional function $P(x,y)$ on the Cartesian product $A \times B$ has the property that $P(a,b)$, a and b being substitutes for x and y in $P(x,y)$, is true or false for any ordered pair $\langle a,b\rangle \in A \times B$. If A is the set of all chemists and B is the set of all known chemical compounds, then $P(x,y) \equiv$ "x discovered y" is a propositional function on $A \times B$. For example, P(*Waksman*, streptomycin) = "*Waksman* discovered streptomycin", P(*Fischer*, streptomycin) = "*Fischer* discovered streptomycin" are true and false, respectively.



A binary relation R in the set A is, intuitively, a proposition such that for each ordered couple $\langle a,a'\rangle$ of elements of A one can determine whether aRa' (a is a relation, R, to a') is or is not true. Any subset R of $A \times B$ is called a binary relation, R, from A to B. Formally stated in terms of the set concept, the binary relation R of $A \times B$ is:

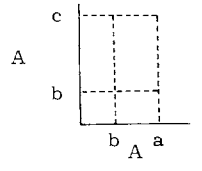
$R \subset A \times B$

$\langle a,b\rangle \in R = aRb$



A binary relation R in A is called an *equivalence relation* if:

E I: $\forall a \in A : a\,R\,a$



$(a,a) \in R$ (Reflexive) The relation R cortains the diagonal

E II: $(a\,R\,b) \Rightarrow (b\,R\,a)$

$(a,b) \in R$
$(b,a) \in R$ (Symmetric) The relation R is Symmetric about the diagonal

E III: $(a\,R\,b) \wedge (b\,R\,c) \Rightarrow (a\,R\,c)$

$(a,b) \in R$
$(b,c) \in R$ $\Big\}$ $(a,c) \in R$ (Transitive)

The equivalence class $[a]$ of any element $a \in A$ is the set of elements to which a is related. If the equivalence relation R is "x is congruent to y modulo 2" in the set N of integers, these are two distinctive equivalence classes, the *even* and the *odd* numbers. In chemistry most reasoning is done by analogy, *i.e.* by classification according to equivalence relations. For this to be meaningful, the pertinent equivalence relation must always be defined.

1.3.2. Topology [2d-g,i,j]

In modern mathematics the notion of a set is an undefined term whose use is governed by various axioms. This notion is used only as a framework from which mathematical theories are developed by defining axioms and applying logical deduction. Any mathematical structure has at its foundation a set, but one usually imposes an extra structure. Concepts of *neighborhood*, *open set*, *limit*, and *continuity*, necessary for the formalisms that follow, can be applied to a set A only if it has been supplied with a topology. A topological space is a set equipped with a topological structure.

If we let A be any non-empty set, a class T of subsets of A is called a topology on A if T satisfies the following axioms:

T I: A and $\emptyset$ belong to T.
T II: The *union* of any number of sets in T belongs to T.
T III: The *intersection* of any two sets in T belongs to T.

The pair (A,T) is called a topological space and the members of T are called the open sets of the topological space (A,T). If only one topology on A is considered we refer to the topological space A. Sometimes it is necessary to use different topologies on the same set to produce the formalism best suited for the solution of a problem. Here a comment by *Coleman* [2j] is appropriate. "... the chief skill needed is the ability to switch adroitly from one topology to another as rapidly as a quick change artist exchanges personalities. In such situations the old notations and habits of mind are very inhibiting ..."

If an open set T contains a point p, the open set T is called a neighborhood of p.

A family, $\{V_\alpha | \alpha \in T\}$, of sets is called a *basis* for a topology if the family of arbitrary unions of these sets forms a topology.

To illustrate the defined concept of topological space, one can see that a topological structure on the set of real numbers R is defined by using the open intervals and their unions as the open sets T. (R can be represented by a real line whose points are paired with the real numbers in a natural manner.) In this example, the neighborhood concept is obvious. The neighborhood of a point on a real line is any open interval which contains this point (compare the sequence rules discussed in Section 2.3.).

Open and *interior* are best illustrated with the concept of the open interval of real numbers.

Open interval from a to b: $]a,b[= \{x | a < x < b\}$
Closed interval from a to b: $[a,b] = \{x | a \leqq x \leqq b\}$

We can further define our topology to include the Hausdorff separation property:

T IV: Any two points of a space A have disjoint neighborhoods M and N whose intersection is the empty (null) set, *i.e.*, $M \cap N = \emptyset$.

A set A is called a metric set if there is given for any two points a and b a real number $D(a,b)$, the distance between a and b. A metric in a set A is a function $D : A \times A \rightarrow R$ such that:

T V: $D(a,a) = 0$
T VI: $D(a,b) = D(b,a) > 0$, for $a \neq b$
T VII: $D(a,b) \leq D(a,c) + D(c,b)$

Each metric D induces a topology. For example, by using the balls $\boldsymbol{B}_{(a,\gamma)} = \{x|D_{(a,x)} < \gamma\}$ for all $\gamma > 0$, $a \in \boldsymbol{A}$, the balls and all their unions are the topology on $\boldsymbol{A}$.

Let $(\boldsymbol{A}_i, \boldsymbol{T}_i)$ be a finite family of topological spaces where $i \in \boldsymbol{I}$ with $\boldsymbol{I}$ being a finite set of indices. The Cartesian *product topology* $\prod_1^n \boldsymbol{T}_i$ of $\prod_1^n \boldsymbol{A}_i$, is that topology having the open sets $\boldsymbol{U}_i \times \ldots \times \boldsymbol{U}_n$, where $\boldsymbol{U}_i \in \boldsymbol{T}_i$, as a basis.

The mutual neighborhood relations within families of intersecting sets can be described graphically by the nerve of the family. The nerve of an n-fold non-empty intersection is given by an $n-1$ dimensional graph (simplex); the non-empty intersection of two sets is represented by a line, a non-empty intersection of three sets by a triangle (see Fig. 3).

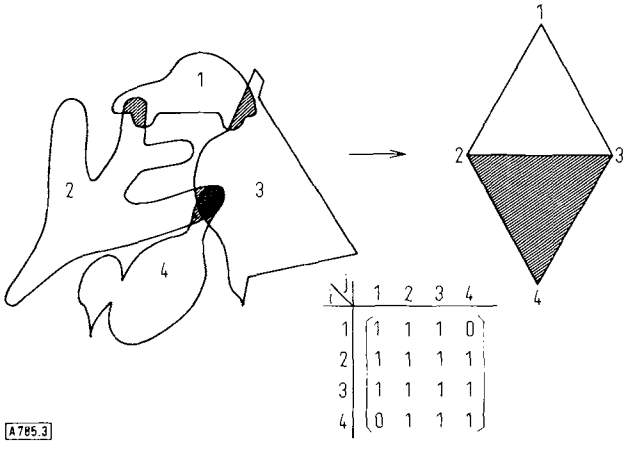


Fig. 3. Graph and matrix representation of neighborhood relations of a family of intersecting sets (nerve).

Such graphs can also be represented by matrices, using zero and one to indicate whether two sets are disjoint or have a non-empty intersection respectively. If matrix element $a_{ij} = 0$, this indicates that sets i and j are disjoint, and $a_{ij} = 1$ means their intersection is not empty (cf. Fig. 3). The secular determinants of the HMO theory are based upon such topological matrices. By their very definitions, these matrices are symmetrical across the main diagonal. If one replaces the connecting lines between pairs of points by arrows (as in category theory) the direction of the connection can be expressed by the indices of the matrix elements; $a_{12} = 1$, $a_{21} = 0$ means point one is connected with point two by an arrow $1 \rightarrow 2$. A formalism for the representation of molecules including all the steric features could be based upon category theory. However, such a treatment would afford a formalism which, except for computer use, is too complicated for practical purposes (see Section 4).

For the description of complicated reaction mechanisms with consecutive and parallel reactions (see ref. [6,7]), the category theory offers interesting possibilities. If we represent the reactants, products and all the observed and hypothetically assumed intermediates of a reaction by points and represent the observed and assumed reaction by arrows, the mapping of the sets of arrows onto the sets of points describes the reaction kinetic scheme. Here, the recent discussion[6] of topological (homology theoretical) concepts of "chemical reaction" and "reaction mechanism" is of particular interest. In this context, thermodynamic equilibria can be viewed as equivalence relations.

1.3.3. Groups[2a,b,g,j]

Another structure that can be imposed upon a set is the group structure. A set is called a group $\boldsymbol{G} = (\boldsymbol{A},\varphi)$ if there is a mapping $\varphi: \boldsymbol{A} \times \boldsymbol{A} \rightarrow \boldsymbol{A}$ (we write $\varphi(a \cdot a') = a \cdot a'$) satisfying the following conditions:

G I: The associative law is obeyed, *i.e.*, $(a \cdot a') \cdot a'' = a \cdot (a' \cdot a'')$ for all $a, a', a'' \in \boldsymbol{A}$.

G II: There exists an element $e \in \boldsymbol{A}$ (called the *unit element*) such that $e \cdot a = a$ for all $a \in \boldsymbol{A}$.

G III: For each $a \in \boldsymbol{A}$ there exists an element a^{-1} (called the *inverse element*) such that $a^{-1} \cdot a = e$.

The group $\boldsymbol{G} = (\boldsymbol{A},\varphi)$ is characterized by the set $\boldsymbol{A}$ and the mapping φ. Two groups are compared by mappings of the underlying sets that comprise the structures, *i.e.*,

$$(\boldsymbol{A},\varphi) \xrightarrow{f} (\boldsymbol{B},\psi)$$

If the condition

$$f(a \cdot a') = f(a) \cdot f(a')$$

is satisfied, such mappings are called *homomorphous*. A special case is a homomorphism which is a one to one mapping of a group onto another group, a bijection (see Fig. 2). Such a map is called an *isomorphism*. In this case the two groups have the same structure. Any homomorphism of a given group into the general linear group $\boldsymbol{GL}(n,\boldsymbol{R})$ of non-singular $(n \times n)$ matrices with real entries

$$(\boldsymbol{A},\varphi) \xrightarrow{f} \boldsymbol{GL}(n,\boldsymbol{R})$$

is a *representation* of the group $(\boldsymbol{A},\varphi)$. If this mapping is an isomorphism into $\boldsymbol{GL}(n,\boldsymbol{R})$ we have a *faithful representation*.

A group is characterized by its multiplication table, a square array of group elements arranged to show the results of the combination of group elements. If we have a group of order two with elements A and B and let the combination of these elements be defined such that

$$AA = BB = A$$
$$AB = BA = B$$

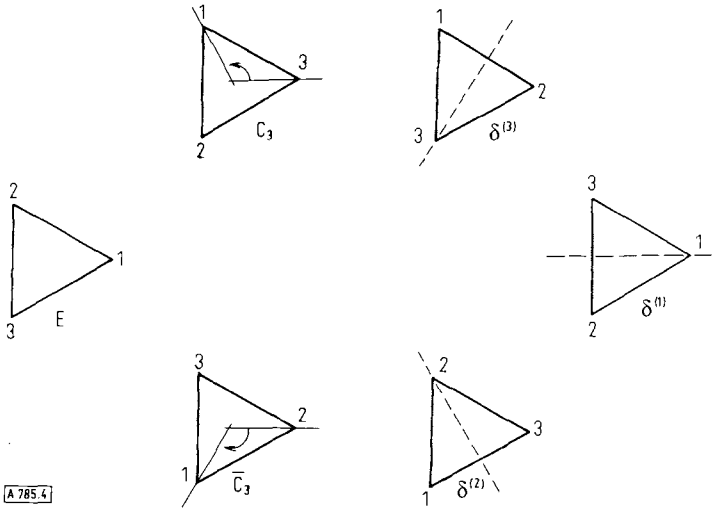
this statement could be represented by the multiplication table

	A	B
A	A	B
B	B	A

If we take the real number $+1$ as the element A and the real number -1 as element B, and make multiplication the group operation, we have a particular realization of the above group with the multiplication table

	$+1$	-1
$+1$	$+1$	-1
-1	-1	-1

The concept of a symmetry group is illustrated by Fig. 4.



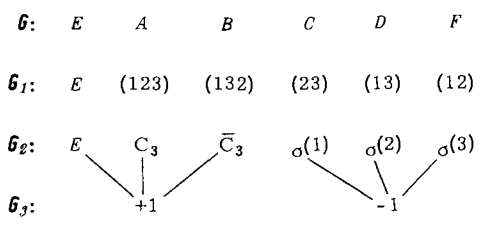


Fig. 4. Rotations C_n and reflections σ.

[7] *E. Ruch* and *I. Ugi*, Theor. Chim. Acta *4*, 287 (966); Top. in Stereochem. *4*, 99 (1969).

The operations that bring this triangle in Fig. 4 into a position indistinguishable from its original position, *i.e.* self-coincidence, are called *symmetry operations*. Symmetry operations may be performed sequentially. We define, for any set of symmetry operations R and S, a law of combination φ symbolized by RS, meaning first apply S, then R. Sequentially performed symmetry operations obeying the combination law φ form groups $G = (A,\varphi)$.

If we map the symmetry operations G_2 of Fig. 4 on the letters $A-F$

the multiplication table obtained is that of the group symmetry operations.

	E	A	B	C	E	F
E	E	A	B	C	D	F
A	A	B	E	F	C	D
B	B	E	A	D	F	C
C	C	D	F	E	A	B
D	D	F	C	B	E	A
F	F	C	D	A	B	E

Notice that the group $\{(+1)(-1)\}$ also satisfies the same multiplication table, but that the latter group is homomorphic to the first two.

Order, subgroup, and coset are further basic concepts of group theory essential for our discussion. In a group G containing g elements, g is called the *order* of the group. Any collection of the elements of G which by themselves form a group H is a *subgroup* of G. Every group contains two trivial or *improper subgroups*, the unit element, E, and the whole group itself, the rest of the subgroups considered *proper*. The set of subgroups does not correspond to a partition of the original group as E must be a member of *every* subgroup.

Let $H = \{A_1, A_2 \ldots A_h\}$ and R_1, R_2 .... be elements of G not contained in H; then the collection defined by

$$HR_k = \{A_1R_k, A_2R_k \ldots A_hR_k\}$$

is called the *right coset* of H with respect to R_k. Analogously, the double coset HR_kH' ($R_i \in G$, $R_i \notin H$, $R_i \notin H'$) is obtained from the two subgroups H and H' and their relative complement. Notice that the coset HR_k is not a group as it does not contain the identity element E, the same also applying to HR_kH'.

The symmetry group of a regular polygon with n vertices is of the order $2n$. It contains n rotations and n reflections.

$$G = \{E = C_n^n, C_n, C_n^2 \cdots C_n^{n-1} = \bar{C}_n, \sigma, \sigma C_n \cdots \sigma C_n^{n-1}\}$$

Since this group G can be generated from the rotations C_n and the reflections σ, these are called the *generators* of G.

Symmetry operations that leave one point of a figure unmoved form a *point group*.

Three dimensional point groups are characterized by the following generators:

C_n = positive rotations moving 360°/n (C_n axis normal to the plane of the paper).
σ_v = reflection across a vertical plane.
σ_h = reflection across horizontal plane.
σ_d = reflection across a vertical plane bisecting the angle between two C_2' axes.
C_2' = rotation through 180° about axes normal to the principal C_n axis.
S_n = improper positive rotations through 360°/n.

The Schoenflies notation is used to denote the point group symmetries in terms of their generators. C_n: $\{C_n\}$, C_{nv}: $\{C_n,\sigma_v\}$, C_{nh}: $\{C_n,\sigma_h\}$, S_n: $\{S_n\}$, D_n: $\{C_n,C_2'\}$, D_{nd}: $\{C_n,C_2',\sigma_d\}$, D_{nh}: $\{C_4, C_2',\sigma_h\}$, T: $\{C_2^z, C_3^{xyz}\}$, T_d: $\{\bar{S}_4^z, C_3^{xyz}\}$, T_h: $\{C_2^z, C_3^{xyz}, i\}$, O: $\{C_4^z, C_3^{xyz}\}$, O_h: $\{C_4^z, C_3^{xyz}\}$, Y: $\{C_3, C_5\}$.

The trajectory followed by a given point resulting from sequentially applied group operations is called its orbit. One can use this concept for numbering a symmetrical set of points (see Fig. 6).

An informative mapping of one three-dimensional Euclidean space E^3 onto another $\bar{E}^3$ can be represented by an orthogonal matrix

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \quad ; \quad A \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} a_{11}x + a_{12}y + a_{13}z \\ a_{21}x + a_{22}y + a_{23}z \\ a_{31}x + a_{32}y + a_{33}z \end{pmatrix} = \begin{pmatrix} \bar{x} \\ \bar{y} \\ \bar{z} \end{pmatrix}$$

Each row in the resulting matrix is the new coordinate of the original point. The distance relation between the points as well as the origin is maintained. A has the following properties:

M I: $a_{11}^2 + a_{12}^2 + a_{13}^2 = 1$
$a_{21}^2 + a_{22}^2 + a_{23}^2 = 1$
$a_{31}^2 + a_{32}^2 + a_{33}^2 = 1$

M II: $a_{11}a_{21} + a_{12}a_{22} + a_{13}a_{23} = 0$
$a_{11}a_{31} + a_{12}a_{32} + a_{13}a_{33} = 0$
$a_{21}a_{31} + a_{22}a_{32} + a_{23}a_{33} = 0$

M I and M II state: The product of the matrix A and its transpose A^T (the 'mirror image" of A across its main diagonal) is equal to the unit matrix E_3 symbolized:

$$AA^T = E_3$$

The product of any two orthogonal matrices is an orthogonal matrix and the inverse of such a matrix is its transpose:

$$AA^{-1} = E_3 = A^{-1}A$$
$$A^{-1} = A^T$$

A set of all orthogonal matrices is a group $O(n)$. We define the group operation as multiplication.

If we define:

$$SO(n) = \{A \in O(n) \mid \text{Det } A = +1\}$$

as that group, resulting from the transformation, whose determinants are equal to +1, it can be shown that a three-dimensional figure retains its "handedness" as a result of the operation (see Sections 2.2. and 2.5.) and the result can be defined as a rotation. If the Det $A = -1$ a three-dimensional figure reverses its "handedness" upon transformation, this result corresponding to a reflection.

We have a choice as to the number of dimensions allowed in the representation space E^n of a molecule. An E^2 space would allow some molecules to be chiral [*e.g.. (2a) – (2c)*] when they would not be so in E^3. However, since all E^1 and E^2 can be embedded into E^3, we use the E^3 space to describe chemical systems. Further, we will consider achirality as equivalent to $O(3)$ invariance.

The symmetric group S_n of n letters or symbols consists of the $n!$ mappings of a set of n letters on itself.

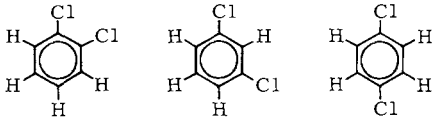
$$\left\{\begin{matrix} 1\ 2\ 3\ \ldots\ n \\ \downarrow\ \downarrow\ \downarrow\ \quad \downarrow \\ 1\ 2\ 3\ \ldots\ n \end{matrix}\right\} \quad \left\{\begin{matrix} 2\ 1\ 3\ \ldots\ n \\ \downarrow\ \downarrow\ \downarrow\ \quad \downarrow \\ 1\ 2\ 3\ \ldots\ n \end{matrix}\right\} \textit{ etc.}$$

These mappings are transformations from one arrangement of the numbers $1 \ldots n$ to another and are called permutations. The symmetric group S_n, the group of all permutations on n letters is of great general importance in mathematics and science. Permutations play a central role in this paper.

φ is an action, φ:
$g \times X \rightarrow X$, such that the transformation g (elements of the group G) on the set X reproduce the set X where g (all $g \in G$) acting on $x \equiv (gx)$ and $g[g'x] = [gg']x$. Each $g \in G$ is a bijection of X onto X. A family of such bijections is called a symmetry. A Cartesian product $(X_1 \times X_2 \times \ldots \times X_n)$ which is symmetrized with respect to the permutational transformation (permutation of the indices) of the group S_n is called the symmetrized Cartesian product of $X = SP^n X$.

$$SP^n X = \frac{(X_1 \times X_2 \times \cdots \times X_n)}{S_n}$$

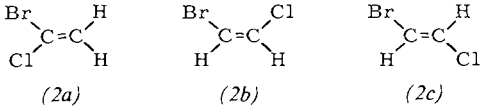
2. Classification of Molecules



2.1. Isomers

An equivalence relation in a set divides that set into pairwise disjoint classes. The members of an equivalence class are "the same" with reference to the defining relation.

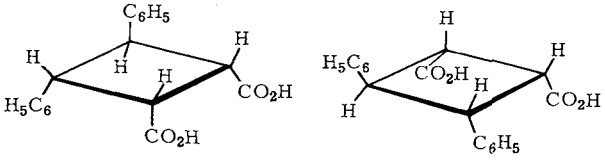
Equivalence relations are the basis for many useful classifications in chemistry whereby order is achieved. This order provides for the possibility of a systematic nomenclature for chemical systems. A clear example of the utility of a classification for chemical systems according to equivalence relations is the periodic system of elements.



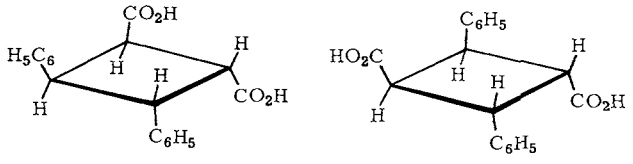
The set of all chemical compounds can be divided into those classes which have the same empirical formula, *i.e.*, the isomers. Those compounds classified according to the criterion of molecular skeletal similarity form a further class, *i.e.*, topologically similar compounds. We can now define the concept of *permutational isomers*, chemical compounds which have in common the same molecular skeleton and set of ligands, differing only by the distribution of the ligands on the skeletal positions.

Chemical constitution can be defined as a set of neighborhood relations between the atoms of a molecule [7]. This can be visualized in terms of bonds and bonded neighbors. Those permutational isomers which differ only by ligand permutations at constitutionally equivalent positions are the subclass of stereoisomers [8].

(1a) *(1b)* *(1c)*

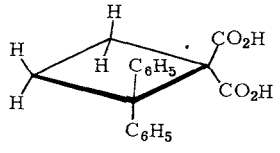


The three isomeric dichlorobenzenes *(1a)–(1c)* are permutational isomers having skeleton VI (see Section 2.4.2), but are not stereoisomers.



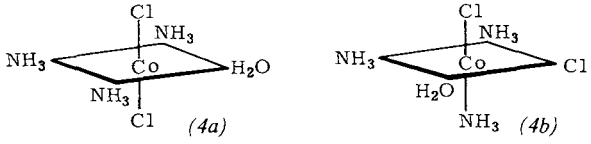
(2a) *(2b)* *(2c)*

[8] a) *E. L. Eliel:* The Stereochemistry of Carbon Compounds. McGraw-Hill, New York 1962; Stereochemie der Kohlenstoffverbindungen. Verlag Chemie, Weinheim 1966; b) *K. Mislow:* Introduction to Stereochemistry. Benjamin, New York 1965; Einführung in die Stereochemie. Verlag Chemie, Weinheim 1967.



All the bromochloroethylenes *(2a)–(2c)* are permutational isomers because they have the same skeleton I, and they differ only by permutations of the ligand set. *(2a)* differs in chemical constitution from *(2b)* and *(2c)*, which are stereoisomers.

(3a) *(3b)*



(3c) *(3d)*

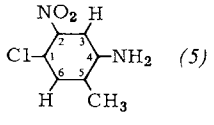
(3e)

The isomers *(3a)*[$\equiv$*(3b)*], *(3c)–(3e)* are all permutational isomers; *(3a)* is identical with *(3b)* and can be brought into coincidence with *(3b)* by rotation and translation. Of these permutational isomers, the truxinic acids *(3a)* and *(3c)* are mutual stereoisomers, whereas α-truxillic acid [9] *(3d)* and the reference isomer *(3e)* (see Section 2.4.4.) differ in chemical constitution from the other species.

(4a) *(4b)*

The determination of whether *(4a)* and *(4b)* are stereoisomers or non-stereoisomeric permutational isomers is relevant only to some problems, and involves an arbitrary decision as to whether the two "axial" chloro ligands distort the O_h symmetry of the skeleton sufficiently to create a distinction between "axial" and "equatorial" skeletal positions [10]. If such a distortion occurred, the constitutional equivalence of the ligand positions would be destroyed, violating a precondition for *(4a)* and *(4b)* being stereoisomers.

The non-stereoisomeric permutational isomers arise from molecular skeletons whose equivalent skeletal positions become non-equivalent on attachment of a ligand. In fact, those skeletons with a symmetry that precludes the non-equivalence of skeletal positions regardless of the ligand



[9] *A. Mustafa*, Chem. Rev. *57*, 1 (1952).

[10] *E.g.: J. Lewis* and *R. G. Wilkins:* Modern Coordination Chemistry. Interscience, New York 1960; *F. A. Cotton* and *G. Wilkinson*, Advanced Inorganic Chemistry, Interscience, New York 1966; Anorganische Chemie. Verlag Chemie, Weinheim 1967; *C. K. Jørgensen:* Inorganic Complexes, Academic Press, New York 1963; *R. F. Gould*, Werner Centennial, A.C.S. Publ. Washington, D.C., 1967.

distribution (like XXVII) are rather the exception than the rule. Likewise, those skeletons with a symmetry (like VI) which allow only constitutionally different, non-stereoisomeric permutational isomers, are also in the minority. A consistent nomenclature for permutational isomers would simultaneously be a solution to the remaining unsolved problems of stereochemical nomenclature.

Any isomer nomenclature must be so devised that there is a well defined and clear correspondence between names and isomers. One must be able to determine, unequivocally and, if possible, easily, all constitutional and stereochemical features of a given isomer from its name, and be able to classify a given isomeric species according to unambiguous criteria. It would be a convenient feature of such a nomenclature if it contained both the (*R*),(*S*) [11] and the (*E*),(*Z*)-nomenclature [12] and related nomenclatures [13] as special cases (subsets).

The simplest type of unequivocal assignment of nomenclature names to molecules with a given skeleton and set of ligands is the kind of nomenclature which is used, for instance, for benzene derivatives. Thus an adequate description of a given molecule is achieved by numbering the skeletal positions and including the position numbers with the ligands (which substitute hydrogen) in the nomenclature name. For instance, *(5)* would be 1-chloro-2-nitro-4-amino-5-methylbenzene.

(5)

A variety of other names could be found for *(5)*, however, by the same procedure (if no further definitions were included in the nomenclature) depending upon which ligand occupied skeleton position number one, and whether the numbering was carried out clockwise or counterclockwise. However, no matter how the numbering is selected, the resulting name can always be used to reconstruct *(5)*. Such simple nomenclatural procedures cannot be applied to chiroids and molecules with highly symmetrical three-dimensional molecular skeletons, *e.g.*, XXII–XXIX, as no simple unequivocal correlations of molecules and names can be achieved.

2.2. Chirality Problems

In order to establish a basis for such a universal nomenclature some implications of chirality must be discussed. *Lord Kelvin* [14] introduced the concept of chirality as follows: "I call any geometrical figure or group of points *chiral* and say it has *chirality* if its image in a plane mirror ideally realized, cannot be brought to coincide with itself."

Achiral objects have symmetries which include reflections and improper rotations. Whether an object is chiral in Euclidean space or not depends also upon its dimensionality and the dimensions of the space in which it is observed (see Section 1.3.3.). For example, a two-dimensional chiral object, such as an idealized, suitably substituted ethylene [*e.g.*, *(2a)–(2c)*] is chiral in two dimensional space E^2, but achiral in three dimensional space, E^3.

Lord Kelvin's intuitive definition of chirality serves most purposes of stereochemistry well, although in certain exceptional cases (see below) it does not provide an unambiguous basis for the mathematical treatment of chirality problems.

The mathematical description of chirality is related to representations of orientation-preserving transformations by orthogonal matrices (see Section 1.3.3.).

Along with the objects classified as chiral and achiral, there is a class of objects called *amphichiral* [2k]. These are characterized by the fact that they are chiral according to *Kelvin*'s definition but achiral according to orientation-preserving transformations from $\boldsymbol{O}(n)$.

We call an object *K* amphichiral if there exists an orientation-preserving mapping, *h*, such that, h: $E^3 \rightarrow E^3$ with $h(K) = \rho(K)$, *i.e.*, *K* is amphichiral if there is an orientation-preserving homomorphism of E^3 taking *K* into its mirror image. For example, the twisted loop and the trefoil knot are amphichiral objects.

Amphichiral systems might be of significant importance in chemistry and biochemistry. The discovery of cyclic and catenated nucleic acid structures leads one to suspect that amphichiral superstructures of nucleic acids are responsible for neoplastic processes by interfering with the transfer of information on chirality.

We propose to make the distinction between chiroids and achiroids only with respect to the action of orthogonal matrices rather than the criterion of the superimposibility of an object and its mirror image by reflection in a plane mirror and rigid motions.

The set of operators $A = \{e =$ "leave the object as it is", $i =$ "convert the object into its mirror image"$\}$ with the combination law $\varphi =$ "apply the operation to the result of the preceding operation", forms a group $I = (A,\varphi)$. Converting the mirror image of an object into its mirror image leads back to the original object $(i \cdot i = e)$.

The inversion group *I* is isomorphic to, and is represented by, the group $V = (\{(+1),(-1)\}$, multiplication) (see below). With regard to achiral objects it is isomorphic to $(\{(+1)\}$, multiplication). In stereochemistry a chiroid χ_R with an (*R*)-configuration as the standard situation can produce the (*S*)-chiroid χ_S as the result of the operator *i* acting upon an (*R*)-chiroid.

$$\{\chi_S\} = i \cdot \{\chi_R\}$$

A chiroid with two elements of chirality χ and χ' occurs in four stereoisomeric forms.

$$\{\chi_R,\chi'_R\}\ \{\chi_S,\chi'_S\}\ \{\chi_R,\chi'_S\}\ \{\chi_S,\chi'_R\}$$

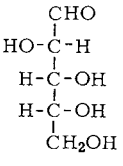
[14] *Lord Kelvin,* Baltimore Lectures, 1884 and 1893. C. J. Clay and Sons, London 1904, pp. 436, 619.

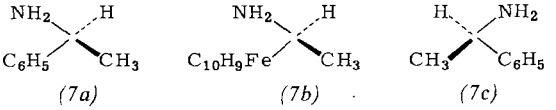


This class of stereoisomers is generated from $\{\chi_R, \chi'_R\}$ by the direct product group $I \times I'$ where I (see above) acts upon χ and I' acts upon χ'. The above set is isomorphic with

$$V \times V' = \{(+1)(+1)', (-1)(-1)', (+1)(-1)', (-1)(+1)'\}$$ and is ahomomorphism onto: $V = \{(+1), (-1)\}$.

This relation can be used for the classification of diastereoisomers [13].

The (*R*),(*S*)-nomenclature of chiroids with many elements of chirality essentially corresponds to a mapping of the direct products of the group I onto the group V or its direct products.



The nomenclatural designation (2(*S*),3(*R*),4(*R*),5)-tetrahydroxypentanal [8a] for D-arabinose *(6)* is based upon the direct product group $I_2 \times I_3 \times I_4$ and corresponds to $(-1)(+1)(+1)$. The classification of sugars into D- and L-sugars makes use of a mapping of the set of sugars into V rather than an ordered product of the V's.

(6)

The (*R*),(*S*)-nomenclature is currently accepted for chiral stereoisomers. It is far superior to the classical D,L-nomenclature [8] which is not based upon rigorous definitions. The (*R*),(*S*)-nomenclature was conceived in order to discriminate between enantiomers and to classify the absolute configurations of chiral molecules or elements of chirality unambiguously according to the criterion of either *homochirality* or *heterochirality*, concepts originated by *Lord Kelvin* and further refined by *Ruch* [15c] for chiroids of category *a* (see below).

Two chiral objects χ and χ' are termed homochiral if it is possible to define a criterion by which χ and χ' are similar, whereas, by the same criterion, χ' and $\bar{\chi}$, the antipode of χ, are dissimilar. If one finds, by the same criterion, that χ' and $\bar{\chi}$ are similar (and χ and χ' are not) $\bar{\chi}$ and χ' are heterochiral. As it is used here, the term "chiral" does not refer to the action of an orthogonal matrix. It is used only to discuss a suitably defined series of compounds in a manner some chemists find useful. In the following figure *(7a)* – *(7c)* the criteria for comparison is that three ligands must be identical and distributed in a like manner. As C_6H_5 and $C_{10}H_9Fe$ are different yet on equivalent skeletal positions, *(7a)* and *(7b)* are homochiral, whereas *(7c)* is heterochiral to *(7a)* and *(7b)*.

(7a) *(7b)* *(7c)*

[15] a) *E. Ruch, A. Schönhofer*, and *I. Ugi*, Theor. Chim. Acta *7*, 420 (1967); b) *E. Ruch* and *A. Schönhofer*, Theor. Chim. Acta *10*, 91 (1968); c) *E. Ruch*, Theor. Chim. Acta *11*, 183 (1968); d) *E. Ruch* and *A. Schönhofer*, Theor. Chim. Acta, in press; e) *E. Ruch*, personal communication; f) *E. Ruch, W. Hässelbarth*, and *B. Richter*, Theor. Chim. Acta, in press; see also *G. Polya*, Acta Math. *68*, 145 (1937); g) *E. Ruch*, Lectures at Zürich and Los Angeles 1969.

Accordingly, the classification of a chiral object with regard to homochirality is possible only by comparison with a chiral reference system.

It is possible to communicate the fact that some object is "right handed", only by making the statement that it is homochiral to some other comparable "right handed" object.

Despite its obvious merits, the (*R*),(*S*)-nomenclature is not the ultimate solution to the problem of stereochemical nomenclature for the following reasons:

First, it is limited to configurational assignments.

Second, in the case of molecules with complex molecular skeletons, its underlying definitions do not provide a basis for dealing with the molecule as an entity, but require consideration of the molecule by (tetrahedral) subunits and thus sometimes makes additional definitions necessary.

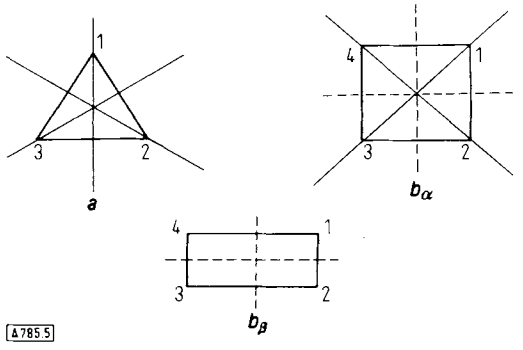
Third, and most serious, the (*R*),(*S*)-nomenclature is confined to chiroids of *class* ***a*** [15b,c], for chiroids of *class* ***b*** [15b,c] its definitions become meaningless unless they are arbitrarily extended. The (*R*),(*S*)-nomenclature does not therefore allow for the consequence of two different *chirality classes* ***a*** and ***b***. This nomenclature was conceived before *Ruch* [15] showed by the group theoretical analysis of chemical chirality that there are two different classes, ***a*** and ***b***, of chiroids.

A class of chiroids for which there is a non-arbitrary right-left classification is termed a class of category *a*, otherwise a class of category *b*. A molecule belongs to category *a* if and only if it has either only two skeletal positions, or if each skeletal plane of reflection contains $n-2$ skeletal positions, $n > 2$ being the number of skeletal positions [15e].

Let us now consider *Ruch*'s [15b,c] classification:

By definition, any transformation of a chiroid χ_a of *class* ***a*** into its antipode $\bar{\chi}_a$ must pass through some state in which all differences between χ_a and $\bar{\chi}_a$ vanish. This can be visualized in terms of a sharp achiral border without loopholes between χ_a and $\bar{\chi}_a$, such that all compounds on the χ_a-side of the border are homochiral to χ_a, and that beyond that achiral border any chiroid is homochiral to $\bar{\chi}_a$.

For chiroids of *class* ***b*** there is no such sharp border between the antipodes χ_b and $\bar{\chi}_b$ (*class* b_β) or the border has loopholes (*class* b_α). Accordingly, chiral molecules of *class* ***a*** are subject to classification by statements of homochirality, like right- and left-handedness or the D,L or (*R*),(*S*)-nomenclature, and chiroids of *class* ***b*** are not.



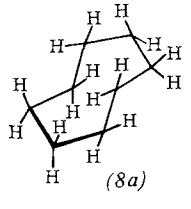
Let a chiral molecule be represented by an achiral skeleton with n ligand bearing positions and n ligands (groups) attached to the framework. Then, the following applies:

Chiroids of *class* ***a*** do not contain any skeletal planes of reflection or improper axes of rotation where more than two non-equivalent ligands are attached to skeletal positions not coincident with the stated fixes of symmetry. For these chiroids of *class* ***a*** there are no reflections or improper rotations of the skeletal symmetry group which exchange more than two non-equivalent ligands when the chiroid is transformed into its antipode. For the molecules in *class* ***a*** to become achiral, it is necessary and sufficient to remove or to make equal two non-equivalent ligands which do not

occupy skeletal positions not coinciding with skeletal planes of reflection or improper axes of rotation (see Section 1.3.3.).

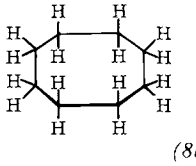
For chiroids of *class* $\boldsymbol{b}_\beta$ there are only those skeletal planes of reflection or improper axes of rotation that allow more than two non-equivalent ligands to occupy skeletal positions outside any of these skeletal planes or improper axes of symmetry. It is not possible to transform a chiroid of *class* $\boldsymbol{b}_\beta$ into its mirror image by permuting only two differing ligands; more than two non-equivalent ligands must be exchanged in order to generate the antipode. More than two ligands must be removed or equalized in order to destroy chirality.

Chiroids of *class* $\boldsymbol{b}_\alpha$ have at least one skeletal plane of reflection or improper axis of symmetry of type $\boldsymbol{a}$ and at least one of type $\boldsymbol{b}_\beta$. This classification is illustrated by the two-dimensional examples shown below.



A785.5

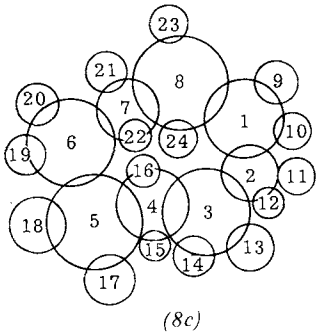
Fig. 5. Reflection across the lines —— or ------ transforms the laminae into their mirror images. Two of the distinguishable vertices (, ..., 4 lie outside the lines ——, more than two lie outside the lines -------.



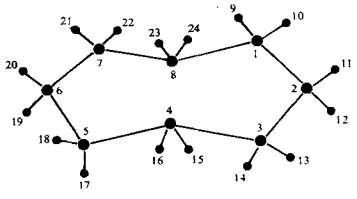
Class $\boldsymbol{b}$ contains various types of molecules. For some, the concept of handedness has no meaning. However, it is possible to dissect others into elements of chirality of *class* $\boldsymbol{a}$. For example, the cyclopropane (XI) and prismane derivatives (with D_{3h} skeleton and six ligands) can be dissected into tetrahedral elements of chirality which can be described in terms of the (*R*),(*S*)-nomenclature. Conversely, it is not possible to apply the (*R*),(*S*)-nomenclature meaningfully to a molecule whose skeleton consists of a central atom with valencies directed towards the vertices of a trigonal prism with six different ligands.

2.3. The Nerve and Beyond

Now the various types of mathematical structures can be combined to represent molecules in a detailed manner. We will describe a cyclooctane molecule *(8a)* first in topological terms.



(8a)



(8b)

Neighborhood relations provide the chemical constitution of cyclooctane. They are given by bonds and bonded neighbors and can be described by an indexed family of 24 intersecting sets, *e.g.* a family of open spheres *(8c)*. The *nerve* of this family *(8d)* represents the chemical constitution of cyclooctane.

(8c)

(8d)

No information beyond the neighborhood relations is included in the nerve of the molecule. All stereochemical features of a molecule are lost when it is represented by its nerve. Cyclooctane's behavior is that of a molecule possessing D_{8h} symmetry. This is usually described by stating that cyclooctane has a D_{8h} *time average symmetry*. While this notion serves some purposes well it is not at all well founded. Geometrical properties cannot be averaged like scalar properties. We will make use of the highest symmetry which a molecule or its skeleton can be imagined to attain within its given constraints. The constraints of a given molecule and its skeleton can depend upon the time scale inherent to the method of observation. Symmetrical molecules suffering distortion, as well as those having none of the symmetry described as time average symmetry in any of its vibrational, internal rotational or conformational states can all be represented without auxiliary hypotheses using the highest available symmetry concept.

The highest attainable D_{8h} symmetry of the cyclooctane molecule can be described by a permutation group. The indexed open spheres of *(8c)* are employed as the coordinates of the carbons and hydrogens of cyclooctane. Then the permutational transformation properties of the coordinate system represent not only the skeletal symmetry, considering the equivalence of the hydrogens, but the symmetry of the whole molecule. When the necessity arises to differentiate between the hydrogen atoms of the various molecular ligands in substituted cyclooctanes one must further define a mapping process. This mapping must correlate the various parts of the molecule with suitably chosen coordinates. The coordinates of the eight equivalent carbon atoms of cyclooctane are not needed for the description of the steric features of the molecule and its derivatives. Therefore, the partially symmetrized product, $\boldsymbol{SP^{D_{8h},16}}\ \boldsymbol{X}$, of sixteen indexed copies of one set is adequate as a coordinate system for the idealized D_{8h} skeleton of cyclooctane. The subgroup $\boldsymbol{H_{16}}$ of the symmetric group $\boldsymbol{S_{16}}$ is used as a partial symmetrizer of the product set $\{\boldsymbol{X_{16}} \times \boldsymbol{X_2} \times \ldots \times \boldsymbol{X_n}\}$. The indexed set $\{p_1, \ldots, p_{16}\}$ of points with disjoint neighborhoods, $p_i \in \boldsymbol{X_i}$, can be used as the set $\{\boldsymbol{X_1}, \boldsymbol{X_2}, \ldots, \boldsymbol{X_{16}}\}$. This is obtained from one point p_1 by sequentially applying the generators C_8 and σ_h to p_1 and assigning odd indices, $2s-1$ ($s = 1, \ldots, 8$), to the points on the orbit of C_8. We then reflect this set of points (Fig. 6a) across a plane parallel to and above the

plane of the paper. Now, assign the even indices $2s$ to σ_h mirror images of the points with $2s-1$ indices (Fig. 6b).

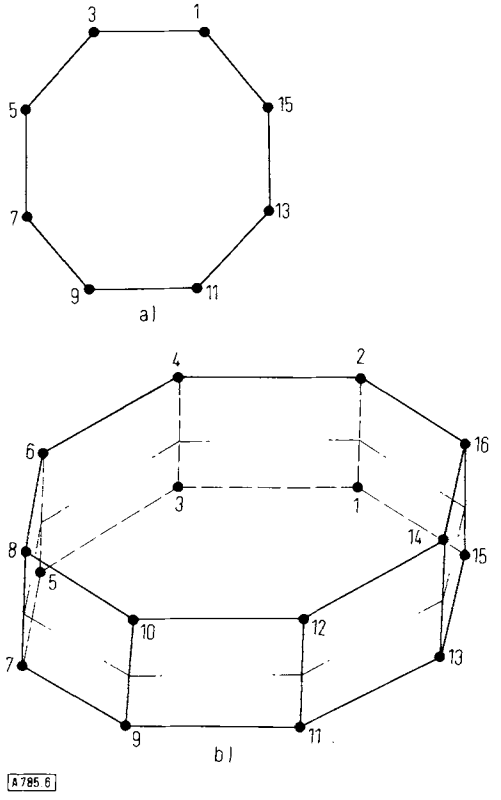


Fig. 6. Sequential application of the point group symmetry operations (generators) C_8 and σ_h to a point (odd indices $2s-1$ ($s = 1, \ldots, 8$) assigned to orbit of C_8).

We may now formally consider the carbon atoms. The carbon atom with the index one belongs to a distinguished point, the cross-section of the neighborhoods of those atoms to which the carbon is directly connected. Thus, the assignment is in accord with skeletal symmetry.

In principle, as is illustrated by Fig. 7, the simultaneous use of product sets and the descriptions of neighborhood relations by non-empty intersections of τ_1, τ_2, and τ_3 of $\prod_{1}^{3}\tau_i$ is possible. To accomplish this, sets must be used at different "levels" and symbolized by double indexing.

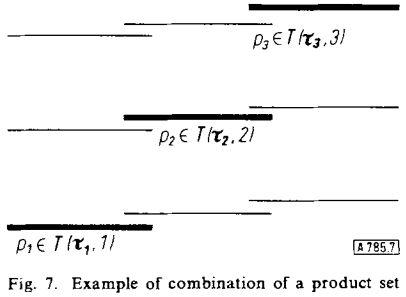

Fig. 7. Example of combination of a product set with the description of neighborhood relations by non-empty intersections.

A physical feeling for these operations can best be visualized by looking upon neighborhood relation operations as vertical projections and product topological and group theoretical operations as horizontal projections. This approach avoids violation of the product of sets definition by the intersections.

Representation of cyclooctanes substituted by a numbered set of sixteen distinguishable ligands $L = \{L_1, L_2, \ldots, L_{16}\}$ is achieved through the bijective mapping of the ligands on the skeleton and thus assigning the skeletal coordinate of each ligand. By using the partially symmetrized set of coordinates $SP^{D}{}_{8h,16}$ X the fact that some skeletal coordinates are symmetry equivalent is accounted for and one is allowed to select that one among the equivalent bijections which is the best according to some criterion. The latter may be defined as that mapping where the highest number of ligand and coordinate indices match.

$$\begin{array}{ll} L_i\colon & i = 1\ 2\ 3\ \ldots\ 16 \\ & \downarrow\ \downarrow\ \downarrow\ \ldots\ \downarrow \\ X_i\colon & i = 1\ 2\ 3\ \ldots\ 16 \end{array}$$

Since the ligands of molecules are not *per se* indexed, a procedure must be established for assigning the indices to the n ligands of a molecule. This produces, for example, a one to one mapping of a set of n ligands onto the numbers $1, 2, \ldots, n$ that we call the indices of the coordinates Y_l of the ligands such that $L_1 \in Y_1$, $L_2 \in Y_2$, $\ldots$ $L_l \in Y_l$ $\ldots$ $L_n \in Y_n$. This is equivalent to the statement that the set of ligands belongs to the product of the coordinates. We propose to assign the ligand coordinates l according to the sequence rule of *Cahn, Ingold,* and *Prelog* [11], which permits the ordering of a set of distinguishable ligands. The coordinate index $l = 1$ is assigned to the ligand with the highest sequential priority, $l = 2$ to the second highest priority ligand, ... and $l = n$ to the ligand with the lowest priority.

If there are several equivalent ligands then the corresponding index interval is assigned as illustrated by the following example:

Let L be the sequentially ordered set of ligands for a given molecule [like *(3a)*]. The coordinate indices are

L_i: HO_2C^-, HO_2C^-, $C_6H_5^-$, $C_6H_5^-$, H^-, H^-, H^-, H^-

Y_i: $[1 \leq 1 \leq 2]$ $[3 \leq 1 \leq 4]$ $[5 \leq 1 \leq 8]$

The equivalence of ligands (see the example above) is taken into account, just as the symmetry equivalence of skeletal positions is, by partially or fully symmetrizing the Cartesian product $\{Y_1 \times Y_2 \times \ldots \times Y_n\}$ of the ligand coordinates Y. The ligand coordinate spaces Y_i correspond to open intervals in a line of sequential points. This line of points represents the sequence of all ligands that can occur in permutational isomers. Sequential intervals are the open sets of the topology on the linear sequential manifold. The partially symmetrized Cartesian product.

$$SP^{m'n}Y = \frac{(Y_1 \times Y \times \ldots \times Y_n)}{H'_m}$$

refers to the subgroup H'_m of permutations of non-distinguishable ligands, a subgroup of S_n, and becomes equal to S_n, if all ligands are equals as in the case of cyclooctane.

The bijective mapping of the index set of the partially (or fully) symmetrized ligand coordinates Y_l onto the index set of partially (or fully) symmetrized skeletal coordinates X_s permits unequivocal classification of topological isomers and is introduced by us as the basis of a permutational nomenclature.

There is a bijective mapping from the set of these mappings onto the given class of isomers. According to *Ruch* and *Schönhofer* [15d] the total number of isomers in such a class

can be calculated from the number of double cosets of H_m and H_n in S_n [15d]. The use of the permutational nomenclature system is illustrated by the flow sheet shown in Fig. 8.

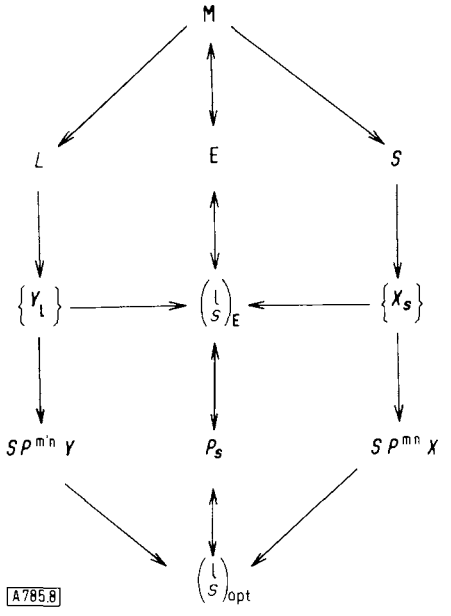

Fig. 8. Flow sheet for generation of the descriptor of permutation isomers.

Here, $L \leftarrow \mathbf{M} \rightarrow S$ symbolizes the division of a molecule into a skeleton and a set of ligands. Coordinate assignment and numbering is represented by $\{Y_l\}$ and $\{X_s\}$.

The n ligand and skeletal indices l and s of the set $\{Y_l\}$ and $\{X_s\}$ are correlated by mapping in a $(2 \times n)$ unit matrix, the $\binom{l}{s}_E$ matrix. We use the term matrix for any rectangular array of mathematical symbols. If these mappings are represented by permutations, this corresponds to the identity permutation e (see 2.4).

$$\binom{l}{s}_E = \begin{pmatrix} 1 & 2 & \ldots & n \\ 1 & 2 & \ldots & n \end{pmatrix}.$$

Among the $\binom{l}{s}$ matrices of equivalent mappings $SP^{m'n}Y \rightarrow SP^{mn}X$ that matrix $\binom{l}{s}_{opt}$ which is obtained from $\binom{l}{s}_E$ by the most simple s permutation, P_s, is chosen as the descriptor of a given molecule.

In the context of their solution of the Polya problem, *Ruch et al.* [15f,g] demonstrated that the number of distinguishable isomers of a given class of isomers corresponds to the number of double cosets PxG ($x \in S_n$); P and G are the subgroups which correspond to the skeletal symmetry of the skeleton with n positions and the permutation of equivalent ligands. The various isomers correspond to systems of representatives of the double cosets PxG. Therefore, a nomenclature system for permutational isomers can only be adequate and non-arbitrary if it corresponds to a system of the above double coset representatives.

Ruch et al. will soon report on a proof that the descriptions of the present paper (which are here derived according to a mapping formalism – which is closer to chemistry – rather than by a formalism that is in immediate relation to the double cosets) are indeed equivalent to a representation system of the PxG double cosets.

2.4. Describing Molecules by Permutations[16]

2.4.1. Descriptor

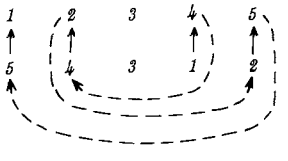
The permutational isomers are described by mapping the indexed set of ligands L_l onto the indexed set of permutational coordinates X_s, the equivalent of the molecular skeleton. This mapping is represented by a $(2 \times n)$ matrix notation using the $\binom{l}{s}$ matrices of the indices l and s. An effective nomenclature for permutational isomers results from this matrix representation. That permutational transformation, P_s, of the permutational coordinates s which generate the matrix $\binom{l}{s}_M$ of a given molecule **M** from the matrix $\binom{l}{s}_E$ of a reference molecule **E** according to

$$\binom{l}{s} = P_s \binom{l}{s}_E \qquad (1)$$

is called the descriptor of the molecule **M**. The descriptor is an unambiguous symbolism for the nomenclatural classification of the permutational isomers [16].

2.4.2. Skeleton

The permutational descriptors are based upon the following definitions:



S I: A molecule **M** is represented by an achiral skeleton S_n with n ligand positions and a corresponding set of n ligands $L_1 \ldots . L_n$.

S II: A permutational coordinate system is introduced to represent the molecular skeleton, such that the permutational transformation properties of the coordinates correspond to the symmetries of the skeleton.

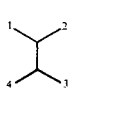
S III: A set of skeletal position numbers $s = 1, 2, 3, \ldots, n$ is assigned to the n skeletal positions of S_n by a convention which is defined for each type of skeleton, and is characteristic of the given class of permutational isomers according to the rules S I – S IX. The result is a standard skeleton (see I – XXIX) whose skeletal numbers correspond to the indices of the skeletal coordinates.

---

[16] The following may serve to illustrate permutations and descriptors: The permutation $P_s = (1425)$ represents the cycle $5 \leftarrow 2$ ($\downarrow$ $\uparrow$ and means 1 replaces 4 (or is the image of 4) and similarly, $1 \rightarrow 4$ $4 \rightarrow 2$, $2 \rightarrow 5$, $5 \rightarrow 1$. The ordered set $A = \{12345\}$ is transformed into and mapped onto $B = \{54312\}$ by the permutation $P_s = (1425)$. Given that permutation P_s, which represents the mapping of set A onto set B, is found from the matrix $\binom{A}{B} = \begin{Bmatrix} 12345 \\ 54312 \end{Bmatrix}$; following the arrows

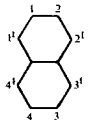
gives the operator $P_s = (1425)$. When used as a descriptor, the operator $P_s = (1425)$ generates $\binom{1}{s} = \begin{Bmatrix} 12345 \\ 54312 \end{Bmatrix}$ from $\binom{1}{s}_E = \begin{Bmatrix} 12345 \\ 12345 \end{Bmatrix}$ according to $\binom{1}{s} = P_s \binom{1}{s}_E$. Now, the descriptor (1425) expresses the following mapping: Skeletal position 1 carries the ligand with the sequential number 4, position 4 carries ligand 2, position 2 carries ligand 5, and position 5 carries ligand 1; at position 3, unaffected by P_s, the ligand number 3 matches the skeletal number.

S IV: The skeletal numbers are assigned such that, whenever possible, the configurations of the reference isomers **E** of *class* ***a*** have the (*R*)-configuration (see XVII and XXVII).



S V: If the observer looks along a principal C_n axis [2b] the assigned skeletal numbers increase in a clockwise manner.

S VI: If there are several C_n cycles, belonging to the same principal C_n-axis, the cycle which is closer to the observer has the lower numbers *s* (see XVI). The portion of the cycle with the lowest *s* lies within a plane that includes the principal axis and is the same for each one. If this is not possible, the lowest *s* lies in a clockwise direction, less than 90° from this plane.



S VII: Pairs of skeletal positions which belong to the same atom have consecutive *s* (see XI).

S VIII: If there are several non-equivalent sets of symmetry equivalent skeletal positions, separate sets of skeletal position numbers $s = 1 \ldots\ldots n$, $s' = 1' \ldots\ldots n'$, $s'' = 1'' \ldots\ldots n''$, *etc.*, are assigned. Similarly separate sets of ligand numbers $1 = 1 \ldots\ldots n$, $1' = 1' \ldots\ldots n'$, $1'' = 1'' \ldots\ldots n''$ are associated with these.

S IX: Skeletal positions and ligands on a principal symmetry axis of the skeleton are described by primed or multiply primed 1 and *s* (see VII).

XXIX (O_h)

2.4.3. Ligands

L I: A set of ligand numbers $l = 1, 2, 3, \ldots n$ is assigned to the ligands $L_1 \ldots L_n$ of **M** according to the *sequence rule* [8,11], in the order of the sequential priorities of the ligands. The number 1 is assigned to the ligand which has the highest sequential priority and n to the ligand with the lowest sequential priority [11].

L II: If there are n_i ligands ($L_i = L_{i+1} = L_{i+2} \ldots = L_{i+n_i-1}$) of the same kind in the set, they are given the corresponding n_i ligand numbers $l = i, i+1, \ldots, i+n_i-1$.

2.4.4. Reference Isomer

E I: The reference isomer **E** is that permutation isomer in which the ligands $L_1 \ldots L_n$ of **M** are attached to the positions of the standard skeleton (see I–XXIX) so that the ligand numbers l and the skeletal position numbers *s* match. We represent this mapping by the *unit matrix* $\binom{l}{s}_E$ of the set of isomers.

$$\binom{l}{s}_E = \begin{Bmatrix} 1\ 2\ 3\ 4 \ldots\ldots n \\ 1\ 2\ 3\ 4 \ldots\ldots n \end{Bmatrix}$$

E II: The reference matrix with more than one set of equivalent skeletal positions is that matrix in which the ligand numbers l, l′, l″, *etc.* of all sets are superimposed upon all corresponding skeletal numbers *s*, *s′*, *s″*, *etc.*

$$\binom{l}{s}_E = \begin{Bmatrix} 1 \ldots\ldots n\ 1' \ldots\ldots n'\ 1'' \ldots\ldots n'' \ldots\ldots \\ 1 \ldots\ldots n\ 1' \ldots\ldots n'\ 1'' \ldots\ldots n'' \ldots\ldots \end{Bmatrix}$$

The mapping of $l \rightarrow s$ of a set of n indexed ligands onto an indexed set of n skeletal coordinates can be particularly well represented by $(2 \times n)$ matrices. An $(n \times n)$ matrix will also represent this mapping. In the latter case, all matrix elements a_{sl} are *zero* except for a *one* in each row and column. $a_{sl} = 1$ expresses that *s* and l belong together, and $a_{sl} = 0$ means *s* and l are not mapped onto each other. The $(n \times n)$ matrices of the reference isomers are unit matrices E_n.

$$E_n = \begin{array}{c|c} \begin{matrix} 1 & 2 & 3 & 4 & \ldots & n \end{matrix} & l/s \\ \hline \begin{pmatrix} 1 & 0 & 0 & 0 & \ldots & 0 \\ 0 & 1 & 0 & 0 & \ldots & 0 \\ 0 & 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 0 & 1 & \ldots & 0 \\ \vdots & & & & & \vdots \\ 0 & 0 & 0 & 0 & \ldots & 1 \end{pmatrix} & \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \\ \vdots \\ n \end{matrix} \end{array}$$

2.4.5. Optimum Projection

A molecule **M** can generally be described by many equivalent mappings (see Section 2.4.7.) in which the l and *s* belong together in different ways. This is due to the equivalence of some skeletal positions ***S*** (topological coordinates) and, in certain cases, the equivalence of some of the ligands $L_1 \ldots L_n$. Some of these different mappings correspond to different spatial orientations of **M**. These different arrangements can be compared to the different *Fischer projections* [8a] of a molecule. For the comparison of **M** with its reference isomer **E** the optimum mapping, $\mathbf{M}_{opt}$ of **M** is chosen.

O I: The optimum mapping $\mathbf{M}_{opt}$ is that mapping of **M** whose matrix $\binom{l}{s}_{opt}$ is most similar to $\binom{l}{s}_E$.

O II: We consider that mapping of **M** to be most similar to $\binom{l}{s}_E$ whose matrix $\binom{l}{s}_{opt}$ can be transformed into $\binom{l}{s}_E$ by the simplest permutation of the skeletal numbers, *s*. The *s*-permutations correspond to permutations of the rows of the $(n \times n)$ matrices. The simplest permutation is the permutation which involves the smallest number of *s*, if possible in small cycles. Accordingly, $\mathbf{M}_{opt}$ is that arrangement of **M** in whose matrix there is a maximum set of superimposable ligand and skeletal numbers $l = s$.

In terms of an $(n \times n)$ matrix representation the optimum arrangement is that one in which as many *ones* as possible are matrix elements of the main diagonal, and those *ones* which are off the main diagonal can be brought into it by the simplest permutation of rows.

O III: If there is more than one such matrix the alphanumerically lowest set of non-matching l and *s* is preferred. If this is not sufficient to identify the optimum matrix $\binom{l}{s}_{opt}$, then that matrix is preferred for which the difference $l - s$ is the smallest. This corresponds to a $(n \times n)$ matrix where the diagonal zeros are as close to the upper left corner of the matrix as possible.

O IV: The optimum matrix $\binom{l}{s}_{opt}$ of an isomer with non-equivalent sets of equivalent skeletal positions is that matrix which is generated from $\binom{l}{s}_E$ by the simplest, alphanumerically lowest permutation of the unprimed *s*.

If **M** does not happen incidentally to be given in its optimum arrangement, its matrix $\binom{l}{s}_{opt}$ can be determined as follows:

O V: First, the ligand and skeleton numbers, l and *s* are determined according to L I – S IX for the particular arrangement of **M**, and are then represented by the $\binom{l}{s}$ matrix.

O VI: If **M** contains sets of equal ligands (like $n_i \geq 2$ equal ligands $L_i = L_{i+1} \ldots + L_{i+n_i-1}$), then, at first, only a corresponding range $i \leq l \leq i + n_i$ of the ligand numbers is "reserved" for these ligands:

$$\begin{matrix} i,\ i+1 \ldots\ldots i+n_{i-1} \\ L_i,\ L_{i+1} \ldots\ldots L_{i+n_i-1} \end{matrix}$$

In the corresponding $(n \times n)$ representation the matrix element $a_{sl} = x = \{^1_0$ is used for $i \leq l \leq i + n_{i-1}$ if the skeletal position *s* carries one of the equal ligands $L_i = L_{i+n_i-1}$.

O VII: The ligand and skeleton numbers, l and *s* of **M** are adjusted to an optimum matrix, $\binom{l}{s}_{opt}$ by permuting

the skeletal numbers s in the $\binom{l}{s}$ matrix or the rows in the (n × n) matrix. Only those permutations of s are permitted which correspond to transformations of the permutational coordinates into equivalent coordinates, *i.e.*, permutations which correspond to the rotational symmetry operations (of the subgroup $\boldsymbol{H}$) of the skeletal symmetry group $\boldsymbol{G}$.

O VIII: If not all of the ligands $L_1 \ldots L_n$ are different, *i.e.*, if there is at least one set of $n_i \geq 2$ of equal ligands ($L_i = L_{i+1} \ldots = L_{i+n_i-1}$), and some of the ligand numbers l had only been pre-assigned by O VI (for final assignment after establishing $\binom{l}{s}_{pre}$), a *pre-optimum* matrix $\binom{l}{s}_{pre}$ is obtained by applying O VII. The pre-optimum matrix $\binom{l}{s}_{pre}$ is transformed into $\binom{l}{s}_{opt}$ by assigning the n_i individual numbers ($i \leq l \leq n_i$) of the ligands $L_i \ldots L_j \ldots L_{i+n_i-1}$ in such a manner that as many as possible of them match the skeletal numbers of $\binom{l}{s}_{pre}$. In the (n × n) representations this is done by simply replacing that x in each row which is on the main diagonal or that is permutationally "closest" to it by a one, and all other x's by zero.

2.4.6. Assigning Descriptors

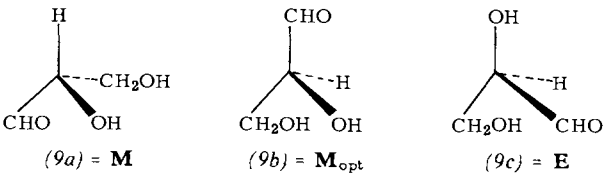
The conversion of the reference matrix $\binom{l}{s}_E$ (see Section 2.4.4.) into the $\binom{l}{s}$-matrix of a given permutational isomer **M** is given by a permutation $\boldsymbol{P_s}$, the *descriptor* of **M**, according to equation (1),

$$\text{with } \boldsymbol{P_s} = (\ldots n_i\ 1\ n_1 \ldots n_j\ 2\ n_2 \ldots n_k\ 3\ n_3 \ldots n\ n_n) \qquad (2)$$

$$\text{and } \binom{l}{s} = \begin{Bmatrix} n_1 & n_2 & n_3 \ldots 1 & \ldots 2 & \ldots 3 & \ldots n_n \\ 1 & 2 & 3 \ldots n_i \ldots n_j \ldots n_k \ldots n \end{Bmatrix} \qquad (3)$$

We propose to use the *descriptor* $\boldsymbol{P_s}$ of **M** as the nomenclature name of the isomer **M**, because the set of permutational isomers is in an unequivocal relation to the set of these operators $\boldsymbol{P_s}$. The operator $\boldsymbol{P_s}$ gives unequivocal instructions as to how to construct its corresponding isomer from a given molecular skeleton $\boldsymbol{S_n}$ (see I–XXIX) and a set of ligands $L_1 \ldots L_n$. The identity operator $\boldsymbol{P_s} = (e)$ represents the reference isomer **E**, according to $(e)\binom{l}{s}_E = \binom{l}{s}_E$.

The set of descriptors of a set of isomers is not a group, but the set of permutations which interconvert all the isomers is a group $\boldsymbol{G}$. Those permutations which interconvert the stereoisomers among the permutational isomers, belong to a subgroup of $\boldsymbol{G}$.



2.4.7. Examples

2.4.7.1. Simple Skeletons

One might infer from the preceeding definitions that use of this nomenclature involves lengthy and complicated operations. This is however, not the case, as one can readily demonstrate with the examples of Section 2.4.7. Any systematic nomenclature which appears less complicated is bound to contain arbitrary rules and oversimplifications which will severely limit its generality and accuracy (see Section 2.3 and footnotes [15d–15g]).

Example 1

The spatial arrangement of *(9)*, ($s = 1, \ldots, 4$, see XXVII, $l = 1, \ldots, 4$ with OH = 1, CHO = 2, CH_2OH = 3, and H = 4) is represented by $\binom{l}{s}_{(9a)}$ which is converted into $\binom{l}{s}_{(9b)}$ by the s-permutation *(1 3 4)* or the equivalent l-permutation (1 4 3) [16].

(9a) = **M** *(9b)* = $\mathbf{M}_{opt}$ *(9c)* = **E**

$$\left\langle \tfrac{1}{s} \right\rangle_{(9a)} = \begin{Bmatrix} 4 & 1 & 2 & 3 \\ 1 & 2 & 3 & 4 \end{Bmatrix} \qquad \left\langle \tfrac{1}{s} \right\rangle_{(9c)} = \begin{Bmatrix} 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \end{Bmatrix}$$

$$(1\ 3\ 4)\ \left\langle \tfrac{1}{s} \right\rangle_{(9a)} = \left\langle \tfrac{1}{s} \right\rangle_{(9b)} = \begin{Bmatrix} 4 & 1 & 2 & 3 \\ 4 & 2 & 1 & 3 \end{Bmatrix} = (1\ 2)\ \left\langle \tfrac{1}{s} \right\rangle_{(9c)}$$

oder:

$$(1\ 3\ 4) \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}_{(9a)} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}_{(9b)} = (1\ 2) \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}_{(9c)} = (1\ 2)\ \boldsymbol{E_4}$$

The l-permutation (1 4 3) corresponds to a counterclockwise 120° rotation (C_3) of the ligands, L_1, L_3, L_4.

The permutation *(1 2)* converts *(9c)* into *(9b)* and is therefore the descriptor of *(9b)* [≡*(9a)*]. The steric formula of *(9b)* is reconstructed from the descriptor *(1 2)* as follows: The ligands OH, CHO, CH_2OH, and H are written in this sequence. When these ligands are attached to the *(1 2)*-transform of the standard framework in their sequential order, OH → 2, CHO → 1, CH_2OH → 4, the formula *(9b)* results.

The matrix

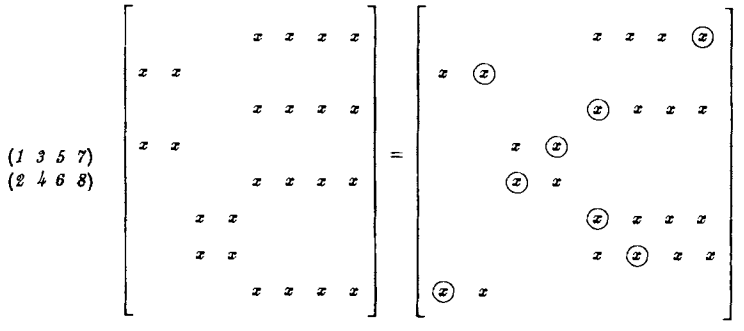
$$\begin{matrix} \beta \\ \alpha \\ \gamma \end{matrix} \left| \begin{Bmatrix} 4 & \mathbf{1} & \mathbf{2} & 3 \\ 1 & 2 & 3 & 4 \\ 4 & \mathbf{2} & \mathbf{1} & 3 \end{Bmatrix} \right| \left\langle \tfrac{1}{s} \right\rangle_{(9b)} \equiv (1\ 2)$$

contains an abbreviated formalism for deriving the descriptor *(1 2)* for *(9a)*. The rows are written in the order α, β, γ. The α-row contains the s in their natural order. The sequential numbers of the ligands are mapped upon the numbers of the skeletal positions to which the individual ligands are attached (row β). The γ-row is obtained from the α-row by the permutation *(1 3 4)*; this permutation (which corresponds to a 120° rotation around *2*) brings 3 and 4 into coincidence with *3* and *4*. The β- and γ-rows correspond to $\binom{l}{s}_{opt}$ which is transformed into $\binom{l}{s}_E$ by the permutation *(1 2)*.

The descriptor *(1 2)* is obtained by permuting row γ such that it matches row β. Since the pairs 3–*3* and 4–*4* match already, only *1* and *2* must be permuted in order to transfer those mappings 1–*2*, 2–*1* into 1–*1*, 2–*2*.

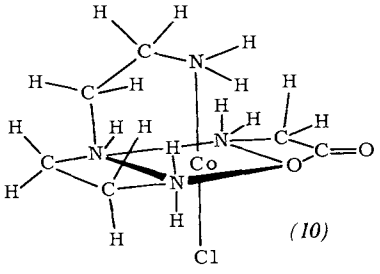
Example 2 (see XII) [9]

The molecule of *(3a)* (=**M**) contains three sets of equivalent ligands for which the corresponding intervals of l are "reserved" (*i.e.*, CO_2H = 1,2; C_6H_5 = 3,4; H = 5–8), according to Section 2.4.3. Then, if {l} is mapped onto {s} (see above) the pre-optimum matrix $\binom{l}{s}_{pre}$ (see Section 2.4.5) is generated by the permutation *(1 3 5 7) (2 4 6 8)* which represents a 90° rotation of the skeleton. A comparison of the s in γ, and the l in β make the assignments of all the l except 5 and 8 obvious. The aim is simply to match as many l and s as possible. The assignment of 5 and 8 is not so simple. Since an optimum assignment of an isomer should be, whenever possible, that assignment which leads to the reference isomer *via* the most simple permutation of s, 8 is assigned to *1* and 5 to *3* so that these interchanges may be made directly. Then, the $\binom{l}{s}_{opt}$ is $\binom{6}{7}$.



δ	7	**1**	**8**	2	**5**	4	**3**	6
β	5-8	1, 2	5-8	1, 2	5-8	3, 4	3, 4	5-8
α	*1*	*2*	*3*	*4*	*6*	*6*	*7*	*8*
γ	*7*	*8*	*1*	*2*	*3*	*4*	*5*	*6*

$\left\{\begin{matrix}\delta\\ \gamma\end{matrix}\right\} \equiv \left\{\begin{matrix}1\\ s\end{matrix}\right\} \equiv (1\,8)\,(3\,5)$



The only non-matching ($^{\delta}_{\gamma}$) mappings are $1-8$, $8-1$, and $3-5$, $5-3$. By this nomenclature *(3a)* is thus *(1 8)(3 5)*-dicarboxy-diphenylcyclobutane.

The (8 × 8) representation for this is as follows (see XII) (those matrix elements which are zero are left out; those *x* which become one are encircled):

(1 3 5 7)
(2 4 6 8)

$\equiv (1\,8)\,(3\,5)\,E_8$

(10)

Example 3 (see XII)

The steric formulas *(3c)* and *(3d)* of the *(1 7)(3 5)*- and *(1 5)(3 7)*-dicarboxy-diphenyl-cyclobutanes are derived from the *descriptors* as follows:

The permutations (1 7)(3 5) and (1 5)(3 7) of the ligands 1 (CO_2H) and 7 (H) as well as 3 (C_6H_5) and 5 (H) of the reference isomer *(3e)* generate *(3c)* and *(3d)*. In this case the l- and the *s*-permutations have the same effect.

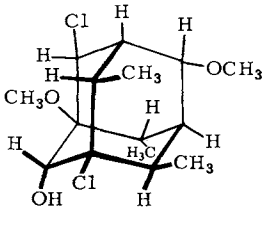
For comparison, try naming the truxinic acids *(3c)* and *(3d)* by any other nomenclature, and then reconstruct their steric formulas!

Example 4

The steric formula *(4a)* of the *(2 4)*-dichloro-aquo-triammino-cobalt(III) ion is obtained by first writing down the ligands in sequential order (Cl = 1,2; H_2O = 3; NH_3 = 4,5,6) and then attaching them to the *(2 4)*-transform of the skeleton XXIX to form *(4a)*. The reference isomer is *(4b)*.

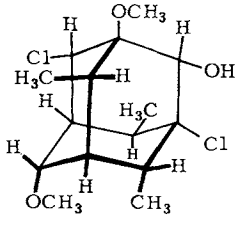
Example 5

For the purpose of assigning ligand numbers, the coordinating moieties of the multidentate ligands of *(10)* are treated as separate ligands.



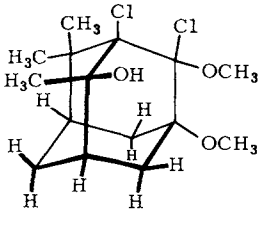
Accordingly, the ligand numbers of *(10)* are,

Cl	$^{\ominus}O_2C\text{-}CH_2\text{-}NH_2$			$NH(CH_2CH_2NH_2)_2$	
1	2		3	4	5,6



δ	**5**	3	2	1	6	**4**	$\equiv \left\{\begin{matrix}1\\ s\end{matrix}\right\}_{opt}$
β	5,6	3	2	1	5,6	4	
α	*1*	*2*	*3*	*4*	*5*	*6*	
γ	*4*	*3*	*2*	*1*	*6*	*5*	

and the descriptor of the chiral complex *(10)* is *(4 5)*-chloro-aminoacetato-diethylenetriamine-cobalt.



Example 6

(11a) = **M**

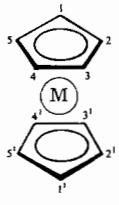
(11b) = $\mathbf{M}_{opt}$

(11c) = **E**

δ	4	3	**1**	**2**	9'	**2'**	**5**	12'	**11'**	**1'**	**6'**	7'	**8'**	**3'**	**10'**	**4'**
β	3,4	3,4	1	2	7'-12'	2'	4'-6'	7'-12'	7'-12'	1'	4'-6'	7'-12'	7'-12'	3'	7'-12'	4'-6'
α	*1*	*2*	*3*	*4*	*1'*	*2'*	*3'*	*4'*	*5'*	*6'*	*7'*	*8'*	*9'*	*10'*	*11'*	*12'*
γ	*4*	*3*	*2*	*1*	*9'*	*10'*	*11'*	*12'*	*6'*	*5'*	*8'*	*7'*	*1'*	*2'*	*3'*	4'

(7' 8')

The unprimed and primed skeletal numbers of XXVI are arranged in one line (α), and the (assigned or preassigned) sequential numbers of the ligands (1: Cl; 2: OCH_3; 3,4: H; 1': Cl;



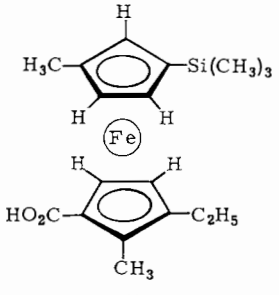
2′: OCH_3; 3′: OH; 4′–6′: CH_3; 7′–12′: H) are paired with their positions (β). The unprimed part of the matrix is optimized by a permutation which corresponds to a C_2-rotation [≡(7′ 8′)]. The pre-optimal matrix is converted into the optimal matrix (δ) by assigning the final ligand numbers l. The upper and the lower rows are the rows of $\binom{l}{s}_{opt}$ of *(11b)*. The permutation *(12)* *(1′ 8′ 6′ 11′ 5′) (2′ 3′ 10′)* is therefore the descriptor of *(11a)* ≡ *(11b)*, a chiroid of *class b*. Admittedly, it involves some work to find the descriptor of *(11a)*, but it takes, even in this complicated case, very little effort to reconstruct *(11b)* [≡*(11a)* = **M**] from its descriptor and the reference isomer *(11)* (≡**E**). The attempt to treat a compound like *(11a)* by any other nomenclature would lead to a rather frustrating experience.

2.4.7.2. Composite Skeletons

There are molecules whose skeletons have internal rotational degrees of freedom. These skeletons can be treated as if they were combinations of independent simpler skeletons.

Example 7

The metallocenes [17a] with their internal rotation are considered to be a combination of two C_{5v} skeletons (V).

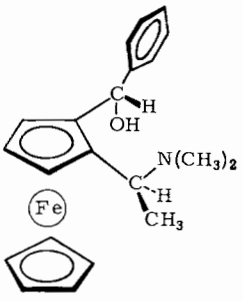


(12)

In the case of permutational isomers with these composite skeletons containing independent equivalent parts, the unprimed skeletal numbers *s* are assigned to that moiety which carries the greatest number of different ligands.

The assignment of the skeletal numbers *s* is done as shown in formula *(12) i.e.*, the metal is coordinated to those sides of the rings from which the skeletal numbers appear to be numbered in a counter-clockwise sequence. This definition is intended to have general validity for metal complexes which contain symmetrical subskeletons whose skeletal positions lie in a plane or whose idealized representations lie in a plane.

Example 8



δ	3′	**1′**	5′	**4′**	2′	≡(1′ 4′)
β	3′-5′	1′	3′-5′	3′-5′	2′	
α	*1′*	*2′*	*3′*	*4′*	*5′*	
γ	*3′*	***4′***	*5′*	***1′***	*2′*	
β	**3**	**2**	4,5	4,5	1	≡(2 3)
α	*1*	*2*	*3*	*4*	*5*	
γ	***2***	***3***	*4*	*5*	*1*	

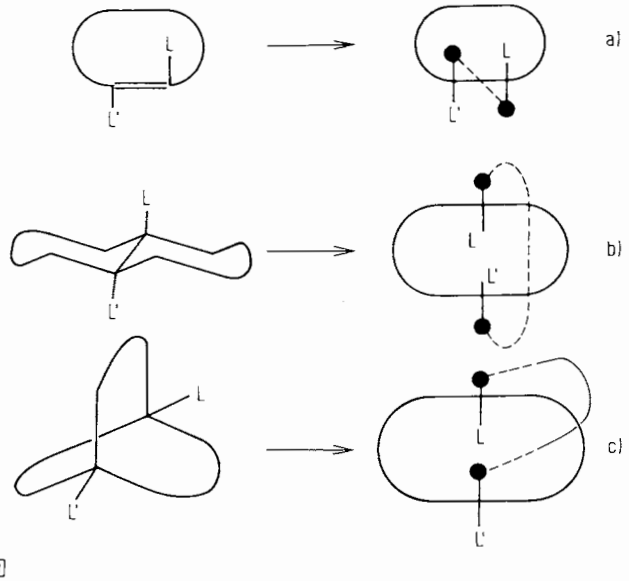
(13)

The primed l and *s* are assigned to the upper ring which has three equal ligands (H). Both rings are represented by their skeletal number *s* and *s′* (α), and the ligand numbers l are assigned and the l′ are preassigned to their corresponding *s*- and *s′* (β). Then the optimum matrices of *(13)* $\binom{l}{s}_{opt}\binom{l'}{s'}_{opt}$ are generated (*via* the pre-optimum of $\binom{l'}{s'}_{pre}$) by cyclic permutations of the *s* and *s′* (γ). The resulting descriptor of *(13)* is *(23)(1′ 4′)*.

[17] a) *K. Schlögl*, Top. in Stereochem. *1*, 39 (1967); b) *D. Marquarding, H. Klusacek, G. Gokel, P. Hoffmann*, and *I. Ugi*, Angew. Chem. *82*, 360 (1970); Angew. Chem. internat. Edit. *9*, 371 (1970).

Example 9

(14)



β	1	2	3-5	3-5	3-5	≡ (e)
α	*1*	*2*	*3*	*4*	*5*	
β	3*	**1***	4*	**2***		≡ (1 2)*
α	*1**	*2**	*3**	*4**		
γ	*3**	***2****	*4**	*1**		
β	**2****	4**	**1****	3**		≡ (1 2)**
α	*1***	*2***	*3***	*4***		
γ	*1***	*4***	***2*****	*3***		

In example 9, chiral side chains are attached to the ferrocene system. In order to describe the permutation of the ligands of those side chains in the description of the whole molecule and in order to differentiate that part of the descriptor which belongs to the side chain, we used starred ligand numbers and starred skeletal numbers for the side chain. If there is more than one side chain which belongs to the system, we use double starred ligands and skeleton numbers. The priorities follow the sequence rule. Accordingly, in *(14)*, the unstarred ligands belong to the ferrocene skeleton; l, *s* with one star belong to the benzyl alcohol group and those l and *s* which are doubly starred belong to the dimethylamino group.

According to the usual procedure, we find the descriptor to be (cf. example 1) *(e) (1 2)* (1 2)***. This is equivalent to the designations which have been used in the past, and corresponds to *(S)(S)(R)* [17b].

2.4.7.3. The Use of Nil

Cyclic molecules which contain multiple bonds, annellations, or bridges can be included in the present concept of permutational nomenclature by dissecting bonds and representing the resulting free valencies by *nils* (= ↑). By this dissection procedure (see Fig. 9), a cycloalkane derivative results with a D_{nh} skeleton which carries 2 z nils if z bonds were dissected. The positions of the nils are determined by the stereochemistry of the dissected molecule.

A 785.9

Fig. 9. Formal dissection of cyclic and polycyclic compounds with multiple bonds (a) or bridges (b, c), the resulting free valencies being represented by nils.

Whether a given skeletal position number of a D_{nh} (cycloalkane) skeletal representation is odd or even is usually obvious. In complicated cases, the solution is obtained unequivocally as shown in Fig. 10.

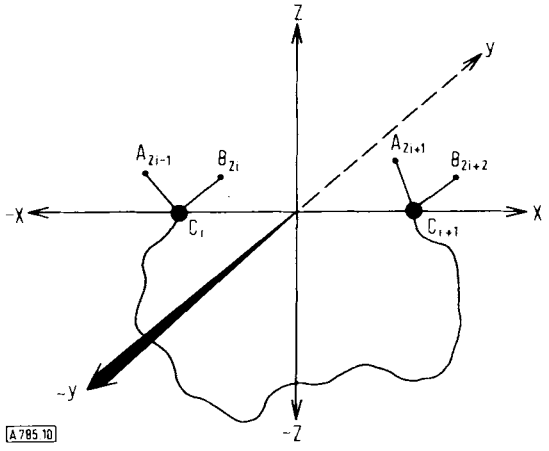


Fig. 10. Unequivocal assignment of skeletal position numbers to a D_{nh} skeleton.

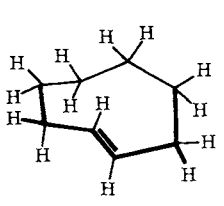
An idealized Cartesian coordinate system is drawn so that two neighboring members, C_i and C_{i+1} of a ring belong to the $-x$ axis and the $+x$ axis. The ring belongs to the space with $y \leq 0$. Ligand positions A_{2i-1} and B_{2i+2} belong to $y \geq 0$. A_{2i-1} and A_{2i+1} have odd s (are above the clockwise ring) B_{2i} and B_{2i+2} have even s (are below) if

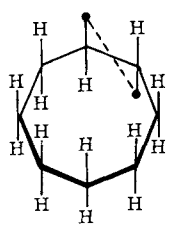
$A_{2i-1}, B_{2i} : z_{2i-1} : y_{2i-1} > z_{2i} : y_{2i}$
$A_{2i+1}, B_{2i+2} : z_{2i+1} : y_{2i+1} > z_{2i+2} : y_{2i+2}$

The descriptors of unsaturated and/or polycyclic compounds are assigned according to these definitions. Whenever the stereochemistry is unknown or purposely neglected, the topological coordinates of the nils are chosen such that the most simple, alphanumerically lowest descriptor results.



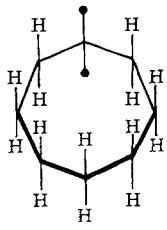
a) *Multiple and Transannular Bonds*

For unsaturated compounds and a wide variety of polycyclic compounds the permutational nomenclature in combination with the concept of nils provides a satisfactory solution to the nomenclature problem, even if chiral skeletons are involved.



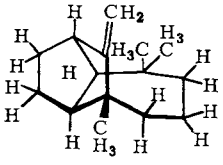
The bonds which are considered to be formed from the nils are designated by attaching the suffixes *ene*, *yne*, and *con*, respectively, to the name of M for double and triple bonds and transannular connections and, in brackets ⟨⟩, the numbers s of the skeletal positions in $\mathbf{M}'_{opt}$ which are connected by these bonds.

Example 10 [18]

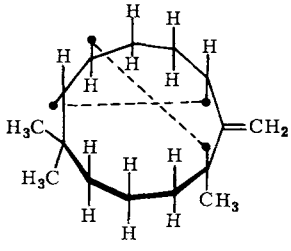


The chiral *trans*-cyclooctane *(15a)* is, for descriptor purposes, considered as a cyclooctane (with an idealized D_{8h} symmetry, see Section 2.3.); the two nils in *(15b)* in adjacent skeletal positions characterize the formation of a *trans* double bond.

(15a)



(15b) (≡ **M** ≡ $\mathbf{M}_{opt}$)



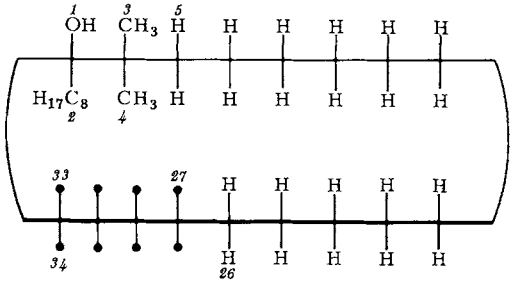
(15c) (= **E**)

The reference isomer of *(15a)* [= *(15b)*] is *(15c)* and the descriptor is *(2 16)*. Therefore *(15a)* is *(2 16)*-cyclooctene-⟨2 – 15⟩.

Example 11 [19]

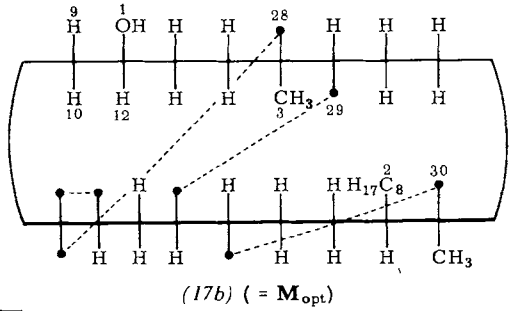
(16a)

(16b)



Longifolene *(16a)* is dissected, as shown by *(16b)*, into a cycloundecane derivative with the ligands CH_2 = : 1,2; CH_3: 3 – 5; H: 6 – 18; ↑ : 19 – 22, and the matrix is

$$\left(\begin{matrix}1\\s\end{matrix}\right)_{opt} = \left\{\begin{matrix} 1 & 2 & \mathbf{19} & 4 & \mathbf{11} & 6 & 7 & 8 & 9 & 10 & \mathbf{3} & \mathbf{5} & 13 & \mathbf{20} & \mathbf{21} & 16 & 17 & 18 & \mathbf{12} & \mathbf{14} & \mathbf{15} & 22 \\ \mathit{1} & \mathit{2} & \mathbf{\mathit{3}} & \mathit{4} & \mathbf{\mathit{5}} & \mathit{6} & \mathit{7} & \mathit{8} & \mathit{9} & \mathit{10} & \mathbf{\mathit{11}} & \mathbf{\mathit{12}} & \mathit{13} & \mathbf{\mathit{14}} & \mathbf{\mathit{15}} & \mathit{16} & \mathit{17} & \mathit{18} & \mathbf{\mathit{19}} & \mathbf{\mathit{20}} & \mathbf{\mathit{21}} & \mathit{22} \end{matrix}\right\}$$

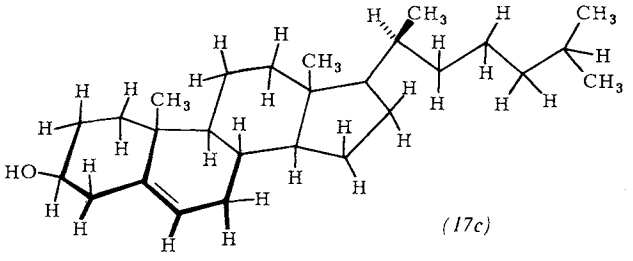


From this follows the descriptor *(3 19 12 5 11) (14 20) (15 21)*-methylene-trimethyl-cycloundecane-*dicon*-⟨3 – 15, 14 – 22⟩.

Example 12 [20]

The steric formula of *(1 9 28 17 30 19 2 10 3) (4 12 29 18) (26 32)*-hydroxy-[*(1′ 2′)*-α,ε-dimethyl-hexyl]-dimethyl-cycloheptadecene-⟨31 – 33⟩-*tricon*-⟨9 – 34, 12 – 27, 17 – 26⟩ is derived by the following steps.

(17a) (= **E**)

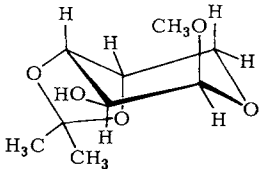


(17b) (= $\mathbf{M}_{opt}$)

[18] *A. C. Cope, C. R. Ganellin*, and *H. W. Johnson, Jr.*, J. Amer. chem. Soc. *84*, 3191 (1962); *A. C. Cope, C. R. Ganellin, H. W. Johnson, Jr., T. V. Van Auken*, and *H. J. S. Winkler, ibid. 85*, 3276 (1963); *A. C. Cope* and *A. S. Mehta, ibid. 86*, 5626 (1964).

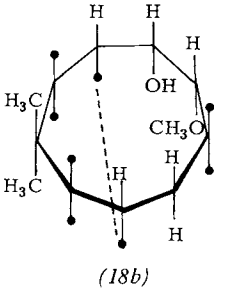
[19] *P. Naffa* and *G. Ourisson*, Chem. Ind. (London) *1953*, 917; *R. H. Moffett* and *D. Rogers, ibid. 1953*, 916.

[20] *J. W. Cornforth, F. Youhotsky*, and *G. Popjak*, Nature *173*, 536 (1954); *B. Riniger, D. Arigoni*, and *O. Jeger*, Helv. Chim. Acta *37*, 546 (1954).



(17c)

The molecule is based upon the skeleton of cycloheptadecane with an idealized D_{17h} symmetry. The 34 skeletal positions are numbered according to the rules of Section 2.4.2. and the reference isomer *(17a)* is generated by attaching the ligands (1: OH, 2: C_8H_{17}, 3,4: CH_3, 5–26: H, 27–34: *nils*). The descriptor *(1 9 28 17 30 19 2 10 3) (4 12 29 18) (26 32)* permutes the coordinate indices of *(17a)* and transforms it into *(17b)*. Then the nils of the skeletal positions *31* and *33* are used to make a double bond, and the pairs of nils at *9* and *34*, *12* and *27*, *17* and *26* are connected to produce the tetracyclic framework of *(17c)*, which is cholesterol.



b) *Heterocycles*

The concept of nils is useful for the description of the aza-, oxa-, and thia-derivatives of the carbocyclic permutational isomers. If the covalency of the heteroatom is lower than four $(4 - x)$, this is taken into account by attaching x nils to the heteroatom. Further, the positions of heteroatoms must be specified. For this purpose the (carbon) atoms of the skeleton are numbered by skeletal nuclear numbers $s_N = 1_N \ldots n_N$, differentiated from the skeletal position numbers s by the subscript N. The nuclear number 1_N is assigned to the skeletal nucleus with the skeletal position number *1* (or numbers *1* and *2*, respectively); number 2_N belongs to the nucleus with the position number *2* (or *3* and *4*, respectively), *etc.* The nature and position of a heteroatom is indicated in the descriptor (see example 13).

Example 13 [21]

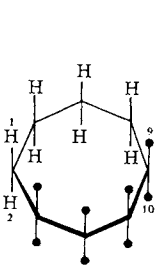
(18a)

(18b)

The methyl-3,4-*O*,*O'*-isopropylidene-β-D-arabinopyranoside *(18a)*, an intermediate in the synthesis of gentosamine is treated as a trioxa-cyclononane.

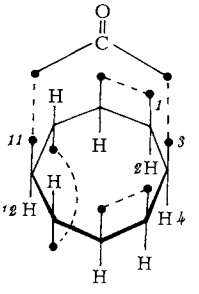
The optimal matrix $\left(\begin{smallmatrix}1\\s\end{smallmatrix}\right)_{opt}$ of *(18b)* yields the descriptor *(1 5 13 3 6 14 4) (10 17)-con-⟨10–18⟩-3$_N$,6$_N$,8$_N$*-trioxa-methoxy-dimethyl-cyclononanol for *(18a)*.

$$\left(\begin{smallmatrix}1\\s\end{smallmatrix}\right)_{opt} = \left\{\begin{array}{cccccccccccccccccc} \mathbf{5} & 2 & \mathbf{6} & \mathbf{1} & \mathbf{13} & \mathbf{14} & 7 & 8 & 9 & \mathbf{17} & 11 & 12 & \mathbf{3} & \mathbf{4} & 15 & 16 & \mathbf{10} & 18 \\ \mathbf{1} & 2 & \mathbf{3} & \mathbf{4} & \mathbf{5} & \mathbf{6} & 7 & 8 & 9 & \mathbf{10} & 11 & 12 & \mathbf{13} & \mathbf{14} & 15 & 16 & \mathbf{17} & 18 \end{array}\right\}$$



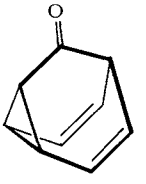
[21] *H. Maehr* and *C. Schaffner*, J. Amer. chem. Soc. *92*, 1697 (1970).

c) *Bridged Molecules*



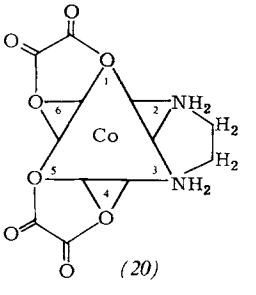
The nil method can be extended to bridged systems, by simply considering the bridges as connections between nils, and describing them by attaching to the name of $\mathbf{M}'_{opt}$ the suffix *pon* (lat.: *pons* = bridge), and in brackets⟨⟩ the numbers s of the skeletal positions which are connected and (between those numbers) the name of the bridge.

Example 14 [22]



The formula of *(19c)*, *(19) (3 12) (5 13) (7 16)*-cyclooctadiene-⟨*1–15, 5–7*⟩-*con*-⟨*10–14*⟩-*pon*-⟨*3*-carbonylo-*11*⟩ follows from *(19a) via (19b)* by generating *(19c)* with the permutation operator *(1 9)(3 12)(5 13)(7 16)* and then connecting the nil ligands as indicated by diene-⟨*1–15, 5–7*⟩-*con*-⟨*10–14*⟩-*pon*-⟨*3*-carbonylo-*11*⟩. The result is barbaralone *(19c)*.

(19a)



(19b)

(19c)

The concept of bridged skeletal positions can, in a slightly modified form, be extended to the chelated metal complexes. As a rule, it suffices to indicate the skeletal positions of the central atoms that are connected by chelating ligands. Permutation of the skeletal positions in a complex having chelating ligands might easily lead to confusion regarding the original skeletal position-ligand relationship. In order to retain the information provided by the original $\left(\begin{smallmatrix}1\\s\end{smallmatrix}\right)$ matrix, those columns of skeletal positions which belong together because of chelation are indicated by brackets and these brackets are retained during s-permutations.

Example 15 [10]

(20)

$$\begin{array}{lc} \delta & \left\{\begin{array}{cccccc} 1 & 5 & 6 & 4 & 2 & 3 \\ 1\text{-}4 & 5,6 & 5,6 & 1\text{-}4 & 1\text{-}4 & 1\text{-}4 \end{array}\right. \\ \beta & \\ \alpha & \left\{\begin{array}{cccccc} 1 & 2 & 3 & 4 & 5 & 6 \end{array}\right. \\ \gamma & \left\{\begin{array}{cccccc} 1 & 5 & 6 & 4 & 2 & 3 \end{array}\right. \end{array} \equiv \left(\begin{smallmatrix}1\\s\end{smallmatrix}\right)_{opt}$$

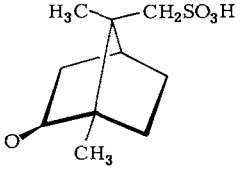
[22] *W. v. E. Doering, B. M. Ferrier, E. T. Fossel, J. H. Hartenstein, M. Jones, Jr., G. Klumpp, R. M. Rubin*, and *M. Saunders*, Tetrahedron *23*, 3943 (1967).

According to $(^{1}_{3})_{opt}$ the descriptor of the chiral complex *(20)* is dioxalato-⟨*1*−*3*, *2*−*4*⟩-ethylenediamine-⟨*5*−*6*⟩-cobalt, and the ⟨*1*−*2*, *3*−*4*⟩-⟨*5*−*6*⟩-isomer is the antipode of *(20)*.

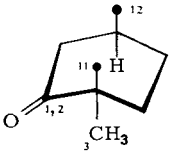
The descriptors of multinuclear metal complexes indicate the connecting bridges and the numbers of the nils of the nuclei which are used for bridging. Ligands inserted into faces of complexes as bridges are symbolized by *pon* and in ⟨ ⟩ brackets the numbers of those ligands between which the additional ligand is inserted (see some of the hepta-coordinate complexes).

A wide variety of polycyclic molecules could not be adequately represented by descriptors unless further operations were defined for the treatment of complications arising from the bridges of certain polycyclic systems.

A bridge of a polycyclic molecule that is capable of existing in various isomeric forms requires a nomenclatural procedure which allows one to describe unequivocally the topology of this bridge in relation to the rest of the molecule. A one-membered bridge of a molecule **M** such as *(21)*

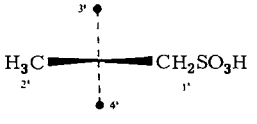


(21)



can be adequately represented by a tetrahedral skeleton XXVII. Positions *1* and *2* carry the ligands L_1 and L_2 and positions *3* and *4* are empty, *i.e.*, occupied by nils, and are used for attaching this bridge to the rest of the molecule **M**, in a manner indicated by the descriptor.

Example 16 [23]

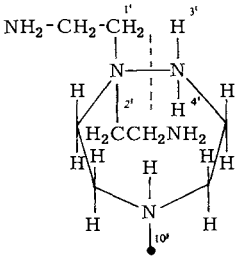


The camphor π-sulfonic acid *(22a)* is an example for compounds with bridges capable of existing in different "epimeric" forms.

(22a)

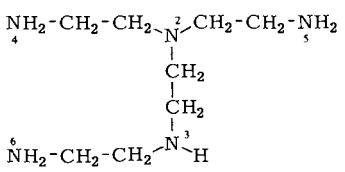
(22b)

(22c)



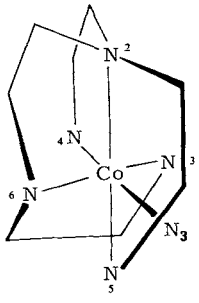
For nomenclatural purposes *(22a)* is "dissected" into *(22b)* and *(22c)*, which leads through the $(^{1}_{3})$-matrices of *(22b)* and *(22c)* to the descriptor (*3 5 12*)-*pon*-⟨*3'*−*5*, *4'*−*11*⟩-[sulfonylmethyl-methyl-methano]-methyl-cyclohexanone for *(22a)*.

Two-membered bridges are derived from I by attaching this system in a specified manner (see above), with its clockwise side toward the positions which must be connected. The most convenient way to describe bridges with three or more members is to describe a corresponding cyclic system and open the ring between two of its members. The resulting chain is fully described by the descriptor of the cyclic system and further, by specifying which bond was transformed into two nils by the prefix *se* (lat.: *secare*) and finally, in brackets ⟨ ⟩, the numbers of skeletal nuclei whose bond was broken.

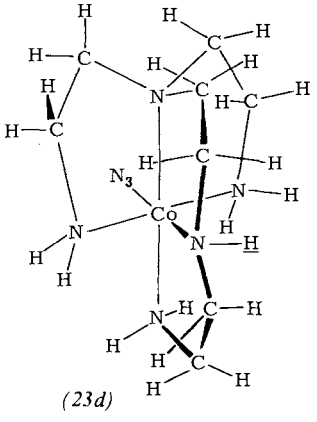


[23] *F. S. Kipping* and *W. F. Pope*, J. chem. Soc. *63*, 549 (1893); *67*, 357 (1895); *A. M. T. Finch* and *W. R. Vaughan*, J. Amer. chem. Soc. *91*, 1416 (1969).

Example 17 (see XXIX) [24]



The (*2 4 3*)-azido-{(*10' 14'*)-*se*-⟨$1'_N$ $2'_N$⟩-1_N, 2_N, 5_N-triaza-bis-[β-aminoethyl]-cycloheptane}-cobalt ion is *(23d)*.



(23a)

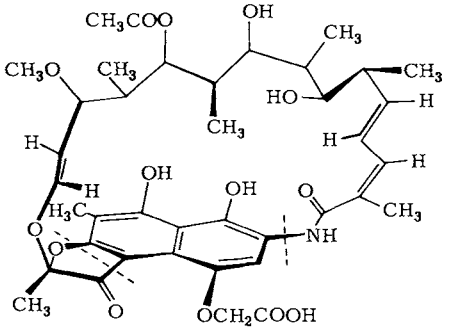
(23b)

(23c)

(23d)

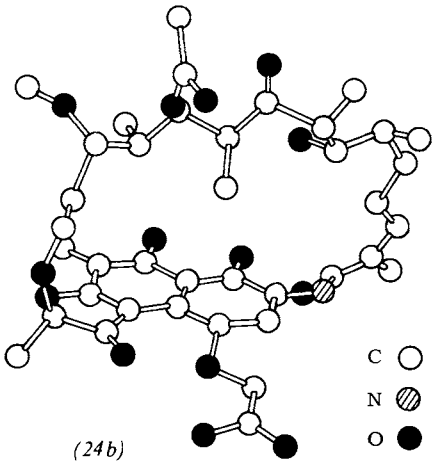
The trenen ligand *(23a)* of the complex *(23d)* is obtained from its reference isomer **E'** = (*1' 2'*)-bis-(β-aminoethyl)-*14'-nil*-cycloheptane by applying its descriptor and attaching a nil to the skeletal position *10'* according to (*10' 14'*), and replacing the carbon atoms at the nuclear positions $1'_N$, $2'_N$, and $5'_N$ by nitrogen. The chirality of the asymmetric nitrogen at *10'* is stabilized by complexation in *(23a)* [= *(23b)*] in the configuration indicated.

The azido group has the highest sequential priority (1) among the ligands of the complex *(23d)*, and the chelating nitrogen atoms of the amine groups are sequentially numbered as indicated in *(23b)*. Hence the reference isomer for the octahedral complex is *(23c)*, a structure that is only conceptual and could not exist for ring strain reasons. The permutation (*2 4 3*) transforms *(23c)* into *(23d)*.



Example 18 [25]

Rifamycin B *(24a)* is treated as a naphthalene derivative with a *se*-azacyclononadecane bridge and an additional oxa-bridge. The combination of the description of the aliphatic bridge *(24d)* and the naphthalene moiety *(24c)* leads to the descriptor (*1 29 26 12 38 2 16 7 17 10 19 8 36 13 24 5 9 37*) (*11 21*) (*6 32 27*)-*se*-⟨1_N−19_N⟩-1_N-aza-17_N-oxa-dioxo-acetoxy-methoxy-dihydro-



[24] *D. A. Buckingham*, *P. A. Marzilli*, and *A. M. Sargeson*, Inorg. Chem. *8*, 1595 (1969).

(24c)

(24d)

2.5. Chiral Descriptors

An observation of chirality relates to a measurement of some property of a chiral system, the numerical value of which will (by definition) be the same for the two antipodes but each will have the opposite algebraic sign [15b,c].

With respect to a class of molecules, we may call a function F_χ a *chirality function* [7,13,15] if it is capable of expressing these numerical values in terms of the nature of the particular molecules, *i.e.*, in terms of the ligands by which the molecules of the given class differ. For chiral permutational isomers with n places for the ligands and a skeletal symmetry S the chirality function F_χ is of the form

$$F_\chi = F_\chi (L_1 \ldots\ldots L_n)$$

The operations of the group S produce permutations P_s, of the L_s. Here the L_s are used as symbols for the ligands, and the indices s refer to the skeletal positions to which L_s is attached.

We use the symbol H' for the subgroups of all permutations belonging to rotations H of S (group order = g). The function F_χ is invariant towards the operations of H and changes its algebraic sign on permutations, S', which correspond to the improper rotations and reflections of S. Accordingly, F_χ vanishes for achiral molecules.

In order to describe observations of chirality, such as optical rotation, ORD, CD, as well as the logarithms of the product ratios of stereoselective syntheses, we use approximations F_χ of chirality functions F_χ [15].

$$F_\chi \simeq F_\chi = F_\chi (\lambda_1 \ldots\ldots \lambda_n) \qquad (4)$$

In the approximated $F_\chi (\lambda_1 \ldots\ldots \lambda_n)$ the variables λ_i represent those properties of L_i which are relevant for a given observation of chirality. The value of the ligand parameter λ_i of L_i differs for the description of different types of chirality observations. The approximation of F_χ by F_χ is achieved by two methods [15b]; 1) the method of the polynomials of the lowest degree, and 2) the method of linear combinations of functions of a minimum set of ligands.

The approximated chirality function $F_\chi(\lambda_1 \ldots\ldots \lambda_n)$ is such that F_χ is invariant towards those permutations P of the variables λ_i which belong to the subgroup H and changes its algebraic sign by permutations representing the coset C. Accordingly, these chirality functions F_χ are invariant towards the projection operator P_A of the antimetric representation of the permutation group S' of the variables $\lambda_1 \ldots\ldots \lambda_n$.

$$P_A F_\chi (\lambda_1 \ldots\ldots \lambda_n) = F_\chi (\lambda_1 \ldots\ldots \lambda_n) \qquad (5)$$

with

$$P_A = \frac{1}{g}\left(\sum_{s\in H} P - \sum_{s\in H} P\right) \qquad (6)$$

This antimetric projection operator (6) can also be used to generate the approximation functions F_χ from monomials (1) or functions of a minimum set of ligands (2) [15b].

Example 19

The subgroup H of the skeletal symmetry group S of XII is

$$H = \{E, C_4^{(1357)}, C_4^{(7531)}, C_2^{(12)}, C_2^{(14)}, C_2^{(15)}, C_2^{(16)}, C_2^{(18)}\},$$

and its coset is

$$C = \{\sigma^{(12)}, \sigma^{(13)}, \sigma^{(15)}, \sigma^{(17)}, \sigma^{(37)}, i, S_4^{(14)}, S_4^{(18)}\}.$$

Therefore, projection operator $P_{A,\mathrm{XII}}$ of the standard skeleton XII is

$$\begin{aligned} P_A = \tfrac{1}{16}\{&E + (1357)(2468) + (7531)(8642) + (12)(38)(47)(56)\\ &(14)(23)(76)(85) + (15)(26)(37)(48) + (16)(25)(34)(78)\\ &(18)(27)(36)(45) - (12)(34)(56)(78) - (13)(24)(75)(86)\\ &(15)(26) - (17)(28)(35)(46) - (16)(25)(38)(47) - \\ &(14)(23)(36)(45)(58)(67)(78)(81) - (18)(27)\\ &(37)(48)(78)(54)(63)(32)(41)\} \end{aligned} \tag{7}$$

The lowest degree, homogeneous polynomial $F_{\chi,\mathrm{XII}}$ is an approximation chirality function of compounds with the skeleton XII. It is generated by applying $P_{A,\mathrm{XII}}$ to the monomial $\lambda_1\lambda_4$ (or an equivalent monomial).

$$\begin{aligned} F_{\chi,\mathrm{XII}} &= P_{A,\mathrm{XII}}\lambda_1\lambda_4 = \\ &= \tfrac{1}{16}\{\lambda_1\lambda_4 + \lambda_7\lambda_2 + \lambda_3\lambda_6 + \ldots\ldots + \lambda_4\lambda_5 + \lambda_8\lambda_1\} = \\ &= \tfrac{1}{8}\{(\lambda_1 - \lambda_5)(\lambda_4 - \lambda_8) - (\lambda_2 - \lambda_6)(\lambda_3 - \lambda_7)\} \end{aligned} \tag{8}$$

This chirality function, based upon the skeletal numbers of XII, can also be obtained from the previously published function $F'_{\chi',\mathrm{XII}'}$ [15b] by applying the permutation $P' = (2'\ 5'\ 3')(6'\ 7'\ 4')$, which converts the original skeletal numbers s' (indices of the XII') into the standard skeletal numbers of XII.

$$\begin{aligned} P'F'_{\chi,\mathrm{XII}} &= (2'\,5'\,3')(4'\,6'\,7')\\ &\{(\lambda'_1 - \lambda'_3)(\lambda'_6 - \lambda'_8) - (\lambda'_2 - \lambda'_4)(\lambda'_5 - \lambda'_7)\}\tfrac{1}{8} = F_{\chi,\mathrm{XII}} \end{aligned} \tag{9}$$

In the reference matrix $\binom{1}{s}_{\mathbf{E}}$ the ligand numbers l and the skeletal numbers s are superimposed. Therefore, in the *standard chirality function*, the skeletal indices i of the λ_i can be replaced by ligand indices i ($\lambda_i \rightarrow \lambda_i'$), by which the standard chirality functions F_χ is transformed into the chirality function $F^{\mathbf{E}}_{\chi,n}$ of the reference isomer. The descriptor $\boldsymbol{P}_s$ of a given permutational isomer generates the specific chirality function $F_{\chi,n}$ of this particular isomer from the reference chirality function $F^{\mathbf{E}}_{\chi,n}$

$$\bar{\boldsymbol{P}}_s F^{\mathbf{E}}_{\chi,n} = F_{\chi,n} \tag{10}$$

The isomer functions $F_{\chi,n}$ are easier to use than the original chirality functions, because the indices i of the λ_i in the isomer functions are the sequential ligand numbers of the ligands of the given set of permutation isomers. With the isomer functions there is no need to draw the particular isomer with numbered skeletal positions in order to assign the indices of the variables λ_i'.

Without knowledge of the particular numerical values of the ligand parameters λ_i the isomer functions can be used to determine whether a descriptor belongs to a chiral or an achiral molecule.

Example 20

The isomer function F_χ of *(17)(46)*-dicarboxy-diphenyl-cyclobutane is (with: $CO_2H = 1,2$; $C_6H_5 = 3,4$; $H = 5\ldots8$),

$$\begin{aligned} \mathbf{P}_S F^{\mathbf{E}}_\chi = F_\chi &= \tfrac{1}{8}(17)(46)\{(\lambda_1 - \lambda_5)(\lambda_4 - \lambda_8) - (\lambda_2 - \lambda_6)(\lambda_3 - \lambda_7)\}\\ &= \tfrac{1}{8}\{(\lambda_7 - \lambda_5)(\lambda_6 - \lambda_8) - (\lambda_2 - \lambda_4)(\lambda_3 - \lambda_1)\}\\ &= \tfrac{1}{8}\{(\lambda_H - \lambda_H)(\lambda_H - \lambda_H) -\\ &\quad (\lambda_{CO_2H} - \lambda_H)(\lambda_{C_6H_5} - \lambda_{CO_2H})\} \neq 0 \end{aligned} \tag{11}$$

and is different from zero; therefore *(3c)* is chiral, whereas its *(15)(48)*-isomer is achiral, because of:

$$\begin{aligned} F_\chi = (15)(48)F^{\mathbf{E}}_\chi &= \tfrac{1}{8}\{(\lambda_5 - \lambda_1)(\lambda_8 - \lambda_4) - (\lambda_2 - \lambda_6)(\lambda_3 - \lambda_7)\}\\ &= \tfrac{1}{8}\{(\lambda_H - \lambda_{CO_2H})(\lambda_H - \lambda_{C_6H_5}) -\\ &\quad (\lambda_{CO_2H} - \lambda_H)(\lambda_{C_6H_5} - \lambda_H)\} = 0 \end{aligned} \tag{12}$$

Another way of determining whether a descriptor $\boldsymbol{P}_s$ describes a chiral or an achiral molecule, without drawing a steric formula, is to generate the matrix $\binom{1}{s}_{\mathrm{opt}} = \boldsymbol{P}_s\binom{1}{s}_{\mathbf{E}}$ and then apply an s-permutation from the coset $\boldsymbol{C}'$ of $\boldsymbol{H}'$ to $\binom{1}{s}_{\mathrm{opt}}$. If the resulting $\binom{1}{s}$-matrix can be brought into "coincidence" with $\binom{1}{s}_{\mathrm{opt}}$ by s-permutations of $\boldsymbol{H}'$, the molecule that is described by the descriptor $\boldsymbol{P}_s$ is achiral, otherwise it is chiral.

3. Dynamic Chemistry

3.1. Permutational Isomerization

3.1.1. General Formalism

Redistribution of ligands on a polytopal framework is called a polytopal rearrangement [26]. The mutual transformations of permutational isomers, called polytopal rearrangements, involve a permutation of at least two skeletal sites, or ligands, respectively.

We wish to differentiate between two types of polytopal isomerizations, regular and irregular. The regular polytopal isomerizations are those that occur without breaking and reforming bonds, conserving neighborhood relations, as in the closely related process of interconversion of conformers. The irregular polytopal rearrangements occur with bond fission and reformation. While irregular rearrangements can be easily treated with this formalism, we restrict ourselves, in this paper, to regular processes.

Polytopal rearrangements, $\mathbf{M} \rightleftharpoons \mathbf{M}'$, can be described by transforming the matrix $\binom{1}{s}$ into $\binom{1}{s}'$ or the reverse by the operation of the ligand or coordinate isomerizer [eq. (13)] on the appropriate matrix.

$$\binom{1}{s}' = I_l\binom{1}{s} = I_s\binom{1}{s} \tag{13}$$

The s permutations are used as descriptors. In order to differentiate those permutations used to describe isomerization reactions from the descriptors, we will use l-permutations, I_l of equation (13) to represent the isomerizations. I_l will be called the *isomerizer*. The isomerizer which describes the transformation of a molecule $\mathbf{M}$ to $\mathbf{M}'$ is derived from their descriptors $\boldsymbol{P}_s$ and $\boldsymbol{P}'_s$ as follows: $\mathbf{M}$ and $\mathbf{M}'$ are generated from their reference isomer $\mathbf{E}$ according to equations (14a) and (14b).

$$\binom{1}{s} = \boldsymbol{P}_s\binom{1}{s}_{\mathbf{E}} = \mathbf{P}_l\binom{1}{s}_{\mathbf{E}} \tag{14a}$$

$$\binom{1}{s}' = \boldsymbol{P}'_s\binom{1}{s}_{\mathbf{E}} = \mathbf{P}'_l\binom{1}{s}_{\mathbf{E}} \tag{14b}$$

In these equations the equivalent s and l permutations $\boldsymbol{P}_s$ and $\mathbf{P}_l$ as well as $\boldsymbol{P}'_s$ and $\mathbf{P}'_l$ are numerically reversed. For example, one obtains $\mathbf{P}_l$ from the inverse $\bar{\boldsymbol{P}}_s$ of $\boldsymbol{P}_s$, by replacing its s with l, *i.e.*, by "deitalicizing" its numbers. The inverse $\bar{\boldsymbol{P}}_s$ of $\boldsymbol{P}_s$ is defined by equation (15).

$$\bar{\boldsymbol{P}}_s \times \boldsymbol{P}_s = e \tag{15}$$

Equation (15) states that if you first apply the permutation $\boldsymbol{P}_s$ and then $\bar{\boldsymbol{P}}_s$ upon the elements of a set, the result is the identity operation, e. Inverse permutations are numerically

[26] We use the term polytopal rearrangements in a more general sense than it has been used by previous authors (cf. [27]).

reverse; for instance if $\bar{P}_s = (1\ 2\ 3\ 4)$, then $\bar{P}_s = (4\ 3\ 2\ 1) = (1\ 4\ 3\ 2)$. Multiplying equation (14a) by $\bar{P}_I$ and equation (14b) by $\bar{P}'_I$ produces equation (16)

$$\bar{P}'_I \begin{pmatrix} 1 \\ s \end{pmatrix}' = \bar{P}_I \begin{pmatrix} 1 \\ s \end{pmatrix} = \begin{pmatrix} 1 \\ s \end{pmatrix}_E \qquad (16)$$

from which equation (17) is obtained by multiplication with P'_I.

$$\begin{pmatrix} 1 \\ s \end{pmatrix}' = P'_I \times \bar{P}_I \begin{pmatrix} 1 \\ s \end{pmatrix} \qquad (17)$$

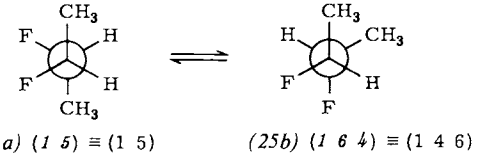
Combining equations (16) and (13) yields equation (18).

$$I_I = P'_I \times \bar{P}_I \qquad (18)$$

The *isomerizer* I_I can be directly obtained from the descriptor, by reversing the sequence of and "de-italicizing" $[\bar{P}_s \times P'_s]$. The product of the isomerizers of a closed cycle of reactions corresponds to the identity operation (*e*).

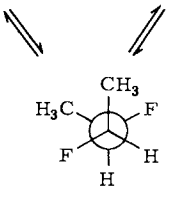
$$\overset{\circlearrowleft}{\prod} P_I = (e) \qquad (19)$$

3.1.2. Conformations



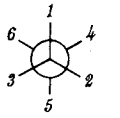
The energetically preferred geometrical configurations of molecules which can be interconverted by movements of some of their parts without breaking bonds are the conformers of a given molecular species (see below) and can be treated by the following methods. The skeletal coordinate systems and their transformations must be chosen taking into account the peculiarities of the conformational interconversions.

Example 21

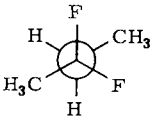


The conformational interconversions of *(25a) – (25c)* are treated on the basis of the (D_{3d}) skeleton *(25d)* and the reference isomer *(25e)*; the isomerizers

$I_{ab} = (1\,4\,6)(1\,5) = (1\,4\,6\,5)$ $\quad I_{ba} = (1\,5\,6\,4)$
$I_{ac} = (2\,5\,3)(1\,5) = (1\,5\,3\,2)$ $\quad I_{ca} = (1\,2\,3\,5)$
$I_{bc} = (2\,5\,3)(1\,6\,4)$ $\quad I_{cb} = (1\,4\,6)(2\,3\,5)$

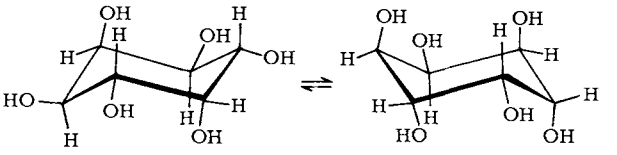


follow from the description according to Section 2.4.6.

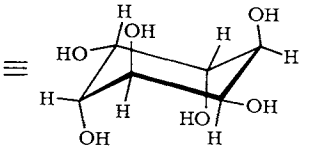


(25a) (1 5) ≡ (1 5) *(25b)* (1 6 4) ≡ (1 4 6)

(25c) (2 3 5) ≡ (2 5 3)

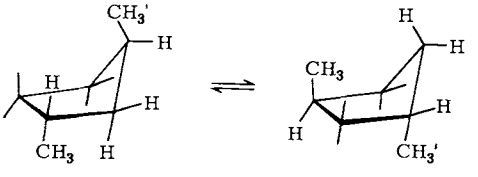


(25d) (≡ XXI)

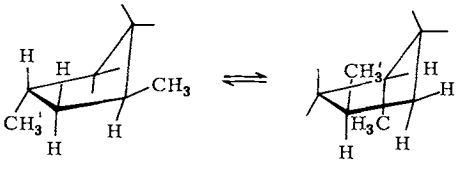


(25e)

Example 22

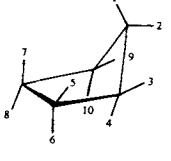


(26a) (1 7) (3 9) (5 11) *(26b)*



(26b)' (2 8) (4 10) (6 12)

The isomerizer (1 7) (2 8) (3 9) (4 10) (5 11) (6 12) of the conformational equilibrium *(26a)* ⇄ *(26b)* of neoinositol is derived in a straight forward manner on the basis of skeleton XIV.



Example 23

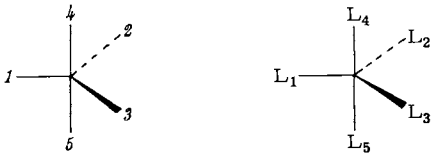
(27a) (2 6) *(27b)* (1 4) (2 7)

(27c) (1 8) (2 3) *(27d)* (1 5) (2 10)

(27e)

The conformation independent descriptor (2 6)-dimethyl-cyclopentane refers to the skeleton XIII whereas the descriptors of *(27a) – (27d)* and the isomerizers of their interconversions (*e.g.*, I_{ab} = (1 4) (2 7) (2 6) = (1 4) (276)) are derived from *(27e)* when $CH'_3 \equiv 1$, $CH_3 \equiv 2$.

3.1.3. Trigonal Bipyramidal Molecules[27,28][*]



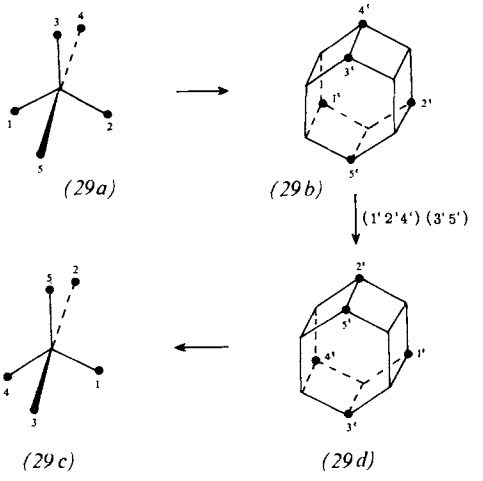
3.1.3.1. General Remarks

A polyhedral skeleton is that molecular skeleton with ligand positions equivalent to the n vertices of a polyhedron (see *e.g.* VII–XIV). There have been several recent attempts to determine the number of interconvertible polyhedral isomers (*Muetterties*[27d] calls these polytopal stereoisomers) and the number of steps needed for the interconversions of these isomers by graph theoretical methods[27b,c] or some matrix equivalent thereof[27f]. In all of these contributions particular attention was focused upon the isomerizations of the pentacoordinate phosphorus compounds by the generally accepted pseudorotation[28] mechanism.

Isomerizations of polyhedral molecules are treated according to the general procedure of Section 3.1.1. If an isomerization process leads to an exchange of ligands between non-equivalent skeletal positions, it must be represented by transformations involving skeletal coordinates of different, non-equivalent sets. The separate treatment of the ligands of non-equivalent coordinates, suitable for nomenclature purposes, can be given up, and the combination of the unprimed and the primed sets of ligands used instead.

Application of this permutational formalism to the rearrangements of pentacoordinate compounds *(28b)* with the skeleton *(28a)* and skeletal coordinates 1 . . . 5 shows, in a straightforward manner, which mechanisms are conceivable[29].

If the ligands of *(28b)* are indexed in sequential order *(28b)* is the reference isomer **E** and is represented by the descriptor (*e*).



(28a) **a** (≡ S_5) *(28b)* **b** (≡ **E**)

3.1.3.2. (2+3)-Turnstile Processes[29]

Of the formal possibilities invoked to explain regular pentacoordinate isomerization, the one alternative to the (1+4)-pseudorotation mechanism that satisfies *all* experimental data is the (2+3)-internal rotation process shown in example 24. We call this process the (2+3)-*turnstile mechanism.*

Example 24

(29a) *(29b)* *(29c)* *(29d)*
