The process described can be used if the substrate does not soften below the transformation temperature of the glass to be applied. This is the simplest and above all the most versatile method, since it allows the application of coatings of multicomponent oxide layers having practically any desired composition[20]. The methods by which substrates with relatively large surfaces can be coated with oxide layers by dipping in organic solutions have been described in detail by *Schroeder*[21]. In analogy with these methods, we dipped the substrates to be coated (metal, glass, *etc.*) in the solution, removed it uniformly, and heated it for a short time at a temperature not exceeding the transformation range of the layer-forming glass. Solid, hard glass layers up to a few thousand Ångströms thick are obtained.

The layer formation itself takes place effortlessly. This is because the films are so thin that the diffusion of the water required for hydrolysis and of the eliminated hydrolysis products is greatly facilitated. For this reason we prepared many multicomponent glasses in thin layers after the formation of a glass had been proved for the borosilicate glass.

Examples are provided by experiments with solutions that lead to the following glass compositions: borosilicate glass layers (composition as described in Section 5.2), phosphate silicate glass layers (containing SiO_2, Al_2O_3, P_2O_5, BaO, B_2O_3, CaO, MgO), lead silicate glass layers (containing SiO_2, PbO, Na_2O), and alkali metal aluminosilicate glass layers (containing SiO_2, Na_2O, Al_2O_3).

All these layers are transparent, hard, and amorphous to X rays[22].

Even these few examples show the scope of the process. A limitation exists with respect to the thickness of the layers. Though some increase is possible by means of additives in the solution or by multiple coating, it is difficult to obtain layers more than 0.5 μm thick; this is no problem in the vapor deposition method. However, even thin layers have technically useful properties. Thus metals can be electrically insulated with multiple borosilicate glass layers. The same layers also prevent or inhibit the scaling of metals, *e.g.* of iron. Thus a coated sheet of iron shows no scaling when heated for 3 hours at 800°C, whereas an uncoated sheet of iron is completely scaled under such severe conditions. The tarnishing of brass *e.g.* at 530°C is also prevented, as is its corrosion. First experiments[23] indicate that in the salt spray test and in the condensation water test, white rust formation or corrosion begins only after 1600 hours, and is then spontaneous. A series of sensitive optical glasses can be very effectively protected against climatic attack by phosphate silicate glass layers (Fig. 6). This is important, since the concentration on certain optical properties in such glasses sometimes necessarily leads to poor stability to climatic conditions. It is also important here that the protective layers should be very thin, as they may otherwise affect the optical properties.

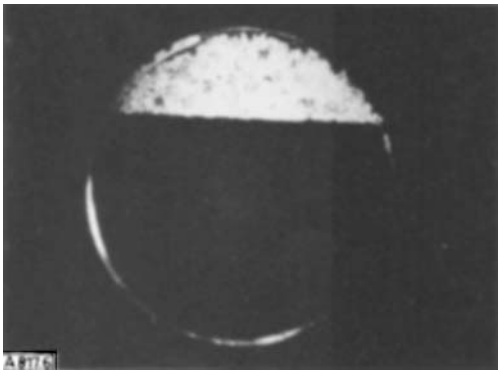

Fig. 6. Protection of an optical glass against climatic attack by coating with phosphate silicate glass. Top: uncoated (corrosion), bottom (coated).

8. Preparation of Starting Glasses for Glass-Ceramics

Glass-ceramics contain finely dispersed crystalline phases in a glass matrix. They are prepared by fusion of a starting glass containing nucleating agents. A controllable partial crystallization is then brought about by heat treatment. Probably the best-known property of some glass-ceramics of this type is their almost vanishingly small coefficient of thermal expansion of $0 \pm 1 \times 10^{-7}/°C$[24].

Starting glasses for glass-ceramics have also been obtained by the route described here. A solution of the alkoxides is first prepared such that the composition, converted to the oxides, corresponds to a Schott glass ceramic (61.4% SiO_2, 21.6% Al_2O_3, 6.8% P_2O_5, 3.8% Li_2O, 1.4% MgO, 0.5% Na_2O, 2.6% TiO_2, 1.9% ZrO_2[25]). This solution, with a total oxide content of 77 g/l, is used to prepare hard, transparent layers by dipping and heating (580°C, 30 min).

Attempts to convert this material into granular material by heating at 620°C yields transparent crumbs together with a few black components. The clear crumbs contain no crystalline material. These crumbs are treated further at 680°C and 830°C, in accordance with the temperature program for the completely analogous glass-ceramic starting glass prepared from the melt. This gives h-quartz solid solutions and nucleation phases containing ZrO_2. The crystallization properties correspond to those of the fused starting glass.

Another starting glass is prepared from a solution having the following composition (converted to oxides): 62.00% SiO_2, 21.86% Al_2O_3, 6.16% ZnO, 2.82% Li_2O, 1.77% TiO_2, 1.77% ZrO_2, 1.61% BaO, 1.11% MgO, 0.50% CaO, 0.40% K_2O[26]. A second solution has the same composition, except that it does not contain the nucleating agents TiO_2 and ZrO_2. It seems interesting to compare the products obtained from the two solutions. Clear layers can be prepared from both solutions; however, the crumbs obtained from both solutions are black. Differential thermal analysis gives a crystallization signal for the substance containing the nucleating agents, and none for the substance with no nucleating agent; this corresponds to the behavior of the fused starting glass.

I am grateful to my assistant of many years' standing, P. Hinz, who carried out all the preparations. I have been greatly assisted in the identification of the reaction products by many colleagues at the Jenaer Glaswerke Schott u. Gen., Mainz, by discussions and investigations. These, together with their assistants, were Dr. Coenen, Dr. Dörr, Dr. Dutz, Dr. Geffcken, Jenemann, Kristen, Lindig, Dr. Mulfinger, Dr. Neuroth, Dr. Petzold, Scheidler and Prof. Schröder. I am very grateful to Dr. Warnach and Ing. Steinhoff for carrying out the difficult pressing experiments.

Nutmeg as a Narcotic

A Contribution to the Chemistry and Pharmacology of Nutmeg *(Myristica fragrans)*

By Dieter Abbo Kalbhen[*]

The abuse of nutmeg for narcotic purposes has led to renewed chemical and pharmacological interest in this drug. Several allylbenzene derivatives whose biological transformation products have structures resembling mescaline and amphetamine have been identified as psychotropic constituents. It is suggested that the intensity of the hallucinogenic action of these compounds is due to the possibility of simulation of LSD-like structural elements.

1. Introduction

Nutmeg has a very checkered history as a medicine. Though it was used in India and in the Arab countries as a spice and as a remedy as early as the year 700 BC, this drug was unknown to the Greeks and Romans, and it was only in the Middle Ages that it was introduced into Europe by Arab merchants and later by Portuguese and Dutch traders. The product, which came from the Moluccas in the East Indies, was the monopoly of the Portuguese and Dutch for a long time. It was not until 1843 that the British and French managed to break this monopoly by growing nutmeg trees on the islands of the Caribbean. Thus nutmegs are now available both from the East Indies and from the West Indies.

Like many other cooking spices, such as cloves, pepper, paprika, caraway, fennel, and aniseed, nutmeg was very important to the ancient Indians and Arabs as a medicine, and it is still found in the folk medicine of these countries. Various nutmeg preparations were and are used as analgesics, stomachics, digestives, hypnotics, aphrodisiacs, and amenorrheal agents. The European physicians of the Middle Ages, who borrowed many recipes and treatments from their Arab colleagues, prescribed nutmeg for an equally wide range of indications.

Whereas the use of nutmeg as a spice has persisted to the present day, its interest and importance in medicine has declined in Europe since the beginning of the 18th century. The end of the 19th century saw a brief return to popularity in the wake of a rumor that nutmeg is an effective abortifacient. Several medical journals at this period reported a high incidence of nutmeg poisoning in women.

Intoxication due to the benumbing and psychotropic effects of nutmeg had been described even earlier. Thus the famous Breslau physiologist *Purkinje*[1] carried out an experiment on himself; the symptoms that he described as resulting from the ingestion of three ground nutmegs are very similar to the effects of hashish. The excessive use of nutmeg in folk medicine as a stomachic, as an abortifacient, or in love potions leads in man to intoxication symptoms that are manifested in outbreaks of sweat, desire to urinate, headaches, nausea, disequilibrium, hysterical laughter, hallucinations, and/or stupor.

Though the hallucinogenic action was described repeatedly around the turn of the century, it was only after the second world war that nutmeg came to be used as a narcotic, and this use was mainly, if not exclusively, confined to the USA. This drug is used particularly by young people, students, hippies, and convicts to attain an intoxicated state with hallucinations. Since nutmeg is generally known as a spice, can be bought anywhere, and has even been used in prison kitchens, it is readily obtainable by the groups mentioned above, and is welcomed by them as a substitute for control-

[*] Priv.-Doz. Dr. D. A. Kalbhen
Pharmakologisches Institut der Universität
53 Bonn, Reuterstrasse 2b (Germany)

led substances such as marihuana, mescaline, and LSD. (The American government has now stopped the use of nutmeg spices in the kitchens of penal establishments.)

2. Constituents and Active Ingredients of Nutmeg

The wide availability and use of nutmeg as a spice and also its psychotropic and toxic effects aroused interest in the composition of this drug some time ago. A detailed analysis was reported by *Power* and *Salway* in 1907 and 1908[2, 3]. These authors showed by various extraction and distillation methods that nutmeg contains 25–40% of fatty oils (nutmeg butter), 8–15% of volatile oils, and 45–60% of structural materials containing cellulose.

The fatty oils from nutmeg have found little interest in medicine, and therapeutic uses have been concentrated mainly on the volatile oil. Thus the German Pharmacopeia valid until the end of 1968 and the Supplement, 6th edition, contained the nutmeg preparations listed in Table 1. The 7th edition of the German Pharmacopeia, which has been valid since January 1, 1969, no longer contains nutmeg and its preparations.

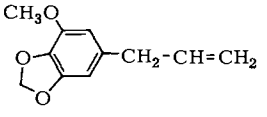
Table 1. Nutmeg preparations listed in the 6th Edition of the German Pharmacopeia (DAB VI) and the relevant supplement (Suppl. VI).

Oleum nucistae, oleum myristicae, nutmeg butter, DAB VI; oleum myristicae aethericum, oleum macidis, oil of nutmeg, DAB VI (also as a constituent of spiritus melissae compositus, DAB VI)
Semen myristicae, nutmeg kernel, Suppl. VI
Mace, Suppl. VI
Nutmeg butter, Suppl. IV

The components listed in Table 2 have been detected qualitatively and quantitatively in the further analytical investigation of the volatile oil of nutmeg, in which excellent results have recently been obtained, in particular by the use of gas-chromatographic methods.

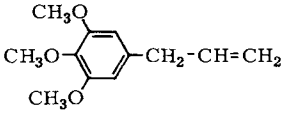
Myristicin *(1)*, elemicin *(2)*, and safrole *(3)* have been identified as constituting the greater part (about 80%) of the group of allylbenzene derivatives.

Table 2. Constituents of the volatile oil of nutmeg.



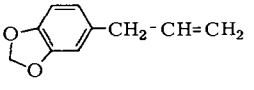
1) Terpene hydrocarbons	
α-pinene	toluene
β-pinene	*p*-cymene
camphene	linalool
sabinene	geranyl acetate
p-mentha-1,4-diene	cineol
p-mentha-1,4(8)-diene	camphor
p-mentha-1,8-diene	citronellol
p-menth-1-en-4-ol (4-terpinol)	citronellal
p-menth-1-en-8-ol	(+)-borneol
2) Allylbenzene derivatives [a]	
myristicin *(1)*	methylisoeugenol *(6)*
elemicin *(2)*	isoeugenol *(7)*
safrole *(3)*	isoelemicin *(8)*
methyleugenol *(4)*	methoxyeugenol *(9)*
eugenol *(5)*	
3) Myristic acid	
4) Unidentified substances	

[a] See Section 3 for formulas.

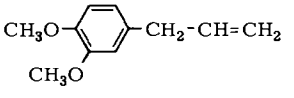


In the search for the medicinally active constituents, it was found that the nuts no longer had any action after the removal of the volatile oil. It was therefore concluded that the volatile oil, and particularly the main constituent myristicin, should be regarded as the active principle. Though *Warburg*[4] questioned the contribution of the volatile oils to the action of nutmeg in 1897, evidence obtained at the beginning of this century indicated that myristicin is responsible for the pharmacological and toxic effects of nutmeg oil[3, 5, 6].

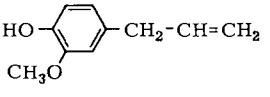
3. Hallucinogenic Ingredients of Nutmeg



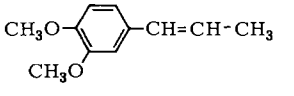
Following repeated confirmation by further investigations that the volatile oils are the principal cause of the effects of nutmeg, later work has been concentrated mainly on the allylbenzene derivatives *(1)*–*(9)* (see Table 2).



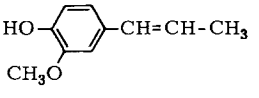
(1), Myristicin



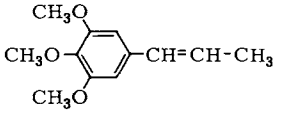
(2), Elemicin



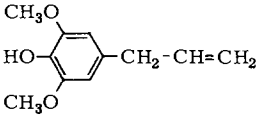
(3), Safrole



(4), Methyleugenol



(5), Eugenol



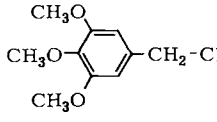
(6), Methylisoeugenol

(7), Isoeugenol

(8), Isoelemicin

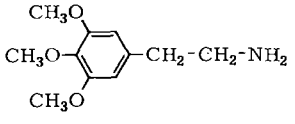
(9), Methoxyeugenol

Of these allylbenzene derivatives, which are present in the volatile oil in quantities that vary with the region in which the nutmeg was grown, only myristicin *(1)* has so far been investigated pharmacologically as a single substance. Slight inhibition of monoamine oxidase occurred in mice, and a distinct psychotomimetic effect (see Section 4) has been detected in man. It should be mentioned in this connection, however that the action was always stronger when the other constituents of the volatile oil were administered at the same time. It is assumed that the terpene hydrocarbons do not themselves contribute to the psychotropic action, but promote the absorption of the allylbenzene derivatives by irritating the gastrointestinal tract.



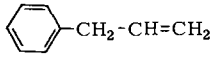
4. Hallucinogenic Action Pattern in Man

The use of nutmeg as a narcotic became known to large numbers, particularly of young people, through the autobiography of racial conflict victim *Malcolm X*[7], which has been widely circulated in the USA. Nutmeg preparations have been taken by many people as a substitute for cannabis, mescaline, or LSD, with the result that considerable knowledge now exists concerning the action pattern in nutmeg poisoning.

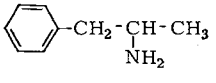


The drug is generally ground, stirred into a drink, and taken in a quantity of 5 to 30 g. The psychotomimetic action, which may range from a slight change in consciousness to very intense hallucinations, begins to take effect 2 to 5 hours after ingestion. Whereas visual hallucinations are less common than in LSD or mescaline intoxication, distinct changes are found in the perception of time and space. A feeling of soaring and of dissociation of the limbs from the body is frequently also reported. The main side effects noted are nausea, headaches, dry mouth, increased pulse rate, and giddy feeling. All the symptoms of nutmeg intoxication usually disappear after 12 to 48 hours. An occasional after-effect is a lasting aversion to the taste and/or smell of nutmeg. For this reason nutmeg is generally used only once or twice, very rarely more often, as a narcotic.

5. Biotransformation of the Allylbenzene Derivatives

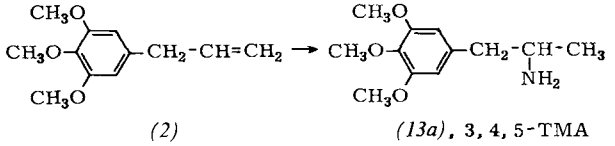


Shulgin has developed an interesting hypothesis to explain the hallucinogenic action of the allylbenzene derivatives[8]. Comparison of the structural formula of elemicin *(2)* with that of mescaline *(10)* shows a certain similarity. *Shulgin*[8] assumes that elemicin *(2)*, myristicin *(1)*, and the other allylbenzene derivatives are transformed into the amino derivative in the human body by direct transamination or by oxidation and subsequent transamination. As was discovered by *Kawabata*[9], the metabolism of allylbenzene

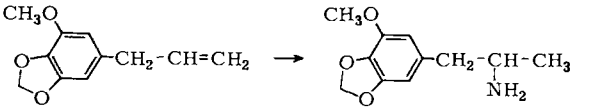


(2), Elemicin

(10), Mescaline

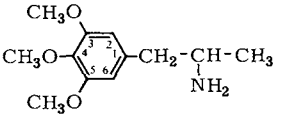


(11)

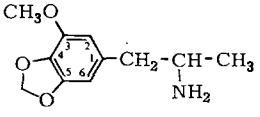


(12), Amphetamine

(11) leads to cinnamic acid, β-hydroxy-β-phenylpropionic acid, and *p*-hydroxyphenylacetic acid. *Barfknecht*[10] later found that allylbenzene fed to rats is partly also converted into amphetamine *(12)*. It therefore seems reasonable to assume the formation of 3,4,5-trimethoxyamphetamine *(13a)* from elemicin *(2)* and the formation of 3-methoxy-4,5-methylenedioxyamphetamine *(14a)* from myristicin *(1)*.



(2) *(13a)*, 3, 4, 5-TMA



(1) *(14a)*, 3-M-4, 5-MDA

As can be seen from the formula of 3,4,5-trimethoxyamphetamine *(13a)*, it contains structural elements of amphetamine *(12)* and of mescaline *(10)*. The compound *(13a)*, which was synthesized in 1947 by *Hey*[11], exhibited twice the hallucinogenetic activity of mescaline in pharmacological tests. It is interesting to note that the stimulatory action component of amphetamine, which is manifested in increased blood pressure, increased pulse rate, and insomnia, is no longer present in the trimethoxy derivative *(13a)*. *Shulgin*[12] has recently synthesized other isomers of trimethoxyamphetamine and examined them for hallucinogenic action (Table 3).

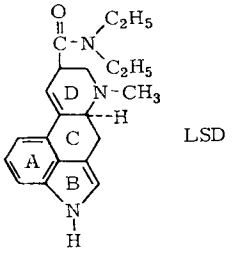
Table 3. Relative hallucinogenic activities of the isomeric trimethoxyamphetamines (TMA) *(13)* and methoxymethylene-dioxyamphetamines (MMDA) *(14)* [activity of mescaline *(10)* = 1].

(13a)

(14a)

Isomer of *(13)*	Posn. of CH_3O	relative activity
a	3,4,5	2
b	2,3,4	0
c	2,3,5	< 7
d	2,3,6	< 10
e	2,4,5	17
f	2,4,6	12

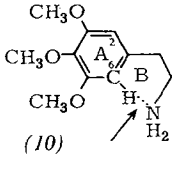
Isomer of *(14)*	Position of CH_3O	Position of $-O-CH_2-O-$	relative activity
a	3	4,5	2
b	2	4,5	21
c	2	3,4	18



Besides the trimethoxy compounds, *Shulgin*[12] also synthesized and investigated substances in which two methoxy groups were replaced by a methylenedioxy group, *i.e.* isomers of *(14a)* (Table 3).

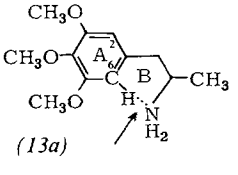
3-Methoxy-4,5-methylenedioxyamphetamine *(14a)* thus corresponds to the metabolite that should be formed in the body from myristicin *(1)* by transamination. The other allylbenzene derivatives in the volatile oil of the nutmeg could also be converted into the corresponding amphetamine derivatives by biotransformation. Detailed studies on the biotransformation of these allylbenzene derivatives are being carried out at present in animal experiments by *Kalbhen* and *Braun*[13].

6. Explanation of the Hallucinogenic Action of the Amphetamine Derivatives



Pronounced quantitative differences are found in a comparison of the hallucinogenic effects of the isomeric trimethoxyamphetamines *(13)*. Since it could be shown that these substances are degraded and excreted by the body at the same rate and by the same metabolic pathway, and that the partition coefficients (between fat and water) of the isomers do not differ greatly, other explanations were sought for the difference in their hallucinogenic activities. *Snyder* and *Richelson*[14] have developed a hypothesis that allows an interesting explanation of this phenomenon.

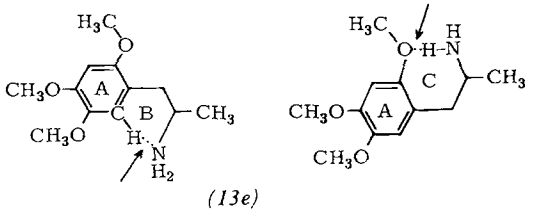
Lysergic acid diethylamide (LSD) is well known to be by far the most potent of the hallucinogenic drugs discovered so far; even in a dose of 50—100 µg in man, it causes very intense hallucinations of long duration. On the basis of this intense action, the above authors assume that the LSD structure possesses optimum characteristics for the production of hallucinogenic effects. Its outstanding structural features are the indole skeleton and the two fused six-membered rings. For greater clarity in the following discussion, the rings have been labeled A, B, C, and D.



LSD

A comparison of the structures of hallucinogenic drugs containing no indole grouping with the structure of LSD shows that *e.g.* mescaline *(10)* and the amphetamine derivatives *(13)* and *(14)*, either formed by the metabolism of myristicin and elemicin or synthesized, have only the benzene ring A in common with LSD. In the case of mescaline, it is quite possible to simulate an indole structure by a change in the conformation of the side chain. This conformation can be stabilized by a hydrogen bond. The extent to which this intramolecular hydrogen bonding occurs naturally depends on the magnitude of the negative charge on C-2 or C-6, and this is determined in turn by the nature of neighboring substituents on the benzene ring. Because of the neighboring trimethoxy groups, the negative charge in mescaline is in fact greatest on C-2 or C-6; in this case, therefore, a sort of ring B can be formed, and hence an indole structure simulated, by intramolecular hydrogen bonding.

(10)



(13a)

It is interesting to observe that no hallucinogenic action could be detected for 2,3,4-trimethoxyamphetamine *(13b)*, in which hydrogen bonds of this nature cannot be formed.

Examination of the possibility of intramolecular hydrogen bond formation for the structures of the six isomeric trimethoxyamphetamines *(13)* yields interesting clues that contribute to the explanation of the difference in activity.

(13a) can form the ring B, and hence simulate the indole structure by hydrogen bonding in the same manner as mescaline *(10)*. This is also possible in *(13e)*. The latter substance can also form a hydrogen bond from the amino hydrogen to the oxygen of the 2-methoxy group, and the resulting structure approximates to ring C in the LSD molecule.

(13e)

It thus seems possible that 2,4,5-TMA *(13e)* can simulate rings B and C of LSD, though a molecule can naturally exist in only one of the two conformations at any given time.

The formation of ring C also depends on the freedom of movement of the methoxy group on C-2. An adjacent methoxy group, *i.e.* in position 3, hinders the free rotation of the methoxy group on C-2, with the result that ring C cannot be simulated. This would explain why the 2,3,5-trimethoxy derivative *(13c)* has a weaker hallucinogenic action than the 2,4,5-trimethoxy derivative *(13e)*, and why the 2,3,4-trimethoxy derivative *(13b)* is practically inactive.

The assumption that adjacent methoxy groups hinder the formation of a ring C conformation is confirmed by the investigation of compounds of the methoxy(methylenedioxy)amphetamine type *(14)*. Whereas *(13b)* is inactive and cannot simulate either ring B or ring C, 2-methoxy-3,4-methylenedioxyamphetamine *(14c)* has a strong hallucinogenic action, which can be attributed to the possibility of formation of a ring C conformation.

[14] *S. H. Snyder* and *E. Richelson* in *D. H. Efron*: Psychopharmacology. Public Health Service Publication No. 1836, Washington 1968, p. 1199.

2-Methoxy-4,5-methylenedioxyamphetamine *(14b)* can also simulate ring C and/or ring B, whereas 3-methoxy-4,5-methylenedioxyamphetamine *(14a)* can assume only a ring B conformation, as is also confirmed by the lower activity of the latter.

(14b)

On examination of the formulas of 2,3-dimethoxy-4,5-methylenedioxyamphetamine and 2,5-dimethoxy-3,4-methylenedioxyamphetamine, it can be predicted on the basis of the above working hypothesis that the second compound will have a stronger action than the first. This has been confirmed by pharmacological tests.

Finally, mention should also be made of 2,5-dimethoxy-4-methylamphetamine (DOM), which has become very popular in the USA as a psychodelic drug under the name STP. The very intense psychotomimetic action of this substance can be explained by the favorable position of the methoxy groups, which allow a ring B or/and ring C conformation. The methyl group on C-4 prevents rapid enzymatic degradation of this compound, and this may help to potentiate the action.

7. Closing Remarks

Though no specific receptor localizations and points of attack on the molecular level have been established as yet for LSD and the other hallucinogenic drugs described here, the above working hypothesis developed by *Snyder* and *Richelson*[14] offers a valuable contribution to the elucidation of the mode of action of these psychotomimetics. The abuse of nutmeg as a narcotic drug has given fresh impetus to pharmacological research in the testing of psychotropically active components, and this research has led through structure-action relations to a model possessing unquestionable interest. However, nutmeg is now almost without significance in practical medicine, and there is little likelihood, in view of its strong taste, that this well-known spice will remain popular for long as a narcotic drug.

Bis(trimethylsilyl)diimine: Preparation, Structure, and Reactivity[1]

By Nils Wiberg[*]

Based on investigations carried out in collaboration with Wan-Chul Joo, Gerhard Schwenk, Wilfried Uhlenbrock, and Michael Veith

Dedicated to my father, Professor Egon Wiberg, on the occasion of his 70th birthday

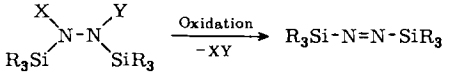
The highly reactive compound bis(trimethylsilyl)diimine (BSD), which was first prepared by oxidation of lithium tris(trimethylsilyl)hydrazide, is light blue, sensitive to thermolysis and hydrolysis, and ignites spontaneously in air. On the basis of electron transfer, acid-base, or free-radical reactions, it acts in particular as a (preparatively useful) redox system and as an agent for the introduction of azo groups. Redox reactions lead by oxidation or reduction of the other reactant through two oxidation stages to hydrazine derivatives or molecular nitrogen, and in the case of electrochemical reduction, to BSD radical-anions. Azo-group transfers, on the other hand, yield new inorganic azo compounds with no change in the oxidation state of the diimine group.

1. Introduction

When we succeeded, in 1968, in synthesizing *bis*(trimethylsilyl)*diimine*[2]

$(CH_3)_3Si—N=N—Si(CH_3)_3$
BSD

as the first diimine completely substituted with silyl groups[3], the unexpectedly long-wave light absorption and the resulting radiant blue color of the compound immediately aroused our particular interest. The investigation of this substance, which has lost none of its original fascination, has proved worth while; it has revealed a varied, unusual, and interesting chemistry.

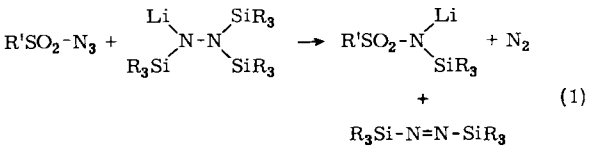


Various investigators had attempted to prepare a bis(silyl)diimine. The ability of carbon to form azo compounds *(1)*, which are often surprisingly stable (for

[*] Priv.-Doz. Dr. N. Wiberg
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstrasse 1 (Germany)

example, azobenzene is stable up to 600 °C[4], makes the synthesis of "azosilanes" *(2)* a challenge in view of

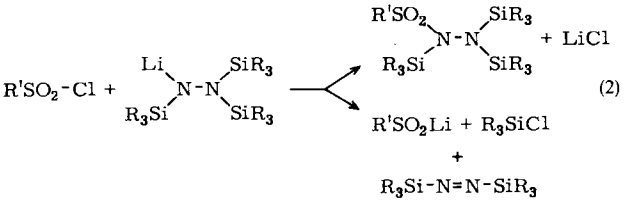
$\geqslant C-N=N-C \leqslant$ *(1)* $\geqslant Si-N=N-Si \leqslant$ *(2)*



the group relationship between carbon and silicon. A possible preparation method was seen in the oxidation of 1,2-bis(silyl)hydrazines *(3)*.

(3) *(4)*

However, several attempts to verify this reaction[5-7] were initially unsuccessful because of failure to find an oxidizing agent that could oxidize bis(silyl)hydrazines *(3)* only to the stage of the readily oxidizable bis(silyl)-diimines *(4)* without oxidizing these further to nitrogen[8]. By the action of *p*-toluenesulfonyl azide on lithium tris-(trimethylsilyl)hydrazide (X = Li, Y = SiR_3 in *(3)*), we were able to obtain BSD as a readily sublimable product that crystallizes in the form of needles and melts at −3 °C[3].



Including BSD and a bis(boryl)diimine that is obtainable from it[10], there are now ten classes of isolable diimine derivatives X—N=N—X (counting diimine itself) in which ligands X are linked to the azo group *via* main-group elements having various atomic numbers:

(1)

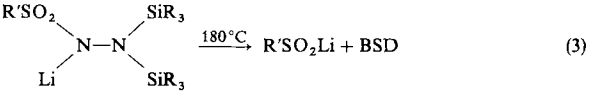
The arenesulfonyl azide, as in its reactions with CH-acidic methylene derivatives[18], evidently adds first to the silylhydrazide to form a nitrogen chain compound $R'SO_2—N=N—\overset{\ominus}{N}—N(SiR_3)—N(SiR_3)_2$, which can decompose after migration of silyl groups to give the final reaction products.

Instead of arenesulfonyl azides, arenesulfonyl chlorides may be used as the oxidizing agents[19]. In this case, however, the reaction no longer follows a single course:

(2)

Since BSD is also difficult to separate from trimethylchlorosilane, the process is less suitable for the preparation of this diimine. However, it may offer advantages in the synthesis of other diimines.

	H—N=N—H [11] yellow			
>B—N=N—B< [10] yellow	≥C—N=N—C≤ [4] yellow-red	>N—N=N—N< [12] colorless	—O—N=N—O— [13] colorless	F—N=N—F [14, 17] colorless
?	≥Si—N=N—Si≤ [3] pale blue	>OP—N=N—PO< [15] violet	$—O_2S—N=N—SO_2—$ [16] deep yellow	(Cl—N=N—F [17]) yellow



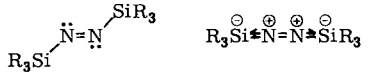
If one disregards diimine, BSD stands out from this series of azo compounds because of its unusual properties. This compound, whose preparation, structure, and reactivity will be surveyed below, reacts extremely violently with itself and with oxygen, and can ignite on contact with air. Since BSD is also readily hydrolyzed, it is not easy to handle. Most of the operations described in the next few sections must therefore be carried out at low temperatures and in the absence of oxygen and moisture.

2. Preparation

BSD can be prepared particularly easily by reaction of an arenesulfonyl azide with lithium tris(trimethylsilyl)-hydrazide in ether at −78 °C (R′ = phenyl, *p*-tolyl)[3]:

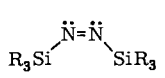
Reaction (2) is evidently initiated by attack of the silylhydrazide on the electrophilic sites of the arenesulfonyl chloride, *i.e.* the sulfur and the chlorine atom. The attack on the sulfur atom leads to elimination of lithium chloride and formation of tris(trimethylsilyl)arenesulfonohydrazide, while the attack on the chlorine atom gives lithium arenesulfinate and *N*-chlorotris(trimethylsilyl)hydrazine, which decomposes into trimethylchlorosilane and BSD.

A third method for the preparation of BSD consists in the thermolysis of *N*-lithiobis(trimethylsilyl)arylsulfonohydrazide at 180 °C:



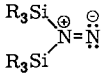
(3)

3. Structure



3.1. Molecular Geometry

Several structures are conceivable for BSD. The compound could contain a *trans*-angular *(5)*, *cis*-angular *(7)*, or linear *(6)* SiNNSi skeleton. In addition to 1,2-bis-(trimethylsilyl)diimine, the positional isomer 1,1-bis(trimethylsilyl)diimine *(8)* must also be considered.



(5)

(6)

(7)

(8)

The formally charged isomeric structure *(8)* is counter-indicated by many physical properties of the compound (*e.g.* volatility, solubility) and by IR[9] and (indirectly) ESR[20] spectroscopic data (cf. Section 3.2.2). Moreover, there is no chemical evidence of the existence of *(8)* even in small equilibrium concentrations in the presence of *(5)*, *(6)*, and *(7)*[21].

A definite decision in favor of one of the three remaining isomers *(5)*, *(6)*, and *(7)* is possible only with reservations. UV spectroscopic studies[9] provide very definite evidence against the linear form (cf. Section 3.2.1), and indicate a relatively large SiNN angle (in comparison with CNN angles in organic diimines). On the basis of the geometry of trimethylsilyl isocyanate and isothiocyanate[22], this angle should be about 150° in BSD.

It is uncertain whether BSD is in the form *(5)* or *(7)*. Even at about −80 °C, the compound gives only one signal in the ^{1}H-NMR spectrum[9]. This could indicate that one isomer is thermodynamically favored or, more probably, that BSD consists of a mixture of *cis*- and *trans*-isomeric molecules undergoing fast interconversion. (Inversion on nitrogen, which generally occurs readily[23], is reported to be additionally favored in silyl-nitrogen compounds[24].)

3.2. Electronic Configuration

A typical term diagram of the inner π and n molecular orbitals of the azo group

in the ground state is shown in Fig. 1 (a)[25]. The energetically lower bonding π orbital and the two n orbitals, as can be seen from the Figure, are each occupied by two electrons, while the energetically higher antibonding π* orbital is empty. The energy difference between the two π levels is more than 6 eV in the normal case. The splitting of the two n levels, on the other hand, was a subject of uncertainty for a long time[26]. According to very recent photoelectron-spectroscopic investigations[27], the energy splitting, with a value of 3.32 eV in the case of azomethane, is surprisingly large. The lower n orbital thus lies below the bonding π orbital.

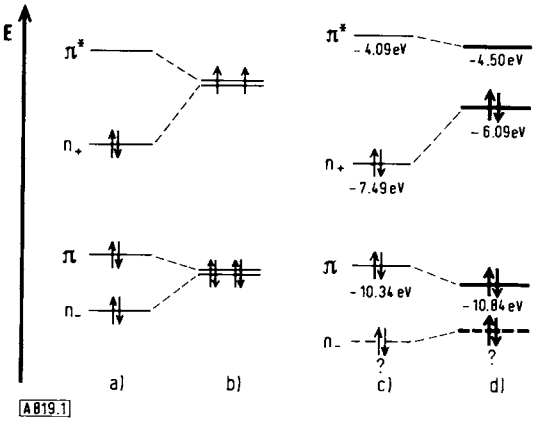


Fig. 1. Term diagram of inner molecular orbitals: a) of the angular azo group; b) of the linear azo group; c) of the azo system of bis(*tert*-butyl)diimine [29]; d) of the azo system of BSD [29].

In addition to the π and n orbitals of the azo group, it is also necessary to consider the σ and σ* molecular orbitals.

3.2.1. The Color of BSD

One of the particularly remarkable properties of BSD is its light blue color. The weak absorption that is responsible for this color, a forbidden $n_+ \rightarrow \pi^*$ transition (cf. Fig. 1 (d)), occurs at 12750 cm^{-1}, *i.e.* in the invisible infrared region of the spectrum. One "sees" only the short-wave tail of the absorption band. Thus the wavelength of the $n_+ \rightarrow \pi^*$ transition of BSD is surprisingly long in comparison with the longest-wavelength UV absorption maximum of yellow to red organic azo compounds (cf. Fig. 1 (c) and (d) and Table 1).

Table 1. UV absorptions (solvent: alkane) [9] and ionization energies (*IE*) [28] of *tert*-butyl- and trimethylsilyl-substituted diimines [29b] (R = CH_3).

	$R_3C-N=N-CR_3$	$R_3C-N=N-SiR_3$	$R_3Si-N=N-SiR_3$
color	pale yellow	red	pale blue
IE (eV)	7.49 ± 0.02	[a]	6.09 ± 0.02
$\lambda_{max}^{n_+ \rightarrow \pi^*}$ (cm^{-1}) (ε)	27200 (12)	20000 (9)	12750 (5) [b]
$\lambda_{max}^{\pi \rightarrow \pi^*}$ (cm^{-1}) (ε)	50000 (1800)	50000 (1100)	52100 (1700) [c]

[a] Accurate determination has so far been prevented by experimental difficulties. *IE* is about 7 eV.

[b] The strongly asymmetric band exhibits fine structure.

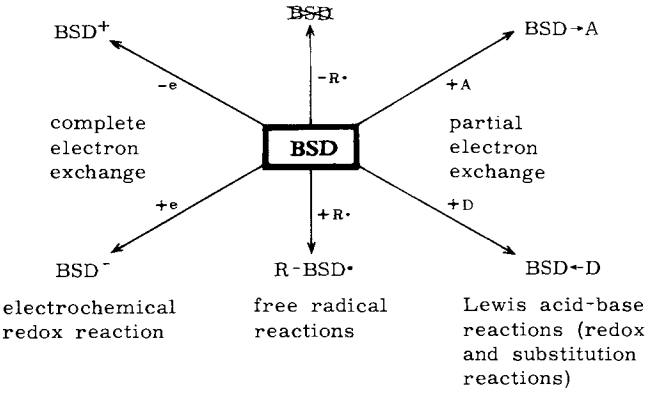
[c] Another band occurs at 40000 (260).

It can be shown experimentally that the bathochromic shift of the $n_+ \rightarrow \pi^*$ absorption of about 2×7200 wave numbers on replacement of the two "trimethylmethyl" groups in bis(*tert*-butyl)diimine by the homologous trimethylsilyl groups is due both to a pronounced increase in the n_+ energy level and to a slight decrease in the π^* energy level (cf. Fig. 1 (c) and (d)[29a]). The mechanism of this mutual approach of the levels, which has not yet been fully elucidated, could be explained, *e.g.*, by inductive and mesomeric effects[30] and by repulsion effects of bonding electrons[31] of the elements E=C and Si bonded to the azo group. It should also be observed that widening of the ENN angle must also bring the n_+ and π^* energy levels closer together.

In the extreme case of the linear skeleton $\geqq$E—N=N—E$\leqq$ (ENN angle = 180°), the n_+ and the π^* levels are in fact degenerate with each other (and the same is true of the n_- and π levels), so that the difference in the energy levels becomes vanishingly small (cf. Fig. 1 (b)). Widening of the ENN angle on replacement of *tert*-butyl groups attached to the azo group by trimethylsilyl groups is indicated by the observed decrease in the molar extinction[26] of the $n_+ \rightarrow \pi^*$ absorption (cf. Table 1).

3.2.2. The Delocalization of Electrons in BSD

Both for the occupied π orbital and for the n_+ orbital of BSD, there is a possibility of interaction with the empty d orbitals of the silicon of suitable symmetry. Nothing is known at present about the magnitude of this interaction, which can be described *e.g.* by limiting resonance structures such as



$$[\rightarrow R_3\overset{\ominus}{Si} \leq \overset{\oplus}{N}=\dot{N}-SiR_3 \leftrightarrow R_3Si-\dot{N}=\dot{N}-SiR_3 \leftrightarrow R_3Si-\dot{N}=\overset{\oplus}{N}=\overset{\ominus}{SiR_3} \leftrightarrow]$$

On the whole, a weak but definite delocalization of the π and n electrons is to be expected, since the ESR spectrum of the BSD radical-anion[20], in the case of the unpaired electron accommodated in the π^* molecular orbital, points to delocalization (though not very extensive) over the entire SiNNSi skeleton.

The ESR line-splitting diagram of the BSD radical-anion corresponds to an interaction in which the nitrogen nuclei are equivalent[20]. The anion is thus not in the unsymmetrical 1,1 form *(8)* but in the symmetrical 1,2-diimine form. This result indicates that uncharged BSD is also in the symmetrical form, and not in the equally conceivable unsymmetrical form.

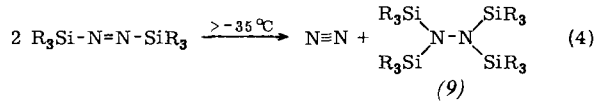
4. Reactivity

BSD is extremely reactive, and reacts with practically anything available. This striking reactivity of the azosilane system can be deduced from the term diagram of the compound (Fig. 1 (d)). The inner molecular orbitals of BSD that are important to chemical reactions, *i.e.* the highest occupied n_+ molecular orbital and the lowest empty π^* molecular orbital, have very high and very low energies respectively, unlike the corresponding orbitals of the azoalkanes. This necessarily makes the compound particularly ready to give up and to receive electrons.

Scheme 1. Reactivity of bis(trimethylsilyl)diimine.

As has been confirmed experimentally, the donation or acceptance of electrons can take place completely in an electrochemical redox reaction or only partly in a Lewis acid-base reaction (a redox reaction in the broader sense). The primary reaction products obtained from BSD in this way (cf. Scheme 1) are BSD cations and anions (BSD^+, BSD^-) on the one hand and BSD-acceptor and BSD-donor complexes (BSD→A, BSD←D) respectively on the other, which can undergo further chemical reaction in most cases. For example, BSD-acceptor complexes cannot generally be isolated; one obtains only their further reaction products, which can be formally described as products of redox or substitution reactions of BSD (cf. Scheme 2, Section 4.3).

It is also to be expected that radicals R which combine the properties of an electron acceptor with those of a donor will also add to BSD to form hydrazyl radicals (R—BSD·). According to the results that we have obtained so far, this is in fact so. However, BSD is fairly stable toward free-radical cleavage of the Si—N bond resulting in destruction of the BSD molecule (~~BSD~~), which could conceivably occur from energetically excited BSD with simultaneous formation of molecular nitrogen. Thus no detectable decomposition of BSD occurs on UV irradiation for several hours, and BSD can be kept indefinitely in daylight. The compound is also very stable toward heat, provided that the molecules have no opportunity for collisions leading to rapid decomposition.



The reactions of BSD are classified according to type in Scheme 1, and numerous examples are given in the following sections.

4.1. Thermolysis Reactions

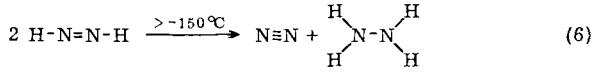
BSD decomposes below 0°C. The thermolysis products, the yields of which depend on the temperature, result from disproportionation, dimerization, and free-radical reactions of BSD.

4.1.1. Disproportionation

The thermolysis products formed from BSD by disproportionation between −35 and −20 °C consist almost exclusively of nitrogen and tetrakis(trimethylsilyl)hydrazine *(9)*, which was synthesized for the first time in this way[3]:

(4)

(9)

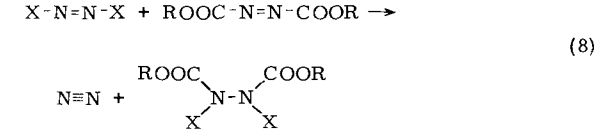


The azosilane BSD thus shows no similarity either in its thermal stability or in its decomposition mechanism to the very stable azoalkanes[32], which decomposed in a first order reaction, mainly into nitrogen and hydrocarbons:

(5)

The decomposition of BSD (4) corresponds, however, to the thermolysis of the parent diimine, which decomposes into nitrogen and hydrazine even at very low temperatures[11].

The thermolysis of BSD thus again supports the empirical observation that from the chemical point of view, silyl groups are less like organyl groups than like hydrogen. The replacement of the hydrogen atoms of diimine by silyl



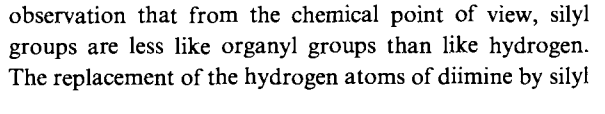
(6)

groups does not affect the stoichiometry of the decomposition of the diimine in any way, but merely leads to a considerable increase in the thermal stability of the molecule.

The similarity of the chemical properties of diimine and BSD is not confined to thermolysis. Both diimine and BSD can transfer their ligands from the azo group to a double-bond system other than their own in a reaction corresponding to the decomposition (4) or (6). For example, both compounds quantitatively reduce both oxygen[11,33] and azodicarboxylic esters[11,34] even at low temperatures, with hydrogenation and silylation respectively of the apolar double bonds (X=H, SiR_3):

(7)

(8)



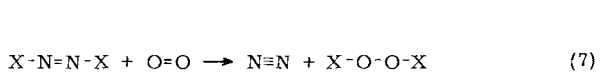
Azoalkanes, on the other hand, do not react with oxygen or azodicarboxylic esters, if one disregards the complicated reactions that take place at higher temperatures. The extremely ready oxidation (7) of BSD is the reason why bis(trimethylsilyl) peroxide can always be found among the products of reactions of BSD (*e.g.* of the thermolysis).

According to our observations so far, the transfer of ligands from the azo groups to double-bond systems, which can generally be achieved in the case of diimine as an uncatalyzed hydrogenation of apolar multiple bonds[11], is possible only with particularly reactive unsaturated systems in the case of BSD, since the thermolysis of BSD otherwise takes precedence. Thus unlike diimine[11], BSD does not react with "normal" carbon multiple bonds *e.g.* of ethylene or cyclohexene[35].

Since the disproportionation of BSD (4) has a reaction order greater than 1, the halflife of the thermolysis depends on the concentration of BSD. In very dilute solution, therefore, BSD can be kept for several days even at room temperature, and at a pressure of 0.001 torr it can be passed through pipes at 300 °C without decomposing since it is very stable toward a first order decomposition with free-radical cleavage of SiN bonds corresponding to the reaction exhibited by the azoalkanes (see above).

4.1.2. Dimerization

If the thermolysis of BSD takes place above −30 °C, tetrakis(trimethylsilyl)tetrazene *(10)* is formed as well as nitrogen and *(9)*[36] in accordance with the overall equation:



(9)

(10)

The compound *(10)*, which is the first example of a silylnitrogen compound with a four-membered nitrogen chain, is formed by a reaction path that has not hitherto been observed for azo compounds, with dimerization of BSD. The contribution of the dimerization of BSD (9) to the total reaction increases with rising temperature, partly at the expense of the disproportionation of BSD (4).

There are three conceivable routes for the formation of the tetrazene *(10)* by dimerization of BSD. These are:

1) Chain addition of two molecules of $(R_3Si)_2N{=}N$;
2) cycloaddition of two molecules of $R_3Si{-}N{=}N{-}SiR_3$ followed by rearrangement of the resulting cyclotetrazane;
3) insertion of the azo groups of two molecules of BSD into Si—N bonds in accordance with:

(10)

Since 1,1-bis(trimethylsilyl)diimine has never been detected despite attempts to intercept it[21], the first reaction path can probably be ruled out. The second reaction path is opposed *inter alia* by the Woodward-Hoffmann rules on the conservation of orbital symmetry[37], which forbid supra,supra-cycloaddition such as is to be expected here. We therefore consider the remaining reaction path (10) which may be formally regarded as a substitution reaction (cf. Section 4.4) as probable.

4.1.3. Free-Radical Reactions

With rising temperature, the thermolysis of BSD leads not only to *(9)* and *(10)* but also to increasing quantities

of tris(trimethylsilyl)hydrazine *(11)* and bis(trimethylsilyl)amine *(12)* in accordance with the overall equations[36,38]:

$$3\ R_3Si\text{-}N{=}N\text{-}SiR_3 \xrightarrow[+2\ H]{>-30\,^\circ C} N{\equiv}N + 2\ \underset{R_3Si}{\overset{R_3Si}{\diagdown}}N\text{-}N\underset{SiR_3}{\overset{H}{\diagup}} \qquad (11)$$

(11)

$$2\ R_3Si\text{-}N{=}N\text{-}SiR_3 \xrightarrow[+2\ H]{>-30\,^\circ C} N{\equiv}N + 2\ \underset{R_3Si}{\overset{R_3Si}{\diagdown}}N\text{-}H \qquad (12)$$

(12)

On the basis of equations (4), (9), (11), and (12), the silyl-nitrogen compounds are formed in yields of 21% of *(9)*, 20% of *(10)*, 28% of *(11)*, and 6% of *(12)* at 180°C with *benzene* as the thermolysis medium. The hydrogen atoms required for the formation of compounds *(11)* and *(12)* come from the methyl groups attached to the Si in BSD. The molecules that are damaged by removal of hydrogen react further to form a large number of secondary products that have not yet been investigated.

With *toluene* instead of benzene as the thermolysis medium, the hydrogen abstraction takes place exclusively from the *C*-bound methyl groups. In addition to the thermolysis products *(9)* to *(12)*, the main product found under these conditions is a hydrazone *(13)* formed in accordance with

$$4\ R_3Si\text{-}N{=}N\text{-}SiR_3 + H_3C\text{-}R' \longrightarrow N{\equiv}N + 2\ \textit{(11)} + \underset{R_3Si}{\overset{R_3Si}{\diagdown}}N\text{-}N{=}CH\text{-}R' \qquad (13)$$

(13)

(R′ = phenyl). Benzyltrimethylsilylhydrazines are also formed as by-products. From the decrease in the yield of *(9)* and the corresponding increase in the yield of *(11)* on replacement of benzene by toluene as the solvent, it can be deduced that the disproportionation of BSD (4) and the free-radical reaction of BSD (11) involve a common intermediate.

It seems possible that the reactions (4) and (11), which proceed independently of the non-radical dimerization of BSD (9), are induced by the free-radical reaction (14a).

$$BSD \xrightarrow[+BSD]{(a)} N_2 + \underset{R_3Si}{\overset{R_3Si}{\diagdown}}N\text{-}N^{\bullet}\underset{SiR_3}{\diagup} + {}^{\bullet}SiR_3 \qquad (14)$$

(b) +BSD

The tris(trimethylsilyl)hydrazyl radical formed in accordance with equation (14) could then react further with the trimethylsilyl radical, either by combining to form the hydrazine *(9)* or by hydrogen abstraction to form the hydrazine *(11)* (cf. also Section 4.3.2).

4.2. "Electrochemical" Redox Reactions

4.2.1. BSD as an Electron Acceptor and Donor

Figure 2 shows the energy levels of inner molecular orbitals of the electron acceptor tetracyanoethylene (TCNE) and of the electron donor tetrakis(dimethylamino)ethylene (TDAE), together with the corresponding orbitals of BSD. TCNE has an extremely low empty π^* orbital, and can therefore accept one or two electrons to form monoanions or dianions ($TCNE^-$, $TCNE^{2-}$)[39]. Conversely, the highest occupied π orbital of TDAE is energetically extremely high; TDAE can therefore give up one or two electrons to form monocations or dications ($TDAE^+$, $TDAE^{2+}$)[40]. Since the empty π^* orbital of TCNE and the occupied π orbital of TDAE are comparable in energy with the π^* and n_+ orbitals of BSD, BSD should possess the properties both of an electron acceptor and of an electron donor and should be capable of accepting or donating one or two electrons:

$$R_3Si\text{-}N{=}N\text{-}SiR_3 \underset{-e}{\overset{+e}{\rightleftharpoons}} R_3Si\text{-}N^{\ominus}\text{-}N\text{-}SiR_3 \underset{-e}{\overset{+e}{\rightleftharpoons}} R_3Si\text{-}N^{\ominus}\text{-}N^{\ominus}\text{-}SiR_3 \qquad (15a)$$

$$R_3Si\text{-}N{=}N\text{-}SiR_3 \underset{+e}{\overset{-e}{\rightleftharpoons}} R_3Si\text{-}N^{\oplus}\text{-}N\text{-}SiR_3 \underset{+e}{\overset{-e}{\rightleftharpoons}} R_3Si\text{-}N^{\oplus}\text{-}N^{\oplus}\text{-}SiR_3 \qquad (15b)$$

BSD does in fact readily undergo electrochemical reduction to the radical-anion BSD^-[30]. On the other hand, the expected high stability of the radical-cation BSD^+ is impressively shown by the appearance in the mass spectrum of a molecular ion signal that is unusually intense for silyl-nitrogen compounds.

The introduction of electrons into the BSD system or the withdrawal of electrons from the system should also be possible by reaction of BSD with electropositive metals or with electronegative nonmetals of the main groups. As can be seen from the following discussion, alkali and

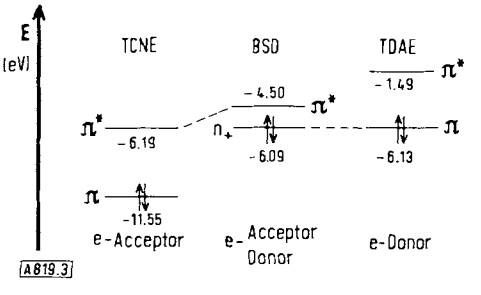


Fig. 2. Term diagram of the highest occupied and lowest unoccupied molecular orbitals of tetracyanoethylene (TCNE), bis(trimethylsilyl)-diimine (BSD), and tetrakis(dimethylamino)ethylene (TDAE).

alkaline earth metals on the one hand and halogens and chalcogens on the other react with BSD, whereas the elements of groups III, IV, and V, as well as hydrogen (in the absence of catalysts) show no reactivity toward BSD.

4.2.2. Reduction of BSD with Electropositive Metals[41]

When alkali metals in ethers are brought into contact with BSD, the quintet signal characteristic of a radical-anion BSD^- is immediately observed in the ESR spectrum[20]. For example, lithium reacts quantitatively with BSD in tetrahydrofuran (THF) at $-78\,^\circ C$ according to (16a) to give Li[BSD]:

$$BSD + Li \xrightarrow[THF]{-78\,^\circ C} Li[BSD] \qquad (16a)$$

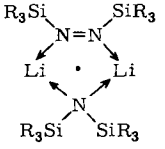
$$BSD + 2\,Li \xrightarrow[(C_2H_5)_2O]{-30\,^\circ C} Li_2[BSD] \qquad (16b)$$

As expected, BSD can also be reduced to the dianion by alkali metals. Thus three days' reaction of BSD with lithium in diethyl ether at $-30\,^\circ C$ affords $Li_2[BSD]$ in accord with (16b).

Unlike the BSD dianion, the resulting BSD radical-anions are stable only at low temperatures, and decompose at higher temperatures, depending on the metal M and the solvent, with loss of nitrogen and formation of products that include $(R_3Si)_2NM$, $(R_3Si)_2N_2M_2$, MN_3, and $(R_3Si)_4N_2$. The course of the reaction is very complex, as can be shown for the reaction of BSD with lithium in THF, which proceeds quantitatively in accordance with

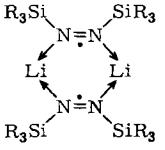
$$2\,BSD + 2\,Li \xrightarrow{THF} 2\,(R_3Si)_2NLi + N_2 \qquad (17)$$

This reaction is induced at $-60\,^\circ C$ by the formation of the compound Li[BSD] as in eq. (16a). The latter compound then decomposes in a first order reaction (with a half life of ≈ 1 hour at $-45\,^\circ C$) into nitrogen and lithium bis(trimethylsilyl)amide *(14)*.



$$2\,Li[BSD] \rightarrow N{\equiv}N + 2\,\underset{(14)}{LiN(SiR_3)_2} \qquad (18)$$

However, one finds a total of only 50% conversion in accordance with equation (18), from which it follows that a reaction product (which must be *(14)*) stabilizes unreacted Li[BSD] by "complex formation".



$$Li[BSD] + (14) \rightarrow \underset{(15)}{\text{"Li[BSD]·LiN(SiR}_3)_2\text{"}} \qquad (19)$$

Freshly prepared Li[BSD] accordingly does not decompose at $-45\,^\circ C$ if an equimolar quantity of *(14)* is added to the reaction solution.

Since the ESR spectrum of a solution of the complex *(15)* points to three nitrogen atoms in the molecular complex, two of which must be similarly bound, we consider the following structural formula *(15)* to be possible:

(15)

(16)

Li[BSD] evidently also forms a complex with itself (suggested formula *(16)*), since only in this way can the reaction order of 1 found for the decomposition of Li[BSD] be simply explained on the basis of an intramolecular rearrangement[42]. Complex formation of this type is also indicated by the observation that Li[BSD] is also formed from $Li_2[BSD]$ and BSD in THF.

$$Li_2[BSD] + BSD \underset{pentane}{\overset{THF}{\rightleftharpoons}} \underset{(16)}{\{LiBSD\}_2} \rightleftharpoons 2\,Li[BSD] \qquad (20)$$

Conversely, by replacement of the solvent THF by pentane, the compound *(16)* can be converted quantitatively into $Li_2[BSD]$ and BSD; the indicated equilibrium (20) is displaced completely to the left because of the insolubility of $Li_2[BSD]$ in pentane.

The concentration of free Li[BSD] in equilibrium with the complex *(15)* is evidently so small that the decomposition of the complex into nitrogen and *(14)* *via* Li[BSD]

$$2\,(15) \rightarrow N_2 + 4\,(14) \qquad (21)$$

proceeds only very slowly; the first halflife of the decomposition (21) is about 1 week at $-45\,^\circ C$. However, all the initially formed Li[BSD] ultimately decomposes in accordance with equation (18), with quantitative formation of nitrogen and lithium bis(trimethylsilyl)amide *(14)*.

It should be mentioned in passing that Li[BSD] can also be stabilized by complex formation with BSD in diethyl ether.

$$Li + 3\,BSD \xrightarrow{ether} \{Li[BSD] + 2\,BSD \longrightarrow Li(BSD)_2]^+\,BSD^- \qquad (22)$$

4.2.3. Oxidation of BSD with Electronegative Nonmetals[43]

The oxidizing power of nonmetals increases from left to right and from bottom to top of the periodic table. In agreement with this, BSD reacts with the halogens and the more strongly oxidizing chalcogens oxygen, sulfur, and selenium, but not with tellurium or the elements of group V. However, the reactions with electronegative nonmetals never led to BSD cations. This is understandable if one considers the positive charge produced on the BSD system on cation formation (cf. equation (15b)), which greatly facilitates nucleophilic substitution of the anion belonging to the BSD cation.

For example, tetrakis(dimethylamino)ethylene (TDAE) reacts quantitatively with halogen to form TDAE dihalide[40]. The reaction of BSD with halogen, on the other hand, leads not to BSD dihalide but only to its formal further reaction products, nitrogen and trimethylhalosilane.

$$TDAE + Hal_2 \rightarrow TDAE^{2+}\,2\,Hal^- \rightarrow \text{no further reaction} \qquad (23)$$

$$BSD + Hal_2 \rightarrow (BSD^{2+}\,2\,Hal^-) \rightarrow N{\equiv}N + 2\,R_3Si{-}Hal \qquad (24)$$

Corresponding to reaction (24), oxygen (cf. reaction (7)), S_8, and red selenium oxidize BSD to nitrogen.

$$BSD + 1/8\ E_8 \rightarrow N{\equiv}N + R_3Si{-}E{-}SiR_3 \quad (25)$$
E = S, Se

The rate of the oxidation reaction decreases with increasing atomic weight of the chalcogen (the same is true of the halogens), and the oxidation is increasingly suppressed by the thermolysis of BSD in the order O, S, Se, Te:

	O_2	S_8	Se_8	Te_n
% oxidation	100	47	2	0
% thermolysis	0	53	98	100

The halogenation and chalcogenation of BSD naturally need not follow the reaction (24). The reactions (24) and (25) can probably be assigned to the redox reactions, which will be discussed below.

4.3. Redox Reactions in the Broader Sense

4.3.1. BSD as a Lewis Acid and Lewis Base

The ability of BSD to act as an electron acceptor and as an electron donor, which is clear from the term diagram (Fig. 2), should also be reflected in Lewis acid and Lewis base properties. Whereas only the complete electron acceptance can be achieved preparatively in the case of electrochemical redox reactions (formation of BSD^-, BSD^{2-}), the opposite is true of the acid-base reactions, which proceed with partial electron transfer; in other words, only reactions of BSD with Lewis acids involving partial electron donation (formation of BSD→A) have so far been observed, *e.g.* the reactions of BSD with lithium ions (cf. reaction (22)) and with trinitrobenzene (λ_{max} of the CT absorption of BSD·*n*TNB : 21100 cm^{-1}), which proceed with acid-base complex formation and with EDA complex formation respectively[44,44a].

Such adducts of BSD with Lewis acids frequently cannot be isolated since they are unstable and evidently decompose for the following reasons. Lewis acids S—B generally contain basic centers B as well as acidic centers S. As a result of adduct formation between BSD and the acid S—B (=A in Scheme 1) the acidic centers nitrogen and silicon of the BSD, which initially acts as a base, are activated to such a degree that they react with the (also activated) basic centers of the reactant S—B that initially acted as the acid.

As a whole, therefore, the reaction corresponds to the addition of S—B to the azo double bond or substitution of a silyl group attached to the azo group by S. The substitution product is very often unstable, and decomposes with elimination of $R_3Si{-}S$ (cf. Scheme 2).

Typical examples are provided by the reactions of BSD with *sulfur dichloride* and *sulfur dioxide* EX_2 (X = Cl, O) to form nitrogen, sulfur, and trimethylchlorosilane or nitrogen and bis(trimethylsilyl) sulfoxylate at −78 °C. The formation of these products can be readily explained on the basis of Scheme 2:

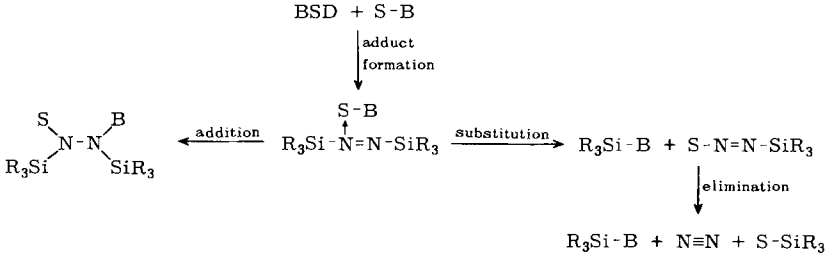
$$R_3Si{-}N{=}N{-}SiR_3 \xrightarrow[-N{\equiv}N]{EX_2} \begin{cases} X{=}Cl: & R_3Si{-}X{+}E{+}X{-}SiR_3 \\ X{=}O: & R_3Si{-}X{-}E{-}X{-}SiR_3 \end{cases} \quad (26)$$

The reaction sequence adduct formation, addition (adduct formation, substitution, elimination) corresponds overall to reduction (oxidation) of BSD through two oxidation stages to give a hydrazine derivative (to give nitrogen):

$$\text{>N-N<} \xleftarrow{\text{reduction}} \underset{\text{BSD}}{\text{-N=N-}} \xrightarrow{\text{oxidation}} N{\equiv}N \quad (27)$$

Redox reactions of the type (27) (and also substitution reactions) are of preparative interest, since they often proceed quantitatively. Reduction and oxidation reactions will therefore now be discussed in more detail (substitution reactions in Section 4.4).

4.3.2. Reduction of BSD (BSD as Oxidizing Agent)

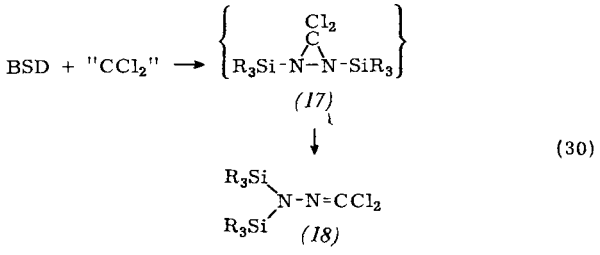


A typical addition reaction with reduction of BSD is the reaction of BSD with *organometallic compounds* (S—B = M—R′ in Scheme 2), which leads in high yields to metal bis(trimethylsilyl)organylhydrazides (M = Li, MgBr, R′ *e.g.* = methyl [cf. also reaction (52)], *n*-butyl, phenyl)[19].

$$BSD + M{-}R' \longrightarrow \begin{matrix} M & & R' \\ & N{-}N & \\ R_3Si & & SiR_3 \end{matrix} \quad (28)$$

Metal hydrides (S—B = R'_nM—H) can evidently also add to BSD, as was shown by the reaction of BSD with trimethylsilane to form tris(trimethylsilyl)hydrazine *(11)*[35].

$$BSD + R_3Si{-}H \longrightarrow \begin{matrix} R_3Si & & H \\ & N{-}N & \\ R_3Si & & SiR_3 \end{matrix} \quad (29)$$
(11)



However, reaction (29) probably does not follow Scheme 2, since it proceeds in benzene only under the conditions of the thermolysis of BSD, and is completely suppressed

Scheme 2. Redox and substitution reactions of bis(trimethylsilyl)diimine.

in toluene by the free-radical thermolysis of BSD (Section 4.1.3)[45]. Trimethylsilane probably adds to BSD by a free-radical chain reaction.

Another example of the reduction of BSD is the reaction of BSD with "dichlorocarbene" formed as an intermediate from chloroform.

(30)

The product is not the expected compound *(17)*, but an open-chain isomer *(18)*. The dichlorocarbene required for reaction (30) can be formally obtained by reduction of CCl_4 with BSD (cf. Section 4.3.3); the reaction of BSD with carbon tetrachloride thus proceeds overall in accordance with equation (31)[35]:

$$2\,BSD + CCl_4 \rightarrow N_2 + 2\,R_3SiCl + \textit{(18)} \qquad (31)$$

In agreement with investigations on diimine[11], addition of a *diene* (butadiene) to BSD (Diels-Alder reaction) has not been observed.

4.3.3. Oxidation of BSD (BSD as a Reducing Agent)

We have so far found oxidations of BSD to be much more common than reductions. Many nonmetals (cf. Section 4.2.3), nonmetal halides, and nonmetal chalcogenides, as well as many other compounds, can oxidize BSD to nitrogen. This is illustrated below by some reactions of chlorides, oxides, and azides with BSD.

Reduction of Chlorides[46]

With the exception of silicon tetrachloride, all the chlorides of elements E of main groups IV–VII react with BSD. The nearer the elements of the chlorides ECl_n are to the right of the Periodic Table, the more extensively they are reduced at −78 °C in methylene chloride:

		(PCl_3)	SCl_2	ClCl
	$(GeCl_4)$	$AsCl_3$	"$SeCl_2$"	BrCl
	$SnCl_4$	$SbCl_3$	$TeCl_2$	ICl
Reduction to:	E^{II}	E^0	E^0	E^{-I}

It has also been found that in analogy with the reduction of $SnCl_4$, $TiCl_4$ is reduced to $TiCl_2$ by BSD, whereas the formally expected $GeCl_2$ is not obtained, since it evidently reacts further with BSD (cf. reaction (31)). PCl_3 is not reduced to elemental phosphorus by BSD. On the other hand, SCl_2 can be reduced to the oxidation state −II of sulfur at "higher" temperatures (0 °C, cf. reaction (25)). Selenium and tellurium were used in the form of the tetrachlorides, but the reduction of these compounds by BSD must proceed *via* the dichlorides.

The reaction of BSD with *disulfur dichloride* is particularly interesting. It leads quantitatively, in accordance with

$$2\,BSD + S_2Cl_2 \xrightarrow[-78\,^\circ C]{CH_2Cl_2} 2\,N_2 + 2\,R_3SiCl + \underset{\textit{(19)}}{R_3Si{-}S{-}S{-}SiR_3} \qquad (32)$$

to bis(trimethylsilyl)disulfane *(19)* if S_2Cl_2 is added dropwise to a cooled solution of BSD. (Similarly, reaction of BSD with *trisulfur dichloride* leads to bis(trimethylsilyl)trisulfane in a reaction resembling (32).) One possible explanation of reaction (32) could be that, corresponding to the expected reaction (26), S_2Cl_2 is first reduced by BSD to disulfur, which could then react further with BSD, in analogy with reaction (7) with oxygen, to form the disulfane *(19)*, which decomposes readily in accordance with

$$\textit{(19)} \rightarrow R_3Si{-}S{-}SiR_3 + 1/8\,S_8 \qquad (33)$$

Diselenium dichloride probably also reacts in accordance with equation (32), but instead of the expected bis(trimethylsilyl)diselane, one obtains bis(trimethylsilyl)selane and selenium (cf. reaction (33)).

The reductions of some chlorine compounds ECl_n of the nonmetals of the first short period (E = N, O, F) with BSD, which have not yet been mentioned, differ from the reactions discussed so far, since these compounds contain positive chlorine. Instead of the central element E, therefore, only the ligand chlorine can be reduced. This is clear from a comparison of the reactions of BSD with bis(organyl)chloroamine and bis(organyl)-chlorophosphane in methylene chloride:

$$BSD + R_2N{-}Cl \rightarrow N_2 + R_3SiCl + R_2N{-}SiR_3 \qquad (34)$$

$$BSD + 2\,R_2P{-}Cl \rightarrow N_2 + 2\,R_3SiCl + R_2P{-}PR_2 \qquad (35)$$

(Concerning reaction (35), cf. Section 4.4; for the reaction of BSD with CCl_4, cf. reaction (31).)

Reduction of Oxides[46]

Whereas the σ bonds of the nonmetal chlorides readily undergo reductive cleavage by BSD, this agent preferentially attacks only π bonds in the nonmetal oxides, so that the choice of possible reaction partners for BSD is smaller in the case of the oxides than in the case of the chlorides. Reduction reactions have so far been observed only for carbon, nitrogen, "oxygen", and sulfur oxides (carbon dioxide does not react with BSD). Only the reactions of BSD with sulfur oxides will be discussed below.

Sulfur dioxide, as was mentioned earlier (cf. reaction (26)), is reduced to bis(trimethylsilyl) sulfoxylate *(20)* by BSD at −78 °C[47].

$$BSD + SO_2 \rightarrow N_2 + \underset{\textit{(20)}}{R_3SiO{-}S{-}OSiR_3} \qquad (36)$$

The very unstable sulfoxylate *(20)*, which was obtained in this way for the first time, decomposes above $-40\,^{\circ}C$ into sulfur dioxide, sulfur, and hexamethyldisiloxane. In the presence of sulfur trioxide, this decomposition takes place even at $-78\,^{\circ}C$, and in this case, as expected, hexamethyldisiloxane is obtained as the SO_3 adduct, bis(trimethylsilyl) sulfate *(21)*[48].

$$(20) \xrightarrow[-1/2\,SO_2,\,-1/2\,S]{} (R_3Si)_2O \xrightarrow{+SO_3} R_3SiO{-}\overset{\overset{O}{\|}}{S}{-}OSiR_3 \quad (37)$$
$$\underset{\overset{\|}{O}}{(21)}$$

The sulfoxylate *(20)* is also formed from BSD and sulfuryl chloride, since BSD probably first reduces the chloride SO_2Cl_2 to SO_2 (cf. above),

$$BSD + SO_2Cl_2 \rightarrow N_2 + 2\,R_3SiCl + SO_2 \quad (38)$$

which then reacts further in accordance with equation (36).

Sulfur trioxide is also reduced by BSD. The reaction product to be expected here in accordance with reaction (36), *i.e.* bis(trimethylsilyl) sulfite

$$BSD + SO_3 \rightarrow N_2 + R_3SiO{-}\overset{\overset{O}{\|}}{S}{-}OSiR_3 \quad (39)$$
$$\underset{(22)}{}$$

cannot be isolated, since it appears to be thermally unstable and reacts rapidly with further sulfur trioxide in a reaction similar to (37) to form sulfur dioxide and silyl sulfate *(21)*.

$$(22) \xrightarrow[-SO_2]{} (R_3Si)_2O \xrightarrow{+SO_3} (21) \quad (40)$$

Since SO_2 can react first with BSD and then with SO_3 in accordance with equations (36) and (37), the overall reaction of BSD with sulfur trioxide ultimately corresponds to the formation of nitrogen, sulfur, and bis(trimethylsilyl) sulfate *(21)*.

$$3\,BSD + 4\,SO_3 \rightarrow 3\,N_2 + S + 3\,(21) \quad (41)$$

Sulfur monoxide, which should occur as an intermediate in the reaction of BSD with thionyl chloride (cf. reaction (38)), should also react with BSD in the same way as oxygen (reaction (7)):

$$BSD + \text{"SO"} \xrightarrow{?} N_2 + R_3Si{-}S{-}O{-}SiR_3 \quad (42)$$
$$\underset{(23)}{}$$

However, the reaction of thionyl chloride with BSD leads not to the compound *(23)*, but to products that include sulfur and hexamethyldisiloxane (formally the decomposition products of the compound *(23)*) in accordance with

$$2\,BSD + SOCl_2 \rightarrow 2\,N_2 + 2\,R_3SiCl + 1/8\,S_8 + (R_3Si)_2O \quad (43)$$

Like SCl_2, therefore, SO is reduced to sulfur. The fundamental possibility of reaction of element-oxygen groups with BSD in the sense of reaction (42) is strongly indicated by the reaction of BSD with *nitrosobenzene*:

$$BSD + Ph{-}N{=}O \rightarrow N_2 + R_3Si{-}\overset{\overset{Ph}{|}}{N}{-}O{-}SiR_3 \quad (44a)$$

or with *benzophenone*:

$$BSD + 2\,Ph_2C{=}O \rightarrow N_2 + Ph_2\overset{\overset{R_3SiO}{|}}{C}{-}\overset{\overset{OSiR_3}{|}}{C}Ph_2 \quad (44b)$$

Reduction of Azides[49]

Finally, the reactions with azides to form amines also merit attention among the oxidations of BSD:

$$BSD + X{-}N_3 \rightarrow 2\,N_2 + X{-}N(SiR_3)_2 \quad (45)$$

Since BSD reacts only with electrophilic azides XN_3 below $0\,^{\circ}C$ (X = *e.g.* acyl, *p*-toluenesulfonyl[50], $(RO)_3Si$[51], but not phenyl, R_3Si) and the rate of the reaction (45) is increased by polar reaction media, (45) is probably induced by electrophilic attack of the azide on the azo system (formation of the adduct *(24)*) in accordance with the general reaction Scheme 2. *(24)* could then readily change into the observed products by migration of silyl groups.

$$X{-}N{=}N{-}\overset{\uparrow}{N}{=}N{-}SiR_3 \rightarrow X{-}N\begin{matrix}SiR_3\\SiR_3\end{matrix} + 2\,N{\equiv}N \quad (46)$$
$$\underset{(24)}{R_3Si}$$

Hydrazoic acid also reacts with BSD in accordance with equation (45) (X = H); in this special case, however, the reaction could also be initiated by attack on BSD by a proton (cf. Section 4.4).

4.4. Substitution Reactions

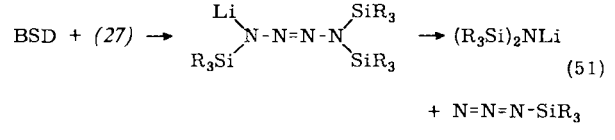
4.4.1. BSD as "Azo-ation" Agent

Corresponding to the general Scheme 2 of the reaction of BSD with Lewis acids S—B, BSD substitution reactions proceed in accordance with equations (47) and (48).

$$R_3Si{-}N{=}N{-}SiR_3 + S{-}B \rightarrow R_3Si{-}B + S{-}N{=}N{-}SiR_3 \quad (47)$$
$$\underset{(25)}{}$$
$$S{-}N{=}N{-}SiR_3 + S{-}B \rightarrow R_3Si{-}B + S{-}N{=}N{-}S \quad (48)$$
$$\underset{(26)}{}$$

Such reactions thus correspond to transfer of the azo group to S; BSD thus acts as an "azo-ation agent" for S, and could therefore be used for the preparation of inorganic azo compounds *(25)* and *(26)*. However, the substituted diimines expected according to equations (47) and (48) are frequently not obtained, since they are often unstable and *e.g.* lose nitrogen (cf. Section 4.3) or react further with BSD (cf. Sections 4.4.2 and 4.4.3).

Thus the *protolysis* of BSD (S—B in Scheme 2 = H—X; X = *e.g.* OH, OR, $OSiR_3$, NH_2, NHR, N_3, Cl, SO_4H) leads not to diimine, which is probably formed as an intermediate in accordance with



$$BSD + 2\,H{-}X \rightarrow 2\,R_3Si{-}X + H{-}N{=}N{-}H \qquad (49)$$

but to nitrogen and hydrazine (in the form of its HX adduct) together with other products (cf. Section 4.4.3). The reaction of BSD with *methyllithium* (S—B = Li—R), which proceeds with simultaneous addition (Section 4.3.2) and substitution, leads not to the expected substitution product lithium trimethylsilyldiimide, which is undoubtedly formed as an intermediate

$$BSD + Li{-}R \rightarrow R_3Si{-}R + \underset{(27)}{Li{-}N{=}N{-}SiR_3} \qquad (50)$$

but to lithium azide and lithium bis(trimethylsilyl)amide. Both compounds may be formally regarded as products formed by further reaction of the azo compound *(27)*[19].

On consideration of reaction (28) and the thermolysis and hydrolysis reactions of silylated diimines summarized in Scheme 3 (cf. Section 4.4.3), it seems particularly probable to us that the diimide *(27)* adds to BSD to form a tetrazene compound, which then decomposes:

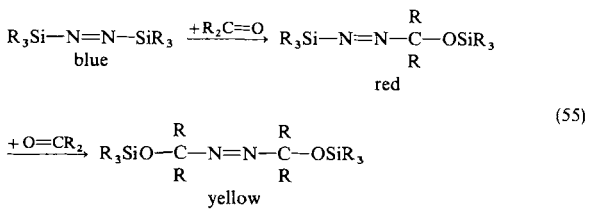
$$BSD + (27) \rightarrow \quad \rightarrow (R_3Si)_2NLi + N{=}N{=}N{-}SiR_3 \qquad (51)$$

According to our results[52], the trimethylsilyl azide formed would react rapidly with methyllithium to give tetramethylsilane and lithium azide, so that including equations (50) and (51), the reaction course found experimentally can be represented by:

$$2\,BSD + 2\,LiR \rightarrow 2\,R_4Si + LiN_3 + (R_3Si)_2NLi \qquad (52)$$

In the reaction of BSD with *bis(organyl)chlorophosphanes* (S—B = R'_2P—Cl), instead of the azo compound *(28)* that is expected according to equation (47), and which, according to experimental results, is probably formed as a reaction intermediate:

$$BSD + R'_2P{-}Cl \rightarrow R_3Si{-}Cl + \underset{(28)}{R'_2P{-}N{=}N{-}SiR_3} \qquad (53)$$



one again finds only its further reaction products (cf. Section 4.4.2).

On the other hand, the reaction of BSD with *diphenylboron chloride* (S—B = Ph_2B—Cl) proceeds as expected in accordance with equations (47) and (48).

$$BSD + 2\,Ph_2B{-}Cl \rightarrow 2\,R_3Si{-}Cl + \underset{(29)}{Ph_2B{-}N{=}N{-}BPh_2} \qquad (54)$$

This reaction allowed the preparation of the first pure azoborane *(29)*[10].

Insertion of the carbonyl group of *acetone* (S—B = $R_2C{=}O$) into the Si—N bond of BSD also occurs in the sense of reactions (47) and (48):

(55)

The reactions of BSD with organylchlorophosphanes and with water will now be discussed as examples of BSD substitution reactions in more detail.

4.4.2. Reaction of BSD with Organylchlorophosphanes[46]

The reactions of BSD with organylchlorophosphanes are sometimes rather complicated. The ease with which they proceed increases with the degree of chlorination of the phosphorus, *i.e.* with increasing acidity of the reactant. Thus triphenylphosphane does not react with BSD; diphenylchlorophosphane reacts at −30 °C, phenyldichlorophosphane reacts slowly at −78 °C, and phosphorus trichloride is violently attacked by BSD at −78 °C. The nature of the reaction products is strongly dependent on the reaction medium as can be illustrated for the reaction of *bis(organyl)chlorophosphanes* with BSD.

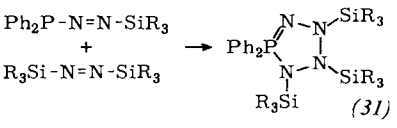
With *methylene chloride* as the solvent, bis(organyl)chlorophosphanes react to form tetrakis(organyl)diphosphanes

$$BSD + 2\,R'_2P{-}Cl \xrightarrow{CH_2Cl_2} N_2 + 2\,R_3Si{-}Cl + R'_2P{-}PR'_2 \qquad (56)$$

The reaction proceeds in accordance with equation (53) *via* a phosphanoazo compound *(28)*, the formation of which can be correlated with a deep green-blue color that appears during the reaction. According to our investigations so far, *(28)* decomposes with liberation of nitrogen.

$$\underset{(28)}{R'_2P{-}N{=}N{-}SiR_3} \rightarrow N{\equiv}N + R'_2P{-}SiR_3 \qquad (57a)$$

The bis(organyl)trimethylsilylphosphane (which can be isolated in the case of R′ = mesityl) finally reacts with bis(organyl)chlorophosphane as follows[52].

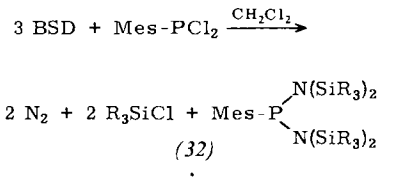


$$R'_2P{-}SiR_3 + Cl{-}PR'_2 \rightarrow R_3Si{-}Cl + R'_2P{-}PR'_2 \qquad (57b)$$

With *diethyl ether* as the solvent, bis(organyl)chlorophosphanes react much more slowly than in methylene chloride. The product obtained on reaction of BSD with diphenylchlorophosphane is tris(trimethylsilyl)diphenylphosphamidine *(30)* which can then react further with an excess of

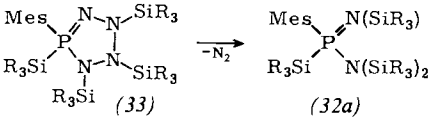
$$2\,BSD + Ph_2P{-}Cl \xrightarrow{ether} N_2 + R_3Si{-}Cl + \underset{(30)}{Ph_2P(=N(SiR_3))(N(SiR_3)_2)} \qquad (58)$$

diphenylchlorophosphane (*e.g.* to form $[Ph_2P{-}Ph_2P{=}N{-}PPh_2{=}N{-}\overset{\oplus}{P}Ph_2{-}PPh_2]Cl^{\ominus}$). This reaction leads surprisingly to a compound with isolated nitrogen atoms. The diimine group must therefore have been split during the formation of *(30)*.



We assume that the reaction (58) again proceeds first *via* the phosphanoazo compound *(28)* in accordance with equation (53) (R′ = phenyl), and that *(28)* then undergoes "1,3-dipolar" addition with BSD, as in related cases[53,54], with formation of the adduct *(31)*:

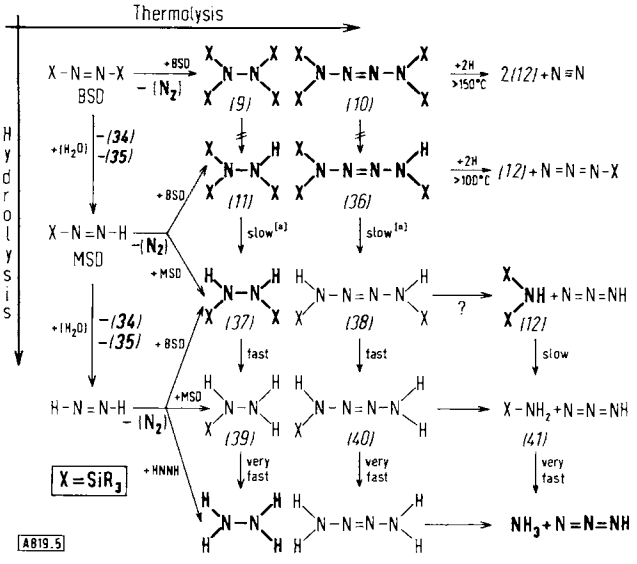
(59)



The compound *(31)* could decompose, after migration of two silyl groups to phosphorus-bound nitrogen atoms, into the final products, *i.e.* nitrogen and *(30)*.

Reactions of BSD with organyldichlorophosphanes or even with phosphorus trichloride are even more complicated than those with bis(organyl)chlorophosphanes. This is connected with the greater number of reactive chlorine atoms. For example, the reaction of BSD with *mesityldichlorophosphane* leads *inter alia* to the phosphane *(32)*:

(60)



The formation of *(32)* can be readily explained on the basis of the earlier discussions. Mesityldichlorophosphane first undergoes a reaction corresponding to the sequence of equations (53), (56) to give $Mes(R_3Si)PCl$, which reacts further with BSD in accordance with the sequence (53), (59) to give compound *(33)*. Like *(31)*, compound *(33)* can then decompose to form a phosphamidine *(32a)*, which would rearrange into the final product *(32)*.

(61)

4.4.3. Reaction of BSD with Water[35]

When BSD is brought into contact with water at 20–40 °C, the reaction products include tetrakis(trimethylsilyl)hydrazine *(9)*, tetrakis(trimethylsilyl)tetrazene *(10)*, hydrazine, ammonia, and ammonium azide, as well as nitrogen, trimethylsilanol R_3SiOH *(34)*, and the condensation product of the latter $(R_3Si)_2O$ *(35)*. A detailed investigation of the hydrolysis of BSD showed that the reaction of BSD with water takes place in two main reaction steps, which differ greatly in their rates. Several fast reactions first lead to the products shown in bold type in Scheme 3, which can be detected as such (reaction time for the *primary hydrolysis*: a few hours). Apart from bis(trimethylsilyl)hydrazine *(37)*, which reacts further with water even during the primary hydrolysis, some of these compounds, *i.e.* *(11)*, *(36)*, and *(12)*, are slowly hydrolyzed to hydrazine, ammonia, and ammonium azide with formation of *(34)* and *(35)* (reaction time for the *secondary hydrolysis*: a few weeks).

Scheme 3. Hydrolysis of bis(trimethylsilyl)diimine.
[a] Hydrolysis leads to 1,1-bis(trimethylsilyl)hydrazine and tetrazene.

The following observations should be added in connection with Scheme 3. *(9)* and *(10)* are formed by thermal disproportionation and dimerization of BSD with itself (Section 4.1). The formation of *(11)* and *(36)* can also be explained by corresponding reactions of BSD with mono(trimethylsilyl)diimine (MSD)[55]. It may therefore be assumed that the hydrolysis of BSD (as expected) proceeds *via* MSD as an intermediate. MSD then reacts on the one hand with BSD by disproportionation and dimerization to give nitrogen, *(11)*, and *(36)* (predominating principal reaction), and on the other with water to give diimine. The relationship of the reactions of BSD with BSD and of BSD with MSD is particularly clearly shown by a feature of the reaction (cf. Section 4.1.2), *i.e.* the increase in yield both of tetrazene *(10)* and of *(36)* with rising reaction temperature. The decomposition of diimines by two pathways (disproportionation, dimerization), which was first observed in the thermolysis of BSD, is thus evidently of more general importance.

Whereas *(9)* and *(10)* react only unmeasurably slowly with water[56], *(11)* and *(36)* are hydrolyzed slowly but measurably to hydrazine and ammonium azide respectively (secondary hydrolysis). The unexpected formation of ammonium azide can be explained as follows: The silyltetrazene *(36)* is hydrolyzed to tetrazene, which decomposes in turn, with migration of hydrogen, into ammonia and hydrazoic acid (= ammonium azide)[36,57]. The fundamental possibility of such a decomposition is shown *e.g.* by the thermolysis of *(36)*, which leads quantitatively to *(12)* and trimethylsilyl azide above 100 °C[35].

Contrary to expectation, *(10)* does not decompose in a similar manner into tris(trimethylsilyl)amine and trimethylsilyl azide, but gives *(12)* and nitrogen above 150 °C. This free-radical decomposition, which corresponds to the

thermolysis of organic tetrazenes[12], is probably due to the fact that decomposition with migration of silyl groups is impossible on steric grounds, as was shown by examination of the Stuart model of *(10)*. The tetrazene *(38)*, which has not yet been isolated as such, should decompose in the same way as the tetrazene *(36)*, though more rapidly because of the comparatively lower steric hindrance.

Since the compounds *(11)* and *(36)* undergo only very slow hydrolytic decomposition and no thermolysis under the reaction conditions, neither of these compounds can be the source of the small quantities of hydrazine and of ammonium azide formed in the primary hydrolysis. However, initially formed hydrazine and ammonium azide could be further reaction products of the doubly silylated hydrazine *(37)* and tetrazene *(38)*. According to the above arguments, both compounds should be formed from diimine (the final product of the hydrolysis of BSD by the "direct" route) and BSD with disproportionation and dimerization. It has in fact been possible to show the probable presence, as a reaction intermediate at the beginning of the hydrolysis of BSD, of the 1,2-isomer *(37)* of bis(trimethylsilyl)hydrazine, which is itself sensitive to water[58]. On the other hand, attempts to find bis(trimethylsilyl)tetrazene *(38)* have so far been unsuccessful. The hydrolysis (and possibly also the thermolysis or a reaction with BSD) of this tetrazene is evidently so fast that only its decomposition products are found.

The compounds *(37)* and *(38)* could be formed from two molecules of MSD. However, since the concentration of the very reactive MSD probably remains small during the hydrolysis, this reaction probably makes only an insignificant contribution to the process as a whole. For the same reasons, reaction of diimine with MSD or diimine is also less likely[59].

On the whole, therefore, the reaction of BSD with water is a complicated system of successive and simultaneous hydrolysis, disproportionation, nitrogen chain degradation, and nitrogen chain formation reactions. The situation is further complicated by the fact that ammonium azide and hydrazoic acid can also react with BSD in protolysis (Section 4.4.1) or redox reactions (Section 4.3.3). The latter reaction is probably responsible in particular for the formation of ammonia (*via (12)* and its hydrolysis).

5. Outlook

It can be seen from this report that the reactive azosilane BSD has diverse and unusual chemical capabilities as a redox system and as an acid-base system, which have presented us, and will probably continue to present us, with many unexpected reactions (consider, *e.g.*, BSD as a complex ligand). The observation that the chemical behavior of BSD is similar to that of diimine also deserves special interest in this connection. It appears that the change in properties on transition from nitrogen-hydrogen compounds to their silyl derivatives is only slight, so that the latter offer "thermally stable" model compounds for the investigation of the reactions of "thermally labile" nitrogen-hydrogen compounds.

Thus, to give another example, tetrazene (N_4H_4) could conceivably decompose into:

1) Hydrazine and nitrogen ($\rightarrow N_2H_4+N_2$);
2) Diimine ($\rightarrow 2\ N_2H_2$);
3) Ammonia and hydrazoic acid ($\rightarrow NH_3+HN_3$).

The thermolysis and hydrolysis of silyltetrazenes (Section 4.4) now point to the third possibility, and oppose the thermodynamically favored first possibility, whereas the second reaction, according to results obtained so far (Sections 4.1 and 4.4) can probably proceed only in the reverse direction.

Our assumption of a close chemical relationship between silyl-substituted and unsubstituted nitrogen-hydrogen compounds offers encouragement to prepare and investigate other silylnitrogen-hydrogen compounds, which should also be ideal starting materials for the synthesis of "naked" nitrogen-hydrogen compounds. Since feasible methods for the preparation of such silyl derivatives, according to preliminary results, again lead *via* BSD, our fascinating "BSD adventure" has certainly not yet reached the limit of its possibilities.

I am particularly grateful to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for generous financial support of our investigations, as well as to Dr. W.-Ch. Joo, Dr. G. Schwenk, Dipl.-Chem. W. Uhlenbrock, and Dipl.-Chem. M. Veith for their untiring and inspired cooperation.

[55] Under the hydrolysis conditions (20–40 °C), only small quantities of *(11)* and vanishingly small quantities of *(12)* are formed by thermolysis of BSD. Most of the *(11)* and *(12)* that are produced in large quantities during the hydrolysis must therefore be formed in some other way.

[56] *(9)* and *(10)* are also hydrolyzed to hydrazine and ammonium azide by aqueous acids [36].

[57] Accordingly, hydrolysis intermediates such as *(38)* or *(40)* could decompose into hydrazoic acid and silylamines *(12)* and *(41)*, which hydrolyze further to form ammonium azide.

[58] The hydrazine *(37)* is formed in large quantities in the protolysis of BSD with a little ammonia.

[59] According to literature data [11], the thermolysis of diimine should lead only to nitrogen and hydrazine, so that the formation of ammonium azide is apparently due not to the decomposition of diimine, but necessarily to the hydrolysis of the silyltetrazenes *(38)* and *(40)*.

Biological Membranes

By Werner Gross[*]

Membranes are essential components of living cells. They act as barriers and pumps, as enzyme supports, and also as a means of protection. Their chemical makeup from proteins, lipids, carbohydrates, ribonucleic acids, and water is well known, but there is as yet no generally accepted model for their structure. It is also by no means certain that all membranes have the same structural plan.

1. Introduction

Membranes are structures of universal occurrence in living nature. All cells, even those of the most primitive microorganisms, are enclosed by a plasma membrane. Since the biochemical reactions taking place in the cytoplasm require a constant environment, the intracellular space must be separated from the extracellular space. The cell organelles, such as nuclei, mitochondria, and vacuoles, are also enclosed by membranes. The reaction spaces (compartments) separated in this way by membranes differ qualitatively and quantitatively in the substances that they contain; it must therefore be concluded that all membranes possess selective permeability. However, further generalizations appear to be possible only within limits, in view of the morphological and chemical differences between the membranes.

The plasma membranes of liver cells and of erythrocytes have been investigated in some depth, whereas less is known at present about the membranes of the microorganisms. The investigations on function and on structure are closely linked. Results of functional studies led to certain requirements regarding the membrane architecture, and morphological results contributed to an understanding of functional processes. Morphological views and biochemical and physiological studies have contributed in a similar manner to the current picture of biological membranes. A number of monographs and reviews on this rapidly growing field of research have been published[1-13].

Physical methods of investigation (IR, NMR, and ESR spectroscopic and X-ray analysis) have been used to a particularly large extent in the study of the components of membranes and their interactions. Since lipids and proteins do not usually give ESR signals, these membrane components must be labeled with synthetic organic radicals such as 3-maleimido-2,2,5,5-tetramethylpyrrolidin-1-oxyl[14] or nitroxide[15]. Spin labeling can be introduced into thiol and amino groups of the proteins by means of the first of these radicals, and into fatty acids and cholesterol by the second.

Increasing use is also being made of optical rotatory dispersion and circular dichroism measurements[16], and investigations based on differential thermal analysis[17] have shown that phase transformations occur in phospholipids even in physiological temperature ranges[18,19]. As a result of these methods, important conclusions have recently been drawn concerning the behavior of individual membrane components, interactions between similar and different molecules, and their phase. By refined preparation methods and the use of new detergents for solubilization, it has been possible to isolate membranes and membrane fragments that yielded more reliable analytical results. This has led to a considerable increase in knowledge of the pattern of structural components in biological membranes.

Growing numbers of investigations are being carried out on microorganisms, which offer the following advantages over animal cells. (a) Some microorganisms have no intracellular structures that could lead to serious contamination during the isolation of their plasma membrane, apart from mesosomes. (b) The concentration of certain membrane proteins can be varied by induction and repression of the protein synthesis. This offers the possibility of labeling these proteins by incorporation of radioactive amino acids and isolating them[20]. (c) The composition of certain membranes can be modified experimentally. Thus a mutant of *E. coli* that requires fatty acids for growth and that incorporates them into its membrane has been isolated[21]. In yeast, the pattern of the mitochondrial lipids depends on the partial pressure of oxygen during growth[22]. The plasma membrane of *Mycoplasma laidlawii* is rich in lipids[23]; its composition is determined by the nature of the culture medium. Extreme membrane compositions have been found for halophilic bacteria[24].

2. Properties of Biological Membranes

It has been assumed since the turn of the century that a submicroscopic lipid layer surrounds the cell and separates the cytoplasm from the extracellular space. This assumption is based in part on the work of *Overton*[25] on the ability of lipophilic and hydrophilic substances to penetrate into the cell. The dependence of the rate of penetration of a substance on its lipid solubility was later confirmed by the classic experiments carried out by *Collander*[26] on the cells of *Chara* plants. Determinations of the erythrocyte surface area and the area that was required by the lipids extracted from the membrane showed that the area occupied by the lipids was twice as large as the erythrocyte surface area. *Gorter* and *Grendel*[27] concluded from their results that the erythrocyte surface is formed by a bimolecular lipid layer.

The views on the molecular arrangement of the lipids within biological membranes were derived from what is

[*] Priv.-Doz. Dr. W. Gross
Institut für vegetative Physiologie der Universität
6 Frankfurt (Main), Ludwig-Rehn-Strasse 14 (Germany)

known about the behavior of such substances at interfaces. During the 1930's, *Danielli* and *Davson*[28] described a membrane model in which the membrane is assumed to consist of lipids and proteins. Their model was modified more than two decades later by *Robertson*[29] on the basis of electron-microscopic observations (concept of the "unit membrane").

The surface tensions found for cells in aqueous media are small (around 1 erg/cm^2). The surface tension of a droplet of fat is 70 times as great. Absorption of proteins on such droplets of fat causes a considerable decrease in the surface tension, so that it seems reasonable to assume that proteins are present on the cell surface. Though this is correct, such a conclusion does not necessarily follow. A bimolecular lipid layer should behave differently from a droplet of fat, since compensation of the opposing tensions occurs in a bimolecular layer, and the difference may be very small[30]. Since the surface tension is not constant, but depends on the pressure, elastic properties can be ascribed to the cell surface. This elasticity points to the presence of proteins, since a pure lipid layer would not be elastic[31].

Strong arguments in favor of the existence of a substantially continuous lipid layer are provided by investigations on the electrical properties. Biological membranes have a high electrical resistance. For plasma membranes, the value varies between 10^3 and 10^5 ohm·cm^2. After damage to the membrane or during stimulation, the conductivity is increased by a few orders of magnitude[32], since the ion permeability in the affected regions of the membrane is changed. (For conflicting interpretations of the electrical phenomena, see [33].) Synthetic membranes have an even higher electrical resistance, which can be reduced by two to four orders of magnitude by substances such as the "excitability inducing material" (EIM)[*], the cyclodepsipeptides, and the polyene antibiotics. Thus EIM causes a decrease in resistance from 10^8 to 10^4 ohm·cm^2[34]. The electrical capacity of the cells is about 0.5 to 1.0 μF/cm^2.

Plant cells and microorganisms are additionally surrounded on the outside by a cell wall, whose chemical composition is different from that of the cell membrane[8]. A clear separation of the cell wall and the cell membrane is possible in gram-positive bacteria. If the cell wall of *B. megaterium* is dissolved in an isotonic sucrose solution by lysozyme, spherical protoplasts are formed[35]. When the osmolarity is reduced, the protoplasts burst, and the remaining membranes can be isolated. It has been shown conclusively by permeability investigations on such protoplasts that the membrane, and not the wall, forms the osmotic barrier between the intracellular and the extracellular spaces. It was shown in the case of isolated plasma membranes of *E. coli* that such membrane preparations are biologically intact. These membranes, which are closed to form vesicles, can accumulate certain amino acids in the interior of the vesicles[36]. After the removal of the cell contents had been achieved in a number of cases, several functions could be definitely assigned to the plasma membrane. In the case of erythrocytes, it was possible to remove the cell contents by reverted hemolysis[37]. The cell contents were squeezed out of giant nerve fibers and replaced by solutions of known composition. The action potential was recognized in this way as a membrane function[38].

[*] EIM is probably a protein.

3. The Ultrastructure of Biological Membranes

Since the 1950's, increasing use has been made of the electron microscope in the investigation of biological membranes[29, 39–45]. The plasma membrane of an erythrocyte is 80—100 Å thick. Imaging in the electron microscope after fixation with osmium tetroxide or potassium permanganate shows a trilaminar structure (Fig. 1), *i.e.* two outer dark lines, in which the fixing medium has deposited,

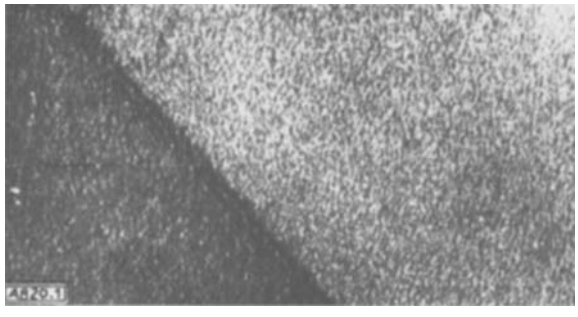

Fig. 1. Surface of a human erythrocyte. Electron micrograph after fixation with permanganate (from [29], p. 3). The trilaminar structure of the plasma membrane is clearly visible. Magnification: 280000 ×.

separated by a central light zone. This sandwich structure has been found for several membranes, and this was therefore postulated to be a general structural principle. This concept of the "unit membrane" is a further development of the Danielli-Davson model (the differences between the two models will be discussed in Section 7).

A favored object for investigation was the myelin sheath of the nerve fibers, though myelin probably occupies a special position in its chemical composition. The birefringence of the myelin sheath was discovered as early as the 1930's, and it was assumed to consist of alternating lipid and protein layers[46, 47]. It is now known that the myelin sheath develops from the plasma membrane of the Schwann cell (Fig. 2), the mesaxon being wound up in a

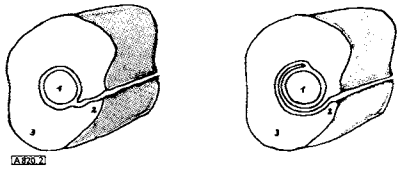

Fig. 2. Development of the myelin sheath (highly schematized). The myelin sheath develops from the plasma membrane (gray) of the Schwann cell. 1 = axon; 2 = mesaxon; 3 = Schwann cell. Left: initial stage of development; right: intermediate stage.

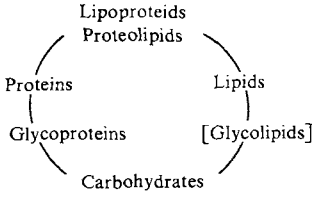
spiral and the individual layers then coalescing. It was found from the thickness of the repeating units that there is probably no other material enclosed between the lamellas. X-ray diffraction studies have confirmed these assumptions concerning the myelin structure.



More recent findings have cast doubt on the postulate of a general structural principle of biological membranes.

Sjöstrand[48] showed with the aid of high-resolution electron micrographs that several membranes, including those of the endoplasmic reticulum, exhibit a granular ultrastructure. Further conclusions follow from the picture of the inner mitochondrial membrane[2]. Liver cell membranes exhibit a globular structure after treatment with ethylenediaminetetraacetic acid. Plan views show a characteristic hexagonal pattern, which suggests that they are built up from subunits[49].

Despite the ease with which biological membranes can be imaged, conclusions concerning the actual structure on the basis of electron micrographs are associated with some uncertainty; this situation has frequently been discussed in detail. Little is known about the reactions of the fixing medium with the membrane components. It would be premature to take it as certain that OsO_4 reacts only with proteins or that the original protein conformation could not be altered[50]. The fixation does not necessarily "freeze in" the morphological situation. Crosslinks produced by the fixing agent between proteins could change the position of the latter within the membrane. Removal of water can also lead to changes in state or influence the interactions between the membrane components. Considerable differences were discovered on measurement of the thicknesses of various membranes. However, the determinations were complicated by the fact that the membranes cannot always be clearly delimited and that the results depend on the fixing method. New paths are now being followed with the freeze-etching technique. The electron-microscopic investigations have contributed considerably to present-day views on membrane architecture. However, the question of the importance to be placed on individual items of evidence must go unanswered for the present.

4. Membrane Components

In order to determine the chemical composition, it is necessary to obtain pure membranes. Isolation is facilitated by the use of labeling enzymes (see Section 4.1.2). The components of biological membranes are proteins, lipids, water, ribonucleic acids, and covalently bound carbohydrates. Scheme 1 illustrates the relations between the combined components.

Scheme 1. Position of the combined membrane components. Lipoproteins and proteolipids differ in their solubility. The glycolipids belong to the group of lipids.

4.1. Proteins

Classification of the membrane proteins is difficult. Despite fluid transitions, three groups can be distinguished; these are transport proteins, enzymes, and structural proteins.

4.1.1. Transport Proteins

These are mostly proteins that bind substances having low molecular weights in a specific manner. In some cases they have been broken down into several binding components. If gram-negative bacteria are transferred from a sugar solution of high osmolarity into a salt solution of low osmolarity, about 5% of the membrane proteins pass into solution[51]. Some of these solubilized proteins exhibit enzymatic activity, while others have characteristic binding specificities without catalytic function *in vitro*. Some of these "dumb" proteins are probably involved in transport processes[52–54]. These proteins, which have recently been very intensively studied, are listed in Table 1. Their molecular weights are around 30000.

Table 1. Membrane proteins that are probably involved in transport processes. The proteins were isolated almost exclusively from microorganisms.

Membrane protein	Molecular weight	Ref.
Sugar transport:		
M-protein (galactosides)	31000	[20]
Heat-stable protein	9400	[55]
β-Galactoside permease	—	[56]
Galactose-binding protein	—	[57]
Galactose-binding protein	35000	[58]
Galactose carrier	—	[59]
Glucose-6-phosphate-binding protein	—	[60]
Glucose-binding protein	—	[61]
L-Arabinose-binding protein	32000	[62]
L-Arabinose-binding protein	35000	[63]
Amino acid transport:		
Leucine-binding protein	34000	[64]
Leucine-binding protein	36000	[58]
Leucine-binding protein	37000	[65]
Arginine-binding protein	—	[66]
Tryptophan-binding protein	>200000	[67]
Histidine-binding protein	—	[68]
Phenylalanine-binding protein	—	[69]
Ion transport:		
Sulfate-binding protein	32000	[70]
Calcium-binding protein	25000–28000	[71]
Phosphate-binding protein	—	[72]

4.1.2. Enzymes

Many enzymes are components of membranes or are associated with them. They are either located exclusively in the membrane (marker enzymes) or they are at least more highly concentrated in the membrane than in the adjoining parts of the cell.

Contamination of the membranes cannot be ruled out in every case. Some of the enzymes have been isolated only with difficulty. Even lipid extractions led to a loss of activity, but this could be partly reversed by addition of phospholipids. Cytochrome oxidase, succinate dehydrogenase, and β-hydroxybutyrate dehydrogenase can be reactivated in this way.

Benedetti and *Emmelot*[49] investigated liver cell membranes and found 24 enzymes, including a Na^+-K^+-stimulable adenosine triphosphatase, a *p*-nitrophenyl phosphatase, and a phosphodiesterase. Enzymes were also located histochemically in some cases[73].

4.1.3. Structural Proteins

A protein obtained from the membrane of erythrocytes has been described in detail as a structural protein[74]. This protein could be resolved into fractions by electrophoresis

at pH 9. *Criddle et al.*[75] have prepared a structural protein from bovine heart mitochondria that is insoluble in water and accounts for about 40% of the total protein. Though several arguments indicate that it is homogeneous, this has not yet been proved. This structural protein forms complexes with other mitochondrial proteins. *Woodward* and *Munkres*[76] characterized a mitochondrial structural protein from *Neurospora*. The mitochondrial structural proteins are probably essential to the full activity of the respiratory chain. Structural proteins have also been detected in other membranes, and their apparently universal occurrence suggests a general function.

4.2. Lipids

Several synopses of the lipid composition of membranes and cell organelles have been published (*e.g.*[77]). The ratio of the quantity of lipids to the quantity of proteins varies considerably from one membrane to another. Thus the lipid content of myelin[*] is about 70%, that of the mitochondria[*] is only about 30%, and that of the endoplasmic reticulum is about 50%. The lipid composition also differs[78]. In the membranes of the mitochondria and microsomes, phosphatidylcholine and phosphatidylaminoethanol account for about 80% of the total lipids, whereas their content in myelin is only 25%. Cardiolipin has been detected only in mitochondrial membranes. However, the cholesterol content of myelin is much higher than that of the membranes of mitochondria and microsomes. In the case of liver mitochondria and microsomes, it corresponds to *ca.* 5% of the total lipids[78]. Bacterial membranes contain little or no cholesterol. Cholesterol can be incorporated into the cell membrane of *Mycoplasma laidlawii* if it is provided in the culture medium. Data on the lysophosphatide content of the membranes should be regarded with caution, since the results may be influenced by autolysis.

Table 2. Lipid and fatty acid composition of an "average erythrocyte" (mammal).

Compound	Amount	
Lipids:		
Cholesterol	27%	
Phospholipids	60%	
Phosphatidylcholine		31%
Phosphatidylaminoethanol		27%
Phosphatidylserine		12%
Phosphatidylinositol		3%
Phosphatidic acid		2%
Sphingomyelin		25%
Gangliosides	6.5%	
Other glycolipids (sulfatides, cerebrosides)	6.5%	
Fatty acids:		
Palmitic acid	30%	
Stearic acid	16%	
Oleic acid	17%	
Linoleic acid	10.5%	
Arachidonic acid	10%	
Other fatty acids	16.5%	

The lipid composition of erythrocytes depends on the species[79]. It is illustrated in Table 2 for an "average erythrocyte". The most abundant lipid is cholesterol, and this is followed by the group of phospholipids. The phosphatidylcholine content of erythrocytes varies considerably from species to species. It is scarcely detectable in sheep erythrocytes, while its value in pig erythrocytes is 25% and in rat erythrocytes 50%. Glycolipids seem to occur exclusively in plasma membranes. Even within the classes of lipids, the fatty acid composition varies, and the fatty acid pattern of biological membranes fluctuates over a wide range. It also depends on the temperature and the diet[80]. In human erythrocytes, five fatty acids make up more than $^3/_4$ of the total fatty acid content.

Interesting recent observations indicate that lipids are involved in syntheses. Thus a lipid fulfils a catalytic function in the biosynthesis of the peptidoglycan of the bacterial cell wall[81].

4.3. Water

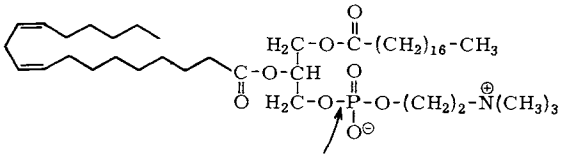
Little attention has been paid so far to water as a membrane component, and the literature data are scanty. Water, which constitutes about 30—50% of the membrane volume, is essential for a number of membrane functions, such as ion permeability and associated electrical phenomena[82,83]. Since little is known about the role of water either in synthetic or in biological membranes, it has been disregarded in most membrane models. However, it must have an influence on other membrane components.

4.4. Ribonucleic Acids

RNA has been detected in several bacterial membranes. The maximum RNA content in liver cell membranes is around 10 μg/mg of protein[49]. RNA has also been found in other animal membrane fractions, though adsorption of RNA on the membranes during preparation cannot be entirely ruled out.

4.5. Carbohydrates

The carbohydrates present in the membrane are bound either to lipids (glycolipids) or to proteins (glycoproteins). The glycoproteins are localized mainly in the outer layer of the plasma membrane.



5. Interactions between the Membrane Components

The fact that membranes can be isolated shows that they are stable structures, and do not collapse like a lipid film when removed from their natural environment. Investigations with organic solvents and with mild detergents indicate that covalent bonds between lipids and proteins are of no importance. On the contrary, stabilization appears to be due to ionic bonds, hydrogen bonds, London-van der Waals forces, and hydrophobic bonds.

Phosphatidylcholine (α-lecithin) may be taken as an example of the structure of membrane lipids. Phosphatidylcholines from liver mitochondria and from the endoplasmic reticulum have approximately the same fatty acid composition[80]. Close packing of the molecules within the

[*] The inner and outer mitochondrial membranes differ in their composition. The composition of myelin depends on the state of maturity.

membrane is possible in the physiological pH range. In erythrocyte membranes, the removal of the polar groups of the phospholipids by phospholipase C (the arrow points to the cleavage site) does not lead to breakdown of the membrane structure, so that ionic bonds between proteins and lipids cannot be entirely responsible for stabilizing the structure[84].

According to the "unit membrane" concept, the proteins should be spread on a central bimolecular lipid film. The β-conformation of the membrane proteins should allow closer contact, and hence stronger interactions, between protein and lipid. However, the absence of the IR band at 1630 cm^{-1} indicates the absence of proteins with the pleated sheet structure. Optical rotatory dispersion and circular dichroism studies indicate, on the contrary, that the membrane proteins probably have a globular structure and a high content of α-helix[16,85–88].

The hydrophobic character of many membrane proteins is shown by their poor water-solubility and their solubility in organic solvents. Since these membrane proteins do not differ in any obvious respect from water-soluble proteins in their amino acid compositions, their lipophilic nature can hardly be due to the primary structure, but must result from higher structures such as the α-helix[89]. NMR studies on erythrocyte membranes have shown that the signals of the methylene protons of the hydrocarbon chains in the membranes are strongly influenced by proteins[90,91], probably as a result of hydrophobic bonds between the two components. In the case of phosphatidylcholine, the signals of the paraffin chains disappear from the NMR spectrum on addition of cholesterol. The mobility of the chains appears to be restricted[92]. Differential calorimetric studies on mixtures of phosphatidylcholine and cholesterol have further confirmed this assumption[19].

6. Myelin Figures (Liposomes)

When hygroscopic phospholipids such as phosphatidylcholine come into contact with water, tubular or spherical bodies known as myelin figures (and special forms as liposomes) are spontaneously produced. The physicochemical properties of the phospholipids have been discussed in detail by a number of authors[93,94]. The formation of myelin figures depends on the method, the species of phospholipid, and the temperature. The paraffin chains melt above a critical temperature, and this results in the coexistence of crystalline order of the polar groups and a more disordered liquid phase of the paraffin chains (mesophase). The lipids are in a liquid-crystalline state. The critical temperature is low in the case of phospholipids with short-chain unsaturated fatty acids. Myelin figures are therefore formed at room temperature only by phospholipids that pass into a liquid-crystalline phase at low temperatures. Phospholipids with long-chain saturated hydrocarbons cannot form myelin figures at 25 °C; this becomes possible only when the temperature is raised.

The myelin figures can be recognized under the optical microscope as coiled or layered structures. They are birefringent. Electron-microscopic investigations have shown that they consist of a series of bimolecular lipid layers, which show no tendency to coalesce (Fig. 3). Water is intercalated between the lipid lamellas, and the thickness of the lamellas varies between 80 and 120 Å, depending on the water content. In some cases, very homogeneous structures with a molecular weight of a few million appear,

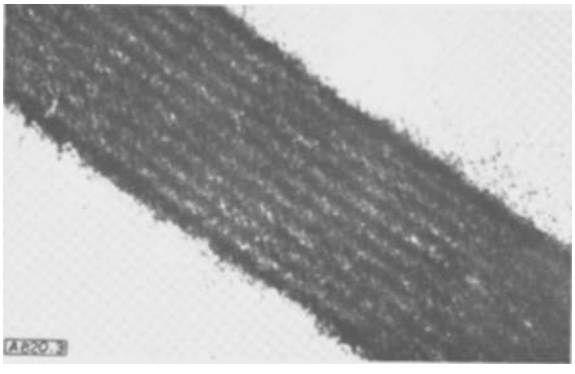


Fig. 3. Electron micrograph of myelin figures from phospholipids after fixation with osmium tetroxide (taken from [95]). Magnification: 825000 ×.

while in others the figures are heterogeneous and the diameters of the cylinders differ. A relatively stable phospholipid dispersion in which the liposomes are roughly equal in size can be obtained by ultrasonic treatment.

Their structure and behavior make liposomes suitable for use as models of biological membranes; several research groups[96–100] have carried out extensive studies on these particles. Since the liposomes enclose water during their formation, they can be used for permeability studies. Efflux experiments with anions and cations have shown that sufficiently small liposomes have no pores; anions and cations permeate at different rates. Observations made on synthetic membranes of identical or similar chemical composition have added to the picture of the permeability properties[101,102].

After fixation with OsO_4, myelin figures exhibit a trilaminar structure similar to that of biological membranes. This trilaminar structure is even more pronounced after addition of proteins to the lipid lamellas. It is often assumed that the hydrophilic groups of the phospholipids are oriented outward in the bimolecular film, while the hydrocarbon chains of both layers of molecules are turned inwards, but it is possible that the orientation of the molecules is exactly the opposite. This question cannot be answered by an electron micrograph alone.

7. Membrane Models

In 1935, *Danielli* and *Davson*[28] proposed a membrane model based mainly on the results of functional and physicochemical studies on plasma membranes. This model is

shown in Fig. 4a. A central lipid layer is separated on both sides from the water-filled compartments, the intracellular space and the surrounding medium, by protein layers. These views of *Danielli* and *Davson* determined the picture of the ultrastructure of biological membranes for a number of years.

This model was modified in three points by *Robertson*[44, 45], mainly on the basis of electron-microscopic evidence. The number of lipid layers was limited to two; instead of being globular, the proteins were assumed to be spread on the lipid layer, and the membrane was assumed to have an asymmetric structure. *Robertson* also suggested that this concept was generally valid ("unit membrane"). These views are illustrated schematically in Fig. 4b. In the center

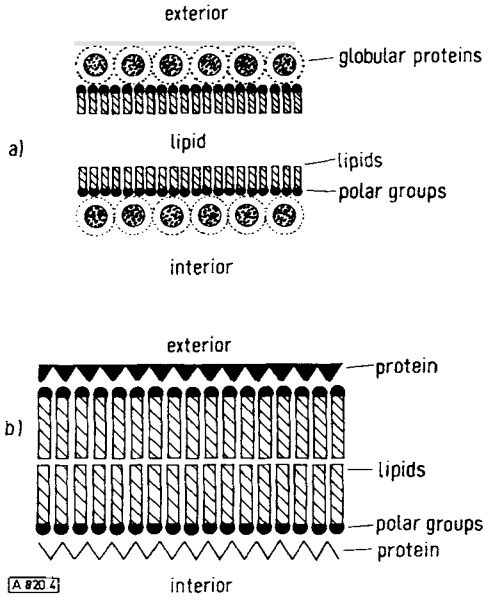

Fig. 4. Membrane models (after [29]).
(a) Danielli-Davson membrane model;
(b) *Robertson*'s membrane model ("unit membrane"). The proteins are in the β-conformation and are different from one another.

is the lipid film, about 50 Å thick, which consists of two layers of molecules. The hydrophobic parts of the molecules are turned toward the inside of the membrane, while the hydrophilic groups are directed outward, and form bonds with the spread proteins.

According to recent investigations, however, the β-conformation of the proteins no longer appears to be tenable. It was also difficult to reconcile several observations with *Robertson*'s concept. Thus, thickness determinations on various membranes showed considerable differences. The typical trilaminar picture could be obtained even for mitochondrial membranes whose lipids had been removed by extraction. The membranes do not collapse despite the extraction of the lipids. It appeared that the rapid restoration of the membrane after lesions could be readily explained by the incorporation of preformed structural elements as subunits. Electron-microscopic plan views of biological membranes often show structuring that suggests that they are built up from subunits.

Results that initially seemed convincing were thus collected. However, a number of arguments have not been able fully to stand up to critical reexamination. The extractions of lipids from the mitochondrial membranes were incomplete. Protein bridges could penetrate the lipid layer and connect the two protein layers, with the result that the collapse of the membrane is prevented. The structure made up from subunits as seen in the electron micrograph could be confined to the protein layer, or it could be an artefact. The "unit

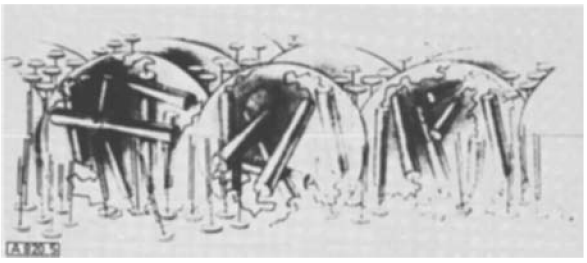

Fig. 5. Membrane model proposed by *Sjöstrand* (p. 10 of [48]) to explain electron-microscopic findings for cytoplasmic membranes. Construction of the membrane from globular proteins, between which the lipids are interposed.

membrane" model has recently been opposed by "subunit" models, according to which the membrane structure can be described as a two-dimensional aggregate of lipoprotein subunits[48, 88, 89, 103, 104]. To illustrate this type of approach, *Sjöstrand*'s membrane model[48] is shown in Fig. 5.

The answers to the questions which of the models is preferable and what modifications are necessary will have to await the outcome of further investigations.

8. Functions of Biological Membranes

8.1. Membranes as Barriers and Pumps

Membranes on the one hand are permeability barriers between two spaces, and on the other they must allow the passage of substances between these spaces in both directions. Thus the plasma membrane must not be equally permeable to all substances, but must be able to select among the substances offered to it for passage. The passage of some substances through the membrane is hindered, while that of others is facilitated. According to the "unit membrane" concept, the osmotic barrier for hydrophilic substances is the quasi-liquid lipid phase in the interior of the membrane. The greater ease of penetration of lipophilic substances has already been mentioned.

In the use of Fick's law to describe the *diffusion* of particles through biological membranes, difficulty is encountered in the determination of the diffusion constant[*]. This led to the use of another parameter, the diffusion coefficient, to describe the diffusion. Some substances passed through the membrane much more rapidly than one would expect in the case of diffusion. In these cases, the rate of entry of a substance tends toward a maximum with increasing concentration *(facilitated diffusion, active transport)*[112]. Since the investigations by *Osterhout*[105], it is usually assumed that mobile carriers within the membrane are responsible for translocations of this nature. The essential features of

[*] The diffusion distance and the concentration profile are not accurately known for biological membranes.

the transport are structure specificity, ability to be inhibited and activated, and saturation behavior[30, 106-111].

Absorption and secretion in metazoa are the responsibility of highly specialized cells such as those of the intestinal or renal epithelia. High molecular weight compounds or particles can pass through the membrane by pinocytosis or phagocytosis.

8.2. Conduction of Stimuli

Biological membranes can be stimulated by electrical, mechanical, chemical, and thermal stimuli. The stimulation is associated with electrical phenomena that occur as a result of the movement of ions (K^+, Na^+, and Cl^-) through the membrane. This involves localized changes in the permeability of the membrane. K^+, Na^+, and Cl^- are unevenly distributed in the intracellular and extracellular spaces. This uneven distribution is probably due to the difference in the concentrations of macromolecular polyelectrolytes on the two sides of the membrane (Donnan distribution) and essentially to the ion pumps. Membrane-bound adenosine triphosphatases that can be stimulated by Na^+ and K^+ are evidently involved in the active transport of ions[113].

The potentials that arise on porous membranes as a result of the different penetration rates of the ions can be described by the Nernst equation or, if the salt concentration on both sides of the membrane is the same, by Planck's formula. *Hodgkin* and *Katz*[114] have published a formula for the determination of the resting potential of biological membranes in which the permeability coefficients of $K^+ : Na^+ : Cl^-$ are assumed to be related as 1 : 0.04 : 0.45. At the instant of stimulation, a radical change occurs in the permeability of the membrane, and the ratio of the permeability constants can now be expressed as 1 : 20 : 0.45. The action potential can thus be attributed to an extreme increase in the sodium permeability.

8.3. Membranes as Receptors

The membranes are the sites of action of many hormones that influence the permeability or act on the membrane enzymes. The membrane enzymes then liberate a transmitter substance (second messenger), which intervenes in the metabolism. The surface structures of the cells play a decisive role in immunochemistry. The contact inhibition of growing cells must also be initiated by the cell membrane. This contact inhibition is lacking in tumor cells[115].

8.4. Membranes as Enzyme Supports

Reference has already been made to the large number of membrane-bound enzymes. Thus the components of the respiratory chain are bound to the mitochondrial membrane, and a high degree of order is achieved in the sequence in this way. Protein synthesis in animal cells takes place on the membranes of the endoplasmic reticulum, and on the plasma membrane in bacteria. The division of the cell into reaction spaces (compartments) by membranes ensures that many metabolic sequences can proceed undisturbed.

8.5. Membranes as Protection

The plasma membrane protects the cell when its environmental conditions change. By exclusion or neutralization of certain substances, interference with intracellular biochemical reactions is avoided. Enzymes that are dangerous to the cells are enclosed by membranes (in *e.g.* lysosomes) and withheld from their substrates in this way. Many additions could be made to the list, but the functional versatility of membranous structures is clear from the points mentioned.

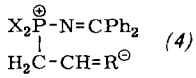
A Novel Type of 1,3-Dipolar Cycloaddition: 1,2-Aza-P^{V}-phosphol-1-ines from Methyleneaminophosphanes[1]

By *Alfred Schmidpeter* and *Werner Zeiss*[*]

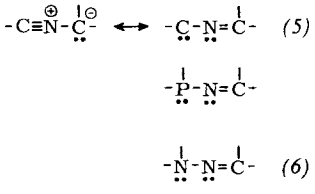
Dedicated to Professor Egon Wiberg on the occasion of his 70th birthday



The recently synthesized methyleneaminophosphanes *(1)*[2] react with electrophilic olefins *(2)* such as acrylonitrile and methyl acrylate to give stable 1:1 adducts. The products are crystalline and, unlike the readily soluble yellow starting compounds *(1)*, are colorless and relatively sparingly soluble. It follows from the characteristic J_{PCH} and J_{PCCH} values of the ^{1}H-NMR spectra that the olefin *(2)* is bound *via* its methylene group to the phosphorus of *(1)*, and from the non-equivalence of the two methylene protons that the formerly olefinic bond does not rotate in the adduct; furthermore, the X residues bound to the phosphorus are also non-equivalent. Thus, the spectra confirm a cyclic structure *(3)*.

(1) + *(2)* → *(3)*

The 1,2-aza-P^{V}-phosphol-1-ines *(3)* are the first cyclic phosphazenes having less than six members in the ring; the five-membered ring phosphazenes prepared previously do not exist as such, but as tricyclic dimers[3,4].



The possibility of these compounds being open-chain betaines *(4)* can be ruled out. Only doubly activated olefins such as dicyanoethylene, but not the olefins used here, yield stable betaines on reaction with triaryl- or trialkylphosphanes. Moreover, for a betaine structure *(4)* to be plausible the two X-residues and the two methylene protons of the central X_2PCH_2 group respectively would have to be equivalent.

(4)

However, *(4)* must be considered as a possible intermediate in the cycloaddition.

The reaction under discussion is a 1,3-dipolar cycloaddition and, as a consequence, compounds *(1)* represent a novel type of 1,3-dipoles with dominating nucleophilic character. The dichloromethyleneaminophosphane *(1)*, X = Cl, does not react with the dipolarophiles used here. As 1,3-dipoles, the methyleneaminophosphanes are unique in that the "uncharged" and "all-octet" canonical forms coincide. In some ways they are to be compared with the nitrile ylides *(5)*; as in many other cases X_2P— can to a certain extent replace XC—.

(5)

(6)

Equalization between nucleophilic and electrophilic ends of the dipoles in the cycloaddition of methyleneamino-

Table. NMR data of azaphospholines *(3)*. The chemical shifts are referred to H_3PO_4 (external) and TMS (internal) and are quoted negatively towards low field.

Cis and *trans* indicate the position with respect to the proton on C–4. Assignment of the signals of the two methyl protons was based on the assumption that $J_{HCCH\,cis} > J_{HCCH\,trans}$ [5]. Only the two intense transitions of the AB spectrum were found in the two cases of particularly small shift differences between *cis* and *trans* methylene protons; the quoted δ-values are calculated on the assumption that $J_{HCH} = 15 \pm 1$ Hz. Assignment of signals for the X-methyl protons was not possible; corresponding δ- and *J*-values are correlated in the table.

8 München 2, Meiserstrasse 1 (Germany)

phosphanes is rendered possible by the formation of a phosphazene-(pd) π bond. It certainly remains weaker than *via* a (pp)π bond. This possibility, and consequently also the dipolar activity are completely lacking in the case of the homologous hydrazones *(6)*, unless the betaine charges being formed can be eliminated by a secondary reaction.

Acetylenedicarboxylates also react as dipolarophiles with methyleneaminophosphanes to give 5*H*-1,2-aza-P^{v}-pho^{v}-pholes:

$$(CH_3)_2P\text{-}N{=}CPh_2 + CH_3O_2C\text{-}C{\equiv}C\text{-}CO_2CH_3 \rightarrow$$

(7)

Compound *(7)* is symmetrical in regards to the plane of the ring and consequently gives a simple ^{1}H-NMR spectrum: a doublet for the equivalent P methyl groups (δ^1H -1.74×10^{-6}; $J_{PCH}=13.9$ Hz) and two singlets for the ester methyl protons (δ^1H -3.80 and -3.54×10^{-6}).

Experimental:

A solution of the dimethyl- or diphenyldiphenylmethyleneaminophosphane *(1)*, X = CH_3, C_6H_5, in ether or methylene chloride is stirred for about 20h at room temperature with an equimolar amount of the dipolarophile.

Dimethoxydiphenylmethyleneaminophosphane *(1)*, X = OCH_3, is heated together with the dipolarophile in the absence of solvent at 50 °C for a short time or in acetonitrile under reflux for 2h. The product crystallizes either spontaneously or on addition of ether and is analytically pure after washing with ether.

1,3,5-Triaza-phosphorines and -diphosphorines from 1,3,5-Triazine[1]

By *Alfred Schmidpeter* and *Caspar Weingand*[*]

Dedicated to Professor Egon Wiberg on the occasion of his 70th birthday

Ammonolysis of trichlorobis(dialkylamino)phosphoranes *(1)* affords the hydrochlorides of aminophosphazenes *(2)* and aminodiphosphazenes *(3)*, from which the free bases can be liberated[2]. Mild ammonolysis does not lead to (complete) condensation to cyclooligophosphazenes $[(R_2N)_2PN]_n$. However, compounds *(2)* and *(3)* can be considered as open-chain elements of the cyclophosphazene structure that have been terminated by added NH_3. In this sense together with another suitable structural unit they permit the condensation to be completed by elimination of ammonia with formation of heterocycles. Thus warming *(2)* or *(3)* with a stoichiometric amount of *s*-triazine yields 2,2-bis(dialkylamino)-1,3,5,2-triazaphosphorines *(5)* or 2,2,4,4-tetrakis(dialkylamino)-1,3,5,2,4-triazadiphosphorines *(6)*, respectively.

(9)

These products form a bridge between *s*-triazine *(4)* and the cyclotriphosphazenes *(9)*, and both contain two types of nitrogen ring members that are differentiated by being flanked by either one or two carbon or phosphorus atoms. Treating *(5)* or *(6)* with methyl iodide methylates exclusively a ring nitrogen atom—not the exocyclic nitrogen. Even with this limitation two methylated products are possible, but there is selective formation of 5-methyl-1,3,5,2-triazaphosphorinium iodide *(7)* (in which the symmetry of the starting material is preserved) and 1-methyl-1,3,5,2,4-triazadiphosphorinium iodide *(8)* (in which the symmetry is destroyed) (cf. Table 1). Thus the nitrogen atom with the fewer phosphorus neighbors is always the more nucleophilic[3]:

$$\text{-}\overset{|}{P}{=}N\text{-}\overset{|}{P}{=} < \text{-}\overset{|}{P}{=}N\text{-}\overset{|}{C}{=} < \text{-}\overset{|}{C}{=}N\text{-}\overset{|}{C}{=}$$

This is in accord with the results obtained on protonation and alkylation of other triazadiphosphorines[4], but it was not be expected from comparison of the basicities of the ring nitrogen atoms of the end members of the series: *s*-triazines are very weak bases[5], whereas pK values of 7.5 to 8.5 were found for compounds *(9)*[6].

The chemical shifts for the C and P ring members of *(5)* and *(6)* are remarkably close to, although always at

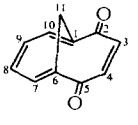
		p	−18.3				49.2		−2.73 (3)	11.2				

[a] Work performed together with *Klaus Schumann*.
[b] *o* and *p* denote *ortho*- and *para*-position, respectively, to the methylated nitrogen atom.

somewhat lower field[7] than, those of the symmetric compounds *(4)*, $\delta^{13}C = -39.0 \times 10^{-6}$[8] and *(9)*, R = CH_3, $\delta^{31}P = -25 \times 10^{-6}$[9]. On the other hand, the chemical shifts of the ring methine protons of *(5)* and *(6)* have moved to higher field by 1.3 and 1.4 ppm, respectively, in comparison with that of *(4)* $\delta^1H = -9.25 \times 10^{-6}$[10]. This can be interpreted as a considerable weakening of the magnetic anisotropy of the triazine ring caused by inclusion of $P(NR_2)_2$ as a ring member in place of CH; inclusion of a second $P(NR_2)_2$ ring member makes, however, little difference to this. In comparison, benzene protons are shifted by *ca.* −1.6 ppm by the anisotropy of the ring. A large endocyclic PNCH coupling[11] is characteristic for all the compounds described here; the value for *(8)* is the largest $^3J_{PH}$ value ever reported.

2,2-Bis(dialkylamino)-1,3,5,2-triazaphosphorines and 2,2,4,4-tetrakis(dialkylamino)-1,3,5,2,4-triazadiphosphorines



A benzene solution of an aminophosphazene *(2)* or aminodiphosphazene *(3)* is treated with two-thirds or one-third, respectively, of the equimolar amount of *s*-triazine. When the mixture is heated to the boiling point ammonia is evolved and the triazine dissolves. After 3–4 h the benzene is distilled off and the residue is then distilled at 1 torr and a bath-temperature of 120 °C (R = CH_3 or C_2H_5) or is chromatographed (R = *n*-C_4H_9) in CH_2Cl_2 on Al_2O_3. The products are colorless liquids and analytically pure and are obtained in yields of 70–90%.

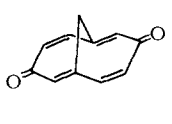
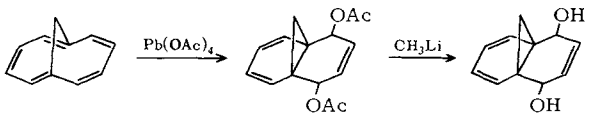
Dicarbonyl Derivatives of 1,6-Bridged [10]Annulenes

By *Emanuel Vogel, Elmar Lohmar, Walter A. Böll, Bernd Söhngen, Klaus Müllen, and Harald Günther*[*]

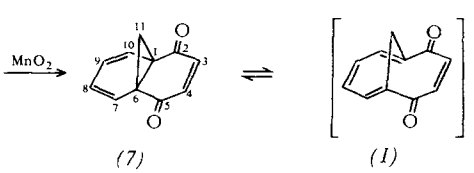


For a systematic comparison of bridged [10]annulenes[1] with the classical aromatic compounds benzene and naphthalene it would be of considerable interest to clarify the problem of whether dicarbonyl derivatives of 1,6-methano[10]annulene *(4)* are to be regarded as "quinones". It can easily be seen that the same number and same types of "quinones" can be derived from *(4)* as from naphthalene. Bicyclo[4.4.1]undeca-3,6,8,10-tetraene-2,5-dione *(1)*, bicyclo[4.4.1]undeca-3,5,8,10-tetraene-2,7-dione *(2)*[2], and bicyclo[4.4.1]undeca-1,4,6,9-tetraene-3,8-dione *(3)* may be named as representative members. We here report attempted synthesis of the compound *(1)*.

(1)



(2)



(3)

On treatment with lead tetraacetate in glacial acetic acid at 60–80 °C, 1,6-methano[10]annulene *(4)* affords the *cis*-1,4-diacetate *(5)*, m.p. 145–147 °C, in 30% yield with high stereoselectivity. The presence of the norcaradiene structural moiety in *(5)* and the *cis*-configuration of the acetate groups follow compellingly from the ^1H-NMR spectrum [(in $[D_6]$benzene) AA'BB' system, centered at $\tau = 3.9$ (4H); singlets at 4.38 (2H), 4.61 (2H), and 8.27 (6H); AB system at 7.48 and 9.82 with $J = 6.2$ Hz (2H); $J(^{13}C—H)$

of the proton at highest field: 159 Hz]. The configuration of the acetate groups in relation to the cyclopropane ring still remains to be clarified. When the diacetate was treated with ethereal methyllithium at −50 °C, a diol of m.p. 151–152 °C (yield 74%) was formed which, according to the NMR spectrum has structure *(6)*. The diol *(6)* can be converted by manganese dioxide in benzene almost quantitatively into a yellow dicarbonyl compound, m.p. 107–108 °C, which is stable in absence of light and oxygen and to which the norcaradiene structure *(7)* must be assigned unambiguously on the basis of spectral findings.

The NMR spectrum of the dicarbonyl compound (in [D_6]acetone) shows an AA'BB' system (H^7—H^{10}) centered at $\tau = 3.52$, a singlet at 3.49 (H^3, H^4), and an AB system at 7.41 (*anti*-H^{11})[3] and 9.22 (*syn*-H^{11}) with $J = 4.1$ Hz. The coupling constants of the olefinic protons H^7—H^{10}[4] (see Table 1), on the one hand, and the geminal coupling of the CH_2 protons on the other provide a decisive argument in favor of structure *(7)*. The electron spectrum [(in methanol), $\lambda_{max} = 226$ ($\varepsilon = 15400$), 271 (2240), 324 (248), 405 nm (186)] also supports the structure *(7)*; the IR spectrum, with a broad carbonyl band at 1665 cm^{-1} (in KBr) is not very revealing.

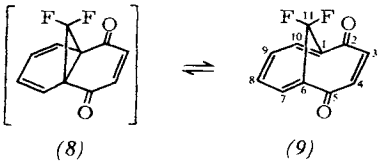

Table 1. Chemical shifts (τ values in ppm) and H,H coupling constants (Hz) of the olefinic protons in *(7)* and *(9)*.

	H^7, H^{10}	H^8, H^9	H^3, H^4	$J_{7,8} = J_{9,10}$	$J_{8,9}$	$J_{7,9} = J_{8,10}$	$J_{7,10}$
(7)	3.25 [a]	3.88 [a]	3.49	9.75	6.03	0.83	1.21
(9)	2.82	2.44	3.38	6.74	10.59	0.12	1.34

[a] The assignment of H^7, H^{10}, and of H^8, H^9, respectively, is uncertain.

The replacement of the two methylene protons in *(7)* by fluorine offers the possibility of shifting the position of the equilibrium between the norcaradiene and the cycloheptatriene tautomer in favor of the latter [*(7)*⇌*(1)* *versus* *(8)*⇌*(9)*], for, as the thermal behavior of perfluorocyclopropanes shows, ring strain is considerably increased by geminal fluorine substituents[5].

11,11-Difluoro-1,6-methano[10]annulene[6] reacts with lead tetraacetate in glacial acetic acid in the same way as *(4)*, although less readily (reflux), yielding a symmetrical *cis*-1,4-diacetate (m.p. 171–172 °C; yield 10%). The ^{1}H-NMR spectrum of the compound confirms the expectation that in this case we are dealing with a cycloheptatriene derivative, and the same applies to the diol [m.p. 175–176 °C (several recrystallizations from ethyl acetate); crude yield 78%] obtained from the diacetate by means of methyllithium at −50 °C. Finally, oxidation of the crude diol with manganese dioxide in acetone afforded the desired 11,11-difluorobicyclo[4.4.1]undeca-3,6,8,10-tetraene-2,5-dione *(9)* as a light-sensitive yellow compound of m.p. 119–120 °C (yield 50%).

(8) *(9)*

Structure *(9)* was proved by the NMR spectra. The ^{1}H-NMR spectrum ([D_6]-acetone) contained an AA'BB' system (H^7—H^{10}) disturbed by H, F coupling and centered at $\tau = 2.62$, as well as a singlet at 3.38 (H^3, H^4), whereas the ^{19}F-NMR spectrum [($CDCl_3$); CCl_3F as external standard] contained an AB system at 103.5 and 110.8 ppm with $J = 238$ Hz. The presence of a cycloheptatriene is convincingly shown by the coupling constants of the olefinic protons H^7—H^{10} (see Table 1) and by the absorption of these protons at relatively low field strength[7]. Furthermore, the ^{19}F-NMR parameters point to this type of structure, for if the CF_2 group were part of a cyclopropane ring the fluorine atoms should not only absorb at higher field strengths but also should show smaller geminal coupling[8–10].

The electron spectrum of the compound [(in methanol) $\lambda_{max} = 210$ ($\varepsilon = 27900$), 236 (15350), 245 (15100, sh), 318 (2600), 398 (325), 415 nm (300)] indicates, in accord with structure *(9)*, stronger conjugation than in the norcaradiene *(7)*. The IR carbonyl absorption [relatively sharp band at 1658 cm^{-1} (in KBr)] corresponds, as does that of *(7)*, to that of an α,β-unsaturated ketone or of a quinone[11].

Chemical and physicochemical studies of *(7)* and *(9)* are in progress to provide further information about the quinonoid nature of these dicarbonyl compounds.

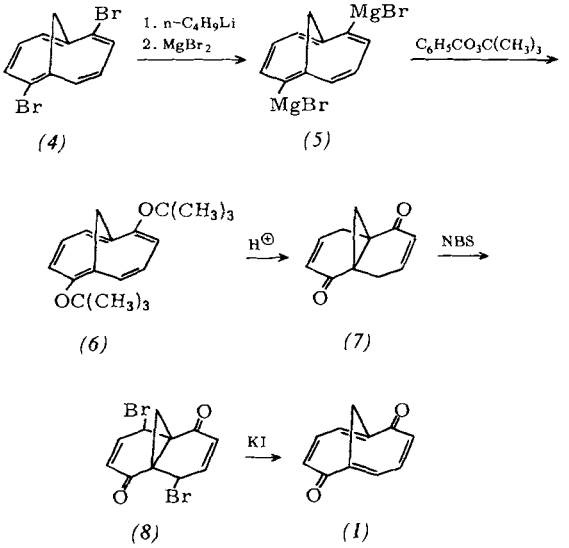
Bicyclo[4.4.1]undeca-3,5,8,10-tetraene-2,7-dione

By *Emanuel Vogel, Walter A. Böll*, and *Elmar Lohmar*[*]

Bicyclo[4.4.1]undeca-3,6,8,10-tetraene-2,5-dione *(2)*, a diketo derivative of 1,6-methano[10]annulene corresponding to *p*-benzoquinone or 1,4-naphthoquinone, defies attempts at synthesis because, contrary to expectation, it has a

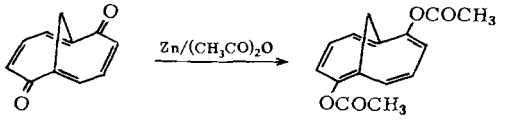


[*] Prof. Dr. E. Vogel, Dr. W.A. Böll, and Dr. E. Lohmar
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

higher free energy than its valence isomer with the norcaradiene structure *(3)*[1]. With bicyclo[4.4.1]undeca-3,5,8,10-tetraene-2,7-dione *(1)*[2], an isomer of *(2)*, a cycloheptatriene-norcaradiene equilibrium is ruled out. Thus only a strong tendency of *(1)* to polymerize should stand in the way of its synthesis.

(1) *(2)* *(3)*

A route to *(1)* was opened by the known 2,7-dibromo-1,6-methano[10]annulene *(4)*[3]. For converting *(4)* into 1,6-methano[10]annulene-2,7-diol or its keto tautomers we used a procedure that had already proved its value for the preparation of 2-hydroxy-1,6-methano[10]annulene from 2-bromo-1,6-methano[10]annulene[4]; in this, the appropriate bromide was converted into the Grignard reagent and this was treated with *tert*-butyl perbenzoate[5], yielding the *tert*-butyl ether which is readily cleaved by acid. The dibromide *(4)* did not, in the event, react with magnesium in the desired manner, but the bifunctional Grignard reagent *(5)* could be obtained by interchange of the metal between the dilithium compound, generated from *(4)* with butyllithium in ether[6], and anhydrous magnesium bromide. When *(5)* was treated with ethereal *tert*-butyl perbenzoate at 0 °C, subsequent chromatography on aluminum oxide followed by distillation afforded the di-*tert*-butyl ether *(6)* as a pale yellow liquid, b.p. 108–110 °C/0.01 torr (yield 50%) [NMR spectrum (in CCl_4): ABC system at $\tau = 2.4$–3.4 (6H) and singlets at 8.69 (18H) and 10.55 (2H)]. Fission of *(6)* effected by a catalytic amount of *p*-toluenesulfonic acid in benzene at 80 °C for 10 min gave a homogeneous colorless substance of composition $C_{11}H_{10}O_2$ and m.p. 138–140 °C (56% yield), which spectra



(4) *(5)* *(6)* *(7)* *(8)* *(1)*

showed conclusively to be the diketone *(7)* with cyclopropane structure [NMR (in $CDCl_3$): AB system with triplet splitting of each line at $\tau = 3.1$–4.2 (4H), quartet at 7.0 (4H), and singlet at 8.33 (2H); UV (in cyclohexane): $\lambda_{max} = 214$ ($\varepsilon = 20\,500$), 331 nm (150); IR (in KBr): carbonyl band at 1650 cm^{-1}]. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone did not dehydrogenate *(7)*, so an attempt was made to approach *(1)* by way of the dibromide *(8)*. With two equivalents of *N*-bromosuccinimide (NBS) in boiling carbon tetrachloride, *(7)* gave a crystalline dibromo substitution product (crude yield *ca.* 80%); this was obviously a mixture of the three possible stereoisomeric dibromides *(8)* since the NMR spectrum of this product contained two singlets and an AB system for the cyclopropane protons. Potassium iodide[7] in acetone dehalogenated the dibromide mixture to the desired bicyclo[4.4.1]undeca-3,5,8,10-tetraene-2,7-dione *(1)* which was obtained as yellowish-orange crystals (from acetone), m.p. 147–148 °C (yield *ca.* 50%), after chromatography on silica gel.

Proof of the structure of *(1)* was provided by the NMR spectrum. This showed only an ABC system at $\tau = 3.0$–3.8, assigned to the six vinylic protons, [chemical shifts and coupling constants determined by analysis: $\tau_{3,8} = 3.71$, $\tau_{4,9} = 3.11$, $\tau_{5,10} = 3.75$; $J_{3,4} = 11.52$ Hz, $J_{3,5} = -0.06$ Hz, and $J_{4,5} = 5.22$ Hz (positional numerals as in formula *(1)*)][8] plus a singlet at $\tau = 6.83$ arising from the CH_2-bridge protons, and it thus has the form expected from the C_2 symmetry of *(1)*. Further the UV and IR spectra are in accord with structure *(1)* [λ_{max} (in cyclohexane) = 244 ($\varepsilon = 3750$, sh), 342 (7300), 431 nm (1600); carbonyl or double-bond bands (in KBr) at 1625, 1635, and 1645 cm^{-1}].

The physical and spectroscopic properties determined so far for *(1)* leave it open whether this compound can be described as a quinone. The chemical behavior appears to justify such a description, for treating *(1)* with zinc and acetic anhydride in the presence of pyridine leads readily to reductive acetylation that affords the aromatic

(1) *(9)*

2,7-diacetoxy-1,6-methano[10]annulene *(9)* of m.p. 130–131 °C; this product is identical with that obtained by acid-catalyzed reaction of *(6)* with acetic anhydride.

[7] When sodium iodide is used, *(1)* is accompanied by an iodine-containing product, presumably the diiodide corresponding to *(8)*; when kept, this product decomposes to *(1)* in an apparently reversible reaction.

[8] We thank *H. Schmickler* for analysis of the ABC system.

Interaction between the Orbitals of Lone Pair Electrons in Dicarbonyl Compounds[1]

By *Dwaine O. Cowan, Rolf Gleiter, Joseph A. Hashmall, Edgar Heilbronner,* and *Volker Hornung*[*]

As a result of EHT and CNDO/2 calculations *J. R. Swenson* and *R. Hoffmann*[2] prophesied that interaction between the non-bonding orbitals n_1 and n_2 of the two carbonyl groups in a dicarbonyl compound would lead to molecular orbitals with clearly split orbital energies. This should be true even when n_1 and n_2 are widely separated in space. It was shown that the interaction mechanism is mainly of the "through-bond" type[3], in as far as the linear combinations

$$n_+ = (n_1 + n_2)/\sqrt{2}$$
$$n_- = (n_1 - n_2)/\sqrt{2}$$

which differ little in energy as a result of "through-space" interaction, can mix strongly with other σ-orbitals of appropriate symmetry. The orbital diagram of s-*trans*-glyoxal shown in Fig. 1 affords an example of this type of interaction.

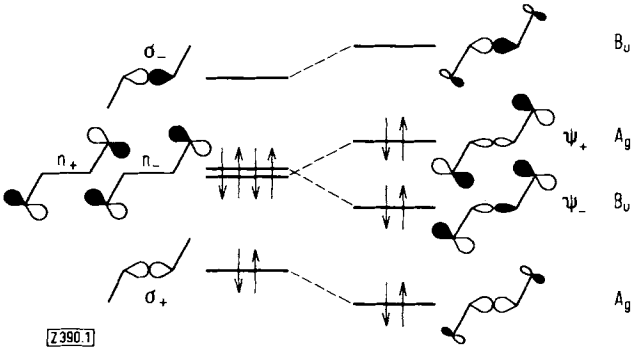

Fig. 1. Schematic orbital diagram of the "through-bond" interaction between the linear combinations n_+ and n_- in s-*trans*-glyoxal (symmetry C_{2h}).

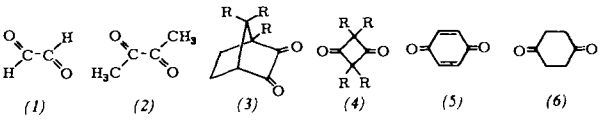
The theoretical predictions of *Swenson* and *Hoffmann*[2] are confirmed by the results of this photoelectron-spectroscopic investigation. In Table 1 are given the differences

$$\Delta(n) = I_v(\psi_J) - I_v(\psi_K)$$



between the vertical ionization potentials $I_v(\psi_J)$ and $I_v(\psi_K)$ of those bands that are assigned in the photoelectron spectrum to an ionization process in which the photoelectron vacates those molecular orbitals to which n_+ and n_- contribute with maximum weight. If the validity of *Koopmans'* theorem[4] is assumed, *i.e.*, if

$$I_v(\psi_J) = -\varepsilon_J \text{ and } I_v(\psi_K) = -\varepsilon_K$$

then $\Delta(n)$ observed should correspond to the difference in the orbital energies of the molecular orbitals ψ_J and ψ_K:

$$\Delta(n) = \varepsilon_K - \varepsilon_J$$

Table 1. Experimental and theoretical splittings $\Delta(n)$ of dicarbonyl compounds. Column 1: no. of compound. Column 2: symmetry of the preferred conformation. Column 3: vertical ionization potentials, position of the maximum of those bands in the photoelectron spectrum to which the orbitals ψ_J and ψ_K are assigned. Column 4: experimental splitting $\Delta(n)$. Column 5: calculated splitting $\Delta(n)$, as obtained from the extended Hückel theory (EHT). All values are given in eV.

[b] Symmetry under the assumption of axially symmetric methyl groups.
[c] In [2]: 0.68 eV, geometry unspecified.
[d] In [2]: 0.47 eV, geometry unspecified.

Remarks:

1. For two carbonyl groups bonded directly to one another, as in glyoxal *(1)*, biacetyl *(2)*, and camphorquinone *(3)*, the theory requires that $\Delta(n)$ is almost independent of the torsion angle φ. [EHT results for *(1)*: φ = 0° (s-*cis*), $\Delta(n) = 1.49$ eV; φ = 90°, $\Delta(n) = 1.62$ eV; φ = 180° (s-*trans*), $\Delta(n) = 1.48$ eV]. In particular—though perhaps surprisingly—the splitting $\Delta(n)$ for the s-*cis*- and s-*trans*-configurations should be the same. This conclusion is confirmed by the results found for *(1)*, *(2)*, and *(3)* (see Table 1).

2. In 2,2,4,4-tetramethyl-1,3-cyclobutanedione *(4)* the "through-bond" interaction between the two linear combinations n_+ and n_- and the C—C σ-orbitals of the cyclobutane ring[5] take place in such a way that the orbital assigned to the irreducible representation B_{2u} of D_{2h} is 0.7_5 eV higher in energy than the B_{3g} orbital (cf. Fig. 2).

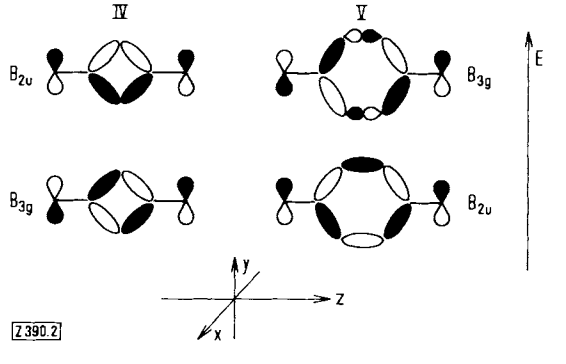

Fig. 2. Schematic diagram of the molecular orbitals ψ_J and ψ_K of 1,3-cyclobutanedione and *p*-benzoquinone to which the linear combinations n_+ and n_- make the largest contributions (symmetry D_{2h}).

3. For *p*-benzoquinone *(5)*, the splitting required by theory for those molecular orbitals to which n_+ and n_- contribute most, yields an assignment of the bands in the photoelectron

[*] Prof. Dr. D. O. Cowan, Dr. R. Gleiter, Dr. J. A. Hashmall, Prof. Dr. E. Heilbronner, and Dr. V. Hornung

CH-4056 Basel, Klingelbergstrasse 80 (Switzerland)

spectrum of *(5)* which differs from that given previously[6]. This leads to the sequence $n, \pi, n, \pi, \ldots$ for the four uppermost occupied molecular orbitals (arranged in order of decreasing energy) and not to $n, n, \pi, \pi, \ldots$ as originally presumed. In this case, unlike that of *(4)*, the order of the orbitals referring to the irreducible representations B_{2u} and B_{3g} is reversed.

4. In the photoelectron spectrum of 1,4-cyclohexanedione *(6)* the splitting $\Delta(n)$ cannot be determined unambiguously. The band assigned to the ionization of the "lone" electron

(7)

pairs is somewhat broadened and its shape near the maximum is indicative of a splitting of $\Delta(n) = 0.1_5$ eV. Such a small value suggests that the twist conformation *(7)* (symmetry D_2)[7] is the preferred one.

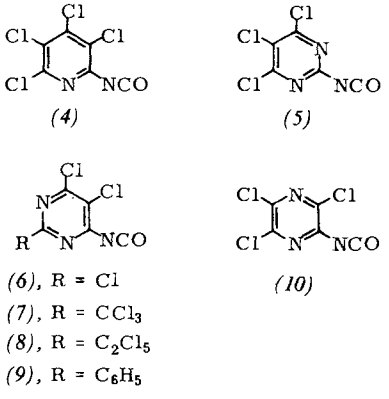
Pyridine, Pyrimidine, and Pyrazine Derivatives with an Isocyanato Substituent Vicinal to Nitrogen

By *Ulrich von Gizycki*[*]

No derivative of pyridine, pyrimidine, or pyrazine has previously been isolated in which an isocyanato group occurs in the vicinal position to nitrogen. 2-Isocyanatopyridine could be obtained only as dimer[1]; and 2-isocyanato-3-methylpyridine *(2)* is stable only in its dimeric form *(3)*, m.p. 212–215 °C. This dimer *(3)* is obtained in quantitative yield by reaction of 3-methyl-2-pyridinamine with diphenyl carbonate *via* the intermediates *(1)* and *(2)*.



We have found that electronegative substituents hinder this dimerization, so that 2-pyridinamines substituted in this way can be converted into the monomeric isocyanato derivatives. This reaction occurs very smoothly when the aminoheterocycle is treated with oxalyl chloride. It can be applied also to pyrimidinamines and pyrazinamines.

Isocyanato-*s*-triazines

By *Ulrich von Gizycki*[*]

Only one isocyanato-*s*-triazine, namely the 2,4-dichloro-6-isocyanato derivative *(1)*, has previously been isolated, and that from tetrameric cyanogen chloride by a route that cannot be generalized[1].

We have found that mono- and di-isocyanato derivatives of *s*-triazine can be readily prepared in good yield by reaction of the appropriate *s*-triazinamine with oxalyl chloride.

(1), R = Cl
(2), R = F
(3), R = CCl_3
(4), R = Cl
(5), R = CCl_3
(6), R = C_6H_5

The isocyanato derivatives *(1)*–*(6)* are colorless solids or liquids that distil without decomposition and are highly reactive (Table 1). In their IR spectrum the NCO band lies at 2250 cm^{-1}. The reaction proceeds better the more electronegative is the substituent R.

Table 1. Properties of the isocyanates *(1)* to *(6)*.

Isocyanate	B. p. (°C/torr)	At room temp.	Yield (%)
(1)	105–106/10–12	Solid	93

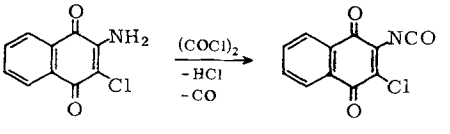
Isocyanatoquinones

By *Ulrich von Gizycki*[*]

Quinones carrying an isocyanato substituent in the quinonoid ring have so far been unknown. We now report syntheses of two representatives of this new class of compound.



When a mixture of finely powdered 2,5-diamino-3,6-dichloro-1,4-benzoquinone (100 g), oxalyl chloride (400 g), anhydrous butyl acetate (200 ml), and anhydrous chlorobenzene (550 ml) is boiled under reflux until gas evolution ceases (~36 h), then, on cooling, red needles of 2,5-dichloro-3,6-diisocyanato-1,4-benzoquinone *(1)* (about 50 g) separate.

(1)

M. p. of *(1)*: 259—260 °C. IR: NCO band at 2205 cm^{-1}, CO at 1665 and 1675 cm^{-1}. Bis(ethylurethane): orange needles, m. p. 220—221 °C.

Yellow 2-chloro-3-isocyanato-1,4-naphthoquinone *(2)* was obtained analogously in 75% yield from 2-amino-3-chloro-1,4-naphthoquinone (50 g) and oxalyl chloride (200 g) in anhydrous *o*-dichlorobenzene.

(2)

The isocyanate *(2)* crystallizes after filtration and concentration of the solution to one-third of its volume.

M. p. of *(2)*: 140—142 °C. IR: NCO band at 2200 cm^{-1}, CO at 1670 cm^{-1}. Ethylurethane: yellow needles, m. p. 135—136 °C.

Bond-Bond Interaction in Polysilanes[1]

By *Hans Bock* and *Walther Ensslin*[*]

Linear methylpolysilanes $H_3C-[Si(CH_3)_2]_k-CH_3$ are the more readily excited the longer the chain length k: the long-wavelength UV bands approach the edge of the visible spectral region[2,3] and the mass-spectroscopically determined first ionization energies IE_1[2,3] are always lower than those of the corresponding polyenes. The various IE_1 values have previously been interpreted[2] by means of the "Sandorfy C" model which was developed for alkanes and which approaches σ-molecular orbitals by linear combinations of sp^3 hybrid orbitals (Fig. 1).

The basic method of calculation uses the empirically calibrated ratio $m=\beta_{geminal}:\beta_{vicinal}$[4] and predicts an asymmetrical splitting of the eigenvalues ε_n (Fig. 1: ε_1 and ε_2) relative to α_{SiSi}. To verify the splitting scheme it was of interest to measure the higher ionization energies IE_n ($n>1$) of polysilanes.

Photoelectron (PE) spectrometry provides the energy differences IE_n between the ground state of a neutral molecule and the states of its radical cation, which, if the validity of *Koopmans*' theorem[5] is assumed, can be correlated with the negative SCF eigenvalues ε_n of the ground-state molecular orbitals. Fig. 2 shows the PE spectra[6] of the linear ($k=1$, 2, 3, 4) methylsilanes, the branched tetrakis(trimethylsilyl)silane, and the cyclic derivatives $[Si(CH_3)_2]_r$ ($r=5$ or 6). The corresponding numerical values are given in Table 1.

Fig. 1. Linear combination and eigenvalue scheme according to the "Sandorfy C" model.

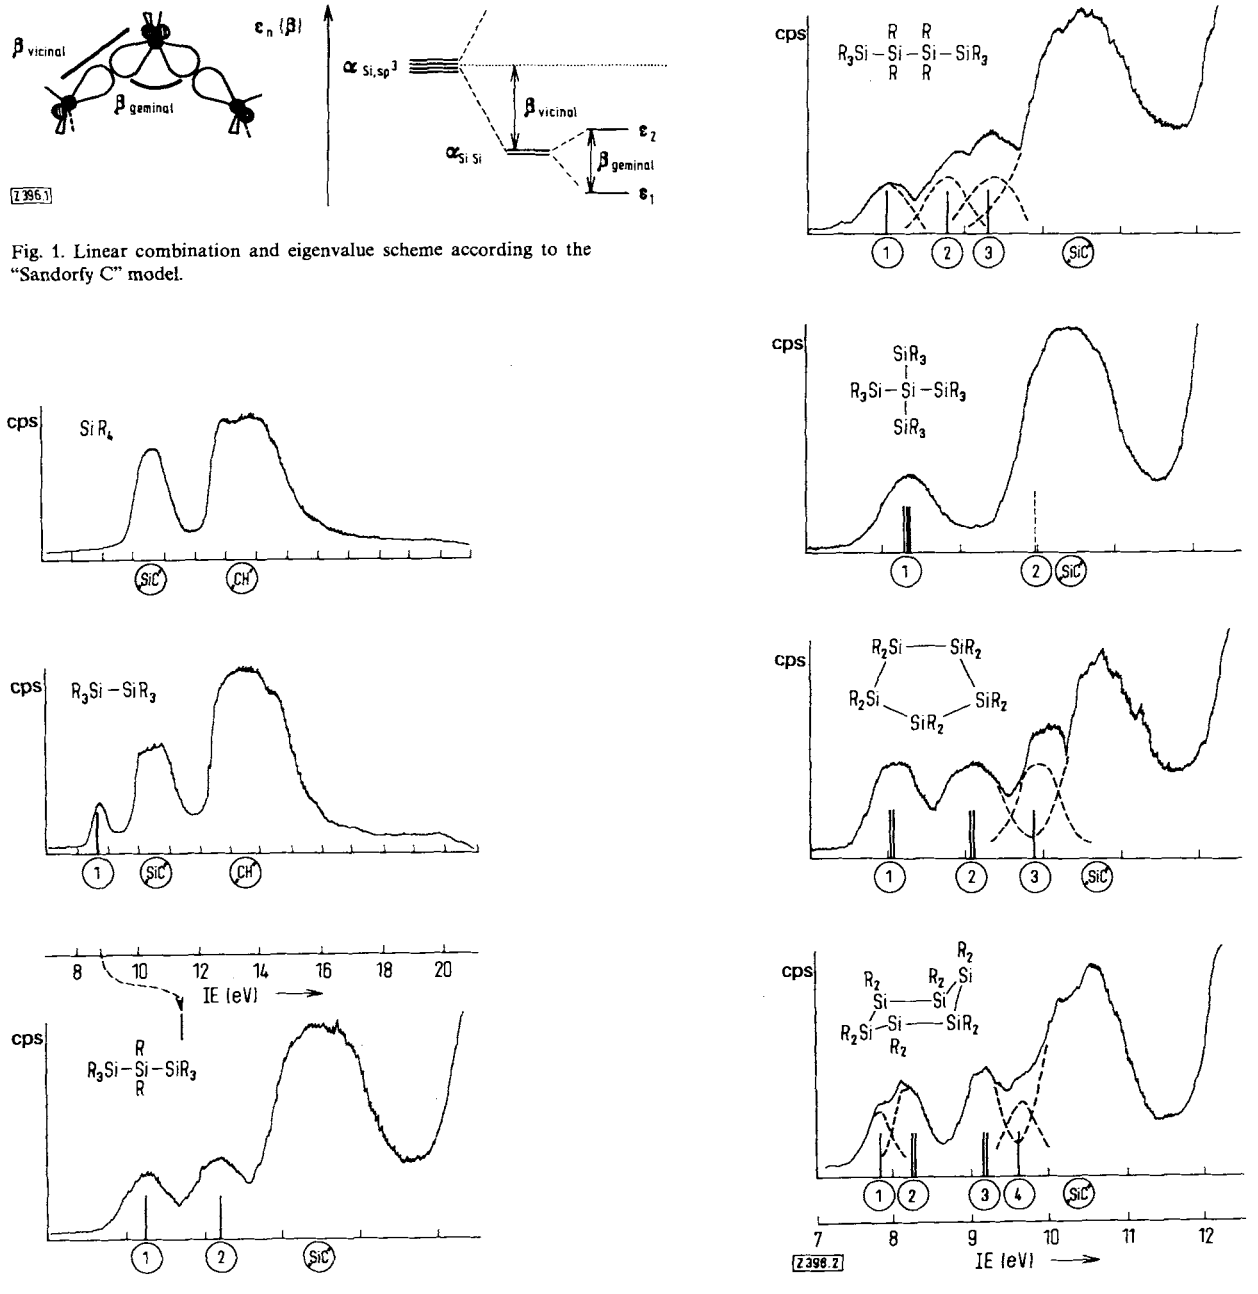

Fig. 2. PE spectra of linear, branched, and cyclic methylsilanes (R = CH_3).

[*] Prof. Dr. H. Bock and Dipl.-Chem. W. Ensslin
Chemische Institute der Universität
6 Frankfurt 70, Ludwig-Rehn-Strasse 14 (Germany)

Table 1. Vertical ionization energies IE_n (eV) of the PE bands n.

Compound		①	②	③	④	(SiC)
$R-(SiR_2)_k-R$	$k=1$					10.5
	$k=2$	8.69				10.4
	$k=3$	8.19	9.14			10.4
	$k=4$	7.98	8.76	9.30		10.5
$Si(SiR_3)_4$		8.24	(9.9)			10.4
$(SiR_2)_r$	$r=5$	7.94	8.91	9.80		10.7
	$r=6$	7.79	8.16	9.12	9.78	10.4

Comparison of the PE spectra of tetramethylsilane and hexamethyldisilane shows that in the latter the largely unchanged, intense "SiC" and "CH" band systems are preceded by an isolated band that has to be ascribed to the ionization from a molecular orbital with a preponderant SiSi contribution. This assignment is confirmed by the appearance of two and three bands, respectively, of comparable intensity in the PE spectra of silane chains with $k=3$ and $k=4$. Retention of the midpoint in this "splitting" shows that "SiC" and "CH" contributions to the "SiSi" molecular orbitals are negligible. From the tetrahedral symmetry of the Si_5 skeleton of tetrasilylsilane, one would expect a 3:1 splitting into t_2 and a_1 molecular orbitals; in the PE spectrum the t_2 band is at 8.24 eV, and the a_1 band is indicated to lie within the "SiC" peak at about 9.9 eV. Cyclic silanes should show intensity patterns 2:2:1 (D_{5h}: $e_1'+e_2'+a_1'$) and 1:2:2:1 (chair form D_{3d}: $a_{1u}+e_g+e_u+a_{1g}$), in which the last band always falls under the initial ascent of the following "SiC" band system and thus shows an exaggerated intensity.

These findings can be rationalized by a simple LCBO (linear combination of bond orbitals) model (Fig. 3).

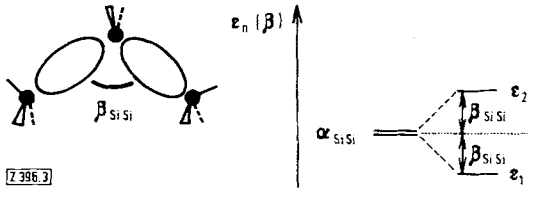

Fig. 3. Bond-bond interaction and eigenvalue scheme according to the LCBO model.

The internal parametrization is carried out using the ionization energy of hexamethyldisilane ($IE_1=8.69$ eV $=\alpha_{SiSi}$), which also absorbs end-group effects and other neglected interactions. The coefficients x_n of the orbital eigenvalues $\varepsilon_n=\alpha_{SiSi}+x_n\beta_{SiSi}$ can be taken from HMO tables[7]. The resulting linear regression (Fig. 4):

$$IE_n = 8.69\text{ eV} + x_n\,0.5\text{ eV}$$

has the small standard deviation SE = 0.02 eV.

From the excellent correlation between the experimental and the calculated values (Fig. 4) several conclusions can be drawn. First the delocalization of electrons in σ-skeletons becomes particularly obvious in the case of the methylpolysilanes, because the PE ionization energies can be interpreted in terms of a simple model. Further, the applicability of *Koopmans'* theorem indicates comparable stabilization of the radical cation states of straight-chain, branched, and cyclic methylpolysilanes. Moreover, since the LCBO approximation used is the border-line case of the "Sandorfy C" model in which the ratio $\beta_{geminal}:\beta_{vicinal}$ approaches zero, *i.e.*, $\beta_{vicinal}$ becomes very large, the influence of antibonding molecular orbitals of suitable symmetry must be negligibly small. Finally, a bonding contribution from unoccupied silicon orbitals of π-symmetry can also be excluded because the midpoint α_{SiSi} is retained in the splitting scheme.

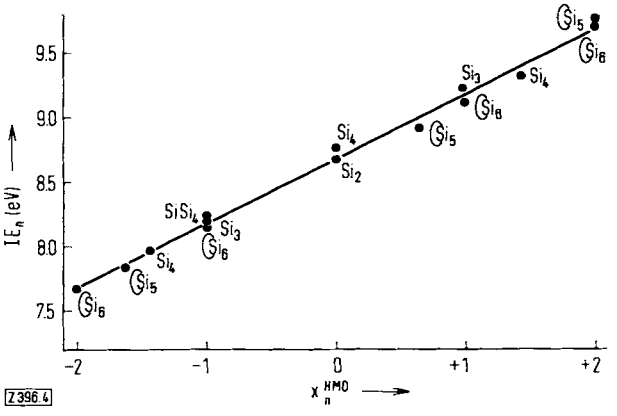

Fig. 4. Correlation of the vertical ionization energies IE (eV) of linear, branched, and cyclic polysilanes with HMO eigenvalue coefficients x_n.

Oxidative Amination of Hydroquinones[1]

By *Wolfram Schäfer* and *Antonio Aguado*[*]

Substituted 2,5-diamino-1,4-benzoquinones *(1)* can be prepared by (a) 1,4-addition of primary amines to benzoquinones *(2)*, $R^1=H$, followed by oxidation[2] or (b) nucleophilic replacement of readily eliminable groups in *(3)*, $R^1=CH_3CO$ or $COOCH_3$, $R^4=Hal$, OCH_3, or SC_2H_5[3,4].

(2) *(1)* *(3)*

[*] Priv.-Doz. Dr. W. Schäfer, Dr. A. Aguado, and Dipl.-Chem. U. Sezer
Max-Planck-Institut für Biochemie
8 München 15, Goethestrasse 31 (Germany)

In (a) maximally 50% of the quinone is converted into *(1)*, and in (b) the preparation of the starting material is demanding[5]. Oxygen in the presence of copper sulfate has been recommended[6, 7] for oxidation of the substituted hydroquinones formed as intermediates by the 1,4-addition, but this method is successful only with secondary alkylamines. 4,5-Dianilino-1,2-benzoquinone is formed from pyrocatechol in the presence of aniline and silver oxide in glacial acetic acid[8].

We have found that substituted 2,5-bis(arylamino)-1,4-benzoquinones *(1)* can be prepared in good yield and purity by oxidizing the hydroquinones corresponding to *(2)* with sodium iodate in the presence of the amine (Table 1).

Table 1. 2,5-Bis(arylamino)-1,4-benzoquinones *(1)* prepared by oxidative amination.

R^1	$R^2=R^3$	Dec. pt. (°C)	Yield (%)
$COCH_3$	C_6H_5	199	91
	C_6H_4-*o*-CH_3	183	85
	C_6H_4-*m*-Cl	179	83
	C_6H_4-*p*-OCH_3	216	86
	3-pyridyl	222	81
$COOCH_3$	C_6H_5	202	89
	C_6H_4-*o*-CH_3	217	87
	C_6H_4-*m*-Cl	212	89
	C_6H_4-*o*-Cl	193	88
	C_6H_4-*p*-OCH_3	226	89
CH_3	C_6H_5	147	72
Br	C_6H_5	307	63
$CON(CH_3)_2$	C_6H_5	245	80

General procedure:

A solution of hydroquinone (0.1 mol) and arylamine (0.22 mol) in methanol/water (2—3 l; amount and proportions depending on the solubility of the components) is stirred vigorously with sodium iodate (0.3 mol) for 5—20 h. The product that is precipitated is filtered off, washed, and crystallized from alcohol.

The arylamino group on C-2 of *(1)*, $R^1=COCH_3$ or $COOCH_3$, $R^2=R^3=$aryl, can be replaced by primary amino groups; with alkylamines the reaction occurs quantitatively within a few minutes (faster with acetyl- than with ester-quinones), and with arylamines the replacement can be forced by an excess of reagent and higher reaction temperature (boiling methanol or butanol). The structures of the products are proved (Table 2) by considering the amino group that is replaced[9]. The exchange of amino groups makes unsymmetrically substituted 2,5-diamino-1,4-benzoquinones readily accessible for the first time.

Table 2. Substituted 2-(alkylamino)-5-(arylamino)- and 2,5-bis(arylamino)-1,4-benzoquinones *(1)* synthesized by amine exchange.

	C_2H_5	C_6H_5	161
	n-C_4H_9	C_6H_4-*p*-CH_3	147
	H	C_6H_4-*m*-Cl	254
	CH_3	C_6H_4-*m*-Cl	223
	C_2H_5	C_6H_4-*m*-Cl	188
	n-C_4H_9	C_6H_4-*p*-F	156
	n-C_4H_9	C_6H_4-*p*-CN	194
	CH_3	C_6H_4-*p*-OCH_3	245
	CH_3	C_6H_4-*p*-F	249
	C_6H_4-*p*-Cl	C_6H_5	209

General procedure:

The alkylamine (0.2 mol) is added to a solution of *(1)*, $R^1=COCH_3$ or $COOCH_3$, $R^2=R^3=$aryl (0.1 mol), in methanol or methanol-tetrahydrofuran and the reaction is followed by thin-layer chromatography. The solution is concentrated as soon as the starting material has disappeared, and the crude product is recrystallized from methanol or glacial acetic acid.

A New Method of Preparing Heterocyclic Quinones[1]

By *Wolfram Schäfer, Antonio Aguado*, and *Utku Sezer*[*]

The substituted quinones *(1a)* to *(1e)*[2–4] can be used as starting materials for synthesis of heterocyclic quinones by condensations leading to a heterocyclic ring.

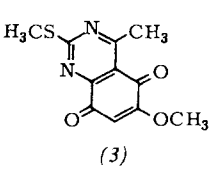
(1) *(2)*

	R^1	R^2	R^3
(1a)	CH_3	OCH_3	OCH_3
(1b)	OCH_3	OCH_3	OCH_3
(1c)	OCH_3	Cl	OCH_3
(1d)	CH_3	[NHAlkyl,	NHAryl]
(1e)	CH_3	NHAryl	NHAryl
(1f)	CH_3	NH_2	[NHAlkyl, NHAryl]

Compound *(1a)* reacts smoothly with hydrazines or hydrazides in methanol at room temperature to give indazolequinones *(2a)* substituted on N-2 (see Table 1)

[*] Priv.-Doz. Dr. W. Schäfer and Dr. A. Aguado
Max-Planck-Institut für Biochemie
8 München 15, Goethestrasse 31 (Germany)

by way of intermediate 2-hydrazinobenzoquinones. Quinones of type *(1d)* and *(1e)* react analogously with hydrazine itself, hydrazines, hydrazides, semicarbazide, or thiosemicarbazide in boiling methanol, to yield indazolequinones *(2b)* with a substituted amino group on C-5. These products can also be obtained by replacing the methoxy group in compound *(2a)*. Yields are between 73% and 95%. The acyl group of 2-acylindazolequinones, as of acylimidazoles[5], can be readily removed by hydrolysis. During reaction of *(1d)* and *(1e)* with acetylhydrazine, semicarbazide, or thiosemicarbazide, the acyl groups of the hydrazino compounds are removed.



Benzoisoxazolequinone *(2c)* is formed in 80% yield from *(1c)* and sodium azide in methanol. 3-Acetyl-2,5-bis(arylamino)-1,4-benzoquinones[1] react with hydroxylamine in boiling methanol to give *ca.* 90% yields of the benzisoxazolequinones *(2d)*. Reductive opening of the isoxazole ring by phenylhydrazine or by catalytic hydrogenation and

Table 1. Indazolequinones and benzisoxazolequinones prepared.

	CH_3	NHC_6H_4-*p*-CH_3	O	180
	CH_3	NHC_6H_4-*m*-Cl	O	199
	CH_3	NHC_6H_4-*o*-Cl	O	185

subsequent oxidation of the intermediate hydroquinone by air leads to the 2-amino-1,4-benzoquinones *(1f)* and *(1g)*, which are also obtained from *(1d)* and *(1e)* by means of ammonia. The reaction provides proof of the structure of the quinones *(2)*.

Reaction of *(1a)* or *(1b)* with compounds containing the structural elements of an amidine leads to quinones to which a six-membered heterocycle is fused: *S*-methylthiuronium sulfate and *(1a)* in the presence of sodium methoxide in methanol yield 6-methoxy-4-methyl-2-(me-

(3)

(4)

thylthio)quinazoline-5,8-quinone *(3)* in 65% yield (m.p. 188 °C), and *(1b)* reacts with 2-aminopyridine to give 7-methoxy-5-oxo-5*H*-pyrido[2,1-*b*]quinazoline-6,9-quinone *(4)* in 79% yield (dec. *ca.* 290 °C).

The structures of the products were proved by elemental analyses and spectroscopic measurements (MS, IR, UV, and NMR) as well as by the synthetic routes.

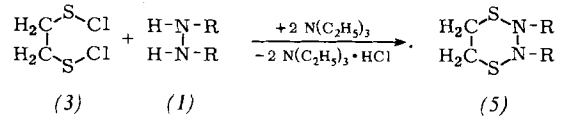
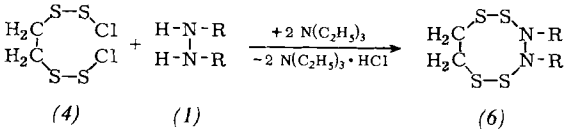
Preparation of Some Hydrazine Derivatives Containing Nitrogen-Sulfur Bonds[**][1]

By *Karl-Heinz Linke*, *Rudolph Bimczok*, and *Herbert Lingmann*[*]

Diels and *Wulff*[2] were able to add ethanethiol to the N=N double bond of diethyl azodicarboxylate to obtain diethyl 1-(ethanesulfenyl)hydrazine-1,2-dicarboxylate. An attempt by us to synthesize this compound by reaction of ethanesulfenyl chloride with diethyl hydrazine-1,2-dicarboxylate *(1)* in the presence of triethylamine afforded instead diethyl 1,2-bis(ethanesulfenyl)hydrazine-1,2-dicarboxylate *(2)*, a distillable oil (b.p. 54—56 °C/0.01 torr), which was identified by analysis and its IR spectrum.



(1)



(2)

The molecule peak ($m/e = 296$) did not appear in the mass spectrum of *(2)*, which however showed a fragment of half this mass with great intensity, which is to be explained by cleavage of the N—N bond. As formation of disubstituted products is clearly favored and as the stability of ring compounds is expected to be greater[3], we treated 1,2-bis(chlorosulfenyl)ethane *(3)*[4] and 1,2-bis(chlorodisulfanyl)-

(3) *(1)* *(5)*

ethane *(4)*[5] with *(1)* in the presence of triethylamine and we thus obtained the cyclic compounds diethyl 1,4,2,3-dithiadiazacyclohexane-2,3-dicarboxylate *(5)* and 1,2,5,6,3,4-tetrathiadiazacyclooctane-3,4-dicarboxylate *(6)*, respectively.

Formation of the six-membered ring is favored to such an extent that it is unnecessary to use the dilution technique for the preparation. The two compounds are colorless crystalline substances: *(5)* m.p. 90°C (dec); *(6)* m.p. 94–95°C. They were characterized by elemental analysis, IR and mass spectra, and chemical degradation.

There is no N—H vibration in the IR spectra. The N—N stretching vibrations and the S—S stretching vibration in compound *(6)* can, however, be discerned. Both compounds break down in the mass spectrometer in similar ways: after removal of the ester groups the two nitrogen atoms are lost simultaneously as N_2, whence the existence of N—N bonds can be concluded. That these heterocycles are hydrazine derivatives was confirmed also by degradative reactions: *(1)* is formed on desulfuration of *(5)* or *(6)* with Raney nickel.

Experimental:

Compound *(5)*: The chloride *(3)* (4.1 g, 0.025 mol), dissolved in ether (50 ml), is add dropwise during 30 min into a vigorously stirred solution of *(1)* (17.6 g, 0.1 mol) and triethylamine (5.1 g, 0.05 mol) in anhydrous ether (500 ml) at 0°C. After 3 hours' stirring, filtration from triethylammonium chloride and cooling, the product *(5)* crystallizes. It is recrystallized from ether. Yield: 4.5 g (67%).

Compound *(6)*: *(1)* (4.4 g, 0.025 mol) and triethylamine (5.1 g, 0.05 mol) are dissolved in dioxane (150 ml). *(4)* (5.7 g, 0.025 mol) is diluted with ether (150 ml). The two solutions are dropped simultaneously during 3 h into vigorously stirred anhydrous ether (250 ml) at 0°C. When reaction is complete, the mixture is filtered and the solvent is removed. The product *(6)* is isolated by preparative thin-layer chromatography with dichloromethane on silica gel H (R_F=0.4). Yield: 1.0 g (12%).

Hydrosilylation of a N=N Double Bond[**][1]

By *Karl-Heinz Linke* and *Hans Jürgen Göhausen*[*]

Although hydrosilylation of olefins and acetylenes is of great preparative importance[2], no corresponding reaction with an azo compound as unsaturated component has previously been reported. During our investigations of addition reactions of diethyl azodicarboxylate *(1)*[3] we have added triphenylsilane *(2)* by its Si—H group to the N=N double bond of the azo ester with formation of diethyl (triphenylsilyl)-1,2-hydrazinedicarboxylate *(3)*.

$(C_6H_5)_3Si\text{-}H + R\text{-}N{=}N\text{-}R \rightarrow (C_6H_5)_3Si\text{-}\overset{R}{\underset{|}{N}}\text{-}\overset{R}{\underset{|}{N}}\text{-}H$

(2) *(1)* *(3)*

R = $CO_2C_2H_5$

The reaction is effected either in boiling benzene or at room temperature in the same solvent under irradiation by UV light[4]. Addition of di-*tert*-butyl peroxide greatly increased the yield (Table 1), so the addition clearly occurs by a radical mechanism.

Table 1. Yields of *(3)* under various conditions. The initial solution was in all cases 0.32 M in *(1)* and *(2)*.

Reaction conditions	Reaction time	Yield (%)
Boiling benzene without peroxide	11 days	15.3
Boiling benzene with peroxide	11 days	71.5
Irradiation without peroxide	3.5 h	20.6
Irradiation with peroxide	3.5 h	77.0

Compound *(3)* is soluble in all the usual organic solvents except light petroleum and crystallizes in colorless needles, m.p. 117–118°C (dec). It was characterized by elemental analysis, IR spectrum, and mass spectrum.

The IR spectrum showed the N—H stretching vibration at 3295 cm^{-1}, two C=O bands at 1745 and 1700 cm^{-1}, and C—H stretching vibrations at 3075, 3005, and 2980 cm^{-1}. Further strong absorptions occur at the following wave numbers: 1515, 1430, 1372, 1310, 1240, 1112, 1050, 740, 705, 695, 530, and 505 cm^{-1}.

The 70-eV mass spectrum of *(3)* shows, besides the molecular ion at m/e=434, only one fragment in which the Si—N—N skeleton remains intact, namely, $M^+ - (C_6H_5 + H)$, m/e=356. This is accompanied by fragments $(C_6H_5)_3Si^+$ (m/e=259) and

$$N(CO_2C_2H_5)\text{—}NH\text{—}CO_2C_2H_5^+ \quad (m/e=175)$$

whose further degradation can also be followed.

π-Allylpentakis(trifluorophosphine)tantalum[1]

By *Thomas Kruck* and *Hans-Ulrich Hempel*[*]

Transition metals for which trifluorophosphine complexes have so far been reported belong to Groups 6A, 7A, and 8[2]. We have now prepared a PF_3 complex of a metal of

[*] Prof. Dr. K.-H. Linke and Dipl.-Chem. H. J. Göhausen
Institut für Anorganische Chemie der Universität
5 Köln, Zülpicher Strasse 47 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

[*] Prof. Dr. Th. Kruck and Dipl.-Chem. H.-U. Hempel
Institut für Anorganische Chemie der Universität
5 Köln, Haedenkampstrasse 2 (Germany)

Group 5 A by treatment of an ethereal solution of tetrakis-(π-allyl)tantalum *(1)*[3] with an excess of trifluorophosphine under pressure, whereupon π-allylpentakis(trifluorophosphine)tantalum *(2)* was formed.

$$2\ (\pi\text{-}C_3H_5)_4Ta + 10\ PF_3 \xrightarrow[20\,^\circ C]{20\ atm.}$$

(1)

$$2\ (\pi\text{-}C_3H_5)Ta(PF_3)_5 + 3\ C_6H_{10}$$

(2)

Compound *(2)* sublimes at room temperature and 10^{-4} torr and forms ruby-red crystals that can be kept without decomposition under nitrogen at −35 °C. In the solid state, *(2)* is stable in air at room temperature for some time, but decomposes even under nitrogen within a few days at 20 °C.

The mass spectrum of *(2)* at 20 eV shows the molecular ion at $m/e = 662$ and fragments that arise by successive loss of PF_3 groups[4].

The assumption, based originally on the noble-gas rule, that the π-allyl group would be symmetrically bound was confirmed by the ^{1}H-NMR spectrum, which contained three signals with intensity ratios 1:2:2 at $\tau = 5.47$ *(meso)*, 7.50 *(syn)* and 8.68 *(anti)*[5].

The form of the P—F vibrations in the IR spectrum resembles that of halogenopentakis(trifluorophosphine)rhenium complexes[6], thus suggesting that the PF_3 groups form a distorted square pyramid, with the allyl group lying over the basal plane of the pyramid.

Attempts to replace all four allyl groups by trifluorophosphine to form the species $[Ta(PF_3)_6]$ have so far all failed, and reactions of *(1)* with PF_3/H_2 mixtures under increased pressure, which could have led to $HTa(PF_3)_6$, afforded only metallic tantalum and propane.

[1+2]Cycloadditions of Isocyanides to Alkynes[1] [**]

By *A. Krebs* and *H. Kimling*[*]

We report the formation of cyclopropenimines in [1+2]-cycloadditions of isocyanides to alkynes. Cyclopropenimines have been postulated as intermediates in reactions of isocyanides with electron-deficient alkynes but so far have not been isolated from such systems[2-4]. We have now obtained cyclopropenimines from strained cyclic or electron-rich alkynes and isocyanides; in these cases the cyclopropene system is not destabilized by electron-withdrawing substituents at the C=C-double bond. Thus, 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne *(1)*[5] reacts in benzene with the isocyanides *(2a)–(2c)* to give *(3a)–(3c)*; the rate of addition decreases considerably in the order *(2a)* > *(2b)* > *(2c)* (Table 1).

(1) *(2)* *(3)*

(a), R = *p*-$O_2NC_6H_4$
(b), R = C_6H_5
(c), R = Cyclohexyl

Table 1. Time (*t*) for the addition of *(1)* to *(2a)–(2c)* at 25 °C. Yields and properties of *(3a)–(3c)*.

	t (days)[a]	Yield (%)	M.p. (°C)	IR (KBr, cm^{-1})
(3a)	0.12	80	156–158	1835
(3b)	3	78	122–124	1825
(3c)	14	36	146–148	1840

[a] *t*: Time for 90% conversion of *(1)* (determined by NMR, molar ratio 1:1, 0.5 M solution).
[b] From *(1)* and *(2c)* at least one other product is formed in addition to *(3c)*.

The structures of *(3a)—(3c)* were proved by elemental analysis, mass, ^{1}H-NMR and IR spectra[6, 7] as well as by hydrolysis to the ketone (m.p. 182 °C), which was also synthesized by addition of dichlorocarbene to *(1)* and subsequent hydrolysis.

The ^{1}H-NMR spectra of *(3a)—(3c)* are temperature dependent; at low temperatures the methyl groups appear as two singlets which coalesce at higher temperatures. The free enthalpies of activation $\Delta G_c^{\neq}$ for the *syn-anti* isomerizations were calculated (Table 2) from the coalescence temperatures T_c, the chemical shift differences Δν and the line widths b_E at low temperatures.

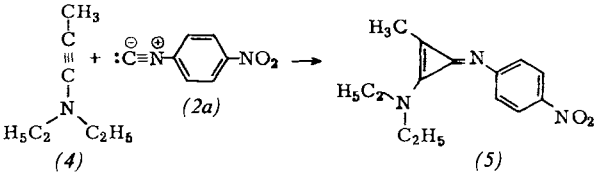

Table 2. ^{1}H-NMR data (60 MHz) and free enthalpies of activation $\Delta G_c^{\neq}$ for the *syn-anti* isomerization in *(3a)–(3c)*.

	Δν (Hz)	T_c (±2, °C)	b_E (Hz)	$\Delta G_c^{\neq}$ (±0.2, kcal/mole)
(3a)[a]	11.6	+ 8	2.5	14.7
(3b)[a]	8.8	+ 79	1.6	18.7
(3c)[b]	2.2	+145	1.6	23.8

[a] In $[D_8]$-toluene.
[b] In diphenyl ether.

Thus, the $\Delta G_c^{\neq}$ values and the influence of the *N*-substituents on the barrier to inversion are in the same order of magnitude as in other imines[8].

Diphenylacetylene, 2-butyne, and cyclooctyne do not react with the isocyanides *(2a)—(2c)* under analogous conditions to yield cyclopropenimines. However, 1-diethyl-

amino-1-propyne *(4)* adds *(2a)* with formation of *(5)* ($t = 12$ days at 25 °C).

The structure of *(5)* (m.p. 90—91 °C; yield 34%) was proved by elemental analysis, mass, ^{1}H-NMR and IR spectra (1880 cm^{-1}).

These additions may, like the analogous carbene reactions, proceed by a concerted (cheletropic) or a two-step mechanism[9]; investigations are in progress.

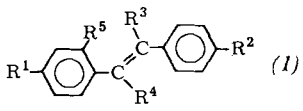
New, Nonplanar *trans*-Stilbenes Exhibiting Nematic Phases at Room Temperature



By *William R. Young, Arieh Aviram*, and *Robert J. Cox*[*]

In 1969, *Kelker* and *Scheurle* reported the preparation of *N*-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline, which exhibits a nematic mesophase between 20 and 41 °C[1]. This compound suffers, however, from two drawbacks: it is yellow and it hydrolyzes in the presence of ambient moisture[2].

We have now investigated some *trans*-stilbene derivatives that are unique among the nematogenic azo[3], azoxy[3], azomethine[3], nitrone[4], and stilbene[3,5] compounds in combining an inherently colorless appearance with a relatively high degree of resistance toward moisture, long wavelength ultraviolet light, and oxygen.

In an earlier publication[5] we postulated that the high melting points of *trans*-stilbene and related *para*-substituted derivatives is a consequence of the planar configuration of these molecules[6], and it was hypothesized that nonplanar, low melting nematic materials could be prepared by the introduction of small, globular substituents in the *alpha*, *beta*, or *ortho* positions of the molecule. The use of alkyl substituents in the *para* positions might also prove beneficial, as has been demonstrated for the azomethines[1].

We have synthesized a series of *trans*-stilbene derivatives *(1)*. The precursors for all of these compounds are the appropriately substituted benzyl phenyl ketones, which were prepared by the standard Friedel-Crafts acylation procedure employing a phenylacetyl chloride and a benzene derivative. The stilbenes *(1a)* and *(1b)* were synthesized from the ketones by $LiAlH_4$ reduction, dehydration with $NaHSO_4$, and low temperature recrystallization. The methyl derivatives *(1c)* and *(1d)* were prepared from their appropriate ketones in an analogous manner, except that methylmagnesium iodide was employed as the reducing agent. The chloro compounds *(1e)* to *(1l)* were synthesized by reaction of benzyl phenyl ketones with phosphorus pentachloride, followed by filtration through silica gel and low temperature recrystallization.

[a] Nematic-isotropic transition temperature.
[b] Monotropic transition.
[c] On cooling, the nematic phase is indefinitely stable at 18 °C.
[d] Smectic-nematic transition temperature.

Although additional corroborating experiments must be pursued, it can be tentatively concluded from the properties of the compounds shown in the table that our hypotheses are correct.

Two of the stilbenes, *(1h)* and *(1i)*, can be classified as room temperature nematic materials. Although the former substance is nematic at room temperature only in its supercooled state, neither has crystallized after several weeks at 18 °C, even in a thin film. The methyl branch may be detrimental to rapid crystallization. The stilbene *(1j)*, which is the only substance listed that contains two alkyl moieties as the wing groups, is a normal liquid at ambient temperatures and exhibits a smectic as well as a nematic phase.

Quite large enantiotropic nematic ranges are exhibited by *(1f)* and *(1g)*, and even longer ranges can be obtained by preparing binary mixtures. A formulation containing 60 mole-% *(1f)* and 40 mole-% *(1g)*, for example, has a nematic range of 8 to 59 °C.

All of the stilbene compounds *(2)* are white, crystalline solids at appropriate temperatures. The short wavelength cutoff of these materials is exemplified by the ultraviolet spectrum of stilbene *(1g)* in ethanol, $\lambda_{max} = 305$ nm ($\varepsilon = 28\,000$), $\lambda_{cutoff} = 350$ nm. Each one of the nematic phases observed as a colorless, turbid, mobile phase in a capillary tube could also be detected under a polarizing microscope equipped with a Mettler Hot/Cold Stage.

Several of the compounds have been employed in their nematic states in the following experiments: the observation of dipole-dipole splitting in the nuclear magnetic resonance spectrum of a solute molecule dissolved in a nematic host[7,8]; the reproduction of the dynamic scattering effect, described by *Heilmeier* and co-workers[9], when suitable dopants are introduced into the cell[10]; the appearance of color bands, characteristic of a cholesteric mesophase, upon addition of cholesteric compounds to the mesomorphic stilbenes.

They are, in addition, potentially useful as stationary phases for gas chromatography[11] and as solvents in infrared[12], ultraviolet/visible[12], and ESR[13] spectrometric experiments.

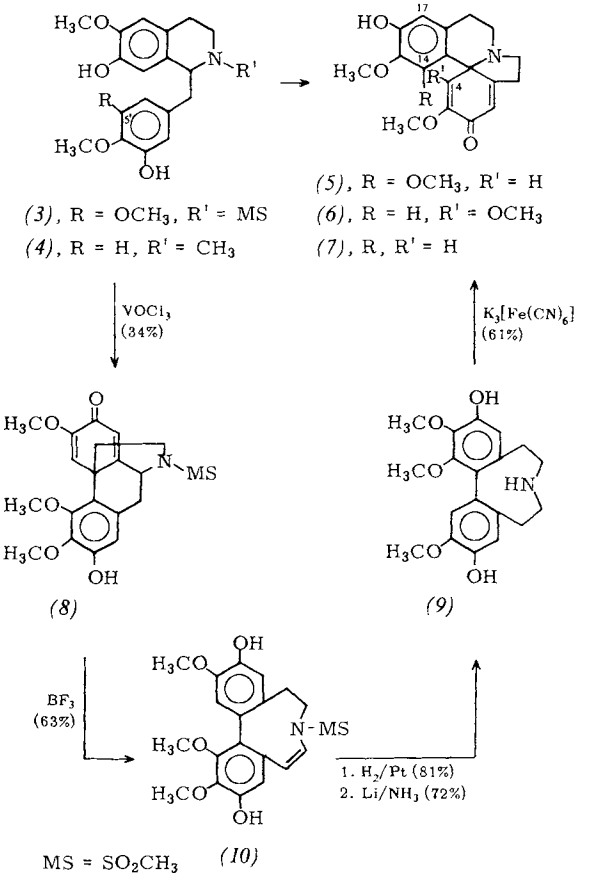
Model Reactions for the Biosynthesis of Erythrina Alkaloids[1]

By *Burchard Franck* and *Volker Teetz*[*]

By feeding with radioactively labeled precursors *Barton et al.*[2,3] recently provided a proof that the skeleton of the Erythrina alkaloids (which have curare-like action) as well as that of morphine and other alkaloids is derived from a benzyltetrahydroisoquinoline *(1)*. The conversion of *(1)* into *(2)* must occur in three steps:



(1) *(2)*

1. Ring opening "a" in *(1)*;
2. Ring closure "b" in *(2)*;
3. Ring closure "c" in *(2)*.

[*] Prof. Dr. B. Franck and Dipl.-Chem. V. Teetz
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

The third of these steps has already been clarified[3,4]. We now report on the preparative realization of this biogenetic scheme by synthesis of erythrinane *(5)* from the benzyltetrahydroisoquinoline *(3)*.

Oxidation of *N*-mesyl-5'-methoxynorreticuline *(3)* with $VOCl_3$[5] in CH_2Cl_2 gave the morphinandienone *(8)* in a yield of 34%, which is very high for an oxidative morphinan ring closure[6] [m.p. 235—238 °C; IR bands in KBr, 1665, 1640, 1615 cm^{-1} (dienone[7])] (ring closure b). Under very mild catalysis by BF_3/ether at 20 °C, which precludes an apomorphine rearrangement, *(8)* is rearranged to the isomeric biphenyl derivative *(10)* (ring opening a)[8]. This compound absorbs 1 mol of H_2 in presence of Pt/charcoal in methanol and in the NMR spectrum ($CDCl_3$, TMS = 10) shows three aromatic ($\tau = 3.60$, 3.45, and 3.14) and two *cis*-olefinic protons ($\tau = 4.63$ and 3.76; $J = 10.5$ Hz). Catalytic hydrogenation of *(10)* and subsequent demesylation by lithium in liquid NH_3 leads to the secondary amine *(9)* which can be condensed oxidatively by $K_3[Fe(CN)_6]$ in 5% $KHCO_3$ solution to give 14-methoxyerysodienone *(5)* (ring closure c). The structure of *(5)* is proved by the follow-

ing analytical findings: IR spectrum in KBr: 1680, 1655, and 1620 cm^{-1} (dienone[2,4]); NMR spectrum ($CDCl_3$, TMS = 10): $\tau = 4.28$, 3.79, and 3.77 (H on C-4, C-1, and C-17[2]); UV spectrum in methanol: $\lambda_{max} = 216$, 238, and 280 nm. These IR and UV data rule out the structure of the isomeric 4-methoxyerysodienone *(6)* which could have arisen by condensation of the nitrogen with the more highly substituted phenol portion.

The ready availability of the morphinandienone *(8)* (see below) is decisive for this new erythrinane synthesis with average yields of 60% per step. In view of these results norreticuline (*4*; R' = H) can be considered as biosynthetic

precursor for the Erythrina alkaloids that are derived from erysodienone *(7)*. It would first condense to the corresponding morphinandienone, whose *N*-methyl derivative, isosalutaridine[7] is found in Nature[10]; rearrangement analogous to *(8)* → *(10)* must then follow.

Morphinandienone (8):

Compound *(3)* (2.54 g) in anhydrous CH_2Cl_2 (2.5 l) was treated with $VOCl_3$[5] (2.4 g) in CH_2Cl_2 (120 ml) at −78 °C. and left at that temperature for 2 h. The mixture is then warmed to 20 °C, stirred for 2 h, washed with a saturated aqueous solution of Titriplex III (E. Merck), Na_2SO_4, and $KHCO_3$, and dried. The organic phase is evaporated and the residue is treated with warm ethyl acetate (20 ml), whereupon most of the morphinandienone *(8)* crystallizes. Further amounts of *(8)* can be obtained from the mother liquor by filtration through a short Al_2O_3 column (activity III) and elution of the leading zone. Total yield after recrystallization from CH_2Cl_2/ethyl acetate = 860 mg (34%).

1,4-Dihydro-1,4-bis-(trichlorosilyl)pyridine from Si_2Cl_6 and Pyridine[**]

By *D. Kummer* and *H. Köster*[*]

During our investigation of reactions of organic nitrogenous bases with Si—Si compounds[1,2] we have prepared a stable dihydropyridine derivative, namely, 1,4-dihydro-1,4-bis(trichlorosilyl)pyridine *(1)*.

The compound is formed when Si_2Cl_6 reacts with pyridine in the molar proportions 1:1 in benzene.

(1)

[*] Prof. Dr. D. Kummer and Dipl.-Chem. H. Köster
Institut für Anorganische Chemie der Universität
75 Karlsruhe 1, Englerstrasse 11 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

^{1}H-NMR study of the course of the reaction shows that the 1,2-isomer is not formed as intermediate. Compound *(1)* can be separated in a state of purity by distillation of the reaction mixture. It is a colorless liquid that is stable in absence of air and moisture. The composition and structure are proved by the analytical findings: b.p. 69 °C/0.17 torr; ^{1}H-NMR (AA'LL'X type), $H_{2(6)}$ $\tau = 3.77$, $H_{(3,5)}$ $\tau = 5.24$, H_4 $\tau = 6.98$, $J_{2,3} = J_{5,6} = 8.2$ Hz; $J_{2,4} = J_{6,4} = 0.8$ Hz, $J_{4,3} = J_{4,5} = 4.4$ Hz (in CCl_4); mass spectrum, molecule ion at $m/e = 344.808$. This reaction provides a new route to stable 1,4-dihydro-1,4-bis(silyl)pyridines about which little is known[3]. NMR studies have shown that other halodisilanes such as Si_2F_6 and $Cl_2(CH_3)Si—Si(CH_3)Cl_2$ also react with pyridine to give dihydropyridine derivatives.

At the same time the reaction is a new type of base-catalyzed reactions of Si—Si compounds with organic nitrogenous bases. In previous reactions the disilane disproportionated to monosilane and oligosilane, this being followed in many cases by formation of the base adduct[4]. This disproportionation occurs also as side reaction in the 1:1 reaction. It becomes evident by appearance of a white insoluble adduct $SiCl_4 \cdot 2$ pyr and cannot be wholly suppressed in favor of formation of *(1)*. The yield of *(1)* is thus dependent on the reaction conditions.

Experimental:

A solution of pyridine (0.55 g, 7.0 mmol) in benzene (30 ml) is dropped with stirring into one of Si_2Cl_6 (1.90 g, 7.1 mmol) in benzene (30 ml) at 25 °C. The mixture becomes yellow and a small amount of a white precipitate of $SiCl_4 \cdot 2$ pyr is formed. After an hour the mixture is filtered, the benzene is condensed from the solution, and the residue is fractionated under reduced pressure. The yield is 0.96 g of *(1)*. All operations must be conducted with complete exclusion of air and moisture.

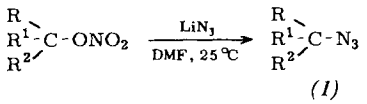
Preparation of Tertiary Alkyl Azides

By *Paul Margaretha, Sonja Solar*, and *Oskar E. Polansky*[*]



Very few syntheses of tertiary alkyl azides have been described in the literature[1]: *Pritzkow* and *Timm*[2] were able to obtain *tert*-butyl azide only in dilute cyclohexane solution; *Logothetis*[3] prepared 1,1-dimethyl-4-pentenyl azide from the corresponding alcohol and HN_3 in $CHCl_3$.

We have found a method that gives good yields of tertiary alkyl azides *(1)*, namely, treatment of alkyl nitrates with

[*] Prof. Dr. O. E. Polansky, Dr. P. Margaretha, and S. Solar
Max-Planck Institut für Kohlenforschung,
Abteilung Strahlenchemie
433 Mülheim, Stiftstrasse 34—36 (Germany)

[**] Above 200 °C the reaction mixture is sensitive to shock and is a high explosive.

lithium azide in dimethylformamide at room temperature[**].

(1)

	R	R^1	R^2	Yield (%)
(a)	CH_3	CH_3	CH_3	75
(b)	CH_3	CH_3	C_2H_5	67
(c) [3]	CH_3	CH_3	$-(CH_2)_2CH=CH_2$	70

The structure of the products was proved by NMR, IR, and mass spectroscopy.

Experimental:

The alkyl nitrate (0.1 mol)[4] and lithium azide (0.15 mol)[5] are stirred in dimethylformamide (50 ml) for 8 h at room temperature. *(1a)*, b.p. 72 °C, is obtained by direct distillation of the solution; the other, higher-boiling azides are isolated as follows: dilution of the solution with water (1 l), extraction with ether (3 × 50 ml), and drying of the ether phase; *(1b)* is distilled at atmospheric pressure (b.p. 104 °C); *(1c)* is distilled in a vacuum (b.p. 22—25 °C/2 torr) since it isomerizes to the corresponding triazoline at higher temperatures[3].

Structure of Ternary Copper(II) and Chromium(II) Fluorides

By *Hans Georg von Schnering, Bernhard Kolloch*, and *Alfons Kolodziejczyk*[*]

It was reported recently[1] that the structure of Sr_2CuF_6 involves square-planar and tetrahedral CuF_4 coordination but that structures of $SrCuF_4$, $CaCuF_4$, and $SrCrF_4$ involve only tetrahedral CuF_4 or CrF_4 coordination. This does not accord with results of our investigations of single crystals of Sr_2CuF_6 (greenish-blue), $SrCuF_4$ (bluish-green), $CaCuF_4$ (pale blue), and $BaCuF_4$ (colorless) that we obtained from melts (Pt crucibles) or by sintering (Ag bomb).

Sr_2CuF_6 crystallizes orthorhombically, and not tetragonally, in space group Bbam: $a=5.708(1)$, $b=5.708(1)$, $c=16.446(2)$ Å; $Z=2$. The symmetry could be established unequivocally. Atomic positions: Sr in 8(d) with $z=0.1621$, Cu in 4(b), F(1) in 8(e) with $x=0.2495$, F(2) in 16(g) with $x=0.6716$, $y=0.1749$, $z=0.0830$ ($R=9.5\%$ with 160 reflections *hkl*). The arrangement of Sr, Cu, and F(1) and the values of the F(2) parameters correspond with the data of *Hagenmuller et al.*[1], but, as a result of the change in symmetry, the Cu coordination found by us differs decisively from the reported value. Interatomic distances: Cu—F = 1.954 Å (4 ×), square planar; Sr—F = 2.469, 2.481, 2.484, 2.491 Å (each 2 ×), cubic.

$SrCuF_4$ and $CaCuF_4$ as well as $SrCrF_4$ crystals are of tetragonal $KBrF_4$ type, also with square-planar Cu(II) or Cr(II) coordination [$SrCuF_4$: $a=5.643(2)$, $c=10.672(5)$ Å; $CaCuF_4$: $a=5.377(2)$, $c=10.320(5)$ Å]. Here too the different findings of other authors[1] can be attributed to symmetry errors. Thus it was found for these three compounds that the X-ray intensities correspond to almost homometric pairs of structures, in which a decision between a tetrahedral and a square arrangement appears at first impossible, since the relative parameters of the F atoms depend on the zero point adopted for the metal lattice. However, the F parameter and thus the origin could be unambiguously established by the reflections *hkl* ($l=2n+1$). The compounds crystallize in the space group I4/mcm. Atomic positions: Sr, Ca in 4(a); Cu, Cr in 4(d); F in 16(l) with $x=0.1648$, $z=0.1230$ ($SrCuF_4$) or $x=0.1757$, $z=0.1281$ ($CaCuF_4$) or $x=0.1803$, $z=0.1240$ ($SrCrF_4$) ($R=6.6\%$, 6.2%, or 7.9%, respectively). Interatomic distances: Cu—F 1.858 or 1.880 Å (each 4 ×); Cr—F 1.980 Å (4 ×), Sr—F 2.506 or 2.496 Å (each 8 ×); Ca—F 2.349 Å (8 ×).

$BaCuF_4$, like $BaZnF_4$[2], is orthorhombic [$Cmc2_1$; $a=4.476$, $b=13.972$, $c=5.551$ Å; all atoms in 4(a) 0*yz* with (y; z) = Ba (0.1370; 0.000), Cu (0.4074; 0.0239), F_I (0.4812; 0.3365), F_{II} (0.3020; 0.2427), F_{III} (0.3291; −0.2454), F_{IV} (0.9321; 0.0350); with 440 reflections $R=8.1\%$]. However, a detailed consideration reveals distinct differences, particularly for the Cu—F distances [1.852, 1.872, 1.909, 2.018, and 2.265 (2 ×) Å]. The Ba atoms are surrounded by nine F atoms (Ba—F = 2.670 to 2.926 Å). In the structure of $BaCuF_4$ there is a (4 + 2) coordination whereas in the other fluorides the Cu atoms are bonded to only four F atoms. This possibly provides the reason for the differing colors. As shown by comparison with the analogous Ag(II) compounds[3], the $BaZnF_4$ type[2] and the Ba_2ZnF_6 type[4] are favored when the radii of the metals differ greatly; if this difference is small the $KBrF_4$ or Sr_2CuF_6 type is formed.

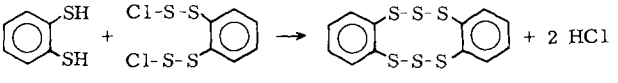
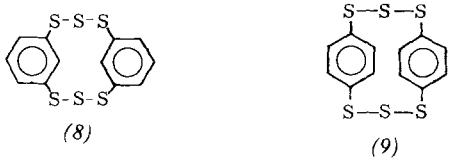
Synthesis of Bis(chlorodisulfanyl)benzenes and Hexathia[3.3]cyclophanes[1]

By *Franz Fehér, Klaus Glinka*, and *Franz Malcharek*[*]

We recently reported the synthesis of bis(chlorosulfanyl)-benzenes[2] and reaction of the 1,2-isomer with geminal dithiols[1]. We have now obtained the three isomeric bis-(chlorodisulfanyl)benzenes *(4)* to *(6)* by reaction of the benzenedithiols *(1)* to *(3)* with an excess of dichloromonosulfane.



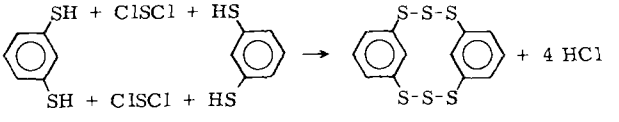
[*] Prof. Dr. F. Fehér, Dr. K. Glinka, and Dipl.-Chem. F. Malcharek
Institut für Anorganische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)



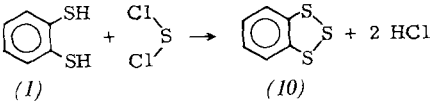
(1), *o* — *(4)*, *o*
(2), *m* — *(5)*, *m*
(3), *p* — *(6)*, *p*

Like the bis(chlorodisulfanyl)alkanes[3], the compounds *(4)* to *(6)* are obtained as orange-red oils that cannot be crystallized. The bis(chlorodisulfanyl)benzenes are stable at room temperature as pure substances and in solution. Satisfactory NMR and mass spectra could be determined for all three isomers. However, we were unable to obtain crystalline derivatives on treating *(4)* to *(6)* with piperidine, morpholine[2], or acetone[4].

When the dilution principle is applied, the bis(chlorodisulfanyl)benzenes react with the corresponding benzenedithiols to give the hexathia[3.3]cyclophanes. Hexathia[3.3]orthocyclophane *(7)* (dibenzo[*d*,*i*][1,2,3,6,7,8]hexathiocin) is thus formed from *(1)* and *(4)*, and we obtained hexathia[3.3]metacyclophane *(8)* and hexathia[3.3]paracyclophane *(9)* similarly as yellow crystals. All attempts to synthesize mixed hexathia[3.3]cyclophanes led to uncrystallizable oils with whose investigation we are currently occupied.



(1) *(4)* *(7)*



(8) *(9)*

Compounds *(8)* and *(9)* can also be obtained, but in poorer yield, by reaction of equimolar amounts of *(2)* or *(3)* with SCl_2. The corresponding reaction of *(1)* with

(2) *(2)* *(8)*

SCl_2 did not give the expected product *(7)*; only a viscous oil was isolated, which according to its mass spectrum has a molecular weight of 172[5]; it is probably trithia[3]orthocyclophane (1,2,3-benzotrithiole) *(10)*.

(1) *(10)*

Benzenedithiols:

The three isomeric benzenedisulfonyl chlorides can be converted into *(1)* to *(3)* by reduction with Zn/HCl[4, 6, 7]. This reaction can be effected appreciably more simply if red phosphorus and a catalytic amount of iodine in boiling glacial acetic acid are used as reducing agent[8]. *o*-Benzenedithiol *(1)* is, however, not obtainable in this new way, all attempts to do so giving only a solid polysulfide.

Bis(chlorodisulfanyl)benzenes:

A 0.005 M solution of *(1)* to *(3)* (0.71 g) in anhydrous carbon tetrachloride was dropped, with stirring, into freshly distilled dichloromonosulfane (70 ml) at −20°C, addition being complete in 15 min. The mixture is then allowed to come to room temperature and the volatile components are removed in a vacuum, leaving the products *(4)* to *(6)* as clear red oils in almost quantitative yield.

Hexathia[3.3]cyclophanes:

0.005 M solutions of *(4)* to *(6)* in CCl_4 (100 ml) and of *(1)* to *(3)* in diethyl ether (100 ml) are dropped separately but synchronously from two dropping funnels into ether (1.6 l) during 8 h. Removing the solvents then leaves *(7)* to *(9)* as crude products.

(8) and *(9)* can also be prepared by reaction of equimolar amounts of ethereal solutions of *(2)* and *(3)* with freshly distilled SCl_2 in ether in the above manner.

(7): flat yellow small rods from CS_2. Yield 57%. Softens at 160°C. Mol. wt. (mass-spectrographic) 344.

(8): yellow needles from ether. Yield 51% (15% by the second method). M.p. 116°C. Mol. wt. (mass-spectrographic) 344.

(9): small yellow leaflets from CH_2Cl_2. Yield 42% (6%). Softens at 150°C. Mol. wt. (mass-spectrographic) 344.

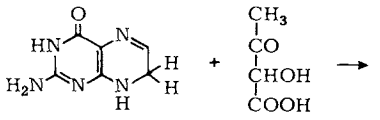
Structure of the Red Eye Pigments of the Fruit Fly *Drosophila melanogaster*[**]

By *Heinrich Schlobach* and *Wolfgang Pfleiderer*[*]



Viscontini et al.[1] reported the separation, from *Drosophila* eyes, of the red pigment fraction that absorbs at about 500 nm and made several proposals for the constitutions of the three components, drosopterin *(3)*, isodrosopterin *(4)*, and neodrosopterin. Since none of the monomeric dihydropterin structures postulated could explain the long-wave absorption, the relatively small R_F values, or the unusually high optical rotations of drosopterin and isodrosopterin, we suggested, in 1963, that these pigments might be dipteridinyl derivatives[2].

Starting from an observation by *Forrest*[3], we have found that reaction of 7,8-dihydropterin *(1)* and 2-hydroxy-3-

[*] Dipl.-Chem. H. Schlobach and Prof. Dr. W. Pfleiderer

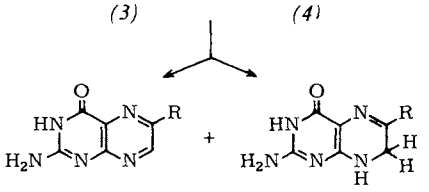
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

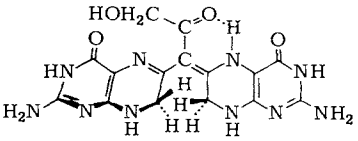


oxobutyric acid *(2)* gives a 70% yield of a mixture of *(3)* and *(4)*, both of which we obtained pure in 10% yield by one separation on a cellulose column. UV, ORD, CD, and fluorescence spectra, as well as chromatographic and electrophoretic comparison, revealed no difference between the natural and the synthetic materials.

(1) *(2)*

Drosopterin + Isodrosopterin

(3) *(4)*



(5), R = OH *(9)*, R = OH
(6), R = NH_2 *(10)*, R = CO_2H
(7), R = H
(8), R = CO_2H

Molecular-weight determinations in an ultracentrifuge gave values around 430±5%, as were found also by *Sugiura* and *Goto*[4]. Spectral comparison with dimeric xanthopterin derivatives had led first[5] to constitutions involving direct C—C linkage of two pterin rings at the 7 positions, but such structures were ruled out by the products obtained on alkaline hydrolysis of *(3)* and *(4)*. On treatment with 1% ammonia solution drosopterin and isodrosopterin gave a large number of hydrolysis products, among which xanthopterin *(5)*, 6-aminopterin *(6)*, pterin *(7)*, pterin-6-carboxylic acid *(8)*, 7,8-dihydroxanthopterin *(9)*, and 7,8-dihydropterin-6-carboxylic acid *(10)* could be identified by chromatographic comparisons and by determination of remission spectra. In addition, a yellow-fluorescing degradation product was found whose UV spectrum was related to that of sepiapterin[6]. 0.1 N NaOH or 4% Na_2CO_3 solution degraded *(3)* and *(4)* to the same products, except for *(6)*.

Elemental analyses of crystalline drosopterin and isodrosopterin gave molecular formulas $C_{15}H_{20}N_{10}O_6$ which, according to NMR spectra, must refer to stable dihydrates of the molecule $C_{15}H_{16}N_{10}O_4$; however, we have not yet succeeded in effecting dehydration without decomposition. NMR spectra of *(3)* and *(4)* are not very informative and are difficult to interpret, but from the spectra in [D_6]DMSO, CF_3COOH, and conc. H_2SO_4 it can be deduced that no methyl or methine group is present. Catalytic hydrogenation of *(3)* and *(4)* with Pt/H_2 causes decoloration and absorption of 2 equivalents of hydrogen, yielding products that have UV spectra characteristic of 5,6,7,8-tetrahydropterins[7].

The synthesis of drosopterin and isodrosopterin certainly involve a two-fold *Michael* addition of the methyl group of 2-hydroxy-3-oxobutyric acid to the azomethine function of *(1)* since the latter is readily accessible to nucleophilic attack[8], and this is followed by dehydrogenation and decarboxylation. This synthetic pathway together with the facts given above strongly suggest structure *(11)*.

Compounds *(3)* and *(4)* are not merely isomeric, but, contrary to earlier suppositions[9], are clearly shown to be enantiomers by the ORD[10] and CD spectra, which are symmetrical about the zero line. The very large optical activities of the two optical antipodes are due to an inherent-

(11)

ly dissymmetric chromophore, which in turn results from non-planarity of the two 7,8-dihydropterin rings caused by steric hindrance. The hindrance to free rotation around the C—C single bond at positions 6 is, as shown by a model, due mainly to the neighboring methylene groups, and the steric effects are so great that it has not yet been possible to interconvert *(3)* and *(4)* by thermal isomerization. So far as we know, the red eye pigments drosopterin and isodrosopterin thus constitute a new class of atropisomeric natural pigments.

Monothioformic Acid[1]

By *Gerhard Gattow* and *Rudolf Engler*[*]

The existence of monothioformic acid HCOSH has been signaled in the literature[2].—The free acid is formed on treatment of Na[HCOS] or K[HCOS] (prepared by hydrolysis of phenyl formate with NaHS or KHS) with 18% HCl and it can be distilled from the solution in a vacuum at −5 °C.

The pale yellowish acid (m.p. −68 °±1 °C, $d_4^{20}=1.34\pm0.02$ g/ml, $n_D^{20}=1.4880\pm0.0005$, $K_a=9\times10^{-3}$ in H_2O), which polymerizes to $[HCOSH]_x$ even at 30 °C, is very readily soluble in $CHCl_3$ and CH_2Cl_2 but less so in water. $[HCOSH]_x$ dissolves almost only in aqueous sodium hydroxide and then with partial disproportionation to $[HCO_2]^-$ and $[HCS_2]^-$[3]. In the mass spectrum of $[HCOSH]_x$ there appear, besides the molecular ion at $m/e=62$, the disproportionation products at $m/e=46$ (HCOOH) and 78 (HCSSH)[4] in the ratio 1:1, together with small amounts of $[HCOSH]_2$ but no trimeric unit[4].

[*] Prof. Dr. G. Gattow and Dipl.-Chem. R. Engler
Institut für Anorganische Chemie und Kernchemie der Universität
65 Mainz, Joh.-Joachim-Becher-Weg 24 (Germany)

Aqueous solutions of the $[HCOS]^-$ ion and of the monomeric acid show visible and UV absorptions at 211 and 247 nm and additionally at 223 nm respectively. The ^{1}H-NMR spectrum[5] of HCOSH contains two singlets at $\delta_{C-H}=10.18$ and $\delta_{S-H}=4.66$ ppm. The singlet in the ^{1}H-NMR spectrum of the $[HCOS]^-$ ion [measured in D_2O against sodium 2,2,3,3-tetradeuterio-3-(trimethylsilyl)propionate] at $\delta=10.64$ ppm fits well into the series of ions $[HCOO]^-$ at $\delta=8.42$ ppm and $[HCSS]^-$ at $\delta=12.22$ ppm[3].

IR spectrum of $[HCOS]^-$: 2810 (m), 1610 (m), 1525 (s), 1352 (m), 946 (m), 844 (s) cm^{-1}[6]. IR spectrum of HCOSH: 3310 (w), 2850 (m), 2540 (m), 1661 (s), 1339 (m), 1235 (w), 1160 (w), 1055 (w), 946 (s), 727 (s), 692 (s), and 666 (s) cm^{-1}[6].

From the UV and ^{1}H-NMR spectra it can be seen that HCOSH exists preferentially in the thiol form; only the weak bands in the IR spectrum at 3310 (O—H) and 1235 (C=S) cm^{-1} indicate very small amounts of acid in the hydroxy form. This is in accord with results obtained in the study of monothioacetic acid[7].

Both *S*- and *O*-esters of HCOSH can be prepared: the *S*-methyl ester is formed on reaction of Na[HCOS] with methyl iodide, and the *O*-ester on reaction of methyl orthoformate and H_2S in the presence of $ZnCl_2$ and hydroquinone[8]. ^{1}H-NMR spectrum of $HCO(SCH_3)$: $\delta_{CH}=10.12$ and $\delta_{CH_3}=2.34$ ppm; of $HCS(OCH_3)$: $\delta_{CH}=9.66$ and $\delta_{CH_3}=4.02$ ppm.

Bromine Isocyanate

By *Waldemar Gottardi*[*]

Birckenbach and *Linhard*[1] failed to obtain bromine isocyanate *(1)* by treating silver isocyanate with bromine in ethyl chloride at −80 °C, obtaining instead the acyclic dimer, *N,N*-dibromocarbamoyl isocyanate *(2)*.

(1)

(2)

Since monomeric chlorine isocyanate[2] and iodine isocyanate[3] can be prepared it appeared that it should be possible to synthesize *(1)* if the reaction conditions were chosen so as largely to exclude dimerization. This can be done by reaction of gaseous Br_2 with AgNCO at 150 °C and condensation of the resulting *(1)* at −196 °C.

$$Br_2 + AgNCO \xrightarrow[1\ torr]{150\,^\circ C} (1) + AgBr$$

Carbonyl isocyanate is formed as by-product, in proportions increasing as the temperature is raised; at 250 °C it is the main product.

Bromine isocyanate in the solid state (below −60 °C) forms yellow crystals that melt to a brown unstable liquid that dimerizes to crystalline *(2)* very rapidly. In this, *(1)* differs from chlorine isocyanate which dimerizes under these conditions to the cyclic 1,3-dichlorouretidinedione[4]. *(1)* is characterized, not only by this ready polymerization but also by extreme sensitivity to moisture; the cyanic acid formed on hydrolysis can be detected by IR spectroscopy. Purification of *(1)* is accompanied by great losses because its volatility is comparable with that of cyanic acid and of bromine $[HCNO \geqslant (1) \geqslant Br_2]$ and because liquid *(1)* is unstable, so that *(1)* has in fact not been obtained completely free from bromine.

The IR spectrum of *(1)* (condensed on a KBr disk cooled in liquid N_2) showed bands in the 4000—400 cm^{-1} region at 3440 m, 2256 s, 2164 vs, 2120 ms, 1289 ms, 690 ms, 566 s, and 473 m cm^{-1}. Molecular weight (mass-spectrometric): 122.

Experimental:

A column (length 15 cm, ∅ 2 cm) of a finely ground (24 h) mixture of AgNCO (prepared according to[5]; 40 g) and roasted quartz powder (20 g) is pre-heated for 12 h at 200 °C; gaseous bromine (taken from a trap cooled at −45 °C) is passed at 1 torr in a dynamic vacuum through this column while it is heated at 150 °C. The reaction products are condensed at −196 °C. *(1)* can be largely purified by several fractional recondensations in the temperature range −45 to −85 °C.

Trisboranephosphite and Tetrakisboranephosphate Ions

By *Erwin Mayer*[*]

Oxyacids of non-metals and their ions show a surprising chemical resemblance to compounds in which the oxygen is replaced by an isoelectronic BH_3 group[1]. Boranecarbonyl, H_3BCO, and the boranecarbonate ion, $[H_3BCO_2]^{2-}$, react similarly to CO_2 and CO_3^{2-}. Of the analogs of phosphorus-oxygen ions, the bisboranephosphite ion *(1)* which is isoelectronic with hypophosphite is already known[2–4]:

$$H_3P \cdot BH_3 + BH_4^- \longrightarrow [H_2P(BH_3)_2]^- + H_2$$

(1)

[*] Dr. W. Gottardi
Institut für Anorganische und Analytische Chemie der Universität
A-6020 Innsbruck, Innrain 52a (Austria)

[*] Dr. E. Mayer
Institut für Anorganische und Analytische Chemie der Universität
A-6020 Innsbruck, Innrain 52a (Austria)

The two hydrogen atoms of *(1)* that are bonded to phosphorus react no further with BH_4^- because of their low acidity. Stepwise removal of both these protons is, however, possible by reaction of *(1)* with *n*-butyllithium; trisboranephosphite *(2)* and tetrakisboranephosphate *(3)*, which are isoelectronic with, respectively, phosphite and phosphate, are then formed by subsequent addition of diborane:

$$[H_2P(BH_3)_2]Li + n\text{-}C_4H_9Li + 0.5\ B_2H_6 \rightarrow [HP(BH_3)_3]Li_2 + C_4H_{10}$$
(2)

$$[HP(BH_3)_3]Li_2 + n\text{-}C_4H_9Li + 0.5\ B_2H_6 \rightarrow [P(BH_3)_4]Li_3 + C_4H_{10}$$
(3)

The reaction must be carried out stepwise: adding first 2 mol of *n*-butyllithium per mol of $[H_2P(BH_3)_2]Li$ and then adding one mol of diborane does not lead to formation of *(3)*.

The compounds *(2)* and *(3)* are sparingly soluble in diethyl ether but soluble in dimethoxyethane and in acetonitrile; thus the $LiBH_4$ formed as by-product can be separated by extraction with ether.

Compounds *(2)* and *(3)* are crystalline salts that dissolve in water without decomposition and are oxidized by air. Solvated salts crystallize from concentrated solutions in dimethoxyethane.

Compound *(2)* was isolated in a pure state and was characterized by analysis and by its ^{1}H-NMR spectrum, but *(3)* was obtained only together with *(2)* and $LiBH_4$ as impurities.

The ^{1}H-NMR spectrum of *(2)* in D_2O consists of two groups of signals. A 1:1:1:1 quartet at $\tau = 9.57$ is formed by coupling of the BH_3 protons with ^{11}B ($J_{B-H} = 86$ Hz). A doublet at $\tau = 8.18$ is formed by coupling of the PH proton with ^{31}P ($J_{P-H} = 274$ Hz). The two doublet components are further split, by coupling with the nine equivalent protons bonded to boron, into a decet with the expected intensities ($J_{H-H} = 6$ Hz). The ^{1}H-NMR spectrum of *(3)* consists of a 1:1:1:1 quartet at $\tau = 9.58$ ($J_{B-H} = 86$ Hz).

In the series $H_3P \cdot BH_3$, $[H_2P(BH_3)_2]^-$, $[HP(BH_3)_3]^{2-}$ the increasing negative charge on the complex causes increased shielding of the protons bonded to phosphorus ($\tau = 5.69$[5], 6.90[6], and 8.18, respectively). However, the chemical shifts of the BH_3 protons alter only slightly: $\tau = 9.47$[5], 9.57[6], 9.57, and 9.58, respectively, for $H_3P \cdot BH_3$, $[H_2P(BH_3)_2]^-$, $[HP(BH_3)_3]^{2-}$, and $[P(BH_3)_4]^{3-}$.

Experimental:

$[HP(BH_3)_3]Li_2$: $[H_2P(BH_3)_2]Li$ (8.17 mmol) was dissolved in ether and treated at −196 °C with an equivalent amount of *n*-butyllithium, then allowed to warm to room temperature and stirred for 2 h. A white precipitate was formed. Then B_2H_6 (4.08 mmol) was condensed in at −196 °C. After this mixture had warmed to room temperature the solvent was pumped off and the residue was washed several times with diethyl ether, after which the $[HP(BH_3)_3]Li_2$ was extracted with dimethoxyethane; the yield was 46% (3.79 mmol). The salt melts at 200 °C with slow evolution of hydrogen.

$[P(BH_3)_4]Li_3$: Preparation and working up were as for $[HP(BH_3)_3]Li_2$, but $[HP(BH_3)_3]Li_2$ was used as starting material. The yield was 37%. All the reactions were carried out with exclusion of oxygen.

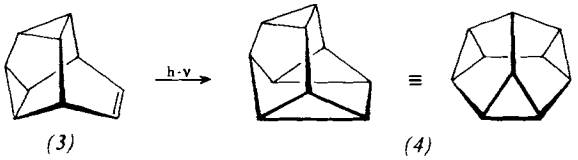
Hexacyclo[4.4.0.0^{2,4}.0^{3,9}.0^{5,7}.0^{8,10}]decane, a Bridged *cis*-Trishomobenzene

By *Armin de Meijere*, *Dieter Kaufmann*, and *Otto Schallner*[*]



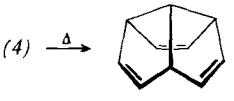
The importance of homoconjugation within the concept of homoaromaticity[1] has recently been demonstrated for *cis,cis,cis*-1,4,7-cyclononatriene *(1)*[2].

(1)

(2)

The valence tautomer of this molecule, a trishomobenzene *(2)* which arises formally by cyclopropanation of the three double bonds of benzene, has not yet been prepared[3]. We now report a synthesis of the hydrocarbon *(4)* which has the structural characteristics of *(2)*[4].

Irradiation studies with the two isomeric bishomobarrelenes[5] have shown that it is the *anti*-isomer that preferentially undergoes photochemical rearrangement[6], and this finding accords with results in the homobornadiene system[7]. By analogy it was to be expected that on irradiation of the bridged bishomobarrelene *(3)*[8] a rearrangement would occur which could lead to the hydrocarbon *(4)*.



(3) *(4)*

Compound *(3)* was therefore irradiated at −10 °C in pentane under nitrogen for 48 h[9]. Following the progress of the reaction by gas chromatography showed that after this time some 70% of the starting material had reacted. The reaction mixture contained, besides *(3)* (53%) and three as yet unidentified components (together *ca.* 17%), a 30% yield (by gas chromatography) of a compound which according to its mass spectrum had a molecular weight of 130[10].

[*] Dr. A. Meijere, D. Kaufmann, and O. Schallner
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

This product could be obtained pure (isolated yield *ca.* 5%) by preparative gas chromatography under mild conditions. Its ^{1}H-NMR spectrum (100 MHz, CCl_4) showed it to have the structure of a hexacyclo-[4.4.0.0^{2,4}.0^{3,9}.0^{5,7}.0^{8,10}]decane *(4)*. The spectrum contained three signals in the intensity ratio 3:1:6 [$\tau = 7.16$ (m, 3H), $\tau = 7.42$ (m, 1H), $\tau = 8.37$ (m, 6H)]. The neighborhood relationship of the three types of protons was proved by double resonance experiments: irradiation at $\tau = 7.16$ converted the signal at $\tau = 8.37$ into a singlet, and irradiation at $\tau = 8.37$ converted the signal at $\tau = 7.16$ into a singlet and that at $\tau = 7.42$ into a quadruplet. The molecular formula $C_{10}H_{10}$ was confirmed by high-resolution mass spectrometry. The IR spectrum is in accord with the proposed structure (point group C_{3v}). The compound shows only end absorption in its UV spectrum.

'Diademane' *(4)* forms highly volatile, colorless crystals melting at 96–97 °C (with rearrangement). When warmed it rearranges smoothly to triquinacene *(5)*[11] (half-reaction time *ca.* 60 min at 90 °C), which was identified by means of its characteristic ^{1}H-NMR spectrum. This $-[_\pi 2_s + _\pi 2_s + _\pi 2_s]$-cycloreversion, which is an allowed con-

(5)

certed process according to the principle of conservation of orbital symmetry[12], is perhaps here made extra easy by the considerable ring strain which, according to models, appears to be present in the molecule.

Attempts to determine this strain energy and to study the electronic interaction between the three cyclopropane rings of *(4)* by means of photoelectron spectroscopy are in progress.

Trifluoroarsine as Ligand for a Complex [**]

By *Jörn Müller* and *Klaus Fenderl* [*]

Trifluorophosphine forms many stable complexes with transition metals in their lower oxidation states[1], but the only arsenic trihalide complexes described previously are the trichloro compounds $Mo(CO)_{6-n}(AsCl_3)_n$ where $n = 1$ to 3[2,3].

We now report the preparation of the first trifluoroarsine complex *(1)*, by ligand exchange, starting from the cycloheptene compound $C_5H_5Mn(CO)_2C_7H_{12}$ which has been described as very labile[4].

$$C_5H_5Mn(CO)_2C_7H_{12} + AsF_3 \xrightarrow[3h]{C_6H_6,\ 55\,^\circ C} C_5H_5Mn(CO)_2AsF_3 + C_7H_{12}$$

(1)

After removal of the solvent, excess of AsF_3, and liberated cycloheptene, dicarbonylcyclopentadienyl(trifluoroarsine)-manganese(I) *(1)* was isolated as yellow crystals in 30 to 40% yield by sublimation in a vacuum at 20 °C (m.p. 64 °C, dec.). The compound is very sensitive to hydrolysis and not particularly stable thermally. It is formed also by UV irradiation of a benzene solution of $C_5H_5Mn(CO)_3$ *(2)* in presence of AsF_3, but separation of *(1)* and *(2)* did not prove possible.

In the mass spectrum (50 eV) of *(1)* the following characteristic fragments appeared alongside the molecular ion $C_5H_5Mn(CO)_2AsF_3^+$ ($I_{rel.} = 6.3$): $C_5H_5Mn(CO)_2AsF_2^+$ (0.6), $C_5H_5Mn(CO)AsF_3^+$ (1.7), $C_5H_5Mn(CO)AsF_2^+$ (2.5), $C_5H_5MnAsF_3^+$ (5.7), $C_5H_5MnAsF_2^+$ (3.7), $C_5H_5Mn(CO)_2^+$ (7.8), $C_5H_5MnCO^+$ (18), $C_5H_5Mn^+$ (78), MnF^+ (5.4), and Mn^+ (100). The relatively high intensities of the $C_5H_5Mn(CO)_n^+$ ions indicate that AsF_3 must be similar to CO ligands in its donor-acceptor strength[5].

The symmetrical AsF stretching vibration of complexed AsF_3 lies at 694 cm^{-1} (KBr disk); it is shifted by only 11 cm^{-1} towards longer wavelengths relative to its position for the free ligand.

Table 1. Spectroscopic properties of the AsF_3 and PF_3 complexes *(1)* and *(3)*.

	ν_{CO} (cm^{-1})	k_{CO} (mdyn/A)	$\tau_{C_5H_5}$	*IP* (eV)
(1)	2006 1953	15.83	4.90	8.34
(3)	1996 1938	15.63	5.02	8.24

To obtain more information on the donor-acceptor behavior of AsF_3 ligands we have compared a few spectroscopic properties of *(1)* with those of the PF_3 complex $C_5H_5Mn(CO)_2PF_3$ *(3)*[5]. Table 1 contains the ν_{CO} vibrations (*n*-hexane) and CO valence force constants (calculated according to [6]), as well as the chemical shifts of the ^{1}H-NMR signals of the C_5H_5 ligands (measured in deuterioacetone) and the ionization potentials (measured by the electron impact method), for *(1)* and *(3)*. The values show that the electron density on the central Mn atom is lower in *(1)* than in *(3)*. Thence it follows that AsF_3 has an elec-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

tron-attracting action still more powerful than that of the already powerful acceptor PF_3.

This remarkable property can be ascribed at least in part to the weaker donor character of AsF_3 than of PF_3 ligands. The ionization potentials measured by us amount to 11.7 eV for PF_3 and 12.8 eV for AsF_3; the lone pair involved in the ionization thus lies at a lower energy level in the case of AsF_3.

The fluorine atoms in *(1)* can be very readily exchanged in nucleophilic reactions, even at room temperature, without simultaneous attack on the Mn—As bond. If a benzene solution of *(1)* is treated with ethanol at 20 °C, a very rapid reaction affords

$C_5H_5Mn(CO)_2AsF_2OC_2H_5$

together with a small amount of

$C_5H_5Mn(CO)_2AsF(OC_2H_5)_2$

The PF_3 complex is inert under these conditions.

New Method of Preparing Iminosulfur Oxydifluorides

By *Wolfgang Sundermeyer, Achim Roland*, and *Konrad Seppelt*[*]

It is not always possible to prepare a desired iminosulfur oxydifluoride by the method most used hitherto[1], namely, reaction of an NH_2 group with sulfur oxide tetrafluoride. This is due, not only to the relatively great stability of OSF_4, but also to the facts that the relevant amines in part do not react and in part do not exist, the latter particularly in those cases where two or more NH_2 groups should be attached to one atom. As a result, compounds containing more than one $NS(O)F_2$ group attached to one atom are accessible only by special reactions and indeed are known only in three cases, namely, $F_2C(NSOF_2)_2$, $OC(NSOF_2)_2$[2], and mercury bis(iminosulfur oxydifluoride), $Hg(NSOF_2)_2$ *(1)*[3].

Synthesis of the last-mentioned compound and its reactions with polar halides have now provided a method of introducing the $NSOF_2$ group, by means of which a large number of new iminosulfur oxydifluorides can be prepared. For instance, phosphorus trichloride reacts with *(1)* in methylene chloride to give phosphorus tris(iminosulfur oxydifluoride) *(2)*.

$$3\ \underset{(1)}{Hg(NSOF_2)_2} + 2\ PCl_3 \rightarrow 2\ \underset{(2)}{P(NSOF_2)_3} + 3\ HgCl_2$$

Similarly, arsenic tris(iminosulfur oxydifluoride), $As(NSOF_2)_3$ *(3)*, is obtained from arsenic trichloride, and silicon tetrachloride can be converted into silicon tetrakis(iminosulfur oxydifluoride) *(4)*, which is to date the most highly substituted compound of this type.

$$2\ \underset{(1)}{Hg(NSOF_2)_2} + SiCl_4 \rightarrow \underset{(4)}{Si(NSOF_2)_4} + 2\ HgCl_2$$

It is evident that alkyl- and aryl-substituted inorganic halides can be subjected to this reaction. For example, all the members of the series $(CH_3)_xSi(NSOF_2)_{4-x}$ have been prepared [*(4a)* to *(4c)*], and it could thus be shown that compounds with more than two $NSOF_2$ groups are also stable, although the Si—N bond itself usually reacts with S—F compounds.

The most interesting example so far of an iminosulfur oxydifluoride of a Group 6 B element is thionyl bis(iminosulfur oxydifluoride) *(5)* which is formed by the reaction of *(1)* with thionyl chloride. Analysis and the mass spec-

trum lead to the conclusion that this is a homogeneous substance, but spectroscopic findings, in particular the ^{19}F-NMR spectrum, indicate the presence of isomers.

$$Hg(NSOF_2)_2 + OSCl_2 \rightarrow OS(NSOF_2)_2 + HgCl_2$$
(1) *(5)*

Experimental:

The imide *(1)* (15 g) is suspended in methylene chloride (*ca.* 50 ml; partially dissolved; 5 g/100 ml), treated with the appropriate inorganic halide [slight excess of *(1)*; if necessary, diluted with CH_2Cl_2), and heated under reflux for 5—10 h. The products are obtained analytically pure by fractional distillation in a vacuum.

All the products are water-clear liquids of unexpectedly high stability and low sensitivity to hydrolysis. Boiling points are similar to those of the corresponding bromides (differences *ca.* +7 °C per $NSOF_2$ group). Physical data of the products, whose structures are proved by elemental analysis and by mass spectra, are shown in Table 1[4].

As we have also shown in previous experiments[3, 5], the OSN, F_2SN, and $F_2S(O)N$ groups can be regarded as resembling pseudohalides although the corresponding anions have not yet been isolated—but we have obtained all the *N*-haloiminosulfur oxydifluorides $XNSOF_2$ (X = F, Cl[6], Br, and I[7]). If this view is accepted, compound *(5)* is the first stable thionyl pseudohalide (cf. [8]).

CONFERENCE REPORTS

Porous Plastic Foils as Functional Models of Excitable Nerve Membranes

By *U. F. Franck* and *S. Searty*[*]

Membranes are among the most important functional building units of living organisms, where they undertake physicochemical processes that are essential for life. Such processes are, above all:

a) separation of materials;
b) energy transfer;
c) transfer and processing of information.

In spite of the variety of these processes they can be referred in principle to two elementary properties of membranes, namely:

a) selectivity with respect to permeability;
b) capability to couple in all the processes that can occur in the neighborhood of the membrane.

Selectivity leads to effects such as electric potentials, mechanical pressure *etc.* On the other hand, coupling mechanisms enable membranes to exhibit excitability, rhythmic behavior, and propagation phenomena.

Such phenomena play an important part in rapid transfer of information in nerves, muscles, and sensorial organs.

Coupling mechanisms of this kind are observed also with non-living membranes, *e. g.*, with porous plastic foils (PVC, polystyrene, *etc.*). The kinetic behavior of such membranes, which contain traces of fixed ions in their pores, is analogous to that of excitable nerve membranes, and all the fundamental electrophysiological properties such as excitability, accommodation, action potential, and rhythmic behavior can be demonstrated with these materials.

Mechanism of the Radiolysis of Cyclohexane

By *Horst Herler*[*]

Cyclohexane is very useful in studying reactions that are initiated by ionizing radiation since it contains only one kind each of C—C and C—H bonds. The three main products—hydrogen, cyclohexene (C_6H_{10}), and bicyclohexane ($C_{12}H_{22}$)—are formed by rupture of C—H bonds. Absorption of ionizing radiation leads to excited and ionized cyclohexane molecules and to electrons. Experimental results and theoretical considerations both indicate that most of these electrons are thermalized whilst still in the Coulomb field of their parent ion. A few electrons, however, have sufficient energy to escape from the parent ion, the number of these amounting to *ca.* 0.10 electron per 100 eV. The lifetime of ions and electrons up to their recombina-

[*] Dipl.-Chem. H. Herber
Institut für Radiochemie der Technischen Universität München
8046 Garching (Germany)

tion is important for the possibility of ion-molecule reactions. According to *Freeman* and *Fayadh*[1] recombination occurs in $10^{-10\pm1}$ s.

The amounts of the main products of radiolysis of cyclohexane are increased by addition of small quantities of organic compounds such as benzene, anthracene, and pyrene; the amounts of all three products are maximal at *ca.* 10^{-4} mole of aromatic compound per liter.

$$C_6H_{12} \rightsquigarrow C_6H_{12}^+ + e^- \quad (1)$$

$$C_6H_{12} \rightsquigarrow C_6H_{12}^* \quad (2)$$

$$C_6H_{12}^+ + e^- \rightarrow C_6H_{12}^* \quad (3)$$

$$C_6H_{12}^* \rightarrow C_6H_{10} + H_2 \quad (G \approx 1.2) \quad (4)$$

$$C_6H_{12}^* \rightarrow C_6H_{11}^\cdot + H_{kin}^\cdot \quad (5a)$$

$$H_{kin}^\cdot + C_6H_{12} \rightarrow C_6H_{11}^\cdot + H_2 \quad (5b)$$

$$C_6H_{12}^+ + C_6H_{12} \rightarrow C_6H_{13}^+ + C_6H_{11}^\cdot \quad (6a)$$

$$C_6H_{13}^+ + e^- \rightarrow C_6H_{11}^\cdot + H_2 \quad (6b)$$

$$C_6H_{12}^+ + C_6H_{12} \rightarrow C_{12}H_{22}^+ + H_2 \quad (7)$$

$$C_{12}H_{22}^+ + e^- \xrightarrow{M} C_{12}H_{22} \quad (8)$$

$$C_6H_{12}^* \rightarrow C_6H_{11}^\cdot + H_{th}^\cdot \quad (G \approx 1.5) \quad (9)$$

$$C_6H_{11}^\cdot + C_6H_{11}^\cdot \rightarrow C_6H_{10} + C_6H_{12} \quad (G \approx 1.8) \quad (10)$$

$$C_6H_{11}^\cdot + C_6H_{11}^\cdot \rightarrow C_{12}H_{22} \quad (G \approx 1.8) \quad (11)$$

Aromatic compounds can scavenge electrons and species having a positive charge; in such reactions, the mobility of electrons may make attachment of electrons more effective than charge transfer, and this increases the lifetime of cyclohexane radical cations. As a result, product formation by ion-molecule reactions should have greater importance, since the efficiency of product formation by ion-molecule reactions is greater. Indications of this in the case of cyclohexane are provided by investigations with electron scavengers, for the probability of ion-electron recombination is about 0.7 if that for ion-molecule reactions is set = 1.

Electrolytic Reduction of Higher Metal Halides in Methanol

By *H.-J. Seifert*[*]

VCl_3 can be reduced electrolytically in methanolic solution exactly as in an aqueous medium. Green $VCl_2 \cdot 2CH_3OH$ can be isolated on concentration of the violet solution of V^{2+}. Treatment with organic complexing reagents such as pyridine, acetonitrile, tetrahydrofuran (THF), dimethylformamide (THF), *etc.*, permits preparation of complexes containing these ligands with removal of the methanol. Similar results are obtained with VBr_2. Methanolic solutions of VI_2 can be obtained by the precipitation reaction:

$$VCl_2 + 2KI = VI_2 + 2KCl\downarrow$$

Iodine compounds of quadrivalent vanadium can be prepared in the same way, specifically those of types $[VOL_5]I_2$, where L = DMF or DMSO, and $VOI(OCH_3) \cdot 3$ pyridine.

[*] Prof. Dr. H.-J. Seifert
Institut für Anorganische und Analytische Chemie der Universität
630 Giessen, Ludwigstrasse 21 (Germany)

Complexes of VCl_2 can be divided into two groups: 1. Compounds of type $VCl_2 \cdot 4L$, which are blue or violet and have temperature-independent magnetic moments of ~3.8 BM. 2. Compounds of type $VCl_2 \cdot 2L$, which are green and have magnetic moments lower than the spin-only values and strongly temperature-dependent. X-ray and reflection spectra of the hydrates show that group 1 compounds contain isolated octahedra, whereas in compounds of group 2 the octahedra are fourfold edge-connected $[VCl_{4/2}L_2]$. Solution spectra show that VCl_2 is completely dissociated in all solvents.

$TiCl_4$ can be reduced in methanol to the trivalent state. A solvate $TiCl_3 \cdot 4CH_3OH$ can be isolated from such solutions, and can also be made to exchange its methanol. Thus blue $TiCl_3 \cdot 3DMF$ and green $TiCl_3 \cdot 2DMF$ have been isolated. $TiCl_3$ exists in solution as a 1:1 electrolyte: $[TiCl_2(DMF)_4]^+Cl^-$.

WCl_6 is reduced to the quadrivalent, or further to the trivalent, state in dilute solution containing HCl. Chloro complexes $[N(CH_3)_4]_2WCl_6$ and $[N(CH_3)_4]_3W_2Cl_9$ can be isolated from the reduced solutions. On reduction of concentrated solutions a green, acid-insoluble precipitate was formed, of composition $W_2Cl_4(OCH_3)_4(CH_3OH)_2$; single-crystal photographs show a W—W distance of 2.47 Å and, at the present stage of the study, indicate union by oxygen bridges. A compound $[N(CH_3)_4]_2W(OCH_3)Cl_5$ can be isolated from the mother liquors. The monomeric compounds of W^{IV} have magnetic moments of ~1.6 BM, but the dimeric ones are almost diamagnetic with 0.26 BM.

The Combustion of Elemental Boron in Air; A Thermodynamic Study[1]

By *Eberhard Büchner* and *Ingo Husmann*[*]

Boron is used as an additive for improving the performance of rocket propellants; however, it does not suffice to energize a propulsive unit having only one thrust chamber. Satisfactory results have been obtained only with an experimental set-up having two thrust chambers[2] in which the boron is heated in the first chamber and then burnt in the second in the presence of air.

On combustion of boron in air a predominantly gaseous, homogeneous or heterogeneous mixture is formed whose composition can be determined by a newly derived method of calculation. In the case of heterogeneous mixtures the separation of boric anhydride as condensed phase is taken into consideration. Elemental (unchanged) boron occurs as condensed phase in mixtures containing little oxygen. Further calculations were carried out for the case of boron nitride being present as condensed phase.

The above mentioned method of calculation takes into consideration the possible formation of the following species during combustion of boron in air: B, B_2O_3, B_2O_2, BO_2, BO, BN, N_2, N, NO, O_2, and O. If sufficient air is supplied to the system, considerable amounts of BO_2 are formed in addition to the main product of combustion B_2O_3.

[*] Doz. Dr. E. E. Büchner and Dipl.-Ing. I. Husmann
Institut für Flugantriebe der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

In an heterogeneous system with liquid B_2O_3 the accompanying gaseous phase is, in accord with the supposition of the method of calculation (sliding equilibrium), in equilibrium with gaseous boron oxides, so that the proportion of liquid B_2O_3 can be calculated by difference.

If the total composition is known then the enthalpies of the combustion products at given temperatures and pressures are also known, and an enthalpy-entropy curve can be plotted after calculation of the respective entropy values. The thrust chamber isobars each intersect the isenthalpic lines of the calorific value of the mixture at a point from which the isentropically assumed expansion occurs.

The intersection of these isentropic lines with the expansion isobar (*e.g.* 1 bar under ambient conditions) afford the enthalpy difference which is convertable into kinetic energy and from which the emission velocity of combustion products after having passed the nozzle of the second thrust chamber can be calculated. For a mixture of boron + air, $\lambda = 1.1$[3], the discharge rate for an expansion ratio 20:1 is 1893 m/s, the thrust chamber temperature under a pressure of 20 bar is 2717 °K, and the expansion temperature (20:1) 2070 °K.

Organic Reactions in the Plasma of Glow Discharges

By *Harald Suhr*[*]

When electrons with an energy of a few eV impinge on organic molecules, the latter are partially altered and rearrangements, fragmentations, or, at high pressures, bimolecular processes can occur. Some of these processes have long been known but were not suitable for preparative purposes because in previous work the substances were largely destroyed with formation of low-molecular gases and tar. A procedure has now been worked out by which electron impact processes can be utilized preparatively. The apparatus is similar to that for vacuum distillation in which a high-voltage or high-frequency glow discharge is produced in the vapor space. Simple laboratory apparatus (with about 100 watts) produce 0.1–1 mole of product per kWh.

A number of reactions occur particularly well in the plasma. They were worked out first with the parent compounds, but can be extended to substituted compounds. High yields are obtained in dehydrogenating dimerization, *e.g.*, of benzene to biphenyl and of methylated aromatic compounds to 1,2-diarylethanes. Rearrangement of alkyl aryl ethers and *N,N*-dialkylanilines to respectively, alkylphenols and *N*-alkyl derivatives of alkylated anilines, and *cis-trans*-isomerizations, are also among favored plasma reactions. Among eliminations, particularly good yields are obtained in decarbonylations, *e.g.*, of benzophenone to biphenyl, of camphor to trimethylbicyclohexane, and of naphthols to indenes, and in decarboxylations of carboxylic acids and their anhydrides to hydrocarbons. Dehydrogenations with ring closure, *e.g.*, the reaction of diphenylamine to give carbazole, and of hydroxybiphenyl to give dibenzofuran illustrate interesting possible applications of plasma chemistry.

Plasma reactions take place mainly through radicals. The electrons transfer the energy of the external field to the molecules. This yields excited molecules, ionized molecules, or negative ions, which give the products either directly or after decomposition to radicals. Different mechanisms are found with individual classes of compound; some resemble those of pyrolysis, others those of photolysis or the processes in the mass spectrometer, and yet others have no relation to known mechanisms.

The reactions of organic molecules in the plasma offer interesting preparative possibilites. Several processes have been worked out on a laboratory scale; application on an industrial scale is certainly a possibility.

New Sulfides of Metals

By *Welf Bronger*[*]

If the binary metal sulfides are considered in relation to their positions in the Periodic Table it is noticeable that very marked changes in properties occur near where the transition metals are inserted. The structure shows this particularly clearly: thus sulfides crystallize in salt-like structural types when derived from metals that have empty or completely filled d shells—to a smaller extent this is true also for metals with half-occupation—whereas sulfides of metals with partially filled d shells crystallize in structural arrangements where metal-metal interaction can be recognized. In this connection it appeared interesting to synthesize and study the structure of sulfides that contain both a main-group metal and a transition metal in ternary compounds.

Sulfides with heavy alkali metals on the one hand and with d elements on the other, were prepared by reactions in a melt under an inert gas. The starting materials were mixtures of alkali-metal carbonates or sulfides, transition metal, and sulfur. The following phases were thus synthesized:

$K_2Mn_3S_4$	$KFeS_2$		$K_2Ni_3S_4$
$Rb_2Mn_3S_4$	$RbFeS_2$	$Rb_2Co_3S_4$	$Rb_2Ni_3S_4$
$Cs_2Mn_3S_4$	$CsFeS_2$	$Cs_2Co_3S_4$	$Cs_2Ni_3S_4$
			$K_2Pd_3S_4$
			$Rb_2Pd_3S_4$
			$Cs_2Pd_3S_4$
			K_2PtS_2

X-ray investigation of single crystals showed that the ferrates have a structure characterized by edge-junction of the sulfur tetrahedra surrounding the iron atoms[1, 2] to form chains. In the manganates and cobaltates these sulfur polyhedra were joined by edges two-dimensionally into layers[3, 4]. In the palladates[5] and platinate[6] (the structure of the nickelate is still unknown) the ligands surround the transition metal in a planar arrangement, and the sulfur rectangles are joined by sides to give here too either layers or chains. In general, the structures of these compounds

[*] Prof. Dr. W. Bronger
Institut für Anorganische Chemie der Technischen Hochschule
51 Aachen, Templergraben 55 (Germany)

permit differentiation into sulfides with a greater similarity to alloys and the more salt-like complex compounds of the transition metals. The more metallic structural units are distinctly separated from the ionic ones by formation of layers or chains.

Problems of High Speed Liquid Chromatography

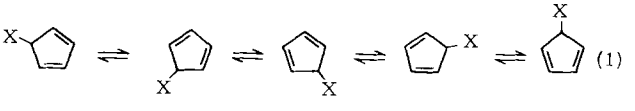
By *Heinz Engelhardt*[*]

The theoretical relations derived for gas chromatography are valid also for liquid chromatography. However, the differences in the relative numerical values of the physical quantities (viscosity, diffusion coefficient, *etc.*) concerned in, for instance, the equation for zone spreading as a function of flowrate cause a shift in the relative influences of the various terms of this equation.

Thus the longitudinal diffusion term (the B term) has very little influence in liquid chromatography, since the rate of diffusion in the mobile phase is slower than in gases by a factor of 10^4. On the other hand, this same slow diffusion leads to preponderance of the term (the C_m term) for resistance to mass transfer in the mobile phase, namely that between the moving mobile phase between the particles and the stagnant mobile phase in the pores of the carrier. This band broadening can be overcome to some extent by decreasing the depth of the pores; this can be effected by decreasing the diameter of the particles ($<10\,\mu m$), since then the pore depth also becomes smaller, or by using thin-layer particles (porous layer beads) in which a thin porous surface layer ($\sim 1\,\mu m$) is placed on an inpenetrable core. This surface layer can be produced either by etching the surface of the particles, as in the carrier material Corning GLC 100 (Corning Glass Works, Corning, N. Y.) or by precipitating a thin porous layer of silica gel as in the carrier materials Corasil (Waters Assoc., Framingham, Mass.) and Zipax (Dupont, Wilmington, Del.). If the particle diameter is increased, then, in order to obtain the same flowrate, a higher pressure must be applied, the limits being set by the apparatus. Such particles were compared by observing the band broadening in relation to velocity (H. vs. velocity) and the number of effective plates/sec (measure of the speed of analysis).

The carriers differ in their loading capacity for the stationary phase. Surface-etched particles give sticky fillings even with light loading (0.4% of 3,3'-oxydipropionitrile), whereas the others can be much more heavily loaded (up to 2.6% of 3,3'-oxydipropionitrile) without appearing sticky. The number of effective plates/sec created is largest with Zipax. If, however, the difference in particle size is taken into account, Corasil and Zipax appear to be equal as regards the possible speed of analysis at equal pressure drop. Comparable values were obtained for the Corning glass beads only with substances that were very strongly retarded on the other carriers.

Corasil and Zipax are active adsorbents because a silica gel with a large specific surface area is used for the porous surface layer. This activity is evidenced in a variety of ways: The relative retention is a function of the amount of stationary phase on the support. The uncoated carrier adsorbs stationary phase from the solvent saturated with the stationary phase until a steady state is reached. Reproducible results cannot be obtained with loadings lower than that corresponding to this steady state. Only with the Corning glass beads are the values of relative retention independent of the amount of loading.



If all of the pores on a porous carrier are almost completely filled with stationary phase (*e.g.*, Porasil A with 100% w/w of 3,3'-oxydipropionitrile), band broadening in the stationary phase preponderates and lower plate heights are found for strongly retarded substances than for those eluted at the beginning. With these heavily loaded columns there is no reasonable loss of stationary liquid phase (using completely saturated eluants) due to mechanical erosion which limits the life of columns with porous layer beads. On these columns the sample size can be very large without overloading.

Cyclopentadienylboranes

By *Hans Grundke* and *P. I. Paetzold* (lecturer)[*]

σ-Cyclopentadienyl compounds XCp are subject to, *inter alia*, two types of equilibration, namely, valence tautomerism (1) and sigmatropic hydrogen shift (2):

When $X = R_2Al$ only reaction (1) is observed, when $X = R_3Si$ both reactions occur, but when $X = R_3C$ only reaction (3) takes place. How do cyclopentadienylboranes R_2BCp behave?

We prepared cyclopentadienyldiethylborane Et_2BCp *(1)* [and analogously diethyl(methylcyclopentadienyl)borane *(2)*] by reaction of chlorodiethylborane-pyridine with NaCp and subsequent removal of the pyridine by BF_3:

$$Et_2BCl\cdot Py \xrightarrow[-NaCl]{+NaCp} Et_2BCp\cdot Py \xrightarrow[-BF_3\cdot Py,\ -OEt_2]{+BF_3\ OEt_2} \underset{(1)}{Et_2BCp}$$

The by-way through the pyridine adduct is necessary since, in the presence of Lewis acids such as free Et_2BCl, *(1)* rapidly dimerizes by a Diels-Alder reaction; this dimeriza-

[*] Dr. H. Grundke and Prof. Dr. P. I. Paetzold
Institut für Anorganische Chemie der Technischen Hochschule
51 Aachen, Templergraben 55 (Germany)

tion occurs slowly at room temperature, but in one minute at 75 °C even in absence of a catalyst.

The ^{1}H-NMR spectrum of *(1)* contains signals with the following shifts from TMS (relative intensities in parentheses): $\tau = 0.7$ to -1.6 (10), -3.17 (2), -6.79 (2), and -7.50 (1); on general experience these signals can be ascribed to the two ethyl groups, a CH_2 group, and two olefinic CH groups. Reaction (1) is excluded by the CH_2 signal, and similarly isomer *(a)* in equilibrium (2) can be excluded. *(c)* is excluded because it is known that with boron the nuclear resonance frequency of *ortho*-ligands is lowered (*e.g.*, with compounds $C_6H_5BX_2$ and $C_6F_5BX_2$), so that the spectrum shows the existence of only one *ortho*-olefinic proton, as in *(b)*. Moreover, a CNDO-MO calculation[1] shows *(b)* to be about 7 kcal more stable than *(c)*.

The fission of the signals of two olefinic protons in the ratio 1:1 in the spectrum of *(2)* then accords with expectation.

The ^{1}H-NMR spectrum of the dimers of *(1)* contains signals for only two olefinic protons, at -6.35 and -6.55 ppm, together with signals of 28 other protons at higher shifts; hence follows that the two bulky boryl groups are bound to olefinic centers and, as expected, not to the junction centers of the cycloaddition. However, the diene components then cannot have structure *(b)* but must be *(c)*—an indication that there is an equilibrium between *(b)* and *(c)* in which the more stable *(b)* preponderates greatly.

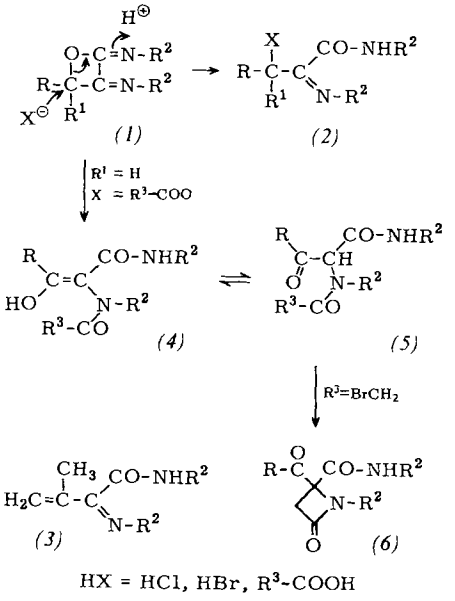
New Synthesis of Heterocycles by means of Isocyanides

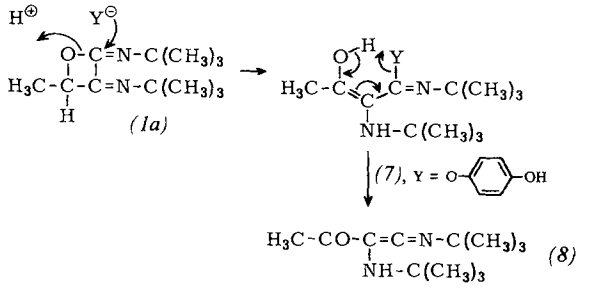
By *H.-J. Kabbe*[*]

Numerous aliphatic aldehydes and ketones, as well as aromatic aldehydes, react with isocyanides in the presence of catalytic amounts of boron trifluoride, to give 2,3-bis(alkylimino)oxetanes *(1)*[1]:



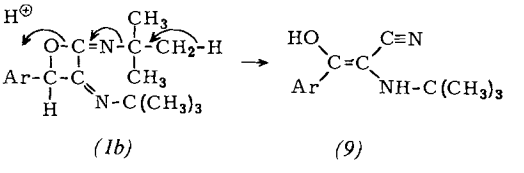
(1)

These oxetanes are remarkably stable both thermally and towards bases but can be cleaved by acids HX. This normally affords the β-addition products *(2)*, but occasionally unsaturated amides such as *(3)* are formed by isomerization[2].



When the oxetanes *(1a)* are derived from aldehydes their reaction with carboxylic acids leads to acyl migration and formation of α-(acylamino)-β-hydroxyacrylamides *(4)*; if bromoacetic acid is used as addend, hydrogen bromide is split off from the tautomeric keto form *(5)* and the β-lactam *(6)* is obtained[3].

Neutral, weakly acidic, or basic compounds HY add to *(1a)* only under the influence of an additional acid and



HX = HCl, HBr, R^3-COOH

then to the acyl-carbon, yielding compounds such as *(7)* (with hydroquinone/boron trifluoride). *(7)* easily splits off hydroquinone, giving the ketene imine *(8)*[4].

(8)

In the presence of approximately equimolar amounts of boron trifluoride, oxetanes *(1b)* prepared from aromatic aldehydes and *tert*-butyl isocyanide split off isobutene and pass into the cinnamonitriles *(9)*.

Rheological and Boundary Layer Problems in Printing

By *W. Kunz*[*]

All printing processes involve the transference of printing ink onto substrate and, at least in the classical processes—letterpress, offset, and gravure printing—interaction takes

[*] Dr. W. Kunz
Burda GmbH, Forschungsleitung
76 Offenburg, Postfach 360 (Germany)

place between liquids (printing inks) and solids (material to be printed on). These interactions are determined by the rheological properties of the liquids and by boundary-layer physical factors.

These interactions between different materials appear most decisive in the gravure process, in which a very low-viscosity printing ink is transferred from very small hollows that are etched to different depths. A problem arising in this process concerns the transference: the rate of transference is in the order of 2 milliseconds whereas all viscosity measurements—whether carried out with a rotation viscometer or with a cup viscometer—require seconds to minutes.

Two instruments have been developed for determining boundary-layer physical factors such as surface tension and contact angle *viz.* (i) an apparatus based on the bubble pressure method has been developed for the measurement of surface tension of the gravure inks, and (ii) a contact angle projector.

Curves which can be plotted for the wetting of printing material, and printing metals, with printing inks facilitate an interpretation of the failures in the printing process. With the aid of a special interference method, the behavior of the printing ink in a single etched hollow can be shown on a film[1]. Examination of the film showed that an exact impression of an individual hollow cannot be expected at the currently employed rates of printing with printing inks having the same rheological properties as those previously used in the profession.

Relations between the Structural Elements and the Flow Behavior of Polymers and their Solutions

By *Martin Hoffmann*[*]

For viscosities η at low and high shear forces τ, critical shear forces τ_w of the structural viscosity, Young's moduli in the rubbery region of the relaxation behavior of entangled polymers, concentrations φ^+, above which entanglements form a network, and intrinsic viscosities $[\eta]$ one may formulate quantitative relations to structural parameters (molecular-weights M and their distribution, concentration, chemical nature, especially the molar volume V_g of the structural unit) or at least qualitative ones (different types of branching, distribution of chemical composition, sequences of like structural units, heterogenity as a consequence of phase separation, crystallinity). For $M < M_c$ viscosity at high temperatures is proportional to $M^{1.45}/V_g^3$. This applies also to $\eta_{\tau=\infty}$ for $M > 2\,M_c$, whilst $\eta_{\tau=0}$ is proportional to $M^{3.45}/V_g^7$. τ_w is proportional to φ^2/V_g^2.

These relations and their dependence on concentration are connected by the molecular weight M_c between entanglements, M_c being proportional to V_g^2/φ. In mixtures of chemically similar molecules having the same free volume and the molecular weights M_1 and M_2 an average M_v should be used in the above relations instead of φ_2 and M_2. The exponent a in M_v has a value of 0.72 for $M_v < 2\,M_c$ and a value of 0.87 for $M > 2\,M_c$. This leads directly to the concentration dependence of viscosity of such mixtures. $[\eta]$ is proportional to $(M_2/M_1)^{0.59} - 1$, which means that the end-to-end distance h is $h \sim M^{0.59}$ in contrast to assumptions used hitherto.

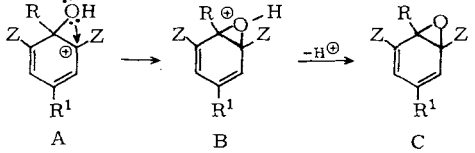
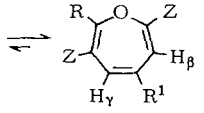
A New Route to the Oxepin System

By *Anton Rieker*[*]

In the presence of acid, cyclohexadienediols of type *(1)* (R = CH_3, C_6H_5, *p*-tolyl, *m*-tolyl, *p*-$(CH_3)_2NC_6H_4$; R^1 = C_6H_5, *tert*-butyl, mesityl, *p*-$CH_3OC_6H_4$; Z = CH_3, C_6H_5, *tert*-butyl) split off water, and the group R of the mesomeric cation (A) migrates to afford the 2-R-substituted cyclohexadienones *(2)*.



(1) A



(2) *(3)*

When limited amounts of trifluoroacetic acid in methanol and low temperatures are used, then provided that Z = $C(CH_3)_3$, the compounds *(2)* can be isolated in substance [NMR spectra, AB system of the protons H_A/H_B with characteristic coupling (2.5 Hz); IR, intense carbonyl bands at 1650—1670 cm^{-1}; UV, λ_{max} = 305 to 330 nm, ε = 2500 to 7000, with usually a pronounced shoulder around 380 nm (n—π^* transtition of the C=O group)]. Using an excess of acid leads to fragmentation of the dienones *(2)* in which Z = *tert*-butyl, which affords the phenols *(3)* in yields exceeding 90% together with isobutene.

If R and Z are chosen so that the dienones *(2)* are sterically hindered (R = substituted phenyl; Z = *tert*-butyl) and the nucleophilicity and thus the migration aptitude of the group R is reduced below that of $(CH_3)_2NC_6H_4$ (namely, R = C_6H_5, *p*-tolyl, or *m*-tolyl, and R^1 is as above), then it

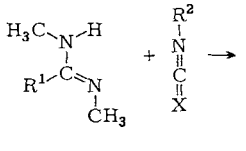
A B C

X = *(4)*

[*] Doz. Dr. A. Rieker
Chemisches Institut der Universität
74 Tübingen, Wilhelmstr. 33 (Germany)

could be shown by NMR spectroscopy that acidic rearrangement of the diols *(1)* gave a new intermediate X, which on further treatment with acid was converted into *(2)* and finally into *(3)*. When the experimental conditions were chosen suitably, the compounds X could also be isolated in crystalline form [for $R=p\text{-}CH_3C_6H_4$, $R^1=p\text{-}CH_3OC_6H_4$, $Z=C(CH_3)_3$ in CH_3OH at $-50°C$ with 1 equiv. of CF_3COOH in 70% yield; m. p. 115 °C].

NMR spectra (coupling of the β,γ protons: 0.7—1 Hz), IR spectra (C=C vibration at *ca.* 1635, ether bands at 1080 cm^{-1}), and UV spectra ($\lambda_{max}=310$—330 nm, $\varepsilon=3300$—8000) confirm the oxepin structure *(4)* of X. Further structural proof is provided by the ^{13}C Fourier transform NMR spectra. Photolysis of the oxepins *(4)* leads to 2-oxabicyclo[3.2.0]hepta-3,6-dienes. The oxepins must have been formed by 1,2-migration of the hydroxyl group of (A) to give (B) and deprotonation of (B) to the benzene epoxide (C).



Lecture at Tübingen on February 12, 1971 [VB 291 IE]

Hydrogen Bridges with Nitrogen as Donor and Acceptor

By *Gerhard Schwenker*[*]

The products obtained on reaction of amidines with heterocumulenes (isocyanates or isothiocyanates) differ according to the type of substitution of the amidine, the reactivity of the heterocumulene, and the experimental conditions[1]. Amidines with hydrogen on N-1 give dipolar molecules *(1)* which afford carbamoyl- *(2a)* or (thiocarbamoyl)-amidines *(2b)* by proton transfer.

In *(2a)*, but not in *(2b)*, there are strong intramolecular hydrogen bridges recognizable by the bathochromic shift of the NH bands to around or below 3000 cm^{-1}. The cause is as follows: In an unperturbed system of five sp^2-hybridized atoms the donor and the acceptor approach one another to within about 2.4 Å in the conformers able to form intramolecular hydrogen bridges. This requires an extremely strong, symmetrical bridge, which however is unlikely. Thus one must assume appreciable widening of the relevant angle and as a consequence a closer approach of the peripheral substituents. The range of existence of these conformers is thus limited by the steric demands of the peripheral substituents and size of the angle broadening required, the latter decreasing with increasing polarity of the N—H bond and thus with increasing bond enthalpy. In *(2b)* the sulfur atom, which is larger than the oxygen atom, causes such great steric hindrance that one of the other conformers is thermodynamically more favorable.

(1a), X = O; *(1b)*, X = S *(2a)*, X = O; *(2b)*, X = S

Experimental findings support this view. Systematic increase in size of the substituents R^1 in *(2a)* (H, CH_3, C_2H_5) first increases the bathochromic shift of the NH bands, this being explained by the compression of the bridge; with iso-C_3H_7 and *tert*-C_4H_9, however, there is no longer any indication of hydrogen bridges, so that for *(2a)* with substituents of this size a conversion into another conformation is assumed. Increasingly strongly electron-attracting substituents R^2 (CH_3, C_6H_5, *p*-C_6H_4Cl, *p*-$C_6H_4NO_2$) permit closer approach of the donor and acceptor owing to increase in the N—H bond moment; this can be recognized by increasing bathochromic shifts of the NH bands. In the sulfur compounds *(2b)*, however, even C_6H_5 as R^2 leads to such an increase in the acidity of the N—H bond that the proton transfer *(1)*→*(2)* no longer occurs, and exchange reactions take place instead.

Improved Determinations of Intermolecular Potentials

By *Bernhard Schramm*[*]

A knowledge of intermolecular potentials is an essential basis for statistical calculations of macroscopic properties of matter. Information about potential energy curves can be gained, *e.g.* from the temperature dependence of the virial coefficients or transport phenomena of gases and from measurements of the scattering cross-section with the aid of molecular beams.

Let us assume that the potential energy between two particles depends only on their mutual separation. It must be made up of a long-range attractive component (responsible for condensation of gases) and a repulsive component that is effective at shorter ranges (responsible for separation in crystal lattices). Superposition of the two components gives a potential energy minimum having coordinates r_{min} and ε. The best known expression for potential energy that contains only these two free parameters is the Lennard-Jones potential:

$$\varphi(r)=\varepsilon[(r_{min}/r)^{12}-2(r_{min}/r)^6]$$

On suitable choice of r_{min} and ε, it can be used for calculation of the second virial coefficient and transport parameters over wide ranges of temperature. However, more accurate measurements uncover deviations that cannot be accounted for by experimental error. Moreover, two different sets of potential parameters are required for calculations of virial coefficients and transport factors respectively.

These drawbacks can be lessened by permitting free choice of a third parameter such as the power of the repulsive term. This leads to the $n-6$ potentials by way of the equation:

$$\varphi(r)=\varepsilon/n-6[6(r_{min}/r)^n-n(r_{min}/r)^6]$$

[*] Dr. B. Schramm
Physikalisch-chemisches Institut der Universität
69 Heidelberg 1, Im Neuenheimer Feld 1 (Germany)

An increase in n makes the potential curve steeper and the potential trough thus narrower. Nevertheless, this modification of the potential curve does not suffice to accurately and simultaneously reproduce the virial coefficients and the viscosity in a large temperature range. For such a satisfactory representation it is necessary to be able to vary the long-range attractive forces and the repulsive forces independently of each other.

Table. Potential parameters and potential for argon.

Potential parameters r_{min} (Å)	ε/k[a] (°K)	Potential
3.84	119	Lennard-Jones 12-6 potential
3.77	148	11-6/24-6 potential
3.67	153	*Klein* and *Hanley*, 11-6-8 potential [1]
3.757	147.7	*Barker* and *Pompe* [2]
3.81	138	*Dymond* and *Alder* [3]

[a] k = Boltzmann's constant.

This condition is fulfilled if the intermolecular potential for distances $r \leqq r_{min}$ (to the left of the potential minimum) is described by a different $n-6$ potential from that used for $r \geqq r_{min}$. In this way the available data for the virial coefficients and the viscosity of argon can be reproduced within the limits of experimental accuracy by an 11-6/24-6 potential (*i.e.* $\varphi(r)$ = 11-6 potential for $r \leqq r_{min}$, $\varphi(r)$ = 24-6 potential for $r \geqq r_{min}$). In the Table the potential parameters found are compared with those considered for argon by other authors within the past few years. It clearly appears that the intermolecular potential of argon has a deeper trough and a steeper course of the attractive portion than the 12-6 potential. Molecular beam measurements afford $r_{min} = 3.7 \pm 0.2$ Å and $\varepsilon/k = 147 \pm 3$ °K[4].

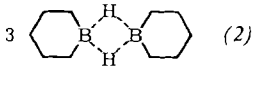
SELECTED ABSTRACTS



One-step preparation of nitriles from carboxylic acids is possible by a new method described by *J. Lücke* and *R. E. Winkler*. The acid (1 mole) is heated for one hour with amidosulfuric acid (1.5–2 mole) and urea (1–1.5 mole). Yields are good. For example, *o*-chlorobenzoic acid affords the nitrile in 85–90% yield; with urea alone the yield amounts to *ca.* 50%; with amidosulfuric acid alone it is about 7%. / Chimia *25*, 94 (1971) / –Ee.

[Rd 339 IE]

Bis(perhydroborin) *(2)* **and** ***B*-alkylperhydroborins** have been prepared by *H. C. Brown* and *E.-I. Negishi via* a simple new route. 1,5-Bis(perhydroborin-1-yl)pentane *(1)* reacts rapidly with borane at 25 °C to give bis(perhydroborin) *(2)*. The starting material *(1)* is obtained by hydroboration of

(1)

(2)

1,4-pentadiene with borane and subsequent thermal isomerization. *(2)* reacts with olefins at 25 °C to give *B*-alkylperhydroborins in excellent yield. If these compounds are required only as intermediates it is unnecessary to isolate the bis(perhydroborin) or the *B*-alkylperhydroborins. / J. Organometal. Chem. *26*, C67 (1971) / –Kr.

[Rd 340 IE]

Tetrakis(pentacarbonylmanganese)uranium, the first complex to have a bond between uranium and a transition metal, has been obtained by *R. L. Bennett, M. I. Bruce*, and *F. G. A. Stone*. Solutions of sodium pentacarbonylmanganate and uranium tetrachloride in THF, which had turned deep red on standing at room temperature for 3 h, afforded a 50% yield of an orange powder that proved to be pure $U[Mn(CO)_5]_4$. It is extremely sensitive to air and decomposes at 180 °C. / J. Organometal. Chem. *26*, 355 (1971) / –Ee.

[Rd 341 IE]

Use of ferrate(VI) ion as a new selective oxidizing agent is reported by *R. J. Audette, J. W. Quail*, and *P. J. Smith*. K_2FeO_4 rapidly oxidizes primary amines and alcohols to aldehydes and secondary alcohols to ketones at room temperature. Double and triple bonds, aldehyde groups, tertiary alcohol- and amine functions are not affected. The reaction must be carried out in an aqueous, strongly basic medium. Yields are moderate to good and no by-products are formed. Formation of aldehydes from primary amines is explained by hydrolysis of imine intermediates. / Tetrahedron Lett. *1971*, 279 / –Kr.

[Rd 342 IE]

Silylammonium compounds have been obtained by *R. E. Highsmith, J. R. Bergerud*, and *A. G. MacDiarmid*. Whereas treatment of silylamines with protonic acids usually leads to Si—N bond cleavage, reaction with $HCo(PF_3)_4$ and $HCo(CO)_4$ below 0 °C results in protonation of the amino group. $(CH_3)_2N—Si(CH_3)_3$ gave $[(CH_3)_2N(H)Si(CH_3)_3]^+ [Co(PF_3)_4]^-$ *(1)* and the tetracarbonylcobaltate *(2)* respectively. This compound could also be obtained from $(CH_3)_2NH$ and $(CH_3)_3SiCo(CO)_4$. Compound *(1)* sublimes at about 80 °C in vacuum. Compound *(2)* decomposes at room temperature to give darkly colored products. / Chem. Commun. *1971*, 48 / –Ee.

[Rd 346 IE]

Evidence for the existence of a "silylenoid" species in the *trans*-$PtCl_2[(C_6H_5)_3P]_2$-catalyzed disproportionation of

pentamethyldisilane *(1)* has been found by *K. Yamamoto, H. Okinoshima,* and *M. Kumada.* The "dimethylsilylene" formed by α-elimination inserts into Si—H bonds to give homologs of *(1)*.

$$(CH_3)_3Si{-}Si(CH_3)_2H \xrightarrow[\text{complex}]{Pt} \sum CH_3[Si(CH_3)_2]\,H \quad (n=1-6)$$
(1)

Further support for this concept comes from the reaction of *(1)* with tolan in the presence of the platinum complex

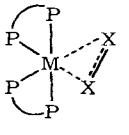
$$2\,(CH_3)_3Si{-}Si(CH_3)_2H + 2\,C_6H_5{-}C{\equiv}C{-}C_6H_5$$
(1)
$$\downarrow\ PtCl_2[(C_6H_5)_3P]_2$$
$$2\,(CH_3)_3SiH + \text{(2)}$$

(2): a 1,4-disila-2,5-cyclohexadiene bearing H_3C, CH_3, H_5C_6, C_6H_5 substituents on the two silicon atoms.

which yields the disilacyclohexadiene derivative *(2)*. / J. Organometal. Chem. *27*, C31 (1971) / –Kr.

[Rd 343 IE]

Incorporation of S_2 and Se_2 units into rhodium and iridium complexes has been accomplished by *A. P. Ginsburg* and *W.E. Lindsell.* Under the conditions mentioned the complexes *(1)* and *(2)* gave the new compounds *(3)–(5)*:



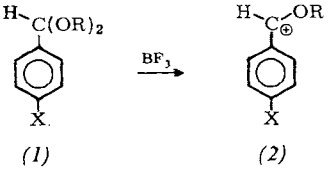
$$[Ir(dppe)_2]Cl + S_8 \xrightarrow[C_6H_6/CH_2Cl_2]{25\,^\circ C,\ 16\ h} [Ir(S_2)(dppe)_2]Cl$$
(1) *(3)*

$$[Ir(dppe)_2]Cl + Se_8 \xrightarrow[CH_2Cl_2]{20\,^\circ C,\ 72\ h} [Ir(Se_2)(dppe)_2]Cl$$
(1) *(4)*

$$[Rh(dmpe)_2]Cl + S_8 \xrightarrow[C_6H_6/THF]{25\,^\circ C,\ 16\ h} [Rh(S_2)(dmpe)_2]Cl$$
(2) *(5)*

$dppe = (C_6H_5)_2P{-}CH_2{-}CH_2{-}P(C_6H_5)_2$
$dmpe = (CH_3)_2P{-}CH_2{-}CH_2{-}P(CH_3)_2$

(3) and *(4)* are air-stable, *(5)* is hygroscopic. Structures having π-bonded S_2 and Se_2 units were deduced from the

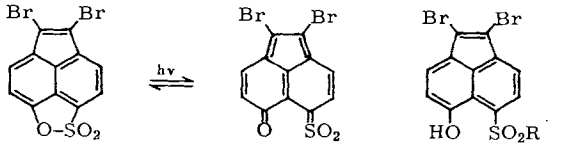


M = Rh, Ir
X = S, Se

NMR and IR spectra. Corresponding O_2 complexes are already known. / Chem. Commun. *1971*, 232 / –Ee.

[Rd 344 IE]

Stable arylalkoxycarbonium ions have been directly observed by *M. Rabinovitz* and *D. Bruck.* Treatment of acetals of type *(1)* with BF_3 in $CDCl_3$ at room temperature affords a stable, deeply colored, clear solution. The ionic nature of the dissolved product *(2)* was established by NMR spectroscopy. Charge delocalization plays an important role in stabilization of the carbonium ion. / Tetrahedron Lett. *1971*, 245 / –Kr.



(1) *(2)*

R = CH_3, C_2H_5
X = H, CH_3, OCH_3

[Rd 345 IE]

5,6-Dibromoacenaphthyleno[5,5a,6-cd]-1,2-oxathiol 2,2-dioxide *(1)*, a precursor of the potential sulfene *(2)*, has been synthesized and studied by *S. T. Weintraub* and *B. F. Plummer.* Irradiation of *(1)* in anhydrous methanol (Hanovia 450-W lamp, Pyrex filter) at room temperature gave the sulfonic ester *(3)*. Compound *(3)* could also be

(1) *(2)* *(3)*, R = OCH_3; *(4)*, R = OH; *(5)*, R = –N⬠

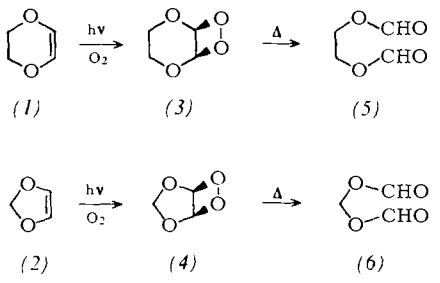
prepared from *(1)* and CH_3O^-/CH_3OH. The acid *(4)* was obtained, after dissolution of the brown precipitate in water, from a methanol solution of *(1)* that had been kept in the dark for two weeks. Compound *(1)* reacts immediately with pyrrolidine (purple coloration) to give *(5)*. The authors interpret these and other findings in terms of the intermediacy of the sulfene *(2)*. / J. Org. Chem. *36*, 361 (1971) / –Ee.

[Rd 347 IE]

Esters of hypophosphorus acid, which were hitherto unknown, have now been prepared by two Russian research groups. *I. F. Lucenko, M. V. Proskurina,* and *A. A. Borisenko* obtained the alkyl esters *(1)* from the dialkoxychlorophosphanes and trialkylstannane in ether or tetrahydrofuran at 30 °C.

$$(RO)_2P{-}Cl + R_3SnH \longrightarrow (RO)_2PH \quad \text{(1)}$$

Esters with a small group R (methyl, ethyl) were not isolable; they decomposed to give yellow, polymeric solids. In contrast, esters having large R could be isolated by vacuum distillation. They are colorless liquids that fume in air while undergoing oxidation with considerable evolution of heat.—*M. G. Voronkov* and *L. Z. Martur* prepared trialkylsilyl esters of hypophosphorous acid by reaction of ammonium hypophosphite with dialkylaminotrialkylsilane or hexaalkyldisilazane at temperatures of

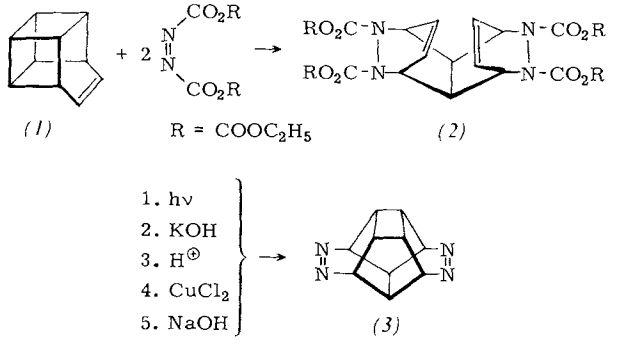


$$NH_4[PH_2O_2] + R_3Si{-}NR_2 \rightarrow HP(OSiR_3)_2 \quad \text{(2)}$$
$$NH_4[PH_2O_2] + R_3Si{-}NH{-}SiR_3 \rightarrow HP(OSiR_3)_2$$

about 100 °C. / Doklady Akad. Nauk SSSR *193*, 828 (1970); Zh. Obshch. Khim. *40*, 2135 (1970) / –Fa.

[Rd 348 IE]

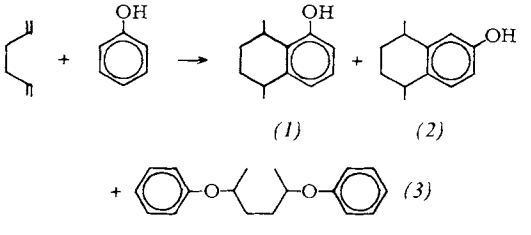
Formation of stable bicyclic dioxetanes on addition of singlet oxygen to 2,3-dihydro-1,4-dioxin *(1)* and 1,3-dioxole *(2)* has been observed by *A. P. Schaap.* Compounds *(1)* and *(2)* are cleaved photooxidatively (at –78 °C in presence of a sensitizer) to give ethylene diformate *(5)* and methylene diformate *(6)* respectively. The



intermediacy of the bicyclic dioxetanes *(3)* and *(4)*, which are relatively stable at room temperature, was proved by NMR spectroscopy. Their thermal decomposition at 60 °C

leads quantitatively to *(5)* and *(6)*. Decomposition is accompanied by chemiluminescence in presence of a fluorescing hydrocarbon such as 9,10-dibromoanthracene. / 161st ACS Nat. Meeting, Abstracts of Papers, ORGN 109, 1971 / -Ma.

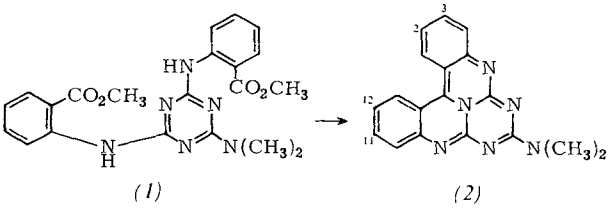
[Rd 349 IE]



2,3,7,8-Tetraazahexacyclo[7.4.1.0^{4,12}.0^{5,14}.0^{6,11}.0^{10,13}]tetradeca-2,7-diene *(3)*, a potential pentaprismane precursor, has been synthesized by *Kei-wei Shen* and *L. J. Winters*. Compound *(3)* was obtained from pentacyclo-[4.4.0.0^{2,5}.0^{3,8}.0^{4,7}]dec-9-ene *(1)* and diethyl azodicarboxylate *via (2)* in a multi-step synthesis. It is thermally very stable, having a halflife of 18 h at 240 °C. Flash vacuum

pyrolysis gives 9,10-dihydrofulvalene as sole identifiable product. / 161st ACS Nat. Meeting, Abstract of Papers, ORGN 88, 1971 / -Ma.

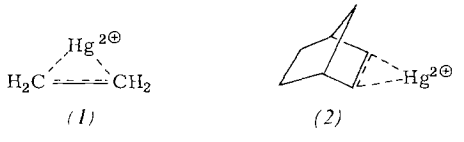
[Rd 350 IE]



Cycloalkylation of phenol with 1,5-hexadiene in CS_2 (molar ratio 4:1) in presence of BF_3-ether is reported by *J. M. Balquist* and *E. M. Degginger* to produce 5,6,7,8-tetrahydro-5,8-dimethyl-1- and -2-naphthol *(1)* and *(2)* respectively, besides 2,5-diphenoxyhexane *(3)*. Reaction

involves initial formation of 5-phenoxy-1-hexene and 2-(1-methyl-4-pentenyl)phenol which react further to give *(1)* and *(3)* respectively. The *p*-alkylated major product *(2)* is formed by reaction of phenol with the diether *(3)*. / 161st ACS Nat. Meeting, Abstracts of Papers, ORGN 140, 1971 / -Ma.

[Rd 351 IE]



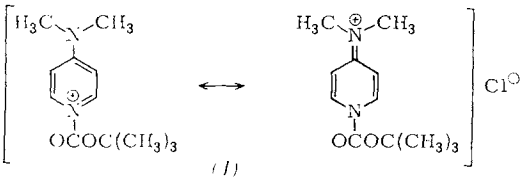
5,6,8,8b,9-Pentaazanaphth[3,2,1-*de*]anthracene *(2)*, a new ring system, has been obtained by *R. A. E. Winter* as product of a novel cyclization. Ring closure of the *s*-triazine derivative *(1)* in boiling acetic acid gave *(2)*, m.p. 302 °C, in 82% yield. Compound *(2)* has a conjugated 20 π-electron periphery and an additional lone pair on the central

nitrogen and may be regarded as the dibenzo analog of the [3,3,3]cyclazines. It is weakly basic, forms a monohydrochloride, and is dinitrated in the 2,12 or 3,11 positions. No deuterated product is formed in [D_4]acetic acid. / 161st ACS Nat. Meeting, Abstracts of Papers, ORGN 87, 1971 / -Ma.

[Rd 352 IE]

Stable mercurinium ions have been observed for the first time by *P. R. Clifford*. Treatment of 2-methoxyethylmercury chloride with $FSO_3H/SbF_5/SO_2$ solution at −78 °C was shown by NMR spectroscopy to yield the ethylenemercurinium ion *(1)* alongside protonated methanol. Similarly, *exo-cis*-3-hydroxy-2-norbornylmercury ac-

etate was found to give norbornylenemercurinium ion *(2)*. Propylene-, ethylethylene-, and cycloalkylene-mercurinium ions were also studied. / 161st ACS Nat. Meeting, Abstracts of Papers, ORGN 150, 1971 / -Ma.



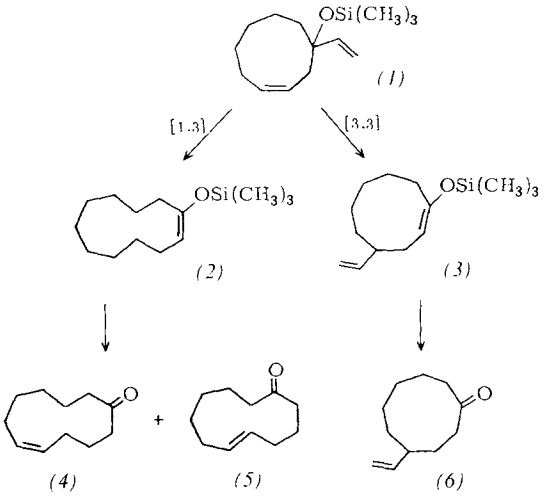
[Rd 353 IE]

S_3, thiozone, has been detected spectroscopically by *B. Meyer, T. Stroyer-Hansen, D. Jensen*, and *T. Oommen*. The species was found in molten sulfur at 300—700 °C, in red sulfur at 77 °K, in sulfur vapor at 450 °C/20 torr, and at 20 °K in noble gas matrices containing photolysis products of S_3Cl_2. All samples exhibited an absorption between 3600 and 4200 Å that can be assigned to thiozone, S_3. Sulfur vapor contains *ca.* 30%, liquid sulfur at 444 °C *ca.* 1%, the photolysis products of S_3Cl_2 in krypton at 20 °K *ca.* 90% of S_3. The species S_3 and S_4 are responsible for the red color of hot liquid sulfur. The presence of thiozone is the cause of the high reactivity of molten sulfur. / 161st ACS Nat. Meeting, Abstract of Papers, INOR 165, 1971 / -Ma.

[Rd 354 IE]

4-Dimethylamino-1-*tert*-butoxycarbonylpyridinium chloride *(1)* is suitable as a water-soluble reagent for *tert*-butoxycarbonylation of amines according to a report authored by

E. Guibé-Jampel and *M. Wakselman. (1)* is a stable compound that reacts with the Na salts of amino acids in aqueous solution. The reaction is very fast at 25 °C. The



(1)

BOC amino acids can be isolated in good yields by solvent extraction. Examples: *N*-BOC-glycine, 85% yield; *N*-BOC-glutamic acid, 70%; N^{ε}-BOC-N^{α}-Z-L-lysine, 80% (Z = benzoxycarbonyl); *N*-BOC-serine, 60%; *N*-BOC-glycine ethyl ester, 90%. / Chem. Commun. *1971*, 267 / –Ma.

[Rd 355 IE]

Ring expansion by two C atoms on "siloxy Cope rearrangement" to give good yields of unsaturated cyclic ketones is described by *R. W. Thies*. For example, the trimethylsiloxy derivative of *cis*-1-vinylcyclonon-3-en-1-ol *(1)* undergoes thermal rearrangement *via* [1.3] and [3.3] sigmatropic

shifts to give six trimethylsiloxy enol ethers [four and two *cis-trans* isomers of *(2)* and of *(3)* respectively] whose hydrolyses lead to the ring-expanded ketones *(4)* and *(5)* and to the cyclononanone *(6)* in high yields. In contrast to the "oxy Cope rearrangement", the reaction is accompanied by neither significant polymer formation nor cleavage to the β-hydroxy olefin. The trimethylsiloxy derivatives are readily obtainable in good yields. / Chem. Commun. *1971*, 237 / –Ma.

[Rd 356 IE]

The vibrational spectra (IR and Raman) of oxalyl bromide in all physical states were recorded by *J. R. Durig, S. E. Hannum*, and *F. G. Baglin*. Whereas solid $(COBr)_2$ occurs only in the *trans* form, the spectra of the liquid contain bands that can be ascribed to the *cis* form. The free enthalpy difference between *cis* and *trans* forms amounts to 2.9 ± 0.1 kcal mol^{-1}, the *trans* form being the more stable of the two. At room temperature, $10 \pm 5\%$ of the liquid is in the *cis* form. Approximate values of the potential function parameters describing the rotation about the C—C bond are given. / J. Chem. Phys. *54*, 2367 (1971) / –Hz.

[Rd 357 IE]

Oxidation of thiacyclobutane and thiacyclopentane with oxygen initiated by Q-switched laser pulses was investigated by *F. P. Miknis* and *J. P. Biscar*. Varying amounts of oxygen were added to a constant amount of liquid C_3H_6S or C_4H_8S in a spherical Pyrex bulb and the gaseous mixture exposed to one pulse from a Q-switched ruby laser. Each pulse had a peak power of over 100 MW and a duration of about 20 ns. With oxygen partial pressures between 100 and 1500 torr the pulses initiated a reaction accompanied by emission of radiation in the entire gas volume. The major products were CO_2, SO_2, and H_2O, in addition H_2S, COS, CS_2, and C_2H_2 were found in amounts depending on the oxygen partial pressure. It is probable that the reaction is started by multiphoton absorption: without Q-switching, *i.e.* if the pulse energy is released over a time interval about 10^3 times longer, no reaction occurred. / J. Phys. Chem. *75*, 725 (1971) / –Hz.

[Rd 358 IE]

BOOK REVIEWS

Radical Ions. Edited by *E. T. Kaiser* and *L. Kevan*. Interscience Publishers, a Division of John Wiley and Sons, New York–London 1968. 1st Edit., ix, 800 pp., numerous figures, bound, £14.00.

With its 13 selected topics from the realm of the chemistry and physical chemistry of radical ions, all of them written by eminent experts, this book offers a near comprehensive survey of the most important modern aspects of the chemistry of cation- and anion-radicals. The single unifying theme—how could it be otherwise—is ESR spectroscopy and the relevant orbital theory. Thus, anyone interested in, for example, the radicals formed by γ-irradiation, does not need to read the previous eight chapters. The book begins with a survey of electron spin densities and their determination from the coupling constants observable in the ESR spectra. The following chapters, however, are all concerned with more specific topics from the chemistry of organic radicals: metal ketyls and related radical ions, semidione radical anions, radical cations, the effect of substituents on the electron spin densities in aryl radicals and its theoretical importance, aromatic anion radicals, radical anions in Group IV elements, and sulfur-containing aromatic radical anions. The book ends with the structure of inorganic radicals, fragments from the irradiation of solid ions, and the electron spin resonance of complex ions of transition metals of the first row.

Each chapter is clearly written in the manner of an essay review and is provided with a good selection of references and graphic illustrations. There are no extensive historical introductions, but emphasis is placed on modern developments. Since a great variety of topics are covered, the reader may treat the work selectively. It is, infact, more a collection of excellent individual articles, rather than a coherent entity. The thoroughness and conciseness with which the individual chapters are written provide an excellent opportunity for readers, even those not directly concerned with this field, to gain an idea of the broad outlines of the rapidly developing radical chemistry. The book is indispensable for the library of any institute of chemistry or physical chemistry.

Karl Dimroth [NB 942 IE]

Phase Equilibria, Basic Principles, Applications, Experimental Techniques. By *A. Reisman*. Academic Press, New York–London 1970. xi, 541 pp., bound $27.50.

Until the mid-1950s, interest in phase equilibria was almost exclusive to metallurgists. Nowadays it calls to mind topics such as semiconductors, nuclear technology, space technology, zone melting, chemical transport reactions, and crystal growing. Whereas the metallurgist was mainly concerned with equilibria of condensed phases at normal pressure, both the gas phase and the influence of high pressures are nowadays becoming increasingly important.

This was one reason why the author wrote the present book. Another reason was that the existing books dealing with this topic use a phenomenological approach and mainly graphical representation at the expense of a more detailed mathematical treatment. New paths in this connection have been opened up by computers.

The thermodynamic basis is first elaborated and tested on the equilibria of one-component systems. In the subsequent binary and pseudobinary systems, the author considers only ideal model systems and deliberately omits such concepts as fugacity or activity. A systematic mathematical treatment of these ideal systems provides an understanding of the laws to which the observed types of phase equilibria are subject. In particular, numerous examples are given to show quantitatively the influence of parameters such as the melting points and heats of fusion of the pure components, dissociation or association in melts or solids, external pressure, and the vapor pressures of the components. The calculated model systems, for which graphs are constructed, are compared with examples from the literature. Even systems as unusual as those that exhibit continuous solid solution formation with a melting minimum are calculated on this basis. A few chapters dealing with ternary systems are then included. The picture is rounded off by examples of applications, such as purification by distillation or zone melting and chemical transport reactions.

The last, less successful, chapter deals with experimental methods. This discussion totally ignores some important methods, such as EMF or calorimetric measurements. Other aspects, such as the operation of a thermocouple, are discussed in too much detail.

In general, the book should facilitate the approach to the complex field of phase equilibria, and a great help here is the fact that it has been restricted to model systems. It is thus suitable both for the advanced student and for the practical worker who wish to forge ahead to the fundamental rules of phase equilibria.

Hans Rau [NB 947 IE]

The Theory of Adsorption and Catalysis. Physical Chemistry, A Series of Monographs. By *A. Clark*. Academic Press, New York – London 1970. 1st ed., x, 418 pp., bound DM 19.50.

The book presents a survey of the present position in the theoretical treatment of adsorption and catalysis. It is in the nature of things that theories based on models occupy the foreground in the first part, which is devoted to adsorption, whereas empirical relations receive more attention in the second part, which deals with catalysis.

A brief outline of the thermodynamics of adsorption serves as an introduction. This is followed by the discussion of localized and non-localized adsorption on homogeneous and heterogeneous surfaces for systems without interaction between neighboring particles and for systems with such an interaction. Adsorption isotherms, heats of adsorption, entropies of adsorption, *etc.*, are derived for these various adsorption systems with the aid of statistical thermodynamics.

One chapter each is devoted to the adsorption forces in physisorption, in chemisorption on metals, and in chemisorption on semiconductors. The dispersion and repulsion forces are discussed, as well as the analogy between chemisorption bonding and chemical bonding and the models for a quantum-mechanical treatment of chemisorption. The description of chemisorption on semiconductors is based mainly on the Hauffe and the Wolkenstein views. The first part of the book ends with a chapter on the kinetics of chemisorption.

The second part is introduced by an examination of the relation between adsorption and catalysis. The kinetics of heterogeneous catalytic reactions is considered separately for reactions in which diffusion plays no part and for diffusion-controlled reactions.

The "geometric factor" is discussed at length in connection with the effects of lattice structure, defects, and particle size on catalytic activity. The "electronic factor" is discussed for metals and semiconductors. A final chapter deals with the adsorbed species and their role in heterogeneous catalysis.

The extensive bibliographies cite references up to 1969.

This well-written summary of present-day knowledge will be a welcome aid to anyone who is concerned with the fundamentals of adsorption and catalysis.

Gerd Wedler [NB 951 IE]

Computer Programs for Chemistry. By *D. F. Detar*. W. A. Benjamin Inc., New York 1968. 1st ed., xx, 207 pp., bound $14.75.

The evaluation of experimental results or the calculation of molecular properties with the aid of computer programs is becoming increasingly important in chemistry. Whenever the considerations are based on a complicated calculation, it is advisable to use programs devised by personnel

who have familiarized themselves with programming problems.

The purpose of "Computer Programs for Chemistry" is to provide readymade programs that can be used directly for the solution of certain chemical problems or that can be incorporated into other programs after slight modification. The present first volume contains FORTRAN IV programs by several authors from the fields of NMR spectroscopy and kinetics, as well as a program for plotting curves (PLOTLN). LAOCN3 and the programs NMRIT and NMREN calculate the position and the intensity of the NMR lines from assumed chemical shifts and coupling constants. If the calculated spectrum is similar to the experimental spectrum, the input parameters can be improved by an iteration process. LSG or LSKIN 1 evaluates the data for a first order reaction, and calculates the best value for the rate constant and the initial and final values of the variables.

All the programs were reproduced by photomechanical reduction from the original programs, and the input and output for one example is given for each program. In addition to the explanation of the input and output, a description is provided for each program. An important part of this is the section "Structure of the Program", which offers the reader the possibility of program analysis. While this part of the description of the program is excellent in the case of LAOCN3, it is too short in the description of the other programs. All the programs have been tested independently, so that any errors are only of a formal nature. Thus on page 22 we should have "last two cards are blank". Similarly, on page 24, a blank card is missing between the data groups on the right half. The variable ISUM (p. 29) is equal to the number of β spins that are increased by 1.

All the programs can be purchased on a program tape, and the lists and cards have also been obtainable from the Quantum Chemistry Program Exchange (QCPE), Indiana University, Bloomington. However, even punching out the program lists bears no comparison with devising a new program as far as the time required is concerned, quite apart from the didactic value of a successful program analysis to the worker.

Günter Ege [NB 949 IE]

Kunststoff-Bestimmungsmöglichkeiten (Methods for the Analysis of Plastics). By *A. Krause* and *A. Lange*. Carl Hanser Verlag, München 1970. 2nd ed., 191 pp., 34 Tables, bound DM 38.—[1].

The aim of the authors is to present the methods most commonly used in practice for the qualitative and quantitative chemical analysis of plastics, including simple physicochemical tests such as the determination of density and refractive index. More complicated physicochemical methods such as IR, UV, and NMR spectroscopy or pyrolysis gas chromatography are not included.

Starting with the behavior of the plastics when heated in an ignition tube and in an open flame and the determination of density, solubility, softening point and melting point, refractive index, acid number, iodine number, etc., qualitative and quantitative methods are described for the determination of characteristic elements. After limiting the possibilities in this way, the special qualitative and quantitative methods for the individual plastics are then described. The book ends with a short section on the analysis of additives, particularly plasticizers, and a section on quality and acceptance tests with lists of the DIN standards and relevant reports in the Bundesgesundheitsblatt.

The strength of the book lies in the deliberate restriction of the subject matter to simple methods, particularly of a chemical nature; this is especially true in view of the large number of more complicated physicochemical methods and the work that they involve. The listing of characteristics in tabular form makes the book easier to use. A critical appraisal of the special qualitative and quantitative methods would have been of interest to the occasional user. The book can be used by anyone who is familiar with the fundamentals of analysis.

Ernst Klesper [NB 953 IE]

Contraception: The Chemical Control of Fertility. By *D. Lednicer*. Marcel Dekker, Inc., New York 1969. 1st ed., xiv, 296 pp., $ 13.75.

The book, whose six chapters are by authorities of excellent repute, presents an informative review based on about 700 references, and is outstanding in its clear arrangement. As an introduction to the rather heterogeneous material, the first chapter deals with the endocrinology of the female body, with special reference to control by the pituitary and the hypothalamus. The subsequent sections discuss the biology, pharmacology, chemistry, and testing of the contraceptives, which are grouped for discussion into steroid and nonsteroid compounds.

In the biological chapters, the effects produced by gestagens and estrogens are described in detail and summarized in tables; the results observed in animals are compared with the clinical findings for human subjects. Current views on the mode of action and the possible sites of action of the contraceptives and of their individual components are also discussed in this connection. The chemical chapters present a survey of the structural formulas and of the synthesis paths. Starting with the classical steroids, the many modifications (substitution, configuration) that have led to the various contraceptives are described. The final chapter contains information on the testing and screening methods, which are grouped according as the effects tested are central or peripheral.

The present monograph provides an excellent introduction to a field whose intensive scientific investigation is of the greatest interest to the further development of mankind. Its special value lies in the fact that on the one hand it acquaints biologists, biochemists, and pharmacologists with the problems of the chemical synthesis of contraceptives, while on the other it makes it easier for the chemist to evaluate pharmacological test results and clinical findings.

Heinz Breuer [NB 957 IE]

Methoden der Organischen Chemie (Methods of Organic Chemistry). (Houben-Weyl), Vol. V, Part 1a: Alkanes and Cycloalkanes, excluding Cyclopropane and Cyclobutane Derivatives. Edited by *Eugen Müller*. Georg Thieme Verlag, Stuttgart 1970. 4th ed., xxciii, 692 pp., 8 Figs., 83 Tables, bound DM 252.—.

The present volume[1] on the preparation of alkanes and cycloalkanes has undoubtedly been long awaited by many chemists in industry and in technical colleges as an im-

[1] Cf. Angew. Chem. internat. Edit. 5 (1966).

[1] Cf. Angew. Chem. internat. Edit. 9 (1970).

portant part of the set. This volume presents all the methods for the preparation of definite hydrocarbons of this type; the industrial methods for the production of hydrocarbon mixtures are not discussed systematically here. The exclusion of the cyclopropane and cyclobutane derivatives from the discussion of the cycloalkanes is justifiable in view of the special character of these ring systems. In my opinion, however, it would have been better to include the *hydrocarbons* having these ring systems, as this would have allowed the demonstration of the limitations of the various preparation methods when applied to small rings.

Among the arylalkanes, only hydrocarbons whose alkyl residue contains at least five carbon atoms are discussed, the others being dealt with in the volume on aromatic hydrocarbons. This division is doubtlessly a compromise, which, though it breaks the system, seems convenient and logical.

Nearly half of the volume (290 pages) is devoted to the reduction methods for the preparation of hydrocarbons. In addition to the text, a large amount of data is presented in very comprehensive tables. This is followed by a chapter on the solvolysis of organometallic compounds and isomerization reactions for the preparation of hydrocarbons. Besides a short chapter on the preparation of hydrocarbons by degradation reactions, there is a comprehensive chapter on synthesis methods. The chapter on the preparation of stereoisomeric hydrocarbons is particularly well written. The volume ends with an important chapter on the synthesis of labeled hydrocarbons.

The volume benefits from the fact that all the chapters were written by the same authors. It therefore gives an impression of unity. The profound experience of the authors is frequently evident, and the consequent critical evaluation of the methods makes the book particularly valuable to the user. On the whole, this volume is a valuable and well-presented addition to the set.

Hermann Stetter [NB 958a IE]

Methoden der Organischen Chemie (Methods of Organic Chemistry) (Houben-Weyl), Vol. V, Part 1c: Hydrocarbons Part 3. Edited by *Eugen Müller*. Georg Thieme Verlag, Stuttgart 1970, 4th ed., ix, 1296 pp., DM 458.—.

The present volume deals with the methods for the preparation and transformation of conjugated dienes. It shows the impossibility of adhering rigorously to an arrangement based on "Methods for the Preparation of Certain Organic Compounds", in view of the decades over which the publication of the parts of this handbook extends.

The first 854 pages are concerned with the preparation of dienes, and in breach of the system it deals not only with hydrocarbons containing conjugated double bonds but also with dienes containing functional groups.

The chapter on the transformation of the dienes is also very large covering a total of 285 pages. It must be pointed out, however, that a particularly large amount of space is devoted to the Diels-Alder diene synthesis.

As a result of the deviations from the system, this part to a very large degree assumes the character of a monograph, and could undoubtedly be used as a handbook independently of the other volumes.

The synthesis methods described are grouped according to whether or not the formation of the conjugated double bonds is accompanied by alteration of the carbon skeleton. This is followed by a chapter on the preparation of dienes from heterocyclic compounds and one on the purification, analysis, and handling of dienes.

The second part contains the following chapters: Oxidations, Additions without Formation of New Carbon-Carbon Bonds, Additions with Formation of New Carbon-Carbon Bonds, Cycloadditions, Photochemical Reactions, Dehydrogenations and Disproportionations, Substitutions, Isomerizations, Reactions of Cyclopentadiene with Metal Compounds.

Next comes the long chapter on the Diels-Alder reaction. Both the preparation method and the reactions of the dienes are presented very comprehensively and systematically. The volume is of great practical value because of the many typical and well-chosen examples, which are supplemented by tables. The excellent chapter on the Diels-Alder reaction deserves special praise.

To conclude, it may be stated that this well-written volume is an important and necessary addition to the set as a whole for all chemists working in technical colleges and in industry

Hermann Stetter [NB 958 b IE]

Kunststoffe I und II, Aufbau und Eigenschaften – Kunststoffsorten – Anwendungen T 7, Kunststoffverarbeitung T8 (Plastics I and II, Structure and Properties – Types of Plastics – Applications T7, Plastics processing T8). By *H. Domininghaus*. VDI-Taschenbücher 1969. 1st Edit. T7: 196 pp., 106 illustrations, 13 tables, DM 11.80; T8: 138 pp., 65 illustrations, 2 tables, DM 11.80.

These two volumes are intended to be an introduction to synthetic materials for users and consumers and also for students in specialist fields. The first part deals with the structure and properties of plastics, the more important types being discussed from the point of view of chemical structure, behavior, and applications, as well as with commercial products. A special section summarizes the most important fields of application and also economic and historical data. The second part is concerned with the methods of processing plastics (preparation, calendering, production of coatings, foams, compression molding, injection molding, extrusion, forming, decoration), and operational problems are discussed. Finally, there is a bibliography, rather arbitrary and not very representative, and a subject index.

The book is certainly a suitable introduction to plastics, particularly for engineers who are mainly interested in the technology of processing. However, the first volume not only contains a large number of printing errors, but also a number of chemically ambiguous formulations which are consequently open to misinterpretation. Thus, in the treatment of the types of polymerization it would be desirable to have a simple system of formulas, and this would certainly have helped to clarify the text. If there is to be another edition the chemical section will need careful revision, since there are also a number of factual errors.

Finally, in the case of the more important properties at least, one would have welcomed some indication of how these properties were defined and measured; the reader will search the subject index in vain for the modulus of elasticity, tensile strength, or thermal stability, although these concepts are used in many places and numerical values are given for them. Anyone who wants to be informed on such fundamental matters will do better to turn to more detailed

presentations. However, the second part of the work can be heartily recommended as an introduction to plastics processing, particularly as the author has made full use of his extensive practical experience.

Dietrich Braun [NB 962 IE]

Festkörperdosimetrie ionisierender Strahlung (Solid State Dosimetry of Ionizing Radiation). By *M. Frank* and *W. Stolz*. Verlag Chemie, Weinheim 1969. 1st Edit., 283 pp., 97 illustrations, 28 tables, DM 48.—.

Ionizing radiation can induce numerous physical and chemical modifications in solid bodies, and the nature and the extent of these modifications enable conclusions to be drawn about the radiation energy absorbed by the solid body. In turn, this enables overall radiation dosage determinations.

This phenomenon has been much studied over the last 20 years particularly in solid state physics, resulting in a large number of publications on this topic. The present book by *Frank* and *Stolz* is the first monograph to be published in German. After an introduction into the general theoretical basis of dosimetry, the methods of integrating solid state dosimetry are described. These include dosimetry by means of thermoluminescence, radiophotoluminescence, exoelectron emission, luminescence decay, coloration of crystals and plastics, and also by means of solid state track detectors. The authors then deal with the methods of scintillation dosimetry and of dosimetry based on radiation-induced changes in conductivity. For each method there is a description of the underlying physical effects and the supporting mathematics, and experimental details of the method are then given together with practical applications. The rapidity with which this field is developing makes a new and amplified edition of this book desirable even at this stage. This is particularly true of the very short chapter on dosimetry using exoelectron emission and solid state track detectors, since a large number of publications on these topics have appeared in the short time since the book was published.

The authors explain in their preface that the book is intended for all those concerned with the problems of dosage measurement in radiation protection, radiation therapy, and radiobiology, and also in work with accelerators, reactors, and other units using radiation. The reviewer would also recommend this book, because of its precise mode of expression and the excellent presentation of the facts, to all students who are thinking of working in one or more of the fields discussed.

J. Hacke [NB 961 IE]

Infrared Spectroscopy. Experimental Methods and Techniques. By *J. E. Stewart*. Marcel Dekker Inc., New York 1970. 1st Edit., 636 pp., numerous illustrations, $ 36.50.

The perfection with which commercial IR instruments are now manufactured in the widest possible range of types has led to IR spectroscopy becoming a method in which the user – particularly in the case of chemists – is as a rule interested only in the possible range of applications and not in the constructional details. This situation is reflected in the literature on the subject. It is all the more pleasant to find in the present volume a very wide-ranging survey of the fundamentals of the construction of modern IR instruments.

The book contains all the essential information on the basic theory of the equipment and on the construction of IR instruments (optical systems and their components, electronic components, detectors, *etc.*), and a wide range of commercially available instruments is surveyed. In individual chapters descriptions are given of interference spectroscopy, absorption, reflection, and emission measurement methods, and also of the constructional basis for more recent applications (study of samples under extreme conditions *etc.*). Each chapter has a bibliography, in some cases very extensive. There is also an author index (7 pages) and a subject index (13 pages).

The book is intended for the specialist concerned with the instrumental problems of IR spectroscopy, and it should prove an important source of information. It should, however, be in the library of all institutions that use IR spectroscopy in any form, so that anyone who regards his spectroscope as more than just a "black box" will have the opportunity of learning more about his equipment as the need arises.

Synthesis and Reactions of Ketenimines[**]

By Grant R. Krow[*]

Ketenimines $R^1R^2C{=}C{=}N{-}R^3$ *were first reported in 1919, but the development of the chemistry of these compounds is of relatively recent origin. These heterocumulenes are becoming of increasing interest as a dehydrating agent for peptide syntheses, as a coreagent in dimethyl sulfoxide oxidations, and as a substrate in the synthesis of heterocycles by condensation with polar multiple bonds and dipolar systems. The cycloadditions are of special interest from the viewpoint of orbital symmetry considerations. Some unusual organometallic complexes of ketenimines have also been synthesized. Recently some triaryl ketenimines have been found to have insecticidal and miticidal activity. Polymeric ketenimines have been implicated as molecular precursors of life.*

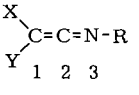
1. Introduction

Ketenimines can be represented by the resonance structures *(1)* and *(2)* which emphasize the nucleophilic properties of the heteroatom and the β-carbon atom, and by structure *(3)*, which accounts for the electrophilic nature of the α-carbon atom.

$R_2C{=}C{=}\ddot{N}{-}R$ $\quad$ $R_2\ddot{C}{-}C{\equiv}\overset{\oplus}{N}{-}R$ $\quad$ $R_2C{=}\overset{\oplus}{C}{-}\ddot{N}{-}R$

(1) $\quad$ *(2)* $\quad$ *(3)*

Under those circumstances where structure *(2)* makes a large contribution to the resonance hybrid, ketenimines will be similar in properties to enamines *(4)* and ynamines



$R_2C{=}CH{-}NR_2$ $\quad$ $RC{\equiv}C{-}NR_2$ $\quad$ $R_2C{=}C{=}O$

(4) $\quad$ *(5)* $\quad$ *(6)*

(5). As resonance form *(3)* increases in importance, ketenimines will react similarly to ketenes *(6)*.

2. Stability and Principles of Synthesis

Most ketenimines are colorless or pale yellow oils or low melting solids, distillable at high vacuum. The infrared spectra exhibit characteristic cumulene absorption at 2000–2050 cm^{-1}. The smaller trialkylketenimines resinify easily and have not been isolated in pure form. Ketenimines are known with *N*-alkyl, -aryl, -hydrogen, -phosphorus, -nitroso, and -boron substituents and having N—Sn, N—Si, and N—Ir bonds. Substituents present on the carbon have been alkyl, aryl, hydrogen, trifluoromethyl, trimethylsilyl, ethoxycarbonyl, cyano, sulfonyl, phosphoranylidene, and carbonyl groups. Stable ketenimines with amino, alkoxy, or thioether substituents directly bonded to either the ketene or imine portions have not yet been synthesized; nor have *N*-halo, *N*-ethoxycarbonyl-, or *N*-sulfonylketenimines been reported.

For purposes of the present discussion the syntheses of ketenimines have been divided into four classes in which

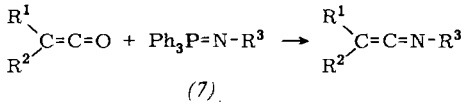
(i) the terminal groups =CXY or =NR are formed by substitution reactions utilizing heterocumulenes (Section 3);

(ii) the ketenimine group (atoms 1–3) supplied as a nitrile anion or nitrile radical is substituted on nitrogen (Section 4);

(iii) the carbimino group (atoms 2, 3), supplied as an isocyanide, is added to atom 1, supplied *via* an acetylene, cyclopropenone, or carbene (Section 5);

(iv) a molecule containing a linear sequence of atoms (atoms 1–3) is converted into a ketenimine by an elimination reaction, an intramolecular rearrangement, or an

[*] Dr. Grant R. Krow
Department of Chemistry, Temple University
Philadelphia, Pennsylvania, 19122 (USA)



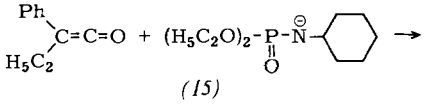
[**] The designation "ketenimine" has been adopted by Chemical Abstracts. The compounds are named as 1-alkenylideneamines in the IUPAC rules for the nomenclature of organic compounds.

elimination-rearrangement. The rearrangement reactions involve migration of a substituent from what will ultimately be the central carbon (atom 2) of the ketenimine to the nitrogen of the ketenimine (Section 6–8).

3. Ketenimines from Ylides by Substitution in Heterocumulenes

3.1. Substitution in Ketenes

The oxygen of a ketene can be replaced by a substituted imino function. *Staudinger*[1] investigated the reactions of various ketene derivatives with triphenyliminophosphorane *(7)*; although yields were not specified, ketenimines prepared in this manner are listed in Table 1.



(7)

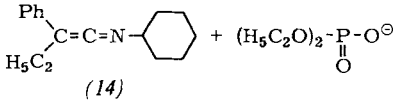


Table 1. Ketenimines $R^1R^2C{=}C{=}N{-}R^3$ prepared form ketenes.

	Ketenimine R^1	R^2	R^3	Physical properties	Ref.

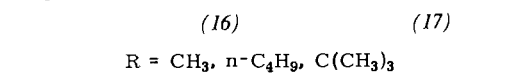
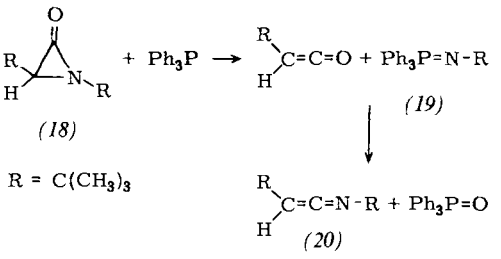
(9)	Ph	Ph	CH_3	yellow, liquid	[1]
(10)	H	H	Ph	colorless (polymerizes)	[1]
(11)	$COOC_2H_5$	$COOC_2H_5$	Ph	colorless, crystalline	[1]
(12)	CH_3	CH_3	Ph	green, oil	[1]
(13)	H	H	C_2H_5	(polymer only)	[1]
(14)	Ph	C_2H_5	C_6H_{11}	oil	[2]

Dialkylphosphoramidate anions *(15)* also react with ketenes to form ketenimines. By this route *Wadsworth* and *Emmons*[2] prepared phenyl(ethyl)-ketene-*N*-cyclohexylimine *(14)* in 58% yield.



(15)

(14)



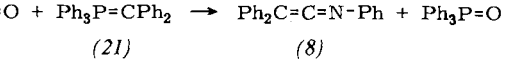
Recently *Raasch*[3] has synthesized the antistatic agents bis(trifluoromethyl)ketene-*N*-alkylimines *(17)* by reaction of bis(trifluoromethyl)thioketene with the formal ylides dialkylsulfur diimides *(16)*.

(16) *(17)*

R = CH_3, n-C_4H_9, $C(CH_3)_3$

In a somewhat novel reaction *Bergmark* and *Corcoran*[4] have found di-*tert*-butylaziridinone *(18)* to react with triphenylphosphane to give *tert*-butylketene-*N*-*tert*-butylimine *(20)* in unspecified yield, probably *via* intermediate *tert*-butylketene and the iminophosphorane *(19)*.

(18)



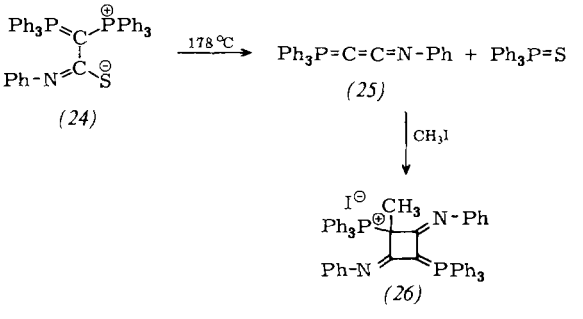
R = $C(CH_3)_3$

(19)

(20)

3.2. Substitution in Isocyanates

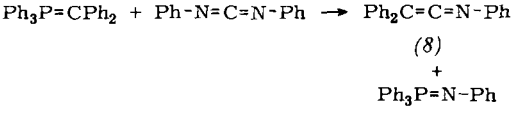
In their initial reports on the synthesis of ketenimines, *Staudinger* and *Meyer*[5] in 1920 reacted phenyl isocyanate with diphenylmethylenetriphenylphosphorane *(21)* to prepare ketenimine *(8)*[6].



(21) *(8)*

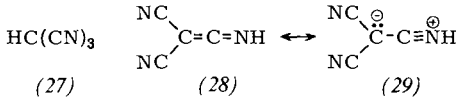
The ylide route has been especially effective in the synthesis of heterocumulenes. A cumulene ylide *(22)* has been used by *Ratts* and *Partos*[7] to prepare a cumulene imine *(23)* (isolated as its amide) from methyl isocyanate.

(22) *(23)*



Birum and *Mathews*[8] have prepared the unique compound *(25)*, which can be regarded as a cumulene ylide and as a ketenimine, by thermal cleavage of the phosphonium inner salt *(24)* prepared from hexaphenylcarbodiphosphorane and phenyl isothiocyanate. Ketenimine *(25)* was identified by its 5.0 μm infrared band and by conversion into a cyclic dimer *(26)* with methyl iodide.

(24) *(25)* *(26)*

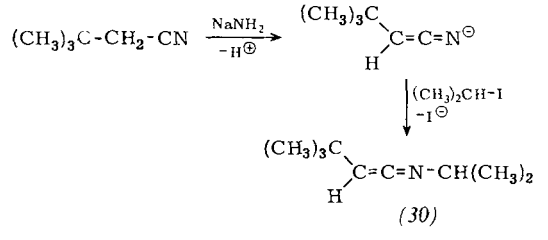


3.3. Substitution in Carbodiimides

When stirred at 160–180 °C for 4 h diphenylmethylenetriphenylphosphorane and diphenylcarbodiimide undergo ylide exchange. Diphenylacetanilide, the hydrolysis product of triphenylketenimine *(8)*, was isolated in 94% yield[9].

4. Ketenimines *via* Nitrile Derivatives

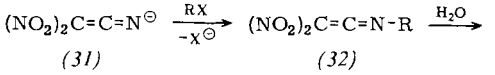
Nitriles containing α-hydrogens can be considered as tautomers of ketenimines. Although the tautomeric equilibrium usually favors the nitrile, *Trofimenko*[10a] has reported that cyanoform *(27)* exists as dicyanoketenimine *(28)*. Resonance forms such as *(29)* probably stabilize the ketenimine structure[10b].



(27) *(28)* *(29)*

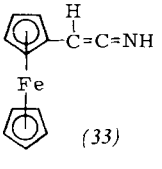
4.1. Alkylation of Nitrile Anions

A variety of ketenimines have now been prepared *via* substitution reactions of ambident nitrile anions on nitrogen. Although alkylation of this ambident ion generally



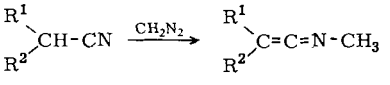
occurs on carbon, *tert*-butylketene-*N*-isopropylimine *(30)* has been isolated[11] in 56% yield on *N*-alkylation of the sterically hindered *tert*-butylacetonitrile anion with the bulky isopropyl iodide as alkylating agent.

(30)



Similarly, *N*-alkylation of the dinitroacetonitrile anion *(31)* with organic halides has been found[12] to give amides arising from ketenimines *(32)*.

(31) *(32)*



Dewey[13] has synthesized the stable ferrocenylketenimine *(33)*, which is protonated on nitrogen, by treatment of ferrocenylacetonitrile anion with methylmagnesium chloride in ether and subsequent addition of methanol. Compound *(33)* exhibits a strong ketenimine absorption at 2185 cm^{-1}. Normal aromatic ketenimines absorb at 2002–2016 cm^{-1}.

(33)

Treatment of a nitrile substituted by strongly electron-withdrawing *alpha* substituents with diazomethane generates a nitrile anion. *N*-Alkylation of such an anion by the methyldiazonium ion yields a ketenimine. Ketenimines thus prepared by *Dijkstra* and *Backer*[14] are shown in Table 2.

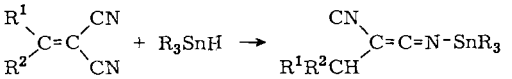


Table 2. Ketenimines prepared from nitriles with diazomethane [14].

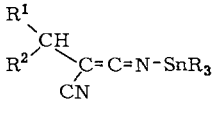
4.2. *N*-Substitution of Nitrile Anions by Heteroatoms

Tin: Nitriles have been used as precursors for preparing *N*-stannylketenimines. Polar 1,4 addition of a trialkyltin hydride *(39)* to an alkylidenemalononitrile *(38)* results in formation of an *N*-trialkylstannylketenimine *(40)*.



(38) *(39)* *(40)*

It is possible to modify this reaction by using an alkylmalononitrile and a trialkylstannyldiethylamine *(41)*, a sodium alkylmalononitrile and a trialkyltin chloride *(42)*, or an α-bromoalkylmalononitrile and a lithiotrialkyltin compound *(43)*. Some *N*-stannylketenimines prepared[15] are shown in Table 3.

[a] Polymerizes readily.

Silicon, boron, tin: The synthesis of ketenimines by 1,4-addition to α,β unsaturated dinitriles has been extended by *Abel, Crow*, and *Wingfield*[16]. A formal 1,4 insertion reaction of 1,1-bis(trihalogenomethyl)-2,2-dicyanoethylene into a variety of tin, silicon, and boron bonds (Table 4) has

(56)

been shown to generate ketenimines *(55)* under mild conditions. With the exception of some of the *N*-trialkylstannylketenimines, all the products undergo rapid alcoholysis and hydrolysis, the non-metalloid product reverting to the dicyano form *(56)*.

Silicon: *Krüger* and *Rochow*[17] have prepared the *N*-silylketenimine *(57)* by reaction of sodium bistrimethylsilylamide with acetonitrile at −60 to +30 °C, followed by treatment of the ether-insoluble nitrile anion with trimethylchlorosilane. Mono- and diphenylacetonitrile gave ketenimines *(58)* and *(59)*, respectively.

Phosphorus: *Partos* and *Speciale*[18] found that reaction of chlorodiphenylacetonitrile *(60)* with triethyl phosphite results in formation of an *N*-phosphorus-substituted ketenimine *(61)*.

(60) *(61)*

N-Phosphorusketenimines *(63)* were also obtained[19] when trimethyl phosphite was reacted with α-bromo-α,β-dicyanopropionates *(62)*. Some ketenimines prepared in this way are shown in Table 5.

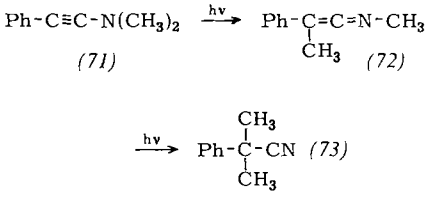
4.3. Alkylation of Nitrile Radicals

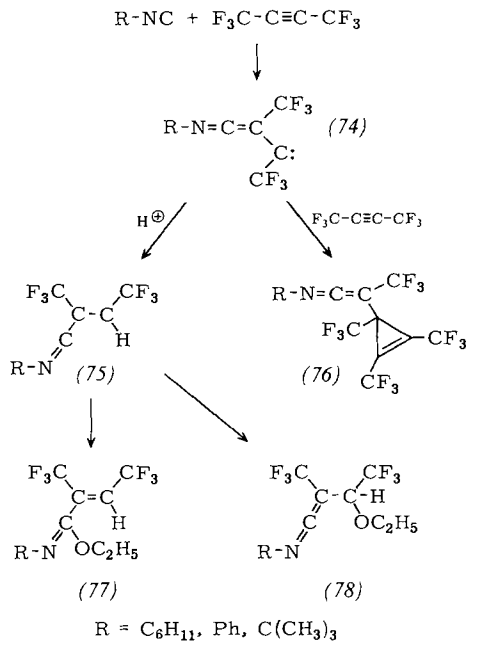


Dimerization of the thermal or photochemical decomposition products[20] of 2,2-azobis(isobutyronitrile) *(68)* results in formation of a small amount of ketenimines *(69)* as well as the normal product, tetramethylsuccinodinitrile *(70)*. Both products arise from isobutyronitrile radicals, *(69)* from combination of a carbon and nitrogen radical, *(70)* from combination of two carbon radicals.

(68) *(69)*

(70)

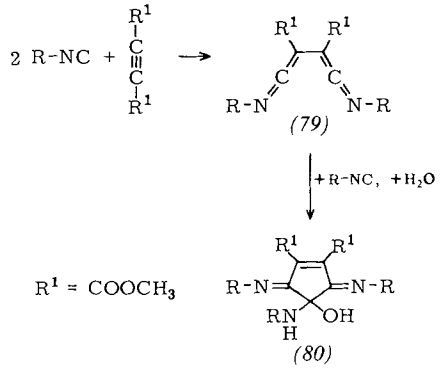
Selvarajan and *Boyer*[21] have recently identified ketenimines as products of unsensitized irradiation at 254 nm of *N,N*-dimethyl(phenylethynyl)amine *(71)* in cyclohexane. Ketenimine *(72)*, identified by its 2020 cm^{-1} band in the crude photolyzate, is an assumed intermediate in the formation of α-phenylisobutyronitrile *(73)*.



(71) *(72)*

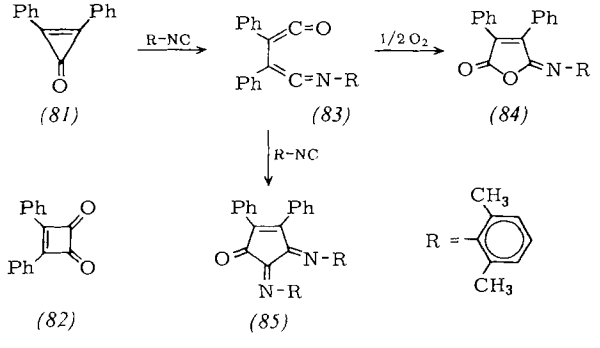
(73)

5. Ketenimines from Addition Reactions of Isocyanides



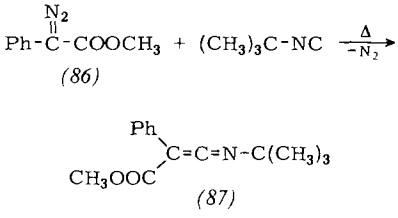
5.1. Addition of Isocyanides to Alkynes

Oakes, David, and *Nagel*[22] have found 2:1 adducts of hexafluoro-2-butyne and isocyanides formed in inert solvents to have the cyclopropenyl ketenimine structure *(76)*. Identified by a ketenimine cumulene absorption at 4.80 μm in their infrared spectra, the stable pale yellow



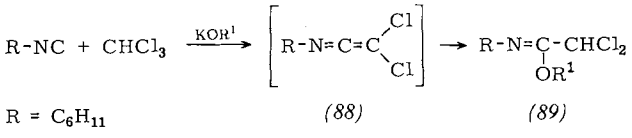
liquids conceivably are formed *via* the carbene *(74)*. In the protic solvent ethanol, ketenimine *(77)* is formed.

Takizawa and co-workers[23] have isolated the bisketenimine *(79)* in 3% yield as an intermediate in the reaction of an aryl isocyanide with dimethyl acetylenedicarboxylate.

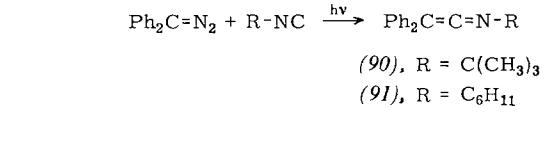


5.2. Addition of Isocyanides to Cyclopropenones

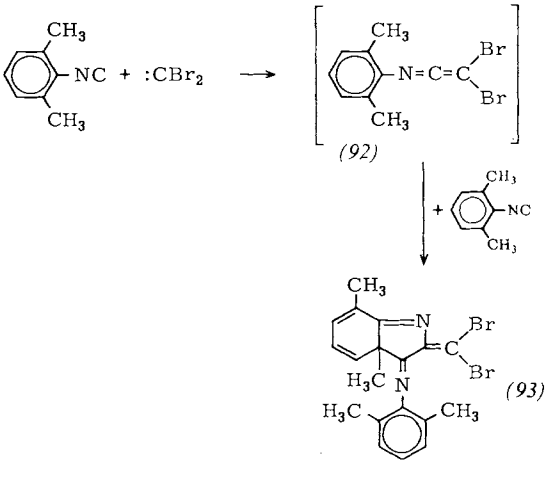
Takizawa[24] has also postulated a ketenimine intermediate in the reaction of diphenylcyclopropenone *(81)* with 2,6-dimethylphenyl isocyanide. The products *(84)* and *(85)* isolated from this reaction can be explained *via* the intermediacy of the "ketene-ketenimine" *(83)*. The same products result from addition of diketone *(82)* to 2,6-dimethylphenyl isocyanide.



5.3. Addition of Isocyanides and Carbenes



Ciganek[25] has shown that carbenes and isocyanides, two formally divalent species, can react to generate ketenimines. Thermolysis of methyl phenyldiazoacetate *(86)* in *tert*-butyl isocyanide gave ketenimine *(87)* in 51% yield.



An earlier attempt[26] to prepare ketenimine *(88)* by reaction of dichlorocarbene (generated from potassium trichloroacetate in alcohol) with cyclohexyl isocyanide gave *N*-cyclohexyldichloroacetimidate *(89)*.

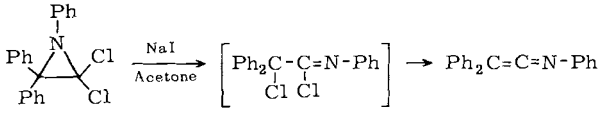
Boyer and *Beverung*[27] photolyzed diphenyldiazomethane at 2537 Å in the presence of cyclohexyl isocyanide to form *N*-cyclohexyldiphenylketenimine *(91)*. Absorption at 4.90 μm identified the ketenimine, which was isolated in 50% yield as its amide. *Green* and *Singer*[28] prepared ketenimines *(90)* and *(91)*, in 25—30% and 45—50% yields respectively, by the same method.

Takizawa and *Obata*[24] have observed 2,6-dimethylphenyl isocyanide to react with dibromocarbene to yield indolenine derivatives *(93)*. The intermediacy of ketenimine *(92)* is postulated in order to explain this result.

6. Ketenimines *via* Simple Elimination Reactions

6.1. Dehalogenation of α-Chloro Imidoyl Chlorides

Stevens and *French*[29] found that α-chloro imidoyl chlorides *(94)*, which are readily synthesized from amides, can be dehalogenated with sodium iodide in acetone. Although the dehalogenation method fails to produce ketenimines with dialkyl substitution on carbon, the synthesis is successful for preparing diaryl-*N*-alkyl- and triarylketenimines. *p*-Nitrophenylketene-*N*-arylimines can be prepared by dehalogenation, but not by dehydrohalogenation (see Section 6.2). *Singhal*[30] has found that dehalogenation of α-chloro imidoyl chlorides can also be effected with copper metal at 20—50 °C. Zinc fails to dehalogenate α-chloro imidoyl chlorides, however.



$$Ph_2CH\text{-}\underset{\underset{O}{\|}}{C}\text{-}NHPh \xrightarrow{2\ PCl_5} Ph_2\overset{\overset{Cl}{|}}{C}\text{-}\overset{\overset{Cl}{|}}{C}\text{=}N\text{-}Ph$$

(94)

$$\xrightarrow[Acetone]{NaI} Ph_2C\text{=}C\text{=}N\text{-}Ph$$

(8)

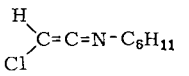
A recent variant of the above procedure[31] utilizes dichloroaziridines, prepared by reaction of imines with dichlorocarbene, as precursors of α-chloro imidoyl chlorides. Refluxing the dichloroaziridine *(95)* with sodium iodide in acetone generates triarylketenimine *(8)* in excellent yields.

(94a) *(94)* *(8)*

6.2. Dehydrohalogenation of Imidoyl Chlorides

Stevens and *French*[32] found that imidoyl chlorides *(95)* bearing a single *alpha* hydrogen atom can be dehydrohalogenated to ketenimines *(8)* by means of triethylamine. The yields by this route have been improved[33a] using triphenylphosphine, bromine, and triethylamine in refluxing dichloromethane. This approach is especially useful

$$Ph_2CH\text{-}\underset{\underset{O}{\|}}{C}\text{-}NHPh \xrightarrow{PCl_5} Ph_2CH\text{-}\overset{\overset{Cl}{|}}{C}\text{=}N\text{-}Ph$$



(95)

$$\xrightarrow{(C_2H_5)_3N} Ph_2C\text{=}C\text{=}N\text{-}Ph$$

(8)

for ketenimines with dialiphatic substitution on the ketene portion of the cumulene and the dehydrohalogenation method has been used[33b] to prepare a diethoxycarbonyl-substituted ketenimine *(96)*, and reportedly the unstable chloroketenimine *(97)*[52].

$(H_5C_2OOC)_2C\text{=}C\text{=}N\text{-}Ph$ *(96)*

(97)

In Table 6 is shown a comparison made by *Stevens* and *French*[32] of the dehydrochlorination and dechlorination procedures for the synthesis of ketenimines. The dehydrochlorination procedure was superior except in the case of diphenylketene-*N*-methylimine *(100)*.

Table 6. Comparison of syntheses of ketenimines ($R^1R^2C\text{=}C\text{=}N\text{—}R^3$) carried out by *Stevens* and *French* [32].

	R^1	R^2	R^3	Yield (%) (based on starting amide) dehydrochlorination	dechlorination

(99)	*n*-C_4H_9	C_2H_5	*n*-C_4H_9	57.0	—
(100)	C_6H_5	C_6H_5	CH_3	2.4	42
(101)	C_6H_5	C_6H_5	*n*-C_4H_9	69.0	63
(102)	C_6H_5	C_6H_5	*p*-tolyl	65.0	56

6.3. Dehydration of Secondary Amides

Stevens and *Singhal*[34] found that dehydration of secondary amides with phosphorus pentoxide and pyridine is a useful method for preparing triarylketenimines such as *(8)*,

$$Ph_2\text{-}CH\text{-}\underset{\underset{O}{\|}}{C}\text{-}NHPh \xrightarrow[Pyridine]{P_2O_5} Ph_2C\text{=}C\text{=}N\text{-}Ph$$

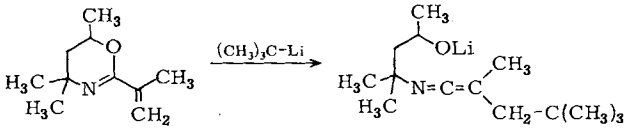
(8)

except when the *N*-aryl group contains a strongly electron-withdrawing substituent such as the *p*-nitro group. The dehydration procedure is successful also for preparing diarylketene-*N*-*n*-alkylimines. A list of diphenylketene-*N*-aryl(or *N*-alkyl)imines prepared by *Stevens* and *Singhal*[34] appears in Table 7.

Table 7. Diphenylketene-*N*-aryl(alkyl)imines $Ph_2C\text{=}C\text{=}N\text{—}R$ prepared by *Stevens* and *Singhal* [34] using the dehydration procedure.

	R	Yield (%)
(102)	*p*-CH_3—C_6H_4	87
(103)	*p*-Br—C_6H_4	69
(104)	*p*-H_3CO—C_6H_4	69
(105)	*o*-CH_3—C_6H_4	84
(106)	*p*-H_3CS—C_6H_4	75
(107)	*o*-H_3CO—C_6H_4	67
(108)	*n*-C_4H_9	50
(109)	*p*-NO_2—C_6H_4	0
(110)	*p*-H_3CSO_2—C_6H_4	30
(111)	*tert*-C_4H_9	0

The dehydration procedure can be modified by converting the amide first into a thioamide and treating this with mercuric oxide[35]. In another variation, *Singer* and *Davis*[36]



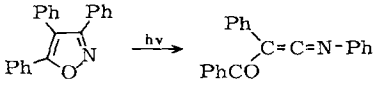
utilized triethylamine instead of pyridine as base in order to prepare a trialkylketenimine. A list of ketenimines prepared by *Singer* and *Davis* appears in Table 8. The dehydration procedure is inferior to the dehydrohalogenation procedure for all-aliphatic and dialiphatic *N*-aromatic ketenimines.

Table 8. Ketenimines $R^1R^2C{=}C{=}N{-}R^3$ prepared by *Singer* and *Davis* [36] using the dehydration procedure.

	R^1	R^2	R^3	Yield (%)
(112)	CH_3	CH_3	C_6H_{11}	18
(113)	CH_3	CH_3	C_6H_5	20
(114)	C_2H_5	C_6H_5	*sec*-C_4H_9	20
(115)	C_2H_5	C_6H_5	C_6H_5	20
(116)	C_6H_5	C_6H_5	*sec*-C_4H_9	25—30
(8)	C_6H_5	C_6H_5	C_6H_5	25—30

6.4. Ring Opening of 2-Vinyl-1,3-oxazines

Meyers and *Kovelsky*[37] have isolated a hygroscopic salt *(118)* from treatment of oxazine *(117)* with *tert*-butyllithium. Strong infrared absorption at 2010 cm^{-1} identified this salt as the ketenimine.

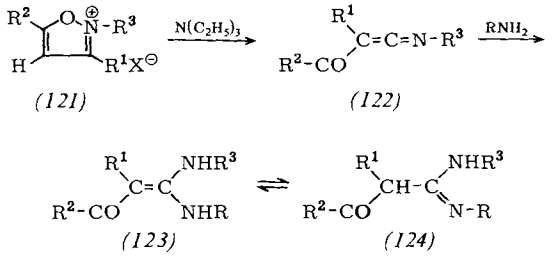


(117) *(118)*

7. Ketenimines by Rearrangement Reactions

7.1. Photolysis of Triarylisoxazoles

Schechter and *Kurtz*[38] have shown that irradiation of a triphenylisoxazole *(119)* with 3000-Å or 2537-Å light results in isomerization to benzoylphenylketene-*N*-phenylimine *(120)*. The yield of *(120)* was 40% and the method



(119) *(120)*

represents a rapid and convenient way of preparing a ketoketenimine.

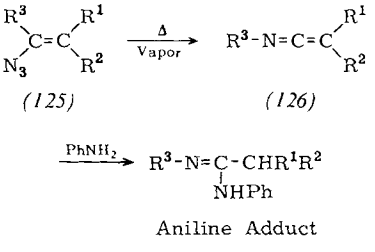
8. Ketenimines by Elimination-Rearrangement

8.1. Basic Decomposition of Isoxazolium Salts

N-tert-Butylisoxazolium salts *(121)* bearing hydrogen in the 4-position have been converted by *Woodward* and *Woodman*[39] into isolable ketoketenimines *(122)* by treatment of the salts with triethylamine. A bulky, branched substituent R^1 is not necessary for the success of the approach[40]. The yellow oily ketoketenimines, stable at 0 °C, were identified by characteristic infrared absorption for the cumulene linkage at 4.9 μm, and by their reaction with amines to form tautomeric acylketene aminals *(123)*

(121) *(122)*

(123) *(124)*



of acyl amidines *(124)*. *Olafson* and *Marino*[41] have recently reviewed the use of isoxazolium salts in peptide syntheses.

Table 9. Isolated ketoketenimines $R^2COC(R^1){=}C{=}N{-}R^3$ *(122)*.

CH_3	Ph	CH_2Ph	[40]
CH_3	Ph	Ph	[40]
H	H	*tert*-Butyl	[40]

8.2. Photolysis or Pyrolysis of Vinyl Azides

Smolinsky[42] has inferred the formation of small amounts (<5%) of ketenimine *(126)* from infrared bands in the 4.9–5.0-μm region of a crude pyrolyzate obtained upon vapor-phase pyrolysis of vinyl azides *(125)*. *Friedrich*[43] has isolated HCl, ethanol, or aniline adducts of ketenimines formed by thermal decomposition of azides at 60–70 °C.

(125) *(126)*

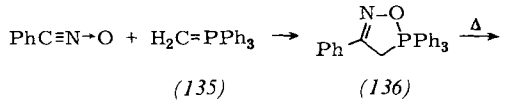
Aniline Adduct

Of special interest is ketenimine *(130)*, the tautomer of cyanoform. The tetramethylammonium salt of *(130)* can be isolated if the reaction is carried out in acetone/water.

Table 10. Ketenimines $R^1R^2C{=}C{=}N{-}R^3$ *(126)* from vinyl azides.

	R^1	R^2	R^3	Yield (%)	Ref.
(127)	H	H	Ph	5	[42] [a]
(128)	CN	CN	Ph	79	[43] [b]
(129)	CN	CN	CH_3	58	[43] [b]
(130)	CN	CN	H	61	[43] [b]
(131)	$COOC_2H_5$	H	CH_3	20	[44] [c]
(132)	$COOC_2H_5$	CH_3	CH_3	20	[44] [c]

[a] Identified by its 4.9—5.0 μm infrared band.
[b] Isolated as its HCl adduct.
[c] Identified by ketenimine infrared band at 4.87 μm.



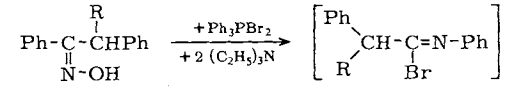
Harvey and *Ratts*[44] have also obtained ketenimines *(131)–(132)* in low yield by photolysis of vinyl azides. The ketenimines can be detected by the infrared band at 4.87 μm, but are destroyed during attempted distillation. A list of ketenimines prepared from vinyl azides appears in Table 10.

8.3. Reaction of Nitrile Oxides with Phosphorus Ylides

Bestmann and *Kunstmann*[45] found that benzonitrile oxide and ethoxycarbonylphosphorane *(133)* yielded ketenimine *(134)* in 68% yield when heated. *Huisgen* and *Wulff*[46] similarly formed ketenimine *(137)* when the

(133) *(134)*

(135) *(136)*

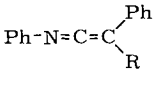


$H_2C{=}C{=}N{-}Ph + Ph_3P{=}O$

(137)

adduct *(136)* of benzonitrile oxide and methylenetriphenylphosphorane *(135)* was heated to 130 °C. Ketenimine *(134)* could be distilled; however, identification of ketenimine *(137)* was made through its aniline adduct.

8.4. Reaction of Ketoximes with Dibromotriphenylphosphorane and Base



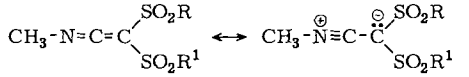
Masaki, *Fukui*, and *Ohta*[47] treated oxime *(138)* with dibromotriphenylphosphorane and two equivalents of triethylamine at room temperature in acetonitrile to generate

(138)

R = Ph, H

(139)

(140)



a ketenimine. The ketenimine probably arises by dehydrobromination of an intermediate imidoyl bromide *(139)*. When R is hydrogen, the yield of ketenimine *(140)* is 75%.

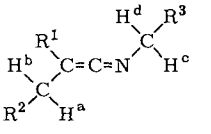
9. Physical Properties of Ketenimines

The ketenimine system is potentially axially dissymmetric in an analogous manner to allenes. The ability to observe axial dissymetry, however, depends upon the configurational stability of the ketenimine, which might invert its configuration either by rotation about the imine or inversion of the nitrogen lone pair. The calculated barrier to interconversion is $\leqslant 10$ kcal/mole[48] in agreement with available experimental evidence.

9.1. Structure by X-Ray Methods

X-ray studies[49–51] have shown that with strong electron-withdrawing sulfone groups on the ketene portion and a methyl group on the imine portion of ketenimine *(141)*, the CH_3—N—C bond angle is 180°. Large contribution of resonance structure *(142)* can account for the linearity in the crystalline state. When the *N*-methyl group is replaced by an *N*-ethyl group, however, the CH_2—N—C bond angle is 144°.

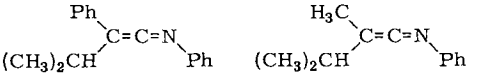
(141a), R = Ph, R^1 = Ph



(141b), R = Ph, R^1 = CH_3

(142)

9.2. NMR Investigation of Stereochemistry

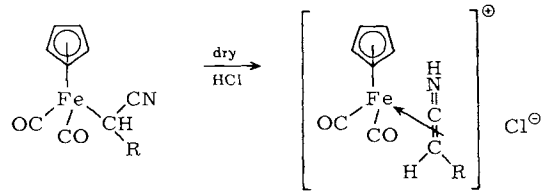


An attempt[52] to observe the effects of the barrier to interconversion of ketenimines on the chemical shift of diastereotopic methylene hydrogens in ketenimines *(143)* to *(146)*, shown in Table 11, was unsuccessful. The protons H^a, H^b or H^c, H^d appeared magnetically equivalent over a temperature range of −60 to +80 °C.

Table 11. Ketenimines used in an attempt to observe diastereotopic hydrogens [52].

	R^1	R^2	R^3
(143)	Ph	CH_3	*tert*-C_4H_9
(144)	Ph	Ph	*tert*-C_4H_9
(145)	Ph	CH_3	Ph
(146)	H	$C(CH_3)_2Cl$	*tert*-C_4H_9

Jochims and *Anet*[53] have used the NMR method to determine the barriers to racemization of *(147)* and *(148)*. At −113 °C the methyl protons of the isopropyl group of

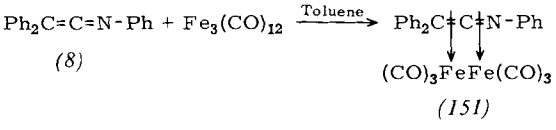


(147) *(148)*

(147) separate into a pair of doublets with a chemical shift difference of 4 Hz, corresponding to a free energy of activation for racemization of 9.1 ± 0.2 kcal/mole. The barrier in *(148)* is raised to 12.2 ± 0.3 kcal/mole.

10. Metal Complexes of Ketenimines

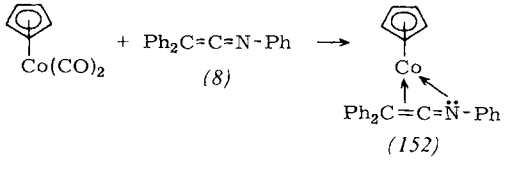
10.1. Metal π Complexes



The ketenimine-iron π complex *(150)* was synthesized[54] by proton-catalyzed isomerization of σ complex *(149)*. The uncomplexed imine function can be identified by the characteristic infrared bands at 1554 cm^{-1}.

(149a), R = H
(149b), R = CH_3

(150a), R = H
(150b), R = CH_3

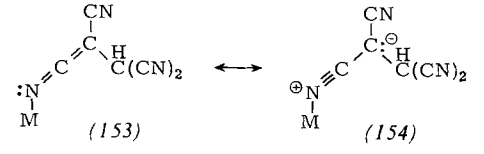


An iron complex *(151)* postulated[55] to be a di-π-complex is formed when triphenyl ketenimine *(8)* is heated with triiron dodecacarbonyl. In addition an unknown dimer of

(8) *(151)*

the ketenimine with CO inserted is formed. Diphenylketene-*N*-methylimine *(9)* forms a similar di-π-complex when reacted with $Fe_3(CO)_{12}$.

In contrast to the di-π-ketenimine-iron complex *(151)* is the σ-π-ketenimine-cobalt complex *(152)*. The cobalt complex is air-stable, can be chromatographed on alumina, and, unlike the free ketenimine *(8)*, is resistant to hydro-



(8) *(152)*

lysis. The presence of the imine bond in uncomplexed form is inferred from infrared spectral evidence (band at 1565 cm^{-1}).

10.2. Keteniminato Transition Metal Complexes

A number of keteniminato transition metal complexes have been prepared[56] which contain a nitrogen-transition metal σ bond. X-ray studies have shown the structure of

(153) *(154)*

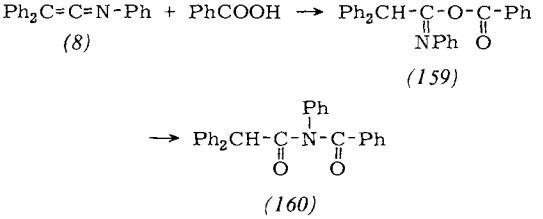
M = $-Ir(PPh_3)((CN)_2C{=}C(CN)_2)(CO)$

an iridium-tetracyanoethylene complex to be *(153)*[57]. An iridium-N—C bond angle of 162° is indicative of the relative importance of resonance structure *(154)*.

11. Chemical Behavior of Ketenimines

As the formal dehydration products of amides, ketenimines are readily converted into amide derivatives (Table 12). They add amines to form amidines *(155)*[58], water (catalyzed by acid) to form amides *(157)*, alcohols (catalyzed

Table 12. Some reactions of triphenylketenimine *(8)*.



Reagent	Product	
$PhNH_2$	$Ph_2CH-C(=NPh)-NHPh$	*(155)*
H_2S	$Ph_2CH-C(=S)-NHPh$	*(156)*
H_2O/H^+	$Ph_2CH-C(=O)-NHPh$	*(157)*
CH_3OH/CH_3O^-	$Ph_2CH-C(=NPh)-OCH_3$	*(158)*
HCl	$Ph_2CH-C(=NPh)-Cl$	*(95)*
Cl_2	$Ph_2C(Cl)-C(Cl)=NPh$	*(94)*

by alkoxide) to form imidates *(158)*, and chlorine to form α-chloro imidoyl chlorides *(94)*[29]. Practical use has been made of ketenimines as dehydrating agents for a variety of purposes, as will be discussed in Section 11.1.

11.1. Ketenimines as Dehydrating Agents

11.1.1. Activation of Carboxyl Groups with Ketenimines

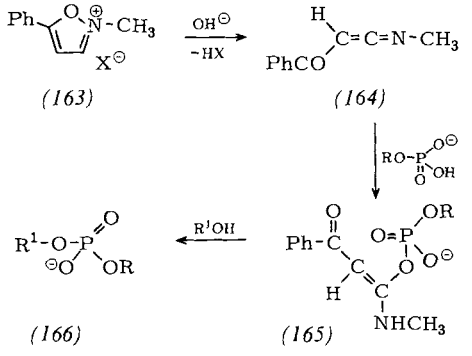
Triphenylketenimine dehydrates dicarboxylic acids, such as phthalic acid, to form anhydrides[59]; monocarboxylic acids react to form *N*-acyl amides *(160)*; which are rearrangement products of *O*-acyl imidic acids *(159)*. The intermediates *(159)* formed from *N*-protected amino acids can react with amino acid esters to form peptide bonds[60];

(8) *(159)* *(160)*

the active acylating agent *(159)* can be purified and stored, and the coupling reaction can be done in polar or nonpolar solvents. The reagent *(159)* can also be used to acylate alcohols.

Woodman and *Davidson*[61] found acetylketene-*N*-*tert*-butylimine *(161)* and acetic acid to result in a 95% yield

of the acetyl ester *(162)*. In order to prepare generally useful enol ester acylating agents, it is sufficient to start



$$CH_3CO\text{-}CH{=}C{=}N\text{-}C(CH_3)_3 + CH_3COOH \longrightarrow$$
(161)

$$CH_3\text{-}\underset{\displaystyle O\text{-}CO\text{-}CH_3}{\overset{\displaystyle |}{C}}{=}CH\text{-}CO\text{-}NH\text{-}C(CH_3)_3$$
(162)

with the isoxazolium salt *(121)*. Compound *(121)*, $R^1=H$, $R^2=CH_3$, $R^3=C(CH_3)_3$ is the precursor of ketenimine *(161)* (see Table 9).

11.1.2. Preparation of Phosphorylating Agents

An excellent phosphorylating agent of the enolphosphate type is prepared from an isoxazolium salt *(163)* and phosphoric acid. Initial attack of base on the isoxazolium salt generates an acylketenimine *(164)* which is attacked by phosphoric acid monoester to form the active phosphorylating agent *(165)*. The reagent was used in the synthesis of nucleotide esters *(166)*, where R^1OH is a nucleotide, and the approach is presumably applicable to oligonucleotide synthesis[62].

(163) *(164)* *(166)* *(165)*

Some simple phosphates prepared from isoxazolium salts appear in Table 13.

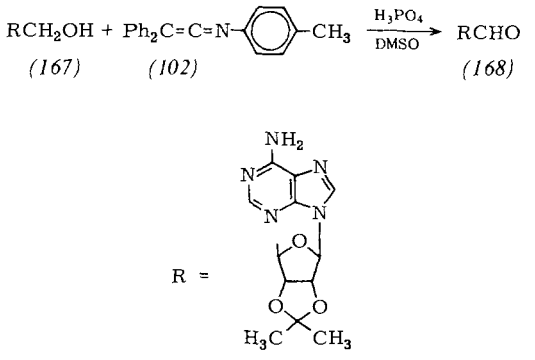


Table 13. Phosphates *(166)* prepared from isoxazolium salts [62].

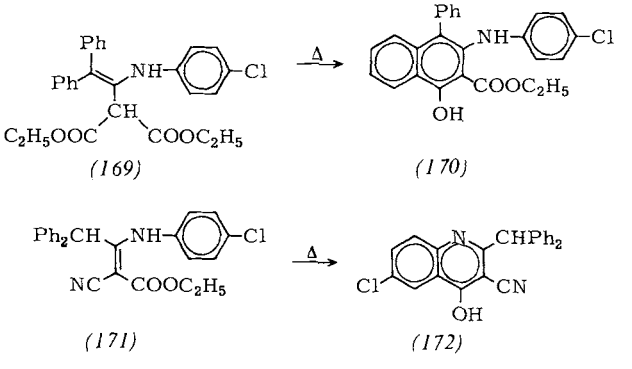
$$R^1\text{-}O\text{-}\underset{\displaystyle {}^{\ominus}O}{\overset{\displaystyle O}{P}}{=}O \quad \underset{\displaystyle OR}{} \qquad (166)$$

R	R^1	Yield (%)
CH_3	Ph	89
C_2H_5	Ph	70
$(CH_3)_2CH$	Ph	73
$Ph{-}CH_2$	Ph	81

11.1.3. Oxidations Utilizing Ketenimines

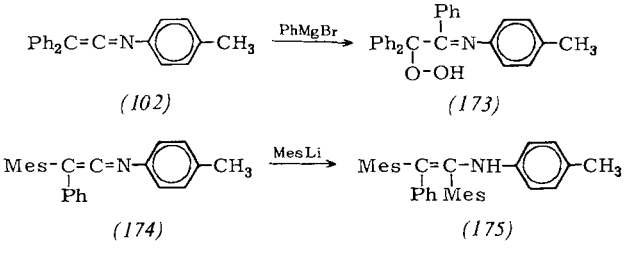
Diphenylketene-*N*-*p*-tolylimine *(102)* has been used[63] in a novel oxidation of the 5'-hydroxyl group of an adenosine nucleoside *(167)*. The aldehyde *(168)* was obtained in 60% yield by the action of dimethyl sulfoxide and phosphoric acid on ketenimine *(102)*. This procedure has also been utilized in the oxidation of hydroxy steroids such as testosterone and cholesterol[64].



(167) *(102)* *(168)*

11.2. Additions of Carbanions and Grignard Reagents to Ketenimines

11.2.1. Reaction with Carbanions

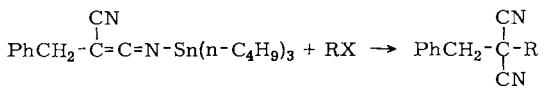


Diethyl malonate anion adds to triarylketenimines to give the α,β-unsaturated isomer *(169)* while ethyl cyanoacetate anion gives the α,β-unsaturated isomer *(171)*. Pyrolysis of these adducts yields the heterocycles *(170)* and *(172)* respectively[65].

(169) *(170)* *(171)* *(172)*

11.2.2. Reaction with Grignard Reagents

Stevens and *Gasser*[66] have isolated hydroperoxide *(173)* from the reaction of diphenylketene-*N*-*p*-tolylimine *(102)* with phenylmagnesium bromide. With the sterically hindered mesitylphenylketene-*N*-*p*-tolylimine *(174)* and mesityllithium only vinylamine *(175)* was isolated, however.

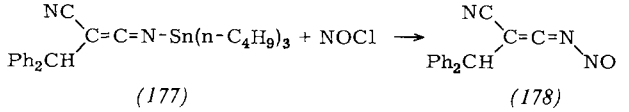


(102) *(173)* *(174)* *(175)*

11.3. Conversion of Ketenimines into Nitriles

11.3.1. Cleavage of the N—Sn Bond

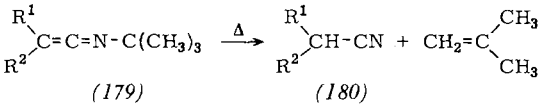
N-Stannylketenimines react with a variety of reagents which cleave the nitrogen-tin bond to generate substituted malononitriles[15]. In Table 14 are shown the products *(176)* of cleavage of *N*-tri-*n*-butyl-stannylketenimine *(44)*



(44) (176)

Table 14. Cleavage products *(176)* of *N*-stannylketenimines *(44)*.

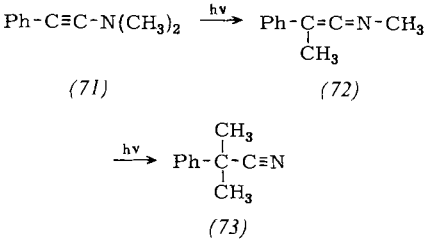
R	X	Yield (%)
H	C_2H_5O	68
$PhCH_2$	Br	85
CH_2=CH—CH_2	Br	94
$COOC_2H_5$	Cl	38
Ph_3C	Cl	67
Br	Br	90
PhCO	Cl	94



Preliminary studies[67] indicate that *N*-nitrosoketenimine *(178)* rather than the corresponding nitriles is formed when NOCl in tetrahydrofuran is used to cleave the tin-nitrogen bond of *(177)*.

(177) (178)

11.3.2. Pyrolytic and Photolytic Cleavage of Ketenimines

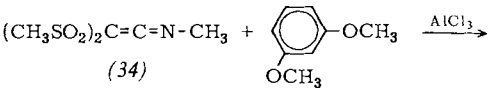


Several ketene-*N*-*tert*-butylimines *(179)* have been pyrolyzed at 145–160 °C in chloroform[68] to produce isobutylene and the nitriles *(180)*. *N*-Alkyl bond cleavage of ketenimine to nitrile has also been effected photolytically. Irradiation

(179) (180)

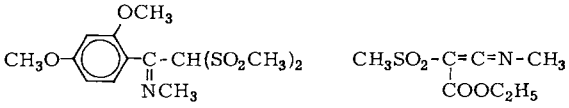
R^1 = Ph, R^2 = $COOCH_3$

R^1 = CF_3, R^2 = CF_3



(71) (72)

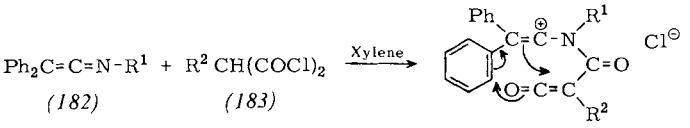
(73)



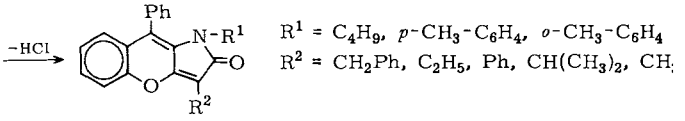
of ynamine *(71)* at 254 nm in cyclohexane[71] afforded trace amounts of dimethylbenzonitrile *(73)*, presumably *via* intermediate ketenimine *(72)*, identified by its infrared absorption.

11.4. Lewis-Acid-Catalyzed Aromatic Substitution with Ketenimines

Dijkstra and *Backer*[14a] found that ketenimine *(34)* undergoes an aluminum-chloride-catalyzed Friedel-Crafts reaction with resorcinol dimethyl ether in the absence of hydrochloric acid to give the imine *(181)*. Ketenimine *(36)* failed to undergo such an addition.

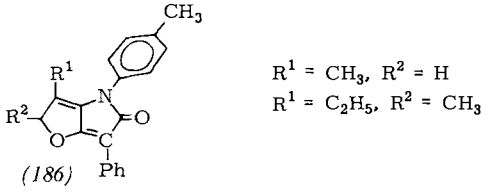


(34)



(181) (36)

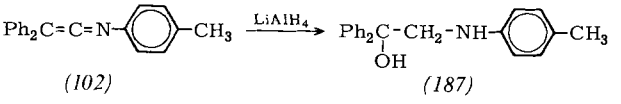
11.5. Electrophilic Addition of Acid Chlorides to Ketenimines



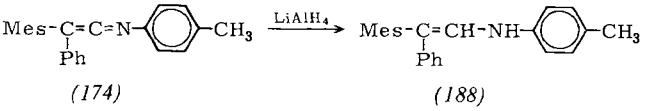
The structurally unusual heterocycles *(185)* have been synthesized[69] from ketenimines *(182)* and monosubstituted malonic acid chlorides *(183)* in refluxing xylene. Dimethyl- and diethylketene-*N*-*p*-tolylimines react with phenylmalonyl chloride to yield the heterocycles *(186)*.

(182) (183) (184)

(185)



(186)

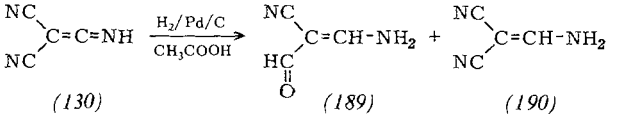


11.6. Reduction of Ketenimines

11.6.1. Hydride Reductions

Stevens and *Gasser*[66] found that amino alcohol *(187)* results from reduction of diphenylketene-*N*-*p*-tolylimine *(102)* with $LiAlH_4$. This reaction is assumed to proceed

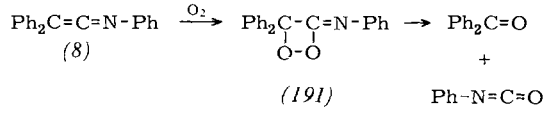
(102) (187)



(174) (188)

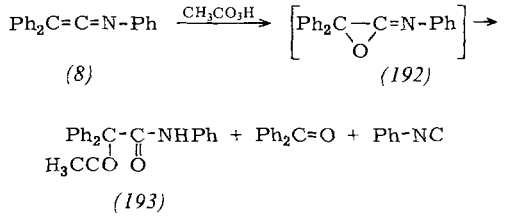
through a hydroperoxide. The sterically hindered mesitylphenylketene-*N*-*p*-tolylimine *(174)* was reduced by $LiAlH_4$ to give a stable vinylamine *(188)*.

11.6.2. Catalytic Hydrogenation



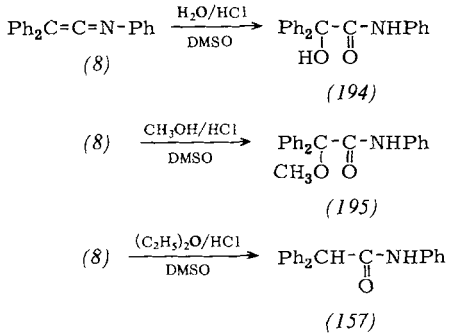
Catalytic reduction of cyanoform *(130)* yields compounds derived from the ketenimine tautomer[70]. 3-Amino-2-cyanoacrolein *(189)* and 3-amino-2-cyanoacrylonitrile *(190)* have been isolated as products.

(130) *(189)* *(190)*



11.7. Oxidation Reactions of Ketenimines

Thermal cleavage of triphenylketenimine *(8)* with oxygen yields diphenyl ketone and phenyl isocyanate[1]. The products probably result from cleavage of an intermediate oxygen adduct *(191)*.

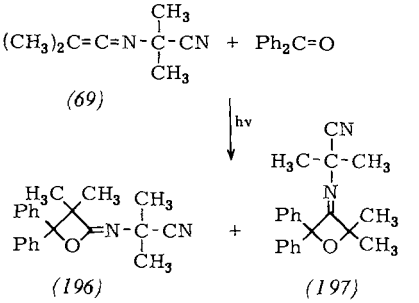


(8) *(191)*

Peracetic acid oxidation[71] cleaves triphenylketenimine *(8)* to form diphenyl ketone, phenyl isocyanide, and α-acetoxyamide *(193)*. The cleavage, presumably occurring *via* an α-imino epoxide *(192)*, is formally a reverse Passerini reaction.

(8) *(192)* *(193)*

The α-hydroxy amide *(194)* is formed from ketenimine *(8)* in 92% yield by the action of aqueous HCl in dimethyl sulfoxide. Use of methanolic HCl in dimethyl sulfoxide gave 70% yield of α-alkoxy amide *(195)*. When ether, dimethyl sulfoxide, and dry HCl were used, simple hydrolysis to amide *(157)* without oxidation of the ketenimine occurred during workup[72].



(8) *(194)* *(195)* *(157)*

11.8. Photochemical $[_\pi2_s+_\pi2_s]$ Cycloadditions of Ketenimines

Ketenimines should not differ markedly from alkyl-ethylenes in their capacity to function as $_\pi2_s$ components in cycloaddition reactions[73]. Indeed, a number of four-membered heterocycles have been synthesized by the photochemically allowed $[_\pi2_s+_\pi2_s]$ process. In certain cases described here this process may be stepwise but it is nevertheless expedient to consider the electrocyclic process in terms of allowed concertedness.

11.8.1. Cycloaddition of Carbonyl Compounds

Bartlett and *Singer*[74] observed photocycloaddition of aromatic aldehydes and ketones across the C=C double bond of dimethylketene-*N*-(2-cyanoisopropyl)imine *(69)* to give 2-iminooxetanes *(196)* and 3-iminooxetanes *(197)*. Those compounds that readily undergo photoadduct formation have an n—π* configuration for their lowest lying triplet state. Accordingly, 1-naphthaldehyde, with a lowest lying π—π* triplet state, failed to undergo photocyclization.

(69) *(196)* *(197)*

Table 15 shows a correlation of photoreactions of *(69)* with the energy required to convert an aromatic ketone from its ground state to its triplet state. The ketone also determines whether 2- or 3-iminooxetane is formed.

In a benzophenone-ketenimine reaction, cyclization proceeds *via* a triplet ketone reactive state[36]. In the case of fluorenone, however, adduct formation involves both singlet and triplet states[75].

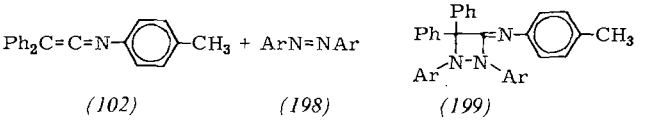


Table 15. Correlation of photoreactions of dimethyl-*N*-(2-cyanoisopropyl)ketenimine *(69)* with triplet energies of carbonyl compounds.

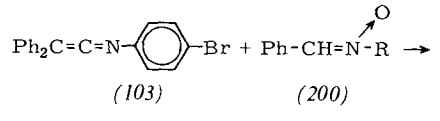
Carbonyl compound	E_{S-T} (kcal)	Adduct Yield (%)	Adduct Structure
cyclopropylphenyl ketone	—	0	—
acetophenone	74	43	2-imine + 3-imine
benzaldehyde	72	50	3-imine
benzophenone	70	95	2-imine + 3-imine
fluorenone	53	80	2-imine
1-naphthaldehyde	57 [a]	0	—

[a] Lowest lying triplet state results from a π—π* conversion.

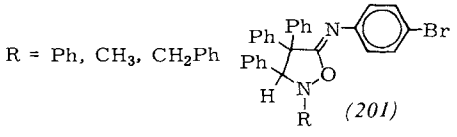
11.8.2. Cycloadditions with Azobenzenes

Diphenylketene-*N*-*p*-tolylimine *(102)* adds under photolytic conditions[76] to various symmetrically substituted azobenzenes *(198)* to form diazetidinimines *(199)*. Some electron-donating substituents on the azobenzene system increase the rate of cyclization; however, electronic effects of substituents appear to be less important than the position of the substituent, as *o,o'*-dihydroxyazobenzene does not react.



(102) *(198)* *(199)*

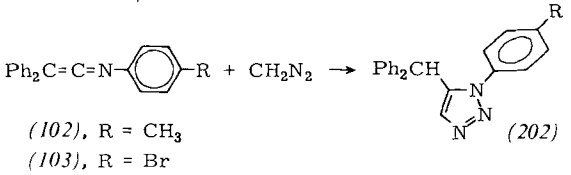
11.9. Thermal $[_\pi 4_s + _\pi 2_s]$ Cycloadditions



In the symmetry-allowed concerted $[_\pi 4_s + _\pi 2_s]$ reaction, ketenimines can serve as the $_\pi 2_s$ component either by utilizing the C=C or C=N linkages. Although triarylketenimines are not exceptionally reactive[77], several cycloadditions have been reported with ketenimines as $_\pi 2_s$ components in which the $_\pi 4_s$ component is a reactive 1,3 dipole.

11.9.1. Cycloaddition with Nitrones

Several 5-iminoisoxazolidines *(201)* have been synthesized[78] by the addition of nitrones *(200)* to diphenylketene-*N*-*p*-bromophenylimine *(103)*. An iminoisoxazolidine structure was assigned on the basis of known nitrone reactions and the manner in which nucleophiles add to ketenimines. Infrared absorption at 1680 cm^{-1} and mass spectral fragments at *m/e* 347 and 349 support the heterocyclic structure *(201)*.

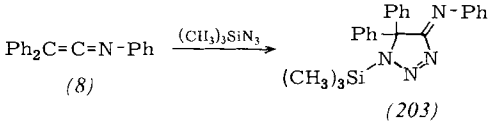


(103) *(200)*

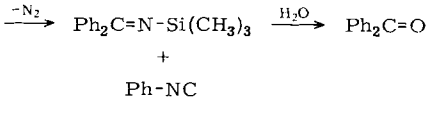
(201)

11.9.2. Cycloaddition with Diazomethane

Triarylketenimines *(102)* and *(103)* reacted[79] with diazomethane by way of 1,3-addition to the imine function *(202)*. Other examples of cycloadditions to ketenimines have all involved the C=C double bond. 1,3 Cycloaddition did not occur, however, with diazoethane, phenyldiazomethane, and diphenyldiazomethane.



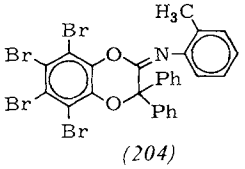
(102), R = CH_3
(103), R = Br



(202)

11.9.3. Cycloaddition with Trimethylsilyl Azide

Trimethylsilyl azide has been found to react with triphenylketenimine *(8)* on heating at 100 °C for 24 h[80]. Hydrolysis

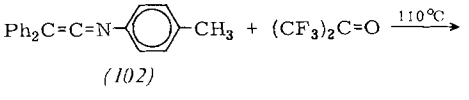


(8) *(203)*

of the reaction mixture afforded diphenyl ketones and phenyl isocyanate. The products presumably arise *via* decomposition of cycloadduct *(203)*.

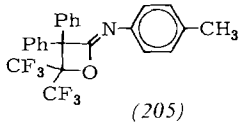
11.9.4. Cycloadditions with *o*-Quinones

Diphenylketene-*N*-*o*-tolylimine reacts[81] with perhalogenated *o*-quinones to give quantitative yields of lactone anils *(204) via* a formal $[_\pi 4_s + _\pi 2_s]$ pathway.



(204)

11.10. Thermal $[_\pi 2_s + _\pi 2_a]$ Cycloadditions

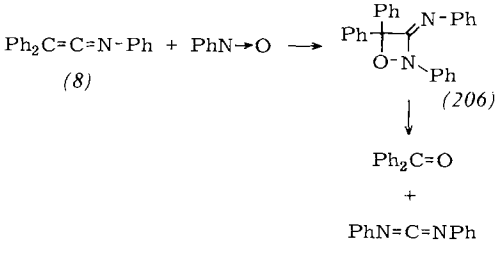


11.10.1. Ketones and Ketenimines

In principle ketenimines, functioning as vinylium ylides, are ideally constituted to play an antarafacial role as the $_\pi 2_a$ component in concerted thermal $[_\pi 2_s + _\pi 2_a]$ cycloadditions. This mode of addition, however, is not facile; attempted reactions of triphenylketenimine with phenyl isocyanate, sulfene, and phenylsulfene were unsuccessful[82].

It has been found[83], however, that diphenylketene-*N*-*p*-tolylimine *(102)* and bis(trifluoromethyl) ketone form a 2-iminooxetane adduct *(205)* when heated to 110 °C. If formed in a concerted process, the 2-iminoxetane may

(102)

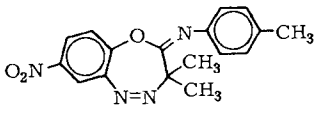


(205)

have arisen *via* a $[_\pi 2_s + _\pi 2_a]$ mode. No 3-iminooxetane was observed.

11.10.2. Nitroso Compounds and Ketenimines

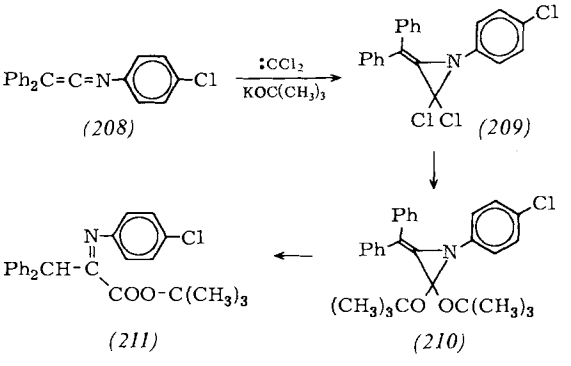
Nitrosobenzene reacts with triphenylketenimine in refluxing chloroform to yield diphenyl ketone and diphenyl carbodiimide[84]. The presumed intermediate 3-iminooxazetidine *(206)* could be identified in solution by its 1705 cm^{-1} infrared band.



(8) *(206)*

11.11. Thermal $[_\pi 6 + _\pi 2]$ Cycloadditions

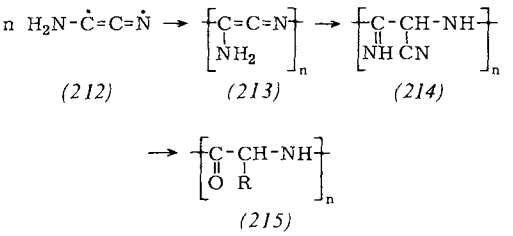
Halogen- or nitrosubstituted diazo-*o*-quinones react[85] with dimethylketene-*N*-*p*-tolylimine in inert solvents to form 2-imino-1,4,5-benzooxadiazepines *(207)*. Formation



of *(207)* is formally a $[_\pi 6 + _\pi 2]$ cycloaddition in which one component must be used antarafacially for a concerted reaction.

(207)

11.12. Cheletropic Reactions



Ichimura and *Ohta*[86] have postulated the addition of dichlorocarbene to ketenimine *(208)* to form *(209)* in order to explain the formation of imine *(211)*. It is not known if dichlorocarbene adds to the C=C or C=N double bond, so this mechanism must be considered speculative.

(208) *(209)* *(211)* *(210)*

12. Ketenimines and Prebiological Protein Synthesis

Ketenimines have been implicated in chemical evolution studies to explain prebiological protein formation. *Kliss* and *Mathews*[87] have postulated that HCN formed by solar irradiation of a methane-ammonia atmosphere dimerized to yield the 1,3 biradical aminocyanomethylene *(212)*. Polymerization of this biradical results in formation of polyaminoketenimines *(213)*[88].

(212) *(213)* *(214)* *(215)*

Tautomerism of *(213)* followed by saturation with HCN forms a stereoregular helical polymer *(214)* which is eventually converted into polyglycine *(215)* (R = H) by hydrolysis and decarboxylation. The formation of polypeptides with side groups other than hydrogen occurs before hydrolysis by reaction of the nitrile groups of the polycyanide *(214)* with hydrogen cyanide, hydrogen sulfide, and acetylene, expected components of a primitive atmosphere. *Mathews* and *Moser*[89] have found in support of this proposal that HCN polymerization catalyzed by anhydrous ammonia followed by gradual hydrolysis results in the synthesis of polypeptides containing at least eight of the common α-amino acids.

It is likely that this polymerization sequence led to formation of a protein dominated layer which became concentrated in the oceans of primeval Earth and that this process is still occurring on Jupiter and other planets with atmospheres of methane and ammonia, the molecular precursors of HCN and life.

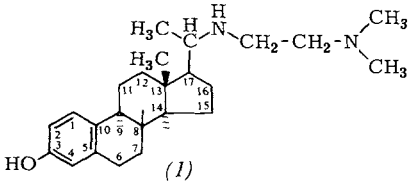
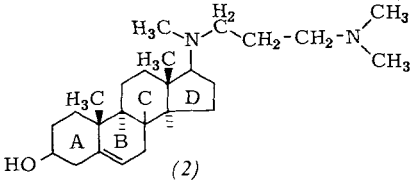
Approaches to Total Synthesis of Heterocyclic Steroidal Systems[**]



By H. O. Huisman[*]

In heterocyclic steroids the carbon atoms of the steroid skeleton (positions 1 to 17) are replaced in part by hetero atoms. The term generally denotes compounds containing one or two nitrogen, oxygen, and/or sulfur atoms. The part of the molecule containing the hetero atom is either introduced as a preformed unit or is constructed by stepwise synthesis. The examples given in the present article contain the hetero atoms in ring A, ring B, between rings A and B, and/or between rings C and D.



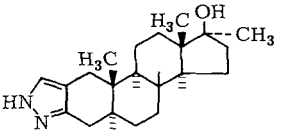
1. Introduction

Modified steroids have attracted a great deal of attention for several reasons: In the first place, their preparation itself is a stimulating challenge to the organic chemist, often demanding development of new and generally useful reactions; secondly, the investigations of reaction mechanism and stereochemistry, based upon the steroidal framework, provide fundamentally significant and frequently fascinating chemical problems; and thirdly, the biological properties of modified steroids have proved to be of interest.

A special class of modified steroids is represented by steroidal systems containing atoms other than carbon, usually nitrogen, oxygen, and sulfur, at various positions

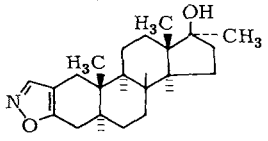
(1)

(2)



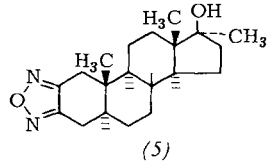
in the molecule. Such compounds have been prepared by partial or by total synthesis and some of them possess interesting pharmacological properties.

The two compounds *(1)*[1,2] and *(2)*[3-6] containing nitrogen atoms in the side chain of the steroid molecule serve as examples. These aza steroids exert a hypercholesterolemic activity[7-13].

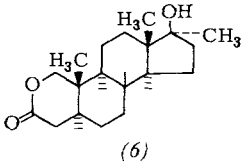


[*] Prof. Dr. H. O. Huisman
Laboratory of Organic Chemistry
University of Amsterdam
Amsterdam (The Netherlands)

[**] Lecture presented at the Second International Congress of Heterocyclic Chemistry, Montpellier, July 7—11, 1969.

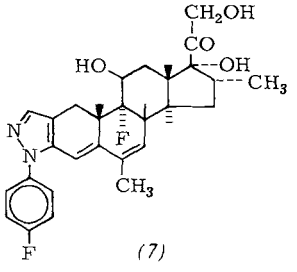


The four compounds *(3)*[14], *(4)*[15], *(5)*[16,17], and *(6)*[18] are representatives of heterocyclic steroids with high degree of separation of anabolic from androgenic activity. They contain a pyrazole-, isoxazole-, oxadiazole-, and a lactone ring respectively.



(3)

(4)

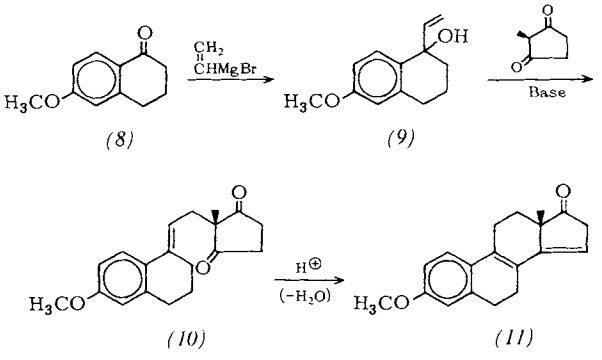


(5)

(6)

Pyrazole derivatives of 9-fluorocortisol systems, such as compound *(7)*[19], are heterocyclic steroids which possess potent anti-inflammatory activity.

(7)



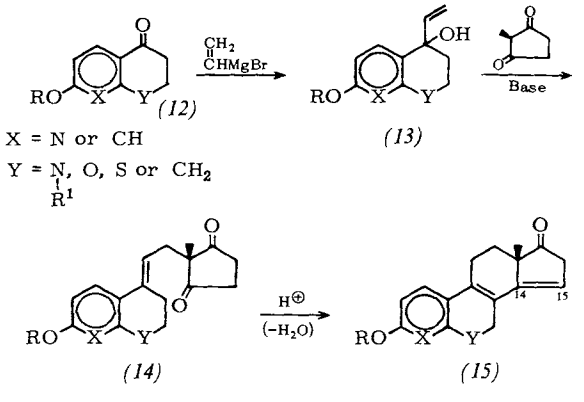
It may be noted that in all the examples mentioned—except compound *(6)*—the hetero atoms are located outside the steroidal nucleus. Thus only compound *(6)* can be termed a *heterocyclic* steroid. In our laboratory we have largely concentrated on the development of synthetic approaches leading to heterocyclic steroidal systems.

In principle, two different routes are available for the total synthesis of the complex steroid framework containing one or more hetero atoms. One approach starts from mono- or bicyclic hetero systems; alternatively, the heterocyclic component of the steroid nucleus may be constructed in a sequence of special synthetic techniques.

2. Utilization of Suitable Mono- or Bicyclic Hetero Systems to Construct the Heterocyclic Steroidal Skeleton

2.1. Approaches Based on *Torgov*'s Carbocyclic Steroid Synthesis

A synthetic scheme that holds considerable potentiality for variations in the nature of the precursor components is represented by the transformation of 6-methoxy-α-tetralone *(8)* to the steroidal skeleton *(11)* in three facile



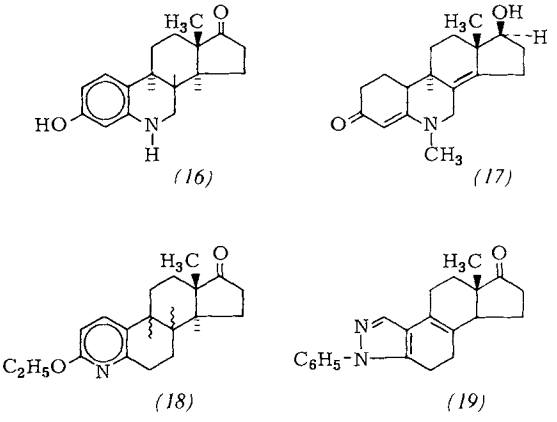
(8) *(9)* *(10)* *(11)*

steps in good overall yields. This elegant total synthesis was developed by *Torgov et al.*[20] at Moscow.

It is obvious that α-tetralone should be replaceable by various heterocyclic analogs, provided the nature and location of the hetero atom(s) do not adversely affect the sequence of reactions involved.

Using appropriate aza-, oxa-, and thia-α-tetralones *(12)*, tetracyclic systems *(15)* have been prepared according to Scheme 1.

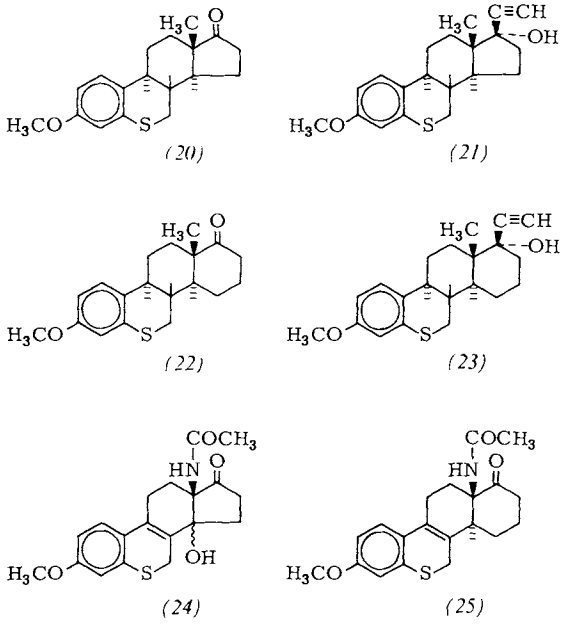
(12) *(13)* *(14)* *(15)*



X = N or CH

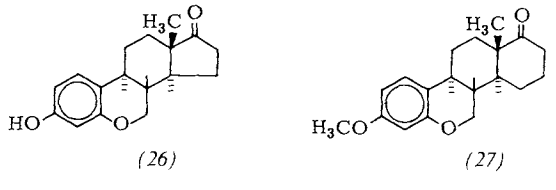
Y = N, O, S or CH_2 (R^1)

Scheme 1.



Neither the mechanism of the condensation reaction by which the *seco*-diones *(14)* are formed, nor the mechanism of the cyclodehydration reaction which leads to the tetracyclic systems *(15)* will be discussed here. Nor will details of how the tetracyclic systems *(15)* have been further elaborated to various aza, oxa, and thia steroids be given. Most of this work has been extensively reviewed elsewhere[21].

However, in order to emphasize the versatility of this three-step synthesis, the various heterocyclic steroidal systems synthesized by this method are summarized in Table 1.



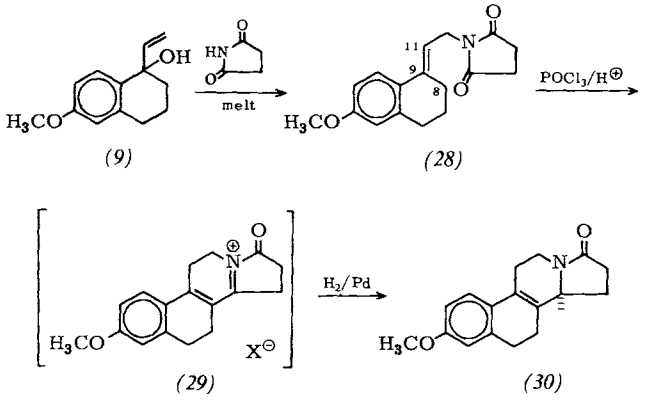
(16) *(17)* *(18)* *(19)*

The D-homo thia steroidal systems *(22)* and *(23)* have been obtained by using methylcyclohexadione instead of methylcyclopentadione in the condensation reaction. The thia steroidal systems *(24)* and *(25)*, which both contain an acetylamino group in place of an axial methyl group at

(20) *(21)* *(22)* *(23)* *(24)* *(25)*

position 13, have been synthesized by using acetylaminocyclopentadione and acetylaminocyclohexadione respectively in the condensation reactions.

(26) *(27)*



Recently we have utilized heteroanalogs of the cyclopentadione systems in the above reaction scheme for the synthesis of ring D-modified steroids. From a consideration of the mechanism of the addition and cyclization steps, it is apparent that the choice of a dione analog is subject to several structural restrictions. In view of its weak acidic character and cyclic lactam structure the candidate selected was the readily available succinimide system. Furthermore, the chemical properties of the latter system necessitated

Table 1. Heterocyclic steroids synthesized by *Torgov*'s method.

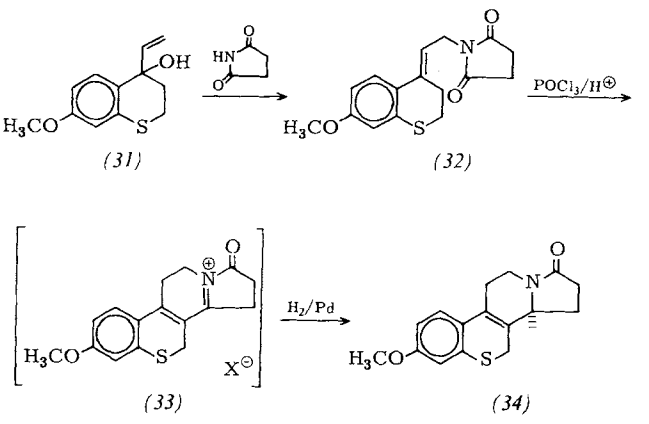
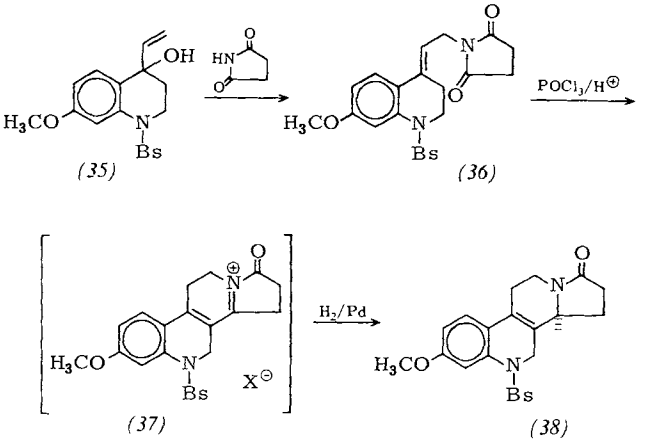
modification of the usual reaction conditions. A generally applicable new technique for this type of condensation was found by carrying out the reaction in a melt in presence of a base, usually potassium succinimide. In this way slow reaction of the succinimide at low temperatures and instability of the vinyl alcohol *(9)* at high temperature could be overcome.



The sequence of reactions is given in Scheme 2. Cyclodehydration of the *seco*-steroid *(28)* was carried out by treatment with a mixture of phosphorus oxychloride and water, in which the latter served as a proton source for acid-catalyzed isomerization of the 9,11 double bond to the 8,9 position prior to the cyclization step. The unstable cyclization product *(29)* was directly hydrogenated to the 13-aza-steroidal system *(30)*[42,43].

(9) *(28)* *(29)* *(30)*

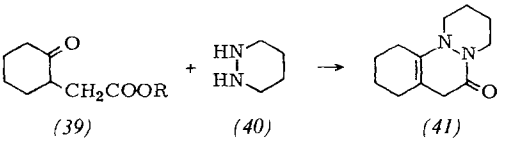


Scheme 2.

Reaction of succinimide with vinyl alcohols derived from heterocyclic analogs of 6-methoxy-α-tetralone should, in principle, lead to heterocyclic steroidal systems containing an assortment of combinations of elements. An example illustrating the application of Scheme 2 to this class of compounds may be seen in the synthesis of the 6-thia-13-aza-steroidal system *(34)* starting with the vinyl thia alcohol *(31)*[43,44].

(31) *(32)* *(33)* *(34)*

Another example is the synthesis of the 6,13-diaza-steroidal system *(38)*[43,45] starting with the vinyl aza alcohol *(35)*.

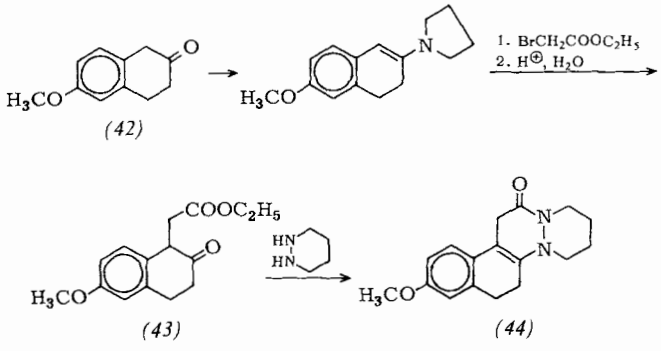


(35) *(36)* *(37)* *(38)*

Bs = C_6H_5-SO_2-

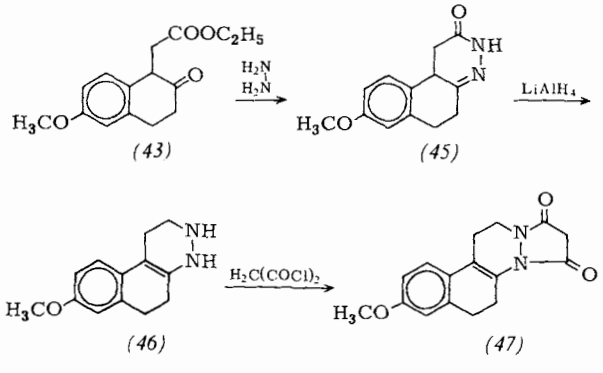
2.2. Approaches by Condensation Reactions with Hydropyridazines

A second general approach using accessible heterocyclic precursors, and one which is potentially open to ample variations, is embodied in the reaction of perhydropyridazine *(40)* with an alkyl (2-oxocyclohexyl)acetate *(39)*.



(39) *(40)* *(41)*

The direct condensation yields a tricyclic system *(41)*[46,47] containing vicinal nitrogen atoms at a bridgehead location. The reaction actually proceeds in two consecutive steps; initial amide formation is followed by a fast intramolecular cyclization[*].

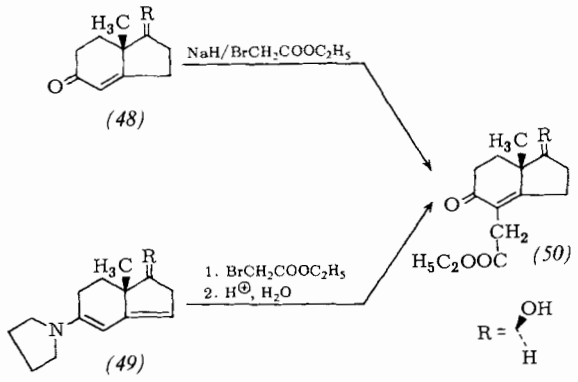


Depending upon the availability of the appropriate γ-keto esters *(39)* it is easy to visualize that the reaction sequence offers an attractive approach to 5,10- or 13,14-diaza-steroidal systems. Both these objectives have been achieved in our laboratory.

The starting point for a 13,14-diaza-steroidal skeleton was 6-methoxy-β-tetralone *(42)* which was conveniently monoalkylated with ethyl bromoacetate at the α-position, *via* its pyrrolidine enamine to the γ-keto ester *(43)*. Reaction of the latter with perhydropyridazine in boiling xylene afforded the 13,14-diaza-D-homo-steroidal system *(44)*[48].

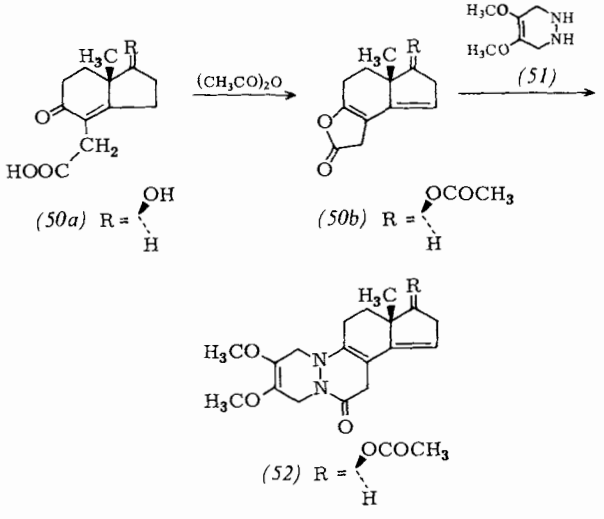
(42) *(43)* *(44)*

A slight modification of the hydrazine condensation principle may be seen in the synthesis of the 13,14-diaza-15,17-dioxo steroid *(47)*[48], where the tricyclic hydrazine *(46)* is itself prepared by the reaction of *(43)* with hydrazine hydrate, followed by reduction of *(45)*. The structure of *(47)* was evidenced by its IR, NMR and mass spectral (exact mass) data.



(43) *(45)* *(46)* *(47)*

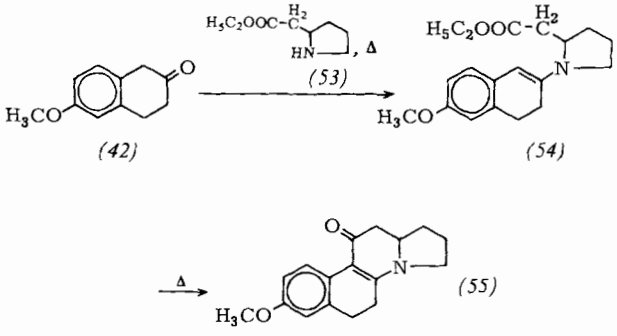
In order to introduce the vicinal nitrogen atom between rings A and B of the steroidal nucleus (Positions 5 and 10), it is necessary to operate with a functionalized tetrahydropyridazine and a γ-keto ester component incorporating preformed rings C and D.



The intermediate *(50)* was obtained by alkylation of the bicyclic ketone *(48)*, in presence of base or, preferably, *via* the enamine *(49)*.

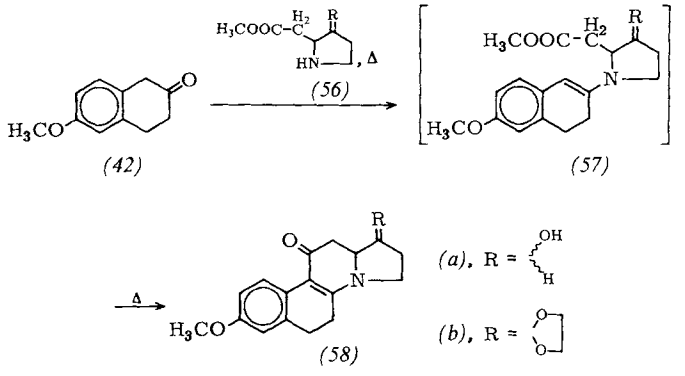
[*] The two-step sequence has been substantiated by isolation of the intermediate amide, which undergoes rapid cyclization.

(48) *(49)* *(50)*



By heating the γ-keto acid *(50a)* with acetic acid anhydride, the lactone *(50b)* is formed, which upon condensation with 4,5-dimethoxy-1,2,3,6-tetrahydropyridazine *(51)* affords the 5,10-diaza-steroidal system *(52)*[49,50].

2.3. Approaches by Intramolecular Cyclizations of Enamine Esters

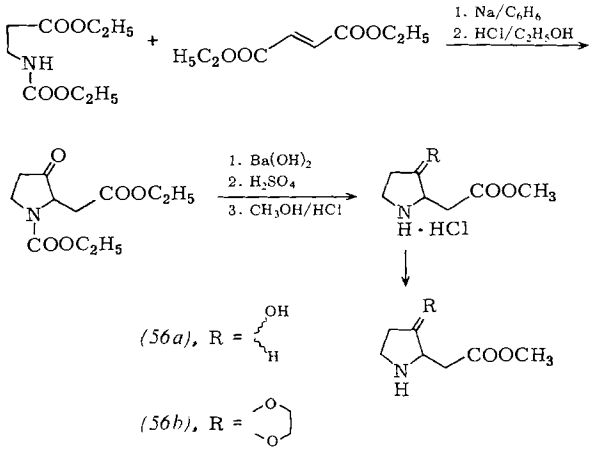


A third approach for building up aza-steroidal systems, especially the 14-aza-steroid skeleton, proceeds by intramolecular cyclization of enamine esters derived from β-tetralone and appropriately substituted pyrrolidines.

The principle of the reaction is illustrated by the condensation cyclization sequence upon heating a mixture of 6-methoxy-β-tetralone *(42)* and pyrrolidyl-2-acetate *(53)*. The intermediate enamine ester *(54)* is readily cyclized to the 11-keto-14-aza-steroidal system *(55)*[51] upon heating in glycol.

(42) *(54)* *(55)*

Substitution at C-17 in the steroidal system leading to 11-oxo 14-aza steroids *(58a)* and *(58b)* was achieved by reaction of the β-tetralone system with 3-substituted pyrrolidine esters *(56a)* and *(56b)*.

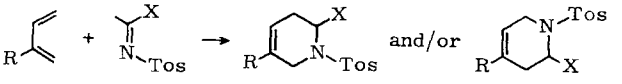


(42) *(57)* *(58)*

(a), R =

(b), R =

The 3-substituted pyrrolidine esters[52] are synthesized as shown in Scheme 3.



(56a), R =

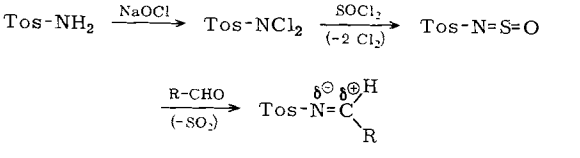
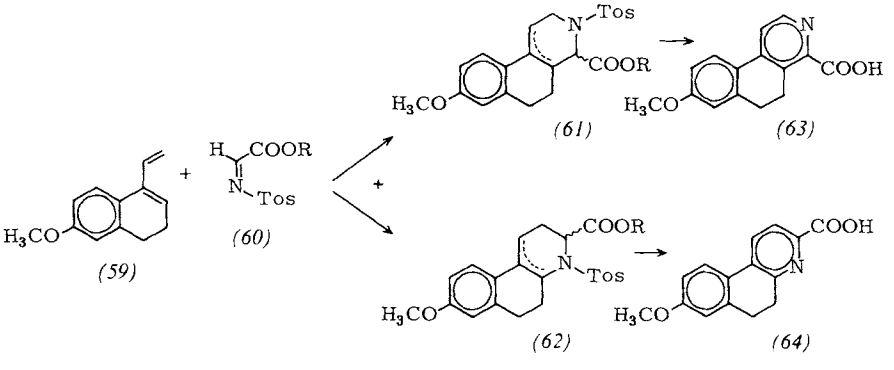
Scheme 3.



structural parameters satisfy certain requirements. For instance, electron-demanding groups such as trihalomethyl,

Scheme 4. X = CCl_3, $COOR^1$.



alkoxycarbonyl, or sulfonyl activate an imine sufficiently for it to act as dienophile in Diels-Alder reactions.

The practical difficulties connected with the synthesis of such highly reactive imines could be solved by using an adapted method for their preparation, which made it possible to carry out large scale preparations (Scheme 5).

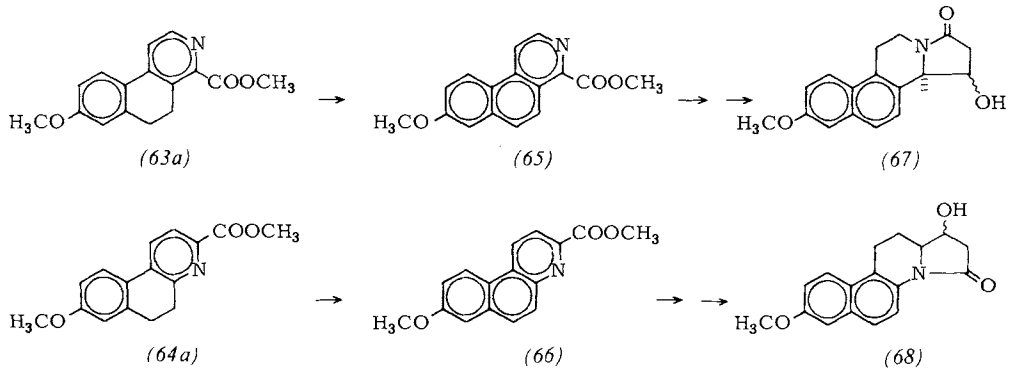
Scheme 5. R = CCl_3, $COOR^1$.

A knowledge of the electronic and steric factors[*] which govern the direction of addition is of special interest in this type of Diels-Alder reaction. We have carried out a large number of investigations in order to gain fundamental information about the reactivity of diene systems and the direction of addition of the different imines to the dienes. However, this article will consider only those aspects which are of immediate importance in the synthesis of aza steroids.

(59) *(60)* *(61)* *(62)* *(63)* *(64)*

3. Construction of the Heterocyclic Component of the Steroid Nucleus in a Critical Synthetic Sequence

3.1. Preparation by Diels-Alder Cyclization



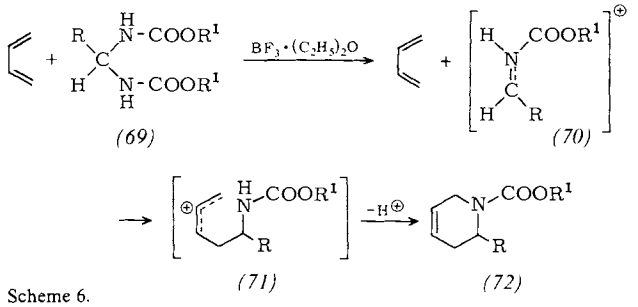
Use of Diels-Alder cyclization to form heterocyclic systems provides a general synthetic concept with a wide range of potential applications in steroid synthesis. Our own specific interests centered upon the reaction of suitable dienes with imines (Scheme 4).

Imines are generally recognized as being unreactive in cycloaddition reactions. However, some pioneering work of *Kresze* and collaborators[53] has indicated the possibility of a concerted type of addition of imines, provided that the

By reacting the imino ester *(60)* with the diene *(59)*, a laboriously separable mixture of isomeric adducts *(61)* and *(62)* is obtained, which, however, after alkaline hydrolysis yields the dihydrobenzoquinoline acids *(63)* and *(64)* (readily separated *via* fractional crystallization).

The corresponding methyl esters of these acids, *(63a)* and *(64a)* respectively, were dehydrogenated to the benzoquinolines *(65)* and *(66)*, which where converted *via* standard procedures to the 13-aza- and 14-aza-equilenine systems *(67)* and *(68)*[55, 56].

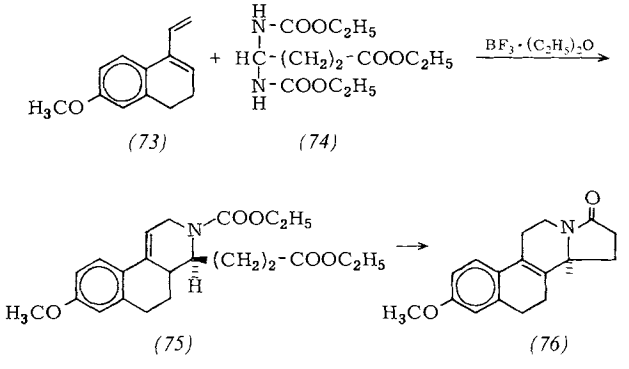
[*] General information about these factors was obtained from a series of experiments wherein the mode of addition of simple dienes was studied. Results will be published separately [54].



(63a) (65) (67)

(64a) (66) (68)

3.2. Preparation by a Pseudo Diels-Alder Reaction (Urethane Approach)

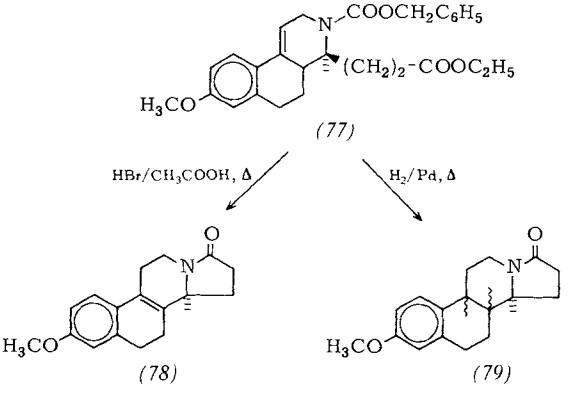


A second approach is based on a reaction type that formally resembles a normal Diels-Alder cycloaddition between an imine and a diene, but is mechanistically of a different class[57]. One could call it a pseudo Diels-Alder reaction; it proceeds as shown in Scheme 6.

(69) (70) (71) (72)

Scheme 6.

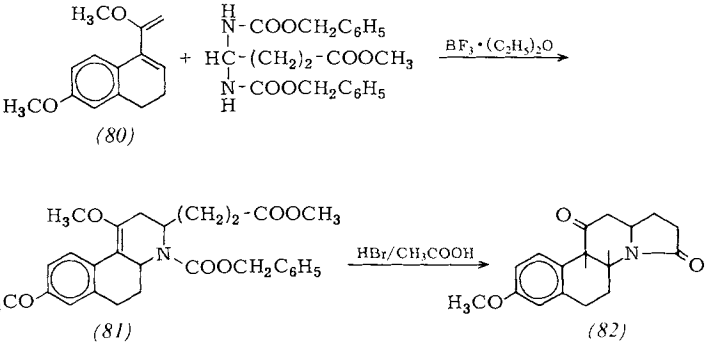
Under the influence of BF_3·ether, a diene reacts with a dicarbamate *(69)* to give a tetrahydropyridine derivative *(72)*. The type of reaction involved in this addition is most probably the following: After the generation of a carbonium ion intermediate *(70)* an addition complex *(71)* is formed which then cyclizes to give the heterocyclic system



(73) (74) (75) (76)

(72). Promoting factors in this condensation are, among others, the stability of the ion *(70)*, the presence of stabilizing groups R, and especially the rigidity of the diene. The last factor obviously reflects a favorable entropy factor necessary for a smooth cyclization of the ionic intermediate. Experimental evidence for this observation comes from a large series of reactions with a variety of diene systems[58].

The original synthetic scheme developed made use of a particular advantage of this method in which the choice available in the substituent R could be exploited by choosing a group which potentially includes the factors of ring D in the steroid molecule. The diene *(73)* reacts with the dicarbamate *(74)* to give the tricyclic intermediate *(75)* which after hydrolysis of the ester groupings cyclizes to the 13-aza steroid *(76)*. However, the yield in the last step, the cyclization reaction, was rather low.

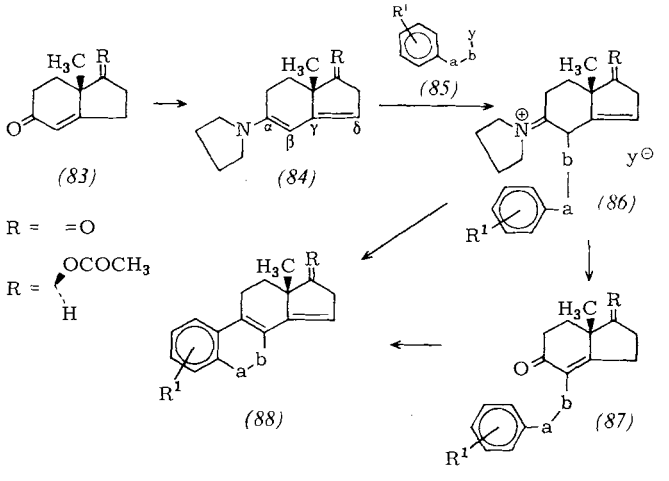


A considerable improvement in the yield of the cyclization step was achieved on use of the benzylurethane moiety instead of the ethylurethane group in *(75)*. The crystalline adduct *(77)* was obtained *via* the indicated route and

(77) (78) (79)

smoothly converted into the aza steroids *(78)* and *(79)* by treatment with hydrobromic acid/acetic acid and hydrogenation over palladium on carbon[59], respectively.

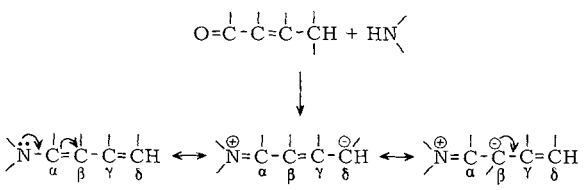
The method outlined was further applied to the synthesis of 11-oxo 14-aza steroids using diene *(80)* as starting material. In view of the polarization of the diene system one should expect predominant formation of the 14-aza



(80) (81) (82)

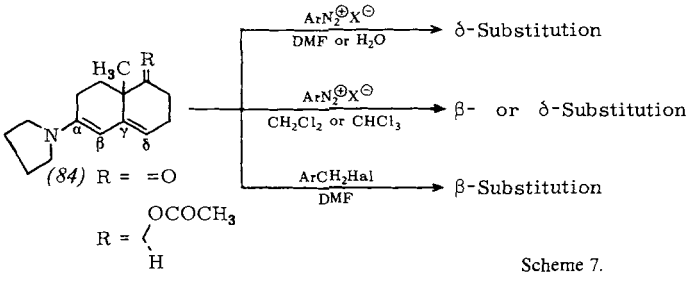
isomer *(81)*, which was actually observed. Acid-catalyzed cleavage of the benzyloxycarbonyl group led to the 14-aza-steroidal system *(82)*[60].

3.3. Preparation by Condensations of Suitable Dienamine Systems



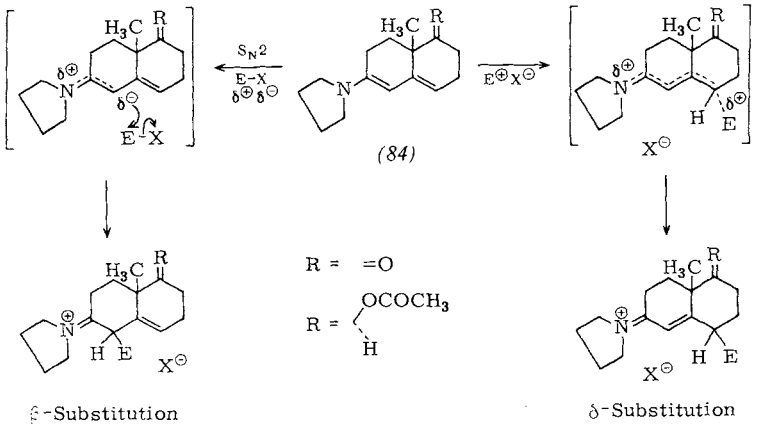
The principle of the method may be outlined as follows: A dienamine *(84)* of the readily accessible bicyclic α,β-unsaturated ketone *(83)*—which eventually serves as the C/D portion of the steroid nucleus—is connected, *via* the β-carbon, to an appropriate functionalized aromatic derivative, such as *(85)*. Hydrolysis of the intermediate iminium salt *(86)* unmasks the carbonyl function, which then serves as the point of cyclization of the aromatic ring; the overall process results in the formation of the steroidal skeleton *(88)*. It is conjectured that the intermediate *(86)* can also directly undergo a cyclization reaction involving nucleophilic attack.

For the scheme to operate several essential requirements must be satisfied: a) electrophilic attack on the enamine must occur on the β-position (and not on the δ); b) Y should be a good leaving group; and c) the aromatic ring should be sufficiently activated so as to undergo electrophilic attack by the carbonyl carbon under the influence of suitable acidic reagents.



A dienamine system has, in principle, three nucleophilic centers—the nitrogen atom, and the β- and δ-carbon atoms. The latter derive their nucleophilic character by interaction of the free electron pair of the nitrogen with the π-electrons of the double bond.

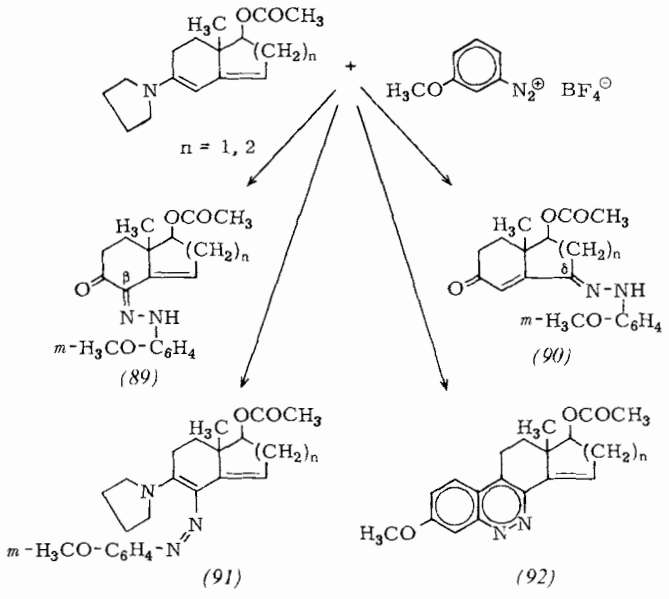
A comparison of dienamines with dienol ethers[61] and a consideration of the value of the chemical shift of the olefinic protons of cyclic dienamines both suggest a charge distribution in the dienamine where the β-carbon has a



higher electron density than the δ-carbon. This charge distribution has been substantiated by HMO calculations[62] of the electron-density along the dienamine system: α-C = +0.0754; β-C = −0.1258; γ-C = +0.0080; δ-C = −0.0629.

An interesting insight into the electrophilic pattern of dienamines is afforded by the reaction of systems such as *(84)* with reagents of different reactivities and under varying reaction conditions (see Scheme 7).

Scheme 7.

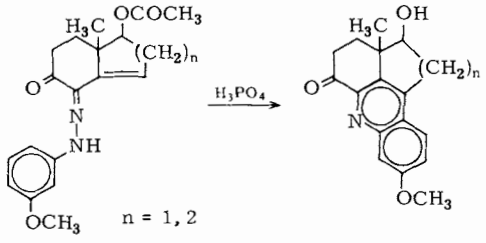


The following rationalization may be offered for the substitution pattern of the dienamine system. β-Substitution results from nucleophilic attack (S_N2) by the atom with the higher charge density and involves bond cleavage in the transition state[*]. With a charged electrophile, such

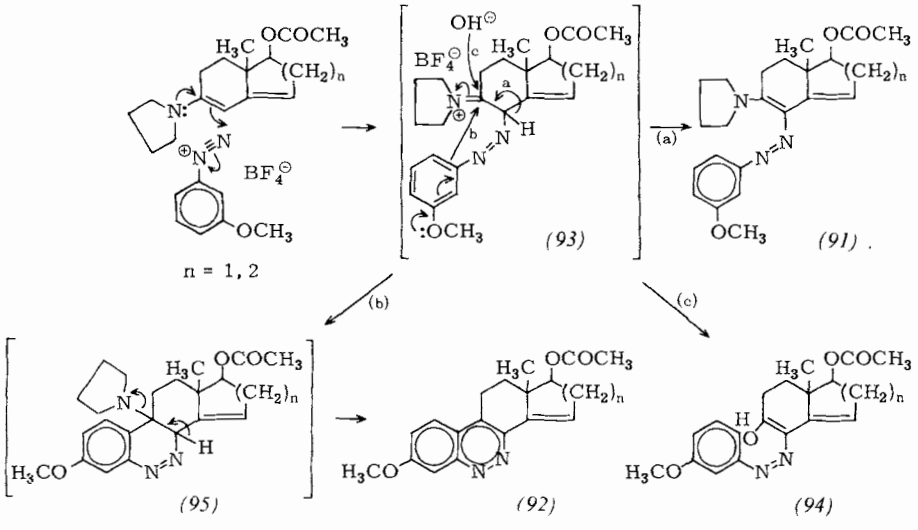
Scheme 8.

[*] We have so far no evidence for an initial attack on the nitrogen followed by an N→C migration. However, this and related questions concerning the mechanism are presently being investigated.

as a diazonium salt in polar solvents, the transition state—essentially a "clipping-on" process—closely resembles the

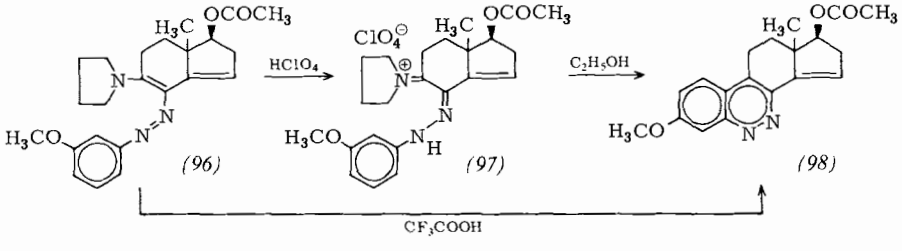


end product and its structure may consequently be dominated by the thermodynamic stability of the product. This results in the formation of the conjugated iminium salt, *i.e.* the product of δ-substitution[*]. In methylene chloride or chloroform, however, reaction of diazonium salts may proceed *via* the simultaneous operation of both mechanisms (Scheme 8).



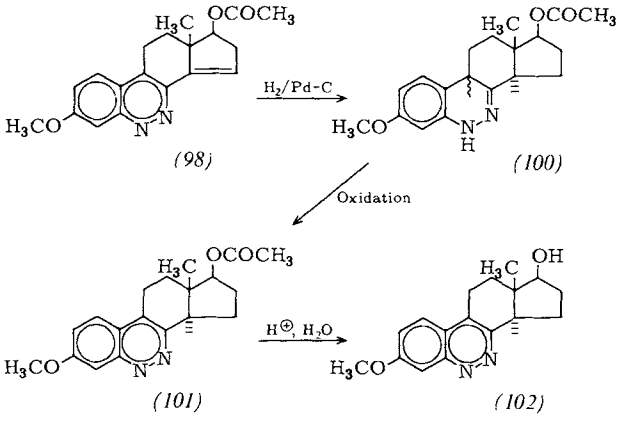
[*] We are aware that alternative explanations can be offered for δ-substitution. A study of the influence of solvent effects of substituents in the diazonium salts is being conducted at present to settle the issue.

The products of the diazonium salt reaction with the dienamine in CH_2Cl_2 or $CHCl_3$ have been identified as the expected β-hydrazone *(89)* and δ-hydrazone *(90)* and, what was of greater interest, the azoenamine *(91)* and the 6,7-diaza-steroidal system *(92)*[63].

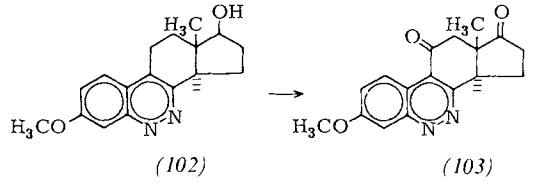


The origin of the β-substitution products can be seen in the different fates of the initially formed iminium ion *(93)*. Loss of a proton (path a) leads to the azo enamine *(91)* while hydrolysis (path c) gives the hydrazone *(94)* depicted in its tautomeric form [cf. *(89)*]. Formation of the steroidal system *(92)* can be explained by an intramolecular nucleophilic attack by the aryl moiety on the iminium function

(path b), followed by loss of pyrrolidine from the intermediate product *(95)*.



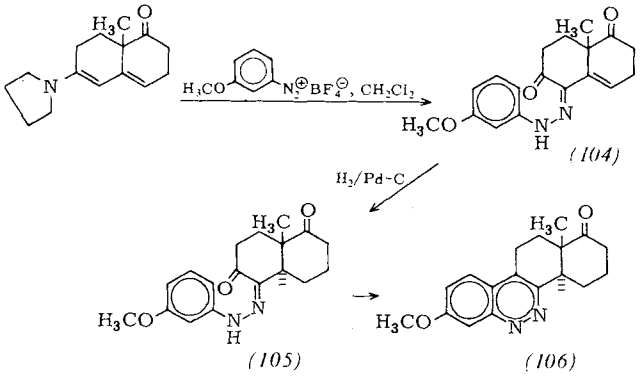
That this indeed was the course of events is supported by the fact that both heating of the azo enamine *(96)* [cf. *(91)*] in trifluoroacetic acid and refluxing the iminium perchlorate *(97)* in ethanol resulted in the formation of the steroidal system *(98)* [cf. *(92)*] in high yield.



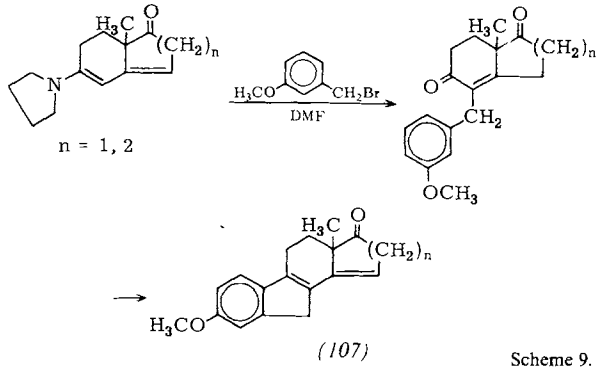
Attempts to cyclize the β-substituted hydrazone *(89)* to the steroidal skeleton were unsuccessful. Instead, under

acidic conditions, cyclization led to the quinoline derivative *(99)*.

Elaboration of the steroidal system *(98)* to the 6,7-diaza analogs of estrogenic hormones was then undertaken.



Catalytic reduction over Pd—C effects partial hydrogenation of the heterocyclic ring, and complete reduction of the 14,15-double bond. Only a single product *(100)* is isolated in which, while the stereochemistry of the proton on C-9 remains unsettled, the configuration of that on C-14 is shown to be α- by oxidation to *(101)*, whose NMR spectrum reveals *trans* C/D ring linkage. Acidic hydrolysis of *(101)* gives the corresponding alcohol *(102)*.



Attempts to convert *(102)* into 6,7-diazaequilenin methyl ether by oxidation with CrO_3/pyridine gave, interestingly, the 11-oxo derivative *(103)* of the desired compound. The relative ease of oxidation of the 11-position has also been observed with other oxidizing agents. Methods of specific oxidation of the OH group on C-17 are at present under investigation.

In view of the problems associated with the selective oxidation of the hydroxyl function on C-17 an approach starting from the β-hydrazone *(104)* was developed. Catalytic reduction of the β-substituted hydrazone resulted in a single product *(105)* which gave 3-methoxy-6,7-diazo-D-

homoequilenin *(106)* (3-methoxy-D-homo-6,7-diazaestra-1,3,5(10),6,8-pentaen-17-one) on treatment with polyphosphoric acid. The stereochemistry of the proton on C-14 in *(105)* and in *(106)* has been established by a comparison of the NMR spectrum of *(106)* with those of the carbocyclic D-homoequilenin and D-homo-14β-isoequilenin methyl ethers[64].

Scheme 9.

It is obvious that following the general dienamine approach, as outlined above a variety of heterocyclic steroids, modified in ring A and/or B, could in principle be constructed. *U. K. Pandit*, who initiated the dienamine approach in our laboratory, is currently elaborating the method in various directions. Following the same principle, he recently has also succeeded in synthesizing the carbocyclic β-nor-steroidal skeleton *(107)*[65] (Scheme 9).

In conclusion, I would like to express my sincere thanks to my associates, Dr U. K. Pandit and Dr W. N. Speckamp, who have initiated and guided so many research problems to a successful end. I also wish to thank my other collaborators who have contributed so much to the subjects I have discussed in this paper: Mrs Drs J. L. van Bruynsvoort-Meray, Mrs Drs M. A. Th. Dzcubas-Sluyter, Mrs K. de Jonge, Drs M. A. Douw, Drs H. Evers, Drs J. C. Hubert, Drs H. de Koning, Drs W. M. B. Könst, Drs G. C. Pietzsch, Dr M. J. M. Pollmann, Dr J. A. van Velthuysen, Dr E. R. de Waard, Dr J. G. Westra, and Dr W. A. Zunnebeld.

Chemical Bonding in Solids[**]

By Hermann Hartmann[*]

The most important of the current quantum-mechanical models of solids can be divided into one-electron (band) models and incomplete polyelectron theories. There are no complete polyelectron theories at present. However, the interatomic exchange forces become less important in lattices with high coordination numbers; a theory of metallic phases can therefore be developed, in principle, on the basis that the antisymmetrization is only local in atoms or groups of atoms.

The question of the chemical bonding in solids is simply the question of their energy content in their lowest energy state, all the free atoms in their ground states being taken as the reference point. The state of lowest energy of a solid is the equilibrium state reached in the vicinity of the absolute zero of temperature. The energy content of the solid for this case is denoted by E_0.

It is fairly certain that E_0 can fundamentally be found, apart from relativistic corrections, with the aid of quantum mechanics. However, only approximate calculations are possible in practice. Such calculations generally involve the introduction of simplifying assumptions, so that one is ultimately dealing not with the solids themselves but with models that are more or less similar to the solids.

One assumption that is nearly always introduced in connection with solids is the separation of the movements of the nuclei and of the electrons, which was shown by *Born* and *Oppenheimer* to be plausible in view of the large difference in mass between atomic nuclei and electrons[1]. The motion of the electrons is thus first treated in relation to stationary atomic nuclei; in particular, the energy of the ground state of the electrons E_E, which is increased by a quantity corresponding to the interaction energy of the supposedly stationary nuclei, is determined as a function of the coordinates describing the positions of the nuclei, which we shall denote by τ_1, τ_2, *etc.*

If this function

$$E_E = E_E(\tau_1, \tau_2, \ldots) \tag{1}$$

has an absolute minimum with the value

$$E_{E0} = E_E(\tau_{10}, \tau_{20}, \ldots) \tag{2}$$

at the point $\tau_1 = \tau_{10}$, $\tau_2 = \tau_{20}$, *etc.*, the set of atoms present in the reference state are said to be capable of forming a stable condensate.

The nuclear motion is dealt with in the next step, the function (1) now assuming the role of a potential energy. If the energy corresponding to the state of nuclear motion with the lowest energy is E_{K0}, then

$$E_0 \approx E_{E0} + E_{K0} \tag{3}$$

in the Born-Oppenheimer approximation.

If the entire treatment is repeated after introduction of additional external and possibly time-dependent forces (which can be described by parameters), it is possible to give criteria for the function that replaces eq. (2), *i.e.*

$$E^*_{E0} = E^*_E(\tau_{10}, \tau_{20}, \ldots c, t) \tag{4}$$

on the basis of which stable condensates could be designated as solid or liquid, according to their fluidity. Since the fluidity properties provide only a problematic basis for the definition of "solids", it is more convenient to refer to a stable condensate as a solid if τ_{10}, τ_{20}, *etc.* in eq. (2), apart from small nonsystematic deviations, denote lattice points in a three-dimensionally periodic arrangement of the atomic nuclei.

The function E_{E0} (2) provides information on the geometry of the solid when the atomic nuclei occupy their "normal positions". It describes the lattice type of the phase that is stable at absolute zero.

If one is interested in solids that are stable only under other conditions (temperature different from zero and presence of external forces), the calculations indicated above must initially be carried out with inclusion of the external forces. It is then necessary, however, to determine not only the ground states for the motion both of the electrons and of the nuclei but also the excited states, and subsequently to determine the normal properties of the system under the given conditions by the known methods of statistical mechanics. Relative minima of the function E_E (1) may be of some importance at finite temperatures. These minima, which are described *e.g.* by the values τ'_{10}, τ'_{20}, *etc.*, τ''_{10}, τ''_{20}, *etc.* of the coordinates, generally correspond to lattices with different geometries.

In the theoretical chemistry of solids, interest has so far been concentrated mainly on the determination of the function E_E (1). In most investigations, in fact, the normal positions τ_{10}, τ_{20}, *etc.* were determined experimentally, or else it was assumed to be necessary to determine only a common factor of these quantities. The latter procedure means that the lattice type is given and the lattice constants are regarded as the quantities to be determined.

In most cases, therefore, attempts were made to determine the energy

$$E_{E0} = E_E(\tau_{10}, \tau_{20}, \ldots)$$

(for given τ_{10}, τ_{20}, *etc.*), or after introduction of

$$\tau_{i0} = \sigma\rho_{i0}$$

attempts were made to find the value σ_0 of σ that minimizes the function

$$E_E(\sigma\rho_{10}, \sigma\rho_{20}, \ldots)$$

for a given ρ_{i0}, *i.e.* to find the value of σ_0 such that

$$E_{E0} = E_E(\sigma_0\rho_{10}, \sigma_0\rho_{20}, \ldots).$$

Two methods have been used for the solution of these problems:

1. Treatment of the solid as a one-electron problem and subsequent formulation of the electronic ground state of the solid in accordance with the Aufbau principle ("filling" of the one-electron states with electrons in accordance with Pauli's exclusion principle).

2. Treatment of the solid as a true many-electron problem.

In method 1, the potential energy of the electron system, including the interaction energy of the fixed atomic nuclei, is

$$V = -\sum_i\sum_j \frac{Z_j e^2}{r_{ij}} + \sum_i\sum_{i<i'} \frac{e^2}{r_{ii'}} + \sum_j\sum_{j<j'} \frac{Z_j Z_{j'} e^2}{r_{jj'}} \tag{4}$$

where j (or j') is a number indentifying an atomic nucleus and i (or i') is a number identifying an electron; Z_j (or $Z_{j'}$) is the number of charges on the j-th (or j'-th) atomic nucleus and e is the elementary charge. The first sum in eq. (4) represents the interaction energy of the electrons with the nuclei, the second that of the electrons with one another, and the third that of the nuclei with one another. V thus depends in a very complicated manner on the coordinates of all the nuclei and of all the electrons.

Any given electron is in interaction with all the (stationary) nuclei and with all the other electrons. Since the motion of these other electrons is periodic in the final analysis (they would otherwise escape from a finite solid body), it is reasonable to imagine an interaction energy of the chosen electron with the other electrons that is averaged over time, and which then depends only on the position of this electron. If the interaction of the electron with the nuclei is added to this interaction, it is reasonable to picture the electron as moving in an "effective" electric field, so that its effective potential energy can be expressed by

$$v = v(q)$$

where q is a symbol for the three coordinates of the electron.

The expression

$$V_{eff} = \sum_i v(q_i) \tag{5}$$

would then give the effective potential energy of the electron system. A well-known procedure[2] nowadays is to collect the terms in

$$V = V_{eff} + (V - V_{eff}) \tag{6}$$

as indicated and to choose v such that $|V - V_{eff}|$ is generally, *i.e.* for most configurations, small in relation to $|V_{eff}|$. Then

$$V \approx V_{eff} = \sum_i v(q_i) \tag{7}$$

The Schrödinger equation with this expression as the potential energy can be obtained immediately, and in order to find the one-electron states and their energy values ε, one need only solve the representative one-electron Schrödinger equation

$$-\frac{\hbar^2}{2m}\Delta\psi + v(q)\psi = \varepsilon\psi \tag{8}$$

To improve the ε values, a perturbation calculation must be carried out with the eigenfunctions of eq. (8) and $(V - V_{eff})$ as perturbation operators.

All one-electron theories of solids are based on this scheme. The simplest approximation with $v(q) = \text{const.}$ is the Sommerfeld theory[3]. *Peierls*' theory[4] is based on a weakly periodic v, and *Bloch*'s theory[5] on a strongly periodic v. An additional assumption regarding the form of the eigenfunction of eq. (8) is that introduced by *Wigner* and *Seitz*[6]. *Slater*'s extensions of the *Wigner-Seitz* approach, *e.g. Slater*'s method of augmented plane waves[7], are also based on eq. (8) and its conditions. The methods mentioned are known collectively as band theories.

A point to which insufficient thought is often given is the need to recognize clearly, in the application of the one-electron theories, that the function $v = v(q)$ that describes the effective field can only be chosen plausibly, but does not itself occur in nature, and thus is not definite. It is unequivocally a model relation, and this means that its (plausible) application gives a model that is not identical with the solid.

As to method 2, there are as yet no complete polyelectron theories of solids.

Eigenfunctions of polyelectron systems depend on the coordinates of all the electrons:

$$\psi = \psi(q_1, q_2, \ldots) \tag{9}$$

They must be antisymmetric. If T is an operator by which the coordinates of two electrons are interchanged in ψ, then

$$T\psi = -\psi \tag{10}$$

must be valid for all such interchanges.

Theories in which only local antisymmetrization in atoms or groups of atoms is introduced as an approximation must be described as incomplete polyelectron theories. If the atoms or groups of atoms in question are denoted by the subscript k, one can write

$$\psi = \psi_1\psi_2\cdots = \prod_k \psi_k \tag{11}$$

where ψ_k is an antisymmetric eigenfunction of an atom or of a group of atoms. The complete function ψ (11) is not completely antisymmetric under these conditions.

From the standpoint of the valence structure approximation[8], the assumption of only local antisymmetrization is equivalent to ignoring exchange interactions between different atoms or groups. Empirical parameters, *e.g.* "ionic radii", are introduced in some cases to compensate for this.

This group of theories includes in particular the Madelung theory[9] of ionic crystals and its extension by *Hund* and *Heisenberg* through the inclusion of polarization effects[10]. The crystal field theory[12], which acquired new life from the success of the methodically equivalent ligand field theory[11], deals with polarization effects in incomplete shells.

As I pointed out a long time ago[13], the interatomic exchange effects become less important on purely combinatorial grounds in lattices with high coordination numbers. In principle, therefore, a theory of metallic phases can be developed on the basis of only local antisymmetrization. Investigations on magnesium and zinc are in progress. An investigation on inert-gas crystals[14] also belongs to this field.

Interatomic as well as intraatomic exchange effects are taken into account in the statistical treatments of solids, which ultimately arise from the work of *Lenz* and *Jensen*[15]. However, since quantum mechanics is used only for averaging in statistical studies, these again cannot be described as complete polyelectron theories.

Gamma Resonance Spectroscopy and Chemical Bonding[**]

By Rudolf L. Mössbauer[*]

Gamma resonance spectroscopy makes it possible to observe directly hyperfine interactions in solids. In the field of chemistry the feature of greatest interest is the measurement of isomeric shifts of gamma lines because these shifts are proportional to the electron density at the nucleus and can thus give detailed information about the electronic structure of the chemical bond. After a brief introduction to gamma resonance spectroscopy, this paper deals with the fundamental problem of the interpretation of measured isomeric shifts in terms of electron densities and then gives representative examples of chemical information that can be obtained for transition elements from the shifts and the splitting of the gamma lines.

1. Introduction

Gamma resonance spectroscopy is based on the possibility of observing in solids gamma emission and absorption lines of natural width, *i.e.* lines with a frequency definition as much as ten orders of magnitude sharper than that achieved in the commonly observed broadening of gamma lines due to the Doppler effect[1]. The method is restricted to relatively low-energy gamma transitions and often requires the use of low temperatures to minimize the background of nonresonant gamma radiation which is always present outside the range of the natural line widths[2]. Figure 1 gives a summary of those elements for which gamma resonance spectroscopy has so far been possible. A characteristic feature is the absence of any light elements. Figure 1 also shows, however, that gamma resonance spectroscopic measurements can be carried out in all series of transition elements. Figure 2 illustrates the principle of measurements of this kind.

The hyperfine interactions between the electric and magnetic moments of the atomic nuclei and the fields which act on them in solids lead to shifting and splitting of the nuclear levels, which can appear as isomeric shifts and

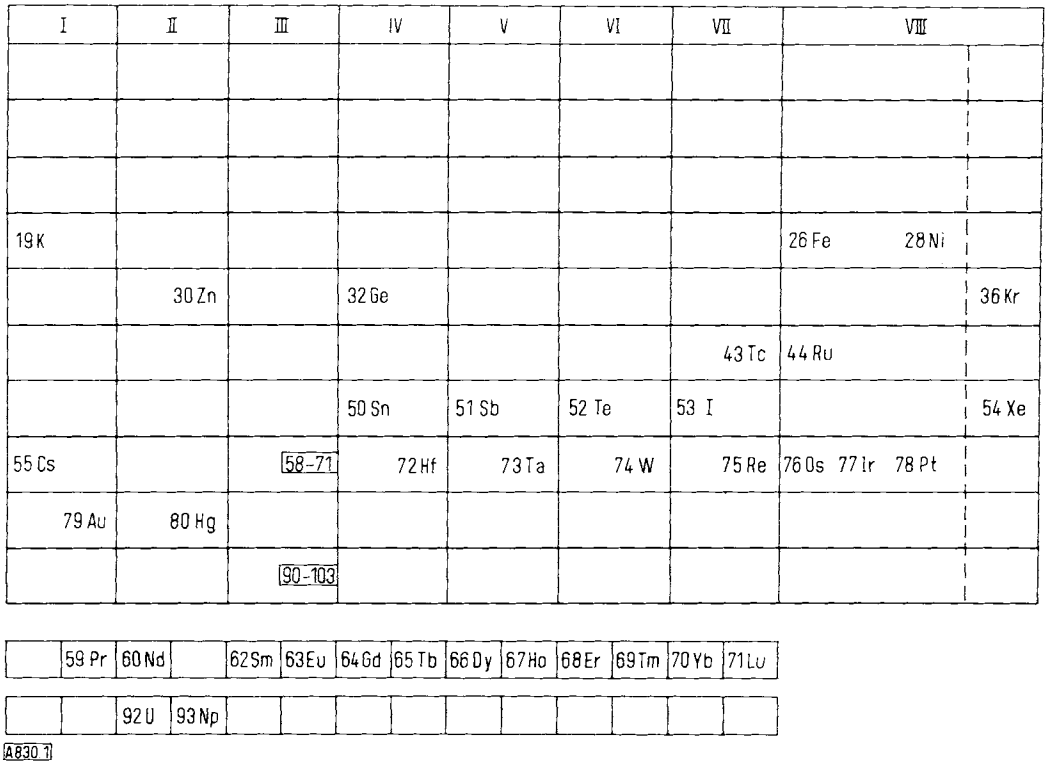

Fig. 1. Summary of those elements with which gamma resonance spectroscopy has so far been possible. For many elements usable gamma transitions exist in several isotopes and at different energies.

magnetic dipole or electric quadrupole splitting of the gamma lines. While under normal circumstances these changes in the frequency of gamma lines due to hyperfine interactions are completely swamped by the latter's Doppler broadening, the method of resonance spectroscopy often makes it possible to observe directly the frequency changes because of the increased resolution due to the use of natural line widths. In chemistry it is primarily the study of isomeric shifts and quadrupole splitting of the gamma lines that is of interest. In what follows we shall

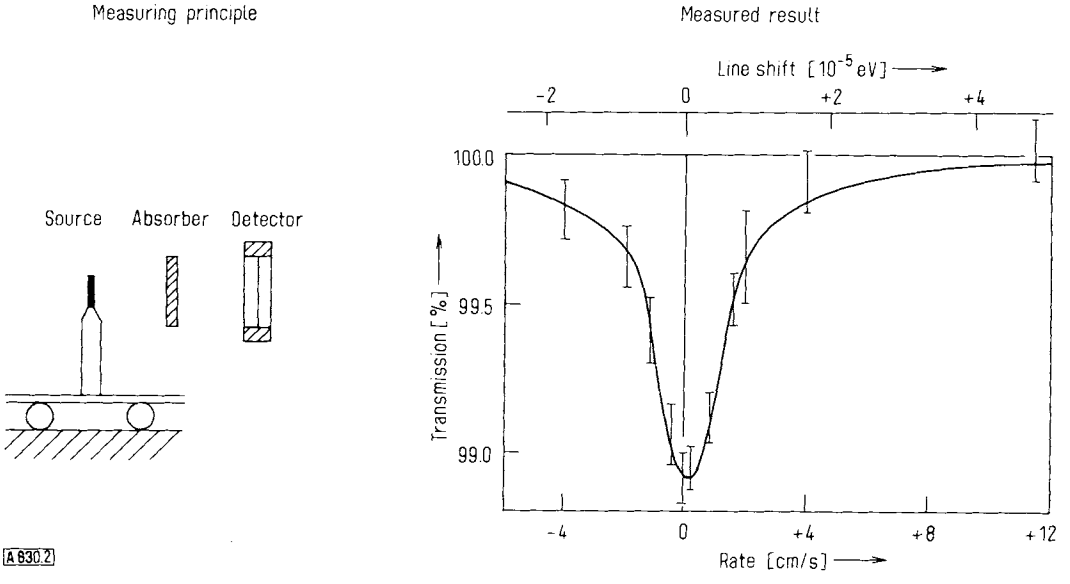

Fig. 2. Principle of the measurements in gamma resonance spectroscopy. The left-hand part of the figure shows the experimental arrangement, consisting of a radioactive source and a resonance absorber with atomic nuclei identical to those in the gamma source. The source and the absorber are often placed in a low-temperature cryostat. The detector measures the gamma radiation passing through the absorber as a function of the relative velocity between the source and the absorber, which is generally produced by means of an electromagnetic drive system. The result of such a measurement is shown on the right-hand side of the figure: a resonance absorption maximum, *i.e.* a minimum in the intensity received at the detector, occurs at zero relative velocity of the source and the absorber, at which the source and the absorber are exactly in resonance and thus have the same fundamental frequency. This perfect resonance absorption can be disturbed by exploiting the linear Doppler effect: a change in the relative velocity of the source and the absorber causes a reduction of the resonance absorption and hence a corresponding increase in the intensity recorded by the detector. In this way with an emission line having a natural line width Γ we spread an absorption line of the same natural line width and obtain for the recorded intensity, in the ideal case, a line width $2\,\Gamma$ [2b].

discuss the methods and the chemical information content of such studies. The discussion of practical examples will be restricted to stable compounds of the 3d-, 4d-, and 5d transition elements[3].

2. Isomeric Shifts of Gamma Lines

A system consisting of a nucleus and an electron shell will be in a state of minimum energy if the nuclear charge is concentrated at a point. Any increase in the charge radius of a nucleus, or indeed any increase in the electron density at a nucleus of finite extent, leads to an increase in the energy of the total system. Thus, the energetic position of any nuclear level of a nucleus incorporated in a solid depends both on the nuclear radius and on the electron density at the nucleus. There is a similar dependence for the frequencies of the gamma transitions between the individual nuclear levels. In analogy to the optical isotopic shift, the isomeric shift is given by:

$$S_a - S_b = (v_a/c)E_0 - (v_b/c)E_0 = C\{|\psi(0)|_a^2 - |\psi(0)|_b^2\} \quad (1)$$

where $S_a - S_b$ is the energy shift of two gamma lines, with respect to one another, for a gamma transition of energy E_0 in one and the same nuclear isotope, situated in two different chemical environments a and b, while $v_a - v_b$ represents the difference of the Doppler velocities for the two compounds. The quantity $|\psi(0)|^2$ represents the total nonrelativistic electron density at the site of the nucleus. The constant C, which is a characteristic of the nuclear radiating transition in question, is a function of the charge distributions of the nucleus in the initial and final states. Assuming a uniform nuclear charge distribution, a good approximation is:

$$C = (2\pi/5)Ze^2(R_1^2 - R_0^2)S'(Z) = (4\pi/5)Ze^2R^2(\Delta R/R)S'(Z) \quad (2)$$

where R_0 and R_1 denote the charge radii of the ground state and of the first excited state respectively; $R = (R_1 + R_0)/2$. $S'(Z)$ is a correction factor calculated approximately by *Bodmer*[4], which takes into account the modification of the nonrelativistic electron density due to relativistic effects, in particular the variations in the wave functions in the region of the nucleus. A table of values of $S'(Z)$ for all atomic numbers Z has been given by *Shirley*[5]. It must be emphasized that the factor $S'(Z)$ does not in any way represent a conversion factor that would allow a conversion of the nonrelativistic wave functions occurring in equation (1) at the position of the nucleus into a relativistic type.

Only the s electrons of the outermost electron shell, *i.e.* the shell which directly takes part in chemical bonding, contribute directly to the total electron densities appearing as a difference in eq. (1). Measurements of the isomeric shift thus give direct information on the proportion of s electrons in a chemical bond. In the case of heavy nuclei the relativistic $p_{1/2}$ electrons can also give considerable probability densities at the nucleus, but in many cases there will be no substantial difference in the occupancy of the $p_{1/2}$ shells, so that the contribution of the $p_{1/2}$ electrons to isomeric shifts can be neglected in most cases.

While the s electrons make direct contributions to the electron density at the nucleus, the electrons in partially filled shells, such as occur in the transition elements, contribute indirectly to the isomeric shifts, by the "screening effect" they have on the s electrons.

As will be explained later, it is often difficult to break down a measured isomeric shift into the contributions originating directly from s electrons and indirectly from screening non-s-electrons.

A study of isomeric shifts can be carried out in all series of nd-transition elements. For this purpose the most suitable transition in the range of 3d-elements is the 14.4-keV transition in ^{57}Fe, in the 4d-element range the 90-keV transition in ^{99}Ru, while in the range of 5d elements the most suitable are the 73-keV transition in ^{193}Ir, the 36-keV transition in ^{189}Os, and the 77-keV transition in ^{197}Au.

2.1. The Problem of Calibrating the Isomeric Shift

Measurements of isomeric shifts yield, as can be seen in equation (1), a factor C which originates in the physics of the nucleus and an electronic factor $\Delta|\psi(0)|^2$, the total nonrelativistic electron density difference at the nucleus for two different compounds. There is as yet no known method of measuring these two factors separately. To determine one of the two factors, therefore, one is obliged to find the other by calculation. In practice, in the present state of the art, a measurement is first carried out of the isomeric shift of a selected nuclear isotope for two different valence states of the electron shells. Comparison of the measured values with the electron densities calculated for the two valence states then gives directly the value of C which is specific to the particular nuclear transition, *i.e.* essentially the quantity $\Delta R/R$. This determination of C is a central problem in the interpretation of measured isomeric shifts. Solution of this problem makes it possible to establish for the nuclear transition considered a practically linear relationship between the isomeric shifts and the electron densities at the nucleus, a process usually described as calibration of the isomeric shift. Once the calibration constant C has been determined, total electron densities can be found directly for the whole enormous complex of chemical compounds in which the nuclear transition concerned can be measured. The electron densities at the nucleus are often a sensitive indication of the effective valence state of the atom measured. In this way information on the nature of chemical bonding can be obtained directly from the isomeric shifts.

The difficulty that arises in the method of calibration described above lies in the fact that while it is possible in principle to carry out reliable Hartree-Fock calculations of electron densities at the nucleus, such calculations presuppose a knowledge of the real electron configurations of the atoms or ions considered. While these configurations are generally known for free particles, the corresponding information is often lacking in the case of ions incorporated in solids, in which the isomeric shifts are actually measured. For calibration purposes therefore, as a general principle,

compound pairs in which the electron configurations are more or less certain are chosen, as for example in purely ionic compounds. Deviations from this ideal state, which is never achieved in practice, give rise to errors in the calibration constant C. Such errors, are however, of secondary importance if one is mainly interested in drawing qualitative conclusions about the nature of the chemical bonding, for example in systematic trends in a large series of compounds. For quantitative conclusions a precise determination of C is essential, and this problem has not so far been satisfactorily solved.

2.2. Isomeric Shifts in 3d Transition Elements: The 14.4-keV Transition in ^{57}Fe

As an illustration of the difficulty of the calibration problem Table 1 gives a collection of diverse values given for the ratio $\Delta R/R$ in the 14.4-keV transition in ^{57}Fe by various investigators. Table 2 gives values of nonrelativistic electron densities $|\psi(0)|^2$ for the most important configurations of iron. The differences in the s-electron densities at the nucleus are due to the screening effect of 3d electrons on the s electrons. This screening effect apparently acts mainly on the 3s electrons, while the s electrons in the two inner shells are hardly affected by it.

Table 1. Relative change in the nuclear radius $\Delta R/R$ for the 14.4-keV transition in ^{57}Fe.

Method	$\Delta R/R$	Ref.
Measurements on Fe^{II} and Fe^{III} compounds of highest ionicity	-1.8×10^{-3}	[6]
Deduction using effective charges from X-ray absorption measurements	-5.0×10^{-4}	[8]
Combination of optical data and MO calculations	-8.5×10^{-4}	[9]
MO calculation taking into account the screening by 4d- and 4p electrons	-9.0×10^{-4}	[10]
Comparison of the calculation of inner electron polarization with high-pressure measurements	-4.0×10^{-4} -5.2×10^{-4}	[11] [12]

The values of $\Delta R/R$ given were calculated with the aid of the nonrelativistic wave functions calculated by *Watson* [7]. To take into account the relativistic corrections for the s-electron densities, all values of $\Delta R/R$ in the table must be reduced by the factor $S'(Z)=1.33$.

Table 2. $|\psi(0)|^2$ in units of the cubic Bohr radius a_0^3 for electrons with the same spin orientation, after *Watson* [7].

Configuration	$Fe(3d^64s^2)$	$Fe^{2+}(d^6)$	$Fe^{3+}(d^5)$	$\lvert\psi(0)\rvert^2(d^6)-\lvert\psi(0)\rvert^2(d^5)$
1s	5377.873	5377.840	5377.625	0.215
2s	493.968	493.796	493.793	0.003
3s	68.028	68.274	69.433	−1.159
4s	3.042			

In their calibration of the isomeric shift in ^{57}Fe, *Walker et al.*[6] assumed that the iron ions in the complex salts of highest ionicity, *e.g.* in $Fe_2(SO_4)_3\cdot6H_2O$ or in $FeSO_4\cdot7H_2O$, can be associated with pure d^5- or d^6 configurations. For Fe^{III} at least this assumption is very suspect, since in this case the iron ion would have to carry three units of charge, a condition that seems to be very difficult to realize. In fact, on the basis of X-ray absorption measurements, *Goldanskii*[8] arrived at effective charges of +1.9 for Fe^{II} and only +1.2 for Fe^{III}. *Jørgensen*[13] calculated, from optical data, an effective charge of +1.7 for Fe^{III} in high-spin complexes. From self-consistent charge and configuration MO calculations, *Viste et al.*[14] obtained, among other things, for $[Fe^{III}F_6]^{3-}$ a 4s population of iron equal to 0.32. On the basis of these results, *Danon*[9] used a $3d^54s^{0.32}$ configuration for $[Fe^{III}F_6]^{3-}$ and a $3d^6$ configuration for the Fe^{II} complex of highest ionicity, and hence arrived at the value of $\Delta R/R$ given in Table 1.

Special interest attaches to the low-spin iron complexes, which are often distinguished by the absence of isomeric shifts between the formal di- and trivalent states of the iron. Classic examples of this are the complexes $[Fe^{II}(CN)_6]^{4-}$ and $[Fe^{III}(CN)_6]^{3-}$, which exhibit only a slight mutual isomeric shift. A possible interpretation is back bonding, *i.e.* the transfer of electrons from the metal ion to empty π^* antibonding orbitals of the ligands. A transfer difference of one electron between Fe^{2+} and Fe^{3+} might explain the absence of isomeric shifts in the low-spin $3d^5$- and $3d^6$ configurations of the cyano-complexes but, as will be shown in greater detail later, this hypothesis is surely too simple.

2.3. Isomeric Shifts in the 4d Transition Elements: The 90-keV Transition in ^{99}Ru

Measurements of the isomeric shift in ruthenium compounds enable observations to be made over an unusually wide range of different valence states. Figure 3 shows three

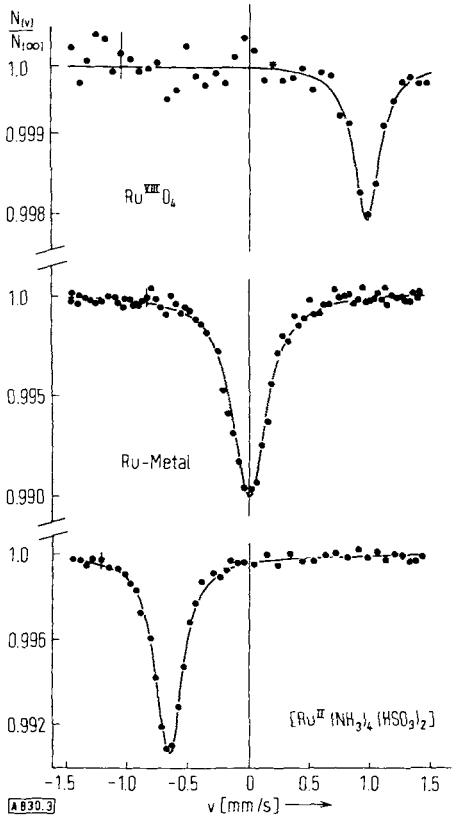

Fig. 3. Gamma resonance spectra of ruthenium compounds, measured at 4.2 °K for the 90-keV gamma transition in ^{99}Ru, using a metal source exhibiting no hyperfine splitting [15].

representative spectra and Figure 4 a graphical representation of the results of some measurements of isomeric shifts[15]. The isomeric shift is decisively influenced by the charge transfers which arise in the formation of molecular

measured at the nucleus of M, insofar as s electrons are transferred; otherwise there is a decrease. The individual effects that occur can best be seen from an MO scheme, as represented in Figure 6 for the case of an octahedral

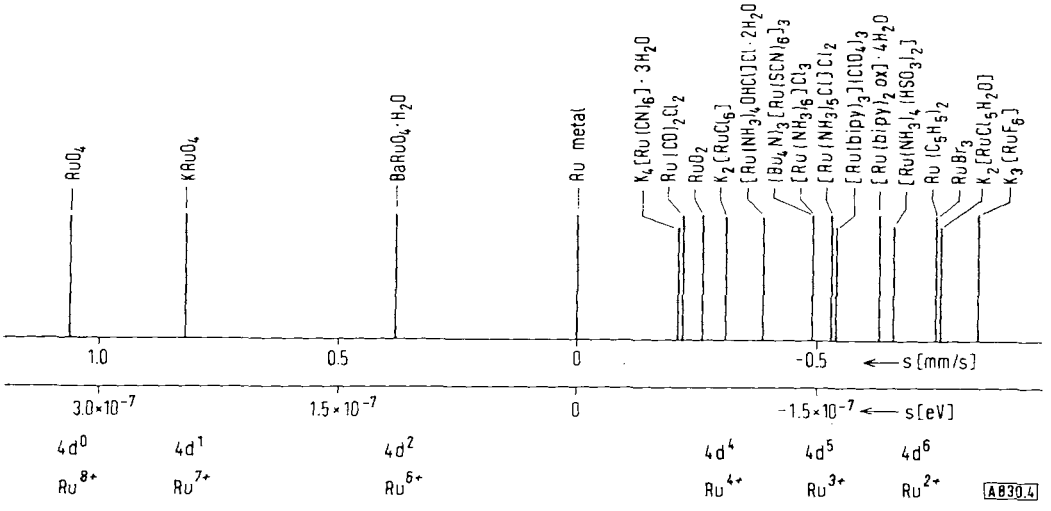

Fig. 4. Isomeric shifts of the 90-keV gamma radiation from ^{99}Ru for various compounds of ruthenium, relative to metallic Ru (reference point). The lower part of the figure shows the formal valence states and the formal electron configurations of the Ru ions in the compounds investigated [15].

orbitals from the metal orbitals and ligand orbitals. This is demonstrated in Figure 5, where a metal orbital and a ligand orbital, both of which belong to the same irreducible representation, combine to form a bonding and an antibonding molecular orbital. An increase in the bonding increases the distance between the two molecular orbitals.

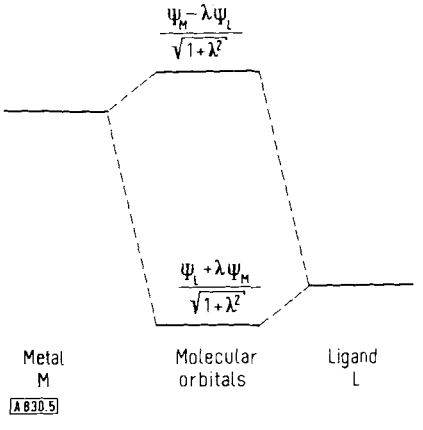

Fig. 5. Combination of a metal orbital and a ligand orbital to form a pair of molecular orbitals (MO). The coupling increases with increasing λ. Overlap contributions have been neglected. In the bonding MO an increase in λ corresponds to an L→M charge transfer, in the antibonding orbital to an M→L transfer.

The bonding orbital here assumes a more marked M character, this corresponding to a charge transfer L→M, while the opposite applies to the antibonding orbital. For the same occupancy of the two orbitals there is no charge transfer at all with increasing coupling. A lower occupancy of the metal orbital, placed higher by chance in Figure 5, on the other hand, leads to increasing charge transfer on coupling, which is in the direction L→M in the example chosen. The result is an increase in the isomeric shift

environmental symmetry. This type of symmetry is found in the majority of the compounds given in Figure 4. It should be observed that the position of the metal orbital

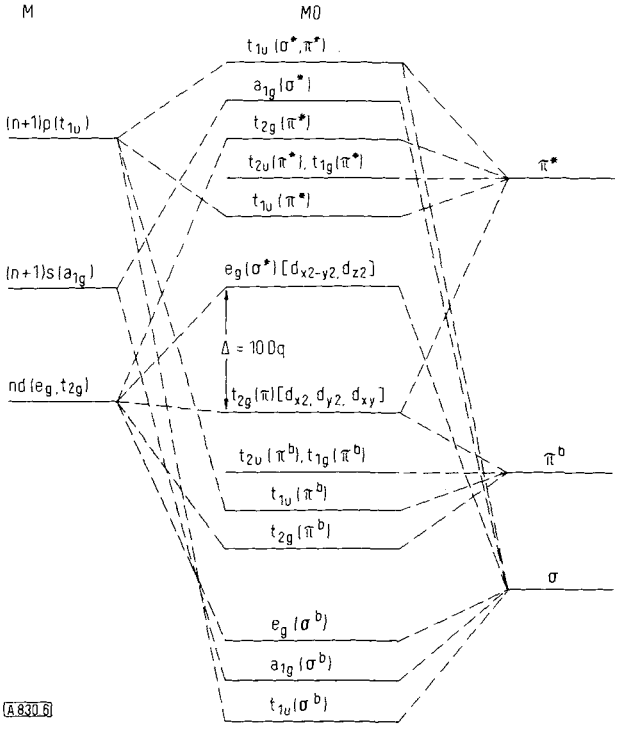

Fig. 6. MO level scheme for octahedral metal complexes for ligands with internal π-bonding [16].

in Figure 6 is determined by the actual electron configuration of the metal ion, and therefore does not correspond to the configuration of the free ion. Details of the level structure, for the given case of $n=4$ for ruthenium, are certainly considerably influenced by the strong spin-orbital

coupling, so that the following remarks can only have a qualitative character.

For an octahedral environmental symmetry of the central Ru ion, there is a splitting of the 4d shell, which is relevant to the optical and magnetic characteristics, leading to $t_{2g}(\pi)$ and $e_g(\sigma)$ molecular orbitals. The different states of oxidation are distinguished by different occupancies of the t_{2g} state. Thus, for example, for the octahedral complexes of Ru^{II}, Ru^{III}, and Ru^{IV} the formal configurations $(t_{2g})^6$, $(t_{2g})^5$, and $(t_{2g})^4$ apply.

The rise in the electron densities $|\psi(0)|^2$ with increasing valence which can be seen in Figure 4 can be ascribed qualitatively to the parallel process of a decrease of 4d electrons *i.e.* the progressive reduction of the screening of s electrons, in the inner shells. However, this view is in no way conclusive, for increasing occupancy of 5s orbitals could equally be assumed. In fact, in a quantitative description all electron-transfer processes between the ligands and the metal ion must be taken into account. Table 3 gives a summary of the more important of these processes, which in ruthenium can appear as a result of the coupling of ligand and metal orbitals to molecular orbitals and thereby lead to a change in the electron density at the nucleus. It is the differences in the contributions of these different electron-transfer processes which give rise to differences between the isomeric shifts of compounds having the same formal valence. Leaving this aside, Figure 4 demonstrates the possibility of classifying the valences of ruthenium in its complexes from measurements of the isomeric shifts. Only $K_4[Ru(CN)_6]\cdot 3H_2O$, $K_4[Ru(CN)_6]$, and $RuBr_3$ appear to behave differently. For the first two compounds a marked occurrence of a type of bonding designated as back-bonding can be assumed, in which the t_{2g} orbitals undergo considerable coupling with initially unoccupied antibonding π^*-ligand orbitals. According to *Shulman et al.*[17], such an effect can cause a marked abstraction of electrons from the metal ion and thus explain the fact that isomeric shifts of the two hexacyano-complexes should not be associated with the nominally divalent but with the nominally tetravalent state of ruthenium, corresponding to the transfer of two electronic charges from the metal to the ligands. In fact, measurements of isomeric shifts directly point to the existence of marked back-bonding. Thus, isomeric shift data are really predestined for a classification of chemical valences.

Table 3. Change of electron density at the nucleus and electron-transfer process for octahedral symmetry.

	Electron-transfer process	$\Delta\|\psi(0)\|^2$
1.	$\sigma_L \rightarrow \sigma_M(4d)$	<0
2.	$\pi_L \rightarrow \pi_M(4d)$	<0
3.	$\pi_M(4d) \rightarrow \pi_L$	>0
4.	$\sigma_L \rightarrow \sigma_M(5s)$	>0
5.	$\sigma_L, \pi_L \rightarrow \sigma_M(5p), \pi_M(5p)$	<0

The measured isomeric shift in $RuBr_3$ corresponding to a nominally divalent state cannot be interpreted at all unambiguously. However, this compound exhibits diamagnetic behavior, which is quite unusual for a formal $(t_{2g})^5$ configuration.

2.4. Isomer Shift Measurement under High Pressure

Isomeric shifts are usually observed in different chemical compounds, the bonding state, which is characterized by a large number of parameters, being varied in steps. If, however, the isomeric shifts are measured as a function of pressure, continuous variation of the bonding parameters over a wide range in one and the same compound can be achieved. Such high-pressure studies have so far been almost exclusively restricted to those isotopes that can be measured at normal temperatures, since the considerable experimental problems of low-temperature high-pressure resonance spectroscopy have not yet been satisfactorily solved.

Drickamer et al.[18] carried out a study of isomeric shifts, in particular on compounds of iron, and by comparison with optical studies obtained valuable information on the chemical behavior of iron. For example, in many cases the measurements showed increasing reversible reduction, as the pressure was increased, of high-spin Fe^{III} into Fe^{II}, for example in $Fe_2(SO_4)_3$, $FePO_4$, and Fe(III) citrate. They interpret this reduction as the result of a progressive lowering with compression of the ground state orbitals of the metal relative to the ligand orbitals, which facilitates thermal electron transfer, *i.e.* an L→M electron transition from a ligand orbital bonding weakly or not at all to a 3d-metal orbital, with the establishment of thermal equilibrium. The pressure-induced reduction is thus not associated with a transition point; instead the electron transfer made possible by the pressure causes reduction at a single ion, with simultaneous electrical and mechanical disturbance of the adjacent ions, the reducibility of which is thereby decreased. Increasing pressure thus favors electron transfer, but on the other hand it leads to an increased inhibition of reduction in adjacent ions.

The strongly covalent low-spin iron complexes exhibit a particularly interesting pressure-dependent behavior, the most striking representatives being the cyanoferrates(II) and -(III), and their derivatives. At pressures around 200 kbar and temperatures around 150°C, *Drickamer*'s experiments with salts such as K_4X, Na_4X, Zn_2X, Ni_2X, and Cu_2X (where $X=[Fe(CN)_6]$), showed a low-spin → high-spin conversion. This is contrary to the naive expectation that with increasing pressure an increase in the crystal electric field should favor a high-spin → low-spin transition. According to *Drickamer et al.*[18], this precisely opposite effect is due to a lowering of the metal orbitals relative to the weakly bonding or nonbonding ligand orbitals. This also signifies an increase in the energetic distance between metal orbitals and antibonding (π^*) ligand orbitals. In parallel with this process there is a reduction of the back-bonding effect, whereby the metal-cyanide bonding is weakened.

In the case of the high-spin iron complexes, *Drickamer et al.*[18] found that the electron density at the nucleus increases with increasing pressure. To interpret this they assumed a radial expansion of the 3d electrons increasing with pressure, with a consequent reduction of the 3d-3s screening and hence an increase in the s-electron density at the nucleus. In this interpretation the predominant part

in the variation of the isomeric shift with pressure is ascribed to the screening 3d electrons. Making the reasonable assumption of increasing covalency with increasing pressure, with purely 3d-electron participation in the bonding we are really dealing with an M→L electron transfer in the antibonding orbitals which is also manifested in a reduction of the optically observed Racah parameters. At the same time, however, an overcompensating L→M transfer occurs in the bonding orbitals, so that overall there is an increase in the screening effect and hence a reduction of the electron density $|\psi(0)|^2$, contrary to the experimental findings. It is therefore reasonable to assume participation of 4s electrons in the bonding, so that a small L→M transfer is sufficient to explain the sign of the pressure dependence of the isomeric shift observed experimentally. The assumption of 4s participation in the bonding is indeed the basis of the calibration of the isomeric shift in ^{57}Fe carried out by *Danon*, *Goldanskii*, and *Šimánek et al.* and given in Table 1.

Šimánek et al.[11,12] attempted a calibration of the isomeric shift in the case of the 14.4-keV transition in ^{57}Fe by comparing experimental data with theoretical calculations of the variation with pressure. This work is of interest mainly because the calculations gave as the preponderant effect for the occurrence of the isomeric shift the overlapping of the ligand orbitals with the closed 1s-, 2s-, and 3s shells of the iron ion. Such overlap contribution to the isomeric shift is a direct consequence of the Pauli principle, which would exclude the electrons from the overlap region of s-metal orbitals and ligand orbitals and hence cause an increase in the electron density at the nucleus due to s-metal orbitals. Mathematically, this overlap effect, which can be calculated on the basis of the Heitler-London model, can be described by orthogonalization of the ligand orbitals relative to the filled s-metal orbitals. According to *Šimánek et al.*[11,12], the predominant mechanism for the increase of electron density at the nucleus with increasing pressure is also given by the overlap effect, through its strong dependence on the distances between metal ions and ligands. This is indeed valid if a contribution due to 4s electrons can be neglected, as is the case with many compounds of Fe^{II}. On the other hand, in ionic compounds of trivalent iron the contribution of the 4s electrons cannot be neglected. Here the overlap effect even leads to an increase in the direct contribution of the 4s electrons to the isomeric shift, so that the contribution of the 4s electrons becomes preponderant. Quantitative follow-up of this reasoning, such as was carried out by *Šimánek et al.* for the examples of FeO and $KFeF_3$, suffers especially from the inadequate knowledge of the modifications which the ligand orbitals used for the calculation of the overlap undergo in solids as compared with the atomic case.

Finally, it should be emphasized that the overlap effect described by *Šimánek et al.* differs basically from the phenomena occurring within the framework of an MO description. It is not possible to exclude *a priori* the possibility that MO considerations may indeed yield relatively good values for energy levels which are amenable to optical experiments, but only a poor approximation for the interpretation of isomeric shift data if overlap effects of the kind outlined here really make the predominant contribution.

2.5. Isomeric Shift and Chemical Systematics

In qualitative interpretations it is frequently attempted to correlate the measured isomeric shifts of a large range of chemical compounds of one and the same nuclear isotope systematically with suitable parameters. In this way it is often possible to establish a relationship between the isomeric shifts and electronegativity differences. However, such a single-parameter correlation is only meaningful, if at all, when it is restricted to isomorphous compounds which differ only in the degree of ionization and not in the nature of the bond.

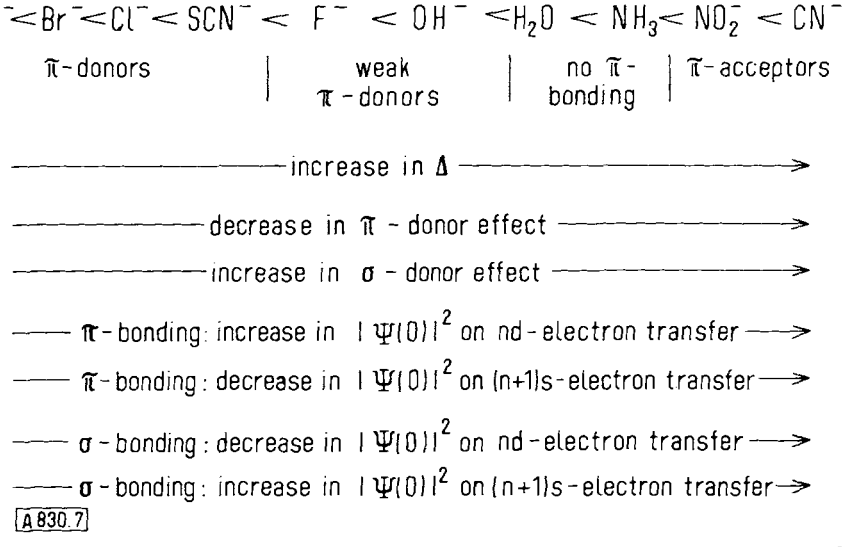

Fig. 7. Spectrochemical series of frequently occurring ligands and variation of the electron density $|\psi(0)|^2$ at the nucleus for transition elements.

For many transition-element complexes it is possible to establish for the isomeric shifts of the central metal a correlation with spectrochemical behavior, the systematics of which have resulted in the formulation of the spectrochemical series of ligands. The active parameter of this series is the splitting of the d orbitals in the ligand field, observed in absorption spectra. For example, for a given metal ion in octahedral and also in the square environmental symmetry, the splitting Δ of the d orbitals increases in accordance with the spectrochemical series given in Figure 7. This series is probably valid for other environmental symmetries.

The variation of Δ can be understood directly from the coupling constants λ (see Fig. 5). The ligands occurring in the spectrochemical series differ in their σ or π donor or acceptor properties, *i.e.* in their ability to effect electron transfers of the L→M type (donor) or M→L type (acceptor). Strongly covalent compounds are distinguished by their approximately obeying the principle of electroneutrality, this leading to a synergic coupling between the σ- and π-orbitals, in which the M→L transfer associated with strong π-acceptor capacity is more or less compensated by a correspondingly large L→M σ-donor transfer. *Graham*[19] deduced the existence of such a synergic coupling principle from the behavior of Mn complexes. At the start of the spectrochemical series there are ligands with predominant π-donor properties, which leads to destabilization of the antibonding orbitals (see Figs. 5 and 6), and hence results in smaller values of Δ. Toward the end of the series the π-donor capacity decreases, and finally changes to a π-acceptor capacity, which goes along with a σ-donor capacity; both effects lead to an increase of Δ, since the π-acceptor action stabilizes the antibonding π-orbitals while the σ-donor effect destabilizes the σ-orbitals. In connection with the isomeric shift, in charge transfers of this kind, we have to make a clear distinction between the opposing effects of d- and s electrons. Progression along the spectrochemical series involves a reduction of the L→M charge transfer caused by π bonding, and hence an increase in the isomeric shift. In parallel with this, however, there is an increase in the L→M charge transfer caused by σ bonding, which can occur by means of both s- and d-electron transfer. When the synergic coupling principle is strictly maintained, the result is in the normal case an increase in the isomeric shift in the spectrochemical series.

The optically measurable spectrochemical behavior is directly influenced by the transfer of s- and d electrons changing with the bonding. As far as the isomeric shift is concerned, s-electron transfers have a considerably larger influence than d-electron transfers. The ratio of nonrelativistic electron density changes at the nucleus which occur on the addition of an nd-electron or the subtraction of an (n+1)s-electron can be determined by Hartree-Fock calculations. If, for example, we define the change of configuration $\{\Delta nd\} = \{nd^6(n+1)s^1\} - \{nd^5(n+1)s^1\}$ or $\{\Delta(n+1)s\} = \{nd^6(n+1)s^1\} - \{nd^6\}$, we obtain for the ratio $\zeta = \delta|\psi(0)|^2_{\{\Delta(n+1)s\}}/\delta|\psi(0)|^2_{\{\Delta nd\}}$ values of approximately 2.5 for Fe, 3.1 for Ru, and 3.4 for Ir. While the proportions of s- and d-electron transfers must be given much the same weight in respect of the effective charge, in respect of the isomeric shift the s-electron transfers have the stronger effect.

Measurements of isomeric shifts do not make it possible to determine directly the relative proportions of s- and d-electron transfers as we progress along the spectrochemical series. Such a separation might, however, be possible with a knowledge of the effective charge difference, which is associated with a charge transfer $n_d(M\rightarrow L) - n_d(L\rightarrow M) - n_s(L\rightarrow M)$.

To illustrate the correlation between the isomeric shift and the spectrochemical series, Figure 8 shows a collection of the isomeric shifts for compounds of gold, using the 77-keV transition in ^{197}Au. The Au^{I} complexes have linear structures almost throughout, whereas the Au^{III} compounds exhibit a square arrangement of the ligands. The change of the isomeric shift substantially follows the spectrochemical series. A striking exception is the position of tetrafluoroaurate, although this may be due to the different coordination (CN=6). A characteristic feature of the data given in Figure 8 is that the compounds of Au^{I} and Au^{III} with the same ligands exhibit relatively small isomeric shifts with respect to one another.

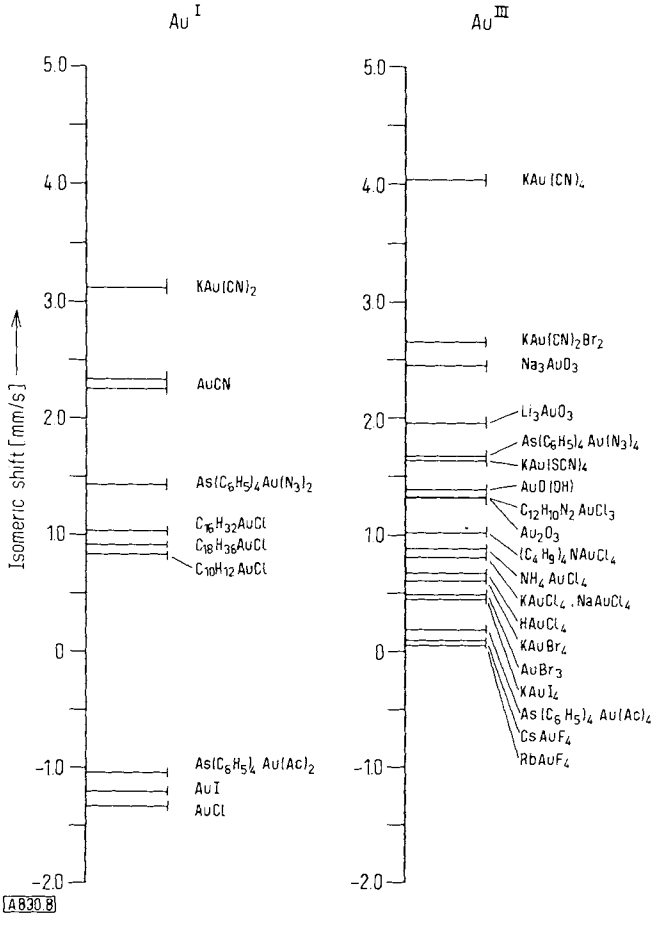

Fig. 8. Isomeric shifts of the 77-keV gamma transition in ^{197}Au for compounds of mono- and trivalent gold; after [20].

Rough estimates show that these shifts are an order of magnitude smaller than would correspond to the $5d^{10} - 5d^8$ transition, so that the actual configurations differ substanti-

ally from the formal ones. Since in the Au^{I} compounds the 3d-molecular orbitals are fully occupied, and the differences in the isomeric shift must therefore be ascribed to charge transfers to σ orbitals, it can be concluded on the basis of an MO description that in respect of the isomeric shift the screening effect of d-electron transfer is overcompensated by the direct effect of s-electron transfer.

An analogous correlation between isomeric shifts and the spectrochemical series can in general be expected for the strongly covalent complexes of the transition elements, especially the low-spin complexes. *Bancroft et al.*[21] confirmed this for a long series of low-spin complexes of Fe^{II}. For the high-spin complexes, with their often lower covalence, there should rather be a correlation with the nephelauxetic series of ligands, since this series substantially reflects the electronegativity[22]. *Danon* for example, established such a correlation for the high-spin complexes of Fe^{II}[23].

3. Relativistic Line Shifts

Relativistic time dilatation leads to a quadratic Doppler effect, which is also manifested in a shift of the gamma lines and which must therefore be taken into account in the interpretation of isomeric shifts. This relativistic line shift can be made clear on the basis of quantum mechanics[24]. The emission of a gamma quantum of energy E_0 corresponds to a mass loss $\Delta m = E_0^2/mc^2$ on the part of the emitting nucleus. This results in a slight increase in the internal energy of the lattice, with an equal decrease in the energy of the emitted quantum, *i. e.* the relativistic line shift ΔE. The applicable relation is $\Delta E = -E_0 \Delta E_{mol}/(2N_L mc^2)$, where ΔE_{mol} is the change of internal energy of the crystal per mole, N_L is Avagadro's number, and m is the mass of the emitting nucleus. Expressed in terms of Doppler velocities v and the internal energies of two compounds 1 and 2, $v_{relativistic} = E_{mol}(T_1) - E_{mol}(T_2)/(2N_L m)$. A relativistically determined Doppler shift of this kind occurs in principle even when the temperatures of the source and the absorber are the same, if the compounds studied have different bonding strengths and hence have different internal energies at the same temperature. Relativistic line shifts are generally small compared to the normally observed isomeric shifts. For example, in the 14.4-keV transition in ^{57}Fe, a temperature difference of 100 °C corresponds to a relativistic line shift which is about an order of magnitude smaller than the isomeric shift between two typical high-spin compounds of Fe^{II} and Fe^{III}. The contribution of the relativistic line shift to the total line shift need therefore only be taken into account in extreme cases, say the case of a large temperature difference or of very different bonding strengths of the test substances used.

4. Electric Quadrupole Splitting of the Gamma Lines

In addition to the isomeric shifts, electric quadrupole splitting of the gamma lines can provide independent information concerning the nature of the chemical bonding. Such quadrupole splitting occurs if at least one of the nuclear states participating in a gamma transition has a nuclear spin $> \frac{1}{2}$ and if at the same time the environment of the nucleus exhibits a symmetry lower than cubic. The component q_{ii} of the tensor of the electric field gradient is given by

$$q_{ii} = (1 - \gamma_\infty) q_{ii}(\text{lattice}) + (1 - R_Q) q_{ii}(\text{ion}).$$

Here the contributions q_{ii} (lattice) due to the surrounding lattice ions and the contribution q_{ii} (ion) due to the valence electrons are each multiplied by Sternheimer factors, which describe an induced charge polarization of the electrons in closed shells. Table 4 contains the relative contributions of q_{ii} (ion) for p- and d orbitals.

Table 4. Electric field gradients for p- and d orbitals.

Orbital	$q_{zz}/\langle 1\ r^3\rangle_{nl}$	$\eta = (q_{xx} - q_{yy})/q_{zz}$
p_x	+2/5	0
p_y	+2/5	0
p_z	−4/5	0
$d_{x^2-y^2}$	+4/7	0
d_{z^2}	−4/7	0
d_{xy}	+4/7	0
d_{xz}	−2/7	+3
d_{yz}	−2/7	−3

In many cases in compounds of the transition elements both nd- and (n+1)p orbitals make direct contributions to the electric field gradient. The lattice component of the field gradient q_{ii} is then generally small compared to that of the valence electrons. This latter contribution depends on the degree of overlap of the partially filled molecular orbitals and the ligand orbitals, and is thus influenced by the degree of covalence of the bond. In addition, however, a contribution from the formally closed electron shells of the metal ion to the field gradient at the nucleus is possible if these shells have sufficient overlap with the ligand orbitals. The perturbation of mainly closed p shells caused by such overlapping—essentially an orthogonalization effect—can lead to substantial quadrupole splitting insofar as closed p shells exhibit particularly large values of the $\langle r^{-3}\rangle$ radial integral which determines the quadrupole splitting.

Calculations by *Sawatzki et al.*[25] for ^{27}Al in Al_2O_3 showed that there the effect of overlapping with closed shells makes the predominant contribution to the electric field gradient. In a way these discussions represent a parallel case to the calculations made by *Šimánek et al.*[11, 12], which demonstrated the significance of the overlap effect for isomeric shifts.

The qualitative magnitude of quadrupole splitting can often be derived from the symmetry of the particular orbitals. Thus, the 3d shell of iron in the high-spin Fe^{III} complexes has a spherical symmetry and the result may be a smaller field gradient q_{ii} (lattice) originating in the ligands. Conversely, in the analogous case of Fe^{II} complexes a highly nonspherical symmetry exists, which typically gives rise to large quadrupole splitting. In the low-spin compounds of iron, as is to be expected, the Fe^{II} complexes exhibit a very small and the Fe^{III} a somewhat larger quadrupole splitting.

By way of illustration, Figure 9 shows for complexes of mono- and divalent gold, a correlation between the quadrupole splitting and the isomeric shift. Such a correlation is understandable if we again start from the assumption of a synergic coupling of σ- and π-bonds. The increase of the isomeric shift with increasing rank of the ligand in the spectrochemical series corresponds to a transfer of s electrons due to strengthened σ_s bonding. This increase must necessarily go together with an intensification of σ_d bonding whereby the quadrupole interaction is directly influenced. However, this argument has only a qualitative character, and it is not, for example, in any way possible to conclude that a linear relation exists between the isomeric shift and quadrupole interaction, since even with proportionality of the s- and d contributions in the σ-bonds, the electron transfers always affect the isomeric shift and the quadrupole splitting to a different degree. Direct proportionality between the two quantities measured can perhaps be assumed for small transfers.

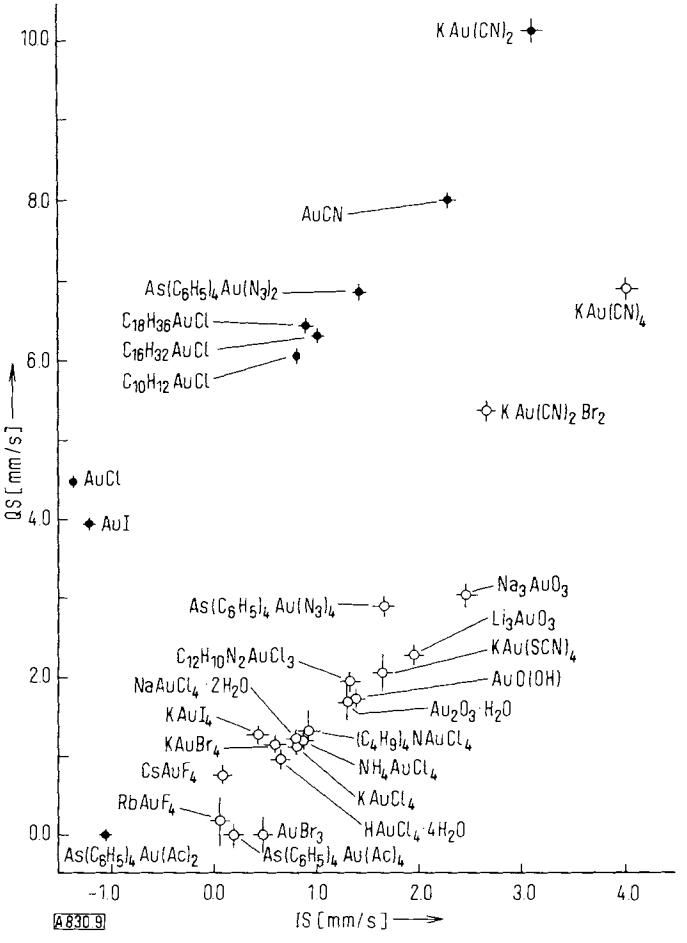

Fig. 9. Correlation between quadrupole splitting QS and isomeric shift IS for compounds of Au^{I}(●) and Au^{III}(○); after [20].

In principle, the sign of the electric field gradient can be taken from the difference in the intensity of the components of the split hyperfine spectrum. However, this method fails for nuclear transitions of the type $I=\frac{1}{2}\leftrightarrow I=\frac{1}{2}$, as for example in the 14.4-keV transition in ^{57}Fe. Here, in polycrystalline substances with more or less isotropic bonding forces, all that is observed as a result of quadrupole interaction is two gamma lines of equal intensity. Determination of the sign of the electric field gradient in this case requires either the use of single crystals or splitting of the nuclear level by means of strong external magnetic fields.

5. Final Remarks

To sum up, it can be said that the method of gamma resonance spectroscopy is capable in a unique manner of yielding information concerning the nature of the chemical bond. Measurements of isomeric shifts can be used directly for the classification of chemical valence states. At the present stage of development, however, the interpretation of these measurements is first and foremost of a very qualitative nature. So far there are no reliable experimental or theoretical methods of determining the relation between the isomeric shift and the electron density at the nucleus. In other words, the problem of calibration of the isomeric shifts still awaits a satisfactory solution. A closely associated problem is that in most cases it has not, so far, been possible to resolve the indirect contribution of the screening electrons from the direct contribution of the s electrons. For a solution of this problem, direct determination of the effective charges of the bound metal ions would above all be of great interest. Unfortunately knowledge of the molecular orbital energies yields this information only very indirectly. High-pressure experiments should in future assume increasing importance for detailed interpretation of isomeric shift data. Systematic comparisons with force constants and with bond lengths and angles—in many cases still unknown—are further possible aids to interpretation. Notwithstanding the often qualitative nature of its statements, gamma resonance spectroscopy has in a few years substantially contributed to our understanding of chemical bonding.

Methods and Applications of Nuclear Magnetic Double Resonance

By Wolfgang von Philipsborn[*]

In double resonance spectra, transitions between energy levels of a nuclear spin system are measured in the presence of two (or more) oscillating magnetic fields. Experiments of this nature form the basis of what is nowadays one of the most important techniques of NMR spectroscopy. Depending on the method selected, they can be used to unravel complex spectra, to measure hidden or weak resonances, or to determine the relative signs of coupling constants, as well as in stereochemical or kinetic studies. This wide and steadily growing range of applications of double resonance is described with the aid of specific examples.

1. Introduction

NMR spectroscopy is nowadays an essential part of molecular spectroscopy and an indispensable aid in the investigation of the structures of organic and inorganic compounds. Several progress reports on various aspects of the field have appeared in this journal[1-6]. Particularly great progress has been made in recent years in the development and application of double and multiple resonance methods. An effort is therefore made below to describe the methods that are of most interest to chemists, and to demonstrate their use in spectral analysis and for the solution of structural problems. As the literature is extremely abundant, a comprehensive review is impossible here, and the examples were therefore chosen for their illustrative character.

2. Phenomenology and Instrumental Principles

In double resonance experiments, transitions between energy levels of a nuclear spin system in a polarizing static magnetic field H_0 are measured in the presence of two oscillating magnetic fields H_1 and H_2. H_1 is used to observe the resonance of one type of nucleus, and H_2 for the perturbation of a second type of nucleus. The method is based on a proposal made by *Bloch* in 1954, and was successfully realized in the very same year[7]. This first reported experiment was concerned with the determination of the Larmor frequency ($\omega = \gamma H_0$) of ^{13}C in $^{13}CH_3I$; the procedure used

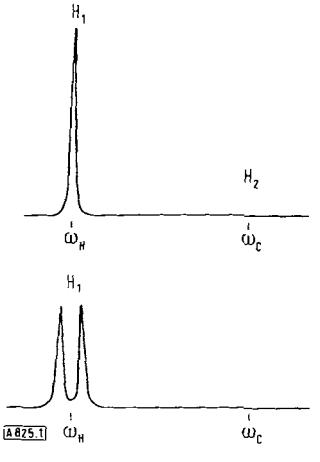

Fig. 1. Schematic illustration of the proton spectrum of $^{13}CH_3I$ (bottom) and *Royden*'s ^1H-{^{13}C} double resonance experiment [7]. Observing field H_1, perturbing field H_2.

was to look for the frequency ω_2 of the perturbing field H_2 that simplifies the proton doublet observed with H_1 to an optimal singlet (Fig. 1). The experiment is thus also

[*] Prof. Dr. W. v. Philipsborn
Organisch-chemisches Institut der Universität
CH-8001 Zürich, Rämistrasse 76 (Switzerland)

the simplest case of spin decoupling, since the strong perturbation of the ^{13}C nuclei leads to a breakdown of proton-carbon spin coupling. However, double resonance and spin decoupling are not synonymous, since decoupling effects occur only under certain conditions.

In view of the large number of double resonance experiments known, some classification is necessary. First of all, one distinguishes between *homo*nuclear and *hetero*nuclear experiments, according to whether the nuclear spins in question belong to nuclei of the same type or of different types. This affects the experimental conditions, inasmuch as a second radio frequency can be used for H_2 in the heteronuclear case, whereas in the homonuclear case the second frequency is produced mostly by audio modulation of the spectrometer frequency. The technique of heteronuclear double resonance has been described in two reviews[8, 9]. A comprehensive description of the theory and practice of double resonance with special reference to homonuclear experiments has been published by *Hoffman* and *Forsén*[10]. Since the present article is concerned mainly with the phenomenology and application of double resonance, the reader is referred to the literature for a more profound theoretical study[8, 10].

The experimental methods can best be further classified according to the energy of the perturbing field. The energy γH_2[Hz] ($\gamma = \gamma/2\pi$; γ = gyromagnetic ratio of the nuclei irradiated by H_2; H_2 = amplitude of one of the rotating components of the perturbing rf-field) may be compared here with the nuclear spin interaction $J_{NN'}$ [Hz], the line width $\Delta\nu_{1/2}$ [Hz], or the reciprocal relaxation times $1/T_1$ and $1/T_2$ [Hz]. As the amplitude of the perturbing field decreases, it is possible to distinguish the following cases, where A is the nucleus under observation and X is the perturbed nucleus in any spin system:

Amplitude of the perturbing field [Hz]	Effect on the observed A resonance	Terminology
$\gamma H_2 \gg n \cdot J_{AX}$ (n depends on the nature and number of equivalent X nuclei	Reduction of the number of resonance lines	Spin decoupling
$\gamma H_2 \approx J_{AX}$	Reduction of the number of resonance lines by selective irradiation of the X resonance	Selective spin decoupling
$\gamma H_2 \approx 1/T_2 \approx \Delta\nu_{1/2}$	Additional splitting by submultiplet formation	Spin tickling
$\gamma^2 H_2^2 (T_1 T_2)_X \approx 1$	Changes in the relative intensities of the multiplet lines	Generalized Overhauser effect [a]

[a] Cf. [10] and Section 3.4.

The various double resonance experiments yield different kinds of information, and are illustrated in Section 3 with the aid of some typical examples. The following abbreviation is commonly used for the formal description of such experiments: A-{X} denotes an experiment in which the X resonance in an AX system is totally or partly irradiated by H_2, whereas the A resonance is observed by means of H_1. This can be achieved under various conditions, which determine the appearance of a double resonance spectrum. Since there are five experimental parameters, *i.e.* H_1, ω_1; H_2, ω_2, and H_0, and since ω_1 and ω_2 are related to H_0 by the Larmor conditions for A and X, at least one of the quantities H_0, ω_1, and ω_2 must be varied to enable a double resonance spectrum to be recorded.

The following measuring techniques are distinguished:

1. Variation of field "field sweep":	$\omega_i - \omega_2 = \text{const.}$, $H_0 \pm \Delta H$ variable, *i.e.* the X spectrum is scanned with $\omega_2(H_2)$, while A is scanned with $\omega_1(H_1)$.
2. Variation of frequency "frequency sweep ω_1":	$\omega_2/H_2 = \text{const.}$, $\omega_1 \pm \Delta\omega$ variable; the additional irradiation is fixed for X, whereas $\omega_1(H_1)$ sweeps over the entire A spectrum.
3. Variation of frequency "frequency sweep ω_2": (INDOR [a])	$\omega_1/H_1 = \text{const.}$, $\omega_2 \pm \Delta\omega$ variable; the same line in the A spectrum is always observed, whereas the perturbing field H_2 scans the resonance lines of X.

[a] INDOR = abbreviation for "internuclear double resonance".

In contrast with normal "single resonance" spectra, field-sweep and frequency-sweep double resonance spectra differ from one another. The field-sweep method can be readily used in the homonuclear case when ω_1 and ω_2 are produced by audio modulation of the transmitter frequency ω_0. It is particularly suitable for spin decoupling, and is historically the older technique. However, the number of experiments required for the decoupling of the A nuclei from several nuclei with different chemicals shifts (*e.g.* {X} {Y} ...) is obviously equal to the number of different nuclei. If $\omega_A - \omega_X \gg 2\pi J_{AX}$ (and this is so in first-order spectra), the difference in the modulation frequencies $\omega_1 - \omega_2$ corresponds to the relative chemical shift of A and X, $\omega_A - \omega_X$. It follows therefore that spin decoupling can also be used to determine the (relative) chemical shift of the X nucleus if this resonance is hidden under the resonances of other nuclei. In a frequency-sweep experiment, one of the two fields, H_1 or H_2, must be accurately fixed at a certain point in the spectrum (at ω_1 or ω_2); this is facilitated by field frequency stabilization of the spectrometer. If the perturbing field H_2 is fixed at the resonance of a nucleus which is coupled to several partners the coupling with all the partners can be eliminated in one experiment. The techniques most commonly used at present are 2 and 3.

Another important factor is whether the magnetic fields H_1 and H_2 are stationary or transient, *i.e.* whether their application is of short duration. An additional parameter in double resonance experiments is therefore the rate of change of frequency for the observing and perturbing fields (sweep rate). This is particularly important in experiments in which intensity changes are observed as a result of changes in the populations of the energy levels (Overhauser effects). Time-dependent intensity changes of this nature in double resonance experiments are discussed in Section 3.5.

3. The Methods and their Uses

The double resonance methods indicated in Section 2 can be applied to a wide variety of problems, as is clear from the following survey:

Method	Use
Noise decoupling (broad-band decoupling) heteronuclear	Simplification and sensitivity enhancement in spectra of nuclei that give low intensities, *e.g.* ^{13}C-{^{1}H} and also ^{19}F-{^{1}H} experiments.
Spin decoupling heteronuclear and homonuclear	Structure elucidation by definite identification of spin-coupled nuclei and simplification of complicated multiplets; detection of hidden resonances; simplification of spectra of multispin systems to obtain preliminary sets of parameters for computer calculations.
Selective spin decoupling	Assignment problems within complex and overlapping multiplets; determination of the relative signs of scalar nuclear spin couplings.
Spin tickling	Accurate measurement of the frequencies of hidden resonance lines; assignments in strongly coupled spin systems; identification of subspectra; determination of the relative signs of coupling constants; construction of energy level diagrams.
Overhauser effects	
(a) Generalized OE (spin pumping) (GOE)	Accurate measurement of the frequencies of hidden resonance lines by INDOR spectroscopy, determination of proton sequences, elucidation of structures; determination of relative signs of coupling constants; construction of energy level diagrams; indirect determination of the chemical shifts of nuclei giving low intensities, *e.g.* ^{13}C, ^{14}N, ^{31}P, by heteronuclear INDOR spectroscopy.
(b) Classical *inter*molecular internuclear OE	Investigation of relaxation processes in liquids and gases.
(c) *Intra*molecular internuclear OE (NOE)	Semiquantitative determination of internuclear distances, solution of stereochemical problems; measurement of relaxation and correlation times; intensity enhancement of weak nuclear resonances, *e.g.* ^{13}C.
Transient double resonance experiments	Kinetic studies on spin systems with chemical exchange, determination of exchange rates and spin-lattice relaxation times.

Their value will now be demonstrated with the aid of specific problems. The space devoted to the various examples does not necessarily reflect their relative importance, which should in fact be greatest for the less well known, more recent methods.

3.1. Spin Decoupling

This is the oldest method. The disappearance of spin-spin coupling in an A-{X} system can be best understood if one considers the double resonance experiment in a rotating system of coordinates ("rotating frame"). For a system of Cartesian coordinates rotating about the direction of the static magnetic field H_0 (z axis) with a frequency ω_2, the time-dependent perturbation caused by H_2 becomes a stationary perturbation in the x direction. H_0 then appears to be reduced to $H'_0 = H_0 - \omega_2/\gamma$, and the X nucleus perturbed by H_2 is exposed to an effective field $\vec{H}'_0 + \vec{H}_2$. If ω_2 corresponds to the resonance frequency of the X nucleus, this leads to $H'_0 = 0$ and to an effective quantization of X in the direction of $H_2(x)$, *i.e.* perpendicular to H_0, the z direction, in which the A nucleus observed with H_1 ($H_1 \ll H_2$) and coupled with X is quantized. Since the scalar nuclear spin coupling is given by the product $J_{AX} \cdot \vec{I}_A \cdot \vec{I}_X$, orthogonal quantization of A and X results in a collapse of the spin coupling.

The analytical importance of spin decoupling for the unraveling of complex NMR spectra was recognized very early, and experiments with this aim were carried out first on heteronuclear[7, 8, 11, 12] and later on homonuclear systems[13]. Heteronuclear experiments of the type H-{X} and X-{H} can greatly simplify the spectra of protons in compounds containing ^{2}H, ^{11}B, ^{14}N, ^{19}F, or ^{31}P and facilitate the interpretation of the spectra of the corresponding hetero nuclei[9]. It is essential in experiments of this type that the transmitting coil of the spectrometer be able to accommodate both Larmor frequencies and that it be tuned accordingly or that a second transmitting coil be incorporated[14]; the second radio frequency may be advantageously supplied by a frequency generator.

An important and frequent application is the decoupling of the protons from deuterium in specifically deuterated organic compounds. The proton resonances in such cases are greatly broadened as a result of ^{1}H, ^{2}H spin coupling and deuterium quadrupole relaxation effects (Fig. 2), However, for kinetic studies by NMR line shape analysis the line width should be as small as possible. An example is provided by the determination of the free enthalpy of activation ($\Delta G^{\neq} = 8.1$ kcal/mole) for the ring inversion of cyclooctane on the basis of the ^{1}H resonance of $C_8D_{15}H$ with ^{1}H-{^{2}H} decoupling[15]. Similarly, $\Delta G^{\neq} = 10.2$ kcal/mole was found for the ring inversion of cyclohexane from the temperature-dependent ^{1}H spectra of $C_6D_{11}H$[16a–c].

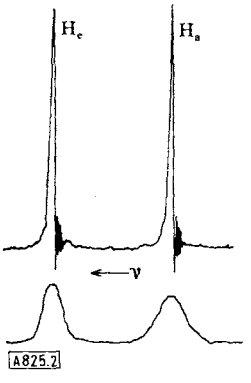

Fig. 2. Proton spectrum of [D_{11}]-cyclohexane at −100 °C (bottom) and with decoupling from the deuterium nuclei (top); $\nu_e - \nu_a = 28.7$ Hz (60 MHz) [16c].

The advantage of this double resonance technique is that the kinetics in complex spin systems such as in C_8H_{16} and in C_6H_{12} can be reduced to a simple two-center exchange in $C_8D_{15}H$ and $C_6D_{11}H$ respectively (Fig. 2), with the result that more accurate thermodynamic activation parameters can be obtained. The vicinal proton coupling constants in 2,2,3,3,4,4,5,5-octadeuteriocyclohexane have also been determined from the ^{1}H-{^{2}H} double resonance spectrum[17]. Heteronuclear ^{1}H-{^{14}N} and ^{1}H-{^{11}B} decoupling have proved excellently suited for the analysis

of nitrogen heterocycles, such as pyrrole[18] and pyridine[19] and of boranes[20]. ^{11}B-{^1H} decoupling has been used for the analysis of the ^{11}B spectra of carboranes[21]. For further examples and instrumental details the reader is referred to [8, 9].

decoupling of the ^1H resonance, the carbon spectra can be greatly simplified and the signal/noise ratio for this low-intensity nucleus can be improved (cf. also Section 3.4.3). Figure 4 shows the application of this double resonance process to the ^{13}C spectrum of pyridine that contains

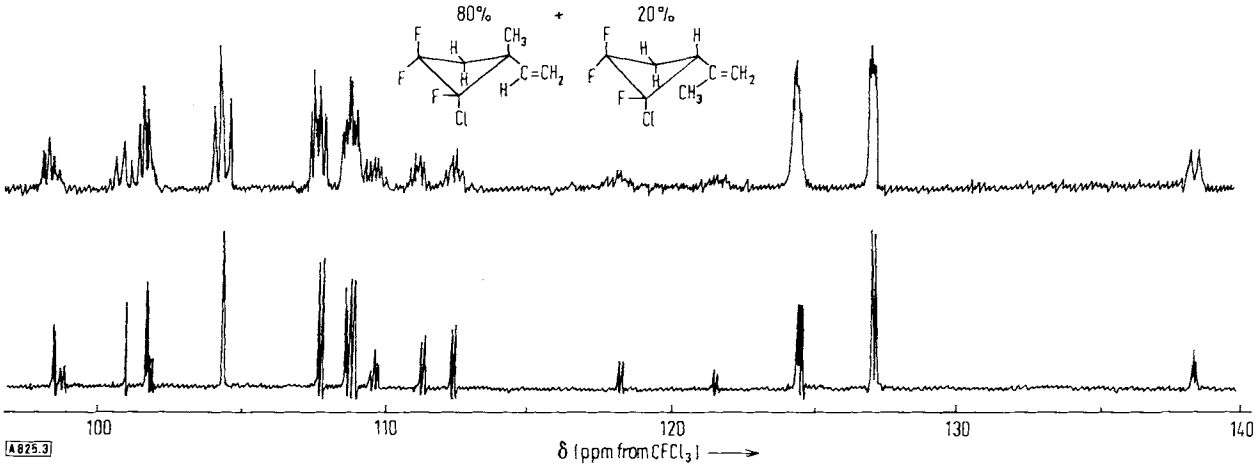

Fig. 3. ^{19}F spectra of a mixture of two substituted cyclobutanes, which are themselves mixtures of *cis-trans* isomers; top: normal spectrum, bottom: proton noise-decoupled spectrum [22].

Difficulties are encountered in the use of the decoupling technique when the resonances of the types of nuclei to be irradiated extend over a large frequency range. This is so in ^1H-{^{19}F} and ^{19}F-{^1H} experiments because of the magnitude of the proton-fluorine coupling. A similar problem arises when one wishes to measure the ^{13}C resonances of a molecule with complete decoupling of all protons. The required frequency range (a few hundred to one thousand Hz) of the perturbing field H_2 is achieved by a method known as *noise decoupling*[22]. In this method, the perturbing field H_2 can be applied pseudo-randomly over a wide frequency range (*e.g.* 1000 Hz) with the aid

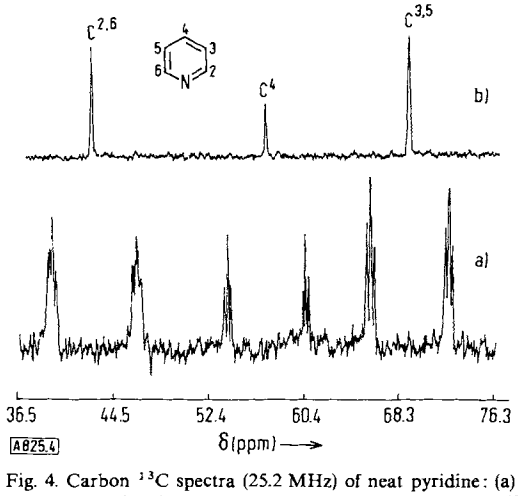

Fig. 4. Carbon ^{13}C spectra (25.2 MHz) of neat pyridine: (a) 16 computer-accumulated spectral scans; (b) 1 scan, measured with {^1H} noise decoupling; chemical shifts relative to CS_2 (Varian Assoc.).

of a shift pulse generator, so that all the nuclei are covered in a very short time. The first examples were described by *Ernst* for the ^1H,^{19}F double resonance (Fig. 3); however, the most important use nowadays is in the measurement of the ^{13}C resonance of organic compounds. By complete

the carbon isotope in natural abundance (1.1%). The importance of such ^{13}C-{^1H} double resonance spectra for the elucidation of structures becomes obvious when one considers the noise-decoupled carbon spectrum of 4-allyl-4-methyl-2,5-cyclohexadien-1-one (Fig. 5)[23].

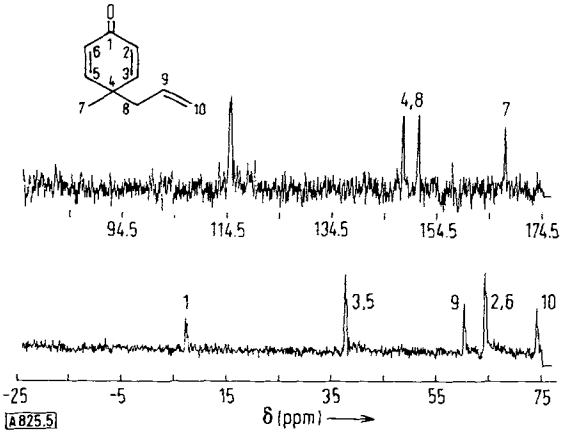

Fig. 5. Carbon ^{13}C spectrum (25.2 MHz) of 4-allyl-4-methyl-2,5-cyclohexadien-1-one in $CHCl_3$, {^1H} noise decoupling; chemical shifts relative to CS_2 [$\delta(CHCl_3) = 115.0$ ppm].

The conditions for homonuclear (*e.g.* ^1H, ^1H) experiments are nowadays satisfied by the equipment of standard spectrometers, and have been described in detail[8-10]. We shall therefore confine ourselves here to a brief description of the difference between homonuclear field-sweep and frequency-sweep double resonance spectra. Figure 6 shows the 100 MHz spectrum of the alkaloid fruticosine, the structure of which was verified by double resonance experiments[24]. The region between 2.4 and 4.8 ppm contains the signals of twelve protons, six of which are assigned to two separate AMX systems, H-C(4)-C(3)HOH and $H_2C(10)$-C(11)H. Six separate irradiations are required here, since only one spin coupling is eliminated in each

experiment. This disadvantage disappears in the frequency-sweep method.

The irradiation of the H^5 resonance in mannosan triacetate (Fig. 7) simplifies the signals of all the protons coupled with this nucleus, *i.e.* H^2, H^3, H^4, $H^{6'}$ and $H^{6''}$[25]. This

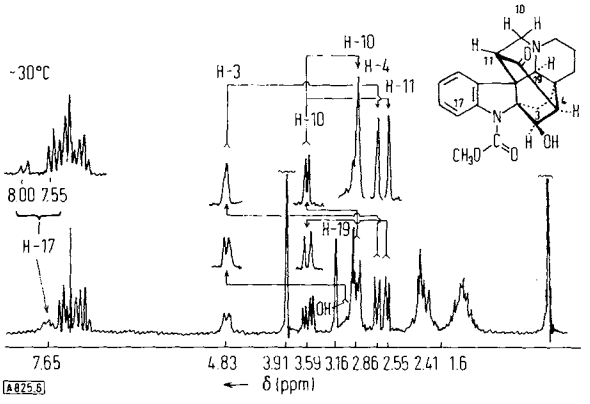

Fig. 6. ^1H spectrum of the alkaloid fruticosine (100 MHz) and field-sweep double resonance spectra; irradiation position ↑, observation position ↓ [24].

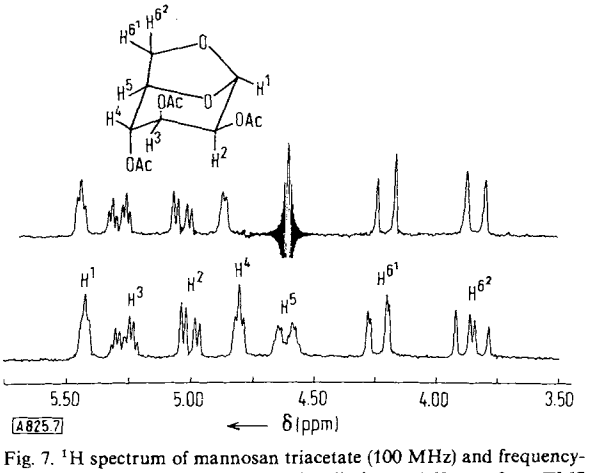

Fig. 7. ^1H spectrum of mannosan triacetate (100 MHz) and frequency-sweep double resonance spectrum; irradiation at 4.62 ppm from TMS [25].

example can also serve for the demonstration of the frequency shifts that occur in double resonance spectra. In the double resonance spectrum of Figure 7, the signals of all the decoupled protons are displaced to different frequencies in relation to their original position, the shift being greatest in the neighborhood of $\omega_2(H_2)$. The irradiation of the X resonance with H_2 causes a shift in the Larmor frequency of the nucleus A under observation as a result of the Bloch-Siegert effect[26]:

$$\omega_A \rightarrow \omega_A + \frac{\gamma^2 H_2^2}{2(\omega_A - \omega_2)} \approx \omega_A + \frac{\gamma^2 H_2^2}{2(\omega_A - \omega_X)} \quad (1)$$

In experiments in which $\omega_A - \omega_X \gg 2\pi J_{AX}$ is not satisfied, moreover, the value of ω_2 for optimum decoupling differs from the chemical shift of the X nucleus ω_X:

$$\omega_2 \rightarrow \omega_X + \frac{\gamma^2 H_2^2}{\omega_A - \omega_X} \quad (2)$$

Both correction terms are easily explained[27]. In frequency-sweep experiments, eq. (2) must be taken into account in fixing ω_2. In the field-sweep technique, the variable is $\omega_1 - \omega_2$, so that eq. (1) and (2) enter into the correction formula:

$$(\omega_1 - \omega_2) = (\omega_A - \omega_X) - \frac{\gamma^2 H_2^2}{2(\omega_A - \omega_X)} \quad (3)$$

The frequencies of the lines observed in double resonance spectra can thus be regarded only as approximations to the values for the unperturbed spin system. This is important when spin decoupling is used to simplify complicated systems in accurate analyses. Nevertheless, an important application of this double resonance method is the determination of preliminary sets of parameters for iterative computer calculations (cf. Fig. 16).

3.2. Selective Spin Decoupling

The spin decoupling method cannot be applied to strongly coupled spin systems or to systems with overlapping multiplets, since perturbation of the lines of neighboring nuclei is unavoidable. However, double resonance spectra that are easy to interpret and that can be used for assignment purposes are obtainable by reduction of the amplitude of the perturbing field H_2 so that only part (an accurately defined part) of a multiplet is perturbed. This "selective" decoupling method can be best illustrated for a three-spin AMX system ($I = \frac{1}{2}$) (Fig. 8).

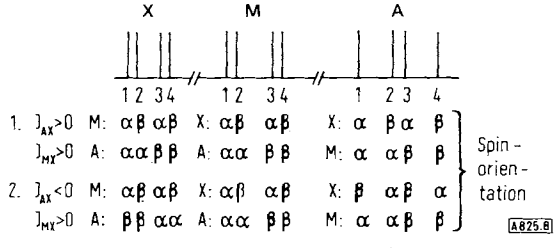

Fig. 8. Schematic three-spin AMX spectrum ($I = \frac{1}{2}$) and spin orientations of the nuclei for the various lines with like and unlike signs of J_{AX} and J_{MX}.

Irradiation on the right-hand M doublet produced by J_{AX} simplifies only one of the corresponding X doublets to a singlet. This is understandable if one considers that the two M doublets (M_1, M_2) and (M_3, M_4) are produced by different molecules, which differ in the spin state (α or β) of the A nucleus. The same is true of the two X doublets. Irradiation of the M resonance in one type of molecule can decouple only the X nuclei in the same type of molecule. The information obtained from selective decoupling of this nature is the same as from a total decoupling experiment, and it can be used *e.g.* in questions of assignment in the elucidation of structures.

The question which of the two X doublets is decoupled by irradiation of M_3 and M_4 depends only on the relative signs of J_{AX} and J_{MX} (Fig. 8). This double resonance (DR) method is thus suitable for the determination of signs of coupling constants, and was first applied to the diethylthallium ion $(C_2H_5)_2Tl^+$[28], furan-α-carboxylic acid[29], and fluorinated ethanes[30]. Figure 9 shows the M and X part of the 100 MHz spectrum of the vinyl protons of

furan-α-carboxylic acid and a selective decoupling experiment carried out by frequency sweep[*]. It shows that $J_{AX}=J_{4,5}$ and $J_{AM}=J_{3,4}$ are of like sign (cf. Fig. 8).

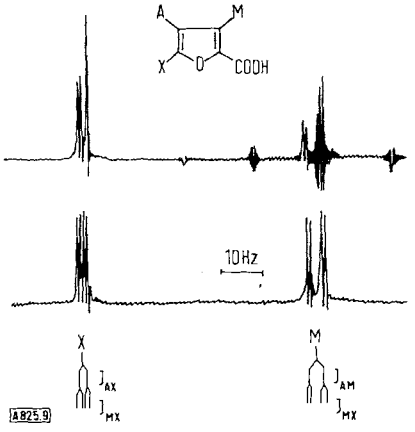

Fig. 9. ^{1}H spectrum of the M and X protons of furan-α-carboxylic acid (bottom) and selective decoupling experiment by irradiation of the two highest-field lines of M.

[*] The original experiment by *Freeman* and *Whiffen* [29] was carried out under field-sweep conditions.

Similar DR experiments can be carried out in heteronuclear systems. Figures 10a and 10b show the 100 MHz proton spectrum and the 94.1 MHz fluorine spectrum of 2-fluoro-4-allyl-4-methyl-2,5-cyclohexadien-6-one. Irradiation of the two lowest-field lines of H-5, *i.e.* elimination of $J_{5,F}$, simplifies the left-hand branch of the fluorine spectrum from a septet to a sextet (Fig. 10c). It follows that the signs of $J_{3,5}$, $J_{5,6}$, $J_{3,F}$, and $J_{6,F}$ are the same[31].

It is even possible in certain cases to determine the magnitudes and relative signs of unresolved spin couplings. It can be seen from Figure 11 that elimination of J_{AX} in the X part of an AMX spectrum by selective irradiation of suitable A transitions produces an unsymmetrical X triplet, from which $|J_{MX}|=|(\Delta_1-\Delta_2)|/2$ and the relative signs of J_{MX} and J_{AM} can be found even when J_{MX} is very small and not resolved in the original spectrum. Irradiation of the four lowest-field lines of H-5 (Fig. 10d) changes the two doublets of H-3 ($J_{3,6}$ not resolved) into two triplets that are unsymmetrical toward the right, from which one obtains $J_{3,6}\approx 0.1_5$ Hz, with *opposite* signs for $J_{5,6}$ and $J_{3,6}$. Since $J_{5,6}$, as a vicinal H,H coupling, has a positive sign[32], $J_{3,6}$ must have a negative sign.

The relative signs of the nuclear spin coupling constants can be determined by various DR experiments (cf. the survey

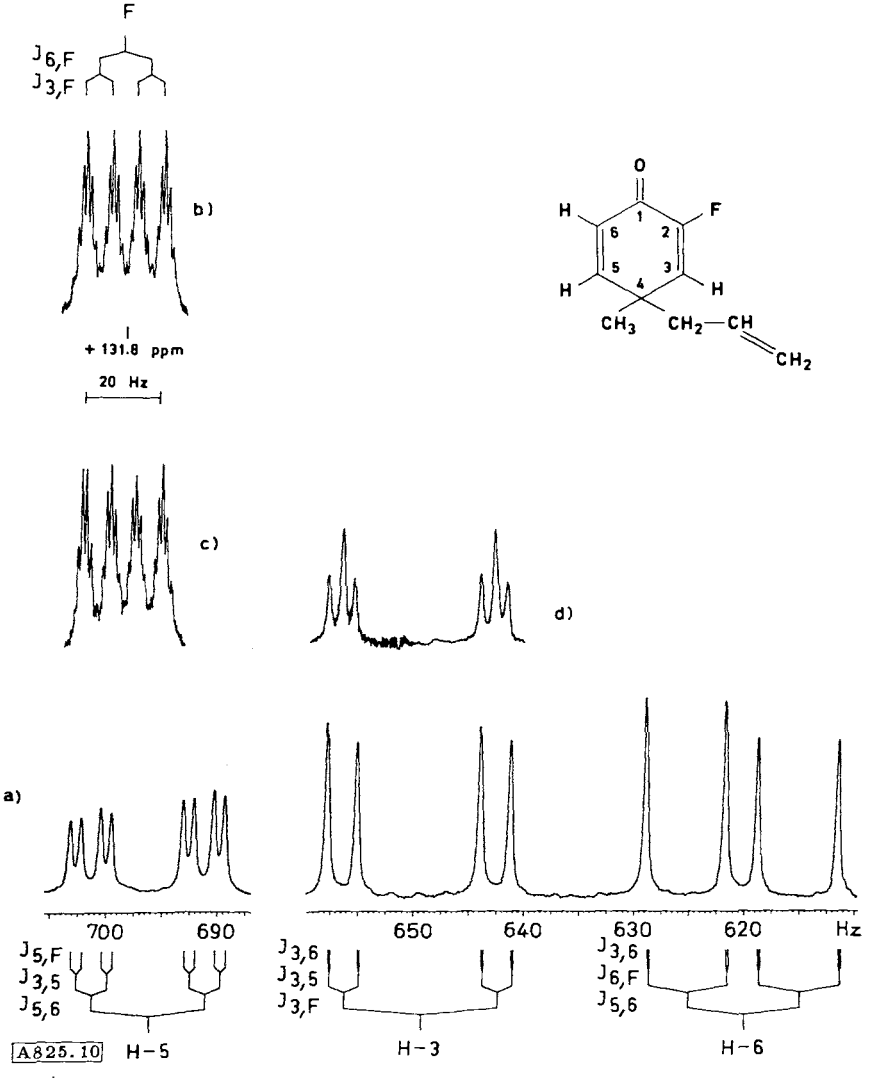

Fig. 10. ^{1}H spectrum (a) and ^{19}F spectrum (b) of 2-fluoro-4-allyl-4-methyl-2,5-cyclohexadien-1-one; (c) selective ^{19}F-{^{1}H} decoupling experiment; (d) ^{1}H-{^{1}H} decoupling to eliminate $J_{3,5}$ [31], cf. Fig. 11.

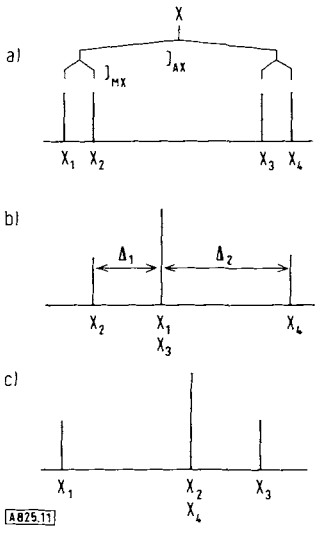
on p. 474). Together with the magnitude of J and the chemical shift, it is a further source of information on which structural and theoretical conclusions can be based. Since the relative signs of most of the typical H,H couplings are now known, their determination can be of decisive value in the investigation of unknown structures, particularly in



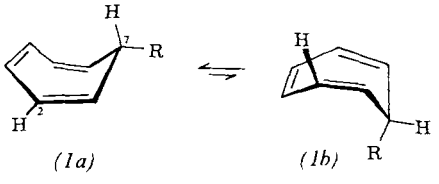


Fig. 11. Schematic representation of the X part of an AMX spectrum: (a) normal spectrum, (b) and (c) double resonance spectra with selective irradiation of the A part and elimination of J_{AX}.

stereochemical problems, in cases where $|J|$ alone does not allow any definite conclusions. For example, the preferred conformation *(1a)* of 7-substituted cycloheptatrienes was deduced from the (negative) sign of the allylic coupling $J_{2,7}$[33].

There is no doubt that too little attention has been given to the significance of the relative signs of coupling constants for structural problems.

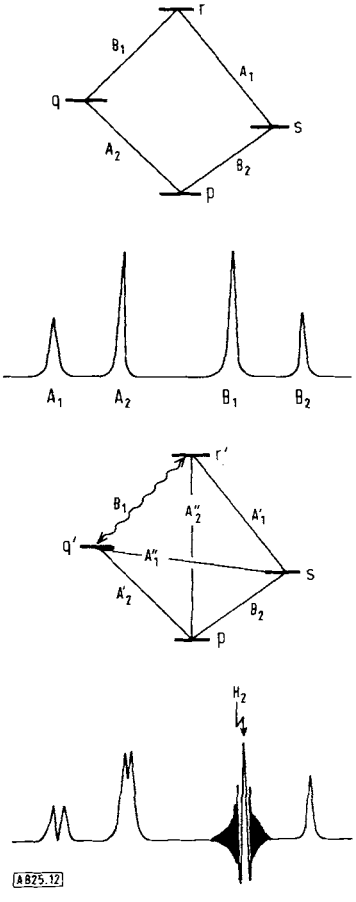
On the other hand, these experimentally determined signs have proved to be important test quantities for quantum-chemical calculations of the scalar nuclear spin coupling.

(1a) *(1b)*

This spin coupling takes place *via* the bonding electrons, is an intrinsic phenomenon of the molecule, and is therefore independent of nuclear magnetic resonance. It is thus of direct interest to the theory of molecular structure. Calculations have been carried out for σ and particularly for π electron systems[34]. A comparison of the results with experimental coupling constants and their relative signs enables interesting conclusions to be drawn regarding the validity of the underlying theories, the mechanisms of scalar spin coupling, and the nature of the chemical bonding in σ systems[35], π systems[36], and organometallic compounds[37].

3.3. Spin Tickling

If the amplitude of H_2 is further reduced and γH_2 reaches the order of magnitude of the line width $\Delta\nu_{1/2}$ or of the reciprocal transverse relaxation time T_2^{-1}, the perturbation is confined to one transition and the associated energy levels. Under these double resonance conditions, spectral lines that have an energy level in common with the perturbed transition will be split into submultiplets[38]. The magnitude of the doublet splitting observed in nondegenerate systems[*] is proportional to the amplitude of H_2 and the square root of the intensity of the irradiated line. Lines that are regressively[40] connected to the perturbed transition normally give well resolved doublets, whereas progressively connected lines give poorly resolved (broad) doublets. The tickling experiment can be best illustrated by the schematic spectrum and energy-level diagram of an



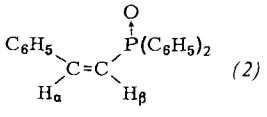


Fig. 12. Schematic representation of an AB spectrum and energy-level diagram (top); tickling experiment for the B_1 transition (bottom) and energy-level diagram with transitions in the rotating frame.

AB system (Fig. 12). *Freeman* and *Anderson*[38a] have developed a theory that has been extended by *Lippmaa et al.*[38b], and which can explain the phenomena observed in tickling experiments. It is again advantageous to choose a system of Cartesian coordinates that rotates around the direction of the magnetic field H_0 (z axis) with a frequency ω_2 ("rotating frame"). If the transition B_1 (q↔r) in Figure 12 is perturbed by H_2, the line A_2 that is progressively connect-

[*] Splitting into several lines is observed in degenerate systems [27]; for spin tickling with nuclei having $I=1$, cf. [39].

ed to B_1 splits into a doublet, since the eigenstate q appears in the two new states q′ and r′ as a result of mixing of the states q and r. From the standpoint of the rotating system of coordinates, the two A_2 lines can then be assigned to the transitions p↔q′ and p↔r′. The same is true of the transition A_1 that is regressively connected to B_1. If ω_2 is exactly the same as ω_{qr} (B_1), the two doublet lines A_2' and A_2'' have the same intensity and appear at distances of $\pm\frac{1}{2}\gamma_B H_2$ from A_2. On the other hand, if ω_2 differs somewhat from ω_{qr}, an unsymmetrical doublet is observed. Since the additional irradiation with H_2 is fixed on a certain line (± 0.1 Hz) in tickling experiments, a field frequency stabilized spectrometer is required for this method. Corresponding experiments have been carried out under field-sweep conditions, and give different results[38a].

This double resonance method is excellently suited for the determination of the exact frequencies of hidden or overlapping resonance lines, since the doublet splitting depends very sensitively on the perturbing frequency ω_2[41]. A

(2)

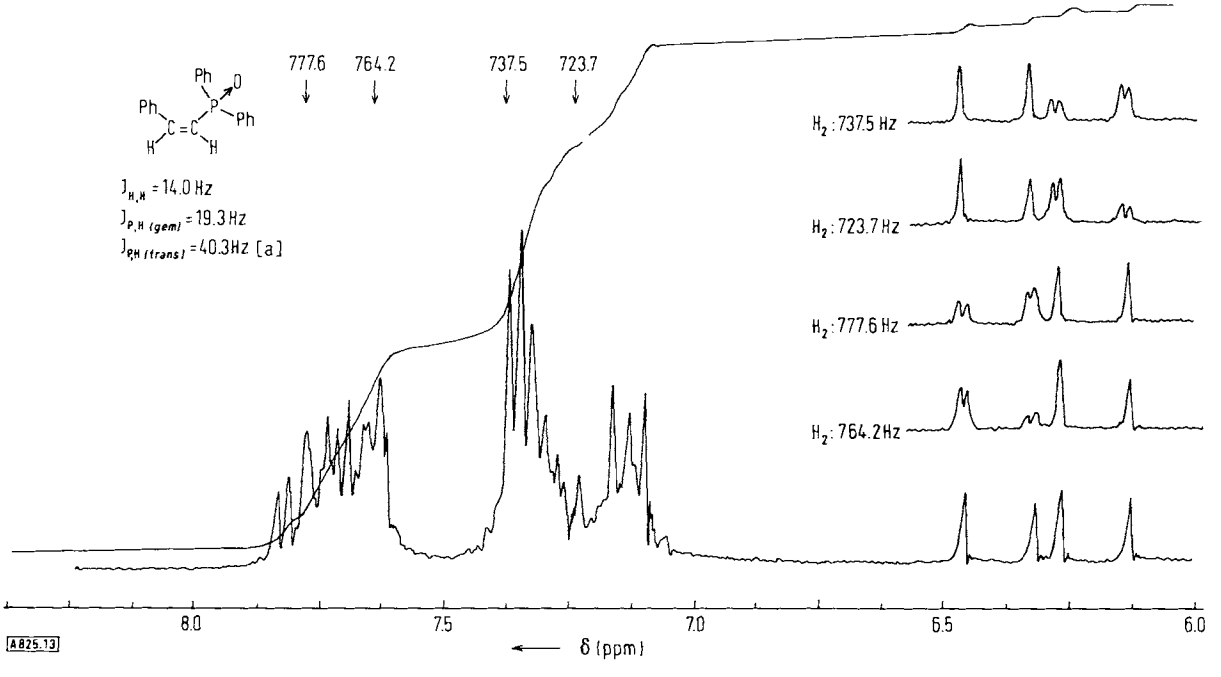
typical application in the elucidation of structures is shown in Figure 13. The problem here is to determine the configuration of the olefinic double bond in styryldiphenylphosphane oxide *(2)* from the ^{1}H-NMR spectrum.

is to be expected for the vicinal *cis* and *trans* proton-phosphorus couplings. However, J_{HP}^{vic} can be found only from the hidden H_α multiplet, the lines of which can be determined very accurately by tickling experiments (Fig. 13). The coupling constant $J_{HP}^{vic}=40.3$ Hz obtained from the four lines is greater than $J_{HP}^{trans}=30.2$ Hz in trivinylphosphane, whereas J_{HP}^{cis} in this compound is only 13.5 Hz. This result proves the *cis* configuration of the protons in the phosphane oxide *(2)*[43].

The spin tickling technique can also be used for the determination of the chemical shifts of low-intensity, heavy nuclei. The chemical shifts of ^{129}Xe in xenon fluorides[44] and of ^{103}Rh in triphenylphosphane-rhodium complexes[45] have been measured in this way.

However, this method of establishing the positions of hidden or weak resonances is very laborious and time-consuming if a very large frequency range must be scanned in very small intervals (≈ 0.2 Hz) with ω_2. In such cases the INDOR technique (ω_2 sweep) is superior to spin tickling. This technique is discussed in Section 3.4.2.

Another important use of spin tickling is in the determination of the relative signs of coupling constants. Figure 14 shows the energy-level diagrams for a three-spin system with the four possible combinations of signs for J_{AB}, J_{AC}, and J_{BC}. Reversal of the sign of a coupling constant leads to interchange of the transitions of the two nuclei in question in the corresponding rectangles. This changes the connection of the energy levels and hence the tickling pat-



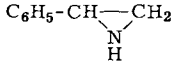


Fig. 13. ^{1}H spectrum of styryltriphenylphosphane oxide *(2)* (100 MHz) and tickling experiments to determine the frequencies of the four hidden lines of H_α [43].

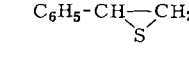


[a] Calculated from spin tickling data.

Whereas the β vinyl proton is visible, the α vinyl proton is completely masked by the phenyl resonances. Thus only $J_{HH}^{vic}=14.0$ Hz can be found from the ^{1}H spectrum, while J_{HP}^{vic} cannot. The magnitude of J_{HH}^{vic} does not allow a definite distinction between the *cis* and *trans* arrangements of the vinyl protons[42] On the other hand, a greater difference

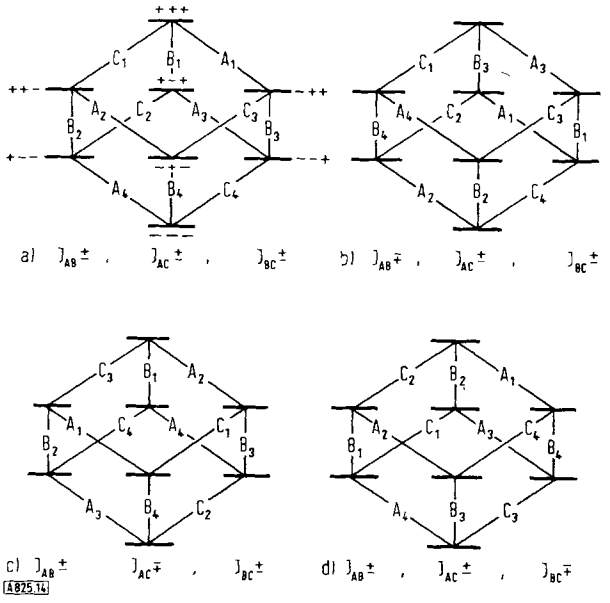
tern. It has been shown in this way[46] that the coupling constants of the geminal methylene protons in the α,β-epimino

(3)

(4)

derivative *(3)* and in the α,β-epithio derivative *(4)* of styrene have opposite signs.

Figure 15 illustrates the spectra of *(3)* and *(4)* and a comparison of the double resonance spectra on irradiation of the A_1 transition. Whereas the lines B_1, B_3 and C_1, C_3 have



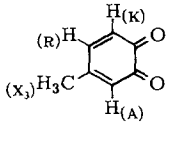


Fig. 14. Energy-level diagrams and transitions for a three-spin system ($\nu_A \gg \nu_B \gg \nu_C$) with the four combinations of signs of the coupling constants, $|J_{AB}| > |J_{AC}| > |J_{BC}|$.

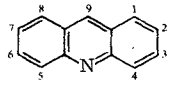

energy levels in common with A_1 in the imine *(3)*, the transitions that share energy levels with A_1 in the case of the sulfide *(4)* are B_2, B_4 and C_2, C_4. This is in agreement with the energy-level diagrams (a) for the imine and (d) for the sulfide, *i.e.* the coupling constants $J_{BC}=J_{gem}$ have opposite signs in the two styrene derivatives. Since the signs of all three couplings are the same for *(3)* and vicinal H,H coupling constants are absolutely positive, the geminal coupling in *(4)* must have a negative sign, as is observed for cyclopropanes. The change in the sign of J_{gem} in three-membered rings is a particularly interesting case of the structure dependence of the signs of nuclear spin coupling constants.

Tickling experiments are particularly suitable for multiple resonance studies. Thus the same sign was found for the three coupling constants of the vinyl protons in 4-methyl-

(5)

o-benzoquinone *(5)* in one experiment[47]. The six-spin system ($AKRX_3$) formed by the three ring protons and the methyl group was first simplified to an AKR system by

$J_{1,9}$ and $J_{3,9}$: negative[*]
$J_{2,9}$ and $J_{4,9}$: positive

(6)

[*] Based on a positive sign for J_{ortho}.

strong irradiation at the methyl resonance, and one R line was simultaneously perturbed by a weak field in a triple resonance experiment (Fig. 16). The alternance of the signs of the long-range H,H spin coupling constants in acridine *(6)* have been demonstrated similarly by a triple resonance analysis of 1-methylacridine and 2-methylacridine[48].

This result confirms theoretical predictions concerning the relative signs of proton-proton coupling in aromatic systems[36].

Since tickling experiments not only give the relative signs of the coupling constants but also the nature of the connection (progressive or regressive) of the observed transition with the irradiated transition, double resonance experiments of this type are the best method for the construction

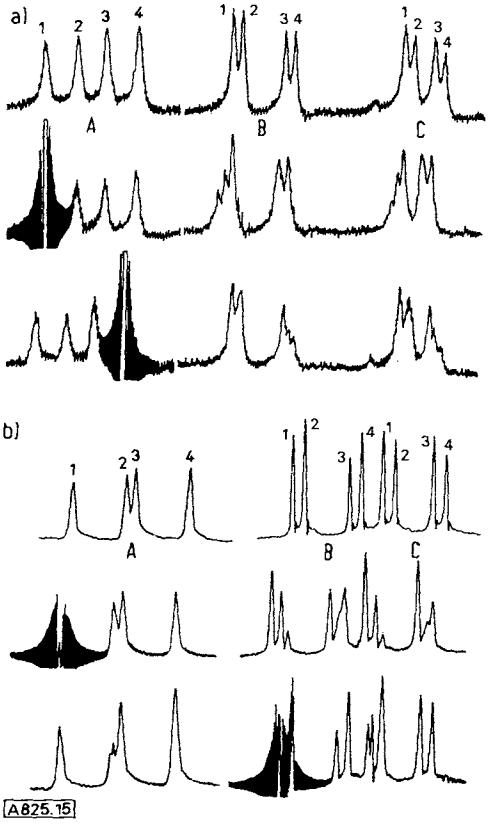

Fig. 15. ^1H spectra and tickling experiments on the side-chain protons of (a) styrenimine *(3)* and (b) styrene sulfide *(4)* [46].

of complete energy level diagrams[38a]. Other important uses occur in the identification of the components of subspectra in complicated multispin systems and in the analysis of the spectra of oriented molecules[49].

The splitting into submultiplets of the lines connected to the perturbed transition is always accompanied by a change in the intensities of these lines. The population changes in the levels of the perturbed transition increase the intensity of the progressive transitions and reduce that of the regressive transitions[27]. Intensity changes of this nature always also occur in the double resonance experiments discussed so far, since a weaker field H_2 is sufficient for this. The condition for these pure population changes is $\gamma^2 H_2^2 T_1 T_2 \geq 1$, and the effect on the intensities is known as the generalized Overhauser effect (GOE)[10]. A wide range of applications can be found for such effects.

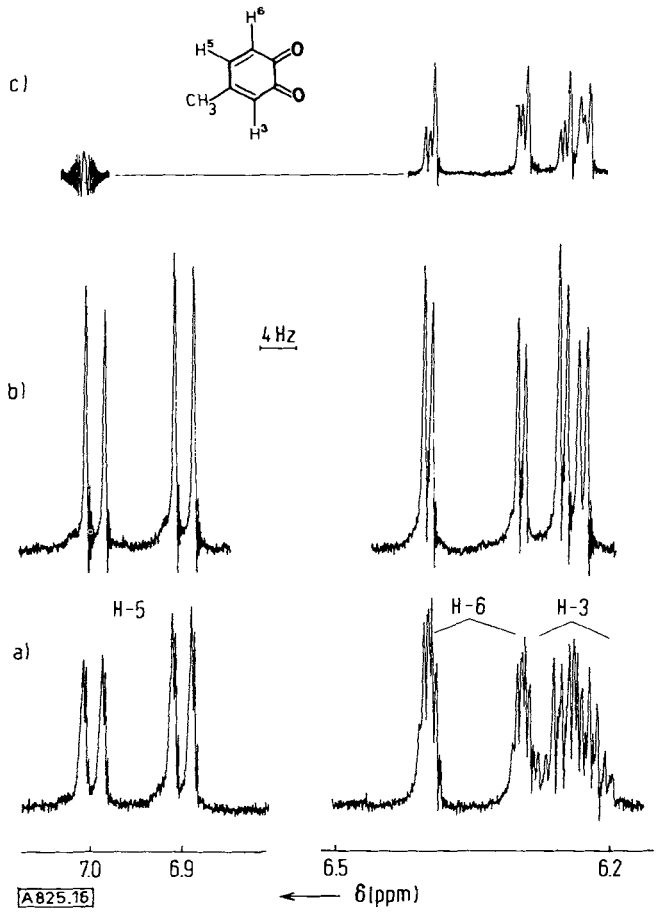

Fig. 16. ^1H spectra of 4-methyl-*o*-benzoquinone *(5)* [47]; (a) normal spectrum ($CDCl_3$, 100 MHz); (b) double resonance spectrum with irradiation of the methyl protons; (c) triple resonance spectrum with irradiation of the methyl protons and tickling of the lowest-field line (700.5 Hz) of H-5.

3.4. Overhauser Effects

In this section we shall discuss double resonance experiments that are based essentially on population changes in the energy levels and which cause corresponding intensity changes in the spectra. The Overhauser effect is really the polarization of nuclei as a result of the saturation of the electron spins in metals[50, 51]. However, it has become common practice to apply the same name to corresponding *inter*molecular and *intra*molecular internuclear polarization effects based on the relaxation mechanism (dipolar coupling). On the other hand, intensity changes observed in double resonance for connected transitions in spin systems with exclusively scalar coupling are collectively known as the "generalized Overhauser effect"[10]. Since this effect follows directly on the last section, it is convenient to discuss it here.

3.4.1. Generalized Overhauser Effect (GOE)

The first effect of this type was observed by *Anderson* and *Freeman*[27] in tickling experiments. These authors perturbed one line in the X_3 part of the AX_3 spectrum of acetaldehyde and found a change in the relative intensities in the quartet of the A part. These intensity changes occur because the irradiation with H_2 causes a change in the populations of certain energy levels as compared with the thermal equilibrium populations. A quantitative treatment[52a] of the processes requires a precise knowledge of the (thermal) relaxation mechanisms and times, which would have to be determined for each spin system. The reader is referred to a detailed review[52b] for a discussion of the physical processes involved. A qualitative description of the situation that is adequate for practical purposes has been presented by *Kaiser*[53], who also described the first practical applications of this effect. Under certain conditions regarding the relaxation times, the following general rules can be established (cf. Fig. 17):

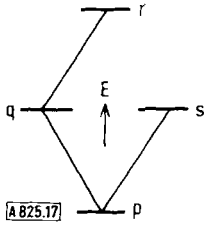

Fig. 17. Connection of transitions in the energy level diagram: q↔r is progressive and p↔s regressive with respect to p↔q.

1. Irradiation of a line (transition) influences only lines that have an energy level in common with it.

2. Irradiation of a nondegenerate line reduces the intensity of a regressive line and increases the intensity of a progressive line.

This Overhauser effect may also be regarded as a consequence of "spin pumping". The information obtained from such experiments is fundamentally the same as that obtained from spin tickling, *i.e.* the relative signs of coupling constants, the assignment of transitions to certain energy levels, and the location of hidden or weak resonances. This will be illustrated here by the normal spectrum and the double resonance spectrum of *m*-dinitrobenzene. This compound gives an AB_2C spectrum (Fig. 18), which can be described approximately as a first order spectrum[53]. Very weak irradiation of the transition 23 increases the intensities of lines 8 and 10 and decreases those of lines 7 and 13. This can be understood from the energy level diagram (Fig. 19), and the signs of all four coupling constants of the aromatic protons are found to be the same. Other examples are the analysis of the AX_3 system of acetaldehyde and the ABM_3X system of *trans*-crotonaldehyde[53], and the determination of signs for 2,6-dinitrobenzaldehyde[54].

The intensity changes, which are sometimes very small, must be detected by comparison with unperturbed lines. However, measurement by the INDOR sweep technique is recommended, since signal intensities are also influenced by instrumental effects (*e.g.* momentary changes in the field then be used above all to find the positions of hidden or homogeneity)[53]. The generalized Overhauser effect can weak resonance lines.

3.4.2. INDOR Spectroscopy

In the INDOR sweep technique, as was mentioned in Section 2, the frequency ω_2 of the perturbing field H_2 is

varied over the entire spectral range, while the observation field H_1 is used for the measurement of a monitor line (ω_1). This method was first described and used by *Baker*[55]. The characteristic feature of such an experiment is that a change in the intensity of the monitor line occurs whenever ω_2 coincides with the frequency of a line that has an energy level in common with the monitor transition at ω_1. This intensity change is plotted as a function of ω_2, and the corresponding INDOR signals are positive for progressive transitions and negative for regressive transitions. The relative intensity changes due to the Overhauser effect are thus recorded as more easily recognizable, absolutely positive or absolutely negative signals[*].

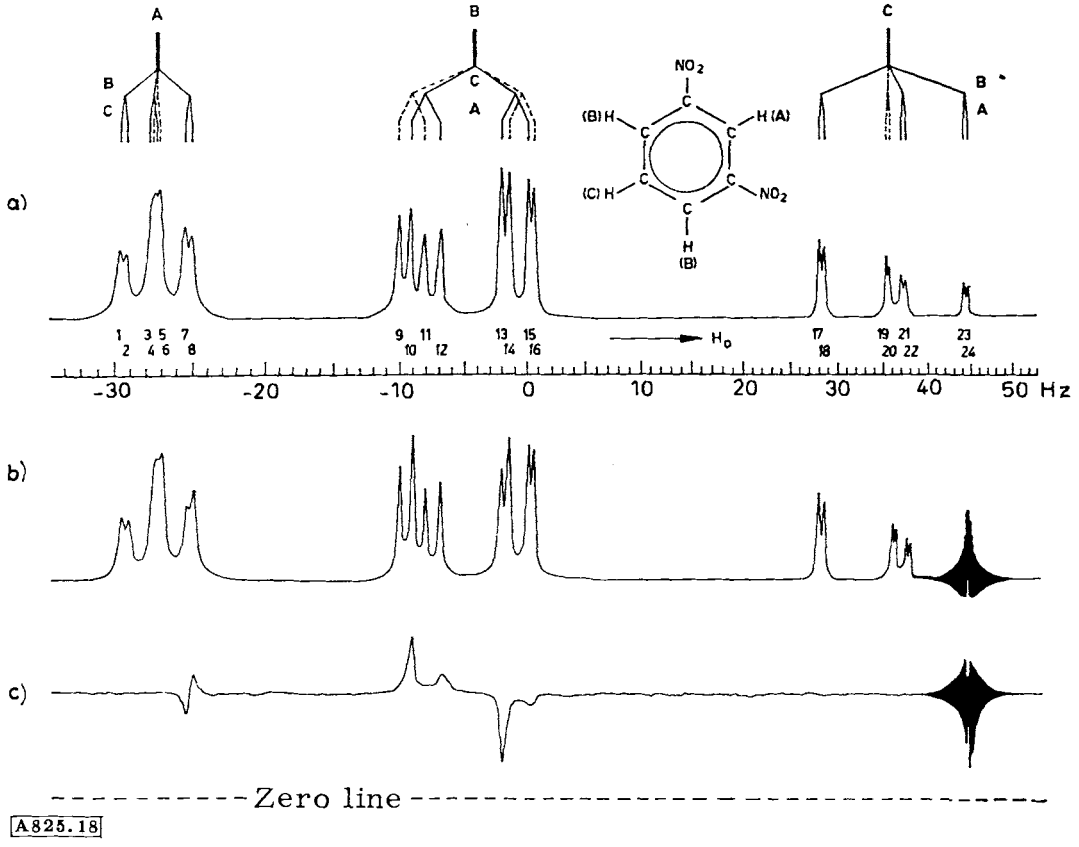

Fig. 18. (a) ^1H spectrum (AB_2C) of *m*-dinitrobenzene (56.4 MHz). The differences between the full and the dotted lines in the splitting diagram would disappear in the limiting AM_2X case. (b) Double resonance spectrum with weak irradiation of line 23; lines 7 and 13 ↓ (regressive), lines 8 and 10 ↑ (progressive). (c) Double resonance INDOR spectrum (ω_2 sweep) with line 23 as the monitor line: positive INDOR signals at the frequencies of lines 8 and 10, negative INDOR signals at the frequencies of lines 7 and 13. Weak INDOR signals also appear at the frequencies of lines 12 and 15 because of partial overlapping of lines 23 and 24. Cf. [53, 10] and energy level diagram in Fig. 19.

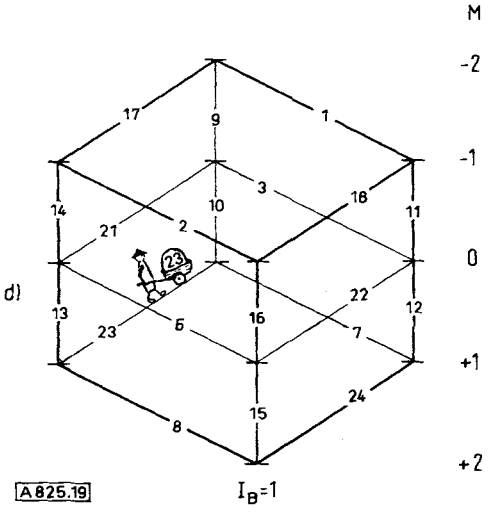

Fig. 19. Energy level diagram of the symmetrical states ($I_B = 1$) for the four-spin system of *m*-dinitrobenzene with an illustration of spin pumping on irradiation of line 23 (Fig. 18) [10, 53].

INDOR experiments have been carried out both on heteronuclear and on homonuclear systems. However, applications so far have not been very numerous. According to a review by *Kowalewski*[56], they are concerned either with the determination of the chemical shifts of nuclei other than protons or with the determination of signs of coupling constants. Heteronuclear ^1H-{^{31}P} INDOR experiments have been successfully used for the analysis of mixtures of organophosphorus compounds[57]. In the homonuclear version, the method is also excellently suited for the accurate determination of the frequencies of hidden resonances of a proton that exhibits scalar coupling with the monitor proton. This double resonance technique has great potential here for the elucidation of the structures of complex molecules[58].

The INDOR principle is illustrated in Figure 20 for a three-spin AMX system. If a nondegenerate monitor line is chosen (A_1), two INDOR signals appear for each proton

[*] The use of higher amplitudes of H_2 leads to tickling effects that result in an increase of the negative INDOR signals and a decrease of the positive signals.

coupled with A. However, if $J_{AX}=0$ and the monitor line is degenerate (A_1, A_2), four signals are obtained for M, but none for X. To obtain the entire INDOR signal of the M nucleus, two experiments with different A lines are necessary in the A———X case (Fig. 20b), whereas one is sufficient in the A—M—X case (Fig. 20d). If the M and X signals are hidden in a practical case, therefore, not only can the line frequencies of M and X be determined with great accuracy (±0.1 Hz), but the coupling constants of these nuclei can also be found.

The intensive application of the INDOR technique allows the complete determination of the structure of a thermal dimerization product *(8)* of 11,13-dioxo-12-methyl-12-aza[4.4.3]propellane *(7)*[58].

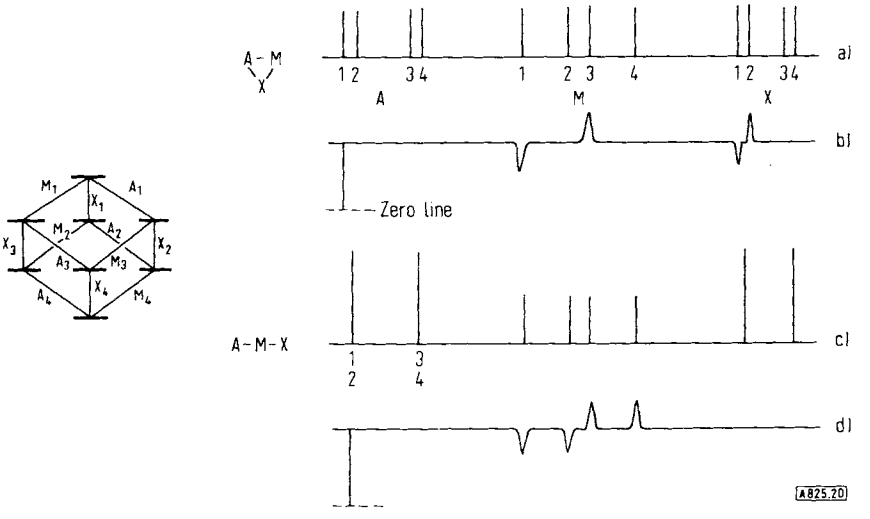

Fig. 20. Schematic spectra of an AMX system and energy-level diagram: (a) normal spectrum, $J_{AM}>J_{MX}>J_{AX}>0$; (b) INDOR spectrum for case (a), monitor transition A_1; (c) normal spectrum, $J_{AM}>J_{MX}>0$, $J_{AX}=0$; (d) INDOR spectrum for case (c), monitor transitions A_1, A_2.

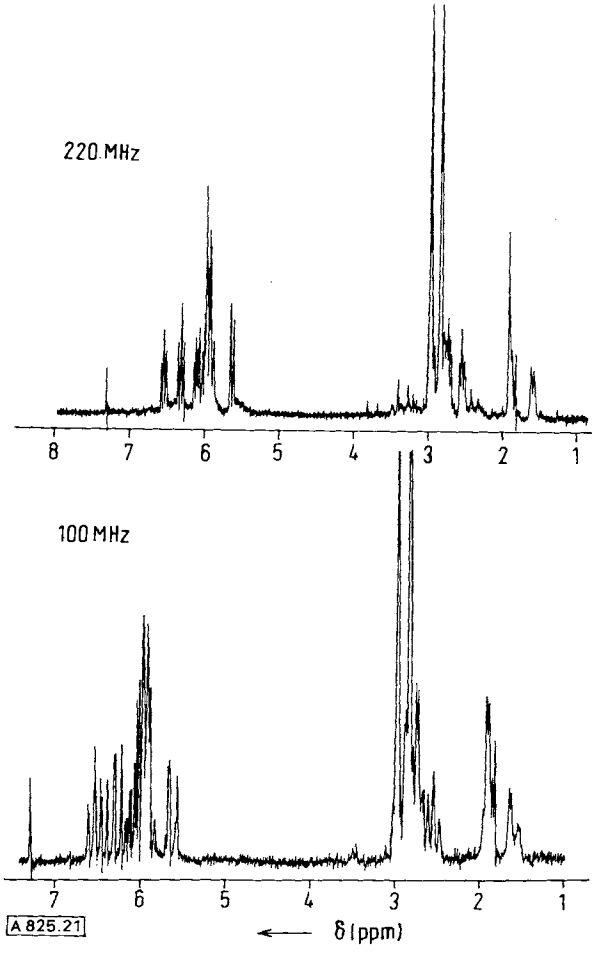

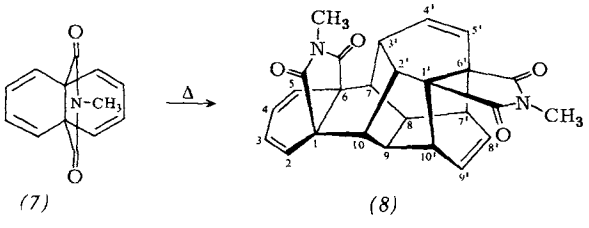

Fig. 21. Proton spectra of the propellane dimer *(8)* at 100 MHz and 220 MHz ($CDCl_3$) [58].

The 100 MHz and 220 MHz spectra of the dimer (Fig. 21) are extremely complex, and conventional double resonance methods cannot be applied. Only four of the sixteen ring protons are resolved in the spectrum. Of these, the two

(7) *(8)*

vinyl protons H-4′ and H-8′ in particular may be used as monitor protons. Figure 22 shows the determination of the four lines of H-5′, while Figure 23a illustrates the detection of ten lines of the protons H-9′, H-7′, and H-10′, all of which are coupled with H-8′, but are hidden in the spectrum. INDOR lines can also be used as monitor lines for consecutive INDOR experiments (Fig. 23b), and this allows the elucidation of proton sequences. The technique has been applied for the same molecule, and Figure 24 illustrates that starting with only three observed protons, eleven of the twelve protons of the skeleton are detected in this way. The use of the INDOR method is not restricted to first order spectra. Thus the chemical shift and coupling parameters of the ABCX system of the four protons of the dimer *(8)* have been established by determination of 32 INDOR frequencies and subsequent evaluation with the aid of an iterative computer program. Other uses of $^1H,^1H$ INDOR in structural studies have recently been published[59-61]. This technique has also proved useful in the

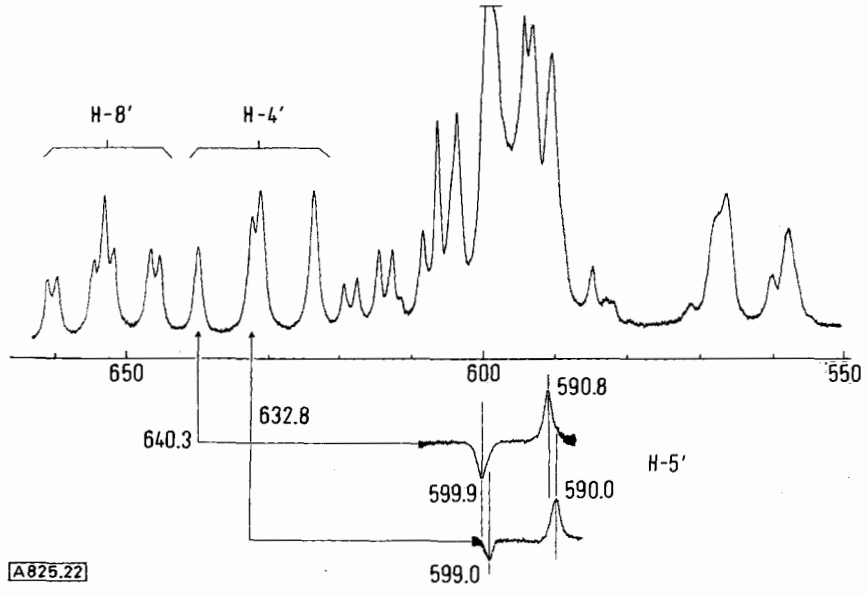

Fig. 22. 100 MHz spectrum of the vinyl region of the dimer *(8)* and INDOR experiments for the determination of the four hidden lines of H-5'; frequencies in Hz [58].

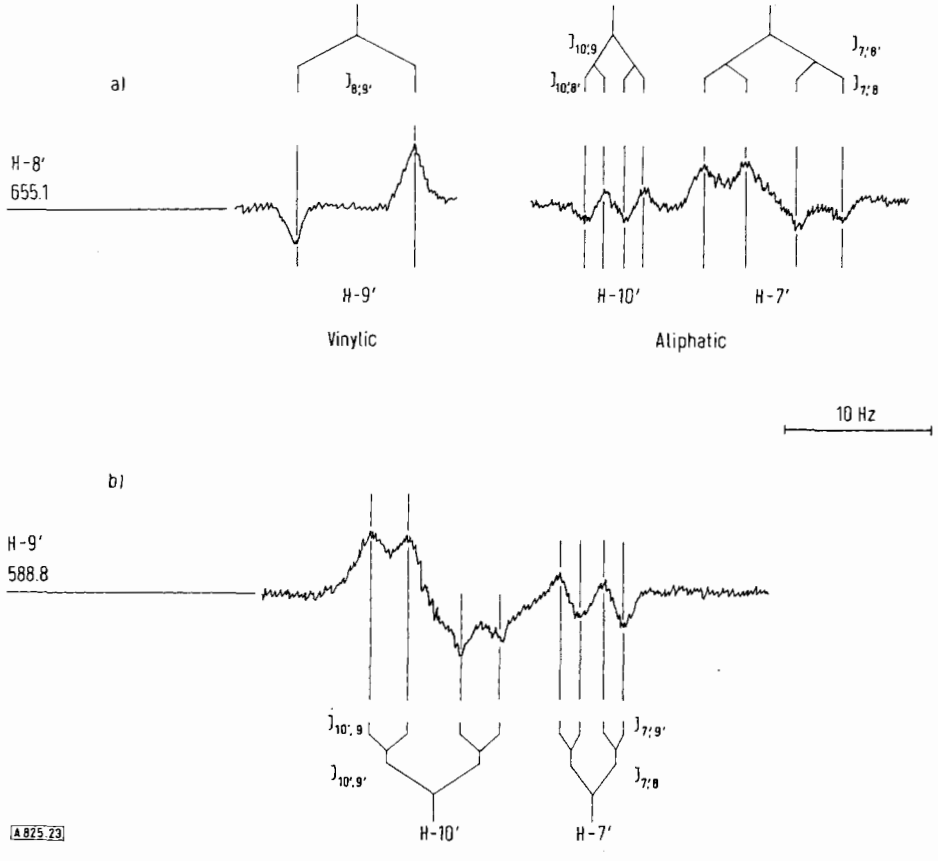

Fig. 23. (a) INDOR spectra of H-9', H-7', and H-10' of the dimer *(8)*, measured with a monitor line (655.1 Hz) of H-8'. (b) Consecutive INDOR spectra of H-7' and H-10', measured with an INDOR line (588.8 Hz) of H-9' as the monitor frequency [58].

analysis of the ^{19}F spectra of *threo/erythro* mixtures[62]. It may be expected that INDOR spectroscopy will find wide use in the elucidation of structures.

The first applications, however, were in heteronuclear double resonance, and made use of the high sensitivity of the ^{1}H or ^{19}F nuclei for the measurement of the resonances of nuclei whose direct measurement is difficult because of low natural abundance and small gyromagnetic constants (*i.e.* poor sensitivity) and because of long relaxation times[55]. This group includes the nuclei ^{13}C, ^{14}N, ^{29}Si, and ^{31}P. The measurement of the carbon resonance in organic compounds is particularly facilitated in this way[41, 63, 63a, 64]. However, methods of this type have now

been displaced by Fourier spectroscopy, combined with noise decoupling (see Sections 3.1 and 3.4.3).

Whereas the experiments described so far proceed under quasi-stationary conditions, and the new populations for the energy levels in question are established under the influence of relaxation processes, INDOR experiments can also be carried out under conditions that correspond to a

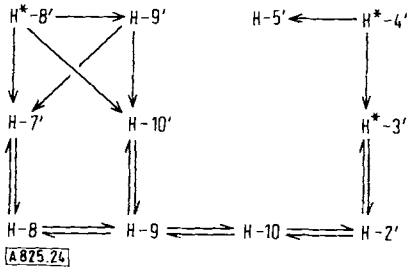

Fig. 24. Proton sequence for the dimeric propellane *(8)*, deduced from INDOR experiments. The arrows point from the monitor proton to the INDOR proton. Protons that can also be observed directly in the spectrum are marked with an asterisk.

fast adiabatic passage across the {X} resonance. The "transient nutations"[65] (Torrey oscillations[66]) that then occur in the monitor resonance, which is also saturated, provide information similar to that obtainable from normal INDOR signals (see Section 3.5.3).

3.4.3. Internuclear Overhauser Effects (NOE)

Apart from the chemical shifts and coupling constants, the relaxation times T_1 and T_2 are the most important parameters in NMR spectroscopy, since they determine the excess of nuclei that remain in the lower energy level when the spin system absorbs energy from the rf field H_1. For protons,

$$\frac{n^s}{n^0} = (1+\gamma^2 H_1^2 T_1 T_2)^{-1} \qquad (4)$$

where n^s is the population excess in the lower level in the presence of H_1, and n^0 is that in the absence of H_1. Since the signal intensity is proportional to the population excess n^s, the intensity of an NMR signal can be increased by reducing T_1 or T_2 by means of external factors.

One of the mechanisms that allow proton relaxation in liquids is the magnetic dipole-dipole interaction between nuclei in different molecules, *e.g.* as a substrate-substrate or substrate-medium interaction. The movement of the molecules produces fluctuating dipole fields, with the result that transitions are induced between Zeeman levels

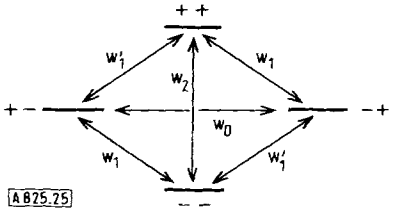

Fig. 25. Energy-level diagram and transition probabilities for a two-spin system with dipole-dipole interaction.

of the nuclei[67]. We now consider a pair of nuclear spins (I,S) that exhibits no scalar coupling and for which the only relaxation path available is the internuclear dipole-dipole mechanism. The transition probabilities corresponding to the change in the quantum number m ($\Delta m = 0, \pm 1, \pm 2$) are denoted by w_0, w_1, and w_2 (Fig. 25). If one of the nuclear resonances (S) is saturated by a strong perturbing field H_2 (*i.e.* $n_S^s = 0$), the change in the longitudinal magnetization of I is given[68] by

$$M_I - M_I^0 = \left(\frac{w_2 - w_0}{w_0 + 2w_1 + w_2}\right) M_S^0 \left(\frac{\gamma_S}{\gamma_I}\right) = (w_2 - w_0)\, T_{1I} M_S^0 \left(\frac{\gamma_S}{\gamma_I}\right) \qquad (5)$$

For the homonuclear case (*e.g.* protons), $M_I^0 = M_S^0$ and $\gamma_S = \gamma_I$, and we obtain

$$\frac{M_I}{M_I^0} = 1 + \left(\frac{w_2 - w_0}{w_0 + 2w_1 + w_2}\right) = 1 + (w_2 - w_0) T_{1I} \qquad (6)$$

M_I^0 = magnetization of I in the absence of H_2;
M_I = magnetization of I on saturation of S by H_2.

Calculations based on a pure dipole-dipole interaction between I and S have shown that $(w_2 - w_0)/(w_0 + 2w_1 + w_2)$ assumes the value $\frac{1}{2}$, *i.e.* that the maximum increase in the intensity of the I resonance to be expected for protons under these circumstances is 50%. The internuclear Overhauser effect (NOE) was first observed by *Kaiser*[69] for the signal of the chloroform proton in a mixture of chloroform and cyclohexane when the cyclohexane protons were saturated. The relaxation time T_1 of the $CHCl_3$ protons can also be determined here as the time constant of the build-up and breakdown of the additional magnetization, which agrees well with the value obtained from the direct saturation of the $CHCl_3$ resonance. However, the observed increase in intensity was only 34%. This means that the chloroform protons are not relaxed exclusively *via* the cyclohexane protons, but that there are also other relaxation paths (*e.g. via* the paramagnetic oxygen in the solution) that contribute to the total transition probability $(w_2 + 2w_1 + w_0)$ and hence to the effective relaxation time T_1.

$$\frac{1}{T_{1I}} = \frac{1}{T_{1S}} + \frac{1}{T'} \qquad (7)$$

If there is only scalar coupling between I and S, the saturation of S causes more or less saturation also of the I-spins, *i.e.* a decrease in the signal intensity[70]. The two effects may therefore be expected to be superimposed if a chemical bond exists between the nuclear species.

However, the significance of the NOE to structural chemistry, which was recognized by *Anet* and *Bourn*[71], is that it can be observed between protons of the same molecule if these are close together in space. The contribution to the longitudinal relaxation time T_1 of a nucleus I due to *intra*-molecular dipole-dipole relaxation by a second nucleus S is given by

$$\frac{1}{T_{1IS}} = \frac{\hbar^2 \gamma_I^2 \gamma_S^2}{d^6} \tau \qquad (8)$$

where τ is a correlation time for the molecular rotation and d is the internuclear distance between I and S. The intramolecular NOE should therefore depend very critically on the internuclear distance. It was soon found that this effect is suitable for the study of molecular structures, particularly for the solution of stereochemical problems. This can be illustrated by the differentiation between the two isomeric ethylideneazabicyclo[2.2.2]-octanes *(a)* and *(b)* (Fig. 26). The compounds were in a mixture and gave different chemical shifts for the methyl and bridgehead protons. Saturation of one methyl resonance (principal component) increased the intensity of one bridgehead proton signal by 31% and had no effect on the signal of the second bridgehead proton. Irradiation of the methyl resonance of the minor component gave no Overhauser effect, so that the main component must have structure *(a)* and the minor component structure *(b)*[72]. It has not been possible to achieve this differentiation with certainty by any other spectroscopic method.

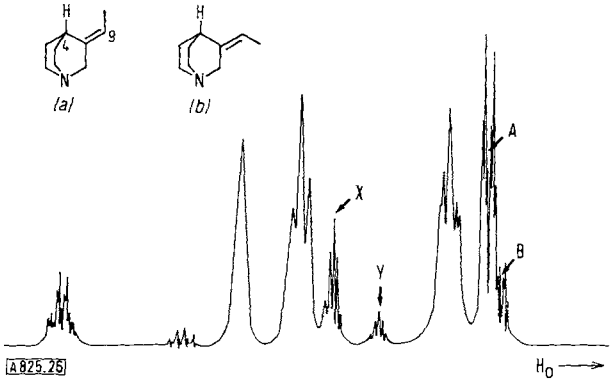

Fig. 26. ^{1}H spectrum of a mixture of the isomeric azabicyclo[2.2.2]-octanes (*a*) and (*b*); A and B correspond to the methyl groups on C-9, and X and Y to the C-4 methine protons. Saturation of the A resonance produces a 31% increase in the intensity of the X resonance and has no effect on Y. Saturation of the B resonance has no effect on the X and Y resonances, *i. e.* A and X may be assigned to the structure (*a*) [72].

Similar investigations have been carried out on innumerable different structures[73], *e. g.* for alkaloids[74, 75], terpenes[76], steroids[77], and penicillin derivatives[78], and the method is extremely elegant for the solution of difficult stereochemical problems. The NOE has been used for the investigation of the preferred conformation of nucleotides with respect to the N-ribose linkage (the *syn-anti* problem)[79]. It must be noted, however, that great care is necessary in the evaluation of NOE data in systems with mobile conformations, since transfer of spin saturation becomes possible if the time constant of the conformational change is smaller than the relaxation time of the nucleus[80]. In such cases it is necessary to use the temperature dependence of the NOE or transient methods. Negative as well as positive NOE values are sometimes observed. It has been shown[75] that alternating signs are to be expected when dipole-dipole interaction is the dominant relaxation mechanism in a series of neighboring protons.

A	B	C	D
saturated	NOE positive	NOE negative	NOE positive

It would be possible in principle to use the NOE for the measurement of relaxation times, correlation times, and interatomic distances. *Bell* and *Saunders*[81] have described a correlation of a large number of NOE values with the internuclear distances d, and have experimentally confirmed the d^6 dependence required by the theory (Fig. 27). Quantitative relaxation studies using the NOE have been carried out on amides by *Brownstein* and *Bystrov*[82].

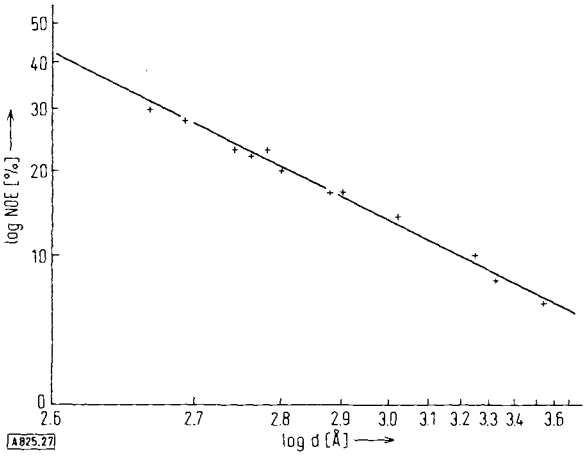

Fig. 27. NOE observed in methyl compounds as a function of the internuclear distance CH_3—H (double logarithmic plot). The straight line has a slope of -6 [81].

Another important application of the Overhauser effect lies in the signal enhancement of low-intensity nuclei. The direct measurement of the ^{13}C carbon resonances is nowadays usually carried out under the conditions of complete decoupling of the carbon nuclei from the protons of the same molecule (noise decoupling; see Section 3.1). Not only is the entire intensity thus concentrated in one line, but this is additionally enhanced by a heteronuclear intramolecular NOE. The factor γ_S/γ_I must be taken into account in eq. (5) for heteronuclear systems, the value of this factor for a $\{^1H\}$-^{13}C system being 3.976. ^{13}C-$\{^1H\}$ noise decoupling thus leads to much greater NOE values than in the homonuclear case. An enhancement of 200% has been observed in the ^{13}C resonance of H—^{13}COOH[83a]. This effect can also be seen in Figure 4, which shows the improvement of the signal/noise ratio in the ^{13}C spectrum of pyridine as a result of the combination of decoupling and the Overhauser effect. Carbon atoms that are not directly bonded to hydrogen atoms give practically no NOE, so that the relative intensities of the ^{13}C resonances often allow the differentiation of tetrasubstituted from monosubstituted, disubstituted, and trisubstituted C atoms. However, the factors that determine the relative intensities of ^{13}C signals are extremely diverse and are the subject of intensive research[83b]. The ^{1}H, ^{13}C spin coupling information is normally lost in noise-decoupled spectra. However, if the perturbing field for the protons is applied for only a short time, one can obtain non-decoupled ^{13}C spectra that are still intensified by the NOE[84]. If the NOE is undesired for quantitative evaluations of ^{13}C spectra it may be eliminated by an addition of paramagnetic compounds[84a].

3.5. Transient Double Resonance Experiments

3.5.1. Double Resonance and Chemical Exchange

The NMR spectra of nuclei that are taking part in a chemical exchange, *e.g.* between the two centers A and B,

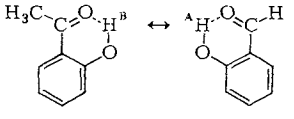
$$\underset{T_{1A},\ T_{2A}}{A} \longleftarrow H \longrightarrow \underset{T_{1B},\ T_{2B}}{B}$$
$$\tau_A \qquad\qquad \tau_B$$

are influenced by this exchange if the average residence times in A and B, τ_A and τ_B, are so short that they become comparable with the transverse relaxation times T_{2A} and and T_{2B}. This is the basis of line shape analysis, which allows the study of kinetic processes by means of high-resolution NMR spectroscopy[6]. Since $T_1 > T_2$ in most cases, the range of application of NMR spectroscopy can be extended toward slower reactions by linking τ_A and τ_B with T_{1A} and T_{1B}. *Hoffman* and *Forsén*[85] have developed a double resonance method for this purpose; the method has been applied to proton exchange reactions. When a proton is transferred between the centers A and B, the effective lifetime of a spin state in a given location (*e.g.* H bonded to A) is determined by the new time constant τ_{1A}:

$$\frac{1}{\tau_{1A}} = \frac{1}{T_{1A}} + \frac{1}{\tau_A} \tag{9}$$

The change in the z magnetization of the proton in A is then given[86] by

$$\frac{dM_z^A}{dt} = \left(\frac{M_0^A}{T_{1A}}\right) - \left(\frac{M_z^A}{\tau_{1A}}\right) + \left(\frac{M_z^B}{\tau_B}\right) \tag{10}$$



Strong additional irradiation of the proton in B causes saturation of its resonance ($M_z^B = 0$), and solution of eq. (10) then gives

$$M_z^A = M_0^A\left(C \cdot e^{-t/\tau_{1A}} + \frac{\tau_{1A}}{T_{1A}}\right) \tag{11}$$

In the steady state ($t = \infty$), the ratio of the magnetization of H in A with and without double resonance is

$$\frac{M_z^A}{M_0^A} = \frac{\tau_{1A}}{T_{1A}} \tag{12}$$

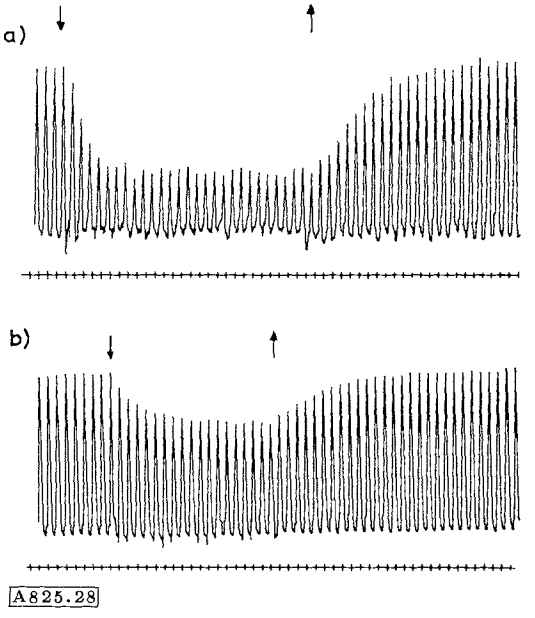
which is the ratio of the signal intensities of HA. $\tau_{1A} < T_{1A}$, *i.e.* τ_A comparable with T_{1A}, then leads to a decrease in the intensity of HA, which means a transfer of saturation from HB to HA by chemical exchange. The time constant τ_{1A} can be obtained by a semilogarithmic plot of $M_Z^A - M_0^A(\tau_{1A}/T_{1A})$

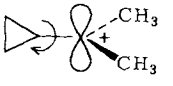
(10) *(9)*

against t after τ_{1A}/T_{1A} has been found from the stationary double resonance experiment (eq. (12)). Combination with eq. (12) and eq. (9) then gives T_{1A} and τ_A. The time constants τ_{1B}, τ_B, and T_{1B} are obtained in a similar manner from a B-{A} experiment.

This method can be used for the quantitative investigation of the intermolecular exchange of the OH protons in a 5.7:1 mixture of salicylaldehyde *(9)* and 2-hydroxyacetophenone *(10)*[85].

Figure 28 shows the exponential decrease and increase in the OH signal intensity of *(9)* when the strong perturbing field for the OH resonance of *(10)* is switched on and off. The evaluation of the decisive time interval (a few seconds) and the measurement of the intensities of HA without the perturbing field H_2 and after the prolonged action of H_2 (stationary case) gave $\tau_A = 11.53$, $\tau_B = 2.17$, $T_{1A} = 5.43$, and $T_{1B} = 3.70$ s. The time constants τ_{1A} and τ_{1B} are 3.75 and 1.33 s respectively.





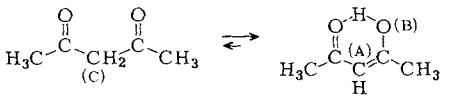


Fig. 28. (a) Decrease and increase in the OH signal intensity of salicylaldehyde *(9)* when the saturation field H_2 for 2-hydroxyacetophenone *(10)* is switched on (↓) and off (↑) in a mixture of the two compounds. (b) Analogous experiment for the OH resonance of *(10)*. The scale interval is one second [92].

Other applications of the relaxation method have now been reported. It was possible in this way to extend the NMR kinetics of the ring inversion in undecadeuteriocyclohexane to the temperature range −97 to −117 °C and τ_A values of 3.8 to 236 s[16c]. The energy barrier for internal rotation in the cyclopropyldimethylcarbonium ion *(11)* has also been determined[87].

(11)

The method can also be extended to exchange processes between three non-equivalent centers. Thus the average residence times of the protons at the oxygen, methylene, and vinyl centers in the keto-enol equilibrium of acetylacetone have been determined in this way[87].

(12a) (12b)

The residence times in this case are again so long ($\tau_A = 14.0$, $\tau_B = 14.2$, $\tau_C = 3.8$ s) that the chemical exchange has no effect on the normal NMR spectrum at room temperature.

The saturation transfer technique can also be used qualitatively to detect the presence of exchange processes. The conformational mobility of [18]-annulene at room temperature was detected in this way, since saturation of the "inner" vinyl protons results in the disappearance of the resonance of the "outer" vinyl protons[88]. The same principle forms the basis of an experiment in which the OH resonance in phenols is detected by irradiation of the water signal and transfer of saturation to the OH protons[89]. The phenomenon can be described in general form in the density-matrix formalism[89a]. In spin systems with scalar coupling, the saturation transferred by chemical exchange is transferred further to adjacent coupled nuclei, *i.e.* a *negative* Overhauser effect (NOE) is observed[88, 90, 91]. This is due to the fact that for scalar coupling, $w_0 > w_2$ in eq. (6), and hence $M_1/M_1^0 < 0$[70].

3.5.2. Transitory Selective Irradiation (TSI)

In the use of the generalized Overhauser effect to deduce the energy-level diagram of a multispin system, the changes in population should preferably be confined to the levels of the irradiated line. Only then do Overhauser effects occur exclusively in "directly connected" lines. In the stationary experiment, the perturbing field H_2 must act for a time T_2^* corresponding to the reciprocal line width of the irradiated transition. The optimum observation time (t) for the intensity changes after H_2 is switched on is

$$T_2^* \ll t \ll T_1$$

where T_1 may be regarded as the shortest reciprocal thermal transition probability T_{pq} (spin-lattice relaxation time). Maximum intensity changes are observed when the perturbing field H_2 traverses the line in an adiabatic fast passage. Such TSI experiments[92] give particularly clear Overhauser effects, since relaxation losses are minimized and population changes occur only in the levels of the perturbed line.

3.5.3. Transient Nutations (Torrey Oscillations)

This double resonance method[65] again allows the construction of the energy-level diagram, *i.e.* the determination of the relative signs of coupling constants. The phenomenological picture is similar to that in INDOR spectra, but the monitor line is also saturated by an intense field H_2. Whenever H_2 meets a line that has an energy level in common with the monitor line, a sudden transfer of population occurs to the common energy level, since the populations of the levels are reversed in the perturbed line[66]. The sudden spin pumping initiates positive or negative "Torrey oscillations" in the monitor resonance, which allow the differentiation of regressive and progressive transitions (Fig. 29)[65]. This technique also allows the detection of weak lines, *e.g.* combination lines, and has been used for the indirect measurement of the ^{13}C resonance[63, 64]. As a transient method, it is less influenced by relaxation effects than normal stationary Overhauser experiments, and gives results similar to those obtained by the TSI technique.

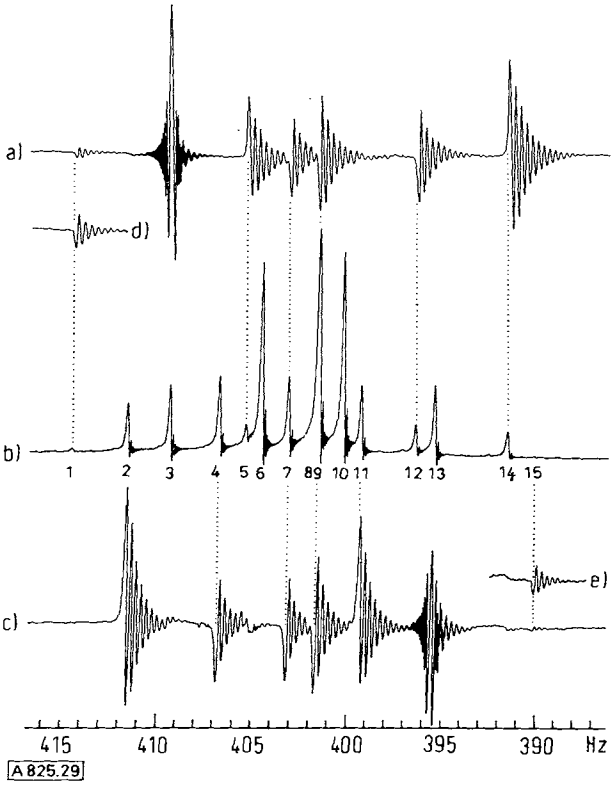

Fig. 29. (b) ^1H spectrum of 2-chlorothiophene (60 MHz) [65]. "Transient nutations" obtained (a) in the monitor line 3 and (c) in the monitor line 13. Signals for which the initial deflection is positive indicate progressive transitions, and negative signals indicate regressive transitions. (d) and (e) illustrate Torrey oscillations that correspond to very weak transitions, and which are obtained by increasing the amplitude of H_2.

3.5.4. Double Resonance and Fourier Transform Spectroscopy

When a nuclear spin system is stimulated by an intense rf pulse of short duration, all the spectral information is contained in a time-dependent signal that describes the decrease in the transverse magnetization. This signal can be converted into the conventional spectrum by Fourier transformation[93]. The technique requires only very short "exposures" of the order of 10—100 μs, and so allows the study of population changes produced by double resonance (Overhauser effects) and their relaxation processes. Since the H_1 pulse need only be applied after the perturbing field H_2 has been switched off, the Overhauser effects can be observed in this way without additional decoupling or tickling effects[94]. The importance of the use of the Fourier transform technique in double resonance experiments will undoubtedly increase in the future. It can be expected that Fourier-transformed ^{13}C-{^1H} pulse spectra in particular

will find a wide field of applications[95]. Besides the ^{13}C chemical shifts, spin-lattice relaxation times (T_1) of the individual carbon atoms also may be determined with this technique[96]. In this way a new parameter for structural studies becomes accessible.

4. Closing Remarks

Nuclear magnetic double resonance has developed during the past few years into a versatile research field. Whereas some of the techniques described here are already in routine use in commercial instruments, others require special instrumental arrangements. With the development of more versatile NMR spectrometers that are not designed only for the measurement of protons, more use will be made of heteronuclear double resonance experiments. This may be expected to lead in particular to rapid advances in carbon resonance, which holds a new dimension for organic chemistry. The broad spectrum of applications of double resonance to structural and spectroscopic problems has been illustrated in this article by a number of examples to provide the reader with a picture of the present situation. New methods and new applications may be foreseen for the future.

I am grateful to Dr. W. Regel, Dr. O. Sciacovelli, Dipl.-Chem. R. Hollenstein, R. Wagner, and K. Hochreutener for their assistance and experimental skill and to Dr. T. Winkler for the critical examination of the manuscript.

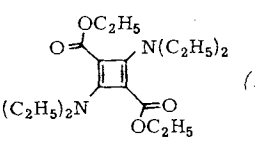
Crystal and Molecular Structure of Diethyl 2,4-Bis(diethylamino)cyclobutadiene-1,3-dicarboxylate[**]



By *Hans Jörg Lindner* and *Brigitte von Gross*[*]

We have carried out an X-ray structure analysis to clarify the molecular structure of diethyl 2,4-bis(diethylamino)-cyclobutadiene-1,3-dicarboxylate *(1)*[1], which should provide further insight into the π-electron system of this compound. For these measurements single crystals were sealed under nitrogen in capillaries[2].

[*] Dr. H.J. Lindner and B. von Gross
Institut für Organische Chemie der Technischen Hochschule
61 Darmstadt, Schlossgartenstrasse 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Crystal data: yellow needles, m.p. 50–52 °C. $M = 338.2$, monoclinic; lattice constants: $a = 17.62$, $b = 13.81$, $c = 9.76$ Å, $\beta = 125.3°$, $U = 1954.2$ Å^3, $Z = 4$, $D_{calc.} = 1.1495$ g/cm^3.

(1)

Space group $P2_1/n$. The intensities of 2715 symmetry-independent reflections from layers 0...14 *kl* were measured with an automatic Weissenberg diffractometer with nickel-filtered Cu-K_α radiation; of these, 986 reflections were so weak that they could not be used for determination of structure.

The phases of 240 reflections with $E > 1.6$ were determined by *Karle* and *Karle*'s symbol addition method[3]. Fourier synthesis calculated with these E values and phases led to a complete structural model which has so far been refined to an R factor of 0.12 by Fourier syntheses and LSQ calculations[4].

The unit cell contains two pairs of symmetry-independent centrosymmetric molecules at two-fold special positions. The mean values of the bond lengths and bond angles of the two molecules are given in Fig. 1. Standard deviations for the bond lengths are 0.015 Å and for the bond angles 1°.

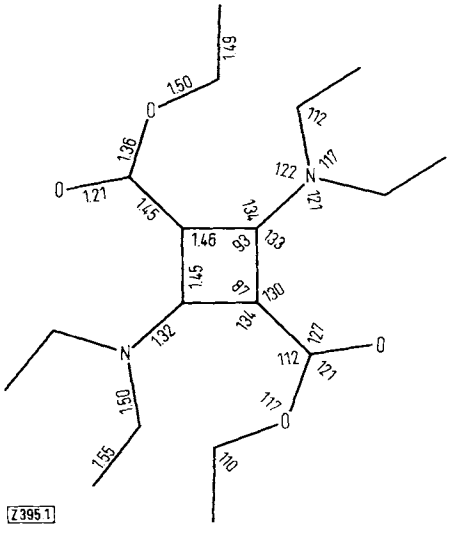


Fig. 1. Bond lengths and bond angles of *(1)*.

The four-membered ring of *(1)* contains, within experimental error, sides of equal length (1.46 Å) and angles of 93° and 87°. The C—N bond lengths indicate a high double-bond character. The C—C bonds between the four-membered ring and the ester groups are shortened.

The four-membered ring is planar within experimental error. Unlike the amino groups, the ester groups are displaced by about 20° from the plane of the four-membered ring.

Dimethyl *N,N*-Dichlorophosphoramidate – A Warning

By *Hans Dieter Block* and *Reinhard Schliebs*[*]

Zwierzak et al.[1] synthesized dialkyl esters of *N,N*-dichlorophosphoramidic acid *(1)* by treating the corresponding dialkyl esters of phosphoramidic acid *(2)* with chlorine in aqueous, acetate-buffered solution.

We found that the diethyl ester of *(1)* is obtained in the form of a stable compound after distilling the reaction

$$(RO)_2P(O)NH_2 + 2\ Cl_2 \longrightarrow (RO)_2P(O)NCl_2 + 2\ HCl$$
(2) *(1)*

$R = CH_3;\ C_2H_5$

mixture and that its preparation does not present any problems, even on a kg scale.

Preparation of compound *(1)*, $R = CH_3$, on a 0.5-mole scale also proceeded in accordance with expectations. When working with 1.5 mole of starting material, on the other hand, a violent detonation took place after the reaction had gone to completion and after the mixture had been stirred for one hour.

The essential difference between the two preparations lay in the longer reaction time required when 1.5 mole of the starting material was reacted (6 hours as compared with 2 hours). It may be assumed that under these conditions either the amide *(2)*, $R = CH_3$, or the *N,N*-dichloroamide *(1)*, $R = CH_3$, undergoes partial hydrolytic cleavage of the P—N-bond, possibly leading to the formation of explosive nitrogen-chlorine compounds.

Zwierzak[2] himself never observed any explosive decomposition of *(1)*, $R = CH_3$; but on the other hand he never carried out any preparations using more than 0.15 mole.

It therefore seems advisable not to use amounts greater than about 0.2 mole when synthesizing *(1)*, $R = CH_3$, to keep the reaction time short and to observe the usual precautions for working with explosive substances.

Homologation of Cyclic Ketones by Isocyanomethyllithium[1]

By *Ulrich Schöllkopf* and *Peter Böhme*[*]

Isocyanomethyllithium *(2)*, which is obtained from methyl isocyanide and butyllithium in tetrahydrofuran[2], provides a method of introducing aminomethyl groups into carbonyl compounds conveniently and in good yields[3,4]. From cycloalkanones one thus obtains 1-(aminomethyl)-1-cycloalkanols which, *inter alia*, are important as starting materials for *Tiffeneau-Demjanov* ring expansion[5]. For example, cyclohexanone *(1)* and *(2)* afford 1-(isocyanomethyl)-1-cyclohexanol (77% yield), which is converted by methanolic hydrogen chloride into the amine hydrochloride *(4)* (>63%). Diazotization with sodium nitrite in aqueous acetic acid then yields the intermediates *(5)* and *(6)* and finally cycloheptanone *(7)*. 1-(Isocyanomethyl) derivatives are obtained from cycloheptanone and cyclododecanone in 95% and 90% yield, respectively, and thence the amine hydrochlorides in about 80% and 67% yields respectively.

[*] Prof. Dr. U. Schöllkopf and P. Böhme
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

This homologation could be more profitable than the route *via* the cyanohydrin[5,6] or the nitromethyl adduct[5,7], because the reaction of the ketone with *(2)* is irreversible

(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)*

and the catalytic hydrogenation is replaced by a simple methanolytic process[8].

Cycloheptanone (7) from cyclohexanone (1):

Butyllithium (0.1 mol; 40.9 ml of a 2.45 N solution in pentane, cooled to −70 °C) is added dropwise to a stirred solution of methyl isocyanide (4.1 g, 0.1 mol) in anhydrous tetrahydrofuran (150 ml) kept under nitrogen at −60 °C. Cyclohexanone *(1)* (0.1 mol, 9.8 g) is added dropwise to this solution at such a rate that the temperature does not rise above −55 °C. After *ca.* 10 min glacial acetic acid (0.1 mol, 6 g) in tetrahydrofuran (10 ml) is dropped in, and the mixture is poured into ice-water (300 ml) and extracted with ether (3 × 100 ml). The ethereal extracts are dried over $MgSO_4$ and freed from solvent at water-pump vacuum (rotary evaporator). There remains the compound *(3)* (10.7 g, 77%) as a yellow oil, b.p. 80 °C/0.1 torr. IR spectrum (film): 2145 cm^{-1} (νNC); 3440 cm^{-1} (νOH).

Crude *(3)* (2 g, 14.4 mmol) is added portionwise (violent reaction!) to a solution of gaseous hydrogen chloride (2 g) in methanol (10 ml), then after 24 h at room temperature precipitation is effected by addition of ether (first *ca.* 50 ml, to provide crystals, and then a further *ca.* 100 ml). This provides in all 63% (1.5 g) of *(4)* as white platelets, m.p. 211 °C. On concentration of the mother liquor a further amount of *(4)* is obtained but this contains traces of *(1)* and is discarded.

The salt *(4)* (1.65 g, 10 mmol) is dissolved in water (15 ml) and glacial acetic acid (3 ml) and treated, under cooling by ice-salt, with a solution of $NaNO_2$ (1.04 g, 15 mmol) in water (5 ml)[7]. The mixture is left for 24 h and then allowed to come to room temperature, neutralized with $NaHCO_3$, and extracted with ether (3 × 70 ml). The extracts are dried over $MgSO_4$ and freed from solvent, affording the product *(7)* (0.8 g, 71.5%). IR spectrum (film): 1699 cm^{-1} (νCO), identical with that of an authentic specimen.

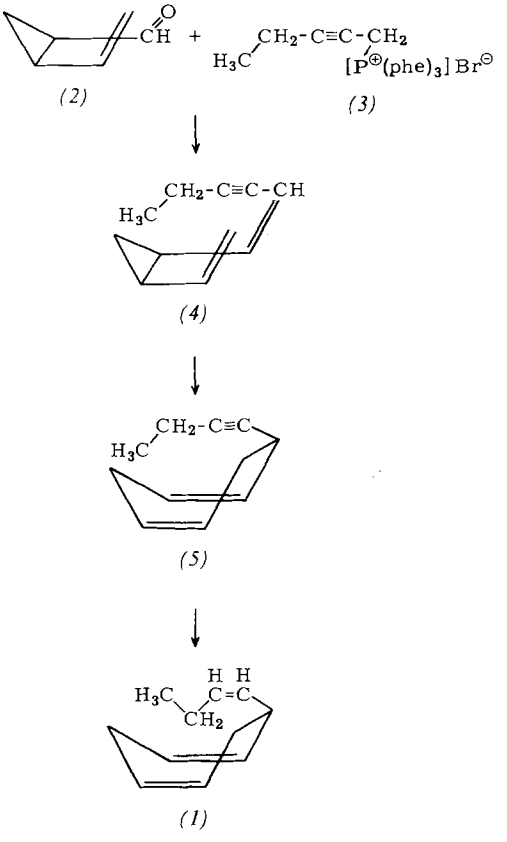
Synthesis of the Sex Attractant of *Ectocarpus siliculosus*[**]

By *Lothar Jaenicke, Timothy Akintobi*, and *Dieter G. Müller*[*]

The sperm attractant (sirenin) of the female gametes of the brown alga *Ectocarpus siliculosus* is a hydrocarbon $C_{11}H_{16}$ having the structure of an all-*cis*-1-(cyclohepta-2',5'-dienyl)but-1-ene *(1)*[1].

It has a center of asymmetry at the branching carbon atom. On account of the very small amounts of substance formed and given off by the sexually receptive female algae for a short time during the state of maturity, the optical rotation could not be determined. Considering its volatility, we ascribe to the compound the spherical (*S*)-structure *(1)*[2].



The compound is closely related to the dictyopterenes recently isolated by *Moore*[3] from the marine alga *Dictyopteris*. These substances are cyclopropane derivatives, $C_{11}H_{16}$, that can be converted into the corresponding cycloheptadienes by the Cope rearrangement, given the appropriate conformation of the *cis-trans*-isomers. In contrast, *Ectocarpus* gives off sirenin directly as the cycloheptadiene: Fractions of sirenin processed very carefully below room temperature do not display UV absorption above 200 nm and show the same NMR spectrum as the gas-chromatographically purified substance[2]. In particular, there is no indication of a cyclopropane structure between τ = 8.8 and 9.7 in the NMR spectrum.

In the meantime we have synthesized the racemate of the all-*cis*-1-(cyclohepta-2,5-dienyl)but-1-ene using the following method; Ethyl *cis,trans*-2-vinylcyclopropanecarboxylate is prepared from diazoacetic ester and butadiene by the method of *Vogel*[4]. Reduction to the carbinol by lithium alanate followed by oxidation with MnO_2 gives the *cis,trans*-2-vinylcyclopropanecarbaldehyde *(2)* which

undergoes a Wittig reaction[5] with the triphenylphosphonium salt *(3)* from 1-bromo-2-pentyne[6] in benzene. The product *(4)* is isolated in 51% yield by vacuum distillation (80—91 °C/9 torr). Gas-chromatographic analysis (10% OV-225-cyano-silicone rubber on Chromosorb W)

(2) *(3)* *(4)* *(5)* *(1)*

shows it to contain the four anticipated isomeric cyclic hydrocarbons $C_{11}H_{14}$. The mixture of isomers is hydrogenated in methanol over a Lindlar catalyst. By preparative gas chromatography (10% Apiezon L on Chromosorb B), the fraction having the same retention time as the *Ectocarpus* sirenin is separated from the mixture of isomers (yield: 30% calculated on the amount of starting material). Its physical properties and odor are identical with those of the natural hydrocarbon *(1)* obtained from *Ectocarpus siliculosus*.

The retention indices of the synthetic cycloheptadienylbutene *(1)* correspond to those of natural sirenin on polar and apolar columns. NMR spectrum: A triplet corresponding to three protons appears at $\tau = 9.05$ ($-CH_3$); a multiplet corresponding to two protons at 8.0 (CH_3-CH_2-); a multiplet at 4.7 corresponding to two protons ($CH_3-CH_2-CH=CH-$); a complex multiplet at 6.55 (one proton) ($-CH=CH-CH(CH-)_2$); a multiplet at 4.45 corresponding to four protons

($-CH=CH-CH_2-CH=CH-$);

a complex multiplet at 7.2 (two protons)

($-(CH=CH)_2CH_2-$);

a multiplet at 7.8 corresponding to two protons

($-CH=CH-CH_2-CH<$).

For the NMR spectrum of the natural product cf.[1].

The structure *(1)* given for the *Ectocarpus* sirenin[1] is thus confirmed by the synthesis[***].

Reversibility of the Bromination of *N*-Alkylanilines[1]

By *Franz Effenberger* and *Peter Menzel*[*]

Except for alkylation, sulfonation, and iodination, electrophilic substitution of aromatic compounds is held to be irreversible[2]. However, isomerization, disproportionation, and dehalogenation have also been observed when brominated aromatic compounds are heated in the presence of Lewis acids[3].

Stabilization of the intermediate σ-complexes which may be influenced by steric and electronic factors is essential for ease of the reverse reaction in electrophilic substitutions[3,4]. Since NR_2 substituents stabilize cationic intermediates particularly effectively[5], isomerization and dehalogenation are most likely to be observed with *N,N*-dialkylhaloanilines.

Upon heating 0.1 M solutions of the hydrobromides *(1)* to *(6)* in $CHCl_3$ at 120 °C in a sealed vessel for 3 hours, the aniline mixtures listed in Table 1 are obtained; even under these rather mild conditions we find large amounts of

(1) *(7)* *(8)* *(9)* *(2)*

isomerization, dehalogenation, and dealkylation products. Though much slower, these reactions take place already at 80 °C; at 60 °C, 160 hours' heating is necessary to effect significant changes.

Isomerization and disproportionation of *p*-bromophenols at room temperature have recently been reported[6]. In

7 Stuttgart, Azenbergstrasse 14–18 (Germany)

view of our results, however, this does not seem to be a true reversal of aromatic substitution by way of σ-complexes; an alternative route *via* tautomeric quinonoid intermediates is rather more likely. The efficiency of substituents in stabilizing a positive charge in the transition state is given by the σ_p^+ values which are −0.92 for OH and −1.70 for $N(CH_3)_2$[7]. Thus, reversibility of electrophilic bromination of phenols should be achieved only under appreciably more vigorous conditions than those required for *N,N*-dialkylanilines.

Our results show the electronic influence of the NR_2 group to be decisive for isomerization and dealkylation. Due to steric hindrance of mesomerism, *ortho*-substituents favor *N*-protonation and thus dealkylation, as shown by the reactions of *(4)* and *(6)*.

Table 1. Mixtures of anilines obtained by heating the anilinium bromides *(1)* to *(6)*.

Hydrobromide of	Products (mol-%) [a] -*N,N*-dimethylaniline		-*N*-methylaniline		-aniline	
2-Bromo-*N,N*-dimethylaniline *(1)*	2-Br	8.2 (4.2) [b]	2-Br	22.9 (16.5) [b]		
	4-Br	35.0 (14)	4-Br	5.8 (8.5)		
	2-H	16.3 (18)	2-H	3.7 (13.0)		
			2,4-Br_2	8.1 (19.5)		
4-Bromo-*N,N*-dimethylaniline *(2)*	4-Br	75.0	4-Br	4.8		
	4-H	13.4				
	2,4-Br_2	2.3	2,4-Br_2	4.5		
2,4-Dibromo-*N,N*-dimethylaniline *(3)*	2,4-Br_2	35.4	2,4-Br_2	50.3		
	4-Br	14.3				
2,6-Dibromo-*N,N*-dimethylaniline *(4)*	2,6-Br_2	30.0	2,6-Br_2	54.3	2,6-Br_2	10.1
			2-Br	5.6		
2,4-Dibromo-*N*-ethyl-*N*-methylaniline *(5)*			2,4-Br_2	6.6	2,4-Br_2-*N*-Et-*N*-Me	33
					4-Br-*N*-Et-*N*-Me	20
					2,4-Br_2-*N*-Et	30
					aniline	8
2,6,*N,N*-Tetramethylaniline *(6)*	2,6-Me_2	75.6	2,6-Me_2	24.4		

[a] The bases were liberated by passing in NH_3; the product composition was determined by gas chromatography, the individual compounds being identified by comparison of the retention times with those of pure substances. *W. Blum* has confirmed the assignments by a GC-MS combination Finnigan system DA-150.

[b] Product compositions in parentheses are those obtained after heating for 160 hours at 120 °C.

We assume the anilines obtained to be formed *via* cationic intermediates *(7)–(9)*, as formulated for reaction of *(1)* in the above scheme. In an S_N2 reaction cation *(7)* is dealkylated by the $Br^{\ominus}$. *C*-Protonation of *(1)* affording *(8)* is followed by dehalogenation to dimethylaniline which then gives the isomerization product *(2) via (9)*. Incorporation of labeled $^*Br$ in the course of the reaction of *N,N*-dimethyl-*p*-bromoaniline·H*Br is proof that *(2)* may be dehalogenated again by way of *(9)*, and that free Br_2 must occur during the overall reaction. The large proportion of starting material recovered when *(2)* is heated must be ascribed to preferential rebromination of dimethylaniline at the *para*-position. Longer reaction times favor dealkylation, as shown by the product composition after 160 hours' heating of *(1)* at 120 °C. These also are not equilibrium concentrations, though, since irreversible oxidations (discoloration) become more and more pronounced with longer reaction times.

Since CH_3 rather than C_2H_5 is lost preferentially from *(5)*, the dealkylation is indicated to be of S_N2 type. If HBr is replaced by acids with less nucleophilic anions, the share of isomerization and dealkylation products decreases; *N,N*-dialkylbromoanilinium perchlorates remain practically unchanged under our experimental conditions.

Optically Active Selenoxomethylphenylpropylphosphoranes and Their Transformations

By *W. Stec, A. Okruszek*, and *Jan Michalski*[*]

We have found that the previously unreported[1] optically active selenoxotriarylalkyl(triaryl-)phosphanes can be readily obtained by addition of elemental selenium to optically active tertiary phosphanes. Since the stereochemistry of the addition of selenium to phosphanes was obscure, some additional studies on the transformation of optically active selenoxotriarylalkyl(triaryl-)phosphanes were considered necessary. Correlation of known absolute configurations of phosphanes[2] and oxophosphoranes[2] with those of selenoxophosphoranes was therefore undertaken. Optically active selenoxophosphoranes can be readily converted into the corresponding oxophosphoranes by two stereoselective routes, as well as reduced stereoselectively to the parent phosphanes (Scheme 1).

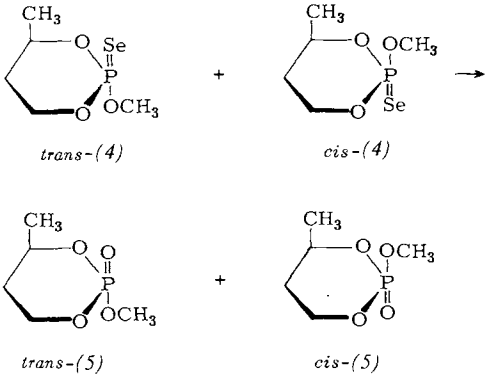
Żwirki 36, Łódź 40 (Poland)

Treatment of (+)-(*S*)-methylphenylpropylphosphane *(1)*[3], $[\alpha]_{578}^{20} = +17.3°$ (toluene) with stoichiometric amounts of elemental selenium in benzene gave (+)-(*R*)-selenoxomethylphenylpropylphosphane *(2)*[4], $[\alpha]_{578}^{20} = +16.9°$[5], m. p.

Scheme 1



60–75 °C, while addition of selenium to (−)-(*R*)-*(1)*, $[\alpha]_{578}^{20} = -9.0°$ (toluene), produced (−)-(*S*)-*(2)*, $[\alpha]_{578}^{20} = -8.8°$, m. p. 55–75 °C. Multiple fractional crystallization of compounds *(2)* from cyclohexane improved their optical purity. Both enantiomers of *(2)* have m. p. 75–76 °C and $[\alpha]_{578}^{20}$ (+ or −) 20.2°.

The compound (+)-(*R*)-*(2)*, $[\alpha]_{578}^{20} = +19.7°$, is readily reduced by $LiAlH_4$ in boiling THF to (+)-(*S*)-*(1)*, $[\alpha]_{578}^{20} = +17.8°$ (toluene). The same reduction of (−)-(*S*)-*(2)*, $[\alpha]_{578}^{20} = -20.2°$, gave (−)-(*R*)-*(1)*, $[\alpha]_{578}^{20} = -18.65°$ (toluene). The yields of both reactions were over 80%. An attempt to reduce the selenoxophosphoranes *(2)* with other reducing agents such as Raney-Ni or $SiHCl_3/(C_2H_5)_3N$ were partially successful only in the former case[6].

Oxidation of the optically active selenoxophosphoranes *(2)* with nitric acid[8] and with potassium permanganate in aqueous pyridine[7] proceeds *via* stereochemically different courses. When (−)-(*S*)-*(2)*, $[\alpha]_{578}^{20} = -11.3°$, was treated with $KMnO_4$ in pyridine/water (2:1) v/v), (−)-(*S*)-oxomethylphenylpropylphosphorane *(3)*, $[\alpha]_{578}^{20} = -9.7°$, was formed. The same enantiomer *(2)*, $[\alpha]_{578}^{20} = -20.2°$, oxidized with HNO_3 gave (+)-(*R*)-*(3)*, $[\alpha]_{578}^{20} = +17.9°$. Treatment of (+)-(*R*)-*(2)*, $[\alpha]_{578}^{20} = +20.2°$, with HNO_3 produced (−)-(*S*)-*(3)*, $[\alpha]_{578}^{20} = -17.9°$. Oxidation with N_2O_4 followed a similar stereochemical course to that with HNO_3. Thus, from (+)-(*R*)-*(2)*, $[\alpha]_{578}^{20} = +20.2°$ the oxophosphorane (−)-(*S*)-*(3)*, $[\alpha]_{578}^{20} = -3.2°$ was isolated after treatment with a 10% solution of N_2O_4 in CH_2Cl_2. (−)-(*S*)-*(2)*, $[\alpha]_{578}^{20} = -20.2°$, gave (+)-(*R*)-*(2)*, $[\alpha]_{578}^{20} = +5.6°$. The considerable racemization is undoubtedly caused by action of N_2O_4 on the resulting oxide *(3)*[8].

Since the stereochemistry of the oxidation of phosphane *(1)* with HNO_3[8] and with H_2O_2[2] is well established we conclude from our experiments that addition of selenium to optically active tertiary phosphanes proceeds with retention of configuration. The absolute configuration *R* has been therefore assigned for dextrorotatory selenoxophosphorane *(2)*. A retention mechanism is also proposed for reduction of the selenoxophosphorane *(2)* to parent phosphane as well as for its oxidation with $KMnO_4$ in pyridine/water solution to the corresponding oxophosphorane, while oxidation of *(2)* with HNO_3 or N_2O_4 proceeds *via* inversion.

Close analogy of the stereochemical transformations is observed in the case of the corresponding thioxophosphoranes, except for the oxidation with N_2O_4. Since only little is known about the mechanism of oxidation of phosphanes and the thioxo- and selenoxophosphoranes with the oxidizing agents mentioned above, interpretation of this observation is difficult.

Scheme 2.

In contrast to the oxidation of acyclic selenoxophosphoranes *(2)* described above oxidation of diastereomeric 2-methoxy-4-methyl-4*H*-5,6-dihydro-1,3,2-dioxaphosphorin 2-selenides *(4)* to the oxides *(5)*[9] is highly stereoselective; an epimerization was not observed[10].

[1] A racemic asymmetric selenoxotriarylphosphorane containing an amino group has been prepared by *W. C. Davies* and *F. G. Mann*, J. Chem. Soc. *1944*, 274.

[2] *L. Horner*, Pure Appl. Chem. *9*, 225 (1964).

[3] Optically active phosphanes *(1)* were prepared by alkaline hydrolysis of diastereoisomeric benzylmethylphenylpropylphosphonium dibenzoyltartrates (*K. F. Kumli, W. E. McEwen*, and *C. A. Vander Werf*, J. Amer. Chem. Soc. *81*, 248, 3805 (1959)) followed by reduction of the oxophosphoranes *(3)* with $SiHCl_3/(C_2H_5)_3N$ (*L. Horner* and *W. D. Balzer*, Tetrahedron Lett. *1965*, 1157).

[4] Both selenoxophosphoranes *(2)* gave the correct elemental analysis and NMR spectra and their purity was checked by thin-layer chromatography.

[5] Rotations refer to solvent methanol unless otherwise stated.

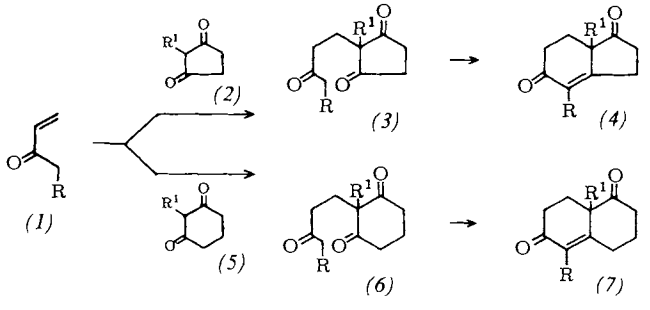
[6] The reduction of racemic *(2)* with 5-fold excess of Ni-Raney in boiling ethanol for 7 hours yielded only 27% of *(1)*.

[7] Retention of configuration during oxidation of methylphenylpropylthioxophosphorane with $KMnO_4$ in pyridine has been described by *L. Horner* [2].

[8] The procedure for oxidation with HNO_3 and N_2O_4 was identical to that described for transformation of the corresponding optically active thioxophosphoranes (*J. Michalski, A. Okruszek*, and *W. Stec*, Chem. Comm. *1970*, 1495).

[9] *W. Stec, A. Okruszek*, and *M. Mikołajczyk*, Z. Naturforsch., in press.

[10] *(4)* was prepared by addition of elemental selenium to 2-methoxy-4-methyl-4*H*-5,6-dihydro-1,3,2-dioxaphosphorin; *cis-(4)*: b. p. 85—87 °C/0.2 torr, NMR ($CDCl_3$): $\delta(OCH_3) = 3.8$ ppm, $J_{POCH} = 14.4$ Hz; *trans-(4)*: b. p. 100—102 °C/0.2 torr, NMR ($CDCl_3$): $\delta(OCH_3) = 3.7$ ppm, $J_{POCH} = 14.4$ Hz. The ratio of the diastereomeric dioxaphosphorins *(4)* and *(5)* (±5%) was determined by gas-liquid chromatography.



New Type of Asymmetric Cyclization to Optically Active Steroid CD Partial Structures[**]

By *Ulrich Eder*, *Gerhard Sauer*, and *Rudolf Wiechert*[*]

Synthesis of optically active 7a-alkyl-5,6,7,7a-tetrahydro-1,5-indandiones *(4)* and 8a-alkyl-1,2,3,4,6,7,8,8a-octahydro-1,6-naphthalenediones *(7)*, which are important CD starting materials for total synthesis of steroids[1-5], has hitherto been effected from the racemic bicyclics *(4)* and *(7)*, respectively, by microbiological transformation of one antipode[7] or by conventional resolution of the racemate[2,4]. Both methods give at best 50% yields based on the amounts of starting material.

Compounds *(3)* and *(6)* each contain a prochiral center which should be utilizable in an economical process for preparation of the chiral bicyclics *(4)* and *(7)*.

In the synthesis of compounds *(3)* and *(6)* by Michael addition of the vinyl ketones *(1)* to the cyclic 1,3-diketones *(2)* and *(5)* the yield and purity of the products could be

appreciably increased by working in an aqueous medium without a basic catalyst.

Table 1. Compounds synthesized.

however, variable over a wide range (1:0.1 to 1:2) and its effect is mainly on the reaction time[6].

Experimental:

A solution of 2-methyl-2-(3'-oxobutyl)-1,3-cyclopentanedione *(3a)* (10 g) in acetonitrile (150 ml) was treated with L-proline (3 g) and 1 N $HClO_4$ (15 ml) and refluxed for 22 h. The mixture was then cooled and diluted with saturated sodium chloride solution. The crude product was distilled off in a high vacuum. Yield 7.81 g of *(4a)*, b.p. 97—100 °C/0.01 torr. $[\alpha]_D^{RT} = +303°$ (1% in C_6H_6). Optically pure *(4a)*, m.p. 65—66.5 °C, $[\alpha]_D^{RT} = +362°$ (1% in C_6H_6)[2, 7] (5.9 g), was obtained by crystallization.

Calculation of the Intermediates and Transition State in Electrophilic Aromatic Substitution[1]

By *Werner Jakubetz* and *Peter Schuster*[*]

Dedicated to Prof. M. Pailer on the occasion of his 60th birthday

The cation $[C_6H_7]^+$ has long been postulated as intermediate in electrophilic hydrogen exchange of benzene and constitutes the simplest transition state in the course of electrophilic aromatic substitutions[2]. It was recently detected in solution by use of $[SbF_6]^-$ as counter-ion[3].

(except the CH distances for the protons not concerned in the exchange) and the most important angles were optimized for the energy minimum and the transition state.

The energy minimum corresponds to a Dewar-type π-complex[6]. The seventh proton is out of the plane of the ring and exactly above the center of a C—C bond. The other bond lengths in the ring alternate; the whole cation is folded along an axis through C-3 and C-6, with a dihedral angle $\alpha = 178.6°$. The excess proton has the lowest electron density ($q_H = +0.27$). It is interesting that the bridge protons in B_2H_6 carry a similar charge ($q_H = +0.20$). The rest of the charge on the cation is distributed almost uniformly over all the other atoms. CNDO/2 minimum geometry and charge distributions are shown in Figure 1.

From our calculations it follows that the saddle point of the energy surface and thus the transition state of the substitution reaction is identical with the optimized σ-complex. The bond lengths accord with expectation. The positive charge is distributed over the seven H atoms and the C atoms 2, 4, and 6 in alternating manner typical of charged π-electron systems.

As the CNDO calculation shows, transition of the π-complex into the σ-complex requires an energy of ~20 kcal/mol. If a π-complex were converted into an equivalent one without proton exchange occurring, an energy of only ~15 kcal/mol would need to be provided. Such energy differences, however, carry systematic errors, but are nevertheless very useful as relative values[1, 5]. For π-complexes and related structures the numerical values are always too large, so we expect that the six equivalent

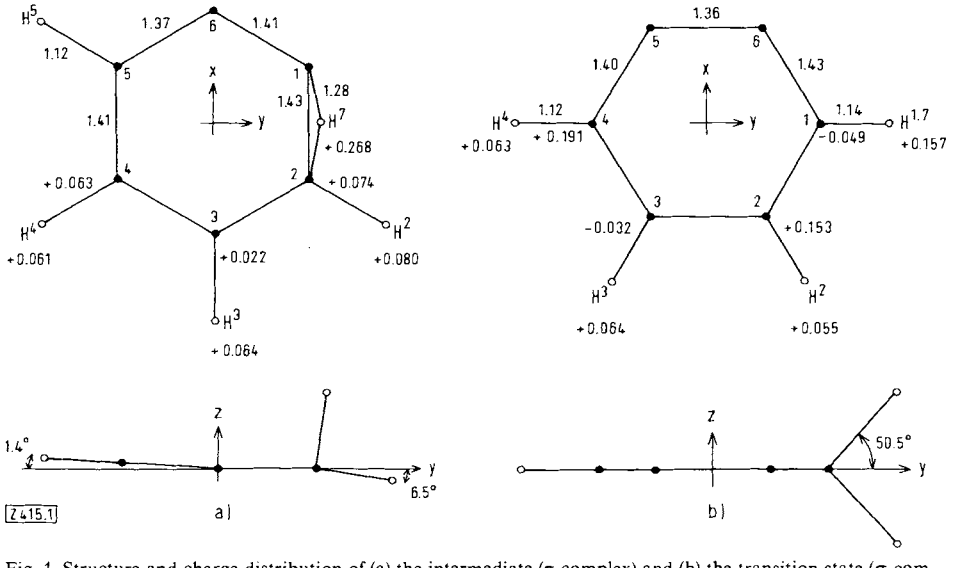

Fig. 1. Structure and charge distribution of (a) the intermediate (π-complex) and (b) the transition state (σ-complex) in the reaction $C_6H_6 + H^+$ (bond lengths in Å; all C—H separations in the ring plane are assumed as 1.12 Å, as in the CNDO energy minimum of benzene).

For comparison: C_6H_6: $R_{CC} = 1.38$; $R_{CH} = 1.12$ Å; $q_C = +0.011$, $q_H = -0.011$. — B_2H_6: $R_{BB} = 1.60$, R_{BH}(bridge) $= 1.33$, R_{BH}(ext.) $= 1.16$ Å; $q_B = -0.065$, q_H(bridge) $= +0.196$, q_H(ext.) $= -0.065$.

For study of this intermediate the energy surface for interaction of benzene and H^+ has been calculated point by point. We selected the semi-empirical method of *Pople et al.*[4]—CNDO/2—as we obtained good results with this method of calculation for description of hydrogen bridges[5] and weak π-complexes[1]. All the bond lengths

π-complexes would rapidly rearrange at room temperature.

To provide more information about the bonding of the seventh proton in the complex $[C_6H_7]^+$ the canonical SCF molecular orbitals were localized by *Boys'* method[7]. Together with the two nearest C atoms this proton forms a three-center bond which takes up two electrons and is surprisingly similar to the "hydride bridges" in diborane, B_2H_6 (Table). For the case of B_2H_6 it is possible to compare

Institut für Theoretische Chemie der Universität
A-1090 Wien, Währingerstrasse 38 (Austria)

the CNDO/2 and *ab-initio* calculations[8], which show the reliability of the approximation chosen.

In the ^{1}H-NMR spectrum of the cation $[C_6H_7]^+$ *Olah et al.*[3] found at room temperature one single signal which was split at lower temperatures. These authors

Localized proportion (%)		96.7	99.7	

[a] The linear combination coefficients of CNDO calculations refer to orthogonalized (Löwdin) atomic orbitals and thus their absolute values in bonding molecular orbitals are greater than the corresponding coefficients in *ab-initio* calculations which refer to ordinary non-orthogonal atomic orbitals.

assigned the structure of a σ-complex to the solvated cation. According to our calculations the π-complex should be more stable in the gas phase. This need not contradict our results since π- and σ-complexes can differ considerably in their solvation energies and in their interaction with the counter-ion.

Recently *Helgstrand*[9] reported CNDO/2 calculations on the σ-complex of $[C_6H_7]^+$. This author's results agree well with ours, especially as regards bond angles and CH distances.

An Optically Active Phospholene Oxide

By *G. Ostrogovich* and *F. Kerek*[*]

We have been able to prepare the levorotatory form of 3-methyl-1-(*p*-diethylaminophenyl)-2-phospholene 1-oxide *(1)* *via* its salt with (+)-9-camphorsulfonic acid. To the best of our knowledge this is the first resolution of a chiralic phosphacyclic compound[1].

Methylene chloride solutions of *(1)*[2, 3] (16.5 mmol in 10 ml) and (+)-9-camphorsulfonic acid (previously dried in vacuum over P_2O_5; 16.2 mmol in 160 ml) were thoroughly

(1)

mixed and the solvent subsequently removed in vacuum. The residual syrup was dissolved in 75 ml boiling benzene and the hot solution rendered slightly turbid by addition of 3–4 ml *n*-heptane. By very slow and careful cooling, approximately 4.1 g of the camphorsulfonate of *(1)* could be obtained.

After double recrystallization from benzene with a little *n*-heptane the specific rotation and melting point were constant ($[\alpha]_D^{20} = -40.3°$ (benzene); m.p. 103–104 °C). The difference between the UV spectrum (in cyclohexane) of compound *(1)* ($\lambda_{max} = 277$ nm; $\log \varepsilon = 4.45$) and that of the salt ($\lambda_{max} = 281$ nm; $\log \varepsilon = 3.03$) shows that an ammonium (and no phosphonium) salt is present.

The (−)-enantiomer of *(1)* recovered by treatment with dilute KOH was extracted with $CHCl_3$ and, after removal of solvent, recrystallized twice from *n*-heptane ($[\alpha]_D^{20} = 69.4°$ (0.6 mol/l in benzene). The ORD curve is given in Figure 1.

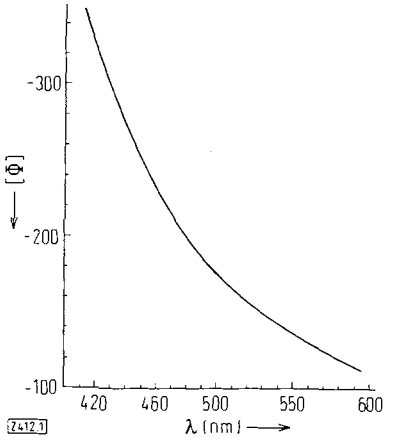

Fig. 1. ORD spectrum of (−)-3-methyl-1-(*p*-diethylaminophenyl)-2-phospholene 1-oxide, (−)-*(1)*, in anhydrous ethanol [7].

The similarity in constitution of (−)-*(1)* and racemic *(1)* was established from the IR, UV[5, 6], and NMR[4, 6] [$\tau = 5.88$ ppm (vinyl H), $J_{PH} = 25$ Hz] spectra and by elemental analysis[2].

Crystalline π-Radicals Containing Germanium[**]

By *Hartmut B. Stegmann, Klaus Scheffler,* and *Fritz Stöcker*[*]

No success has previously attended attempts to prepare paramagnetic organogermanium compounds by, in particular, dissociation of hexaaryldigermanes[1]. Hyperfine structure that could be ascribed to magnetic coupling of a free electron with ^{73}Ge has never been found in ESR studies of radical anions containing germanium[2] or of Ge-substituted alkyl radicals[3-5]. We have, however, now isolated paramagnetic compounds containing germanium as products of the reaction of 2-amino-4,6-di-*tert*-butylphenoxyl *(1)* with diarylgermanium dihalides. Structure *(4)* is indicated by elemental analysis[6], mass spectra, and chemical behavior.

The new compounds can also be prepared from the corresponding tin[7] and lead compounds[8] when these are treated with diarylgermanium halides.

(4a), R = C_6H_5, m. p. 196 °C; *(4b)*, R = p-$CH_3C_6H_4$, m. p. 241 °C

The radicals *(2)* to *(4)* are stable, so that they can be isolated without special procedures. The diamagnetic N—H heterocycles are formed on reduction by H_2/Pt and are at once oxidized by atmospheric oxygen back to the radicals. Concentrated mineral acids degrade the radicals. Elimination of the organometallic group affords the phenoxazinyl radical *(5)*[9] without loss of the paramagnetism being observed.

The radicals *(4a)* and *(4b)* in ethanol or benzene afford first a 15-line ESR signal. This hyperfine structure (HFS) (Fig. 1) can be interpreted as due to magnetic coupling of the free electron with two pairs of protons and the ^{14}N nucleus.

HFS components that could be ascribed to Ge coupling are to be expected only at increased sensitivity. In the natural isotope mixture there is only one magnetic nucleus, ^{73}Ge, in 7.6% amount. This isotope has nuclear spin $I = 9/2$, so that the ten Ge-HFS components can be observed with very weak intensity only at the edges of the spectra and, further, are split by the protons and nitrogen present in the molecule. Actually, with 390-fold increase in spectrometer sensitivity, further HFS components that we

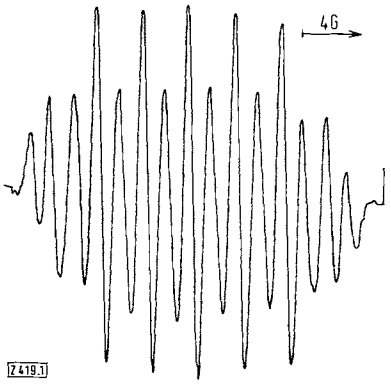

Fig. 1. ESR spectrum of *(4a)* in benzene at room temperature.

ascribe to the ^{73}Ge can be found both on the low-field and on the high-field side of the main spectrum (Fig. 2).

Since the magnetic coupling with the ^{73}Ge is relatively small, each of the two lines furthest from the center are single and correspond to the terms $m_{^{73}Ge} = +9/2$ and

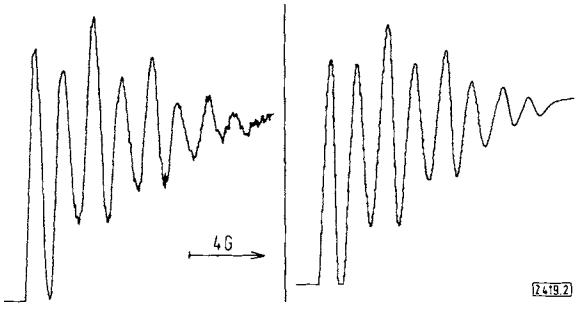

Fig. 2. Left: high-field side of the ^{73}Ge isotope spectrum of *(4a)* in benzene at room temperature. Right: simulated high-field isotope spectrum.

$-9/2$. The remainder of the isotope spectrum is degraded. The HFS found is in very good agreement with these considerations, as the simulation[10] (Fig. 2) of the spectrum shows.

In accord with the other findings, the ESR spectrum shows the new organogermanium derivatives to be 11,11-disubstituted 1,3,7,9-tetra-*tert*-butyldibenzo[*d*,*g*][1,3,6,2]dioxagermanocin-5-yls. The coupling parameters are

ascribed by us principally by analogy with the corresponding tin compounds[7] (Table 1).

As expected, the substituent R has only slight influence on the coupling constants. The large line widths (*ca.* 700 mG) may be ascribed to the unresolved proton HFS of the

Table 1. ESR data for the radicals *(4)* (gauss), measured in benzene at room temperature; ΔH = line width.

	$a_{H_{4,6}}$	$a_{H_{2,8}}$	a_N	$a_{^{13}C}$	g	ΔH

Homolysis of the Ethane C—C Bond: Detection of Tris(phenylthio)methyl by ^{13}C-Labeling[**]

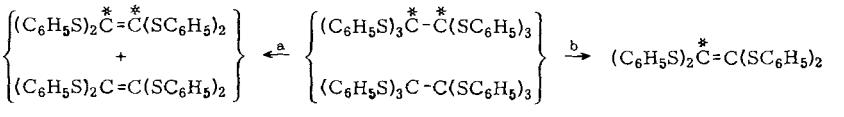
By *Dieter Seebach, Hartmut B. Stegmann,* and *Albert K. Beck*[*]

Since the beginning of the century hexaphenylethane *(1)* has been held to be the simplest ethane whose C—C bond dissociates already at room temperature. However, it was shown recently[1] that the trityl radical *(2)*[2] really dimerizes to *(3)*[3]. We have reported[4] that the persubstituted ethane *(4)* at slightly above 100 °C affords a radical that is readily detected by ESR spectroscopy; we have assigned the spectrum, which shows no hyperfine structure, to the methyl *(5)* mainly on the basis of chemical findings: four

(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)*

of the five products isolated in >95% yield after pyrolysis of *(4)* are derived from the "half molecule"[5]; the fifth is the ethylene *(6)* which could arise directly from the ethane *via (7)*.

By using the ethane labeled by ^{13}C on the central atoms we can now answer the following questions:



1) Do we really observe the ESR spectrum of the methyl *(5)*?

2) If so, is the ready dissociation of the ethane *(4)* caused by stabilization of the methyl formed owing to delocalization of the unpaired electron over the three S atoms?

3) Is the ethylene *(6)* also formed *after* dissociation of the ethane?

On catalysis by HCl (14 days' stirring at 20 °C), formic acid (60% labeled by ^{13}C; 0.50 g, 10.8 mmol) and thiophenol (3.30 ml, 33.0 mmol) gave[6] a 72% yield of labeled tris(phenylthio)methane; the NMR spectrum of its methine H is shown in Fig. 1a: $J_{^{13}C-H} = 168$ Hz, 60% of ^{13}C and 40% of ^{12}C molecules. When heated with xylene, samples of the labeled ethane *(4)* prepared from the methane[7] gave the ESR spectrum shown in Fig. 1b[8]. The relative intensities of the three lines (3:4:3) correspond to a methyl radical with 60% content of ^{13}C. The coupling constant $a_{^{13}C} = 43.69$ gauss is large[9] and so indicates that the lone electron is only slightly delocalized over the three S atoms of the tris(phenylthio)methyl. Since the appropriate π-σ-parameters are unknown it is not yet possible to determine the spin density distribution exactly[10]. The spectrum cannot be brought into accord with the paramagnetic molecule *(7)*, as is shown by a glance at the spectrum simulated[11] for this ethyl radical (Fig. 1c).

The question of how *(6)* is formed was solved by the following scrambling experiment:

unscrambled mixture — scrambled product

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

If the ethylene is formed without previous dissociation of the ethane (route a), pyrolysis of a mixture of labeled and unlabeled ethane will give ethylene of isotope composition different from that obtained after a preceding dissociation (route b). The figures given in Table 1 show that complete

Table 1. ^{13}C isotope distribution, determined by mass spectroscopy and calculated, of the ethylene *(6)* formed on pyrolysis of a 1:1 mixture of labeled (60%) and unlabeled *(4)* (10 hours' refluxing in pyridine under argon).

No of ^{13}C atoms in *(6)*	Percentage distribution of masses 460, 461, 462 calculated without scrambling	calculated with scrambling	found

1	24.0	42.0	39.1
2	18.0	9.0	8.4

scrambling takes place. We proved in a separate experiment that no crossing between labeled and unlabeled ethylene *(6)* occurs at 250°C, and thus formation of the ethylene molecule must be preceded by homolysis of the ethane bond.

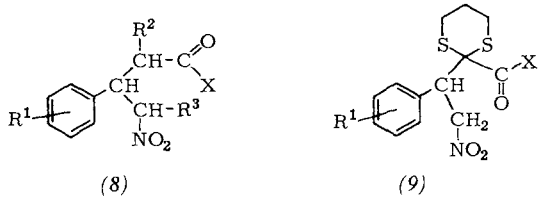
[**] We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

The amine does not interfere in many of the reactions of *(1)*, the use of which for elaboration of indole alkaloids is reported here.

The hallucinogens bufotenine *(2)* and psilocine and its derivatives *(3)*, which are of interest as psychomimetic drugs[4] in psychiatry, can be synthesized from the precursors *(4)* (by oxidative ring closure[5]) and *(5)* (by aryne ring closure[6, 7a]) respectively; however, preparation of *(4)* and *(5)* is cumbersome[5, 6, 7b], and other methods (*Fischer-Bischler*, *Reissert*, and *Speeter-Anthony*) of preparing *(2)* and especially *(3)* and similar tryptamines require many steps[4–6, 7b].



We have found that one arrives at the skeleton of compounds *(4)* and *(5)* by the following route: Addition of *(1)* to nitrostyrenes *(7)*[8] affords[3, 9] almost quantitative yields (Table 1) of the nitro amides *(6)*, whose reduction by lithium tetrahydridoaluminate leads directly to the 2-aryl-1,4-butanediamines (Table 1). The structures of the adducts *(6)* and the amines obtained from them are proved by elemental analyses and spectroscopic properties.

The synthesis is variable: Not only may the benzene ring contain different types of sensitive substituents ($OCH_2C_6H_5$, Cl, Br) (Table 1), but also the dimethylacetamide may be replaced by diethylacetamide [→*(8a)*], dimethylpropionamide [→*(8b)*], 1,3-dithiane-2-carboxamide [→*(9)*], or ethyl acetate [→*(8c)*], and the nitrostyrenes *(7)* by nitrophenylpropenes [→*(8d)*] (Table 2).

Table 2. Physical properties and yields of compounds *(8)* and *(9)*.

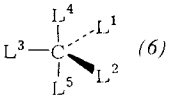
A Reexamination of the Limiting Mechanisms of Aliphatic Nucleophilic Substitution

By *Paul D. Gillespie* and *Ivar Ugi*[*]

The limiting mechanisms concerning aliphatic nucleophilic substitution reactions introduced by *Ingold* and co-workers have been a part of the basic textbook knowledge of organic chemists for three decades[1]. These ideas have served the chemist well as a model for mechanistic thought and have provided reliable interpretations of and predictions for many reactions. Doubt no longer exists concerning the intermediacy of carbonium ions with tricoordinate carbon[2] in an S_N1 elimination addition mechanism. However, the questioning has never ceased regarding the nature of the pentacoordinate carbon species *(3a)* involved during the limiting S_N2 and S_Ni process[3-10].



(1) *(2)* *(3a)* *(4a)* *(5)*

Scheme 1. N = nucleophile, L = ligand.

Experimental evidence supporting the presently accepted S_N2 concept is primarily kinetic and stereochemical in nature[1,5,6,11]. Second order kinetics have established that both reacting species *(1)* and *(2)* participate in formation of the transition state for the rate-determining step and the well-known stereochemistry of Walden inversion have contributed to the supposition that the trigonal-bipyramidal carbon species *(3)* with apical entering and leaving groups is a transition state in the reaction (Scheme 1)[11,12].

The assumption that *(3a)* must be a transition state and not an intermediate was due to the natural aversion to presume any stability in a pentacoordinate carbon compound[1,11]. However, some authors have pointed out that intermediates corresponding to a well in the potential energy surface might be formed in the course of S_N2 reactions[2b,4-6]. Recently, several examples of relatively stable pentacoordinate carbon compounds, $CH_5^{\oplus}$[2], $CCl_5^{\ominus}$[13], and $CBr_5^{\ominus}$[14], as well as theoretical work yielding stability estimates for the model systems $CH_5^{\ominus}$[7-10] and $CH_3F_2^{\ominus}$[9] have appeared in the literature. The latter information combined with recent experimental and theoretical investigations on pentacoordinate molecules[15a,b] and their role during chemical reactions[15c] stimulated us to reexamine the mechanistic concepts upon which the interpretation of nucleophilic substitution on saturated carbon is based.

(6)

Table 1 contains binding energy (BE) data, obtained by the use of the CNDO/2[17] approximation, for pentacoordinate carbon compounds *(6)* with a trigonal-bipyramidal skeletal structure. The various isomers, not treated in prior calculations[9], are included for each compound.

Table 1. Equilibrium geometry binding energies (BE) of Walden species and their permutation isomers [16].

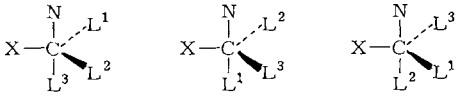
The BE of *(6a)* as a function of the C—F bond distance shows that any small displacement of the F ligands from their equilibrium position (similarly for the H ligands) leads to an increase in the energy of the "Walden species" [see *($6a_1$)—($6a_4$)], *i.e.*, it can be stated that *(6a)*

[*] P. Gillespie, M.A., and Prof. Dr. I. Ugi
Department of Chemistry
University of Southern California
Los Angeles, Calif. 90007 (USA)

corresponds to a local minimum in the potential surface and, by definition, is an *intermediate*, not a transition state. This holds for the other model species *(6b)*—*(6k)* of Table 1 as well. Approximations contained in the CNDO/2 method and the neglect of zero point energies are not critical for establishing the intermediate nature of these species and presumably for the qualitative comparison between the BE for the permutation isomers in Table 1. *Berthier, David,* and *Veillard*[9a] found that the potential energy of the "Walden species" *(6a)* is lower than that of $CH_3F+F^{\ominus}$, which may be due to neglected differences in zero point energies[17] of *(6a)* and the latter. These differences become important when either the number or type of bonds or ligands change.

BE comparison between isomers *(6a)*—*(6c)*, *(6d)*—*(6g)*, and *(6h)*—*(6k)* indicate that the polarity rule[15c] does not seem to hold for pentacoordinate carbon compounds; in fact the opposite seems to be true[*]. This phenomenon may be due, in part, to the fact that the ligands are required to carry more electron density than they would in some neutral species, combined with the fact that the hydrogens carry the majority of the excess charge since fluorine already enters with a negative charge. Further, lack of d orbitals in the basis set eliminates a pathway for electron density to be passed back to the carbon atom in these model calculations. This results in the highly negatively charged hydrogen atoms seeking apical sites in an effort to avoid each other. Such relative stabilities of the permutation isomers of the trigonal-bipyramidal system, though, do not cause difficulties for understanding the steric course of the S_N2 and S_Ni reactions (see below).

There are two types of limiting bimolecular mechanisms, S_N2 and S_Ni, for S_N processes at a saturated C-atom which proceed *via* a pentacoordinate intermediate *(6)* with a trigonal-bipyramidal molecular skeleton as addition-elimination processes accompanied by a change in coordination number of carbon: 4→5→4. For both of these types of bimolecular S_N processes the transformation of the tetracoordinate C-compound into the pentacoordinate species results from an *attack on any face* [see *(3a)*—*(3d)*] of the tetrahedron by the nucleophile such that the entering group assumes an apical position in the intermediate. The latter decomposes by apical departure of the leaving group. Recently, the necessity for *apical entry and departure* has been confirmed in an elegant manner by *Eschenmoser et al.*[18]. Their experiments demonstrate that if the steric requirements for both apical entry and departure are not fulfilled, no nucleophilic substitution *via* pentacoordinate species takes place. Observations from these experiments are well in accord with the concepts developed in this and preceding papers[15] and in particular with the properties of cyclic pentacoordinate species with three- to five-membered rings *vs.* those with six-membered rings.



Scheme 1 illustrates a process corresponding to the classical S_N2 mechanism except that *(3a)* is an *intermediate*, not a transition state. Since pentacoordinate carbon compounds with the more electronegative ligands

[*] *Note added in proof* (May 28, 1971):
The polarity rule [15c] seems to apply only in systems where substantial d orbital participation exists. We are led to this position as a result of recently completed BE comparisons between the various isomers of PH_3F_2 and PH_2F_3 calculated in one case employing d orbitals in the CNDO/2 basis set and in another case without. While the former set of data shows clearly that these systems comply with the polarity rule, the latter data set indicates that this rule does not hold, leading one to believe hybridization changes in the bond system weigh heavily in determining ligand positions on a molecular skeleton.

Table 2. Bond orders, β values and valence shell electron populations for *(6a)* and *(6b)*. Diagonal elements on C are orbital electron populations. Italic entries are the bond orders while the first entry in each column is a core energy term whose negative product with the bond order represents the orbital contribution to the eletronic energy. The *z*-axis is the apical direction, the *x*-axis is in the equatorial plane with C—H(13) the $+x$ direction.

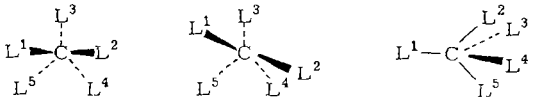
in the equatorial plane are preferred, the formation of a methane derivative *(4)* not only from *(3a)* but from the isomers *(3b)*—*(3d)* as well is to be expected.

(3b) *(3c)* *(3d)*

Although formation of the latter three intermediates may be favored over that of *(3a)*, they do not lead to a substitution process by apical departure if none of the ligands L^1 to L^3 has sufficient leaving properties unless reorganization by BPR or TR processes[15] (BPR = Berry pseudorotation, TR = turnstile rotation) forms intermediates with an apical leaving group. BPR and TR processes always transform *(3b)*—*(3d)* into such pentacoordinate molecules which by apical departure of X lead to *(4b)*, *i.e.*, configuration retention (corresponding to an S_Ni process).

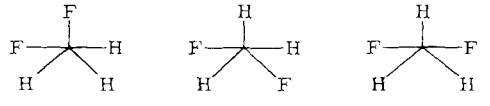


(4b) *(3e)*

Double TR processes[15] in *(3b)*—*(3d)* yield the inversion product *(4a)* upon decay of the trigonal-bipyramidal intermediate if N and X simultaneously belong to the trio of the double TR process, and yield *(4b)* by all other double TR processes. Furthermore, *(3a)* can also undergo BPR or TR reorganization to give *(4a)* and *(4b)*, *e.g.*, *via (3e)*.

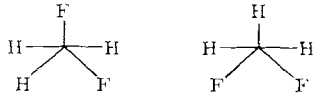
It appears that the generally observed inversion of configuration resulting from bimolecular nucleophilic substitution on saturated carbon is due to the fact that rearrangement processes required for retention lead to energetically disfavored trigonal-bipyramidal isomers and have, in general, relatively high potential energy barriers. They therefore occur more slowly than the elimination of apical ligands of pentacoordinate intermediate *(3)*.

Table 3 contains the BE data of some BPR and TR barrier models of *(3a)*⇄*(3b)* and *(3b)*⇄*(3c)*. One can determine, by comparing the BE of certain BPR and TR transition states with the BE of the parent trigonal bipyramid, that



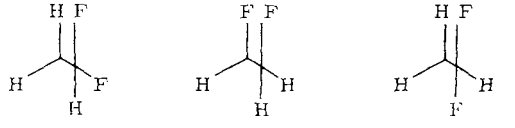
(7) *(8)* *(9)*

the energy barrier for positional exchange is less than 10 kcal/mole on the average, far less than the barriers predicted by earlier calculations[7,8].



Since pentacoordinate molecules with a trigonal-bipyramidal skeleton possessing diequatorial three- to five-membered rings are far more strained than the corresponding apical-equatorial analogs[15c], one can expect, assuming apical entry and departure, that bimolecular S_N processes of three- to five-membered cyclic systems will not proceed exclusively with inversion but predominately with retention.

Table 3. BE data of the conceivable barrier situations *(7)*, *(8)*, and *(9)* for positional exchange in $CH_3F_2^{\ominus}$ trigonal-bipyramidal species of the kind *(3a)*⇄*(3b)* and *(3b)*⇄*(3c)*. Figures under formulas are in kcal/mole.



Cpd.	L^1	L^2	L^3	L^4	L^5	∢ L^1—C—L^2 (°)	∢ L^3—C—L^5 (°)

If a cyclobutane derivative *(10)* undergoes a nucleophilic substitution under conditions where the bimolecular S_N2 process is faster than the S_N1 (which would lead to a detectable carbonium ion rearrangement[11]), we are led to expect an S_N process with configurational retention

(10) *(11)*

(12a) *(13a)*

[(10)→(13)]. Since diequatorial three- to five-membered rings are energetically disfavored in trigonal-bipyramidal molecules[5] apical attack by $Y^{\ominus}$ on (10) can only lead to (11); apical departure of $X^{\ominus}$ is only possible after a rearrangement (11)→(12) which is favored if $X^{\ominus}$ prefers apical and $Y^{\ominus}$ equatorial placement on the trigonal-bipyramidal skeleton.

The acceleration of bimolecular S_N processes by substituents, *e.g.*, CN, R—CO, and probably RO, is due to the stabilization of the trigonal-bipyramidal intermediates by those groups, particularly in equatorial positions, and to a lowering of the activation energy for their formation [$k(S_N2)=k_1k_2/k_{-1}+k_2\approx k_1$, if $k_2 \gg k_{-1}$, see Scheme 1].

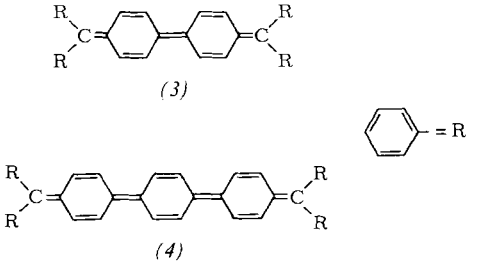
The Energetic Positions of the Lowest Singlet and Triplet State of the Schlenk and of the Müller Hydrocarbon



By *Reinhard Schmidt* and *Hans-Dieter Brauer*[*]

π-Electron systems with an even number of centers and π-electrons, in which in the HMO approximation the two highest occupied HMO's are mutually degenerate, usually occupy a triplet ground state[1,2]. This is also the case, according to more recent work, for the Schlenk hydrocarbon (1)[2,3], but according to *Hückel*[4] the Schlenk hydrocarbon (2) could provide an exception to this rule. Specifically, Hückel estimates that in this case the exchange integral which determines the splitting of corresponding singlet and triplet states is very small, and within the accuracy of the approximation procedure the same energy is obtained for the lowest singlet and triplet state of (2). Accordingly, (2) should possess a biradical ground state and should behave like a "doubled" triphenylmethyl radical[5].

(1) (2)

According to classical valence theory the occurrence of two unpaired electrons in the ground state of compounds (1) and (2) is to be regarded as a consequence of the non-existence of *m*-quinonoid systems, which makes it impossible to compensate the valences in the two halves of the molecules (1) and (2). The situation is quite different when the topology of the system permits intramolecular valence compensation; for example, the Chichibabin hydrocarbon (3), which is isomeric with (2), should, if the atoms lie in one plane, possess a singlet ground state, since the highest occupied HMO is not degenerate[1,4], and this follows both from the standpoint of classical valence theory and from HMO theory; this accords with experience. However, the lowest triplet state of (3) is energetically so low that it is excited even at moderate temperatures. According to ESR spectroscopic investigations of the solid substance the energy difference ΔE between the lowest triplet and singlet ground state of planar (3) is about 5.5 ± 1.0 kcal/mol[6]; and according to *Seel*'s quantum-theoretical calculations[7] a still smaller energy difference ΔE is to be expected for the Müller hydrocarbon (4).

(3) (4)

To discover whether the theoretical ideas concerning the positions of the lowest singlet and triplet states of (2) and (4) are correct, ESR spectroscopic measurements have been carried out with these compounds.

The hydrocarbons (2) and (4) were synthesized according to the publication of *Schlenk* and *Brauns*[8] and of *Müller* and *Pfanz*[9], respectively. To demonstrate molecules in the triplet state, a 0.5% solutions of (2) and a 0.1% solution of (4) in toluene under very pure nitrogen were studied at low temperatures; to avoid complete association, the solutions were heated for a short time at 60°C and then rapidly cooled in liquid nitrogen.

Figure 1 shows the ESR spectrum of the rigid glassy toluene solution of (2) at −120°C; it contains several signals

[*] Dipl.-Chem. R. Schmidt and Priv.-Doz. Dr. H.-D. Brauer
Institut für physikalische Chemie der Universität
6 Frankfurt/Main, Robert-Mayer-Strasse 11 (Germany)

($\Delta m = 1$) characteristic of triplet molecules as well as a very intense $^2\Sigma_{1/2}$ signal at 3260 G; we ascribe the triplet spectrum to monomeric *(2)*. The values of the zero field splitting parameters[10] calculated from the ($\Delta m = 1$) transitions are $|D| = 0.0049\ cm^{-1}$, $|E| \leq 0.0003\ cm^{-1}$. A triplet molecule was also detected for *(4)*; the ESR spectrum of the glassy solidified toluene solution of *(4)* at −120 °C is

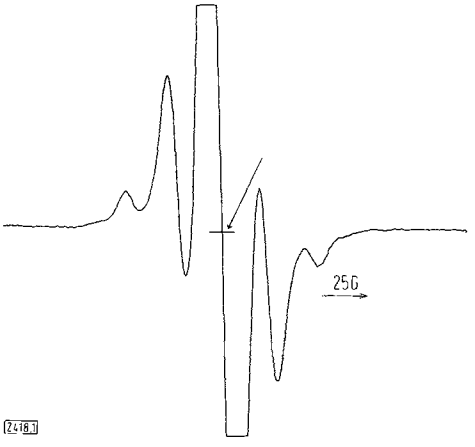


Fig. 1. ESR spectrum of 3,3'-bis(diphenylmethyl)biphenyl *(2)* in glassy solidified toluene at −120 °C. Arrow: 3260 G.

analogous to that of the compound *(2)*; the values obtained for the zero field splitting parameters amount to $|D| = 0.0035\ cm^{-1}$, $|E| \leq 0.0002\ cm^{-1}$. (The zero field splitting parameters of both hydrocarbons are slightly temperature-dependent.) The ($\Delta m = 2$) absorption signal could not be observed for either hydrocarbon.

To answer the question whether the triplet molecules demonstrated for *(2)* and *(4)* are molecules in the triplet ground state or thermally excited molecules in the lowest triplet state, we have measured the temperature-dependence of the ($\Delta m = 1$) signals over the range 153–183 °K; this was evaluated from the relation (1)[11]:

$$I = \frac{C}{T} \frac{3 \cdot e^{-\Delta E/RT}}{1 + 3 \cdot e^{-\Delta E/RT}} \qquad (1)$$

$\Delta E = E_{triplet} - E_{singlet}$, C = constant

Calculations by eqn. (1) from the variation of signal amplitudes with temperature afford for *(2)* a value of ΔE of -0.3 ± 0.15 kcal/mol and for *(4)* a value of ΔE of 0.9 ± 0.3 kcal/mol.

From these investigations it follows that the hydrocarbon *(2)* has a triplet ground state and not a biradical ground state as would appear possible by *Hückel*'s calculations. According to our measurements the triplet ground state, however, is only about 0.3 kcal/mol more stable than the lowest singlet state. On the other hand, as predicted by theory, the Müller hydrocarbon *(4)* has a singlet ground state; the excitation energy of about 1 kcal/mol found for the lowest triplet state is in accord with expectations from theory[7].

Synthesis of (Isothiocyanatoacyl)amino Acids

By *Hans R. Kricheldorf*[*]

N-(Isothiocyanatoacyl)amino acids *(1)* are crystalline compounds that are stable at room temperature and, like isothiocyanato carboxylic acids[1], can be condensed to polypeptides or polyamides *(2)* with loss of COS at elevated temperatures or in presence of catalysts.

$$n\ S{=}C{=}N\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}COOH \quad (1)$$

$$\downarrow -(n-1)\ COS$$

$$S{=}C{=}N\text{-}A\text{-}CO\text{-}[\text{-}NH\text{-}B\text{-}CO\text{-}NH\text{-}A\text{-}CO]_{n-1}\text{-}OH \quad (2)$$

The monomers *(1)* can be synthesized by either of two methods, according to the availability of the starting material:

1. An amino acid in a suitable solvent mixture is converted by the stoichiometric quantity of chlorotrimethylsilane into the trimethylsilyl ester hydrochloride *(3)*[2], which is then acylated by an isothiocyanato carbonyl chloride; the resulting trimethylsilyl *N*-(isothiocyanatoacyl)amino esters *(4)* can be hydrolyzed to the monomers *(1)* by water (or alcohol) rapidly and under mild conditions.

$$\overset{\oplus}{N}H_3\text{-}B\text{-}COO^{\ominus} + (CH_3)_3SiCl \rightarrow \overset{\ominus}{Cl}[\overset{\oplus}{N}H_3\text{-}B\text{-}CO\text{-}OSi(CH_3)_3] \quad (3)$$

$$(3) + SCN\text{-}A\text{-}CO\text{-}Cl \xrightarrow[-2R_3N \cdot HCl]{+2R_3N}$$

$$SCN\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}CO\text{-}OSi(CH_3)_3 \quad (4)$$

2. A dipeptide is converted analogously into the trimethylsilyl ester hydrochloride, and the latter is treated with carbon disulfide and triethylamine, giving the dithiocarbamate *(5)*. Acylation with a chloroformic ester below 0 °C affords the *N*-[(alkoxycarbonylthio)thiocarbonyl]-dipeptide trimethylsilyl ester *(6)*, which can be hydrolyzed to the crystalline acid *(7)* that is thus easily purified and can also be polycondensed. Silylation of *(6)* or *(7)* affords the silyl esters *(4)*.

Both methods can be carried out in one operation and are also suitable for preparation of isothiocyanato oligopeptides.

Institut für makromolekulare Chemie der Universität
78 Freiburg, Stefan-Meier-Strasse 31 (Germany)

$$\ominus\oplus Cl[NH_3\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}CO\text{-}OSi(CH_3)_3] + CS_2 + 2\ R_3N$$

$$\rightarrow R_3\overset{\oplus}{N}H[\overset{\ominus}{S}CS\text{-}NH\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}CO\text{-}OSi(CH_3)_3] \quad (5)$$

$$+\ R_3N\cdot HCl$$

$$(5) + R^1O\text{-}CO\text{-}Cl \xrightarrow{-R_3N\cdot HCl}$$

$$R^1O\text{-}CO\text{-}S\text{-}CS\text{-}NH\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}CO\text{-}OSi(CH_3)_3 \quad (6)$$

$$\downarrow$$

$$R^1O\text{-}CO\text{-}S\text{-}CS\text{-}NH\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}COOH \quad (7)$$

$$(6)\ [\text{or } (7)] \xrightarrow[-R_3N\cdot HCl]{+(CH_3)_3SiCl/R_3N} (4) + R^1O\text{-}Si(CH_3)_3 + COS$$

On treatment of glycylglycine by method 2 it was found that the acids *(7)*[4] were stable, but not the *N*-(α-isothiocyanatoacyl)amino acids *(8)* since the latter cyclize even at 0 °C to thiohydantoins *(9)*.

$$SCN\text{-}A\text{-}CO\text{-}NH\text{-}B\text{-}COOH \xrightarrow{0\,^\circ C} \begin{matrix} A\text{-}CO \\ | \quad \diagdown \\ HN\text{-}CS \end{matrix} N\text{-}B\text{-}COOH$$

(8) *(9)*

Experimental:

1. An amino acid (0.3 mol) in a mixture of acetonitrile (100 ml) and anhydrous chloroform (400 ml) is heated with chlorotrimethylsilane (0.3 mol) at the boiling point for *ca.* 2 h, to give a clear solution or a suspension of the trimethylsilyl ester hydrochloride. An isothiocyanato carbonyl chloride (0.3 mol) and finally triethylamine (61 g, 0.6 mol) are added dropwise to the product at −20 °C. After 60 min the mixture is extracted with dilute citric acid solution (300 ml), and the organic phase is dried and evaporated *in vacuo*, whereupon the product usually separates in crystalline form.

2. A solution or suspension of a dipeptide trimethylsilyl ester hydrochloride, prepared as in method 1, is stirred at room temperature with carbon disulfide (24 g, 0.3 mol) and triethylamine (61 g, 0.6 mol) for 4 h. Then an alkyl chloroformate (0.3 mol) is added dropwise while the temperature is not allowed to rise above 0 °C. After 30 min, a solution of chlorotrimethylsilane (40 ml) in anhydrous chloroform (250 ml) and triethylamine (42 ml, 0.3 mol) are dropped in, then the mixture is stirred for a further hour at room temperature and finally worked up as in method 1.

The IR spectra of the compounds named in the title show three characteristic bands: at 4.7 to 4.8 μm (2100 cm^{-1}; isothiocyanate group), 5.8 to 5.9 μm (1700 cm^{-1}, carboxyl group), and 6.1 μm (1640 cm^{-1}, amide-carbonyl).—*N*-(3-Isothiocyanatopropionyl)-β-alanine, m.p. 75–77 °C; *m*-*N*-(3-isothiocyanatopropionyl)aminobenzoic acid, m.p. 158 to 160 °C; *N*-(6-isothiocyanatohexanoyl)-DL-alanine, n_D^{20} = 1.5288, m.p. 43–46 °C.

The results of C—H and N elemental analyses agree with the theoretical values within ±0.3%.

Synthesis of Dithiophosphinic Acids by Nucleophilic Fission of Perthiophosphonic Anhydrides

By *Klaus Diemert* and *Wilhelm Kuchen*[*]

Dithiophosphinic acids $R_2P(S)SH$ and their salts are of interest as excellent complexing agents and also as intermediates in the synthesis of organophosphorus compounds[1, 2].

We have found that these acids can be prepared conveniently by nucleophilic fission of the readily accessible perthiophosphonic anhydrides *(1)*[3, 4] with Grignard reagents.

$$\begin{matrix} S & S \\ \| & \| \\ RP\text{-}S & PR \\ \quad\diagdown & \diagup \\ \quad\ S & \end{matrix} \xrightarrow[H^\oplus/H_2O]{2\ R'MgX} 2\ \begin{matrix} R & S \\ \diagdown & \| \\ & P \\ \diagup & \diagdown \\ R' & SH \end{matrix}$$

(1)

The resulting acids are isolated, some as such, and some as their salts or Ni(II) complexes. We prepared the compounds listed in Table 1.

The process is especially useful for synthesis of acids containing different substituents R, and also for preparation of bisdithiophosphinic acids *(2)* (previously difficult of access) by use of bifunctional Grignard reagents

$$\begin{matrix} R & & R \\ | & & | \\ HS\text{-}P\text{-}R''\text{-}P\text{-}SH \\ \| & & \| \\ S & & S \end{matrix}$$

(2)

XMg—R″—MgX. In this way we obtained the bifunctional acid *(3)*, m.p. 149 °C ($\delta^{31}P = -50.0$ ppm), in 94% yield.

$$\begin{matrix} H_3C & & CH_3 \\ | & & | \\ XS\text{-}P & \langle\rangle & P\text{-}SX \\ \| & & \| \\ S & & S \end{matrix}$$

(3), X = H
(4), X = Na
(5), X = CH_3
(6), X = $HN(CH_3)_3$

Neutralization of *(3)* afforded the Na_2 salt *(4)*, $\delta^{31}P = -107.1$ ppm, as a fine, colorless, crystalline powder, decomp. >300 °C, which, when warmed with methyl iodide in dioxane, gave the diester *(5)*, $\delta^{31}P = -58.1$ ppm, m.p. 128–132 °C. Compound *(6)* was obtained as colorless crystals, m.p. 249 °C, by reaction of *(3)* with trimethylamine in benzene.

Experimental:

p-Methoxyphenyldithiophosphonic anhydride[4] (22.0 g, 0.054 mol), suspended in diethyl ether (220 ml), was stirred and cooled in ice while a 1M ethereal solution (120 ml, 0.12 mmol) of CH_3MgCl was added. The mixture was heated at the b.p. for 1 h, then cooled and hydrolyzed with 5% H_2SO_4 (200 ml). The ethereal layer was separated, the

Institut für Anorganische Chemie der Universität
4 Düsseldorf, Ulenbergstr. 127/129 (Germany)

aqueous phase was extracted several times with ether, and the combined ethereal layers were dried over Na_2SO_4 and evaporated in a vacuum. The oily residue solidified after some hours to well-formed crystals that were filtered off and dried in a vacuum. This gave *p*-(methoxyphenyl)-methyldithiophosphinic acid, $(p\text{-}CH_3OC_6H_4)CH_3P(S)SH$, in 70.3% yield (16.6 g).

Table 1. Compounds of the type RR'P(S)SX synthesized.

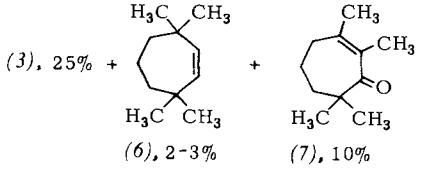
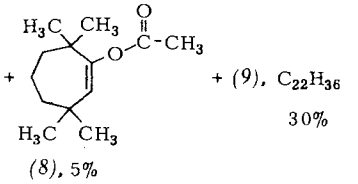
3,3,7,7-Tetramethylcycloheptyne, an Isolable Seven-Membered Carbocyclic Alkyne[1][**]

By *Adolph Krebs* and *Horst Kimling*[*]

3,3,6,6-Tetramethyl-1-thia-4-cycloheptyne *(1)* is a thermally stable compound, which shows no tendency to dimerize or oligomerize even at 140°C[2]. In contrast to *(1)*, cycloheptyne *(2)* could not be isolated—it has a half-life in 0.016 M CH_2Cl_2 solution of less than a minute at −25°C and of about an hour at −76°C[3]. We therefore posed ourselves the question whether introducing two geminal CH_3 groups at each α-position to the triple bond would repress the tendency of the cycloheptyne to oligomerize sufficiently to make the isolation of 3,3,7,7-tetramethylcycloheptyne *(3)* possible.





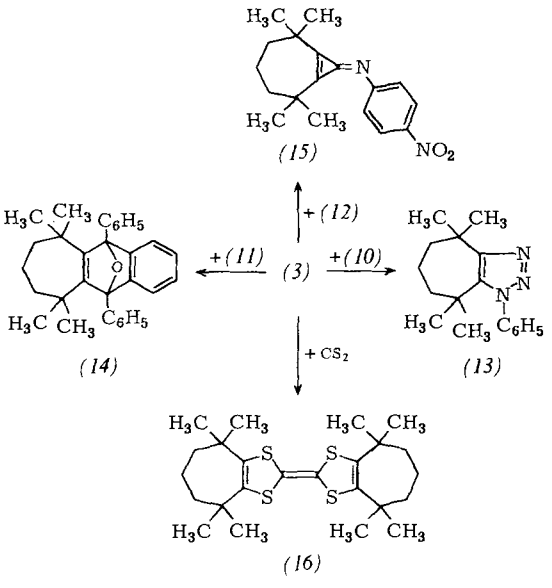
(1) *(2)* *(3)*

(4) *(5)*

We obtained *(3)* analogously to *(1)*, from 3,3,7,7-tetramethyl-1,2-cycloheptanedione *(4)*[4] by way of the bishydrazone *(5)* (yield 63%, m.p. 159—160°C) which was then oxidized by lead tetraacetate.

In this reaction there were formed, besides *(3)*, b.p. 25°C/0.01 torr, the compounds *(6)* to *(9)*, the last being a dimer of *(3)* of as yet unclarified structure.

The structure of *(3)* follows from spectroscopic data [mass spectrum, 150 (M^+); ^{1}H-NMR (60 MHz, CCl_4, referred to TMS), 1.54 ("s", 6 H), 1.13 ppm (s, 12 H); IR (CCl_4), 2190, 2170 cm^{-1} (νC≡C); Raman (no solvent), 2210, 2179, 2158 cm^{-1} (νC≡C)] and from oxidation to *(4)* by O_2.



Compound *(3)* reacts rapidly at 25°C with phenyl azide *(10)*, 1,3-diphenylbenzo[*c*]furan *(11)*, and *p*-nitrophenyl isocyanide *(12)*, giving the corresponding 1:1 adducts *(13)*, m.p. 187—188°C, *(14)*, m.p. 165—166°C, and *(15)*, m.p. 143°C; with CS_2 under analogous conditions it affords the 2:2 adduct *(16)*, m.p. 330°C (dec.). The structures of these adducts are proved by spectroscopic data.

In contrast to *(1)*, *(3)* is unstable at 25°C: in 0.2 M CCl_4 solution its half-life amounts to about 1 day, but in the

[*] Dr. A. Krebs and Dipl.-Chem. H. Kimling
Institut für Organische Chemie der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

pure form it dimerizes within an hour to *(9)*, b.p. 125 °C/0.2 torr [mass spectrum, 300 (M^+); ^{1}H-NMR (60 MHz, CCl_4, referred to TMS), 5.60 (s, 1 H, =CH—), 4.67 (broad signal, 2 H, $=CH_2$), 2.2—1.0 (complex m, superimposed

on three s (each 6 H) at 1.20, 1.12, and 1.07 ppm, total 33 H, aliphatic H); IR (film), 3073 $=CH_2$, 1652 (C=C), 883 cm^{-1} ($=CH_2$); UV (C_6H_{12}), λ_{max} (ε) = 230 nm (11300)].

The addition of *(12)* permits a further comparison of the reactivities of *(1)* and *(3)*: compound *(3)* adds *(12)* about 20 times faster than does *(1)*[5].

These results show the following:

1. Substitution of the S ring member by a CH_2 group [*(1)* → *(3)*] causes a considerable increase in the reactivity of the seven-membered cycloalkyne.

2. Introduction of the four CH_3 groups [*(2)* → *(3)*] leads to a drastic increase in the kinetic stability of the cycloheptyne system; *(3)* dimerizes 10^7 to 10^8 times more slowly than *(2)*, which corresponds to an increase of 9—10 kcal mol^{-1} in the free enthalpy of activation for this reaction.

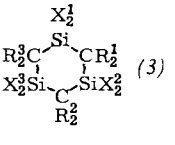
Si-Fluorinated Carbosilanes

By *Gerhard Fritz* and *Malte Berndt*[*]

In connection with our studies on perchlorinated "carbosilanes"[1-4] we now report the formation and properties of *Si*-fluorinated compounds of this type.

[*] Prof. Dr. G. Fritz and Dipl.-Chem. M. Berndt
Institut für Anorganische Chemie der Universität (TH)
75 Karlsruhe 1, Englerstrasse 11 (Germany)

The SiCl group in carbosilanes having an unsubstituted CH_2 bridge can be converted into a SiF group by treatment with ZnF_2. Compounds *(1b)*—*(5b)* are thus formed without skeletal cleavage from *(1a)*—*(5a)*.



(a), X = Cl; *(b)*, X = F

(1a) and *(2a)* react with ZnF_2 at 20 °C in hexachlorobutadiene to give *(1b)*[5] (80% yield) and *(2b)*, respectively. In an analogous reaction in acetonitrile at 80 °C *(3a)* and *(4a)* afford *(3b)*[6] (m.p. 143 °C; sublimes at 75 °C/10^{-3} torr) and *(4b)* (m.p. 75 °C; sublimes at 60 °C/10^{-3} torr). Heating of a mixture of *(5a)* and ZnF_2 to 100—160 °C furnishes *(5b)* (m.p. 260 °C; sublimes at 60—70 °C/10^{-3} torr); above 200 °C, however, compound *(5a)* undergoes ring cleavage. The compounds containing the Si—F group are less sensitive to hydrolysis than those containing Si—Cl.

Reaction of the perchlorinated compounds $(Cl_3Si)_2CCl_2$ *(1c)* and $(Cl_3Si—CCl_2)_2SiCl_2$ *(2c)* with ZnF_2 at 20 °C in hexachlorobutadiene leads to $(F_3Si)_2CCl_2$ *(1d)*[5] (yield ≈95%) and $(F_3Si—CCl_2)_2SiF_2$ *(2d)*, respectively. Some degree of decomposition occurs during formation of *(2d)* and at 100 °C the decomposition reactions predominate to form SiF_4, F_3SiCCl_2H, and $(F_3Si)_2CCl_2$.

By contrast, no chlorine/fluorine exchange takes place at the silicon atoms of perchlorinated cyclic carbosilanes with ZnF_2 or $SbF_3/SbCl_5$. $(Cl_2Si—CCl_2)_3$ *(3c)* and $[(SiCl)_4(CCl_2)_6]$ *(5c)* undergo no reaction, for example, with ZnF_2 at room temperature, and at higher temperatures (80—150 °C) react only with ring cleavage. The completely *Si*-fluorinated derivatives also resist attempted preparation by reaction of ZnF_2 with the SiH groups of the corresponding *C*-chlorinated carbosilanes. Thus while $(C_2H_5)_3SiH$ readily gives $(C_2H_5)_3SiF$ on treatment with PF_5, $(H_3Si—CCl_2)_2SiH_2$ *(2e)* does not react with ZnF_2.

(3)

	X^1	X^2	X^3	R^1	R^2	R^3	M.p. (°C)	Subl. (°C/10^{-3} torr)
(3d)	F	F	F	Cl	Cl	Cl	64	40–60
(3e)	F	F	F	H	Cl	H	43	40
(3f)	F	F	F	Cl	Cl	H	—	—
(3g)	Cl	Cl	Cl	H	Cl	H	—[2, 4]	—[2, 4]
(3h)	F	F	F	H	Br	H	66	50
(3i)	Cl	Cl	Cl	H	Br	H	—[7]	—[7]
$(F_2Si—CCl_2)_4$ *(4c)*							75	60
$[(FSi)_4(CCl_2)_6]$ *(5d)*							240	180

Si-Fluorinated, *C*-chlorinated carbosilanes such as *(3d)*, *(4c)*, and *(5d)* are readily accessible in good yields, however, by photochlorination of the CH_2 groups in compounds of type *(3b)*—*(5b)* (see Table). ^{1}H-NMR studies of the reaction course in CCl_4 solution show that partially chlorinated derivatives, *e.g. (3e)* and *(3f)*, can also be prepared in the same way. Compound *(3e)* may be obtained by fluorination of *(3g)*[2,4] with ZnF_2 at 80°C in acetonitrile or benzene, and *(3h)* likewise from *(3i)*[7].

Si-Fluorinated, *C*-chlorinated carbosilanes are rapidly hydrolyzed by atmospheric moisture and differ considerably in their chemistry from the corresponding perchlorinated compounds. Thus $(F_3Si)_2CCl_2$ *(1d)* reacts with $LiCH_3$ to give $[(CH_3)_3Si]_2CCl_2$, whereas in the case of $(Cl_3Si)_2CCl_2$ *(1c)* methylation starts at the C—Cl bond and initially yields $(Cl_3Si)_2C(CH_3)Cl$[3].

Molecular Perchlorato Complexes of Iridium(I), Rhodium(I), and Cobalt(I)[**]

By *J. Peone, Jr.* and *L. Vaska*[*]

We report the synthesis and some properties of *trans*-perchloratocarbonylbis(triphenylphosphane)iridium(I) *(1)* and -rhodium(I) *(2)*, as well as perchloratodicarbonylbis-(triphenylphosphane)cobalt(I) *(3)*, apparently the first examples of M^I (d^8) perchlorato complexes of transition metals. These compounds are of interest not only because they contain a covalent metal-$OClO_3$ linkage, but also for their versatility as starting materials for a variety of new complexes [*e.g.*, eq. (3)][1].

Complexes *(1)* and *(2)* are prepared by treating a saturated solution of the corresponding chloro compound of iridium(I)[2] and rhodium(I), respectively, in benzene with silver perchlorate (molar ratio 1:1) under nitrogen at 25°C.

$$[MCl(CO)(Ph_3P)_2] + AgClO_4 \rightarrow [M(OClO_3)(CO)(Ph_3P)_2] + AgCl \quad (1)$$
(1), M = Ir
(2), M = Rh

The reaction mixture, protected from light, is stirred for 15 min; the resulting silver chloride is filtered from a yellow-orange solution which, on addition of hexane, produces crystals of the perchlorato complex. Yields ranging from 80 to 95% have been obtained[3]. The yellow crystals of *(1)* are sensitive to O_2 and must be stored under N_2 or *in vacuo*; those of *(2)* are stable in air. The complexes have been identified by elemental analyses, IR spectra, and conductivity measurements (see Table).

(1) and *(2)* resemble their well-known congeners, $[MA(CO)L_2]$ (A = univalent anionic ligand, L = monodentate neutral ligand; *e.g.*, $[IrCl(CO)(Ph_3P)_2]$)[2,4-7], in most of their physical characteristics, but their chemical behavior is considerably more versatile [eq. (2), (3)][1,7]. The complexes *(1)* and *(2)* are insoluble in water and hexane, but soluble in polar organic solvents in which they undergo complete ionization

$$[M(OClO_3)(CO)(Ph_3P)_2] + S \rightarrow [M(S)(CO)(Ph_3P)_2]^+ + ClO_4^- \quad (2)$$
S = acetone, nitromethane, methanol, *etc.*

as evidenced by the conductivity data (Λ_M, Table).

Addition of Ph_3P to a C_6H_6 solution of *(1)* or *(2)* produces an orange [M = Ir, *(4)*] or yellow [M = Rh, *(5)*] precipitate of carbonyl*tris*(triphenylphosphane)metal(I) perchlorate.

$$[M(OClO_3)(CO)(Ph_3P)_2] + Ph_3P \rightarrow [M(CO)(Ph_3P)_3]ClO_4 \quad (3)$$
(1), M = Ir — *(4)*, M = Ir
(2), M = Rh — *(5)*, M = Rh

According to their elemental analyses, solubility characteristics (insoluble in nonpolar, soluble in polar solvents) and the properties summarized in the Table, *(4)* and *(5)* represent tetragonal cationic d^8 complexes analogous to those reported previously[8].

Table. Properties of complexes *(1)* to *(5)*.

	Complex [a]	Λ_M(ohm^{-1}) in CH_3OH [b]	IR in $CHCl_3$ (cm^{-1}) ν_{CO} [c]	IR in nujol (cm^{-1}), $OClO_3(C_{3v})$ and ClO_4 (T_d) absorptions [d]				
(1)	$[Ir(OClO_3)(CO)L_2]$	110	1990	1160(m)	1130(s)	1050(ms)	920(w)	620(ms)
(2)	$[Rh(OClO_3)(CO)L_2]$	100	2000	1160(m)	1130(s)	1070(ms)	920(w)	620(ms)
(3)	$[Co(OClO_3)(CO)_2L_2]$		1950, 2000	1160(m)	1125(s)	1080(ms)	928(mw)	623(ms)
(4)	$[Ir(CO)L_3]ClO_4$	120	2020		1100 (vs, br) [e]			620(ms)
(5)	$[Rh(CO)L_3]ClO_4$	105	2030		1100 (vs, br) [e]			620(ms)

[a] L = $(C_6H_5)_3P$. [b] 10^{-4}–10^{-5} M in complex. Molar conductance (Λ_M) of a standard 1:1 electrolyte, $[(C_3H_7)_4N]PF_6$, in CH_3OH is 110 ohm^{-1}. Acetone and nitromethane solutions of the complexes give similar results (essentially complete ionization). In chlorobenzene, Λ_M = 0.7 for *(1)* and 5.2 ohm^{-1} for *(4)*. [c] *(3)* measured in nujol. All bands very strong (vs). For comparison, $\nu_{CO}(CHCl_3)$ in $[IrCl(CO)L_2]$, 1967 cm^{-1}. [d] Full analysis of the spectra and assignments of the bands are given in ref. [7], see also ref. [9]. [e] Broad band centered at 1100 cm^{-1} and overlapping with a $(C_6H_5)_3P$ band near the same frequency.

[**] This work was supported by the National Institutes of Health (Grant No. HE-09678) and the Environmental Protection Agency (Grant No. AP-00574).

The principal evidence for the coordinated perchlorato group ($OClO_3$) in the crystals of *(1)*, *(2)*, and *(3)* derives

from the infrared data given in the Table. According to previous analyses of the spectra of related complexes[9], these compounds contain $OClO_3$ of C_{3v} symmetry, and *(4)* and *(5)* an uncomplexed $ClO_4(T_d)$ unit. The molecular structures of *(1)* and *(2)* must prevail also in nonpolar solvents as suggested by their electronic spectra in benzene, which are identical with those of the respective complexes in the solid state as well as very similar to the spectra (solution and crystals) of the structurally well-established *trans*-$[MA(CO)L_2]$[7]. Note also the striking solubility difference in benzene between the ionic complexes [*(4)* and *(5)*, insoluble] and the neutral species [*(1)* and *(2)*, soluble]. The latter, by analogy with *trans*-$[MA(CO)L_2]$[4], undergo oxidative addition reactions to produce six-coordinated molecular complexes of tervalent metals[1,7].

Perchloratodicarbonyltris(triphenylphosphane)cobalt(I) *(3)*, a five-coordinated complex, is obtained from a benzene solution of the reactants and precipitated with hexane.

$$[CoCl(CO)_2(Ph_3P)_2] + AgClO_4 \rightarrow [Co(OClO_3)(CO)_2(Ph_3P)_2] + AgCl \quad (4)$$

It appears that the method of synthesis for *(1)*, *(2)*, and *(3)* represents a general route to organometallic perchlorato compounds[10].

Crystal and Molecular Structure of Tricarbonyl(hexaethylborazine)chromium(0)[**]

By *Gottfried Huttner* and *Bernhard Krieg*[*]

It is to be expected that investigation of the structure of π-complexes of transition metals with heterocyclic π-ligands will give an insight into the bonding in π-complexes, particularly on comparison with analogous complexes of carbocyclic systems. Replacing a carbon atom by a hetero atom amounts, in a first approximation, to a change in the electron density distribution in the ligands, and the influence of such changes can be studied in structural investigations.

The first structure determination that we report in this connection is the X-ray analysis of tricarbonyl(hexaethylborazine)chromium(0), a compound that is isosteric with tricarbonyl(hexaethylbenzene)chromium(0). Because of its bulky ethyl groups, the complex is not the ideal representative of the borazine-metal π-complexes, but it was selected for investigation because it is the only borazine complex prepared so far that has been obtained in usable single crystals[7].

The compound, $[(C_2H_5)_6B_3N_3]Cr(CO)_3$, crystallizes in the monoclinic space group $P2_1/c$, with $a = 12.05$, $b = 17.88$, $c = 14.79$ Å, $\beta = 138.6°$, $d_{calc} = 1.214$, $d_{exp} = 1.218\,g\,cm^{-3}$, $Z = 4$. The crystal used for the structure determination measured $0.2 \times 0.3 \times 0.4$ mm. For this, a total of 918 independent reflection intensities were measured on a two-circle diffractometer with $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å. The structure was solved by the heavy atom method and refined to an *R* factor of 0.070 by successive approximations; all the hydrogen atoms were located. The geometry of the molecular skeleton (Fig. 1) corresponds to that of tricarbonylbenzenechromium, as predicted by *Werner et al.*[1]. However, the structure shows some peculiarities.

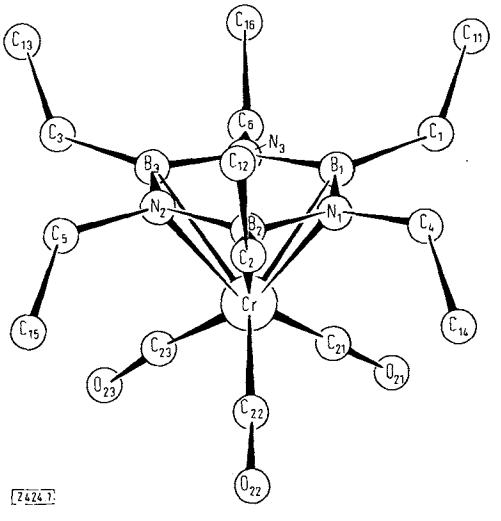

Fig. 1. Molecular structure of tricarbonyl(hexaethylborazine)chromium(0).

The idealized three-fold axis of the tricarbonylchromium group is perpendicular to the borazine ring. The nitrogen atoms of the ring are staggered with respect to the carbonyl groups, and the N—Cr bonds are directed toward the Cr—(CO) bonds. As in the tricarbonylchromium derivatives of 1-methylpyrrole and 1,4-dimethyl-1,2-dihydropyridine, the nitrogen, as the ring atom with the highest electron density, is *trans* to a carbonyl group[2]. The mean Cr—N distance amounts to 2.22 Å; this is considerably shorter than the Cr—B distances (mean 2.31 Å, Table 1); the difference between these bond lengths corresponds approximately to the difference between the covalent radii of boron and nitrogen[3] and it is thus not permissible to conclude that the boron atoms are bonded more weakly to the metal than the nitrogen atoms.

[*] Dr. G. Huttner and Dipl.-Chem. B. Krieg

[**] We thank the Deutsche Forschungsgemeinschaft for their support and the Bayerische Akademie der Wissenschaften for computer time.

The differing Cr—B and Cr—N bond lengths lead to puckering of the borazine skeleton. In contrast to the situation in free hexaethylborazine, which is planar within experimental error[4], the two parallel planes formed by the three boron atoms and the three nitrogen atoms are separated by 0.07 Å. The six-membered ring thus assumes a not very pronounced chair conformation (see the torsion angles in Table 1), which has an effect on the positions of the ethyl groups. Whereas in free hexaethylborazine[4] the ethyl groups project alternately above and

Table 1. Bond lengths, bond angles, and torsion angles in tricarbonyl(hexaethylborazine)chromium(0).

B(1)—N(1)—B(2)—N(2)	6	N(1)—B(2)—N(2)—B(3)	− 8
B(2)—N(2)—B(3)—N(3)	12	N(2)—B(3)—N(3)—B(1)	− 14
B(3)—N(3)—B(1)—N(1)	12	N(3)—B(1)—N(1)—B(2)	− 8
B(1)—N(1)—B(2)—C(2)	−169	N(1)—B(2)—N(2)—C(5)	179
B(2)—N(2)—B(3)—C(3)	−169	N(2)—B(3)—N(3)—C(6)	168
B(3)—N(3)—B(1)—C(1)	−161	N(3)—B(1)—N(1)—C(4)	177

below the plane of the ring, in the complex the ethyl group C(6)—C(16) breaks this alternation. This is possible because the ring puckering increases the distance between the methylene carbon atoms C(6) and C(3), and C(6) and C(1), so that there is no longer strong steric hindrance between their hydrogen atoms.

As in free borazine[5], the bond angles N—B—N (mean value 115°) are smaller than the B—N—B angles (mean 124°). The mean of the B—N separations (1.44 Å) does not differ from that (1.435±0.002 Å) in the free borazine[5]. However, one of the B—N distances (Table 1), at 1.36 Å, deviates appreciably from the mean value; a similar strong deviation was found[6] for the ring distances within a π-bonded ring in the case of tricarbonyl(hexamethylbenzene)chromium(0), where the C—C distances differ by up to 9/100 Å; in neither case is there any immediately obvious explanation of these observations. The Cr—$C_{(CO)}$ distances, at 1.80 Å, are, within experimental error, the same as in tricarbonyl(hexamethylbenzene)chromium(0) (1.80 Å) and indicate a similar donor/acceptor behavior of benzene and borazine.

Stepwise Formation of Bridged Dinuclear Carbonylmetal Complexes[1]

By *Heinrich Vahrenkamp* and *Winfried Ehrl*[*]

Very few reports have hitherto appeared concerning metal carbonyls in which two metal atoms are held together only by an atom that behaves as a Lewis base; their synthesis, *e.g.* that of $(CO)_5W—P(CH_3)_2—Re(CO)_5$[2] gives rise to difficulties. In contrast, dinuclear complexes exhibiting considerable stability, such as $(CO)_4Fe—P(CH_3)_2—P(CH_3)_2—Fe(CO)_4$[3], in which the carbonylmetal groups are linked *via* diphosphanes or diarsanes, have been known for some time. All known complexes of this kind are symmetrical, *i.e.* two identical bridging atoms link two identical metal atoms.

We have now accomplished the stepwise formation of such complexes having two-membered bridges in which the two metal atoms are different and the two bridge atoms are also different. We started with derivatives of hexacarbonylchromium and hexacarbonyltungsten with dimethylphosphido and dimethylarsenido ligands. The reactive complexes $(CO)_5M—E(CH_3)_2—Sn(CH_3)_3$ *(1)*, which are readily accessible photochemically, react with the halides $(CH_3)_2E'Cl$ to give the organometallic Lewis bases $(CO)_5M—E(CH_3)_2—E'(CH_3)_2$ *(3)*. Reaction of the complexes $(CO)_5M—E(CH_3)_2Cl$ *(2)* with the tin compounds $(CH_3)_2E'—Sn(CH_3)_3$ likewise leads to *(3)*. Photochemical reaction of compounds *(3)* with a hexacarbonylmetal affords the dinuclear complexes *(4)* in good yield.

$$(3) + (CO)_5M'(OC_4H_8) \xrightarrow{-OC_4H_8} (CO)_5M—E(CH_3)_2—E'(CH_3)_2—M'(CO)_5 \quad (4)$$

M, M′ = Cr, W; E, E′ = P, As

Each one of the ten conceivable complexes *(4)* with M = Cr or W and E = P or As has been prepared (see Table). *(4a)–(4c)* have already been described[4]. According to this method, *(4e)–(4j)* can be prepared by two analogous routes depending on the reactants.

Table. Properties of compounds *(4)*.

	M	E	E′	M′	M.p. (°C)	^{1}H-NMR [a] δ(E—CH_3)	J(P—H)	δ(E′—CH_3)	J(P—H)

[a] Recorded in benzene; chemical shifts in ppm (TMS internal standard); coupling constants in Hz.

[*] Dr. H. Vahrenkamp and Dipl.-Chem. W. Ehrl
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstrasse 1 (Germany)

The complexes are stable in air; their color ranges from intense yellow in the case of *(4c)* to colorless in the case of *(4b)*, thus paralelling the decrease in arsenic and chromium content. The IR spectra in the CO stretching region of all compounds *(4)* are almost identical and consist of a weak band at about 2065 cm^{-1} and a very strong (sometimes split) band at about 1945 cm^{-1}. The most important analytical information is provided by the ^{1}H-NMR spectrum (see Table) whose assignment is confirmed by measurements at 60 and 100 MHz. All the spectra show the expected number of singlets or doublets and, in particular, permit a distinction to be made between the otherwise highly similar isomers *(4i)* and *(4j)*. In this, as in other cases[5], P—H coupling is stronger over three bonds (8–10 Hz) than over two bonds (6 Hz).

Two extensions of the above reaction scheme come to mind. On the one hand there is the possibility of introducing other metal atoms. Thus $(CO)_5Cr—P(CH_3)_2—P(CH_3)_2$ and $Fe_2(CO)_9$ give a good yield of the yellow, readily soluble compound $(CO)_5Cr—P(CH_3)_2—P(CH_3)_2—Fe(CO)_4$ *(5)*, m. p. 96 °C. However, more important is the use of complexes *(4)* for the synthesis of strongly associated metal-carbonyl clusters. Thus thermolysis[6] of *(4e)* at 250 °C in benzene smoothly yields the new red complex $(CO)_4Cr[P_2(CH_3)_4]W(CO)_4$, dec. pt. 326 °C, whose diamagnetism and IR and NMR spectra indicate structure *(6)* with a chromium-tungsten bond.

(6)

It may be assumed that systematic exploitation of the above reactions will open up a new route to polynuclear transition metal complex systems and thus into the region between molecular compounds and the pure metals.

Procedure:

$(CO)_5W—As(CH_3)_2—Sn(CH_3)_3$ (1 mmol) and $(CH_3)_2PCl$ (1.1 mmol) in benzene (10 ml) are stirred for 2h with exclusion of air. All volatile components are subsequently removed in a high vacuum, leaving $(CO)_5W—As(CH_3)_2—P(CH_3)_2$ as a yellow oil. To this oil is added a solution of $(CO)_5Cr(OC_4H_8)$ (1.2 mmol) produced photochemically[7]. The reaction mixture is evaporated to dryness and the excess of $Cr(CO)_6$ is pumped off. After extraction with warm light petroleum (50 ml) and filtration the filtrate is also evaporated to dryness and the residue is recrystallized from cyclohexane (5 ml). The yield of pale yellow, air-stable *(4i)* is 0.38 g (55%).

Redox Behavior of Insoluble Quinone/Hydroquinones

By *Hartmut Alt, Horst Binder, Alfons Köhling*, and *Gerd Sandstede*[*]

Solutions of quinones and hydroquinones have long been known as reversible redox systems, and the mechanism of oxidation and reduction has been repeatedly investigated. It has been shown that the electrode kinetics of duroquinone in aqueous-methanolic solution corresponds to that of *p*-benzoquinone[1]. We have studied the electrochemical properties (redox potential, reversibility of the reaction, and discharge characteristics) of insoluble quinones as solid electrodes because we were considering quinones as cathode material for secondary cells and fuel cells; the known nitro compounds are suitable only for primary cells as they are reduced irreversibly[2].

We have prepared conducting electrodes from non-conducting quinones by mixing them with graphite in weight ratio 1:1 and compressing the powder mixture between graphite felt disks. In some experiments the electrodes contained the quinones in a gold skeleton. The measurements were carried out with tetrachloro-*p*-benzoquinone (chloranil), tetramethyl-*p*-benzoquinone (duroquinone), and diphenoquinone, which are almost insoluble in aqueous electrolytes. The redox behavior was investigated by cyclic voltammetry using a triangular sweep with slow alteration of voltage[3,4]. The electrode potential[5] is increased linearly with time and after having reached a preselected value continuously reduced. The electrode then responds with an anodic current (oxidation of the hydroquinone to quinone) or—on lowering of the voltage—with a cathodic current (reduction of the quinone to hydroquinone). The cyclic potentiodynamic current-voltage curve obtained in this way for a chloranil electrode in 2 N H_2SO_4 (Fig. 1) is symmetrical with respect to the rest potential. The latter amounts to

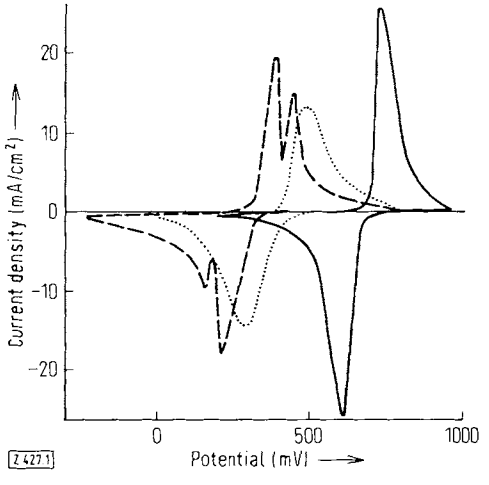

Fig. 1. Cyclic potentiodynamic current-voltage curves of a chloranil electrode. 9 mg of chloranil mixed with graphite in a gold support. Electrode surface, 1 cm^2; alteration of voltage, 40 mV/min. —— 3 N H_2SO_4; - - - - 5 M NH_4Cl; · · · · 2 M $ZnCl_2$.

668 mV and is obtained when quinone and hydroquinone exist simultaneously in the electrode. A redox potential of 664 mV was measured in aqueous-alcoholic solution[6]. The cyclic current-voltage curve (Fig. 1) has a very narrow

[**] Present address: Farbwerke Hoechst AG, Frankfurt-Höchst (Germany)

oxidation maximum and a similar reduction maximum; the charge and discharge polarization is very small. Further, the areas are identical and correspond to the amount of charge contained in the substance. Hence, quinone can be used in the present solid form completely reversibly to the extent of 100%. The cyclic current-voltage curve is stationary; the capacity and the resistance of the electrode change, if at all, only after a long time.

The cyclic current-voltage curve measured in zinc chloride solution shows the same behavior (Fig. 1). The rest potential is *ca.* 400 mV, corresponding to a pH of 4.8. However, in ammonium chloride solution (pH ≈ 4.5) the rest potential is *ca.* 100 mV less than the redox potential calculated on the basis of the theoretical pH-dependence. Further, the current maxima of the cyclic potentiodynamic current-voltage curves are split (Fig. 1); on charge and discharge two maxima are obtained that are separated by *ca.* 70 mV; these maxima are assigned to the two electron transfer reactions quinone/semiquinone and semiquinone/hydroquinone—since chloranil does not form a quinhydrone[6], it must be assumed that the intermediate product is the semiquinone which is stabilized by the ammonium ions and reacts further only at higher (or lower) potential. The discharge curves, measured galvanostatically in dilute sulfuric acid, are almost horizontal at medium current density, at least up to 90% discharge, and the polarization on discharge amounts to only 20 to 60 mV with respect to the rest potential (Fig. 2). Further it can be seen from the

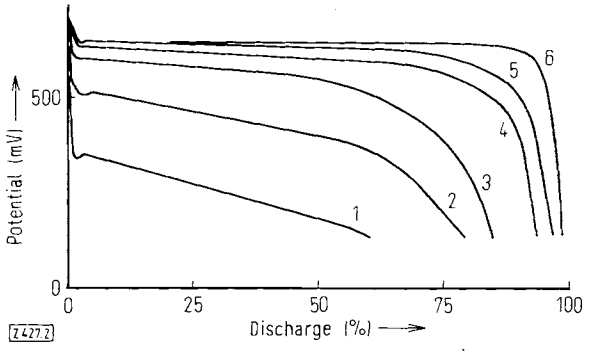

Fig. 2. Discharge curves of a chloranil cathode. 184 mg of chloranil mixed with graphite. Electrode surface, 1 cm²; 3 N H_2SO_4; 25 °C. Curve 1: 600 mA/cm² = 10 C [7]. Curve 2: 300 mA/cm² = 5 C. Curve 3: 120 mA/cm² = 2 C. Curve 4: 60 mA/cm² = 1 C. Curve 5: 30 mA/cm² = 0.5 C. Curve 6: 3 mA/cm² = 0.05 C.

Figure that the quinone cathode can be particularly heavily loaded. It is true that the practical capacity decreases with increasing current density, but it still amounts to 85% of the theoretical value at a discharge rate of 2 C[7]. Even a load of 600 mA/cm² does not lead to voltage breakdown. The chloranil cathode, further, can be heavily loaded even at low temperature; at 0 °C polarization is only *ca.* 50 mV larger than at room temperature. Also, the discharge characteristics in the salt solutions mentioned are almost horizontal. Therefore, it would also be possible to use quinone cathodes in primary cells having greater load capacity for neutral electrolytes, for which purpose zinc might, for example, be introduced as anode material. Again, development of secondary cells would be of interest, because higher energy densities (Wh/kg) can be obtained than with lead accumulators. Our experiments with a chloranil electrode in aprotic solvents have shown that this electrode behaves reversibly also in organic electrolytes, *e.g.*, lithium perchlorate in acetonitrile or propylene carbonate, and this makes it possible to develop a high-energy battery with lithium anodes.

Quinone cathodes in aqueous electrolytes can be regenerated by air. Normally hydroquinones are not oxidized by oxygen, but the capacity of chloranil or duroquinone in contact with catalytically active charcoal was regenerated quantitatively after discharge in dilute sulfuric acid or ammonium chloride solution provided that air is supplied by use of a hydrophobic electrode[8]. Since the active mass was hydrophilic, oxidation of the hydroquinone occurs by an electrochemical mechanism. At the redox potential of the quinone the oxygen is cathodically reduced and the hydroquinone anodically oxidized simultaneously at the same electrode. Regeneration can also be achieved by hydrogen peroxide.

Incorporation of Olefin and Nitric Oxide into Organocobalt Compounds[**][1]

By *Henri Brunner* and *Stephan Loskot*[*]

The system consisting of olefin, CO, and organocobalt compound is of considerable technical importance, particularly for carbonylations[2]. We have studied the system consisting of olefin, NO, and organocobalt compound and report here a synthesis starting from these three components.

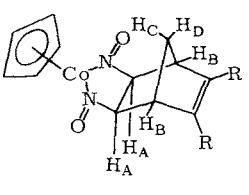
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

$C_5H_5Co(CO)_2$ reacts with NO to give $[C_5H_5Co(NO)]_2$ *(1)*[3]. However, in the presence of norbornene the new complex *(2)* is formed. The latter can also be obtained from *(1)*, norbornene, and NO at room temperature and atmospheric pressure in 90% yield.

Compound *(2)* forms dark crystals, stable in air and soluble with an intense red color in organic solvents except aliphatic hydrocarbons; it is monomeric in benzene. In its mass spectrum the molecular ion appears at $m/e = 278$; fragmentation of the molecule (removal of the olefin, followed by stepwise loss of the NO groups) indicates coordination of the ligands through the NO groups to the cobalt atom. The IR spectrum of *(2)* in KBr does not contain any band in the region of NO ligands bound terminally to metal[4]; an intense band at 1357 cm^{-1} can be ascribed to the NO stretching vibration weakened by back donation.

The signal for olefinic protons in the ^{1}H-NMR spectrum of norbornene lies at $\tau = 4.02$[5]. The corresponding protons of *(2)* give rise to a doublet at $\tau = 7.28$ with a coupling constant of about 1 Hz. The signal for the bridgehead protons is shifted from $\tau = 7.16$ to $\tau = 7.36$ by complex formation. The signal for the π-bonded C_5H_5 ring appears at $\tau = 5.04$.



In order to elucidate the structure of the new type of compound, derivatives were used containing substituted cyclic olefins instead of norbornene. The double Diels-Alder adduct from 2-bromofuran and dimethyl acetylenedicarboxylate yields the complex *(3)* in which both olefinic double bonds have reacted.

(3), R = $COOCH_3$

In the ^{1}H-NMR spectrum of *(3)* the protons H_A and $H_{A'}$ give rise to an AB system with resonances at $\tau = 6.43$ and $\tau = 6.80$ and a coupling constant of 5.7 Hz. These two protons thus occur in the "nitroso" structure *(3)* on neighboring carbon atoms. The "oxime" structure, which would be formed by shift of the protons H_A and $H_{A'}$ on to the oxygen atoms is thus excluded. The signal for the bridgehead proton H_B lies at $\tau = 4.49$. H_B does not couple with H_A and $H_{A'}$.

When the Diels-Alder adduct from cyclopentadiene and dimethyl acetylenedicarboxylate reacts with $[C_5H_5Co(NO)]_2$ and NO, only the unsubstituted double bond reacts, with formation of *(4)*. The ^{1}H-NMR spectrum of *(4)* contains a doublet for H_A at $\tau = 6.77$ and a multiplet

(4), R = $COOCH_3$

for H_B at $\tau = 6.54$. H_C and H_D form an AB system (H_C at $\tau = 7.84$; H_D at $\tau = 8.20$) with a coupling constant of 10 Hz. Each line of the AB system shows additional fine structure. The chemical shifts and coupling constants of the hydrogen atoms H_A to H_D were assigned by double resonance. As was previously noted for *(3)*, H_A and H_B do not couple with one another in *(4)*. The constant of the long-range coupling $H_A - H_D$ amounts to 1.3 Hz.

The long-range coupling between H_A and H_D in *(4)* as well as the absence of coupling of H_A and H_B in *(3)* and *(4)* are considered as characteristic of *endo*-protons H_A in systems of the type *(3)* and *(4)*[6]. The *exo*-structure is thus to be ascribed to the complexes *(3)* and *(4)*.

Similar complexes are formed from ethylene and cyclohexene but have not yet been obtained pure.

Phenylarsenic(v) Trichloride Azide and Phenylarsenic(v) Chloride Nitride[1]

By *Volker Krieg* and *Johann Weidlein*[*]

Phenylarsenic dichloride dissolved in CCl_4 reacts with gaseous chlorine azide[2] exothermally according to

$$C_6H_5AsCl_2 + ClN_3 \rightarrow C_6H_5AsCl_3N_3 \quad (1)$$

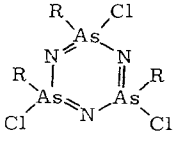
Removal of solvent and unreacted starting materials under reduced pressure leaves highly viscous, orange-red phenylarsenic(v) trichloride azide *(1)*. The compound is only moderately soluble in benzene and is hydrolyzed by water with evolution of considerable amounts of heat. On rapid heating it decomposes, with black coloration, but not explosively. Compound *(1)* is, however, also unstable at room temperature and slowly gives off chlorine and nitrogen; thermal decomposition proceeds according to

$$C_6H_5AsCl_3N_3 \rightarrow C_6H_5AsClN + Cl_2 + N_2 \quad (2)$$

and goes to completion only at about 100 °C in a high vacuum; phenylarsenic(v) chloride nitride *(2)* is evolved. Compound *(2)* is a slightly brownish glass at room temperature whose softening point lies at about 70 °C. The hygroscopic compound dissolves in organic solvents and in weak alkalis. Cryoscopic molecular weight determinations in benzene show the substance to exist as the trimer.

In the IR spectrum of *(1)* the characteristic absorption bands of the azido group can be assigned unequivocally.

[*] Dr. V. Krieg and Dr. J. Weidlein
Institut für Anorganische Chemie der Universität
7 Stuttgart 1, Schellingstrasse 26 (Germany)



They occur at 2055 ($\nu_{as}N_3$), 1240 (ν_sN_3), 470 cm^{-1} (δN_3). Further deformational vibrations of the azido group are probably masked by the strong bands at 670 (r) and 740 cm^{-1} (γC—H). The "X-sensitive" vibrations q, r, t, and y[3] of the C_6H_5As group are shifted by only about 10 cm^{-1} towards longer wavelengths compared to $C_6H_5AsCl_2$[4]. However, a very strong and poorly structured band between 960–1020 cm^{-1}, which is absent from the spectrum of $C_6H_5AsCl_2$, is particularly noticeable. Although the phenyl ring vibration will be present at 1000 cm^{-1}, the main contribution certainly comes from As—N stretching vibrations. The frequency can only be explained in terms of extensive As—N π bonding, as in the arsenic nitride compounds $[(C_6H_5)_2AsN]_4$[5] and $[C_6H_5AsClN]_3$ *(2)* where association gives rise to an alternating sequence of As—N single and double bonds. The α-N atom of the azo group can admittedly function as donor atom owing to its lone pair, as in the organometal azides of Group IIIB elements[2,6]; however, in *(1)* the negative inductive effect of the three chlorine atoms and the phenyl group should rather promote an interaction of the lone pair with an empty d orbital of arsenic. In this way a (p→d)π bond is superimposed on the As—N σ bond.

Table. Characteristic IR frequencies of compounds *(1)* and *(2)*.

[a] Assignment based on vibrational spectrum of $C_6H_5AsCl_2$.
[b] Values given in cm^{-1}.
[c] Designation of "X-sensitive" vibrations (q, r, y, t) according to *Whiffen* [3].

By analogy with tetrameric diphenylarsenic nitride[5] a ring structure can be assumed for trimeric phenylarsenic(v) chloride nitride.

(2), R = C_6H_5

The six-membered ring system can have C_{3v}, C_s, or C_1 symmetry, depending upon the positions of the ligands Cl and R. It is not possible to distinguish between a planar and a puckered As_3N_3 ring on the basis of the IR spectrum alone.

Dynamics of the Photodimerization of 9-Anthroic Acid and Sodium 9-Anthroate[1][**]

By *Dwaine O. Cowan* and *Walter W. Schmiegel*[*]

While many anthracene derivatives are known to photodimerize only the photodimerization of unsubstituted anthracene has been studied in mechanistic detail[2]. To learn more about the effect of solvent and substituents on radiative and nonradiative processes we have studied the photodimerization of 9-anthroic acid in ethanol and benzonitrile and the photodimerization of sodium 9-anthroate in water, deuterium oxide, and benzonitrile.

The material balance (dimer and starting compound) for the preparative photolysis of degassed solutions of the purified acid and sodium salt in each of the solvents was greater than 93% with only traces of nonacidic material. The non-acidic material was principally anthraquinone[3].

Process	Rate	
$A + h\nu \rightarrow A^s$	I_a	Light absorption
$A^s \rightarrow A + h\nu$	$k_F[A^s]$	Fluorescence
$A^s \rightarrow A$	$k_{IC}[A^s]$	Internal conversion
$A^s \rightarrow A^t$	$k_{ISC}[A^s]$	Intersystem crossing
$A^s + A \rightarrow 2A$	$k_{CQ}[A^s]\,[A]$	Concentration quenching
$A^s + A \rightarrow D$	$k_{DIM}[A^s]\,[A]$	Dimerization

Scheme 1.

To obtain meaningful assessments of the photochemical reactivity it is necessary to determine specific rate constants. Quantum yield measurements represent rate ratios and are therefore insufficient to indicate specific reactivities. To obtain the specific rate constants and verify the mechanism suggested in Scheme 1 the following was carried out: *first*, the fluorescence lifetimes in dilute solutions (τ_F^0) were measured by the phase shift method[4]; *second*, the absolute fluorescence quantum yields in dilute solutions (Φ_F^0) were determined by comparison with the fluorescence quantum yield of quinine sulfate after the spectra had been corrected for phototube wavelength response; *third*, relative quantum yields of fluorescence as a function of concentration were measured over the concentration range at which the dimerization was studied[5]; and *fourth*, the low conversion quantum yield of dimer formation as a function of concentration was determined using the equipment previously described[6].

The mechanism given in Scheme 1 would predict the following relationships:

$$\Phi_F^0 = k_F/(k_F + k_{ISC} + k_{IC})$$

$$1/\Phi_F = (k_F + k_{ISC} + k_{IC})/k_F + \{(k_{DIM} + k_{CQ})\,k_F\} \cdot [A]$$

$$1/\Phi_{DIM} = (k_{DIM} + k_{CQ})/k_{DIM} + \{(k_F + k_{ISC} + k_{IC})/k_{DIM}\} \cdot \frac{1}{[A]}$$

This mechanism was found to be consistent with the observations that a plot of the reciprocal of the relative quantum yield of fluorescence $1/\Phi_F$ *vs* the anthracene concentration [A] yields a straight line and a plot of the reciprocal of the quantum yield of dimerization $1/\Phi_{DIM}$ *vs* the reciprocal of the anthracene concentration 1/[A] gives a straight

[*] Prof. Dr. D. O. Cowan[***] and Dr. W. W. Schmiegel

[***] Guggenheim Fellow. On leave from the Johns Hopkins University.

line. Since the intercept of $1/\Phi_{DIM}$ *vs* $1/[A]$ is not unity the concentration quenching process (k_{CQ}) must be important. This may suggest an excimer intermediate but our kinetic data does not demand this intermediate.

$A^s + A \rightleftarrows [A...A]^s$ excimer
$[A...A]^s \rightarrow$ Dimer
$[A...A]^s \rightarrow 2A$

From the slope and intercept of the dimerization graphs and the values of τ_F^0 and Φ_F^0 it is possible to calculate the rate constants given in Table 1. Only qualitative trends in rate constants will be considered in this communication.

All of the values for k_F are similar except for the sodium salt in benzonitrile. For this system the sum of the second order rate constants ($k_{CQ}+k_{DIM}$) exceeds the diffusion controlled collision rate constant (k_{DIFFN}). This may reflect an aggregation phenomenon resulting from ion-pairing. The small rate constant for dimerization and abnormally large concentration quenching rate constant may then be a result of an unfavorable dimerization geometry in the ion pair. The similar values of k_{DIM} of the 9-anthroic acid ion in water, deuterium oxide and the acid in acidic ethanol indicate that coulombic repulsion between the anions is not as large as expected.

The large Stokes shift observed between the absorption and fluorescence spectra of the acid (40 nm in benzonitrile, 50 nm in ethanol) compared to the small Stokes shift of the anion (6—9 nm)[7] should place the lowest excited singlet state of the acid below the second triplet state. Since intersystem crossing is normally to the second triplet which is approximately isoenergetic with the first excited singlet state this lowering of the singlet state energy can nicely account for the lower rate constants found for intersystem crossing of the acid[8].

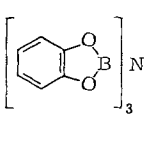
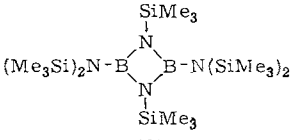
CONFERENCE REPORTS

Structural Problems in Boron-Nitrogen and Boron-Sulfur Chemistry



By *Heinz Hess*[*]

The past few years have seen various structural determinations, employing X-ray and electron diffraction techniques, on boron-nitrogen compounds. The results provide material for a fairly detailed discussion of the boron-nitrogen bond from a structural-chemical viewpoint.



Compounds with tetravalent boron ("borazanes", "cycloborazanes", "amine-boronium salts") generally exhibit only slight variations in the B—N bond lengths; the mean value is 1.58 Å. Compounds in which the B—N bond is seriously weakened by steric or electronic effects represent excep-

(1)

(2)

(3)

[*] Priv.-Doz. Dr. H. Hess
Institut für Anorganische Chemie der Universität
7 Stuttgart, Schellingstrasse 26 (Germany)

tions. Larger variations in B—N bond lengths are found when boron and nitrogen are in trigonal coordination, in agreement with the varying π-bonding component in such bonds. The shortest B—N bonds occur predictably in monoaminoboranes [1,3,5-tris(dimethylamino)-1,3,5-triboracyclohexane *(1)* 1.400 Å[1], dimethylaminodichloroborane 1.378 Å[2]]. When two or three nitrogens are bonded to one boron, and *vice versa*, the B—N bonds tend to be somewhat longer [*e.g.* borazine 1.435_5 Å[3], tris(dimethylamino)borane 1.431 Å[4], tris(1,3,5-benzodioxaborol-2-yl)-amine *(2)* 1.438 Å[5]].

Particular interest attaches to cyclic B—N compounds having further exocyclic nitrogens on the boron atoms. Whereas the 1.498-Å exocyclic B—N bond in monoaminoborazine is markedly longer than the bonds in the ring (1.418 Å[6]), both kinds of B—N bonds are of practically equal length in *B*-tris(dimethylamino)borazine (1.429 and 1.433 Å[7]) and in hexakis(trimethylsilyl)-2,4-diamino-1,3,2,4-diazadiboretidine *(3)* (1.441 and 1.454 Å[8]). This is surprising in compound *(3)* since the exocyclic Si_2N group are twisted by about 70° out of the plane of the ring owing to steric constraints. In contrast, the tris(dimethylamino)borazine molecule is almost completely planar.

The structural chemistry of the boron-sulfur bond has been far less thoroughly studied. Our own X-ray investigations are presently concerned with compounds of the type X_2BSR, XBS, and RSBS (X = halogen, NR_2; R = alkyl, H). On the basis of molecular weight determinations and molecular spectra, these compounds are described in the literature partly as dimers and partly as trimers; such statements, however, often lack a firm backing. As is clear from the chemistry of aluminum[9] the occurrence of polymeric structures must also be reckoned with in the solid state.

Dual Role of Pyridoxal 5′-Phosphate as Chemical and Conformation-Determining Active Group in Glycogen Phosphorylase

By *Ernst Helmreich*[*]

The first α-glucan phosphorylase shown to contain pyridoxal 5′-phosphate *(2)* was rabbit muscle phosphorylase a. Meanwhile pyridoxal 5′-phosphate has been found in all α-glucan phosphorylases. Removal of this group yields a crystalline, inactive apoenzyme[1]. In the rabbit, phosphorylase contains more pyridoxal 5′-phosphate than all the other pyridoxal 5′-phosphate-dependent enzymes together[2].

[*] Prof. Dr. E. Helmreich
Physiologisch-Chemisches Institut der Universität
87 Würzburg, Koellikerstrasse 2 (Germany)

The imine group linking the pyridoxal 5′phosphate to an ε-aminolysyl group of the phosphorylase protein can be reduced with $NaBH_4$. The resulting reduced phosphorylase still possesses about 60% of its original activity. This important experiment[3] shows that—in case pyridoxal 5′-phosphate should participate directly in phosphorolysis of the α−1→4 glycosidic bonds in glycogen—such a reaction

(1), R = H
(2), R = H_2O_3P

must follow a completely different course from all previously encountered enzyme catalyses involving pyridoxal 5′-phosphate. (In the other cases—transformations of amino acids—pyridoxal 5′-phosphate participates *via* its 4-formyl group.)

In aqueous solution, pyridoxal *(1)* and its analogs lacking the 5′-phosphate group exhibit a pH-dependent *intermolecular* proton transfer between nitrogen and the oxygen in position 3. In the case of pyridoxal 5′-phosphate and its analogs an additional *intramolecular* transfer occurs involving three proton-donor-acceptor groups[4]. In order to establish whether the pyridoxal 5′-phosphate in the phosphorylase also participates in an enzymatic acid-base catalysis as a "proton shuttle", the three protonatable groups were modified. Apart from the 3-*O*-methyl derivative, which has been synthesized and studied by *Pocker* and *Fischer*[5], and the *N*-oxide, previously obtained by *Fukui*[6], the monomethyl ester of pyridoxal 5′-phosphate and 3-*O*-methylpyridoxal 5′-phosphate *N*-oxide were synthesized for the first time and investigated. These analogs were bound stoichiometrically with sufficient affinity to the apoenzyme. The phosphorylases bearing these analogs have the same quaternary structure as the native active enzymes, but except for 3-*O*-methylpyridoxal 5′-phosphate-phosphorylase they were all inactive. The 20% activity of pyridoxal 5′-phosphate *N*-oxide-phosphorylase arises from deoxygenation of the *N*-oxide to pyridoxal 5′-phosphate by a cysteine group of the apophosphorylase[7].

To decide whether 1) the pyridinium nitrogen and/or the phosphate group participate as proton-donor-acceptor groups in catalysis, or whether 2) these groups induce a conformation of the active site that is necessary for catalysis, or 3) fulfill both functions, the pH-dependent fluorescence quantum yield of $NaBH_4$-reduced pyridoxamine compounds *(1)* and *(2)* and analogs covalently bonded to the enzyme was measured[9], using the method of *Cortijo* and *Shaltiel*[8]. Using this method and kinetic measurements of tritium-hydrogen exchange with phosphorylase[10] the search was opened for an analog-bearing enzyme having

the same, or at least a very similar, conformation of the active site as that of pyridoxal 5'-phosphate-phosphorylase. The inactive phosphorylase carrying the pyridoxal 5'-phosphate monomethyl ester exhibits the greatest similarity to the active enzyme. However, no proof has yet been obtained of any homology of conformation by hybridization of the active and the above inactive phosphorylase. Once such a proof has been obtained it may be assumed that the phosphorylase with the ester group is inactive because the phosphate group (pK 6.2) required for the chemical reaction—an acid-base catalysis—is blocked. Experiments to substantiate or disprove this assumption are in progress.

Reactions at Coordinatively Unsaturated Surface Compounds

By *Hans L. Krauss*[*]

The phenomenon of the formation of "surface compounds" by reaction of "free" surfaces, and the special case of saturation of SiO_2 surfaces by the components of water (silica gel ≡polysilicic acid) have led us to a more detailed investigation of the reaction of such polysilicic acid with other acids, specifically with chromic acid. In favorable cases some 85% of the SiOH groups react and are involved in bichromate bridges. The upper limit for this anhydride formation, *i.e.*, formation of surface compounds, is set by the nature of the surface and the number of available OH groups; in favorable cases compounds containing *ca.* 6.5% of chromium are obtained.

Chromic polysilicic anhydride is stable up to *ca.* 1000 °C, but it is sensitive to reducing agents; *e.g.*, it can be reduced quantitatively to Cr(II) compounds by H_2, CO, or hydrocarbon vapors. CO is optimal for this reaction as it produces no water. The resulting Cr(II) surface compound is coordinatively unsaturated and correspondingly reactive and energy-rich, like a "naked" surface; it therefore tends to attain an energetically more favorable state either by reoxidation or by additional coordination.

The *reoxidation*, which occurs with O_2, halogens, NO, *etc.*, regenerates Cr(VI) compounds, a remarkable orange-red chemiluminescence (616 nm) occurring on reoxidation with oxygen. The Cr(II) compound provides an extremely good oxygen getter, the oxygen equilibrium pressure being 10^{-27} atm. (Cl_2 reacts analogously by way of a chromium(IV) compound to chromyl chloride.) Corresponding reactions have been observed with almost all the transition metals.

As "naked surfaces", the reduced surface compounds also seek to decrease their energy by coordination of further ligands. The Cr(II) compound reacts, for instance, with N_2, CO, NH_3, HCl, aromatic hydrocarbon vapors, olefins, *etc.*, yielding complexes. These adducts have been subjected to more detailed study by optical and gravimetric methods.

Complex formation of olefins is followed by polymerization; acetylene yields 1,3,5-substituted benzene derivatives.

The presence of three free coordination sites on the metal is postulated as required for the polycondensation reaction. Ethylene could then polymerize by a σ/π interchange mechanism; the primary formation of a π-complex containing two molecules of olefin would be followed by a disproportionation step (ethyl-Cr or H—Cr σ-bond). All the experimental data fit this hypothesis, *e.g.*, the formation of atactic polypropene from propylene and α-methyl ketones on use of ethylene as reducing agent.

Chromatographic Resolution of Racemates[**]

By *Gottfried Blaschke*[*]

Systematic investigation of chromatographic resolution of racemates on optically active adsorbents[1] has hitherto been hindered because detecting the resolution by optical rotation is insensitive and liable to interference. By using the double labeling technique we have developed a method of detection that can be carried out even with very small amounts of racemate. This method yields the ratio of enantiomers in each chromatographic fraction rapidly, accurately, and without interference by optically active impurities. Our test material was mandelic acid.

In each case we mixed equal amounts of optically pure[2] [^{3}H]-(*R*)-(−)-mandelic acid (20 μC/mg) and [^{14}C]-(*S*)-(+)-mandelic acid (1 μC/mg), which gave the doubly labeled test racemate; we diluted this with inactive, racemic mandelic acid and then carried out the chromatography. We were then able, by scintillation spectrometry, to determine the ^{3}H/^{14}C-ratio and thus both the ratio and the absolute concentrations of the two antipodes in the eluate.

In this way we studied the chromatographic resolution of mandelic acid on more than 50 optically active adsorbents whose chirality and functional groups were varied systematically. Because of the great sensitivity of the measurements, even 2—10 g of any one adsorbent sufficed for these studies. The optically active adsorbents used were prepared as follows: 1) By treating optically active alcohols or amines with crosslinked or non-crosslinked poly-

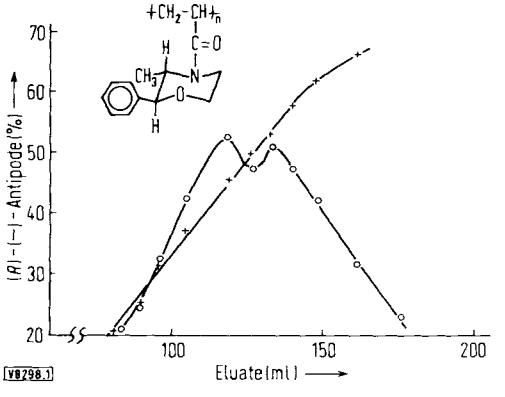

Fig. 1. Chromatographic resolution of 3.9 mg of racemic mandelic acid on 5.1 g of the polyacrylamide from *trans*-(2*S*,3*S*)-2-methyl-3-phenylmorpholine. Column 11.2 × 1.2 cm. Eluant benzene-dioxane 95:5. —o—o—o— rel. concentration of mandelic acid; ×—×—×— content of (*R*)-(−)-antipode.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

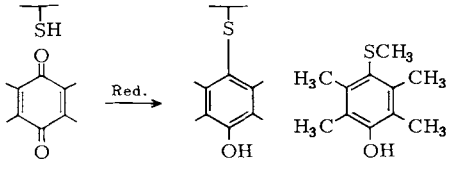
acryloyl chloride; 2) by treatment of optically active amino esters and tertiary amines with crosslinked chloromethylated polystyrene; and 3) by polymerization of optically active acrylic esters and amides.

Resolution was studied in each case with 1—10 mg of doubly labeled racemic mandelic acid on 10-cm columns. With almost all the adsorbents enrichment of one antipode was definitely detectable, at least in the first and last fractions of the eluate. With cinchonine polyacrylate prepared by method (1) it amounted to 18%, the (*R*)-(−)-antipode being enriched in the first fractions. The separation on ephedrine esters [*N*-benzylephedrine polyacrylate 30%, (*S*)-(+)-antipode eluated first] was even more marked and could be further improved if the chiral center were built into a rigid skeleton (Fig. 1).

It is remarkable that the elution profile shows two maxima. By using longer columns of the synthetic adsorbents it is now possible for the first time to resolve racemates quantitatively. Further, the second racemate tested by us, namely, methyl mandelate, is also partly separated into its antipodes on the adsorbents reported above.

Lecture at Kiel on February 11, 1971 [VB 298 IE]
German version: Angew. Chem. *83*, 547 (1971)

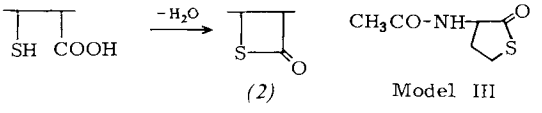
[1] For a review see *G. Losse* and *K. Kuntze*, Z. Chem. *10*, 22 (1970).



[2] Radiochemical and optical purities were proved by isotope dilution analysis. Reproducible results were also obtained with the test racemate [^{3}H]-(*S*)-(+)-mandelic acid/[^{14}C]-(*R*)-(−)-mandelic acid. Isotope effects thus did not interfere.

Model Reactions for Oxidative Phosphorylation: Sulfur Compounds as Carriers of the Phosphoryl Group

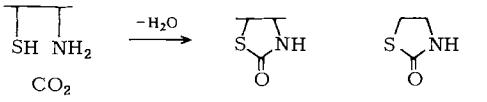
By *Edmund Bäuerlein* and *Theodor Wieland*[*]



For more than ten years *Th. Wieland*'s school have ascribed particular importance to mercapto groups for transfer of the phosphoryl group[1]. Butyl thiophosphate, $C_4H_9S—PO_3^{2\ominus}$, had been synthesized and studied as a model for a sulfur-containing coenzyme phosphate, CoA phosphate[2].

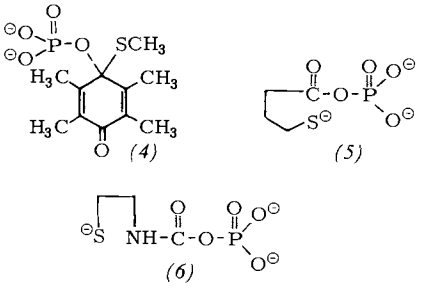
Reaction between one member of the electron-transport chain and the mercapto groups of proteins can lead to *p*-(alkylthio)phenol (*S*-alkylmonothiohydroquinone) *(1)*[3].

(1) Model II



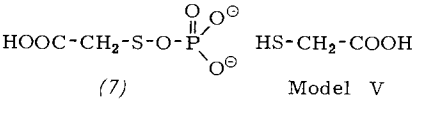
Functional groups such as carboxyl and mercapto attached to the protein may react with each other to give cyclic thioesters of type *(2)*[4].

(2) Model III



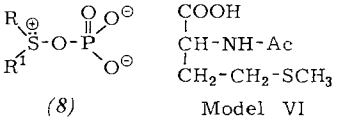
[*] Dr. E. Bäuerlein and Prof. Dr. Th. Wieland
Max-Planck-Institut für medizinische Forschung,
Abteilung Chemie
69 Heidelberg, Johnstrasse 29 (Germany)

Mercapto and amino groups attached to a protein can react with CO_2 to give cyclic carbamic thioesters of type *(3)*[5].



(3) Model IV

If the model compound II, III, or IV is oxidized with bromine in anhydrous pyridine in presence of ADP and phosphate, then high yields (27—38%) of ATP are obtained by way of the unisolable, high-energy, phosphorylated compounds such as the quinol phosphate *(4)*, the acyl phosphates *(5)*, or the carbamoyl phosphates *(6)*.



(4) *(5)* *(6)*

In the same system a new type of reaction was discovered, namely, direct oxidation of a mercapto compound, specifically mercaptoacetic acid[6] (model V, 34% of ATP). The mixed anhydride *(7)* of sulfenic and phosphoric acids must be assumed as the high-energy phosphorylated compound. *Lambeth* and *Lardy*[7] used a thioether (sulfide), namely, *N*-acetylmethionine (model VI) in the same system (36% of ATP); *(8)* is presumably the high-energy phosphorylated intermediate.

(7) Model V

(8) Model VI

As a model for cytochromes, hemin[8] was used successfully as oxidant of the mercaptoacetic acid (15% of ATP), which was the most effective of the mercapto compounds tested for ATP formation[9]. Thiols are better mediators than H_2S or sulfides.

Our investigations with a lipophilic medium showed that the yield of ATP obtained on oxidation of mercaptoacetic acid by hemin is appreciably increased[9] (22% of ATP) by the presence of its disulfide, dithiobis(acetic acid). Unexpectedly, oxidation of the disulfide alone (in presence of ADP and phosphate) also led to synthesis of ATP (13.7%); the thiosulfinate (disulfide monoxide)

can be assumed to be the first product of this oxidative phosphorylation.

Comparative experiments in an atmosphere of oxygen or nitrogen showed that there was pronounced oxygen-dependence of ATP formation in all the hemin experiments made[10]. Thus our results indicate that, rather than the monomeric cytochrome c, the cytochrome-c oxidase which probably has quaternary structure is the site of the redox reaction between mercapto groups and two groups of hemin compounds (cytochrome a and a_3).

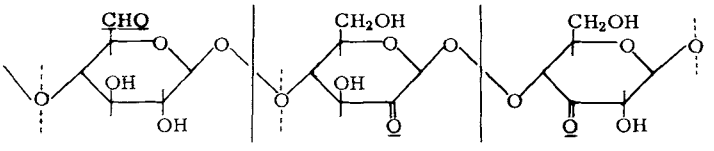
The Chemistry of Lignin-removing Bleaching

By *Thomas Krause*[*]

Lignin-removing bleaching of cellulose pulps is usually carried out in several stages. The bleach sequence consists, in principle, of a chlorination stage (which leads to partial degradation of the lignin to alkali-soluble products), alkaline extraction of the degradation products, and one or several oxidative stages in which hypochlorite and/or chlorine dioxide is used as bleaching agent. The following details are extracted from the voluminous literature on the reactions of lignin and carbohydrates in the individual bleaching stages:



The chlorination stage leads, when chlorine water (pH = 1.5 to 2.0) is used, to colored *o*-quinonoid compounds owing to chlorination of the phenylpropane units of lignin at positions 5 and 6, followed by hydrolysis of ether linkages both on the aromatic ring and in the aliphatic side chains.

Further amounts of chlorine are consumed in slow oxidative reactions that probably cause fission of C—C bonds between the phenylpropane units or removal of aliphatic side chains. These reactions occur in that way only if the aromatic ring does not contain other 5- or 6-substituents and if the phenolic hydroxyl groups are not etherified. The lignin molecule is cleaved by these reactions into alkali-soluble fragments. The residual lignin in the cellulose pulp is highly condensed. The subsequent hypochlorite bleaching stage causes only very little chlorination. Oxidations lead first to *o*-quinonoid structures; if further favored by use of higher temperatures, however, they proceed until the aromatic nucleus is degraded to CO_2 and organic acids (*e.g.*, oxalic and maleic acid).

R = phenylpropane unit.

Bleaching by chlorine dioxide takes a similar course. This bleaching agent has the advantage that it does not attack carbohydrates. Treatment with either chlorine or hypochlorite degrades the carbohydrates (cellulose and hemicelluloses) by oxidation. The keto groups at position 2 and/or 3, or the aldehyde groups at position 6, formed in the carbohydrate monomers, cause labilization of the β-

——: oxidized group; ¦ alkali-labile bond.

glucosidic bond to alkali and shortening of the chain by hydrolytic fission of these bonds in the alkaline medium.

Partial inhibition of carbohydrate degradation can be achieved by small additions of chlorine dioxide at the chlorination stage or of sulfamic acid at the hypochlorite stage.

Lecture at Darmstadt on March 5, 1971 [VB 299 IE]

Problems and Results in the Chemistry of Peroxosilicon and Peroxosulfur Compounds

By *Armand Blaschette*[*]

1. Cleavage of benzil and substituted benzils by H_2O_2, which is known to depend on nucleophilic attack by HO_2^- on a carbonyl-carbon atom of the α-diketone, is specifically catalyzed by alkali-metal silicates in aqueous solution at pH > 7. Kinetic analysis of the catalyzed reaction, and in particular the discontinuous pH-dependence of the catalysis constant, shows that the catalytic effect is to be ascribed to formation of several peroxosilicate species in different

[*] Dr. Th. Krause
Institut für Makromolekulare Chemie, Lehrstuhl II,
der Technischen Hochschule
61 Darmstadt, Alexanderstrasse 24 (Germany)

[*] Dr. A. Blaschette
Institut für Anorganische Chemie der Technischen Universität
33 Braunschweig, Pockelsstrasse 4 (Germany)

states of substitution and/or protonation and having different nucleophilic reactivities in equilibria of the type

$$(HO)_3SiO^- + HO_2^- \rightleftharpoons (HO)_2(HOO)SiO^- + HO^-$$

2. Stable sodium ethoxoperoxosilicates having the analytical composition

$$(Na^+)_x[(OO)_x(HOO)_{n-x}Si(OC_2H_5)_{4-n}]^{x-}$$

are obtained by perhydrolysis of tetraethoxysilane with 100% H_2O_2 in anhydrous ethanol in the presence of sodium ethoxide and these may contain up to 44% of peroxidic oxygen (corresponding to, *e.g.*, $x=2$, $n=3$) according to the molar ratio $Si(OC_2H_5)_4:H_2O_2:NaOC_2H_5$ used. The matter of the chemical homogeneity of these peroxosilicates requires further investigation.

3. The very reactive trimethylsilyl peroxosulfates

$$(CH_3)_3SiOSO_2OOSi(CH_3)_3 \text{ and } (CH_3)_3SiOSO_2OOSO_2OSi(CH_3)_3$$

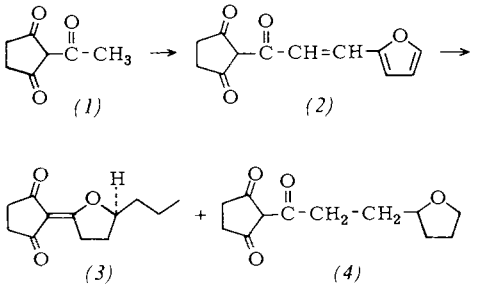
which are unstable at 20 °C are formed on treatment of bis(trimethylsilyl) peroxide with SO_3 in the molar ratio 1:1 or 1:2, respectively, in CH_2Cl_2 at −30 to −20 °C.

Dibutyl peroxide and SO_3, however, give only adducts[1].

4. $K_2S_2O_8$ and $[(C_6H_5)_4As]_2S_2O_8$ react with SO_3 in CH_2Cl_2 (molar ratio 1:2) in a heterogeneous reaction to give monoperoxotetrasulfates $K_2S_4O_{14}$ and $[(C_6H_5)_4As]_2S_4O_{14}$ quantitatively. If this reaction is carried out with the molar ratio 1:1, equimolar mixtures of monoperoxotetrasulfates and unchanged peroxodisulfate are formed instead of the expected monoperoxotrisulfate $M_2S_3O_{11}$[2]. Experiments in which $^{35}SO_3$ is used show that formation of $S_4O_{14}^{2-}$ from $S_2O_8^{2-}$ and SO_3 does not occur exclusively by addition of SO_3 molecules to terminal oxidic oxygen atoms of the peroxodisulfate anion but that part of the SO_3 is inserted into the S—OO bonds of the $S_2O_8^{2-}$[3].

5. Alkyl sulfamoyl peroxides—representatives of a new class of compound—are obtained in diethyl ether at −40 °C as follows:

$$ROOH + ClSO_2NH_2 + C_5H_5N \rightarrow ROOSO_2NH_2 + [C_5H_5NH]Cl$$



Above −10 °C they decompose rapidly by heterolysis of the O—O bond. The following decomposition products have been isolated so far: (a) R = propyl: sulfamic acid, propanal, propyl and isopropyl propionate; (b) R = butyl: sulfamic acid, butanal, isobutanal, and butyl butyrate; (c) R = *tert*-butyl: acetone and *tert*-butyl acetate.

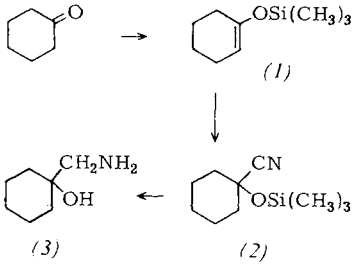
(5)



(6)

reactions of *(1)* and *(3a)*, *e.g.* isomerization to *(2)* and hydrogenation with Lindlar catalyst to *(4a)* respectively, are largely determined by these bonds. *(3c)* is considerably more reactive than *(3b)* because its pair of triple bonds are restricted from orienting themselves into a position of non-interference. In attempts to synthesize *(2)* by coupling 1-ethynyl-8-iodonaphthalene as the copper acetylide, dibenzonaphthacene *(6)* was formed instead. / Chem. Ber. *104*, 1170, 1182, 1191 (1971) / –Kr.

[Rd 365 IE]

β-Amino alcohols such as *(3)* have been prepared by *W. E. Parham* and *C. S. Roosevelt* by a new route from ketones such as cyclohexanone. Anhydrous HCN was added to the trimethylsilyl ether *(1)* of the corresponding enol to give the cyanide *(2)*, which, after reduction of the nitrile

(1) *(3)* *(2)*

group and hydrolysis of the trimethylsilyl group, afforded the β-amino alcohol *(3)*. The method is particularly suitable for sterically hindered ketones, *e.g.* 1,2,3,4,4a,9a-hexahydro-9-fluorenone. / Tetrahedron Lett. *1971*, 923 / –Kr.

[Rd 366 IE]

The nature of the rotational barrier in acetaldehyde has been investigated by *R. B. Davidson* and *L. C. Allen*. With the aid of SCF—MO calculations they analyzed the changes of attractive and repulsive forces between non-bonded atoms on rotation about the C—C bond. The calculated rotational barrier (1.09 kcal mole^{-1}) is in good agreement with the experimental one (1.16 kcal mole^{-1}). In acetaldehyde, the attraction between methyl H and O dominates the barrier, whereas in ethane H—H repulsion is the most important factor. The balance of attractive and repulsive potentials between non-bonded atoms is further discussed considering substituent effects on rotational barriers. It is stressed that the neglect of attractive interaction is a serious defect of simple models of hindered rotation. / J. chem. Physics *54*, 2828 (1971) / –Hz.

[Rd 371 IE]

The catalytic activity of palladium in acetylene hydrogenation has been studied by *Y. Inoue* and *I. Yasumori*. There are conspicuous differences in activity between Pd foils annealed at less than 200 °C (L) or above 800 °C (H) after cold-working. The overall activity of L foils is considerably larger than that of H foils, but the product ratio ethylene/ethane is about 30 for H foils and less than 15 for L foils. Fast changes in H_2 pressure during the reaction effects a rapid response in reaction rate on L foils; on H foils the rate changes slowly during a transition period of up to 1 h. Similar differences in response are observed on rapid displacement of H_2 by D_2. It is concluded that L catalyst works by adsorption of hydrogen on its surface, whereas the activity of H catalyst is due to hydrogen absorption in the bulk of the metal. / J. physic. Chem. *75*, 880 (1971) / –Hz.

[Rd 369 IE]

The reactions of triallylchromium(III) and of tetraallyldichromium(II) with 2-butyne have been investigated by *R. P. A. Sneeden* and *H. H. Zeiss*. The catalytic activity of triallylchromium in the polymerization of olefins is already well-known. Both chromium compounds mentioned were allowed to react with 2-butyne under identical conditions; in each case the same four products were obtained, but in different relative amounts. (1,2,3,4-Tetramethyl-, pentamethyl-, and hexamethylbenzene, along with traces of 1,2,3,5-tetramethylbenzene.) Allyl groups originally bonded to chromium are not involved in product formation except in the case of hexamethylbenzene. The mechanisms of these reactions remain unexplained. / J. Organometal. Chem. *28*, 259 (1971) / –Ee.

[Rd 368 IE]

For the IR analysis of gas mixtures a modified matrix isolation method is suggested by *M. M. Rochkind*; it is called pseudo matrix isolation (PMI) by the author. The gas is diluted 1:100 with nitrogen, and the mixture is frozen in "pulses" of 0.1 to 0.5 mmoles onto an IR transmitting substrate cooled by liquid H_2. The technique compares favorably with conventional IR methods of gas analysis since rotational structure of gas spectra is suppressed and intermolecular interactions modifying the characteristic frequencies in pure frozen gases are virtually eliminated. The method is suitable for qualitative and quantitative analyses; detection limits of 0.05 μmoles per cm^2 covered with the frozen mixture are not uncommon. / Spectrochim. Acta *27 A*, 547 (1971) / –Hz.

BOOK REVIEWS

Physikalische Chemie (Physical Chemistry). By *E. A. Moelwyn-Hughes*, edited and translated by *W. Jaenicke* and *H. Göhr*, with the special assistance of *H.-D. Sabel*. Georg Thieme Verlag, Stuttgart 1970. 1st ed., 714 pp., 269 Figs., 309 Tables. DM 59.80.

The German translation of the second English edition of the well-known book by *Moelwyn-Hughes* is very different in structure from the textbooks on physical chemistry that have been used until now in German universities. The first five chapters (about 150 pages) deal with the principles of the kinetic theory of gases, quantum theory, and chemical thermodynamics. Separate chapters are devoted to the intermolecular energy and partition functions. Considerable space (about 100 pages) is allotted to monatomic, diatomic, triatomic, and polyatomic molecules, including the discussion of light dispersion, light absorption, the Raman effect, and X-ray and electron scattering. Chapters 12 to 17 (about 200 pages) deal with the states of matter (crystalline state, gaseous state, metallic state, liquid state, solutions, ions). The chapter on interfacial phenomena is followed by the discussion of the chemical equilibria in homogeneous systems and of the equilibria in heterogeneous systems, which also embraces phase equilibria and electromotive forces. The last three chapters, which occupy about 100 pages, deal with kinetics. Some mathematical problems are discussed in an Appendix.

This arrangement of the material has both advantages and disadvantages. The reader who has already been introduced to physical chemistry will welcome the self-contained treatment of the monatomic or polyatomic molecules, the states of matter, or kinetics. He will learn much from seeing how many problems can be solved by simple models with the aid of statistics or how various theories are used in attempts to deal with a given problem. While the beginner will find the first five chapters relatively easy to understand, he will have difficulty in recognizing the relations between the various thermodynamic equations derived, since items that belong together are often necessarily situated far apart because of the arrangement of the book.

An excellent introduction to the use of statistical thermodynamics is offset by a quantum-mechanical treatment of the chemical bond that is too brief by present-day standards.

Very commendable features are the numerous references and the many exercises, which include not only calculations but also many questions designed to test the student's understanding.

The book would probably make excessive demands on the beginner, but it is a true mine of information for the advanced student.

Gerd Wedler [NB 952 IE]

Undergraduate Instrumental Analysis. By *J. W. Robinson*. Marcel Dekker, Inc., New York. 1st Edit., 379 pp., *ca.* DM 44.—.

During the past decade the methods of instrumental analysis – in particular absorption spectroscopy in the IR, UV, and visible ranges, NMR spectroscopy, mass spectrometry, and gas chromatography – have become a fundamental part of inorganic and organic chemistry. Nevertheless, up to the present no generally accepted methods have been developed in West Germany for the teaching of these techniques.

The present book attempts, with considerable success from the instructional point of view, to present instrumental analysis to the beginner along the lines of "What is instrumental analysis?" After a general introduction (survey of analytical methods, observation of errors, sample handling, *etc.*), the book gives an introduction to spectroscopy and the basic principles of spectrometric systems. Then follow chapters on NMR, IR, and Raman spectroscopy, UV absorption spectroscopy, atomic absorption, colorimetry and polarimetry, flame photometry, emission spectroscopy, X-ray spectroscopy, chromatography, thermal analysis, mass spectrometry, and electrochemistry. In each chapter the theoretical and practical principles of the method are described, and an indication is given of the range of applications on the basis of simple and (in general) well chosen examples. Each chapter

closes with a bibliography, notes on instructive experiments for the reader to perform in order to drive home what he has learnt, and problems. The material is extremely well arranged, and the illustrations (as far as equipment is concerned, at any rate) are useful for teaching purposes.

To whom could this book be recommended? Only students in their first year, who are studying instrumental analysis as such within the framework of a general chemistry course or of specific lectures and practical sessions, but who are not interested in the individual techniques. The very number of methods treated shows that with its 379 pages this book can only be regarded as an introduction; thus, the chapter on mass spectrometry occupies only 17 pages. A student involved in practical work in inorganic, organic, or physical chemistry, who wants to know only about the methods of specific interest to himself (*e.g.* mass spectrometry, IR, UV, and NMR spectroscopy) and their possible range of applications, will reject the book as "too elementary" and turn to more reasonably priced handbooks. Students of biology, medicine (clinical chemistry), and members of the academic profession, who only require a superficial knowledge of the individual methods of instrumental analysis will find the book's approach admirably suited to their requirements.

The book can be heartily recommended to all concerned with the teaching of instrumental analysis, for this is a truly impressive demonstration of how even complicated theoretical and practical principles can be presented simply and in the way most suitable for teaching purposes.

4. AUG. 1971

Non Aqueous Solvents. By *T.C. Waddington.* Studies in Modern Chemistry Series, edited by *W.C. Agosta* and *R.S. Nyholm.* Thomas Nelson and Sons Ltd., London 1969, 1st Edit., 88 pp., DM 22,—.

The selected ranks of this series, aimed particularly at advanced students, where each volume reflects the latest situation in its own speciality, are now joined by a new work on non-aqueous ionizing solvents. The author has considerable experience in this field, not only from his own research on anhydrous liquid hydrogen halides and anhydrous sulfuric acid but also as the editor of a collective work (Non Aqueous Solvent Systems. Academic Press, London and New York 1965).

The book deals on the one hand with solvents similar to water, *i.e.* weakly self-dissociating protonic solvents such as ammonia, hydrogen fluoride, and sulfuric acid in Chapter 2 and aprotic solvents such as the arsenic halides, antimony trichloride, iodine monochloride, and bromine trifluoride in Chapter 5; on the other hand, it also discusses solvents that do not resemble water so closely, since they either hardly dissociate of themselves at all, such as dinitrogen tetroxide and sulfur dioxide in Chapter 3 and the oxide-halides nitrosyl chloride and phosphorus oxychloride (Chapter 4), or are practically completely dissociated, such as the molten salts (Chapter 6). Wherever possible, the solvents are compared with one another within each chapter. The general ideas are summarized in Chapter 1, which serves as an introduction.

The author does not aim at a complete survey of the material concerned, but rather, by means of selected examples, at a complete review of the principles governing the behavior of ionizing non-aqueous solvents. From the viewpoint of coordination chemistry, this is most successful. However, the Brønsted and Lewis theories for the acid-base behavior of protonic and aprotic solvents are given extremely scanty treatment, and the solvent theory, which has rendered such important service in the development of the chemistry of water-like solvents, is not even mentioned.

The author follows an old-established practice in not quoting original papers but rather reviewing articles from monographs. This, together with the well thought out problems at the end of each chapter, emphasizes the fact that this volume is the instruction manual of choice for anyone looking for an introduction to ionizing non-aqueous solvents.

Jochen Jander [NB 966 IE]

Die Physik. Ihre Sprache und Untersuchungsmethoden (Physics. Its Language and Methods of Investigation) by *K. Kramer* and *K. Lüders.* Verlag Chemie, Weinheim 1970. 1st Edit., viii, 157 pp., 102 figures, 12 tables, bound, DM 22.50.

We are told in the foreword that the book is based on a series of university extension courses. The authors begin with an introduction to some fundamental concepts which they discuss with reference to selected subject areas (electron guns, optics of charged particles, vacuum, low temperatures, high magnetic fields, particle accelerators, electron spin resonance, nuclear spin resonance, structural analysis, and conductivity). They go on to give the reader an outline of the modern investigation methods used in physics. Naturally enough, within the scope of such a book it is impossible to proceed beyond the basic principles of the chosen subjects. The authors have succeeded in presenting a vivid impression of the wide range of modern methods of investigation. An evident desire always to press on quickly to topical problems is no doubt responsible for the fact that even relatively complicated quantitative relationships are sometimes presented in a highly concise form. To derive full benefit from the book it is desirable that the reader should already have acquired some knowledge of physics, or that he should be in the process of doing so within the framework of an appropriate course of study.

Werner Buckel [NB 967 IE]

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry), 8th fully revised edition. System No. 49: Niobium. Part A.

Historical, Occurrence. The Element. Principal editor: *Herbert Lehl.* 1969. iv, xvi, 356 pp., 76 figures, linen. DM 426.—.

The first chapter of Part A presents the absorbing history of the discovery of niobium and the naming of the element. It was not until 1949 that the name was finally settled by a IUPAC decision in Amsterdam. A short paragraph on the physiological effects of niobium (with the rather vague observation that the toxicity of metallic niobium may be assumed to be similar to that of vanadium, and yet experiments are then described that gave no indication that niobium has a toxic action) and its compounds is followed by a chapter on the industrial preparation of the raw

[1] Cf. Angew. Chem. internat. Edit. *10*, 204 (1971).

materials. Special technical difficulties are encountered in the separation of the elements niobium and tantalum.

The remainder of the volume describes, in almost 330 pages, the preparation and the physical and chemical properties of the element, which is obtained by reduction of the oxides, halides, and oxide halides or by electrolytic methods. The growing importance of niobium as a material can be seen from the space devoted to the description. The use of niobium as the metal in electrical engineering and in reactor construction has necessitated an increase in production by more than 1000% over the past 10 years. New uses are also continuously being found for niobium compounds. Niobium hydride, which has a higher H density than water, is a useful neutron moderator. Niobium oxides are used as electrical resistors, ferroelectrics, piezoelectrics, catalyst materials, fluxes, *etc.*, Niobium nitrides, niobium borides, and niobium carbides are used as electrical resistors. Niobium carbides are also used as "hard metals". Considerable space is devoted to the 14 isotopes of niobium, their enrichment, and their separation.

Because of the metallurgical importance of niobium, the crystallographic, mechanical, electrical, and magnetic properties of the element have been intensively studied. This is true in particular of its superconductivity (superconductor of the 2nd type). Of all elements, niobium has the highest jump-temperature, *i.e.* 9.49 °K for highly purified niobium. The 26 pages devoted to the chemical behavior of the element are again a reflection of the increasing use of niobium as a material.

The remaining 40 pages of the volume deal with the detection and determination of the element. The articles that have been published since 1950, on detection and the special methods of detection and determination of the element, and those that have appeared since 1955, on determination and separation, are grouped and listed in a very clear manner.

The literature is covered in full up to the end of 1965, and in part up to 1968. It should be pointed out that the volume contains very large quantities of information taken from literature that is not easily accessible.

System No. 49: Niobium. Part B 1.

Compounds up to Niobium and Bismuth. Principal editor: *Herbert Lehl.* 1970. vi, xxvi, 424 pp., 121 figures, linen DM 515.—.

Whereas Part A, which deals with the element, is of particular interest to physicists, metallurgists, and engineers, Part B, of which this is the first volume, will appeal mainly to the chemist, though the compounds of niobium also include substances that are of physical and technical interest now, and will probably be even more so in the future (see the review of Part A). These will undoubtedly include the compounds in the niobium-nitrogen system, in which superconducting high-temperature phases having the approximate composition NbN occur.

In accordance with the Gmelin system, however, the compounds with hydrogen and oxygen are discussed first in the present volume. The niobium-oxygen system is extremely rich in phases. The discussion of the niobium-nitrogen compounds, which were briefly mentioned above, is followed by the chemistry of the niobium fluorides, chlorides, bromides, and iodides. The niobium-halogen systems are extremely rich in nonstoichiometric compounds, which result from the tendency of the element to form cluster ions such as $[Nb_6Cl_{12}]^{n+}$ or $[Nb_6Br_{12}]^{n+}$ containing niobium-niobium bonds. These cluster ions, the structure of which has only recently been elucidated, are described jointly for the systems Nb—Cl and Nb—Br. Structural groups containing Nb—Nb bonds, such as $[Nb_6I_8]$ or $[Nb_2I_8]$, are also found in the niobium-iodine system.

Among the niobium(v) oxide chlorides $NbOCl_3$, NbO_2Cl, $Nb_4O_9Cl_2$, and Nb_3O_7Cl described in the literature, it is probable that only $NbOCl_3$ exists as an equilibrium phase in the system $NbCl_5$—Nb_2O_5. In the niobium-sulfur system, which is described next, there are subsulfides $Nb_{1+x}S$, monosulfides $Nb_{1-x}S$, sesquisulfides $Nb_{1+x}S_2$, disulfides, and trisulfides. Niobium atoms are also linked directly to one another in the niobium(IV) sulfide halides, *e.g.* the compound NbS_2Cl_2. The extremely large number of phases is again striking in the niobium-selenium and niobium-tellurium systems.

The niobium-boron system, which is discussed in the next section, is characterized by two congruently melting phases NbB_2 and NbB, two incongruently melting phases Nb_3B_4 and Nb_3B_2, and two eutectics. Apart from their industrial importance, the niobium borides are interesting from the standpoints of lattice structure, electronic structure, and chemical bonding. Bonding relations of similar complexity are also found for the carbides and silicides of niobium. The chapter on niobium-carbon is confined to the systems Nb—C, Nb—C—O, Nb—C—N, Nb—C—N—O, and Nb—C—B—(N), whereas salts of organic acids, carbonyl compounds, organoniobium compounds, and coordination compounds are discussed in Volume B 3.

The niobium-silicon chapter deals not only with the niobium silicides Nb_4Si, Nb_3Si, Nb_5Si_3, and $NbSi_2$ but also with the systems Nb_2O_5—SiO_2, Nb—Si—N, Nb—Si—B, and Nb—Si—C. A number of compounds that are of interest to the molecular chemist, though they have not yet been adequately investigated, are found in the niobium-phosphorus system, in which, besides the niobium phosphates, a series of compounds of $NbCl_5$ and $PCl_5([PCl_4][NbCl_6])$ or $OPCl_3$ and the niobium phosphorus nitride chlorides such as $NbNCl_2(PNCl_2)_{10}$ or $NbOCl_2(PNCl_2)_{10}$ are discussed. The volume ends with reports on the niobium-arsenic, niobium-antimony, and niobium-bismuth systems, which have not yet been studied very deeply.

The literature is fully covered up to 1968 in Volume B 1, and a number of important articles of later date are also mentioned.

Ekkehard Fluck [NB 968 IE]

Grundlagen der Organischen Chemie (Fundamentals of Organic Chemistry), by *H. R. Christen.* Verlag Sauerländer, Aarau, und Diesterweg-Salle, Frankfurt (Main) 1970. 1st Edit., 928 pp., numerous figures, bound DM 72.—.

The "Grundlagen der allgemeinen und anorganischen Chemie" (Fundamentals of General and Inorganic Chemistry) published by the same author in 1968 is now followed by the organic counterpart. A similar layout and arrangement has been used here. The subject matter is presented from the point of view of the reactions and the physicochemical principles, and the description of substances is deliberately avoided.

However, this layout is no longer as unconventional in a textbook of organic chemistry as the author suggests in

the foreword. Most of the modern textbooks in English in particular are arranged in this way. The layout of the present book is very similar *e.g.* to that of the excellent textbook by *D. I. Cram* and *G. S. Hammond*.

The present book is divided into three large parts:

1. Survey of the principal groups of organic substances.
2. Organic reactions.
3. A few special chapters on organic chemistry.

The first part contains an introduction, which is essentially a discussion of bonding states and of analysis. This is followed by a discussion of hydrocarbons, compounds with simple functional groups, and compounds with unsaturated functional groups.

The second part is divided into the chapters: General, Structure and Reactivity, Nucleophilic Substitutions on Saturated C Atoms, Elimination Reactions, Electrophilic Additions to C—C Multiple Bonds and Related Reactions, Other Additions to Double and Triple Bonds, Nucleophilic Substitutions on Unsaturated C Atoms, Nucleophilic Additions to Carbon-Hetero Multiple Bonds, Electrophilic Substitutions on Aliphatic C Atoms, Aromatic Substitution I: Electrophilic Substitution, Aromatic Substitution II: Nucleophilic Substitution, Free-Radical Reactions, Oxidations and Reductions and Rearrangements.

The third part contains the chapters: Heterocyclic Compounds, Lipids, Terpenes, Steroids, Carbohydrates, Proteins and Conjugated Proteins, Synthetic High Molecular Weight Substances, and Dyes.

A set of questions is appended to the subject matter of each chapter. The choice of examples and the presentation of the material with reference to physico-chemical aspects and reaction mechanisms are excellent. The formulas, figures, and tables are very clear and well selected. This textbook can be unreservedly recommended, and should play an important part in instruction at German universities in the near future.

However, I am of the opinion that a textbook of this type is suitable for the study of organic chemistry only if the student also has access to a book that concentrates on the material side. This is in fact recommended by the author in his foreword.

Hermann Stetter [NB 969 IE]

Free Nitroxyl Radicals. By *E.G. Rozantsev*, translated by *B. J. Hazzard*. Plenum Press, New York–London 1970. 1st Edit., xiv, 249 pp., $ 19.50.

Nitroxyl radicals, which are mainly derived from the 2,2,6,6-tetramethylpiperidine-1-oxyl type, are among the most interesting and most extensively studied radicals of organic chemistry because of their ready availability, their unusual stability (which enables them to undergo many chemical reactions without loss of their free-radical nature), and their very simple ESR spectra. Much of the existing knowledge of these radicals is due to the work of *E.G. Rozantsev*, who leads a section dealing with stable free radicals at the Moscow Academy of Sciences, and his colleagues. This is the source, not only of the main syntheses and transformations that proceed without loss of free-radical character, but also of many physical and biochemical studies concerned with the use of these radicals in a wide range of fields. Their importance has grown immensely in biochemistry during recent years, partly in connection with the concept of spin-labeling.

The translation of the book from the original Russian into English provides easier access to the results of these studies, which have appeared in numerous publications, mostly in Russian journals. It is regrettable that the more recent literature (published since 1968) is not covered, particularly in view of the extremely interesting developments that have taken place during this period. Moreover, the translation (surprisingly even in the short introductory chapter, which was not taken from the original) contains a series of outdated or incorrect structural formulas (*e.g.* pp. 2, 32, 48, 149) and some textual obscurities that could have been avoided by a more competent translator.

The book, which is intended mainly for the preparative chemist, requires no mathematical background and is easy to understand. It contains good illustrations of the ESR spectra, as well as all the important data on the chemistry and the physico-chemical properties of this group of radicals. The chapters on the di-, tri-, and tetraradicals, the mutual effects of the ESR spectra in connection with the conformation, and the review of the possible applications, which are becoming increasingly numerous, are particularly interesting. The book ends with a preparative section containing detailed instructions for the synthesis of various nitroxyl radicals.

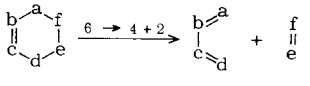
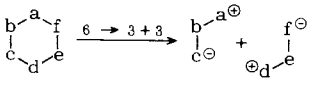
Generation of Carbenes by Thermal Cycloelimination



By Reinhard W. Hoffmann[*]



The growth of interest in carbenes has led to a need for methods that allow their generation in unimolecular decomposition processes, possible also in the gas phase, without troublesome by-products. Besides the decomposition of diazo compounds, thermal cycloeliminations from carbocycles and heterocycles with odd numbers of ring atoms have been found to be suitable for this purpose. The problems, structural requirements, and scope of such cycloelimination reactions are discussed in the present progress report. The advantages of carbene generation by thermal cycloelimination are demonstrated with reference to dialkoxycarbenes, which are very difficult to obtain in any other way.

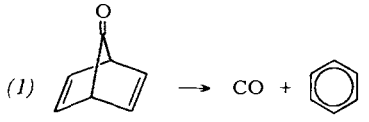
1. Introduction

Cycloelimination is the cleavage of a carbocycle or heterocycle into two or more, usually independent fragments. Cycloelimination is thus defined as the reverse of a cycloaddition. It can be classified in the same way as the latter[1], and is also subject to the selection rules[2] imposed by the conservation of orbital symmetry.

Cycloeliminations from a ring having an even number of members can lead to fragments that all contain an even number of former ring atoms; the retro-Diels-Alder reaction serves as an example of a [6→4+2] cycloelimination. Since even fragments, such as $>C=C<$, $N\equiv N$, $>C=\underset{|}{C}-\underset{|}{C}=C<$, have saturated valences and are therefore of relatively low energy content, a [6→4+2] cycloelimination is normally favored over a [6→3+3] cycloelimination[3], which leads to odd fragments.

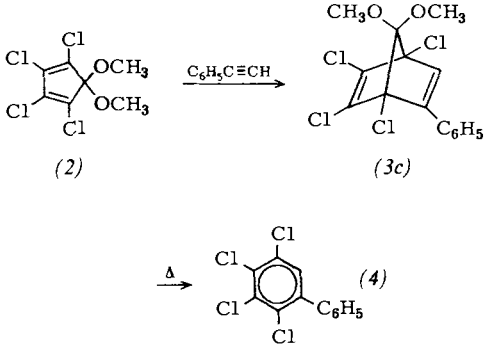
[*] Prof. Dr. R. W. Hoffmann
Institut für Organische Chemie der Universität
355 Marburg, Lahnberge (Germany)

Odd fragments generally[4] do not have their valences saturated and are therefore reactive intermediates such as 1,3-dipoles, carbenes, or nitrenes. Cycloelimination from rings with odd numbers of ring atoms must inevitably yield such odd fragments.



Cycloeliminations lead in a coupled reaction to two or more fragments[5]. If one of the fragments is a high-energy, reactive intermediate, thermal cycloelimination can still be achieved under relatively mild conditions provided that the other fragment is thermodynamically very stable, as in the case of molecular nitrogen or benzene. In cycloeliminations of this type, the exothermic formation of the stable fragment makes the endothermic formation of the reactive intermediate possible.

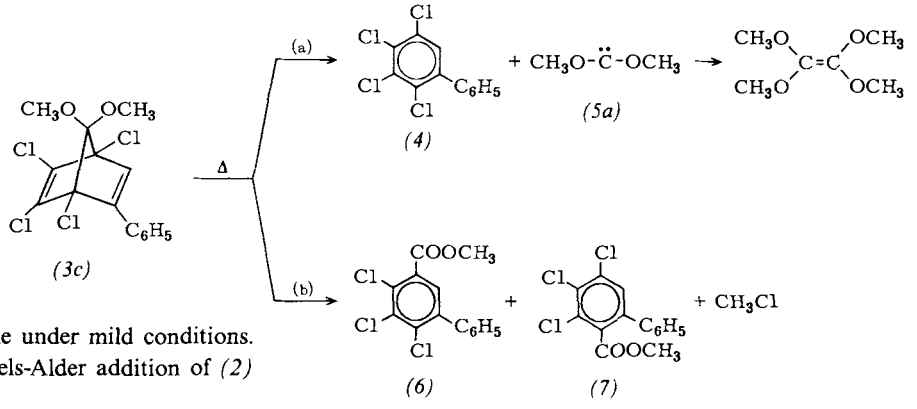
Cycloeliminations may be thermally or photochemically initiated, and do not require the presence of other reagents. It follows from this and from the reasons given earlier that cycloeliminations provide an ideal method of producing bifunctional reactive intermediates in the absence of interfering reactants. Hence, carbenes and 1,3-dipoles, as well as torsionally strained alkenes, angularly strained cycloalkynes, and dehydroaromatic compounds, can be generated, to study their intramolecular and intermolecular stabilization reactions.



The present report summarizes what we have learned so far about the production of carbenes by thermal cycloeliminations, while the progress report that follows[6] presents a survey of photochemical cycloeliminations.

2. Cycloeliminations from Norbornadienes

The thermal [5→4+1] cycloelimination of carbon monoxide from norbornadienone *(1)* proceeds so readily that *(1)* has so far been intercepted only as a reactive intermediate[7],

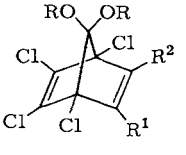


but has not been isolated[8]. The cycloelimination of carbenes, closely related to carbon monoxide in structure, should therefore also be possible under mild conditions. This is demonstrated by the Diels-Alder addition of *(2)*

to phenylacetylene, which led not to *(3c)* but to *(4)*[9]. Reinvestigation[10, 11] showed that *(3c)* can be isolated if the reaction is carried out under mild conditions. Only at 100—150 °C does the substance decompose with formation of *(4)* and [as a further reaction product of dimethoxycarbene *(5a)*] tetramethoxyethylene (see Scheme 1).

Cleavage of the bridge to give the esters *(6)* and *(7)* competes with this thermal cycloelimination of carbene *(5a)*.

β-Chloroalkyl esters are similarly formed on thermolysis of the cyclic acetals *(3j)*—*(3n)*. The competition of ring



Scheme 1.

cleavage and cycloelimination is typical of the thermolysis of many 1,2,3,4-tetrachloro-7,7-dialkoxynorbornadienes, as shown in Table 1.

Closer investigation of the thermal decomposition of *(3c)* showed[11] that it is a first order reaction and that the rate of cycloelimination [path (a)] is practically independent of the polarity of the solvent ($k_{CH_3CN}/k_{cyclohexane} \approx 4$), whereas the ring cleavage [path (b)] is strongly favored by polar solvents ($k_{CH_3CN}/k_{cyclohexane} \approx 400$). The com-

[a] Products of this reaction path were only detected qualitatively.
[b] The free dicarboxylic acid was used for the reaction.

petition between paths (a) and (b) can therefore be controlled by suitable choice of solvent (cf. Table 2), the cycloelimination predominating in apolar media.

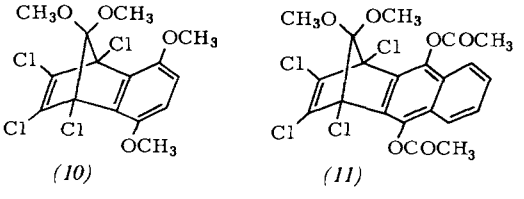

Table 2. Ratio of the reaction paths (a):(b) (cf. Scheme 1) in the thermolysis of *(3c)* as a function of the solvent [10, 11].

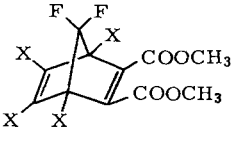
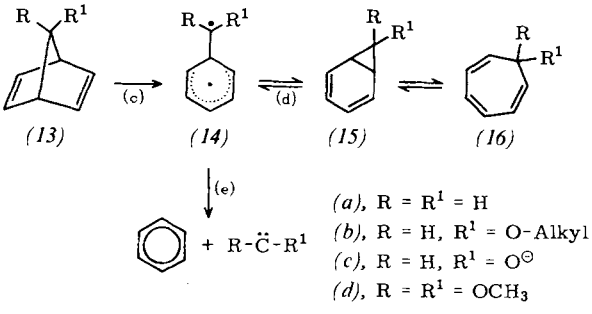


Solvent	115 °C (a):(b)	125–130 °C (a):(b)
Cyclohexane	12.6:1	
CCl_4		1.7:1
Pure		1.4:1
1,2-Dimethoxyethane	0.54:1	
CH_3OH	0.31:1	0.65:1
Pyridine		0.41:1
Acetonitrile	0.14:1	

Assuming that formation of *(6)* begins with rate-determining cleavage of *(3c)* to form the zwitterion *(8)*, it is understandable that the process is favored by polar solvents. *(8)* corresponds to the intermediate of a nucleophilic aromatic substitution, and should therefore readily lose chloride *via (9)* to give *(6)*[17]. In the pyrolysis of 1,2,3,4-tetrachloro-7,7-dimethoxynorbornadiene *(3a)* in ethanol, some ethyl 2,3,4-trichlorobenzoate, evidently formed from a cation analogous to *(9)*, was isolated. This product could not have been formed by transesterification of the initially formed methyl ester, since this reaction is too slow under the applied conditions[12].

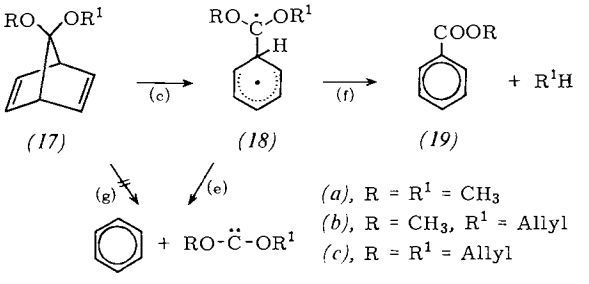
The ring cleavage [path (b)] is favored not only by polar solvents but also by substituents on the ring that stabilize a negative charge. Thus path (b) is considerably more prominent in the thermolysis of *(3b)* than in that of *(3a)*. Finally, the reaction of *(2)* with esters of acetylenedicarboxylic acid leads [*via* the adduct *(3)*, $R^1 = R^2 = COOCH_3$] only to ring-opened products[18–20]. (Similar observations are reported in [21, 22].)



As expected, the cycloelimination of dimethoxycarbene *(5a)* becomes increasingly easy with increasing stability of the resulting aromatic compound. Thus the temperatures required for cycloelimination from *(10)* or *(11)* are about 100 °C higher than those required for cycloelimination from *(3a)*[10, 21], since with *(10)* or *(11)* the gain in aromatization energy is less than on formation of *(4)*. Similarly, difluorocarbene was liberated from *(12)* in good yields only at temperatures above 450 °C[23]. Thus it must be stabilized to a smaller degree than dimethoxycarbene *(5a)*.

2.1. Mechanism of the Cycloelimination

The cycloelimination of a carbene from a norbornadiene may proceed in one step as a symmetry-allowed cheletropic reaction. However, a non-concerted path is nevertheless possible. This becomes clear when one considers the cycloeliminations from *(3)* in the light of the thermal behavior of other norbornadiene derivatives (see Scheme 2).



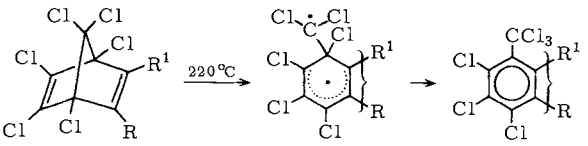
Scheme 2.

Thus norbornadiene *(13a)* isomerizes when heated to give cycloheptatriene *(16a)*[24]. Similar reactions are found for 7-alkoxynorbornadienes *(13b)* and 7-phenylnorbornadiene[25], as well as for norbornadien-7-olate *(13c)*[25a]. The isomerization *(13)*→*(16)* has been formulated as proceeding *via (14)* and *(15)*[25,26]. A comparison of the temperatures required for the rearrangement, *i.e.* 450 °C for *(13a)*, 270 °C for bornadiene[27], 170 °C for *(13b)*[25], and 25 °C for *(13c)*[25a], showed that the rate-determining step *(13)*→*(14)* is facilitated by radical-stabilizing substituents on C-7. *(13d)* should therefore isomerize particularly readily; in this case, however, cycloelimination of dimethoxycarbene *(5a)* was observed on heating at 150 °C[28]. From the above, it is therefore deduced that the same step (c) is involved and is rate-determining in the cycloelimination as well as in the isomerization. This readily explains why the cycloelimination of *(5a)* from *(3a)* proceeds at a temperature about 70 °C lower than that required in the case of *(13d)*, since the four chlorine substituents in *(3a)* should considerably facilitate the formation of the intermediate *(14)*.

According to this view, it is not at the stage *(13)* but at *(14)* that the reaction path branches to give either cycloelimination or isomerization to *(16)*. Since the ring closure of *(14)* to form norcaradiene *(15)* [path (d)] should be exothermic, the cleavage of *(14)* [path (e)]

can compete with path (d) only if it also is exothermic [unless the temperatures chosen are so high that the equilibrium between *(14)* and *(16)* is established (cf. Section 3)]. Of course, exothermicity is conveyed to path (e) not only by the stability of the aromatic fragment formed but also by that of the carbene.

Evidence indicating that the cycloelimination of dialkoxycarbene from *(13d)* proceeds *via (14)* as an intermediate can be obtained from intramolecular competition experiments in which an additional partitioning of the reaction at *(14)* is introduced (Scheme 3). The intermediate *(18a)*≡*(14d)* can thus in principle undergo an irreversible free-radical elimination to form *(19a)* [path (f)], but this is only of minor importance compared to cycloelimination in the gas-phase pyrolysis of *(17a)*[28–30].

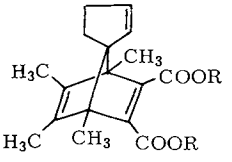


Scheme 3.

Elimination of a radical R or R^1 from a dialkoxyalkyl radical such as *(18)* should become more facile with increasing radical stability of R or R^1[31]. Thus in the pyrolysis of *(17b)*, the formation of *(19b)* and the cycloelimination of the carbene were equally fast[29,32], whereas in the case of *(17c)* the formation of *(19c)* predominated over the cycloelimination. Elimination of the allyl radical thus proceeds at the expense of carbene formation. This is in accordance with Scheme 3[33], provided the rate of step (e) does not vary much for the substrates *(18a)*—*(18c)*.

Finally, other irreversible reactions starting with *(14)* can completely suppress cycloelimination, as occurs when *(20)* is heated above 220°C[11,34]. In this case rearrangement *via (21)* to *(22)*, without elimination of dichlorocarbene, is observed.

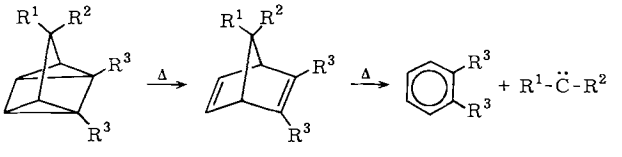
The hypothesis that the cycloelimination of dimethoxycarbene *(5a)* from *(13d)* proceeds *via (14d)* can also be confirmed by other experiments, since the steps between *(14)* and *(16)* in Scheme 2 are very probably reversible, as has been shown for a derivative with $R=R^1=CH_3$[35]. *(14d)* should thus be accessible independently by heating



(20) *(21)* *(22)*

R	R^1
$ClCH_2$	$ClCH_2$
H	$ClCH_2$
H	CH_2OCOCH_3
H	$COOC_2H_5$
H	C_6H_5
$COOCH_3$	$COOCH_3$

(16d), a process that should give the same products as the thermolysis of *(13d)*. *(16d)* does in fact decompose into dimethoxycarbene and up to 54% of benzene at 130 to 350°C[36,37].

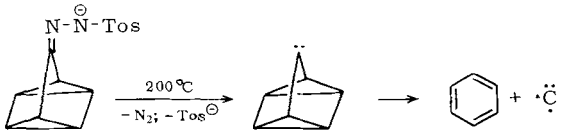


The pyrolysis of *(16d)* also leads to products[38] that are not formed on thermolysis of *(13d)*. *(16d)* cannot therefore be an intermediate in the pyrolysis of *(13d)*, as was once suggested[25].

It is quite possible, however, that the equilibrium between the compounds of the types *(14)* and *(16)* is established in the cycloelimination of an unstabilized carbene, *e.g.* of 2-cyclopenten-1-ylidene from *(23)* at 350°C[39].

(23)

Quadricyclane derivatives *(24)* can also be used for cycloeliminations of this type. As can be seen from Table 3, this requires higher temperatures, and it can therefore be assumed that *(24)* does not decompose directly to products but undergoes fast cycloelimination only after symmetry-forbidden isomerization to *(25)*. *(25e)* has in fact been isolated upon careful pyrolysis of *(24e)*[40].



(24) *(25)* *(26)*

Table 3. Cycloeliminations from quadricyclane derivatives *(24)*.

	Substrate *(24)*				*(26)*		
	R^1	R^2	R^3	*T* (°C)	yield (%)	further products	ref.

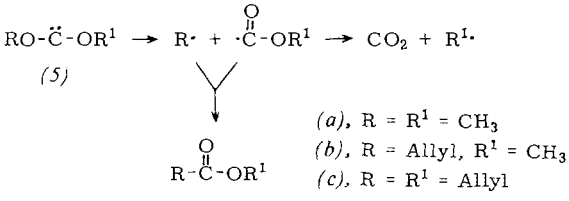
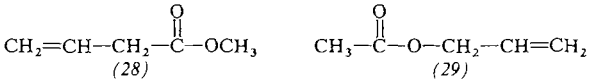
[a] Detected qualitatively.

A carbene functionality at the one-carbon bridge of norbornadiene (or quadricyclane) is sufficiently rich in energy to allow the elimination of the bridge as atomic carbon[41b].



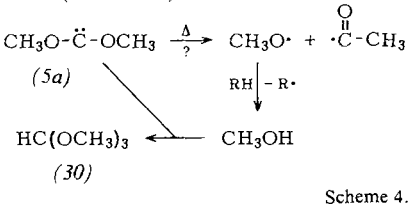
2.2. The Carbenes Liberated

In most of the examples investigated so far, a dialkoxycarbene was liberated by cycloelimination from a 7,7-disubstituted norbornadiene. If the cycloelimination leads to a 1,3-dioxolan-2-ylidene (2-carbena-1,3-dioxolane) *(27)*, this immediately undergoes further cycloelimination[42] to give carbon dioxide and an olefin[11,12,28,41a].



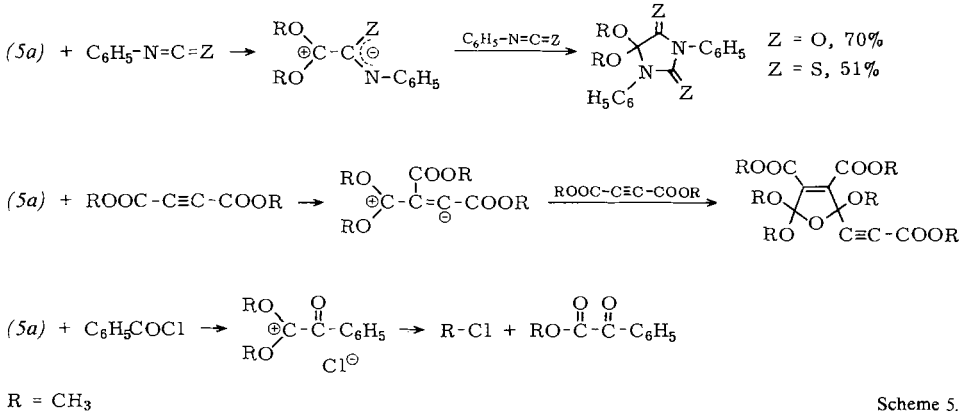
(27)

In the case of dimethoxycarbene *(5a)*, the nature of the further reaction products is strongly dependent on the manner in which the cycloelimination is carried out. If *(3c)* is pyrolyzed rapidly in the condensed phase, corresponding to a high stationary concentration of *(5a)*, the carbene is almost completely dimerized to tetramethoxyethylene[10,11]. If on the other hand *(3c)* is pyrolyzed at a high dilution in the gas phase, *(5a)* isomerizes to form methyl acetate[10,11,28,43]. This rearrangement probably proceeds *via* free radicals in which formation of methyl acetate competes with further fragmentation into carbon



dioxide and ethane[28]. This fragmentation is favored by residues R that form stable free radicals. Thus the fragmentation of *(5b)* predominates over the rearrangement at 240 °C, and *(5c)* gives only carbon dioxide and biallyl[32].

In the rearrangement of *(5b)*, the migration of the allyl residue to give *(28)* competes with that of the methyl group to give *(29)*. The allyl residue migrates only about

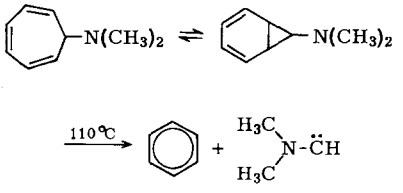


twice as rapidly as the methyl, indicating that free-radical character is not yet very pronounced in the transition state, *i.e.* that the transition state of the rearrangement occurs early on the reaction coordinate. Moreover, deuterium labeling suggested that in the migration of the allyl residue, the allyl moiety separates completely from the remainder of the molecule, as is necessary for a free-radical rearrangement. Thus an equally conceivable [2,3]-sigmatropic process was not observed at the high temperature of 240 °C[32].

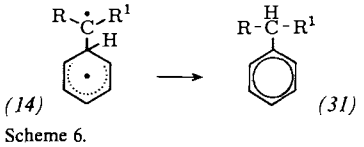
It is not yet certain whether dialkoxycarbenes undergo a different type of thermal decomposition into alkoxyl and acyl radicals in the condensed phase[44,45]. In any case, 60—70% of methyl orthoformate *(30)* is formed on pyrolysis of *(3c)* or *(13d)* in the presence of hydrogen donors[11,28]. The formation of this ester could proceed as shown in Scheme 4. The propensity of *(5a)* to add methanol is confirmed independently by the fact that *(5a)* can be intercepted in good yields as *(30)* in the pyrolysis of *(3c)* in methanol[10] (cf. also[36]).

Scheme 4.

Dialkoxycarbenes have also been intercepted in many other reactions that leave no doubt as to their formation in the cycloelimination from 7,7-dialkoxynorbornadienes. Thus the pyrolysis of *(3c)* in the presence of air gave dimethyl carbonate as an autoxidation product of *(5a)*[10,11], while *O,O*-dimethyl thiocarbonate was formed in the presence of sulfur[10]. A [1+2] cycloaddition of *(5a)* to electrophilic olefins has not yet been achieved[11,46], but as one would expect from its nucleophilic character, *(5a)* adds to electrophilic multiple bond systems to form 1,3-dipoles[47], the further reaction products of which have been isolated[46] (Scheme 5). The carbene *(5a)* has been acylated in a similar manner.



Scheme 5.

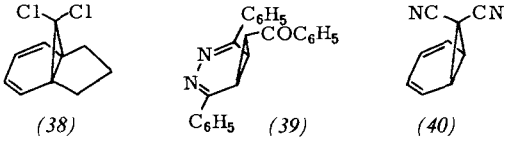


The cycloelimination from norbornadiene derivatives can be used not only for the liberation of dialkoxycarbenes, but also for the production of $(CH_3)_2Si$[48], $(C_6H_5)_2Si$[49], and $(CH_3)_2Ge$[50], as well as of C_6H_5P[51] and C_6H_5As[52], the stabilization reactions of which have not yet been investigated.

3. Cycloelimination from Norcaradienes

The thermal cleavage of 7,7-dimethoxycycloheptatriene *(16d)* into dimethoxycarbene *(5a)* and benzene (Section 2.1) was interpreted as a cycloelimination from a 7,7-dimethoxynorcaradiene *(15d)*. Cycloeliminations that probably proceed *via* norcaradienes can also be achieved from other cycloheptatriene derivatives. Thus dimethylaminocarbene is eliminated, though only in a yield of about 5%, from 7-dimethylaminocycloheptatriene at 110 °C[53,54].

A temperature of 470 °C is required for the cycloelimination of unsubstituted methylene from cycloheptatriene[55]. These [3→2+1] cycloeliminations are a reversal of the well-known [1+2] cycloaddition of carbenes to aromatic compounds[56]. When heated, cycloheptatrienes normally isomerize *via* norcaradienes and biradicals of the type *(14)* to form derivatives of toluene[35]. At the reaction temperature, which is usually higher than in the pyrolysis of norbornadienes, the intermediate *(14)* is stabilized by migration of a hydrogen atom to form *(31)*.



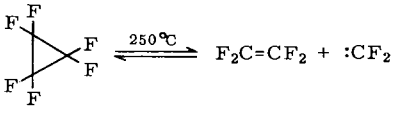
Scheme 6.

Cycloelimination of carbenes from norcaradienes can therefore be expected only if the carbene formed is sufficiently stabilized or if the hydrogen shift is not possible on structural grounds. The latter situation is found in the following examples.

When *(32)* is heated at 250 °C the intermediate *(34)* is formed *via* the norcaradiene *(33)* and eliminates methylene[57].

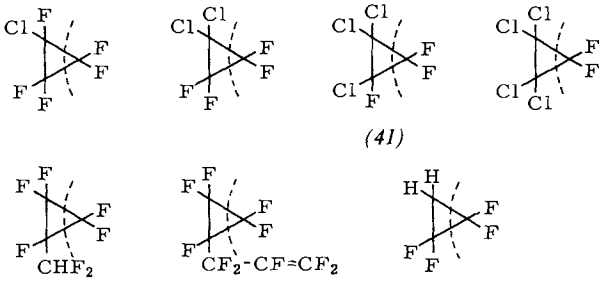
The intermediate *(36a)* that occurs in the thermolysis of 1,6-methano[10]annulene *(35a)*, on the other hand, does not liberate methylene but isomerizes to form *(37a)*[58]. Only when the carbene to be eliminated is also stabilized, as in the cases of *(35b)* and *(35c)*, is cycloelimination of the dihalocarbene observed in yields of more than 90% at 250 and 60 °C respectively[58, 59].

If the norcaradienes that are present only in equilibrium with cycloheptatrienes undergo thermal [3→2+1] cycloeliminations, the same should also be expected of norcaradienes that are present entirely as such. This is in fact so for *(38)*, which yields dichlorocarbene at 150 °C[58, 59], and for *(39)*, which loses benzoylcarbene at 195 °C[60].



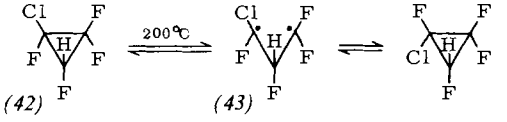
On the other hand, no dicyanocarbene is lost from norcaradiene *(40)* since isomerization to phenylmalononitrile (Scheme 6) occurs very readily[61]. However, cycloelimination, even of energy-rich carbenes, from norcaradienes can be achieved photochemically in medium to good yields[6, 60–62].

4. Cycloeliminations from Cyclopropanes



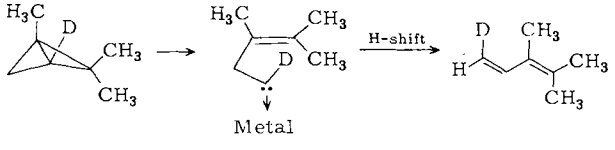
In a cycloelimination from a monocyclic system the gain in stabilization energy in the even fragment can no longer be as great as in the examples in the last section. It is therefore to be expected that [3→2+1] cycloeliminations of this type can be achieved thermally only if the carbenes liberated are stabilized and particularly low in energy.

Authentic[63] thermal cycloeliminations of carbenes are in fact known only for fluorinated cyclopropane derivatives, the deciding factor in this case probably being the low energy of difluorocarbene. Thus hexafluorocyclopropane liberates difluorocarbene in a yield of more than 85% at 250 °C[64, 65], and the carbene dimerizes to tetrafluoroethylene if it is not intercepted by cycloaddition to other olefins.



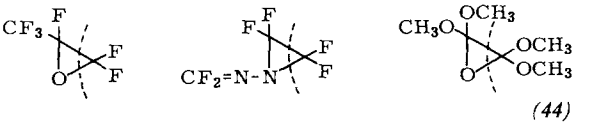
A cyclopropane ring can in principle be broken in three ways. Thus dichlorocarbene, chlorofluorocarbene, and difluorocarbene could be liberated from *(41)*. As is shown

by the following examples[65–67], only the most stable carbene, difluorocarbene, is liberated in such cycloeliminations at 160—270 °C.



(41)

The structurally similar compound *(42)* undergoes a clean *cis-trans* isomerization in the same temperature range[68] which is best explained by cleavage to form the biradical *(43)*. Therefore the cycloeliminations from the other perhalogenated cyclopropanes probably proceed nonconcertedly *via* an intermediate corresponding to *(43)*.

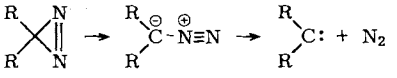


(42) *(43)*

Strained cyclopropane ring systems such as bicyclo[1.1.0]-butane derivatives undergo rearrangements when treated with $[Rh(CO)_2Cl]_2$, $[C_6F_5Cu]_4$, Cu_2Cl_2, or $HgBr_2$ at temperatures as low as 0—50 °C. This rearrangement is most readily accounted for in terms of a [3→2+1] cycloelimination to form a carbene-metal complex[68a]. Undoubtedly this process is considerably facilitated by the ring strain in the starting materials.

5. Cycloeliminations from Three-Membered Heterocycles

The thermal [3→2+1] cycloelimination is not confined to perhalogenated cyclopropanes. Perhalogenated oxiranes and aziridines also generate the most stable possible carbene, and do not split off the hetero atom, as is shown by the following examples[68–70].



(44)

(44), which is formed only as an intermediate, probably decomposes similarly into *(5a)* and dimethyl carbonate[71].

In the case of the oxiranes and aziridines, the cycloelimination may be preceded by electrocyclic ring opening to give a 1,3-dipole[72]. Whereas this has been verified for the photochemical cycloelimination of carbenes from oxiranes [6, 73], the question has not yet been answered for the thermal reactions described above.

The cycloelimination of a carbene from diazirines is particularly favored by the low energy of molecular nitrogen. Diazirines readily yield carbenes both thermally and photochemically; a preceding electrocyclic ring cleavage to give a diazoalkane has been detected at least in the latter case[74, 75].

Since the cycloeliminations from diazirines have already been reviewed[74, 76], we shall merely mention here that these reactions are the only established route to mixed hetero-substituted carbenes such as $CH_3O—\ddot{C}—F$ and $NC—\ddot{C}—F$[77] (and potentially also $CH_3O—\ddot{C}—Cl$, $CH_2=CH—\ddot{C}—Cl$, or even $CH_3—\ddot{C}—O—COCH_3$[78]), and that they allow the study of the interaction of carbenes with strong acids such as trifluoromethanesulfonic acid[79] or with oxidizing agents such as Cl_2, N_2O_4, or NO_2Cl[80].

6. General Considerations

In retrospect, it can be seen that thermal cycloeliminations allow the liberation of stabilized carbenes, but not of reactive carbenes such as methylene. The fact that it is possible in this way to liberate dialkoxycarbenes whose generation by other routes[81] is unsatisfactory, or to produce difluorocarbene under mild conditions and in the gas phase, is not the real incitement of these investigations. Instead the reason lies in the mechanistic aspects of these reactions.

The cycloeliminations of carbenes discussed here have already been considered theoretically as cheletropic reactions[2]. For all processes of this type an orbital symmetry-allowed path is available, the "choreography" of which prescribes a linear movement of the groups for the [5→4+1] cycloelimination and a nonlinear movement for the [3→2+1] cycloelimination. These hypotheses cannot yet be verified, owing to lack of stereochemical criteria.

The data discussed in Sections 3 and 4 point to a two-step course for the [3→2+1] cycloelimination, and are thus clearly different from the addition of carbenes to olefins, which proceeds in one step and nonlinearly[82]. However, it has already been pointed out in a similar connection that the cycloaddition and its reversal, *i.e.* the cycloelimination, need not follow the same reaction path[83].

Many more data are available on linear cheletropic [5→4+1] cycloeliminations, which are generally one-step processes[2] if stereochemistry is used as the criterion. It is therefore the more surprising that the symmetry-allowed [5→4+1] cycloelimination of dialkoxycarbenes *(5)* from 7,7-dialkoxynorbornadienes *(17)* very probably proceeds in several steps as shown by the data in Section 2. Since most known electrocyclic reactions strictly follow the orbital symmetry rules, it is particularly interesting to

search for the reasons why some deviate from the allowed and hence normally energy-favored path.

It may be characteristic of the present system that the reversal, *i.e.* the symmetry-allowed [4+1→5] cycloaddition of a carbene to an aromatic compound, is unknown. The reactions of carbenes with aromatic compounds have always been found instead to result in [2+1→3] cycloaddition to give norcaradiene derivatives[56]. Perhaps the energy surface of the norbornadienes permits a symmetry-allowed, low-energy transition into the energy surface of the norcaradienes[27], from which, apart from a nonlinear cheletropic elimination, only a stepwise cycloelimination is possible.

The thermal behavior of the norbornadienes and norcaradienes could however simply be due to the fact that two carbon-carbon bonds must be broken simultaneously in a synchronous cycloelimination, whereas the cleavage of only one bond requires less energy and leads directly to a stabilized intermediate *(14)*.

The investigations discussed here were carried out at the Organic Chemistry Institutes of the University of Heidelberg and of the Technische Hochschule Darmstadt. They were made possible by support from the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie, which we gratefully acknowledge.

Generation of Carbenes by Photochemical Cycloelimination

By Gary W. Griffin[*]

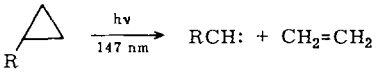
A wide variety of shelf stable substrates undergo photochemical cycloelimination under relatively mild conditions. Suitable substrates include cyclopropanes, oxiranes, aziridines, and diazirines, as well as 3H-pyrazoles and 1,3-dioxolanes. Carbenes prepared from these substrates as well as certain cyclic carbonates, sulfites, and phosphoranes behave chemically in a manner similar to divalent carbon species produced from conventional diazo precursors, namely, they react with alkenes to give cyclopropanes and undergo insertion into C—H bonds of alkanes. In many cases the carbenes formed may also be detected by EPR and optical spectroscopic methods.

1. Introduction

It has become increasingly apparent that divalent carbon intermediates play an important role in the photochemistry of a variety of organic substrates. In many cases the reactions have synthetic utility which may complement conventional techniques for the generation of carbenes. It is our intent in this review to summarize those examples of photoinduced cycloeliminations which lead to carbene formation. In accordance with the precedent established in the related review[1a] on thermolytic cycloeliminations we shall employ the convention suggested by *Huisgen*[1b] in designating the mode of cycloelimination.

To the extent that the reactions described herein are concerted they are subject to orbital symmetry constraints[1c]. For example the [3→2+1] cycloelimination reaction of a cyclopropane to give a carbene if entirely

[*] Prof. Dr. G. W. Griffin
Louisiana State University in New Orleans
Department of Chemistry
Lake Front, New Orleans, Louisiana 70122 (USA)



concerted has been classified as a cheletropic reaction (*i.e.*, a reaction in which two sigma bonds terminating at a single atom are broken in concert) and the orbital symmetry theory and selection rules for such processes have already been advanced[1c, 1d].

When intermediates are implicated in the cycloeliminations reviewed constraints are still imposed on the bond breaking process leading to the intermediate(s) which affects the stereochemical mode of ring opening[1c, 1d]. Where in the author's opinion the data available merit discussion of such theoretical considerations they are included for the reader's benefit.

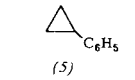
2. [3→2+1] Cycloeliminations

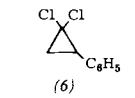
2.1. Carbenes from Cyclopropanes

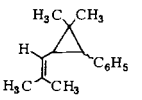
An efficient method of synthesizing cyclopropanes involves cycloaddition of carbenes to alkenes. The [3→2+1] cycloelimination is the reverse of this well-known reaction, *i.e.*, the production of a carbene and an alkene by fragmentation of a cyclopropane. The parent hydrocarbon *(1a)* has been photolyzed in the vapor phase and gives methylene *(2a)* and ethylene[2] while photolysis of benzylcyclopropane

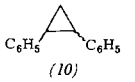
(1) *(2)*

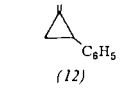
(a), R = H
(b), R = $CH_2C_6H_5$

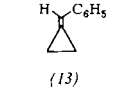


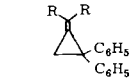


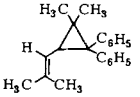


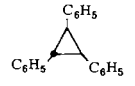


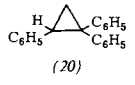


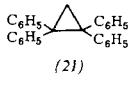


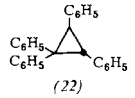


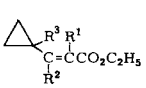


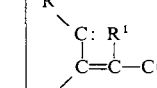












(1b) leads to extensive fragmentation to produce a number of hydrocarbons including ethylene and benylcarbene *(2b)*[3].

Aryl substitution of the cyclopropane ring should be accompanied by concomitant C—C bond weakening and more facile homolytic cleavage. The *cis-trans* thermo- and photoisomerization of aryl and aroyl substituted cyclopropanes reflect decreased bond strength[4]. Several reports of photolytic cycloeliminations involving aryl cyclopropanes are listed in Table 1.

Irradiation of phenylcyclopropane *(5)* in cyclohexene gives rise to methylene addition products, namely the isomeric methylcyclohexenes and norcarane. Methylene *(2a)* generated from *(5)* in hydrocarbon solutions exhibits the same indiscriminate insertion into aliphatic carbon-hydrogen bonds as does methylene generated from diazomethane or ketene[6a]. [3→2+1] Cycloelimination upon photolysis of *(5)* in the vapor phase is postulated to explain the formation of methylene as a primary product[6b]. Competitive photolytic reactions complicate the cycloelimination reaction with alkyl substituted phenylcyclopropanes[7].

1,1-Dichloro-2-phenylcyclopropane *(6)* undergoes photochemical cycloelimination to give primarily dichlorocarbene *(7)*[8]. The addition of *(7)* to olefins appears to occur in a *cis* fashion in a manner similar to that observed for other halocarbenes or carbenoids[9]. The isomeric phenylvinylcyclopropanes *(8)* are photolabile and when

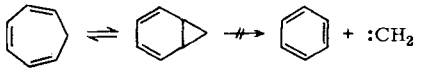
irradiated give the vinylcarbene *(9)* and 2-methyl-1-phenylpropene among other rearrangement products[10].

cis- and *trans*-1,2-Diphenylcyclopropanes *(10)* undergo photointerconversion[4a] and the kinetics have been studied. Geometrical isomerization predominates by a ratio of 4:1 over branching to side products, which prevents attainment of a "true" photostationary state[12]. Upon prolonged irradiation of *(10)* in *n*-pentane (24—48 h) it is possible to achieve fragmentation to the extent of 7—8%[11]. The selectivity factor for secondary *versus* primary C—H insertion for phenylcarbene generated from *(10)* is 8.3 and essentially the same as that observed when conventional phenylcarbene precursors are used[13]. A trimethylene diradical accounts for the geometrical (as well as accompanying structural) isomerization[4a, 4c, 12].

A comprehensive study of the absorption and emission spectroscopy and photochemistry of six phenyl-substituted cyclopropanes has recently been carried out at 77 °K[14]. Long wavelength phosphorescences (maxima $\approx$575 nm, $\tau \approx 7$ ms) are observable for the diphenylcyclopropanes *(10)* as well as for the tri- and tetraphenylcyclopropanes studied. It is suggested that these phosphorescences arise from diradicals of the trimethylene type formed by photocleavage of the cyclopropane ring, presumably in the allowed disrotatory manner[15]. It is proposed that arylcarbenes in general and phenylcarbene in particular arise in turn by subsequent thermal homolysis of trimethylene diradicals. Possibly bond breaking may lead to a singlet diradical, potentially zwitterionic in character, since the sites of charge and spin presumably may be sufficiently close to accommodate orbital overlap. This problem has recently been faced experimentally by *Yankee* and *Cram*[4f] for thermal transformations of certain cyclopropyl systems.

Methylenecarbenes may be generated photolytically from methylenecyclopropanes. For example, irradiation of *(3)*, *(12)*, *(13)*, and *(15)* results in extrusion of methylenecarbenes *(4)*, *(4)*, *(14)*, and *(16)*, respectively, which with the exception of *(16)* rearrange to acetylenes faster than they can be trapped by solvent[5, 16, 17].

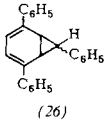


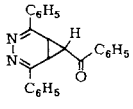
Zimmermann and *Pratt*[18] note that 1,1-dimethyl-2,2-diphenyl-3-(2-methylpropenyl)cyclopropane *(17)* undergoes two types of cycloelimination in *tert*-butanol. Upon photolysis, 1,1-diphenyl-2-methylpropene and presumably the vinylcarbene *(9)* are formed. Diphenylcarbene *(18)*, which is also produced, reacts with the solvent to give benzhydryl *tert*-butyl ether (38%).

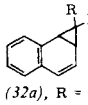
A trend is discernable from the photochemical studies performed on the tri- and tetraphenylcyclopropanes *(19)* through *(22)*. It is apparent from data presented in Table 1 that when two options for cycloelimination exist, namely, formation of phenyl- and diphenylcarbene, then fragmentation to the latter predominates[19]. While no direct spectroscopic evidence for the formation of carbenes from the cyclopropanes *(19)* through *(22)* has yet been obtained, the chemical evidence for formation of these species is convincing. As with *(10)* determination of the relative insertion selectivity of phenylcarbene derived from *(19)* compares favorably with the values obtained using phenyldiazomethane[11, 13]. The formation of diphenylcarbene from *(20)*, *(21)*, and *(22)* is adduced from the behavior observed upon photolysis of these substrates in alkenes and/or methanol[19].

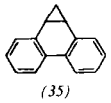
The photochemical response of six α,β-unsaturated esters of the type *(23)* to ultraviolet radiation has been studied by *Jorgenson*[20], who found fragmentation to carbenes *(24)* to be a surprisingly general mode of reaction for such cyclopropylacrylic esters.

2.2. Carbenes from Fused-Ring Cyclopropane Derivatives









Examination of the products obtained on photolysis of cycloheptatriene *(25)* shows that under the conditions employed cycloelimination to methylene does not occur although a substantial driving force might be anticipated for fragmentation of norcaradiene[6b, 21].

(25)

The photolysis of 2,5,7-triphenylnorcaradiene *(26)* in ether (Table 2) affords *p*-terphenyl (4%). *Toda* and coworkers[22] propose that phenylcarbene *(11)* is formed on the basis of analogous reactions of other stable norcaradienes *(vide infra)* although trapping experiments were not successful. Fragmentation of 7-benzoyl-2,5-diphenyl-

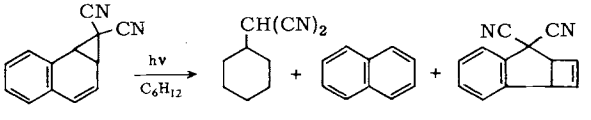
3,4-diazanorcaradiene *(27)* to 3,6-diphenylpyridazine occurs and it is reasonable to assume that a carbene such as *(28)* may be formed as a transient product[23].

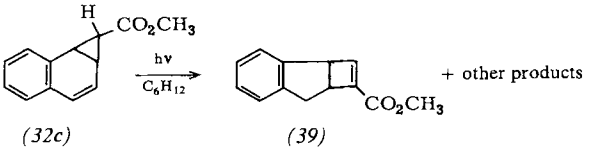
Photolysis of a cyclohexane solution of 7,7-dicyanonorcaradiene *(29)* gave cyclohexylmalononitrile[24]. Furthermore, the yields of insertion products obtained from *(29)* using 2,3-dimethylbutane as a solvent substrate (27% each of primary and tertiary C—H insertion product) were higher than those obtained when dicyanodiazomethane was employed as a precursor for dicyanocarbene *(30)* (12 and 16%, respectively). The similar product ratios observed upon photolysis of *(29)* and thermolysis of dicyanodiazomethane in 2,3-dimethylbutane are cited as evidence that the species formed from these independent sources have essentially the same relative reactivity toward primary and tertiary C—H bonds[24].



Pomerantz and *Gruber* examined the photochemistry of 7*H*-benzocycloheptene *(36)*[25]. Irradiation of dilute solutions of *(36)* in ether leads to benzonorcaradiene *(31)*

(36) *(37)*

(70—80%), which upon prolonged irradiation affords naphthalene and *(37)*. The hypothesis that methylene *(2a)* is transferred in the conversion of *(31)* into *(37)* and naphthalene was substantiated by trapping experiments utilizing cyclohexene.



The photolysis of dicyanobenzonorcaradiene *(32a)* in cyclohexane has been studied by *Ciganek*[24] under conditions similar to those employed with *(29)*; cyclohexylmalononitrile (22%) in addition to naphthalene (22%) and a photoisomer of *(32a)* assigned structure *(38)* (44%) are formed. Irradiation of ethoxycarbonylbenzonorcaradiene *(32b)* in cyclohexane reportedly gives only a small amount

(32a) *(38)*

of the carbene transfer product ethyl cyclohexylacetate (8%), in addition to naphthalene (11%) and intractable material.

Inexplicably, a more complex spectrum of products was observed by *Swenton* and *Krubsack*[26] upon photolysis of methoxycarbonylbenzonorcaradiene *(32c)*. The products include naphthalene (13%), the insertion product methyl cyclohexylacetate (10%), methyl 1- and 2-naphthylacetate [(14%) and (5%), respectively] and *(39)* (11%).

(32c) *(39)*

In one of the earliest photocycloelimination studies dibenzonorcaradiene *(35)* was recommended as a stable, high yield (>90%) source of active methylene for small scale synthesis and ^{14}C labeling[6b]. The C—H insertion selectivity of methylene *(2a)* thus obtained compares favorably with the indiscriminate reactivity reported for methylene generated from diazomethane. The stereochemical mode of addition of methylene formed from *(35)* was examined by irradiation of this precursor in *cis*- and *trans*-4-methyl-2-pentene. In each case the products are identical to those obtained utilizing diazomethane.

2.3. Carbenes from Oxiranes

vic-Diaryloxiranes have been shown to undergo cycloelimination on photolysis in solution to give arylcarbenes and carbonyl compounds. This mode of reaction has been studied extensively and shown to possess broad synthetic utility. The results of these investigations are summarized in Table 3.

trans-Stilbene oxide *(40)* has been irradiated in methanol and alkenes[27, 28]. Under these conditions phenylcarbene *(11)* is trapped as benzyl methyl ether and the appropriate cyclopropane, respectively. According to expectations two epimeric cyclopropanes are obtained from the addition of phenylcarbene derived from *(40)* to noncentrosymmetric olefins, the sterically more hindered, less stable *syn* isomer being formed preferentially. Similar results are obtained with phenylcarbene generated from phenyldiazomethane[32] and quantitative studies of epimer ratios attest to the similarity of the species derived from the two independent sources[11]. It should be noted that phenylcarbene generated from *(40)* adds in a highly stereoselective manner to *cis*-2-butene. Insertion selectivity ratio obtained for phenylcarbene generated from *trans*-stilbene oxide *(40)* with respect to aliphatic primary and aliphatic secondary C—H bonds also compares favorably with the results obtained using phenyldiazomethane[11, 29]. Although no ESR signal corresponding to phenylcarbene could be detected[30], the typical luminescence at 389 and 414 nm due to this species is observed at 77 °K upon irradiation of *(40)* and *(41)* in 3-methylpentane glasses[31].

The fragmentation of the unsymmetrical oxirane *(42)* may occur by two routes. Comparison of the respective phosphorescences of the carbonyl fragments resulting from irradiation of triphenyloxirane *(42)* in 3-methylpentane glass at 77 °K with those of a standard containing equimolar amounts of benzophenone and benzaldehyde indicates that the latter represents the preferred mode of fragmentation (≈70%)[31b]. The relative amounts of benzhydryl and benzyl methyl ether formed from *(42)* (85 and 15%, respectively) when methanol is employed as a trapping agent supports the conclusion that cycloelimination occurs preferentially to give diphenylcarbene *(18)* and benzaldehyde[34]. The emission characteristic of diphenylcarbene at 485 nm is observed upon irradiation of *(42)* in 3-methylpentane glass. The ESR signal of triplet diphenylcarbene *(18)* also is observable upon photolysis of *(42)* at 77 °K[30].

[a] Based on addition to alkenes to give cyclopropanes.
[b] As determined by the extent of insertion in alkanes and/or methanol.
[c] Proposed intermediate.

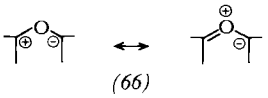
Upon irradiation in methanol/benzene tetraphenyloxirane *(43)* gives benzhydryl methyl ether in essentially quantitative yield[27]. Both benzophenone and diphenylcarbene are observable upon irradiation of this substrate in a rigid glass at 77 °K as described above[30,31b].

2-Methyl-2,3-diphenyloxirane *(44)* also fragments in two ways to give phenylcarbene *(11)* and phenylmethylcarbene *(45)*[33a]. *trans*-2,3-Dimethyl-2,3-diphenyloxirane *(46)* is a superior source of phenylmethylcarbene *(45)*, which is trapped as α-phenethyl methyl ether in methanol. The yields of phenylcyclopropanes which result upon irradiation of *(46)* in alkenes range from 40—60%[34].

A phosphorescence similar to that of acetophenone is apparent in the luminescence spectrum of an irradiated sample of 1,2-diphenyl-1,2-epoxycyclohexane *(47)* and upon warm-up of the matrix an emission similar to *trans*-stilbene appears[31b]. These data suggest that opening occurs to the expected ketocarbene *(48)*; however, the photostability of *(47)* and its lower homolog in solution suggests that under these conditions recyclization is efficient[33b].

Irradiation of *trans*-2,3-diphenyl-2,3-dicyclopropyloxirane *(49)* in methanol affords cyclopropylphenylcarbene *(50)*, trapped as α-cyclopropylbenzyl methyl ether[33c]. A variety of oxirane precursors for cyanophenylcarbene *(52)* have been investigated including *(51)*, *(53)*, and *(54)* which possess synthetic utility[35,37,39,41]. When methanol is employed as a trapping agent α-cyanobenzyl methyl ether is found to be produced in high yield. These oxiranes [in particular *(53)* and *(54)*] appear to be superior to diazophenylacetonitrile as a precursor for *(52)*[40] and photolyses conducted in 2,3-dimethyl-2-butene afford 1-cyano-2,2,3,3-tetramethyl-1-phenylcyclopropane in relatively high yield. In those cases such as *(51)*, *(53)*, and *(55)* where the substitution pattern is unsymmetrical a decided preference for cycloelimination of cyanophenylcarbene *(52)* is apparent as evident from the data in Table 3. In the case of *(51)* the photoelimination of phenylcarbene *(11)* was confirmed by ESR spectroscopy[33d]. The spirooxirane *(55)* represents the only photolabile substrate of this type found to date which undergoes cycloelimination in the absence of *vicinal* diaryl ring substitution.

Photolysis of the glycidic esters *(56)* and *(58)* in 2,3-dimethyl-2-butene affords 1-methoxycarbonyl-2,2,3,3-tetramethyl-1-phenylcyclopropane (20 and 40%, respectively) and the expected oxetanes of the alkene and benz-

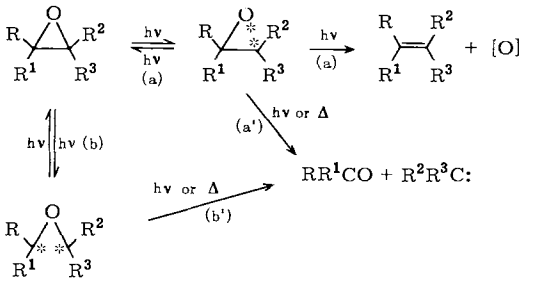


aldehyde or benzophenone[37,42]. Furthermore methoxycarbonylphenylcarbene *(57)* formed from *(56)* is trapped by methanol to give α-methoxycarbonylbenzyl methyl ether and with 2-methyl-2-butene the epimeric 1-methoxycarbonyl-1-phenyl-2,2,3-trimethylcyclopropanes. A minor product in the latter case is 1,1,2-trimethyl-3-phenylcyclopropane[37,42].

2-Methoxy-2,3-diphenyloxirane *(59)* conceivably could undergo cycloelimination to methoxyphenylcarbene and benzaldehyde and/or phenylcarbene and methyl benzoate. Irradiation of *(59)* in 2-methyl-2-butene and 2,3-dimethyl-2-butene confirms that the preferred mode of cleavage is to phenylcarbene and methyl benzoate[41,43]. Photocycloelimination also is essentially unidirectional in the case of 2-methoxy-2,3,3-triphenyloxirane *(61)*[33c]; in methanol the methyl ether of benzhydrol is the major adduct. Luminescence and ESR studies confirm the intermediacy of diphenylcarbene. No evidence was obtained for cycloelimination to give benzophenone and methoxyphenylcarbene which, by analogy with other related systems, should give the dimethylacetal of benzaldehyde upon reaction with methanol[33c]. These results are consistent with those reported independently by *Temnikova* and *Stepanov*[43].

As anticipated on the basis of the behavior of the structurally related oxiranes *(59)* and *(61)*, 2-acetoxy-2,3,3-triphenyloxirane *(62)* undergoes photocleavage to give diphenylcarbene. No products derived from phenylacetoxycarbene were detected[33c]. Similarly, *trans*-2-methyl-2,3-diphenyl-3-acetoxyoxirane *(63)* photofragments to methylphenylcarbene and the mixed anhydride of benzoic and acetic acids[33c,34a].

Irradiation of the oxaspiropentane *(64)* in benzene results in generation of several products. A cyclopropylcarbene *(65)* formed by elimination of acetone from *(64)* is invoked to rationalize the formation of tetramethylcumulene[44].



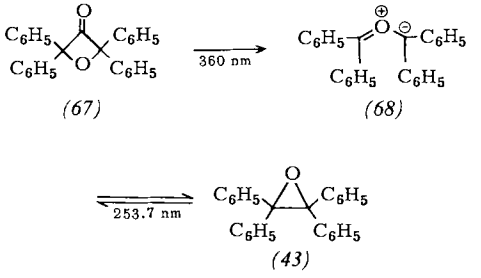
The preferred modes of fragmentation for the unsymmetrical polar substituted aryloxiranes *(51)*, *(53)*, *(56)*, *(58)*, *(59)*, *(61)*, *(62)*, and *(63)* may be predicted if a zwitterionic intermediate such as *(66)* is assumed. The overall cycloelimination is thus viewed as a photo-induced or thermal α-elimination of the carbonyl fragment from

(66)

the more stable possible zwitterion formed by initial C—C oxirane bond cleavage. Further study is required to establish whether this heuristic argument has valid theoretical implications.

The mechanistic pathways delineated in Scheme 1[31b] are consistent with the ESR and optical spectroscopic as well as chemical experimental observations made to date on oxirane substrates. While alkenes are not detected among the solution photoproducts of oxiranes at ambient temperatures they are nevertheless found to be produced at 77 °K in rigid glasses by an intramolecular oxygen extrusion process [path (a)]. It has been proposed that at ambient

Scheme 1. The asterisks are employed to avoid any specific inference with respect to the electronic nature (and/or multiplicity) of the intermediates.



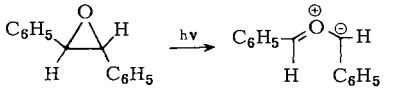
temperatures the reaction rate *via* path (a') may be so fast that it completely dominates the photochemistry of the oxirane. However, as the temperature is lowered, the rates of reaction by paths (a) and (a') become comparable and the products of both reactions are observed[31b]. Further studies in this area are in progress.

2.4. Photochromic Behavior of Vicinal Diaryloxiranes

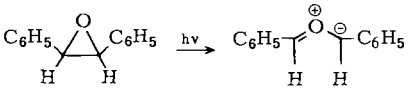
The low temperature photochromic behavior observed for vicinally substituted diaryloxiranes appears to be related to the photocycloelimination reactions. Colors are produced upon irradiation of 2,3-diaryloxiranes in rigid glasses at 77 °K. The colors are stable at 77 °K; however, bleaching occurs upon warming above 140 °K or upon irradiation into the visible absorption bands[31b]. Arylcarbenes and carbonyl compounds are formed to some extent simultaneously and may be observed in the presence of the colored species using optical and ESR spectroscopic techniques. The extent of cycloelimination observed during photolysis warm-up cycles is estimated to be 20—25 times more than originally produced in the initial photolysis[45].

Although the thermal production of additional carbene and bleaching of the color upon warming to near 140 °K occur essentially simultaneously, it is possible that the colored intermediate is not that species from which the additional carbene is derived at least by thermal cleavage. This is clearly apparent from recent work by *Huisgen (vide infra)* and our own work.

We have been able to show that, at λ = 360 nm, 2,2,4,4-tetraphenyl-3-oxetanone *(67)* may be photodecarbonylated under conditions where the oxirane *(43)* is photostable

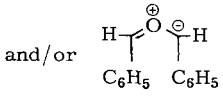


(67) *(68)* *(43)*



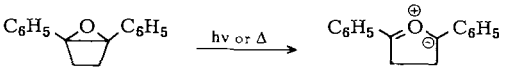
to form a colored intermediate, spectroscopically identical to that obtained from *(43)* at shorter wavelength (λ = 253.7 nm). At the longer wavelength no diphenylcarbene *(18)* is formed from *(67)* even in solution at ambient

temperatures[33e,45]. The formation of a common intermediate *(68)* from *(67)* and *(43)* implicates C—C bond scission in the oxirane photochromic process; *thermal* cleavage of *(68)* appears unfavorable since further fragmentation does not occur at 40 °C.



The ring opening of oxiranes to give colored ylides is subject to orbital symmetry constraints and evidence has been presented by *Do-Minh*, *Trozzolo*, and *Griffin*[45] that the process occurs photochemically in a concerted disrotatory manner. The symmetry allowed transformations are exemplified using *cis*-stilbene oxide *(41)*.

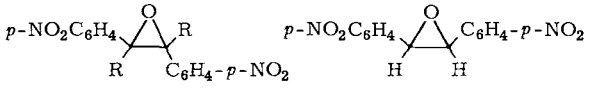
(40) *(69)*



(41) *(70a)*

(70b)

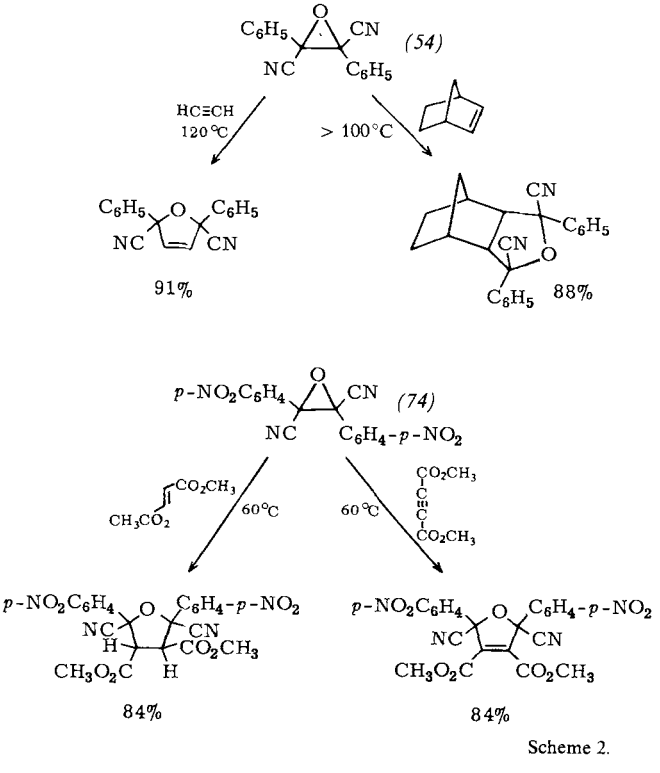
Thermodynamic considerations dictate the mode of disrotation in those cases such as *(41)* where "inward" and "outward" alternatives to give *(70b)* and *(70a)*, respectively, exist. The *exo* ylide *(70a)* is more stable than the other possible structural isomer having *endo* stereochemistry, *(70b)*, and for that matter than the ylide *(69)* obtained from the *trans* isomer *(40)*. The visible spectral absorption maximum of the colored intermediate obtained from *(41)* is red-shifted relative to that from *(40)* which presumably reflects the predominant formation of *(70a)* rather than *(70b)*. Furthermore these conclusions are supported by the work of *Huisgen* and co-workers[46] who have trapped an azomethine structurally related to *(70a)* and derived from a *cis* aziridine *via* the "outward" disrotatory mode.



Direct evidence for the formation of a carbonyl ylide from an oxirane was obtained by *Arnold* and *Karnischky*[47]. Photolysis or pyrolysis (100 °C) of 5-oxabicyclo[2.1.0]-pentane *(71)* gave purple species whose visible absorption spectra were essentially identical. It is proposed that the carbonyl ylide *(72)* is responsible for the purple color.

(71) *(72)*

The oxiranyl ring of *(71)* is incorporated in a fused system which is geometrically constrained to open in a disrotatory manner. Strain is relieved upon bond cleavage which must account for the facile thermal conversion of *(71)* into *(72)* (in violation of orbital symmetry predictions) and the stability of the latter. The colored intermediate may be trapped using conventional dipolarophiles. Previous work in our laboratory had shown that no such behavior is exhibited by the higher homolog *(47)* and the analogous 6-oxabicyclo[3.1.0]hexane[31,33f].

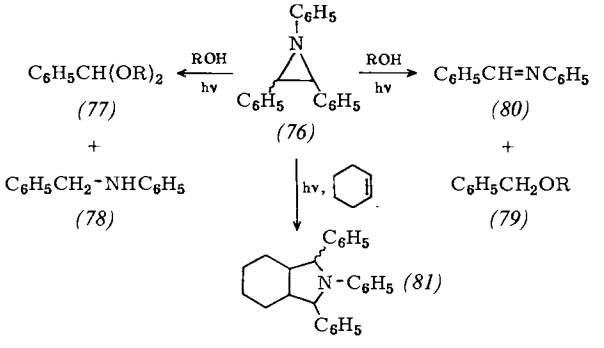


Recently *Huisgen* and co-workers[48] have trapped the carbonyl ylides that are present in thermal equilibrium with several aryloxiranes, including the *cis* and *trans* forms of *(51)* and *(53)*, as well as *(73)*—*(75)*, with a variety of dipolarophiles. The stereochemistry of addition in each case is explicable within the framework of orbital symmetry theory.

(73), R = H
(74), R = CN

(75)

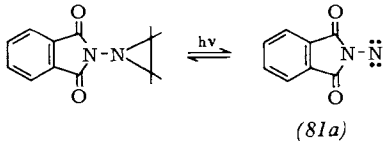
Selected examples of the adducts, isolated in high yield, are shown in Scheme 2; the temperature at which oxirane ring cleavage occurs is remarkably low.



Scheme 2.

Huisgen and co-workers failed to detect phenylcyanocarbene or its reaction products upon heating of oxiranes such as *(51)* or *(53)* to 160 °C, despite equilibration with carbonyl ylides. Thus the latter do not fragment; this is in accord with our observation that tetraphenyloxetanone *(67)* is converted photochemically into the oxirane without formation of diphenylcarbene. Our inability to detect substantial *cis-trans* photointerconversion of oxiranes and photoracemization of active *trans*-stilbene oxide at ambient temperatures in solution may therefore be due to intervention of an efficient cheletropic mechanism (concerted extrusion) under these conditions and/or the

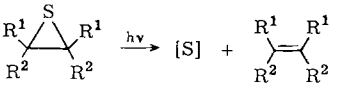
fact that the extinction coefficient of the ylide may be sufficiently greater than that of the residual oxirane to render subsequent photocleavage of the ylide by a second photon to carbene photochemically highly probable. Another alternative is that the intermediate formed by C—O bond cleavage (Scheme 1) may be the carbene precursor. Clearly further work is required to completely define the overall mechanistic path of oxirane photocycloelimination and such is in progress[33c].



2.5. Carbenes from Aziridines

The formation of phenylcarbene upon photolysis of 1,2,3-triphenylaziridine *(76)* has been reported by *Nozaki* and co-workers[49]. Irradiation of *(76)* in alcohols results in cleavage of the aziridine ring to give benzaldehyde acetals *(77)* and *N*-benzylaniline *(78)*. Competitive cycloelimination of phenylcarbene, trapped as the alkyl benzyl ether *(79)*, appears to occur and the residual fragment *(80)* was also detected. This mode of cleavage is formally analogous to the photofragmentation of aryloxiranes.

R = CH_3, C_2H_5, 2-C_3H_7, $C(CH_3)_3$



An azomethine ylide intermediate assumed to be implicated in these reactions may be intercepted with cyclohexene. A pair of stereoisomeric 1,3-cycloaddition products having the 1,2,3-triphenyloctahydroisoindole structure *(81)* are formed. No evidence was found to indicate that phenylnitrene is generated from *(76)*. Similarly attempts to generate phenylnitrene from 1,2,2,3-tetraphenylaziridine proved unsuccessful[33g]. In contrast, the amino nitrene *(81a)* was readily liberated upon irradiation of the corresponding aziridine and undergoes transfer to other olefins[49a]

(81a)

2.6. Cycloeliminations of Thiiranes

Despite their superficial resemblance to aryloxiranes, the photolytic cycloelimination reactions of arylthiiranes *(82)* do not parallel the behavior of the former. A [3→2+1] photocycloelimination to sulfur and alkenes *(83)* appears to be the preferred mode of cleavage; no carbene was detected (Table 4).

(82) *(83)*

Table 4. Examples of photocycloeliminations from thiiranes *(82)*.

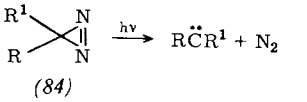
c	C_6H_5	C_6H_5CO	[51, 52]
d	2,2'-biphenylylene		[33b]
e	2,2'-oxydiphenyl		[33b]

2.7. Cycloeliminations of Oxaziridines



A priori two [3→2+1] cycloelimination reactions might be anticipated for oxaziridines; path (a) to give carbenes and nitroso compounds and/or path (b) to give nitrenes and carbonyl compounds.

In those cycloeliminations reported by *Meyer* and *Griffin*[53] and *Splitter* and *Calvin*[54] the reaction invariably proceeds by the latter mode. The arylnitrenes formed from the oxaziridines (or nitrones *via* prior cyclization) have been trapped chemically using substituted amines[53] and detected spectroscopically independently by *Calvin* and co-workers[54] and *Griffin* and *Trozzolo*[33h] using ESR techniques.

2.8. Carbenes from Diazirines

The photochemistry of diazirines *(84)*, established carbene precursors, has been reviewed extensively elsewhere[55,56].

(84)

Irradiation of these cyclic isomers of diazo compounds results in loss of nitrogen and generation of the corresponding carbene. The diazirines whose photodecompositions have been described to date together with the carbene generated in the primary process are summarized in Table 5. The majority of these investigations were conducted in the gas phase and numerous secondary reactions occur.

3. [5→3+2] Cycloeliminations

The photochemical conversion of substituted 3*H*-pyrazoles *(85)* to cyclopropenes *(88)*, which formally may be viewed as a [5→3+2] cycloelimination, is believed to occur by a two photon process. The first step involves formation of the diazoalkane *(86)*, which subsequently loses nitrogen to give a vinyl carbene *(87)*, the immediate precursor of the cyclopropene *(88)*[66,67].

(85) *(86)* *(87)* *(88)*

Those 3*H*-pyrazoles whose conversion to cyclopropenes has been investigated are listed in Table 6. That the penultimate intermediate is the diazoalkane *(86)* is suggested by a transient red coloration during the photolyses[66,68,72]. Direct evidence for the diazo intermediate was obtained by irradiation of the trimethyl-3*H*-pyrazole *(85a)* using a filter which eliminates both visible light and ultraviolet light below 320 nm[68]. Under these conditions the expected diazoalkane is formed in 50% yield.

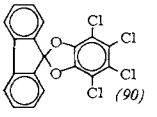
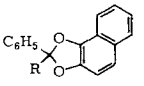
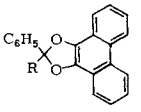
Bentrude[72] has reported that 1,3,2-dioxa-P^v-phospholes undergo photocycloelimination of the [5→3+2] and [5→4+1] types. The former reaction is assumed to give ketocarbenes; however, these intermediates were not trapped.







4. [5→4+1] Cycloeliminations

Generation of arylcarbenes from substituted 1,3-dioxolanes by [5→4+1] cycloelimination reactions of the type depicted for *(89)* have been reported by *Griffin* and coworkers[73]. Additional examples are summarized in Table 7.

(89) *(11)*

Table 7. Examples of photocycloeliminations from dioxolanes. The yields were determined from the extent of ether formation in alcohols.

Dioxolane	Arylcarbene	Yield (%)

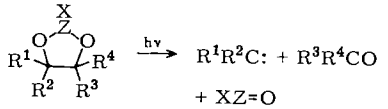
	$(C_6H_5)C$: *(18)*	5

5. [5→2+2+1] Cycloeliminations

A variety of 1,3-dioxolanes such as *(94)* undergo cycloelimination of the [5→2+2+1], rather than [5→4+1] type; *i.e.*, it is not invariably the ring carbon atom flanked by the oxygen atoms which is extruded in the divalent form. The course of the reaction may be altered by incorporating a trigonal center or heteroatom in position 2. This mode of cycloelimination is observed in the case of several 1,3-dioxolanes[29,74,75] (Table 8).



Irradiation of the cyclic arylcarbonates *(94a)*—*(94e)* results in photofragmentation to arylcarbenes, carbonyl compounds, and carbon dioxide[29,74]. Diphenylcarbene *(18)*, trapped as benzhydryl methyl ether, is formed in 60% yield upon photolysis of *(94a)* in methanol. The sulfite *(94a)* also affords *(18)* in high yield (≈40%) upon irradiation in methanol[74]. The other fragments in this case are benzophenone and sulfur dioxide. Tetraphenyloxirane *(43)* could not be detected among the photolysis products of either *(94a)* or *(94b)*.

A [5→2+2+1] cycloelimination reaction yielding carbene and carbonyl compound has been reported by *Bischoff* and *Brandstaedter*[76]. Photolysis of 3,5-dimethyl-3,5-dihydroxy-1,2-dioxolane *(95a)* gives formic acid which is formulated as arising from methylene. Irradiation of the related 4,4-dichloro compound *(95b)* in cyclohexene

Table 8. Examples of photocycloelimination from dioxolanes *(94)*.

The Anomalous Temperature Dependence of Enzyme-Catalyzed Reactions[**]

By Gerhard Talsky[*]

Breaks or curvatures in the plot of log v_{br} vs. $1/T$ have been described in the literature for a number of reactions. If sufficiently small temperature intervals are used in the investigation of the temperature dependence (STI method) a trend line is obtained instead. It is then possible to distinguish regions of linear behavior and regions of anomalous behavior. The effects of e.g. the pH, the ionic strength, and added salts as well as of the size of the enzyme and substrate molecules on the anomalies were examined. The anomalous temperature dependence of the reaction rate was found to be a particularly sensitive indicator of the reaction event on the enzyme. The course of the reaction is evidently affected even by relatively small changes in conformation, particularly in the region of the active center.

1. Introduction

The temperature dependence of the rate constant k of chemical reactions is generally described by the Arrhenius equation [eq. (1) and (2)]:

$$k = A\,e^{-E_{exp}/RT} \tag{1}$$

$$\ln k = \ln A - E_{exp}/RT \tag{2}$$

If a plot of $\ln k$ against $1/T$ in accordance with equation (2) gives a straight line, the experimental activation energy E_{exp} can be calculated from the slope of that line. In simple reactions, E_{exp} contains the true activation energy as well as the temperature dependence of all the reaction parameters.

However, enzyme reactions are not simple reactions, but consist of a series of partial steps. For example, the enzymatic hydrolysis of an ester can be represented schematically as indicated by equation (3):

$$\mathrm{EH + AcOR} \rightleftharpoons \mathrm{(EHAcOR)} \rightleftharpoons \mathrm{(EHAcOR)_1^* \cdots (EHAcOR)_i^*} \rightleftharpoons \mathrm{(EAcHOR)^*} \rightleftharpoons \mathrm{(EAcHOR)} \rightleftharpoons \mathrm{EAc + HOR} \tag{3a}$$

$$\mathrm{EAc + H_2O} \rightleftharpoons \mathrm{(EAcH_2O)} \rightleftharpoons \mathrm{(EAcH_2O)_1^* \cdots (EAcH_2O)_i^*} \rightleftharpoons \mathrm{(EHAcOH)^*} \rightleftharpoons \mathrm{(EHAcOH)} \rightleftharpoons \mathrm{EH + AcOH} \tag{3b}$$

The enzyme (EH) and the acyl ester (AcOR) initially form an adsorption complex, the Michaelis complex, which is activated by a change in conformation. The acylenzyme (EAc), which can actually be isolated under favorable circumstances, is then formed *via* at least two steps[1]. EAc is then converted in the presence of water into the enzyme-product complex (EHAcOH), again by a number of reaction steps, and the complex, after deactivation and restoration of the original conformation of the enzyme, decomposes into the product (AcOH) and the enzyme, which can then enter into a new cycle.

[*] Priv.-Doz. Dr. G. Talsky
Institut für Technische Chemie der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

[**] From the "Habilitationsschrift" by *G. Talsky*, "Anomalous Temperature Dependence of Enzyme Reactions", Technische Universität München 1969.

The rate constant k assumes a complex value in composite reactions of this type, and it is then composed of the rate constants of the individual steps. Even in this case, however, the temperature dependence of the rate constant of the overall reaction k_{br} as well as the overall reaction rate v_{br} which is proportional to it should obey the Arrhenius equation.

However, enzyme-substrate systems for which this is not true have been described; the most important enzymes are listed in Table 1.

Table 1. Examples of enzymes from enzyme-substrate systems whose reaction rates exhibit anomalous temperature dependence.

Oxidoreductases	*Hydrolases*
Alcohol dehydrogenase [2]	Acetylcholinesterase [9]
Bacteria dehydrogenase [3]	Lipase [10, 11]
L-Amino oxidase [4]	Trypsin [11]
Xanthine oxidase [5, 6]	Chymotrypsin [10]
Transferases	Cathepsin [10]
Phosphorylase [7]	Papain [12]
Levan saccharase [8]	Myosin ATPase [13, 14]
	Urease [15—17]
	Invertase [11]
	Lyases
	Fumarase [18, 19]

There are two basic types of anomalies, *i.e.* convex curves (continuous transition from one activation energy to another), as in the case of acetylcholinesterase[9], and two intersecting straight lines (sudden change from one activation energy to another), as in the cases of pancreas lipase[10, 11], trypsin[11], and invertase[11].

The convex course of the curve obtained when log v_{br} is plotted against $1/T$ in the case of acetylcholinesterase was attributed by *Wilson* and *Cabib*[9] to a change in rate-determining step from acetylation at low temperatures to deacetylation at higher temperatures. *Stern*[20] has discussed two successive reactions with different temperature coefficients for a curve of this type.

Sharp breaks in the Arrhenius diagram, on the other hand, cannot be explained by means of the usual kinetic concepts. According to *Kistiakowsky*[34], who carried out a critical study of the anomalous temperature dependence of reactions of urease, the activation energies of the two reactions

would have to differ by about 200 kcal/mole if the break is limited to a range of 2 °C. He therefore considers only the curved plot, and not the sharp break, to be real. *Kistiakowsky* explains the anomalies by an equilibrium between active and inactive forms of the enzyme.

2. Temperature Dependence of the Reaction Rate at Small Temperature Intervals

From the examples of anomalous temperature dependence of the reaction rate quoted in the literature we first selected the system pancreas lipase—tributyrin[*]. When the rate of the hydrolysis of glycerol esters by lipase is determined in the usual manner at intervals of 5 to 10 °C, the test points obtained in the plot of log v_{br} *vs.* $1/T$ are equally compatible with two intersecting straight lines or with a curved plot, depending on the interpretation[21] (Fig. 1a). To obtain more accurate information about the course of the curves,

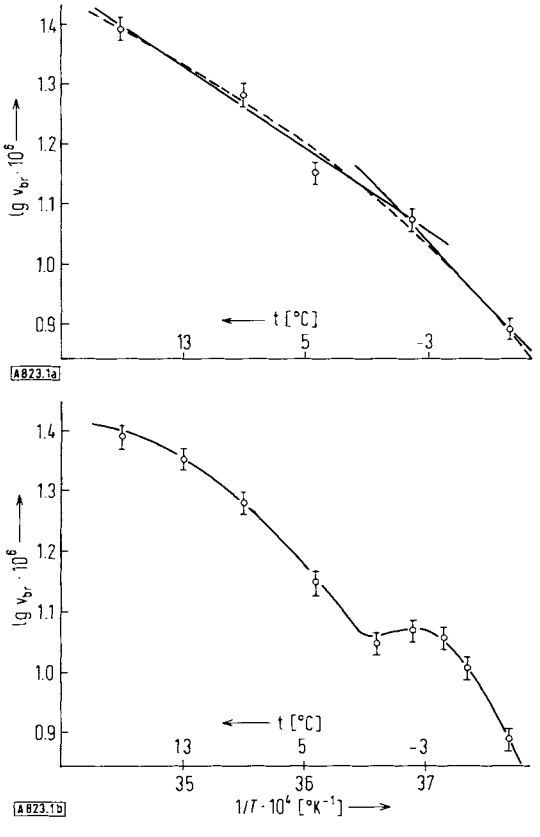

Fig. 1a. Temperature dependence of the hydrolysis of tributyrin by lipase from pig pancreas. Conditions: [substrate] = 27.3×10^{-2} mole. l^{-1}; [sodium taurocholate] = 5.95×10^{-3} mole. l^{-1}, [$CaCl_2$] = 2.4×10^{-2} mole. l^{-1}, [NH_4Cl] = 1.2×10^{-2} mole. l^{-1}, [glycol] = 4.7 mole. l^{-1}; 1 mg of lipase protein. l^{-1}, pH = 8.12, temperature intervals 4—7 °C.

Fig. 1b. Conditions as for Fig. 1a, but temperature intervals 1—2 °C.

particularly in the region of the transition between the two linear portions, we determined the reaction rate at smaller intervals (about 1 to 2 °C) and also recorded it continuously while the temperature was steadily raised or lowered.

[*] Tributyrin is glycerol tributyrate.

Careful evaluation of the results led to a conclusion that was surprising at first. A wavelike course was found in the critical temperature ranges of the curve[21–23] (Fig. 1b). If measurements are carried out in a similar manner over a wider temperature range, the result is a trend line whose very reproducible deviations from the fitted straight lines lie well outside the maximum error range of ±4% (Fig. 2)[22, 23].

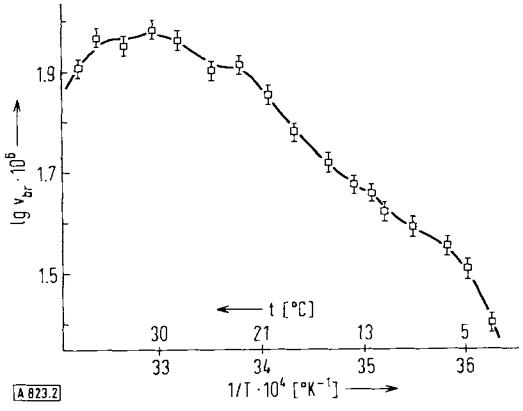

Fig. 2. Temperature dependence of the hydrolysis of tributyrin by lipase from pig pancreas. Conditions: [substrate] = 20.5×10^{-2} mole. l^{-1}, [glycol] = 3.59 mole. l^{-1}, pH = 8.10, 1 mg of lipase protein. l^{-1}.

To record the time-concentration curves automatically, we used an Autotitrator (Radiometer, Copenhagen) with glass-calomel electrodes[22]. The pH was kept constant (pH-stat) and the acid liberated was titrated automatically with 0.02 N NaOH under nitrogen. The initial rates v_0 were found in this way.

The reality of the anomalies found by us was established in various ways:

(a) The deviations of some experimental points from a fitted straight line were much greater than the experimental error determined[23];

(b) the reproducibility of the deviations was good when the same enzyme preparations were used[24, 27];

(c) even when the temperature was raised continuously, the reaction rate did not increase steadily in accordance with an exponential function, but exhibited discontinuities[21]; and finally

(d) the hydrolysis of the substrate *without* enzyme proceeded normally in accordance with the Arrhenius equation.

The question why such effects were not observed earlier can be answered as follows. In normal kinetic measurements, one usually determines only a few experimental points at fairly large intervals for use in the calculation of the activation energy; deviations were treated as errors and disregarded. Moreover, the reaction was carried out in the presence of fairly large quantities of buffers or salts, which often reduce the anomalies. It is therefore quite understandable that anomalous curves were not found *e.g.* by *Bender et al.*[35] with acetyltrypsin or by *Follman et al.*[36] with ribonuclease.

Having verified the anomalous temperature dependence of the hydrolysis of tributyrin by lipase, we then examined

the possibility of influencing the anomalous regions by varying the reaction conditions and systems in order to find out more about the reason for and basis of this phenomenon.

3. Modification of the Anomalous Regions

3.1. Sizes of the Enzyme and Substrate Molecules

On comparison of the anomalous temperature dependence of reactions of urease (MW 473000[24]) and xanthine oxidase (MW 290000[25]) with that of reactions of papain (MW 20700[26]), trypsin (MW 23800[21,27]), and chymotrypsin (MW 21000[21,27]), it is found that the course of the curve, which can almost be described as "harmonically oscillating" for enzymes with higher molecular weights, becomes more irregular at lower molecular weights. The same is true of the substrates. In the case of trypsin or chymotrypsin, for example, if N^{α}-benzoyl-L-argininamide, N^{α}-benzoyl-L-arginine ethyl ester, and tyrosine ethyl ester are used as substrates instead of the high molecular weight casein, which is itself structured, linear regions appear between the sections of anomalous behavior. This is also found for the system ribonuclease—cyclic cytidine-2',3'-monophosphate[28]. With enzymes having relatively low molecular weights and simple low molecular weight substrates, the regions of normal and anomalous temperature dependence are evidently separated. Because of their greater simplicity, systems of this type are better suited to the investigation of the anomalies. This is illustrated in Figure 3 for the case of trypsin and xanthine oxidase.

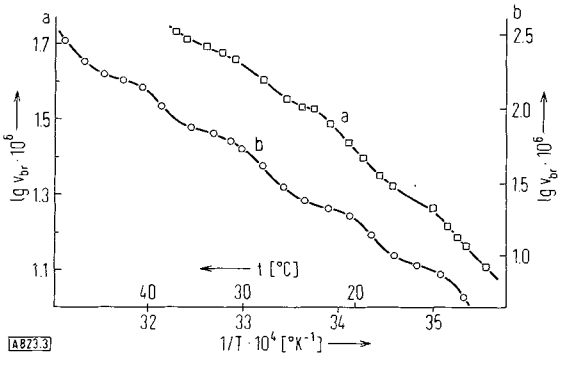

Fig. 3. Curve a: Temperature dependence of the cleavage of N^{α}-benzoyl-L-arginine ethyl ester by trypsin. Conditions: [substrate] = 3.8×10^{-3} mole. l^{-1}, [trypsin] = 1 mg. l^{-1}, pH = 9.6. Curve b: Temperature dependence of the oxidation of salicylaldehyde by xanthine oxidase. Conditions: [salicylaldehyde] = 1.5×10^{-2} mole. l^{-1}, [phosphate buffer, pH = 7.4] = 5×10^{-2} mole. l^{-1}, [methylene blue] = 6.25×10^{-5} mole. l^{-1}, [xanthine oxidase] = 18 µg. ml^{-1}.

3.2. Modified Enzymes

It is known from comparative biochemical studies that homologous proteins and enzymes usually differ slightly in their physical or immunological properties according to individual, organ, or source (animal, plant, bacterium, or fungus). Whereas the active site and certain parts of the molecule are identical for all species, changes in the amino acid sequence occur at other parts of the molecule[29]. Enzymes of this type may therefore be regarded as the simplest naturally modified enzymes.

The temperature dependence of the reaction rate of such enzymes, *e.g.* trypsin from pig pancreas and from bovine pancreas shows the same "basic curve characteristics" but though the structural differences are only small, the enzymes can be characterized relatively easily by the small temperature interval method (STI method, Fig. 4, curves a and c)[21]. Partially autolyzed trypsin (MW 17500) from which a part of the sequence (MW 6000) has been removed, (but not from the vicinity of the active site)[30] can also be clearly distinguished in this way, though the specific activity of such a modified enzyme is practically the same as that of the native enzyme (Fig. 4, curve b). Similar results are obtained on examination of α-, β-, γ-, and δ-chymotrypsin[31].

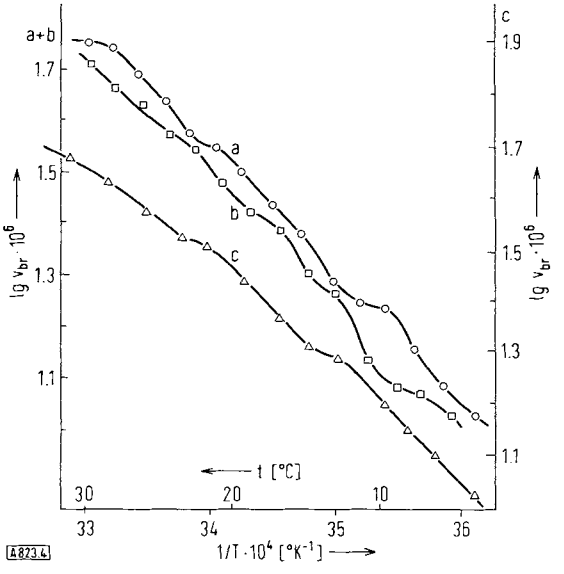

Fig. 4. Curve a: Temperature dependence of the cleavage of N^{α}-benzoyl-L-arginine ethyl ester by *pig* trypsin. Conditions: [substrate] = 3.8×10^{-3} mole. l^{-1}, [trypsin] = 1 mg. l^{-1}, pH = 9.6. Curve b: identical with a, but with partly autolyzed *bovine* trypsin having MW 17500 [30]. Curve c: identical with a, but with *native bovine* trypsin.

Chemical modification, provided that it does not affect the active site, has a similar effect on the temperature dependence of the reaction rate. Thus in the case of chymotrypsin in which two of the three terminal amino groups have been reacted with fluorescein isothiocyanate, it was possible to show that modification of the molecule even at points remote from the active site influences the anomalous ranges. The same is true if the additional terminal amino group in partially autolyzed trypsin (compared with native trypsin) is substituted or if the enzyme is acetylated[21,31].

On the other hand, if trypsin is bound either by adsorption or covalently to high molecular weight supports such as *p*-aminobenzylcellulose, the plot of log v_{br} *vs.* $1/T$ is practically linear between 10 and 50 °C[32].

3.3. Effects of the Reaction Medium

3.3.1. Homogeneous and Heterogeneous Phases

In the investigations on pancreas lipase, the reaction rate was found to be strongly dependent on the distribution of

the sparingly water-soluble glycerol ester[23]. It therefore appeared possible that the anomalies were connected with this. However, systems containing Tween 20 (a readily water-soluble lauryl sorbitan polyethylene glycol ether) as the substrate also exhibit anomalous temperature dependence, showing that the distribution of the substrate is actually of no importance to this phenomenon. This was confirmed by the later experiments with other enzyme-substrate systems, all of which proceeded in the homogeneous phase.

3.3.2. pH Value of the Reaction Medium

The rates of enzymatic reactions are usually strongly dependent on the pH value of the solution; this is attributed to the difference in the charge of the amino acids at the active site, which are important to the catalysis. We had already observed in the case of pancreas lipase[23] that an increase in the pH value, irrespective of the pH optimum of the enzyme reaction, shifts ϑ_A toward lower temperatures[*]. At the same time, the anomalous region became more significant with decreasing pH. In the trypsin-casein and trypsin-N^{α}-benzoyl-L-arginine ethyl ester systems, on the other hand, the amplitude of the curve decreased with decreasing pH. This apparently contradictory behavior becomes understandable when one considers that the isoelectric point of lipase is pH 5.2, while that of trypsin is 10.8. The anomaly is evidently intensified in the vicinity of the isoelectric point, irrespective of the pH optimum of the enzyme reaction.

3.3.3. Salt Content of the Reaction Solution

Enzymatic processes are often more or less strongly influenced by anions and cations. At low salt concentrations, specific action on the active site can lead both to acceleration and to inhibition of the reaction[21]. Larger quantities of ions, on the other hand, also lead to a nonspecific loss of activity, and ultimately to denaturing and precipitation of the protein. Whenever possible, therefore, we avoided the use of buffers and salts in our determinations. The small quantities of Na^+ and Cl^- ions introduced into the system to adjust the pH value did not interfere with the reactions under investigation, and could therefore be disregarded.

In the case of pancreas lipase, the addition of salts was found to cause a shift of ϑ_A[23]. These effects could be followed more easily in the case of the system trypsin—N^{α}-benzoyl-L-arginine ethyl ester, because of the greater simplicity and clarity of the reaction[21]. For example, 0.1 mole/l of NaCl cause an almost parallel displacement of the linear portions of the curve. This suggests that the reaction event is not affected outside the anomalous regions. On the other hand, ϑ_A does not always occur in the same position.

Trypsin behaves differently in the presence of 0.03 mole/l of $CaCl_2$, whose activity-increasing and stability-increasing action is well known. In this case, in addition to the shift of ϑ_A, the slope of the linear sections also changes, indicating that the calcium ion affects the catalytic process too.

The system ribonuclease—cyclic cytidine-2',3'-monophosphate is even more sensitive to salts. This is shown *e.g.* by the increase in the negative optical rotation of a 1.295% aqueous solution of the enzyme from $\alpha_{23}^{365} = -3.275°$ (in the absence of NaCl) to $-3.295°$ (0.033 mole/l NaCl); the optical rotation remains constant on further addition of sodium chloride (checked up to 0.1 mole/l)[21,33]. It is interesting, however, to note that as the negative optical rotation is increased by the addition of salt, the anomalies become weaker, and entirely disappear at a concentration of 0.1 mole/l; at this point, the plot of log v_{br} *vs.* $1/T$ is a straight line. In the present case at least, the changes in structure that are expressed in the change in optical rotation proceed hand in hand with the appearance of anomalies.

3.4. Partial Denaturation

We hoped to obtain further information on the anomalous temperature dependence of the reaction rate by careful denaturation of the enzymes; we expected the structure of the protein to change, but without an excessive decrease in activity.

If the activity of pancreas lipase and the temperature dependence of the hydrolysis rate are followed during incubation of the enzyme for about 38 h at 0 °C, no anomaly can be detected between 10 and 25 °C at a residual activity of 69.3%[23]. As a control, we also investigated a mixture of 70% of native and 30% of completely denatured enzyme. In this case, the anomalies were fully retained, and conversion to equal concentrations of active enzyme gave practically coincident curves.

The influence of denaturation was observed even more clearly in the hydrolysis of casein by trypsin. When the enzyme is incubated for 30 minutes at 50 °C, the amplitudes of the trend lines are higher than those obtained after incubation for 15 minutes or with free native enzyme; in contrast, after heating for 60 minutes at 50 °C, the curve obtained follows a normal course between 5 and 20 °C and exhibits a temperature optimum at 13 °C[21].

Mention should also be made of experiments carried out in the presence of 6 mole/l of urea. The added urea breaks hydrogen bonds and changes the solvation of the molecule, and this leads to unfolding and partial denaturation of the protein. Accordingly, the plot of log v_{br} *vs.* $1/T$ was only slightly curved, and showed no characteristic anomalous temperature dependence.

4. Discussion of the Anomalies

The anomalous temperature dependence of the reaction rate, which was first discovered by us for lipase[22,23], has now been observed with a total of 29 enzyme-substrate systems. In view of the deviations that occur, at least in partial regions, from the linear behavior expected from the Arrhenius equation, it must be concluded that the

[*] ϑ_A is the temperature at which the deviation from the "Arrhenius line" begins.

conditions for the Arrhenius equation, *i. e.* the independence of E_{exp} of temperature and/or the unchanged steric situation at the reaction site and in its immediate vicinity (steric factor), are not satisfied in these cases.

Let us assume, for example, that the enzyme is present simultaneously in two non-interconverting forms with different activities, possesses two active sites that catalyze the reaction with different activation energies, or could form two different activated enzyme-substrate complexes. If the two parallel reactions differ in their temperature dependence, the reaction with the greater activation energy will predominate at higher temperatures. This would give a concave plot of log v_{br} *vs.* $1/T$, but not a convex curve. However, this is exactly the opposite of the anomalies described so far, with one exception. Only *Massey*[18] gives an activation energy of 8.8 kcal/mole above 18 °C and only 5.8 kcal/mole below 18 °C for the fumarase-catalyzed hydration of fumarate at pH values above the optimum, *i.e.* pH = 7. *Patat* and *Kolb*[19], on the other hand, did not obtain an anomalous curve; they were able to explain the deviations reported by *Massey* on the basis of the temperature dependence of the extinction coefficient of fumarate (4% for every 10 °C). When this correction is applied, a uniform activation energy of 7.3 kcal/mole is obtained for pH = 7.8 (phosphate buffer).

The anomalies with continuous transition can be explained in this way, but not the sharp break (intersection of two straight lines), and much less the trend lines found by the small temperature interval technique.

For the enzymatic formation of levan, *Ebert et al.*[8] have interpreted the observed sharp break in the Arrhenius diagram of the synthesis reaction on the assumption that the overall reaction is made up of several simultaneous steps. However, this "coupled simultaneous reaction" can explain only breaks with higher values of the activation energy at lower temperatures; they cannot explain trend lines.

After the first experimental observations[22], we assumed that the anomalous behavior was due to the change in the conformation of the enzyme and hence of the enzyme-substrate complex at least in the vicinity of the active site, which proceeds in a manner comparable with a reversible phase transition. The later results supported and justified this interpretation.

If native and modified enzyme, whose active sites do not differ and which react by the same mechanism, are allowed to act on an identical substrate, the temperature dependence of the reaction rate should be the same, provided that the other part of the enzyme molecule is of no importance to the anomalies. However, since the resulting curves are different, conformational effects must be invoked as an explanation.

A relationship between the optical rotation and the anomalies in the log v_{br} *vs.* $1/T$ plot has also been detected in the hydrolysis of cyclic cytidine-2',3'-monophosphate by RNase[21, 28, 33]. Investigations on trypsin yielded similar evidence; however, the observed anomalous changes in rotation and pH were at the limit of accuracy of the measurements. No corresponding relations have so far been definitely detected with the rotatory dispersion, the fluorescence, the dielectric constant dispersion, and the behavior on differential thermal analysis.

According to these results, the conformational changes must be very small, and may even merely be changes in the positions of a few amino acids. From an estimate in which the sensitivity of the methods used was taken into account, a change of less than 5% is to be expected in the axial ratio of the globular protein.

From the observation that partially denatured enzymes exhibit normal temperature dependence of the reaction rate, as well as from the modification experiments, it is deduced that the relation between the actual catalysis and the process responsible for the anomaly is only *indirect*. Moreover, with changing pH, the maximum enzyme activity and the point at which the anomalous regions are most pronounced do not necessarily coincide. The cause of the phenomenon therefore very probably lies at the binding site of the substrate and in its vicinity.

If the initial rate v_0 at various temperatures is plotted as a function of the substrate concentration [S] for the system trypsin—N^{α}-benzoyl-L-arginine ethyl ester, one should expect the resulting "Michaelis curves" to lie synchronously one above the other. However, the v_0 values found at 15.35 °C are all lower than those found at 14.20 and 16.80 °C (Fig. 5)[21]. 15.35 °C lies precisely in the anomalous region for the overall reaction[*]. We see this as further evidence that the anomalies are due to changes in the enzyme-substrate complex.

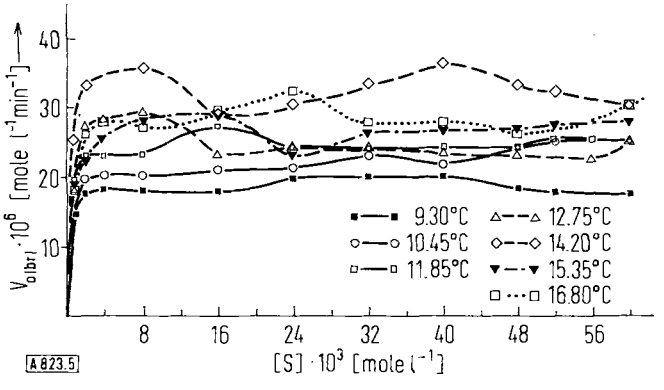

Fig. 5. Dependence of the hydrolysis of N^{α}-benzoyl-L-arginine ethyl ester (= S) by trypsin on the substrate concentration at 9.30, 10.45, 11.85, 12.75, 14.20, 15.35, and 16.80 °C. Conditions: [substrate] = 1×10^{-3} to 60×10^{-3} mole. l^{-1}, [trypsin] = 1 mg. l^{-1}, pH = 9.59.

As can be seen from Figure 5, we have here an enzyme-substrate system in which the dependence of the reaction rate on the substrate concentration does not obey the Michaelis-Menten relation. To calculate the Michaelis

[*] *B. H. Havsteen* (University of Aarhus, 1969) has detected similar anomalous regions for the temperature dependence both of the overall reaction rate and of the Michaelis constant K_m for chymotrypsin and maloamidinochymotrypsin (personal communication).

[**] K_m is a substrate constant indicating the substrate concentration at which the rate corresponds to half of the maximum value. Depending on the theory used, K_m can be expressed by rate constants of the forward and reverse reactions. According to the view of *Michaelis* and *Menten*, for example, $K_m = (k_{-1})/(k_{+1})$, while according to *Briggs* and *Haldane*, $K_m = (k_{-1} + k_{+2})/(k_{+1})$. Models in which several intermediates or covalent intermediate compounds are formulated lead to more complicated expressions (cf. *e.g.* [39, 40]).

constant K_m[**], it is necessary to use the section of the curve in the region of low substrate concentrations, since the course deviates strongly from the normal "Michaelis curve" at higher concentrations. The experimental velocity thus lies far below that calculated from the Dixon diagram. This has also been observed for other enzyme-substrate systems such as lipase—triglyceride[23], xanthine oxidase—aldehyde[25], urease—urea[24], and chymotrypsin—tyrosine ethyl ester[37,38], but will be discussed only after the investigations have been concluded.

For the hydrolysis of tyrosine ethyl ester by chymotrypsin A, on the basis of NMR measurements on the reacting substrate, *Fink* and *Patat*[38] report a sharp break in the temperature dependence of the substrate addition process at about 19 °C. However, we had found one of the anomalous regions in the log v_{br} *vs.* $1/T$ plot of the overall reaction at this temperature[21]. On the other hand, the same plot gives a straight line for the last reaction step leading to the product, *i.e.* for the postulated multicenter reaction[38].

Kinetic analysis of the hydrolysis of cyclic cytidine-2',3'-monophosphate by RNase led us to similar results (see below)[28]. Experiments are being carried out at present on the hydrolysis of esters by trypsin, in which we are investigating the formation of the enzyme-substrate complex, the acylation and deacylation, and the overall reaction independently of one another in an effort to localize the reason for the anomalies in this system more accurately[31].

Unlike in the above examples, the dependence of the reaction rate on the substrate concentration can be described by the Michaelis-Menten view for the systems lipase—Tween 20[21] and RNase—cyclic cytidine-2',3'-monophosphate[33]. A plot of K_m against $1/T$ for RNase gives two straight lines with different slopes and with a wavelike transition at the same place in the plot of log v_{br} *vs.* $1/T$[28]. The anomalies become less pronounced with increasing substrate concentration. This is as expected, since with increasing substrate saturation, the equilibrium of the formation of the activated enzyme-substrate complex has less influence on the overall reaction rate, and this becomes more distinctly a function of k_{+2}, the rate constant of the last reaction forming the product. k_{+2}, unlike K_m, is always influenced *constantly* by temperature changes, even in the anomalous region, *i.e.* a logarithmic plot of k_{+2} against $1/T$ gives a straight line[28]. The anomalous temperature dependence of the overall reaction thus depends on the contribution of the formation of the enzyme-substrate complex.

Experiments with inhibitors support the above findings. For example, anomalous regions are found as well as the normal regions in the temperature profile of the inhibition of trypsin with soybean inhibitor[31]. Moreover, a temperature anomaly is found at about 22 °C, *i.e.* in the same region as for K_m, for the constant K_p of the competitive product inhibition of RNase by the 3'-cytidylate formed[28]. This suggests that the postulated small change in conformation has a similar effect on the binding of the inhibitor and of the substrate, with the result that the course of the reaction changes.

5. Model for Description of the Temperature Anomalies

To obtain an idea of what assumptions are necessary in order to be able to describe the experimentally observed anomalous regions by means of a model, we carried out a detailed study of the course of the curve for the system trypsin—N^{α}-benzoyl-L-arginine ethyl ester between 4 and 21 °C[21,33]. This part of the curve is shown in Figure 6. If we assume that practically only $(ES)_I$ is present below T_1, only $(ES)_{II}$ above T_2, and both forms in equilibrium between T_1 and T_2, the decrease in the substrate concentration with time, *i.e.* the rate of the hydrolysis, is found to be

$$-\frac{d[S]}{dt} = A_1 e^{-(E_{exp})_I/RT}[(ES)_I] + A_2 e^{-(E_{exp})_{II}/RT}[(ES)_{II}] \quad (4)$$

S = substrate, E = enzyme, (ES) = enzyme-substrate complex, E_{exp} = experimental activation energy

where in this case $(E_{exp})_I = (E_{exp})_{II}$, but $A_1 \neq A_2$. If the anomalous region is confined to 3.28° with $T_1 = 284.9$ and $T_2 = 288.18$ °K (11.74 and 15.02 °C respectively), the enthalpy of the transition is found, after rearrangement of the van't Hoff reaction isobar, to be

$$\Delta H = \frac{2.303 R T_2 \times T_1}{T_2 - T_1} \times \log \frac{K_{T_2}}{K_{T_1}} \quad (5)$$

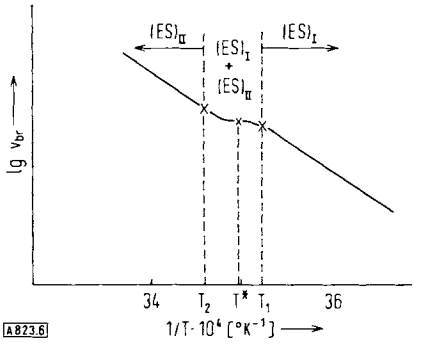

Fig. 6. Anomalous temperature dependence of the hydrolysis of N^{α}-benzoyl-L-arginine ethyl ester by trypsin. Conditions: [substrate] = 3.8×10^{-3} mole. l^{-1}, [trypsin] = 1 mg. l^{-1}, pH = 9.6. For further details see text.

If we also postulate that the concentrations of the forms I and II are 0.99 and 0.01 respectively at T_1 and 0.01 and 0.99 respectively at T_2, we find a value of 457.2 kcal/mole for ΔH; this value is too high to be understood. Similar difficulties are encountered *e.g.* in the treatment of the helix-coil transition of polypeptides or DNA. It is therefore necessary to resort to the additional assumption of cooperative processes. In this case the apparent rate constant is

$$K_{app} = K^n \quad (6)$$

where K is the equilibrium constant of the elementary process and n is the "cooperative length". The rate is then given by:

$$-\frac{d[S]}{dt} = v_{br} = e^{-E_{exp}/RT}\left[A_1 \frac{1}{1+K_{T_2(app)}} + A_2 \frac{K_{T_2(app)}}{1+K_{T_2(app)}}\right] \quad (7)$$

where

$$K_{T_2(app)} = e^{n\Delta H/R} \quad \frac{T_2 - T^*}{T_2 \times T^*} \qquad (8)$$

n = cooperative length, ΔH = bond enthalpy of *one* cooperative bond or interaction, T^* = temperature at which the concentrations of $(ES)_I$ and $(ES)_{II}$ are equal ($K_T = 1$).

Insertion of $n = 80$ and $\Delta H = 5$ kcal/mole in the above equation gives points that satisfactorily reproduce the course found experimentally for the curve (Fig. 7); it is therefore possible to give at least a formal description of the temperature dependence. However, one would then expect, contrary to observations so far with physical methods (Section 4), that a more distinct change in structure might be detected in view of the chosen "cooperative length", provided that this change was not largely confined to the interior of the folded molecule.

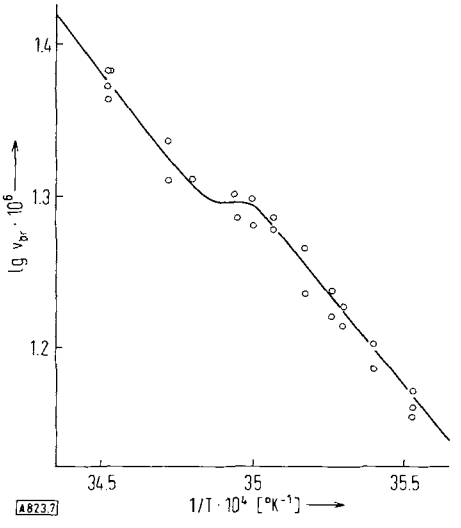

Fig. 7. Temperature dependence of the hydrolysis of N^{α}-benzoyl-L-arginine ethyl ester by trypsin. Conditions: [substrate] = 3.8×10^{-3} mole. l^{-1}, [trypsin] = 1 mg. l^{-1}, pH = 9.6.

6. Outlook

The temperature dependence of the rates of many enzyme reactions does not follow the Arrhenius equation, but follows a trend line on careful measurement at small temperature intervals. Indications of changes in the elementary processes have also been obtained from the kinetic analysis of the overall reaction. Thus by following the temperature dependence accurately, it is possible to detect small structural changes in the enzyme or in the enzyme-substrate complex with greater sensitivity than *e.g.* by measurement of the optical rotation.

It should also be possible to obtain additional information for the biotechnics of enzymatic processes. Examples are the change in the enzymes on conservation, particularly on freeze-drying, and the development of very stable enzymes for the industrial synthesis of specific chemical products.

The investigations were kindly supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. I am grateful to Fräulein Dipl.-Chem. G. Klunker and Fräulein K. Thomass as well as to Dr. W. Müller, Dr. G. Fink, Dipl.-Chem. Ch. Gramsch, Dipl.-Chem. J. Maris, Dipl.-Chem. D. Wolf, and Dipl.-Ing. H. Rusche for their cooperation, and to Frau R. Ehmer for her technical assistance.

Tetrakis(methylmercurio)phosphonium Salts[**]

By *Dietrich Breitinger, Klaus Geske,* and *Walter Beitelschmidt*[*]

We have extended our studies of (methylmercurio)ammonium complexes[1,2] to compounds of elements of Group VB. We have prepared tetrakis(methylmercurio)-phosphonium salts $[P(HgCH_3)_4]X$, where $X = BF_4$, PF_6, or SbF_6, by the action of phosphane on methylmercury compounds CH_3HgX[3].

The IR and Raman spectra indicate point group T_d for the cation $[P(HgCH_3)_4]^+$. Assignment of the vibrations of the central PHg_4 tetrahedron (corresponding values for $[N(HgCH_3)_4]^+$ are given in parentheses) follows from the selection rules, band intensities and band form, polarization state in the Raman effect (RE) and splitting in the solid-state spectrum (site symmetry effects): ν_1 (a_1) 119 cm^{-1} (RE, polarized: $\rho \approx 0$) (141 cm^{-1}), ν_3 (t_2) 354 cm^{-1} (IR; RE, depolarized) (584 cm^{-1}), ν_4 (t_2) 54 cm^{-1} (–; RE) (66 cm^{-1}). The force constants for the P—Hg—(N—Hg) bond are estimated from the ν_1 (a_1) vibrations as $f + 3f' = 1.7_7$ mdyn·Å^{-1} (2.5_2 mdyn·Å^{-1}). The P—Hg bond is obviously weaker than the N—Hg bond.

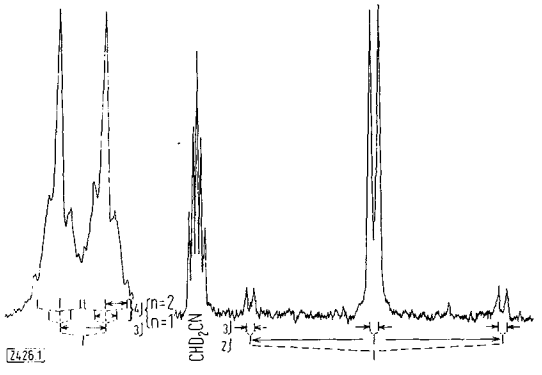

Fig. 1. ^{1}H-NMR spectrum of $[P(HgCH_3)_4]PF_6$ (saturated CD_3CN solution; 90 MHz; CHD_2CN at $\tau = 8.09$ ppm); left, main signal resolved.

In the ^{1}H-NMR spectrum[4] of $[P(HgCH_3)_4]PF_6$ (Fig. 1) the main signal is at $\tau = 9.28$ ppm (9.27 ppm). This indicates similar distribution of the cationic charge over the peripheral H atoms in the phosphonium and the ammonium complex (Pauling electroneutrality principle). The constants for the short-range coupling between ^{1}H and ^{199}Hg are found to be $^2J = J_{HgCH} = 155$ Hz (173 Hz), corresponding to the differing electronegativities of the central atoms. Coupling between the peripheral protons and the central P atom leads to a doublet splitting of main signal and satellites with $^3J = J_{PHgCH} = 4.8$ Hz. Finally, long-range coupling effects appear, due to the various nuclide compositions of the cations $[Y(^{199}HgCH_3)_n(^{200}HgCH_3)_{4-n}]^+$ (Y = N, P; $0 \leqslant n \leqslant 4$; ^{200}Hg represents all the non-coupling Hg nuclides); the coupling constants $^4J = J_{HgYHgCH} = 2.3$ Hz (3.5 Hz) are found.

X-ray analysis of single crystals of $[P(HgCH_3)_4]PF_6$ showed space group C_{2h}^5—P $2_1/c$ and the lattice parameters $a = 8.28$ Å, $b = 16.59$ Å, $c = 12.15$ Å, and $\beta = 92.3°$; with $Z = 4$, $d_{calc} = 4.17$ g·cm^{-3} to be compared with $d_{obs} = 4.12$ g·cm^{-3}. The compound was thus shown to be isotypic with the analogous ammonium salt[5]. From the number of formula units in the unit cell, from group-theoretical considerations, and from the IR spectrum of the anion the cations and anions could be assigned to general positions.

Experimental:

CH_3HgX was prepared by metathesis of AgX with methylmercury bromide in diethyl ether or 2-propanol. Phosphane was led into the solution at room temperature with exclusion of air, until the crystalline precipitate that was rapidly formed no longer increased in amount. Recrystallization from 2-propanol gave, for example, analytically pure $[P(HgCH_3)_4]PF_6$ in 10% yield (based on CH_3HgBr).

$H[PO_2ClF]$ and $H[PO_2BrF]$, Two New Dihalooxophosphorus Acids[**]

By *Hans Falius* and *Klaus-Peter Giesen*[*]

Of the free dihalooxomonophosphorus(v) acids, only the compounds $H[PO_2F_2]$ and $H[PO_2Cl_2]$ are as yet known, while a dibromo acid could be obtained only in the form of its salts[1]. Of the mixed dihalooxo acids only a few esters, alkylamides, and arylamides have been described[2], and the free mixed acids are all previously unknown; they cannot be prepared from organic derivatives as the phosphorus-halogen bond is cleaved by hydrolysis.

The fluorophosphorus(III) acid, $H[PHO_2F]$, obtained recently[3], appeared to be suitable as starting material for preparation of mixed halofluorophosphorus acids. Its reaction with chlorine or bromine in fact rapidly gave the two mixed dihalo acids $H[PO_2ClF]$ *(1)* and $H[PO_2BrF]$ *(2)*, respectively.

$$H[PHO_2F] + X_2 \rightarrow H[PO_2XF] + HX$$

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Highly viscous liquids were obtained as by-products, which were not examined but presumably are polyphosphorus acids formed by condensation. Reaction with iodine is very slow; in ether it leads to red precipitates consisting, according to the reaction conditions, of red phosphorus or P_2I_4.

The acid *(1)* can also be obtained by mild partial hydrolysis of $POCl_2F$.

$$POCl_2F + H_2O \rightarrow \underset{(1)}{H[PO_2ClF]} + HCl$$

The acids *(1)* and *(2)* are liquid at room temperature and insoluble in apolar solvents. *(1)*: $d_4^{20} = 1.522\ g\,cm^{-3}$, $n_D^{20} = 1.3674$. *(2)*: $d_4^{20} = 2.140\ g\,cm^{-3}$. B. p. 215 °C was extrapolated from a few vapor pressure values for *(1)* below 40 °C; the evaporation enthalpy amounts to $\Delta H_{298} = 10900\ cal\,mol^{-1}$, and the evaporation entropy to $\Delta S_{298} = 25.1\ cal\,mol^{-1}\,°K^{-1}$. Although *(1)* is stable when moisture is excluded, *(2)* slowly becomes yellow (Br_2), especially in light. Both compounds are hydrolyzed in aqueous solution, and then consume 3 equivalents of alkali hydroxide. Accordingly, $H_2[PO_3F]$ and HCl or HBr are formed, as was confirmed by chromatography. $Li[PO_2ClF]$ *(3)* and $Li[PO_2BrF]$ *(4)* were obtained on treatment of ethereal solutions of *(1)* or *(2)*, respectively, with LiBr; they also are hydrolyzed and then require 2 equivalents of NaOH for neutralization.

Doublets appear in the ^{19}F- and ^{31}P-NMR spectra (external standards: CF_3COOH, 85% H_3PO_4) of *(1)* and *(2)* because of FP and PF coupling.

	$H[PO_2ClF]$ *(1)*	$H[PO_2BrF]$ *(2)*
^{19}F-NMR	$\delta = -33.3$ ppm	$\delta = -46.3$ ppm
	$J_{FP} = 1055$ Hz	$J_{FP} = 1106$ Hz
^{31}P-NMR	$\delta = +1.96$ ppm	$\delta = +15.9$ ppm
	$J_{PF} = 1050$ Hz	$J_{PF} = 1103$ Hz

The acids *(1)* and *(2)* scatter so feebly that Raman spectra could not be obtained. Therefore, the IR spectra of the salts *(3)* and *(4)* were measured.

$Li[PO_2ClF]$ *(3)*, Nujol suspension, values in cm^{-1}: 1254 vs $\nu_{as}PO_2$, 1133 vs ν_sPO_2, 876 vs νPF, 630 vs νPCl, (551 vw), 490 w δ, 452 s δ, 381 vs δ, 274 s δ.

$Li[PO_2BrF]$ *(4)*, KBr disk, values in cm^{-1}: 1282 vs $\nu_{as}PO_2$, 1160 vs ν_sPO_2, 874 vs νPF, 558 s, 522 s νPBr(?).

Experimental:

(1): a) $H[PHO_2F]$ (8.4 g, 0.1 mol) is added dropwise to a solution of Cl_2 (10–12 g) in stirred and ice-cooled anhydrous CCl_4 (100 ml). The CCl_4, HCl, and excess of Cl_2 are removed at reduced pressure and the residual oil is fractionated in a high vacuum below 50 °C. *(1)* condenses in a cold trap at −23 °C (solid + liquid CCl_4). After several successive distillations under these conditions the yield amounts to *ca.* 30% (3.5 g).

b) H_2O (18 g, 1 mol) is added dropwise to a solution of $POCl_2F$ (137 g, 1 mol) in anhydrous ether (400 ml) stirred vigorously at −70 °C. After removal of the cooling-bath the mixture is stirred until it reaches room temperature and no further evolution of HCl can be observed. The ether is removed at reduced pressure and the residue is fractionated as in a). The yield is *ca.* 50% (60 g).

(2): Preparation analogous to *(1)* a). CCl_4 100 ml, Br_2 7.5 ml, $H[PHO_2F]$ 8.4 g (0.1 mol). Yield *ca.* 25% (4 g).

Molecular Structure of Bis(hexamethylbenzene)-ruthenium(0)[**]

By *Gottfried Huttner*, *Siegfried Lange*, and *Ernst O. Fischer*[*]

As a result of ^1H-NMR investigations *Fischer* and *Elschenbroich* suggested that the diamagnetic bis(hexamethylbenzene)ruthenium(0) has a structure in which the C_6 skeleton is no longer planar[1]. This proposal has been substantially confirmed by the present X-ray structure analysis.

The compound crystallizes in the monoclinic space group $P2_1/c(C_{2h}^5$, No. 14) with cell constants $a = 15.51$, $b = 8.07$, $c = 16.73$ Å, $\beta = 90°$, $V = 2094$ Å^3, $d_{calc} = 1.305$, $d_{exp} = 1.339$ g/cm^3, $Z = 4$.

The analysis is based on a total of 2696 different independent non-zero intensities in the range $0 \leq \sin\vartheta/\lambda \leq 0.65$, which were obtained from two crystals on a Weissenberg diffractometer with monochromated radiation ($Mo_{K\alpha}$, $\lambda = 0.71069$ Å). An empirical absorption correction[2] was applied as well as the usual Lorentz and polarization factor corrections. The structure was determined by conventional Patterson and Fourier methods. Refinement in an anisotropic model led to an agreement factor of $R_1 = 0.043$. All hydrogen atoms were located. Their contributions to the structure factors were included in the calculations.

The geometry of the molecule could roughly be classified by mirror symmetry [C_s; mirror plane through Ru and the centers of bonds C(11)—C(16) and C(21)—C(26)]. However, deviations of some of the individual bond lengths and bond angles from this idealized symmetry are significant (Fig. 1).

One of the rings in the molecule is planar ($\sigma = 0.009$ Å) with a mean C—C distance of 1.410(4) Å. Comparison with the C—C distance in hexamethylbenzene (1.39 Å)[3] seems to indicate strong participation of the antibonding orbitals of the benzene ring in the complex bonding. The distance of the Ru atom from the best plane of the atoms of this ring amounts to 1.75 Å; the projection of the Ru on to this plane lies approximately in the center of the ring.

The second ring is bent about the axis C(12)—C(15). The distance of the Ru from the best plane through atoms C(12), C(13), C(14), and C(15) ($\sigma = 0.009$ Å), amounts to 1.73 Å. This plane makes an angle of 5.2° with that of the planar ring and an angle of 42.8° with the plane defined by C(12),

[**] We thank the Leibniz-Rechenzentrum der Bayerischen Akademie der Wissenschaften for computer time and the Deutsche Forschungsgemeinschaft for support of this investigation.

C(11), C(16), and C(15) ($\sigma = 0.001$ Å). Similar relations were found for the six-membered ring of π-cyclopentadienyl[hexakis(trifluoromethyl)benzene]rhodium[4]. However, whereas for the latter compound the bending of the benzene nucleus could be ascribed to the influence of the trifluoromethyl groups[5], the present structure shows that the distortion can be caused simply by an excess of two electrons over the noble gas configuration of the central atom. The cyclic conjugation in the ring is thus considerably disturbed (see Fig. 1). The bond length C(16) to C(11) of 1.327(10) Å is that of a pure double bond.

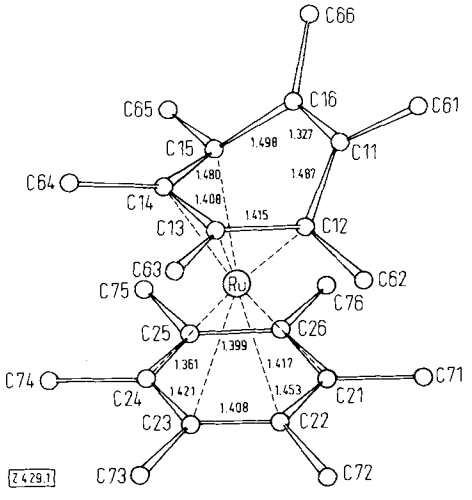

Fig. 1. Molecular structure of bis(hexamethylbenzene)ruthenium(0). None of the standard deviations of the C—C bond lengths in the rings exceeds 0.012 Å.

N-Alkylimino Acid Anhydrides as Intermediates in Anodic Oxidation of Aliphatic Carboxylic Acids in Acetonitrile

By *Hans Günter Thomas*[*]

In the anodic oxidation of aliphatic carboxylic acids in acetonitrile[1] products are obtained that are to be ascribed to attack by a carbonium ion on the acetonitrile.

If isobutyric acid is electrolyzed in acetonitrile with carbon electrodes at −10 °C or below, there are formed, besides propene, carbon dioxide, and hydrogen in a total yield of *ca.* 70%, *N*-isopropylacetamide *(1a)*, *N*-acetyl-*N*-isobutyrylisopropylamine *(2a)*, and isobutyric anhydride *(3a)*. Electrolysis of pivalic acid under the same conditions affords, besides isobutene, carbon dioxide, and hydrogen as main products, *N-tert*-butylacetamide *(1b)* and pivalic anhydride *(3b)*.

A first thought is to regard *(1)* as the product of a Ritter reaction; but then the formation of compounds *(2)* and *(3)* cannot be explained. Control experiments excluded the possibility that diacylamines *(2)* could be formed by acylation of *(1)* by *(3)* under the conditions of the electrolysis. Nor can the diacylamines acylate the starting acid

with formation of *(3)*. Rather, a common intermediate must underly the formation of compounds *(1)* to *(3)*. This could be the imino acid anhydride *(4)*, which belongs to a class of compounds which has as yet not been synthesized in the aliphatic series and of which there are so far only cyclic examples[2].

Imino acid anhydrides *(4)* are transformed into diacylamines *(2)* by a known rearrangement reaction[3]; reaction of the imino acid anhydrides with isobutyric acid or pivalic acid affords a straightforward explanation of the formation of the acetamides *(1)* and the anhydrides *(3)* in a ratio 1:1.

The rearrangement product *(2b)* was not found after electrolysis of pivalic acid, perhaps because of steric hindrance at the nitrogen atom.

Although imino acid anhydrides of type *(4)* could not be isolated in the pure state[4], electrolysis at low temperatures provides a method of producing these compounds *in situ* and studying their acylating powers for substances containing OH, NH_2, and SH groups.

Electrolysis of isobutyric acid in acetonitrile:

A solution of isobutyric acid (132 g, 1.5 mol) in anhydrous acetonitrile (2100 ml) containing a little (2 g, 0.02 mol) triethylamine is electrolyzed in a gas-tight circulating apparatus with cylindrical carbon electrodes, at −10 °C, a constant current density of 0.2 A/dm², and 6 to 9 V terminal voltage, until gas chromatography showed that not more than 20% of the isobutyric acid remained unconsumed.

[*] Dr. H. G. Thomas
Institut für Organische Chemie der Technischen Hochschule
51 Aachen, Templergraben 55 (Germany)

For working up, the acetonitrile was distilled off through a Vigreux column; the liquid residue (107 g) distills between 25 and 42 °C/0.1 torr without a column. The distillate (90.5 g) obtained consisted of isobutyric acid 23.6%, amide *(1a)* 28.0%, anhydride *(3a)* 40.8%, and diacylamine *(2a)* 7.5%.

Experimental Evidence for Kink Formation

By *G. Lagaly* and *Armin Weiss*[*]

In the past years some types of movements in polymers have been interpreted by formation and rearrangements of kinks and jogs[1, 2], *i.e.* special rotational isomers of the hydrocarbon chains containing *gauche* bonds (Fig. 1). The formation of kinks and jogs is mainly concluded from relaxation properties[3–5]. Since by conformational changes from *trans* to *gauche* the length of the alkyl chain decreases by a multiple of 1.27 Å, kink formation should become evident by chain length measurements.

In the systems studied so far (polymers and alkanes) kink formation occurs statistically or in small kink blocks between unaltered alkyl chains. Therefore, hitherto, it has been impossible to measure the decrease in the chain length directly. Now, we have succeeded in demonstrating the shortening of the alkyl chains as a consequence of kink formation by direct X-ray measurements.

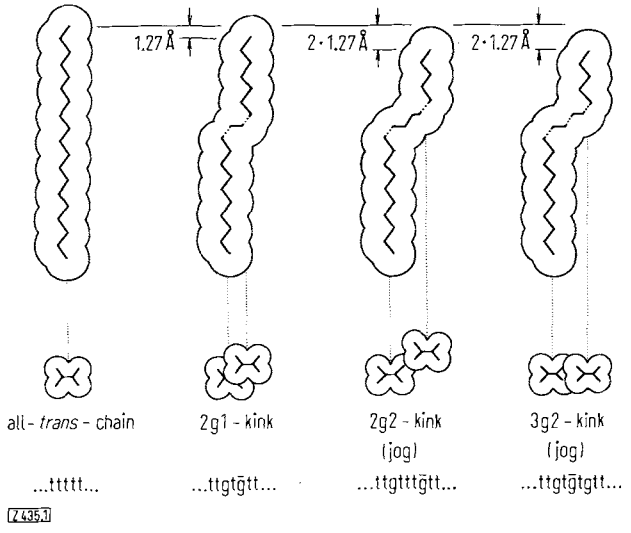

Fig. 1. Some conformations of the alkyl chains with kinks and jogs.

[*] Dr. G. Lagaly and Prof. Dr. Armin Weiss
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstrasse 1 (Germany)

The *n*-alkanol complexes of *n*-alkylammonium layer silicates[6] were used as models. In these compounds the alkanol molecules and the alkylammonium ions arrange themselves in bimolecular layers between the silicate sheets, with the alkyl chains perpendicular to the silicate layers. Since the distance between the silicate layers (= basal spacing) can be easily measured by X-ray analysis, the thickness of the bimolecular interlayer can be determined with high accuracy and the shortening of the alkyl chains can be directly detected.

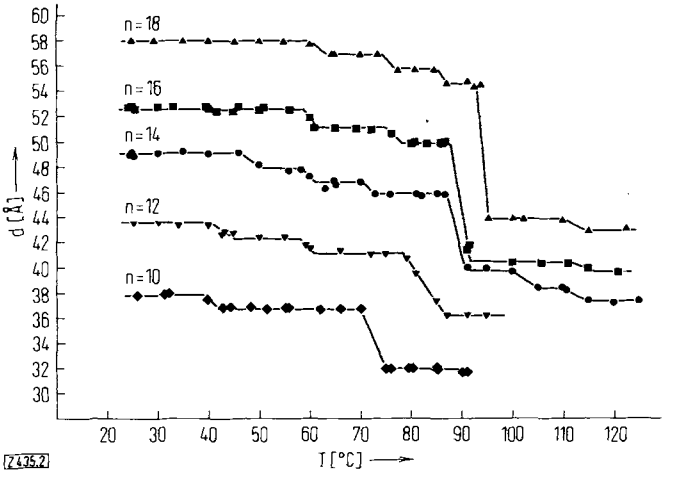

Fig. 2. Variation of the basal spacings *d* of *n*-alkanol complexes of *n*-alkylammonium beidellites with temperature (*n* = number of carbon atoms in the alkanol molecule = number of carbon atoms in the alkylammonium ion).

The basal spacings of the alkanol complexes decrease in regular steps of 1.1—1.3 Å with increasing temperature. Fig. 2 shows, as examples, the basal spacings of the *n*-alkanol complexes of *n*-alkylammonium beidellites. (The chain lengths in the alkanol molecules are equal to the chain lengths in the alkylammonium ions.) The change in the basal spacings with increasing temperature are reproducible and reversible, but hysteresis is often observed. The height of the steps corresponds exactly to the shortening of the alkyl chains as calculated for kink formation.

From these results it can be concluded that simple ("2g1") kinks are introduced in the alkyl chains with increasing temperature. The number of kinks per chain, however, seems to have an upper limit; exceeding this limit, the structure rearranges to a high temperature form with drastically reduced basal spacings. It has to be assumed that this transformation is caused by a rearrangement of simple 2g1 kinks to high order kinks (= jogs). If the temperature is raised still further, additional small steps in the decrease in the basal spacings are observed.

The results reported in this paper indicate that kink formation and kink rearrangements have to be considered in discussions of bimolecular films of long chain alkyl compounds[7].

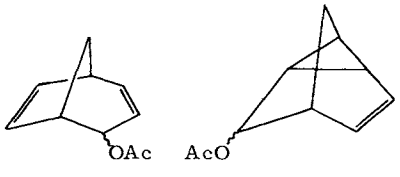
An Energy Surface for Acetolysis *via* C_8H_9 Cations from *exo*-Tetracyclo[3.3.0.0^{2,8}.0^{4,6}]oct-3-yl *p*-Nitrobenzoate[**]

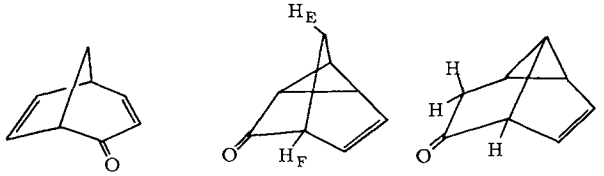


By *Wolfgang Lotsch* and *Andrew S. Kende*[*]

We wish to report equilibration and deuterium labeling studies involving a series of tautomeric C_8H_9 cations derived from *exo*-tetracyclo[3.3.0.0^{2,8}.0^{4,6}]oct-3-yl *p*-nitrobenzoate *(1)*, R = *p*-nitrobenzoyl[1]. These data permit construction of an energy surface relating the three distinct carbon skeletons observed in this rearrangement network.

(1)

Acetolysis of pure *exo-(1)*, R = *p*-nitrobenzoyl, in glacial acetic acid containing an equivalent of sodium acetate gave after 5.5 h reflux a 93% yield of mixed acetates, purified by vacuum distillation at 35 °C. Preparative gas chromatography[2] of the distillate yielded 60% of the mixed epimeric acetates *(2)*, 37% of epimeric tricyclic acetates *(3)*, and *ca.* 3% of unidentified by-product different from either *exo-* or *endo-(1)*, R = acetyl; the presence of more than 0.1% of either of the latter could have been detected.



(2) *(3)*

The mixture of bicyclic acetates *(2)* (69% *exo* and 31% *endo*)[3] was saponified and oxidized by chromium trioxide-pyridine complex in methylene chloride[4] to an unsaturated ketone *(4)*, $\nu_{max}^{CCl_4}$ 1690 cm^{-1}, parent *m/e* = 120, identified by IR and NMR comparison with authentic bicyclo[3.2.1]octa-3,6-dien-2-one[5]. In a similar manner, the tricyclic acetates *(3)* (59% *exo* and 41% *endo*)[6] were oxidized to a ketone *(5)*, $\nu_{max}^{CCl_4}$ 1740 cm^{-1}, *m/e* = 120. This ketone was distinguished from the isomeric alternative *(6)* by 90-MHz decoupling studies which, *inter alia*, clearly demonstrated the 6-Hz vicinal coupling between bridgehead proton H_F and one of the bridge protons, H_E.

[*] Dr. W. Lotsch and Prof. A. S. Kende
University of Rochester, Department of Chemistry
Rochester, New York 14627 (USA)

[**] A. S. K. makes acknowledgment to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for partial support of this research. The award of a Deutscher Akademischer Austauschdienst Fellowship to W. L. is gratefully acknowledged.

Gas chromatographic analysis of acetate composition as a function of solvolysis time revealed that the kinetic acetolysis products of *(1)* are the unrearranged acetates *exo-(1)*, R = Ac, and *endo-(1)*, R = Ac[7], but that the

(4) *(5)* *(6)*

percentage of tricyclic acetates *(3)*, and then of bicyclic acetates *(2)*, gradually increases as secondary equilibration of acetates occurs. The 5.5-h mixture is the equilibrium mixture which can be independently reached starting with a sample of *exo-(1)*, R = Ac (Table 1).

Table 1. Composition of acetates from *exo-(1)*, R = *p*-nitrobenzoyl or *exo-(1)*, R = Ac.

Starting material	Reaction time (h)	*exo-(1)*, R = Ac (%)	*endo-(1)*, R = Ac (%)	*(2)* (%)	*(3)* (%)
exo-(1), R = *p*-nitrobenzoyl	0.17	30	46	13	11
	1.00	9	16	43	32
	2.00	4	4	54	38
exo-(1), R = Ac	1.00	15	15	39	31
	2.00	5	5	53	37

The mechanism leading from *(1)* to systems *(3)* and *(2)* is further delineated by the fate of deuterated *exo-(1)*, R = *p*-nitrobenzoyl[8], on solvolytic rearrangement. The isolation and oxidation sequence described above converts the latter to the corresponding deuterated rearrangement ketones [D$_1$]-*(5)* and [D$_1$]-*(4)* which are labeled specifically (Figure 1).

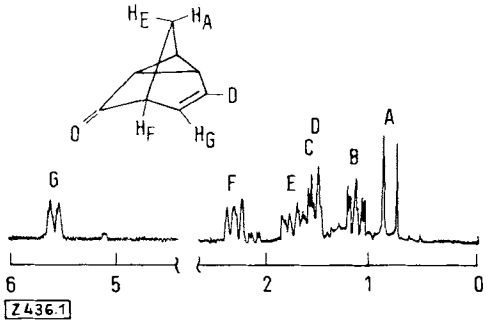


Fig. 1. NMR spectrum of [D$_1$]-*(5)* in C_6D_6 solution, measured in ppm relative to internal $(CH_3)_4Si$ (not shown) at 90 MHz.

These data implicate stepwise, stereospecific cleavage of first one, then the second cyclopropane ring to yield ultimately the allylic cation of the bicyclic series[9]. Moreover, the labeling pattern unambiguously excludes any degeneracy arising from equilibration of the C_3, C_2, and C_1 bridges in the bicyclic cation despite the availability of simple 1,2-shifts which would achieve that result.

If our equilibration results are taken in conjunction with the recent kinetic data obtained by *Diaz*, *Sakai*, and *Winstein*[7] an approximate energy diagram for the isomerizations observed in this C_8H_9 network may be con-

structed (Figure 2). For simplicity only the solvolyses of the *exo* isomers of the *p*-nitrobenzoates are indicated (heavy lines); the isomerization steps are shown by the dashed lines connecting the three carbonium ions. The

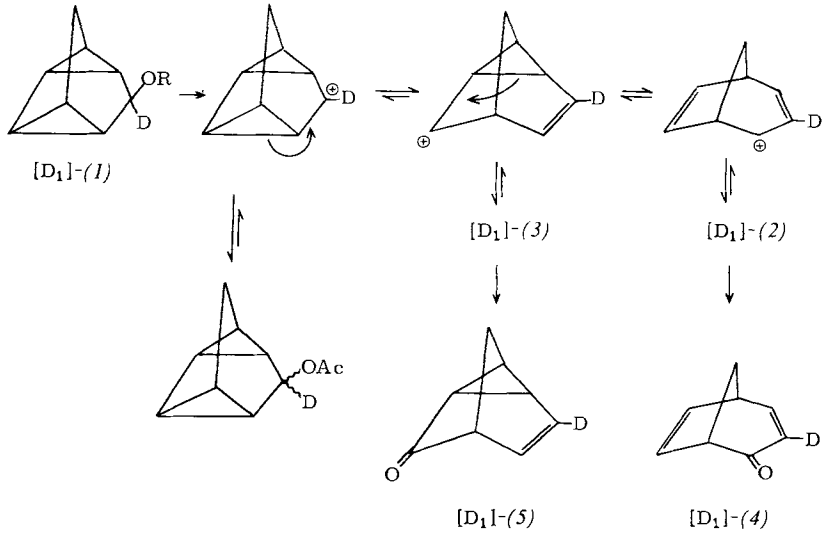

diagram assumes a typical[10] frequency factor A of $10^{11}\ s^{-1}$ for the solvolyses, a local minimum of *ca.* 5 kcal $mole^{-1}$ for each cation relative to the solvolysis transition state, and an equilibrium concentration of *exo-(1)*, R = Ac, of 0.01%.

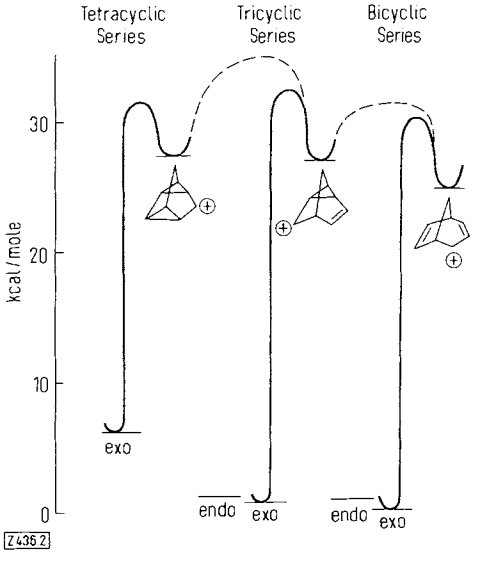

Fig. 2. Diagram depicting ΔH for reaction pathways relating tetracyclic, tricyclic, and bicyclic *p*-nitrobenzoates and the corresponding carbonium ions from solvolysis.

All of the data are consistent with equilibration *via* at least three distinct carbonium ions; there is no evidence for a single common intermediate having the bishomocyclopentadienyl cation structure.

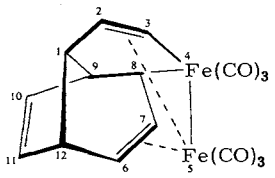
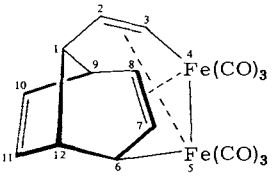
Diferratricyclododecatriene: An Iron Heterocycle Showing Rapid Degenerate Valence Isomerization[1]

By *Rudolf Aumann*[*]



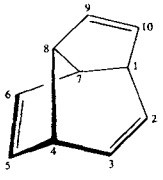
We recently described the autogenous intramolecular rearrangement *(1a)*⇌*(1b)* of diferratetracyclododecadiene[2].



We now report the rapid degenerate valence isomerization of the iron heterocycle, $C_{10}H_{10}Fe_2(CO)_6$ *(2)*, m. p. 89 °C, which is isomeric with *(1)*. 4,4,4,5,5,5-Hexacarbonyl-4,5-diferratricyclo[7.3.0.0^{6,12}]dodeca-2,7,10-triene *(2)* is form-

[*] Dr. R. Aumann
Organisch-chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

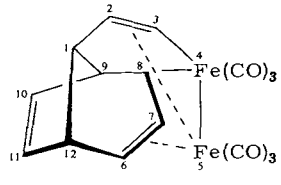
ed in 10% yield when $Fe_2(CO)_9$ reacts with bullvalene[3,4]. Its composition follows from the mass spectrum and elemental analysis.



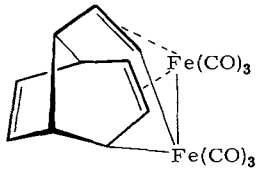
(2a)

(2b)

The CH skeleton was determined from the coupling pattern observed on NMR analysis. The geometry of the uncomplexed part of the molecule differs only slightly from that of tricyclo[5.3.0.0^{4,8}]deca-3,7,9-triene *(3)*[5], as shown by a comparison of the NMR coupling constants of *(2)* and *(3)*:



(2): $J_{9,10}=2.5$; $J_{10,11}=5.9$; $J_{11,12}=2.5$ Hz
(3) [5]: $J_{6,7}=2.0$; $J_{5,6}=5.9$; $J_{4,5}=3.0$ Hz



The CH skeleton of *(2)* is characterized by the observed long-range couplings: $J_{7,9}\approx J_{7,12}\approx 1.3$; $J_{1,6}\approx J_{1,8}\approx 1.5$; $J_{6,8}=2.0$; $J_{1,10}=J_{1,11}=0$ Hz[6]. $J_{13_{C(3)-H(3)}}$ indicates sp^2 hybridization of C-3. The vicinal coupling $J_{2,3}=9.5$ Hz accords with assumption of a strain-free, complexed double bond between C-2 and C-3[7,13].

The Mössbauer spectrum[8] of *(2)* shows different *s*-electron densities at the nuclear sites of the two iron atoms ($IS_{FeA}=0.13_0\pm0.01$; $IS_{FeB}=0.24_6\pm0.01$ mm/s) and different field gradients ($QS_{FeA}=0.90\pm0.01$; $QS_{FeB}=1.14\pm0.01$ mm/s).

Since the IR spectrum does not indicate any bridging carbonyl group, we suggest structures *(2a)* and *(2b)* for *(2)*. Formulation as *(2a)* is favored in view of the Mössbauer measurements, but it must be emphasized that *(2a)* and *(2b)* are approximations so far as the method of writing the valence bonds is concerned. Both *(2a)* and *(2b)* have pendants in the ferracyclopentadiene and ferracyclohexadiene complexes, where comparable bonding relations have been proved by X-ray structure analyses[9].

A

B

The dynamic NMR spectra of *(2)* reproduced in Fig. 1 result from rapid simultaneous exchange in magnetic surroundings between the proton pairs H(10)/H(11), H(9)/H(12), and H(6)/H(8), which can occur only by mutual rearrangement of the enantiomers A and B. As expected, in this process the signals assigned to the protons H(1), H(2), H(3), and H(7) remain largely unchanged.

The NMR signals of H(10) and H(11) coalesce when the temperature is raised (Fig. 1). Since coalescence of the signals from H(9) and H(12), and from H(6) and H(8), is

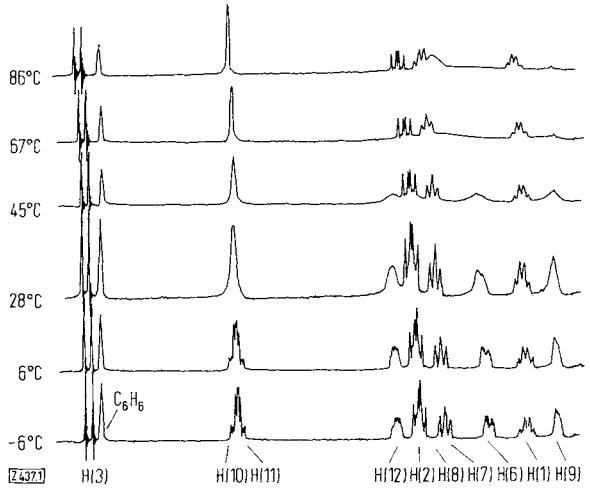


Fig. 1. The dynamic NMR spectra of *(2)* (10% solution in C_6D_6, 100 MHz).

to be expected only above the decomposition temperature of *(2)*, exchange of the magnetic surroundings of these proton pairs was demonstrated (Fig. 2) by the double resonance relaxation method developed by *Forsén* and *Hoffman*[10].

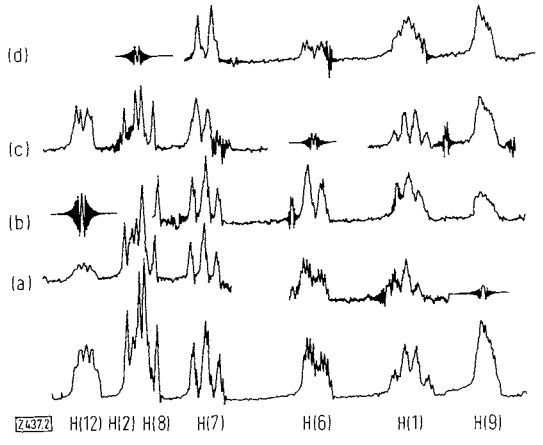

Fig. 2. Double resonance relaxation experiments with the proton pairs H(9)/H(12) (a, b) and H(6)/H(8) (c, d) of *(2)* (metastable C_6D_6 solution at −6°C; 100 MHz).

As can be seen from Fig. 2(a), "saturation" of H(9) by a strong electromagnetic field leads to a decrease in intensity ("partial saturation") of the signal of the proton H(12) that "exchanges" with H(9). Contrariwise, a decrease in the intensity of the H(9) signal is achieved by "saturation" of H(12) [Fig. 2(b)]. Similar effects can be demonstrated for the proton pair H(6)/H(8) [Fig. 2(c) and (d)]. The decrease in intensity is due to an equilibrium whose position is determined by the rate of exchange and the spin-lattice relaxation[10]. The following Eyring parameters for racemization of *(2)* have been calculated from quantitative measurements of the establishment of equilibrium[11] be-

tween the proton pair H(9)/H(12) between $-12.5°$ and $+12.0°C$:

$\Delta H^{\neq} = 10.4 \pm 1$ kcal mol^{-1}
$\Delta S^{\neq} = -18.5 \pm 3$ kcal deg^{-1} mol^{-1}
$\Delta G^{\neq} = 16.2$ kcal mol^{-1} [12]

(2) can be considered as a model compound showing each geometric step in the transfer of a vinyl group from one metal to another.

Desorption Spectra in the Adsorption System Iron/Nitrogen[1]

By *Gerd Wedler* and *Dieter Borgmann*[*]

Discussion of the mechanism of ammonia synthesis on iron catalysts has been generalized again by the recent work of *Brill*, *Ruch et al.*[2–4], and *Schmidt*[5], so that particular interest attaches to studies of the adsorption state of the nitrogen on very pure iron surfaces such as can be obtained by evaporation under ultra-high vacuum. The adsorption states in such systems can be characterized by measuring the surface potential and the desorption spectra, *i.e.* the temperature-dependence of the desorption[6]. The latter is obtained by loading the adsorbent with gases at a low temperature and then recording the changes in pressure above the adsorbent with change in temperature when the adsorption system is heated with continuous pumping off of the gases. The adsorbate is desorbed at lower or higher temperature according to the strength of its binding to the adsorbent, and this desorption can be recognized by a temporary pressure maximum. The desorbed gas can also be analyzed qualitatively by using a quadrupole mass spectrometer[7] in place of an ionization gauge for measuring the pressure.

Figure 1 shows the desorption spectrum of nitrogen that had been adsorbed at 77 °K on a *ca.* 90 Å-thick iron film that was obtained by evaporation at $77\,°K/2 \cdot 10^{-10}$ torr

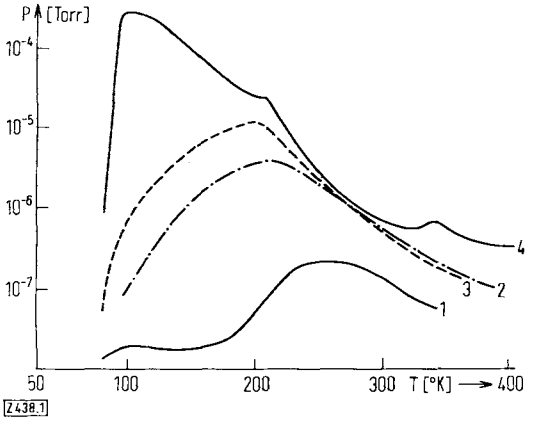

Fig. 1. Desorption spectra in the system iron/nitrogen. Curve 1, $\Theta = 0.013$; curve 2, $\Theta = 0.024$; curve 3, $\Theta = 0.05$; curve 4, $\Theta = 0.5$.

and annealed at 400 °K. The nitrogen was prepared within the apparatus by thermal decomposition of degassed sodium azide; mass-spectrometric analysis did not disclose any impurity in it. The coverage Θ is used as parameter in Fig. 1; it is referred to the monomolecular coverage ($\Theta = 1$), which in the adsorption system iron/nitrogen at 77 °K can be reached only at an equilibrium pressure of $P > 10^{-4}$ torr and corresponds to $7.5 \cdot 10^{14}$ molecules of N_2 per cm^2.

If the iron film is covered with nitrogen only up to $\Theta = 0.013$ (curve 1), desorption sets in above 170 °K and a desorption maximum is observed at 265 °K. This maximum shifts to lower temperatures (200 °K) as the coverage is increased (curve 2, $\Theta = 0.024$; curve 3, $\Theta = 0.05$), indicating that for the adsorption state characterized by this maximum the strength of bonding between the adsorbent and the adsorbate decreases with increasing coverage.

A shoulder is evident on the left side of the desorption maximum curve, even at $\Theta = 0.05$, and this must be ascribed to a second adsorption state of the nitrogen. This state becomes predominant on further increase of the coverage: at $\Theta = 0.5$ (curve 4) its desorption maximum is very highly developed immediately above 77 °K, while the species desorbing at 200—265 °K is then evident only as a shoulder.

At $\Theta > 0.1$, besides these two adsorption states, a third is observed that shows a desorption maximum at 330 °K (curve 4). Although we are here concerned with a state involving the strongest bonding between the adsorbate and the adsorbent, it is formed in detectable amount only at the higher coverages.

It follows from the height of the pressure increase that the number of molecules characterized by the desorption maximum between 77° and 90 °K greatly exceeds that of those in other states. The reversible adsorption occurring at 77 °K and $\Theta > 0.5$ also leads to this state, shifting the desorption maximum to still lower temperatures. This species of adsorbed nitrogen is positively polarized, as is shown by the decrease of the work function of the iron[8] on adsorption.

[*] Prof. Dr. G. Wedler and Dipl.-Chem. D. Borgmann
Institut für Physikalische Chemie II der Universität
852 Erlangen, Fahrstrasse 17 (Germany)

The state with desorption maximum between 200° and 265 °K is the only one occurring at $\Theta < 0.05$. It follows from the constancy of the height of the maximum that its amount is not further increased by increase of the coverage. It can amount to, at most, 5% of the total amount bound to the iron surface. *Richter*[8] has shown that this species makes the work function of the iron film increase, whence it follows that nitrogen present in this state is negatively polarized.

Still smaller must be the amount of the state that occurs first at $\Theta = 0.1$ and has its maximum at 330 °K, this being shown by the height of its pressure maximum. It can be formed at only very few sites on the surface, and even the smallest quantity of impurity prevents its appearance. The fact that this, the most firmly bound, state appears only at relatively high coverages shows that its formation involves an activation process. *Tompkins et al.* have made similar observations for adsorption of nitrogen on other body-centered cubic metals such as titanium and molybdenum[9] or tungsten[10].

It is certain that the molecular, physically adsorbed nitrogen with the desorption maximum at 77—90 °K does not play a decisive role in ammonia synthesis; and, as the species with a desorption maximum at 330 °K can no longer be observed in presence of even traces of impurity, it seems that the species most interesting for investigation of the ammonia synthesis should be the nitrogen that is desorbed between 200° and 275 °K.

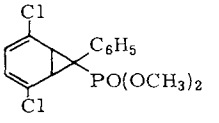
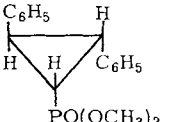
Two New Norcaradiene-Cycloheptatriene Equilibria[**]



By *Harald Günther, Budi D. Tunggal, Manfred Regitz, Hans Scherer, and Toni Keller*[*]

We recently reported characteristic ^{13}C-NMR data for norcaradienes and cycloheptatrienes[1]. By further ^{13}C- and ^1H-NMR measurements it has now been shown that ethyl 7-phenylcycloheptatriene-7-carboxylate *(1b)*[2] and dimethyl 7-phenylcycloheptatriene-7-phosphonate *(2b)*[3] exist in valence-tautomeric equilibrium with the corresponding norcaradiene forms *(1a)* and *(2a)*, respectively, whereas dimethyl 2,5-dichloro-7-phenylnorcaradiene-7-phosphonate *(3)* exists, within the accuracy of our measurements, solely as the bicycle[4].



(a) ⇌ *(b)*

(1), R = $COOC_2H_5$
(2), R = $PO(OCH_3)_2$

(3)

(4)

Fourier transform ^{13}C-measurements showed that the resonances for C(1) and C(6) in *(1)* and *(2)* are found clearly at higher field than those for the α-C atoms of cycloheptatriene[1]. They are, however, appreciably deshielded with reference to the corresponding carbon resonances in the norcaradiene system[1] (see Table 1). The unusual position of these resonances must thus be a manifestation of a reversible equilibrium of type *(a)* ⇌ *(b)* where rapid exchange leads to an average value.

[**] Part 2 of Applications of ^{13}C Resonance Spectroscopy.—Part 1: see [1]. Presented at the 161st Meeting of the American Chemical Society, Los Angeles, March 28 to April 2, 1971.

This interpretation is confirmed by the temperature-dependence of the ^{1}H-NMR spectra of *(1)* and *(2)* (Table 1). After line broadening and signal splitting, the spectra of the norcaradienes *(1a)* and *(2a)* are observed on cooling to −120 °C. The cycloheptatrienes *(1b)* and *(2b)* could not be observed directly so far, apparently because of their low concentration and the overlapping of their resonance signals with those of the norcaradienes. The dynamic process is also indicated for *(1)* by the temperature-dependent ^{13}C resonance signals for C(1) and C(6); here we were able to establish a diamagnetic shift (Table 1) and signal broadening on decrease of the temperature.

To estimate the equilibrium constants K for *(1a)*⇌*(1b)* and *(2a)*⇌*(2b)* we have determined the resonance frequencies of the α-protons in the triene forms by means of model compounds. In 7-monosubstituted cycloheptatrienes replacing isopropyl by C_6H_5, $COOC_2H_5$, or $PO(C_6H_5)_2$ causes deshieldings of 0.18, 0.21, and 0.18 ppm for these protons[5, 6]. If the substituent effects are considered as additive, one obtains $\delta_{1,6}=5.53$ and 5.50 ppm for *(1b)* and *(2b)*, respectively. Using these data, K values were determined from the temperature-dependence of the α-proton resonance between 30° and −100 °C, on the assumption that, of the norcaradienes with different configurations at C(7) (phenyl *endo* or *exo*), one form is dominant in both cases; then, by *van't Hoff*'s method, these K values led to the thermodynamic data for the equilibria listed in Table 1.

Compound *(3)* is shown to be a norcaradiene by both the ^{13}C- and the ^{1}H-NMR data (Table 1). The large vicinal coupling constant $J_{1,6}$ is particularly characteristic of this. With the help of the model compound *(4)*[5] it was further possible to clarify the configuration at C(7) in *(2a)* and *(3)*, since we were able to determine unambiguously the extent of *cis*- and *trans*-coupling between the proton and the phosphorus nucleus on the three-membered ring. For $^3J_{H,P}(cis)$ and $^3J_{H,P}(trans)$ in *(4)* we found values of 16.91 and 1.58 Hz, respectively. Since the H,P coupling in *(2a)* and *(3)* amounts to 17.0 and 16.2, respectively, the phenyl group occupies the *endo*-position in both systems.

The ability of substituents on C(7) to stabilize a norcaradiene[6, 7] is found, on the basis of these and other[8] observations, to be in the order:

Production of F Atoms, H Atoms, and OF Radicals

By *Heinz Gg. Wagner, Jürgen Warnatz*, and *Cornelius Zetzsch*[*]

When studying the rate of reactions of fluorine atoms it is generally necessary to ensure the presence of no—or very little—F_2 in the reaction mixtures, since F_2 in particular generally reacts very rapidly too. Hitherto F atoms have been obtained for such measurements either by microwave discharge in mixtures of CF_4 and He or by titration of NF_2 with N atoms[1]. Reports[2, 3] have already appeared, but without quantitative data, on the production of F atoms from F_2 in microwave discharges. Our own experiments gave at first poor yields of F and relatively high residual concentrations of F_2; appreciably better yields are obtained only if dry fluorine free from HF is used.

Production of F atoms

When a mixture of He and a few parts per thousand of fluorine, purified by freezing out HF and H_2O by liquid nitrogen, is allowed to stream through an electrodeless microwave discharge, the F_2 is almost completely dissociated. At a pressure of 3.5 torr, a flow velocity of 17 m/sec and 100-watt discharge energy the fluorine is consumed to a residue of about 1%. These data refer to the apparatus described in Ref. [1]. The F atoms thus obtained are very well suited for study of reactions of F atoms, since hardly any interfering substance remains present with them.

Production of H atoms

If the mixture of He and F atoms is titrated with H_2 to disappearance of the F atoms, the very rapid reaction leads to a mixture of He, HF, and H atoms with a very low content (*ca.* 1%) of H_2. When small concentrations of H atoms suffice, this process can have advantage over the direct production of H atoms from H_2 in a discharge where an appreciable proportion of the H_2 does not dissociate.

Production of OF

The radical OF has not previously been observed directly in the gas phase, although it is known in a N_2 matrix[4].

If F atoms, produced as above, are mixed with ozone, it is observed that the O_3 is totally consumed at F atom excess. In agreement with *Schumacher*'s results[5], the stable product is O_2. F atoms are consumed in the reaction and reformed during further reaction. OF occurs as intermediate and is later consumed. Since no other O—F compound could be observed with the same concentration profile, it is very unlikely that the mass peak of the OF ion at $m/e=35$ arises by fragmentation of another O—F compound. From these results it can be concluded that, analogously to the reactions of Cl, Br, and I with O_3, the following reaction occurs[6–8]:

$$F + O_3 \rightarrow OF + O_2$$

The rate constant at room temperature is found to be

$$k \approx 5 \cdot 10^{12}\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}$$

Subsequent reactions of OF in this system, which will be reported later, are slow enough to permit the study of their reactions with other compounds. Under the above

[*] Dr. J. Warnatz, Prof. Dr. H. Gg. Wagner, and Dr. C. Zetzsch
Institut für Physikalische Chemie der Universität
34 Göttingen, Bürgerstrasse 50 (Germany)

mentioned conditions the concentration of OF amounts to *ca.* 10^{-11} mol cm^{-3}.

The same results for the reaction with O_3 are obtained by using F atoms produced in a microwave discharge in a mixture of CF_4 and He. However, when the F atoms are produced by reaction of NF_2 with an excess of N atoms, the maximal concentration of OF is very much lower, as also is the consumption of F atoms at the beginning of the reaction. It can be assumed that OF is here consumed by the rapid subsequent reaction:

$$N + OF \rightarrow NO + F$$

New Type of Reaction Resulting from the Action of O_2 on Diarylperfluoroacylphosphanes[**]

By *Ekkehard Lindner* and *Hans-Dieter Ebert*[*]

We recently reported the unusual result of oxidizing diphenyl(trifluoroacetyl)phosphane[1,2], which reacts with molecular oxygen to afford racemic 1-(diphenylphosphoryl)-2,2,2-trifluoroethyl diphenylphosphinate. Further work has shown that the formation of the ester is due to a new type of reaction that occurs generally when a perfluoroacyl and two aryl groups are bonded in the phosphane used [cf. *(1)*].

(1) *(7)*

(7a), R = C_6H_5, $R_f = CF_3$ *(7d)*, R = C_6D_5, $R_f = CF_3$ [3]
(7b), R = C_6H_5, $R_f = C_2F_5$ *(7e)*, R = p-$CH_3C_6H_4$, $R_f = CF_3$
(7c), R = C_6H_5, $R_f = C_3F_7$

A prerequisite for this course of the reaction is the presence of a small amount of H_2O, which affords the H atom on the center of chirality; on the other hand, the solvent is only of subordinate importance since the same products are formed in similar yields (*ca.* 25%) in benzene, toluene, cyclohexane, hexane, and even C_6D_6 or dodecafluorocyclohexane. The compositions and structures of the new 1-(diarylphosphoryl)1*H*-perfluoroalkyl diarylphosphinates *(7a)* to *(7e)* follow from elemental analyses, mass, ^1H-, ^{19}F-, ^{31}P-NMR, IR, and Raman spectroscopic studies. The coupling scheme in the high-resolution ^1H-NMR spectrum is characteristic for the proton on the asymmetric C atom (C*), and the two ^{31}P signals indicate two phosphorus atoms in different chemical environments (Table 1). In the IR spectrum the band for $\nu(C{-}H_{aliphat.})$ absorbs at *ca.* 2925 cm^{-1} (solid; KBr).

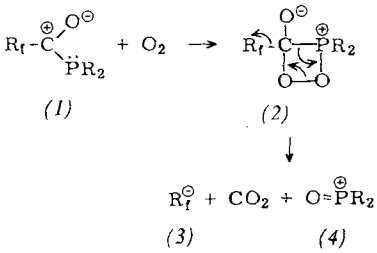

Table 1. Parameters of the ^1H- and ^{31}P-NMR spectra of compounds *(7a)* to *(7c)* (TMS or H_3PO_4 as standard).

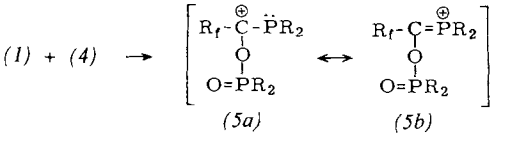
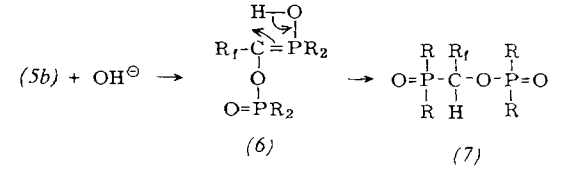
Compound	Nucleus	Coupling constant [Hz]	δ (ppm)	Measured at [MHz]
(7a) in [D_6]-Acetone	^1H	$^2J_{HP} = 12.5$ $^3J_{HP} = 4.7$ $^3J_{HF} = 7.8$	− 6.128	90
(7a) in [D_3]-Nitromethane	^{31}P		−23.170 −36.670	30
(7b) in [D_3]-Nitromethane with [D_6]-DMSO	^1H	$^2J_{HP} = 12$ $^3J_{HP} = 6$ $^3J_{HF} = 12$	− 6.2	60
(7b) in CH_3CN	^{31}P		−22.7 −35.2	36.43
(7c) in [D_3]-Nitromethane with [D_6]-DMSO	^1H	$^2J_{HP} = 12$ $^3J_{HP} = 4.5$ $^3J_{HF} = 12$	− 6.23	60

The corresponding alkali diarylphosphinates and fluorinated alcohols are formed on alkaline hydrolysis of *(7a)* to *(7e)*:

$$(OPR_2)_2OCHR_f + 2\,HO^- \longrightarrow 2\,R_2P(O)O^- + R_fCH_2OH$$



On the basis of these results we suggest the follow course for the formation of compounds *(7)*[4]: In the first step, O_2 adds to *(1)*; a transition state is assumed to consist of



(1) *(2)*

(3) *(4)*

(5a) *(5b)*

(6) *(7)*

(2), which decomposes into *(3)*, *(4)*, and CO_2; a similar mechanism has been formulated for the oxidation of alkylidenephosphoranes[5]. The ions *(3)* and *(4)* do not combine. We assume rather that *(4)* attacks a second molecule of the starting material *(1)*, while the R_f^- ion *(3)* reacts with H_2O to yield R_fH and HO^-. The HO^- then clearly adds to the cation *(5b)*, forming *(6)*. In a final step, *(6)* stabilizes itself to the ester *(7)*. The stable by-products CO_2 and 1*H*-perfluoroalkane (R_fH) were unambiguously identified in all cases.

Isomerization of Quinone Methides to Alkenylphenols[**]

By *Dietrich Braun* and *Bertold Meier*[*]

During our studies of oxygen polyradicals[1] we have found a new synthesis of sterically hindered polymerizable phenol derivatives by isomerization of the stable 2,6-di-*tert*-butylbenzoquinone methides *(1)* to the corresponding alkenylphenols *(2)*.

(1) *(2)*

┼ = tert-Butyl; R = H, CH_3, Phenyl

The isomerization occurs extremely rapidly and quantitatively on use of neutral aluminum oxide. Use of acid aluminum oxide is possible but leads to yields of only 50—60% because part of the isomeric compounds are bound to the catalyst as carbonium ions or react further by oligomerization. Basic aluminum oxide is not suitable because sterically hindered phenols are oxidized in a basic medium by atmospheric oxygen, yielding oily products when the reaction mixture is worked up. It is also impossible to isolate the alkenylphenols if the aluminum oxide is replaced by traces of protic or Lewis acids. This method of isomerization is superior to the classical processes (dehydration of carbinols or decarboxylation of substituted cinnamic acids)[1] because the alkenylphenols are immediately provided in a very pure state.

Experimental

2,6-Di-*tert*-butylbenzoquinone 4-dimethylmethide[2] (1 g, 0.00406 mol), anhydrous neutral aluminum oxide (1 to 2 g), and light petroleum (15 ml; b.p. 50—70 °C) are heated and stirred magnetically under nitrogen (gas stream) in a round-bottomed flask, fitted with a reflux condenser, in an oil-bath (70—80 °C). The deep yellow color disappears at once. The reaction is complete in 5—15 min. After cooling, the mixture is placed together with the aluminum oxide on a silica gel column and eluted with anhydrous light petroleum (50 ml). Removal of the solvent affords 2,6-di-*tert*-butyl-4-isopropenylphenol (0.95—1.0 g, 95—100%), m.p. 77—78 °C.

Nucleophilic Aromatic Substitution: A New Synthetic Route to Biphenyls[1]

By *Franz Effenberger, Klaus Nagel*, and *Wolfgang Agster*[*]

The most important methods for preparation of biphenyls are the Ullmann[2] and Gomberg reactions[3], which involve radical or organometallic intermediates; furthermore, biaryls are formed by benzidine rearrangement[4] and oxidative dimerization[5], as well as in the course of reactions involving aryne intermediates[6].

By treating aminobenzenes *(1)* with reactive haloarenes *(2)*, we have now obtained a polar aryl-aryl linkage *via* nucleophilic aromatic substitution, yielding biphenyl derivatives *(4)* to *(6)*.

In all cases, closure of the new C—C bond is preceded by formation of charge-transfer (CT) complexes *(3)* which may be isolated in crystalline form if reaction conditions are kept sufficiently mild. Only when heated do the CT complexes lose HCl to give biphenyls *(4)* to *(6)* (Table 1). The reactivity of the components *(1)* and *(2)* may be varied within wide limits. When tripyrrolidinobenzene is treated with chlorotrinitrobenzene *(2a)* the reaction mixture begins to boil. Upon introduction of an alkyl group R^2 into the aminobenzene *(1)*, the two *ortho* pyrrolidino rings are twisted out of the aromatic ring plane[7, 8]; reduced mesomeric interaction results in a decrease in electron density and thus also in the reactivity at the free ring positions. Consequently, heating is required for reaction of 1-methyl-2,4,6-tripyrrolidinobenzene with *(2a)*; with 1-ethyl-2,4,6-tripyrrolidinobenzene, the reaction does not proceed beyond the CT complex stage. For the haloarenes, 2-chloro-4-nitrobenzoic acid represents about the limit of reactivity towards tripyrrolidinobenzene.

The structure of the new biaryls is established by elemental analyses, molecular-weight determinations, and NMR spectra. Unexpectedly, compounds *(4)* to *(6)* are obtained as dark red to black, shiny crystals; from position, intensity, and structure of the visible absorption bands which determine the color (Table 1), interpretation as charge-transfer transitions is rather likely. Intermolecular CT interaction can be ruled out since Lambert-Beer's law holds unambiguously even at low concentrations. For a check, we have prepared comparable CT complexes *(7)*, which, as expected, show increasing dissociation as the concentration is lowered.

The geometry of the biphenyls *(4)* to *(6)* is fixed to a large extent, thus allowing a more detailed study of the intramolecular charge transfer on which we report in the accompanying Communication[9].

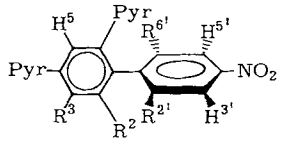
Intramolecular Charge Transfer in (Dialkylamino)nitrobiphenyls[1]

By *Ewald Daltrozzo*, *Franz Effenberger*, and *Peter Fischer*[*]

The deep color of the new biaryls reported in the previous Communication[2] must be ascribed to a charge transfer (CT) transition. Since within the region $7.5\cdot10^{-4}$ to $7.5\cdot10^{-6}$ mole/liter the absorption is independent of concentration, intermolecular origin of this CT interaction can be ruled out. For interpretation of intramolecular charge-transfer processes, knowledge of the molecular geometry is a prerequisite: information about the structure of the biphenyls *(1)* to *(3)* may be gained from the ^{1}H-NMR spectra.



In *(1a)* and *(2a)* to *(2f)*, the signals of the *ortho*-pyrrolidino groups are shifted to higher field by about 0.30 ppm (β-methylene protons) and 0.60 ppm (N—CH_2) respectively, relative to those of the para-amino substituents (Table 1). Improved shielding due to steric hindrance of resonance by the nitrophenyl substituents[2] does not suffice to account for these large shifts, especially of the β-CH_2 hydrogen nuclei[3]; it must rather be assumed that the *ortho*-dialkyl-

amino groups protrude deep into the diamagnetic anisotropy field of the nitrobenzene. The characteristic structure of the methylene multiplets, though, is not split further; within the NMR-time scale, the NR_2 groups must therefore be placed symmetrically with respect to the plane of the nitroarene [cf. *(4)*].

Admixture of contact charge transfer in chlorinated hydrocarbons gives a bathochromic shift. As has been observed for tetracyanoethylene[6], CH_2Cl_2 is a far more effective donor than CCl_4; for interaction of the amino system with halomethanes as acceptors[7], the opposite effect is to be expected.

Table 1. ^{1}H-NMR data and longest-wave UV absorptions of biphenyls *(1)* to *(3)*.

[a] (o) denotes pyrrolidino substituents in the 2- and 6-positions, (p) those in the *p*-position to the biphenyl linkage; in each case, the center of the characteristic multiplet is given as the signal position.
[b] 7.5×10^{-5} M in CH_3CN.

In *(2d)*, a hydrogen bridge can be formed from the COOH group to the *ortho*-dialkylamino-nitrogen; the resulting decrease in electron density on the N-atom shifts the $N-CH_2$ signal by -0.14 ppm. This shows how sensitive the NMR signals are even to small changes in structure.

(4)

Therefore the fact that the $H^{3',5'}$ signal position is almost identical for *(2a)* to *(2f)* (while electron affinities of the nitrophenyl units differ widely) seems to us good proof that in the ground state there is no significant interaction between the two aromatic component systems.

While several papers on intramolecular CT complexes have recently been published[4], intramolecular CT interaction in biphenyls has not been observed previously. The near constancy of the band position for *(2a)* over a series of solvents (Table 2) again ascertains the intramolecular origin of the longest-wave absorption of *(1)* to *(3)*.

Gradation of band positions in the order *(2a)*→*(1a)*→*(3a)* (561.5, 548.5, 533 nm), as well as for the sequence *(2a)*→*(2f)*, shows the energy of the CT transition to be determined by both the electron density of the amino and the electron affinity of the acceptor component. There is no straightforward correlation, though, with the $E_{1/2}^{Red}$ values of the nitroarenes.

For an interpretation of the charge transfer several possible mechanisms must be taken into account:

(a) interaction of the n-electron pair of one *ortho*-nitro-oxygen atom and orbitals of C-2 and C-6 of the aromatic amine;

(b) direct interaction between the lone pair of the *ortho*-pyrrolidino nitrogen and, particularly, positions 1', 2', and 6' of the aromatic nitro compound [see *(4)*];

(c) "normal" charge transfer from the electron-rich amino to the electron-deficient nitro component (overlap between p_z orbitals of one aromatic system and σ orbitals of bonds 1—2 and 1—6 of the other arene).

Transfer between the amino benzene and the *ortho*-nitro groups as in (a) is rather unlikely since, on the basis of orbital symmetry, there is no bonding interaction between any of the molecular orbitals participating in the long-wave transitions. By PPP calculations[8], position and intensity of the lowest-energy absorption may be reprod-

uced satisfactorily even without taking process (b) into account, and without specific adjustment of parameters[9,10]! Thus, in the first electron transition (CT band), charge is transferred primarily from the *ortho* nitrogen atoms and from C-1 of the aminobenzene to C-1′ and the *ortho*-nitro groups of the second component; hyperconjugative σ-π interaction as in (c) has been taken into account by introducing pseudo-π centers.

Table 2. Lowest-energy UV-absorption bands of *(2a)* in various solvents.

	C_6H_{12}	CCl_4	Dioxane	Dimethoxyethane	CH_2Cl_2	Acetone	CH_3CN	CH_3OH
E_T-value [5]	31.2	32.5	36.0	38.2	41.1	42.2	46.0	55.5
$\tilde{\nu}$ (cm^{-1})	17940	17610	17970	17950	17040	17860	17810	18050
$\Delta\tilde{\nu}_{1/2}$ (cm^{-1})	3730	3930	4620	5010	4620	5090	5090	5250
ε_{max}	7240	7030	5720	5740	6300	5690	5750	5560

An estimate as to the relative contributions of mechanisms (b) and (c) to the charge transfer observed will be possible as soon as dialkylamino biphenyls become available with different gradation between N-basicity and π-electron density at the free aromatic ring positions.

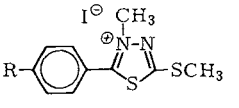
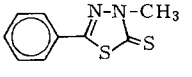
X-Ray Photoelectron Spectroscopy of Mesoionic Compounds

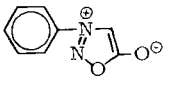


By *Manfred Patsch* and *Peter Thieme*[*]

Photoelectron spectroscopy (ESCA)[1] makes it possible to determine the binding energy of core electrons, this energy appearing as the difference between the excitation energy and the kinetic energy of the emitted electrons. Since the excitation energy is an imprecise quantity the method becomes rather inaccurate and requires that there shall be considerable charge differences in the atoms that are to be differentiated. Such large charge differences are found among mesoionic heterocycles, being recognizable in the large dipole moments of these compounds. Dipole moments have previously formed the basis for study of the structure of, and charge distribution in, mesoionic compounds[2]. As the following results show, the ESCA method can be used to obtain further information.



We have determined the X-ray photoelectron spectra (ESCA spectra)[3] of 3-methyl-2-phenyl-1,3,4-thiadiazole-5-thiones *(1)*[4] and *(2)*[5] (recorded as mesoionic compounds in the literature), their methiodides *(3)* and *(4)*[6], as well as phenylsydnone *(6)*[7].



(1), R = H
(2), R = Cl

(3), R = H
(4), R = Cl

(5)

(6)

The binding energies of the nitrogen-1*s* electrons in *(1)* and *(2)* differ by about 2.3 eV (Fig. 1), in the methiodides *(3)* and *(4)* by about 1.2 eV (Fig. 2). For the sulfur-2*p* electrons in *(1)* and *(2)* a difference in binding energy of about 2.5 eV is found (Fig. 1). In *(3)* and *(4)* the 2*p* electrons of the two sulfur atoms show a single signal (Fig. 2), *i.e.* here the sulfur atoms are equivalent in respect of their charge densities; their electron-binding energy corresponds to that of thioethers.

In 4-methyl-2-phenyl-1,3,4-thiadiazole-5-thione *(5)*[8], which is isomeric with *(1)*, the difference in binding energy of the N-1*s* electrons is only 0.9 eV, and that of the S-2*p* electrons 2.1 eV. The charge separation in *(5)* is thus distinctly smaller than in *(1)*, as is also expressed in the dipole moments (Table 1). Two values were also found for the nitrogen- and oxygen-1*s* electrons in phenylsydnone *(6)* (Table 1).

The electron-binding energies obtained by the ESCA method depend on the shielding of nuclear charge by the electronic environment and are larger the smaller the shielding or the larger the effective nuclear charge; according to *Siegbahn et al.*[11] this dependence is approximately linear. The ESCA values are also related to the electronegativity of the atoms concerned and of attached atoms;

Hauptlaboratorium der Badischen Anilin- und Soda-Fabrik AG
67 Ludwigshafen (Germany)

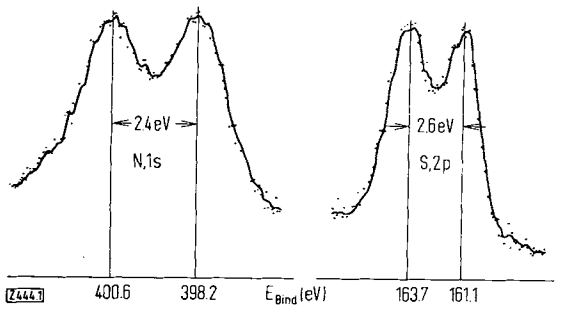

Fig. 1. X-ray photoelectron spectra of *(1)*.

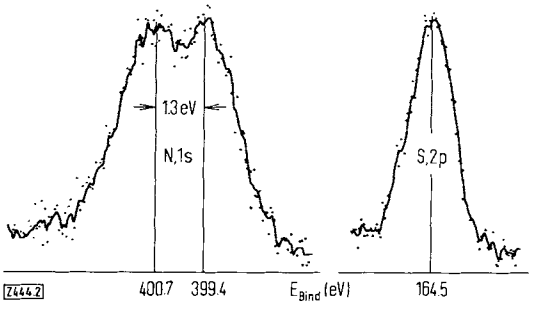

Fig. 2. X-ray photoelectron spectra of *(3)*.

they can be correlated satisfactorily with the units of charge obtained from the Pauling electronegativity relations[10]. Thus a difference of 2.3 eV for the binding energy of the N-1*s* electrons in *(1)* and *(2)* corresponds to a charge difference of 0.46 charge unit. *Carlson* found a comparable value for 7-methylinosine, a typical betaine, with 2.6 eV ≡ 0.52 charge unit[11]. The difference of 2.5 eV for the S-2*p* electrons in *(1)* and *(2)* represents, by a similar calculation, a charge difference of 0.49 charge unit. These results confirm *Katritzky*'s view that a betaine structure predominates in the ground state of mesoionic 1,3,4-thiadiazolethiones and similar compounds, with charge distribution as shown in the formulations *(1)*, *(2)*, and *(6)*.

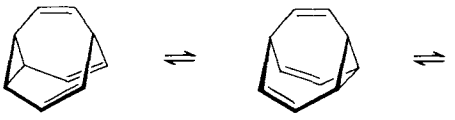
Nomenclature for Intramolecular Exchange Processes



By *Gerhard Binsch, Ernest L. Eliel*, and *Horst Kessler*[*]

We wish to propose a system of nomenclature for describing the interchange of identical ligands between distinguishable chemical and/or magnetic environments. Such interchanges correspond to "null reactions", involving no change in chemical structure, but they can frequently be studied quantitatively by dynamic NMR spectroscopy. Names have been suggested for the process of exchange, notably "degenerate isomerization", "isodynamic change"[1], and "automerization"[2]. We should like to point out that a useful, alternative classification can be based on the recently developed nomenclature[3-5] in which identical ligands in stereochemically different environments are designated as "enantiotopic" or "diastereotopic"[3], the overall term for the two cases being "heterotopic"[4] or "stereoheterotopic"[5]; in contrast, ligands in identical chemical surroundings are called "homotopic"[4-6]. We therefore propose that the process leading to exchange of the positions of identical ligands be called "topomerization"; in this context, it is sometimes convenient to have a name for the indistinguishable species involved in the exchange and we suggest they be called "topomers".

It may sometimes be desirable (and often, though not always, possible) to employ sub-classifications, similar to those used for isomerization. Thus bullvalene *(1)*[9] represents a case of multiple valence bond or constitutional topomerization, whereby one and the same ligand (carbon, hydrogen) is placed in four chemically different positions

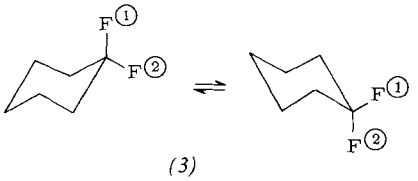
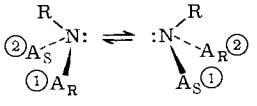
Robert-Mayer-Strasse 7—9 (Germany)

(allylic, two kinds of vinylic, cyclopropanoid). Examples of *cis-trans* topomerization or diastereotopomerization of the type *(2)* (*e.g.*: X=CN, Y=C_6H_5, A=$N(CH_3)_2$) have

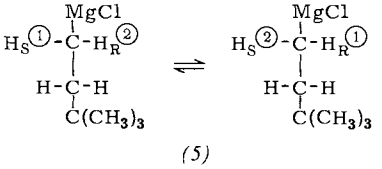


(1)

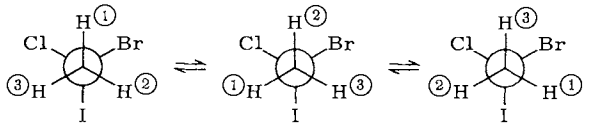


recently been studied[10] by dynamic NMR spectroscopy. Another well-known case of diastereotopomerization is that of the cyclohexane ring inversion, *e.g. (3)*[11]. Enantiotopomerization is represented by *(4)*; the enantiotopic groups A_R and A_S might, in principle, be distinguishable in a chiral solvent when inversion is slow. The

(2)

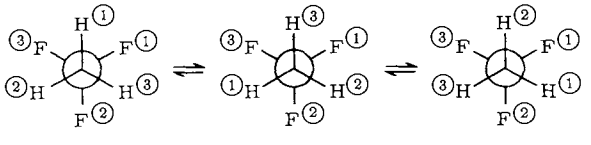


(3)

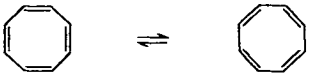


(4)

enantiotopomerization *(5)* has in fact been studied experimentally[12] in achiral solvents. This becomes possible because the enantiotopic nuclei are anisogamous[13]; the methylene proton NMR spectrum of *(5)* changes from an AA'BB' type (or $[AB]_2$ type in the notation of *Haigh*[15]) to an A_2B_2 type on increase of the exchange rate. Case *(6)*, like case *(3)*, may be described as one of conformational topomerism[16, 17].



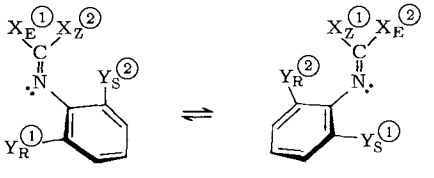
(5)



(6)

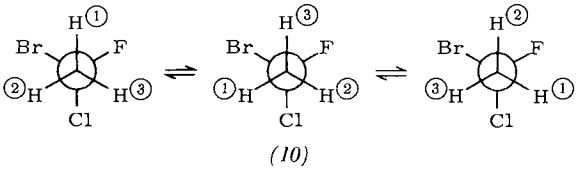
In the examples *(1)*—*(6)* the exchanging ligands differ in "topicity" and hence we are dealing with "heterotopomerizations", more specifically, in cases *(2)*—*(6)*, with "stereoheterotopomerizations". But even if the exchanging ligands are homotopic, the exchange process may still be

(7)



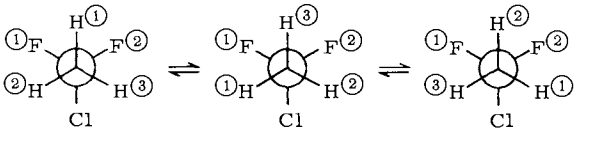
detectable by dynamic NMR spectroscopy. The internal rotation in 1,1,1-trifluoroethane *(7)* provides an example of such a "homotopomerization". Here the three hydrogen atoms (and also the three fluorine atoms) are structurally equivalent in each of the three conformers, but the expected inequality of the *gauche* and *anti* hydrogen-fluorine coupling constants should lead to spectra of the $[AX]_3$ type[15] when rotation is slow on the NMR time scale and of the $[A_3X_3]$ type in the fast-exchange limit. The bond-shift process in cyclooctatetraene *(8)* represents another intriguing case of (constitutional) homotopomerization,

(8)



detectable in principle from a study of [per-^{13}C]cyclooctatetraene, where the spectrum pertaining to the averaged planar form would be of the $[[AX]_2]_4$ or $[AX]_8$ type depending on the rate of the bond-shift process[18].

Finally we wish to point out that a detailed classification of topomerization processes and/or of topomers along the lines suggested in this note may not always be possible.



(9)

The in-plane nitrogen inversion process *(9)*[20], which simultaneously interchanges the diastereotopic ligands X and the enantiotopic ligands Y, can be characterized uniquely (as enantiotopomerization or diastereotopomerization) with reference to specific ligands, but the classification of the topomers involved would necessarily have to be ambiguous. Similarly, the internal rotation *(10)* corresponds to a homotopomerization with respect to the fluorine ligand, but to a diastereotopomerization with respect to the three hydrogen atoms. Finally case *(11)*, a homotopomerization with respect to either fluorine atom, is a "mixed" topomerization with regard to the three hydro-

(10)

(11)

gen atoms. ("Mixed" because positions labeled 2 and 3 in the first conformer on the left are enantiotopic and 2 and 1—or 3 and 1—are diastereotopic.) Both cases *(10)* and *(11)* represent heterotopomerization with respect to the hydrogen atoms. The even more complicated situation in

the stereochemically nonrigid six-coordinate molecule $FeH_2[P(OC_2H_5)_3]_4$ has recently been analyzed quantitatively[21].

We believe that a detailed nomenclature capable of coping with the most general case would become so unwieldy as to lose its appeal for the majority of situations commonly encountered in practice. For a rigorous description of very complex topomerizations it will clearly be necessary to resort to a formal permutational approach.

[16] For cases of this type, see *W. E. Heyd* and *C. A. Cupas*, J. Amer. Chem. Soc. *91*, 1559 (1969) and reference [10a].

[17] Topomerization by rotation about the carbon-carbon bond of *(6)* is confined to cyclic permutations (123⇌231⇌312); the remaining permutational possibilities (213, 132, 321) are inaccessible by rotation. The situation could be characterized by an extension of the Cahn-Ingold-Prelog rules, where the labeling determines the priority sequence and the "configurational" symbol is enclosed in square brackets. In the topomers of *(6)* the methyl group then belongs to the [*R*] family.

[18] This experiment has not been carried out, but we known about the bond-shift process from an NMR study of the closely related heterotopomerization in [mono-^{13}C]cyclooctatetraene [19].

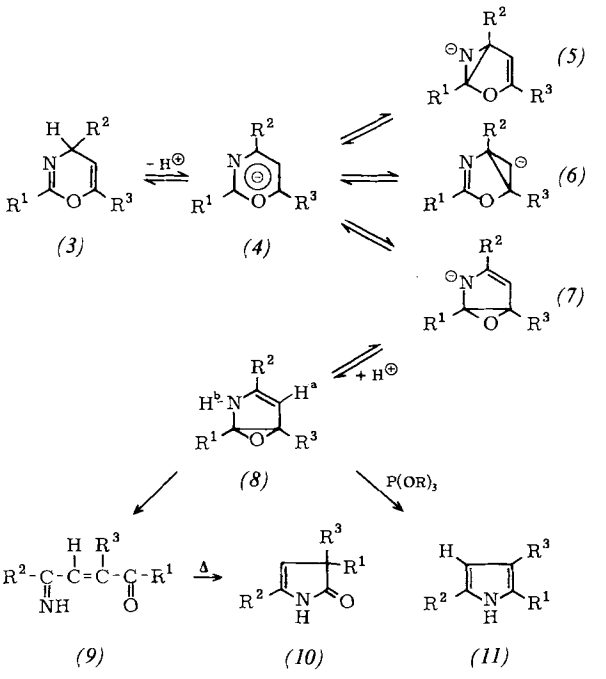
Synthesis of a 6-Oxa-2-azabicyclo[3.1.0]hex-3-ene: Heterocyclic 8π-Systems as Reactive Intermediates[**]



By *Richard R. Schmidt*[*]

Cyclic conjugated planar $4n$-π systems are destabilized by resonance and according to *R. Breslow*[1] are antiaromatic. The electronic destabilization confers high reactivity on these systems, which thus become interesting intermediates.

Planar systems, as small as possible, with bond angles of *ca.* 120°[2] are particularly advantageous models for antiaromatic behavior. Such systems should be readily obtainable in the heterocyclic series if one starts from six-membered dihydro heterocycles *(1)* and *(2)*[3]. If these are converted into the corresponding anions, substantially planar 8π electron systems result.

(1) *(2)*

(3) *(4)* *(5)* *(6)* *(7)* *(8)* *(9)* *(10)* *(11)*

4*H*-1,3-Oxazine *(3)* was used as an example. When it is treated with butyllithium in anhydrous tetrahydrofuran (THF) at −78 °C a deep blue intermediate (λ_{max}^{THF} = 570; 612 nm)[4] is formed, to which we ascribe the structure *(4)*. This 8π system undergoes rapid further reaction, yielding a new, colorless product. For an intramolecular reaction the conversion into especially the valence-tautomeric anions *(5)*, *(6)*, and *(7)* must be taken into account. The anion *(7)* is thermodynamically more stable than *(5)* or *(6)*, and indeed careful working up of the reaction mixture permits isolation of a compound whose analytical and spectroscopic data and subsequent reactions accord only with its formulation as the triphenyl derivative *(8)* of the previously unknown 6-oxa-2-azabicyclo[3.1.0]hex-3-ene[5].

In protic solvents compound *(8)* rearranges rapidly, even at room temperature, into the open-chain iminobutenone *(9)* (in ethanol, $\tau_{1/2}^{20\,°C}$ = 2 h), presumably in a pericyclic $[\sigma_s^2+\sigma_s^2+\pi_s^2]$ reaction. On thermolysis, the pyrrolinone *(10)*[6] is obtained from *(8)* by way of *(9)*. By variation of the substituents R^1, R^2, and R^3 it can be proved that in this reaction R^1 migrates to the C atom to which R^3 is bonded[7]. On treatment of *(8)* with triethyl phosphite the pyrrole *(11)* is formed in 50% yield.

The equilibrium between *(4)* and *(7)* lies much to the side of the latter; it can also be set up from *(8)*[7]. The

chemical and physical properties of the intermediate *(4)* are under further investigation.

Experimental:

1,3,5-Triphenyl-6-oxa-2-azabicyclo[3.1.0]hex-3-ene (8)

Compound *(3)* (1.87 g, 6 mmol) is dissolved in anhydrous THF (40 ml). *n*-Butyllithium as 20% solution in hexane (4 ml) is added dropwise to the above reaction mixture under nitrogen at −78 °C (bath temperature) within 5 min. After 20 min the mixture is worked up at 0 °C with water and chloroform, and the organic phase is dried with K_2CO_3. The solid product remaining on evaporation is treated with a little cold ethanol, filtered off rapidly, well dried, and recrystallized in small portions from anhydrous cyclohexane. M.p. 130—145 °C with rearrangement to *(10)*. Yield 1.27 g (68%) of *(8)*.

Spectra of (8):

UV: $\lambda_{max}^{CCl_4}$ = 345, 267 nm, lg ε = 3.47, 4.47.

IR: between 1550 and 1700 cm^{-1} there is only a weak band at 1594 cm^{-1}, which is assigned to the phenyl nuclei.

NMR (in $CHCl_3$ with TMS as internal standard): H^a = 3.76, H^b = 6.45. In $CDCl_3$/L-α-phenylethylamine (4:1) splitting of H^a into two signals shows that *(8)* exists as a pair of enantiomers.

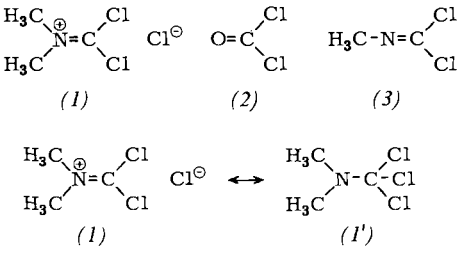
Dichloromethylenedimethylammonium Chloride ("Phosgene Immonium Chloride")[**]: A Versatile Immonium Salt[1]

By *Heinz Günter Viehe* and *Zdenek Janousek*[*]



Dedicated to Professor F. Bohlmann on the occasion of his 50th birthday

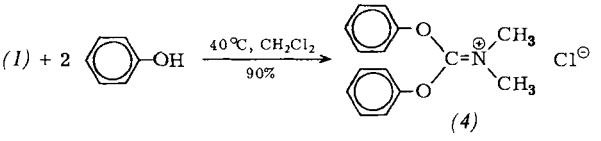
Owing to its greater double bond polarization the immonium salt dichloromethylenedimethylammonium chloride *(1)* should be more reactive than phosgene *(2)* and methylchloroformimidoyl chloride *(3)* in nucleophilic chlorine substitution.

[*] Prof. Dr. H. G. Viehe and Dipl.-Chem. Z. Janousek
Université de Louvain
Laboratoire de Chimie Organique
Naamsestraat 96, B-3000 Louvain (Belgium)

[**] Trade name (Aldrich).

The dissociation equilibrium between the salt *(1)* and the covalent structure *(1')* is almost completely displaced in favor of the salt.

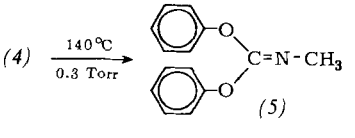
(1) *(2)* *(3)*



(1) *(1')*

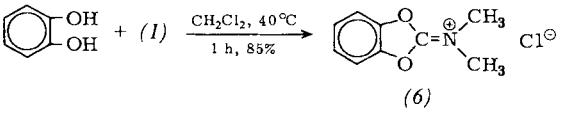
In spite of this expected reactivity[2] and of the many potential synthetic applications of the related compounds *(2)* and *(3)*[3], compound *(1)* has hardly been studied so far. Thus *(1)* is mentioned as a white salt which explodes on heating[4] and which produces dimethylcarbamoyl chloride on hydrolysis[4, 5]. Diethyl and bis(*p*-Cl—C_6H_4) analogs have been described as intermediates in the synthesis of trifluoromethylamines[5, 6].

It is the purpose of this communication to report on the chemical and spectroscopic characterization of *(1)*. Compound *(1)* is obtained in about 90% yield by chlorination of tetramethylthiuram disulfide in CH_2Cl_2 and is isolated as a white hygroscopic solid[4], m.p. about 180 °C (decomp.); IR (Nujol): 1625 cm^{-1}; NMR (CD_3NO_2): δ = 4.07 ppm (s)[7].



Pyrolysis of *(1)* begins at about 130 °C and becomes very rapid at 190 °C. The principal product is *(3)*, which proved to be identical with an authentic sample[8].

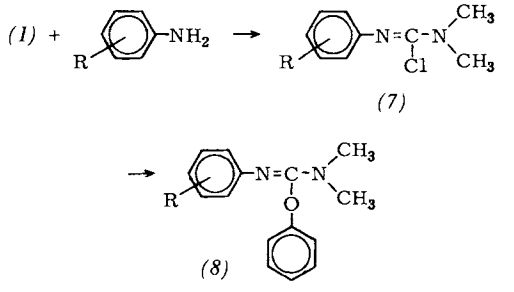
Refluxing *(1)* (2.65 g, 16.4 mmol) with phenol (3.10 g, 32.8 mmol) in CH_2Cl_2 (15 ml) for one hour produces the ammonium salt *(4)* (4.1 g, 90%); NMR ($CDCl_3$): δ = 3.76 (6H,s) and 7.25 ppm (10H,m); IR ($CHCl_3$): 1710, 1600, and strong absorption between 1150 and 1250 cm^{-1}. Hydrolysis of *(4)* by acid or base yields diphenyl carbonate.



(4)

Pyrolysis of *(4)* (4.1 g at 140 °C/0.3 torr) generates the new compound diphenyl *N*-methyliminocarbonate *(5)*. The resulting oil was distilled at 100 °C/0.3 torr (3.0 g,

(5)



91%); m.p. 42 °C (from pet. ether); NMR ($CDCl_3$): δ = 3.03 (3H,s), 7.20 ppm (10H,m); IR ($CHCl_3$): 1710, 1590, 1490, and a large peak at about 1200 cm^{-1}; mass spectrum: 227 (M^+), 134, 106, 94.

(6)

Pyrocatechol reacts with *(1)* in the same manner as phenol, forming the analogous immonium salt *(6)*, which is characterized by its facile hydrolysis to *o*-phenylene carbonate.

Ammonolysis of *(1)* with liquid ammonia gives dimethylcyanamide in 35% yield. Reaction of *(1)* with two moles of dimethylamine yields tetramethylurea dichloride, which forms tetramethylthiourea on treatment of the reaction mixture with an aqueous solution of sodium sulfide. Even very weak primary amines produce the corresponding chloroformamidines *(7)* with *(1)*.

(7)

(8)

Cpd.	R	Solvent, temp. (°C)	Yield	NMR ($CDCl_3$), δ (TMS = 0)
(7a)	*p*-$COOC_2H_5$	CH_2Cl_2 40	96	1.23 (3H/s), 3.08 (6H/s), 4.30 (2H/m), 6.82 (2H/d), 7.92 (2H/d)
(7b)	*p*-NO_2	ClC_6H_5 100—110	80	3.22 (6H/s), 6.93 and 8.16 (4H/2 doublets, J = 9 Hz)
(7c)	2,4-$(NO_2)_2$	ClC_6H_5 80	87	2.83 (6H/s), 7—9 (3H)

To synthesize *N,N*-dimethyl-*N'*-*p*-nitrophenyl-*O*-phenylisourea *(8b)*, a solution of sodium phenoxide (3.48 g, 30 mmol) in dioxane (80 ml) is added to a solution of *(7b)* (6.83 g, 30 mmol) in dioxane (200 ml). After 3 hours' stirring at 40 °C the precipitated NaCl is filtered off and the solvent is removed. The oily product is purified by column chromatography on silica gel, yield 3.1 g (35%), m.p. 98—99 °C (from ether); NMR ($CDCl_3$): δ = 3.08 (6H,s), 7.95 (2H,d,J = 8 Hz), the other doublet being covered by the multiplet at δ = 6.73—7.30 ppm (7H); IR ($CHCl_3$): 1640, 1578, 1500, 1330 cm^{-1}; mass spectrum: 286 (M^+), 209, 192, 72.

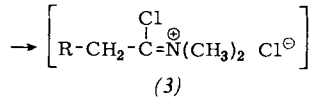
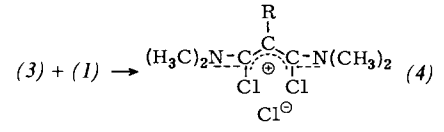
Condensation of Dichloromethylenedimethylammonium Chloride ("Phosgene Immonium Chloride")[**] with *N,N*-Dialkylcarboxamides[1]

By *Zdenek Janousek* and *Heinz Günter Viehe*[*]



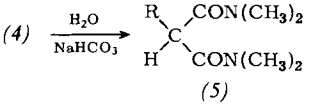
Dedicated to Professor F. Bohlmann on the occasion of his 50th birthday

We have found the immonium salt dichloromethylenedimethylammonium chloride *(1)* to undergo condensation with CH active compounds[2]. Thus when compound *(1)* (0.2 mol) and *N,N*-dimethylcarboxamides *(2)* (0.1 mol) [or their α-chloro immonium chloride derivatives *(3)*] are refluxed together in CH_2Cl_2 or $CHCl_3$ for one to three hours, the new 1,3-dichloromalonylcyanines *(4)* are formed in high yields. During the reaction, heating is continued until the evolution of HCl ceases and a clear solution results. Compounds *(4a)*—*(4d)* crystallize on removal of the solvent; they may be recrystallized from benzene/CH_2Cl_2.



Compounds *(4)* are 1,3-dielectrophiles which permit facile cyclization reactions[2].

(1) *(2)*



(3)

(4)

Cpd.	R	Yield (%)	M.p. (°C)	NMR ($CDCl_3$), δ (TMS = 0) (ppm)
(4a)	H	91	114–116	3.66 (12H/s), 5.88 (1H/s)
(4b)	C_2H_5	88	65–67	1.2 (3H/t), 2.7 (2H/m), 3.28 and 3.57 (12H, 2 singlets)
(4c)	C_6H_5	90	oil	3.58 (12H/s) 7.4 (5H/m)
(4d)	Cl	88	94	3.68 (12H/s)

Hydrolysis of a suspension of *(4a)*—*(4d)* with aqueous $NaHCO_3$ solution (one hour's stirring) produces the malonylamides *(5a)*—*(5d)*, which can be recrystallized from ether after extraction from the reaction mixture with CH_2Cl_2 and evaporation of the solvent.

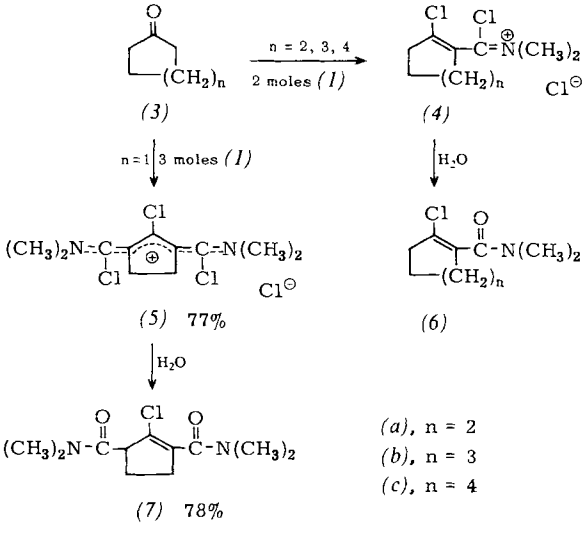
Reaction of Dichloromethylenedimethylammonium Chloride ("Phosgene Immonium Chloride")[**] with Carbonyl-Activated Methylene Groups[1]

By *Heinz Günter Viehe, Zdenek Janousek*, and *Marie-Agnès Defrenne*[*]

Dedicated to Professor F. Bohlmann on the occasion of his 50th birthday

The immonium salt dichloromethylenedimethylammonium chloride *(1)* reacts readily with protic compounds[2] *via* chlorine substitution. Reaction with *N,N*-dimethylcarboxamides yields the new and versatile dichloromalonylcyanines *(2)*, thus demonstrating the high reactivity of *(1)* towards active methylene groups[1].



(1) *(2)*

R = H, C_2H_5, C_6H_5, Cl

A similar condensation is now described for *(1)* with carbonyl-activated methylene compounds such as cycloalkanones, phenylacetone, acetophenone, ethyl malonate, and acetoacetates.

Cycloalkanones *(3)* react with *(1)* in refluxing chloroform, either by monocondensation (*n* = 2, 3, 4) or by dicondensation (*n* = 1) to give the immonium chlorides *(4)* or the trichloropentamethinecyanines *(5)*. Hydrolysis of *(4)* and *(5)* gives the amides *(6)* and the diamide *(7)* respectively. The overall yields of *(6a)*, *(6b)*, and *(6c)* amount to 72, 87, and 75% respectively.

(3) *(4)* *(5)* 77% *(6)* *(7)* 78%

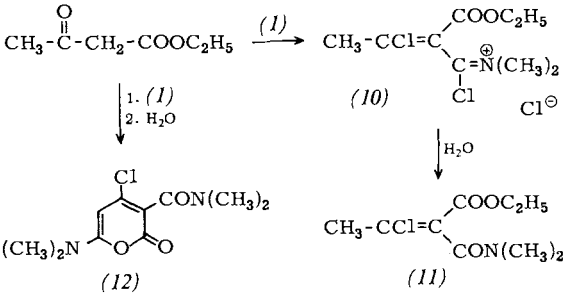
[**] Trade name (Aldrich).



Cpd.	Time (h)	B. p. (°C/torr)	IR ($CHCl_3$) (cm^{-1})
(6a)	3	99–102/0.6	1635, 1497, 1445, 1390, 1130, 1270
(6b)	2	130/0.6	1630, 1492, 1441, 1391, 1264, 1120
(6c)	1	140/0.6	1619, 1480, 1438, 1387, 1262

Cpd.	Mass spectrum	NMR ($CDCl_3$), δ (TMS = 0) (ppm)
(6a)	187 (M^+), 152, 143	1.78 (4H/m), 2.38 (4H/m), 3.00 (6H/s)
(6b)	201 (M^+), 166, 93	1.80 (6H/br.), 2.37 (2H) and 2.65 (2H/br.), 3.00 and 3.05 (6H/2 singlets)
(6c)	215 (M^+), 180	1.62 (8H/br.), 2.30 and 2.55 (4H/2 multiplets), 3.05 and 3.08 (6H/2 singlets)

Phenylacetone reacts with *(1)* to give the expected immonium chloride *(8)* which on alkaline hydrolysis immediately gives the acrylamide *(9)* in 75% overall yield; b. p. 138 °C/0.15 torr; NMR ($CDCl_3$): δ = 2.17 (3H,s), 2.96 (6H,s), 7.26 ppm (5H,s); IR ($CHCl_3$): 1630, 1490, 1440, 1390 cm^{-1}; mass spectrum: 223 (M^+), 188.

Whereas the reactions of *(1)* with simple aliphatic ketones are still under study, the particularly active ethyl acetoacetate was found to give either the expected monocondensation product *(10)*, which is hydrolyzed to the malonic acid derivative *(11)*, or the α-pyrone *(12)* by dicondensation and hydrolysis.

Propio-, benz-, and phenylacetaldehyde reacted only *via* substitution of the oxygen by chlorine and were not examined further.

From the above reactions it would appear that compound *(1)* is generally milder than other Vilsmeier reagents[3].

N,N-Dimethyl-(2-chloro-1-cyclohexenyl)carboxamide (6a) via the immonium salt (4a):

Cyclohexanone (4.90 g, 50 mmol) and compound *(1)* (17.8 g, 110 mmol) are stirred under reflux in chloroform (60 ml) for 3 hours until *(1)* has dissolved completely and liberation of HCl has ceased. About half of the solvent is distilled off and a mixture of dry ether (40 ml) and pet. ether (10 ml) is added with stirring. The precipitated red oil *(4a)* crystallizes; the crystals are collected and washed thoroughly with dry ether. Yield 11.8 g (98%); m. p. 122—125 °C (decomp.) from $CHCl_3$; NMR spectrum ($CDCl_3$): δ (TMS = 0): 2.04 (4H,m), 2.80 (4H,m), 4.20 and 4.29 (6H,2 singlets).—Compound *(4a)* (6.7 g, 27.6 mmol) is stirred with H_2O (15 ml) and an excess of solid $NaHCO_3$. After 30 min, the mixture is extracted with CH_2Cl_2, dried with Na_2SO_4, and the solvent is evaporated off. The oily residue is distilled to give 3.70 g (71%) of *(6a)*. Compounds *(6b)* and *(6c)* can be prepared similarly.

Ethyl 2-(1-chloroethylidene)-N,N-dimethylmalonamate (11) and (4-chloro-6-dimethylamino-3-α-pyronyl)-N,N-dimethylcarboxamide (12):

Compound *(1)* (26.4 g, 0.163 mol) and ethyl acetoacetate (18.0 g, 0.138 mol) are refluxed in chloroform (150 ml) with stirring for 2 hours until a clear solution is obtained. The intermediate *(10)* is hydrolyzed with a suspension of $NaHCO_3$ in water. Distillation affords 7.5 g (27%) of *(11)*, b. p. 100/0.2 torr; NMR ($CDCl_3$): δ = 1.30 (3H,t), 2.63 (3H,s), 2.97 and 3.03 (6H,2 singlets), 4.25 ppm (2H,q, J = 7.5 Hz); IR (film): 1725, 1680, 1500, 1450, 1400, 1280, 1240, 1190, 1120, 1060, 1030 cm^{-1}.—*(12)* is prepared similarly from *(1)* (8.1 g, 50 mmol) and methyl acetoacetate (2.9 g, 25 mmol). The crude product is hydrolyzed, extracted with ether, and the residue is recrystallized from CCl_4. M. p. 150—151 °C, yield 1.1 g (20%); NMR ($CDCl_3$): δ = 3.11 (12H,s), 5.37 ppm (1H,s); IR ($CHCl_3$): 1713, 1630, 1600, 1532, 1411, 1097 cm^{-1}; UV (CH_2Cl_2): λ_{max} = 370 nm (ε = 33400); mass spectrum: 244 (M^+).

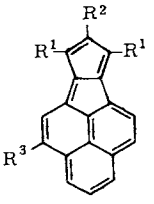
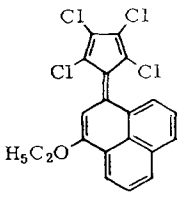
5-Ethoxy-1,2,3-trichloropentaleno[3,2,1-*cd*]-phenalene: A Perturbed [16]Annulene[1]

By *Ichiro Murata, Masaki Okazaki,* and *Tomoo Nakazawa*[*]



Recently, we reported the synthesis of 5-ethoxy-1,3-di-*tert*-butylpentaleno[3,2,1-*cd*]phenalene *(2)*, the first compound containing the pentalenophenalene skeleton *(1)*. Because of its properties we described *(2)* as a novel example of a peripheral 16 π electron model[2].

Our recent studies on 5-ethoxy-1,2,3-trichloropentaleno-[3,2,1-*cd*]phenalene *(3)*, which was obtained from 2-ethoxy-9,10,11,12-tetrachloropentaphenafulvalene *(4)*[3], support this view.

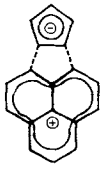


When a solution of *(4)* (0.438 mg) and a trace of triethylamine in chloroform (20 ml) was degassed, sealed under

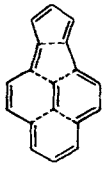
[*] Prof. Dr. I. Murata, M. Okazaki, and Dr. T. Nakazawa
Department of Chemistry, Faculty of Science, Osaka University
Toyonaka, Osaka 560 (Japan)

high vacuum, and kept at 30 °C, the color of the solution gradually turned from blue to wine red. The change can be followed spectrally, *i. e.*, it shows the gradual disappearance of *(4)* [λ_{max} = 410 and 608 nm] with simultaneous increase in absorbance at 552 nm [three isosbestic points at 385, 427, and 555 nm]. Preparative-scale reaction of *(4)* (60 mg) in chloroform (20 ml) in the presence of triethylamine (75 mg) under nitrogen at 30 °C for seven hours led to the isolation of *(3)* in 31% yield.

(1), $R^1 = R^2 = R^3 = H$



(4)



(2), $R^1 = t\text{-}C_4H_9$, $R^2 = H$, $R^3 = OC_2H_5$

(3), $R^1 = R^2 = Cl$, $R^3 = OC_2H_5$

After repeated chromatographic purification on basic alumina, compound *(3)* crystallized as unstable red prisms having no definite melting point. The new compound was characterized by elemental analysis and spectroscopy. Mass spectrum: $m/e = 372$ (M^+, 74%), 343 ($M-C_2H_5$, 100%). The presence of the pentalenophenalene skeleton *(1)* was inferred from the similarity of the IR spectrum (1640, 1590, 1560 cm^{-1}) to that of *(2)*[2]. UV spectrum: λ_{max} (cyclohexane) = 293 (log ε = 4.43), 307 (4.45), 319 (4.46), 360 (3.90, sh), 482 (3.95, sh), 512 (4.13), 542 (4.17), 584 nm (3.95); λ_{max} (acetonitrile) = 287, 304 (sh), 313, 370 (sh), 478 (sh), 518, 549, 597 nm. The NMR spectrum shows signals for the ethoxy group at δ = 1.36 (t, J = 7.0 Hz) and 3.95 ppm (q, J = 7.0 Hz), a singlet for H-4 at 5.01 ppm, an AB system (H-9, H-10) at 6.40 and 6.71 ppm (J = 8.0 Hz), and an AMX system (H-6, H-7, H-8) at 6.03, 6.82, and 6.53 ($J_{6,7}$ = 8.4 Hz, $J_{7,8}$ = 7.0 Hz)[4]. These values resemble those obtained for compound *(2)*[2] and for the perturbed [12]annulene, pyracylene[5]. Ring closure of *(4)* to give the pentacyclic *(3)* results in all the signals of the vinyl protons being shifted more than 1.5 ppm to higher field.

(5)

(6)

In 1958 *Reid* predicted the dipolar structure *(5)* for the hypothetical compound *(1)*[6]. The physical properties of our compounds *(2)* and *(3)*, *i.e.* slight solvatochromism in the electronic spectrum, relatively high chemical shifts of the protons on the phenalene nucleus, and small dipole moment [μ = 2.31 D in the case of *(2)*] indicate, however, that the ground state of these molecules are best represented by the perturbed [16]annulene *(6)* rather than the dipolar form *(5)*.

It is still undecided as to how the conversion of *(4)* into *(3)* actually takes place. According to orbital symmetry considerations, the thermally and the photochemically induced ring closure with participation of eight π electrons should proceed in a conrotatory and in a disrotatory fashion respectively. Our reaction can, in fact, be explained by this concept[7]; however, an ionic mechanism is both electronically and geometrically just as plausible[2]. Since the rate of transformation depends very strongly on the polarity of the solvent (at 30 °C in acetone: $t_{1/2} \approx 45$ min, in *n*-pentane: > 10 h), we favor the ionic mechanism. Furthermore, we have found that the allowed disrotatory ring closure does not take place in the photolysis of *(4)* at −78 °C.

Solvated Electrons in Liquid and Solid Solutions

The following report reviews the Discussion Meeting held by the Deutsche Bunsengesellschaft at Herrenalb (Germany) from March 29 to March 31, 1971.

The "solvated" or "stabilized" electron, regarded some time ago as a curiosity of metal-ammonia solutions, later recognized by radiation chemists familiar with the ways of short-lived species in other systems too, has won a firm place in the catalog of "interesting materials". The Discussion Meeting arranged by *U. Schindewolf* and *D. Schulte-Frohlinde*, attended by 86 participants from 13 countries and comprising about 30 introductory and short papers, provided an impressive review of the state and direction of investigations that have raised questions of interest equally to chemists and physicists.

Many of the papers were still concerned with the electrons in alkali-metal/ammonia solutions—apparently so readily accessible, yet whose various modes of occurrence are so difficult to study—where the main interest remains fundamentally in the transition from nonmetallic to metallic behavior in the liquid phase. In this transition, the concentration of electrons is relatively high, so optical-absorption and magnetic procedures fail, and other methods of investigation must be sought—thermoelectric measurements *(P. Damay, P. Chieux)*, dielectric behavior *(K. G. Breitschwerdt, H. Radscheit)*, reflection spectroscopy under pressure *(R. Vogelsgesang, U. Schindewolf)*, or ultrasound measurements and the influence of static pressure, which demonstrate the increase in compressibility of the "soft" electron solvates in ammonia over that of the solvent itself *(M. H. Parker, D. E. Bowen; K. W. Böddeker, R. Vogelsgesang)*.

It could be seen that the investigations are being extended in several directions. In spite of experimental difficulties, use will be made in the future of cesium solutions *(B. R. Dewald)* and, to a much greater extent than hitherto, of lithium solutions, so as to provide a better understanding of the influence of cations on the behavior of the dissolved electrons, a theme that stood out in many papers. Further effort is being directed toward the search for new solvents. In some cases it is possible to dissolve the alkali metals by addition of certain cyclic polyethers *(J. L. Dye, M. T. Lok, G. M. deBacker)*.

A fundamental limitation lies in the use of alkali metals. So other processes for producing solvated electrons are gaining in importance: electron field emission into aliphatic and aromatic hydrocarbons *(W. F. Schmidt, W. Schnabel)*, γ-irradiation of the ammono system *(J. Belloni)*, UV flash photolysis of dilute aqueous alkalis *(G. Kenney-Wallace, D. C. Walker)*, pulse radiolysis of the most varied solvent systems *(L. Dorfmann; N. Getoff, H. Lehmkuhl, F. Schwörer; U. Schindewolf)*, as well as supercritical ammonia, in which electrons can be recognized as "solvated" at solvent densities down to 0.1 g/ml at 150°C *(R. Olinger, U. Schindewolf)*. It is still an open question whether electrons acquire a temporary "hydrated" state during electrolysis of aqueous solutions—there cannot be many that do *(D. C. Walker; D. Postl, U. Schindewolf)*.

Since the concentration of electrons in all non-ammoniacal solvents is small (mostly $<10^{-4}$ mol/l) and their lifetime is short, absorption spectra still play the largest role in the study of these solutions *(F. S. Dainton; L. Dorfman)*. Laser excitation has been used in attempts to "manipulate" the absorbing electrons *(G. Kenney-Wallace, D. C. Walker)* or to influence their subsequent reactions *(G. C. Barker)*. Meanwhile, the nonmetal/metal transition observed when supercritical metal vapors are compressed can also be followed by optical methods *(F. Hensel)*.

The production of electrons by radiation-chemical methods, and their investigation in frozen and particularly such aqueous solutions, have naturally attracted much attention since, after some guesswork, the occurrence of "hydrated" electrons has been finally proved in such systems *(K. Eiben, D. Schulte-Frohlinde; J. Jortner)*. The studies were concerned with the nature of added or radiation-induced "trapping sites" *(J. J. Weiss)*, with luminescence phenomena *(M. Magat; J. Moan)*, and with the chemical reactivity to electron scavengers which provides information about, *inter alia*, the mobile "dry" electrons before they are solvated, *i.e.*, before they can be detected optically *(K. Eiben, H. Wieczorek; H. B. Steen)*. Electrons trapped in the anion vacancies of ionic crystals (F centers) find themselves in a relatively well-ordered environment, which can be traced through several crystal layers by the hyperfine structure of ENDOR spectra *(H. Seidel)*.

The depth to which the solvated electron has penetrated into chemical studies is illustrated by the fact that "applications" are already being discussed, for instance, for clarification of complicated reductive reactions *(A. Henglein)*. Other papers were concerned with pulse-radiolytic or radiation-chemical reactions with halogenated hydrocarbons *(R. Köster, K.-D. Asmus)*, with carboxylic acids *(O. Mićić, V. Marković)*, with transition-metal complexes *(I. G. Murgulescu, J. Paun)* in aqueous solution, and with organoaluminum compounds in ether *(N. Getoff, H. Lehmkuhl, F. Schwörer)*. Also reactions of metal-ammonia and metal-amine solutions with water and alcohols have been studied kinetically *(R. R. Dewald)*.

Whereas experimentalists may perhaps find it difficult to comprehend the nonmetal/metal transition, theory approaches the convenient "cavity model" for solvated electrons with mistrust. So far as liquid solutions are concerned it is only in ammonia that the electron appears to be strictly localized in the cavities suggested by the measureable increase in volume, whereas in water, for instance, the charge is distributed over wide areas *(G. Howat, B. C. Webster)*. The extraordinary stability of the electron dissolved in ammonia is rationalized by its abnormally high entropy, which enters the rate constants of the reactions—including decomposition—as an important factor alongside the activation energy *(G. Lepoutre, A. Demortier)*; the relation between the activation entropy and the activation volume here leads back to the cavity concept *(R. Olinger, U. Schindewolf)*. The detailed studies of conditions required for existence of excess electrons in polar and nonpolar liquids *(J. Jortner)*, extension of the polaron theory *(V. Shubin)*, and the theory of charge-transfer processes in polar media *(R. Dogonadze)* will refine the concepts and doubtless provide stimulus for further experimentation.

A special feature of this Discussion Meeting was the open-minded relation between theory and practice that proved to be of mutual stimulation to the participating radiation chemists and physical chemists and of metal and solid-state physicists.

Stereochemistry of Macromolecules

By *Rolf C. Schulz*[*]

The shape of a macromolecule depends mainly on the structure and arrangement of the monomeric units, as well as on the experimental conditions. The stereochemical problems discussed in this lecture referred therefore principally to the primary structure.

The concept of tacticity introduced by *Natta* is generally applied only to sterically ordered polyvinyl compounds, but it can be shown that this concept is also applicable to polycondensates (in general, heterochain polymers). A prerequisite for appearance of tacticity is that each monomeric unit shall contain at least one center of stereoisomerism. In polyvinyl compounds such centers may be carbon atoms of the main chain bearing two different substituents or C=C double bonds. In addition, any chiral group that can be built into the main chain can give rise to tactic arrangements. Heterochain polymers thus offer a variety of possibilities.

Simple examples are polyethers, polyamides, and polyesters with asymmetric carbon atoms in the main chain, for example, polypropylene oxide, poly-α-amino acids, polyesters of lactic, 3-hydroxypropionic, and tartaric acids, *etc.* In contrast to isotactic polyvinyl compounds, isotactic heterochain polymers are optically active. Polyamides and polyurethanes have been described that contain atropisomeric biphenyl or binaphthalene groups in place of asymmetric carbon atoms and can thus occur in isotactic forms. Some become atactic on thermal isomerization. Further, several *all-trans*-polyazo compounds have been prepared; and these constitute a further type of sterically ordered and thus tactic polymer; they can be partially converted into the *cis*-isomers by irradiation. Further, some examples of polyesters of *cis*- and *trans*-cyclopropanedicarboxylic acid and some spiro compounds have been described.

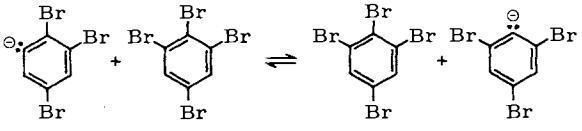
The Base-Catalyzed Halogen Dance



By *Joseph F. Bunnett*[*]

On treatment with potassium anilide in liquid ammonia, 1,2,4-tribromobenzene rearranges to its 1,3,5 isomer. When the hydrogen positions are fully deuterated, both the 1,3,5- and the recovered 1,2,4-tribromobenzene are obtained deuterium-free. When the 1-position is initially labeled with radioactive bromine, the recovered 1,2,4-tribromobenzene has the radiolabel equally distributed among the 1-, 2-, and 4-positions.

1,3-Dibromo-4-iodobenzene, when exposed to potassium anilide in liquid ammonia, affords its 1,3,5-isomer as well as 1,2,4-tribromobenzene and 1-bromo-3,5-diiodobenzene.

Isomerization of 1,2,4-tribromobenzene is also catalyzed by potassium *tert*-butoxide in DMF. However, neither with this reagent in DMF nor with potassium anilide in liquid ammonia does 1,3,5-tribromobenzene revert to its 1,2,4-isomer. On the other hand, reversion does occur if 1,2,3,5-tetrabromobenzene is supplied as co-catalyst, and the same equilibrium proportions of 1,2,4- and 1,3,5-tribromobenzene are obtained starting from either compound. The tetrabromobenzene does not need to be added in order to co-catalyze rearrangement of 1,2,4-tribromobenzene because it is generated in the reaction mixture by disproportionation.

The requirement for tetrabromobenzene co-catalyst rules out any reaction mechanism which does not assign an essential role to the tetrabromobenzene. Specifically, a conceivable aryne mechanism and a mechanism (for isomerization) of 1,2-shifts in *o*-halophenyl anions are rejected. A mechanism which does accommodate all the experimental evidence is one involving reversible acid-base reactions to form *o*-halophenyl anions *(1)* and the attack by such anions on halogen of a tetrahalobenzene *(2)*, so as to capture a positive halogen entity[1].

Mechanism and Application of Anionic Lactam Polymerization

By *Georg Falkenstein*[*]

Mono- and di-substituted carbamoyl lactams and *N*-lactamcarboxylic esters are recognized as particularly effective activators of anionic lactam polymerization.

It has been found that activated anionic lactam polymerization occurs largely by nucleophilic polyaddition of lactam anions to the endocyclic carbonyl-carbon atom of the temporarily terminal acyl lactam ring. This explains also the effect of the cited activators; they replace the first polymerization member, *N*-ε-aminocarbamoyllactam, which would otherwise be formed relatively slowly and secondarily from lactam anions and lactam; and in this way they bring about chain growth.

Possibilities for optimization of the activator efficiency were demonstrated on simple models. Guide lines are provided by the Hammett substitution constants, the pK_B values of the carbamoyl-nitrogen atom of the disubstituted carbamoyl lactams, and the absorption bands of the exocyclic carbonyl groups of the *N*-lactamcarboxylic esters or monosubstituted carbamoyl lactams. Activators can thus be prepared "to measure", which is of great interest for the various types of polymerization process. The polymerizates obtained in the presence of the new activators show particularly favorable mechanical properties.

[*] Dr. G. Falkenstein
Badische Anilin- und Soda-Fabrik
Kunststofflaboratorium
67 Ludwigshafen (Germany)

The considerable amount of research already carried out in industry and Institutes in the field of anionic lactam polymerization contrasts with the, so far, relatively modest application in practice.

At present, the most important processes are: (i) pressureless casting of shaped parts and semifinished products similar to metal casting; (ii) centrifugal casting for the manufacture of rotationally symmetrical parts, in which the mold is rotated about an axis in order to utilize the resulting centrifugal force; and (iii) rotational casting for the manufacture of hollow parts using a two-axis principle in which the axes are at 90° to each other.

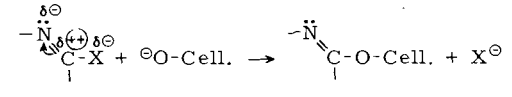
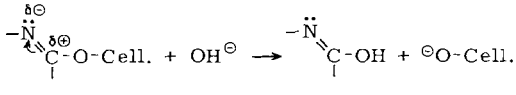
Chemistry of Reactive Dyes

By *Edgar Siegel*[*]

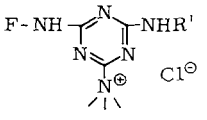


In 1954 *Rattee* and *Stephen* discovered that cellulose reacts with dichloro-*s*-triazine dyes in dilute aqueous alkaline solution in technically interesting yields without hydrolysis of the main amount of the dissolved dye. Since then more than 40 ranges of reactive dyes have come on the market.

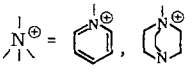


The mono- and di-chloro-*s*-triazine, trichloropyrimidine, 2,3-dichloro-6-quinoxalinecarbonyl, and β-sulfatoethyl sulfone dyes, which are still important today, have been supplemented during the last five years by a series of new systems.

The main object of the new developments was higher reactivity of the dye with cellulose, combined with greater stability, that is, lower reactivity at the fiber-dye bond that is formed. This purpose was achieved by use of leaving groups that are more electronegative than chlorine, thus causing temporary activation at the electrophilic C atom which disappears along with the leaving group (HO-Cell. = cellulose).



δ⊕ for X = F > $\overset{\oplus}{N}R^1R^2R^3\ Cl^{\ominus}$ > SO_2R > Cl



New reactive systems based on this principle bear the following substituents introduced into amino-group containing dyes: 5-chloro-2,4-difluoro-pyrimidylamino [Levafix® P-A, Levafix® E-A, Verofix® (Bayer); Drimaren® R, Drimalan® F (Sandoz)]; 5-chloro-2-methanesulfonyl-4-methylpyrimidylamino [Levafix® P (Bayer)], and β-(2,2,3,3-tetrafluorocyclobutyl)acryloylamino (Hoechst).

In this connection, mention should also be made of the monochloro-*s*-triazine dyes whose reactions are catalyzed by tertiary amines; the annexed formulas show dyes with attached catalyst (ICI, CIBA).

Further, increased reactivity has been achieved in a conventional manner, *i.e.*, without temporary activitation, by introducing the following groups: 2-chloro-4-methoxy-*s*-triazinylamino [Cibacron Pront® (Ciba-Geigy)] or 2,4-dichloro-5-pyrimidinecarbonylamino [Reactofil® (Ciba-Geigy)].

Dyes have also been introduced with two or more monochloro-*s*-triazinylamino groups in the molecule [Procion® Supra (ICI)].

In the Calcobound dyes of American Cyanamide cellulose is combined with groups that react in acid solution, namely, *N*-hydroxymethylmelamine groups. 2-Bromoacryloylamino [Lanasol® (Ciba-Geigy)] and 5-chloro-2,4-difluoropyrimidylamino dyes (Verofix, Drimalan R) are the first to allow dyeing of wool with fixation yields of more than 85–90% and thus in a technically satisfactory manner.

Lecture at Tübingen on April 23, 1971 [VB 305 IE]

Extraction of Transplutonium Elements by Alkylammonium Salts

By *Werner Müller*[*]

Alkyl-substituted ammonium salts are used for extraction of trivalent transplutonium elements from concentrated chloride or nitrate solutions[1].

In organic solution the alkylammonium salts exist mainly as ion pairs; their formation constants increase with the strength of the acid and the polarity of the diluent. Polar diluents stabilize the ion pairs, which can dissociate in very dilute solution. The weak solvation by nonpolar diluents causes self-association of the alkylammonium salts in concentrated solution and enhances the extraction of hydrate water and excess of acid into the organic phase. Correspondingly, extraction of the metal complexes is increased if a polar diluent such as chloroform is replaced by an alkylbenzene or cyclohexane.

On extraction of trivalent transplutonium elements from weakly acid, highly concentrated chloride solutions by tridodecylammonium chloride, ion pairs $R_3NH^+MCl_4^-$ are formed, which may be associated with additional molecules of the extractant. The differing strengths of these complexes permit separation of the element pairs Cf-Es and Am-Cm as well as their separation from the trivalent lanthanides. Am and Cm can be separated from each other by extraction from lithium nitrate solution by quaternary alkylammonium nitrates.

Extraction chromatography by tridecylmethylammonium nitrate on kieselguhr as carrier, which was previously used for purification of Am and Cm in milligram amounts[2, 3], has now been extended successfully to the separation and purification of ^{241}Am, ^{243}Am, and ^{244}Cm in multigram quantities[4].

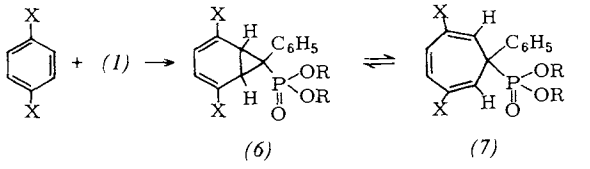
PO-Substituted Carbenes

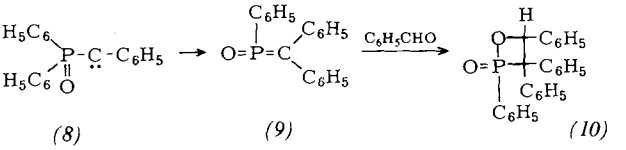
By *Manfred Regitz, Hans Scherer*, and *Annemarie Liedhegener*[*]

Carbenes containing $OP(OR)_2$ or OPR_2 groups have been produced by photolysis of correspondingly substituted diazo compounds. The former type of carbene shows pronounced triplet reactivity: Treatment of *(1a)* with cyclohexene gives, besides the norcarane *(2)*, the abstraction products *(3)*, *(4)*, and *(5)*. The reaction with *p*-xylene as H-donor occurs in a similar sense (no norcaradiene is formed!). Also, *cis*- and *trans*-butene are cyclopropanated non-stereospecifically.



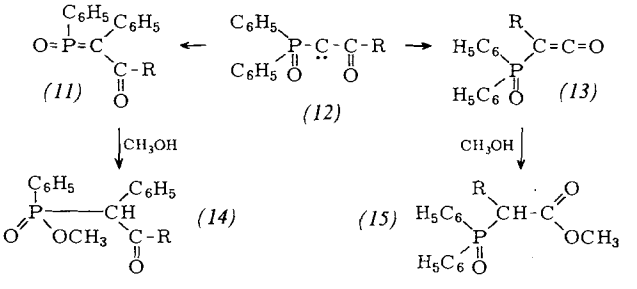
(1a) *(2)* *(3)*

(4) *(5)*



With benzene or substituted benzenes the carbenes *(1)* yield 1:1 adducts. The problem of their structure—whether of norcaradiene *(6)* or cycloheptatriene type *(7)* or a valence-tautomeric equilibrium *(6)*⇄*(7)*—was decided for series *(b)* in favor of the equilibrium on the basis of the temperature-dependent ^{1}H-NMR spectra[1]; the same is true for the series *(c)* and *(d)*. However, the cyclopropanation product of 1,4-dichloro- and 1,4-dimethoxy-benzene appears to be the homogeneous norcaradiene *(6e)* or *(6f)*, respectively, with an *exo*-PO group ($^3J_{H,P} \approx 16$ Hz)[1].

(6) *(7)*



(b) X = H, R = CH_3; *(c)* X = H, R = C_2H_5; *(d)* X = H, R = iso-C_3H_7; *(e)* X = Cl, R = CH_3; *(f)* X = OCH_3, R = CH_3.

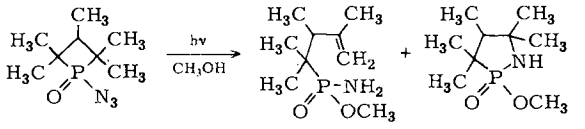
The reactivity of carbenes containing OPR_2 groups is expressed preponderatingly by their tendency to rearrange. Thus *(8)* passes into the methyleneoxophosphorane *(9)* by *P/C*-phenyl migration, and the product can be trapped by benzaldehyde which leads to formation of the 1,2-oxaphosphetane *(10)*.

(8) *(9)* *(10)*

Acylcarbenes *(12)* containing OPR_2 groups undergo competing rearrangements (*P/C*-phenyl or *C/C*-R migration) to the heterocumulenes *(11)* and *(13)*, which in methanol react further to afford the esters *(14)* and *(15)*. Reductive elimination of N_2 from the parent diazo compounds and OH insertion into the carbenes are side reactions.

(11) *(12)* *(13)*

(14) *(15)*



R = CH_3, C_6H_5, or *p*-X-C_6H_4;
X = Br, OCH_3, $N(CH_3)_2$, or NO_2.

Lecture at Mainz on April 29, 1971 [VB 306 IE]
German version: Angew. Chem. *83*, 625 (1971)

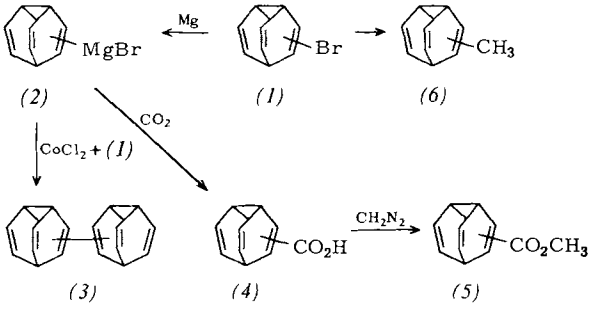
Photolysis of 1-azidophosphetane 1-oxides such as *(1)* leads, according to a report by *M. J. P. Harger*, to products whose formation results from loss of nitrogen and ring opening [*(2)*] or ring expansion [*(3)*]. Photolysis of 1-azido-2,2,4,4-tetramethyl-phosphetane 1-oxide gave, as

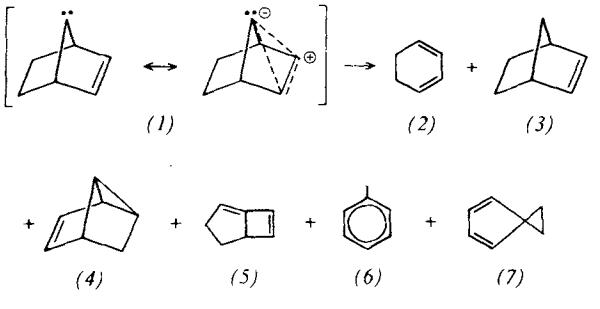


(1) *(2)* *(3)*

expected, two isomeric products of ring expansion in approximately equal amounts along with the open-chain compound. / Chem. Commun. *1971*, 442 / –Ee.

[Rd 362 IE]

Molecules with fluctuating bonds have been studied, primarily on the basis of their temperature-dependent spectra, by *J. F. M. Oth, E. Machens, H. Röttele*, and *G. Schröder*. The bibullvalenyl *(3)*, the bullvalenecarboxylic acid *(4)*, and its methyl ester *(5)* are obtainable from the bromobullvalene *(1)* by way of the Grignard compound *(2)*. Methylbullvalene *(6)* is prepared directly from *(1)* and



(2) *(1)* *(6)* *(3)* *(4)* *(5)*

methylmagnesium iodide in the presence of $CoCl_2$. In the case of bibullvalenyl *(3)* only the three isomers bound *via* the olefin groups are to be found in the equilibrium mixture. Isomers in which the substituents belong to an olefinic grouping also predominate in the case of the monosubstitution products *(2)* and *(4)*—*(6)*. / Liebigs Ann. Chem. *745*, 12 (1971) / –Ee.

[Rd 363 IE]

7-Norbornenylidene *(1)*, a potentially nonclassical carbene, occurs, according to a report by *R. A. Moss, U.-H. Dolling*, and *J. R. Whittle*, in the pyrolysis of the lithium salt of 7-norbornenone tosylhydrazone at 190—191 °C/0.05 torr.

(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)*

The carbene decomposes mainly to the products *(2)* to *(7)*, compound *(5)* being present in about 67% yield (based on the sum of all products). / Tetrahedron Lett. *1971*, 931 / –Ee.

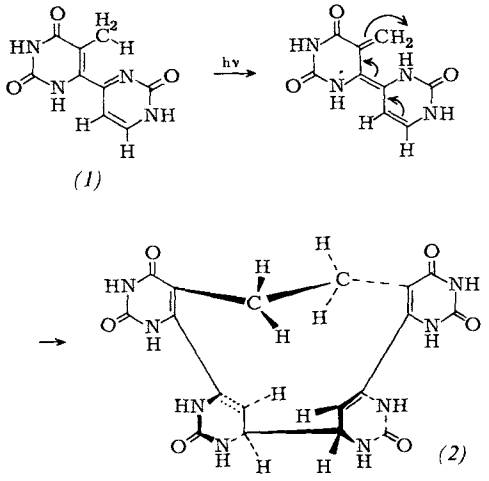
[Rd 367 IE]

Charge-transfer bands of amine-aromatic hydrocarbon complexes could be detected in absorption by *H. Ishida* and *H. Tsubomura*. Until now, only the fluorescence of these complexes (at about 500 nm) was known, from solutions of, *e.g.*, anthracene and tri-*n*-butylamine in *n*-hexane. The corresponding absorption bands were obscured by the strong absorption of amines in the corresponding spectral region (250—280 nm). In the adsorbed state, these absorption bands could be measured: spectra were recorded of thin layers of silica gel on which anthracene and amine had been adsorbed. With this system, however, no fluorescence is found. This can be rationalized in terms of the large Stokes shift between absorption and fluorescence maxima: this large shift is due to a considerable change of nuclear coordinates between the lowest vibrational levels of ground state and excited state. In the adsorbed complex the relaxation process that normally populates the lowest vibrational level of the excited state is strongly perturbed. Therefore, no fluorescence is observed. / Chem. Phys. Lett. *9*, 296 (1971) / –Hz.

[Rd 372 IE]

The photochemistry of piperidinoanthraquinones is reported by *A. K. Davies, J. F. McKellar*, and *G. O. Phillips*, and its relevance to phototendering of fabrics by related anthraquinonoid vat dyes. The dependence of electronic spectra on the dielectric constants of solvents shows that the longest wavelength absorption of the unprotonated forms of these compounds is due to an intramolecular charge transfer (CT). On acidification, the CT band of 1-piperidinoanthraquinone (1-PAQ) disappears; the lowest energy absorption is now a shoulder at about 400 nm of $n \rightarrow \pi^*$ character. In this excited state, 1-PAQ is a strong hydrogen abstracting agent with respect to H donors as, *e.g.*, cellulose. In an alkaline medium, the photolysis of 1-PAQ finally forms the dianion; 2-PAQ, however, is converted into the relatively stable radical anion (semiquinone). / Proc. Roy. Soc. *A 323*, 69 (1971) / –Hz.

[Rd 373 IE]



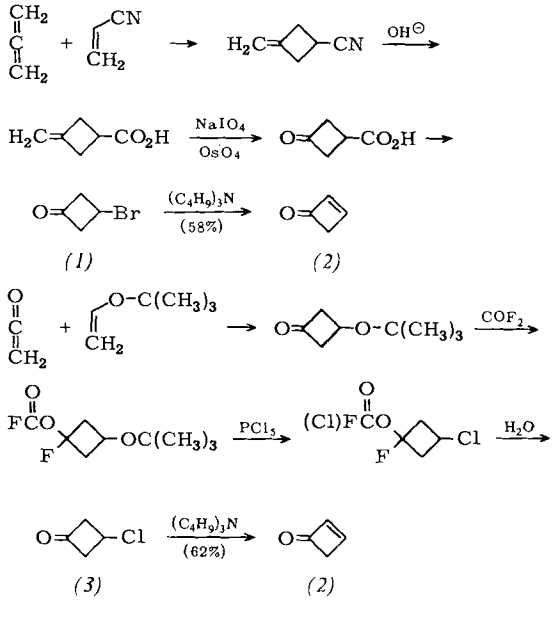
Gaseous mixtures of $AlCl_3/Al_2Cl_6$ and $NaAlCl_4$ are electrical conductors, as has been shown by *E. W. Dewing*. The conductances were measured in a concentric electrode arrangement, end currents being eliminated by measurements with the central electrode displaced in an axial direction. At 500—900 °C values of 10^{-11} to 10^{-6} ohm^{-1} cm^{-1} were measured. From the dependence of conductance on temperature, total pressure, and $NaAlCl_4$ partial pressure the author concludes that the conductivity is due to the ionization process

$$NaAlCl_4 + AlCl_3 = NaAlCl_3^+ + AlCl_4^-$$

This reaction is endothermic with $\Delta H \approx 70$ kcal mol^{-1}. The results are not consistent with Na^+, $NaAl_2Cl_6^+$, $Na_2AlCl_4^+$, or Na_2Cl^+ being the positive ions participating in the conduction process. / J. Phys. Chem. *75*, 1260 (1971) / –Hz.

[Rd 374 IE]

A pyrimidine phototetramer is described by *S. Yi Wang* and *D. F. Roades*. Compound *(2)* was obtained in 55% yield on irradiating an aqueous solution of 4-(2-oxo-1,2-dihydro-4-pyrimidyl)thymine *(1)* with 360-nm light. Previously, *(1)* has been prepared from acid hydrolyzates of

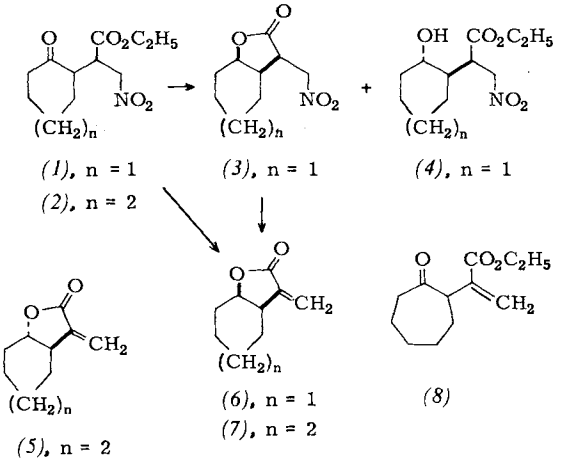


(1) *(2)*

UV irradiated DNA as well as by irradiation of a uracil/thymine mixture in the frozen state. *(2)* is formed by head-to-head and tail-to-tail dimerization of *(1)*. The conformation of the dimer was determined x-ray crystallographically using single crystals. Similar photoreactions as in the formation of *(2)* (H withdrawal at thymine CH_3 groups) could also occur during irradiation of the DNA. / J. Amer. Chem. Soc. *93*, 2554 (1971) / –Ma.

[Rd 375 IE]

The synthesis of cyclobutenone *(2)* from 3-bromo- or 3-chlorocyclobutenone [*(1)* or *(3)*] has been accomplished for the first time by *J. B. Sieja*. *(1)* and *(3)* were prepared from allenes and ketones. Cyclobutenone *(2)*, whose structure could be confirmed by IR, UV, and mass spectrometry, rapidly polymerizes. Even at −78 °C considerable

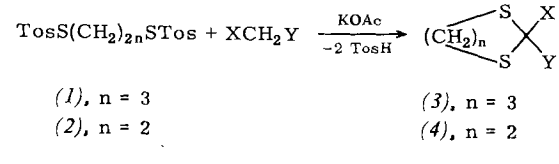


(1) *(2)* *(3)* *(2)*

polymerization takes place within 12 h. / J. Amer. Chem. Soc. *93*, 2481 (1971) / –Ma.

[Rd 376 IE]

A new synthesis of α-methylenebutyrolactones reported by *J. W. Patterson* and *J. E. McMurry* proceeds in three steps: 1. enamine formation, 2. Michael addition of ethyl β-nitroacrylate, and 3. reduction with $NaBH_4$ and simultaneous lactonization and elimination of the nitro group. The morpholine enamine of cyclohexanone adds to ethyl β-

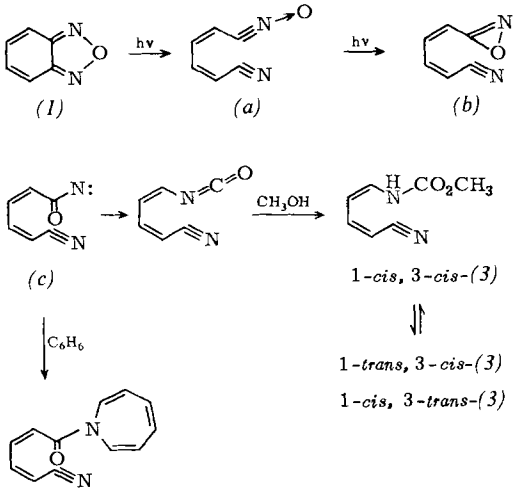


(1), n = 1 *(3)*, n = 1 *(4)*, n = 1
(2), n = 2
(5), n = 2 *(6)*, n = 1 *(8)*
(7), n = 2

nitroacrylate to give the adduct *(1)* (81% yield after hydrolysis). Reduction of *(1)* with $NaBH_4$ in methanol (1 h, 0 °C) affords, in almost quantitative yield, a 50:50 mixture of *cis*-nitromethyllactone *(3)* and *trans*-hydroxy ester *(4)*. On treatment with one equivalent of diisopropylamine (in $CHCl_3$, room temperature), *(3)* is converted into the *cis*-α-methylenebutyrolactone *(6)*. The morpholine enamine of cycloheptanone gives the adduct *(2)* (49%) and the elimination product *(8)* (21%); reduction of *(2)* with $NaBH_4$ gave an 86:14 mixture of *cis*- and *trans*-α-methylbutyrolactone *(5)* and *(7)* (91%). / Chem. Commun. *1971*, 488 / –Ma.

[Rd 378 IE]

Dithiotosylates as reagents in organic synthesis are reported by *R. B. Woodward*, *I. J. Pachter*, and *M. L. Scheinbaum*. Trimethylene- and ethylene dithiotosylate, *(1)* and *(2)*, react with activated methylene groups to give 2,2-substituted 1,3-dithianes *(3)* and 1,3-dithiolanes *(4)* respectively. The dithioketal groups of *(3)* and *(4)*, unlike the acetal

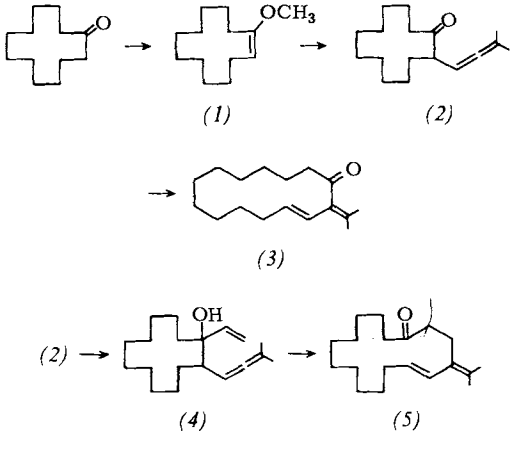


(1), n = 3 *(3)*, n = 3
(2), n = 2 *(4)*, n = 2

groups of the analogous oxygen compounds, are remarkably acid stable and consequently further rearrangements of such protected methylene compounds are possible even in an acid medium. The methylene group can be regenerated by Raney nickel reduction, and converted into a carbonyl group by Hg^{2+}-catalyzed hydrolysis. Carbonyl compounds having less reactive CH_2 groups can be activated by conversion into an enamine or an hydroxymethylene derivative prior to reaction with *(1)* or *(2)*. Reliable methods were developed for the preparation of *(1)* and *(2)*. / J. Org. Chem. *36*, 1137 (1971) / –Ma.

[Rd 379 IE]

The photochemistry of benzofurazane has been investigated by *M. Georgarakis*, *H. J. Rosenkranz*, and *H. Schmid*.

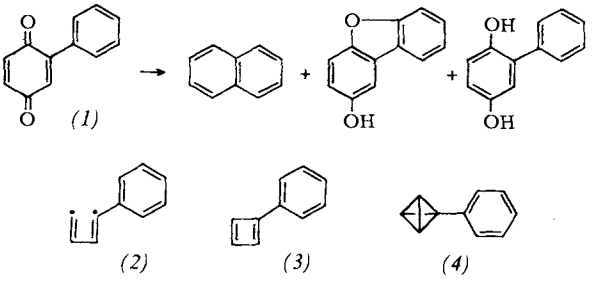


Irradiation of *(1)* in benzene (8×10^{-3} mol/l, 10—12 °C, argon, Hg high-pressure vapor lamp) gives the azepin derivative 2-*cis*,4-*cis*-5-cyano-2,4-pentadiene *(2)* as the main product (16%). Subsequent addition of methanol in the dark leads to additional formation of the 1-*cis*,3-*cis* form of methyl *N*-(4-cyano-1,3-butadien-1-yl)carbamate *(3)*. Irradiation of *(1)* in methanol leads to a mixture of

the stereoisomeric forms of *(3)* (18%), from which the pure 1-*trans*,3-*cis* isomers can be obtained. The reaction products are formed *via* the nonisolable reactive intermediates *(a)*, *(b)*, and *(c)* (nitrene). / Helv. Chem. Acta *54*, 819 (1971) / –Ma.

[Rd 380 IE]

The ring expansion of cyclododecanone by two and four carbon atoms is described by *R. C. Cookson* and *P. Singh*. Condensation of 1-methoxy-1-cyclododecene *(1)* with 2-methyl-3-butyn-2-ol yields, through a Cope rearrangement of the intermediate enol ether, 2-(3,3-dimethylallenyl)-cyclododecanone *(2)*. On UV irradiation *(2)* isomerizes with 1,3-acyl migration to give *(3)*, from which 2-isopropyl-cyclotetradecanone can be obtained by hydrogenation. The alcohol *(4)*, obtained from *(2)* by addition of vinyl-

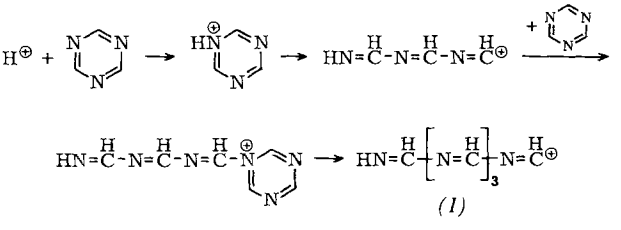


magnesium bromide, is converted by thermal Cope rearrangement into the compound *(5)*. / J. Chem. Soc. *C 1971*, 1477 / –Ma.

[Rd 381 IE]

Novel fluorides of divalent palladium have been prepared by *B. Müller* and *R. Hoppe*. Pure PdF_2 (bright violet) was obtained for the first time from mixtures of Pd/PdF_3 at 500—750 °C in F_2/Ar. The fluoro complexes $M^{II}[PdF_4]$, M = Ca, Sr, Cd, Pb, Ba, could be prepared from mixtures of $MF_2 + PdF_2$ (700 °C, closed system) as well as by thermal degradation of $M^{II}PdF_6$ (750 °C, Ar). These tetrafluoropalladates belong to the tetragonal $K[AuF_4]$-type compounds. $CaPdF_4$ is crimson, $SrPdF_4$ carmine, $CdPdF_4$ blue, $PbPdF_4$ crimson, and $BaPdF_4$ (impure) and Ba_2PdF_6 are orange-red. / Naturwissenschaften *58*, 268 (1971) / –Ma.

[Rd 382 IE]



The flash-vacuum thermolysis of phenyl-*p*-benzoquinone *(1)* has been investigated by *H. J. Hageman* and *U. E. Wiersum*. At 800 °C, three major products were observed: naphthalene (54 mol-%), 2-hydroxydibenzofuran (8%), and phenyl-1,4-hydroquinone (*ca.* 8%) [conversion of *(1)* *ca.* 60%]. The formation of naphthalene can be interpreted as an intramolecular trapping of either a butadiene diradical *(2)*, cyclobutadiene *(3)*, or tetrahedrane derivative *(4)* by the phenyl ring. A similar behavior was observed for several

substituted phenyl-*p*-benzoquinones. / Chem. Commun. *1971*, 497 / –Ma.

[Rd 383 IE]

Poly(methinimine), polynitrile *(1)* has been prepared for the first time by *D. Wöhrle* by thermally induced ring-opening of 1,3,5-triazine-zinc chloride complexes under N_2 at 200—350 °C. The polymeric mixture formed in 10—60% yield is purified by extraction with acetone and reprecipitation from H_2SO_4. The IR spectra show characteristic bands at 3170 cm^{-1} (CH stretching vibration). It is assumed that an initially occurring proton-donating complex from Lewis acis ($ZnCl_2$) and cocatalyst (1,3,5-triazine or HPO_3) triggers the ring cleavage to the polymer

having a polymethinimine structure. / Tetrahedron Lett. *1971*, 1969 / –Ma.

[Rd 384 IE]

Chemische Elementaranalyse mit kleinsten Proben (Elemental Chemical Analysis with Very Small Samples). By *G. Tölg*. Verlag Chemie, Weinheim 1967. 1st Ed., viii, 228 pp., 66 figs., 5 tab. bound, DM 32.—.

The development of elemental organic analysis is strongly influenced by the needs of biology, biochemistry, and medicine, and this means that the amount of substance required is tending to become smaller and smaller. The author, an international expert in this field, presents an excellent review of the current achievements, including descriptions of procedures requiring only a few micrograms (in some cases only a few nanograms) of the elements to be determined.

The book is divided into two parts. The first is a general section, and is concerned with the basic principles of handling such small quantities—weighing, measuring, transferring—and the appropriate safety precautions, together with the equipment, relating these topics as closely as possible to practical needs. The second, more specific part gives methods for the determination of carbon, hydrogen, oxygen, nitrogen, sulfur, fluorine, chlorine, bromine, iodine, phosphorus, and arsenic. Several reliable methods are given in each case, which is particularly important for ultramicroanalysis. It is gratifying to find that many of the methods are characterized by their standard deviation. Special attention is paid to titrimetric procedures (usually in combination with electrical indication) and photometric techniques. Most of the methods, which, incidentally, are all described with a refreshing degree of clarity, are accompanied by descriptions and illustrations of equipment specifically intended for the purpose. This book is a valuable addition to the literature devoted to analysis, and is heartily recommended.

Günther Kraft [NB 976 IE]

Neuere Methoden der Präparativen Organischen Chemie (Newer Methods of Preparative Organic Chemistry). Edited by *W. Foerst*. Verlag Chemie, Weinheim 1970. Vol. 6, vi, 297 pp., 3 figs., 60 tab., bound, DM 38.—.

This is the last volume of a series begun in 1944. It contains ten articles (in most cases considerably expanded) from Angewandte Chemie on the following topics (the date at the end of each reference is the year in which the article appeared in Angewandte Chemie):

Preparation, properties, and reactions of polychloroamine derivatives (*H. Holtschmidt et al.*, 1968),

Directed aldol condensations (*H. Reiff*, 1968),

Carboxylic acid syntheses from 1,1-dichloroethylene (*K. Bott* and *H. Hellmann*, 1966),

Diazo group transfer (*M. Regitz*, 1967),

Isocyanide dihalide syntheses (*E. Kühle*, *B. Anders*, and *G. Zumach*, 1967, 1969),

Synthesis and reactions of cyanic esters (*E. Grigat* and *R. Pütter*, 1967),

Ring closure reactions with carbon monoxide (*J. Falbe*, 1966),

Synthesis of isocyanates and carbodiimides (*H. Ulrich* and *A. A. R. Sayigh*, 1966),

Additions to the activated C—C triple bond (*E. Winterfeldt*, 1967),

s-Triazine derivatives by polar cycloaddition of isocyanates (*H. Ulrich* and *R. Richter*).

Each chapter contains numerous descriptions of preparations, which are thorough enough to make reference to the original literature unnecessary. It is hardly necessary to emphasize here the other advantages and the usefulness of this collection to all preparative chemists, university lecturers, and students, since this was done quite adequately in the reviews of Volumes IV and V[1]. As with the previous issues, this new volume can be recommended without reservation.

There is an underlying note of sadness in the editor's introduction, as though he were bidding farewell to a class of reader who is rapidly becoming extinct. In this he is only partly justified. Certainly there is a decreasing tendency, particularly among the younger generation of chemists, to have one's own personal copy of the essential literature to be kept at home on the bedside table, and there is an increasing tendency to expect the company or the state to pay for everything. But, evidently, this does not influence the intensity of research, since there is no decrease in the number of papers published in journals or monographs. Indeed, there is a journal devoted to synthesis alone. The style and the objectives of the research are changing, and we shall have to tread new paths if we are to keep fully abreast of new developments. Over the past 25 years, *Foerst*'s "Neuere Methoden" have played an important part in this endeavor. It is about time to devote some thought to the next 25 years.

Hans Musso [NB 977 IE]

[1] Cf. Angew. Chem. internat. Edit. 7, 83 (1968).

Laboratory Techniques in Biochemistry and Molecular Biology. Vol. 1. By *T. S. Work* and *E. Work*, North-Holland Publishing Comp., Amsterdam 1970. 1st ed., 572 pp., numerous figs. and tab., bound, DM 90.—.

The current rapid progress in natural sciences is largely due to the development of new methods of analysis and separation which give high sensitivity and resolution. However, these methods are often so difficult to perform and interpret that they can only be mastered and usefully employed by an expert. Nevertheless, they can be learned directly or indirectly from someone experienced in their use.

The North-Holland Publishing Co. were alert to this need and have started a series on "Laboratory Techniques in Biochemistry and Molecular Biology" under the general guidance of *T. S.* and *E. Work*. The aim of this series is to give practical instruction and information on the use of modern methods. The initial contributions are on gel chromatography (*L. Fischer*, Uppsala), gel electrophoresis (*A. H. Gordon*, Mill Hill) and immunochemical reactions (*J. Clausen*, Copenhagen), bound together into one sturdy and attractively presented volume. In each case there are detailed notes on the use of the method, the way in which the instruments used work, and on critical evaluation of the results: there is also a list of suppliers and commercially available variants.

The individual sections live up to the promise of their authors' reputations, even on close and critical study.

Rapid developments in this field will of course mean that now there are even more recent variants of instruments, which no longer have the faults of their predecessors, and this inevitably overtakes a carefully compiled book such as this. Examples of omissions due to this factor include a detailed account of the electrofocusing technique, rapid analysis of enzymes in acrylamide gel, the more recent gel electrophoresis methods, the theoretical derivations for particle weight determination of proteins by gel filtration, and many others. But the material that is here is first class and extremely useful for any practising biochemist. The individual sections of the hard cover compilation are to be issued as separate paperbacks, which is very sensible, since any experimenter who is using or thinking of using these methods will want the appropriate book at hand. It would also be a good idea if these were just as sturdily bound as the main volume, since it is probable that they will be handed around from one worker to the next.

L. Jaenicke [NB 982a IE]

Laboratory Techniques in Biochemistry and Molecular Biology. Vol. 2. By *T. S. Work* and *E. Work*, North-Holland Publishing Comp., Amsterdam 1970. 1st ed., 408 pp., bound, Dfl. 75.—.

The second volume of "Laboratory Techniques" consists of two very timely sections: automatic enzyme determination, and the principles of cellulose-exchanger chromatography.

D. B. Roodyn, known as the author and editor of a whole series of extremely valuable monographs, here presents a review of over 200 pages of the techniques by which serial analysis and series of analyses needed in modern clinical and biochemical laboratories can be automated and programmed. Although as far as equipment is concerned the author places most emphasis on the Technicon Autoanalyzer, his presentation is by no means one-sided, since he tries to bring out the fundamental principles and to be just to the other methods. This is extremely well done. Descriptions are given of continuous and discontinuous sampling, single and multiple enzyme analyses, serial characterization of the physicochemical parameters of enzymes, data processing, and presentation of the results. In an appendix a FORTRAN program for a general enzyme analysis system is given, together with a summary of all the published automated enzyme determinations up to 1968. For all his enthusiasm for his subject, the author's presentation is critical and balanced. This is a book by a practical man for the practical man, who will here find an advisor reliable in every respect.

Before any chemical research can begin, the substances to be used or investigated must be purified. For complex biological materials and macromolecules, ion exchangers based on cellulose have very recently been introduced and have proved themselves extremely useful. *E. A. Peterson* is one of the pioneers in this field. His 170-page monograph results from the wealth of experience he has accumulated over the past 15 years. It begins with a description of the cellulose ion exchanger, and then turns to the theoretical foundations of chromatography and the effect of varying the parameters. The next sections, of special value from the practical viewpoint, deal with selection of the chromatographic conditions, preparation of the exchanger, packing and charging of the columns, the actual way in which elution is carried out, and treatment of the eluate. Finally, some current biochemical applications of importance are described. Here too valuable tips are given and the commercially available instruments are listed. The wealth of information given will enable even the novice chromatographer to approach his task with a certain amount of confidence and to make sense of his findings.

In both parts of this book the clear presentation, the circumspect and practical arrangement of the material, and the excellent appearance are particularly praiseworthy. This book should be available to every biochemist.

L. Jaenicke [NB 982b IE]

Gas Chromatography, Principles, Techniques and Applications. By *A.B. Littlewood.* Academic Press, New York 1970. 2nd. Edit., 546 pp., 152 figures, DM *ca.* 90.—.

The second edition of *Littlewood*'s book, like the first, is divided into three general sections on principles, techniques, and applications of gas chromatography. The strength of the book lies in the particularly clear and lucid treatment of the theory in Chapters 1–6. However, the discussion of the theoretical relations separately from the applications in the last few chapters will occasionally make it difficult for the analyst using the book to find explanations for practical observations that he is unable to interpret. Moreover, a comprehensive treatment of the diverse applications of gas-chromatographic methods can scarcely be achieved in the space of one textbook. Applications should be discussed in a textbook only to make the relations easier to understand and to facilitate the use of the special literature. This task is approximately fulfilled by the last part of the book.

As far as the second part of the book is concerned, the reviewer is of the opinion that it would have been better to place the emphasis on other phenomena and relations. The theory and construction of detectors such as the thermal conductivity cell and the argon detectors are described in too much detail. The analyst nowadays *buys* an instrument or an important part of an instrument, such as a detector, and will only rarely be able to make technical modifications and improvements. The properties of a detector that play a large part in determining the reliability and accuracy of quantitative analyses, such as sensitivity, dead volume, linear dynamic range, drift behavior, and calibration factors are important in this connection. The treatment of the argon detectors, with the possible exception of the electron capture detector, in no way reflects their practical importance, which is decreasing. Chapters 9 and 10 could have been shortened in favor of Chapter 11 in particular. Reaction gas-chromatographic methods and combined methods, column changing techniques, and automation of the analysis and of the evaluation are more important than some relations discussed in Chapters 9 and 10.

Finally, the reviewer would ask the publisher to make the print clearer and to draw more attention to important conclusions and basic principles by the use of bold type and indentations. To sum up, we can only say that the strength of the book lies in the clear and easily understandable treatment of the theory, though the book can also provide some important hints for practical problems.

Gerhard Schomburg [NB 973 IE]

Physical Chemistry, an Advanced Treatise. Vol. IV: Molecular Properties. Edited by *H. Eyring, D. Henderson,* and *W. Jost.* Academic Press, New York–London 1970, 1st Edit., xx, 832 pp., numerous figures, $ 39.—.

All the important fields of physical chemistry are to be covered in eleven volumes by well-known specialists for scientists and advanced students. Three volumes deal with properties of atoms and molecules: III. Electronic Structure of Atoms and Molecules, IV. Molecular Properties, and V. Valency. The present volume IV contains the following chapters: 1. The Variety of Structures Which Interest Chemists *(S. H. Bauer)*; 2. Rotation of Molecules *(C. C. Costain)*; 3. The Vibrations of Molecules *(G. W. King)*; 4. Vibrational Spectra of Molecules *(J. R. Hall)*; 5. Spectra of Radicals *(D. E. Milligan* and *M. E. Jacox)*; 6. The Molecular Force Field *(T. Shimanouchi)*; 7. Interactions among Electronic, Vibrational, and Rational Motions *(J. T. Hougen)*; 8. Electric Moments of Molecules *(A.D. Buckingham)*; 9. Nuclear Magnetic Resonance Spectroscopy *(R. M. Golding)*; 10. ESR Spectra *(H.G. Hecht)*; 11. Nuclear Quadrupole Resonance Spectroscopy *(E. Schempp* and *P.J. Bray)*. 12. Mössbauer Spectroscopy *(N.N. Greenwood)*; 13. Molecular-Beam Spectroscopy *(C.R. Mueller)*; 14. Diffraction of Electrons by Gases *(S.H. Bauer)*.

Many chemists successfully apply physical methods to the determination of molecular properties. However, their theoretical knowledge is at best superficial, since many detailed discussions are incomprehensible to them and seem difficult to apply on the basis of their earlier training. This series is therefore very welcome in its aim of guiding the chemist to a high level in the fields of physical chemistry. Most of the authors do in fact manage to make the theory accessible, in as much detail as is necessary, by means of useful formulas and examples. Experimental data are kept very brief, while the range of applications is outlined with typical examples, numerous tables, and comprehensive literature lists. The book is excellent and stimulating, and I hope that it will be widely used, with many advanced students among its readers.

Bernhard Schrader [NB 974 IE]

Phase Diagrams, Materials Science and Technology. Vol. II. The Use of Phase Diagrams in Metal, Refractory, Ceramic and Cement Technology. By *A. M. Alper.* Academic Press, New York–London 1970, 1st Edit., viii, 354 pp., numerous figures, bound $ 16.—.

Whereas Volume I[1] was concerned mainly with the thermodynamic principles and the theoretical aspects, the emphasis in Volume II is entirely on practical applications. It begins with a short section by *A. Muan* on the influence of the oxygen partial pressure on the formation of oxides of the types A_2O, AO, *etc.* This section is made easy to understand by the fact that general diagrams for the binary, ternary, *etc.* cases are given first and are then discussed further for particular systems such as wüstite-magnetite *etc.* The equations in this section are not entirely free from errors, but this should not trouble the user too much.

This section is followed by nine monographs. The relation between the phase equilibrium and the constitution and fine structure in ceramic-metal systems *(J. White)* and the use of these systems in cement chemistry *(F. P. Glasser; D. L. Johnson,* and *I. B. Cutler)*, in the industrial bonding of different metals or of metals and ceramic materials *(A. Prince)*, and for the production of refractory materials *(H. M. Kraner* and *A. M. Alper; R. C. Doman, R. N. McNally,* and *H. C. Yeh)* are discussed. Heat treatment for the production of alloys having given properties *(G. Krauss* and *J. F. Libsch)* and its relation to phase equilibria in multicomponent systems are discussed here, as is the application to extraction metallurgy *(J. Taylor)*. Special mention should be made of a detailed thermodynamic and molecular-theoretical article by *T. B. Massalski* and *H. Pops* on the stability and classification of intermetallic phases, which satisfactorily shows the significance of the atomic structure in the consideration of the diagrams.

Like the first volume, the present second volume can be warmly recommended to all those involved in scientific and practical studies in the field in question.

Klaus Schäfer [NB 970a IE]

Phase Diagrams, Materials Science and Technology. Vol. III. The Use of Phase Diagrams in Electronic Materials and Glass Technology. By *A. M. Alper.* Academic Press, New York–London 1970. 1st Edit., xviii, 325 pp, numerous figures, bound $ 16.50.

This third volume deals mainly with applications of phase diagrams to the production of substances having predetermined properties. The substances in question are mainly semiconductors, but nonconductors such as glass are also discussed.

The volume begins with a fairly long article on crystal growth *(J. W. Nielsen* and *R. R. Monchamp)*. The techniques for the production of very pure semiconductor materials are briefly described, and the aptness of one method or another is discussed on the basis of the phase diagram, e.g. the production of single crystals in the neighborhood of and at a "greater" distance from a stoichiometric composition. Closely related to this are applications to the synthesis of semiconductor materials consisting of two or more components *(M. B. Panish)*.

A short article *(V. F. Zackay, M. F. Merriam,* and *K. M. Ralls)* is devoted to the recently used superconduction in rapidly cooled systems for the characterization of new crystalline states in alloys; the superconduction is also discussed in the more general section on rapidly cooled metastable alloy phases *(B. C. Giessen* and *R. H. Willens)*.

The last four chapters deal with the miscibility gaps in liquid metal oxides *(E. M. Levin)*, the relations between phase diagrams and the structure of glass-forming oxide melts *(E. F. Riebling)*, cryoscopy in salt melts *(T. R. Kozlowski)*, and the kinetics of the dissolution of solid phases in solvents *(A. R. Cooper)*. In this last section, the phase diagrams are used as an excellent source of the data that characterize a solution; they may thus be regarded as a means of predicting the final solution behavior. The section, though only short, gains special importance through the contributions on glass formation and cryoscopy.

This volume, which is entirely written by leading scientists closely connected with industry, is almost more important than the previous two to industrial engineers or chemists.

Klaus Schäfer [NB 970b IE]

[1] Cf. Angew. Chem. internat. Edit. *10*, 205 (1971).

Aquatic Chemistry. By *W. Stumm* and *J. Morgan*. John Wiley and Sons Ltd., Chichester 1970. 1st ed., 583 pp., bound, £ 11.75.

This is an excellent textbook. In collaboration with *Morgan*, *Stumm* has developed his Harvard lectures into a compendium in which the fundamental chemical reactions in aquatic chemistry are described, with particular emphasis on the thermodynamic aspects. The clear layout of the sets of formulas and the illustrative matter is a considerable aid to the student. The authors' aim to establish a theoretical basis for the chemical behavior of natural waters, *i.e.* the oceans, estuaries, rivers, lakes, and ground water, has been quite definitely achieved.

The consideration of the chemical processes involved in the distribution and circulation of chemical substances in natural waters, the fundamental reactions taking place during water treatment, and the quantitative mathematical treatment of the variables which determine the composition of natural waters, are all amplified by numerous exercises and calculations drawn from practical experience. It is precisely this that gives the work its vigor as a textbook, and will remind even the already qualified worker that it is worth while having another look at thermodynamics.

Wilhelm Husmann [NB 979 IE]

The Neurosciences: Second Study Program. Ed. by *F.O. Schmitt*. The Rockefeller University Press, New York. 1st Edit., 1970, 1100 pp. 607 figures. Linen, $ 30.— for individuals, $ 60.— for libraries.

"We are at the beginning, and not near the end, of the process of understanding development. This is not the time to summarize, but a time to prospect and project into the future; and the best thing is to turn for guidance to the living object which teaches us the lessons and also teaches us the real problems to which we are to direct our questions". This quotation from *Paul Weiss*, reproduced at the beginning of one of the chapters, could well serve as a motto for the book as a whole. It is of course true that this is already the second report of a three-week conference of the Neurosciences Research Program, the first having been published in 1967. It is also true that the report's 1000 or more pages of A 4 size offer the reader an outstanding survey of current knowledge of the structure and function of animal and human nervous systems. Nevertheless, it is precisely from these facts that it follows just how incomplete and in many respects rudimentary this knowledge is. There are many reasons for this situation: The extraordinary complexity of the brain, which is never likely to be completely unraveled with the methods presently available, the inability to carry out experimental work with the human brain—although it is precisely this organ which has undergone the greatest change in the course of man's evolution from his animal forebears, and which must therefore show much weaker analogies to the corresponding animal organ than in the case of, say, the liver, lungs, or the kidney—and finally the problem that the integrating functions of the brain (learning, memorizing, thinking, feeling) are at best difficult, if not impossible to quantify. And yet, one must not lose sight of the fact that, like all other organs in the human body, the brain involves physical and chemical processes, and that what we call intellect stems from a finely balanced interplay of molecules and ions. Anyone who approaches this volume from this standpoint and who is not deterred by the profusion of anatomical and biological terms perhaps unfamiliar to the chemist, will find himself richly rewarded. Eighty-eight chapters cover eight general subjects:

Evolution of brain and behavior
Development of the nervous system
Determinants of neural and behavioral plasticity
Complex psychological functions
Neural subsystems and physiological operations
Communication and coding in the nervous system
Aspects of molecular neurobiology
Recognition and control at the molecular level

The volume is copiously and instructively illustrated. Unfortunately, in the case of figures taken from other books, abbreviations are sometimes reproduced without explanation. Whereas this may be all right for the initiated, it does represent an additional difficulty to those less familiar with the field. It is to be hoped that the editors of future volumes of this kind will generally have a thought for interested scientists working in adjacent disciplines, on whose collaboration neuroscience research will after all have to rely if it is to make any real progress. More diagrams, to explain the principles involved or the terminology used, would be of tremendous help, even when they might be familiar to the specialist. Notwithstanding such reservations, the present volume, like its predecessor, undeniably represents a historic milestone in the literature on neurosciences research.

Helmut Grünewald [NB 971 IE]

Arzneimittelwirkungen (Effects of Pharmaceuticals). By *E. Mutschler*. Wissenschaftliche Verlagsanstalt, Stuttgart 1970. 1st ed., xvi, 477 pp., 77 figs., bound, DM 48.—.

The object of this book was to provide an introduction to pharmacology for pharmaceutical chemists, chemists, and biologists, at the same time giving them the requisite background knowledge of medicine. Accordingly, the book contains introductory chapters on anatomy and physiology, which present what is needed for understanding of this subject in brief, precise, and memorable form. This is helped by the chapter "Explanation of medical terms" at the end of the book, and also by the extensive and extremely useful subject index.

In the general part of the book the author explains important pharmacological concepts such as conditions of action, receptor theory, structure-effect relationships, and side effects. In the following, more specific, section he deals with the nervous system, endocrine glands and their hormones, circulation, kidneys and the urinary tract, the gastrointestinal tract, essential substances, infective diseases, chemotherapy of malignant tumors, and poisoning.

The author knows how to clarify and impress on the reader the difficult interrelationships of this complex subject. He has also undertaken to keep his book continually updated, which in view of the rapid development of this field will be quite a task. This can be seen from the fact that today, only a year after the appearance of the first edition, there is already additional material to be added (*e.g.* the inclusion of L-Dopa therapy in the section on Parkinson's desease).

With this book, *Mutschler* has undoubtedly fulfilled his aim of providing instruction in pharmacology together with the appropriate background knowledge of medicine. Every scientist concerned with pharmacology should have a copy. It should also prove to be a useful source of information for doctors.

Ernst Biekert [NB 980 IE]

Molecules and Life. An Introduction to Molecular Biology. By *M. V. Volkenstein*. Plenum Press, New York—London 1970. 1st ed., xii, 513, pp., 207 figs., numerous tab., bound, $ 15.00.

Physicists who had become tired of their subject may boast of having opened the field of molecular biology. Provided that they are not regarded merely as molecular geneticists, they can be said to have used the tools and the underlying philosophy of physics to place biology on a quantitative footing. Since then any physicist writing on a topic such as molecules and life has always aroused great expectations. In the present case, however, these expectations have not been fulfilled; this is not a work of startling originality, but rather a mediocre presentation of biochemistry from the viewpoint of a physicist, *i.e.* without any chemistry. The fundamentals of physical chemistry and information theory are painstakingly laid out, and an attempt is made to use them to describe biological processes mathematically. This is certainly valid, very important, and it has never been correlated in a book in this way before. But whom is it going to help? The many biological platitudes will be of no use to the physicist, though they may well bring a smile to the face of the biologist; he in his turn will not understand the physical topics in the manner in which they are presented. The book is thus a failure, although it must be admitted that all the physical problems are derived in a completely unambigous manner. They remain, however, just as dull as the entire surrounding structure, which has been diligently but unimaginatively stuffed full of facts. There is a great need for a textbook of biophysical chemistry or physical biochemistry, or whatever one may choose to call it, but this book will not make any student enthusiatic over molecular biophysics.

Some absurdities in the text are not the fault of the translation, which could not get far enough away from the original, as a comparison with the German edition will show. In both cases one is assured that the manuscript has been specially revised for that particular language version. Personally, I was unable to find any differences, and in some cases even the same slips occur (*e.g.* "lamp filament chromosome").

A truly stimulating textbook on molecular physics still remains to be written. When it appears, let us hope that the author is not so much of a self-made biologist, and also has a fresher style of writing.

L. Jaenicke [NB 981 IE]

Art in Organic Synthesis. By *N. Anand, J. Bindra* and *S. Ranganathan*. Holden-Day, Inc., San Francisco 1970. 1st ed., xiv, 414 pp., numerous figs., bound, $ 11.00.

"There is excitement, adventure, and challenge, and there can be great art, in organic synthesis". With these words of *R. B. Woodward*, one of the great pioneers in organic synthesis, as a motto, the authors have collected together in alphabetical order more than 100 examples of post-1940 syntheses which are characterized by their intelligent planning and their use of novel reactions and reagents. The compounds synthesized are natural products or unusual or strained molecules which were prepared in order to confirm their predicted properties. A few examples will give an idea of the high standard of selection: aflatoxin B_1, aromatic $(C_nO_n)^{2-}$ ions (squaric acid, *etc.*), normal and bridged annulenes, bullvalene, chlorophyll, colchicine, Dewar benzene, α-ecdysone, helicin, morphine, penicillin, quinine, twistane, and vitamin B_{12}. Each synthesis is presented clearly and concisely, with a short introduction of principles and special features, a clearly presented reaction scheme, and literature references. The indexes at the end of the book are arranged by names of reactions, types of reaction, reagents, authors, and substances. The literature has been reviewed up to the middle of 1969. There are a few printing errors and some unhelpful abbreviations, but these hardly detract from the usefulness of the book.

This work is more than a collection of examples for seminars and lectures on organic synthesis. It offers the practising chemist an invaluable guide to the selection of analogous reactions, methods and reagents and also serves as a literature source. Particular attention is paid to the strategies (so important in the solution of complex synthesis problems) for the selection of key and relay compounds, converging synthetic routes, *etc.* Since the selection of syntheses is representative, there is also the possibility of using the frequency of references in the reaction name index as a highly informative indication of the range of possibilities of a given method in research and teaching. The book can be recommended as a valuable information source for all branches of organic chemistry.

Burchard Franck [NB 983 IE]

Molten Salts. Characterization and Analysis. Ed. by *G. Mamantov*. Marcel Dekker, New York 1969. 1st ed., xvi, 611 pp., bound, $ 16.75.

This book contains twenty papers from a symposium held at Atlantic City in September 1968. The first three contributions deal with the fundamental ideas of structure and energetics of molten salts, the concept of complex ions in ionic melts, and relationships with phase equilibria. The next six papers concern the results of ultraviolet, infrared, and Raman spectroscopy, NMR spectroscopy of ^{205}Tl salt solutions, and the use of neutron diffraction in the study of short-range order. In the four papers devoted to transport, the introduction of the glass-transition temperature for the treatment of low-melting systems is noteworthy, as also are the proof of electron conduction, *e.g.* in Cu^{I}/Cu^{II} halide solutions, and the use of ultrasonic relaxation. The other papers are on miscellaneous topics, including distribution equilibria between metal and fluoride melts, double-layer capacity at dropping electrodes, solubility of halogens, electrode reactions in fluoride melts, chronopotentiometric studies, and lastly the thermochemistry and mechanism of redox reactions of oxygen in nitrate melts.

All the contributions include recent research results relating to a more or less limited part of the entire field; however, most of them take the form of comprehensive reviews, and from the subject viewpoint they are brought together in such manner that even the reader new to the subject will obtain a full and up-to-date picture.

There is also a great deal of detailed information on experimental techniques and material problems. The book is thus of interest not only to those immediately concerned with the chemistry of molten salts, but also to anyone concerned with chemical processes at high temperatures.

Hubert Kühnl [NB 984 IE]

Introduction to Electronic Absorption Spectroscopy in Organic Chemistry. By *E. S. Stern* and *C. J. Timmons*. Edward Arnold Publ. Ltd., London 1970. 3rd ed., vi, 277 pp., numerous figs., bound, £ 5.10.

The present book, the extensively revised 3rd edition of Gillam and Stern, deals with electron absorption spectroscopy in organic chemistry. In less than 300 pages the authors have only two possibilities: either a presentation of the basic theory with brief illustrative examples of spectra or an interpretation of the results with appropriately chosen theoretical data. They have in fact chosen the latter course.

The book is clearly arranged and is divided into ten chapters. In Chapter 1 the general basis of spectroscopy is discussed, and this is followed by the measurement and representation of absorption spectra. It should be particularly noted that the authors emphasize the physically meaningful presentation of spectra by means of wave numbers (p. 23). Chapter 3 gives a general survey of the basic principles and examples of the assignment of spectral bands on the basis of a large amount of experimental material. Chapters 4—7 review the spectra of the more important chromophore systems: molecules with only one functional group, conjugated chromophore systems, aromatic hydrocarbons with derivatives, and hetero-aromatics. The value of this chapter is enhanced by the numerous graphical presentations, spectra, and tables. Chapter 8 deals with the application of absorption spectroscopy to qualitative analysis, Chapter 9 with the spectroscopic determination of organic compounds, and the last chapter with the relationships between UV absorption spectroscopy and molecular structure.

The appendix reviews the bibliography of electron spectroscopy and also gives general information on solvent and temperature effects. A detailed list of references is appended to each chapter. The book is clearly printed and is easy to read.

It is thus a valuable and needed complement to the many works on electron excitation spectroscopy with their predominantly theoretical basis, and can be recommended to any student of chemistry.

Imaging and Analysis of Surfaces with a Scanning Electron Microscope and Electron Spectrometer[**]

By Reimer Holm[*]

The topography and the composition of a surface are in many cases of equal importance (catalysis, electroplating, pretreatment of foils and sheet metal, corrosion, passivation, adsorption, coating of fibers, etc.), and this explains the great interest in methods of investigation that reveal both. If the demands on the resolving power, the analytical possibilities, and the thickness of the surface layer are not too exacting, combined devices like the scanning electron microscope and its analytical accessories can be used. When it is necessary to avoid the compromises involved in simultaneous imaging and analysis, the investigations must be carried out with separate equipment. As an example of a method for the analysis of surfaces we consider briefly photo- and Auger electron spectroscopy (ESCA).

1. Principle of the Scanning Electron Microscope

It has been an old dream of scientists to possess a device enabling them to image a surface with the highest possible spatial resolution, *i.e.* to study its topography, and in addition to obtain the most complete possible information on the composition of this surface. There is, at present, no such universal apparatus, although numerous attempts have been made using electrons, ions, and X-rays[1]. The scanning electron microscope may be considered as a good approximation as regards the demands of microscopy. As a supplement to this we shall discuss a special surface analysis technique which utilizes photo- and Auger electron spectroscopy with X-ray excitation (ESCA). The two methods have, in comparison with others, the advantage that preparation is fairly easy, that they can be used universally, and that they are therefore suitable for routine industrial investigations.

[*] Dr. R. Holm
Farbenfabriken Bayer A. G.
Ing.-Abt. Angewandte Physik
509 Leverkusen (Germany)

[**] Since it is impossible to list the large number of publications dealing with the scanning electron microscope; the reader is referred to the following bibliographies:

O. C. Wells; IBM Research Center
Post Office Box 218
Yorktown Heights
New York 10598 (USA)

G. Pfefferkorn and *U. Ehrenwerth*; Institut für medizinische Physik der Universität
44 Münster, Hüfferstrasse 68 (Germany)

The idea of a scanning electron microscope goes back to *M. Knoll* and *M. von Ardenne*. It was taken up again by *Oatley et al.*[2a] and applied to the imaging of the surfaces.

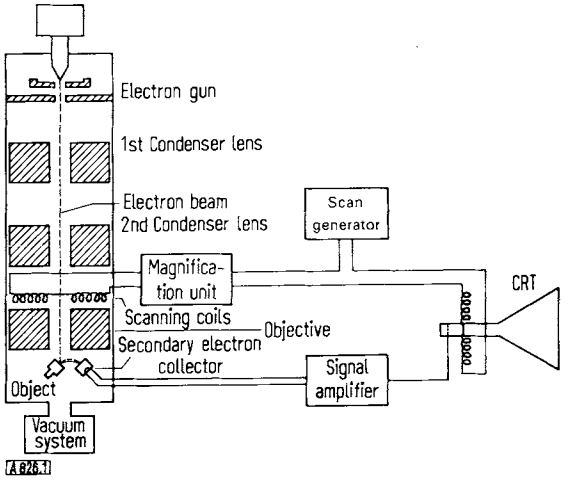

Fig. 1. Block circuit diagram of a scanning electron microscope ("Stereoscan", Cambridge Scientific Instruments).

The scanning electron microscope works on the pantograph principle: The essential elements are two electron beams operated synchronously by a scan generator (Figs. 1 and 2). The primary beam is produced in an evacuated column by thermionic emission, and is focused to a dia-

meter of about 100 Å by electromagnetic lenses. This beam scans the object point by point and line by line. The other beam records the picture point by point and line by line

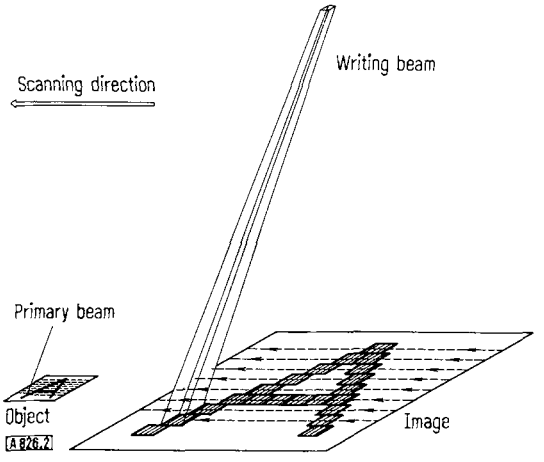

Fig. 2. Analysis and reconstruction of a picture by the scanning method (according to [2b]).

on the phosphor screen of a cathode ray tube. The magnification is given by the ratio of the picture area to the scanned area of the object.

When the primary beam impinges upon the object, a variety of interactions occurs between the electrons and the solid material (Fig. 3). Both secondary electrons and

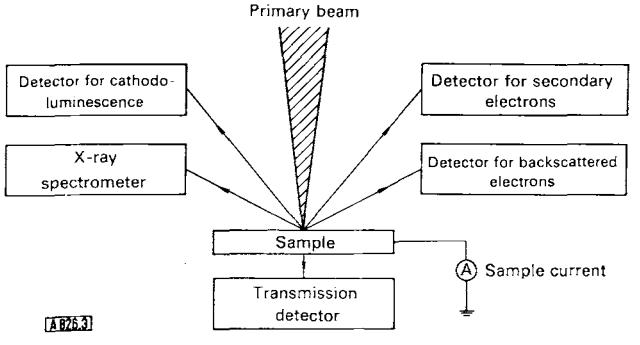

Fig. 3. Interactions between electrons and matter inserted in the scanning electron microscope for picture formation.

backscattered electrons are used for imaging the surface. The secondary electrons are generated by impact ionization or the Auger effect. They possess a significantly lower energy than the primary electrons and those that are backscattered elastically or with only small energy losses. The secondary electrons are collected by a side-mounted positively charged electrode and are processed in the attached electronics so that their number controls the brightness of the corresponding point on the CRT screen. In such an imaging device there is no limitation by a particular lens optics. In particular, the aperture of the primary beam is very small (10^{-2} to 10^{-3} rad $\approx$ 0.6 to 0.06°). One thus obtains a depth of field that is at least 500 times greater than that of the optical microscope.

The number of secondary electrons emitted depends on the properties of the region struck by the beam (Fig. 4)[3a]. The incident primary electrons penetrate the surface of the sample, and in the schematically drop-shaped region drawn secondary electrons are released by scattering processes. Only a few of them have a chance of leaving the surface. On spikes and edges the escape surface becomes much larger than for a smooth plane surface, and the spikes therefore appear bright (relief contrast). Heavy elements emit better than light elements (material contrast), and an electric field may inhibit or enhance the yield coefficient (potential contrast).

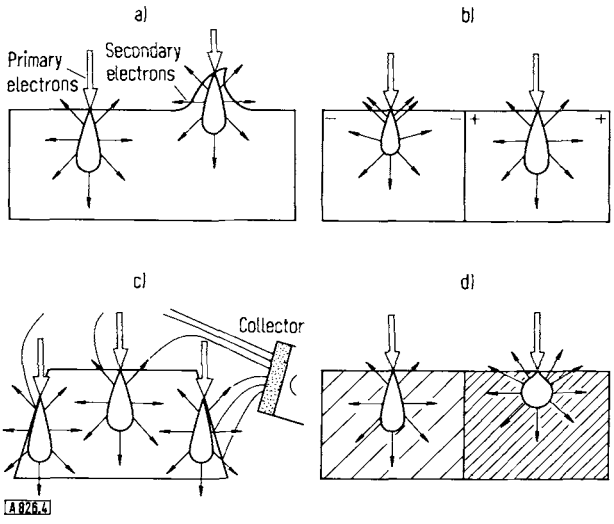

Fig. 4. Contrast mechanisms in secondary electron pictures in the scanning electron microscope (according to [3b]).

(a) Effect of topography: spikes and edges are brighter than plane surfaces.

(b) Effect of electric charge: negatively charged points are brighter than positively charged ones.

(c) Effect of position relative to the collector: a surface turned toward the collector is brighter than one turned away from it.

(d) Effect of chemical composition: regions of heavy elements are brighter than those of light ones.

The secondary electrons are never emitted only from the point of incidence of the primary beam, but always come from a certain diffusion region around it. This diffusion region is particularly small in heavy metals, and thus in this case it is possible to obtain a spatial resolution of about 200 Å; this corresponds to a useful magnification of 5000 to 10000 times.

Conducting objects can be investigated in the scanning electron microscope without any particular preparation. To avoid electrostatic charging, insulating samples must be coated with conducting substances. Carbon is chosen as a high-adhesion conductive coating, and to improve the resolving power and secondary electron emission yield, roughly 200-Å thick coating of gold is evaporated on top of this.

2. Applications of the Scanning Electron Microscope

The illustrated examples, which are taken mainly from the fields of process engineering and applications technology, cover only a small part of the many possibilities of the scanning electron microscope. The nonwoven fabric used as a dust filter (Fig. 5) and the knotted wool fiber

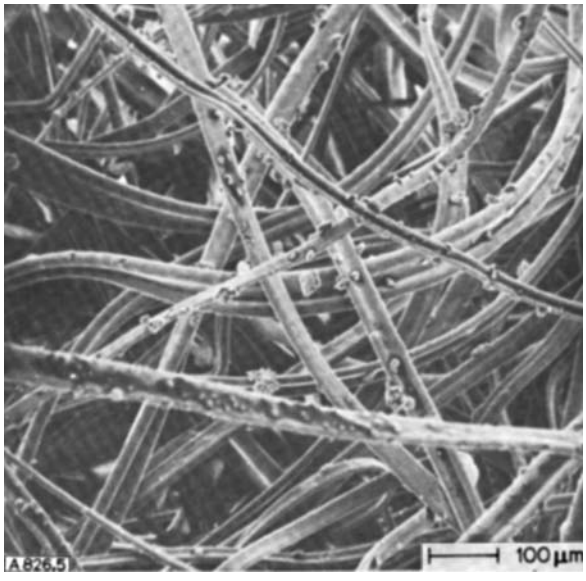

Fig. 5. Nonwoven fabric used as a dust filter.

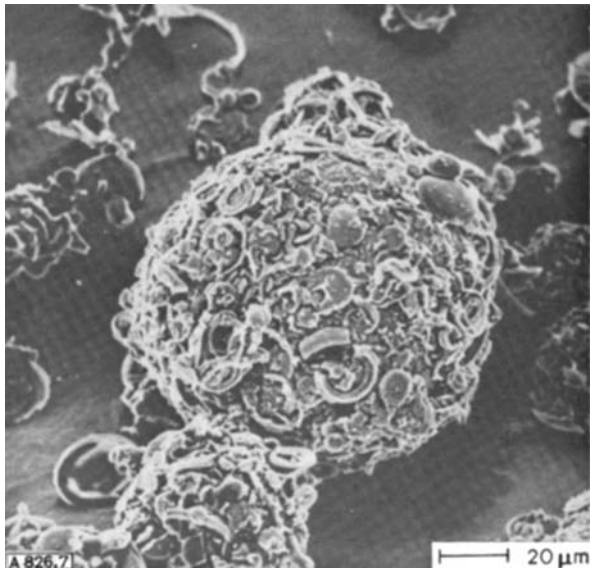

Fig. 7. Latex rendered flowable by diatomaceous earth.

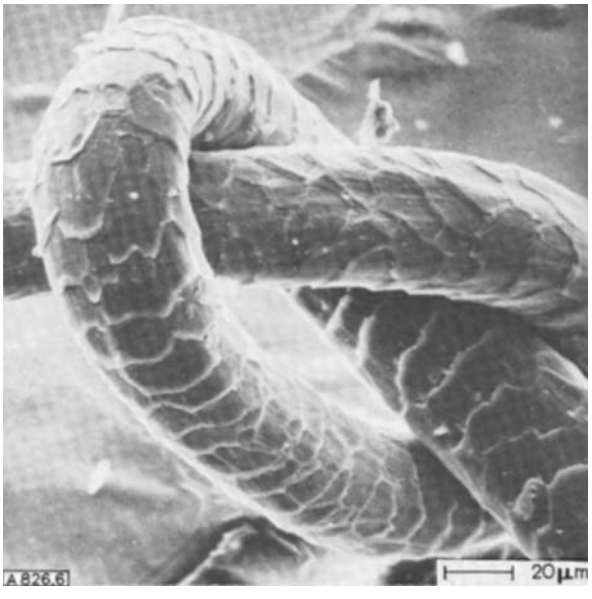

Fig. 6. Knotted wool fiber.

Fig. 8. Corroded steel surface.

(Fig. 6) demonstrate the depth of field of the microscope. In the case of the polybutadiene latex in Fig. 7 it is easy to see the diatoms which were used to make it flowable. Fig. 8 shows a nonuniformly corroded metal surface, with remains of nonconducting corrosion products visible in the depressions. In contrast to the light-optical picture they appear bright, as a result of charging.

Figures 9—12 show several stages in leather processing[4]. The grain layer (Fig. 9) is roughened (Fig. 10), then impregnated (Fig. 11) and primed (Fig. 12). The lacquer can now be applied. This should be compared with the surface of a microporous foil (without finish), used as a synthetic leather, Fig. 13. Carbon crystals with the theoretically required helical structure are often found in pyrolysis furnaces[5]. The twinned crystal shown in Fig. 14 was produced by the coalescence of two closely neighboring cylindrical crystals, both of which had originally their own helical structure.

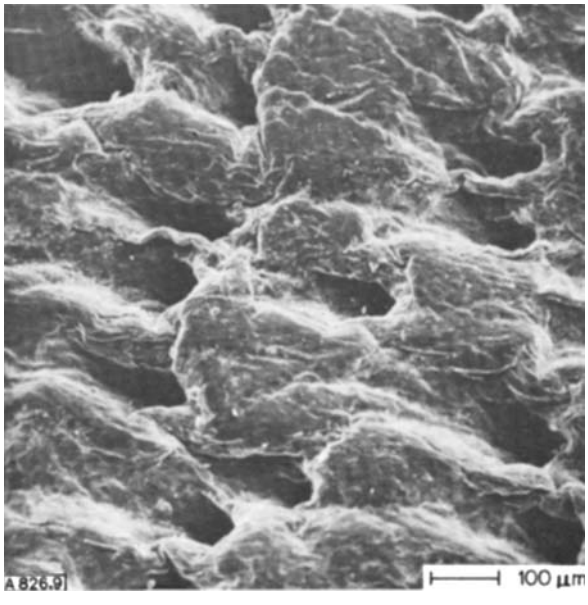

Fig. 9. Grained layer of leather.

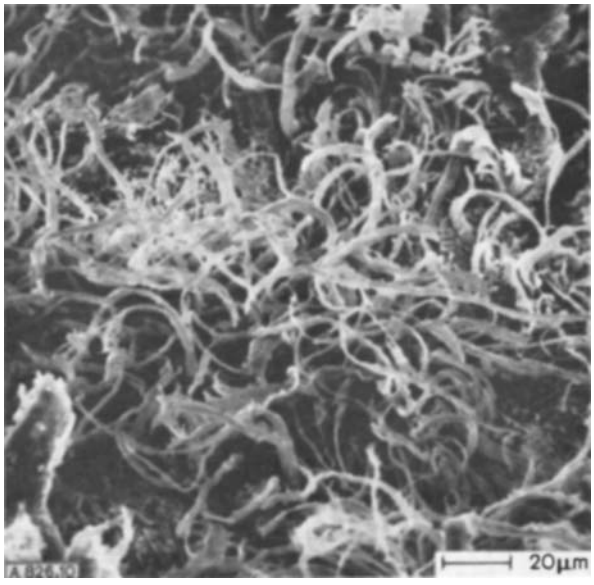

Fig. 10. Grained layer of leather, roughened.

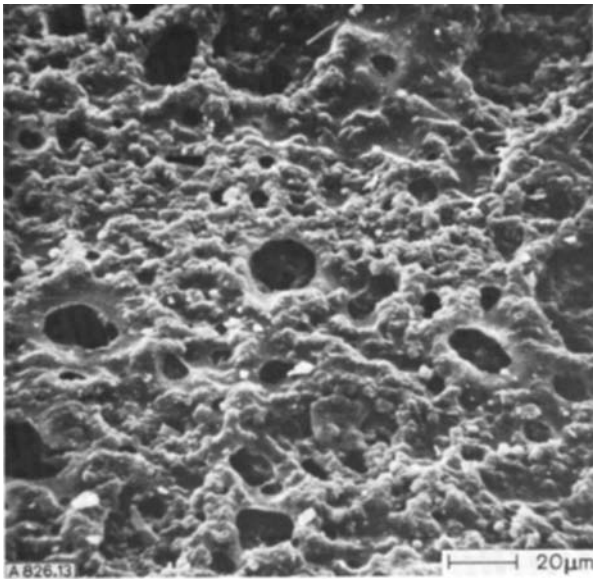

Fig. 13. Unfinished surface of a microporous foil.

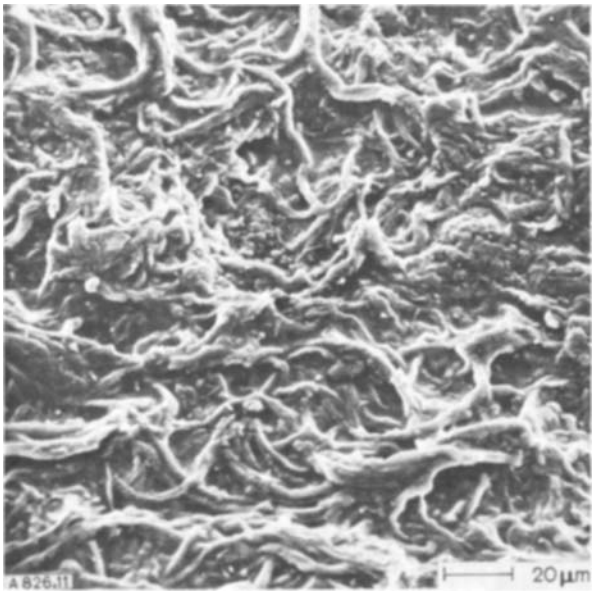

Fig. 11. Grained layer of leather, roughened and impregnated.

Fig. 14. Carbon crystal from a pyrolysis furnace.

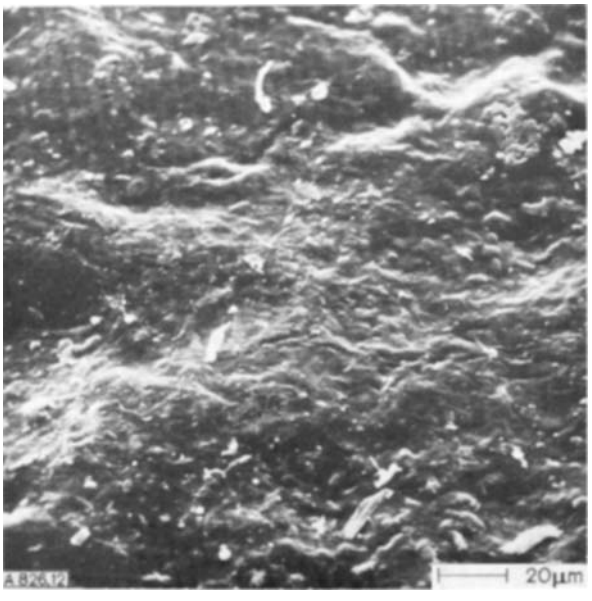

Fig. 12. Grained layer of leather roughened, impregnated, and primed.

Because of the depth of field it is very easy to photograph fracture surfaces, *e. g.* of high polymers, with the aid of the scanning electron microscope. Interpretation of the pictures in order to get a relationship between the morphology of the fracture surface and the macroscopic deformation processes for high polymers is still only tentative. One has to consider the physical (*e. g.* the free volume) and the chemical structure of the material (*e. g.* in the case of ABS the styrene-acrylonitrile copolymer matrix with discontinuously distributed polybutadiene), as well as features that are connected with the fracture process itself (*e. g.* deformation rate).

Figures 15 and 16 give a clear example of this case: the ABS polymer, the deformation rate, and the fracture temperature are the same in both cases. Figure 16 shows a structure typical for a fracture with large plastic deformation (crazing) while Fig. 15 resembles brittle fracture, perhaps a low-temperature fracture. The difference lies in the physical structure: the specimen of Fig. 16 is freshly

extruded, while that of Fig. 15 has been stored for a long time at room temperature or somewhat above it. The example shows that investigations of fracture surfaces of polymers are only meaningful if the thermal and mechanical history of the specimens is taken sufficiently into account[6].

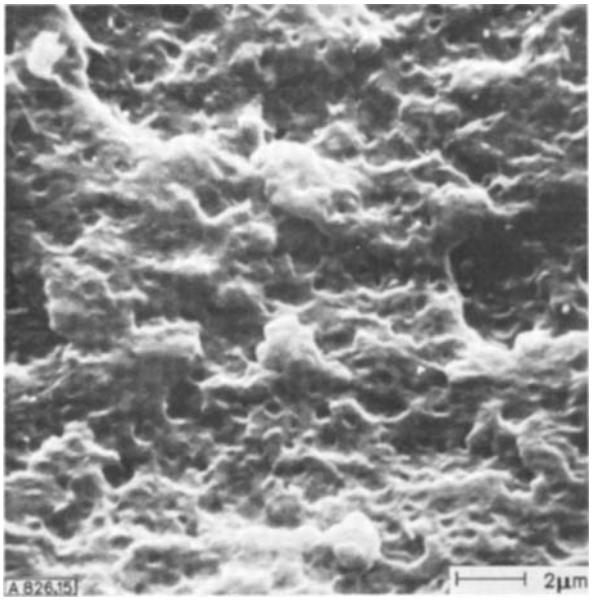

Fig. 15. Fracture surface of an ABS polymer after prolonged storage.

The properties of polymers reinforced with glass fibers depend to a large extent on the adhesion between the matrix and the glass fibers; the adhesion is improved by the addition of special coupling agents[7]. Figure 17 is typical of poor adhesion: long unwetted glass fibers stick out of the fracture surface. Fig. 18 shows, on the other hand, a relatively good adhesion: the fracture runs predominantly in the matrix, the fibers are wetted. Mechanical measurements can detect smaller differences than the scanning electron microscope, but they are not so easy to interpret.

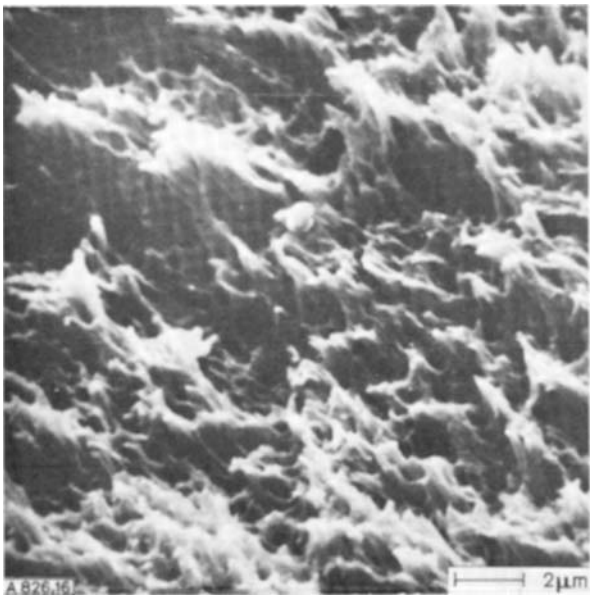

Fig. 16. Fracture surface of a freshly extruded ABS polymer.

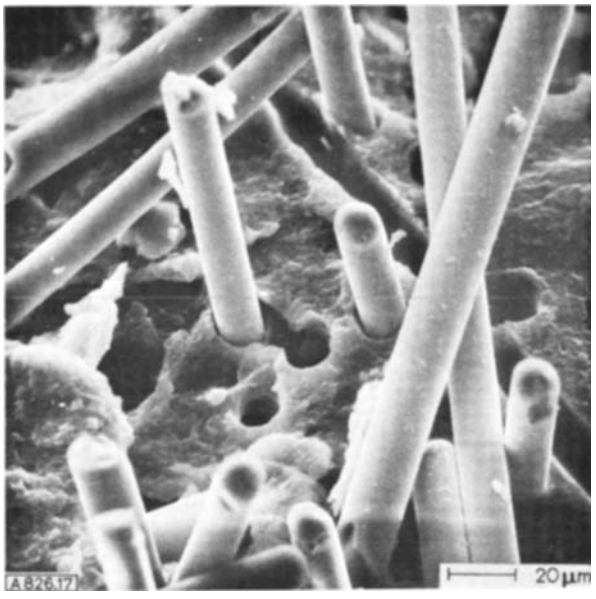

Fig. 17. Fracture surface of a glass-fiber-reinforced polymer with poor adhesion between the matrix and the glass fiber.

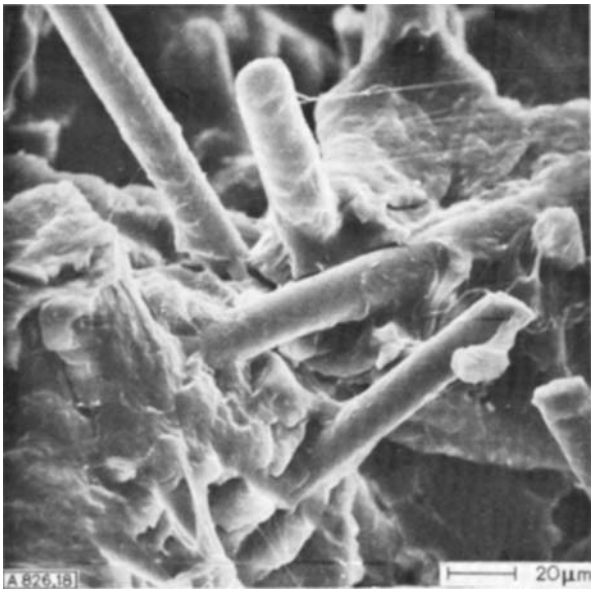

Fig. 18. Fracture surface of a glass-fiber-reinforced polymer with good adhesion between the matrix and the glass fiber.

With a suitable arrangement of the primary beam, the sample, and the collector, the scanning electron microscope already gives striking three-dimensional pictures. The impression of depth can be increased further by taking proper stereoscopic pairs[8]. Unfortunately, for various reasons the measurement of height, as in photogrammetry, is subject to large errors.

The pictures illustrating this paper were taken with a scanning time of 40—100 s. The development of new scanning coils has made it possible to scan at television frequencies, though with a certain loss of picture quality. Thus one can observe dynamic events like the stretching of foils and fibers with the scanning electron microscope[9].

In all the cases considered so far the scanning electron microscope has been used as a pure microscope. Because of its depth of field, it is applied above all to the imaging of

rough fracture and outer surfaces. There is an increasing interest in going beyond mere imaging to examine the composition of the surface. Material differences of the surface may be detected with the scanning electron microscope either chemically by selective etching and staining[10] or physically by exploiting the different interactions between the electrons and the solid. As an example of the first class, one might consider etching with oxygen in a gas discharge (cold combustion), *e.g.* to separate inorganic

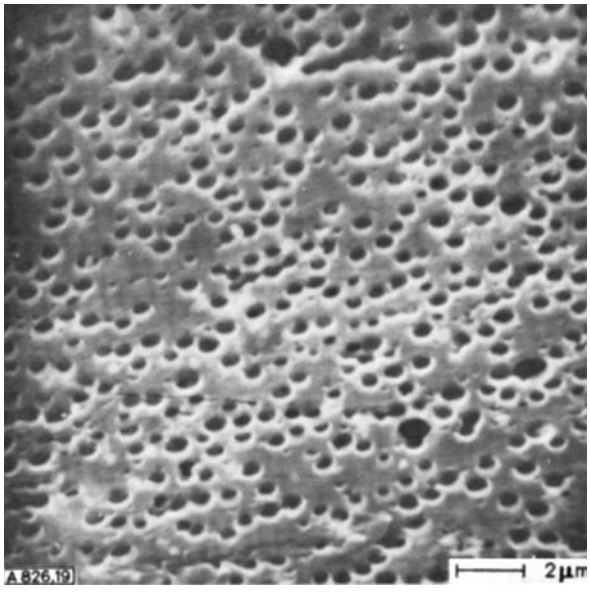

Fig. 19. ABS polymer roughened with chromic acid.

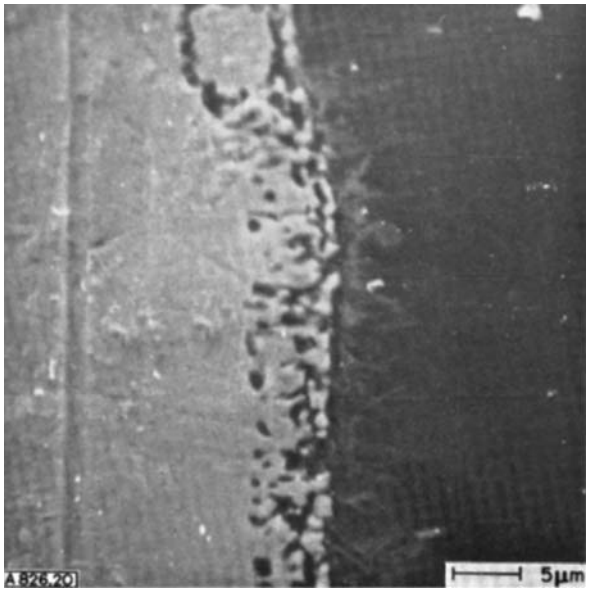

Fig. 20. Boundary between enamel (dark) and metal (bright). Polished section.

and organic materials[11]. Included in this class is the selective elimination of polybutadiene particles from ABS plastics with chromic acid (Fig. 19) as a pretreatment for electroplating[12]. Only the second class will be treated extensively in the following.

Of the interactions between electrons and solid in Fig. 3 only the emission of secondary electrons has been considered so far. However, the function of picture brightness control can also be assumed by backscattered, absorbed (sample current), or transmitted electrons (in thin films). In fact, we need not even confine ourselves to electrons—photons (in the cathodoluminescence mode) or electrical pulses generated by X-rays may serve the same purpose. The scanning principle is thus shown to be especially versatile; each interaction offers new possibilities for the imaging of surfaces or the recognition of material differences. In Fig. 3 no particular attention was paid to the Auger effect, which is treated in Section 3; the Auger electrons are included in the secondary electrons.

It has already been mentioned in Fig. 4 that in secondary electron images regions with heavy elements appear bright. Fig. 20 shows as an example a polished section (to avoid relief contrast) at right angles to an enamel/metal interface. The metal appears bright because of its higher atomic number, while the enamel appears dark. Between

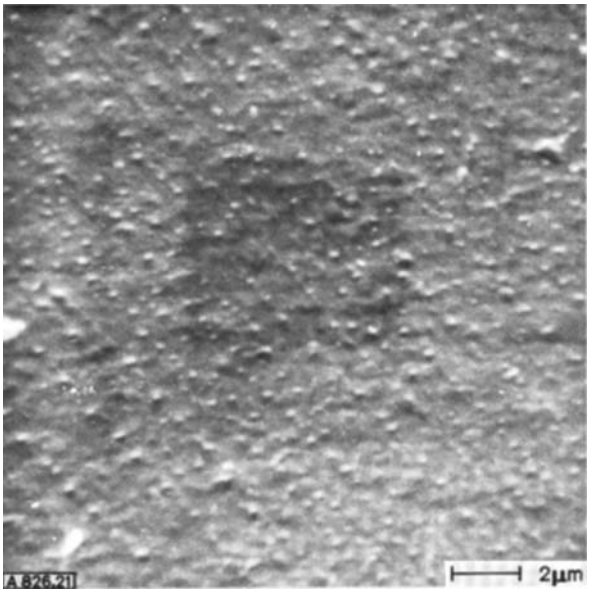

Fig. 21. Surface of a pigmented coating, primary beam voltage 5 kV.

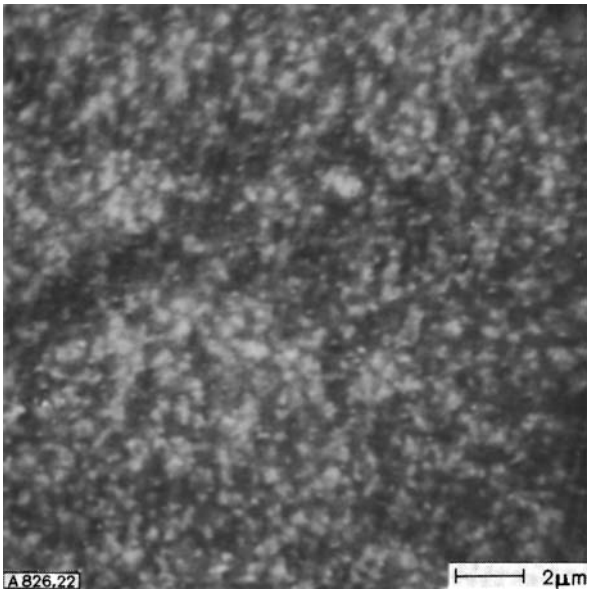

Fig. 22. Surface of a pigmented coating, primary beam voltage 20 kV.

them is the boundary, the involved structure of which guarantees good adhesion. There is a further effect in addition to the light-dark representation due to the difference in atomic number. This effect may be demonstrated on the example of a pigmented coating[13, 14]. Fig. 21 shows a coating surface which was imaged with 5 kV primary beam voltage. One can only see the pigments which protrude out of the coating surface. At 20 kV primary voltage the picture is entirely different (Fig. 22). A large number of indistinct bright spots predominates. These are pigments that lie below the surface; they are bright because of the difference in atomic number between the pigment and the other components of the coating, and indistinct because of the scattering processes suffered by the electrons within the coating. Thus the scanning electron microscope never images the mathematical surface of an object but "sees" a little way into the specimen[3a]. How deeply it sees it depends on the penetration power of the electrons, *i. e.* on the primary beam voltage and the density of the material under investigation.

If nature does not provide a sufficient difference in atomic number, in some cases it may be introduced by suitable preparation. In ABS plastics the polybutadiene phase can be stained with the aid of OsO_4. Thus the distribution of the polybutadiene *e. g.* in an injection-molded part can be made visible as the pigments in a coating[10] (Fig. 23; cf. also Fig. 19).

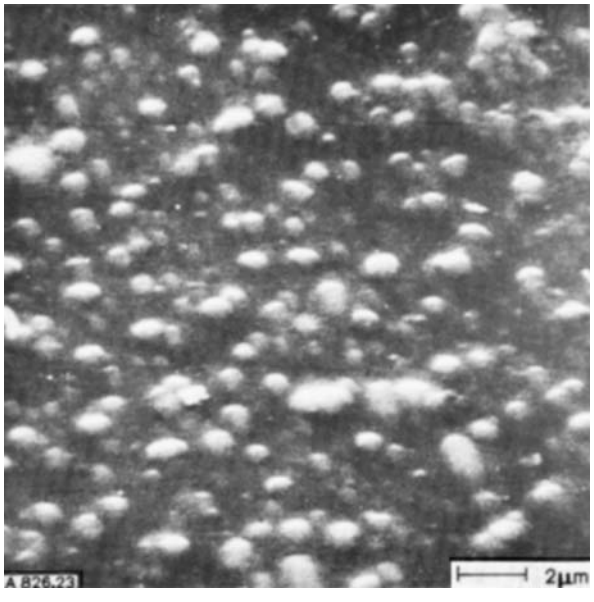

Fig. 23. Surface of an ABS injection-molded part after treatment with OsO_4.

The cathodoluminescence mode of operation allows an entirely different way of discriminating between materials. The emission of visible light during electron bombardment is well known from every cathode ray tube. However, the phenomenon is not confined to the inorganic compounds used there, such as crystalline zinc oxide or zinc sulfide, but is also exhibited by a range of organic dyes. Above all, the wide range of optical brighteners lends itself to a specific characterization of other organic substances. One thus obtains a method of discriminating between materials

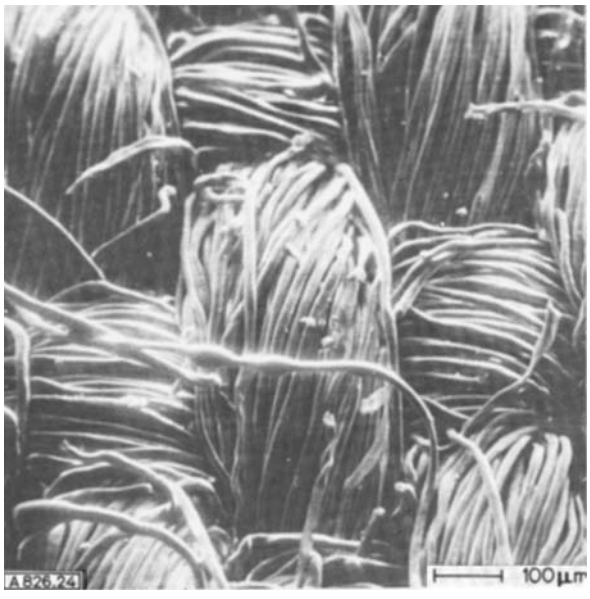

Fig. 24. Cotton-polyester mixed fabric after laundering test with addition of brightening agents. Picture using secondary electrons.

independently of the atomic number, in the purely organic field; a type of fluorescence microscopy with the depth of field of the scanning electron microscope can be carried out[14, 15].

The cotton/polyester mixed fabric shown in Fig. 24 was subjected to a laundering test. Only the cotton fibers picked up the brightening agent from the liquor. The difference between them and the polyester fibers cannot be detected in the secondary electron picture; on the other hand, with the cathodoluminescence technique (Fig. 25), the cotton fibers appear bright, whereas the polyester fibers appear as dark shadows.

It is often very difficult to demonstrate the presence of thin finishing agent films using secondary electrons. It therefore appears better to add brightening agents to the coating

Fig. 25. Cotton-polyester mixed fabric after laundering test with the addition of brightening agents. Picture using cathodoluminescence.

and apply the cathodoluminescence technique. As an example, consider the antifelting treatment of wool with Synthappret LKF®. Only the scales of the yarn should be stuck together to prevent felting (cf. Fig. 6). If the whole yarn is coated by the finishing agent, then the good properties of the wool as regards absorption and loss of water are lost. In Fig. 26 the required irregular distribution of

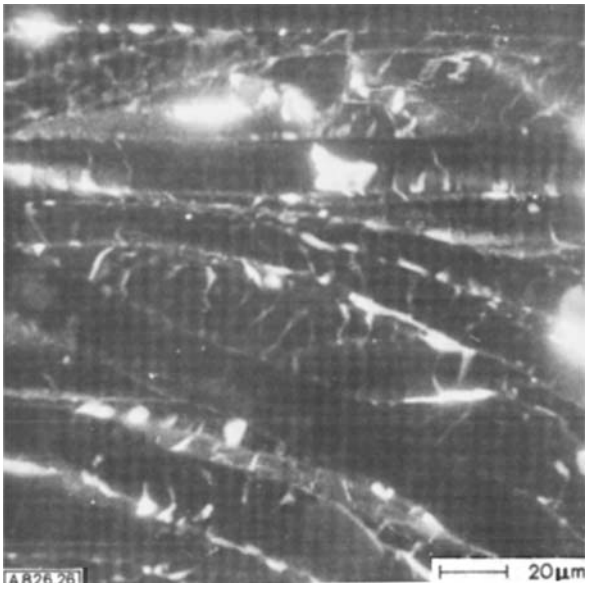

Fig. 26. Wool treated with Synthappret LKF® and brightening agent. Picture using cathodoluminescence.

the finishing and in particular the adhesion of scale edges have been made visible by the addition of a suitable brightening agent. Other examples of applications are the determination of the binder distribution in nonwoven fabrics, and the detection of faults in bleached fabrics. One problem is the destruction of the brightening agent by electron bombardment. Coumarin derivatives are more stable in this respect than stilbene derivatives.

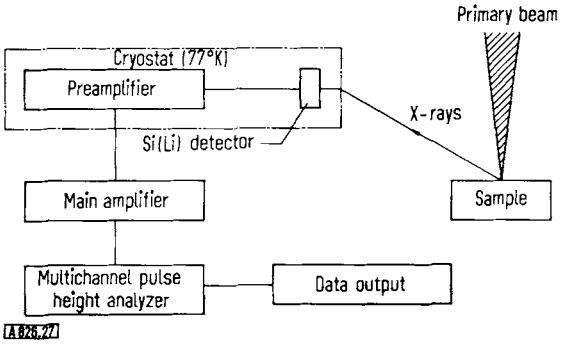

Fig. 27. Energy-dispersive X-ray spectrometer on the scanning electron microscope.

The interactions discussed so far only give material contrast and thus some indications for the analysis, not the elemental composition itself. This is made possible by the detection of the emitted X-rays. If the scanning electron microscope is regarded as an X-ray tube then the object under investigation plays the part of the anode. Since the beam currents in the scanning electron microscope are of the order of 10^{-10} to 10^{-12} A, the X-rays are not intense enough to allow analysis with crystal spectrometers within sufficiently short times. Energy dispersive analysis with the aid of solid-state detectors[16] is therefore better for the scanning electron microscope. Also, since semiconductor detectors cover a larger solid angle, they are preferable in the scanning electron microscopes to crystal spectrometers for geometrical reasons.

The system works on the following principle (Fig. 27): The semiconductor crystal transforms the X-rays into electrical pulses whose height is proportional to the energy of the incident X-ray quanta. These pulses are amplified, sorted, and stored in a multichannel pulse-height analyzer. After a few minutes of counting one obtains the energy spectrum of the characteristic X-rays of the elements in the region struck by the primary beam. The semiconductor industry can today supply lithium-drifted silicon detectors with an energy resolution of better than 200 eV; using these, it is possible to detect elements with atomic numbers $Z>11$ simultaneously and to distinguish between them.

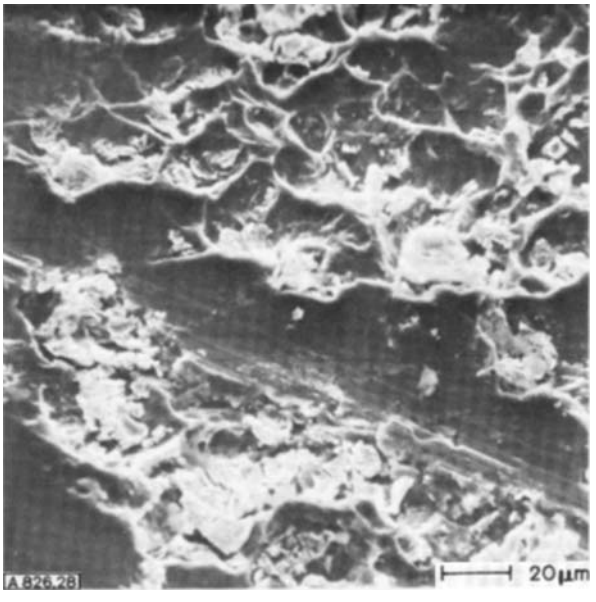

Fig. 28. Surface of a platinized titanium sheet. Picture using secondary electrons.

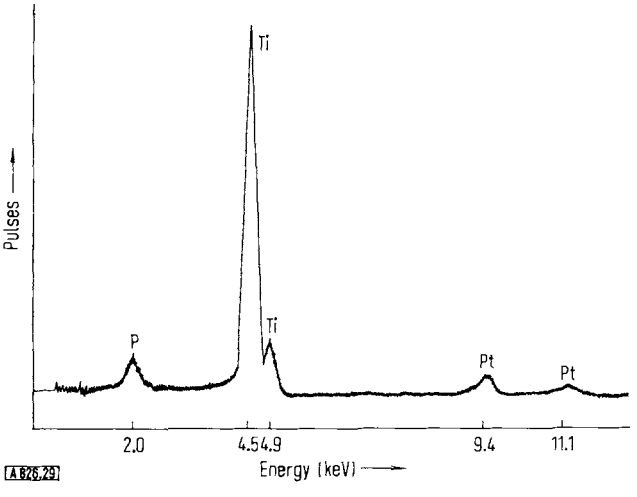

Fig. 29. Integral X-ray spectrum for Fig. 28.

At first sight the results from a scanning electron microscope resemble those of the microprobe (electron beam microanalyzer). Both devices make use of scanning, and both use the same interactions between electrons and solid for the analysis, in particular the emission of X-rays. The difference lies in the point of emphasis. The microprobe is an analytical apparatus; the imaging facilities serve largely for orientation while the analysis is being carried out, and for the representation of inhomogeneous element distributions. Hence, less emphasis is placed on the quality of the

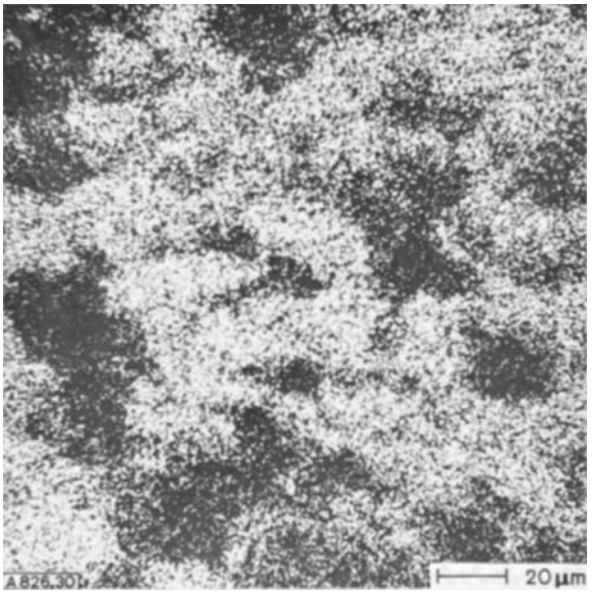

Fig. 30. Titanium distribution for Fig. 28.

imaging (the diameter of the primary beam is a few thousand angstroms) than on the extensive analytical possibilities: detection of light elements is possible as well, with high beam intensities (10^{-6} to 10^{-8} A) and a high spectral resolution in a crystal spectrometer. The scanning electron microscope, on the other hand, is first of all a microscope, and if the advantages of the low beam current and fine

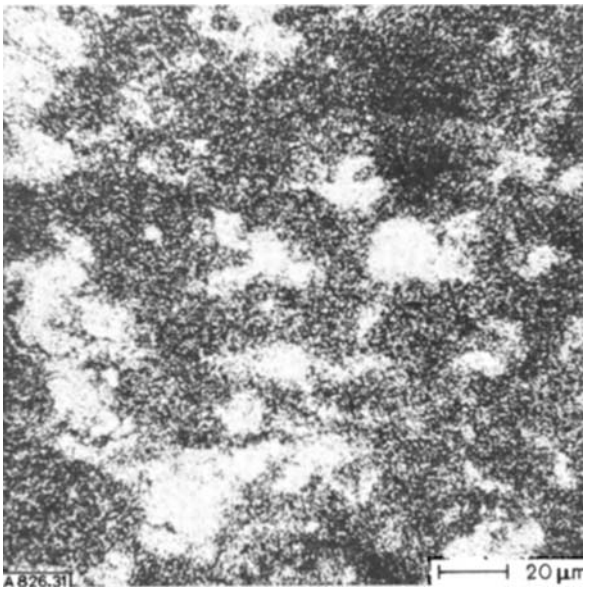

Fig. 31. Platinum distribution for Fig. 28.

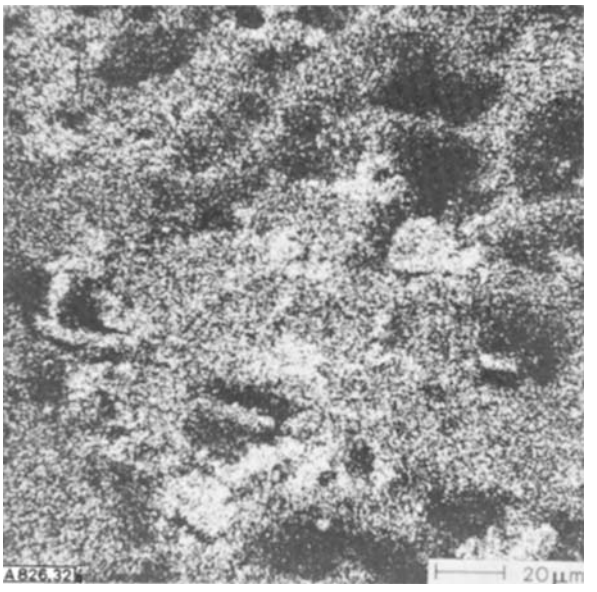

Fig. 32. Phosphorus distribution for Fig. 28.

focusing are to be kept, one is compelled to accept limitations in the analysis.

The information comes from a surface layer up to 20000 Å in thickness, depending on the penetration depth of the electrons. Since X-rays have a larger range in materials than slow electrons, X-rays may also come from deeper layers than those electrons by which the pigments in Fig. 22 were made visible. On the one hand, this can be exploited to analyze layers on or near the surface (with the possibility of varying the primary beam voltage); on the other hand, one cannot without further work conclude anything about the composition of the bulk from one spectrum.

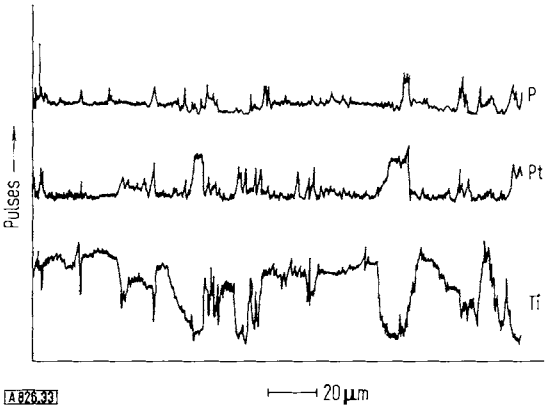

Fig. 33. Line scan for Fig. 28.

The detection limit of the scanning electron microscope for a homogeneously distributed element is about 0.1%; the process cannot therefore be considered as a method of trace analysis. The real advantage of its combination with an X-ray spectrometer lies in the possibility of investigating inhomogeneous distributions of elements at high spatial resolution and of carrying out a microanalysis. The spatial distribution of an element is displayed either in element pictures or in line scans. We start from the integral X-ray spectrum of an object region and choose

the energy interval in which the characteristic radiation of the desired element lies. In the element distribution picture the regions that emit X-rays of the selected energy appear bright. In the line scan the abundance of an element is plotted along a line.

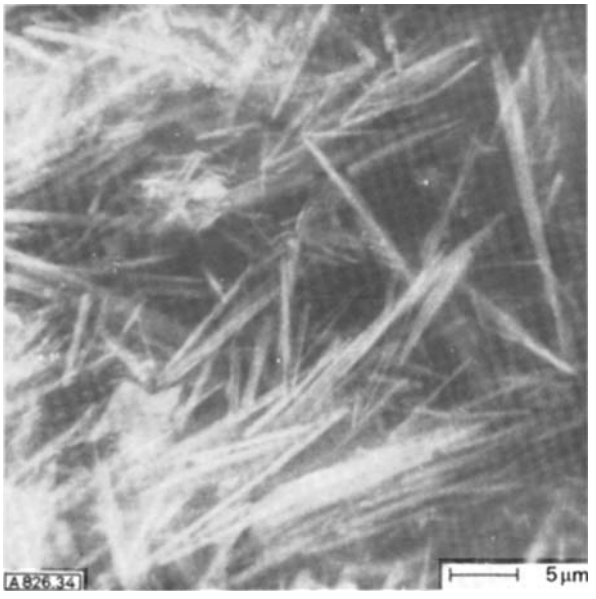

Fig. 34. Section from a spot in faulty PVC sheet.

Fig. 28 shows the surface of a platinized titanium sheet that had been used as a catalyst. From the X-ray spectrum (Fig. 29) one can deduce the presence of titanium, platinum, and phosphorus. The element distribution diagrams (Figs. 30 and 31) are complementary to one another and confirm the expectation that platinum and titanium will appear bright and dark respectively in the secondary electron image. Phosphorus appears above all on the edge of the platinum regions (Fig. 32); this cannot be seen in the secondary electron image (Fig. 28). The same information can be obtained from the line scan in Fig. 33. The material was analyzed along the line indicated by the arrows in Fig. 28.

The scanning electron microscope in combination with an X-ray system is suitable for easy identification of pigments, fillers, or dirt in polymers, alloys, enamels, *etc.* White

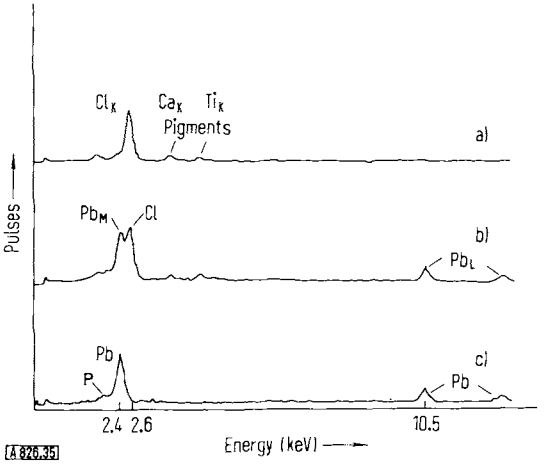

Fig. 35. X-Ray spectrum for Fig. 34.

specks were found in a blue-colored PVC sheet and with higher magnification these were seen to contain needle-shaped crystals (Fig. 34). The X-ray spectrum (Fig. 35) indicates lead and phosphorus. Such a salt of lead was added to the PVC as a stabilizer, but it was poorly dispersed. Precipitates were found in the fracture surface of an austenitic steel (the spherical deposits in Fig. 36) and could easily be analyzed with the aid of the X-ray system (Fig. 37).

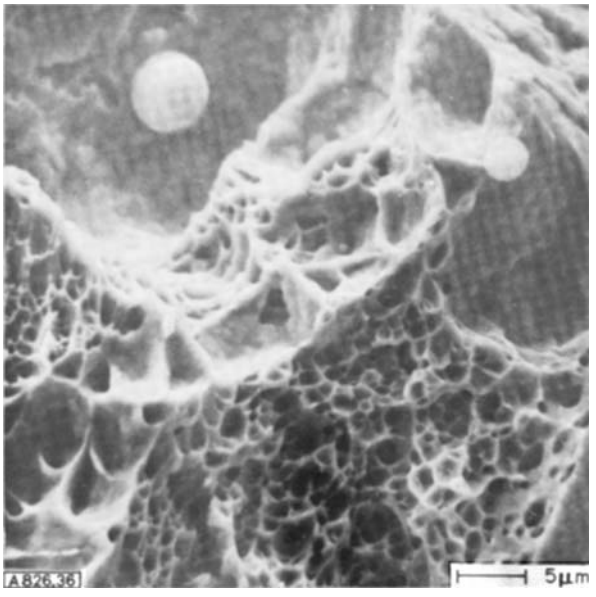

Fig. 36. Fracture surface of an austenitic steel with inclusions.

The investigation of a surface under a scanning electron microscope has certain limitations that cannot be overcome with a combined system for imaging *and* analysis. On the one hand, the spatial resolution of the scanning electron

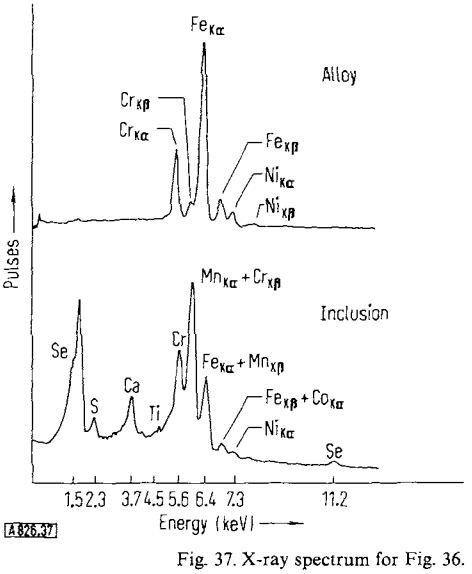

Fig. 37. X-ray spectrum for Fig. 36.

microscope is only 100—200 Å. A higher resolution (down to a few angstroms) can only be achieved by investigating a replica under the transmission electron microscope; this means, however, that the possibilities for material differentiation and analysis are lost. On the other hand, the X-ray detector can only cover elements with an atomic number

$Z > 11$. The detection of lighter elements as well can only be achieved at the expense of the imaging properties (microprobe). Basically, one obtains only an analysis of the elements, and no information on the compounds formed from them. On the other hand, the information from a scanning electron microscope (no matter whether it is a surface image or an element distribution picture) comes from a surface layer which is 1000—20000 Å thick; typical surface effects, which occur in layers less than 100 Å thick, are therefore lost because of intensity problems. Surface analysis methods provide further information, but they are not localized methods.

At the present time there are only two methods of surface analysis that comply with the additional requirements of versatility and easy application: secondary ion mass spectroscopy[17] and photo- and Auger electron spectroscopy[18], which should be regarded as a supplement to scanning electron microscopy.

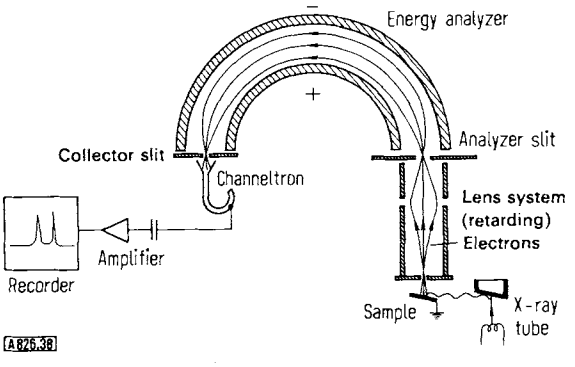

Fig. 38. Block circuit diagram of an electrostatic electron spectrometer ("ES 100", AEI Manchester).

By the term electron spectroscopy we mean here the measurement of the kinetic energy of electrons emitted by a substance on irradiation with UV light, X-rays, or electrons. We shall limit ourselves here to the investigation of solids and excitation with X-rays. *K. Siegbahn* gave the name ESCA (electron spectroscopy for chemical analysis) to this special case. Fig. 38 shows the block diagram of a modern electrostatic electron spectrometer. X-rays (*e.g.* $Al_{K\alpha}$, $Mg_{K\alpha}$) are directed at the specimen; the kinetic energy of the electrons emitted from the surface is then measured with the aid of a spherical condenser; a Channeltron serves as the detector. All solids and substances that can be condensed at -150 °C can be investigated in this way. The measurement requires a vacuum of better than 5×10^{-6} torr.

Electron spectroscopy is based on the photoelectric and the Auger effect (Fig. 39). An X-ray quantum of energy $h\nu$ may have sufficient energy to liberate an electron from the K shell of an atom with ionization energy E_K. The electron thus liberated has then a kinetic energy

$$E_{kin} = h\nu - E_K$$

After this primary process there are two possible relaxation processes for the excited atom. On the one hand, an electron, of, *e.g.*, the L_{III} shell can fill up the hole in the K shell, the energy released in the process being radiated as a $K\alpha_1$ line (X-ray fluorescence). If this energy is greater than the ionization energy of an L electron, the energy can also be transferred within the atom without the occurrence of radiation to a second electron which is emitted (Auger effect). To estimate the kinetic energy of the Auger electron we may proceed as if the X-ray quantum liberated by the transition of an L_I electron into the K shell were to ionize the L_{III} shell. The kinetic energy of the emitted L_{III} electron is then

$$E_{kin} \approx E_K - E_{L_I} - E_{L_{III}}$$

It is important to note that ESCA reproduces directly the electronic level of the atoms involved in the photoelectric or Auger effect. The position of the energy levels can be calculated unambiguously from the recorded spectra.

Whether X-ray fluorescence or the Auger effect is more probable depends on the atomic number of the element. As shown in Fig. 40, for the lighter elements the Auger effect is significantly more probable than X-ray fluorescence. This explains the difficulties in detecting light elements when using the X-ray spectrometer on the scanning electron microscope. Since the photoelectric and the Auger effect occur in all elements, electron spectroscopy is applicable with nearly the same sensitivity to all elements and is not subject to the limitations of say X-ray fluorescence which is only practicable for elements with $Z > 11$.

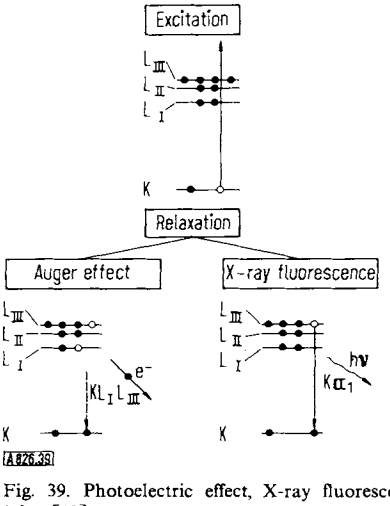

Fig. 39. Photoelectric effect, X-ray fluorescence, and Auger effect (after [18]).

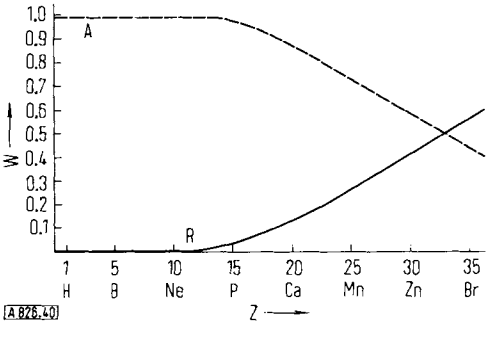

Fig. 40. Probabilities (W) of X-ray fluorescence (R) and Auger effect (A) (only for K and L shells) (after [18]).

Exceptions are hydrogen and helium, which have only one electron shell.

On passing through matter electrons lose energy, these losses being not continuous but quantized (excitation of plasmons of surface and volume type)[19]. This point is demonstrated by the fact that in the electron spectrum a line is always accompanied by a satellite (more or less continuous energy distribution) on the side of lower kinetic energy; the line is separated from this satellite by at least one minimum (cf. Fig. 41). This minimum is of fundamental importance because one can be sure of having in the principal line only those electrons that have not lost any energy, corresponding to the O-phonon transition in the Mössbauer effect. Of course, only those electrons can contribute to this line that come from the uppermost monolayers. Hence electron spectroscopy constitutes a suitable method of investigating surfaces.

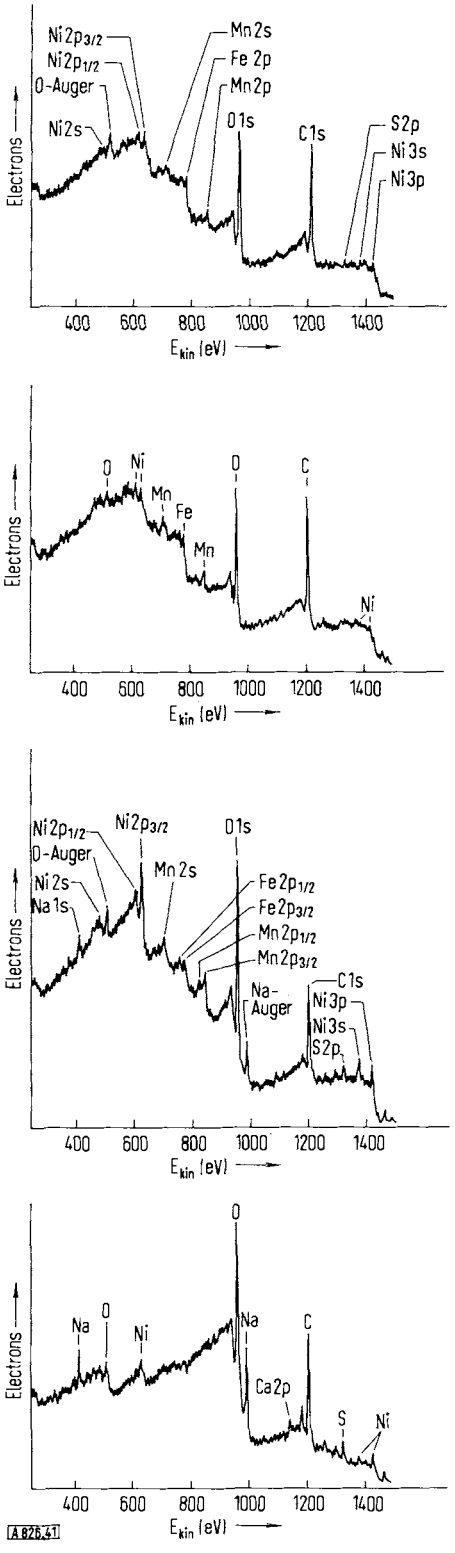

Fig. 41. ESCA, overall spectra of steel surfaces pretreated in various ways.

The width of the lines in the electron spectrum is 1—2 eV. There are contributions from: 1) the natural line width of the level under investigation, and 2) the width of the incident X-ray line. The energy level shifts of an atom under the influence of neighboring atoms (chemical bonds, hydrogen bridges, van der Waals forces, crystal effects, *etc.*) are up to 10 times as large. Detection of such shifts gives the possibility of contributing to the determination of the structure of inorganic and organic molecules. Information is obtained on the electron density in the environment of the nucleus and it is possible to make deductions regarding the oxidation state and valence. In electron spectroscopy the shifts are measured directly, while in X-ray fluorescence, for example, only the difference between the shifts of two terms is susceptible to measurement.

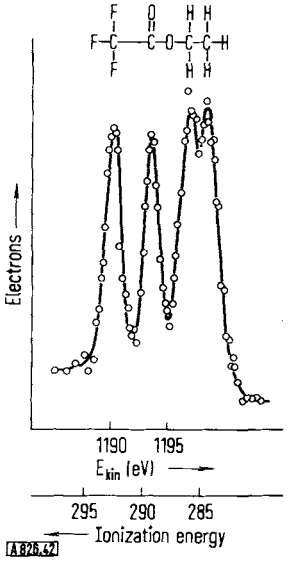

Fig. 42. C1s photoelectron spectrum of ethyl trifluoroacetate (after [18]).

The order of magnitude of chemical shifts is evident from the C 1s photoelectron spectrum of ethyl trifluoroacetate, the example quoted by *K. Siegbahn* (Fig. 42)[18]. If some charge is partly removed from an element participating in a polar bond, then the remaining electrons are more tightly bound to the nucleus. This is made evident in the higher ionization energy and in the electron spectrum by a lower kinetic energy of the photoelectrons. For this reason the C 1s line of carbon in the CF_3 group appears at lower kinetic energies than the C 1s line of carbon in the CH_3 group.

The overall region of observed shifts is, however, too small in comparison with the line width to allow replacement of other spectroscopic methods for structure investigation by ESCA. The ratio of the maximum shift to the halfwidth is of the order of 10; an analogous ratio for *e.g.* nuclear

magnetic resonance is greater than 1000. The disadvantage of the lower selectivity is in general not removed even by the advantage of having a way of studying bond effects in all the partners involved.

The situation is different in surface analysis. In this case every indication going beyond elemental analysis is useful information about surface compounds that cannot be obtained in any other way. It has already been pointed out in connection with Fig. 41 that the information from an ESCA spectrum is derived from the uppermost atomic or molecular layers. The mean escape depth of the photoelectrons is about 20—30 Å[20], for an energy of 1200 eV. Hence electron spectroscopy is to a much greater extent than scanning electron microscopy a method of surface analysis. However, an escape depth of 30 Å means that not only the first monolayer of atoms is analyzed. For routine applications this has the advantage that one does not need ultrahigh vacuum, since although a low absorption of residual gas causes a loss of intensity, it does not otherwise hinder the measurement. The relatively large escape depth of photo- and Auger electrons becomes evident for instance in the fact that in metals stored in air one obtains mostly a doublet for each line. The electrons with the lower kinetic energy come from the oxide (or hydroxide) layer; the electrons with the higher kinetic energy come from the metal lying below it. Fig. 43 shows the $4f_{5/2}$ and $4f_{7/2}$ photoelectron spectra of tungsten sheets oxidized to different extents. If one knows the escape depth for the kinetic energy involved, such a spectrum can reveal the thickness of a passivation layer as well as its composition.

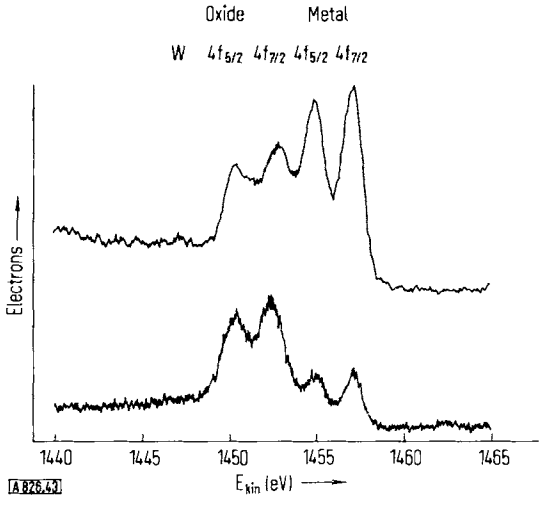

Fig. 43. W4f photoelectron spectra of variously oxidized tungsten sheets.

Further fields of application are found in catalysis, in the analysis of absorption layers, and in the investigation of pretreatments of foils or sheets (cf. Fig. 41; the differences are not evident in the X-ray spectrum, since they involve only very thin surface layers), in corrosion protection, in electroplating, or in the analysis of finishing coatings on fibers. Fig. 44 shows the analysis of a coupling agent of the aminosilane type on glass fibers. For the effect of a coupling agent, see Figs. 17 and 18. From the overall spectrum (Fig. 44 above) one can tell which elements are present. The regions for C 1s and N 1s were recorded again (at a different spectrometer sensitivity) with an expanded abscissa. Comparison measurements yield the energy positions, the line widths, and line shapes of the C 1s levels for carbon atoms in various compounds. It follows in our example from the

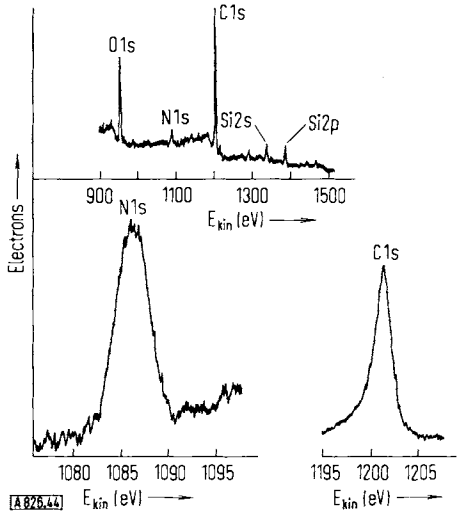

Fig. 44. Electron spectrum of a coupling agent on glass fibers.

asymmetry of the C 1s line (left flank) that not only C—H bonds but also, to a smaller degree (about 20%), C—O bonds (C—OH or ester bonds) are present. As the line shape is well reproducible it is possible to use graphical or

computer deconvolution. The broad N 1s line also indicates that nitrogen does not occur only in one state of binding.

Since the Auger effect can also be excited by electron bombardment, the question arises whether it may be possible to couple the scanning electron microscope and an electron spectrometer. For commercial scanning electron microscopes this is not practicable because of the poor vacuum. The pressure must be lowered to at least 10^{-8} torr, otherwise only contamination layers will be analyzed. This will happen particularly in the case of Auger lines of low kinetic energy since the escape depth is then also reduced. The Auger effect can in fact be observed on operation of a scanning electron microscope at an improved vacuum (ion getter pumps, metal seals) and it has already been utilized in surface analysis of metals[21].

Difficulties arise in the case of insulators due to electrostatic charging. There is the additional danger of destruction of the surface layer by intense electron bombardment, which is greater than the possible damage by X-rays. Measurement of chemical shifts is feasible only with sharp Auger lines. The large line width frequently observed stems from the width of the outer energy level from which the Auger electron is usually liberated. Thus a combination of electron microscope and electron spectrometer is possible in principle; in practice, however, such a system will be used only for those problems which require surface analysis with high spatial resolution and which cannot be solved by X-ray fluorescence methods.

Reactions of Atoms

By Heinz Georg Wagner and Jürgen Wolfrum[*]

Several methods for the quantitative investigation of reactions of free atoms in the gas phase have been developed in recent years. The present article deals with reactions of hydrogen, carbon, oxygen, and halogen atoms with simple molecules. The results of such investigations are of fundamental importance for the understanding of chemical reactions and for many technical applications, such as explosion and combustion processes, halogenations, and chemical lasers.

1. Introduction

Reactions of atoms are among the simplest of chemical processes. They offer favorable conditions for a quantitative theoretical treatment and demonstrate many properties typical of neutral particle reactions. These properties include not only the rate constants and the apparent (Arrhenius) activation energies, but also information about the activated complex, the "rearrangement" of the reactants during the reaction process, and the probabilities of various reaction pathways, *i.e.* the formation of various reaction products, the distribution of the reaction energy over the products, *etc.* In addition, the influence of electronic excitation and high kinetic energy of the reactants can also be readily investigated for atoms.

From the practical side the use of fast reactions of free atoms and radicals for the production of energy from combustion processes is one of the oldest of all chemical techniques. It has recently become increasingly clear that the rapid expansion of the use of combustion processes has reached a point such that the natural atmosphere is already being considerably affected. A thorough knowledge of the elementary steps taking place in explosion and combustion processes (see *e.g.* Sections 2 and 4) is therefore not only necessary in order to extract the maximum energy from the reaction process, but is also essential to the success of efforts to suppress the formation of undesirable products such as CO, NO, O_3, and the incomplete combustion of the hydrocarbons used. The reactions of free atoms also play an important part in many photochemically or radiation-initiated processes such as occur in the atmosphere or in industrial applications (*e.g.* reactions of halogen and hydrogen atoms with hydrocarbons; see Sections 2.4 and 5.3). The intensive study of atomic reactions recently led to the discovery of the chemical laser. The chemical laser, which is still in the early stages of its development, shows promise of interesting applications *e.g.* in the production of plasmas, for the probable initiation of controlled nuclear fusion, and for the solution of numerous technical problems. Some atomic reactions that are important to chemical lasers will be described (see Sections 2.2 and 5.1).

It has been known for a long time that even careful analysis of the stable starting materials and end products of a chemical reaction usually gives only limited information concerning the individual reaction steps. Efforts must therefore be made to isolate these elementary steps from the overall reaction. At temperatures of a few thousand degrees Kelvin, at which the atoms in question exist in appreciable concentrations in thermal equilibrium with

[*] Prof. Dr. H. Gg. Wagner and Dr. J. Wolfrum
Institut für Physikalische Chemie der Universität
34 Göttingen, Bürgerstrasse 50 (Germany)

stable molecules, only a few collisions are usually necessary for further reaction of the atoms (reaction times at atmospheric pressure 10^{-8}—10^{-7} s). At lower temperatures (200—1000 °K) and reduced pressure (a few torr), however, the reaction times become easily measurable (10^{-3} to 10^{-1} s). Methods of producing atoms under such conditions have been known for a long time, *e.g.* in the form of electric discharge or photolysis. It is only during the last few years, however, that reliable quantitative results have become obtainable in this way through greatly improved analytical techniques for the accurate determination of atoms and radicals. These include various spectroscopic methods, such as electron spin resonance and mass spectroscopy, as well as the sensitive detection of chemiluminescence or resonance fluorescence in the presence of atoms. Detection of individual atoms was achieved for the first time on the basis of surface ionization (Langmuir-Taylor detector) for alkali metal atoms, whose reactions with halogen compounds could be investigated in great detail in crossed molecular beams. This method probably provides the most detailed information on the microscopic course of a chemical reaction of neutral particles. Some typical findings for reactions of alkali metal atoms have recently been described[1]; a detailed description may be found *e.g.* in [2–4].

Molecular beam scattering experiments with other types of atoms have now also been reported[5], but few results are available as yet for the atomic reactions in the H-C-N-O system which are of great practical importance. Molecular beam studies will therefore not be discussed further in this progress report, which will deal instead with recent results for reactions of hydrogen, carbon, oxygen, and halogen atoms[*] with simple molecules, including the investigation methods used. The selection of the examples is naturally rather limited and arbitrary; however, very comprehensive collections of the known rate constants of elementary reactions have already been published[6–9].

2. Hydrogen Atoms

2.1. Reaction with H_2

The exchange reaction of hydrogen atoms with hydrogen molecules is the classic textbook example of an atomic reaction, and indeed this reaction fulfills better than any other the prerequisites for a complete theoretical treatment of a elementary chemical process. The first experimental and theoretical studies with this aim were carried out more than 40 years ago, but for a long time the cause of the discrepancy found was uncertain. It is only recently that advances have been made in both fields which allow a meaningful quantitative comparison of the results.

Figure 1 shows an Arrhenius plot of recent results[10–18] from experiments (points) and calculations (continuous lines) for the rate constant of the reaction

$$D + H_2 \longrightarrow HD + H;\ \Delta H_0^\circ = -0.8\ \text{kcal mole}^{-1} \qquad (1)$$

[*] Reactions of N atoms and excited N_2 molecules have been described by *G. R. Brown* and *C. A. Winkler*: Angew. Chem. *82*, 187 (1970); Angew. Chem. internat. Edit. *9*, 181 (1970).

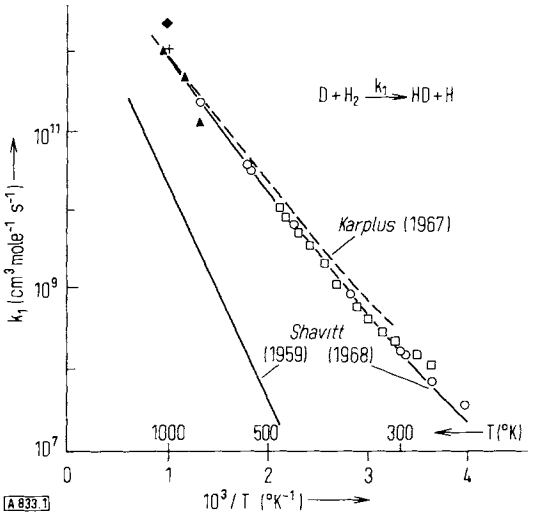

Fig. 1. Calculated (curves) and measured (points) rate constants for the reaction $D + H_2$.
□ [10], ○ [11], + [12], ◆ [13], ▲ [14]; —— [16, 17], - - - [18].

It is clear that the direct observation of the reaction (empty circles and squares) covers a much wider temperature range and gives more accurate values for the rate constant than earlier measurements (shaded points), in which only the overall reaction

$$H_2 + D_2 \longrightarrow 2HD$$

could be investigated.

Figure 2 shows an apparatus for direct measurement of the rate constants of reaction (1) and of other atom-molecule reactions. It consists of a flow system connected to an electron spin resonance (ESR) spectrometer and a mass spectrometer[19].

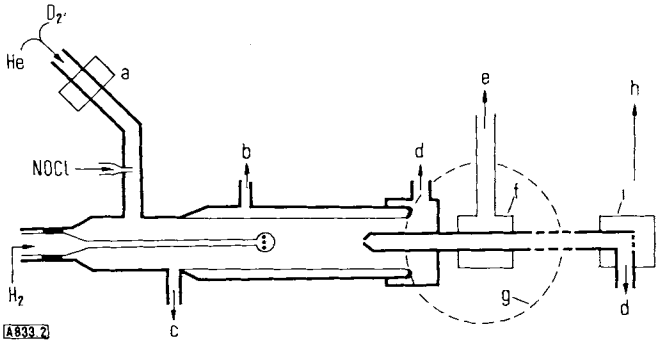

Fig. 2. Flow system for the direct investigation of atom-molecule reactions [19].
The quartz flow reactor can be heated to temperatures between 200 and 1100 °K by means of a thermostat (b) or a furnace. The gases to be dissociated (in this case D_2) pass through a side arm in a carrier gas (helium or argon), into an electrodeless microwave discharge (a: power 50—200 W). Stable reactants (in this case H_2) are mixed with the atoms through a mobile inlet at various points in the flow reactor (mixing time 10^{-3} s). The total pressure (c: manometer, d: pump) is usually between 2 and 10 torr, the reaction times are $\approx 10^{-2}$ s, and the lifetimes of the atoms for recombination on the wall, with suitable treatment of the vessel walls (*e.g.* rinsing with 5% HF solution), is 1—0.1 s. Because of the low concentration of atoms (partial pressure of the atoms 10^{-2} to 10^{-3} torr), no appreciable recombination of the atoms with one another takes place during the reaction time. Gas samples are taken from the flow reactor by means of a quartz probe, and are allowed to expand to 0.1 torr and are then rapidly pumped through the resonator (f) of the ESR spectrometer (e) (g: magnetic pole). Atoms can be quantitatively detected here even at a partial pressure of 10^{-5} torr. Stable components (after recombination of the atoms on the wall) can then be analyzed *e.g.* by means of a mass spectrometer (h) or a gas chromatograph (i: ion source).

Whereas only nonspecific methods for the detection of atoms (measurement of the heat of recombination of the atoms on metal surfaces, Wrede-Harteck gauge) were available during the classic experiments of *Wood* and *Bonhoeffer*, a precise, specific detection of the atoms is now possible by ESR spectroscopy (the atoms absorb on the basis of differences in line splitting at various magnetic field strengths). Atomic H-D exchange processes such as reaction (1) can readily be observed by this method.

Not only experimental measurements but many purely theoretical calculations of rate constants have also been attempted. The basis of such calculations is a precise knowledge of the forces acting between the reactants during the reaction. These forces can be represented by one or (if a change in the electronic state occurs during the reaction) by several "potential energy surfaces", which give the potential energy of a molecule[*] as a function of the positions of all the atoms for a given electronic state. For a diatomic molecule, they correspond to the well-known potential-energy curves with only one internuclear distance parameter, while for a triatomic molecule already three

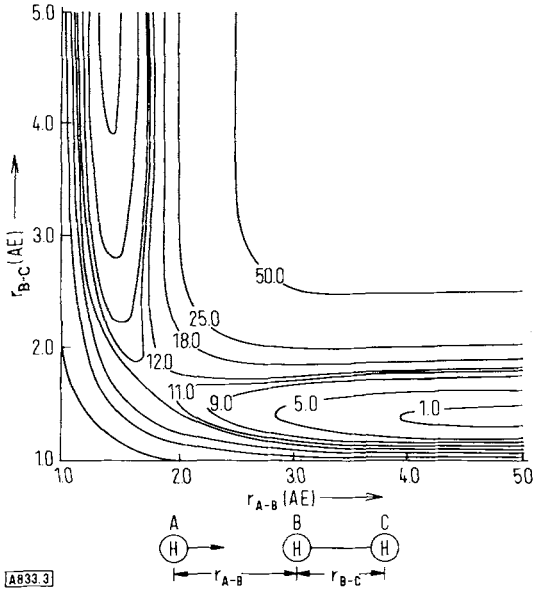

Fig. 3. Quantum-mechanically calculated potential-energy surface for the reaction $H+H_2$ [20]. Contour lines in kcal mole^{-1}, internuclear distances in atomic units (1 AU = 0.52 Å).

distances have to be considered. The situation is simplified if in the reaction between an atom and a molecule, one considers only the case in which the reacting atom (A) collides at a constant angle with the molecule (BC). The potential energy of the "molecule" ABC then depends only on two distances (r_{A-B}, r_{B-C}), and can be represented as an energy "contour map". Figure 3 shows such a map for the reaction[**] $H+H_2$[20]. It was calculated quantum-mechanically without the aid of experimental information and taking into account the interaction of a total of 15 orbitals (1 s, 1 s', 2 p_x, 2 p_y, 2 p_z for each H atom). In contrast with earlier calculations, there is no indication of a stable H_3 complex, *i.e.* a potential well at the saddle point.

[*] In the case of a reaction, all the particles are considered together as a sort of "supermolecule".

[**] For the reaction $H+H_2$, the energy barrier is lowest for the collinear approach.

The rate constant of reaction (1) can now be obtained in two quite different ways using the potential-energy surface. One method is to apply transition state theory[21], for which the properties of the activated complex and the height of the potential-energy barrier E_c[*] are derived from the potential-energy surface. Only a small part of the entire surface, that surrounding the saddle point, is needed for this calculation[**].

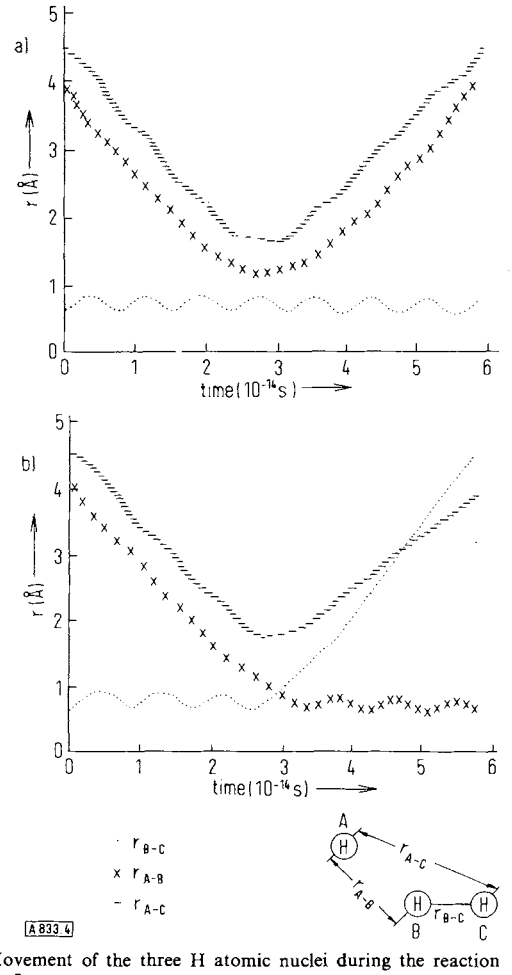

Fig. 4. Movement of the three H atomic nuclei during the reaction $H+H_2$ [23].

Figure 1 contains the results obtained in this way by *Shavitt* for the reaction (1). An energy surface calculated quantum-mechanically by *Boys* and *Shavitt*[15], which takes into account only the interaction of a total of 6 orbitals (1 s, 1 s' for each H atom), was used initially for this purpose; the potential-energy barrier obtained was too high ($E_c = 15.4$ kcal/mole), with the result that the agreement with the experimental data was unsatisfactory[16]. Much better agreement is obtained[17] by the use of the surface shown in Figure 3, where a total of 15 orbitals were taken into account in the calculation.

An entirely different method was used by *Karplus et al.*[23]. Instead of considering the H_3-complex, these authors

[*] A discussion of the relationships between the potential-energy barrier (E_c), the threshold energy (E_0), and the experimental Arrhenius activation energy (E_{exp}) may be found in [22].

[**] Within the Born-Oppenheimer approximation the shape of the potential-energy surface does not change when one considers the reaction $D+H_2$ instead of $H+H_2$. However, the difference in the zero-point energies of the H_3 and DH_2 complexes must be taken into account.

followed the movement of three H atoms on the potential-energy surface by stepwise integration of the classical equations of motion. Two examples are shown in Figure 4. The distances between the three atoms involved are plotted as a function of time. In one case (Fig. 4a), no reaction takes place on collision of the H atom (A) with the H_2 molecule (BC); the H_2 molecule exhibits an undisturbed zero-point vibration. The second diagram (4b) shows that a reaction has taken place; the molecule AB has been formed, and the atom C is moving away from AB. Calculations of this type have been carried out for various starting conditions (relative velocities, orientations of the collision partners, and rotational states of H_2). Suitable averaging over a Maxwell-Boltzmann distribution of the starting conditions of the reactants gives the picture shown in Figure 1 for the macroscopic rate constant k_1 as a function of temperature.

The agreement with the experimental data is good at higher temperatures. This substantially classical treatment can no longer be applied at lower temperatures ($T < 300\,°K$), since quantum mechanical tunneling must then be taken into consideration[24, 25].

2.2. Reactions with Halogens

The reactions of hydrogen atoms with Cl_2 and Br_2 play an important part as chain steps in the chlorine- and bromine-hydrogen reaction. The rate constants of these reactions have been known for a long time. *Tal'roze et al.*[26] were recently also able to study the reaction of H atoms with F_2 directly. The rate constants of the four reactions

$$H + F_2 \longrightarrow HF^* + F;\quad \Delta H_0^0 = -98\,(101)\ \text{kcal mole}^{-1}\ [27, 28] \quad (2)$$

$$H + Cl_2 \longrightarrow HCl^* + Cl;\quad \Delta H_0^0 = -45\ \text{kcal mole}^{-1} \quad (3)$$

$$H + Br_2 \longrightarrow HBr^* + Br;\quad \Delta H_0^0 = -30\ \text{kcal mole}^{-1} \quad (4)$$

$$H + I_2 \longrightarrow HI + I;\quad \Delta H_0^0 = -19\ \text{kcal mole}^{-1} \quad (5)$$

are shown in Figure 5[*]. The reactions are all very fast, but it should be noted that reaction (2), which is the most strongly exothermic, proceeds much more slowly than the reactions (3), (4), and (5)[**].

These reactions have recently attracted renewed attention. It was found that the hydrogen halide molecules formed exhibit strong vibrational and rotational excitation, which is manifested in chemiluminescence in the infrared region. By observation of this emission, *Polanyi et al.*[36] found *e.g.* for reaction (3) that approximately 45% of the available reaction energy is converted into vibrational energy of the resulting HCl* (with 1 to 6 vibrational quanta). The distribution of the rotational energy also exhibits pronounced deviations from the equilibrium population (maximum at $J = 12$).

This experimentally determined distribution of the reaction energy over the reaction products provides an insight into the shape of the potential-energy surface that determines the reaction, and also pointed to an interesting possibility of converting chemical energy into radiation energy in a chemical laser.

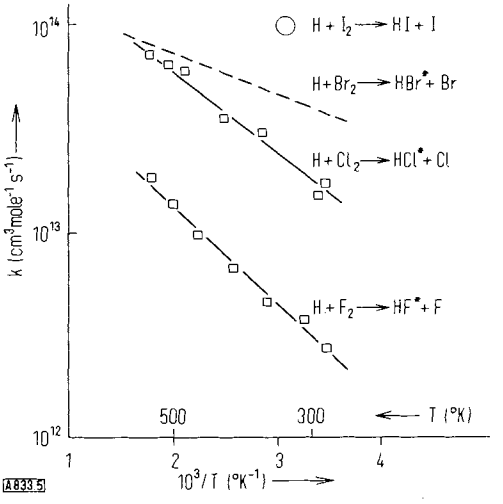

Fig. 5. Rate constants for the reactions of hydrogen atoms with halogen molecules.
□ [26], ○ [31, 32]; --- [29, 30].

The relationship between the shape of the potential-energy surface and the vibrational excitation of the reaction products will be described with the aid of Figure 6.

Two different potential-energy surfaces are shown for the reaction between an atom (A) and a molecule (BC). The linear arrangement of A and BC is again chosen for the sake of simplicity. The approach of A to BC, *i.e.* the decrease in the distance r_{A-B}, corresponds in the contour diagram to the movement of a point along the indicated line ("reaction coordinate") in a valley from right to left. In the first case (Fig. 6a), the point moves uphill, and with increasing height, the path of least potential energy leads increasingly in the y direction, *i.e.* a decrease in r_{A-B} is associated with an increase in the distance r_{B-C} between the atoms in the molecule BC. If the kinetic energy of the collision partners is sufficient, the pass is finally crossed. The point then moves rapidly downward into a valley, which, in an exothermic reaction, is lower than the starting valley by an amount that corresponds to the heat of reaction. The distance between the new molecule AB and the atom C increases without causing any change in the distance r_{A-B}, *i.e.* without stimulating vibration of the product molecule AB. The heat of reaction is liberated in this case only at a very late stage, *i.e.* near the end of the reaction path.

A different picture is obtained if the reaction proceeds on a potential-energy surface of the form shown in Figure 6b. The approach of A corresponds to the movement of a point from right to left in a shallow valley, *i.e.* only a small energy barrier, if any, has to be overcome in the reaction. The valley then suddenly falls away steeply, so that the

[*] The reaction enthalpies, unless otherwise indicated, were calculated from JANAF thermochemical tables (Dow Chemical Company, Midland, Mich. 1965; first addendum 1966).

[**] The example shows that the type of reaction must be taken carefully into account in the application of the empirical rule of *Polanyi et al.* [33, 34], which states that the activation energy in a homologous series of exothermic elementary steps of the type $A + BC \rightarrow AB + C$ decreases for the most strongly exothermic reactions. The rule fails if two atoms or characteristic groups are varied within the homologous series. This is so in reactions (2)—(5) (simultaneous variation of B and C) [35].

point moves rapidly downward, and very small distances r_{A-B} are reached, *i.e.* the atom A is "drawn" by B and can therefore move closer to B than the equilibrium distance in the product molecule AB. The further movement shows that in this case the increase in the distance between the new molecule AB and the atom C is associated with a simultaneous periodic change in the distance r_{A-B}, *i.e.* with stimulation of vibration of the product molecule AB.

These examples illustrate two extreme cases, between which the potential-energy surfaces constructed quantum-mechanically (*"ab initio"*) or by semiempirical methods may be modified for a given reaction until agreement is reached between the experimental and calculated distributions of the energies in the reaction products. For calculations on reaction (3), see [37–39].

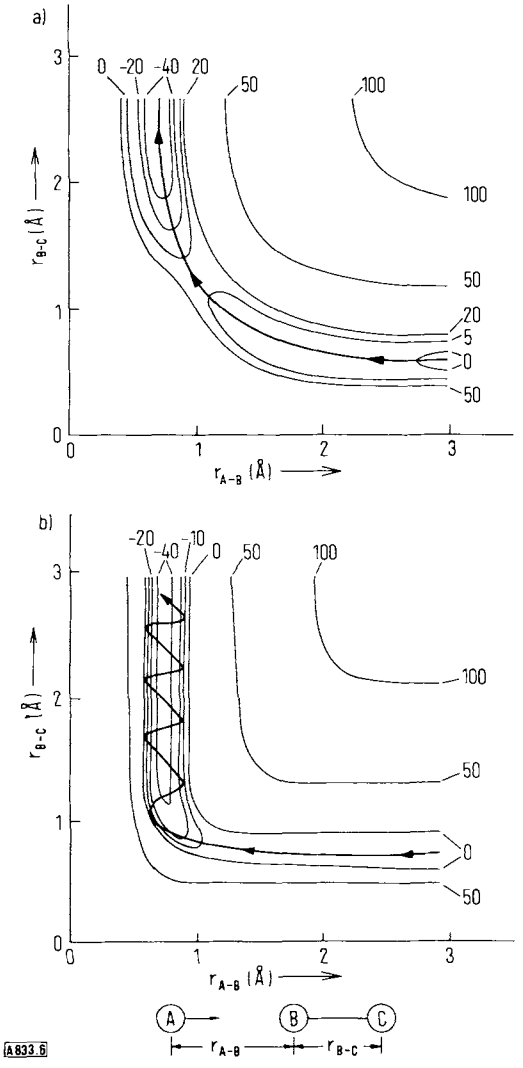

Fig. 6. Relation between the shape of the potential surface and the vibrational excitation of the product molecule for an exothermic reaction A + BC → AB + C. Energy contours in kcal mole^{-1}.

Reaction (3) was also used by *Pimentel et al.*[40,41] for the operation of the first chemical laser. The reaction of chlorine and hydrogen was initiated in this case in a quartz tube by flash photolysis (see Fig. 7).

$$\begin{aligned} Cl_2 + h\nu &\longrightarrow 2Cl \\ Cl + H_2 &\longrightarrow HCl + H \quad \text{(see Section 5)} \\ H + Cl_2 &\longrightarrow HCl^* + Cl \end{aligned} \qquad (3)$$

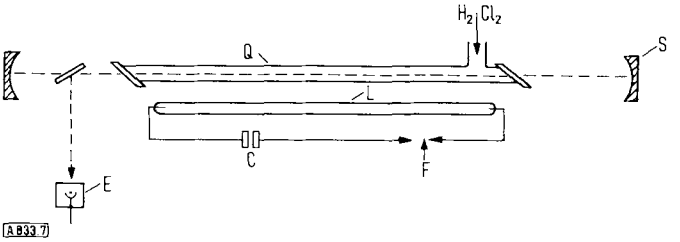

Fig. 7. Scheme of the HCl laser arrangement after *Pimentel et al.* [40]. Q: quartz tube ($d = 14$ mm, $l = 600$ mm) with NaCl windows fitted at the Brewster angle, L: xenon flash lamp, C: condenser ($E = 2000$ Ws), F: spark gap, S: concave mirror, E: InSb photocell.

Oblique NaCl windows fitted at the ends of the reaction tube allowed the IR emission of the HCl* molecule to emerge without loss. This emission was reflected back into the reaction tube by two laser mirrors; and beyond a certain intensity, it causes a concerted emission by the HCl* molecules formed in reaction (3).

2.3. Reaction with O_2 and NO

There are two possibilities for the reaction of hydrogen atoms with O_2. At low temperatures ($T < 500$ °K), addition of the H atom predominates in the presence of a third collision partner (M).

$$H(^2S) + O_2(^3\Sigma) \xrightarrow{+M} HO_2(^2A'); \quad \Delta H_0^0 = -47 \text{ kcal mole}^{-1} \qquad (6)$$
$$k_6 = 8 \times 10^{15} \text{ (M = Ar) cm}^6 \text{ mole}^{-2} \text{ s}^{-1} \text{ at } 298 \text{ °K [42, 43]}$$

In the hydrogen/oxygen explosion at the second explosion limit this reaction path competes with what is probably the most important reaction for combustion processes, *i.e.* the production of O atoms and OH radicals by

$$H(^2S) + O_2(^3\Sigma) \longrightarrow OH(^2\Pi) + O(^3P); \quad \Delta H_0^0 = 16.7 \text{ kcal mole}^{-1} \qquad (7)$$
$$k_7 = 2 \times 10^{14} \exp(-16.8/RT) \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1} \text{ [*] [45, 46]}$$

Whereas reaction (7) proceeds very slowly at room temperature ($k_7 < 10^3$ cm^3 mole^{-1} s^{-1}) for H atoms in the ground state (^{2}S), H atoms in the first excited state (^{2}P) react very rapidly with O_2 to form electronically excited OH radicals[44].

$$\begin{aligned} H(^2P) + O_2(^3\Sigma) &\longrightarrow OH(^2\Sigma) + O(^3P) \\ OH(^2\Sigma) &\longrightarrow OH(^2\Pi) + h\nu \quad (\lambda \approx 3064 \text{ Å}) \end{aligned}$$

NO behaves in the same manner as O_2:

$$H(^2S) + NO(^2\Pi) \xrightarrow{+M} HNO^{\blacktriangle}(^1A''); \quad \Delta H_0^0 = -49 \text{ kcal mole}^{-1} \qquad (8)$$
$$k_8 = 8.7 \times 10^{15} \text{ (M = Ar) cm}^6 \text{ mole}^{-2} \text{ s}^{-1} \text{ at } 293 \text{ °K [47]}$$
(HNO$^{\blacktriangle}$ denotes an electronically excited HNO radical)

The initially formed HNO radical can rapidly react further with H atoms,

$$H + HNO \longrightarrow H_2 + NO; \quad \Delta H_0^0 = -55 \text{ kcal mole}^{-1} \qquad (9)$$
$$k_9 = 10^{11} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1} \text{ at } 298 \text{ °K [48]}$$

[*] The apparent activation energy (E_{exp}) is given here and in the following discussion in kcal mole^{-1}.

so that homogeneous recombination of the H atoms to form H_2 occurs. This property is also shown by nitric oxide in reactions with other atoms (O, halogens, *etc.*) and explains the important part played by NO as a free-radical scavenger in classical kinetics.

NO has recently also been used for the inexpensive quantitative detection of some types of atoms. In the case of H atoms this is achieved as follows: The electronically excited HNO molecule ($HNO^{\blacktriangle}$) formed in reaction (8) can reach the ground state by emission of light.

$$HNO^{\blacktriangle}(^1A'') \longrightarrow HNO(^1A') + h\nu \quad (\lambda \approx 7000\ \text{Å})$$

The intensity of the luminescence ($I_{HNO^{\blacktriangle}}$) is proportional to [H] and [NO], and can be determined quantitatively with a photomultiplier fitted with a suitable filter[49]. At a constant NO concentration, the luminescence can thus serve as a measure of the relative concentration of H atoms.

To determine the absolute concentration of H atoms, the HNO emission is used as an "indicator" for a "titration" of the H atoms in the gas phase. The H atoms are allowed to react *e.g.* with NOCl:

$$H + ClNO \longrightarrow HCl + NO;\ \Delta H_0^0 = -64\ \text{kcal mole}^{-1} \qquad (10)$$
$$k_{10} \geq 2 \times 10^{12}\ \text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}\ \text{at}\ 298\,^\circ\text{K}\ [49]$$

This reaction results in the disappearance of H and the production of NO, which leads to HNO emission in accordance with the above scheme in the presence of H. When the quantity of NOCl added corresponds exactly to the original H concentration, the luminescence completely disappears, since all the H atoms have been consumed. The "end point" can therefore be accurately determined with a photomultiplier. As in a normal titration, one must naturally ensure that no interfering reactions occur.

Other titration and indicator reactions are listed in Table 1.

Table 1. Quantitative detection of atoms by titration in the gas phase.

Atom	Indicator reaction	Emission	Titration reaction	Ref.
H	$H+NO \rightarrow HNO^{\blacktriangle}$	$I_{HNO^*} \sim [H]\cdot[NO]$	$H+ClNO \rightarrow HCl+NO$	[49]
N	$N+N \rightarrow N_2^{\blacktriangle}$	$I_{N_2^*} \sim [N]^2$	$N+NO \rightarrow N_2+O$	[50]
O	$O+NO \rightarrow NO_2^{\blacktriangle}$	$I_{NO_2^*} \sim [O]\cdot[NO]$	$O+NO_2 \rightarrow NO+O_2$	[51]
Cl	$Cl+Cl \rightarrow Cl_2^{\blacktriangle}$	$I_{Cl_2^*} \sim [Cl]^2$	$Cl+ClNO \rightarrow Cl_2+NO$	[52]

2.4. Reactions with Hydrocarbons

Reactions of hydrogen atoms with hydrocarbons are important in the oxidation, pyrolysis, radiolysis, and photolysis of the latter. In the reaction of H atoms with hydrocarbons, the number of products and possible further reactions usually increases very markedly after only a few steps, so that a reliable determination of the primary steps was impossible for a long time. Recent results will be given here for some typical examples which allow an understanding of the reactions of H atoms with hydrocarbons making use of the known bond energies.

In the reaction of H atoms with paraffins, the first reaction step yields H_2 and the corresponding alkyl radical[*].

$$H + RH \longrightarrow H_2 + R^{\bullet}$$

Unsaturated hydrocarbons, as expected, exhibit a different reaction behavior. The first step in this case is addition of the H atom, which usually involves a much lower activation barrier than for the formation of H_2 in the first step (see Fig. 8).

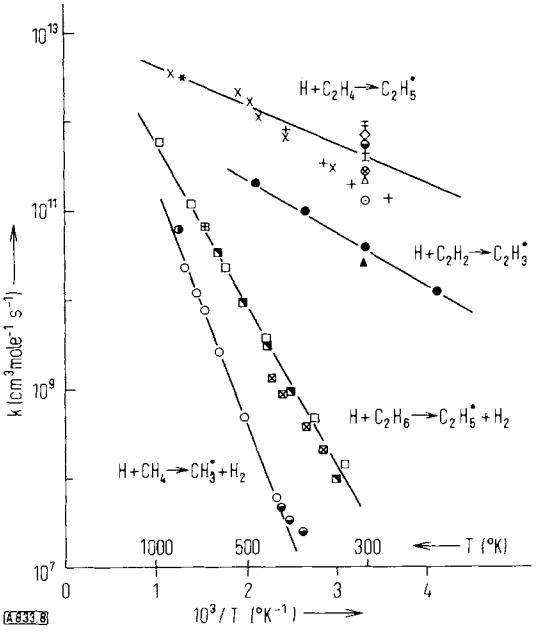

Fig. 8. Arrhenius diagram of experimental rate constants for the reactions of hydrogen atoms with simple hydrocarbons.
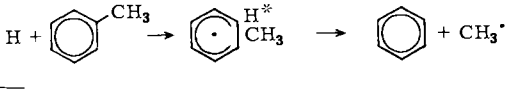
○ [66], ◑ [68], ◒ [67]; ⊠ [71], □ [69], ◪ [70], ⊞ [72]; ● [64], ▲ [65]; * [55], × [56], + [54], ⊙ [57], △ [58], ⊗ [60], ◊ [61–63], ⊕ [59].



The addition of the H atom results initially in the formation of a highly vibrationally excited radical.

$$H + C_2H_2 \rightleftharpoons C_2H_3^{\bullet *} \qquad (11)$$
$$H + C_2H_4 \rightleftharpoons C_2H_5^{\bullet *} \qquad (12)$$
$$H + C_6H_6 \rightleftharpoons C_6H_7^{\bullet *} \qquad (13)$$

There are several possibilities for the further reaction of such radicals:

1. They may decompose back into the starting materials, as indicated in the above scheme.

2. Substitution may occur; for example, the reaction of H with toluene at 390 °K proceeds as follows

[*] Exchange reactions can also be detected with isotopes (*e.g.* tritium atoms with high kinetic energy) [53].

3. They may be deactivated by collisions to below the dissociation limit, and then react further.

Which of these possibilities predominates and determines the further course of the reaction depends on the external conditions (pressure, concentration of the reactants).

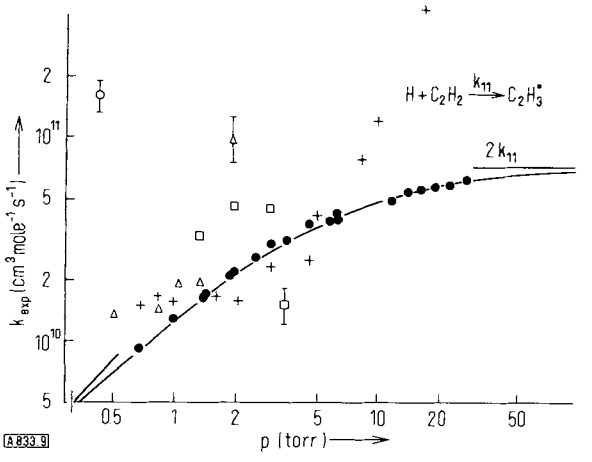


Fig. 9. Dependence of the experimental rate constants (k_{exp}) for the reaction $H + C_2H_2$ on the pressure ($T = 298\,°K$).
+ [77], △ [73], □ [65], ⊽ [78], ⊽ [79], ⊽ [76], ● [64].

The pressure dependence of the rate constant for the homogeneous reaction of acetylene with H atoms is as shown in Fig. 9. Under the conditions indicated, no C_2H_2 is consumed, and the H atoms appear as H_2. Their concentration decreases in accordance with

$$\frac{d[H]}{dt} = -k_{exp}[C_2H_2][H]$$

with the aid of isotopic studies, the following mechanism could be established:

$$H + C_2H_2 \rightleftharpoons C_2H_3^{\bullet *} \quad (11a)$$
$$k_{11} = 3.5 \times 10^{10}\,cm^3\,mole^{-1}\,s^{-1} \text{ at } 298\,°K$$
$$C_2H_3^{\bullet *} + M \longrightarrow C_2H_3^\bullet + M \quad (11b)$$
$$C_2H_3^\bullet + H \longrightarrow (C_2H_4)^* \longrightarrow C_2H_2 + H_2 \quad (11c)$$

At pressures above 50 torr (see Fig. 9), most of the vibrationally excited vinyl radicals (excitation energy $E^* \approx 39$ kcal mole^{-1}) are deactivated to below the dissociation limit, and react further with H[*], so that the reaction course is determined only by the first step (k_{11}). If the reaction is allowed to take place with D atoms instead of H atoms, the main reaction at $p < 1$ torr is substitution (case 2):

$$D + C_2H_2 \longrightarrow C_2H_2D^{\bullet *} \longrightarrow C_2HD + H; \quad (11a')$$
$$\Delta H_0^\circ = -1.6\,kcal\,mole^{-1}$$
$$k_{11} = 10^{13}\exp(-3.60/RT)\,cm^3\,mole^{-1}\,s^{-1}\,[74]$$

The lifetime of $C_2H_2D^{\bullet *}$ for the exothermic removal of a H atom (difference between the C—H and C—D zero-point energies) is much shorter than for the regeneration of D.

[*] The vibrationally excited ethylene $(C_2H_4)^*$ in reaction (11c), on the other hand, decomposes further almost immediately; much higher pressures are required to stabilize this species.

In the reaction of H atoms with an alkene (ethylene in this case), the first two steps are as in the case of acetylene[60]

$$H + C_2H_4 \rightleftharpoons C_2H_5^{\bullet *} \quad (12)$$
$$k_{12} = 8 \times 10^{11}\,cm^3\,mole^{-1}\,s^{-1} \text{ at } 298\,°K$$
$$C_2H_5^{\bullet *} + M \longrightarrow C_2H_5^\bullet + M$$

In the next step of the reaction[*], in contrast with the fate of the vinyl radical, the C—C bond is broken[75].

$$C_2H_5^\bullet + H \longrightarrow C_2H_6^* \longrightarrow 2CH_3^\bullet \quad (14)$$
$$k_{14} \approx 4 \times 10^{13}\,cm^3\,mole^{-1}\,s^{-1} \text{ at } 298\,°K\,[60]$$

Various modern methods have been used to measure the rate constant of reaction (12). It is only recently, however, that correct allowance appears to have been made for the pressure dependence of the secondary reactions which cause the pronounced scatter of the experimental results[61, 63].

If the value of k_{12} for ethylene is known, the absolute values for the addition of H atoms to other olefins can be found from the ratios of the rate constants, which can be determined photochemically (see Table 2).

Table 2. Relative rate constants (based on ethylene) for the addition of hydrogen atoms to olefins at room temperature [80].

Olefin	$k_{Olefin}/k_{C_2H_4}$
Ethylene	≡1.00
Propene	1.53
1-Butene	1.58
Isobutene	3.85
2-*cis*-Butene	0.72
2-*trans*-Butene	0.90
1,3-Butadiene	7.5
1-Pentene	1.36
Trimethylethylene	1.57
2-*cis*-Pentene	0.60
2-*trans*-Pentene	0.67
Tetramethylethylene	1.28

Even more reaction paths are possible in the reaction of H atoms with benzene.

$$H + C_6H_6 \longrightarrow C_6H_7^{\bullet *} \quad (13)$$
$$k_{13} = 10^{13}\exp(-3.8/RT)\,cm^3\,mole^{-1}\,s^{-1}$$

Cyclohexadienyl radicals are formed in the first step[81]. Further reaction with H atoms can then lead both to H_2 and various cyclic C_6 hydrocarbons (cyclohexane, cyclohexene, cyclohexadiene) and, with ring cleavage, to the corresponding acyclic C_6 hydrocarbons[82, 83].

The examples mentioned show that the further course of the reactions of hydrogen atoms with hydrocarbons is strongly dependent on the behavior of the initially formed excited radicals. If the bond energies are known, the theory of unimolecular reactions[84] is a useful tool for the determination of the probabilities of the various reaction paths under the prevailing conditions (pressure, temperature). At high temperatures ($T > 1000\,°K$), it must also be noted that addition and abstraction can compete with each other.

[*] The reaction (14) is also the first subsequent step in the reaction of H atoms with ethane ($H + C_2H_6 \rightarrow C_2H_5^\bullet + H_2$).

3. Carbon Atoms

Reactions of free carbon atoms have been subjected to several qualitative studies, but the measurement of reaction rates is still in its early stages[85–87].

A serious difficulty in the investigation of the reactions of C atoms is their production. *Wolfgang et al.*[85] obtained readily detectable radioactive ^{11}C atoms by the nuclear process $^{12}C(\gamma,n)\rightarrow{}^{11}C$, and these were thermalized by the addition of an inert gas (Ne). *Skell* and *Engel*[86] used C atoms from a carbon arc burning under vacuum, the reactants being condensed on the walls of the vacuum container at 77 °K. These methods have allowed conclusions to be drawn regarding reaction mechanisms. The main final products in the reactions of ^{11}C atoms with hydrocarbons were acetylene and ethylene, whereas the second method led mainly to higher hydrocarbons, which were formed by "insertion" of the C atom into bonds of the substrate molecule.

Two other methods have so far been used for the determination of rate constants. *Wolf et al.*[88] produced ^{14}C atoms by dissociation of $^{14}C_3O_2$ in a microwave discharge. *Braun et al.*[89] have detected carbon atoms in the ground state $C(^3P)$ and in the excited states $C(^1D)$ ($E^*=30$ kcal mole^{-1}) and $C(^1S)$ ($E^*=62$ kcal mole^{-1}) by their absorption in the vacuum UV after flash photolysis of C_3O_2. Table 3 shows a comparison of the rate constants for reactions of C atoms in various electronic states.

Table 3. Rate constants for reactions of carbon atoms in various electronic states [88—91].

Reaction	k (298 °K) (cm^3 mole^{-1} s^{-1}) $C(^3P)$	$C(^1D)$	$C(^1S)$
$C(X)+H_2(^1\Sigma)\rightarrow CH+H$	$<10^6$	2.5×10^{13}	2.3×10^{12}
$C(X)+O_2(^3\Sigma)\rightarrow CO+O$	2×10^{13}	3×10^{12}	—
$C(X)+NO(^2\Pi)\rightarrow CN+O$	6.6×10^{13}	6×10^{13}	—
$C(X)+CH_4(^1A_1)\rightarrow C_2H_2+H_2$	$<10^8$	1.9×10^{13}	—

The results for the reaction with H_2 can be clearly illustrated by the correlation diagram reproduced in Figure 10[92]. Reaction to form $CH(^2\Pi)$ and $H(^2S)$ is endothermic for $C(^3P)$ atoms ($\Delta H_0^0=+20$ kcal mole^{-1}), and is therefore very slow at room temperature[93]. For $C(^1D)$, the formation of $CH(^2\Pi)$ and $H(^2S)$ is exothermic, and proceeds rapidly, whereas the reaction of $C(^1S)$, which is more exothermic by more than 30 kcal mole^{-1}, is at least one order of magnitude slower. This example shows that energy and spin considerations ($C(^1D)$ and $C(^1S)$ have the same spin state, and the reaction with $H_2(^1\Sigma)$ to form $CH(^2\Pi)$ and $H(^2S)$ is "spin-allowed") are often insufficient by themselves for the prediction of the rate of an elementary reaction. However, the result can be explained on the basis of symmetry considerations, according to which there is no "continuous" (adiabatic) potential-energy surface for the analogous reaction of the $C(^1S)$ atoms (see Fig. 10).

Only ten gas-kinetic collisions are necessary for the reaction of a molecule of O_2 with $C(^3P)$ atoms to form CO and O. Formation of CO_2 by "insertion" of $C(^3P)$ has been observed neither at high pressures nor in the liquid phase. It is therefore assumed that the attack of the C atom takes place at the end of the O_2 molecule, and not on the π bond[85].

$C(^3P)$ atoms surprisingly react relatively slowly with hydrocarbons at room temperature. The rate constants for

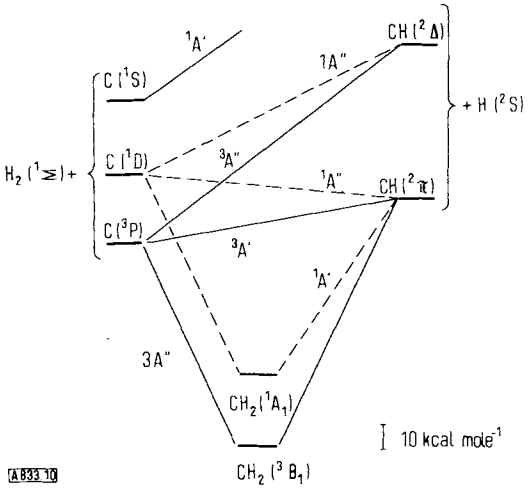

Fig. 10. Correlation diagram for the reactions of H_2 with carbon atoms in various electronic states [92].

the reactions with CH_4, C_2H_2, and C_2H_4 are less than 10^7 cm^3 mole^{-1} s^{-1}[88]. The corresponding reactions of $C(^1D)$ are fast; the reaction with CH_4 leads directly to the formation of C_2H_2 (see Table 3).

4. Oxygen Atoms

Reactions of free oxygen atoms determine the course of many oxidation and combustion processes[94]. As biradicals, they exhibit a great diversity of possible reactions, and the primary products of many of their reactions have only recently been definitely established by direct investigations.

4.1. Generation of $O(^3P)$ and $O(^1D)$ Atoms

If O atoms are generated by an electric discharge in molecular oxygen,

$$O_2(^3\Sigma) \xrightarrow{\text{electric discharge}} O(^3P)$$
$$O_2(^1\Delta_g);\ E^* = 22.5 \text{ kcal mole}^{-1}$$
$$O_2(^1\Sigma_g);\ E^* = 37.5 \text{ kcal mole}^{-1}$$
$$O + O_2 \xrightarrow{+M} O_3$$

metastable oxygen molecules in electronically excited states are obtained as well as O atoms in the ground state $O(^3P)$; these metastable molecules are very insensitive to wall collisions, and can therefore lead to interfering parallel reactions, though not to the same degree as in the case of N_2[95,96]. Ozone is also formed in the presence of O_2.

$O(^3P)$ atoms can also be produced in the absence of O_2 in the "titration reaction" mentioned earlier (cf. Table 1),

$$N(^4S) + NO(^2\Pi) \longrightarrow N_2(^1\Sigma) + O(^3P)$$

in the Hg-sensitized photolysis of N_2O

$$N_2O(^1\Sigma) + Hg(^3P_1) \longrightarrow O(^3P) + N_2(^1\Sigma) + Hg(^1S_0)$$

or on vacuum UV photolysis of NO[97].

$$NO(^2\Pi) + h\nu\ (\lambda < 1915\,Å) \longrightarrow N(^4S) + O(^3P)$$

O atoms can be produced in the first electronically excited state ($O(^1D)$; $E^* = 45$ kcal mole^{-1}) by photolysis of ozone,

$$O_3 + h\nu\ (\lambda < 3100\,Å) \longrightarrow O_2(^1\Delta_g) + O(^1D)$$

$N_2O(\lambda < 2200$ Å), or $O_2(\lambda < 1760$ Å). Their radiation lifetime is very long ($\tau \approx 110$ s), but they can be rapidly deactivated by O_2, N_2, *etc.*[98].

4.2. Reaction with H_2

The reaction of atomic oxygen with H_2

$$O(^3P) + H_2(^1\Sigma) \longrightarrow OH(^2\Pi) + H(^2S);\ \Delta H_0^0 = 1.9\ \text{kcal mole}^{-1} \quad (15)$$

is important as a chain-branching step in the oxygen/hydrogen reaction and numerous other oxidation reactions. Apparent activation energies of between 6 and 12 kcal mole^{-1} were reported for this reaction a few years ago[99, 100]. Figure 11 shows that the rate constants determined by modern methods (shock waves, explosion limits, stirred reactor, flow system) can be represented very well over a wide temperature range (320—2500 °K) by an Arrhenius expression

$$k_{15} = 1.5 \times 10^{13} \exp(-9.4/RT)\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$$

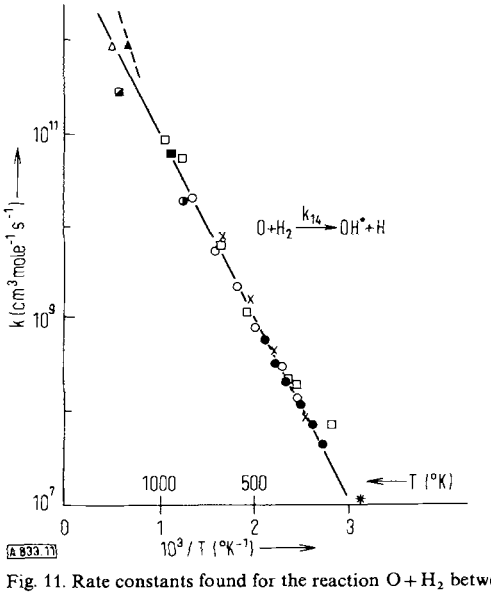

Fig. 11. Rate constants found for the reaction $O + H_2$ between 320 and 2500 °K.
○ [106], □ [107], ● [108], × [104], * [109], ◑ [105], ■ [103], ◪ [110], -△- [101], --▲-- [102].

4.3. Reactions with Alkanes

As in the reaction with H_2, an H atom is apparently also transferred from saturated hydrocarbons to the attacking $O(^3P)$ atom,

$$O(^3P) + RH \longrightarrow R^\bullet + OH^\bullet$$

Table 4. Rate constants for reactions of $O(^3P)$ atoms with alkanes [111, 112].

$O(^3P) + RH \rightarrow R^\bullet + OH^\bullet$	A-Factor (cm^3 mole^{-1} s^{-1})	E_{exp} (kcal mole^{-1})
$O(^3P) + CH_4 \rightarrow CH_3^\bullet + OH^\bullet$	$10^{13.3}$	9.2
$O(^3P) + C_2H_6 \rightarrow C_2H_5^\bullet + OH^\bullet$	$10^{13.4}$	6.1
$O(^3P) + n\text{-}C_4H_{10} \rightarrow i\text{-}C_4H_9^\bullet + OH^\bullet$	$10^{13.8}$	5.1
$O(^3P) + n\text{-}C_7H_{16} \rightarrow i\text{-}C_7H_{15}^\bullet + OH^\bullet$	$10^{14.0}$	4.3

the measured activation energies (E_{exp}) decreasing with decreasing H—R bond strength (see Table 4). The rate of the overall consumption of O atoms increases in proportion to the nature and number of the C—H bonds in the case of higher paraffins. For the attack of O atoms on primary, secondary, and tertiary C—H bonds of the alkanes, many of the experimental results can be described by the following Arrhenius expressions (per C—H bond)[112]

$$k_{primary} = 5 \times 10^{12} \exp(-5.8/RT)\ \text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}$$
$$k_{secondary} = 1.3 \times 10^{13} \exp(-4.5/RT)\ \text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}$$
$$k_{tertiary} = 1.6 \times 10^{13} \exp(-3.3/RT)\ \text{cm}^3\ \text{mole}^{-1}\ \text{s}^{-1}$$

Attack by $O(^1D)$ atoms, on the other hand, takes place without an activation barrier with insertion of $O(^1D)$ into the CH bond.

$$O(^1D) + RH \longrightarrow ROH^*$$

The resulting alcohol molecule exhibits strong vibrational excitation, and can be stabilized only at high pressures or in the liquid phase (see Table 5).

Table 5. Reactions of excited oxygen atoms with alkanes.

$O(^1D) + RH \rightarrow ROH^*$				Conditions	Re
$O(^1D) + CH_4$	$\xrightarrow{+M}$	CH_3OH^*	(70%)	87 °K, liquid Ar	[11

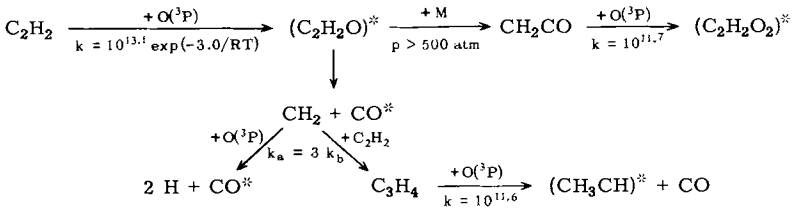
$O(^1D) + C_2H_6$	$\xrightarrow{+M}$	$C_2H_5OH^*$	(97%)	87 °K, liquid Ar	[11
	$\longrightarrow$	$C_2H_4 + H_2O$	(3%)		
$O(^1D) + i\text{-}C_4H_8$	$\xrightarrow{+M}$	$i\text{-}C_4H_7OH^*$	(90%)	300 °K, 1200 torr N_2	[11
	$\xrightarrow{+M}$	$t\text{-}C_4H_7OH^*$	(10%)		

4.4. Reaction of $O(^3P)$ Atoms with Acetylene

The most important of the elementary steps occurring in the reaction of $O(^3P)$ with C_2H_2 are indicated, together with their rate constants, in Figure 12.

An addition complex $(C_2H_2O)^*$ is first formed. The experimental activation energy ($E_{exp} = 3.0$ kcal mole^{-1}; see Fig. 13) required for this step agrees well with the value

obtained in the addition of H atoms (see Section 2.4) to C_2H_2. However, whereas the excited $C_2H_3^*$ radicals can decompose only in a reversal of their formation reaction, several decomposition paths are conceivable for the $(C_2H_2O)^*$ complex.



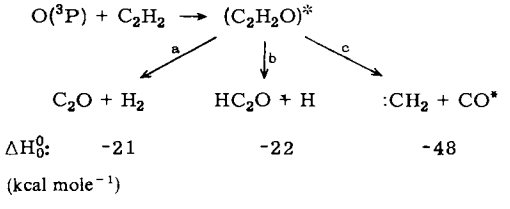


Fig. 12. Elementary steps in the reaction of oxygen atoms with acetylene. Rate constants at $T=298\,°K$, in $cm^3\ mole^{-1}\ s^{-1}$.

The most exothermic decomposition (c) into $:CH_2$ and CO* predominates. The two hydrogen atoms formed on further reaction of the methylene with $O(^3P)$ atoms can be detected quantitatively with an ESR spectrometer (see Fig. 2)[117]. Strong vibrational excitation ($v \leqslant 13$) is found for the CO*[121].

In an excess of C_2H_2, the carbene reacts with acetylene to form C_3H_4, which is present mainly as methylacetylene and allene. Stabilization of the $(C_2H_2O)^*$ complex to

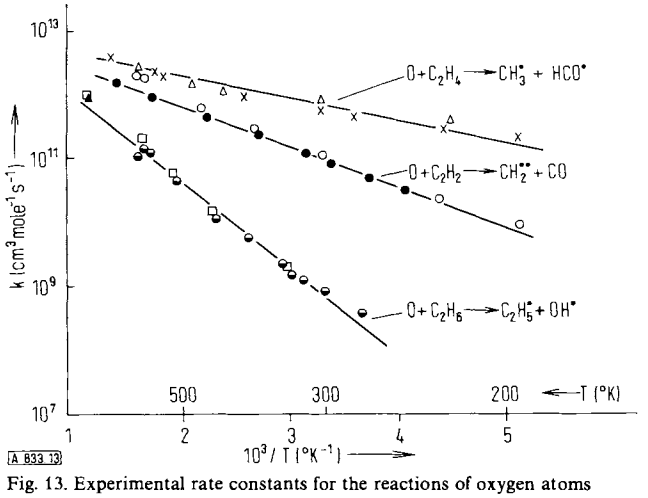

Fig. 13. Experimental rate constants for the reactions of oxygen atoms with C_2 hydrocarbons.
△ [120], × [119], ● [117], ○ [118], □ [111], ⬬ [107], ▲ [116].

ketene occurs only at very high pressures ($p > 500$ atm) or in an argon matrix[122] (20 °K).

In addition to the reactions shown in Figure 12, the decomposition paths (a) and (b), and reactions that lead to the formation of free electrons and ions and to chemiluminescence of CO, OH, CH, and C_2 also occur to a small extent[123–125].

4.5. Reactions with Olefins

The reactions of oxygen atoms with olefins are very similar to the corresponding reactions of the CH_2 radical, which is isoelectronic with O[126, 127].

The addition of $O(^3P)$ atoms is not stereospecific. According to *Cvetanovic*[126], this addition first yields triplet biradicals, whose lifetime is comparable with the period of rotation about the C—C bond, and which isomerize by ring closure and migration of H atoms or alkyl groups to form epoxides, aldehydes, and ketones. On the basis of studies on the addition of $O(^3P)$ atoms to condensed olefins (90 °K), *Scheer et al.*[128] conclude that the isomerization and the localization of the O atom must take place simultaneously. Information on this point should be provided in the future by measurements on the rate constants of reactions of $O(^3P)$ atoms with the corresponding deuterated compounds.

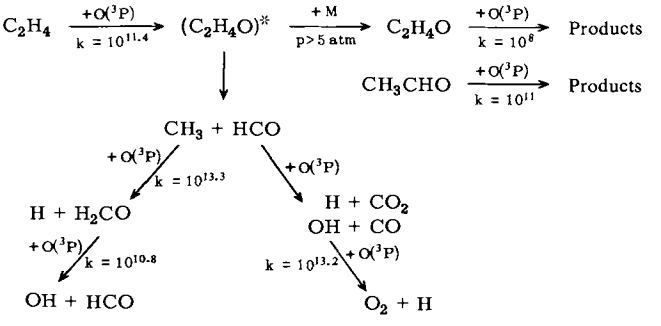

Fig. 14. Elementary steps in the reaction of oxygen atoms with ethylene. Rate constants at $T=298\,°K$, in $cm^3\ mole^{-1}\ s^{-1}$.

Figure 14 shows the elementary steps occurring in the reaction of $O(^3P)$ atoms with ethylene. As in the reaction of H atoms (see Fig. 8), the energy barrier to be overcome is lower than in the case of acetylene (see Fig. 13). Stabilization of the $(C_2H_4O)^*$ complex to form ethylene oxide and acetaldehyde takes place to a considerable extent even at atmospheric pressure. These compounds react further relatively slowly with $O(^3P)$, and can therefore be readily detected as end products and used for the determination

Table 6. Relative rate constants at $T=298\,°K$ for the addition of oxygen, sulfur, and selenium atoms to olefins [129—132].

Olefin	$O(2^3P)$	$S(3^3P)$	$Se(4^3P)$
$H_2C{=}CH_2$	≡ 1	≡ 1	≡ 1
$H_2C{=}CH{-}CH_3$	5.8	7.8	2.6
$H_2C{=}CH{-}CF_3$	0.06	—	—
$H_2C{=}CH{-}C_2H_5$	5.8	11	7.1
$H_2C{=}C(CH_3)_2$	23	56	44.7
$H_2C{=}C(CH_3)CF_3$	0.5	—	—

of relative rate constants. Table 6 gives relative rate constants for some olefins. These values clearly show an electrophilic character of the $O(^3P)$ addition to olefins, which is also evident in the analogous reactions of $S(3^3P)$ and $Se(4^3P)$ atoms.

4.6. Reactions with Sulfur Compounds

During the oxidation of simple sulfur compounds (H_2S, CS_2, COS, S_2), the presence of O atoms can be seen from an intense blue-violet SO_2 chemiluminescence, which was assigned to the recombination of SO with O as early as 1934 by *Gaydon*[133]. However, a definite identification of the elementary steps and the determination of their rate constants became possible only through the isolated investigation of these reactions in a flow system coupled with a mass spectrometer. The mass-spectrometric detection, unlike other spectroscopic methods, is not tied to special properties of the particles to be detected, so that it is possible, in principle, to detect quantitatively all the stable and unstable starting materials, intermediates, and end products of a reaction with high sensitivity. The problem here is the correct "handling" of the unstable particles, which must pass into the ion source as directly as possible, *i.e.* without collisions with the vessel walls.

Most arrangements for the combination of a mass spectrometer with a flow reactor are based on a principle first described by *Eltenton*[134] (see Fig. 15a). A short distance from the end of the flow tube is a plate with an aperture

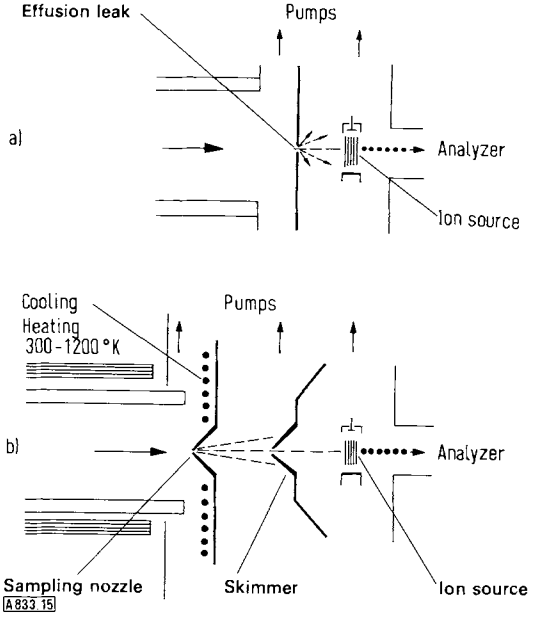

Fig. 15. Sampling for the analysis of unstable particles with the mass spectrometer.

a) Effusion arrangement after [134]; b) molecular beam inlet after [136—138].

10—100 μm wide (corresponding to the mean free path in the tube), through which the gas can diffuse directly into the ion source. Atoms and radicals can indeed be detected in this way, but particles pass into the ion source from a region in which the influence of the wall and of the flow boundary layer is clearly noticeable. For unstable particles, this can cause marked differences in concentration compared to that in the actual reaction. These disadvantages are avoided if the gas samples are taken with a conical probe that is adjusted to the flow[135] and whose aperture is large in relation to the mean free path in the flow tube (see Fig. 15b)[136—138].

The reaction tube is thermally insulated and placed inside a vacuum-tight stainless steel jacket, and can be electrically heated. The sampling probe (quartz cone) is attached to an intermediate vacuum chamber, which is evacuated with a diffusion pump, so that a pressure of between 10^{-3} and 10^{-4} torr is produced with a pressure of 1—20 torr in the flow system and a probe aperture of 1 mm. The gas samples are taken from a region several mm in diameter in front of the tip of the probe, so that only a very small percentage of the entering particles can come into contact with the wall. The density and translational temperature decrease by several orders of magnitude within a few microseconds in the freely expanding jet, and this corresponds to ideal "quenching" of the drawn off sample. The jet impinges on a cone of stainless steel, the "skimmer", which outs out the outer part of the jet. The apex angle of the cone is so chosen that the particles inside the cone do not undergo collisions with the wall of the cone, and the particles reflected from

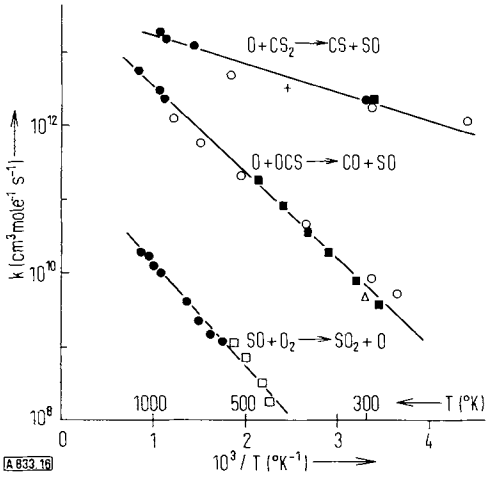

Fig. 16. Experimental rate constants for elementary steps in the oxidation of carbon disulfide and carbonyl sulfide.

● [137, 138], ■ [136], ○ [58], △ [140], + [143], □ [141].

the outer wall do not pass downstream again. With the optimum distance between the aperture of the probe and the skimmer (in this case ≈10 mm), a sharply focused beam of high density enters the ion source.

Figure 16 shows the results (solid points are measurements using the entry system shown in Fig. 15b) for some particularly important elementary steps in the oxidation of CS_2 and of COS, in the form of an Arrhenius diagram. Though the reaction paths followed in the reaction of $O(^3P)$ atoms with CS_2 and with COS are analogous, a higher activation energy is found for the more exothermic reaction with COS. The rate constants found at room temperature for the reactions of $O(^3P)$ atoms with simple sulfur compounds are listed in Table 7.

Vibrational excitation of the product molecules (CO*, SO*, CS*) has been detected in some reactions. These are therefore promising candidates for a chemical laser. The elementary steps that lead to the formation of SO_2 are particularly interesting in connection with the problems of air pollution.

Table 7. Rate constants for reactions of $O(^3P)$ atoms with simple sulfur compounds at room temperature [136 to 148].

Reaction		log k ($cm^3\ mole^{-1}\ s^{-1}$)	$-\Delta H_0^\circ$ (kcal $mole^{-1}$)
$O(^3P)+CS_2(^1\Sigma)$	$\longrightarrow CS^*(^1\Sigma)+SO^*(^3\Sigma)$	12.3	32
	$\longrightarrow OCS(^1\Sigma)+S(^3P)$	< 8	53
$O(^3P)+OCS(^1\Sigma)$	$\longrightarrow SO(^3\Sigma)+CO^*(^1\Sigma)$	9.8	55
	$\longrightarrow CO_2(^1\Sigma)+S(^3P)$	< 7	57
$O(^3P)+SO_3(^3\Sigma)$	$\longrightarrow SO_2(^1A_1)+O_2(^3\Sigma)$	5.6	35
$O(^3P)+H_2S(^1A_1)$	$\longrightarrow OH(^2\Pi)+SH(^2\Pi)$	10.3	14
$O(^3P)+CS(^1\Sigma)$	$\longrightarrow CO^*(^1\Sigma)+S(^3P)$	>13	75
		($cm^6\ mole^{-2}\ s^{-1}$)	
$O(^3P)+SO(^3\Sigma)$	$\xrightarrow{+M} SO_2(^1A_1)$	17.5	130
$O(^3P)+SO_2(^1A_1)$	$\xrightarrow{+M} SO_3(^3\Sigma)$	15.0	83

4.7. Reaction with Ammonia and Hydrazine

At room temperature, ammonia is attacked only slowly by O atoms, as is also the case with H and N atoms. The rate constants plotted in Figure 17 were found in the temperature range from 300—900 °K for the probable primary step

$$O(^3P) + NH_3(^1A_1) \longrightarrow NH_2(^2B_1) + OH(^2\Pi); \quad (16)$$
$$\Delta H_0^\circ = +0.7\ \text{kcal mole}^{-1}$$

The further reaction is relatively complicated. In the absence of O_2, three O atoms are consumed per molecule of NH_3; H atoms, NO, H_2O, and O_2 are formed in a ratio of 1.6:1:0.7:0.6. HNO radicals have been detected as intermediates.

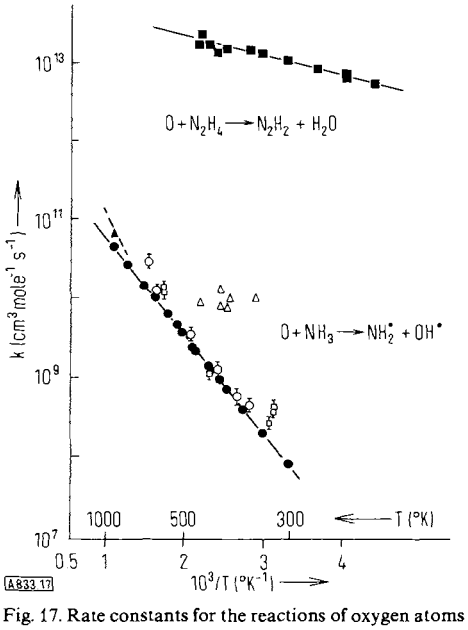

Fig. 17. Rate constants for the reactions of oxygen atoms with ammonia and hydrazine.
△ [149], --▲-- [150], ⊕ [151], ⊖ [153], ● [152], ■ [154].

As can be seen from Figure 17, hydrazine reacts extremely rapidly with atomic oxygen even at low temperatures. The overall reaction corresponds to

$$N_2H_4 + 4.5\,O \longrightarrow 2H + H_2O + 1.4\,O_2 + 0.6\,N_2 + 0.6\,NO + 0.1\,N_2O$$

The products formed in the primary step in this reaction have been detected directly with an arrangement (see Fig. 18) in which the sampling system shown in Figure 15b had been modified in such a way that the beam of O atoms from the flow system was made to react with a free beam of hydrazine in the intermediate vacuum chamber. It was found that the reaction leads *directly* to diimine and water.

$$O(^3P) + N_2H_4 \longrightarrow N_2H_2 + H_2O;\ \Delta H_0^{298} = -81\ \text{kcal mole}^{-1} \quad (17)$$

This reaction thus provided the first direct evidence that $O(^3P)$ atoms can take up two H atoms in one step[154, 155].

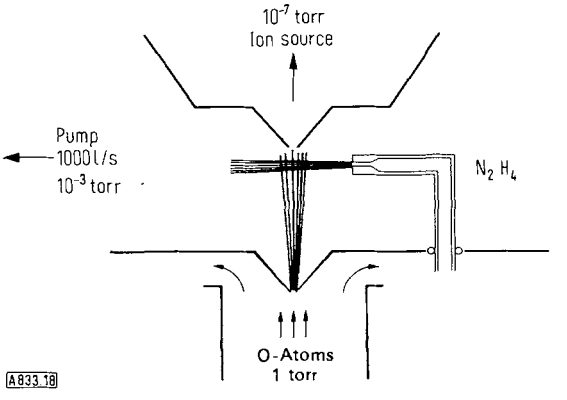

Fig. 18. Scheme of an arrangement for the direct determination of the primary products of elementary steps with crossed free jets [154].

5. Halogen Atoms

5.1. Reaction with H_2

Investigations on the reactions of halogens with hydrogen have played an important part in the development of reaction kinetics, starting with the classic experimental

studies of *Bodenstein*. *Nernst*'s observation that the photochemical chlorine/hydrogen reaction can be explained by the participation of chlorine atoms, as well as the mechanism proposed by *Christiansen*, *Herzfeld*, and *Polanyi* for the thermal reaction of hydrogen and bromine with allowance for the reactions of H and Br atoms, which explained the results of *Bodenstein*'s measurements, have not only established the participation of free atoms in gas phase reactions, but have also made a decisive contribution to our understanding of composite reactions (open reaction sequence, closed sequence, chain reaction).

Halogen atoms can be produced from the molecules either photochemically or thermally at easily accessible wavelengths and temperatures. Much information has therefore been available for a long time concerning the reactions of chlorine, bromine, and iodine atoms with H_2 (see Fig. 19) and other reactants[156].

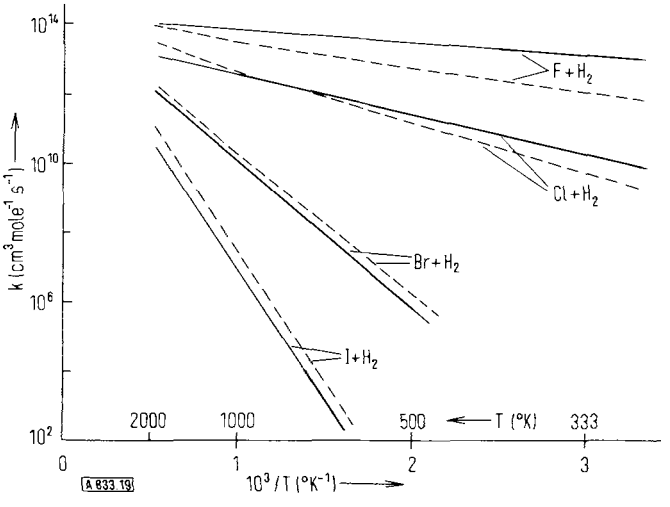

Fig. 19. Rate constants for the reactions of halogen atoms with hydrogen.
——— Experimental values [156, 165—168]; - - - Calculated values [162, 164].

A quantitative investigation of the reaction

$$F + H_2 \longrightarrow HF^* + H;\ \Delta H_0^0 = -32\ \text{kcal mole}^{-1} \qquad (18)$$

has only recently become possible. It was necessary to be able to produce F atoms in the absence of F_2, so that the reaction (18) could be observed without interference by the subsequent step $H + F_2$ (see Section 2.2). F atoms can be produced in the flow system at a low F_2 partial pressure ($[F] \approx 0.1$ torr, $[F_2] \approx 10^{-3}$ torr) by the reaction

$$N + NF_2 \longrightarrow N_2 + 2F$$

and used for the study of reaction (18)[157].

For flash photolysis, the condition mentioned is satisfied by the process

$$UF_6 + h\nu \longrightarrow F + UF_5$$

Pimentel and *Kompa*[158] isolated reaction (18) in a UF_6/H_2 mixture in this way. It can be shown by the pulsed HF laser emission that occurs at $\lambda = 2.7$—2.9 μm that HF* molecules are preferentially formed in the second vibration state ($N_v = 2/N_{v=1} = 3.5 - 5.5$) in reaction (18)[159].

A continuous HF laser emission with a power of 475 W was obtained by *Jacobs*, *Gross*, *et al.*[160] with an arrangement in which F atoms are produced by thermal dissociation of SF_6 (0.03 mole s^{-1}) and mixed with H_2 in an ultrasonic flow. It was possible in this way to obtain 12% of the energy liberated in the reaction (18) as radiation energy.

Cool, *Shirley*, and *Stephens*[161] produced F atoms by the reaction

$$NO + F_2 \longrightarrow FNO + F$$

and allowed them to react with D_2 in a flow apparatus to form DF*. On addition of CO_2, the excitation energy of the deuterium fluoride can be transferred to carbon dioxide (see Fig. 20).

$$DF^*_{(v=1)} + CO_{2(00^00)} \longrightarrow DF_{(v=0)} + CO^*_{2(00^01)}$$

This provided the first true "chemical" laser that does not need any additional energy sources (electric discharge, light flashes, *etc.*). An efficiency of 4.6% and a continuous beam power of 162 W at 10.6 μm have so far been achieved.

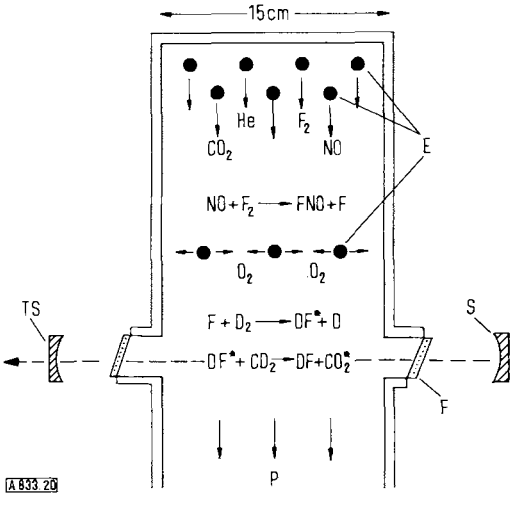

Fig. 20. Continuously operating "purely chemical" laser with a beam power of 162 W [161]. E: injectors, F: NaCl window, S: spherical mirror, TS: partially transmitting mirror, P: pump.

In addition to the experimental rate constants for the reactions of the halogen atoms with H_2, Figure 19 also shows the results of calculations by an empirical method described by *Johnston et al.*[162, 164]. This method (bond energy-bond order method) uses a simple valence model for reactions in which a H atom is transferred. It can be described for the reaction

$$\underset{(a)\ (b)}{H\uparrow\downarrow H} + \uparrow Cl \longrightarrow \underset{(a)\ (b)}{H\uparrow^{n_1}\cdots\downarrow H^{n_2}\uparrow Cl} \longrightarrow \underset{(a)\ (b)}{H\uparrow} + \underset{(a)\ (b)}{H\downarrow\uparrow Cl}$$

The reaction is considered in a linear arrangement. The electron of the transferred H atom (b) is assumed to have a spin orientation that allows a bond of order n_1 with the

second H atom (a) and of order n_2 with the Cl atom. Antibonding occurs between the Cl atom and the remaining H atom (a). Before the reaction, $n_1=1$ and $n_2=0$, while after the reaction, $n_1=0$ and $n_2=1$. During the reaction, n_1+n_2 should always be equal to 1, *i. e.* maximum bonding should always prevail. With the aid of the empirical relations between bond order (n) and bond energy (E) given by *Pauling*[163], this model allows a relatively simple calculation of the potential energy of the system along the reaction path.

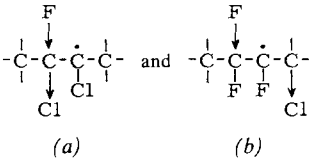
Though this method does not give the entire potential-energy surface for the reaction, the information required for a calculation of the rate constants according to the transition state theory (height of the potential-energy barrier, properties of the activated complex) can be obtained.

Surprisingly good agreement with the experimental values is often obtained when one considers the small amount of calculation and the simple model used.

5.2. Reactions with Hydrocarbons

In the determination of the rate constants of the reactions of halogen atoms with hydrocarbons, the reaction with H_2 is usually used as a reference reaction.

Table 8 gives some examples of reactions of the type



$$RH + F \longrightarrow R^{\bullet} + HF$$

Table 8. Rate constants for reactions of F atoms with hydrocarbons [168].

Reaction	log A (per H-Atom) ($cm^3\ mole^{-1}\ s^{-1}$)	E_{exp} ($cal\ mole^{-1}$)
$F(^2P_{3/2})+CH_3Cl$	13.5	1010
CH_2Cl_2	12.8	100
$CHCl_3$	12.9	600
$CHCl_2F$	13.5	1280
$CHClF_2$	13.1	1260
Primary CH bonds		
$F(^2P_{3/2})+CH_4$	14.5	1150
C_2H_6	13.4	220
C_3H_8	13.2	−60
n-C_4H_{10}	13.1	−60
iso-C_4H_{10}	13.1	−60
neo-C_5H_{12}	13.1	−60
Secondary CH bonds		
$F(^2P_{3/2})+$ *cyclo*-C_3H_6	13.2	−60
C_3H_8	13.2	−60
n-C_4H_{10}	13.1	−60
Tertiary CH bonds		
$F(^2P_{3/2})+$ *iso*-C_4H_{10}	13.3	−60

The data show that from ethane onward, practically every collision of an F atom with RH at room temperature leads to reaction. The influence of the temperature on the reaction rate is therefore very small.

Investigations on the exchange reactions of F atoms with halogenated C_4 hydrocarbons show that the rate of the exchange reaction is practically independent of the position from which the Cl atom is eliminated, *i. e.* the rates of the reactions

(a) (b)

are roughly equal ($k_b/k_a=1.6$). The distribution of the internal energy must take place extremely rapidly[169].

Reactions of I atoms with hydrocarbons

$$I + RH \longrightarrow R^{\bullet} + HI$$

have recently been investigated in particular by *Benson et al.*[170]. The measurements are based on the following mechanism:

$$I_2 + M \rightleftharpoons 2I + M$$
$$RI + I \underset{b}{\overset{a}{\rightleftharpoons}} R^{\bullet} + I_2$$
$$R^{\bullet} + HI \underset{d}{\overset{c}{\rightleftharpoons}} RH + I$$

By making the plausible assumption that $E_b=0\pm1$ kcal/mole, it was possible to determine the enthalpies of formation of numerous hydrocarbon radicals from these investigations.

5.3. Excited Halogen Atoms

Halogen atoms have an important excited state ($^2P_{1/2}$), in which, in contrast with the excitation of atoms considered so far, there is no change in the spin state in relation to the ground state ($^2P_{3/2}$), but rather only a change in the total angular momentum. The energy difference between the two states increases with the atomic weight (see Table 9).

Table 9. Excitation energies for halogen atoms.

	$F(2^2P_{1/2})$	$Cl(3^2P_{1/2})$	$Br(4^2P_{1/2})$	$I(5^2P_{1/2})$
$E(^2P_{3/2} \rightarrow {}^2P_{1/2})$ ($kcal\ mole^{-1}$)	1.15	2.5	10.5	21.7

The greatest difference in reactivity is thus exhibited by $I(5^2P_{3/2})$ and $I(5^2P_{1/2})$ atoms. Thus the activation energy found for the reactions with C_2H_6 and C_3H_8[171]

$$I^*(5^2P_{1/2}) + C_3H_8 \longrightarrow C_3H_7^{\bullet} + HI \qquad (19)$$
$$k_{19} = 10^{10.3} \exp(-5.0/RT)\ cm^3\ mole^{-1}\ s^{-1}$$
$$I^*(5^2P_{1/2}) + C_2H_6 \longrightarrow C_2H_5^{\bullet} + HI \qquad (20)$$
$$k_{20} = 10^{10.4} \exp(-7.0/RT)\ cm^3\ mole^{-1}\ s^{-1}$$

are 19.4 kcal $mole^{-1}$ smaller than for the analogous reactions of iodine atoms in the ground state. However, the

greater reactivity of the excited states frequently is not evident, since deactivation is faster than the reaction.

Systems of Monomolecular Layers—Assembling and Physico-Chemical Behavior

By Hans Kuhn and Dietmar Möbius[*]

Systems of monomolecular layers can form functional units having properties not exhibited by the individual layers. On UV irradiation, for example, an energy transfer takes place from a sensitizer (S) layer to an acceptor (A) layer and results in fluorescence of A. S and A may be cyanine dyes. Monomolecular layers can be manipulated in many ways and combined to construct novel systems; the energy transfer method can be used to establish whether the desired structure has in fact been produced. The monolayer assembling technique can also be used for the investigation of the deactivation of excited molecules; an interesting example is the spectral sensitization of the photographic process.

1. Construction of Organized Systems of Molecules with Monomolecular Layers as Structural Elements

It should be possible to construct functional units in molecular dimensions by fitting molecules together in a predetermined arrangement. Such systems, which have special properties that depend on the arrangement, are of interest as models for biological structures or as tools with structural elements having molecular dimensions. Their preparation requires the development of methods for linking intermolecular bonds similar to those available to the chemist for the planned formation of covalent bonds.

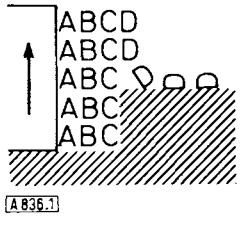

Fig. 1. Assembling monomolecular films of the molecules A, B, C, D.

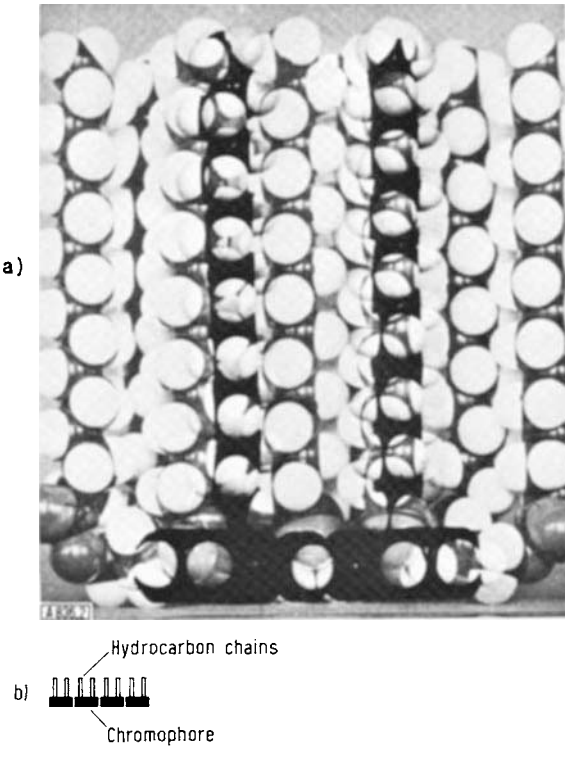
There are several ways in which one could conceivably approach this ambitious goal. One possibility (Fig. 1) is to deposit a monomolecular layer of molecules A on a support, cover this layer with a monomolecular layer of molecules B, and cover this layer in turn with monomolecular layers of molecules C, D, *etc.* This would necessarily lead to a simple, organized system of molecules with a planned order on the molecular level in the direction perpendicular to the layer.

Monomolecular films of fatty acids on a water surface can be prepared by spreading[1]. A solution of the fatty acid is dropped on to the surface of the water. The solvent evaporates, and the fatty acid molecules left behind on the surface of the water are packed to a compact layer. The hydrophilic carboxyl group of each molecule is inserted in the water, while the zig-zag paraffin chains, which are extended perpendicular to the layer, are bound to one another by intermolecular forces. These layers can be transferred to a glass support[2].

Since functional units are made up from different components, molecular functional units in the sense of the objective outlined above cannot be produced with layers of fatty acids alone. By incorporating dye molecules into monomolecular layers[3], on the other hand, it is possible to build up complex systems according to a plan. The cyanine dye *(1)* has two long paraffin substituents and a hydrophilic chromophore. In a mixed layer with a long-chain fatty acid, *e.g.* arachidic acid ($C_{19}H_{39}COOH$), the paraffin substituents of the dye are firmly incorporated into the layer by interaction with the paraffin chains of the fatty



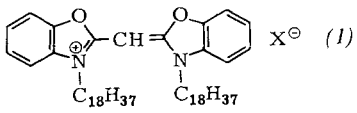


Fig. 2. (a) Model of a mixed layer of dye *(1)* and arachidate. The stearyl substituents of the dye molecule form a close-packed layer together with the arachidate molecules. (b) Symbol for such a layer (the arachidate molecules are not shown).

acid (Fig. 2). The hydrophilic chromophore is inserted in the water. This mixed layer is represented schematically as shown in Figure 2b, the fatty acid being omitted.

2. Energy Transfer in Layer Systems

2.1. System of a Sensitizer S and an Acceptor A as a Molecular Functional Unit

Layer systems can be built up by deposition of mixed layers containing dyes and fatty acid layers on suitable supports. The cross section through such a layer system is shown schematically in Figure 3. A few layers of arachidic acid were first deposited as a base on a glass plate (microscope slide). A layer of the dye *(1)* (S) was then applied over two thirds of the surface (zones 1 and 2), and a pure arachidic acid layer over the last third (zone 3). Zone 1 was now covered with a layer of arachidic acid, and zones 2 and 3 with five layers of arachidic acid. Finally, a mixed layer containing the paraffin-substituted cyanine dye *(2)* (A) was deposited on the entire surface.

(1), R = O
(2), R = S

To check that such a layer structure is not changed by rearrangement processes, it is necessary to find a method by which the distance between the layers of S and A can be determined in the range of 50 Å.

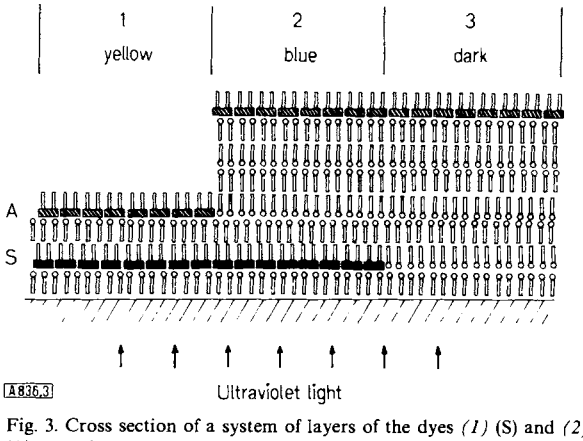

Fig. 3. Cross section of a system of layers of the dyes *(1)* (S) and *(2)* (A) on a glass support. The system is irradiated with ultraviolet radiation, which is absorbed only by S. Zone 1 (chromophores of S and A separated by 50 Å): energy transfer from S to A, yellow fluorescence of A. Zone 2 (S and A separated by 150 Å): blue fluorescence of S. Zone 3 (no S): no fluorescence. On irradiation with blue light, which is absorbed by A, all three zones exhibit the yellow fluorescence of A.

Such a method is provided by the Perrin-Förster energy transfer between dye molecules[4]. S is a dye that absorbs in the ultraviolet and fluoresces blue, while A absorbs blue and fluoresces yellow. If the system is irradiated with ultraviolet radiation, only S absorbs. In zone 2, where A and S are far apart, the blue fluorescence of S should appear. In zone 1, where the distance between A and S is 50 Å, energy transfer to A should take place, and the dye A should fluoresce instead of S. We therefore expect a yellow fluorescence. No fluorescence should occur in zone 3, since S is not present and A does not absorb ultraviolet radiation. This is experimentally confirmed[3, 5].

The system in zone 1 is an example of a simple molecular functional unit. The molecules S and A, which are fixed a short distance apart, have a property that is not exhibited by either of the individual molecules, *i.e.* they fluoresce yellow on excitation with ultraviolet light. The unit consisting of the molecules S and A acting together exercises a function that cannot be exercised by any of its parts alone, but only by the system consisting of both molecules as a whole.

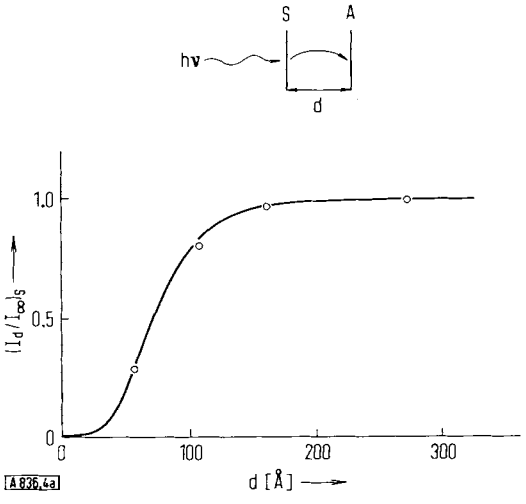

Fig. 4a. System of layers of the dyes S *(1)* and A *(2)* separated by a distance d. Intensity of the fluorescence of S plotted against d; the curve follows eq. *(1)* with $d_0 = 73$ Å.

The effect can be followed quantitatively and the Perrin-Förster theory verified[3]. Conversely, the good agreement between theory and experiment may be taken as indicating the presence of the planned order in the layer structure, and the diffusion of the dye molecules and the presence of holes in the layers can thus be ruled out. Figure 4a shows a plot of the fluorescence intensity of the sensitizer (I_d) against the distance d between the sensitizer and the acceptor layer[3]. The fluorescence intensity is zero, at short distances, and increases with increasing distance. The curve is given by the Förster theory. It follows the relation

$$(I_d/I_\infty)_s = [1 + (d_0/d)^4]^{-1} \quad (1)$$

where $d_0 = 73$ Å. The experimental points lie on the calculated curve. The parameter d_0 is given by:

$$d_0 = \alpha \frac{\lambda}{n} (q A_s)^{1/4} \quad (2)$$

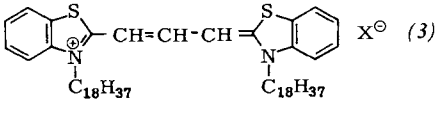
In this equation, α is a steric factor, which depends on the orientation of the transition moments of the sensitizer and of the acceptor; in the present case, in which the transition

moments of S and A are randomly distributed in the plane of the layer, the value is found to be $\alpha = 0.0975$[6]. Also in eq. (2), λ is the wavelength of the fluorescence maximum of S, n is the refractive index of the medium (1.50 for cadmium arachidate layers), q is the quantum yield of the fluorescence of S, and A_s is the absorption of the acceptor layer (1-transmission) at the wavelength λ. In the case of a broad fluorescence band of S, the expression

$$A_s = \int_0^\infty f(\nu)\, A(\nu)\, (\nu_0/\nu)^4\, d\nu$$

has to be used for A_s. In this expression, $f(\nu)$ is the quantum spectrum of the fluorescence of S, normalized according to

$$\int_0^\infty f(\nu)\, d(\nu) = 1$$



$A(\nu)$ is the absorption of the acceptor layer at frequency ν, and ν_0 is the frequency of the fluorescence maximum of S.

The parameter d_0 thus increases with increasing overlap of the fluorescence band of S with the absorption band of A and with increasing quantum yield q of the fluorescence of the sensitizer in the absence of the acceptor. From the experimental d_0 value, a value $q = 0.6$ is found for the case considered in Fig. 4a. This quantity q is the probability of the emission of a fluorescent light quantum by a molecule in the excited state from which the fluorescence can occur. q is relatively difficult to determine; it must lie between 1 and the value of the quantity q', where q' is the ratio of the number of quanta emitted by the dye layer per unit time as fluorescent light to the number of quanta absorbed by the dye layer per unit time.

In the earlier studies on energy transfer, q' and q were not distinguished, *i.e.*, q' was assumed to be equal to q. This agreement is not always found in layer systems. Cases are encountered in which q' and q differ considerably[7].

2.2. System of a Sensitizer S, a Primary Acceptor A, and a Secondary Acceptor A'

Figure 4b shows the results for a ternary system[8]. The same dyes *(1)* and *(2)* are used as the sensitizer S and the primary acceptor A as in the previous example; the secondary A' is the dye *(3)*, whose absorption band occurs in the position of the fluorescence band of A, and which therefore acts, according to the Perrin-Förster theory, as an acceptor for the excitation energy of A. The excitation energy transferred from S to A should thus pass on to the secondary acceptor A'.

(3)

The fluorescence intensity of the primary acceptor A is shown in Figure 4b as a function of the distance d' between the layers A and A'. For short distances d', the excitation energy is entirely transferred to the secondary acceptor A',

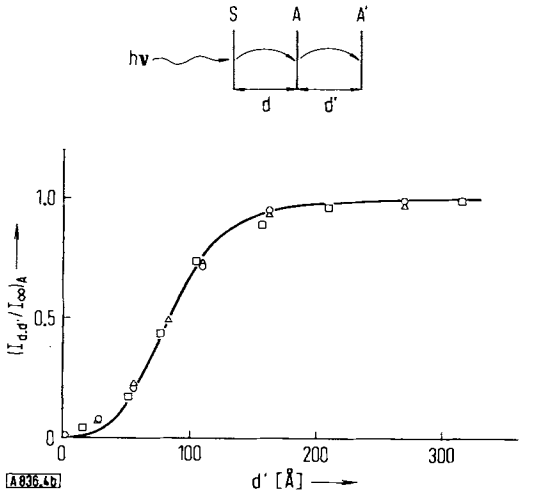


Fig. 4b. System of layers of the dyes S *(1)*, A *(2)*, and A' *(3)* separated by distances d and d', respectively. Intensity of the fluorescence of A plotted against the distance d' between the chromophores of A and A'. The distances d between S and A are 3 Å (squares), 27 Å (triangles), and 54 Å (circles). The curve follows eq. (1) with $d_0 = 83$ Å.

and the fluorescence of the primary acceptor A is quenched. For large distances d', the sensitized fluorescence of A is not quenched. The points lie on the calculated curve. This is found for various values of the distance d between the sensitizer S and the primary acceptor A.

3. Investigation of the Structure of Layer Systems by the Energy Transfer Method

3.1. Determination of the Thickness of a Cell Membrane

The thickness of the membrane of dried red blood cells, according to X-ray scattering measurements, is 80—85 Å[9]. The thickness can therefore be determined by the energy transfer method, which is particularly suitable for this range of distances[10]. A system with a fluorescent layer of the dye *(1)* at various distances over a thin vacuum-deposited layer of gold on a glass slide is first observed under the microscope. Figure 5 shows a photograph of the fluorescence of the cyanine dye *(1)*. The increase in the fluorescence with increasing distance from the gold layer (acceptor) is clearly seen.

Figure 6 shows the fluorescence of a layer system with a cell membrane incorporated. Such cell membranes are obtained by hemolysis of erythrocytes. The fluorescence

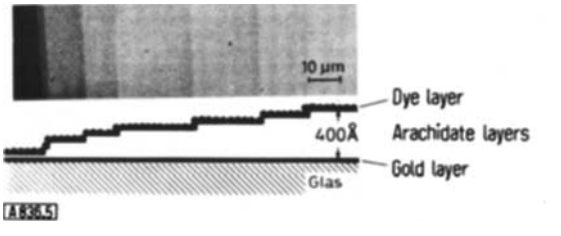

Fig. 5. Photomicrograph of the fluorescence of a layer of dye *(1)* situated at distances from a vacuum-deposited gold layer that increase from left to right; scheme of the layer system shown underneath. Strong quenching of the fluorescence at short distances as a result of energy transfer to the gold layer.

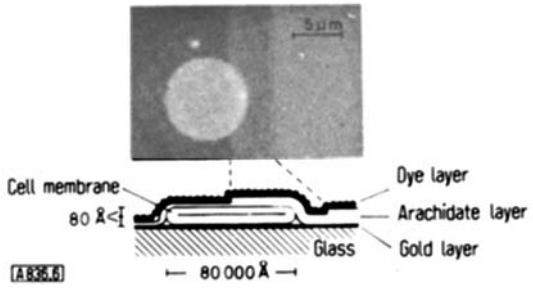
intensity of the dye layer is distinctly increased above the cell membrane because of the greater distance from the gold layer. Comparison with the fluorescence intensity of the dye layer at precisely defined distances from the gold



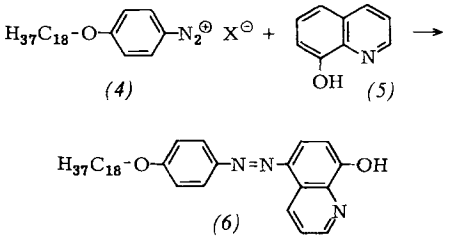


Fig. 6. Photomicrograph of the fluorescence of a layer of the dye *(1)* deposited on the system drawn underneath, which includes an erythrocyte membrane. The dye fluorescence is stronger over the erythrocyte membrane than in the adjacent zones because of the greater distance to the gold layer acting as the acceptor.

layer gave a value of 80 Å for the thickness of a membrane[10]. The feasibility of molecular contact between a monolayer assembly and a biological membrane allows new ways of interference of an organized system with the biological machinery.

3.2. Diffusion through Layer Systems

Small molecules can diffuse readily through a layer system. For example, a completely homogeneous layer of the azo dye *(6)* is formed from a layer of the diazonium salt *(4)* incorporated into a system when the coupling component *(5)* diffuses in and reacts with the salt *(4)*[11].

It is easy to establish by the energy transfer method whether a layer system built up over a diazonium salt is affected by such a process or remains unchanged.

To check this, the system shown on the left of Figure 7 is built up. The diazonium salt *(4)* is covered by only one layer of cadmium arachidate in zone 1, three layers in zone 2, and five layers in zone 3. The layer system is immersed in the solution of the coupling component *(5)*, and the azo dye *(6)* (A) is formed at the same rate in the three parts of the sample. A layer of the dye *(1)* (S) is then deposited over the system (Fig. 7, right-hand part).

The fluorescence of this dye layer is almost completely quenched in zone 1 because of energy transfer to the azo dye layer formed, strongly quenched in zone 2, and only weakly quenched in zone 3. It can therefore be concluded that the structure of the layer system is not changed by the diffusion of small molecules.

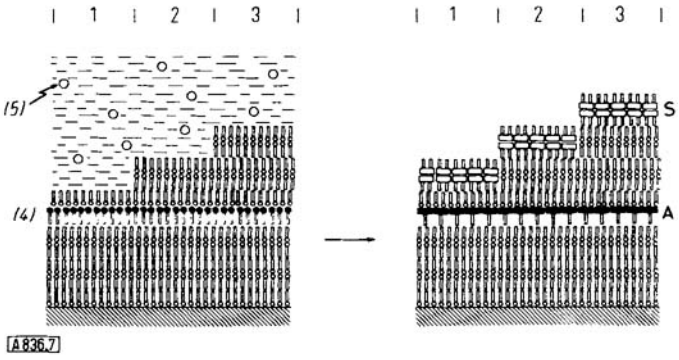

Fig. 7. Coupling reaction after diffusion of the coupling component *(5)* through the system of one (zone 1), three (zone 2), and five (zone 3) arachidate layers deposited on the diazonium salt *(4)*. After the reaction, the layer system is checked by deposition of a layer of dye *(1)* (S) and measurement of the fluorescence quenching of S. The test shows that the coupling component can diffuse in without damaging the layer system.

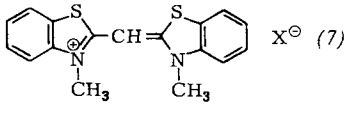

3.3. Adsorbed Monomolecular Dye Layers

In contrast with the fast diffusion of small molecules through layer systems, larger molecules, such as dyestuff ions, should not penetrate into a layer system, but should remain adhered to the surface of the system. In addition to the method we have already seen for producing organized systems by superposition of monomolecular films, this would now offer the possibility of obtaining such systems by adsorption of molecules on a monomolecular layer (Fig. 8).

Fig. 8. Formation of a system of layers of molecules A and B by adsorption of B from the substrate onto a spread monomolecular film of A.

To investigate the adsorption of dyestuff molecules, a layer of the dye *(1)* (S) is covered with a few layers of cadmium arachidate, and the system is immersed in a 10^{-5} M solution of the dye *(7)*. The layer of *(7)* adsorbed

on the surface of the system quenches the fluorescence of the incorporated dye layer.

Figure 9 shows a plot of the fluorescence intensity of the dye *(1)* against the distance d[12]. The experimental results agree well with the calculated values. Penetration of the adsorbed acceptor molecules would have caused stronger quenching of the fluorescence of the sensitizer, since the acceptor molecules *(7)* would have been closer to the sensitizer layer. This is found in systems with cadmium stearate layers instead of cadmium arachidate layers. The

fluorescence of the sensitizer is reduced to 50% at a distance four times as great as that expected. In systems with barium stearate instead of cadmium stearate, the dye molecules can penetrate even more readily into the layer system.

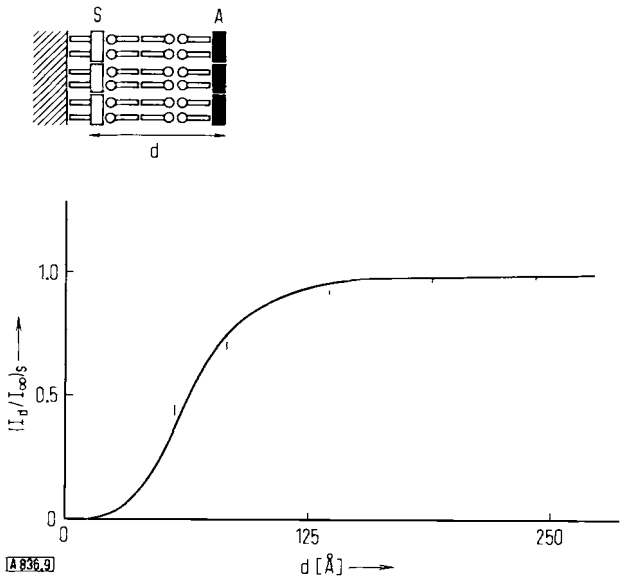

Fig. 9. Structure of a system consisting of a layer of the fluorescent dye S *(1)* and covering layers of arachidate after adsorption of the dye A *(7)* from aqueous solution. The fluorescence intensity $(I_d/I_\infty)_S$ of the layer of S is plotted against the distance d between the chromophores of S and of A. The curve follows the distance law for energy transfer [eq. (1)] with $d_0 = 64$ Å.

3.4. Lipid-Protein Layer Systems by Adsorption of Proteins

The possibility of obtaining organized systems by adsorption of molecules on a monomolecular layer is particularly interesting in the case of proteins that are to be incorporated into a layer system in the undenaturated form in connection with biological problems. The penetration of the protein into the monomolecular layer must be prevented, since this results in denaturation because hydrophobic groups of the protein are transferred from the interior of the molecule to the exterior. Penetration can be avoided by application of a sufficiently high surface pressure to the film on which the protein is being adsorbed. This is achieved by means of a device with which a monomolecular film can be held under any surface pressure and can be pushed to and fro on a water surface (Fig. 10)[13].

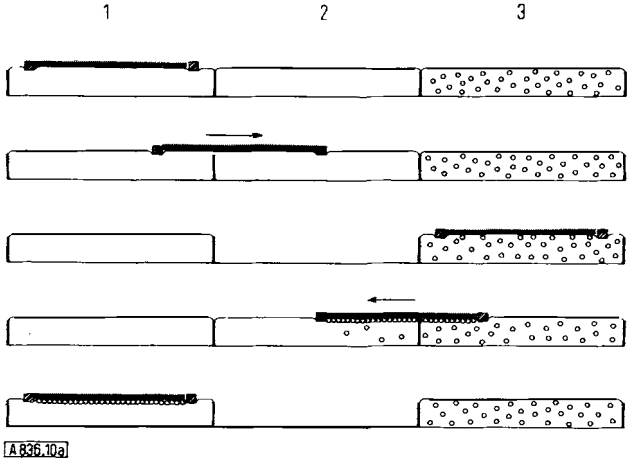

Fig. 10. Investigation of lipid-protein films. (a) Preparation of a lipid-protein film. The lipid film is spread on the water surface in compartment 1 and transferred to the surface of the protein solution in compartment 3. After adsorption of the protein film, the lipid-protein film is transferred back onto the protein-free substrate in compartment 1 for investigation. (b) Trough with six compartments for use in the operations described.

The monomolecular layer of fatty acid is produced in compartment 1. It is then pushed to compartment 2, which contains doubly distilled water as the subphase. The monomolecular layer is then moved to compartment 3, which contains a solution of the protein as the subphase. The film with the adsorbed protein is passed through compart-

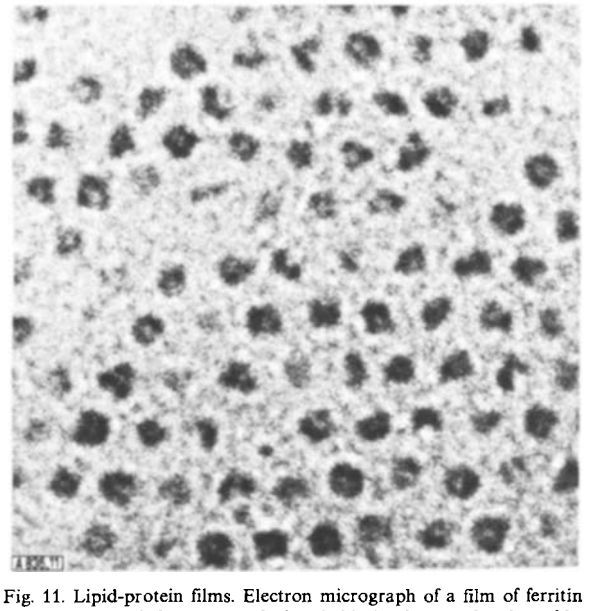

Fig. 11. Lipid-protein films. Electron micrograph of a film of ferritin adsorbed on methyl stearate and trimethyldodecylammonium bromide, molar mixing ratio 1:4. Spherical close packing of the protein molecules.

ment 2 to compartment 1 after a protein-free subphase has been introduced into both compartments. The surface pressure under which the film is held is measured by a Wilhelmy balance and kept to a preset value by a servo system that controls the slide.

The resulting layer of fatty acid with adsorbed protein can be transferred to a support, and its enzymatic activity can be measured[13]. In the case of the iron-rich protein ferritin, the adsorbed molecules can be seen directly under an electron microscope (Fig. 11)[14]. They are in a close packing arrangement.

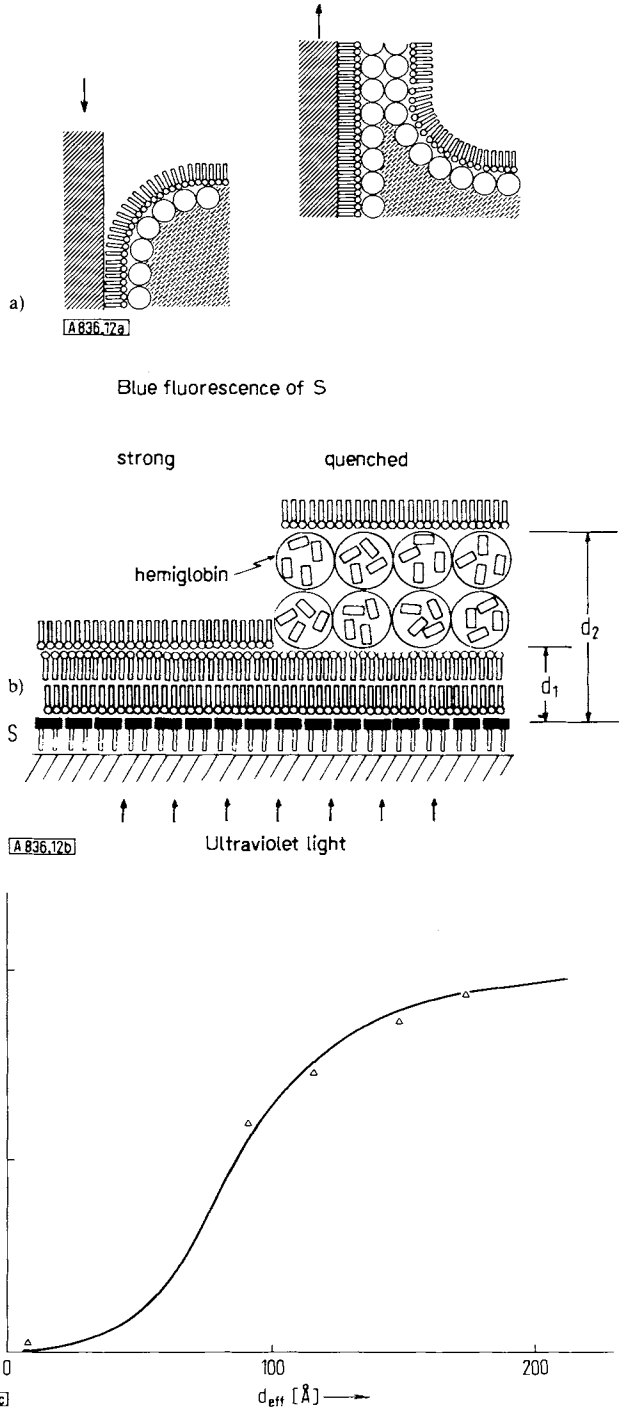

Fig. 12. Lipid-protein films in layer systems on glass. (a) Transfer of lipid-protein films to glass supports. (b) Layer system for the detection of the energy transfer from an excited layer of the dye S *(1)* to the heme groups of a hemiglobin double layer. (c) Intensity $(I_d/I_\infty)_S$ of the fluorescent dye layer as a function of the effective distance d_{eff} which is given by $1/d_{eff}^4 = (1/3)\,[(1/d_1^3) - (1/d_2^3)]\,[1/(d_2 - d_1)]$.

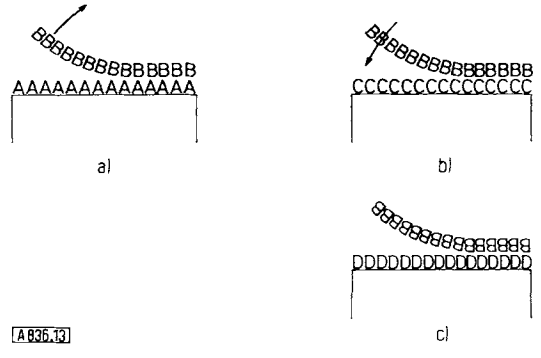
These monomolecular layers of lipid with adsorbed proteins can now be deposited on glass supports in the same way as the pure monomolecular lipid layers. For example, a layer structure may be produced as shown in Figures 12a and 12b[15]. The protein in this case is hemiglobin, which can be deposited as a double layer according to Figure 12a. In a layer system as shown in Figure 12b, the fluorescence in the right-hand section on excitation of the dye *(1)* with UV radiation should be considerably quenched by the energy transfer from the dye to the protein. This is in fact found.

Figure 12c shows the fluorescence intensity of the sensitizer S [dye *(1)*] as a function of the distance d_{eff} between the dye layer and a suitably defined center of gravity of the protein layer. Good agreement is found between the calculated curve and the experimental points. Another protein, *e.g.* plasma albumin, may also be deposited between the layers of the dye and the hemiglobin layer, and one can then check readily by the energy transfer whether the planned structure has been achieved[16]. It thus seems possible to build up functional units of several cooperating enzymes and to check the arrangement in this way.

3.5. Manipulation of Monomolecular Layers

Entirely new possibilities are opened up if a previously prepared layer system can be brought into molecular contact with a suitable surface in one step. To achieve this, one would have to be able to remove a monomolecular layer of the molecules B from the layer A, and to manipulate the layer B in such a way that it can be attached either from the underside or from above to a new monomolecular layer C (Fig. 13). The process can be readily checked at the various stages by the energy transfer method.



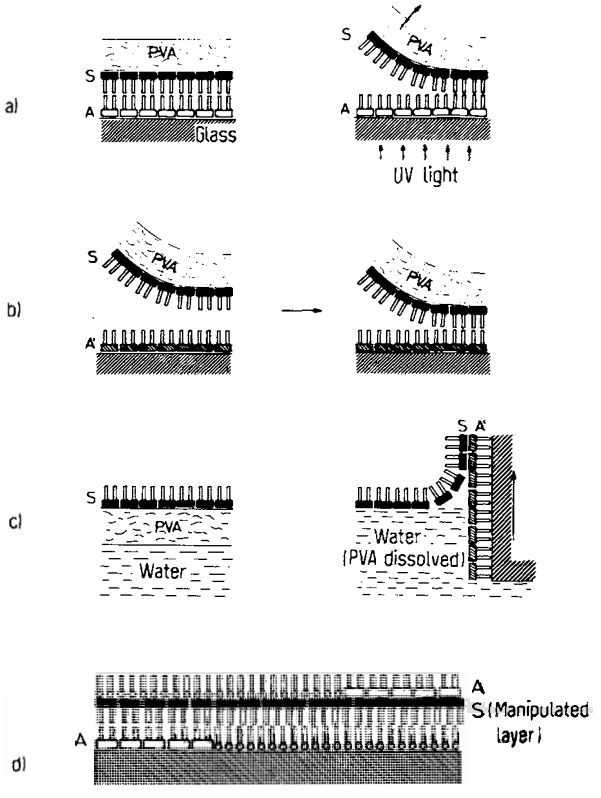


Fig. 13. Manipulation of monomolecular layers (schematic). (a) Complete separation of two monomolecular layers A and B. (b) Deposition of the separated layer B on another monomolecular layer C; molecular contact of B and C. (c) Deposition of the separated and inverted layer on another monomolecular layer D; molecular contact.

To achieve this aim, two monomolecular dye layers are superimposed on a glass support as described above; an aqueous solution of polyvinyl alcohol is then applied[17]. After drying, the polyvinyl alcohol foil can be removed from the glass support, and precise molecular separation of the layers occurs as shown in Figure 14a. To show this, the dyes are so chosen that one acts as the sensitizer [dye *(1)*], and the other as the acceptor [dye *(2)*]. As long as

the dye layers are in contact, energy is transferred to the acceptor on irradiation with light at the wavelength of the absorption band of the sensitizer, whereas energy transfer no longer occurs after separation of the layers. From the completely changed fluorescence observed after removal of the film, it can be concluded that the separation has taken place cleanly between the monomolecular layers of the sensitizer and of the acceptor (Fig. 14a).

A836.14

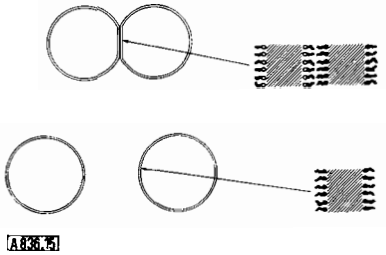

Fig. 14. Experimental procedure for the manipulation of monomolecular layers. (a) Complete separation of a monomolecular layer of S with a film of polyvinyl alcohol from a monomolecular layer of A on glass. (b) Molecular contact of the removed layer S with another layer A' after putting the polyvinyl alcohol film with the layer S on a plate with layer A'. (c) Removal of the polyvinyl alcohol film from the layer of S by application to a water surface and transfer of the inverted layer S to a support with a layer A'. (d) Checking the orientation of the transferred layer S and the molecular contact with adjacent layers A by investigation of the energy transfer from S to A.

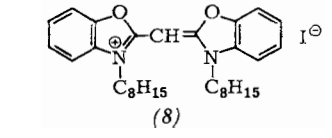
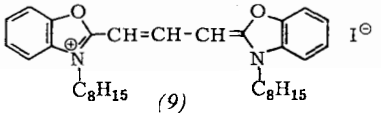
If the polyvinyl alcohol film with one of the dyes is brought back to the support with the other dye or applied to a support carrying a monomolecular layer of another suitable dye, molecularly accurate contact is restored (Fig. 14b). This is shown by the fact that the fluorescence of the sensitizer is quenched at the contact area, while the sensitized fluorescence of the acceptor appears.

To bring the removed monomolecular layer of the sensitizer into molecularly accurate contact with another layer from the reverse side, as indicated in Fig. 13c, one proceeds as follows. The polyvinyl alcohol film is turned round, *i.e.* with the monomolecular layer of the sensitizer on top, and placed on a water surface. The polyvinyl alcohol layer dissolves (Fig. 14c). To show that the process proceeds as planned, the layer of S can be built into a layer system (Fig. 14d, see also Section 2.1). The manipulated layer with sensitizer dye S is brought into contact on its hydrocarbon side with an acceptor dye A in zone 1 of the plate, and on its chromophore side in zone 3. On UV-irradiation, stronger quenching of the fluorescence of the sensitizer S and stronger sensitized fluorescence of the acceptor A are to be expected in zone 3 than in zone 1, since the chromophores of S and A are in direct contact in zone 3, whereas they are separated by paraffin chains in zone 1. The unquenched fluorescence of S should appear in zone 2. This behavior is in fact observed.

This technique can also be used in the case of layer systems with complicated structures. It is possible to divide a system of suitable architecture between precisely determined layers.



Another method of bringing layers into molecular contact and separating them again is by contact and subsequent separation of two soap bubbles. It has been an open question in this case whether such a process takes place in accordance with Figure 15, *i.e.* without diffusion of the molecules from one of the monomolecular layers into the other, or whether rearrangement of the layers occurs. To check this, different fluorescent surface active dyes, *e.g. (8)* and *(9)*, are incorporated into the two soap lamellae. The energy transfer can be investigated with such dyes just as in the layer system described above[18]. It is found that no rearrangement of the layers and no diffusion of dye molecules from one lamella into the other take place during short contact



A836.15

Fig. 15. Double sandwich structure at the contact surface between two soap bubbles. No diffusion of molecules of one soap bubble into the other occurs on separation of the soap bubbles, as is shown by the investigation of the energy transfer between the dyes incorporated into the soap bubbles.

times. The soap lamellae in contact with each other have the double-lamella structure shown in Figure 15. They thus form a bimolecular lipid membrane in the contact zone between two aqueous phases[18].

(8)

(9)

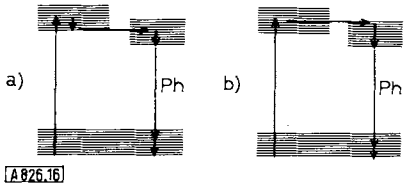
Bimolecular lipid membranes play an important role in biological systems. The experiments described offer a new possibility of producing models of such membranes. Since molecularly accurate separation can be achieved between

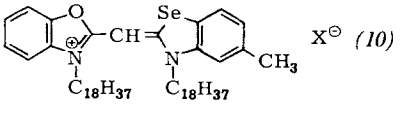
the two layers, it must be possible to study permeation processes with radioactive indicators. Unsymmetrical membranes, which were unobtainable by earlier methods[19], and which are of interest as models of biological membranes, can be prepared by this method.

4. Investigation of the Deactivation of Excited Molecules by the Monolayer Assembling Technique

4.1. Deactivation Pathway in Singlet-Triplet Transitions

An excited dye molecule may be deactivated in such a way that it passes through the lowest vibronic level of the first excited singlet state, or that it avoids this state. The transition to the triplet system can take place from this state (Fig. 16a) or from a higher vibronic level of the excited





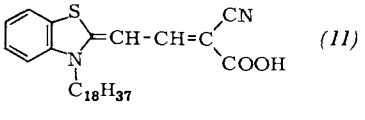


Fig. 16. Deactivation of an excited molecule by emission of phosphorescence. Transition from the singlet to the triplet system (a) from the lowest vibronic term of the first excited singlet state, (b) avoiding this term.

singlet state (Fig. 16b). In the case of deactivation according to Figure 16a, the fluorescence emission occurs in competition with the transition to the triplet system. A specific fluorescence acceptor reduces the population of the state from which the fluorescence takes place, and hence also the population of the triplet state. The phosphorescence that takes place from the triplet state to the ground state is thus quenched by the fluorescence acceptor. In the case illustrated in Figure 16b, on the other hand, the probability of the transition to the triplet system is independent of the population of the state from which the fluorescence takes place. A specific fluorescence acceptor thus does not affect the phosphorescence intensity.

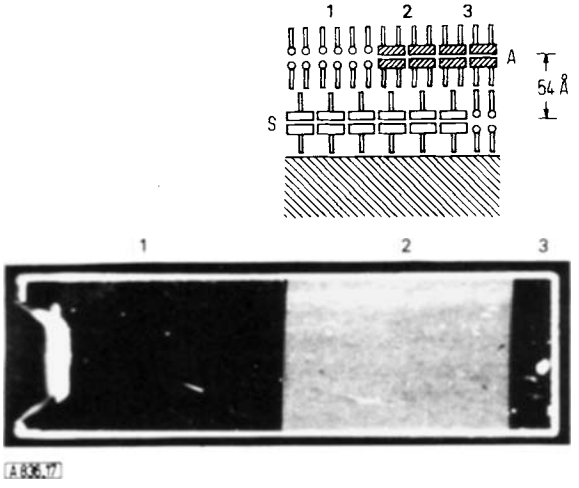
(10)

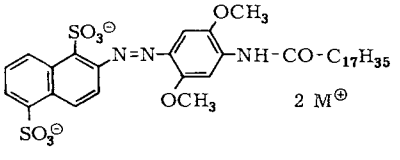
(11)

In the case of the dye *(10)*, the fluorescence is practically completely quenched by application of a layer of the specific fluorescence acceptor *(11)* at a distance of *e.g.* 80 Å, while the intensity of the phosphorescence is reduced only to about half. It may be concluded from the dependence of this effect on distance that the pathways in accordance with Figures 16a and 16b are involved in a ratio of 6:4 in the deactivation of S [dye *(10)*][20]. In contrast with the general view, therefore, the pathway according to Figure 16b cannot be disregarded in comparison with that according to Figure 16a.

4.2. Deactivation of an Excited, Nonfluorescent Dye

An optically excited molecule can be deactivated by emission of fluorescence or by radiationless processes. In the case of a dye that emits no detectable fluorescence, radiationless deactivation processes predominate. In the presence of an acceptor, energy transfer competes with these processes. The emission of a sensitized fluorescence is therefore to be expected in the case of a fluorescent acceptor.





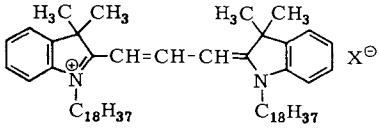


Fig. 17. Sensitized fluorescence of an acceptor layer A after energy transfer from a nonfluorescent sensitizer layer S at a distance of 54 Å. Structure of the sample (top, schematic), photograph of the fluorescence on excitation with violet light ($\lambda = 405$ nm, bottom). Zone 1: S only, no fluorescence; zone 2: sensitized fluorescence of A (red), zone 3: S missing, no fluorescence.

Figure 17 shows a photograph of the fluorescence of a system containing a layer of the azo dye *(12)* (S) and a layer of the fluorescent cyanine dye *(13)* (A) separated by a distance of 54 Å on excitation with blue light. Zone 3 of

(12)

(13)

the sample has no azo dye layer; no fluorescence is observed in this region, whereas the sensitized fluorescence of A is distinctly visible in zone 2. Zone 1 has no A, and exhibits no fluorescence[21].

The distance law, and hence the important parameter d_0, can be determined by measurement of the relative intensities of the sensitized fluorescence. The intensity I_d of the

sensitized fluorescence of A for a distance d between the layers of S and A should then theoretically be given by the relation[22]:

$$(I_d/I_0)_A = [1 + (d/d_0)^4]^{-1} \quad (3)$$

where d_0 is related to q by eq. 2 in Section 2.1.

The energy transfer method thus allows the determination of the quantity q, even in cases of sensitizers that do not emit detectable fluorescence. For the azo dye considered here, it was found that $q = 0.003$[21].

The lowest vibronic level of the singlet excited state of the azo dye can be depopulated by the acceptor, and one can therefore deduce from the intensity of the sensitized fluorescence how many molecules of the nonfluorescent dye have reached this state. By comparison with the number of primarily excited molecules, it is possible to calculate the probability p with which an excited molecule reaches the lowest vibronic level of the excited singlet state. It was found that $p = 0.2$. The quantum yield q' of the azo dye that does not exhibit detectable fluorescence is therefore[21]

$$q' = p \times q = 0.2 \times 0.003 = 6 \times 10^{-4} \quad (4)$$

4.3. Determination of the Multipole Nature of the Emitter by the Energy Transfer Method

For the description of the luminescence and of the energy transfer, it is useful to describe the radiating molecule as an antenna, which gradually dissipates its energy *via* the electromagnetic field or transfers it to the acceptor. Though the emission of light is in reality a discrete process, the classic approach is useful, since it is particularly simple, and the results can be readily translated into the language of the quantum theory. The radiation power L_e given by the classical model can be used to find the probability dW with which the excited molecule emits the light quantum (energy $h\nu$) in the time dt:

$$dW/dt = L_e/h\nu \quad (5)$$

The probability that light is manifested to the usual detectors as a light quantum in a given space and time interval is given by the electric field strength in the electromagnetic field.

A fluorescent molecule can always be described as an oscillating electric dipole, since the fluorescence corresponds to an allowed transition. In phosphorescence (a forbidden transition from the triplet excited state to the ground state of the dye), practically nothing is known about the multipole nature[23]. It is conceivable that the molecule behaves as an electric dipole emitter, but also as a magnetic dipole emitter or an electric quadrupole emitter. In addition to L_e, it is necessary to consider the power L_t that the molecule dissipates radiationlessly to its environment. The quantum yield q defined in Section 2.1 is then determined by the two quantities:

$$q = L_e/(L_e + L_t) \quad (6)$$

An acceptor molecule is now brought to a point at which the electric field strength in the electromagnetic field of the oscillating emitter has the amplitude F_0. The power L_a absorbed by the acceptor is[6]

$$L_a = aF_0^2 \quad (7)$$

where a is a constant.

If the distance r between the emitter and the acceptor is small compared with the wavelength of the luminescence, F_0 is given directly by Coulomb's law or the induction law (Fig. 18). F_0 is proportional to $1/r^2$ for magnetic dipoles, proportional to $1/r^3$ for electric dipoles, and proportional to $1/r^4$ for electric quadrupoles. The power L_a absorbed by a planar layer of acceptors is found by summation over the contributions of all the molecules in the layer. The parameter a introduced above is a measure of the power absorbed by an acceptor molecule in a field alternating with frequency ν. Its value is related to the extinction coefficient of the molecule for light of frequency ν.

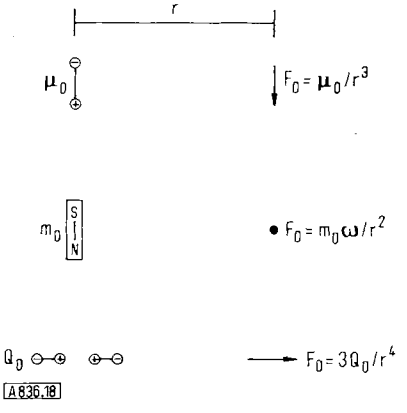

Fig. 18. Oscillating emitters [electric dipole (amplitude μ_0), magnetic dipole (amplitude m_0), circular frequency $\omega = 2\pi\nu$), and electric linear quadrupole (amplitude Q_0)] and amplitude F_0 of the electric field strength at a distance r from the emitters (r small in relation to the wavelength of the luminescence).

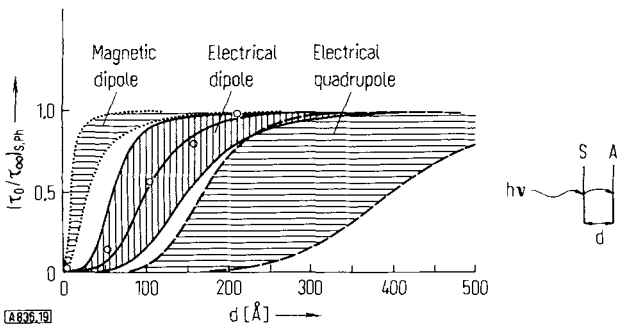
The fraction of the energy of the excited molecules that is emitted in the presence of the acceptor is given by the ratio $L_e/(L_e + L_t + L_a)$. Since the energy transfer to the acceptor competes with the emission of radiation and with the radiationless deactivation in the molecule, the average lifetime of the excited state (τ_d), and hence the decay time of the luminescence, is inversely proportional to this ratio. For an acceptor layer having absorption A, we obtain the relation[6, 24]

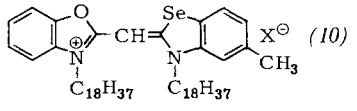
$$(\tau_d/\tau_\infty)_S = [1 + (d_0/d)^p]^{-1} \quad (8)$$

with

$$d_0 = \alpha \frac{\lambda}{n} (qA)^{1/p}$$

where $p = 2$ for a magnetic dipole, $p = 4$ for an electric dipole, and $p = 6$ for an electric quadrupole. α is a steric factor, which can assume values between 0.069 and 0.21[24], λ is the wavelength of the luminescence, and the quantum yield q may lie between the value 1 and the value of q' (Section 2.1).





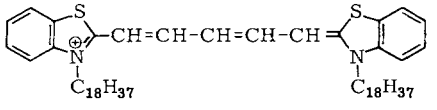


Fig. 19. Decay time $(\tau_d/\tau_\infty)_S$ of the phosphorescence of a layer of S [dye *(10)*] plotted against the distance d from the layer A [dye *(14)*]. Circles: experimental values. The experimental values must lie within the shaded areas for the given emitter types for this system of S and A: the emission of phosphorescence by S is therefore attributable to an electric dipole transition.

Insertion of the experimental values for the example investigated, with the largest and smallest possible values for α and for q, gives the curves in Figure 19 when τ_d is plotted against d. As can be seen from the figure, the quantity d_0 is at most 30 Å for a magnetic dipole, at least 170 Å for an electric quadrupole, and between 60 and 150 Å for an electric dipole. A decrease in the decay time of the phosphorescence can in fact be detected at greater distances[24].

(10)

(14)

The experimental points (Fig. 19) lie on the curve expected for the electric dipole, and a value of $d_0 = 100$ Å is found. This experimental value shows that an electric dipole transition predominates in the case considered here.

The result was confirmed by a second method based on the monolayer assembling technique[24,25]: By measurement of the angular dependence of the phosphorescence emitted by a monomolecular dye layer at an accurately fixed distance in front of a reflecting metal surface.

It would be interesting to realize the other cases experimentally, particularly that of the electric quadrupole emitter, in which the energy transfer should be possible over considerably greater distances than in the case of the electric dipole emitter.

4.4. Luminescence Lifetime of a Molecule in the Vicinity of the Interface between Dielectrics with Different Polarizabilities

The lifetime of the excited state of a molecule is shortened by transfer of part of the excitation energy to the acceptor, with the result that the quantum yield of the luminescence is decreased. Using the monolayer assembling technique it is possible to demonstrate the surprising effect that the lifetime can also be changed without variation of the luminescence quantum yield. The lifetime depends on the distance of the emitter from the interface between dielectrics with different polarizabilities[26-28].

To understand this effect, we again use the classical model for the sake of simplicity, and we again consider first the energy transfer from an excited molecule S, which may be described as a dipole oscillator, to an acceptor molecule A, which is situated in the alternating electric field of this oscillator (Fig. 20). In the classical approach, the oscillator

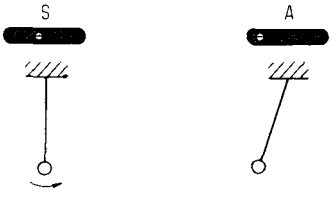

Fig. 20. Classical model of energy transfer. The acceptor molecule A is situated in the electric field of the oscillating dipole S. A oscillates under the influence of S with a phase shift relative to S, and dampens S: energy is transferred from S to A.

A may be described as a damped pendulum, which co-oscillates under the influence of the oscillator S, but with a phase difference with respect to the latter. The field of A in turn acts on the oscillator S and dampens it, so shortening its decay time. In the classical approach, energy is transferred from S to A.

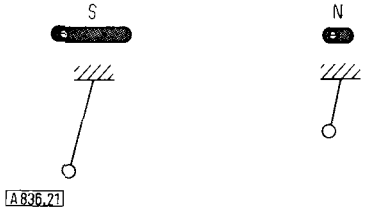

Fig. 21. Classical model of energy transfer. The nonabsorbing molecule N oscillates in phase with S, and does not dampen S: no energy is transferred from S to N.

If A is replaced by a nonabsorbing molecule, the corresponding oscillator is in phase with S, and it then has neither a dampening nor an accelerating effect (Fig. 21). But, this is not quite true, since the field of S takes a certain time to reach the nonabsorbing molecule, and a certain time is also required for the field from the oscillating nonabsorbing molecule to reach the position of S[6]. A certain phase shift thus results between the movement of the oscillator and the field from the induced oscillator. This echo reaches S only after a delay due to the finite propagation velocity of the electromagnetic field, and has an accelerating or retarding effect on the oscillator S, depending on the phase relation between the elongation of S and the echo field. Though the induced oscillator in this case absorbs no energy once it has been induced, the decay time of S is shortened or increased according to the phase relation. The initial excitation energy of the oscillator S is completely emitted as radiation; however, this process takes a shorter or longer time, according to the phase relation.

In the case of Figure 20, the power L_a is the decisive factor, and the effect of the co-oscillating charge of A on L_e is

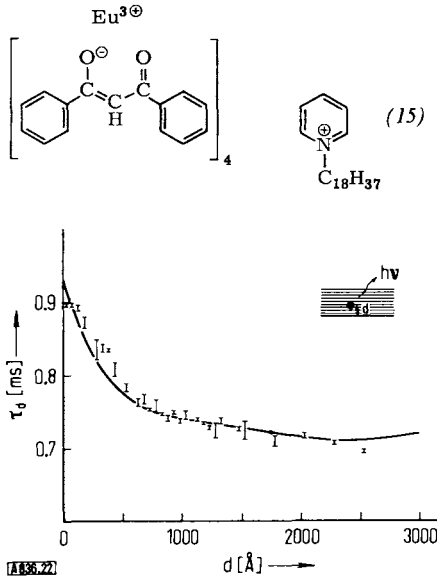

Fig. 22. Lifetime τ_d of the excited state of the luminescent europium complex *(15)* in a layer system as a function of the distance d between the layer of the complex and the interface between the layer system and air. The curve is found on assumption of an isotropic oscillator.

negligible. In the case of Figure 21, $L_a = 0$, and the power L_e emitted by the system as a whole depends on the distance between the oscillator S and the induced oscillator.

Instead of one nonabsorbing molecule, let us now consider many such molecules, *i.e.* a dielectric that is assumed to extend over the shaded area in Figure 22. The induced fields of each molecule add together, and the average lifetime of the sensitizer S is therefore a function of the distance d of the molecule from the interface. A simple relation[28], which is plotted in Fig. 22 for the case $q = 1$, is found for the lifetime τ_d of the luminescence of an isotropic oscillator.

Such an arrangement can be produced by incorporating the luminescent molecules into a layer system. The system is then excited by a light pulse, and the decay time of the luminescence is measured for different values of the distance d between the luminescent molecules and the interface between the layer system and air. The lifetime of the excited state as a function of the distance d is shown in Figure 22 for the europium complex *(15)*. The quantum yield has a very strong effect, and the agreement between the experimental and calculated values confirms the above value $q = 1$. The method should be of interest for the determination of the quantum yield q of the luminescence of the molecule in the luminescent state. Another method for the determination of q, which was described in Section 2.1, also gives the value $q = 1$ in the present case[3].

The emission of a light quantum by a molecule excited at time 0 is a stochastic process. It occurs earlier in one case and later in another, but one can speak of an average lifetime of the excited state. The fact that this average is not a constant of the molecule, but depends on the distance of the molecule from the interface (*i.e.* on the broad environment of the molecule), seems very surprising at first sight, but is immediately obvious in the above classical picture. The wave/particle duality of light is very clearly demonstrated by this result[29].

4.5. Primary Processes in Spectral Sensitization of Photographic Material

Silver bromide is practically insensitive to yellow or red light; a dye must be adsorbed on its surface to sensitize it (Fig. 23a). The dye molecule absorbs a quantum of light, and the electron that then passes into the conduction band of the silver bromide diffuses to an imperfection, where the nucleus of the latent image is formed. The reduction to metallic silver begins at this nucleus during the development process.

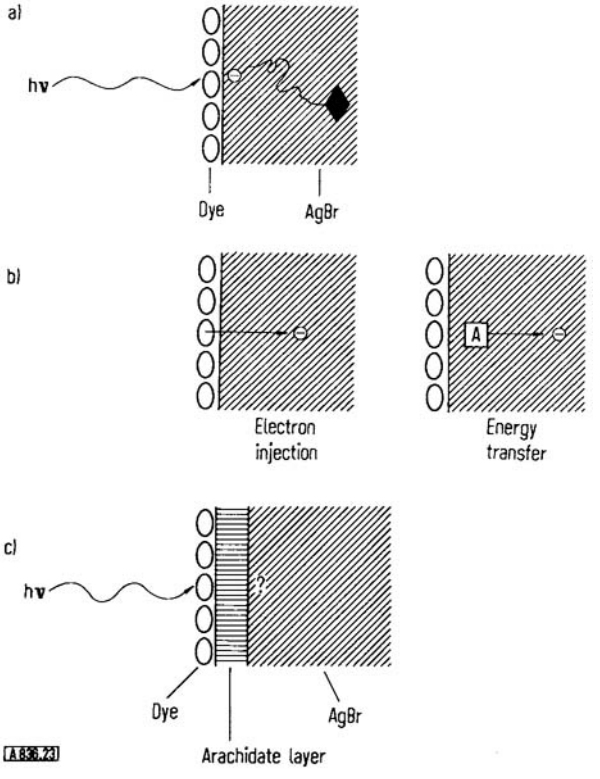

Fig. 23. Spectral sensitization of AgBr by a dye layer. (a) After absorption of light by the dye layer, a nucleus of the latent image is formed in the AgBr crystal. (b) Proposed mechanisms of spectral sensitization by excited dye molecules: electron injection into the conduction band of AgBr; energy transfer to acceptors in the boundary zone of the AgBr crystal, which then deliver an electron into the conduction band. (c) Method of differentiating between these mechanisms: suppression of electron injection by an arachidate layer between the dye and the AgBr.

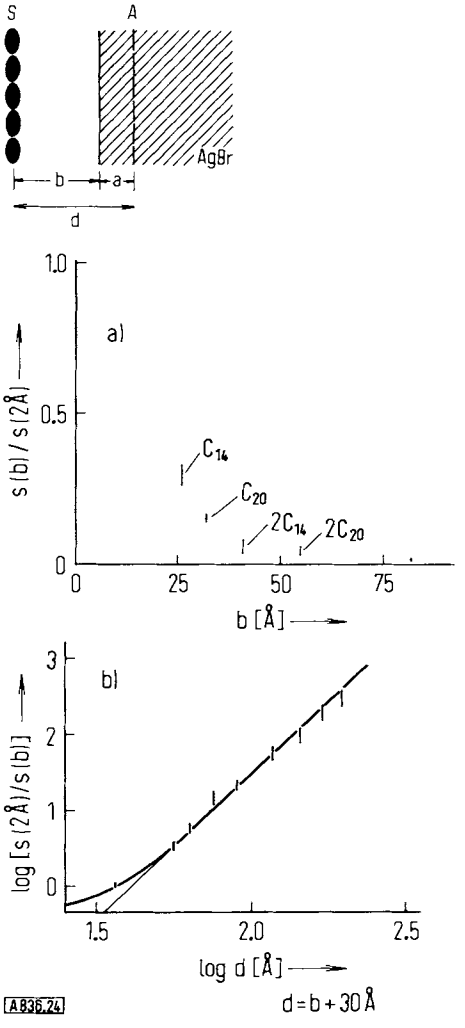
Two hypotheses have been proposed[30] regarding the formation of this conduction electron (Fig. 23b). According to the electron injection hypothesis, this electron originates in the dye. The electron that was promoted into a higher orbital of the dye molecule on absorption can tunnel into the AgBr. According to the energy transfer hypothesis, energy acceptors are situated in the vicinity of the surface of AgBr. After the absorption of the light quantum by the dye molecule, the excitation energy is transferred to such an acceptor. The excited acceptor can deliver an electron to the conduction band of the silver bromide.

The two possibilities are easily distinguished by fixing the dye molecule at a given distance, *e.g.* 30 Å, from the surface of the silver bromide (Fig. 23c). From the foregoing discussion, the energy transfer can take place readily over such a distance, whereas the tunneling of the electron becomes extremely improbable[31]. The dye molecule can be fixed at accurately defined distances from the AgBr surface by

the monolayer assembling technique with interposition of one or more layers of fatty acid. The system is exposed and developed, and one then observes whether a photographic image is produced. The image density is a measure of the sensitization s by the dye.

In Figure 24a, the distance b between the dye layer and the surface of the silver bromide is plotted on the abscissa,



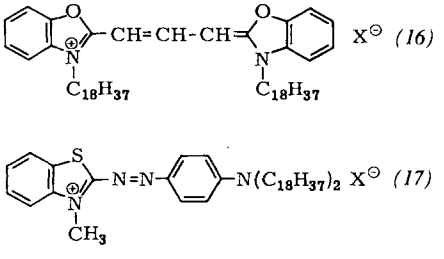


Fig. 24. Spectral sensitization of vacuum-deposited AgBr layers by a monomolecular layer of the dye *(16)* (S). (a) Sensitization $s(b)/s(2\text{ Å})$ as a function of the distance b from the dye chromophore to the AgBr surface (C_{14} = myristic acid, C_{20} = arachidic acid). (b) log $[s(2\text{ Å})/s(b)]$ as a function of the distance $d = b + 30$ Å between an assumed model acceptor layer and the dye chromophores. The curve shows the dependence expected from the energy transfer model. The slope of the straight line, corresponding to this model, is $p = 4$.

while the ratio of the sensitization $s(b)$ at distance b to the sensitization $s(2\text{ Å})$ with direct contact is plotted on the ordinate[32]. The desired distances are obtained by means of one or several monomolecular layers of C_{14} or C_{20} fatty acids. The figure shows that a distinct sensitization occurs at these distances, and decreases with increasing distance b.

The spectral sensitization of the photographic process can be investigated quantitatively at distances up to 300 Å. It is then weaker by a factor of about 1000 than with direct contact, but still large in comparison with the intrinsic sensitivity of silver bromide to the irradiated light of wavelength 500 nm. A photographic image that can be quantitatively evaluated can therefore be obtained by simply exposing for a sufficiently long time at a sufficiently high intensity.

The reciprocal of the sensitization is plotted in Figure 24b in a double-logarithmic graph against the distance d between the dye layer and the hypothetical layer of acceptors in the silver bromide. It is assumed here that these acceptors are situated at an average distance a of about 30 Å below the surface of the silver bromide. The curve agrees with expectations based on the Perrin-Förster theory of energy transfer, according to which s is proportional to $[1+(d/d_0)^4]^{-1}$. d_0 is the distance between the sensitizer and acceptor layers at which every second excited sensitizer molecule just loses its excitation energy by energy transfer to the acceptor. The figure shows the good agreement between theory and experiment over this wide measurement range. The slope of the tangent to the curve gives the exponent in the distance law, and the expected value of 4 is obtained. The intercept of the tangent with the abscissa gives a value of 54 Å for the quantity d_0. The absorption A_s (1-transmission) of the hypothetical acceptor layer at the wavelength of the emission of S can be calculated from the value of the quantity d_0 [cf. eq. (2), Section 2.1]. d_0 is proportional to $A_s^{1/4}$, and one obtains the value $A_s = 10^{-4}$. Since this value is so small, direct spectroscopic identification of these hypothetical acceptors in silver bromide has not yet been accomplished.

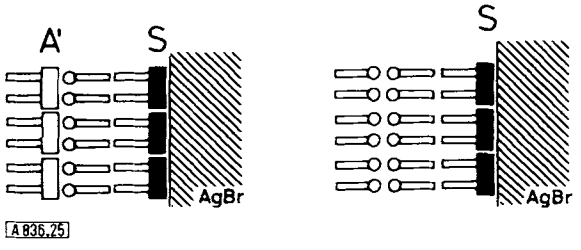

Fig. 25. Effect of a competitor A' [dye *(17)*] for the acceptors in AgBr. A' reduces the sensitization of the photographic process by S [dye *(16)*]. The agreement of the experimental reduction with that calculated on the basis of the energy transfer model shows that there is no electron injection from the excited sensitizer into the AgBr in this case.

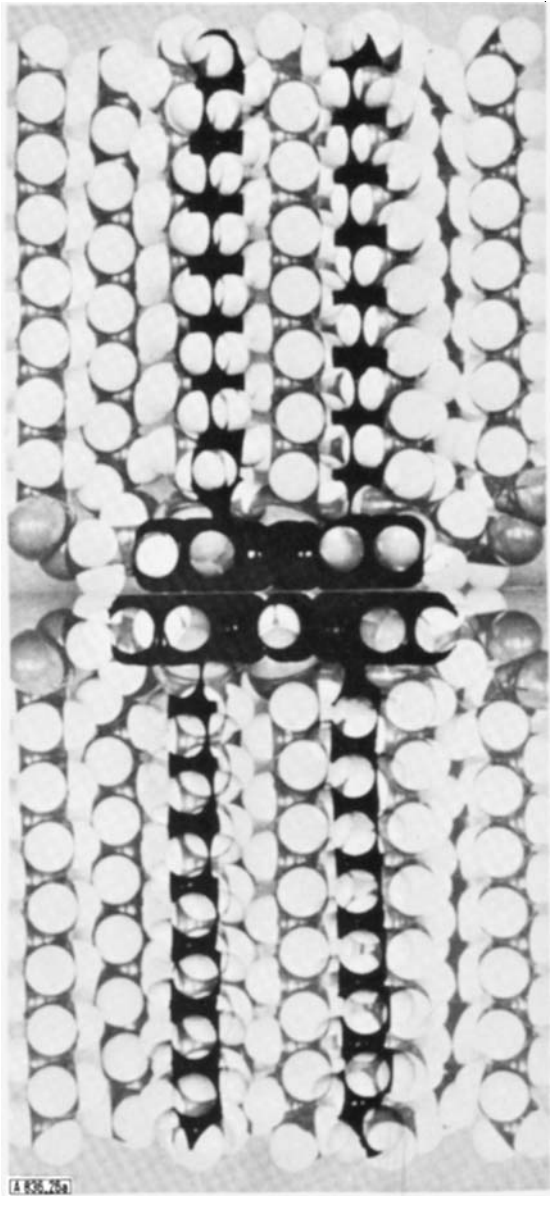
As a further check of these results, let us consider a system in which the sensitizer [dye *(16)*] adheres to the surface of the silver bromide, and in which a monomolecular layer of the dye *(17)* (A') is situated at a distance of about 50 Å from the sensitizer layer[32] (Fig. 25). A' is so chosen that it acts as an acceptor for the excitation energy of S, *i.e.* its absorption band overlaps with the fluorescence band of S. A' should therefore compete with the energy acceptors in the silver bromide, and so reduce the sensitizing action of S. It is possible to calculate the amount by which the sensitization should be reduced at the given distance; the reduction is in fact found to be as expected.

If electron injection also played an important part in the case of direct contact, the energy acceptors A′ would be less effective as competitors.



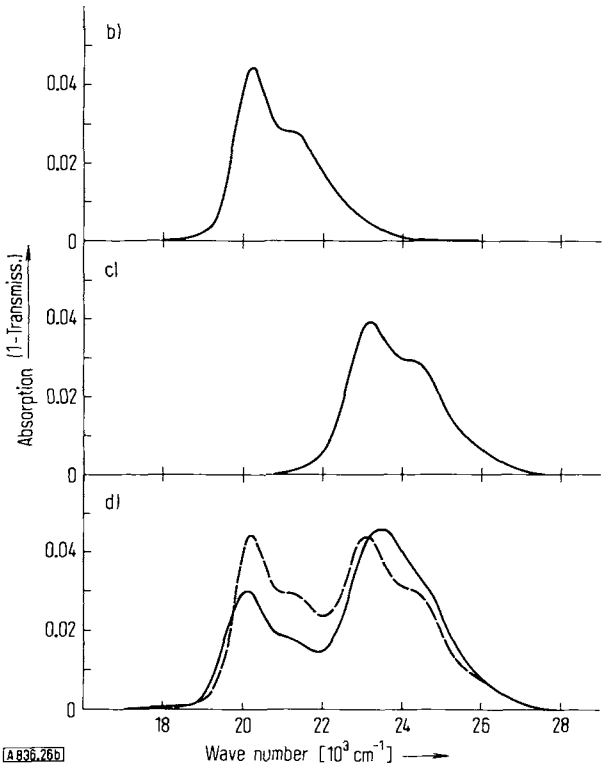
$s_{\text{without A'}}/s_{\text{with A'}} = 1.4 \pm 0.2$ (calc. 1.4)

The results obtained can thus only be explained by the energy transfer hypothesis. It is not yet known how far generalization of the results to other cases of photographic sensitization is possible.

5. Light Absorption by Dye Aggregates in Monomolecular Layer Systems

5.1. Absorption by Sandwich Aggregates

The weak interaction between relatively distant molecules has been discussed above. We shall now examine the interaction between adjacent dye chromophores. The monolayer assembling technique offers a possibility of positioning chromophores sandwich-like one over another[29]. It is possible in this way to produce systems in which the chromophores of the same dye or of different dyes are in direct contact, while the paraffin substituents are anchored in the layers (Fig. 26a). These systems give absorption spectra in which the interaction between the chromophores is reflected.



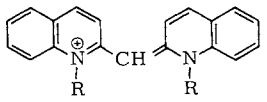


Fig. 26. Formation of mixed dimers of cyanine dyes in sandwich systems of monomolecular layers. (a) Model of a pair of molecules in mixed layers. Absorption as a function of the wave number (b) and (c) in the case of isolated chromophores of the dyes *(16)* and *(2)*, respectively, (d) in the case of molecule pair formation (full curve). The broken curve is the sum of the spectra of (b) and (c).

The absorption spectrum given by the pair of dyes *(16)* and *(2)* is shown by the continuous curve in Figure 26d, while the broken curve is the result of superposition of the absorption spectra (Fig. 26b and 26c) of the individual dye layers[33]. In the case of the pair, the long-wave band is weakened and displaced to longer wavelengths, while the short-wave band is intensified and displaced to shorter wavelengths. This effect can be understood from the coupled oscillator model. This model represents the result of the quantum mechanical calculation, by which the coupling coefficients of these oscillators are evaluated. With the electron gas model the band shifts and intensity changes due to aggregation have been calculated in a number of cases and the differences between experimental and theoretical values were less than 30%[33].

5.2. Absorption of Scheibe Aggregates

This model is applied below to Scheibe dye aggregates[34], *i. e.* to aggregates of dye molecules that have a very narrow, intense absorption band and a narrow fluorescence band that practically coincides with the absorption band[35].

According to *Förster*[36], this band may be assigned to an in-phase oscillation of the equivalent oscillators of all the dye molecules of the aggregate. In the case of the Scheibe pseudoisocyanine [dye *(18)*], the narrow band of the

(18), R = C_2H_5
(19), R = $C_{18}H_{37}$

associate is displaced by 53 nm to longer wavelengths as compared with the monomer band in aqueous solution. The calculation gives the opposite sign for the structures proposed so far[37], *i.e.* the "staircase" or the "ladder" arrangement (Fig. 27), and the same sign but a much smaller value for a structure proposed by *Bird et al.*[38].

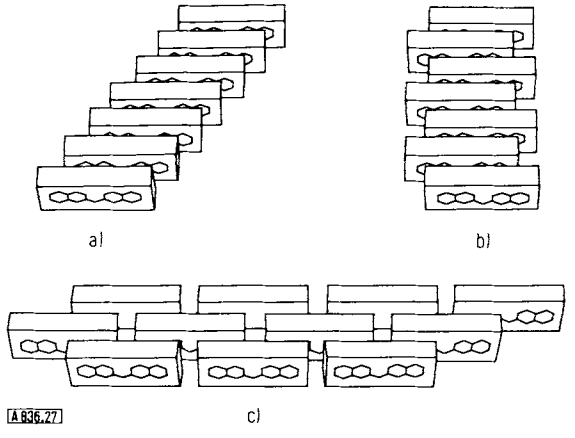

Fig. 27. Structural model for Scheibe aggregates of the cyanine dye *(18)*. (a) Staircase model (−40), (b) ladder model (−52), (c) brickwork arrangement (+44). The figures are the theoretically expected shifts ($\lambda_A - \lambda_M$) of the aggregate band in relation to the monomer band in the absorption spectrum given in nm.

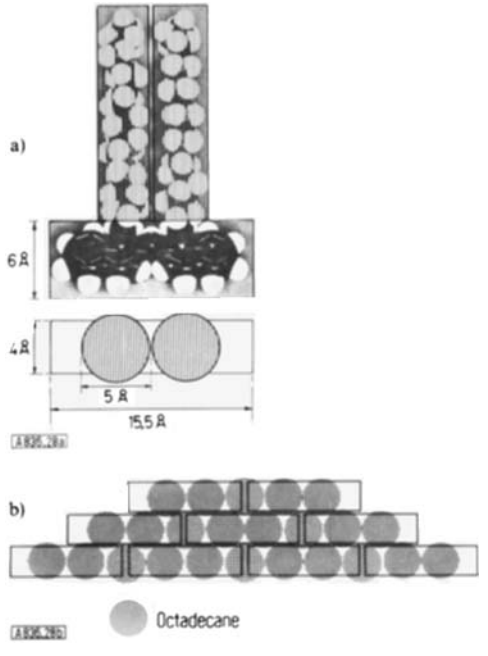

Fig. 28. Structure of Scheibe aggregates (brickwork arrangement). (a) Model of the cyanine molecule *(1)*, views from the side and from above. Chromophore represented as a block and stearyl residues as cylinders. (b) Filling of the gaps between the stearyl residues of the close-packed dye molecules with octadecane gives optimum packing of the stearyl substituents. A mixed layer in the ratio dye: octadecane (1:1) should form Scheibe aggregates particularly well.

A new proposed structure (Fig. 27c, "brickwork" arrangement) gives the correct band shift[34].

One can now try to find a controlled way of producing Scheibe aggregates, even in the case of dyes for which no such aggregates have previously been known[39]. The cyanine molecule *(1)* can be approximately described as a squared block having the dimensions shown in Figure 28a, on which are situated the two cylinders corresponding to the hydrocarbon substituents. It is obvious from this model that close packing of the chromophores is possible only if the paraffin chains are also made to coincide with gaps, *i.e.* the chromophores must be in the brickwork arrangement (Fig. 28b). Such an arrangement is close-packed with regard to the chromophores, but not with regard to the paraffin residues. The layer structure of the hydrocarbon substituents contains a hole large enough for exactly one paraffin chain for each dye molecule. If a mixture of this dye with a long-chain hydrocarbon, *e.g.* octadecane, is spread on a water surface in a molar ratio of 1:1, one would expect a stable mixed layer to be formed, *i.e.* it should be possible in this way to force the formation of Scheibe aggregates. This is in fact found. The typical Scheibe absorption and fluorescence bands are observed (Fig. 29). Table 1 shows that the calculated band shifts of the Scheibe aggregate in relation to the monomer agree well with experiment for several cases.

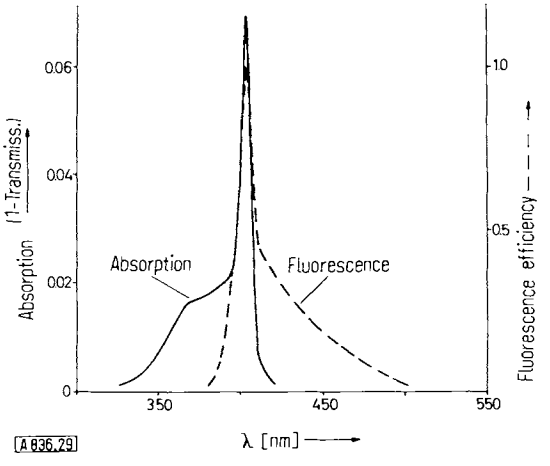

Fig. 29. Absorption and fluorescence spectra of a mixed layer of the dye *(1)* and octadecane in a molar ratio of 1:1. The sharp absorption and fluorescence band at 403 nm is attributable to Scheibe aggregates.

Table 1. Scheibe aggregates of dyes in monomolecular layers. A = aggregate, M = monomer.

Dye	Wavelength of absorption maximum		$\lambda_A - \lambda_M$ (nm)	
	λ_A (nm)	λ_M (nm)	calc.	exp.
(1)	403	388	23	15
(2)	458	432	23	26
(19)	577	533	54	44

When forming the monolayer under usual conditions (increasing the surface pressure to its final value of 30 dyn/cm within less than one minute), the band occurs only in a narrow range of mixing ratios of dye and octadecane of about 1:1. When increasing the surface pressure to its

final value in more than 15 minutes, Scheibe aggregates occur even in pure monolayers of stearyl-substituted cyanine dyes such as *(1)* or *(3)*[40]. Thus the close packing with regard to the paraffin residues as well as the close packing of the chromophores facilitates the formation of the Scheibe aggregates, but is not a necessary condition for their formation.

6. Electrical Phenomena in Layer Systems

6.1. Change in Absorption in an Electric Field

A Scheibe associate monolayer can be incorporated in the usual manner into a system of arachidate layers. The layer system may be prepared on a glass plate with a vacuum-deposited aluminum layer, and covered with a second vacuum-deposited aluminum layer. The result is a capacitor, in which an electric field F of up to 5×10^6 volt/cm can be readily applied to the molecules by application of a potential difference of a few volts[41] (Fig. 30). This leads to a change in the excitation energy $(\Delta E - \Delta E_0)$, *i.e.* a displacement of the absorption band, consisting of a component that depends linearly on F and another component that depends on the square of F:

$$\Delta E - \Delta E_0 = \Delta\mu_y F + \tfrac{1}{2}\Delta\alpha_{yy}F^2 \qquad (9)$$

The shift is given by the changes in the dipole moment $(\Delta\mu_y)$ and in the polarizability $(\Delta\alpha_{yy})$ in the direction of the applied field (y direction). Both components can be easily

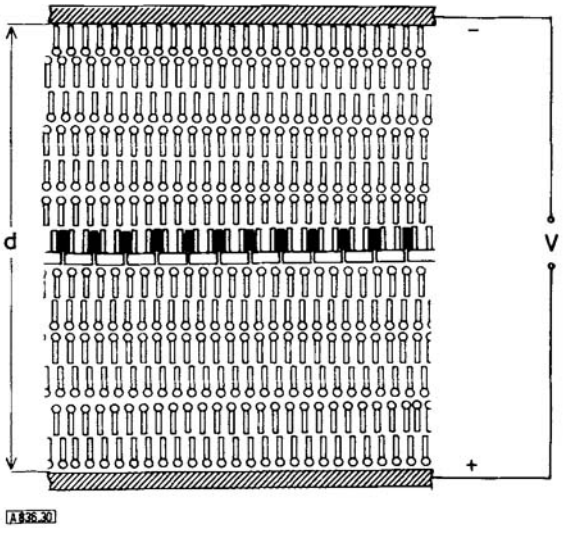

Fig. 30. Investigation of the change in the light absorption of dye molecules on application of an electric field. Layer system with incorporated dye layer between two vacuum-deposited metal layers.

estimated on the basis of the electron-gas model. A consideration in which the branching of the π-electron system is disregarded is sufficient for the first component. The chromophore system then extends over the shaded region in Figure 31a. The wave function of the electron in the highest occupied level has the $1\frac{1}{2}$-cycle wave shown at the bottom left, while on excitation, the electron assumes the two-cycle wave. The points of highest electron density are situated in the antinodes of the wave. It can be seen that on excitation of the molecule, the cloud in the center of the chain is replaced by two clouds underneath, *i.e.* negative charge flows downward in the diagram on excitation, as indicated schematically in Figure 31b.

Thus if the applied field is directed as in Figure 31b, the electron gains energy from the field on excitation, and moves toward the positively charged plate. The absorption band of the individual molecule thus moves toward lower energies on excitation in the field. This results in a corresponding shift of the band of the aggregate; in the classical picture, the equivalent dipole of each dye molecule oscillates more slowly, and the frequency of the coupled in-phase oscillation of these oscillators in the aggregate is also smaller. Reversal of the direction of the applied voltage must lead conversely to a band shift toward higher frequencies. According to this argument, therefore, a linear electrochromic effect is expected, and a value of about +0.2 debye is calculated for $\Delta\mu_y$. The change in polarizability can be determined similarly, and one finds the value $\Delta\alpha_{yy} = +3$ Å^3.

The displacement of the absorption maximum on application of an electric field can be determined experimentally from the change in the absorption. (To obtain simple conditions, the distance between the semitransparent aluminum layers to which the field is applied must be such that the arrangement acts as an interference filter for the measuring light.) One then finds the values $\Delta\mu_y = 0.07$ debye and $\Delta\alpha_{yy} = 1.5$ Å^3, which agree in their signs with expectations ($\Delta\mu_y = 0.2$ debye; $\Delta\alpha_{yy} = 3$ Å^3). In the methods available until now[42], in which molecules are oriented simultaneously by the electric field, it was impossible to separate the dipole moment component from the polarizability component, since both components lead to a quadratic field effect.

6.2. Tunneling of Electrons through Monomolecular Layers

Capacitors consisting of two metal layers and a thin insulating layer can be produced by the monolayer assembling technique. What should happen when a voltage of *e.g.* 1 V is applied to such a capacitor with an insulating layer 30 Å thick? An electron in the metal that hits the potential barrier of the insulator has insufficient energy to overcome this barrier, and it is reflected from the barrier. Because of the wave nature of the electron, however, there is also a certain probability of finding the electron on the other side of the potential barrier, *i.e.* of penetration of the barrier by the electron. This probability is about 10^{-14} in the case of a potential barrier of 1 eV and a barrier thickness of 30 Å, corresponding to an arachidate layer. Thus for every 10^{14} electrons that strike the barrier, only one penetrates. Because of the large number of free electrons in the metal, a measurable current is expected despite the low probability of tunneling. The probability of finding an electron on the other side after it strikes the barrier decreases exponentially with increasing thickness d. Therefore, the same dependence on the barrier thickness is also to be expected for the current.

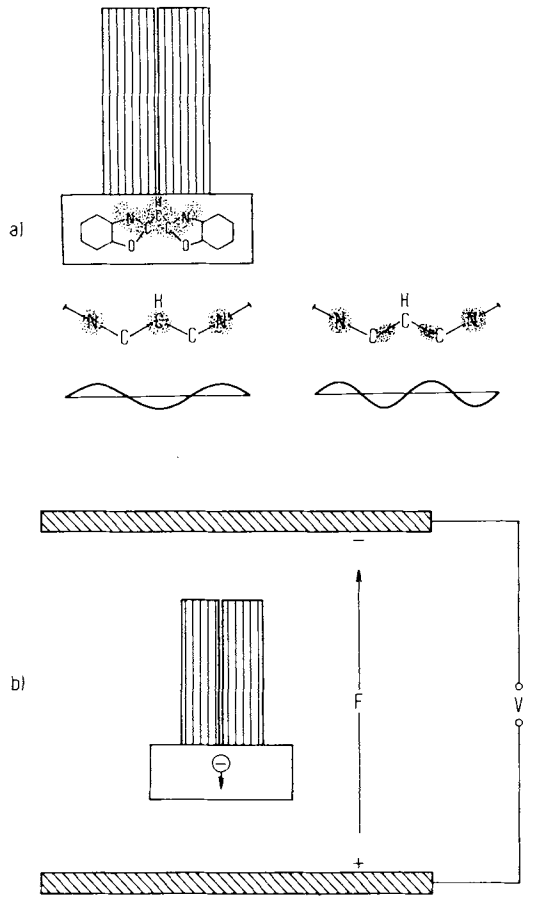

Fig. 31. Change in the excitation energy of a cyanine dye molecule in an electric field. (a) Molecular model showing region of the π-electron system that determines the light absorption. Clouds correspond to the electron wave function in the ground state (left) and in the first excited state (right). The center of gravity of the clouds migrates downward on absorption of light. (b) On absorption of light, negative charge shifts toward the positive electrode. The excitation energy is therefore decreased by the applied electric field.

To determine this dependence experimentally, a monomolecular layer of a fatty acid is first deposited on a microscope slide with a vacuum-deposited aluminum layer. This layer of fatty acid is then covered with mercury or with a vacuum-deposited layer of lead, aluminum, or gold[43, 31]. The tunneling current is in fact found to decrease exponentially with increasing thickness of the fatty acid layer (Fig. 32), and the effects due to the electrode metal (Hg, Al, Pb, Au) can also be quantitatively interpreted.

The excellent agreement between theory and experiment is an extremely sensitive test of the uniformity of the monomolecular layers. Holes or conducting impurities in the layer would strongly influence the electric resistance.

This can be illustrated by an arrangement having an area of 1 cm^2 and a resistance of 1.8×10^7 ohm, *e.g.* in the case of an arachidate layer between an aluminum electrode and a mercury electrode. Let us assume that the fraction $1:10^5$ of the total area exhibits layer imperfections (Fig. 33). Let the distance between the metal electrodes over this small part of the area be slightly reduced, *e.g.* to $\frac{2}{3}d = 18$ Å in the case of an arachidate layer. The properties of the dielectric are assumed to be unchanged. The probability that an electron in the Fermi level will tunnel through the barrier on collision is 10^{-18} for 28 Å and $10^{-18(2/3)} = 10^{-12}$ for 18 Å (Fig. 33). The ratio of the electric current through

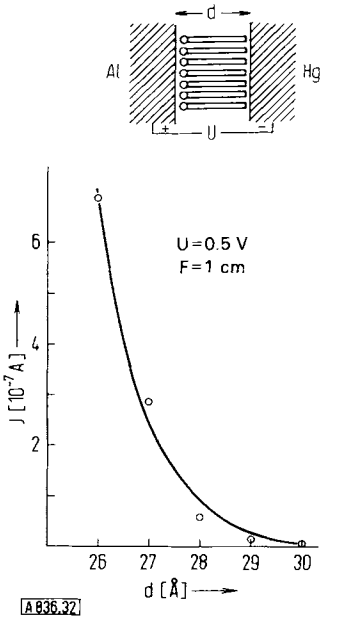

Fig. 32. Experimental investigation of the tunnel effect of electrons. A monomolecular fatty acid layer of thickness d is situated between two metal layers. Current J as a function of d for an area of $F = 1$ cm^2 at an applied voltage of $U = 0.5$ V (Al positive). Circles: experimental values. The curve follows an exponential function.

the layer imperfection to the current through the intact layer in the case considered here is therefore

$$(10^{-12} \times 10^{-5})/10^{-18} = 10$$

The tunneling current due to the imperfection is thus large in relation to the remainder of the current (which agrees with the observed value). This consideration leads to the

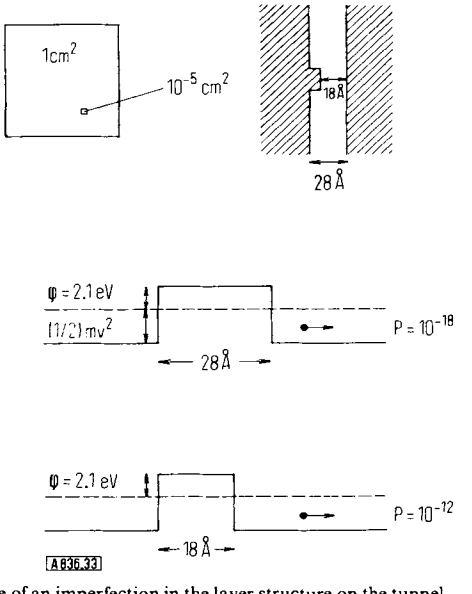

Fig. 33. Influence of an imperfection in the layer structure on the tunneling current. The thickness d of the undisturbed layer is 28 Å. The probability P for tunneling of an electron through the indicated potential barrier is $P = 10^{-18}$, while in the region of the imperfection with $d = 18$ Å, $P = 10^{-12}$. For imperfections amounting to 10^{-5} of the total surface, the tunneling current through the imperfection is ten times that through the intact sample.

conclusion that there is not even such a small proportion of seemingly unimportant layer imperfections.

The negative results of earlier attempts to measure the dependence of the tunneling current on the thickness of the insulating layer in arrangements with monomolecular layers were probably due to this strong sensitivity to imperfections in the layer.

6.3. Photo Current in Monolayer Assemblies

Fig. 34 gives an example of an assembly to investigate the photoconductivity in an organized arrangement[44]. A semitransparent Al layer is coated with several arachidate layers, one monolayer of quinquethienyl *(20)* (mixed layer with arachidate, molar ratio 1:3), and some more layers of arachidate. The second electrode is mercury. The long axes of the quinquethienyl molecules are oriented perpendicular to the layer[44]. A bias voltage U is applied. On illumination of the sample with UV light a photocurrent occurs (rise time less than 2 ms) whose action spectrum agrees with the absorption spectrum of the quinquethienyl layer. The current increases exponentially with increasing voltage U and is proportional to the ratio x/d (x distance between dye monolayer and positive electrode, d distance between the electrodes).

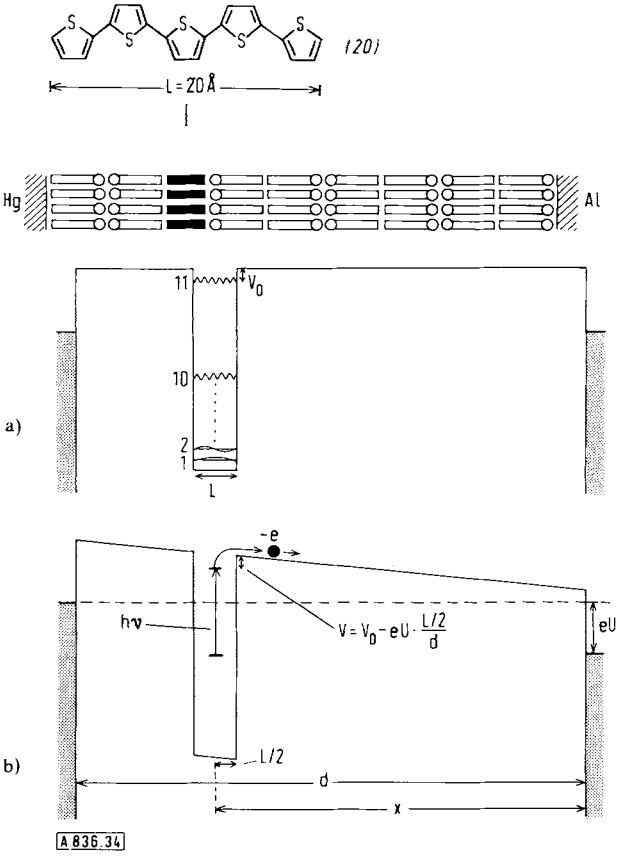

Fig. 34. Photocurrent in monolayer assembly. Monolayer of dye *(20)* between arachidate layers sandwiched between metal electrodes. (a) Potential energy of an electron. Occupied π-electron orbitals 1—10, empty orbital 11. (b) Potential energy when applying a bias voltage U. Energy levels of orbitals 10 and 11. By absorption of light an electron is promoted from orbital 10 to 11 and subsequently lifted to the top of the potential barrier of the arachidate by thermal collisions. Then it moves to the positively biased metal.

When exciting the dye in the arrangement without an applied voltage (Fig. 34a) the electron jumps from the highest occupied to the next orbital and falls back to the ground state, after an average lifetime of the excited state, τ, of about 10^{-11} s. Alternatively, this electron in the excited level of the molecule is thermally excited to the top of the energy barrier of the arachidate and can separate from the dye molecule. When a voltage U is applied to the arrangement, the electron then moves to the positively biased metal (Fig. 34b). The energy barrier between the dye molecule and the positive electrode is diminished by applying the voltage U and according to Fig. 34 this barrier V is

$$V = V_0 - eU\frac{L/2}{d} \tag{10}$$

e is the elementary charge and L the length of the π-electron system. When illuminating the system, n_0 molecules per unit time are excited and n electrons per unit time climb the energy barrier of the arachidate layer. ν_{th} being the frequency of thermal collisions, $\nu_{th}\cdot\tau$ is the number of collisions of the electron during the lifetime of the excited molecule, thus:

$$n = n_0\nu_{th}\tau\exp\left(-\frac{V}{kT}\right) \tag{11}$$

k is Boltzmann's constant and T is the absolute temperature. The current in the external circuit is

$$J = n\cdot e\frac{x}{d} = n_0\nu_{th}\tau e\cdot\frac{x}{d}\cdot\exp\left(-\frac{V_0}{kT}+\frac{eL}{2kTd}U\right) \tag{12}$$

(The charge accumulation in the dye layer is compensated in the dark period in a time large compared with the time of illumination and thus this effect does not influence the photocurrent.)

The observed exponential increase of J with U and the proportionality with x/d is explained by equation (12). By comparison of (12) with the experimental data the value $L = 20$ Å is found, which agrees with the actual length of the molecule. With the known or easily approximated values of the quantities e, n_0, ν_{th}, τ the value $V_0 = 0.4$ eV is obtained. By the tunneling experiments discussed in Section 6.2, $\kappa = 2.2$ eV, where κ is the energy to lift an electron from the top of the arachidate potential barrier up to the vacuum level.

Thus the ionization energy of an electron in the excited level of the dye molecule to vacuum is $I^* = V_0 + \kappa = 2.6$ eV. A value of the order of 3 eV[45] is predicted by theory.

The stearyl-substituted cyanine dyes were prepared by J. Sondermann[46]. *The authors gratefully acknowledge financial support by the Deutsche Forschungsgemeinschaft, the Verband der Chemischen Industrie, and the Adolf-Haeuser-Stiftung.*

Translation of Genetic Information on the Ribosome[**]

By Gerhard Schreiber[*]

The information for protein structure that is contained in the base sequence of the nucleic acids is translated on the ribosome into the amino acid sequence. This translation can be divided into chain initiation, chain growth, and chain termination. Several specific protein factors and nucleic acids are involved in each section.—For chain initiation, start complexes are formed from the initiating amino acyl-tRNA, mRNA carrying the start signal, and the small and large subunits of a ribosome. GTP and the initiating factors are also involved in this process.—In chain elongation, one amino acid at a time is transferred, in a reaction cycle, from the linkage with tRNA into a linkage with the polypeptide chain. The amino acid to be incorporated is initially bound to the ribosome as amino acyl-tRNA, a process for which GTP and protein factors are necessary. The subsequent formation of a peptide linkage is catalyzed by the peptidyl transferase of the large ribosomal subunit. The peptidyl-tRNA with its newly added amino acid residue is then transferred from the amino acyl-tRNA acceptor site A to the peptidyl donor site P of the ribosome. This requires another protein factor and cleavage of GTP into GDP and phosphate.—Chain termination begins as soon as one of the three terminator triplets UAA, UAG, or UGA in the mRNA reaches the ribosome. The mRNA is moving in relation to the ribosome from the 5' end to the 3' end. Release of the completed polypeptide chain from the ribosome is dependent on release factors. Before initiation of a new polypeptide chain, the ribosomes dissociate into their subunits.

1. Introduction

The amino acid sequence of the proteins of a cell is determined by the base sequence of the deoxyribonucleic acids (DNA) of the cell. The information encoded in the base sequence of the DNA is transformed into the amino acid sequence of proteins in two steps. The base sequence of a DNA is first transcribed into the base sequence of a messenger ribonucleic acid (mRNA). The base sequence of the mRNA is then translated on the ribosome into the amino acid sequence of the protein. The translation process can be broken down into three sections:

1. Initiation of the polypeptide chain.
2. Elongation of the polypeptide chain.
3. Termination of the polypeptide chain.

The reactants that take part in the three sections are shown in Table 1. Details are described below.

Table 1. Reactants in translation.

Reaction	Reactants
Chain initiation	Initiating amino acyl-tRNA Mg^{2+} mRNA (initiation region) Initiation factors (F_1, F_2, F_3) [a] Small and large subunit of ribosome GTP
Chain elongation	Amino acyl-tRNA Mg^{2+}, K^+, or NH_4^+ mRNA Binding factors (T_u and T_s) [a] Factor G (translocase) Ribosome GTP
Chain termination	mRNA (termination region) Release factors (R_1 and R_2) [a] Factor S Dissociation factor Ribosome

[a] The designations for the factors found in *E. coli* are given in parenthesis.

[**] Based on a lecture delivered in Freiburg on Feb. 3, 1970. The literature is so extensive that a selection has been made here; a more comprehensive list covering publications up to the Spring of 1969 was published by *Lengyel* and *Söll* [1].

2. Initiation

2.1. Reactants

2.1.1. Initiating Amino Acyl-tRNA

Before the amino acids can be used for protein synthesis, they are activated with adenosine triphosphate (ATP) and bound to transfer ribonucleic acid (tRNA). This reaction is catalyzed by amino acyl-tRNA synthetases [eq. (1)]. The initiating amino acid is *N*-formylated methionine in bacteria, chloroplasts, and mitochondria[2–7], and unformylated methionine in eukaryotes[8]. Bacteria[9] and animal cells[8] each contain two methionine-transferring

$$\text{Amino acid} + \text{ATP} + \text{Enzyme} \xrightleftharpoons{Mg^{2+}} \text{Amino acid·AMP·Enzyme} + \text{PP}$$

$$\underline{\text{Amino acid·AMP·Enzyme} + \text{tRNA} \xrightleftharpoons{Mg^{2+}} \text{Amino acyl-tRNA} + \text{Enzyme} + \text{AMP}}$$

$$\text{Amino acid} + \text{ATP} + \text{tRNA} \xrightleftharpoons{Mg^{2+}} \text{Amino acyl-tRNA} + \text{AMP} + \text{PP}$$

$$\Delta G_0' \approx 0$$

$$\text{Enzyme} = \text{Amino acyl-tRNA synthetase} \qquad (1)$$

tRNA species, *i.e.* $tRNA_F^{Met}$ and $tRNA_M^{Met}$ in bacteria, and $tRNA_1^{Met}$ and $tRNA_2^{Met}$ in animals. Only $tRNA_F^{Met}$ and $tRNA_1^{Met}$ transfer methionine for chain initiation. In

bacteria, methionine that is bonded to $tRNA_F^{Met}$ is subsequently formylated to *N*-formylmethionine (fMet)[10]. Met-$tRNA_1^{Met}$, the initiating amino acyl-tRNA in the cytoplasm of the eukaryotes, need not be formylated for chain initiation[8]. $tRNA_M^{Met}$ and $tRNA_2^{Met}$ bind methionine that is to be incorporated into the interior of the polypeptide chain[11].

The specific tRNA for *N*-formylmethionine is characterized by a special arrangement of the complementary bases. Whereas base pairing begins on the fifth nucleotide from the 3'-OH end in the tRNAs transferring amino acids for chain elongation, *e.g.* $tRNA^{Ala}$ from yeast[12], the first complementary base pair in $tRNA_F^{Met}$ occurs in position six[13].

Methionine is formylated only *after* esterification with tRNA (Fig. 1). tRNA cannot bind *N*-formylmethionine[2]. The formyl group is provided by N^{10}-formyltetrahydrofolic acid[10, 14, 15]. The formylating enzyme, Met-tRNA transformylase, has been concentrated more than 1500-fold from *E. coli*[15]. Its molecular weight is only about 25000, and the sedimentation constant is 2.02, *i.e.* the enzyme is of roughly the same size as one of its substrates. X-ray analysis of the $tRNA_F^{Met}$ from *E. coli* with a resolution of 12 Å indicated an elongated molecular shape. According to this analysis, the $tRNA_F^{Met}$ molecule is in the form of a dimer with a length of 109 Å and a thickness of about 35 Å. A single molecule is 80 Å long, and has an irregularly shaped cross section with a "diameter" of 25 to 35 Å[16–18].

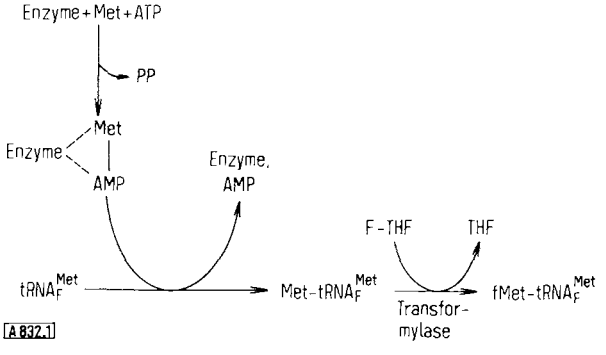

Fig. 1. Activation and formylation of methionine (Met) for chain initiation. THF = tetrahydrofolic acid, F-THF = N^{10}-formyltetrahydrofolic acid, enzyme = methionine-tRNA synthetase.

2.1.2. Mg^{2+} Ions

For a strictly fMet-tRNA-dependent initiation in cell-free systems, the Mg^{2+} concentration must be 4 to 8 mmole/l[19, 20]. Higher Mg^{2+} concentrations lead to nonspecific pseudo-initiations in which the synthesis starts in the middle of a protein instead of at the beginning[21, 22]. However, at high Mg^{2+} concentrations (11 mmole/l), the initiation of the synthesis of a polypeptide still takes place faster with formylmethionyl-$tRNA_F^{Met}$ and AUG (A = adenine, U = uracil, G = guanine) than with other amino acyl-tRNA species and their corresponding codons[23].

2.1.3. mRNA with the Chain Initiation Section

In the mRNA three bases code for each amino acyl-tRNA. The base triplets or codons corresponding to $tRNA_F^{Met}$ and $tRNA_1^{Met}$ are AUG and GUG[8, 9, 24, 25, 122]. The mRNA region providing the start signal for polypeptide chain synthesis must therefore contain the codon AUG or GUG. The mRNA is translated into amino acid sequence from the 5' end to the 3' end[26]. However, neither the triplet AUG nor the triplet GUG was detected among the first 50 nucleotides of the 5' end in bacteriophage RNA[27–30]. Determination of the base sequence of the initiation regions of the RNA of the bacteriophage R 17 showed that the first base of the initiating codon for the coat protein occurs only in position 24, and those for the RNA synthetase and the A-protein (maturation protein) in position 18 of the isolated initiating section[31, 32] (Fig. 2).

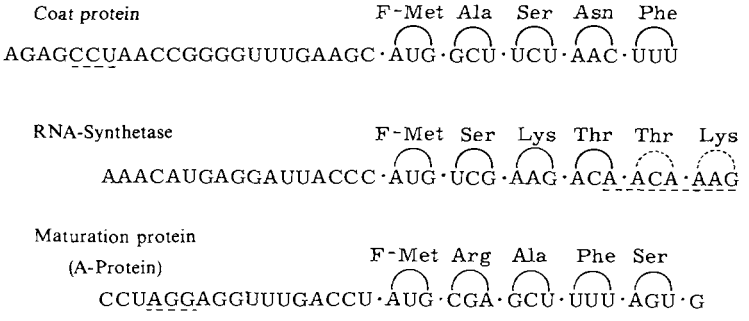

Fig. 2. Base sequence of the three initiating regions of the RNA of the bacteriophage R 17 [31, 32]. Triplets that code for one amino acid are connected by arcs. Sections that have not yet been conclusively verified are indicated by broken lines. Note that the initiating triplet is not situated at the 5' end of the RNA.

Translation of the base sequence of RNA into the amino acid sequence of a protein thus may not begin directly at the 5' end; this conclusion is also supported by the possibility of translation of a cyclic nucleic acid[33, 34]. This may seem surprising at first, but it could be useful for regulation purposes. The RNA region containing the start codon could be held by hydrogen bonds in a double helix in such a way that the initiating codon would be situated in an exposed position at the tip of the helix (Fig. 3)[31, 32]. In

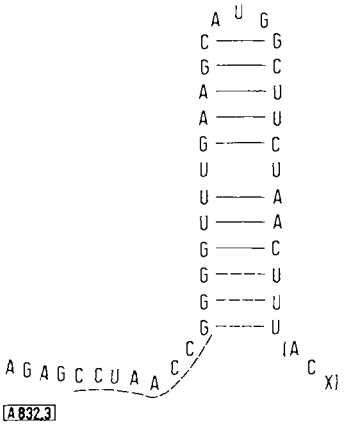

Fig. 3. Exposed position of the initiating codon AUG in the RNA of the bacteriophage R 17 [31, 32]. Sections that have not yet been conclusively verified are indicated by a broken line.

an arrangement like this, the initiating codon would be protected against the action of ribonucleases which attack at the 5' end, and there would also be a possibility of modifying initiation by alteration of the three-dimensional

structure of the RNA. A situation similar to this has been found in the base sequence at the 5′ end of the RNA of the bacteriophage Qβ[35]. Other experiments[36] have shown that the secondary structure of the mRNA does, in fact, play a part in initiation. On modifying the secondary structure of the RNA of bacteriophage f2 by treatment with formaldehyde, additional new starting points occurred along the f2-RNA. This was best explained by assuming that the local rupture of hydrogen bonds leads to changes in conformation of the mRNA, with the result that initiating triplets emerge from the interior to positions that allow initiation.

2.1.4. Initiating Factors

If *E. coli* ribosomes are washed with 0.5 to 2 M NH_4Cl solution, several protein factors that are essential to initiation are released from the 30 S subunit[26, 37–49]. Three factors, F_1, F_2, and F_3, can be separated, and all of these have been purified to homogeneity by analytical electrophoresis on polyacrylamide gel[50–54]. The molecular weight of F_1, which has been crystallized[55], is 9400[50, 55], that of F_2 is 65000—75000[51] or 80000[53], and that of F_3 is 21000 daltons[54, 56]. F_3, a basic protein, is stable to heat treatment and consists of a single polypeptide chain[56]. F_2 and F_3 contain free SH groups[53, 54, 57]. For factor F_3, several variants have recently been described which are specific for the initiation of different proteins[58, 59].

Initiating factors have also been described[60–68] for systems of muscle tissue and reticulocytes. Three factors, M_1, M_2, and M_3, have been distinguished in the reticulocyte system[60]. They are necessary for initiation of the synthesis of the α and β chains of hemoglobin at low Mg^{2+} concentrations and resemble the initiating factors F_1, F_2, and F_3. Only the $tRNA^{Met}$ species that can be formylated are bound to the initiating factors from reticulocytes, while only the $tRNA^{Met}$ species that cannot be formylated are bound to the elongation factors (which will be discussed in Section 3.1.4)[66].

2.1.5. Ribosomes and GTP

Guanosine triphosphate (GTP) and ribosome subunits are also necessary for chain initiation. Structure and composition of the ribosomes are summarized in Table 2. The ribosomes are the supporting framework on which the reactants taking part in the translation fit together in a complicated, 4-dimensional fashion (the fourth dimension being time). In addition to the 80 S-ribosomes in eukaryotes and to the 70 S-ribosomes in prokaryotes, a third class of ribosomes called miniribosomes occurs in mitochondria. They have a sedimentation constant of 55 S (for review see[69]). At least two specific sites on the ribosome have been postulated for binding of amino acyl-tRNA and of peptidyl-tRNA. These two sites, the amino acyl-tRNA acceptor site A and the peptidyl donor site P, can be differentiated by reaction with puromycin. Puromycin, a structural analog of the terminal amino acyl-adenosine portion of an amino acyl-tRNA (Fig. 4)[70], can react with previously formed peptidyl-tRNA[71] to form peptidyl-puromycin and tRNA[72]. However, no further amino acids can be attached to peptidylpuromycin. The result is

Table 2. Properties of the ribosomes and their subunits.

Properties of the ribosomes	Origin: from prokaryotes		from eukaryotes (cytoplasm)	
Particle weight (daltons)	2.8×10^6—3.0×10^6		4×10^6—5×10^6	
Dimensions (Å)	200 × 170 × 170		240 × 200 × 200	
Ratio RNA/protein	1.6—1.8		1	
Sedimentation constants, formation of subunits	70 S → 30 S + 50 S		80 S → 40 S + 60 S

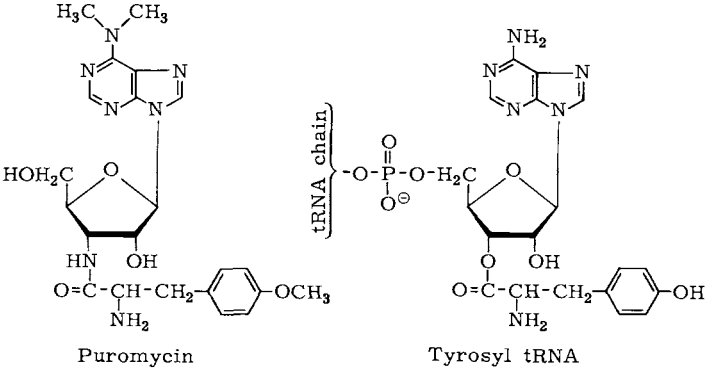

Fig. 4. Puromycin as a structural analog of the terminal amino acyl-adenosine portion of an amino acyl-tRNA.

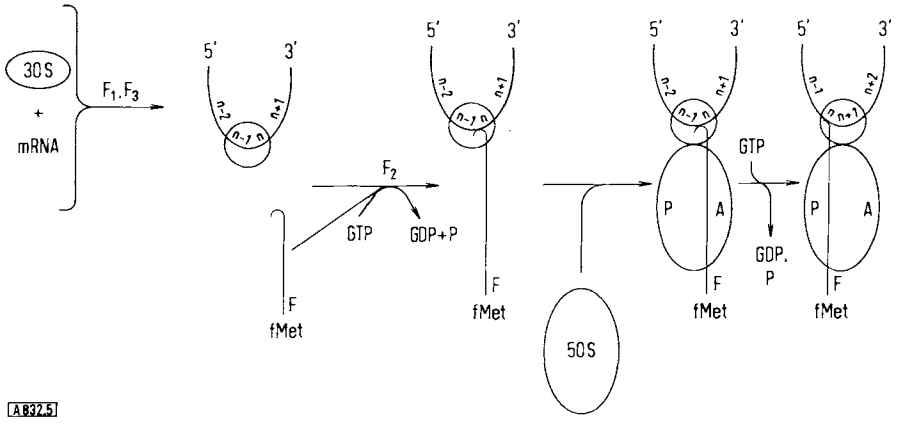
premature chain termination and the occurrence of peptidylpuromycin and free tRNA[73].



The reaction with puromycin can be used to distinguish between the two different binding sites for tRNA on the ribosome. For example, in a cell-free amino-acid incorporating system programmed with poly-U, polyphenylalanine is formed and initially remains bound to the ribosome as polyphe-tRNA[71]. Two types of peptidyl-tRNA-ribosomes are found in such a system, *i.e.* one type that reacts immediately with puromycin and another that reacts with puromycin only after addition of GTP and of the supernatant obtained on high-speed centrifugation during isolation of ribosomes. It is assumed that ribosomes of the first type have bound the peptidyl-tRNA to the peptidyl donor site P, while those of the second have bound the peptidyl-tRNA to the amino acyl-tRNA acceptor site A. GTP and the supernatant are necessary for the transport of the peptidyl-tRNA from the amino acyl-tRNA acceptor site A to the peptidyl donor site P[73]. During this process, GTP is cleaved into GDP and phosphate. Only then can the peptidyl residue be transferred to puromycin by these peptidyl-tRNA-ribosomes.

Recently, studies using polyribosomes in reticulocytes and muscle cells have shown that two tRNA molecules were bound to one ribosome also *in vivo*, with one of the tRNA molecules carrying a nascent polypeptide chain[74].

2.2. Mechanism of Chain Initiation

A general scheme of chain initiation is shown in Figure 5. fMet-tRNA, the initiating region of a mRNA, and the 30 S subunit of the ribosome, in the presence of GTP and initiating factors, combine to form a complex[25, 46, 54, 75–83]. The initiating region of the mRNA is probably bound to

Opinions differ regarding the precise mode of action of the initiation factors, and particularly as to whether GTP can be replaced by GMPPCP in the binding and liberation of F_1 in the initiation complex[50] or not[99]. There are also various views regarding the sequence of binding and liberation of the start factors in the initiation complexes[50, 54, 90, 100]. It is possible that some of the initiation factors are also involved in chain termination[101]. It has been suggested, for example, that the dissociation factor (see Section 4.1.3) is identical with F_1[102] or F_3[54, 103–105]. Some of the properties of the initiation factors are the same as those of elongation factors[106].

A 832.5

Fig. 5. General scheme of the chain initiation (after *Lengyel* and *Söll* [1], modified). For explanation see text.

the 30 S subunit with the assistance of F_1 and F_3[54], and then fMet-tRNA is added[40, 84]. This step requires the presence of F_2. Only then is the 50 S subunit incorporated[85, 86]. F_3 is necessary only for the binding of natural mRNA[87, 88]. The fMet-tRNA is probably bound first to the amino acyl-tRNA acceptor site A of the ribosome[85, 86, 89–91], but is then transferred to the peptidyl donor site P with cleavage of GTP[41]. In the presence of GMPPCP, a compound analogous to GTP in which the β and γ phosphate groups are joined by a methylene bridge and so cannot undergo enzymatic cleavage[92], a complex fMet-tRNA-mRNA-30 S subunit is formed[76, 82]; the 50 S subunit is then added[85, 89] but no fMet-tRNA-ribosomes that can react with puromycin are made[93]. The fMet-tRNA-ribosomes formed with cleavage of GTP, on the other hand, react with puromycin to give fMet-puromycin, free ribosomes, and tRNA[25, 93–95]. Initial binding of fMet-tRNA to the amino acyl-tRNA acceptor site A is also suggested by inhibition experiments with tetracycline, a compound which was previously found to inhibit specifically binding of other amino acyl-tRNAs to the amino acyl-tRNA acceptor site on the ribosomes[96].

Unlike any other amino acyl-tRNA, fMet-tRNA$_F^{Met}$ cannot form a complex with GTP and the elongation factor T (see Section 3.1.4)[97] from which the amino acyl-tRNA molecules are transferred to the ribosome during elongation of the polypeptide chain. On the other hand, only fMet-tRNA$_F^{Met}$ is bound to 30 S subunits in the presence of initiation factors, GTP, and AUG or GUG. The initiation factors "recognize" both the tRNA portion and the formyl group of the fMet-tRNA$_F^{Met}$[98].

For the regulation of protein synthesis at the level of translation by modifying chain initiation, it is of great interest that factor F_3 could be separated recently into several variants which were specific for the initiation of different proteins[58, 59]. Furthermore, *Dube* and *Rudland* showed that initiation factors isolated from *E. coli* infected with the bacteriophage T 4 reprogrammed ribosomes from uninfected *E. coli* in such a way that these ribosomes preferentially recognized the start signals of T 4-RNA[107]. Protein specificity of the initiation is also shown by experiments using RNA of the bacteriophage R 17. This RNA consists of a single filament with the structural genes for the maturation protein (A protein), the coat protein, and the RNA synthetase, arranged in that order from the 5' end to the 3' end[108]. In a cell-free system from *E. coli* programmed with R 17-RNA, added initiating factors that had been obtained from *E. coli* infected with T 4 resulted in the recognition only of the synthetase-initiating section[109]. In a system from uninfected cells, on the other hand, all three initiating sections of R 17-RNA were recognized, with relative preference for the coat protein.

However, a protein specificity in initiation of the translation may also be due to the source of the 30 S subunit of the ribosomes. In a comparison of cell-free protein-synthesizing systems from *E. coli* and *B. stearothermophilus* which had been programmed with RNA from f2, a bacteriophage related to R 17, it was found that the synthesis of all three phage proteins was initiated with *E. coli* ribosomes, whereas only the maturation protein was initiated in the *B. stearothermophilus* system[110–112]. The specificity for this was located in the 30 S subunits. The source of the

50 S subunit and of the initiation factors was of no importance[110].

A thermally unstable factor that enabled ribosomes from uninfected bacteria to use T 4-RNA selectively as mRNA for protein synthesis has been isolated from *E. coli* infected with T 4[113].

The above description is valid for chain initiation in prokaryotes, mitochondria, and chloroplasts. In eukaryotes, unformylated Met-tRNA[8], which could however be formylated by a transformylase isolated from *E. coli*[114-117], was found to be the initiating amino acyl-tRNA. The cytoplasm of liver and yeast cells contains no transformylase.

As the initiating amino acid for globin, methionine is split off at an early stage[118, 119] when the growing polypeptide chain of globin has reached a chain length of 15 to 20 amino acids. Methionine has also been identified as the initiating amino acid for protamine in cell suspensions from trout testes[120]. Enzymatic removal of methionine from the next amino acid, proline, has been detected but probably occurs only after formation of protamine is complete. In *N. crassa*, another eukaryotic organism, though no methionine can be detected as the N-terminal amino acid of completed cell proteins, ^{14}C-methionine is found near the N-terminal end in nascent proteins[121].

The initiating tRNA from eukaryotes can be used as initiating tRNA in cell-free systems prepared from *E. coli*[4, 5, 114-117]. $tRNA_1^{Met}$ is probably the only initiating tRNA in eukaryotes[122]. In view of the rapid formation of methionylpuromycin with Met-$tRNA_1^{Met}$ from liver, it was proposed that Met-$tRNA_1^{Met}$ is bound to the peptidyl donor site P of the ribosome[115].

Initiating factors in systems from mammals have already been discussed in Section 2.1.4. Protein specificity or organ specificity of the initiating factors has also been described for eukaryotes. The factors from reticulocytes and from muscle mainly stimulate the synthesis of globin and of myosin, respectively[64].

3. Chain Elongation

3.1. Reactants

3.1.1. Amino Acyl-tRNA

Most of the amino acids occurring in proteins can be bound to more than one tRNA species. However, there is probably only one activating enzyme for each amino acid[1, 123-125] [eq. (1)]. The specificity of the transfer of the amino acids to one of the appropriate tRNAs is greater than the specificity of the reaction of the amino acid with the enzyme and with ATP[123-127]. For example, Ile-tRNA synthetase also activates valine, and Val-tRNA synthetase also activates threonine, but these "wrong" amino acids are not then transferred to the corresponding tRNA[128-130].

Since the base sequences of a number of tRNAs have now been established, it is possible to deduce the general structural principle of the tRNAs[18, 131]. All tRNAs can be written in "clover-leaf" form with five arms (Fig. 6): the amino acid arm or stem, the dihydrouridine arm (DHU arm), the anticodon arm, and the thymine-pseudouridine-cytosine arm (TΨC arm). The tRNAs can be divided into

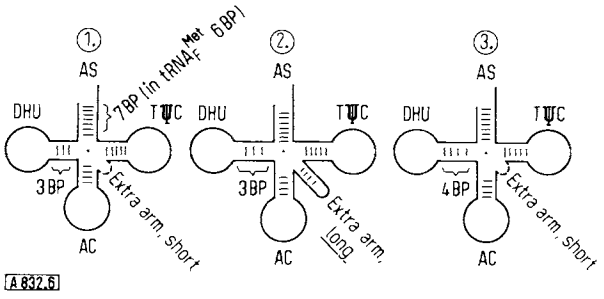


Fig. 6. Grouping of the tRNAs into three classes (after *Staehelin* [131], modified). BP = base pairs, AS = amino acid arm, DHU = dihydrouridine arm, AC = anticodon arm, TΨC = thymine-pseudouridine-cytosine arm.

three classes according to the structure of these arms; the tRNAs of class 1 have three base pairs in the DHU arm and a short extra arm, those of class 2 also have three base pairs in the DHU arm, but a long extra arm, and those of class 3 have four base pairs in the DHU arm and a short extra arm (Fig. 6). Comparison of the base sequence of "normal" wild type tRNA with that of tRNA that has been functionally modified by mutation should provide information about the functional importance of the various tRNA regions. A number of tRNAs have been crystallized,

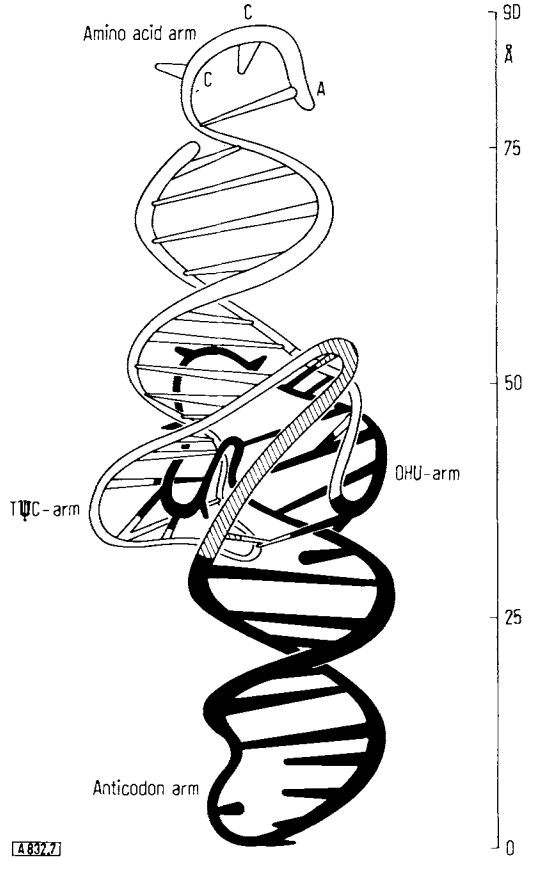

Fig. 7. Model of the three-dimensional structure of $tRNA_F^{Met}$ after *Levitt* [18]. ■: DHU and anticodon arms; □: TΨC and amino acid arms; ▨: extra arm.

with the result that X-ray analyses are now possible[16, 17, 132–140]. On the basis of the data obtained, for example, the three-dimensional tRNA model shown in Figure 7 has been proposed[18].

3.1.2. Mg^{2+}, K^+, or NH_4^+ Ions

Unlike proper chain initiation, elongation can take place at low (4—8 mmole/l) and at high (>10 mmole/l) Mg^{2+} concentrations. At $[Mg^{2+}]>10$ mmole/l, amino acyl-tRNAs are probably bound both to the amino acyl-tRNA acceptor site *and* to the peptidyl donor site of the ribosome. Amino acids are thus incorporated from amino acyl-tRNA into polypeptidyl-tRNA without the need for initiating amino acyl-tRNA or initiating factors[19, 141, 142]. The presence of K^+ or NH_4^+ is necessary for chain elongation[143, 144].

3.1.3. mRNA

Heteropolymeric or homopolymeric polyribonucleotides can be used in cell-free systems as "synthetic" mRNAs. The stimulation of the incorporation of phenylalanine into polyphenylalanine by poly-U, for example, has been studied extensively[145]. The RNA of bacteriophages is often used as "natural" mRNA in cell-free systems. The mRNA of microorganisms is generally polycistronic[146], *i.e.* it contains the structural information for several proteins. The RNA of the bacteriophage R 17 consists of a nucleic acid filament containing the information for the amino acid sequence of the three phage proteins[108]. Arranged sequentially from the 5′-phosphate end to the 3′-OH end, these proteins are: the maturation or A protein (350 amino acids[147]); the coat protein (129 amino acids[148, 149]); and the RNA synthetase (450 amino acids[150]). The nucleotide sequence of the RNA of the bacteriophage f2 differs only slightly from that of the bacteriophage R 17 in the region of the coat protein cistron[151]. Eukaryotic mRNA appears to be monocistronic[152].

3.1.4. Elongation Factors

Protein factors for chain elongation were first isolated from the supernatant obtained by high-speed centrifugation of *E. coli* extracts. Two factors, G and T, were distinguished[153, 154] which could be crystallized[155, 156]. The factor G has a molecular weight of 84000, and dissociates in 4 M urea solution into two subunits with molecular weights of 42550 each, and in 8 M urea solution into a total of four inactive subunits, each of which is reported to have a molecular weight of 23260. Reagents which react with sulfhydryl groups inhibit the activity of factor G[157, 158]. In rapidly growing *E. coli*, the translocase (=factor G) constitutes 2% of the total protein of the ribosome-free extract[159]. The T factors from *E. coli* and from *P. fluorescens* have been resolved into a thermally more stable component T_s and a thermally less stable component T_u[160]. The factor T_u and the factor T_s combine to form a complex which decomposes in the presence of GTP into a T_u-GTP complex and T_s[161].

The three elongation factors S_1, S_2, and S_3 obtained from *B. stearothermophilus* correspond to the factors T_s, G, and T_u. However, they are all relatively stable to heat[162]. Elongation factors have also been isolated from yeast[163, 164]. The elongation factors found in rat liver[165] were later resolved into two fractions named transferase I and transferase II[166, 167]. In their mode of action they correspond to the factors T and G[168–175]. The molecular weight of transferase I is 186000, and that of transferase II is 70000[176]. Transferase II contains SH groups essential for activity[176]. Transferase I is also known as binding enzyme, and transferase II as translocase.

Only one factor T and one factor G have been detected in prokaryotes[177], whereas two or more types of binding enzymes or translocases have been isolated from eukaryotes[177–180]. Of these, it is possible that one type is specific for 70S ribosomes and another for 80S ribosomes[177, 178, 181]. It has also been reported, however, that exchange of the elongation factors between cell-free systems from prokaryotes and from eukaryotes is possible[182, 183] without interfering with the incorporation of amino acids into proteins. Moreover, it is not yet known whether organ specificity occurs for the elongation factors[184, 185]. A mutant of *E. coli* that was resistant to fusidic acid, a specific inhibitor of the translocation (see Section 3.2), was recently reported. This mutant had a modified G factor[186].

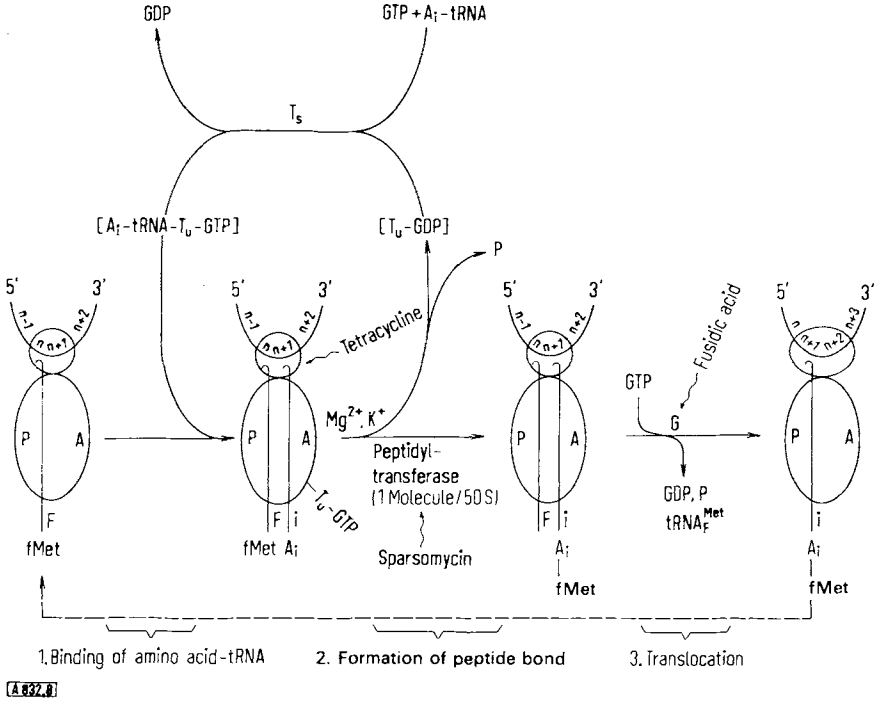
3.1.5. Ribosomes and GTP

GTP is necessary both for binding of the amino acyl-tRNA and for translocation of newly formed peptidyl-tRNA from the amino acyl-tRNA acceptor site A to the peptidyl donor site P.

The properties of the ribosomes were described in Section 2.1.5 and in Table 2. It has been suggested that the large subunit of the ribosomes from rat liver has a tunnel or channel through which the proteins pass that are to be transported into the intracisternal space of the endoplasmic reticulum[187, 188]. The ribosome is situated with the large subunit toward the endoplasmic membrane[189, 190].

3.2. Mechanism of Chain Elongation

A general picture is shown in Figure 8. The following description is based mainly on experiments with cell-free systems incorporating amino acids into protein-like material. A complex is first formed from amino acyl-tRNA, the factor T_u, and GTP[162, 191]. Uncharged tRNA (=tRNA carrying no amino acid) is not bound and does not inhibit the binding of amino acyl-tRNA[97, 162, 192]. The amino acyl-tRNA is transferred from the complex to the amino acyl-tRNA acceptor site A on the ribosome. After binding of the amino acyl-tRNA to the mRNA-ribosome complex, GTP is broken down[193]. This cleavage of GTP appears to occur before the formation of the peptide linkage and before translocation, since fusidic acid, an antibiotic that inhibits GTPase activity of the protein factor G, which is involved in the translocation, does not inhibit cleavage of GTP by T_u+T_s[193]. In the presence of GMPPCP, which cannot be broken down enzymatically into GDP



and phosphate, the amino acyl-tRNA is still bound to the mRNA-ribosome complex, but no peptide linkage is formed, in contrast with the observations with GTP[193–195].

Sparsomycin, an antibiotic that inhibits the formation of the peptide linkage[196, 197], affects neither the binding of amino acyl-tRNA to the ribosome[198] nor the cleavage of GTP by $T_u + T_s$[193]. The factor T_s probably has the function of regenerating amino acyl-tRNA-T_u-GTP from GTP, amino acyl-tRNA, and the complex T_u-GDP which is liberated after binding of the amino acyl-tRNA to the ribosome[199]. The same T_u factor can react with several amino acyl-tRNA species[97].

The first observations on the cleavage of GTP during binding of amino acyl-tRNA to the mRNA-ribosome complex and on the need for a supernatant factor were made with cell-free systems from reticulocytes[200].

tRNA acceptor site, play a part in the reaction with peptidyl transferase[207, 208]. The peptidyl transferase in bacteria appears to catalyze only the reaction of amino acyl-tRNA with a blocked α-amino group. This may be the reason why the amino group of methionine must be formylated in the initiating amino acyl-tRNA in bacteria. During chain elongation, the blocking group is the peptidyl residue. It is possible that, in the course of evolution, a different mechanism has developed in the larger ribosomes from eukaryotes, with the result that specificity of initiation is guaranteed even with an unformylated initiating amino acid.

The newly formed fMet-amino acyl-tRNA is then transferred from the amino acyl-tRNA acceptor site A to the peptidyl donor site P, and the now uncharged $tRNA_F^{Met}$ is released from the peptidyl donor site. The ribosome on the mRNA moves by one triplet in the 5′→3′ direction[209].

A 632.8

Fig. 8. General scheme of the chain elongation (after *Waterson, Beaud* and *Lengyel* [199], modified). A_i = amino acid. For further explanations, see text.

After the binding of the new amino acyl-tRNA to the amino acyl-tRNA acceptor site A, formylmethionine is released from its linkage with $tRNA_F^{Met}$ and is then transferred to the α-amino group of the new amino acyl-tRNA, resulting in formation of a peptide linkage. The fMet-amino acyl-tRNA is still bound to the amino acyl-tRNA acceptor site of the ribosome[194, 201, 202]. The enzyme that catalyzes the reaction, *i.e.* the peptidyl transferase, is a structural protein of the 50S subunit of the ribosome[3, 73, 203, 204]. A 50S subunit contains exactly one molecule of peptidyl transferase[205]. Neither proteins from the supernatant obtained on high-speed centrifugation nor GTP are involved directly in the reaction[3, 203, 204, 206]. However, Mg^{2+} and K^+ or NH_4^+ ions are necessary[143, 144]. The 3′-terminal CCA ends of the tRNA, both in the peptidyl-tRNA bound to the peptidyl donor site and in the amino acyl-tRNA bound to the amino acyl-

The translocation in the cell-free system depends on the presence of the protein factor G and the cleavage of GTP into GDP and phosphate[194, 201, 202, 210–212]. The amino acyl-tRNA coded by the next triplet of the mRNA can now take its place on the vacated amino acyl-tRNA acceptor site of the ribosome, and the cycle can start again.

Like the cleavage of GTP, the translocation is blocked by fusidic acid[211, 212]. Mutants of *E. coli* that are resistant to fusidic acid have a modified G factor[213]. The translocation is also inhibited by GMPPCP[92, 194, 202, 210, 211].

In systems from rat liver, the functions of transferases I and II[165–167] are essentially the same as those of the factors T and G, respectively[168–175]. A single molecule of transferase II can catalyze the translocation on several ribosomes[175]. Transferase II is specifically inactivated by diphtheria toxin[214, 215].

4. Chain Termination

4.1. Reactants

4.1.1. mRNA with the Termination Region

The termination signals in the mRNA are the triplets UAA, UAG, and UGA[216-226]. These are known as ocher, amber, and opal codons, respectively. Since they stimulate neither the binding of one of the known amino acyl-tRNAs to ribosomes[227,228] nor the incorporation of amino acids into protein-like material[229], they have also been called nonsense codons. It was assumed that terminator triplets could immediately succeed one another[230], and this was recently confirmed by the elucidation of the base sequence of the region containing the termination signal of the RNA from bacteriophage R 17[231]. It remains to be seen whether double termination signals generally occur. This would provide protection against the synthesis of nonsensical proteins as a result of mutation of the termination signal, and would thus offer a selection advantage to the organism in question.

4.1.2. Release Factors

The presence of a release factor[232] is necessary for the release of the completed polypeptide chain from the polypeptidyl-tRNA-ribosome complex. Two types of release factors, R_1 and R_2, have been distinguished. R_1 is specific for UAA and UAG, and R_2 is specific for UAA and UGA[233,234]. The factors are present in the cytoplasm, are not dialyzable, and are inactivated by trypsin and *N*-ethylmaleimide, but not by ribonuclease[234]. These properties correspond to those of proteins containing free sulfhydryl groups. The molecular weight of R_1 is 44000, and that of R_2 is 47000. One bacterium is thought to contain about 500 molecules each of R_1 and R_2[235]. With 30000 ribosomes per bacterium[236], this would correspond to one release factor per 30 ribosomes.

The recognition of the terminator triplet is assisted by another protein, the factor S[237].

4.1.3. Dissociation Factor and Ribosomes

After release of the polypeptidyl-tRNA, the mRNA-ribosome complex dissociates[238,239]. The ribosomes are released either directly as subunits or as free 70S-ribosomes[240-243], which then dissociate into subunits. This process involves the action of the dissociation factor[244]. Like the initiating factors, this has been found on the native 30S subunits, but not on 70S ribosomes. However, it appears to be bound to the ribosome before the dissociation begins[245]. The dissociation factor remains on the small subunit after the cleavage of the ribosomes. It is possible that free 70S ribosomes in the cell or in the bacterium are an artefact[246]. The dissociative action of the initiating factors was mentioned in Section 2.2. The dissociation factor may be identical with F_3[54,55,103,105]. In *E. coli*, F_3 is the only dissociation factor[104].

The dissociation factor may be species-specific, since a protein fraction from *Saccharomyces cerevisiae* that exhibited dissociative activity towards ribosomes from *Saccharomyces* had no dissociative action on ribosomes from *Escherichia coli* or from rabbit reticulocytes[247].

4.2. Mechanism of Chain Termination

As soon as one or two of the terminator codons have reached their amino acyl-tRNA acceptor sites in the movement of the mRNA along the 30S subunit, the polypeptide chain synthesis stops[216,218-220]. If a nonsense codon is formed by mutation from a triplet coding for an amino acid, the result is premature chain termination and the synthesis of a protein fragment[248].

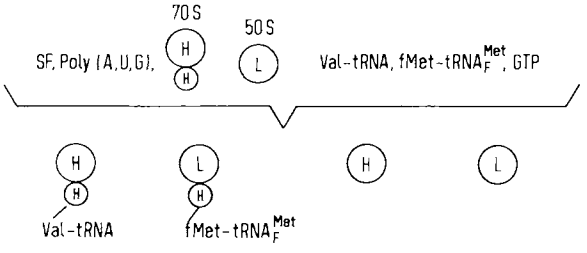
The investigations on chain termination were carried out mainly on mutants of the phages R 17 and f2 with a UAG triplet formed by mutation. Phages in which this triplet was formed at the beginning of the gene for the coat protein were used, and the synthesis of a hexapeptide corresponding to the N-terminal end of the coat protein was observed in cell-free systems[232,249,250]. The hexapeptidyl-tRNA formed was still bound to the mRNA-ribosome complex, and could thus be used as a substrate (Fig. 9) for the detection of the release factor. Another test substrate was the AUG-fMet-tRNA-ribosome complex

1. Hexapeptidyl-$tRNA_6$-ribosome-RNA
2. fMet-$tRNA_F^{Met}$-ribosome-AUG

Fig. 9. Substrates for the detection of the release factor.

formed on incubation of AUG with fMet-tRNA and ribosomes. Formylmethionine was liberated from this complex in the presence of release factors and one of the nonsense triplets[233]. Using these tests, two release factors R_1 and R_2 having the codon specificity described in Section 4.1.2 were isolated[234,235]. It has recently been shown that R_1 and R_2 are necessary not only for the release of incomplete, short oligopeptide fragments but also for the release of completed proteins[251,252].

Formylmethionine is liberated only when formylmethionine-tRNA is bound in the peptidyl donor site P, suggesting that polypeptides are released from the peptidyl donor site. The liberation is inhibited by sparsomycin, chloramphenicol, and other antibiotics[253].



Experiments with a puromycin analog in which the α-amino group had been replaced by a hydroxyl group were recently described[254,255]. The peptidyl transferase was able to transfer the peptidyl residue to the hydroxyl group of the puromycin analog. However, this process was slower than the formation of the peptide linkage. In other experiments, formylmethionine ethyl ester was liberated by nucleophilic attack of ethanol on fMet-$tRNA_F^{Met}$ on the ribosome[256]. The reaction was stimulated up to 20-fold by tRNA or the codon CCA. This raises the question whether the specificity of the peptidyl transferase is modified in chain termination, with the result that the polypeptidyl residue is transferred to a hydroxyl group, *e.g.* of water, instead of to another amino acid. Binding experiments indicate that R_1 and R_2 could be important in the recognition of the terminating codon[253,257], in which the protein factor S has a stimulating effect[237].

Before the formation of a new initiating complex, the ribosomes must dissociate into subunits. The dissociation factor takes part in this dissociation, not as a catalyst, but

in the stoichiometric quantity with respect to the ribosomes[244]. The dissociation of the ribosomes into subunits before the start of the synthesis of a new polypeptide chain was shown by exchange experiments, in which a growing bacterial culture was transferred from a medium containing heavy isotopes into one containing light isotopes[258, 259].

The dissociation of the ribosomes before the binding of the initiating amino acyl-tRNA has also been demonstrated in cell-free systems. "Heavy" 70S ribosomes were obtained from *E. coli* that had been grown in a medium containing D_2O and ^{15}N. "Light" ribosome subunits were isolated from *E. coli* that had been grown in a medium containing H_2O and ^{14}N. "Heavy" 70S ribosomes were then incubated with "light" 50S subunits, poly(A,U,G), initiating factors, Val-tRNA, fMet-$tRNA_F^{Met}$, and GTP under conditions suitable for the synthesis of protein. The mixture was then analyzed by centrifugation in a density gradient. It was found that fMet-$tRNA_F^{Met}$ was bound mainly to hybrid light/heavy ribosomes, whereas Val-tRNA occurred mainly on pure heavy/heavy ribosomes. Free heavy and light subunits were also found.

The experiment is illustrated schematically in Figure 10. It follows that the ribosomes must dissociate into their

A 832.10

Fig. 10. Dissociation of the ribosomes before the initiation of a new polypeptide chain (schematic). H and L denote the use of D_2O and ^{15}N and of H_2O and ^{14}N, respectively, in the medium in which the bacteria were grown and from which ribosomes or ribosomal subunits were isolated. The bracket symbolizes the incubation for the protein synthesis. SF = initiating factors. For further explanations see text.

subunits before the binding of fMet-tRNA required for chain initiation can occur. However, Val-tRNA required for the chain elongation can be bound without dissociation of the ribosomes[77]. Dissociation of ribosomes and the exchange of ribosomal subunits were also detected for eukaryotes[260–265].

When the rate of protein synthesis decreases, 70S ribosomes accumulate. To explain this, it was suggested[246] that ribosomes are normally released from mRNA as subunits. When protein synthesis decreases, subunits accumulate, and can combine to form 70S ribosomes. However, these 70S ribosomes cannot take part in protein biosynthesis. They may be regarded as a sort of pool of subunits that are not required for the time being, but which are remobilized when protein synthesis increases again.

5. Rate of Translation

A survey of the rates found for elongation of the polypeptide chain is presented in Table 3. It can be seen that elongation proceeds only very slowly in cell-free systems. The highest

Table 3. Time required for the elongation of the polypeptide chain.

System	Amino acid/second	T (°C)	Ref.
Viruses			
TMV protein; *in vivo*;	>2—3	15	[266]
(in leaf sections)	>20	28	
f2 phage coat protein; cell-free system from *E. coli*	0.4—0.5	32—33	[239]

reticulocytes	8.3	37	
Globin β chain in rabbit	0.58	20	
reticulocytes	5.2	37	

rates were found for the synthesis of virus protein in tobacco leaves[266] and for the synthesis of β-galactosidase in *E. coli*[269]. The rate of elongation of the polypeptide chain was the same for maximum induction and for only 30% of the maximum induction of β-galactosidase. In hemoglobin, the α chain of the globin is elongated more rapidly than the β chain[276]. The observed rates depend on the temperature. However, the poikilothermic toad-fish *(Opsanus tau)*, an organism which can adapt itself to low water temperatures, manages to maintain a constant elongation rate even at low temperatures[277]. The period of the ribosome cycle, *i.e.* polypeptide chain synthesis + dissociation + reassociation of the subunits, has been found to be 10 minutes at 37 °C in *B. licheniformis*[278] and 7—10 minutes in *B. megaterium*[279]. These values are in agreement with the measured elongation rates if it is assumed that one ribosome translates one polycistronic mRNA filament *in vivo*.

6. Energy Requirement of Protein Synthesis

The activation of the amino acids requires two ATP per amino acid. In *in vitro* experiments in which the factor G was incubated with the amino acyl-tRNA-GTP-T_u complex, it was found that cleavage of GTP, which plays a part in the binding of the amino acyl-tRNA to the mRNA-ribosome, does not allow subsequent translocation. This means that, at least *in vitro*, a quantity of energy equivalent to four ATP is required per amino acid incorporated.

7. Cell-Free Synthesis of Specific Proteins

The mechanism of translation can be studied in cell-free systems performing only some parts of translation. For example, such systems may be able to elongate previously started polypeptide chains, but may not be able to initiate new chains. To investigate the regulation of the synthesis of specific proteins *in vitro*, the complete *de novo* synthesis in a cell-free system is necessary.

The complete *de novo* synthesis of specific proteins in cell-free systems has been described repeatedly (for review of the literature see *Nisman* and *Pelmont*[280]). As long ago as 1962 the *de novo* synthesis of β-galactosidase and of alkaline phosphatase in cell-free preparations of *E. coli* had been reported[281]. When those experiments were repeated under the conditions described for isolation and incubation[281, 282], it was found, however, that the so-called cell-free preparations still contained viable cells, and that the observed synthesis of β-galactosidase could probably be entirely accounted for by those viable cells[283]. Adequate checks for presence of bacteria are missing in many of the published cell-free syntheses of specific proteins in systems from microorganisms.

In recent years, stimulation of the synthesis of viral proteins in cell-free systems from *E. coli* by virus nucleic acids has also been studied. Cell-free synthesis of α- and β-glucosyltransferase[284–286], lysozyme[285, 287–290], d-CMP-deaminase[285] and β-galactosidase[291] in systems from *E. coli* programmed with bacteriophage DNA have been described. The amount of lysozyme synthesized *in vitro*[288] was, however, only 0.1—1% of that made *in vivo*[292]. Finally, cell-free synthesis of monomers of alkaline phosphatase[293] and tryptophanase[294] in systems from *E. coli* may be possible. Also, *in vitro* syntheses of proteins of animal viruses, *e.g.* poliovirus[295] and SV 40-virus[296], in cell-free systems from *E. coli* containing poliovirus-RNA or SV 40-DNA have been published.

Besides contamination by intact cells, which presents special problems in cell-free systems from prokaryotes to which no inhibitors of bacterial protein synthesis can be added, a careful characterization of the product of the reaction is imperative. For cell-free systems incorporating labeled amino acids into the globin part of hemoglobin, for example, considerable amounts of labeled amino acids were found to be incorporated into peptides not belonging to hemoglobin[297]. If cell-free *de novo* synthesis of specific proteins is demonstrated only by incorporation of radioactive amino acids, proteins have to be purified to constant specific radioactivity. Many of the earlier reports on the cell-free synthesis of albumin, in which radioactively labeled albumin was isolated by immunoprecipitation[298–320], have to be reevaluated since immunoprecipitation either on cellulose as supporting material[321, 322] or in solution[323] has been shown not to yield radiochemically pure albumin[323–325]. In a cell-free system from rat liver effectively incorporating ^{14}C-leucine into trichloroacetic acid-precipitable material, no *de novo* synthesis of albumin could be demonstrated if albumin was purified to constant specific radioactivity[326]. Finally, amino acids may be bound to proteins by mechanisms other than protein biosynthesis and thus may simulate incorporation by protein biosynthesis. This possibility is discussed elsewhere in detail[325–327].

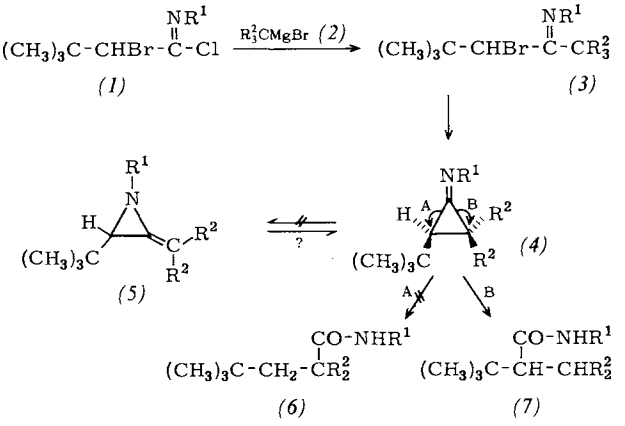
Cyclopropanimines. A Novel Variant of the Favorskii Reaction[**]



By *Helmut Quast, Edeltraud Schmitt*, and *Rolf Frank*[*]

Whereas the thermal valence isomerization of several hetero methylenecyclopropanes has been established[1], the interconversion of methyleneaziridines and cyclopropanimines is still a matter of speculation[2, 3], not least because cyclopropanimines have repeatedly defied attempts at preparation[4]. We now report the first synthesis of a cyclopropanimine and a novel variant of the Favorskii reaction. Since this rearrangement of α-halo ketones is known to occur *via* cyclopropanones[5, 6], a 1,3-elimination starting from the (previously unknown) α′-unsubstituted α-halo ketimines of type *(3)* seemed an attractive approach to cyclopropanimines, which have only been postulated as intermediates so far[2, 3, 6, 7].

Treatment of the imidoyl chlorides *(1a)*—*(1d)*, readily available from the corresponding amides and an excess of thionyl chloride, with the Grignard compound *(2)* in ether at low temperature afforded the imines *(3a)*—*(3d)* in high yield. Potassium *tert*-butoxide in tetrahydrofuran converted *(3a)* and *(3b)* into *(4a)* and *(4b)* (b. p. 20—22 °C/10^{-3} torr) in 93—96% yield. *(3c)* and *(3d)* gave the same reaction, as shown by the IR spectra of the reaction mixtures.

The cyclopropanimine structure *(4a)* and *(4b)* was assigned on the basis of elemental analysis, base equivalent weight, IR, NMR, and mass spectra. *(4a)*, IR[8]: 3050 (CH_2), 1773 (C=N), 973, 1013, 1031 cm^{-1} (cyclopropane ring). The NMR spectrum[8] shows the signals of R^1 at 0.73—0.91 (12 H/m), 1.75—2.91 (2 H/m), and 2.61 ppm ($J = 6.0$ Hz, 1 H/t), a *tert*-butyl singlet at 0.96 ppm, and a multiplet of the ring protons at 0.9—1.7 ppm. The mass spectrum displays a weak molecular ion and fragments of composition $M-CH_3$, $M-C_3H_7$, $M-C_4H_9$, and R^1 (50%). *(4b)*, IR[8]: 2295 (CD_2), 940, 977, 1043, 1064 cm^{-1} (cyclopropane ring). NMR[8]: The multiplet of the ring protons of *(4a)* has collapsed to a slightly broadened singlet at 1.56 ppm (1 H).

Thermolysis and hydrolysis independently support structure *(4)*. *(4a)* remains unchanged at 130 °C. After 27 h at 150 °C quantitative decomposition into *tert*-butylethylene[9] and 2,4-dimethyl-3-pentyl isocyanide[9] has occurred. Not

	R^1	R^2
a	2,4-dimethyl-3-pentyl-	H
b	2,4-dimethyl-3-pentyl-	D
c	methyl-	H
d	isopropyl	H
e	*tert*-butyl	H

even traces (<0.5%) of methyleneaziridines [*e.g. (5a)*], the expected products of a valence isomerization, could be detected. *Thus, there is either no favorable path to the heterocyclic isomers available or the latter are less stable than (4a) by more than 3 kcal/mol.* Experiments to settle this question are under way.

The recently described[3], but unconfirmed[10], isolation of *(6e)* in the reaction of 1,3-di-*tert*-butylaziridinone with methylmagnesium iodide followed by work-up using aqueous ammonium chloride prompted the postulation

[10] *E. R. Talaty, A. E. Dupuy, jr., C. K. Johnson, T. P. Pirotte, W. A. Fletcher*, and *R. E. Thompson*, Tetrahedron Lett. *1970*, 4435. Authentic *(6e)* (m. p. 161.8 °C) shows different IR and NMR data from the compound (m. p. 96—97 °C) supposed to be *(6e)* in ref. [3].

of the steps *(5e)→(4e)→(6e)*. However *(4a)*, which differs only slightly from *(4e)*, could be recovered in 66% yield after 24-h treatment with aqueous ammonium chloride. Hydrolysis of *(4a)* and *(4b)* requires drastic conditions (KOH in dioxane/water, 24 h, 100 °C) and affords 70% of *(7a)*[9] and *(7b)*, respectively. The independently prepared *(6a)* could not be detected by tlc. This regiospecificity of ring opening (path B) parallels the course of the Favorskii rearrangement[5,6]. The described variation of this reaction opens novel synthetic possibilities.

4,4'-Sulfonyldimethylenedibenzoic Acid

By *Helmut Müller*[*]

Bis(4-methylbenzyl) sulfide *(1)* is known[1] to be accessible by reaction of 4-methyl-1-bromomethylbenzene with an alcoholic solution of K_2S. We have also prepared *(1)* by treatment of 4-methyl-1-chloromethylbenzene with Na_2S. Oxidation of *(1)* by, *e.g.*, HNO_3 under the conditions required for oxidation of methyl to carboxyl groups gave terephthalic acid as major product.

However, if *(1)* is initially oxidized to bis(4-methylbenzyl) sulfone *(2)*, continued oxidation by air in acetic acid or by HNO_3 gives 4,4'-sulfonyldimethylenedibenzoic acid [bis(4-carboxybenzyl) sulfone] *(3)*. Compound *(3)* is also

formed on reaction of 4-chloromethylbenzonitrile or methyl 4-chloromethylbenzoate with Na_2S followed by oxidation of the resulting sulfide to the sulfone, which is then hydrolyzed.

The resistance of the methylene groups to oxidation should ensure that *(3)* has an interesting future as a starting material for the production or modification of polyesters and polyamides.

Procedure:

4-Methyl-1-chloromethylbenzene (70 g) is added dropwise to a refluxing mixture of $Na_2S \cdot 9H_2O$ (90 g), water (75 ml), and methanol (20 ml); refluxing is then continued for 5 h. Compound *(1)* (55.5 g, 92%) crystallizes on cooling. Compound *(1)* (25 g), glacial acetic acid (150 ml), and 30% H_2O_2 (50 ml) are refluxed together for 30 min. Addition of water (100 ml) to the reaction mixture furnishes compound *(2)* (22.4 g, 79%).—A mixture of *(2)* (20 g) and 20% HNO_3 (300 g) is heated to 170 °C in an autoclave for 5 h. On cooling compound *(3)* can be filtered off, washed, and dried. We obtained 20.1 g (82%) of *(3)*, neutralization number 328 mg KOH/g (calc. 336). *(3)* was converted into the dimethyl ester and recrystallized, m. p. 228—229 °C.

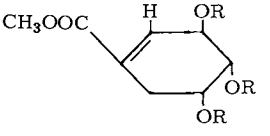
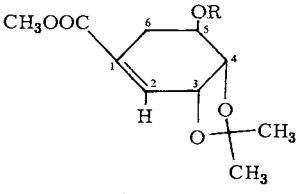
A Stereospecific Conversion of (−)-Methyl Tri-*O*-benzoylquinate to the Corresponding (−)-Methyl Shikimate

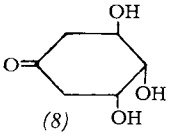
By *J. Cleophax*, *D. Mercier*, and *S. D. Géro*[*]



(−)-Shikimic acid, first isolated from the fruits *Illicium religiosum*[1], has been shown to be a biogenetic key link in aromatic biogenesis[2]. For its preparation, numerous total[2-3] and enzymatic[4] syntheses have been reported; the acid has also been obtained[5] from (−)-quinic acid[**]. We report in this communication a simple conversion of the (−)-methyl 3,4,5-tri-*O*-benzoyl-quinate *(2)* into the corresponding shikimate *(4)*. The requisite starting material *(2)* could be obtained[6] by a selective benzoylation of (−)-methyl quinate *(1)*.



(1), R = H
(2), R = COC_6H_5



(3), R = H
(4), R = COC_6H_5

(5), R = COC_6H_5

(6), R = H
(7), R = $COCH_3$

(8)

Treatment of the (−)-methyl 3,4,5-tri-*O*-benzoyl-quinate *(2)* with sulfuryl chloride (SO_2Cl_2)/pyridine in anhydrous chloroform at −70 °C for two hours and then at −10 °C for 1 hour, gave a syrupy product in quantitative yield, which was crystallized from methanol, giving (−)-methyl 3,4,5-tri-*O*-benzoyl-shikimate, m. p. 60—62 °C, $[\alpha]_D$ −227° (c = 1.3; $CHCl_3$), 78% yield.

Dehydration of the "tertiary alcohol" *(2)* might give rise to the unsaturated ester *(5)*. The presence of the latter could not be detected by thin-layer chromatography. The NMR spectrum of the ester *(4)* did not provide clear evidence of the location of the double bond, due to the

[**] IUPAC-IUB Nomenclature Rules for Cyclitols; European J. Biochem. *5*, 1 (1968).

overlapping multiplets from H-2-vinylic and aromatic protons in the vicinity of 7 ppm. In order to prove unequivocally the structure of the dehydration product, the tribenzoate *(4)* was converted by standard procedures into (−)-methyl 5-*O*-acetyl-3,4-*O*-isopropylidene-shikimate *(7)*.

Treatment of (−)-methyl 3,4,5-tri-*O*-benzoyl-shikimate *(4)* with catalytic amounts of anhydrous methanolic-sodium methoxide yielded (−)-methyl shikimate *(3)*, m.p. 112 to 114 °C, $[\alpha]_D$ −130° (c = 1.88; ethanol), [Ref. [7]: m.p. 115 °C, $[\alpha]_D$ −139° (c = 2; ethanol)]. The latter readily condensed with acetone in the presence of anhydrous copper sulfate to yield the syrupy (−)-methyl 3,4-*O*-isopropylidene-shikimate *(6)*. Acetylation of *(6)* using acetic anhydride/pyridine furnished the ester *(7)*, m.p. 72—74 °C, $[\alpha]_D$ −69° (c = 1.15; chloroform), [Ref. [8]: m.p. 75 to 76 °C].

The 100-MHz NMR spectrum of the ester *(7)* in $CDCl_3$, obtained with the aid of spin decoupling, is compatible only with the structure given. The partial spectrum of *(7)* showed: signals at δ = 6.79 (H-2/quintet), 5.10 (H-5/br. m), 4.65 (H-3/br. m), 4.15 ppm (1 H/t). Irradiation of the vinylic proton H-2 caused the broad multiplet centered at 4.65 ppm to collapse to a form of doublet, $J_{3,4}$ = 6 Hz. The fact that the one-proton multiplet H-5 at 5.10 ppm was absolutely unchanged, excludes unequivocally the presence of the isomer *(5)* in the dehydration procedure. Since trihydroxycyclohexanone *(8)* can be readily converted *via* the triacetyl-[9] or 3,4-isopropylidene derivative[10] into labeled (−)-quinic acid, this method provides a simple route to the specifically labeled shikimic acid.

Preparation of Tris(chloromethyl)amine, $N(CH_2Cl)_3$

By *Ekkehard Fluck* and *Peter Meiser*[*]

Tris(chloromethyl)amine, $N(CH_2Cl)_3$, *(1)*, was first described by *Moeller* and *Westlake*[1] in 1967. They obtained the compound by reaction of aminomethanesulfonic acid, $H_2NCH_2SO_3H$, or the sodium salt of nitrilotrimethanesulfonic acid, $N(CH_2SO_3Na)_3$, with phosphorus pentachloride. In the former case the compound is formed in only very small amounts, in the latter the yield is 23%.

[*] Prof. Dr. E. Fluck and Dipl.-Chem. P. Meiser
Institut für Anorganische Chemie der Universität
7 Stuttgart, Schellingstrasse 26 (Germany)

We have now found that tris(chloromethyl)amine is readily accessible by reaction of phosphorus pentachloride with hexamethylenetetramine, $N_4(CH_2)_6$. The reactants are mixed in a molar ratio of 3:1 and refluxed in benzene or methylene chloride or heated to 100 °C without solvent. Formation of *(1)* according to eq. (1)

$$N_4(CH_2)_6 + 3\,PCl_5 \longrightarrow \underset{(1)}{N(CH_2Cl)_3} + \underset{(2)}{[N(CH_2)PCl_4]_3} \qquad (1)$$

proceeds quantitatively; product *(2)* cannot, however, be isolated. The mechanism of formation of *(1)*, its chemical properties, and the nature of the other products [formed from *(2)*] will be reported later[2]. *(1)* is a colorless, crystalline solid, m.p. 93 °C; NMR (CH_2Cl_2): τ = 4.9; M.W.: 162 (calc.), 156 (cryoscopic, benzene); correct elemental analysis.

Procedure:

A mixture of finely ground hexamethylenetetramine (7.0 g, 0.05 mol), PCl_5 (41.8 g, 0.2 mol), and dry CH_2Cl_2 (150 ml) is refluxed with gentle stirring for 20 h in a 250-ml round-bottom flask fitted with a reflux condenser and drying tube. The solvent is then distilled off; the final solvent residues are removed *in vacuo*, whereupon small amounts of unreacted phosphorus pentachloride may also sublime over. Compound *(1)* is sublimed from the crystalline residue at 70—80 °C/1.5 torr and trapped on a cold-finger; yield 8.0 g (100%). The product can be purified by resublimation or by recrystallization from CH_2Cl_2.

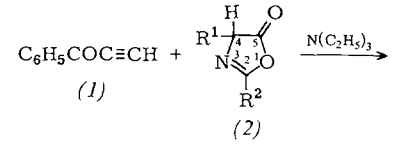
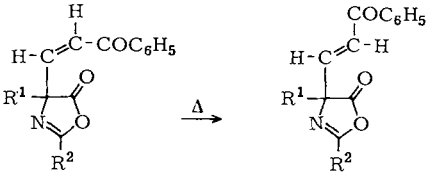
Base-Catalyzed Addition of Oxazol-5-ones to Activated Multiple Bonds[1]

By *Wolfgang Steglich, Peter Gruber, Gerhard Höfle*, and *Wolfgang König*[*]



The use of oxazol-5-ones as nucleophilic reactants in Michael additions has hitherto hardly been studied[2, 3]. Since oxazolone anions are ambifunctional[4, 5] they should, in principle, react with activated multiple bonds at C-2, at C-4, and at the exocyclic oxygen. We have found that the site of reaction is determined primarily by the kind of activated multiple bond.

Thus benzoylacetylene *(1)* adds exclusively to position 4 of 4-isopropyl-2-phenyloxazol-5-one *(2a)*. With triethylamine as a catalyst, *(1)* reacts in methylene chloride at as low a temperature as −10 °C within a few minutes to give the *cis*-olefin *(3a)*, which is converted into the *trans* isomer *(4a)* on brief warming to 100 °C.



The proclivity of *(1)* to add at position 4 is so pronounced that it is influenced but little by steric and electronic effects in the oxazolone anion. Thus 4-*tert*-butyl-2-phenyloxazol-5-one *(2b)* and 4-isopropyl-2-(*p*-nitrophenyl)oxazol-5-one

smoothly form the 4-adducts *(3)* which rearrange to *(4b)* and *(4c)* on heating (Table 1). No less than a 2-trifluoromethyl group is required to modify the electron distribution in the anion sufficiently to direct *(1)* to position 2[6].

[a] All compounds gave correct elemental analyses.
[b] Loses CO_2 on distillation [8].

The group of reagents that add exclusively to position 2 of 2,4-disubstituted oxazolone anions includes acrylonitrile, fumaric and maleic esters, and the corresponding dinitriles. Reaction furnished 2,2-disubstituted pseudooxazolones *(6)* (Table 2). They can be used for 3C-homologization of carboxylic acids[7].

Dimethyl acetylenedicarboxylate, acrolein, and methyl vinyl ketone *(7)* add to both position 2 and position 4, giving mixtures of *(6)* and 4,4-disubstituted oxazolones *(8)*[9]. The reaction of *(2a)* with *(7)* is shown as an example.

Under analogous conditions dimethyl acetylenedicarboxylate and acrolein afford the 2-adducts *(6)* in 34 and 64% yield, respectively. The product ratio *(6h)*/*(8h)* can be varied within limits by modification of the reaction conditions. If triethylamine is replaced by ethyldiisopropylamine, for example, the proportion of *(6h)* falls to 30%; on refluxing with triethylamine in carbon tetrachloride it rises to 70%.

All the 4-isopropyl-2-phenyl derivatives *(6)* and *(8)* studied can readily be distinguished on the basis of their

(8h) (48%) *(6h)* (52%)

$R^1 = CH(CH_3)_2$, $R^2 = C_6H_5$

NMR spectra (in $CDCl_3$). In *(8)* the methyl protons give two adjacent doublets ($\delta \approx 0.93$ and 1.05 ppm, $J = 7$ Hz) which overlap extensively (1.28 and 1.32 ppm) in the case of *(6)*. The methine signal of *(6)* appears considerably farther downfield (3.0 ppm) than that of *(8)* (2.1 ppm). Finally, the phenyl protons of *(6)* give a broad signal at $\delta \approx 7.5$ ppm which is resolved into two separate multiplets at 7.5 and 8.0 ppm (3 and 2 protons, respectively) in *(8)*.

General procedure:

Triethylamine (3—10 mmol) diluted with methylene chloride is added dropwise to a stirred solution of oxazol-5-one (10 mmol) and an activated alkene (alkyne) (10 mmol) in methylene chloride (30 ml). With highly reactive electrophiles (*e.g.* benzoylacetylene or fumaronitrile) only 3 mmol of triethylamine are used, with less reactive ones (*e.g.* fumaric ester) up to 10 mmol. In the former case the reaction time is just a few minutes, in the latter the reaction mixture is allowed to stand for 2—6 h at room temperature. The triethylamine is extracted with ice-cold 0.1 N HCl and the organic phase is dried and evaporated down *in vacuo*. The adducts are obtained very pure and if required can be recrystallized from chloroform/light petroleum.

Chain Lengthening of Carboxylic Acids by Three Carbon Atoms *via* Oxazol-5-one Anions[1]

By *Wolfgang Steglich* and *Peter Gruber*[*]

The carbon atom in position 2 of oxazol-5-ones, the electrophilic center of a masked carboxyl group, becomes nucleophilic on transition to the oxazolone anion[2].

This effect permits extension of the chain of carboxylic acids by three carbon atoms.

The starting point is the corresponding *N*-acyl-DL-valine *(1)* which is accessible in good yields by Schotten-Baumann reaction[3]. Brief warming with 3—5 mol. equiv. of acetic anhydride to 80—100 °C affords the oxazol-5-one *(2)*, which is treated with acrylonitrile/triethylamine in methylene chloride without prior isolation to give the pseudo-oxazolone *(3)*[1,4]. Hydrolysis with dilute alkalis or acids affords γ-keto nitriles *(4)* or γ-keto acids *(5)*, depending upon the reaction conditions, which are readily separable from accompanying α-ketoisovaleric acid.

Since all steps proceed in good yields and are simple in execution [*(1)* → *(4)* requires no isolation of intermediates] (Table 1), the technique represents a real alternative to hitherto established methods of 3C homologization of carboxylic acids[5-7].

General procedure:

Compound *(1)* (0.1 mol) is cyclized with acetic anhydride (0.3—0.5 mol) under the conditions given in Table 1. The reaction mixture is concentrated under vacuum in a rotary evaporator and vacuum-distilled twice with toluene. The residue is dissolved immediately in methylene chloride (40 ml) and treated with acrylonitrile (0.2 mol) at −20 °C. Triethylamine (0.05 mol) in methylene chloride (10 ml) is added dropwise within 30—60 min to the ice-cooled reaction mixture, which is stirred for the prescribed time and then evaporated under vacuum in a rotary evaporator.

[7] *R. Scarpati, G. Scherillo, F. Imperato*, and *R. A. Nicholaus*, Gazz. Chim. Ital. *97*, 654 (1967).

Residual triethylamine is removed by dissolution in ethyl acetate and extraction with cold 0.1 N HCl. The organic phase is evaporated down, 1 N NaOH (300 ml) is added followed by enough methanol, THF, or dioxane to give a homogeneous solution. The mixture is stirred for the prescribed length of time, evaporated down to half its original volume *in vacuo*, and extracted three times with ethyl acetate [after prior acidification in the case of *(5)*!]. If necessary the extract is decolorized with animal charcoal, dried over $MgSO_4$, and the solvent is evaporated off. The resulting oils soon crystallize on standing.

Sequence of Highest Occupied Molecular Orbitals in the Phosphorin System[1, 2]

By *Helmut Oehling*, *Werner Schäfer*, and *Armin Schweig*[*]

The aromatic phosphorins, which are analogs of pyridine, contain a trivalent phosphorus atom of coordination number 2 whose bonding has hitherto hardly been studied. A quantum-mechanical study[3] has shown that the highest occupied molecular orbital (HOMO) is a π-MO, whereas the corresponding orbital in pyridine describes the lone pair (n-MO) on the nitrogen atom. The fundamental importance of the HOMO for properties and reactivity of a compound prompted us to seek experimental confirmation of the theoretical predictions by studying the photoelectron spectrum of 2,4,6-tri-*tert*-butylphosphorin *(1)*.

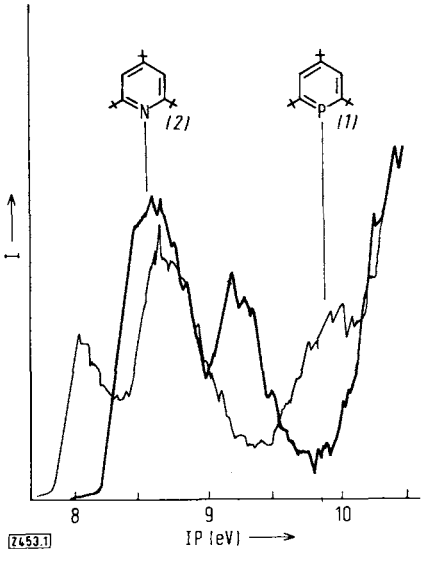

Fig. 1. Sections of photoelectron spectra of 2,4,6-tri-*tert*-butylpyridine *(2)* and 2,4,6-tri-*tert*-butylphosphorin *(1)* in arbitrary intensity units. *IP* = ionization potential.

Figure 1 shows a section of the photoelectron spectrum of *(1)* and, for comparison, of 2,4,6-tri-*tert*-butylpyridine *(2)*[4, 5].

The band maxima in the spectrum of *(1)* lie at 8.0, 8.6, and 10.0 eV, those in the spectrum of *(2)* at 8.6 and 9.3 eV. As expected, the phosphorins are more readily ionized than corresponding pyridines. The band maxima in unsubstituted pyridine are found at 9.6, 9.7, and 10.5 eV[6]. Hence the three *tert*-butyl groups in *(2)* lower the ionization potential (*IP*) by 1.0 to 1.2 eV.

The size of molecules *(1)* and *(2)* precludes direct CNDO/2 calculations[7]; instead calculations were performed on 2,4,6-trimethylphosphorin *(3)* and 2,4,6-trimethylpyridine *(4)*. A series of model calculations on the mono-, di-, and tri-methyl and the mono- and di-*tert*-butyl substituted compounds showed that replacement of a methyl by a *tert*-butyl group shifts the orbital energy by an additive component but that the orbital sequence is retained. For compound *(4)* it is n, π, π, σ and for *(3)* π, n, σ, π (see Fig. 2). These results strongly suggest that the first photoelectron band of *(2)* arises from overlap of an n- and a π ionization, and the second band from a π ionization. The intensity ratio of the first to the second band (2:1) may be regarded as supporting evidence. The same orbital sequence has recently also been suggested for pyridine itself by photoelectron spectroscopy[8].

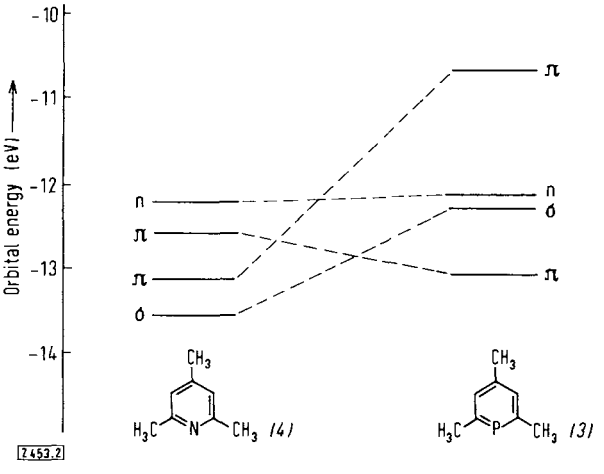

Fig. 2. Correlation diagram for model compounds *(3)* and *(4)*.

According to Figure 2 the first and third band of phosphorin *(1)* should be assigned to a π ionization, while the second band should result from an n- and a σ ionization. Experience shows, however, that semiempirical valence-electron calculations on unsaturated systems afford σ orbitals of too high energy[9], thus making assignment of π, n, π, and σ ionization to the three photoelectron bands more likely.

It is to be expected from Figure 2 that the *IP* of the lone pairs of *(1)* and *(2)* are almost equal. The *IP* of the lone pairs of NH_3 and PH_3 also differ by only 0.25 eV[10]. On the basis of these findings it would appear likely that the n-ionization bands are hidden under the low *IP* side of the bands at 8.6 eV in *(1)* and *(2)*.

The changes in MO energies (Fig. 2) on going from the pyridine to the phosphorin series can be readily interpreted in terms of hybridization and conjugation effects on the basis of the contributions of the atomic orbitals (AOs) on the hetero atom and the neighboring C atoms. Thus the main contributions to the n-MO are made by the 3s- and $3p_x$-AOs of the phosphorus atom and the 2s- and $2p_x$-AOs of the nitrogen, the former having the higher energy. In the phosphorin this energy difference is compensated by a considerably greater contribution of the s-AOs so that the energies of the n-MOs are only slightly different in the two

[*] H. Oehling, W. Schäfer, and Doz. Dr. A. Schweig
Physikalisch-Chemisches Institut der Universität
3550 Marburg, Biegenstrasse 12 (Germany)

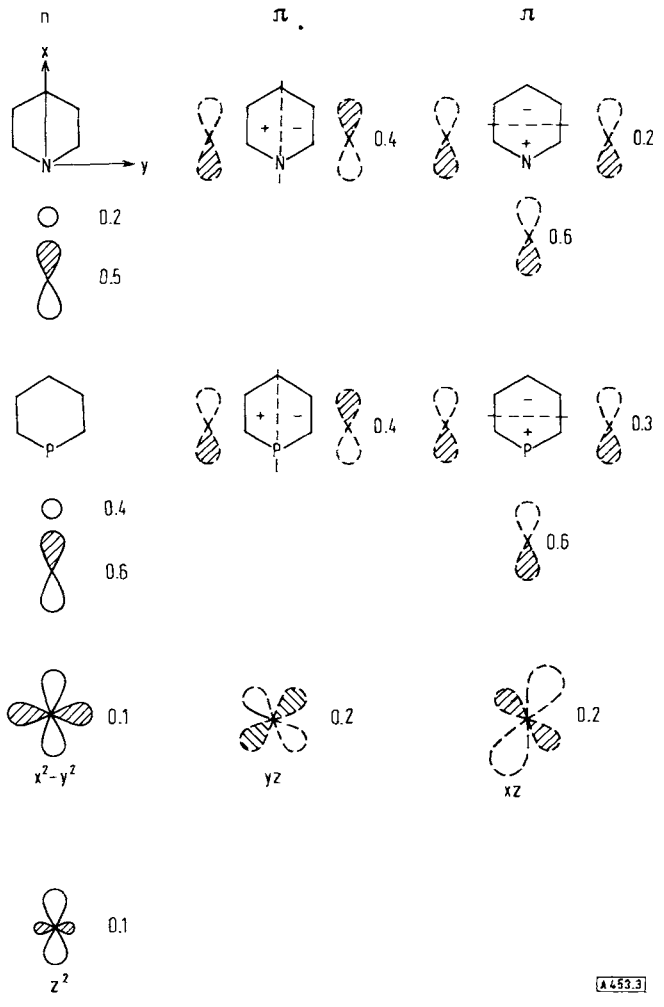

Fig. 3. Contributions of hetero atom AOs to the n-MO and of hetero atom neighboring C atom AOs to the two highest occupied π-MOs. The π-AOs are shown hatched to distinguish them from the σ-AOs.

compounds: The same change in the mixing ratio of s-AO and p-AO was also found on going from NH_3 to PH_3. In pyridine the highest π-MO has a node at the hetero atom whereas in phosphorin the conjugation of the corresponding π-MO can extend over the phosphorus atom *via* the $3d_{yz}$-AO. This d-electron effect leads to a lowering of the energy of this π-MO in phosphorin. The energy of the next lower π-MO in pyridine having an antinode on the hetero atoms is raised so drastically in phosphorin that it is promoted to the HOMO. The reason lies in the markedly less favorable $3_{p\pi}2_{p\pi}$ conjugation between the hetero atom and the neighboring C atoms in phosphorin compared with the corresponding $2_{p\pi}2_{p\pi}$ conjugation in pyridine. Any possible conjugative lowering of the energy of this MO by admixture of the $3d_{xz}$-AO of the P atom is thus overcompensated.

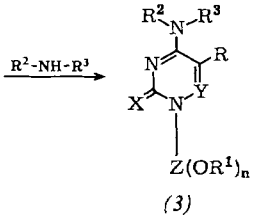
A Simple New Synthesis of Cytidines[**]

By *Helmut Vorbrüggen* and *Ulrich Niedballa*[*]



In the presently known methods for the conversion of uridines into cytidines, the alcoholic hydroxyl groups of uridines have to be acylated before the 4-position can be activated by reaction with P_2S_5/pyridine[1] or Vilsmeyer reagent[2] to give the corresponding cytidines on subsequent reaction with NH_3 or amines.

Protection of the alcoholic hydroxyl groups, activation of the 4-position, and reaction with NH_3 or amines can be combined if one silylates uridines *(1)* (X=O, Y=CH, Z=D-ribofuranose, R^1=H) to give the 4-trimethylsiloxy derivatives *(2)* [$R^1 = OSi(CH_3)_3$] and treats *(2)* in analogy to the 4-*O*-alkyluridines[3] *in situ* with NH_3 or amines to form the cytidines *(3)* (R^1=H). Since NH_3 is liberated on silylation with hexamethyldisilazane (HMDS), uridine and thymidine can thus be converted by HMDS and added

(1) R^1 = H, Ac, Bz

(2) R^1 = $Si(CH_3)_3$, Ac, Bz

(3) R^1 = H, Ac, Bz

[*] Dr. H. Vorbrüggen and Dr. U. Niedballa

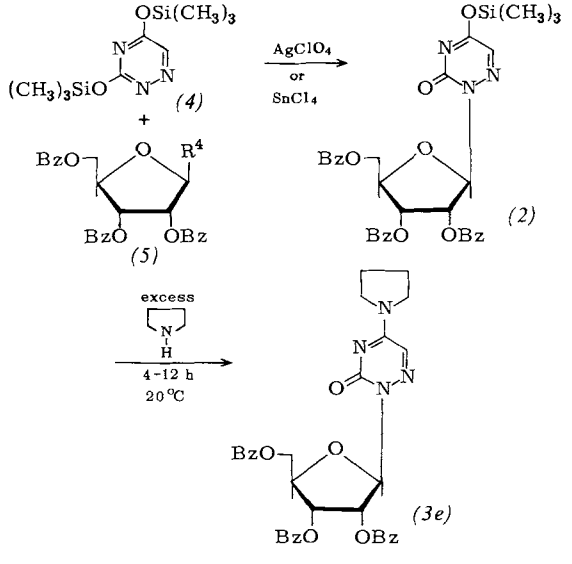
[**] Synthesis of Nucleosides, Part 5.—Part 4: *H. Vorbrüggen* and *U. Niedballa*, Tetrahedron Lett. *1970*, 3571.



excess NH_3 in one step into the corresponding cytidines by heating in an autoclave. Before reaction of *(2)* with primary amines, the HMDS should be distilled off since primary amines are silylated[4] on heating with HMDS and will no longer react with *(2)*. *O*-Acylated uridines *(1)* (R^1 = Ac, Bz) react similarly to give the *O*-acylated cytidines *(3)* (R^1 = Ac, Bz) *via (2)* (R^1 = Ac, Bz).

persilylated derivatives *(2)* [$R^1 = Si(CH_3)_3$]. For the silylation of acylated uridines, especially of acylated 6-azauridines, several hours' heating in benzene with HMDS and trimethylsilyl chloride is sufficient. The reactions of 4-trimethylsiloxy derivatives *(2)* with amines to the free (R^1 = H) or *O*-acylated (R^1 = Ac, Bz) cytidines *(3)* are compiled in the Table.

	(2)				*(3)*					
	X	Y	R	$Z(OR^1)_n$	amine R^2—NH—R^3	solvent	*T* (°C)	*t* (h)	yield (%)	m.p. (°C)

(h)	S	N	H		pyrrolidine	HMDS benzene	22	72	83	162
(i)	O	CH	CH_3	3,5-bis(*O*-trimethylsilyl)-2-deoxy-D-ribofuranose	NH_3	HMDS [b]	150 25 atm	96	65	193 (hydrate)
(j)	O	CH	CH_3		β-phenylethylamine	— [a]	120	144	55	182—184

[a] The HMDS was evaporated off in these experiments *before* addition of the amine.
[b] The reaction was carried out in a glass-lined autoclave.

The free uridines *(1)* (R^1 = H) are converted by standard methods[4] on 4—16 hours' heating with HMDS and traces of trimethylsilyl chloride as catalyst into the activated

R^4 = Cl; $AgClO_4$ in C_6H_6 ⟶ 46% *(3e)*
R^4 = OAc; $SnCl_4$ in $ClCH_2CH_2Cl$ ⟶ 57% *(3e)*

Since the acylated 4-trimethylsiloxy derivative *(2)* (R^1 = Ac, Bz) is also formed as an intermediate in the Silyl-Hilbert-Johnson reaction[5] we have treated the 2,4-bis(trimethylsiloxy) derivative *(4)* of 6-azauracil with the benzoylated D-ribofuranose derivative *(5)* in the presence of $AgClO_4$[6] or $SnCl_4$[7] to give the same intermediate *(2)*, which was converted *in situ* by an excess of pyrrolidine into the acylated cytidine *(3e)* in 46% or 57% yield, respectively. One can thus synthesize acylated cytidines in one step starting from uracils.

Cytidine (3a), R^1 = H:

Uridine (4.88 g, 20 mmol) in HMDS (50 ml) + NH_4Cl (5 mg) was saturated for 30 min at 24 °C with dry NH_3 gas in a 100 ml autoclave and then allowed to react for 48 h at 165 °C/25 atm. After cooling, release of pressure, and evaporation the residue was refluxed for 6 h in methanol, again evaporated, and the residue purified by dissolution in H_2O (100 ml) and treatment with charcoal. After evaporation, 3.9 g = 80% cytidine was obtained, which crystallized spontaneously from ethanol/H_2O, m.p. = 230 °C (dec.).

N^4,N^4-Butylenecytidine (3b), R^1 = H:

Uridine (4.88 g, 20 mmol) in HMDS (100 ml) and trimethylsilyl chloride (0.1 ml) was refluxed with stirring for

16 h at 150 °C in an oil bath. After evaporation of the HMDS, pyrrolidine (4.15 ml, 50 mmol) was added and the mixture heated for 20 h at 140 °C in an oil bath. The excess of pyrrolidine was removed by codistillation with benzene, the residue refluxed for 1 h in methanol (150 ml), the solution decolorized by charcoal, and evaporated. The residue gave 4.4 g = 74% *(3b)*, m. p. = 209—211 °C, on crystallization from ethanol.

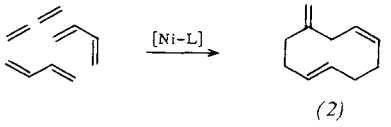
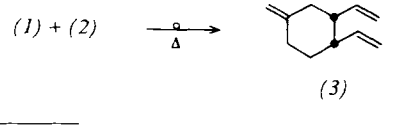
Catalytic Mixed Oligomerization of Butadiene and Allenes



By *Paul Heimbach, Harald Selbeck*, and *Eduard Troxler*[*]

In the presence of nickel(0)-ligand catalysts, butadiene and ethylene or alkynes give *cis,trans*-cyclodeca-1,5-diene[1] or *cis,cis,trans*-cyclodeca-1,4,7-trienes[2, 3].



Reaction of allene and butadiene in the molar ratio 1:10 in the presence of a nickel(0)-tris(2-biphenylyl)phosphite catalyst (Ni—L) in an autoclave gives a 35% yield of 8- and 9-methylene-*cis,trans*-cyclodeca-1,5-diene, *(1)* and *(2)* respectively, alongside large amounts of higher oligomers whose structures were not determined. However, if the butadiene-allene mixture is passed into the catalyst solution in such a manner that the steady-state concentration of the allene remains low, then the same catalyst gives a mixture of *(1)* and *(2)* in 69% yield based on reacted allene.

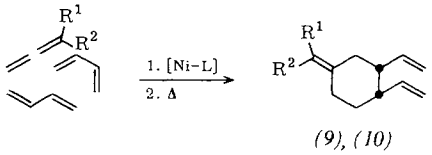
Dr. E. Troxler (as guest)
Exploratory Research
Ciba-Geigy AG
CH-4000 Basel 21 (Switzerland)



The mixture of *(1)* (63%) and *(2)* (35%) (m. p. 53 °C/1.5 torr, $n_D^{20} = 1.5079$) could be concentrated to 98% by distillation using a spinning-band column. Hydrogenation of *(1)* and *(2)* gives methylcyclodecane. *(1)* can be obtained pure by low temperature recrystallization from ethanol (m. p. 3.5—4.0 °C, $n_D^{20} = 1.5088$). 4-Methylene-*cis*-1,2-divinylcyclohexane *(3)* is formed by Cope-rearrangement on heating of *(1)* and *(2)* to 150 °C. Pure *(3)* boils at 179 °C/760 torr ($n_D^{20} = 1.4848$). ^{1}H-NMR, IR, and mass spectra of the mixture of *(1)* and *(2)* and of the pure compounds *(1)* and *(3)* are in agreement with the structures given.

In the course of this investigation we were also able to assign structures to the isomeric ten-membered rings *(4)* and *(5)* formed catalytically from butadiene and propylene[4], as well as *(6)* and *(7)* from butadiene and methylene-

cyclopropane[4, 5]. Heating of a 1 to 2% solution of diazomethane in *(1)*, a mixture of *(1)* and *(2)*, or in *(3)* with copper powder[8] affords three, six, or three isomeric hydrocarbons in an overall yield of 2 to 3%. *(6)*, *(7)*, and *(8)* present in the mixtures could be assigned unequivocally[6, 7].

Besides *(1)* and *(2)*, catalytic mixed oligomerization of butadiene and allene also gives bis(methylene)-twelve membered rings, consisting of two molecules of butadiene and two of allene, in 5 to 13% yield, independent of the catalyst used. The relative positions of the methylene groups were established, *inter alia*, by hydrogenation (PtO_2/glacial acetic acid) to *cis*- and *trans*-1,3-, 1,4-, and,

(9), (10)

(9), $R^1 = R^2 = CH_3$; b. p. 95 °C/10 torr, n_D^{20} 1.4946 (97%)
(10), R^1 or $R^2 = OCH_3$, R^2 or $R^1 = H$; b. p. 96 °C/8 torr, $n_D^{20} = 1.4953$ (99%)

in low yields, to 1,2-dimethylcyclododecanes which were compared with authentic samples[6, 7].

Reaction of 1,1-dimethylallene[9] or methoxyallene[10] and butadiene in presence of nickel-ligand catalysts gives the *cis,trans*-cyclodeca-1,5-diene derivatives corresponding to *(1)* and *(2)* which were isolated after Cope rearrangement

as the six-membered rings *(9)* and *(10)* in 40% [ligand = tris(2-biphenylyl)phosphite] and 45% yield [ligand = triphenylphosphane] based on reacted 1,2-diene.

Configuration of Garosamine, a Branched Chain Amino Sugar[**]

By *Wolfgang Meyer zu Reckendorf* and *Eberhard Bischof*[*]

Garosamine[2] which is obtained by hydrolysis of the gentamycin C_1, C_{1a}, and C_2 complex[1] occupies a special place among the many monosaccharides from antibiotics: It is the only natural branched-chain amino sugar to have been discovered so far. The structure of the methyl glycoside *(1)* of garosamine was confirmed by comparison with synthetic material[3]; however, the configuration of C-4, which is not susceptible to NMR spectroscopy, could only be suggested by IR measurements[3] of the hydrogen bond that may exist between OH at C-4 and NH. These spectroscopic results were later confirmed independently[4]. The cyclization described in the present communication affords chemical proof of the configuration of C-4.

Hydrolysis of the anomers *(1)* (24 h boiling in 1 N HCl) gave the free sugar *(2)* which was converted directly into the benzyloxycarbonyl derivative *(3)* without isolation by treatment with benzyloxycarbonyl chloride in sodium carbonate solution [syrupy liquid; yield 65%; $[\alpha]_D^{20} = +83°$ ($c = 0.9$; methanol)]. On reaction with hydrogen chloride in 2,2-dimethoxypropane (24 h, room temperature) and subsequent separation by layer chromatography (silica gel P; cyclohexane/ethyl acetate 1:1), compound *(3)* gave the pyranose derivative *(7)* [upper zone; syrupy liquid; yield 33%; $[\alpha]_D^{20} = +48°$ ($c = 0.7$; $CHCl_3$)] and the furanose *(4)* [lower zone; syrupy liquid; yield 16%; $[\alpha]_D^{20} = +28°$ ($c = 0.7$; $CHCl_3$)]. The constitutions of the pyranose and furanose forms were established by acylation.

Catalytic hydrogenation of *(7)* proceeded quantitatively to give the base *(8)* [characterized as the hydrochloride; m.p. 201—205 °C; $[\alpha]_D^{20} = +46°$ ($c = 0.5$; methanol)]. On *N*-benzoylation the latter furnished *(9)* [syrupy liquid; yield 43%; $[\alpha]_D^{20} = +38.5°$ ($c = 1$; $CHCl_3$)] which could not be acetylated (tertiary OH). In contrast, hydrogenation of *(4)* gave *(5)* [crystalline hydrochloride; yield 79%; m.p. 210—211 °C; $[\alpha]_D^{20} = +7°$ ($c = 1$; methanol)] which afforded the acetate *(6)* [syrupy liquid; yield 55%; $[\alpha]_D^{20} = -10.5°$ ($c = 1$; $CHCl_3$)] on subsequent *N*-benzoylation (benzoic anhydride/methanol) and acetylation (acetic anhydride/pyridine). Moreover, the mass spectrum of *(5)* (hydrochloride) contains a fragment formed by loss of CH_2OH which is characteristic of furanoses.

The pyranose derivative *(7)* proved very sensitive to alkali. On treatment with an anion exchange resin (Amberlite IRA 400 OH^-) in methanol (2 h, room temperature), *(7)* cyclizes to the oxazolidone *(10)* with elimination of benzyl alcohol [yield 75%; m.p. 123—124 °C; $[\alpha]_D^{20} = \pm 0°$; $[\alpha]_{250}^{20} = -110°$ ($c = 1$; $CHCl_3$); IR: no OH or NH; CO at 1740 cm^{-1}; M.W. 243 (mass spectrum); NMR ($CDCl_3$; δ in ppm): 5.54 (H-1/d); 4.42 (H-2/q); $J_{1,2} = 5$ Hz; 3.79 (H-3); $J_{2,3} = 2.5$ Hz; 3.75 (2 H-5); 1.39, 1.42, 1.59 (3 C—CH_3); 2.97 (N—CH_3)].

A study of models shows that formation of the oxazolidine ring constitutes a proof of the L configuration of C-4. Garosamine is therefore proved as being 3-deoxy-3-methylamino-4-*C*-methyl-L-*arabino*-pentose, in agreement with spectroscopic results.

Problems in the Determination of Very Small Amounts of Elements

By *Günther Tölg*[*]

Selected examples were used to show how analytical procedures for determination of elements in ng and pg quantities can be optimized: this involves special techniques for the decomposition of samples and for separations, with lower blanks and lower losses by adsorption or volatilization, as well as new methods of determination.

Organic matrices can be decomposed in an oxygen plasma excited by microwaves (2450 MHz)[1]; volatile elements (I, As, Se, Cd, *etc.*) are retained in a cold finger attached to the apparatus; Hg in amounts <1 ng are $>90\%$ condensed in a receiver cooled in liquid nitrogen. In cell and tissue samples (*ca.* 1 g), for example, amounts of Be of $<10^{-7}\%$ can then be determined (gas-chromatographically as Be trifluoropentanedionate)[2].

ng amounts of nitrogen can be obtained from many matrices by a modified Kjeldahl method: the ammonia is determined directly in the receiver of a recycling distillation apparatus by coulometry with biamperometric determination of the endpoint[3].

Many cations can be separated in amounts <1 ng by thin-layer chromatography, *e.g.*, as dithizonates, on a *ca.* 2μ-thick film of aluminum oxide produced by anodic oxidation[4]. The aluminum oxide thin film is also useful for separation of organic substances (*e.g.*, metabolites of insecticides, dyes, *etc.*) in amounts of 10^{-9} to 10^{-10} g.

For indirect gas-chromatographic determination of Ni, Zn, and other metals in amounts of 10^{-8} to 10^{-10} g their chelate complexes with polychlorinated xanthates are formed, then separated by thin-layer chromatography, and extracted from the adsorbent by hexane[5]. The xanthates are then decomposed thermally on the column, and the polychlorinated alcohols thus obtained are determined by an electron-capture detector.

1 ng amounts of Se can be similarly obtained by direct gas chromatography[6]: with polychlorinated diols [*e.g.*, 1,4,5,6,7,7-hexachlorobicyclo[2.2.1]hept-5-ene-2,3-bismethanol (Endodiol)] SeO_2 forms volatile selenous esters (Selenodan) which can be detected in amounts as low as 10^{-12} g by an electron-capture detector.

SELECTED ABSTRACTS

Methods for the measurement of photoluminescence quantum yields are reviewed critically by *J. N. Demas* and *G. A. Crosby*. The pertinent literature is covered through early 1969; luminescence quantum yields of solids are excluded. A chapter discussing absolute methods is followed by an account of published standard quantum yields. Instructions are given for the calibration of light sources, monochromators, and detectors. Corrections necessary for the results of most methods are stated. Finally, recommendations about data presentation are made. [The Measurement of Photoluminescence Quantum Yields. A Review. J. Phys. Chem. *75*, 991—1024 (1971); 147 references, 3 figures]

[Rd 385 IE–H]

Methods of sequence analysis of ribonucleic acids are considered in a review article by *M. A. Billeter*. Such a sequence analysis depends upon the possibility of enzymatic cleavage of the nucleotide chain at defined linkages by specific ribonucleases (T_1-ribonuclease, pancreas ribonuclease) and separation of the resulting oligonucleotides by DEAE chromatography with decreasing pH and by *Sanger*'s fingerprinting technique. The isolated oligonucleotides are subjected to alkaline or enzymatic degradation. A new method of sequence analysis for large ribonucleic acid molecules is illustrated for bacteriophage Qβ-RNA. [Über die Sequenzanalyse an Ribonucleinsäure. Chimia *25*, 181—187 (1971); 22 references, 13 diagrams]

Grundpraktikum der organischen Chemie (für Chemiker, Physiker, Biologen und Mediziner im ersten Studienabschnitt) (Fundamentals of Practical Organic Chemistry (for Chemists, Physicists, Biologists, and Doctors in their first semesters)). By *E. Poulsen Nautrup*. Vieweg und Sohn, Braunschweig 1969. iv, 72 pp., 13 figs., DM 7.80.

Under the title "Standardmethoden der praktischen Chemie (Standard Methods in Practical Chemistry)", Vieweg und Sohn publish a loose-leaf collection of preparative methods; as a text on the fundamentals of practical organic chemistry, some of these methods have now simply been put together in book form. Thus, the individual methods remain isolated; no attempt has been made to link them up or arrange them in any sort of order that might justify the name "Fundamentals". The criteria for selection remain unclear: for instance, 13 of a total of 72 pages are devoted to preparation and reactions of diazonium salts, at the expense of other preparations and reactions of greater educational value. The instructional value of specific dye syntheses (p. 55) in the training of physicists, biologists, or doctors is dubious. The description of each individual preparation is divided into the following sections: description of the reaction, course of the reaction, general range of application, safety precautions, and general operating instructions.

In the context of a practical manual for beginners, the notes on safety precautions and the general operating instructions, with their detailed information on the amount of time, equipment, and chemicals required, are very useful. However, students would do better not to read the general descriptions of the reactions. There are at present a whole series of organic chemistry textbooks in which established reaction mechanisms are clearly displayed. One wonders, therefore, how anyone could arrive at the reaction mechanisms as formulated here, which are faulty in so many instances that it is just not worth going into details.

Clear and uniform manner of writing is particularly important in a book intended for beginners. When a group is split off from a molecule, the fate of the bonding electron pair should be perfectly clear (see p. 25). Expressions such as "carban-ion" (pp. 18, 29), "positive effect of the benzene nucleus" (p. 18), or "electron-repelling effect of the OH group" (p. 57) just may not occur. Students should therefore be dissuaded from buying this book, despite the fact that it is precisely the beginner who would benefit from the detailed descriptions of the experiments.

The Present Position of Hemoglobin Research[**]

By Gerhard Buse[*]

Dedicated to Professor Gerhard Braunitzer on the ocassion of his 50 th birthday

Up to the present time hemoglobin has enjoyed pride of place among the objects of study in molecular biology. Investigations on this molecule have culminated in the complete description of its atomic structure in various functional states and point the way for future research on other biopolymers. However, more than just a knowledge of the anatomy of this protein is required before we can make quantitative predictions about its function.

1. Introduction

The red blood pigment hemoglobin is one of the most intensively studied of all macromolecules. More than 500 publications on this topic have appeared during the last two years[1]. The concentrated study of this protein has contributed greatly to knowledge in the field of molecular biology. Only a broad survey can be given in this article, and the selection is subjective; we have been concerned with this molecule mainly from the standpoint of protein chemistry.

The name "hemoglobin" in the title should be taken as a family name. It includes the myoglobins and (as has recently been shown) the erythrocruorin of insects, and possibly also the hemoglobin of leguminous plants[2]. This relationship is confirmed by the reversible binding of O_2 on the Fe^{2+} coenzyme, protoporphyrin IX[3], and by agreement in primary and tertiary structures. No genetic relationship with hemoglobin has so far been found for the other heme proteins that occur in nature, particularly the cytochromes. A possible exception is cytochrome b 562 from *E. coli*[4].

Molecular-biological studies on the hemoglobins began with the X-ray analysis of myoglobin at a resolution of 6 Å, and shortly afterwards at a resolution of 2 Å[5]. This was followed by the conformational analysis of hemoglobin by *Perutz et al.*[6], which showed that this molecule is built up from 2×2 myoglobin-like subunits ($\alpha_2\beta_2$). *Braunitzer et al.*[7] published the primary structure of human hemoglobin in 1961, and *Ingram*[8] interpreted sickle cell anemia as arising from a genetic defect of this molecule. Following these investigations, refinements of the X-ray structures of myoglobin and hemoglobin extending down to atomic resolution, as well as four other X-ray analyses, were published, some 35 primary structures were reported and more than 100 hemoglobin anomalies discovered.

Investigations on the function of this molecule are being carried out at present with the aid of a large number of physicochemical methods. These include kinetic studies with rapid mixing techniques, temperature and field jump methods, flash photolysis, IR spectroscopy, measurement of the optical rotatory dispersion (ORD) and of the circular dichroism (CD), polarography, electron spin resonance spectroscopy (ESR), and recently nuclear magnetic resonance spectroscopy (NMR). The important contributions made by these methods cannot be mentioned in detail here, but have recently been reviewed[9]. The object of the investigations is to clarify the function of this protein on the molecular level and to investigate its genetic formation and modification.

[**] Abbreviations used:

Mb	Myoglobin
Hb	Hemoglobin
α, β, γ, δ, ε	Peptide chains (subunits) of the hemoglobins
RNA	Ribonucleic acid
DNA	Deoxyribonucleic acid
NA...B...C...HC	Helical and interhelical regions of the hemoglobins and myoglobins
His β,F8(97)	Notation for the position of an amino acid, *i.e.* histidine of the β chain in position 8 of the F helix, position 97 of the sequence
pMB	*p*-Chloromercuribenzoate
2,3-DPG	2,3-Diphosphoglyceric acid

2. The Primary Structure and Its Variability

2.1. Biosynthesis

The biosynthesis of hemoglobin was investigated in the reticulocyte system of rabbits. It was found that 9S-RNA of the polysome fraction of mouse reticulocytes could be used in a cell-free rabbit reticulocyte system for the synthesis of β chains of Hb. This was the first protein biosynthesis to be carried out by mRNA from mammals in a cell-free system[10]. Rabbit globin can be obtained *in vitro* in the *E. coli* system with rabbit reticulocyte RNA; this is an excellent illustration of the universality of the genetic code. *N*-Acetylvalyl-tRNA is essential here, as it initiates the synthesis on Val NA1α,β(1)[11]. Other experiments showed that the biosynthesis beginning at the amino end is delayed if no heme can be incorporated into the three-dimensional structure of the molecule after about 90 steps of the synthesis; this indicates that the N-terminal parts of the protein released by the ribosomes orient themselves in space even before they are finally released from the point of synthesis.

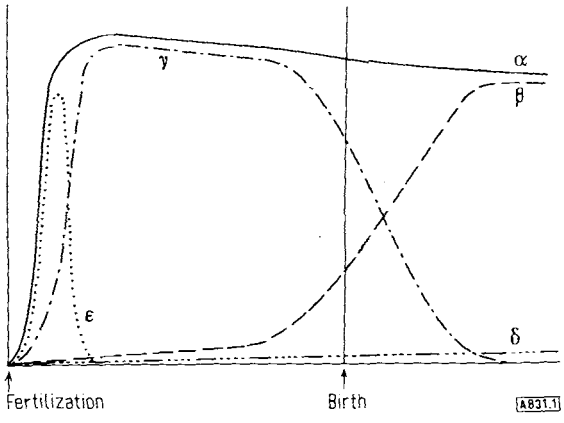
The peptide chain synthesized in this way contains the information for the three-dimensional folding of the molecule and for the binding of heme, and thus determines the properties of the molecule. It is collinear with the sequence of the DNA codons of the corresponding genes. These cannot be studied directly at present, but have been located on a chromosome arm in the case of the dipterous insect genus *Chironomus*[12]. Evidence of collinearity can also be deduced from a number of observations in sequence analyses on hemoglobin[13] and other proteins.

2.2. Primary Structures

Investigations on sperm-whale myoglobins and on human hemoglobin had already shown the basic types of peptide chains that characterize the myoglobins and hemoglobins of vertebrates. The longest chain type occurs in the monomeric myoglobins with 153 amino acids. The sequences known so far are related; they lack cysteine. Position 9 is deleted in human myoglobin, *i.e.* the chain consists of only 152 amino acids[14] (see Table 1). Hemoglobins in birds, amphibians, and teleosts also exhibit the tetrameric construction from α and β chains, which generally consist of 141 and 146 residues respectively. Cysteine occurs here, but no disulfide bridges are formed. The amino end is acetylated in some cases. Data of this kind have been collected since *1967* by *Dayhoff et al.*[19].

In addition to hemoglobin A and myoglobin, there are also a number of other human hemoglobins, such as fetal hemoglobin F, which contains γ chains instead of the two β chains ($\alpha_2\gamma_2$)[16]. The γ chains are no longer synthesized after birth. There is probably also a fetal myoglobin corresponding to the fetal hemoglobin[15]. Moreover, in addition to HbA, the adult also has about 2% of HbA_2 ($\alpha_2\delta_2$)[17], which contains another non-α chain, *i.e.* the δ chain; an embryonal hemoglobin ($\alpha_2\varepsilon_2$)[18] containing the ε chain, the details of which are not yet known, is observed in very early embryonal stages. The ontogeny of these chains is shown in Figure 1.

A deeper insight into the relations between structure and function is provided by the comparative analysis of phylogenetically distant hemoglobins. The hemoglobin of the sea lamprey *(Petromyzon marinus)*, a primitive jawless vertebrate, is monomeric as HbO_2 and polymeric as Hb.



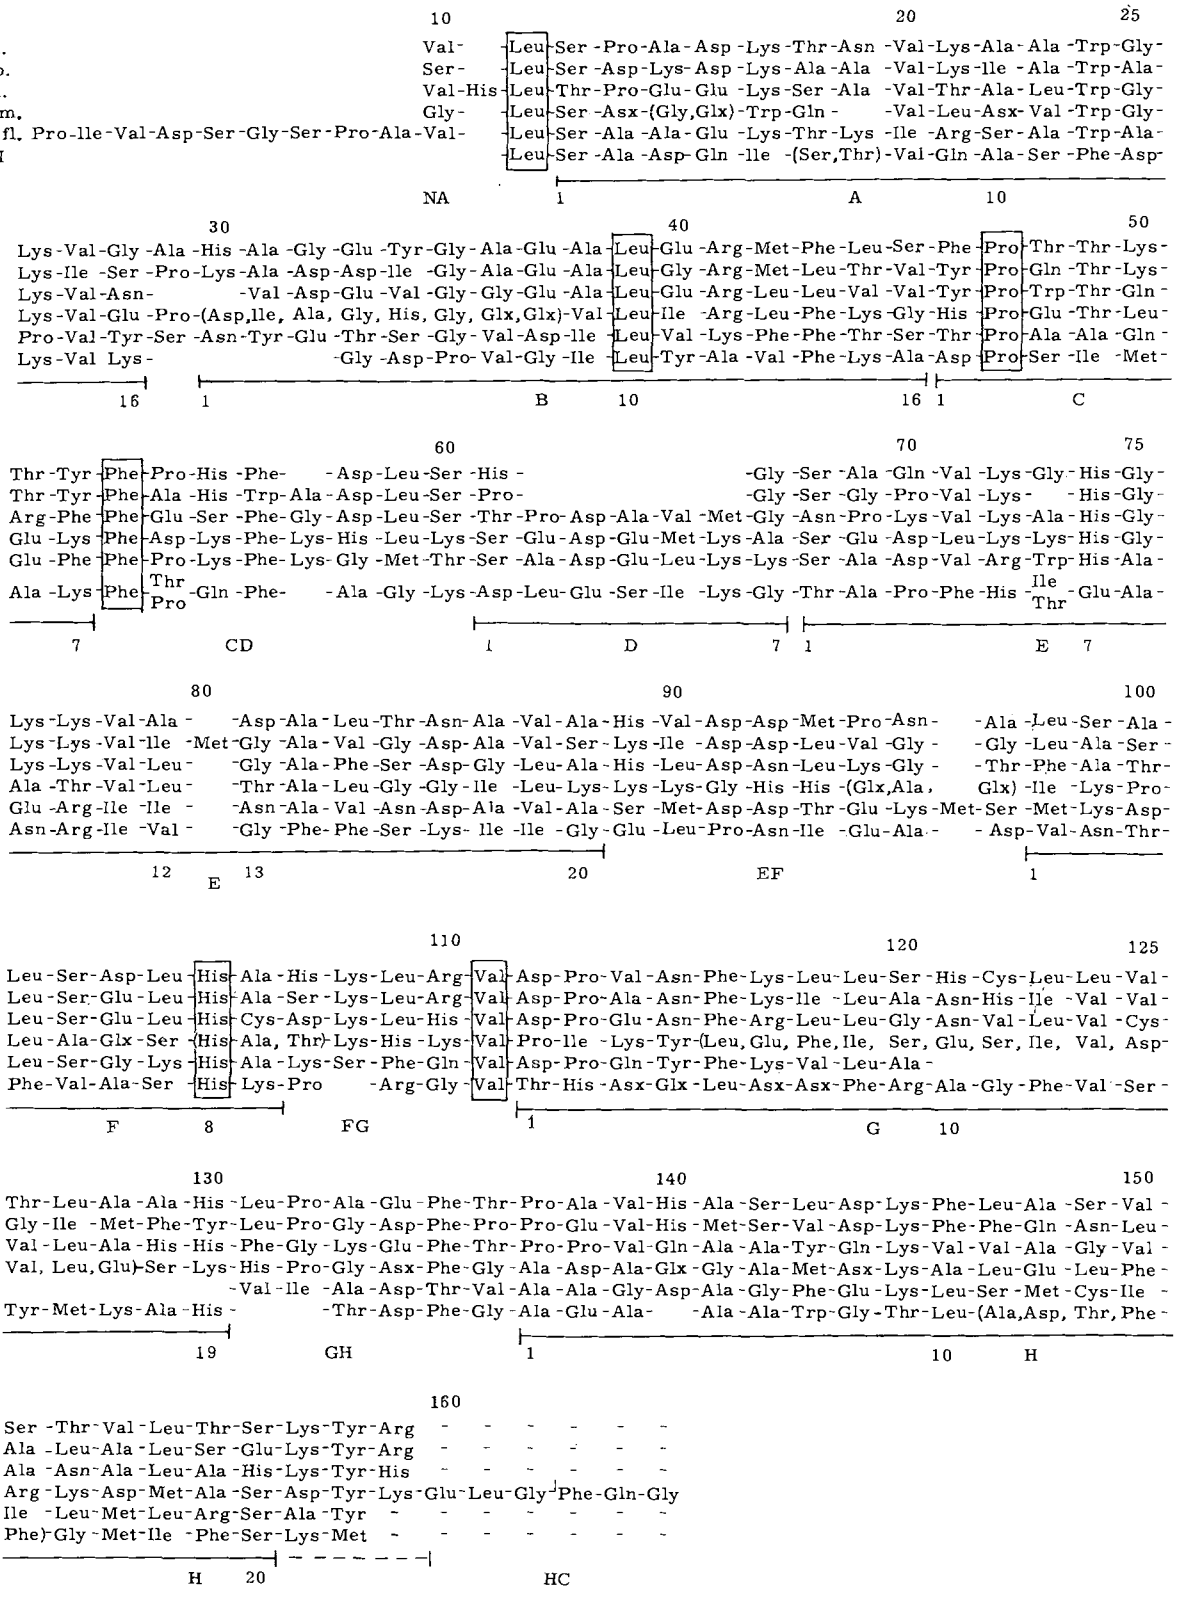


Fig. 1. Ontogeny of human hemoglobins (after *Betke* (ref. [77])).

The globin of the closely related lampern *(Lampetra fluviatilis)* consists of a sequence of 146 amino acids, whose homology with the above hemoglobins is more difficult to establish (see Table 1). The sequence begins with nine residues for which there is no counterpart in other hemoglobins. The molecule is shortened in the C-terminal region, where deletions of up to 10 amino acids have occurred[20]. The numerous monomeric and dimeric hemoglobins of the insect *Chironomus thummi* differ even more. They dissolve freely in the hemolymph of the aquatic larvae. This hemoglobin, which is the only invertebrate hemoglobin to be studied so far, has a peptide chain of only 136 amino acids. The deletions are in the N- and C-terminal parts of the chain[21].

Whereas the hemoglobins and myoglobins known so far of vertebrates have seven amino acids in corresponding positions, this number falls to three or four on comparison with insect hemoglobin. Thus nature achieves the same object here with an entirely different set of structural components. Despite the marked differences from vertebrate sequences, however, a similarity, particularly in the N-terminal region, cannot be overlooked. This justifies the notation used in Table 1 as an expression of a distant phylogenetic relationship. It is surprising to find that the Trp sequence (A 10—15), which is known from the investigations on vertebrates, has been displaced here into the C-terminal region of the chain (H 5—10)[22]. *Chironomus* hemoglobins also contain no cysteine.

The invariant residues in vertebrates include tryptophan A12, which forms another hydrophobic nucleus of the molecule besides the heme, glycine B6, which is the only amino acid that can be placed between the B helix and the superimposed D helix because of the absence of a side chain, proline C2, which forms the corner for the transition into the C helix, phenylalanine CD1 in close π-bond contact with

the heme, histidine E7, the distal heme contact, to which a functional significance was originally assigned, histidine F8, the proximal heme linkage, and tyrosine HC2, which is necessary for the attachment of the H helix to the molecule and for the allosterism of the tetrameric hemoglobin (see Section 3.2). Substitutions of Trp A12, Gly B6, His E7, and Tyr HC2 in insect hemoglobin show that the development has followed different paths in this case. Amino acids such as Val NA1α and His HC3 β which are important to the pH-dependent binding of O_2 in mammalian hemoglobins (Bohr effect), are deleted. This monomeric hemoglobin nevertheless shows a distinct pH dependence of the binding of O_2. The greatest Bohr effect measured so far is in fact found for dimeric components of these larval hemoglobins[23].

2.3. Evolution and Polymorphism of the Globins

The difference in the globin sequences of different species of animals corresponds to the degree to which the carriers are related. This was first recognized by *Zuckerkandl* and *Pauling*[24] on comparison of the sequences of the α chains of horses and of man, which differ in 18 positions. If one assumes similar rates of substitution of the hemoglobins for the two species since their divergence from a common ancestor some 90×10^6 years ago, the α chains of both species have diverged by an average of nine amino acids from the α-chain of the common ancestor. In other words, an average of one amino acid has been exchanged every 10×10^6 years.

The development of this fundamental idea has led in recent years to the systematic comparison of the primary structures of homologous proteins as a means of tracing the phylogeny of the species. Comparative morphology has already thrown considerable light on this topic, but this new method offers a number of obvious advantages:

1. The exchange of an amino acid follows from the alteration of a base in a codon of the DNA. This point mutation is the smallest genetically possible change, *i.e.* the "unit" of evolution (mutation and selection). It can thus be quantified, the data obtained being collected and evaluated by computers.
2. The sequence of the common ancestor can be deduced from a comparison of several sequences. Unlike most fossils, these structures characterize the exact phylogenetic branching points.
3. Comparative studies can in principle be applied to all proteins; the total quantity of information obtainable is therefore greater than by the use of the relatively rough morphological criteria.
4. It has been found that the rate at which amino acids are exchanged varies from protein to protein. The phylogeny can therefore be traced over very long periods (up to 3×10^9 years; phylum formation) in a protein with a low substitution rate, and over shorter periods (species formation) in another protein with a high substitution rate. Hemoglobin is a protein with a medium time scale.

The prerequisites for such studies, such as criteria of homology and convergence, influence of the generation and mutation rates, and gene duplication and deletion, are being discussed at present[25]. Moreover, no answer has yet been found to the question whether different amino acid sequences of a protein result from mutation and selection or mainly from mutation alone[26]. Gene duplications result in an increase in genetic material, which leads in turn to the development of proteins with new functions[70]. According to *Ingram* a primitive hemoglobin gene existed in the hereditary material of the animal kingdom, but it was only with the development of higher vertebrates that gene duplications allowed differentiation into the β type of chain (β—ε) and the α chain. The progressive shortening of these polypeptides in relation to myoglobin points to the increasing specialization to the subunits of a cooperative tetramer (see Section 3.2).

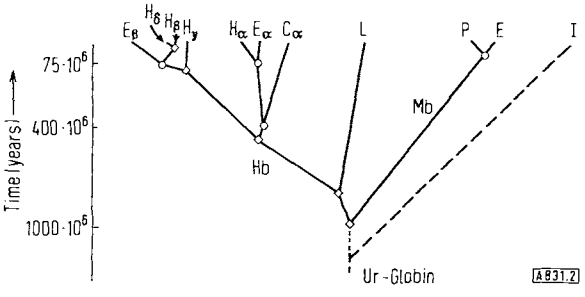

Fig. 2. Phylogenetic tree of the globins (modified after *Dayhoff et al.* [19]). α, β, γ, and δ peptide chains of man (H), horse (E), carp (C), lampern (L), sperm whale (P), and *Chironomus* th. (I) are shown. Hb = hemoglobin, Mb = myoglobin. Rectangles at the branching points indicate duplications of the globin genes, while circles indicate the development within chain types, which is shown for only a few examples for the sake of clarity. The time scale is provisional.

Figure 2 shows a phylogenetic tree deduced from a few very different globin sequences[19]. At least one gene is the carrier of information for one peptide chain. At least six globin-synthesizing genes must therefore occur in man. Investigations on Hb F, in which a whole-number relationship was found for a particular amino acid exchange[27], led the authors to conclude that there are at least two genes of a γ-chain synthesizing type. It was possible to verify by hybridization experiments with mice that this kind of ambiguity is not due to errors in protein biosynthesis[28]. It must therefore be assumed that even more than six genes contain the hemoglobin information, and under certain conditions they put it into effect. This is also confirmed by the observation that anemic goats synthesize an additional hemoglobin that strongly binds O_2[29]. The most pronounced polymorphism of a hemoglobin is found in *Chironomus* larvae, from whose hemolymph at least twelve components can be separated by chromatography and electrophoresis; exchange of neutral amino acids and variations of the length of the peptide chain in homogeneous fractions have also been described[21]. The diversity of these structures makes them suitable subjects for comparative investigations by physicochemical methods. This also offers a possible explanation for the discrepancy between the number of proteins synthesized by a higher organism and the very much greater information capacity of its DNA.

The methods of sequence analysis are suitable for the detection of small differences in primary structures only if used very carefully. The capabilities of present-day protein separation methods are also overtaxed. An important advance may result from the automation of Edman degradation[30]. Further sequences, even of high molecular weight hemoglobins[31], should become known during the next few years, and microheterogeneities should be found in sequences that are already familiar.

The covalent structure of a protein as formed by biosynthesis contains the information for the three-dimensional folding and function of the molecule. If this proposition is accepted, the way is open to a genetic understanding of a protein as a product of a long evolution process involving mutation and selective adaptation; at the same time, one is faced with the task of reading the properties of these substances from their primary structures. This aim is still far beyond the capabilities of theoretical chemistry at present. Once it has been attained, it will be possible (provided that proteins can be synthesized) to use the unsurpassed activities of the biocatalysts for other purposes, *e.g.* in chemical technology and medicine. Thus in addition to its phylogenetic importance, the comparative investigation of primary structures, particularly in the variable hemoglobin, also has a purpose connected with theoretical chemistry; it shows the variety of ways in which the structural units of a protein can be fitted together without appreciably changing the basic function or the conformation. It looks as if the comparative analysis of hemologous sequences could lead to the discovery of hitherto unknown rules of protein structure.

2.4. Abnormal Hemoglobins

The above-mentioned primary structure of hemoglobin A is normally found for all human beings, irrespective of race. It is common to the human population of the earth, and even the hemoglobin of chimpanzees is identical in structure. Deviations from this structure are described as abnormal hemoglobins; they are frequently responsible for diseases. Since the identification of the anomaly of sickle cell hemoglobin (HbS) as amino acid exchange ($\alpha_2\beta_2$6Glu→Val) by combined electrophoresis and partition chromatography of the tryptic peptides (fingerprint) of HbS and HbA[8], more than one hundred other anomalies have now been reported[32]. Their explanation by inheritable point mutations and (in the case of deletions) nonhomologous crossing over of the DNA (exchange of fragments) is generally accepted, though not yet accessible to direct investigation. A significant proportion of 2217 possible one-point mutations[25] has thus been described after only a few systematic investigations. The other mutations may also be expected to be found in the course of time, insofar as they are compatible with life. It was calculated from these investigations that an average of one human being in every 600 has an abnormal hemoglobin. Table 2 shows some examples that particularly contribute to our understanding of the function of the molecule (see also Section 3.3). If one examines the entire list of these changes, one finds that the exchanged residues usually differ in their charge. This is in part due to the investigation method, *i.e.* electrophoresis; the exchange of neutral residues is difficult to detect. In addition to exchanges, deletions of one or more amino acid residues have been described, as in Freiburg and Gun Hill hemoglobins, and hybridization of the β and δ chains[13] has been found in Lepore hemoglobin.

Table 2. Some abnormal hemoglobins (see also Section 3.3).

Type	Position	Exchange
Freiburg	βB5 (23)	Val → 0
E	βB'8 (26)	Glu → Lys

3. Three-Dimensional Structures and Functions

3.1. Tertiary Structure

Our knowledge of the secondary, tertiary, and quaternary structures of hemoglobin and other proteins comes mainly from X-ray analysis.

The X-ray analysis of sperm-whale myoglobin[5], first showed the three-dimensional structure of this type of molecule. More than 70% of the globular protein has a helical structure, which is divided into eight regions (A, B,...H) (secondary structure); the chain is folded in a characteristic manner around the heme (Fig. 3a). Contact is made with the heme through a nitrogen atom of the imidazole side chain of His F 8 (5th coordination site of the heme Fe^{2+}), by polar bonds from the protein to the propionic acid residues of the heme, and above all by van der Waals forces (hydrophobic interactions) with the inward-facing lipophilic amino acid residues of the protein. The tightly packed hydrophobic nucleus is shielded from the surrounding water and kept in solution by hydrophilic side chains. The sixth coordination site of Fe^{2+} is occupied by O_2 in the oxygenated state (HbO_2), and is free in the deoxygenated state (Hb). If the iron of heme is oxidized (Fe^{3+}), the molecule can no longer function; the sixth coordination site is now occupied by water, which forms a hydrogen bond to the histidine E 7.

The subunits of hemoglobin (α, β chains) (Fig. 3b)[6], *Chironomus* hemoglobin, and the hemoglobins of *Glycera di-*

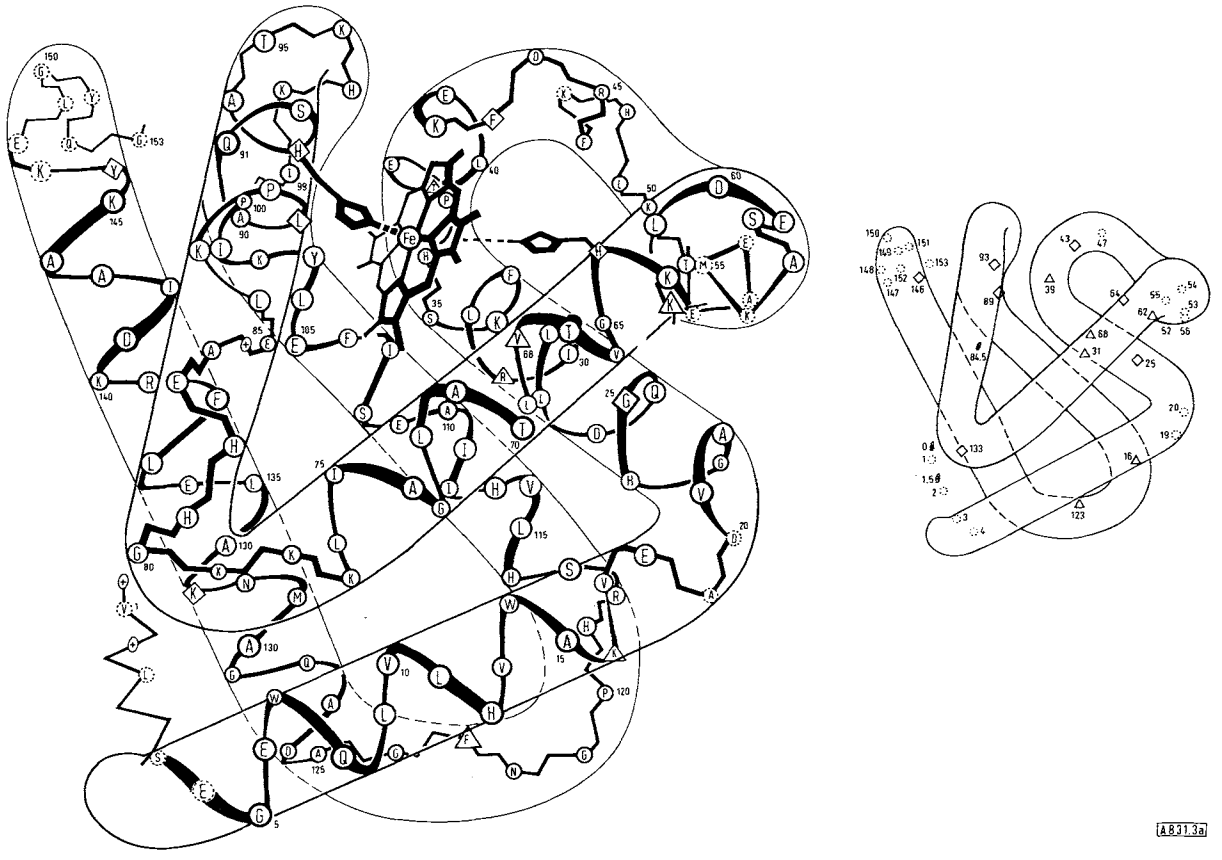

Fig. 3a. Conformation scheme of sperm-whale myoglobin (after *Dickerson* from *Dayhoff et al.* [19]). The amino acids are denoted by their single-letter symbols. In the small drawing, △ indicates invariant residues in vertebrate globins except that of *Lampetra fluviatilis*, ○ denotes residues that are deleted in some vertebrate globins, ◇ means invariant in all vertebrate globins, and ⊕ denotes insertions.

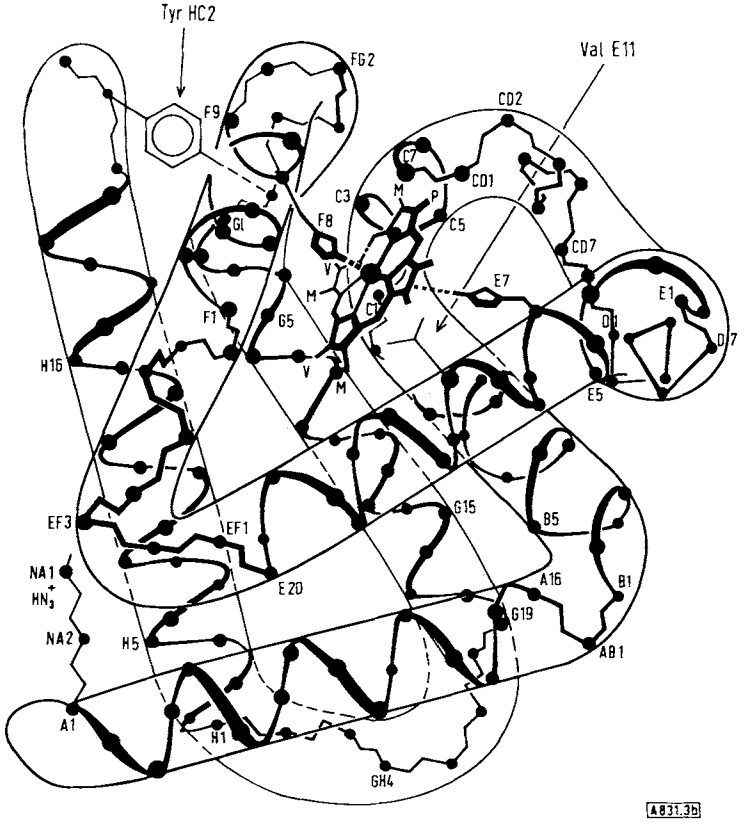

Fig. 3b. Conformation scheme of the β chain of HbA; helical positions and the position of Tyr HC2 are shown (after *Perutz* [64]).

branchiata and *Petromyzon marinus*[34], *i.e.* all the hemoglobins or their subunits on which X-ray studies have been carried out, have a tertiary structure similar to that of myoglobin. Slight deviations are found, such as those that can sometimes be deduced from the examination of the homologous primary structures. The α chain cannot form a D helix because of deletions D 2—6, and both the α and the β type are shortened at the carboxyl end in comparison with myoglobin. Insect hemoglobin exhibits further shortenings; thus one turn of the B helix is missing. The result is that the A helix bends at Phe A 12 and approaches closer to the center of the molecule. CD measurements show how this correction is facilitated by the shortening of the residue A 12 Trp→Phe[35]. The H helix is disturbed by a deletion and bent, while the carboxyl end exhibits a different construction with Met, corresponding to the absence of Tyr H 22 (≙ HC 2 of the α, β chains)[33].

The changes found here are the most pronounced of all those found for hemoglobin tertiary structures. However, though this molecule has little resemblance in its primary structure to the hemoglobin or myoglobin of mammals, the construction of a protein that reversibly binds O_2 is still the same, despite a phylogenetic distance of probably more than 10^9 years. This is true in particular of the general arrangement of the apolar heme contacts, *e.g.* the phenylalanine CD 1, and of the proximal bonding site of the heme iron His F 8. The distal histidine E 7 appears to be a develop-

ment of the vertebrates but its significance becomes somewhat unclear on comparison with the structure of insect hemoglobin. However, the sixth coordination position of the Fe^{2+} seems more readily accessible here, and this may explain the change in the kinetics of ligand binding and of autoxidation[36]. Details of the X-ray structures of *Glycera* and *Petromyzon* hemoglobins have not yet been published.

An interesting addition to the investigations just mentioned is the neutron-diffraction analysis of sperm-whale myoglobin crystallized from a D_2O solution containing ammonium sulfate[38]. The result agrees well with the X-ray findings, apart from the positions of a few amino acid side chains.

3.2. Quaternary Structure and Function

While the investigation of the monomeric hemoglobins was very difficult, the study of the quaternary structure, *i.e.* the noncovalent bonding (hydrophobic interactions, ionic interactions, and hydrogen bonds) of the subunits to form the tetrameric functional unit of vertebrate hemoglobins, was even more so. A regulating organization of this nature is found for many enzymes, and the possibility of studying it in hemoglobin led to the designation of the latter as an "honary enzyme".

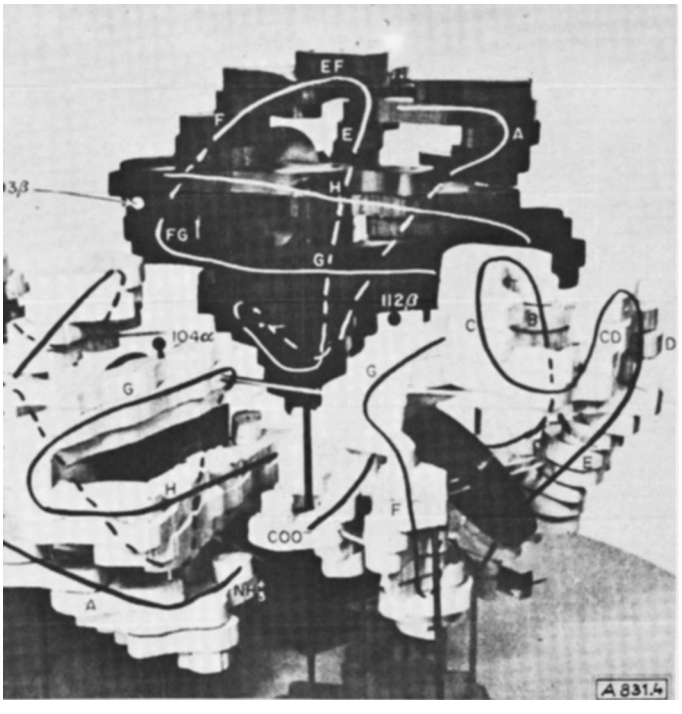

Fig. 4. Structure of hemoglobin according to 5.5 Å X-ray studies (from *Muirhead et al.* [37]). The subunits are parted from one another for clarity, the course of the peptide chain is shown, and a β chain in the foreground of the picture has been removed.

The association of the four subunits of vertebrate hemoglobin is easily influenced. Experiments cannot usually be carried out on hemoglobin in a concentration corresponding to that in the erythrocytes. In fact, the conditions that must be used are often such that the hemoglobin is already largely split into dimers or monomers. It is difficult to make accurate allowance for this situation, since the dissociation of hemoglobin has not yet been conclusively explained.

The dissociation is symmetrical, *i.e.* hemoglobin consisting of two α and two β chains gives two subunits containing one α and one β chain each. It should be noted that $\alpha_1\beta_1$ and $\alpha_2\beta_2$ or $\alpha_1\beta_2$ and $\alpha_2\beta_1$ dimers[*] could in principle be formed (see Fig. 4). The $\alpha_1\beta_1$ ($\alpha_2\beta_2$) contact involves 34 amino acids with about 110 hydrophobic bonds (distance between hydrophobic groups <4 Å), while the $\alpha_1\beta_2$ ($\alpha_2\beta_1$) contact involves 19 amino acids (80 atomic contacts)[37]. The dissociation into dimers probably takes place at the $\alpha_1\beta_2$ contact, *i.e.* it leads to $\alpha_1\beta_1$ ($\alpha_2\beta_2$) dimers[39,43]. Recent studies on hybrid hemoglobins using isoelectric focusing show that this symmetrical cleavage takes place in the same manner in ligand-free hemoglobin as in hemoglobin with ligands (HbO_2, HbCO, $HbFe^{3+}CN^-$, *etc.*)[40].

An $\alpha_1\beta_2$ dimer should not bind two ligands independently[41], since the contact that transmits the interaction of the two bonding sites is retained[42]. If one attempts to summarize the results that have been obtained so far for HbA, one finds the following: HbO_2 (or hemoglobin with other ligands) dissociates into dimers, and probably partly into monomers, in solutions with high salt concentrations (1.0 to 2.0 mole/l of NaCl) and in acidic ($pH<4.7$) and alkaline solutions ($pH>9.0$). Ligand-free hemoglobin dissociates to a much smaller extent[44–46]. Complete dissociation into monomers is difficult, but can be achieved if the SH groups are blocked with *p*-chloromercuribenzoate (pMB). This technique of isolating native subunits of HbA *via* the pMB derivatives[47] was expected to yield information on differences in the functions of the α and β chains. Though numerous investigations have been carried out by many research groups with the aid of methods such as ultracentrifugation, membrane osmometry, and gel filtration, the results as a whole are still unsatisfactory. This may be partly due to the difficulty of producing comparable preparations.

The aim of the physicochemical studies on hemoglobin is mainly to clarify the problem of the regulated binding of oxygen. To bind the four ligands (4 O_2, 4 CO, *etc.*) on the hemes, all four bonding sites must act together (homotropic interaction). This process has also been referred to inaccurately as heme-heme interaction. However, the shortest distance between two heme iron atoms ($\alpha_1-\beta_2$) is 25 Å, so that no direct interaction between them is possible; on the contrary, the interaction occurs indirectly through changes in the conformation of the protein (allosterism). Starting with the hyperbolic oxygen-binding curve of myoglobin and the sigmoid course of this curve for hemoglobin[48] (see also Fig. 7), it is necessary not only to describe the nature of the reversible binding of the O_2 molecule to the sixth coordination site of the heme iron, but also to gain an understanding of the manner in which the subunits work together in hemoglobin (cooperative binding of O_2), for which the sigmoid binding curve is

[*] The subscripts 1 and 2 are used here to distinguish the two α or β chains.

characteristic. It is also necessary to explain the Bohr effect (release of protons on binding of oxygen) and the decrease in oxygen affinity on stoichiometric bonding of polyphosphates, particularly 2,3-diphosphoglyceric acid (2,3-DPG), which is present in high concentrations in the erythrocytes[49].

Hemoglobin is also responsible for about 60% of the transport of the metabolic end product CO_2 back to the lungs; the carbon dioxide reacts with the N-terminal NH_2 groups to form the carbamate[50].

$$R^1{-}NH_3^+ \rightleftharpoons R^1{-}NH_2 + H^+$$
$$R^1{-}NH_2 + CO_2 \rightleftharpoons R^1{-}NH{-}COO^-H^+$$

Protons are released both in the binding of CO_2 and in the uptake of oxygen. The reaction with H^+, 2,3-DPG, or other (poly)phosphates, and probably also CO_2, thus depends on the binding of O_2. The protein intervenes here between different bonding sites (heterotropic interaction). These substances may be called allosteric effectors. They all have an affinity for ligand-free hemoglobin. Myoglobin behaves differently, and the insect hemoglobins occupy an intermediate position. The reaction

$$Hb + 4\,O_2 \rightleftharpoons Hb(O_2)_4$$

is empirically described by the Hill equation

$$Y = Kp^n/(1 + Kp^n)$$

where Y is the percentage saturation of the Hb with oxygen and p is the partial pressure of O_2.

The Hill coefficient n has a value of 1 for myoglobin and for isolated α and β chains[51]; if cooperativity of the four bonding sites is complete, n can theoretically be 4; its value for human hemoglobin is 2.8.

An investigation of the kinetics of ligand binding theoretically requires the determination of eight rate constants[52] from one reaction course on the basis of a simple scheme in which only the binding of four ligands to four bonding sites is considered. This is not possible at present. Two simplified kinetic models have been developed to describe the cooperative binding[53, 54]. However, both the "concerted" reaction mechanism, which describes the transformation of the quaternary structure as an "all or nothing" reaction, and the sequential course, in which the change in the quaternary structure results from a sequence of interdependent changes in the conformation of the subunits (induced fit), agree only in part with the results reported so far. By kinetic studies using temperature and field jump methods, it is possible to resolve the complex process into a few relaxation components, which are assigned to the binding of O_2 and to intermolecular and intramolecular changes in conformation[55].

A significant contribution to this problem was made by *Gibson* and *Parkhurst*[56]. These authors made use of the ability of HbCO to dissociate for a short time into Hb and CO on exposure to light. The Hb molecule (or some subunits) is then free from ligands, though its conformation is still the same as in HbCO. Differences can be detected in the binding of the ligands by means of such investigations. The dissociation and binding of the first three ligands are the rate-determining steps of the homotropic interaction.

ORD and CD studies[57] show that both the binding of O_2 and the association of the subunits are accompanied by changes in the conformation of the molecule[58]. On the whole, α and β chains differ from hemoglobin in their properties. pH-dependent conformational changes have also been observed in monomeric and dimeric insect hemoglobins[59]. Deoxygenated hemoglobin, unlike all other forms with bivalent or trivalent iron (in which water or other ligands such as CN^- are bound), is ligand-free. The bonding state of the heme iron can be established with the aid of magnetochemical methods and ESR spectroscopy[60]. The introduction of spin labeling at certain bonding sites in the globin, *e.g.* on Cys(93)β, also allows the observation of changes in the conformation of the subunits on binding of O_2[61].

X-ray[62] and Mössbauer spectroscopic studies[63] decide the question of the bonding of an O_2 molecule to the Fe^{2+} in favor of *Pauling*'s model. The oxygen molecule forms an angle of 120° with the plane of the heme. Investigations on forms of the iron complex with and without ligands and on model substances indicate that in deoxyhemoglobin, the central iron atom has moved about 0.8 Å out of the plane of the heme toward F 8[64]. In the oxy form, on the other hand, it lies in the plane of the heme. Monomeric deoxy-Hb and HbCO from *Chironomus* show a displacement of only 0.2 Å for the Fe^{2+} in relation to the heme[65].

Important contributions to the elucidation of allosterism on the molecular level, the Bohr effect, and the action of 2,3-DPG have been made by X-ray analysis. The comparative 5.5 Å resolution of equine oxyhemoglobin and human deoxyhemoglobin published by *Perutz et al.* in 1967 showed that the oxygenation of the molecule leads to reorientation of the subunits such that the distance between the Fe atoms of the heme groups $\beta_1\beta_2$ is changed by almost 7 Å, and the contacts on $\alpha_1-\beta_2$ and $\beta_1-\alpha_2$ assume a new steric orientation[37]. No change in the tertiary structure was observable in the 5.5 Å resolution, though logic demands such a change. It was only with 2.8 Å resolution that sufficient details were obtained for a description of the steric course of the change in conformation[64]. The rupture of intramolecular salt bridges plays an important energetic role here (the total change in the free energy ΔG^0 of hemoglobin on oxygen uptake is 10—12 kcal/mole).

The process starts with the movement of the central iron atom into the plane of the heme ring, which occurs on oxygen uptake. This movement is transmitted to the proximal His F 8, with the result that the F helix is drawn into the interior of the molecule and approaches the H helix (Fig. 5). The tyrosine HC 2, which is invariant for all vertebrates, is essential to the subsequent change in the conformation of the subunits. The side chain of this amino acid forms a hydrogen bond to the amide nitrogen of Val FG 5 in deoxyhemoglobin, and the hydrophobic ring of Tyr is enclosed in apolar fashion by the H and F helices. This anchoring of the C-terminal part of the H helix is rendered impossible by the approach of the F helix; Tyr is forced

out of its position, the C-terminal part of the H helix becomes free, and the salt bridges from the C-terminal residues of the α and β chains are opened. The bonds between the α-carboxyl groups of Arg HC 3 (141) α_1 and the amino group of Val NA 1 (1) α_2 and between the guanidinium

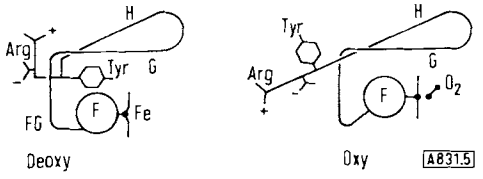

Fig. 5. Scheme of the change in structure of a subunit of hemoglobin on O_2 uptake (after *Perutz* [64]).

ion of the same arginine and the β-carboxyl group of the aspartic acid in H 9 (126) α_2 are broken; the linkage between the α-carboxyl group of His HC 3 (146) β_1 and the ε-amino group of Lys C 5 (40) α_2 and the salt bridge from the imidazolium ring of His HC 3 to the β-carboxyl group of Asp FG 1 (94) β_1 are also broken. The ionic interactions between 2,3-DPG in the hydrophilic central cavity of the tetrameric hemoglobin molecule and side chains of the β chains (Val NA 1 (1), Lys EF 6 (82), His H 21 (143)) become unstable on transition to oxygenated hemoglobin.

Evidence supporting the assumption that the C-terminal amino acids of the α and β chains and the bonding of the 2,3-DPG are important to the conformation of the hemoglobin and hence to the binding of oxygen can be seen in the facts that removal of the histidine and the arginine reduces the Hill coefficient to $n \simeq 1$ and that removal of histidines and of Val NA 1 α are changed to such a degree that 0.7 proton dissociates from the molecule per heme ligand[66].

Since binding of the ligand oxygen to heme iron is easier in the case of the α chains than in the case of the β chains on purely steric grounds, it may be assumed that oxygenation of the two α chains of the molecule occurs first. These subunits are accordingly changed as described above from the conformation of the deoxygenated molecules into that of the oxygenated molecules. The change in the conformation of some subunits increases the readiness of the entire molecule to undergo a change in its quaternary structure. The subsequent reorientation of the β chains facilitates the access of the oxygen to their iron atoms, and the entire molecule, charged with four molecules of oxygen, will now be in the form of oxygenated hemoglobin (Fig. 6). This reaction course contains elements from both of the models mentioned above. The details of the reaction may differ with the medium, but the steric mechanisms should remain unchanged. Moreover there is no indication that these data, which were established for crystals, are not also valid for the dissolved protein.

The fundamental value of this method to the functional analysis of proteins can be deduced from the fact that X-ray analysis allows the detection of fine details of the molecular structure and even the interpretation of their importance to dynamic processes. On the other hand, there is a need for other, complementary methods that directly determine the dynamic parameters of proteins in solution, and which do not stop with an overall examination of the molecules, but again continue to probe down

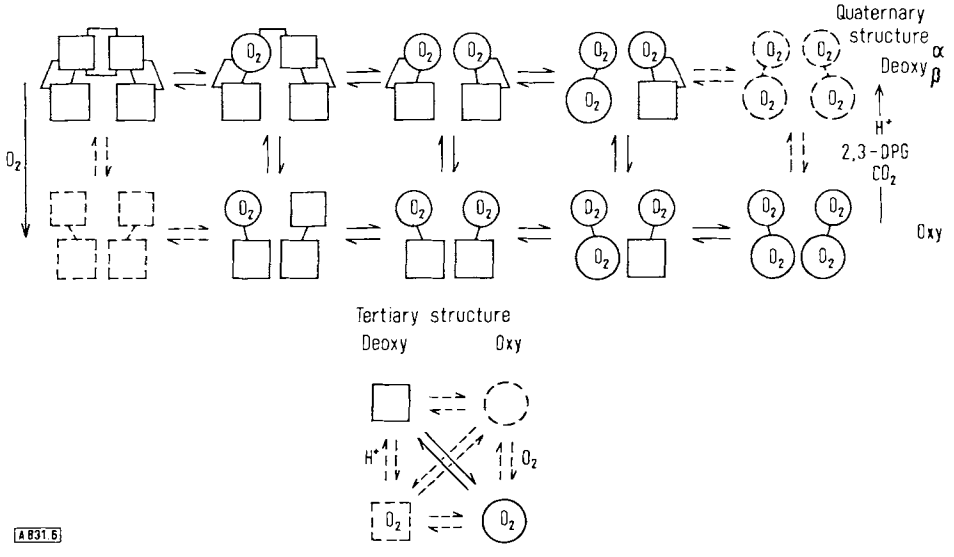

Fig. 6. Scheme of the change in the conformation of hemoglobin on conversion into HbO_2; quaternary structure and tertiary structure (after *Perutz* [64]).

the 2,3-DPG increases the oxygen affinity of the hemoglobin. Removal of the C-terminal histidine of the β chain also causes the Bohr effect to be halved[73]. Blockage of the N-terminal Val NA 1 has a similar effect[50].

The liberation of H^+ results from the approach of the His HC 3 (146) β and probably also the His H 5 (122) α to negative and positive groups in the deoxygenated and oxygenated states respectively. The pK values of these

to atomic dimensions. The results that have recently been achieved with high-resolution NMR spectroscopy are very promising. Signals due to individual amino acid side chains, particularly those of the functionally important histidines, have been identified, and the first steps of a detailed analysis have been taken. Interpretation of the results is again facilitated by comparison of hemoglobins having different primary structures and in various bonding states[67, 68].

3.3. Functional Abnormalities of Hemoglobin

It is fascinating to try to understand the abnormalities of some hemoglobins on the basis of the X-ray model[69]. Only a few examples can be chosen here from the large amount of available data. A number of general results emerge:

a) The exchange of polar residues on the surface of the molecule (in heterozygotes) is not usually accompanied by clinical symptoms, *e.g.* with $HbI_{Toronto}$ α A 3 (5) Ala →Asp; $HbE_{Saskatoon}$ β B 4 (22) Glu→Lys.

b) Practically any alteration of nonpolar side chains in the interior of the molecule leads to losses of ability to function and of stability; this is particularly true of the environment of the heme (60 atomic contacts): Hb_{Turin} α CD 1 (43) Phe →Val loses two CH contacts on the heme, and is unstable. The situation is worse in the case of $Hb_{Hammersmith}$ β CD 1(42) Phe→Ser, in which a polar side chain is introduced in addition to the loss of the two hydrophobic contacts; water enters the heme pocket, and heme is split off.

c) Exchange of amino acids at the contacts of the subunits and the N and C ends affects the function (allosterism, Bohr effect, O_2 affinity, *etc.*) and the dissociation into subunits. Changes in the $\alpha_1\beta_1$ ($\alpha_2\beta_2$) contact, *e.g.* HbE β B 8 (26) Glu→Lys, generally have no effect on the interaction of the subunits, unlike changes in the $\alpha_1\beta_2$ ($\alpha_2\beta_1$) contact, *e.g.* $Hb_{Chesapeake}$ α FG 4 (92) Arg→Leu with reduced interaction and increased O_2 affinity. However, this hemoglobin still has a Bohr effect, which is further reduced in the case of $Hb_{Hiroshima}$ β H 21 (143) His→Asp (Fig. 7).

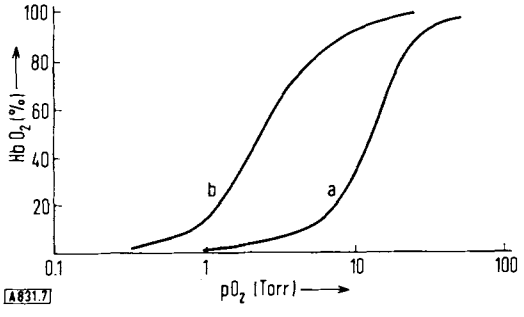

Fig. 7. O_2 binding curves of HbA (a) and of $Hb_{Hiroshima}$ (b) at pH = 7.4 in 0.1 mole/l phosphate buffer and at 20 °C (after *Imai* (ref. [72])

d) A special group is formed by the Hb M types, in which the properties of the bonding site are changed to such a degree that heme iron is in the form of Fe^{3+} (methemoglobin) and does not bind O_2. $Hb_{Milwaukee}$ β E 11 (67) Val→Glu forms an ionic bond with the iron and stabilizes it as Fe^{3+}. Replacement of the distal His E 7 or of the proximal His F 8 by Tyr in the α or β chains leads in all four possible cases to oxidation to Fe^{3+} and consequent loss of ability to bind O_2. Ionic bonds to the Fe^{3+} are presumably also formed in this case. In $Hb_{Zürich}$ β F 8 (92) His→Arg, on the other hand, the distal His is again substituted, but the function is not greatly impaired; this is not a Met-Hb. Arginine does not fit into the heme pocket, and it therefore projects into the solution. It is found here that the distal side chain is not absolutely necessary for the reversible binding of O_2. This agrees with the findings for insect hemoglobin.

It is impossible to grasp in detail the effects, on the molecular level, of every exchange of an amino acid, and precise functional testing is only rarely possible. It would be useful to examine these anomalies systematically and to collect blood conserves of their carriers for medical and scientific purposes. Here again, investigations on the red blood pigment could point the way for the study of molecular defects in other proteins, which will undoubtedly be discovered in the next few years.

Causal therapy of these morbid changes is not possible at present.

Pulse Fourier Transform ^{13}C-NMR Spectroscopy, Principles and Applications[**]

By Eberhard Breitmaier, Günther Jung, and Wolfgang Voelter[*]

As a result of the development of pulse Fourier transform NMR *spectroscopy,* ^{13}C *resonance has become accepted as a means of elucidating the structures of organic compounds having the natural* ^{13}C *abundance. Assignment of the signals is facilitated by broad-band and off-resonance proton decoupling and by knowledge of longitudinal relaxation times. The pulse Fourier technique, which is more sensitive and faster than conventional* NMR *spectroscopy because of multichannel excitation, allows* ^{13}C *measurements within a short time even on dilute samples of high molecular weight compounds without prior enrichment in* ^{13}C.

1. Introduction

The chemical shifts and coupling constants of protons provides such conclusive information about the structures of many organic compounds that proton resonance has grown into one of the most important routine methods of instrumental analysis available to the organic chemist. However, its usefulness is limited for two reasons: Firstly, the center of interest in organic chemistry is not the protons but the carbon skeleton. Thus the physical properties and reactivity of organic compounds are explained by the bonding states of the carbon atoms that can be calculated approximately by quantum-mechanics. Secondly, numerous organic molecules contain too few magnetically nonequivalent protons, so that ^{1}H-NMR spectroscopy provides little or no information about the carbon skeletons of such compounds. The obvious solution is to try to use the magnetic isotope ^{13}C, with nuclear spin 1/2, as a probe for NMR spectroscopy of organic compounds.

2. Problems of ^{13}C-NMR Spectroscopy

The isotope ^{13}C requires much longer times for longitudinal relaxation than the proton, with the result that flipping of the spin states on irradation at radio frequencies is much slower. Moreover, the abundance of ^{13}C in natural carbon is only 1.1%, so that large samples are necessary for the observation of ^{13}C resonance. Finally, ^{13}C resonance is much less sensitive (1.59%) than ^{1}H resonance (100%) at the same magnetic field strength, because of the small gyromagnetic ratio of ^{13}C.

In addition to these fundamental difficulties, routine ^{13}C-NMR spectroscopy has until now also been hindered by instrumental difficulties. Conventional high-resolution NMR spectrometers record the NMR spectra with continuous change of frequency or of magnetic field over the Larmor frequency range of the observed nucleus. Only a narrow frequency band contributes to the excitation of the resonances at any instant. The signal/noise ratio (S/N), which serves as a measure of sensitivity, is consequently low in this technique, which is described as the frequency sweep or field sweep method. The sensitivity can be improved by accumulation of spectra with averaging computers, the noise being averaged out by the CAT (Computer Averaged Transitions) process, since S/N increases with the number of scans n:

$$S/N \sim n$$

Even if the long times that this entails are acceptable, the long-term stability of conventional NMR instruments is usually too low to give a usable ^{13}C-NMR spectrum with long recording times for a saturated, but (because of low solubility) dilute solution of an organic compound.

These fundamental and instrumental difficulties have led to the development of the new recording technique known as pulse Fourier transform (PFT) NMR spectroscopy[1-3]. The basis of this technique is the free induction decay of the Bloch nuclear resonance theory[4, 5]. PFT NMR spectroscopy can be used for any magnetic nucleus. In particular, ^{13}C-NMR spectroscopy of organic compounds having the natural ^{13}C abundance has become a routine method of analysis as a result of the PFT technique.

3. Principles

3.1. The Bloch Nuclear Magnetic Resonance Theory

To observe the nuclear magnetic resonance, the sample is placed in a static magnetic field $\vec{H}_0$, and a radio-frequency field $\vec{H}_1$ is applied perpendicular to $\vec{H}_0$. If the frequency of the field $\vec{H}_1$ is equal to the Larmor frequency ν_L of the nucleus used as the probe, an absorption signal is recorded in the receiver of the NMR spectrometer. The Bloch theory[4, 5] explains the action of the fields $\vec{H}_0$ and $\vec{H}_1$. This theory describes the behavior, not of one nucleus, but of the macroscopic magnetization $\vec{M}$ of a collection of nuclei under the influence of $\vec{H}_0$ and $\vec{H}_1$.

Under the influence of the field $\vec{H}_0$ alone, the axes of rotation of the nuclei precess with an angle α about the direction of the field $\vec{H}_0$ (Fig. 1a). For a nucleus with spin $I=1/2$, this results in a highly populated orientation of low energy in the direction of the field $\vec{H}_0$ and a poorly populated orientation of high energy in the direction opposite to that of the field $\vec{H}_0$ (Fig. 1a; note the number of vectors). The resultant macroscopic magnetization M is thus parallel to the field $\vec{H}_0$ (Fig. 1a in the z direction), and causes a small, measurable nuclear susceptibility.

If the x, y, z coordinate system is considered as rotating about the z axis with the Larmor frequency ν_L, Figure 1a simplifies to Figure 1b, in which $\vec{M}$ rotates in the z axis with frequency ν_L. The radio-frequency field $\vec{H}_1$ with the Larmor frequency ν_L, when applied perpendicular to $\vec{H}_0$,

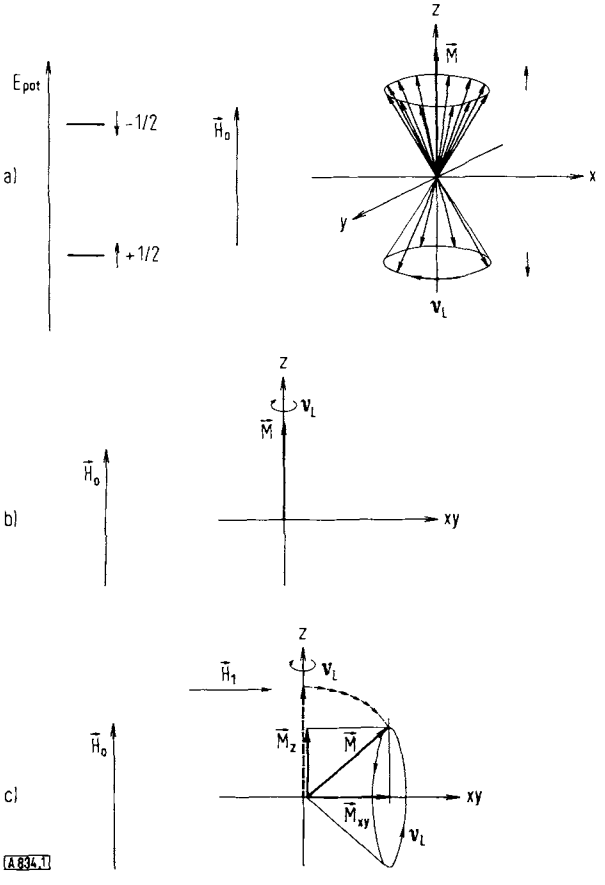

Fig. 1. a) Orientation of the nuclear spin in the field $\vec{H}_0$ and the resulting magnetization $\vec{M}$. b) The rotation of the system of coordinates about the z direction with the Larmor frequency ν_L simplifies a) to b). c) Action of the field $\vec{H}_1$ perpendicular to $\vec{H}_0$ on $\vec{M}$. (Fields $\vec{H}_1$ at 180° to $\vec{H}_0$ thus cause a complete inversion of the population of the spin levels.)

exerts a force on the vector of the macroscopic magnetization $\vec{M}$. The vector $\vec{M}$ escapes from this force by precessing about the direction of $\vec{H}_1$. $\vec{H}_1$ and $\vec{M}$ are in phase, and $\vec{M}$ has two components: $\vec{M}_z < \vec{M}$ in the z direction and $\vec{M}_{xy} < \vec{M}$ in the xy plane (Fig. 1c). The decrease in the magnetization in the z direction (longitudinal magnetization) is a result of resonance. If $\vec{H}_1$ oscillates with the Larmor frequency ν_L, some nuclei reverse their spin more or less rapidly, corresponding to their longitudinal relaxation time T_1. As they do so, they absorb energy from $\vec{H}_1$. The populations of the two orientations become practically equal, and the magnetization consequently decreases from $\vec{M}$ to $\vec{M}_z$.

3.2. Free Induction Decay

After the resonance, the transverse magnetization $\vec{M}_{xy}$ decays exponentially with the transverse relaxation time T_2, losing the phase coherence with the $\vec{H}_1$ field. This process is referred to as free induction decay (FID)[4, 5]. Since the transverse magnetization $\vec{M}_{xy}$ results from components due to the different Larmor frequencies of one kind of nuclei in a molecule, the FID contains all information of the NMR spectrum of that molecule.

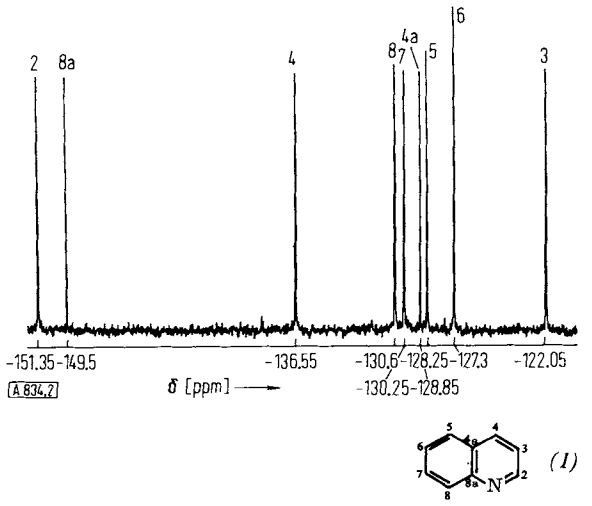
Free induction decays are observable as "wiggles" at high resolution and rapid passage of many resonances (*e.g.* the ^{1}H signal of tetramethylsilane), though wiggles may also be caused by field inhomogeneities. Immediately after passing the resonance condition

$$\nu_{\vec{H}_1} = \nu_{\vec{M}_{xy}} = \nu_L$$

phase and frequency of $\vec{H}_1$ and $\vec{M}_{xy}$ are almost equal. The interference between $\vec{H}_1$ and $\vec{M}_{xy}$ is therefore a beat, which synchronously with the FID, decreases exponentially with T_2.

When the resonance condition has been passed, the vector of the longitudinal magnetization $\vec{M}$ reverts to the z direction exponentially with the longitudinal relaxation time T_1, that means time independent of the FID.

3.3. Pulse Interferograms

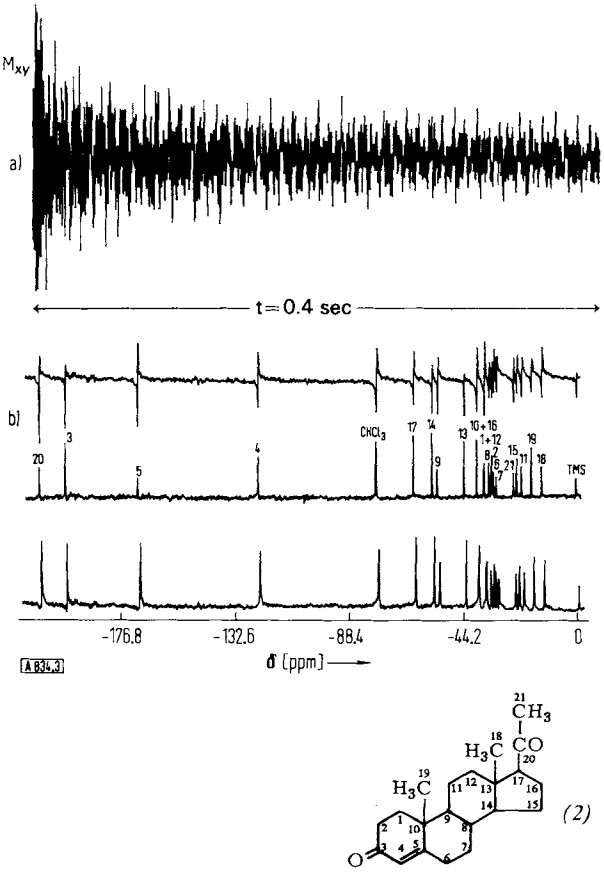


The beat interference signals of the FID can also be initiated by short (a few microseconds) radio-frequency pulses $\Delta\vec{H}_1$ applied at right angles to $\vec{H}_0$.

In pulse NMR spectroscopy, such a pulse encounters a molecule with n magnetically nonequivalent nuclei, *i.e.* n Larmor frequencies ν_L. Instead of one single FID beat interference, the receiver of the spectrometer then records the superimposed interferences of all the excited Larmor frequencies. If the frequency spectrum of the applied pulse is sufficiently large, all n Larmor frequencies of the molecule are excited. The resulting pulse interferogram, which represents the decay of the transverse magnetization $\vec{M}_{xy}$ as a function of time, (see Fig. 3a) thus contains all the information of an NMR spectrum obtained by frequency sweep or by field sweep (Section 2). The time required to register the interferogram is of the order of longitudinal relaxation times T_1[2], *i.e.* in the region of fractions of a second (^{1}H) or seconds (^{13}C).

4. PFT NMR Spectroscopy

4.1. Principle and Advantages



A pulse interferogram is a complex wave function resulting from the superposition of all the Larmor frequencies stimulated by the pulse. Like any complex wave function, therefore, the interferogram can be converted, under certain mathematical conditions, into a spectrum of the Larmor frequencies, *i.e.* into the NMR spectrum itself, by

(1)

Fig. 2. 22.63 MHz PFT ^{13}C-NMR spectrum of quinoline (*1*), transformation of a 15 µs pulse, pulse interval 1.6 s (assignment according to *Pugmire et al.* [7]). The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0.

Fourier transformation[6]. Now a radio-frequency pulse is equivalent to the emission from a multichannel transmitter whose frequency spectrum momentarily stimulates all the Larmor frequencies of a sample simultaneously at

(2)

Fig. 3. a) 22.63 MHz pulse interferogram of progesterone (*2*), ^{1}H broadband decoupled, 1.5 M in chloroform. Accumulation of 1024 pulses, pulse width 30 µs, pulse interval 0.4 s, 4096 data points. b) Fourier transformation of the pulse interferogram of progesterone; from top to bottom: dispersion spectrum; absorption spectrum; magnitude spectrum. The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0. Recorded by Bruker Physik AG, Karlsruhe-Forchheim.

full power. However, the sensitivity of an NMR spectrometer increases with the number of channels that stimulate simultaneously[3]. The Fourier transformation of the pulse interferogram, which can be carried out in seconds by a dedicated computer with wired-in multiplication and division, consequently gives an NMR spectrum whose S/N ratio is significantly greater than that of a conventional NMR spectrum of the same sample. A usable NMR spectrum can be recorded within a few seconds in this way. Figure 2 shows the proton-decoupled ^{13}C-NMR spectrum recorded after Fourier transformation of an interferogram obtained from a single pulse lasting 1.6 seconds for pure quinoline *(1)* having the natural ^{13}C abundance of 1.1%. The advantages of the PFT method over conventional NMR spectroscopy are thus a considerable saving of time and the improvement of the S/N ratio by more than one order of magnitude.

The sensitivity can be further increased if the pulse interferograms are accumulated by means of averaging computers before the Fourier transformation. For example, if the time taken to register an interferogram is 0.5 second, which corresponds to the interval between two pulses, 1000 interferograms can be accumulated in the time required to record conventional NMR spectra (500 seconds). According to Section 1, this corresponds to a further increase in the S/N ratio by a factor of $10\sqrt{10}$. As an example, Figure 3 shows the accumulated ^{13}C interferogram of progesterone *(2)* in 1.5 M solution, together with the corresponding Fourier transforms obtained by three different programs.

4.2. The Technique of PFT ^{13}C-NMR Spectroscopy

4.2.1. Shortening of the Pulse Interval with ^{13}C

The similarity of the Fourier transform of an interferogram to a conventionally recorded NMR spectrum of the same sample increases with the time spent in recording the interferogram. In the accumulation of interferograms, therefore, the pulse interval, *i.e.* the time between two pulses, should be as large as possible, and should in no circumstances be appreciably smaller than the longitudinal relaxation time T_1, since the vector $\vec{M}$ (Fig. 1) rotates again in the $\vec{H}_0$ direction T_1 seconds after the application of the pulse.

Since T_1 for ^{13}C is large (up to 1 minute), the accumulation of ^{13}C interferograms would require long pulse intervals and hence long recording times. This difficulty can be overcome by the use of the spin-echo method[8,9]. In this method, a 90° pulse first turns the vector $\vec{M}$ toward the xy plane (cf. Fig. 1b and 1c). The receiver then records an interferogram in the usual manner. Because $T_2 \ll T_1$ in the case of ^{13}C, this interferogram decays more rapidly than $\vec{M}$ turns back into the $\vec{H}_0$ direction. The application of two further pulses of 180 and 90° immediately after the first 90° pulse accelerates the swing back. The 180° pulse forces the vectors of the transversal magnetization $\vec{M}_{xy}$ into the negative xy plane with simultaneous focusing (spin echo), and the subsequent 90° pulse inclines the focused vector back into the $\vec{H}_0$ direction. The pulse sequence 90°—180°—90° can be repeated within fractions of a second (*e.g.* 0.4 second, Fig. 3). As a result, the time required for accumulation of the interferograms is considerably reduced. This method, which can be applied to ^{13}C, is referred to as "driven equilibrium Fourier transform" (DEFT) NMR spectroscopy[8].

4.2.2. Absorption, Dispersion, and Magnitude Spectra

The computer required for the Fourier transformation chops the interferogram into a few thousand data points, depending on its capacity. It takes 10—20 seconds for the scanning of these data points and the Fourier transformation. Depending on the calculation procedure, the transformation gives an absorption spectrum (v mode, Fig. 3b), a dispersion spectrum (u mode, Fig. 3c), or a magnitude spectrum ($(u^2+v^2)^{1/2}$ mode, Fig. 3d).

Figs. 4a—4c illustrate how the magnitude spectrum results from the absorption and dispersion spectrum.

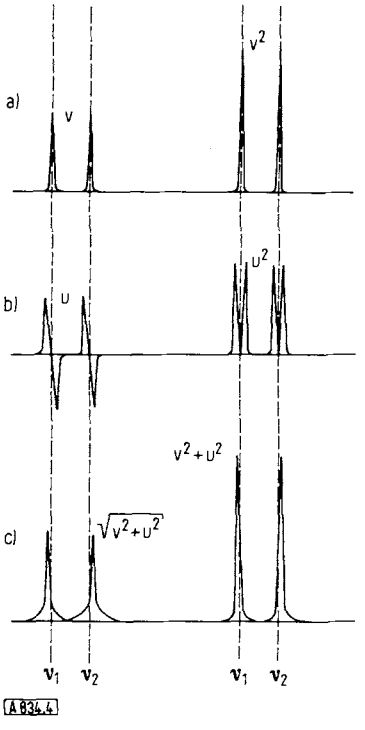


Fig. 4. a) Absorption, b) dispersion, c) magnitude spectrum of two closely spaced signals.

The magnitude spectrum plots the absolute value of the transverse magnetization $\vec{M}_{xy}$ as a function of frequency without reference to the phase. Compared to the absorption spectrum, it has the following advantages:

1. Although exhibiting tailing due to the dispersion part, many signals are more intense (Figs. 3d, 4c).

2. Signals appearing closely together are better separated in the magnitude spectrum due to the dispersion part (Figs. 4a, 4c).

These advantages of magnitude spectra are achieved at the expense of line distortions which are considerable in PFT ^{1}H-NMR spectra. In ^{13}C-NMR magnitude spectra, however, these distortions are mostly within the standard deviation of ^{13}C shifts. Only in the case of weak resonances

near strong signals (*e.g.* solvent peaks) does the frequency distortion of ^{13}C-NMR in the magnitude mode have to be considered[3].

4.2.3. Lock and Standard

A heteronuclear signal, usually the ^{19}F signal of hexafluorobenzene or the ^{2}H signal of deuterium oxide, is used in PFT ^{13}C-NMR spectroscopy to stabilize the field/frequency ratio. Hexafluorobenzene is allowed to rotate with the sample tube in an external centered capillary. Deuterium oxide may be used as the solvent and internal heteronuclear lock substance in the case of water-soluble ^{13}C samples.

The ^{13}C resonance range extends over about 200 ppm. At 22.63 MHz, this is about 4.5 kHz. Carbon disulfide[10] or tetramethylsilane may be used as the standard. The TMS signal is located at a very high field (0 ppm), and the CS_2 signal at a very low field (−192 to −193 ppm relative to TMS, depending upon the solvent, and not −194 ppm as previously reported). Since the region of ^{13}C carbonyl resonance overlaps with the CS_2 signal, whereas only very few signals occur close to and above the TMS signal, TMS has recently gained preference as the standard.

5. Assignment Aids

5.1. ^{1}H Broad-Band Decoupling and Nuclear Overhauser Effect

Since geminal ^{13}C-^{1}H coupling constants are very large (100—250 Hz), the interpretation of ^{13}C-NMR spectra is frequently difficult because of overlapping ^{13}C-^{1}H multiplets. To simplify the spectra and to increase the sensitivity, therefore, the technique of proton broad-band decoupling is often used in PFT ^{13}C-NMR spectroscopy. The ^{13}C sample is continuously irradiated with a second radio frequency $\vec{H}_2$ in addition to the (continuous or) pulse irradiation with the field $\vec{H}_1$. If the frequency band of $\vec{H}_2$ covers the entire range of the Larmor frequencies of the protons, all the ^{13}C-^{1}H multiplets collapse. A singlet therefore appears for each nonequivalent carbon atom. The *S/N* ratio is thus increased by this broad-band decoupling as a result of the collapse of the multiplets, and also by the nuclear Overhauser effect[11].

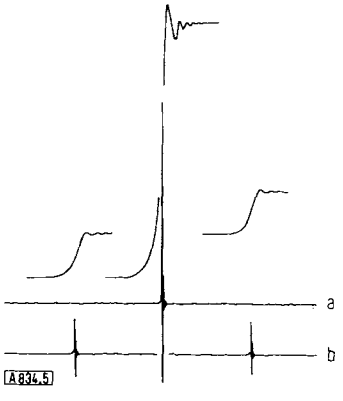

Fig. 5. Nuclear Overhauser effect on ^{1}H broad-band decoupling of ^{13}C-enriched formic acid [12], a) decoupled, b) coupled.

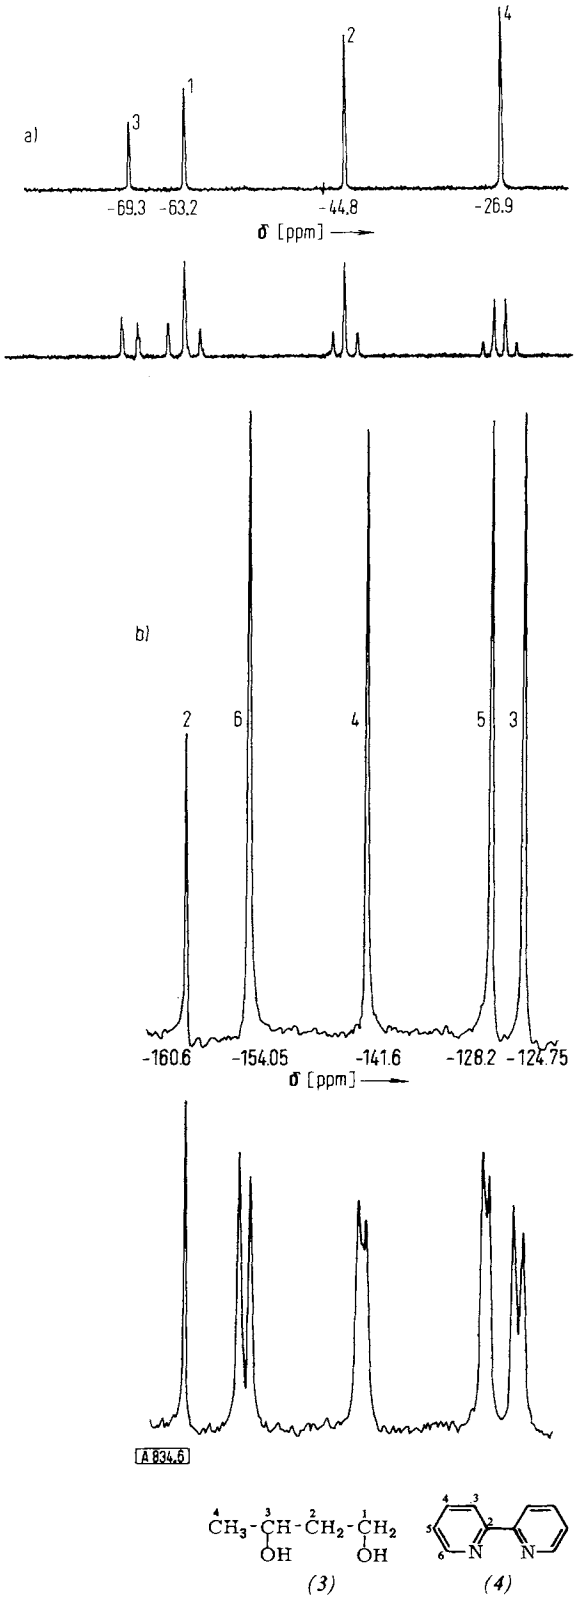

Fig. 6. ^{13}C signal assignment by off-resonance decoupling a) for 1,3-butanediol *(3)*, 22.63 MHz; b) for 2,2'-bipyridine *(4)*, 25.2 MHz. The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0. Recorded by a) Bruker Physik AG, Karlsruhe, b) Varian Ass., Palo Alto.

The nuclear Overhauser effect is based on the fact that the natural population of the (^{1}H) spin levels (Fig. 1b) is changed by double resonance stimulation with the field $\vec{H}_2$, the spin state with the higher energy frequently having a higher population than that with the lower energy.

Subsequent relaxation processes (return of the $\vec{M}$ vectors into the $\vec{H}_0$ direction) also influence the occupation of the spin levels of other nuclei by dipole-dipole (transmitter-receiver) interaction. If the spin levels couple, as *e.g.* in the case of geminal and vicinal nuclei, the nuclear Overhauser effect is particularly strong. It leads in the ^{1}H broad-band decoupling of ^{13}C-^{1}H multiplets to a distinct increase in the signal intensities, as is shown by Figure 5 for the ^{13}C resonance of ^{13}C-enriched formic acid[12].

5.2. "Off-Resonance" Decoupling

Though ^{1}H broad-band decoupling simplifies a ^{13}C-NMR spectrum and increases the sensitivity, this technique suppresses valuable clues to the assignment of the signals on the basis of the ^{13}C-^{1}H multiplets.

"Off-resonance" partial decoupling is a valuable aid to the assignment of ^{13}C resonances in such cases. The resulting sensitivity losses as compared with ^{1}H broad-band decoupling are small (Fig. 6).

In this double resonance method[13, 14], the second frequency $\vec{H}_2$ is a few hundred Hz outside the range of the Larmor frequencies of the protons ("off resonance") instead of inside this range. Vicinal and long-range couplings collapse in these circumstances. For this reason, and because of the accompanying nuclear Overhauser effect, the S/N ratio of ^{1}H off-resonance decoupled spectra suffers only a small decrease in comparison with that of ^{1}H broad-band decoupled spectra.

Depending on the frequency range of the $\vec{H}_2$ field, the geminal ^{13}C-^{1}H coupling constants decrease to 10—50 Hz, with the result that a spectrum of intense multiplets of first order is observed (quartets for methyl, triplets for methylene, doublets for methine, and singlets for quarternary C atoms). Figure 6 shows how the assignment of the signals for 1,3-butanediol *(3)* and 2,2'-bipyridine *(4)* follows from the geminal ^{13}C-^{1}H multiplets of the off-resonance ^{13}C spectra.

5.3. Longitudinal Relaxation Times

If relaxation processes are controlled by intramolecular C—H dipole-dipole interactions, the longitudinal relaxation time T_1 of ^{13}C (spin-lattice relaxation time) should depend in a characteristic manner on the number of hydrogen atoms bound directly to carbon[15]. A knowledge of T_1 is therefore a further aid to the assignment of ^{1}H broad-band decoupled ^{13}C resonances. For this reason, the measurement of T_1 in spin echo Fourier transform (SEFT) ^{13}C experiments is becoming increasingly important[3, 16–18].

In SEFT measurements, a 180° pulse first reverses the orientation of all the nuclear spins (Fig. 1). If a 90° pulse follows immediately, the receiver records an FID interferogram as usual. The subsequent Fourier transformation yields an NMR spectrum whose signals are reversed as a result of the 180° pulse. If the interval t between the 90° and the 180° pulses is $t = 1/2\ T_1$, the magnetization in the xy plane becomes 0, and the signal in the spectrum disappears. If t increases further, the signal is reversed again and its intensity rises. The longitudinal relaxation times T_1 of nonequivalent C atoms can therefore be determined by varying the interval t between 90° and 180° pulses and recording the PFT ^{13}C-NMR spectrum for each t (Fig. 7). The pulse sequence and interval, the accumulation of the interferograms, and the Fourier transformation can be controlled by a computer in such a way that the attached pen recorder displaces the spectra as it records them. The

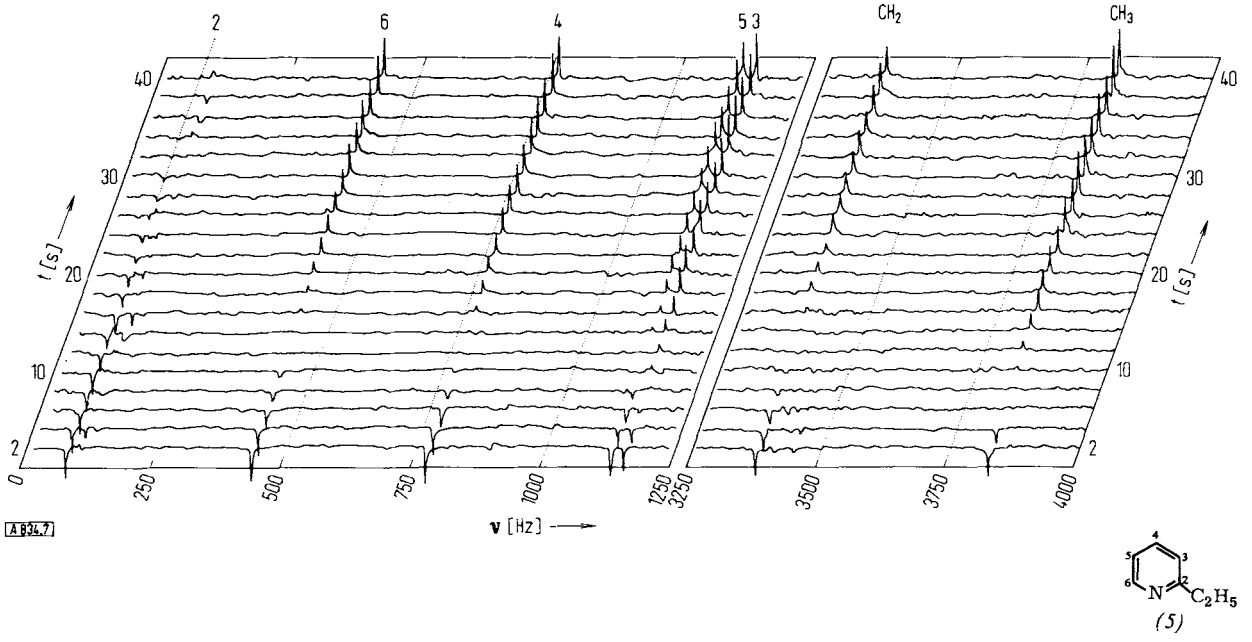

Fig. 7. SEFT measurement of longitudinal relaxation times for 2-ethylpyridine *(5)* [17]. The numbers by the signals indicate the numbering of the C atoms.

result is a three-dimensional representation of the signals as a function of frequency and interval, as shown in Figure 7 for 2-ethylpyridine *(5)*. It can be seen that T_1 increases as the number of directly bonded H atoms decreases:

$$\underset{14.5\,s}{T_1(CH_3)} < \underset{20\,s}{T_1(CH_2)} < \underset{21-23\,s}{T_1(\gtrless C-H)} < \underset{68\,s}{T_1(\gtrless C-)}$$

This sequence confirms that the relaxation process involves mainly protons[15].

Greater longitudinal relaxation times T_1 and the absence of ^{13}C-^{1}H coupling, and hence also of the nuclear Overhauser effect, are therefore the reasons why the ^{13}C signals of quarternary and carbonyl C atoms give the lowest intensities in ^{1}H broad-band decoupled PFT ^{13}C-NMR spectra (see also Fig. 8).

6. PFT ^{13}C-NMR Spectroscopy of Organic Compounds

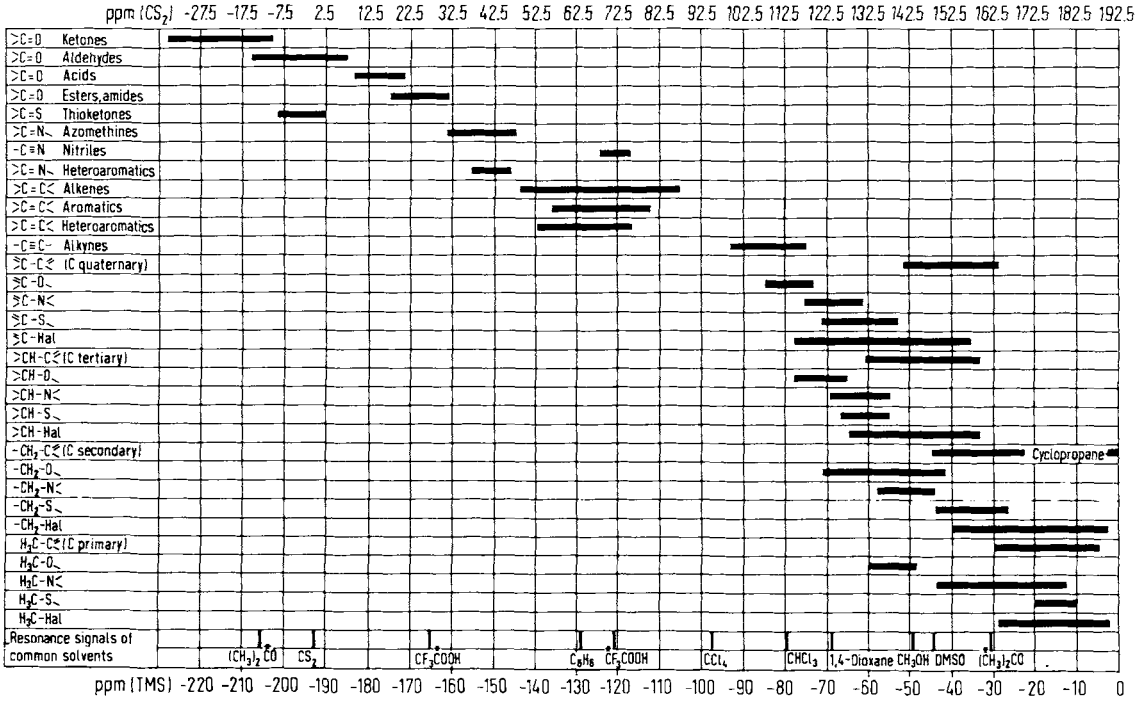
6.1. ^{13}C Chemical Shifts of Organic Compounds

The ^{13}C resonances of most organic compounds extend from 0 to −200 ppm relative to tetramethylsilane as the standard (Table 1). This is twenty times the ^{1}H resonance range. ^{13}C-NMR spectra therefore show changes in the chemical environment of a C atom not only more directly, but also more distinctly than ^{1}H-NMR spectra. ^{13}C resonances frequently follow patterns similar to those of the ^{1}H shifts.

The ^{13}C shifts of *n*-alkanes are located at very high fields. They obey the Grant-Paul additivity relation[19, 20]:

$$\delta_C(k) = B + \sum_l A_l n_{kl}$$

$\delta_C(k)$ = chemical shift of the k-th C atom
B = chemical shift of methane
A_l = additive parameter of the chemical shift of C atom l
n_{kl} = number of C atoms in position l in relation to C atom k.



As the number of H atoms bonded geminally to a C atom increases, the corresponding ^{13}C signal moves to higher fields:

$$\delta_{quarternary} > \delta_{tertiary} > \delta_{secondary} > \delta_{primary}$$
(absolute values relative to TMS)

Electron-withdrawing substituents displace the signals of neighboring C atoms to lower fields; the same is true of hetero atoms in heterocycles.

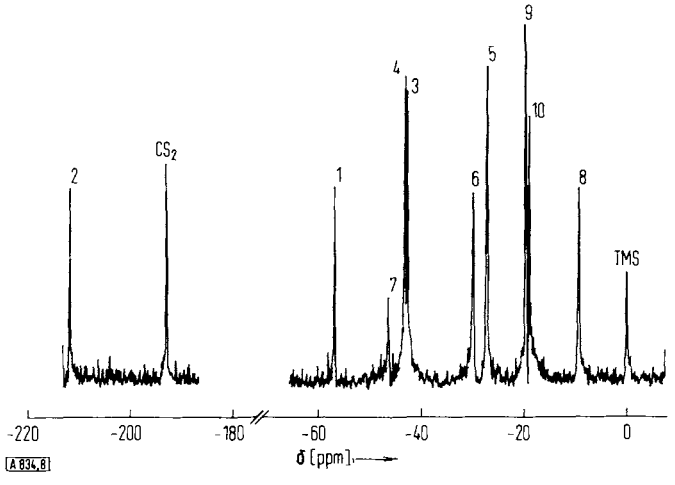
In cycloaliphatic compounds, the ^{13}C resonance of the strained three-membered ring occurs at a surprisingly high field (−2.3 ppm) in relation to the resonances of medium-sized rings (−30 to −24 ppm)[21]. In norcaradienes, however, the ^{13}C signals of the three-membered rings are observed at lower fields than in cyclopropanes themselves[22].

Table 1. ^{13}C-chemical shifts in organic compounds.

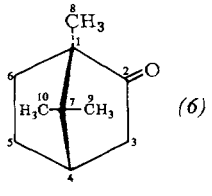
The ^{13}C signals of alkynes are higher than those of the alkenes and aromatic compounds, and the shifts of the latter, unlike the ^{1}H resonances, overlap. For cyclically conjugated π systems, *e.g.* in nonbenzoid aromatic

compounds, the ^{13}C signals move linearly toward higher fields with increasing π-electron density per C atom[23].

The only slightly overlapping regions of the carbonyl resonance allow the differentiation of ketones, aldehydes, carboxylic acids, and derivatives of carboxylic acids:



$\delta_{ketone} > \delta_{aldehyde} > \delta_{carboxylic\ acid} > \delta_{ester\ and\ amide}$



(absolute values relative to TMS)

7. PFT ^{13}C-NMR Spectroscopy of Some Natural Products

7.1. Terpenes and Carotenoids

A number of ^{13}C resonance investigations on carotenoids, terpenes, and particularly norbornyl derivatives have been reported[24-26]. As an example, let us consider the assignment of the signals of the PFT ^{13}C-NMR spectrum of camphor *(6)* (Fig. 8). Methyl carbon (C-8, C-9, C-10), methylene carbon (C-3, C-5, C-6), tertiary carbon (C-4),

(6)

Fig. 8. 22.63 MHz PFT ^{13}C-NMR spectrum of camphor *(6)* in CS_2. 256 pulses, pulse width 40 µs, pulse interval 0.4 s. The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0.

and quarternary carbon (C-1, C-7) can be differentiated by off-resonance decoupling. The carbonyl C-atom (C-2) appears at a very low field. The signals of C-2 and C-4 can thus be conclusively assigned. The signal sequence of the methylene C atoms is found from the β-substitution effects of C-2 (C=O) and C-8 (CH_3) to be C-3, C-6, and C-5, in the order of increasing field. The methyl signals (C-9 and C-10) have not yet been definitely assigned[26].

7.2. Steroids

The total assignment of a larger number of ^{13}C steroid spectra has been achieved by off-resonance decoupling, derivatization (*e.g.* acetylation), or specific deuteration and comparison of spectra[27]. However, no Fourier transform ^{13}C-NMR spectra of this class of natural products have previously been described[28]. Figure 3 shows the spectrum recorded by this technique for progesterone. The off-resonance ^{13}C spectrum gives the signal assignment[27] of the CH_3 groups (C-18, C-19, C-21) and quarternary C atoms (C-10, C-13); a quartet is observed for the former and a singlet for the latter. The methylene C atoms of the steroid skeleton, which absorb at very high fields, are C-11 and C-15. Some of the alicyclic ^{13}C atoms are not influenced by electronic effects; of these, the signals of C-9, C-14 and C-17 occur at very low fields. A comparison of the signal positions for several progesterone derivatives gives the assignment of the resonances of C-1, C-6, C-7, C-8, C-12, and C-16. The C-2 signal can be identified by off-resonance decoupling after deuteration of C-2. The resonances of C-4, C-5, C-3, and C-20 are typical for olefinic and carbonyl carbon atoms[29-34].

7.3. Alkaloids

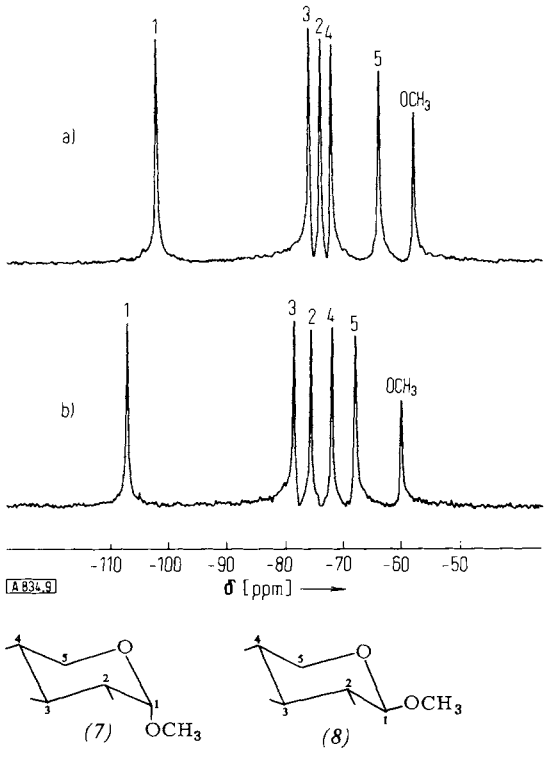
The information obtainable from ^{1}H broad-band decoupled ^{13}C-NMR spectra can be seen particularly clearly in the investigation of alkaloids. The signal assignment of the 20 carbon atoms of the alkaloid gelsemine[37], for example, was achieved purely with the aid of the theory of the chemical shift[19,35,36] and with a minimum of model substances. The presence of polycyclic aliphatic and aromatic rings and of hetero atoms leads to a pronounced differentiation of the ^{13}C signals of alkaloids. The shift differences between the C atoms are therefore large, and this facilitates the assignment on the basis of off-resonance decoupled spectra and the theory of the chemical shift. As was shown in the case of the epimers 10-oxo-de-*N*-morphinan and 10-oxo-de-*N*-isomorphinan, *cis* and *trans* fusion of rings in particular can also be clearly characterized[38].

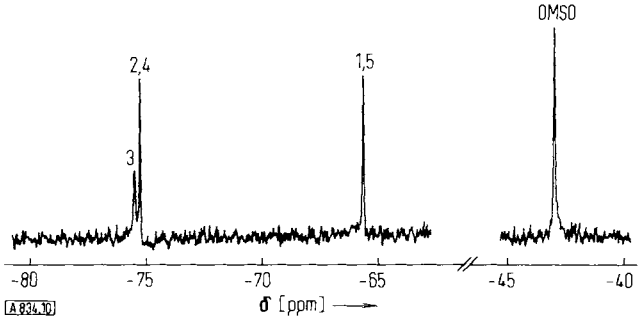
7.4. Carbohydrates

The first publications on the ^{13}C resonance of carbohydrates[39-42] show that this method admirably complements proton resonance. Only one article describes PFT ^{13}C measurements on glycosides[43].

For the cyclohexane and pyranose rings, the ^{13}C signals of ring C atoms with axial substituents usually appear at higher fields than those of corresponding C atoms with equatorial substituents[36,44,45]. The example of the pair of anomers α- and β-methyl-D-xylopyranoside *(7)* and *(8)* (Fig. 9) shows a number of rules that are found for all pyranosides[43].

The signals of the anomeric carbon atoms C-1 are observed at very low fields. The C-1 signal of methyl-α-D-xylopyranoside, because of the axial methoxy group, is





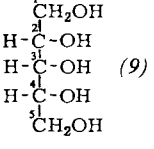


Fig. 9. 22.63 MHz PFT ^{13}C-NMR spectrum of a) α-methyl-D-xylopyranoside *(7)* and b) β-methyl-D-xylopyranoside *(8)*, 2 M in water, 256 pulses, pulse width 30 μs, pulse interval 0.4 s. The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0.

(9)

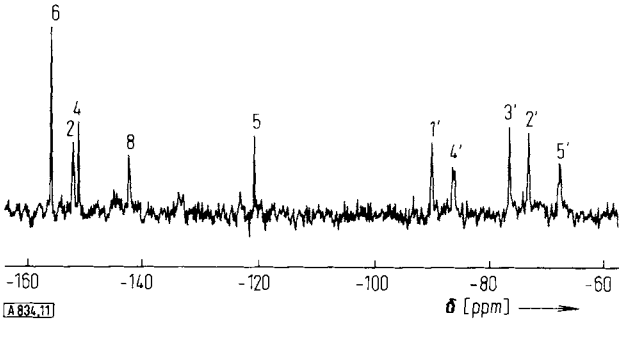
Fig. 10. 22.63 MHz PFT ^{13}C-NMR spectrum of ribitol *(9)* in water: 256 pulses, pulse width 40 μs, pulse interval 0.4 s. The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0.

situated at a field 4.5 ppm higher than that of the C-1 signal of the β-anomer, with its equatorial methoxy group. Similarly, the signal of the axial α-methoxy group, which is situated at a very high field, is 1.9 ppm higher than that of the equatorial β-methoxy group. Since no OR group is attached to C-5, this atom has the highest shielding of all the pyranose carbon atoms (Fig. 9). When the configuration of the methoxy group on C-1 changes from equatorial to axial, the signals of C-2, C-3, and C-5 are displaced to higher fields. The signal of C-4, on the other hand, is practically unaffected.

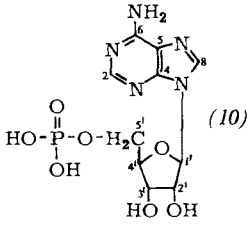
The ^{13}C signals of polyalcohols can be assigned with the aid of the following rules[46]:

1. The ^{13}C signals of the CH_2 or CH_3 groups of deoxypolyols, as expected, are observed at high fields.

2. A hydroxyl group has a strong inductive effect on the C atom attached to it (shift to lower fields)[45].



3. For vicinal polyols, the ^{13}C resonances of secondary alcoholic residues are located at lower fields than those of primary alcoholic residues[46].



4. Carbon atoms which are equivalent due to configurational symmetry produce identical signals, as can be recognized from their higher intensity[46].

Figure 10 illustrates rules 3 and 4 in the PFT ^{13}C-NMR spectrum of optically inactive ribitol *(9)*. Due to configurational symmetry, C-1 and C-5 give one signal at high field, and C-2 and C-4 give another at lower field. The C-3 signal appears at lowest field, with half the intensity of the other two signals. Pentitols and hexitols of lower symmetry, such as arabitol or sorbitol, give five and six signals respectively[46].

7.5. Nucleosides and Nucleotides

The ^{13}C resonance spectra of purine nucleosides and nucleotides contain two groups of signals, as is shown by the PFT ^{13}C-NMR spectrum of adenosine 5′-monophosphate (muscle adenylic acid) *(10)*. The ribofuranose resonances lie between −64 and −99 ppm, and those of

(10)

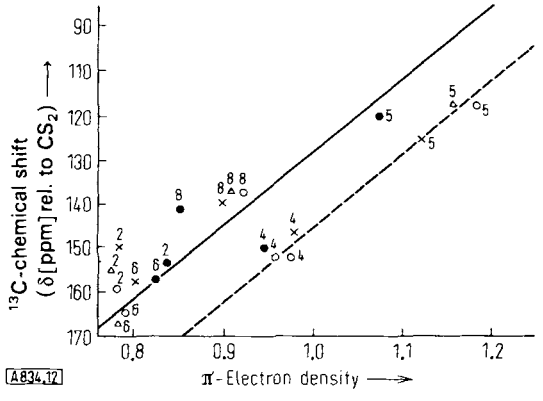


Fig. 11. 22.63 MHz PFT ^{13}C-NMR spectrum of adenosine 5′-monophosphate *(10)* in water: 1024 pulses, pulse width 5 μs, pulse interval 0.4 s. The numbers by the signals indicate the numbering of the C atoms. δ values relative to TMS = 0.

the heterocycle between −95 and −165 ppm (cf. Fig. 11)[47-50]. According to investigations on carbohydrates[39-42] and nucleosides[47-50], the ^{13}C signal of the hydroxymethyl group (C-5′) occurs at a very high field, and that of the anomeric carbon atom (C-1′) at a very low field

within the pentose ^{13}C resonances. Of all the carbohydrate signals, that of C-1′ changes most on variation of the heterocycle. The signal of C-4′ appears as a doublet because of phosphorus-carbon coupling, and is therefore easy to identify. Comparison of ribonucleotides with deoxyribonucleotides allows the assignment of the C-2′ and C-3′ signals.

The signals of C-2 and C-8 of the adenyl residue can be assigned by off-resonance proton decoupling and comparison with the spectra of other purine nucleosides. Further comparisons with the spectra of purine and pyrimidine nucleosides allow the identification of the remaining three quarternary C atoms. In the heterocycle, the C-5 signal appears at the highest field, and the C-6 signal at the lowest field.

It has not yet been possible to detect the helical structure in polynucleotides by ^{13}C resonance using the CAT method. Attempts to determine interactions between various nucleotides from displacements of the ^{13}C resonance have also been unsuccessful so far[47].

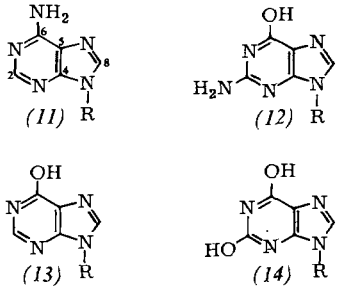

Fig. 12. Relation between ^{13}C chemical shift and π-electron density in the purine nucleosides adenosine *(11)* (●), guanosine *(12)* (△); inosine *(13)* (×), and xanthosine *(14)* (○). The numbers indicate the numbering of the C atoms. R = ribosyl.

Figure 12 shows the relation[48] between the ^{13}C chemical shift and the π-electron density[51] in purine nucleosides. Only the resonances of the ^{13}C—H atoms obey the Spiesecke-Schneider relation[23] (160 ppm/π-electron). The quarternary C atoms obey a different relation (broken line).

7.6. Amino Acids and Oligopeptides

The first ^{13}C resonances of some amino acids were obtained indirectly from INDOR spectra[52] and later from the ^{1}H broad-band decoupled, accumulated 15 MHz ^{13}C-NMR spectra of ^{13}C-enriched (15%) amino acids[53].

The preparation of isotope-enriched amino acids is expensive and time-consuming, and can be considered only for special applications, *e.g.* for the specific incorporation of labeled amino acids into a peptide or for the investigation of enzyme-substrate interactions with ^{13}C-enriched substrates. The advantages of the PFT technique were shown by the ^{13}C spectra of free amino acids, peptides and their derivatives[54–56], and proteins (see Section 7.7) having the natural ^{13}C abundance.

The accumulation of 500 pulses (3.5 minutes) is usually sufficient for recording the spectra of readily soluble amino acids[56]. A satisfactory PFT ^{13}C spectrum (22.63 MHz) of a 0.2 M aqueous solution of the tripeptide glutathione can be obtained in less than 30 min by accumulation of 4000 pulse interferograms with 0.4 s as interval and with ^{1}H decoupling, followed by Fourier transformation[54]. To obtain easily assignable spectra of peptide antibiotics such as gramicidin and smaller peptide hormones such as oxytocin and vasopressin, recording times of about 3 hours are required with 0.05–0.1 M solutions[57].

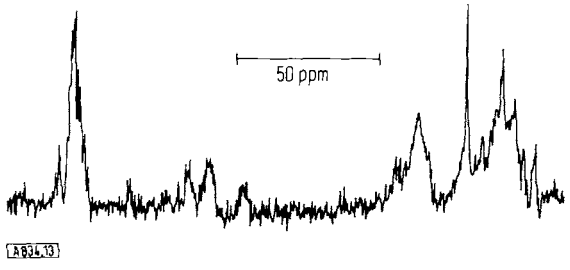

Fig. 13. 22.63 MHz ^{13}C-NMR spectrum of carboxymyoglobin, 8×10^{-3} M in 0.1 M phosphate buffer, 240000 pulses, pulse width 60 μs, pulse interval 0.4 s, 2048 data points. Recorded by Bruker Physik AG, Karlsruhe-Forchheim.

^{13}C-NMR shifts of amino acids and peptides cover a range from about −15 to −180 ppm relative to TMS (see Fig. 13). The ^{13}C resonances of the carbonyl groups (carboxyl, carboxamide, hydrazide, ester and oxycarbonyl groups of protected derivatives, and peptide linkages) appear at the lowest fields (−160 to −180 ppm). The signals of aromatic and heteroaromatic substituents on C-α (phenyl, indolyl, imidazolyl) appear between −120 and −145 ppm. The ^{13}C-α signals are observed between −50 and −65 ppm, and characterize each amino acid. The resonances of C-β and C-γ aliphatic side chains occur at higher fields (−15 to −40 ppm) (for review see[56]). The assignment of signals for the individual amino acids is most readily achieved by comparison of spectra of homologous series or by comparison with the values estimated from the additivity rules given by *Grant et al.*[19, 58], which agree well with the observed ppm values[52]. In cases of doubt, the resonances can be definitely assigned on the basis of off-resonance ^{1}H decoupled spectra or by a change of solvent or of the pH value. The signals of the side chains of amino acids, even in protected derivatives and peptides, appear to depend only slightly on the solvent (2–3 ppm); however, only a few comparative measurements in water, DMSO[56], and methanol[59] have so far been carried out.

The measurement of the pH dependence of the ^{13}C spectra of some simple amino acids and peptides give pK values

for the NH_3^+ and COOH groups that exhibited excellent agreement with those obtained by other methods[52]. With increasing pH value (dissociation of the protons from COOH and NH_3^+), the ^{13}C resonances are slightly displaced to lower fields (2–4 ppm) because of the change in charge density on C-α. According to *Del Re et al.*[60], the charge density distribution can be determined semi-empirically for amino acids[52]. The anomalous shift to lower fields (shift to higher fields) of the ^{13}C signals on deprotonation (protonation) is also observed for amines, carboxylic acids, and phosphoric acid systems. This behavior contrasts with the shift of the ^1H signals to higher fields with rising pH value. This cannot be attributed to inductive effects or to a change in hybridization, since no change in the coupling constants is observed. The opposite shifts of the ^{13}C and ^1H signals can be interpreted to a first approximation as a result of polarization of the C—H bonds by the ammonium or carboxylate group, with the result that the electron density on the carbon decreases, while that on the hydrogen increases[52].

The measurement of the pH dependence of the ^{13}C spectra of polyfunctional amino acids and peptides by the PFT technique allows a new determination of the p*K* and pI values of these compounds[57]. Since the ^{13}C-α signals of cysteine and cystine differ by 13 ppm[54], it is possible to investigate the pH dependence of the redox equilibria of these amino acids and of peptides such as glutathione, whereas this is extremely difficult *e.g.* by polarographic and other methods[61].

7.7. Polypeptides and Proteins

The interpretation of the ^1H-NMR spectra of polypeptides and proteins presents considerable difficulties, despite the development of high-resolution, superconducting magnetcoils and of the CAT technique[62–68]. More information can be obtained from ^1H-NMR spectra by the use of partly deuterated enzymes[69] or by the use of selective contact shift reagents[70], but this often results in a partial loss of resolution.

On the other hand, the singlets of all the carbon atoms can be detected and assigned in the ^1H noise-decoupled PFT ^{13}C spectra, even in the case of decapeptides. Since the line width of the ^{13}C signals is about 1/16 less than that of the ^1H-NMR signals of macromolecules[59], while the chemical shifts are greater, the probability of overlapping of several signals is extremely small except in the carbonyl region. Preliminary investigations of the sequence dependence of the ^{13}C signals show that a definite sequence analysis is possible only up to tripeptides and tetrapeptides[52, 56].

The ^{13}C spectra of the decapeptide antibiotic gramicidin S-A[59] and of the carbohydrate hydrolase lysozyme (molecular weight 14300; 129 amino acids; accumulation for 87 hours)[71] have been recorded by simple accumulation with broad-band ^1H decoupling. Much more informative ^{13}C spectra of larger peptide hormones such as insulin[72], of enzymes such as ribonuclease[73], and of proteins (carboxymyoglobin, Fig. 13) can be obtained in shorter accumulation times (10–20 hours with 0.02 M solutions) by the PTF-NMR technique. Longer accumulation times are limited less by the long-term stability of the magnet than by the capacity of the computer, and do not allow appreciable improvement in the case of the ^{13}C-NMR spectra of complex biopolymers.

The PFT ^{13}C-NMR spectrum of carboxymyoglobin (153 amino acids, Fig. 13) shows the typical absorption region of the peptide and side-chain carbonyl groups at the lowest fields. This region is followed by the resonances of the side chains of aromatic amino acids, particularly the signals of the twelve histidines and six phenylalanines. The C-α signals, then the C-β, C-γ, and methyl resonances of the side chains of aliphatic amino acids appear at higher fields. The signal intensity in the region of the absorption of the guanidinium carbon atoms (at −155 ppm) is naturally lower for myoglobin (4 arginines) than *e.g.* for lysozyme[71] (11 arginines). This interpretation of such ^{13}C spectra of biopolymers is simplified by comparison with a computer-simulated spectrum, as has already been shown for lysozyme[71]. A comparison of the estimated signal intensities of the various resonance regions with the integrated PFT ^{13}C-NMR spectrum of ribonuclease shows that these agree well with the experimental values[73].

The different ^1H resonances of left-handed and right-handed helices are attributed to the magnetic anisotropy of the carbonyl groups. Field effects should have a greater influence on the ^{13}C shifts in ^{13}C-NMR spectroscopy, and should predominate over the magnetic anisotropy effect of the carbonyl group. Thus larger ^{13}C signal shifts should be found between random coil conformations of polypeptides and left-handed or right-handed helices. Direct steric interactions in proteins with special conformations should also result in pronounced sterically induced shifts[52].

The few reported ^{13}C-NMR studies in the peptide field already give evidence that PFT ^{13}C-NMR spectroscopy will provide the answer to many important biochemical questions regarding the carbon skeleton of these biopolymers.

8. ^{13}C-NMR Contact Shifts and Asymmetry Effects

In addition to the recent uses of contact shift reagents in ^1H-NMR spectroscopy, the contact shift of ^1H-decoupled ^{13}C-NMR signals in the presence of paramagnetic metal complexes is also already being investigated[74–77].

Studies on ^{13}C contact shifts for π-electron systems[74, 76, 77] and σ-electron systems[75] show that the ^{13}C resonances, like the ^1H resonances, depend on the concentration of the added shift reagent. The ^{13}C shifts (up to 6 ppm) in nickel pentanedionate complexes of piperidine and *N*-alkylpiperidines have been used for the investigation of the configuration and the nature of the electron spin density distribution through the σ-electron system[75]. The contact interaction also influences the ^{13}C relaxation. Therefore paramagnetic metal ions are used to prevent changes of ^{13}C signal intensities due to nuclear Overhauser effects during ^1H broad-band decoupling[11].

Molecular asymmetry effects on ^{13}C-NMR shifts have been observed for isopropylalkyl alcohols and isopropylalkanes[78]. The nonequivalence ($\delta_A - \delta_B$) of the methyl groups A and B of the isopropyl group due to the proximity of a center of asymmetry increases from 0.1 to 7.2 ppm in the order alkyl = methyl, ethyl, isopropyl, *tert*-butyl. This is explained by the increase in population of a preferred conformation with CH_{3A} ($\delta_A > \delta_B$ rel. to CS_2) between hydrogen and the hydroxyl group on a hydroxymethyl group[78]. This asymmetry shift is much greater for ^{13}C than for ^{1}H. The nonequivalence of the methyl groups in the isopropyl residue in the vicinity of an asymmetric C atom can be observed particularly clearly in the PFT ^{13}C-NMR spectra of valine, leucine, and their derivatives[56]. PFT ^{13}C-NMR spectroscopy can replace ^{1}H-NMR spectroscopy in particular in the structural elucidation and determination of the enantiomeric purity of diastereoisomers.

9. Isotope Effects and Elucidation of Biosynthetic Pathways

In the elucidation of structures and reaction courses, isotopes such as ^{2}H or ^{13}C are frequently introduced into certain positions in a molecule. PFT ^{13}C-NMR spectroscopy can be used to follow such experiments analytically. The isotope shift of ^{13}C signals is very large; thus the ^{13}C triplet of hexadeuteriobenzene is 13 ppm higher than the benzene singlet in the ^{1}H-decoupled ^{13}C-NMR spectrum. Moreover, the positions of deuterium in deuterated compounds can be determined by comparison of the ^{1}H-decoupled PFT ^{13}C-NMR spectra with the simultaneously ^{1}H- and ^{2}H-decoupled spectra. This is illustrated in Figure 14 for *cis*-3,3,4,7,8,8-hexadeuteriotricyclo[5.1.0.0^{2,4}]octane *(15)*[79]. If the ^{13}C-NMR spectrum is only ^{1}H-decoupled, the C atoms bound to ^{2}H appear as weak multiplets because of the absence of the Overhauser effect.

It is also possible with the aid of PFT ^{13}C-NMR spectroscopy to follow each C atom of a natural product during its biosynthesis. By the use of ^{13}C-enriched starting materials ($^{13}CO_2$, ^{13}C-acetate) or ^{13}C-labeled metabolites in the culture media, it is possible to obtain specifically labeled metabolites or end products, which can be analyzed by ^{13}C-NMR spectroscopy. The ^{13}C-labeled positions are recognized by the high intensity of the corresponding signals. In a double experiment, the aflatoxin precursor sterigmatocystine was isolated from cultures of *Aspergillus versicolor* that had been grown in one case with sodium [1-^{13}C]-acetate and in the other with sodium [2-^{13}C]-acetate as a carbon source. It was possible to establish conclusively the source of each carbon atom in sterigmatocystine by interpretation of the ^{1}H-decoupled accumulated 25.15 MHz ^{13}C-NMR spectra of the two labeled metabolites. This work verified a recently published hypothesis on the biogenesis of sterigmatocystine[80].

Though considerable quantities of substance are still required for biosynthetic studies by PFT ^{13}C-NMR measurements, the radioisotope methods that have been usual until now can in many cases be replaced by this new NMR technique.

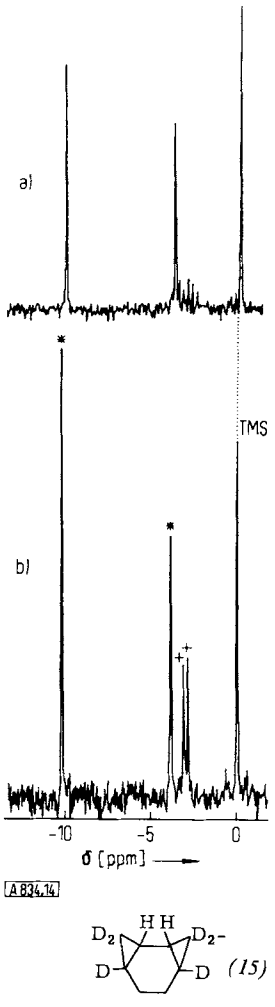

Fig. 14. 22.63 MHz PFT ^{13}C-NMR spectrum of *cis*-3,3,4,7,8,8-hexadeuteriotricyclo[5.1.0.0^{2,4}]octane *(15)*, 20% in hexafluorobenzene/TMS, 4000 pulses, pulse width 40 μs, pulse interval 0.4 s. a) ^{1}H broad-band decoupled, b) ^{1}H and ^{2}H broad-band decoupled, C-^{1}H (*), C-^{2}H (+). δ values relative to TMS = 0.

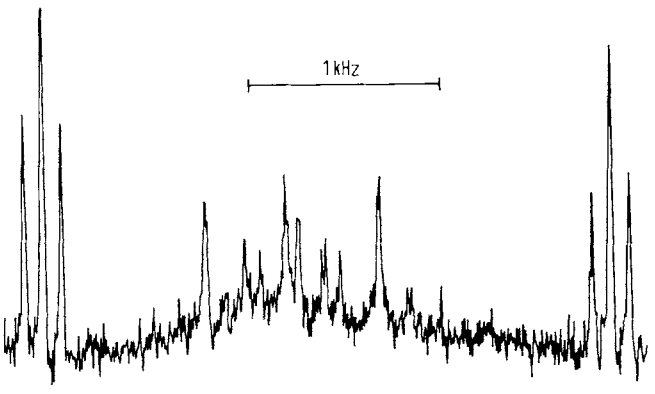
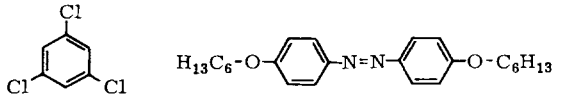


10. PFT ^{13}C-NMR Measurements in Nonliquid Phases

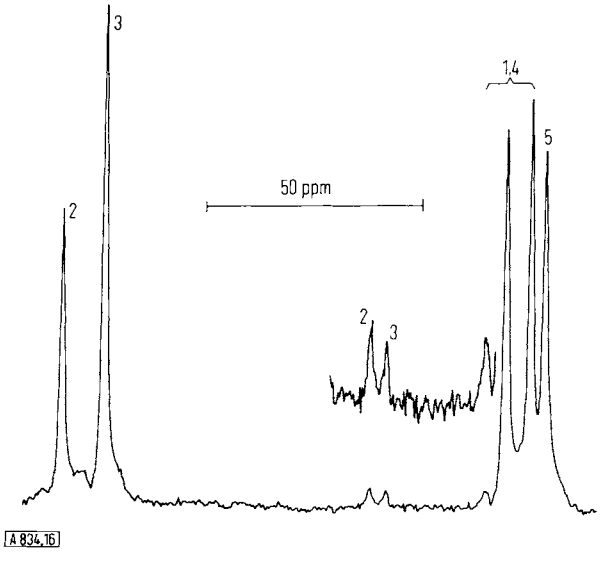


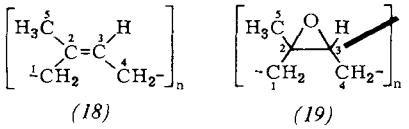
10.1. Nematic Phases

In the liquid phase, the NMR spectrum of a dissolved compound is isotropic, *i.e.* equivalent nuclei produce a single signal. Nematic phases (liquid crystals) restrict the movement of dissolved molecules. In a magnetic field, the dissolved molecules orient themselves in certain directions, which depend on the molecular geometry. The NMR spectrum consequently becomes anisotropic, *i.e.* equivalent nuclei give multiplets as a result of such orientations.

The ^{1}H-NMR spectrum of 1,3,5-trichlorobenzene consists of a singlet in the liquid phase, and of a triplet in the nematic phase (4,4'-di-*n*-hexyloxyazobenzene *(17)* at 80 °C)[81,82].

Because of the low sensitivity of the ^{13}C resonance, it was formerly difficult to record ^{13}C-NMR spectra in nematic phases, since the aggregates of liquid crystals collapse even at medium concentrations of dissolved compounds (approximately 20%)[82]. Figure 15 shows for the case of 1,3,5-





(16) (17)

Fig. 15. PFT ^{13}C-NMR spectrum of 1,3,5-trichlorobenzene *(16)*, 13% in nematic phase 4 (Merck) at 297°K; 85000 pulses, pulse width 40 µs, pulse interval 0.4 s.

trichlorobenzene that the PFT technique enables one to record ^{13}C spectra in nematic phases[79]. The two triplets, which are separated by about 3 kHz, correspond to the C—H atoms. Between these, the C—Cl signals overlap with the broad signal of the nematic phase. The spectrum is being analyzed at present[79].

(18) (19)

Fig. 16. ^{1}H broad-band decoupled 22.63 MHz PFT ^{13}C-NMR spectrum of natural rubber containing 5% of isoprene oxide, 100%, solid, ext. D_2O as lock substance, 8000 pulses, pulse width 40 µs, pulse interval 0.2 s. The assignment of the isoprene units *(18)* is shown in the overall spectrum, and that of the isoprene oxide units *(19)* in the enlarged partial spectrum.

High-resolution NMR studies on polymers have been hindered until now by solubility. Because of the small line width of ^{13}C signals[59], ^{13}C measurements are possible even in highly viscous and solid phases. This has been demonstrated by the recording of PFT ^{13}C-NMR spectra of many polymers in the solid phase[79].

As an example, Figure 16 shows the ^{1}H broad-band decoupled PFT ^{13}C-NMR spectrum of natural rubber containing 5% of isoprene oxide. All the types of C atoms present in this macromolecule can be readily recognized.

We are grateful to Mr. Toni Keller, Dr. Christian Tänzer, Dr. Roger Price, and Dr. Victor Formacek (Bruker Physik AG, Karlsruhe-Forchheim) for many suggestions and for recording numerous PFT ^{13}C-NMR *spectra. We also thank Dr. Roger Price for reading the manuscript.*

Non-rigid Molecular Skeletons—Berry Pseudorotation and Turnstile Rotation[**]

By Paul Gillespie, Peter Hoffman, Hans Klusacek, Dieter Marquarding, S. Pfohl, Fausto Ramirez, E. A. Tsolis, and Ivar Ugi[*]

Molecules rearrange by regular and irregular processes. The former occur with preservation of bonds and coordination numbers while the latter involve rupture and reformation of bonds via states possessing different coordination numbers. For molecules with skeletons that carry n ligands both processes can be represented by permutation operators belonging to the symmetrical group S_n. These operators are obtained from the descriptors of the particular molecules in a simple manner; the conceivable reaction mechanisms correspond to the skeletal symmetry subclasses of S_n. Regular rearrangements—e.g. of phosphorane derivatives with a monocentric skeleton, including their analogs, or of ethane derivatives with a dicentric skeleton—all submit themselves to classification based upon skeletal non-rigidity. Flexible molecular skeletons are representable by a collection of rigid skeletal models which can be interconverted by deformations of bond angles and/or some form of internal rotation. To accomplish mechanistic understanding of these regular processes, it is useful to represent the symmetries of the rigid skeletal models and the existent ligand equivalencies by subgroups of S_n and consider the dependence of the skeletal flexibility upon the given ligand set. This procedure is based on the ideas of Polya and Longuet-Higgins. The former introduced separation of permutational molecular symmetry into skeletal symmetry and ligand set symmetry, which, combined with the total molecular symmetry concept developed by Longuet-Higgins for the treatment of non-rigid symmetric molecules, yield the foundation for the following classification of regular pentacoordinate rearrangements and related processes. It will be shown that with the given quantum chemical properties of the pentacoordinate phosphorus bond system, including participation of the P_{3d} orbital set, not only the BPR[2] mechanism but also single and multiple TR[2] processes must be considered in the interpretation of the observed phenomena. Although some experimental observations can be interpreted by either of the two mechanisms, and certain other regular rearrangements can be explained only by invoking the TR mechanism, no regular processes are known, as yet, that can be explained solely by the BPR mechanism.

1. Introduction

In recent years, chemical compounds with non-rigid molecular skeletons have attracted wide interest. Rearrangements of monocentric molecules that correspond to permutations of ligands or skeletal positions by bond angle deformations at the central atom[5–7], as well as the conformational interconversions of polycentric systems[8–10] by rotation about bond axes, have been the subject of much discussion.

In this paper, we generate a general approach to the description of the static and the dynamic properties of molecules with flexible skeletons, particular attention being paid to pentacoordinate phosphorus compounds and the properties of their bond systems. Further pursuit of *Polya*'s dual symmetry approach[10] that has been extended by *DeBrujin*[10] and *Ruch et al.*[11], in concert with the total molecular symmetry of *Longuet-Higgins*, will yield a formalism that simultaneously contains the symmetry of the rigid molecular models and their regular rearrangements. In this context the descriptors of permutational isomers, as derived previously[1], become very useful.

2. The Classification of Pentacoordinate Molecules

2.1. Symmetry Equivalencies

Chemical compounds can be arranged into classes of isomers, *i.e.* into classes of compounds with the same molecular formula. Within a class of isomers it is possible, in certain cases, to further classify according to the properties of the permutation groups representing the skeleton and ligand set. *Permutational isomers* differ only by the distribution of the ligand set on the molecular skeleton[1]; those with the same chemical constitution are stereoisomers[12].

The concept of permutational isomerism not only provides a basis for the nomenclatural classification of molecules but also for the characterization and interpretation of their

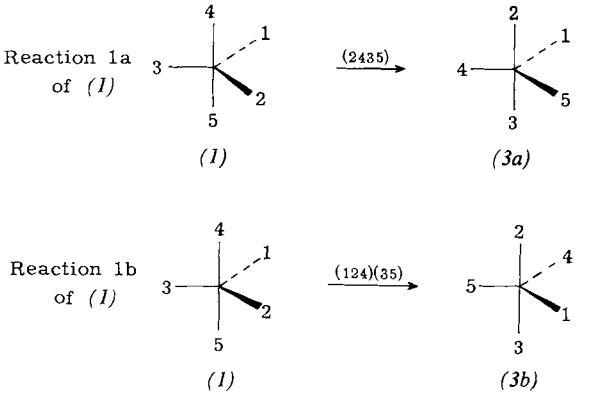
intramolecular rearrangements. This is accomplished by mapping the species under consideration onto algebraic structures[11].

Rearrangement processes of molecules with the general formula *(1a)* are the predominant subject of this paper. Molecules of this type are conceptually viewed as a set of ligands and a pentacoordinate central atom Z whose valencies form a TBP[12] molecular skeleton *(2)* with D_{3h} symmetry.

Skeleton *(2)* can also be represented by the set of numbers, $\mathfrak{S}=\{1,\ldots,5\}$, by assigning skeletal numbers to *(2)*. If we now describe the set of ligands $L=\{L_1,\ldots,L_5\}$ by the set of ligand indices $\mathfrak{L}=\{1,\ldots,5\}$ we are now able to represent

the molecule *(1a)* by the formulas *(1b)+(2)* or *(1c)* respectively. This representation is equivalent to the $2\times n$ mapping matrix $\begin{pmatrix}1\\s\end{pmatrix}_0$. Thus formula *(1b)* is merely an abbreviated notation for *(1a)*, whereas *(1c)*, as well as the matrix $\begin{pmatrix}1\\s\end{pmatrix}_0$, not only corresponds to *(1a)* but contains the statement that with skeletal numbering according to *(2)*, the ligand L_1 occupies the skeletal position *1*, ligand L_2 occupies skeletal position *2*, *etc.* If we now define the rule by which the ligands are to be indexed by employing the *Sequence Rule* of *Cahn, Ingold,* and *Prelog*[13], then *(1c)* or $\begin{pmatrix}1\\s\end{pmatrix}_0$ corresponds to that isomer which we call the reference isomer $\mathbf{M}_0$. The reference matrix $\begin{pmatrix}1\\s\end{pmatrix}_0$ is generated when the ligand index set $\mathfrak{L}$ is mapped onto the skeletal index set $\mathfrak{S}$ such that equal numbers are "paired".

From the reference isomer $(1)\equiv\mathbf{M}_0$ we obtain its permutation isomers $\mathbf{M}_\sigma$ by applying the permutations $\boldsymbol{P}_\sigma$ to the ligands $L_1,\ldots,L_5$ (*e.g.* $(1)\rightarrow(3)$), or the permutations $\boldsymbol{Q}_\sigma$ to the skeletal positions according to eq. (1).



$$\begin{pmatrix}1\\s\end{pmatrix}_\sigma = \boldsymbol{P}_\sigma\begin{pmatrix}1\\s\end{pmatrix}_0 = \begin{pmatrix}\boldsymbol{P}_\sigma 1\\n\end{pmatrix} = \boldsymbol{Q}_\sigma\begin{pmatrix}1\\s_0\end{pmatrix} = \begin{pmatrix}n\\\boldsymbol{Q}_\sigma n\end{pmatrix} \qquad (1)$$

Two such mappings, $\begin{pmatrix}1\\s\end{pmatrix}_\sigma$ and $\begin{pmatrix}1\\s\end{pmatrix}_{\sigma'}$, representing the permutational isomers $\mathbf{M}_\sigma$ and $\mathbf{M}_{\sigma'}$, belong to the same molecule, *i.e.* $\begin{pmatrix}1\\s\end{pmatrix}_\sigma = \begin{pmatrix}1\\s\end{pmatrix}_{\sigma'}$ and $\mathbf{M}_\sigma=\mathbf{M}_{\sigma'}$, if they differ only by the simultaneous permutation $\boldsymbol{R}$ of the ligand indices 1 and the skeletal indices *s* according to eq. (2). With no skeletal symmetry, a pentacoordinate molecule with five different ligands could yield 5! distinguishable isomers corresponding to the 5! different mappings of the set $\mathfrak{L}$ onto the set $\mathfrak{S}$ represented by their $\begin{pmatrix}1\\s\end{pmatrix}_\sigma$ matrices.

$$\begin{pmatrix}1\\s\end{pmatrix}_\sigma = \boldsymbol{R}\begin{pmatrix}1\\s\end{pmatrix}_{\sigma'} \quad \text{or} \quad \begin{pmatrix}\boldsymbol{P}_\sigma n\\n\end{pmatrix} = \begin{pmatrix}\boldsymbol{R}\,\boldsymbol{P}_\sigma n\\\boldsymbol{R}\,n\end{pmatrix} \qquad (2)$$

If however some elements of skeletal symmetry exist, as in *(2)* for example, then the number of distinguishable isomers is reduced. Owing to the D_{3h} symmetry of *(2)*, certain permutational isomers resulting from skeletal or ligand permutations on *(1)* can be interconverted by rotations belonging to the D_{3h} symmetry group and therefore are equivalent.

The C_2 rotations (twofold: $\triangleq 180°$) of the skeleton *(2)* correspond to the permutations *(1 2) (4 5)*, *(1 3) (4 5)* and *(2 3) (4 5)*, and the C_3 rotations (threefold: $\triangleq 120°$) of *(2)* are represented by the permutations *(1 2 3)* and *(1 3 2)* of the skeletal positions. Here, *(1 2 3)* means position *1* replaces position *2*, position *2* replaces position *3* and position *3* replaces *1*, *i.e.* $1\overset{\nearrow 2}{\underset{\nwarrow 3}{\downarrow}}$. These and the identity operation *E* ("do nothing") form a permutation group. The *rigid skeletal equivalence group* $\boldsymbol{G}$ of order $g=6$, represents the rotational symmetries of the rigid skeletal model *(2)* (see Section 4.2.1). Molecules whose $\begin{pmatrix}1\\s\end{pmatrix}$ mappings are numerically transformed into each other by permutations belonging to $\boldsymbol{G}$ are equivalent. With five different ligands on the skeleton *(2)* there are $5!/6=20$ distinguishable permutational isomers corresponding to 10 pairs of antipodes.

Certain ligand permutations, resulting from isomerization processes (see Section 5), are equivalent to certain other permutations due to their skeletal symmetry. For instance, the permutation (2 4 3 5) transforms *(1)* into *(3)* according to *(1)* → *(3a)*. The same isomer results from *(1)* by applying the permutation (1 2 4)(3 5) as well, shown as *(1)* → *(3b)*.

Molecules *(3a)* and *(3b)* are equivalent as they are interconverted by a 120° rotation about the skeletal C_3 axis.

In the $\binom{l}{s}$ matrix representation the equivalence of the permutations (2 4 3 5) and (1 2 4)(3 5) upon *(1)* as well as the permutations (1 2 5)(3 4), (1 3 4)(2 5) and (1 3 5)(2 4) follows from:

$$\binom{l}{s}_{(3a)} = \binom{(2\,4\,3\,5)\,n}{\quad n} = \binom{(2\,4\,3\,5)\,1\,2\,3\,4\,5}{\quad 1\,2\,3\,4\,5} = \binom{1\,5\,4\,2\,3}{1\,2\,3\,4\,5}$$

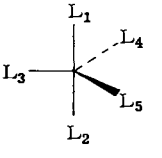
with $R = (2\,4\,3\,5)^{-1}$, $\binom{R}{R}\binom{1\,5\,4\,2\,3}{1\,2\,3\,4\,5} = \binom{1\,2\,3\,4\,5}{1\,4\,5\,3\,2}$

$$\binom{l}{s}_{(3b)} = \binom{(1\,2\,4)(3\,5)\,n}{\quad n} = \binom{(1\,2\,4)(3\,5)\,1\,2\,3\,4\,5}{\quad 1\,2\,3\,4\,5} = \binom{4\,1\,5\,2\,3}{1\,2\,3\,4\,5} = \binom{1\,2\,3\,4\,5}{2\,4\,5\,1\,3} \quad \text{with } R = (3\,5)(1\,2\,4)^{-1} \tag{4}$$

The resulting matrices of eq. (3) and (4) represent the same molecule as they differ only by the skeletal permutation (*1 3 2*) representing a C_3 rotation of the skeleton given by eq. (5).

$$\binom{\quad 1\,2\,3\,4\,5}{(1\,3\,2)\,1\,4\,5\,3\,2} = \binom{1\,2\,3\,4\,5}{2\,4\,5\,1\,3} \tag{5}$$

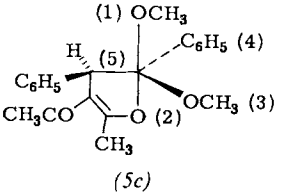
If the ligand set $L=\{L_1,\ldots,L_5\}$ contains sets of equivalent ligands rather than five different ones, these equivalencies must be accounted for by permutations representing the permutational symmetry of the ligand set. When two of the ligands of *(1)* are not distinguishable, there are 10 isomers (rather than 20), with 3 pairs of antipodes.



In 1937, *Polya*[10] recognized that classification and enumeration of the isomers of a skeletal class with n skeletal positions is possible only if the permutations of the skeletal equivalence group $\boldsymbol{G}$ and the permutations of the ligand equivalence group $\boldsymbol{H} \subset \boldsymbol{S}_n$ of the order h are taken into account simultaneously. This he accomplished by considering all arrangements as equivalent which differ only by permutations belonging to $\boldsymbol{H}$ and/or $\boldsymbol{G}$ (see Section 3.4). *Polya* called the distinguishable isomers the ***HG configurations*** and gave a combinatorial procedure to enumerate them, illustrating this concept with a hexacoordinate molecule. Six different ligands on an asymmetric skeleton leads to $6!=720$ isomers, whereas the same ligand set on a skeleton with octahedral O_h symmetry, where $g=24$, yields $6!/24=30$ isomers. A ligand set with subsets of two and three equivalent ligands possesses a ligand equivalence group $\boldsymbol{H}$ of order $h=2!\times 3!=12$ on an asymmetric skeleton where $n=6$ corresponds to $6!/12=60$ isomers. The same ligand set on an octahedral skeleton gives just three distinguishable isomers.

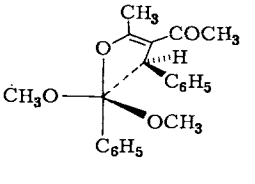
Ruch et al.[11] developed *Polya*'s concept further by noting that the set of isomers in a skeletal class or $\boldsymbol{HG}$ configurations respectively corresponds to a system of representatives of the double cosets of the subgroup $\boldsymbol{H}$ and $\boldsymbol{G}$ of the group $\boldsymbol{S}_n$. Further these authors indicate an elegant group theoretical procedure for enumerating these double cosets.

2.2. Nomenclature

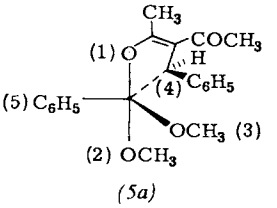


We found that the permutational representation of the mappings of ligand indices, partially symmetrized relative to $\boldsymbol{H}$, onto the set of skeletal indices, partially symmetrized relative to $\boldsymbol{G}$, yields a universally applicable classification for permutational isomers which can serve as a nomenclature system as well[1]. A singular advantage of the use of permutation operators (descriptors) in a nomenclature system is that they provide a basis for the algebraic treatment of permutational isomerization processes and their mechanisms (see Section 5.1).

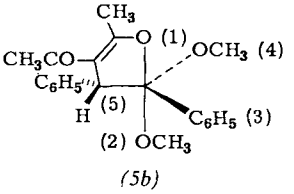
Formerly, pentacoordinate permutational isomers with a TBP skeleton were nomenclaturally characterized by defining some arbitrary isomer (*e.g.*, the most stable, or the first discovered) to be the reference isomer. Ligands are then numbered as a function of their skeletal position, *e.g.* as in *(4)*[5d,14,15], in an arbitrarily chosen spatial orientation. This results in what is called the "a" isomer[14] (or the "12"-isomer[5d] or the "21"-isomer[15], respectively) since the ligands L_1 and L_2 occupy the apical positions.



(4)



These "binary descriptors", in contrast to our permutational descriptors, do not represent the ligand or skeletal permutations that result from permutational isomerizations (*e.g.*, of the reference isomer). However, the binary descriptors have one distinct advantage: in the case of chiral isomers, the descriptors of antipodes can be immediately recognized as they are inverse symbols. Such nomenclature accounts for the TBP skeletal symmetry, but, if equivalent ligand sets exist, it yields different descriptors for the same molecule (see Table 1).



(5c)

(6)

(5a)

(5b)

The following discussion points out the latter shortcoming in some detail. If *(5)*[5a,b] is defined as the a-isomer or the 12-isomer respectively, the numbering of ligands is not unequivocally determined because of the skeletal symmetry; *(5a)*—*(5c)* can equally well serve for indexing the ligands. Independent of its spatial orientation *(5)* may be called the 12-isomer but the descriptors of its permutational isomers are found to be different due to the choice of *(5a)*, *(5b)*, or *(5c)* as the reference. For instance, *(6)* is the 15- or (because of the equivalent methoxy groups) the 51-isomer of *(5a)*; analogously *(6)* is simultaneously the 14- or 41-isomer of *(5b)* or *(5c)*.

3. The Bond System of Pentacoordinate Phosphorus

3.1. Quantum Mechanical Calculations

When treating the large systems we face in this study, one must make a reasonable compromise between the more accurate but far more rigorous and expensive *ab initio* methods and the less expensive semi-empirical calculations. The choice need not limit the usefulness of the data, since properly parametrized semi-empirical methods provide energies, geometries, dipole moments, bond orders, *etc.* that are in good agreement with experimental values.

Table 1. Comparison of the binary and permutational descriptors of pentacoordinate molecules with a TBP skeleton.

Binary descriptors			permutational descriptors									
Five different ligands $L_1,\ldots,L_5$												
[a]	[b]	[c]		$L_1=L_2$	$L_2=L_3$	$L_3=L_4$	$L_4=L_5$	$L_1=L_2$ $L_3=L_4$	$L_1=L_2$ $L_4=L_5$	$L_2=L_3$ $L_4=L_5$	$L_1=L_2$ $=L_3$	$L_2=L_3$ $=L_4$	$L_3=L_4$ $=L_5$
a	21	12	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 4)(2 5)	(1 5)	(1 4)(2 5)

[a] According to [14]; [b] according to [15]; [c] according to [5d].

These shortcomings are easily avoided by independent numbering of the skeletal and ligand positions. Such a procedure immediately affords an unambiguous, generally applicable definition for the reference isomer as well as the means for distinguishing between equivalent ligands. Detailed discussions of NMR data as well as graphical representation of some permutational isomerizations demand that these distinctions be unequivocal. Finally, it should be noted that where ligand equivalencies occur, nondistinguishable isomers have the same permutational descriptors (see Table 1). With five different ligands, the isomers are optical antipodes whose binary descriptors are inverse. In the presence of ligand equivalencies, however, only those pairs of mutually inverse binary descriptors which belong to distinguishable isomers relate to optical antipodes,

(*e.g.*, with $L_1 = L_2$: (1 4) – (2 4), (1 5) – (2 5), (1 4)(3 5) – (2 4)(3 5);
with $L_2 = L_3$: (2 4) – (3 4), (2 5) – (3 5), (1 4)(2 5) – (1 4)(3 5);
with $L_3 = L_4$: E – (1 2), (1 5) – (1 4 5), (2 5) – (1 2 5);
with $L_4 = L_5$: (1 4) – (1 5), (2 4) – (2 5), (3 4) – (3 5);
with $L_1 = L_2$ and $L_3 = L_4$: (1 5) – (2 5) and
with $L_2 = L_3$ and $L_4 = L_5$: (3 4) – (3 5).)

If the calculation method chosen is suitable for the system and is carefully employed, the errors generated by the approximations contained in the method will be small in magnitude and consistent in direction. Such results will adequately represent the trends within a wide range of real chemical systems and there is no loss of information essential to the validity of the interpretations and predictions one can make. Among the semi-empirical quantum mechanical methods available we chose to use the CNDO/2 (Complete Neglect of Differential Overlap) approximation[16,17].

While the details of the CNDO/2 method and its capabilities can be found in the original papers of *Pople et al.*[16] and recent reviews[17], we present a brief comment on the approximations made and the parametrization employed. In this approximation to the solution of the LCAO-SCF equations, only the valence electrons are treated explicitly by choosing a minimal set of basis functions (atomic orbitals) for a molecule in its ground state. The basis functions Φ_μ are treated as an orthonormal set, that is the overlap integrals $S_{\mu\nu}=\int\Phi_\mu\Phi_\nu=1$ are put to zero unless $\Phi_\nu=\Phi_\mu$ in which case they are unity. This results in the complete

neglect of differential overlap between atomic orbitals on the same atom. This approximation does not hold true in the case of orbitals of two different atoms, but it simplifies the calculation considerably without introducing serious errors. All two electron integrals which involve overlapping charge densities between different basis orbitals are likewise neglected so that the electron interaction integrals $\gamma_{\mu\nu}$ account for the repulsions between electrons on adjacent atoms. Approximations are also introduced to account for the effect of adjacent atomic cores upon an electron in any atomic orbital Φ_μ. Finally, approximation is made to calculate the effect of an electron in the field of two atoms simultaneously. The latter, termed a resonance integral β, is estimated by empirical values chosen to fit either experimental data or results obtained from *ab-initio* calculations.

The choice of parameterization (selection of basis functions) would include sp or spd alternatives. Fortunately, a comparison between the two exists for calculations on the bonding between some second and third row elements including PF_5 and SF_6[18]. In each case it was shown that inclusion of d-orbitals in the basis set of the third row ground state atom reduced bond polarity. Calculations on other species where dipole moments are known show that no reliable calculations are obtained without inclusion of d-orbitals for third row elements[7]. Although the question of d-orbital participation in ground state phosphorus is still open[19b, 20–24], d-orbitals were included in our universal basis set. This permits the extent of d-orbital participation to arise quite naturally. The implications of this will be discussed in some detail later on.

Extended Hückel MO calculations on phosphorus(v) halides have resulted in the impression that little d-orbital participation exists and therefore their effect may be neglected to a first approximation[24]. The most severe limitation of the extended Hückel method and the statements regarding d-orbitals that result concerns the choice of the optimum P-3d orbital exponent (Slater exponents)[21, 23]. *Slater*'s procedure for the calculation of screening constants from which one obtains the orbital exponents does not include the d-orbitals. Thus, one must assign an arbitrary value to the d-orbital exponent or determine it by some optimization procedure. In the HMO calculation above[24], the value of 1.0 was chosen for this exponent, which, as one might expect, yields a rather diffuse d-orbital set, predictably resulting in small d-orbital interactions. *Boyd* and *Lipscomb*[21] calculated a series of d-orbital exponents for phosphorus compounds, the optimum being 1.4. This value yields a more contracted d-orbital set, as is also to be expected if one considers the electrostatic field of a ligand set[22a]. In the CNDO/2 calculations a P-3d exponent of 1.6 is employed which approximates the value found by *Boyd* and *Lipscomb*.

Applications of the CNDO/2 method have recently appeared in similar attempts by *Segal et al.*[25] to discuss bonding and energy barriers to isomerization pathways. This rather elegant study revealed that small errors in the absolute values for energies and bond lengths are consistent and, within a given set of isomers, in the same direction.

It must be pointed out that, due to the approximations involving the atomic cores, comparison of the absolute values of various parameters, *e.g.* binding energy, between molecules is valuable only for molecules containing the same number and kind of atoms. Comparison between members of a particular isomer set are valid and lead to predictions of relative stability between isomers. Any comparison of energies between ground state geometries and presumed intermediate geometries must be done on species whose bond lengths and bond angles have been optimized for the lowest energy. In our calculations, bond lengths have been optimized to within less than ± 0.01 Å. An assumed D_{3h} trigonal bipyramidal symmetry was fixed for the pentacoordinate ground state phosphorus compounds. In the assumed geometries of the transition states and ring structures on the trigonal bipyramid, bond angles were optimized to within $\pm 0.5°$. No attempt was made to optimize the O—H or C—H bond distances since the contribution to the total energy was small relative to the calculation expense involved. P—H bond distances were optimized and showed a small energy change for a ± 0.05 Å variation about the equilibrium position.

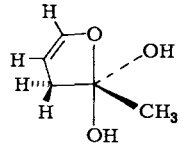
3.2. Binding Energies of Phosphorane Derivatives[26]

Table 2 summarizes the absolute and relative binding energies (BE = Total Energy $-\Sigma$ Core Energies) of some pentacoordinate phosphorus compounds with the TBP skeleton *(2)*. The numbers *1*—*5* at the top of the table indicate the skeletal positions upon which the indicated ligands are placed. The data of Table 2 show that the BE is strongly influenced by the placement of the ligands, the more electronegative ($\approx$ apicophilic)[*] ligands preferring the apical positions (see Section 3.3.1) in agreement with the polarity rule[20, 27, 28]. Model compounds *(13)*—*(18)* (Table 2) have been "synthesized" by the computer, for, while the actual molecules are rather unlikely to exist, their relative BE data do permit one to draw conclusions pertinent to real systems, *e.g. (5)*, whose BE is not accessible because of the effort and expense of the computation required.

Again, while comparison of the absolute binding energies between different isomer sets is not informative, comparison of the relative BE of the members of a set of isomers lead to predictions for relative stabilities. The energetic preference for CH_3 to be equatorial is a trend predicted by the differences noted in *(10)* and *(16)*—*(18)*. The same trend is observed for the equatorial preference by $O^\ominus$ as calculated in *(14)*, *(15)* and *(17)*. The magnitude of the BE differences for $O^\ominus$ equatorial ($O^\ominus_e$) *vs* $O^\ominus$ apical ($O^\ominus_a$) seem relatively consistent in the three examples. In example *(17)* the sum of the relative BE for *(17b)* and *(17c)* are

[*] *Note added in proof*: Calculations done on the series PH_nF_{5-n} with and without d orbitals on the P basis set show an average reduction of electron density by 15% on P, an increase of 15% in bond lengths with an attendant reduction of BE by an order of magnitude when d orbitals are removed. The low energy isomer from PCl_2F_3 changes from diapical F—F to Cl—F when d orbitals are removed. This electronic behavior clearly indicates that reduction of polarity between phosphorus and its ligand set is accomplished by the back donation of electron density from the ligands *via* p orbitals into the empty d orbitals on phosphorus. This results in a 25—35% increase in stability.

Thus, the tendency for ligands to reside in apical positions might better be termed apicophilicity as d orbital effects, steric effects, and some function of electronegativity all combine to determine ligand position in the TBP.



close to the relative BE shown for *(17d)*. Such comparisons demonstrate that the calculation is consistent within a wide range of molecules and indicates that the comparison of energy *differences* between isomer sets may be instructive.

of the ring is high. In the apical-equatorial placement of five-membered ring the overall strain is small. Furthermore, it is noteworthy that *(18b)* with an endocyclic apical P—C bond is considerably more stable than *(18c)* with an acyclic apical P—C bond.

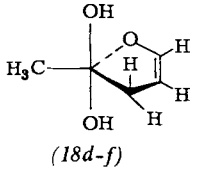


Table 2. Calculated BE of pentacoordinate phosphorus compounds.

For instance, the BE data of *(18)* indicate that, in a cyclic oxyphosphorane derivative, a five-membered ring prefers apical-equatorial placement, again in accord with qualitative experimental observation. It is interesting to note that the BE of *(18d—18f)* with a diequatorial ring is, un-

(18a)

(18d-f)

expectedly (see Ref. [5a] and footnote 11 therein), only slightly dependent upon the magnitude of the endocyclic C—P—O angle α; with small α (~90°) the diequatorial C—P—O strain is large but the rest of the ring is only slightly strained, whereas with large α (~114°) the C—P—O strain is low while the strain in the remainder

Comparison of our data with electron diffraction studies[19a] indicate that the CNDO/2 calculated equilibrium bond lengths for the ground state are overestimated by 5—6%. This is probably due to inaccurate estimation of the β values assigned to the core Hamiltonian; the β values could be altered to fit experiments more closely, but the gain in accuracy would not provide any new or more reliable information since all systems investigated are similarly affected.

3.3. Participation of the P-3d Orbitals in the Bond System

In this section, an attempt is made to call attention to those features of the P-bond system which are of particular interest regarding the problems central to this paper with no claim of a comprehensive theoretical treatment of the bonding in phosphorus compounds[26].

Investigation of the electron densities assigned by the CNDO/2 calculation yields an interesting trend in the comparison between electronic charge distribution for

stabilization of the various isomers we investigated. This is not intended to be a rigorous treatment of the bonding in pentacoordinate phosphorus compounds[26] as our original intention was to provide a framework of understanding for isomerization processes. However, certain interesting possibilities should be pointed out at this time due to the nature of the controversy.

Table 6 is an extract from the density matrix of the program for PF_5. The diagonal elements correspond to electron densities within the prescribed orbital. The sum of these elements is equal to the total valence shell electron density for phosphorus, $\Sigma_P = 3.8890$. Of this, 1.3671 units of electron charge are shown to reside in the five P 3d-orbitals, approximately 35% of the total density. Table 7 is a listing of the off-diagonal matrix elements (italics) which represent the bond orders or resonance integrals of the core Hamiltonian operator. The negative product of these is the stabilizing contribution of the particular ligand orbital with the phosphorus 3 d-orbitals. Tables 8 and 9 are the P 3d-orbital density matrices for *(14a)* and *(14b)* respectively, while Tables 10 and 11 are analogous to Table 7. The total phosphorus electron density difference between the two isomers is 0.044 units; the difference in electron density in the d-orbitals of *(14a)* and *(14b)* is 0.011 units. Approximately 25% of the difference in electron charge takes place *via* the phosphorus d-orbitals. From Tables 10 and 11 one obtains the orbital bond energy contribution difference of 0.0179 a.u., which is equivalent to 30% of the change in binding energy for the two isomers. These results lend strong support to the notion that certain isomers of phosphorus(v) compounds are

phosphorus *vs* the ligand and the binding energy of the molecule. For every example in Table 2, the difference in electron density between phosphorus and the average electron density of the ligand set is lower for the lower energy isomer. Tables 3—5 reproduce the electron densities calculated for phosphorus and its ligands in a representative sample of cases. Further, notice that in each case, electron density on phosphorus in greater for the low energy isomer. It seems clear from this correlation that an increase in stability is gained by virtue of the phosphorus atom receiving some electron density possessed by the ligands. The suggestion[18, 19, 22a] that third row elements may be stabilized by back donation of electron density into the vacant d-orbitals on phosphorus tempted us to speculate upon the extent of d-orbital participation in the stabilized by passing electron density into the d-orbitals on the central atom. The calculations predict that an apical ligand must carry more electron charge than its equatorial counterpart, an experimentally observed reality[19b]. Further, the CNDO/2 program predicts greater double bond character in the equatorial bonds and bond shortening in the equator relative to the apical positions. The calculation also predicts equatorial methyl group participation [cf. *(10)* and *(16)*—*(18)*] with d_{z^2} orbitals on phosphorus which might be an interesting example of "inverse" hyperconjugation where the positive linear combination of atomic hydrogen orbitals produces an orbital with the proper symmetry for combination with the d_{z^2} orbital, having a node in the plane of the d_{z^2} negative doughnut.

Our bonding model then predicts substantial phosphorus d-orbital participation, which also appears to play a substantial role in the determination of ligand position on the trigonal bipyramidal skeleton.

contain two different types of substituents. BE contributions from the P 3d orbitals in a diapical X-P-Y system or a diequatorial X-P-Y_2 system respectively are generally lower than the mean value for X-P-X and Y-P-Y diapical

Although the evidence is far from complete the following generalizations might be drawn:

3.3.1. Apical positions produce less P 3d-orbital interaction than the equatorial ones; therefore, atoms in apical positions must be able to support more electronic charge on themselves since back donation of charge is less likely. Conversely, equatorial positions offer the greatest d-orbital interaction; consequently, less electronegative atoms and anions preferentially occupy these sites [cf. *(14)—(17)*].

3.3.2. An overall weakening of the bond system occurs when either the apical or equatorial ligand subsets or PX_3 and PY_3 equatorial systems [see *(9)*]. This effect is more pronounced for the equatorial system.

The statement 3.3.1 corresponds to the polarity rule[20, 27, 28] which was postulated without consideration of the d-orbitals and 3.3.2 indicates one of the limitations of this rule, which is further limited by its neglect of ligand-ligand interactions (see Section 4.2.4 and note added in proof p. 691).

4. Regular and Irregular Processes

4.1. General Criteria

Pentacoordinate compounds undergo regular and irregular rearrangement processes. Regular processes proceed without rupture and reformation of bonds while this is not true for the irregular process. Intermediates of irregular rearrangements differ in coordination number relative to starting material and products. If bonds are first cleaved and then reformed, the intermediates are lower in coordination number compared to the initial phosphorane while in the event that bonds are formed first, then cleaved, intermediates possess higher coordination numbers. Rearrangements previously interpreted by invoking the BPR mechanism, with few exceptions[30], certainly proceed by regular processes. Thus, an alternative to the BPR mechanism must correspond to a regular process.

The aforementioned regular rearrangement process proceeding with preservation of coordination number is a

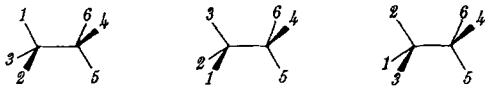
concept of far reaching consequence in chemistry. This allows one to state with precision some important classifications and definitions, which, for a long period, have proved useful in chemistry.

4.2. Molecules with Rigid and Flexible Skeletons



4.2.1. Dynamic Symmetry

The interconversion of permutational isomers by regular processes is possible only if the molecular skeleton involved is flexible, *i.e.* if the molecular skeleton can be represented by some rigid models with numbered positions which themselves can be interconverted with preservation of the coordination numbers of all skeletal centers by deformation of bond angles or by rotations about bonds. Some valence isomerizations may also be thought of as proceeding with preservation of coordination number. An instance of monocentric skeletal flexibility is the numbered TBP model *(2)*, which is transformed by certain bond angle deformations (*e.g.* BPR or TR) with preservation of coordination number 5 into other, equivalent renumbered TBP skeletons. The dicentric skeletal model ethane, *(19a)*, on the other hand, is converted into other corresponding rigid skeletal models *(19b)* and *(19c)* by rotation about the C—C bond conserving both coordination number 4 and all bond angles at both centers.

Equivalencies of skeletal positions arise not only from the symmetry of the rigid skeletal models but also from the skeletal flexibility. Just as one can represent rigid skeletal symmetry by permutation groups $G \subset S_n$, the rigid skeletal equivalence groups, one can also represent the additional equivalencies arising from skeletal flexibility by permutation groups $F \subset S_n$. We employ the term *dynamic skeletal symmetry* for the symmetry of a flexible molecular skeleton which is given by the symmetry of the rigid skeletal models and their interconvertibility by flexibility operations. Dynamic skeletal symmetry is a permutational symmetry which does not yield itself to geometric interpretation in all cases. Often there is no rigid geometric model of corresponding symmetry.

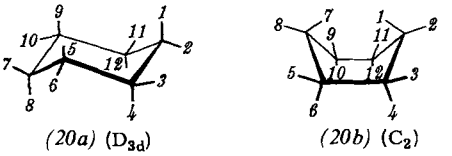
In order that one be able to interpret the properties of nonrigid symmetrical molecules, such as ammonia or methyldifluoroborane, *Longuet-Higgins*[6] introduced the *total molecular symmetry* concept. This comprised all permutational ligand equivalencies in the molecule as well as those due to the symmetries of the rigid molecular models and those due to flexibility. The symmetry of the molecules discussed by *Longuet-Higgins* originates in their skeletal symmetry which corresponds to the molecular symmetry if the necessary ligand equivalencies exist. If one now detaches the ligand set and considers only the skeletal properties of the molecule, one is led from the total molecular symmetry argument to dynamic skeletal symmetry which is independent of the ligand set, existing in molecules possessing skeletal symmetry but actually asymmetric due to ligand inequivalencies.

The dynamic symmetry of a molecular skeleton is in general represented by the product of the skeletal equivalence group G and the skeletal flexibility group F, *i.e.* $D = G \times F \subset S_n (g \leqslant d \leqslant n!)$. This concept is illustrated by the example employing an ethane skeleton *(19)*.

(19a) *(19b)* *(19c)*

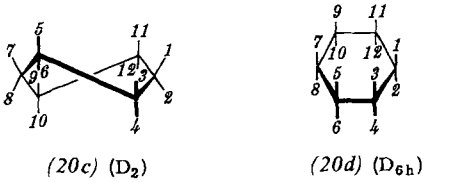
The symmetries of molecules *(19)* are described by the skeletal equivalence group

$$G = \{E,\ (1\,2\,3)(4\,5\,6),\ (1\,3\,2)(4\,6\,5),\ (1\,4)(2\,6)(3\,5),\ (1\,5)(2\,4)(3\,6),\ (1\,6)(2\,5)(3\,4)\} \quad (6)$$



of the order g = 6 and the flexibility which is given by the interconversions of the rigid skeletal models *(19a)*, *(19b)*, and *(19c)* and described by

$$E = \{E,\ (1\,2\,3),\ (1\,3\,2)\} \quad (7)$$



the skeletal flexibility group of the order f = 3. The group product

$$\begin{aligned} D = G \times F = \{&E,\ (1\,2\,3),\ (1\,3\,2),\ (4\,5\,6),\ (4\,6\,5),\ (1\,2\,3)(4\,5\,6),\\ &(1\,2\,3)(4\,6\,5),\ (1\,3\,2)(4\,5\,6),\ (1\,3\,2)(4\,6\,5),\\ &(1\,4)(2\,6)(3\,5),\ (1\,5)(2\,4)(3\,6),\ (1\,6)(2\,5)(3\,4),\\ &(1\,4\,2\,6\,3\,5),\ (1\,4\,3\,5\,2\,6),\ (1\,5\,2\,4\,3\,6),\\ &(1\,5\,3\,6\,2\,4),\ (1\,6\,2\,5\,3\,4),\ (1\,6\,3\,4\,2\,5)\} \end{aligned} \quad (8)$$

of the order d = 3 × 6 = 18 represents the *dynamic symmetry* of the ethane skeleton *(19)*, a permutational symmetry for which there is no isomorphic point group symmetry. If six different ligands are attached to the rigid skeleton *(19a)*, then 6! = 720 mappings of the ligand set onto the set of skeletal positions are possible and six (= g) each of these are equivalent due to the skeletal symmetry leading to 120 distinguishable permutation isomers. Now, introducing skeletal flexibility F leads to the further equivalence of 3 (= f) each of these such that the distinguishable isomers are reduced to 40. This is equivalent to the statement that there are 40 isomeric ethane derivatives, each of these having 3 conformers.

(20a) (D_{3d}) *(20b)* (C_2)

(20c) (D_2) *(20d)* (D_{6h})

With cyclic molecular skeletons, however, it is possible to construct skeletal models *(e.g. (20d))* which have a geometric (point group) symmetry equivalent to the dynamic skeletal symmetry.

It is interesting to note that for *(20a)*, *(20b)*, and *(20c)*, G and F are different for each but yield the same product D in all cases. At the same time D corresponds to the rigid skeletal symmetry of *(20d)* and the dynamic symmetry of *(20)*. In such cases, dynamic symmetry is sometimes incorrectly interpreted as geometrical symmetry, being called the time average symmetry or the maximum possible symmetry of *(20)*[1].

4.2.2. Generalization of the Conformer Concept

If the flexibility F of the TBP skeleton *(2)* is represented by permutations reflecting the equivalence of skeletal positions achieved by TR or BPR processes, the dynamic symmetry here comprises all 5! permutations of the symmetric group S_5. Here, the dynamic symmetry of the TBP skeleton corresponds to a complete symmetry equivalence of all skeletal positions. Such a state is permutationally representable but cannot be geometrically realized as it is impossible to construct a regular three dimensional figure with five equivalent vertices.

For a TBP molecule with 5 different ligands there are 20 conformers (see Section 4.2.3) but only one isomer. By reducing the flexibility of *(2)* one obtains only two isomers (see Graph 6) with three or six conformers respectively.

For an example relevant to this discussion we turn to the case of bullvalene[31]. The observed equivalence of all ten CH groups in this molecule when positional exchange occurs *via* valence isomerization may be considered a special type of skeletal flexibility. It is not possible to find any geometric arrangement in which all CH groups of bullvalene would, in an "instantaneous view", occupy symmetry equivalent positions. This is why bullvalene cannot be "aromatic".

Molecules differing only by permutations of equivalent ligands and/or permutations at such skeletal sites that are equivalent with reference to the *dynamic skeletal symmetry* belong to the same "isolable" isomers or *classical species*[12]. If instead the equivalence of the skeletal positions is related to the *rigid skeletal symmetry*, the molecules belong, in an analogous manner, to the *same conformer*.

We propose to use conformer as a collective term comprising the concepts of the *rotamer* and the *flexomer*. Often a clear distinction between these two species is not possible. Rotamer is used to describe those permutational isomers which, in the idealized case, are interconverted by such skeletal deformations of polycentric skeletons where only dihedral angles are changed without significant change of the bond angles at the skeletal centers. Those permutational isomers called flexomers are interconverted by skeletal motions deforming bond angles at one or more skeletal centers.

Hence, the conformers of a classical species are the distinguishable permutational isomers which are interconverted by regular processes (represented by the permutations of the skeletal flexibility group F) whereas the classical species which refer to the flexible skeletal model are interconverted only by irregular processes[12].

Also, it is both possible and useful, *e.g.*, for the discussion of the Wagner-Meerwein rearrangement, to define an *irregular dynamic skeletal symmetry* where not only the permutations of the skeletal flexibility groups F are included but the skeletal transformations by irregular processes as well.

There are molecules for which some distinguishable conformers vanish in certain temperature ranges while still other conformational differentiation is possible due to some motion belonging to the skeletal flexibility. This is represented by a subgroup F^* of the skeletal flexibility group F. An example might be a methylcyclohexane with a rotating methyl group which does not stop between the rotational barriers, while the axial *vs* equatorial placement of the rotating methyl group and the cyclohexane skeleton *(20a)* is still distinguishable. In such cases the conformers relate to the *partially* dynamic skeletal symmetry ($D^* = G \times F^*$) instead of the rigid skeletal symmetry.

Extension of the conformer concept, as developed above, is useful not only for the present topic but also for the purpose of viewing related phenomena from a common viewpoint.

4.2.3. Stereochemical Quantum Numbers

The classical species and their conformers within an isomer class possessing n skeletal sites, a rigid skeletal equivalence group G and a flexibility group F, are obtained from the reference isomer $\mathbf{M}_{0,0}$ by permutations corresponding to the products of the descriptors of the classical species P_σ or Q_σ and the elements of F (see Table 12). The columns of Table 12 (σ = const.) contain the conformers of the isomers $\mathbf{M}_\sigma$, and the rows (κ = const.) the analogous conformers of the different isomers. It follows that σ and κ then serve the purpose of "stereochemical quantum numbers"[12], σ being the isomer and κ the conformer quantum number.

Table 12. Systems of isomers and their conformers.

κ \ σ	0	1	2		i-1
0	$M_{0,0}$	$M_{1,0}$	$M_{2,0}$		$M_{i-1,0}$
1	$M_{0,1}$	$M_{1,1}$	$M_{2,1}$		$M_{i-1,1}$
2	$M_{0,2}$	$M_{1,2}$	$M_{2,2}$		$M_{i-1,2}$
j-1	$M_{0,j-1}$	$M_{1,j-1}$	$M_{2,j-1}$		$M_{i-1,j-1}$

Using a rigid skeletal model with n sites and n different ligands along with a rigid skeletal equivalence group G one obtains from $\mathbf{M}_{0,0}$ n!/g distinguishable permutation isomers. If one further considers the flexibility of the skeleton, a total of i = n!/d "isolable" isomers ($\mathbf{M}_0, \ldots, \mathbf{M}_{i-1}$), called the classical species of this class of permutation isomers, result from the reference "isolable isomer". The descriptor of the latter coincides with the descriptor of $\mathbf{M}_{0,0}$. Descriptors P_σ or Q_σ of these "classical species" correspond to the descriptors $P_{\sigma,0}$ or $Q_{\sigma,0}$ of the reference conformers $\mathbf{M}_{0,0}, \mathbf{M}_{1,0}, \ldots, \mathbf{M}_{i-1,0}$ (see first row of Table 12) of the "isolable" isomers of $\mathbf{M}_0$.

The l and s-descriptors of the κ^{th} conformer of the σ^{th} isomer $\mathbf{M}_{\sigma,\kappa}$ (σ^{th} column, κ^{th} row of Table 12) are generated by eq. (9).

$$\begin{pmatrix} l \\ s \end{pmatrix}_{\sigma,\kappa} = \begin{pmatrix} \boldsymbol{P}_{\sigma,0}\ n \\ \boldsymbol{Q}_{0,\kappa}\ n \end{pmatrix} = \begin{pmatrix} \boldsymbol{Q}_{0,\kappa}^{-1} \times \boldsymbol{P}_{\sigma,0}\ n \\ n \end{pmatrix} = \begin{pmatrix} n \\ \boldsymbol{P}_{\sigma,0}^{-1} \times \boldsymbol{Q}_{0,\kappa}\ n \end{pmatrix} \tag{9}$$

when $\boldsymbol{P}_{\sigma,\kappa} = \boldsymbol{P}_{0,\kappa} \times \boldsymbol{P}_{\sigma,0}$ or $\boldsymbol{Q}_{\sigma,\kappa} = \boldsymbol{Q}_{\sigma,0} \times \boldsymbol{Q}_{0,\kappa}$.

When one represents the conformational interconversions of a flexible skeleton by a graph, this graph applies to all columns of Table 12 simultaneously and, due to skeletal properties, is independent of the individual distributions of the ligands which are related to the dynamic skeletal symmetry. For example, Graph 5 describes the conformational interconversions of two isomers with a TBP skeleton by the $(TR)^2$ mechanism. These isomers themselves are not interconverted if $(TR)^2$ is the only rearrangement mechanism considered.

If some of the ligands are equivalent, the conformers are representatives of the double cosets[11] of $\boldsymbol{H}$ and $\boldsymbol{G}$; the classical species represent double cosets of $\boldsymbol{H}$ and $\boldsymbol{D}$. In this case, some of the permutation isomers of Table 12 are equivalent because of ligand equivalencies ($\mathbf{M}_{\sigma,\kappa} = \mathbf{M}_{\sigma',\kappa'}$). It can happen that skeletal flexibility not only depends upon the molecular skeleton itself but upon other factors as well, *e.g.* special interactions between individual ligands and temperature.

Particularly strong inter-ligand interactions (ring formation, see Graph 5; hydrogen bonds, bulky groups, *etc.*) may result in the disappearance of some of the conformers $\mathbf{M}_{\sigma,\kappa}$ of $\mathbf{M}_{\sigma}$ (see Ref. 12). The same consequence is observed for the particularly strong preference some ligands show for certain skeletal positions.

4.2.4. Measurable Properties of Permutation Isomers

An equation (10), that permits one to compute the values of some observable parameters $O_{0,0}$ (*e.g.* energy values, equilibrium concentrations, chirality observations, *etc.*) for the reference conformer $\mathbf{M}_{0,0}$ as a function of the ligand set L and its distribution on the skeleton, is transformed into eq. (11) for the corresponding observable $O_{\sigma,\kappa}$ of the permutation isomer $\mathbf{M}_{\sigma,\kappa}$ by the descriptor $\boldsymbol{P}_{\sigma,\kappa}$ of the conformer.

$$O_{0,0} = O_{0,0}(L_1, \ldots, L_n) \tag{10}$$

$$O_{\sigma,\kappa} = \boldsymbol{P}_{\sigma,\kappa} O_{0,0}(L_1, \ldots, L_n) = O_{0,0}(\boldsymbol{P}_{\sigma,\kappa}\{L_1, \ldots, L_n\}) \tag{11}$$

As an example, the approximation [eq. (12)] of the energy $\mathfrak{E}_{0,0}$ of the reference conformer leads (by pairwise interactions) to eq. (13) for its permutation isomer $\mathbf{M}_{\sigma,\kappa}$. $\mathfrak{E}_s(\gamma_i, \lambda_i)$ in eqs. (12) and (13) is a function of the ligand L_i

$$\mathfrak{E}_{0,0} = \sum_i \mathfrak{E}_s(\gamma_i, \lambda_i) + \sum_{\substack{i,j \\ (i \neq j)}} \mathfrak{E}_1(\gamma_i, \gamma_j, \lambda_i, \lambda_j) \tag{12}$$

$$\mathfrak{E}_{\sigma,\kappa} = \boldsymbol{P}_{\sigma,\kappa}\left(\sum \mathfrak{E}_s(\gamma_i, \lambda_i) + \sum \mathfrak{E}_1(\gamma_i, \gamma_j, \lambda_i, \lambda_j)\right) \tag{13}$$

(with parameters λ_i and λ_i') and the i^{th} skeletal position (with parameters γ_i and γ_i'). $\mathfrak{E}_1(\gamma_i', \gamma_j', \lambda_i', \lambda_j')$ describes the interaction of the ligands L_i and L_j. The l-descriptor $\boldsymbol{P}_{\sigma,\kappa}$ permutates the indices of the ligand parameter λ and λ' only, and not the indices of the skeletal parameters γ and γ'.

For molecules with a TBP skeleton *(2)* one can approximate eq. (12) with polynomials of the lowest degree and, considering only the interactions of nearest neighbor, one obtains eq. (14).

$$\begin{aligned} \mathfrak{E}_0 = {} & \gamma_e(\lambda_1+\lambda_2+\lambda_3) + \gamma_a(\lambda_4+\lambda_5) + \\ & + \gamma_{ee}(\lambda_1'\lambda_2' + \lambda_1'\lambda_3' + \lambda_2'\lambda_3') + \gamma_{ae}(\lambda_1'+\lambda_2'+\lambda_3')(\lambda_4'+\lambda_5') \end{aligned} \tag{14}$$

Here, γ_e, γ_a, γ_{ee}, and γ_{ae} are skeletal parameters whose indices a and e relate to the apical and equatorial skeletal positions. One can see from this simple approximation (eq. (14)) that qualitative rules of the type represented by the polarity rule[20, 27, 28] (see Section 3.3.1) have only limited value if the stability of the species in question has been determined considering only one type of interaction.

Approximations of the above type seem to be well suited for the treatment of the conformational problems of molecules with polycentric skeletons, *e.g.* the ethane *(19)* or cyclohexane skeleton *(20)*. In general, one is interested in the energy differences $\Delta\mathfrak{E} = \mathfrak{E}_{\sigma,\kappa} - \mathfrak{E}_{\sigma',\kappa'}$ of two conformers such that the energy contribution from ligand interaction with the skeleton may be neglected as this is approximately the same for all conformers. Thus it suffices to consider just the pairwise interactions between neighboring ligands. The energy difference between conformers is given by eq. (15) where the first two indices of $\mathfrak{E}_{ij,ij}$ refer to the i^{th} and j^{th} skeletal positions and the last two to the ligands L_i and L_j.

$$\mathfrak{E}_{\sigma,\kappa} - \mathfrak{E}_{\sigma',\kappa'} = (\boldsymbol{P}_{\sigma,\kappa} - \boldsymbol{P}_{\sigma',\kappa'})\mathfrak{E}_{0,0} = (\boldsymbol{P}_{\sigma,\kappa} - \boldsymbol{P}_{\sigma',\kappa'}) \sum_{\substack{i,j \\ (i \neq j)}} \mathfrak{E}_{i,j,i,j} \tag{15}$$

5. Formal Classification of the Rearrangement Processes of Pentacoordinate Molecules

5.1. Isomerizers

The reference isomer *(1)* $\equiv \mathbf{M}_0$ and its matrix representation $\begin{pmatrix} l \\ s \end{pmatrix}_0$ are distinguishable by the fact that for $\mathbf{M}_0$ the ligand and skeletal indices l and s behave like contravariant variables. This is to say that the transformation of $\mathbf{M}_0$ into its permutation isomer $\mathbf{M}_\sigma$ is equally well represented by either the ligand permutation $\boldsymbol{P}_\sigma$ or the skeletal permutation $\boldsymbol{Q}_\sigma$ (see eq. (1)) where $\boldsymbol{Q}_\sigma$ is numerically equivalent to $\boldsymbol{P}_\sigma^{-1}$. The latter operator is obtained from $\boldsymbol{P}_\sigma$ by inverting the sequence of its digits. If $\boldsymbol{P}_\sigma = (1\ 2\ 3\ 4\ 5)$

then $P_\sigma^{-1}=(5\,4\,3\,2\,1)=(1\,5\,4\,3\,2)$. The action of P_σ on an ordered set of numbers Z and the subsequent action of P_σ^{-1} on the result reproduces Z.

$$P_\sigma^{-1}\times P_\sigma Z = P_\sigma \times P_\sigma^{-1} Z = Z \tag{16}$$

The interconversion $\mathbf{M}_\sigma \rightleftharpoons \mathbf{M}_{\sigma'}$ of two permutational isomers $\mathbf{M}_\sigma$ and $\mathbf{M}_{\sigma'}$ is described by the permutation operators $I_{\sigma\sigma'}$ and $I_{\sigma'\sigma}=I_{\sigma\sigma'}^{-1}$ which we call the *isomerizers*. They are derived from P_σ and $P_{\sigma'}$ as shown in eq. (1), (1a) and (17).

$$\binom{1}{s}_\sigma = \binom{P_{\sigma'}\,n}{n} \tag{1a}$$

By solving eq. (1) for $\binom{1}{s}_0$ and combining with eq. (1a) one gets eq. (17):

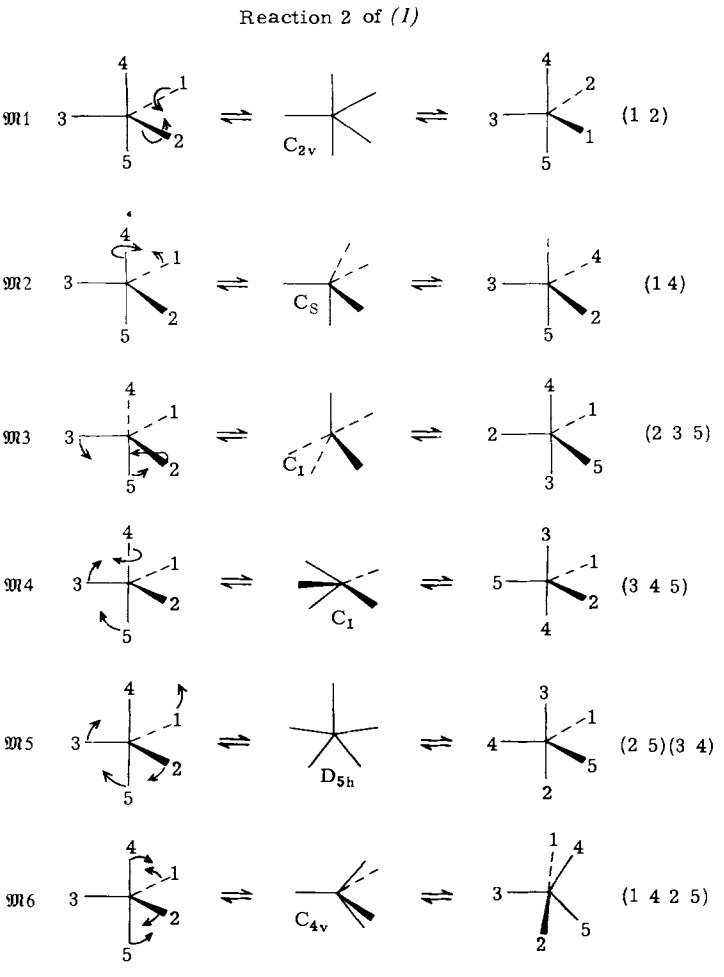
$$\binom{1}{s}_{\sigma'} = \binom{P_\sigma\, P_\sigma^{-1}\, P_\sigma n}{n} = \binom{I_{\sigma\sigma}\, P_\sigma n}{n} \tag{17}$$

Therefore:

$$I_{\sigma\sigma'} = P_{\sigma'} P_\sigma^{-1} \tag{17a}$$

and

$$I_{\sigma'\sigma} = P_\sigma P_{\sigma'}^{-1} \tag{17b}$$



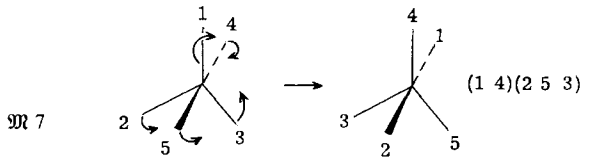
The isomerizers for all molecules of a particular class of permutation isomers with TBP skeletons *(2)* and the ligand set L belong to the symmetric group S_5. Elements of S_5 can be divided into seven classes (of conjugate elements) K_1 — K_5, where $K_1=E$ is the identity operator ("do nothing"):

$$\begin{aligned}
S_5 &= \{K_1,\ldots,K_5\}\\
K_1 &= \{\mathrm{E}\}\\
K_2 &= \{(1\,2),\ (1\,3),\cdots,(4\,5)\}\\
K_3 &= \{(1\,2\,3),\ (1\,2\,4),\ldots,(3\,5\,4)\}\\
K_{2+2} &= \{(1\,2)(3\,4),\ (1\,2)(3\,5),\ldots,(2\,5)(3\,4)\}\\
K_4 &= \{(1\,2\,3\,4),\ (1\,2\,3\,5),\ldots,(2\,5\,4\,3)\}\\
K_{2+3} &= \{(1\,2)(3\,4\,5),\ (1\,3)(2\,4\,5),\ldots,(4\,5)(2\,4\,3)\}\\
K_5 &= \{(1\,2\,3\,4\,5),\ (1\,3\,2\,4\,5),\ldots,(1\,5\,4\,3\,2)\}
\end{aligned} \tag{18}$$

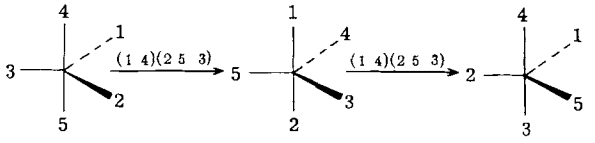
5.2. Mechanistic Alternatives

From eq. (8) it follows that the classes of the group S_5 correspond to the conceivable types of isomerization mechanisms of a class of isomers with a TBP skeleton and the ligand set L. If these permutations represent regular reorganization processes of pentacoordinate molecules with five different ligands on an asymmetric skeleton, each permutation relates to a different process and the classes K_2—K_5 represent types of mechanisms. However, if the pentacoordinate skeleton has some symmetry, *e.g.* a TBP skeleton with D_{3h} symmetry, or some of the ligands are equivalent, then some of the mechanisms of a class $K_x \subset S_5$ have common features and form a subclass[67] within K_x which collectively can be considered a "mechanism".

Muetterties[32] has recently published some conceivable mechanisms, $\mathfrak{M}1$—$\mathfrak{M}6$, for the rearrangement of TBP molecules by regular processes. Skeletal symmetries of the hypothetical barrier situations were included and are shown below with the proper mechanism:



Mechanisms $\mathfrak{M}1$—$\mathfrak{M}6$ are assigned to the classes of the symmetric group S_5 as follows: $\mathfrak{M}1$ and $\mathfrak{M}2$ belong to subclasses of K_2, $\mathfrak{M}3$ and $\mathfrak{M}4$ belong to subclasses of K_3, $\mathfrak{M}5$ belongs to K_{2+2}, and $\mathfrak{M}6$ is represented by the alternating permutations K_{4a} of the class K_4.



$\mathfrak{M}6$ describes the so-called *Berry pseudorotation mechanism*[3] (BPR). The subclass K_{4a} contains only cyclic permutations of four elements where the indices of the apical and equatorial ligands alternate. The cycle does not act on the pivot. K_{4a} is a proper subclass as its elements are mutually conjugate.

The process illustrated by *(1)* → *(3b)* (Reaction 1b; see also Reaction 3, $\mathfrak{M}7$ and Reaction 7 A_1—A_4) is not only a conceivable but also a physically probable alternate possibility as a regular process (see Section 4.1) for the rearrangement of TBP molecules. We choose the name "*Turnstile Rotation*" TR[2,4] to describe this mechanism. That it was not considered by *Muetterties* may be due to the fact that in graphic representation it cannot immediately be recognized as differing from $\mathfrak{M}2$ and $\mathfrak{M}3$ which have 180° and 120° barriers respectively whereas $\mathfrak{M}7$ has a 60° barrier.

Reaction 3 of *(1)*

$(TR)^2 = [(1\ 4)(2\ 5\ 3)]^2$

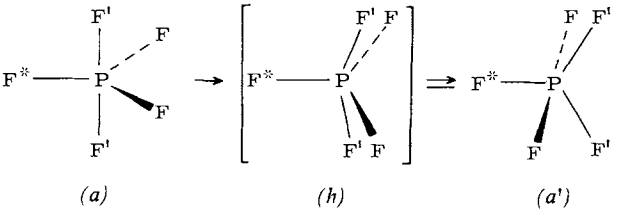
The TR process is described by permutations of a subclass of the class $\boldsymbol{K}_{2+3}$ in which one apical and one equatorial ligand belong to the cycle of two elements and the remaining ligands belong to the cycle of three. By inspection, one sees immediately that two successive TR processes with the same pair-trio, $(TR)^2$, correspond to the result of mechanism 𝔐3 of *Muetterties*, *e.g.* $[(1\,4)(2\,5\,3)]\,[(1\,4)(2\,5\,3)] = (2\,5\,3)$.

An analogous threefold process, $(TR)^3$, *e.g.* $[(1\,4)(2\,5\,3)]^3 = (1\,4)$, leads to the result from mechanism 𝔐2.

Since molecules are not restricted to any certain spatial arrangement, the internal rotation of some moiety of a molecule relative to the rest of the molecule can only be described in terms of a relative internal rotation. Therefore, the "ditopal" and "tritopal" rotations of some part of a molecule cannot be treated separately—as in the mechanisms 𝔐2 and 𝔐3—but in fact, correspond to double and triple TR processes.

Mechanisms 𝔐6 (BPR) and 𝔐7 (TR) yield equivalent results but differ fundamentally in their motions and formal representations.

5.3. BPR Mechanism



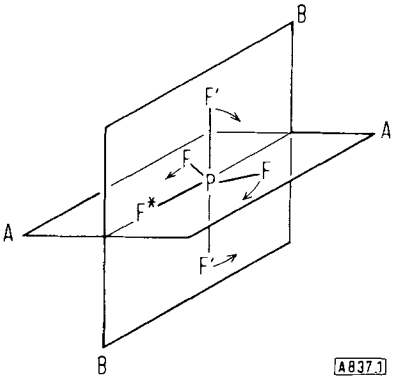
Electron diffraction data[19] of PF_5 *(8)* and analogous phosphoranes as well as IR, Raman spectra[33], and nuclear quadrupole resonance data[34] show that these compounds exist as trigonal bipyramidal compounds in which the apical bond distances are slightly longer than equatorial ones; as expected, the F—P distances are different (see Section 3.2).

However, at temperatures above -100 °C NMR data reveal that for *(8)* there is one fluorine resonance. This equivalency for all fluorine atoms indicates that rapid positional exchange is taking place[3, 35].

Berry[36] assumed that each of two apical and equatorial fluorines were exchanged pairwise by synchronous bending motions while the third equatorial fluorine, the "pivot", does not participate in the motion, but remains in its original skeletal position (marked as the pivot F* in reaction 4).

Here, the F-ligands, originally equatorial, move within plane A (see Fig. 1) from their original position towards the pivot F* (∢ FPF: 120° → 180°) and assume the "new" apical positions. Simultaneously, the ligands F', originally apical, move in plane B away from the pivot F* (∢ F'PF': 180° → 120°) into their "new" equatorial positions. Both pairwise motions occur in a synchronous, concerted fashion. During these flexional motions the bond distances adjust to the new TBP skeletal arrangement. In the idealized cases, the molecule passes through a barrier situation (transition state) with C_{4v} symmetry. After the BPR process the PF_5 molecule is oriented as if the entire molecule had rotated by 90° about the pivotal bond (see Reaction 4), although neither an internal rotation nor a rotation of the whole molecule has taken place; hence the original name, "pseudorotation"[36]. Of all the mechanisms 𝔐1—𝔐7, only the BPR process 𝔐6 occurs without any relative rotation of parts of the molecule with respect to each other. That this is so is immediately obvious upon inspection of Fig. 1, noting that the ligands travel in the A and B planes without internal rotation.

Reaction 4 of *(8)*



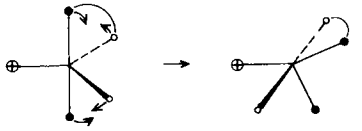


Fig. 1. Components of motion for BPR.

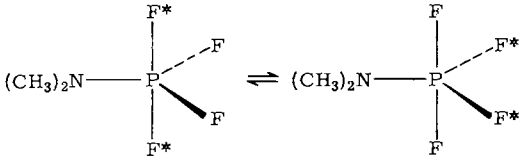
By internal rotation we mean the rotation of a ligand subset of two or three ligands *vs.* the rest of the molecule with synchronous deformation of the bonds at the central atom which, in contrast to the interconversions of rotamers, is a concerted flexion of the TBP skeleton. To determine whether or not a motion contains an internal rotation, it is necessary to analyze the whole process. Motions occurring without angular momentum, such as the flexions described in Fig. 1, are not considered *internal rotations*. As soon as two or more ligands participate in cyclic structures the situation differs fundamentally from the case of acyclic structures, a fact not brought out previously. The following example may illustrate the latter statement. A cyclic TBP molecule *(21)* undergoes a rearrangement by BPR as shown in reaction 5.

Participation of the ligand pair which belongs to the ring corresponds to a rotation of all the ring nuclei and not only

those bonded to the central atom; this rotation is an essential part of the motion.



Reaction 5 of *(21)*

(a) *(b)*

Whitesides and *Mitchell*[38] contributed to the understanding of pentatopal rearrangements in a fundamental manner. They analyzed the temperature dependent ^{19}F-NMR spectrum of *(22)*.

Reaction 6 of *(22)*

(a) *(b)*

At low temperatures ($T \leq -100$ °C) the structure of *(22a)* is frozen, *i.e.* the dimethylamino group and two of the F atoms occupy the equatorial positions and the other two F*, the apical sites. As determined by NMR line shape analysis in the temperature range -100 °C to -50 °C, the apical and equatorial fluorines F* and F exchange their positions in a pairwise, concerted fashion. F and F* do not mix and are distinguishable in the ^{19}F-NMR spectrum as "inseparable couples". From this it may be concluded that none of the previously published "non-Berry" alternatives $\mathfrak{M}$ 1 — $\mathfrak{M}$ 5 of the BPR can be responsible for the positional exchange noted in *(22)*.

On the basis of the BPR mechanism, reaction 6 is interpreted as follows: in agreement with the polarity rule[20, 27, 28] (see also Table 1 and Section 3.3.1) the dimethylamino group of *(22)* with its relatively lower electronegativity tends not to occupy apical positions and thus must serve as the pivot.

5.4. Calculated BPR Model Situations

A choice between two mechanistic alternatives based solely on the results of quantum mechanical calculations would be overtaxing the predictive power of these procedures. Nevertheless, it is interesting to examine the assumed pathways with regard to their energy barriers to rearrangement.

Although the absolute values of the energies calculated for this study contain some uncertainty, comparison of binding energy trends in model species for both mechanisms is realistic. The fact that the calculated energy barriers of BPR and TR are reasonably low and both lie within the 5—10 kcal/mol range of the energy barrier observed for the isomerization of PF_5 indicates that neither mechanism can be excluded for quantum mechanical reasons. Furthermore, the calculated BE data for the essential species of the investigated processes contribute to certain ideas concerning the reaction coordinate diagrams for these mechanisms.

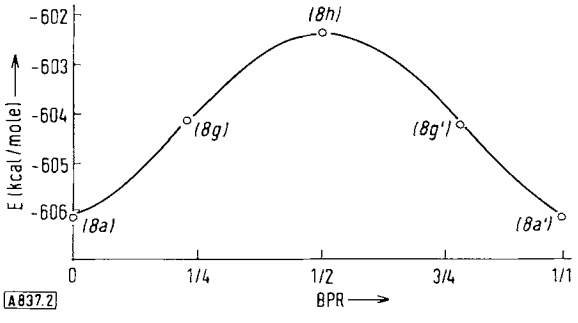
The absolute and relative BE data listed in Table 13 for PF_5 molecules which have undergone some deformation illustrate the BPR process. The calculations were accomplished with the aid of an IBM 360/65 computer using the CNDO/2 calculation method (see Section 3.2). Within the limitations of the latter, the following may be concluded from Table 13:

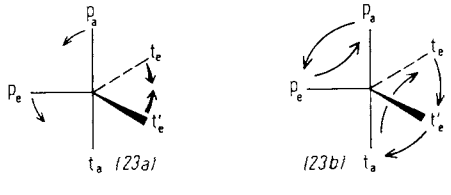
The BPR of *(8a)* and *(8a')* (see also Fig. 2) proceed by synchronous movement of the apical and equatorial ligand pairs *via* species approximated by *(8g)*, *(8h)*, and *(8g')*.

Table 13. BE data for the BPR model situation of *(8)*.

(8)	F—P—F	Angle deformation (°)	Abs. BE (kcal/mol)	Rel. BE (kcal/mol)
(b)	e-e	120 → 90	−596.0	10.1
(c)	e-e	120 → 105	−603.9	2.2
(d)	e-e	120 → 135	−604.3	1.8
(e)	e-e	120 → 180	−579.9	27.2
(f)	a-a	180 → 165	−602.1	4.0
(g)	e-e a-a	120 → 135 180 → 165	−604.1	2.0
(h)	e-e a-a	120 → 150 180 → 150	−602.6	3.5

The rather high value for the BE of *(8e)* suggests that BPR does not occur by a stepwise mechanism, first deforming the diequatorial FPF angle to 180° and then moving the originally apical ligands into their new diequatorial sites. Apical bonds of *(8a)* are "stiffer" than the equatorial.





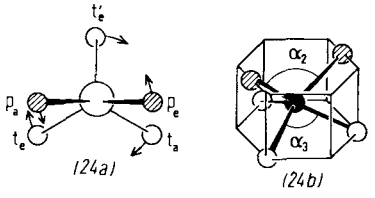


Fig. 2. Calculated reaction coordinate diagram of BPR for PF_5.

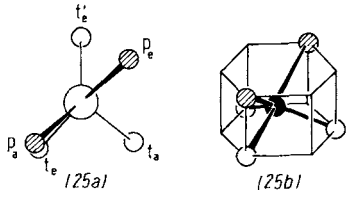
5.5. The TR Mechanism

$\mathfrak{M}$ 7, the TR mechanism, is the only alternative to BPR which is consistent with the results of the Whitesides-Mitchell experiment[38] and all other known observations. The TR mechanism is characterized by its unique motion and is illustrated by the models *(23a)* and *(23b)*.

A displacement of two equatorial ligands (t_e and t'_e in *(23a)*) reducing the original 120° angle to ≈90° combined with the simultaneous bending of the apical and equatorial ligands (p_a and p_e in *(23a)*) by approximately 9° produces the species *(23b)*. An initial relative internal rotation of the ligand pair $p_a + p_e$ *vs.* the ligand trio $t_a + t_e + t'_e$ idealized in *(23b)* is superimposed upon both the above vibrational motions. The combination of these three motions leads to the barrier situation *(24)* (30°-TR) after a relative internal rotation of $\Delta\varphi = 30°$,



(24a) *(24b)*

and from there by further 30° rotation and restoration of the TBP angles yields the new conformer of the original TBP molecule.

In species *(24)*, the 30°-TR barrier state may be viewed as in *(24a)* where p_a and p_e are above the plane of the page and t_e, t'_e and t_a are below the plane. Alternately, one can use the regular hexagonal prism as a steric reference system to illustrate the same geometry.

Further, *(24)* possesses a skeletal plane of reflection giving it C_s symmetry as well as an approximate local C_{2v} skeletal symmetry for the pair and analogous local C_{3v} symmetry for the trio. Another way of describing the TR process makes use of the fact that it can be viewed approximately as a combination of rotations about local C_2 and C_3 axes with a total internal rotation of $\left.\begin{matrix}60°\\300°\end{matrix}\right\} = 180 \pm 120°$. The "staggered" TR-30° barrier, *(24)*, is halfway between two eclipsed TR model structures *(25)*, the 0° TR, which are reached by ±30° relative rotations of the pair (●) *vs.* the trio (○) of *(24)*.

(25a) *(25b)*

5.6. Calculated TR Model Situations

Table 14 contains BE data for TR barrier models *(24)* of PF_5 again obtained by the use of the CNDO/2 method (see Section 3.2 and 5.4). From Table 14, the lowest energy TR barrier is found at $\alpha_2 \approx 85°$ and $\alpha_3 \approx 95°$. It should be pointed out that, within narrow limits, the BE of *(24)* is not very sensitive towards a variation of α_2 and α_3.

The solid line in Fig. 3 represents a TR process according to *(23a)* and *(23b)* (see *(8b)* and *(8l)*). The transition from *(8l)* to *(8a')* proceeds *via* a "mirror image" of the process *(8a)* → *(8l)*.

Again, it is interesting to note that PF_5 in the geometric situation *(8m)*, whose nuclear skeletal coordinates correspond to the average of two eclipsed 0°-TR species, is energetically quite favorable, meaning that some energetically *allowed* pathways are available by which a *switch of ligands* from a pair to a trio or *vice versa* can occur in a TR species, thereby forming new pair-trio combinations.

Table 14. Calculated BE-data (kcal/mol) of PF_5 in the staggered 30°-TR barrier model situation *(24)* as a function of the pair and trio angles α_2 and α_3.

α_3 \ α_2	80°	85°	90°	95°
85°		−591.4	−591.3	−589.5
90°	−594.0	−595.5	−595.0	−592.5
95°	−596.0	−597.0	−595.9	−592.8
100°		−594.4	−592.3	−588.1

The potential surface for the isomerization of PF_5 does not contain high barriers between the BPR barrier model

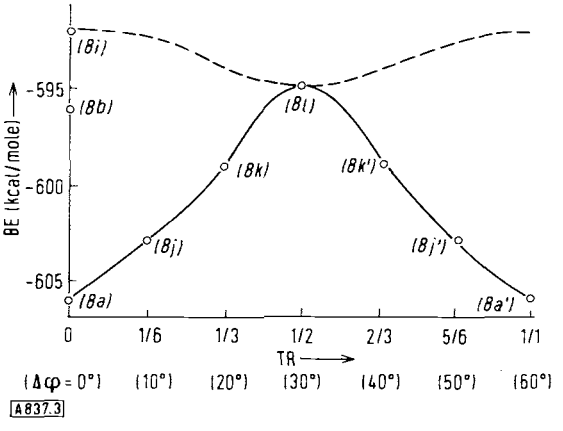


Fig. 3. Reaction diagram for a TR model process of PF_5 with $\alpha_2 = \alpha_3 = 90°$.

(8h) and the staggered 30°-TR model *(8l)*. While these differences arise due to differences in symmetry, they are small enough for interconversions of these species to seem conceivable.

The present BE data show that there are rather wide areas of the potential surface available for the TR barrier situation which may possibly include the BPR barrier geometry as a special case. Hence, the TR process can proceed *via* a "wide pass" on the potential surface, an entropy favored condition, whereas the BPR process, as defined with a C_{4v} barrier situation, is confined to a considerably smaller region of the potential surface at the saddle point.

An investigation of the valence electron distribution in the TR and BPR barrier models of PF_5 does not reveal dramatic differences: electron charge on the central P atom varies by 0.06%; the P 3d contributions to the stability of the species are essentially equal. Deviations of electron density on individual F atoms from the mean value of the ligand set is *ca.* 10% larger in the BPR barrier model. The

latter's pivot ligand bears less electron density than the other four ligands which leads to the conclusion *cum grano salis* that among the conceivable BPR processes, one is preferred whose pivot is the least electronegative of the ligand set, *i.e.* the ligand whose electron density loss yields

A BPR of *(26)* with e as a pivot (Reaction 7A) leads to *(26a)* and is described by the cyclic permutation (a e'' a' e'). The same result *(26)* $\rightleftharpoons$ *(26a)* is achieved by any of the four TR processes (reactions $7A_1$—$7A_4$), represented by one each of the permutations (e e'' a) (a' e'), (e e'' a') (a e'),

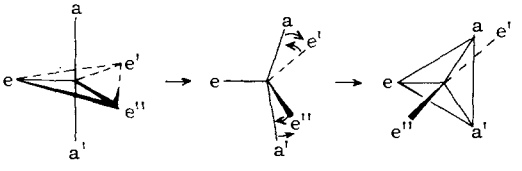
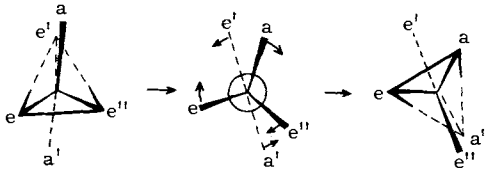
the smallest increase in energy (see Section 2.2). Calculated results also demonstrate that the BE of TR barrier models are less affected by small changes in bond length and angles than the BE of the analogous BPR model. This may be due, in part, to the higher symmetry of the latter, for symmetry is the favorite *panacea* for many obscure relationships. We suspect that for pentacoordinate P compounds, effects mentioned in Section 3.3.2 will contribute to the preference of the BPR mechanism in compounds of the general formula PXY_4 but favor the TR process in compounds of the type PX_2Y_3.

5.7. Common Features and Differences of BPR and TR

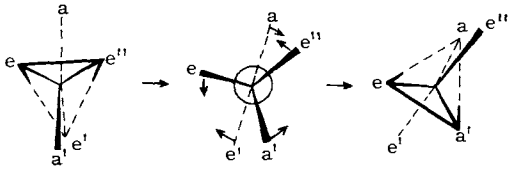


5.7.1. Equivalent Results of BPR and TR

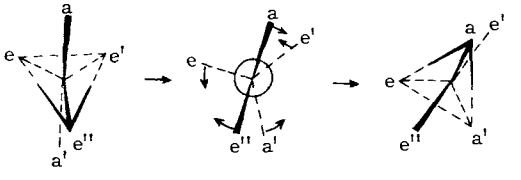
According to reaction 7—$7A_4$ there are four equivalent TR processes for each BPR process. One would expect, therefore, that the TR process has a higher probability than the equivalent BPR process (see Section 5.6).



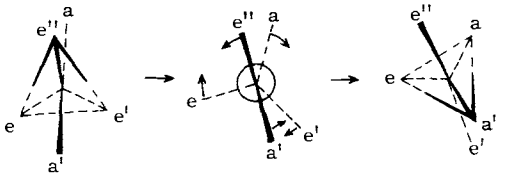
Reaction 7 of *(26)*



Reaction 7A (a e'' a' e')



Reaction $7A_1$ (e e'' a)(a' e')

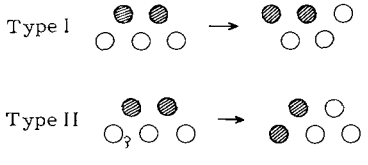


Reaction $7A_2$ (e e'' a')(a e')

Reaction $7A_3$ (e e' a')(a e'')

Reaction $7A_4$ (e e' a)(a' e'')

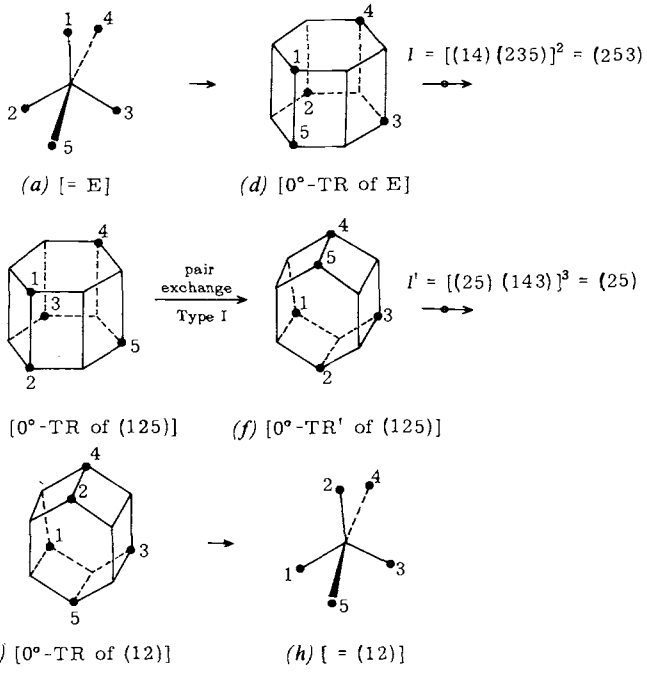
(e e' a) (a e''), and (e e' a) (a' e''). Similarly, *(26)* can be transformed into *(26b)* or *(26c)* by BPR processes to which there are also four equivalent TR processes. The latter are characterized by the fact that they always contain the pivot of the corresponding BPR in the "trio" which then undergoes relative rotation such that the pivot replaces the other originally equatorial ligand of the trio.



If one combines the BPR process of reaction 7A with suitably chosen rotations of the whole molecule, the resulting isomer is identical to the results of reactions $7A_1$—$7A_4$, although the mechanism differs substantially.

While both BPR and TR processes yield the same product, many differences exist between them. Particularly important among these is the fact that the BPR *does not contain any relative internal rotation* about an axis passing through the central atom while the TR process *is an internal rotation.* Resulting motions for both mechanisms differ geometrically relative to their local symmetries operating on a potential surface of different shape (see Section 5.7.3.2).

Both mechanisms, among the alternatives $\mathfrak{M}1$—$\mathfrak{M}7$ available (Section 5.2), can proceed with conservation of angular momentum intramolecularly in the idealized case. BPR accomplishes this since no rotation is involved, while the TR proceeds such that the pair and trio rotate in opposite directions with equal angular momentum but of opposite algebraic sign.



Interconversions of TBP molecules occur by a single BPR or TR step while in other instances several processes are required (see graphs 1—4). The analysis of such sequences reveals a further important difference between the two processes. A repetition of a BPR with the same pivot leads back to the original permutation isomer, $(BPR)^2 = E$, whereas it requires a six-fold TR with the same pair-trio combination to restore the original isomer, $(TR)^6 = E$. It must be pointed out, however, that the $(TR)^2$ may lead to E if the rotational direction of the second TR opposes the first. While it seems reasonable to assume that angular momentum would carry the trio in the same direction, the fact still remains that the direction can reverse in the process. However, the BPR *must* change pivots after each process if more than a single isomer is to be achieved. With TR, "productive" sequences of single steps can be accomplished with the same pair-trio unit.

A sequence of TR with a constant pair-trio combination can proceed step by step, (with a single TR process between two TBP molecules) but it is also conceivable that the result of repeated TR without crossovers (change of pair-trios in a TBP intermediate) is achieved *via* 0°-TR situations bypassing the intermediate TBP. One can envision changes of pair-trio combinations on the barrier level as a "switch" where the pair-trio change occurs between various 0°-TR or 30°-TR situations (*e.g.* (0°-TR)—(0°-TR)',...(30°-TR) to (30°-TR)').

In reaction 8 we employ models to illustrate a conceivable, one step pathway for the inversion of TBP molecules with a 0°—0° switch of type I in which ligand 3 of the trio in *(1e)* combines with the 1—4 pair and forms the trio 1—4—3 of *(1f)*.

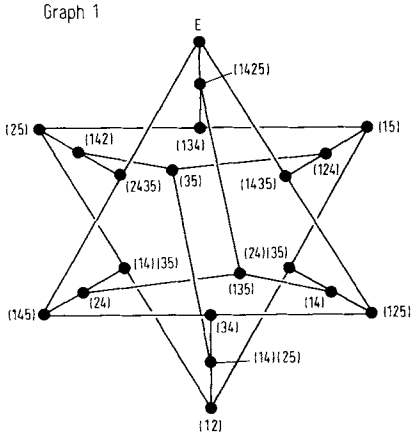
Reaction 8 of *(1)*

(a) [= E] *(d)* [0°-TR of E]

(e) [0°-TR of (125)] *(f)* [0°-TR' of (125)]

(g) [0°-TR of (12)] *(h)* [= (12)]

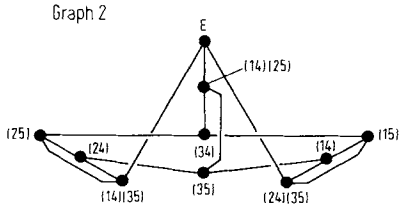
If the barriers for all conceivable switches are sufficiently low, all ligands of a pentacoordinate molecule become directly permutable. Thus the full dynamic symmetry of the TBP skeleton is attained in one step.



5.7.2. Sequences of BPR and TR Processes and Their Graphs

As the TR process yields products equivalent to those of the BPR the graphs[5d, 14, 15, 39, 40] originally developed for BPR processes also hold for TR (see Graphs 1—16 and, for comparison with the graphs of other authors, see Table 1).

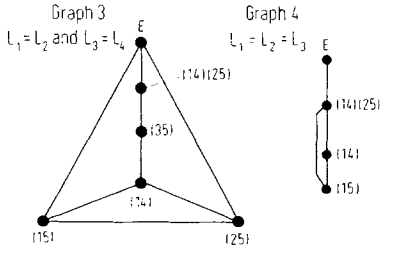
Graph 1: The points correspond to the permutation isomers (with skeleton *(2)* and five different ligands) that are given by their descriptors[11] (see Table 1). Connecting lines are the BPR or TR processes respectively. Pairs of opposing points which are at inversion symmetry locations correspond to pairs of antipodes, *e.g.* E and (1 2). This graph is derived from the one originally proposed by *Ramirez* and *Lauterbur*[14]. As a consequence of the algebraic properties of the isomerizer[1], those permutation isomers in graph 1 connected to E with a single line have descriptors of the class $\boldsymbol{K}_{4a}$ (see Sections 5.1 and 5.2). Those permutation isomers obtained from $\mathbf{M}_0$ ($\equiv$E) by TR^2 have descriptors belonging to a subclass of $\boldsymbol{K}_3$ (two equatorial symbols, one apical; with the seeming exception (1 4 5) = (1 5 2)) or $\boldsymbol{K}_2$ (one equatorial, one apical symbol), respectively. Isomers with descriptors to the class $\boldsymbol{K}_{2+2}$ are obtained from $\mathbf{M}_0$ by two $(TR)^3$ processes with common elements in the pairs.



The descriptor (1 2) of the antipode of $\mathbf{M}_0$ belongs to class $\boldsymbol{K}_2$ (with two equatorial or two apical symbols) and corresponds to a five-fold product of TR or BPR isomerizers; in the case of the TR mechanism, at least two of the pairs must be devoid of common elements (see Section 5.7.3).

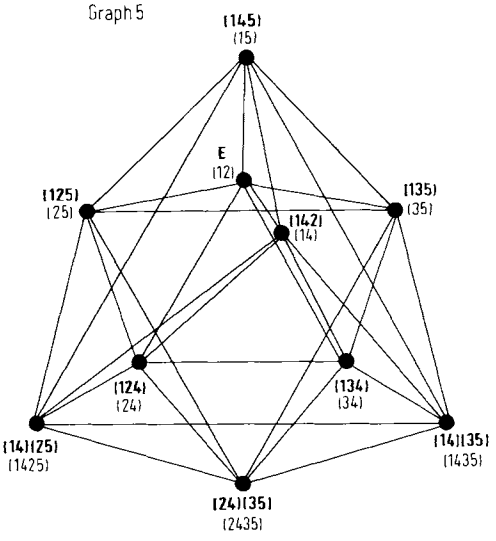
Graph 1

For the configurational inversion of a TBP molecule with five different ligands, certain sequences of five BPR processes with five different pivots are needed (see Graph 1). Configurational inversion by TR also requires a sequence of five processes but, from the fact that four equivalent TR processes exist for each BPR, it follows that there are $4^5 = 1024$ different TR pathways leading to the same inversion product (see probability factor, Section 5.7.1). Among these pathways there are some with a single crossover after the $(TR)^2$ step (*e.g.* $[(2\ 5)\ (1\ 3\ 4)]^3\ [(1\ 4)\ (2\ 3\ 5)]^2$, see Section 5.2).



Graph 2

Graph 2: Ligands L_1 and L_2 are equivalent. Achiral molecules are represented in graphs 2 and 3 by points on the mirror line and pairs of antipodes by points which are located symmetrically on either side of the mirror line.



Graph 3
$L_1 = L_2$ and $L_3 = L_4$

Graph 4
$L_1 = L_2 = L_3$

Graph 3: Interconversions of the permutation isomers of *(1)* by TR^2 processes are mapped on this graph (Reaction 2, $\mathfrak{M}$ 3). Permutation isomers of *(1)* belong to two classes denoted by bold face or regular type descriptors. Processes

Graph 5

symbolized by the lines connect only species of the same class, *i.e.* configurational inversion is impossible[5]. If one considers the mutual interconvertibility resulting from $(TR)^2$ processes as an equivalence relation, then the permutation isomers of a class are homochiral (are the conformers of the same classical species, see Section 4.2) and heterochiral to the elements (conformers) of the other class (antipode species).

5.7.3. Summary of the Common Features and Essential Differences of BPR and TR

5.7.3.1. Common Features

1. Both processes are regular rearrangements of TBP pentacoordinate molecules yielding equivalent products.

2. In both processes apical and equatorial ligands are exchanged pairwise in a synchronous, concerted manner.

3. In the ideal case both processes can proceed with conservation of angular momentum.

4. Both processes are energetically allowed.

5.7.3.2. Differences

1. BPR and TR result in differential partitioning of the ligand set (1 + 4 or 2 + 3) respectively, being represented by different subclasses of permutations belonging to the group $\boldsymbol{S}_5$ and being conjugate with regard to the elements of G.

2. For each BPR there are *four* different TR that produce the same result as the BPR. Thus for each sequence of n BPR, there are 4^n equivalent TR sequences.

3. $(BPR)^2 = E$ with constant pivot while $(TR)^6 = E$ with constant pair-trio and trio rotation direction.

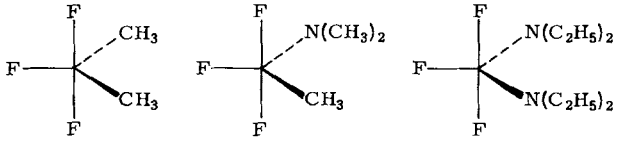
4. All ligands participate in a TR process.

5. The TR process is essentially an internal rotation while this is entirely absent from BPR.

6. Motions leading to the barrier species for each process are different (BPR: C_{4v} skeletal symmetry TR: approximate local C_{2v}- and C_{3v}-skeletal symmetries)

7. Ligand motions and energy barriers vary differently as a function of the ligand set and its distribution on the TBP

skeleton; TBP with apical equatorial rings must rearrange by TR.

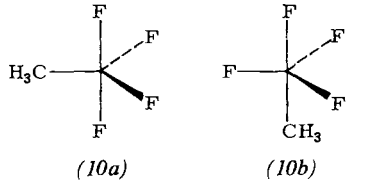


8. Multiple TR sequences can proceed without passing through a TBP intermediate, an ability BPR lacks.

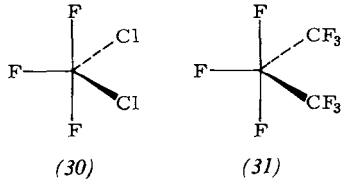
9. TR and their sequences have higher probability than the corresponding sequences of BPR.

6. Discussion of the NMR Spectra from Phosphorane Derivatives and Related Compounds

6.1. Acyclic Systems



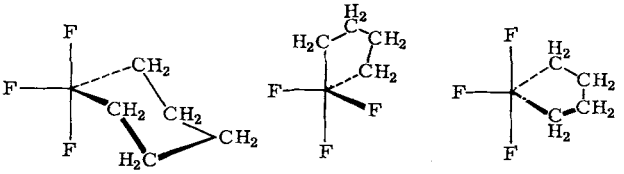
At temperatures below 100°C the ^{19}F-NMR spectra of *(27)*[35], *(28)*[28] and *(29)*[41] indicate two distinguishable fluorines in a ratio of 2:1. It appears then, that no rearrangement of the molecule involving F-exchange between apical and equatorial positions is occurring, either by regular or by irregular processes. Rearrangement by BPR or TR does not take place because any conceivable BPR or TR process produces high energy species having apical methyl or dialkyl amino groups.



(27) *(28)* *(29)*

From CNDO/2 calculations, we see that *(10b)* (Table 2) is 39 kcal/mol more stable than *(10a)*. Fluorine exchange by $(TR)^2$ does not take place in *(27)*—*(29)* either, probably because 0°-TR species with unreasonable energies would be involved (see Section 5.6 and Table 15).

At temperatures above 25°C, *(30)*[35] and *(31)*[35] (as well as *(8)*, *(10)*, and *(22)*)

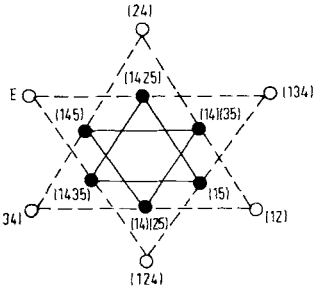


(10a) *(10b)*

(30) *(31)*

exhibit an ^{19}F-NMR signal owing to rapid positional exchange among the fluorines. One can assume that F-exchange proceeds *via* a regular process, for in *(27)*—*(29)* no irregular exchange is observed. Both the BPR and TR are possible for the rearrangement of *(30)* and *(31)*.

In *(10)* and *(22)* the F-exchange operates such that high energy TBP species with an apical methyl or dimethylamino group are avoided, *i.e.*, in the case of BPR the latter groups are pivots and with TR mechanisms, only those processes are allowed in which the pair consists of an apica and equatorial fluorine and the trio rotates such that the organic group proceeds from one equatorial position to another. This is in keeping with the Whitesides-Mitchell experiment (see Section 5.3).

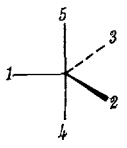


(32) *(33a)* *(33b)*

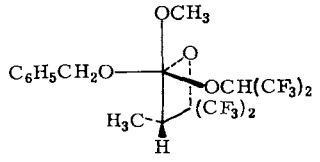
6.2. Cyclic Systems

The cyclic phosphorane derivatives *(32)*[35] and *(33)*[35] differ fundamentally with respect to their TBP stability. In *(32)* the 6-membered ring preferentially exists in the diequatorial position as predicted by the polarity rule; ring strain[9] is not significant in this position. However, *(33)* is in violation of the polarity rule with the apical-equatorial placement of the ring. Enlargement of an endocyclic bond angle or the compression of an endocyclic C—P—C angle to 108° or less leads to high strain energy while the envelope of the 5-membered ring can accommodate a 90° C—P—C angle with almost no strain (see Table 2, *(18)*). An experimental observation that *(33)*, contrary to *(32)*, undergoes F-exchange is in accord with the above argument. BPR rearrangement of *(33)* with F as a pivot or a TR mechanism with the ring as the pair does not require any high energy species for this process. Such is not the case for *(32)*.

NMR studies of *(34)*[42] indicate that although some permutational isomerization has taken place, there is no configuration inversion of the TBP phosphorane, *i.e.* there is no interconversion of molecules of the classes *(34)* **A** and

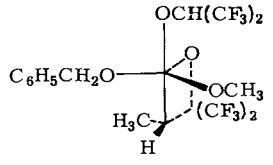


Graph 6



(34) **B**. The isomers E, (1 2 4) and (1 3 4) of the class *(34)* **A** and their epimers (1 2), (2 4) and (3 4) of the class *(34)* **B** carry apical P—C bonds, thus being energetically disfavored. Interpretation of the observations by a $(TR)^2$ mechanism, given in Graph 6, permits the omission of high energy permutation isomers.

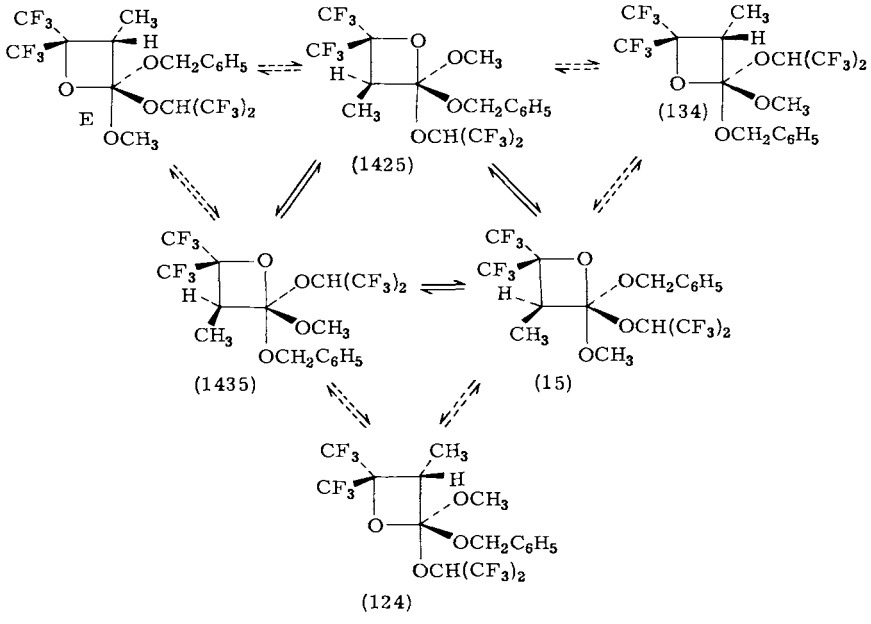
In the graphs 6—16, the energetically favorable molecules are symbolized by and the disfavored ones (*e.g.* oxy-



phosphorane derivatives with apical P—C bonds or diequatorial 5-membered rings, see Table 2, *(16)—(18)*) by O. Solid lines correspond to $(TR)^2$ processes (as well as the equivalent BPR) and the broken lines to the TR processes; $(TR)^3$ processes are denoted by an alternating dash-dot line. At first sight, it seems an advantage to write the formulas of the phosphorane derivatives *(1)* with the TBP skeleton and the sequentially numbered set $L_1,\ldots,L_5$ in such a manner that the ligand set is placed upon the skeleton *(2)* in its standard orientation, according to the instructions given for descriptors[1]. In this way, one finds the formula *(34')* E from the reference isomer *(34)* E of *(34)* (with the sequentially numbered[13] ligand set

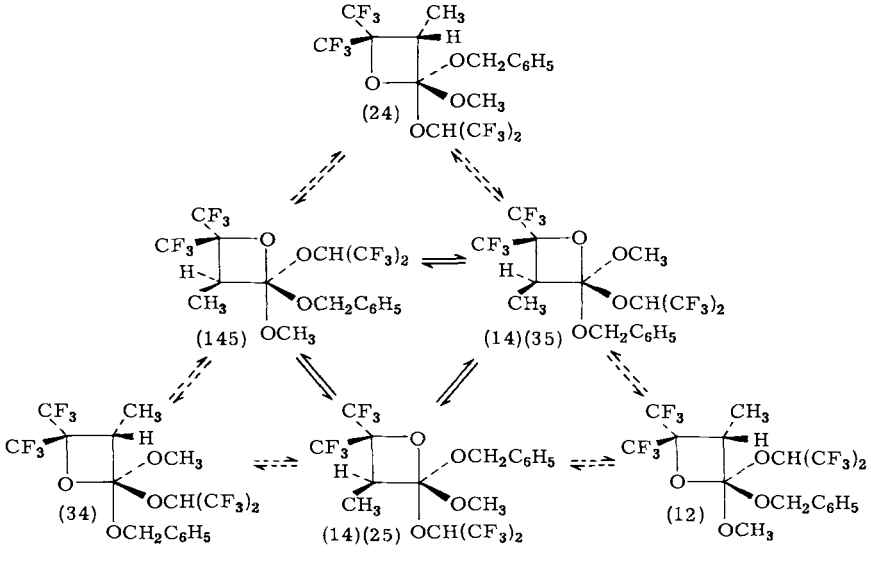
(2a)

(34') E



(34') (24)

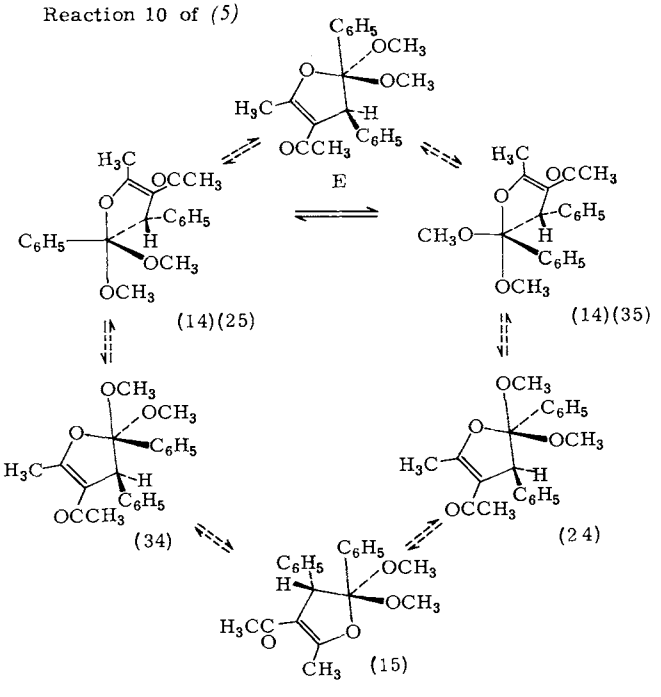
$L_1 = -O-C(CF_3)_2$ (cyclic)
$L_5 = -CH(CH_3)$



$L_2 = -O-CH(CF_3)_2$
$L_3 = -O-CH_2C_6H_5$
$L_4 = -O-CH_3$

and the skeleton *(2)*) by attaching L_1 to position *1*, L_2 to position *2*, *etc.* and permuting the ligands L_2 and L_4. The following formulas result in graphic difficulty. The more

Reaction 9A of *(34)* **A**

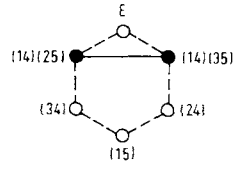


Reaction 9B of *(34)* **B**

readable (and equivalent) formulas *(34)* E and (24) are found by rotating the latter by 180° about the C_2 skeletal axis of symmetry which passes through the central atom and skeletal position *2*. Alternately, one can attach the set of ligands, as described above, to the skeleton *(2a)* which is generated from *(2)* by the permutation (1 3) (4 5) which reduces to a 180° skeletal rotation. For the following examples, the formulas obtained by projecting the descriptor onto a skeleton were not used in each case if they led to graphically awkward representations. Instead, the most readable equivalent formulas were chosen.

Among the following permutation isomers of *(5)*[5a, 6, 43] ($L_2=L_3=OCH_3$, ring L_1+L_5), *(5)* (1 4) is forbidden due to the diapical placement of the 5-membered ring. From the subsequent experimental data (see *(18)*, Table 2, a model for *(5)*) it follows that permutational isomers with a diequatorial 5-membered ring *(5)* (2 5), (3 5) and (2 4) (3 5) occur neither as equilibrating participants in a measurable concentration nor as intermediates of rearrangement processes. The permutation isomers *(5)* (1 5), (2 4) and (3 4) are, as indicated by the polarity rule, further disfavored conformers.

Reaction 10 of *(5)*

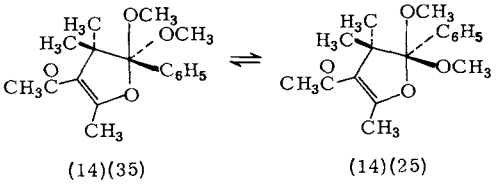


The only stable permutation isomers of *(5)* which occur in observable concentration are *(5)* (1 4) (2 5) and *(5)* (1 4) (3 5).

It can be concluded from the NMR data that at −20° *(5)* exists as a frozen diastereomeric mixture of *(5)* (1 4) (2 5) and *(5)* (1 4) (3 5) in a ratio of about 1:2. (Signals from 4 OCH_3, 2 benzylic protons, 2 CH_3 and 2 ^{31}P are present.) Above 70 °C the interconversion of *(5)* (1 4) (2 5) and *(5)* (1 4) (3 5) is so rapid that it is not observable on the NMR time scale (2 OCH_3, 1 benzylic H, 1 C—CH_3 and 1 ^{31}P); however, the methoxyls do not become equivalent.

The above interconversion takes place as a regular process below 100 °C, since no exchange of C methyl groups is observed. An interpretation of these data by a BPR or the equivalent TR imposes highly unlikely species in the process, either *(5)* E with an apical P—C bond as an intermediate and/or *(5)* (3 4), (1 5) and (2 4) with apical P—C bonds. Since complete exchange of the CH_3O groups has been ruled out by line shape analysis[44], all processes which proceed through an intermediate with a diequatorial ring may be eliminated (see graphs 7 and 1).

Graph 7

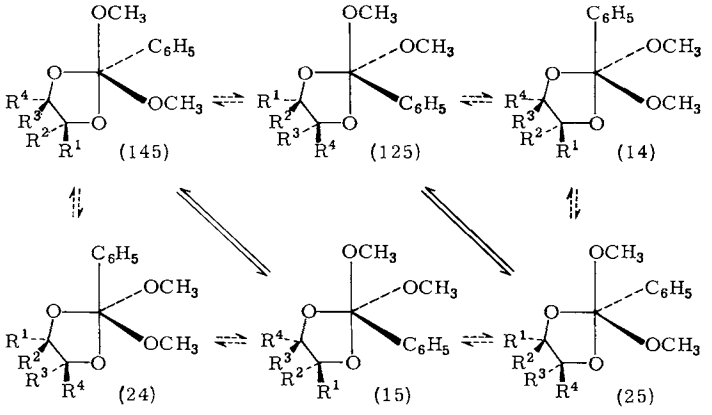


Finally, it should be noted that any conceivable interconversion of *(5)* (1 4) (2 5) and *(5)* (1 4) (3 5) by simple TR or BPR processes must proceed *via (5)* E or *(5)* (1 5) in which the methoxy groups are placed at mirror image skeletal sites (diequatorial or diapical). Both TR pathways (1 4) (2 5)—(3 4)—(1 5)—(2 4)—(1 4) (3 5) and (1 4) (2 5) —E—(1 4) (3 5), which do not proceed *via* intermediates with diequatorial rings, are characterized by the fact that *in each step, the ring can be the pair.* It is a particular advantage for the interpretation of rearrangements of pentacoordinate molecules by a simple or multiple TR mechanism that in the case of systems with four or five membered rings, these and only these must be the pair which seems to be physically reasonable.

Among the possible mechanisms, the double TR with the ring as the pair is the only one which avoids any energetically unreasonable species in order to rationalize the data.

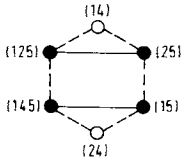
Along with the above example, some of the subsequent cases point out that in the common instance where a pentatopal rearrangement involves a 4—5-membered ring all data can be explained on the basis of a simple or multiple TR in which *the ring is always the pair.*

In analogous systems, *e.g. (35)*[15], without a tetrahedral center of chirality one observes two OCH_3 signals below −8 °C and only one signal above +62 °C. Except for the tetrahedral chiral center the interpretation is similar to the previous case. The pairs of diastereomers of *(5)* correspond to antipode pairs of *(35)*.



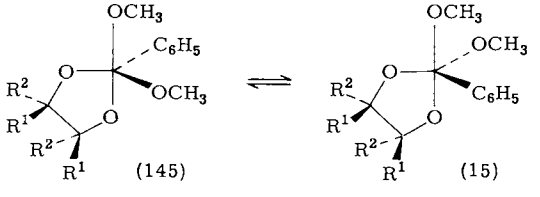
Reaction 11 of *(35)*

At −90 °C to +20 °C for *(36)*—*(38)*[44] ($L_3=L_4=OCH_3$, ring: L_1+L_2), one observes two methoxy group signals in the ^{1}H-NMR spectrum. Reaction 12 is interpreted just like reaction 1 according to Graph 8. In the case of reaction 12, the singular observation that the different apical-equatorial placements of the 5-membered ring are ener-



getically similar is the most significant consideration. Here, also, the ring can be the pair in all TR and $(TR)^2$ processes, avoiding all species with a diequatorial ring.

Reaction 12 of *(36)-(38)*

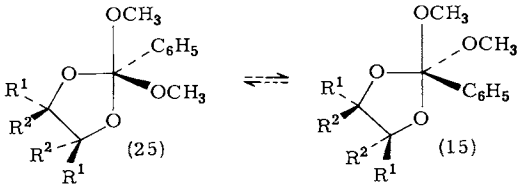


(36): $R^1 = R^2 = CF_3$, $R^3 = COCH_3$, $R^4 = CH_3$
(37): $R^1 = COCH_3$, $R^2 = CH_3$, $R^3 = p\text{-}NO_2\text{-}C_6H_4$, $R^4 = H$
(38): $R^1 = CH_3$, $R^2 = COCH_3$, $R^3 = p\text{-}NO_2\text{-}C_6H_4$, $R^4 = H$

Graph 8

Reaction 13 corresponds to reaction 11 except that the 5-membered ring and its C-bonded set of ligands has a local C_2 axis of symmetry. Consequently, a simple TR, graph 8,

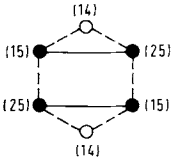
Reaction 13 of *(39)* and *(40)*



(39): $R^1 = COCH_3$, $R^2 = CH_3$
(40): $R^1 = p\text{-}NO_2\text{-}C_6H_4$, $R^2 = H$

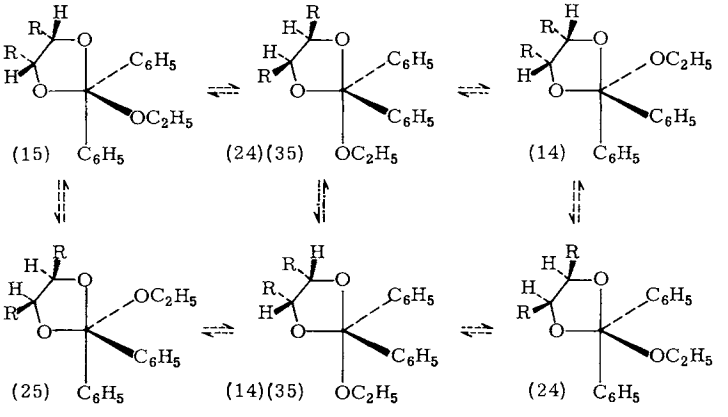
suffices for an inversion of the whole molecule, *i.e.* (1 4 5) =(1 2 5), (1 5)=(2 5). One finds only one OCH_3 signal in the ^{1}H-NMR spectrum above +20 °C[44].

Replacing the local C_2 symmetry of the ring by a local mirror plane symmetry (see Reaction 14) leads to a simplification of graph 8, since the additional equivalence of ligands 1 and 2 in *(41)* and *(42)* means that the permutation isomers (1 2 5) and (1 5) plus (1 4 5) and (2 5) are equivalent (graph 9).



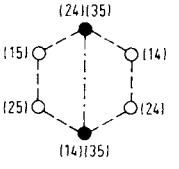
One observes in this case that both the TR and $(TR)^2$ processes yield the same result. However, since the permutation isomers (1 5) and (2 5) are diastereomers and not anti-

Reaction 14 of *(41)* and *(42)*



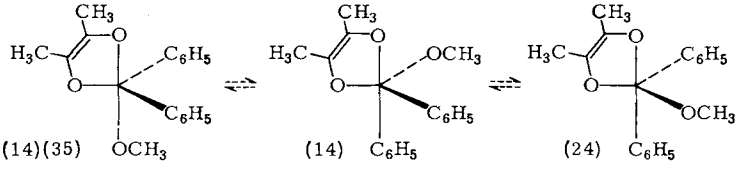
(41): $R^1 = COCH_3$, $R^2 = CH_3$
(42): $R^1 = p\text{-}NO_2\text{-}C_6H_4$, $R^2 = H$

Graph 9

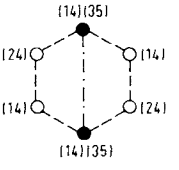


podes, the methoxy groups remain distinguishable; in agreement with this two signals for OCH_3 are found in the ^{1}H-NMR spectrum above +30 °.

Reaction 15 of *(43)*, R = p-NO_2-C_6H_4

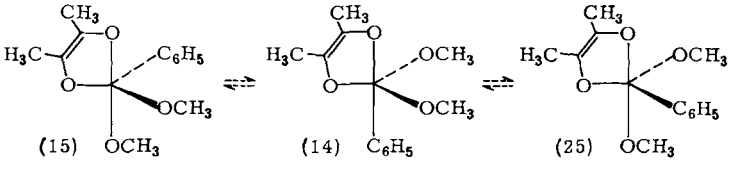


Graph 10



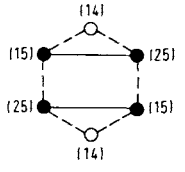
For Reaction 15 ($L_4 = L_5 = C_6H_5$, ring: $L_1 + L_2$) the NMR spectrum shows two benzylic protons at −75 °C, indicat-

Reaction 16 of *(44)*



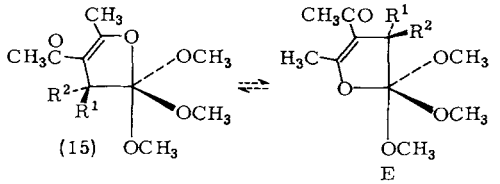
Graph 11

ing a frozen pair of antipodes (1 4) (3 5) and (2 4) (3 5). Antipode invariances are accomplished by an exchange of apical and equatorial benzylic protons; above +30°C only one signal is found for these protons. Here the $(TR)^2$ mechanism with the ring pair is the only process that avoids high energy species in the reaction (see graph 10).



Phosphorane *(44)*[45] produces a ^{1}H-NMR spectrum containing only one C—CH_3 signal between −60° and +160°C. Reaction 16 is interpreted just like reaction 15 but graph 10 can be replaced by the simplified graph 11 since ligands 1 and 2 are equivalent in *(44)*.

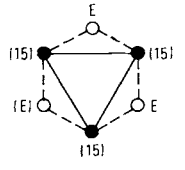
Reaction 17 of *(45)*



Reaction 17 differs from reaction 16 in that stable permutation isomers of *(45)*[45] ((1 5) and (2 5)) are chiral whereas the stable isomers of *(44)* are achiral species (1 4) (3 5).

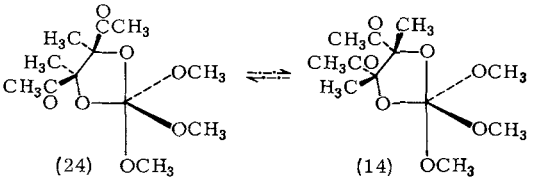
Graph 12

The ^{1}H-NMR spectrum reveals one OCH_3 and one C—CH_3 signal in the range −60° to +160°C which indicates the description of the process depicted in graph 12.



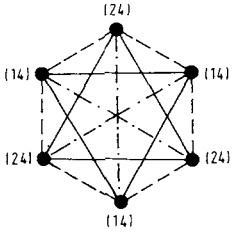
Reaction 18 of *(46)* and *(47)*

(46): $R^1 = C_6H_5$, $R^2 = H$
(47): $R^1 = R^2 = CH_3$



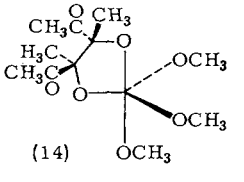
The central atom of TBP molecules with three equivalent ligands cannot be a center of chirality. Consequently, reaction 18 of *(46)* and *(47)* requires only one graph, namely graph 13.

Graph 13

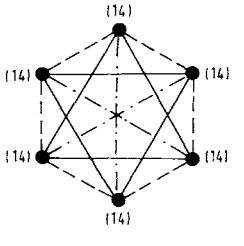


For the frozen structure *(46)* (1 5) three different methoxy peaks exist in the ^{1}H-NMR spectrum at −67°C, and at −28°C only two[15]. Above +25°C or +57°C, respectively, only one methoxy resonance is found.

Reaction 19 of *(48)*



Graph 14

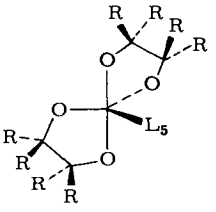


At +30°C, *(48)*[46] ($L_3 = L_4 = L_5 = OCH_3$, ring: $L_1 + L_2$) exhibits one *O*-methyl, one *CO*-methyl, and one *C*-methyl peak in the ^{1}H-NMR spectrum. This can be rationalized by a rearrangement described by graph 14.

A local plane of reflection in the *C*-ligand set of the ring distinguishes *(49)*[46] from *(48)*. For *(49)*, one OCH_3, $COCH_3$ and C—CH_3 is recorded at +30°C. The corresponding graph 15 differs from 14 in that there is only one TBP related descriptor unless one distinguishes between equivalent ligands when assigning the ligand indices.

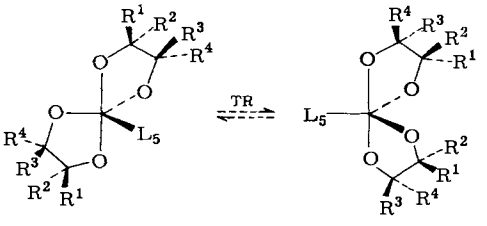
Reaction 20 of *(49)*

Graph 15



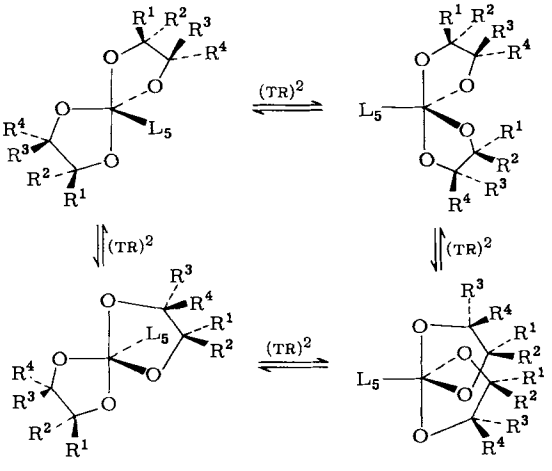
6.3. Spiroidal Systems

Compounds *(50)*[47] and *(51)*—*(54)*[48] possess two types of ^{1}H-NMR spectra as a function of the temperature. In lower temperature ranges two different CH and C—CH_3 signals are recorded, while in a higher range only one signal for each resonance is observed.

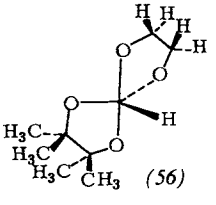


If one retains the original postulate that no 5-membered ring can exist diequatorially, this reaction submits itself

to a TR mechanism for the lower temperature range and a $(TR)^2$ mechanism (with no BPR equivalent) for the upper range indicated in reactions 21a and 21b.

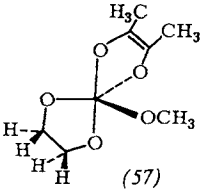


(50): Z = P; R = CH_3; L_5 = H
(51): Z = As; R = H; L_5 = OH
(52): Z = As; R = H; L_5 = OCH_3
(53): Z = As; R = CH_3; L_5 = OH
(54): Z = As; R = CH_3; L_5 = OCH_3
(55): Z = As; R = CH_3; L_5 = C_6H_5



Reaction 21a of *(50)-(55)*

Reaction 21b of *(50)-(54)*

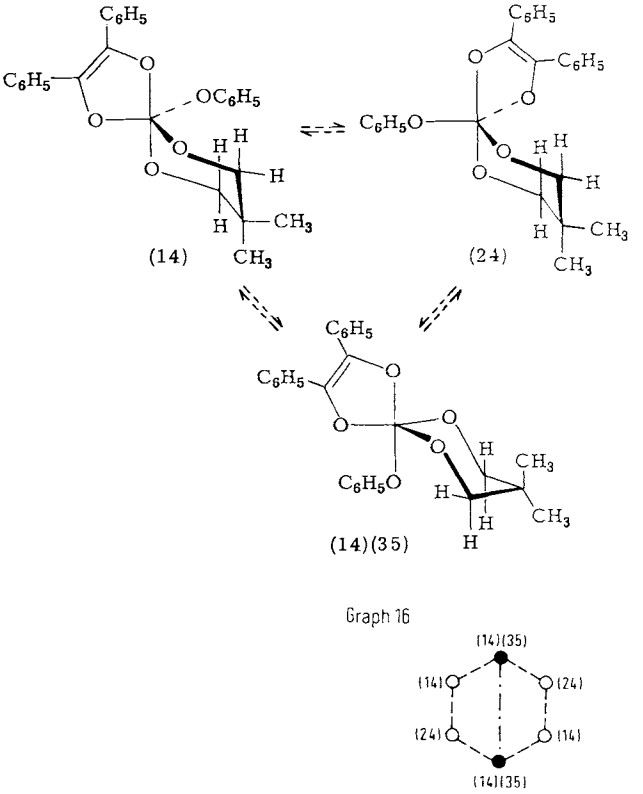


Only one ^{1}H-NMR spectrum is found for *(55)* which corresponds to the low temperature range spectra of *(50)* to *(54)*. From this it follows that the barriers for $(TR)^2$ processes are high for rearrangement in *(55)*. The ^{1}H-NMR spectrum of *(56)*[42] in the range −70 to 0 °C displays two different methyl signals and an AA'BB'X pattern for the methylene protons. Above +37 °C, one resonance is observed for both the methyl groups and the methylene

(56)

protons, the latter exhibiting an A_4X pattern. These data show that in the lower temperature range TR processes dominate when both rings can be the pair. $(TR)^2$ processes predominate in the upper temperature range where both rings must alternate as the pair.

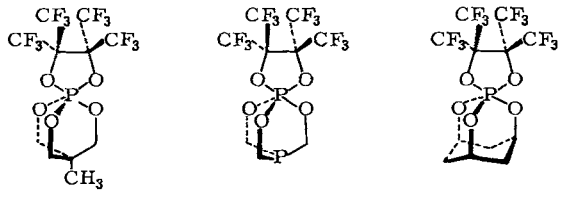
Compound *(57)* contains two substantially different rings, the unsaturated ring being planar while the preferential geometry of the saturated ring is puckered. This deter-



(57)

mines, in part, the strain energy and the magnitude of the O—P—O angle. The ^{1}H-NMR spectrum in the −60 to +110 °C range yields one C—CH_3 signal but a complex pattern from the methylene protons. With the assumption that only the unsaturated ring with the larger O—P—O angle (see Table 2) can function as the pair, TR, $(TR)^2$ and $(TR)^3$ processes yield identical results and thereby are all equally suited for interpretation of the reaction if di-equatorial 5-membered rings are excluded.

Compound *(58)*[49] shows two different C—CH_3 protons and a complex pattern for the methylene protons at +30 °C. By assuming that the 6-membered ring can be apical-equatorial, the data may be rationalized by a single TR process. However, if the 6-membered ring is confined to a diequatorial placement, which is the lowest energy conformation, the $(TR)^3$ is the more likely mechanism.



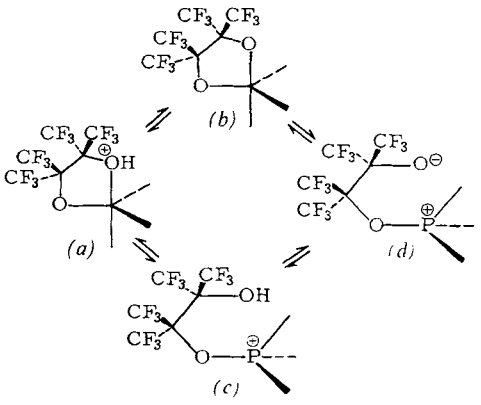
Reaction 22 of *(58)*

Graph 16

6.4. Polycyclic Systems and their Experimentum Crucis

The ^{1}H- and ^{31}P-NMR of *(59)*—*(61)*[1,4,50] were taken over a temperature range of −60 to 0 °C and the ^{19}F-NMR spectrum from −155 to 0 °C.

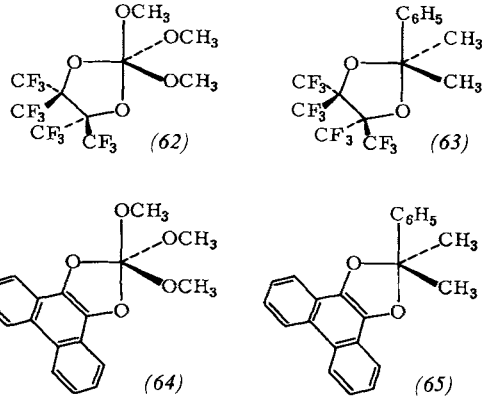
(59) (60) (61)



Complete positional exchange is indicated in the ^{1}H-NMR spectrum for all protons with respect to the local C_{3v} symmetries of the bicyclic systems.

Above -80 °C, the ^{19}F-NMR spectrum of *(60)* gives one single resonance, below which broadening occurs. At *ca.* -90 °C coalescence is observed and below -100 °C the signal forms a sharp, complex multiplet corresponding to a frozen structure with a non-planar 5-membered ring. The sharp ^{19}F-NMR doublet of *(61)* broadens at -120 °C, coalesces at -130 °C, and begins to show a single resonance at -140 °C, sharpening at -150 °C. This dramatic difference in the temperature dependence of rearrangement indicates that the barrier to this process is appreciably lower for *(61)* compared to that for *(60)*[*].

On the basis of the TR mechanism, this is precisely what one would expect. The TBP arrangement of the P bond system in *(61)* can only be realized with strain in the adamantanoid moiety of the molecule thereby costing some energy. When deformed into the 30°-TR barrier state where the adamantanoid moiety possesses C_{3v} symmetry, this energy is released, lowering the energy difference between the ground state and the barrier situation. Further, diequatorial 6-membered rings are energetically favored over their apical-equatorial analogs. Thus, a rearrangement process that prevents the latter situation as an intermediate will lower the rearrangement barrier. Less strain exists in the ground state for *(60)*, it may be almost strain free, hence, energy difference between the ground state and the barrier would be greater.



An argument offered against TR rearrangement processes in the examples *(59)—(61)*, holds that the reaction actually proceeds by an irregular process *via* species arising from opening of the 5-membered ring (see Reaction 23). This possibility is ruled out by the data in Table 16, which clearly indicate:

Reaction 23 of *(59)-(61)*

The ^{31}P chemical shift of oxyphosphoranes which undergo rapid equilibria with open chain dipolar structures containing tetracoordinate phosphorus is strongly solvent dependent (see Table 16, *(63)—(65)*).

The ^{31}P chemical shift of *(61)* is indifferent to even drastic changes in solvent properties. For example, the strongly acidic alcohol, hexafluoroisopropanol does not influence the ^{31}P chemical shift of *(61)* appreciably.

(62) (63) (64) (65)

Table 16. The solvent dependence of the ^{31}P-NMR-spectrum [50] of some phosphorane derivatives (see [51a to 51h] in particular).

Compound	δ ^{31}P [a] in anhydrous solvents $CDCl_3$	DMF [b]	$(CF_3)_2CHOH$	$CDCl_3$ + $(CF_3)_2CHOH$ 2:1	1:1	δ ^{31}P in $CDCl_3$ + 1 mole equivalent water after $\frac{1}{2}$ h	after 24 h
(61)	+42.4 [c]	+41.2	+44.1 [d]	+42.3	+42.4	+42.0 [c]	+42.0
(62)	+49.7 [e]	+48.9	+48.3 [d]	+49.4	+49.6	+49.9 [e]	+49.8
(63)	+10.9	—	−96.8 [d, f]	+ 9.5	+ 9.0	−41.8 [g]	—
(64)	+44.7	—	—	—	—	—	—
(65)	+ 1.5	—	−85.3 [d, h]	−28.7	−53.4	−39.6 [d, g]	—

[*] *Note added in proof:* The variable temperature ^{1}H-NMR of *(61)* was accomplished in the range from ambient temperature to -155 °C in a 3:1 mixture of SO_2 and CF_2Cl_2 ("Freon 12") solvent system. In solution at ambient temperature the three methine protons give rise to one signal, an apparent doublet due to H—P coupling in the group H—C—O—P. The six methylene protons give rise to the usual signals associated with cyclohexane axial and equatorial hydrogens. Broadening of the signals occurs at $\sim -80°$ and coalescence occurs at $-120°$ (T_c).

This is consistent with a rapid positional exchange in *(61)* which is inhibited only at a relatively low temperature.

Ease of hydrolysis is a positive criterion for the tendency to undergo ring opening. Data in Table 16 evidence the stability of *(61)* towards water, excluding any measurable concentration of ring cleavage products.

It seems reasonable to counter the argument presented and conclude that the polycyclic oxyphosphorane derivatives *(59)—(69)* rearrange by rapid, *regular* processes with

relatively low energy barriers. For *ring strain reasons*, *e.g.* the fact that 6-membered rings prefer diequatorial sites, producing higher energy states if an apical-equatorial or diapical geometry is forced upon them (BPR requirement), the *BPR process can be ruled out*. In particular, in the case of *(61)* the observed rearrangement processes are unequivocally regular and can only proceed *via* TR or multiple TR pathways.

7. Analogous Rearrangement Processes of Compounds with Central Atoms Other than Phosphorus

Positional exchange processes in pentacoordinate molecules are not confined to phosphorus compounds as has been demonstrated earlier by the arsenic compounds *(51)—(55)*. Analogous rearrangements have been discussed for silicon[52] and sulfur compounds[53]. Pentacoordinate transition metal compounds such as $Fe(CO)_5$[54], $CF_3Co(CO)_3PF_3$[55], $CoH(PR_3)_4$[56], $IrH(CO)_2(PPh_3)_2$[57], $IrH(CO)_2(AsPh_3)_2$[57], $IrH(CO)_2(AsPh_3)_2$[57], and $IrH(CO)_2[P(p\text{-}F\text{—}C_6H_4)_3]_2$[57] undergo positional exchange.

Further, regular and irregular rearrangement processes are known for monocentric molecules for coordination numbers other than $n=5$. In fact, they exist for $n=3,\ldots,12$[58,59]. Hexacoordinate compounds such as $H_2Fe(PR_3)_4$[5c,56c,60] and $H_2Fe[C_6H_5P(OC_2H_5)_2]_4$[5c,60] as well as the metallocenes[61] deserve particular mention.

Mechanistic interpretation of all these rearrangements is best served by partitioning the pertinent symmetric permutation groups S_n into classes of conjugate elements, which correspond to the partitioning of the number n, and to further classify these on the basis of conjugation with regard to the skeletal symmetry[67] represented by G (see Section 3.2). This avoids the problem of overlooking relevant potential mechanisms.

In hexacoordinate molecules with O_h skeletal symmetry rearrangement by the "twist mechanism", a (3+3) TR mechanism, seems to be quite plausible. This was proposed long ago[62a] and a considerable amount of evidence has been published concerning it[62b]; however, it must be assumed that the 120° barriers are considerably higher in energy than the 60° barriers of comparable (2+3)-TR processes. These (3+3) and (2+3) mechanisms are related in the same manner as the conformational interconversion of ethane and the ethyl carbonium ion[63].

Metallocenes may be considered as hexacoordinate with respect to the orbital bond system[65]. We can also view them as decacoordinated if the C-atoms of the cyclopentadienyl systems are defined as the ligands. Analogously, the arene complexes such as dibenzene chromium[66] are hexacoordinate or dodecacoordinate respectively. In such compounds, the higher of the two coordination numbers determines the energy barriers for the process. Hence, the internal rotations of the metallocenes can be looked upon as (5+5)-TR processes and the analogous rearrangements of dibenzene metal complexes as (6+6)-TR mechanisms.

8. Conclusion

Discussions surrounding intramolecular rearrangement processes require a clear distinction between regular and irregular pathways, *i.e.* such processes which occur with preservation of ligands and coordination numbers and those proceeding with bond rupture and reformation *via* transition states or intermediates with varying coordination number. Regular processes require the presence of flexible mono or polycentric molecular skeletons. The systematic analysis of regular processes begins with the study of pertinent rigid skeletal models and their symmetries making use of the fact that skeletal flexibilities are representable by permutations which generally belong to subgroups of S_n. Skeletal equivalencies must also be treated. Direct products of these leads to the dynamic skeletal symmetry of a system. For the description of the "isolable" isomers (the classical species) of molecules with flexible skeletons one must employ the dynamic skeletal symmetry which permits differentiation between conformers as defined on the basis of rigid skeletal models. Conformers of a classical species are interconverted by skeletal flexibility operations, *i.e.* regular processes, whereas the classical species are interconverted only by irregular processes.

With this concept, one can recognize that rearrangements of molecules which proceed by deformations of bond angles at one center, such as the inversion of ammonia, the *syn-anti* isomerization of oximes, isomerizations of phosphoranes and the internal rotation of metallocenes, do not differ fundamentally from those conformational transformations in molecules with polycentric skeletons. This is true even though the latter rearrange by deformations of dihedral angles as illustrated in the rearrangements of ethane and cyclohexane derivatives and the pseudorotation of cyclopentane derivatives. Use of a collective term, interconversion of conformers, is suitable for all the above processes since it facilitates the uniform theoretical treatment they receive.

Formal mechanistic analysis of rearrangement processes among molecules whose skeletons carry n ligands can be achieved that are based upon the classes of conjugate elements of the symmetric group S_n by further subdividing these classes using the symmetries of the rigid skeletal models[67]. Physical constraints permit one to decide which of these classes and/or subclasses can correspond to regular processes as given by the skeletal flexibility and which of them can only represent irregular processes. A check against overlooking any possible mechanism is one distinct advantage provided by this systematic approach. Conclusions regarding the probability factor are made possible as well by considering the number of elements of a particular class of permutations.

Such an analysis of the conceivable reaction pathways for molecules with a pentacoordinate TBP skeleton indicates two types of regular processes are possible: (i) a purely vibrational process containing no relative internal rotation, and (ii) mechanisms which are primarily internal rotations, the simple and multiple TR processes.

Available experimental data suggest that the previously accepted thought that the BPR process, to the exclusion

of all alternatives (the TR mechanism was unknown until June 1970[4b]) is the best available mechanism for all pentatopal rearrangements is no longer tenable unless the definition of the BPR is altered to include the simple and multiple TR processes.

All of the pertinent data that can be interpreted by the BPR mechanism can also be interpreted by the equivalent TR process but the reverse is not true. There are observations whose interpretation by TR or multiple TR requires fewer additional hypotheses than required for explaining the same evidence on the basis of the BPR concept.

A decision of preference for one of a group of mechanistic alternatives not only requires information concerning energy barriers of the individual processes but also information about the probability factor. Our calculation data demonstrates that energy barriers for the BPR and TR processes are not sufficiently different to provide an unequivocal choice between the two. In some cases the BPR barrier seems favored (*e.g.* certain acyclic phosphoranes) while in other cases, the TR and multiple TR barriers are more attractive (*e.g.* some of the cyclic phosphoranes). TR processes are always favored statistically by at least a factor of 4 in single processes and by a factor of 4^n in a sequence of n single steps. Physically, this means that there is a narrow gap to pass at the barrier for BPR rearrangement while the TR mechanism offers a wide region to cross.

The present empirical data, in keeping with theoretical considerations, suggest that the regular rearrangements of cyclic pentacoordinate molecules proceed by the TR and/or multiple TR mechanism. Analogous acyclic systems can undergo rearrangements by either mechanism. In contrast to sequences of regular isomerizations containing exclusively BPR or single TR steps, reaction pathways employing multiple TR steps can, if necessary, bypass high energy TBP intermediates.

In this paper we have confined ourselves, for the most part, to a discussion of regular isomerizations of stable pentacoordinate phosphorane compounds. Regular and irregular rearrangements of phosphorane intermediates, essential for the understanding of the entire field of phosphorus chemistry, and, in particular, its biochemistry, will be discussed in a subsequent paper.

We wish to thank Prof. F. Anet for helpful discussions concerning NMR data, Prof. G. A. Segal for valuable consultation on quantum mechanical procedures, Prof. O. Schnepp and Dr. C. Kutal for stimulating advice, and also Mr. A. Arora, Mrs. A. Marquarding, and Mrs. S. Cutri for help in preparing the manuscript.

[36] The term pseudorotation was originally introduced for the rapid interconversion of the "envelope forms" of cyclopentane [37]. Since the notation "pseudorotation" has thus already been claimed, we use BPR [2] to denote the reorganization of pentacoordinate phosphorus compounds, as defined by *Berry* [3].

Applications of Mössbauer Spectroscopy to Problems in Solid-State Chemistry[**]

By Norman N. Greenwood[*]

The factors influencing the chemical isomer shift, quadrupole splitting and hyperfine magnetic interactions, are briefly summarized and applications to solid state systems reviewed. New results on the disordered rutile phases Fe_2MgF_6, $FeMg_2F_6$, *and* $FeCoNiF_6$, *and on the trirutile phase* $Li^+Fe^{2+}Fe^{3+}F_6$ *are presented to illustrate the power of the Mössbauer technique in probing details of oxidation states, site symmetries and magnetic ordering. An extensive study on the nonstoichiometric wüstite phase* $Fe_{1-x}O$ *is also reported and analyzed in terms of diffusion broadening at high temperatures and defect clustering in quenched samples; the production of essentially stoichiometric* FeO *by annealing is also discussed. Recent results on the application of large external magnetic fields to diamagnetic compounds of tin are reviewed and results of a Mössbauer investigation of lunar samples returned by the Apollo 11 and 12 missions are discussed.*

1. General

The Mössbauer effect is the recoilless emission and resonant reabsorption of γ-rays. Its importance lies in the production of extremely monochromatic radiation which can be used as a spectroscopic source of energy to probe details of chemical structure and bonding. The underlying theory has been outlined by *R. L. Mössbauer*[1a] in a previous article and has been extensively reviewed[1b]. The effect has so far been demonstrated in 72 isotopes of 42 different elements as indicated in Fig. 1. It can be seen that Mössbauer spectroscopy is potentially a widely applicable technique particularly among the heavier elements.

A841.1

The precise energy of the resonant transition is influenced by three hyperfine interactions which form the basis of its use in solid-state chemistry. The first of these interactions gives rise to a *chemical isomer shift*, δ, and originates in the varying coulombic interaction between the positive nucleus of an atom and its electronic environment. The chemical isomer shift is directly proportional both to the change in nuclear radius on excitation, $\delta R/R$, and to the change in s electron density at the nucleus on going from the source to the absorber. Its magnitude is determined by the following factors:

Department of Inorganic Chemistry
The University
Newcastle upon Tyne. NE1 7RU (England)

2. Shielding effects of p, d, and f electrons on the s-electron density at the nucleus
3. Covalency effects in modifying s, p, and d electron population and distribution, including
   (a) σ withdrawal of electrons by electronegative groups
   (b) deshielding due to d_π back bonding

Some examples of the dependence of chemical isomer shift on oxidation state are given in Fig. 2 which plots observed ranges of δ for four typical Mössbauer isotopes ^{57}Fe, ^{127}I, ^{129}Xe, and ^{237}Np. This shift finds many applications in solid-state chemistry as a rapid, non-destructive probe of oxidation state in minerals and nonstoichiometric compounds. For example the Mössbauer systematics of a variety of metal sulfides of known structure enabled the oxidation state of iron and tin in several sulfide minerals to be unambiguously determined. It was found[2], *e.g.*, that

chalcopyrite is $Cu^+Fe^{3+}S_2^{2-}$, not $Cu^{2+}Fe^{2+}S_2^{2-}$;
cubanite is $Cu^+(Fe^{2+}Fe^{3+})S_3^{2-}$, not $Cu^{2+}Fe_2^{2+}S_3^{2-}$;
stannite is $Cu_2^+Fe^{2+}Sn^{4+}S_4^{2-}$, not $Cu^+Cu^{2+}Fe^{3+}Sn^{2+}S_4^{2-}$
etc.

$(SO_4^{2-})_3$. Variations in the conditions of preparation lead to some replacement of titanium by iron, the actual composition being $Fe_{1+x}Ti_{1-x}(SO_4)_3$; the Mössbauer spectra in such cases showed that the detailed formulation of the stoichiometry was $(Fe^{2+}_{1-x-y}Fe^{3+}_{x+y})$ $(Fe^{3+}_xTi^{3+}_yTi^{4+}_{1-x-y})$ $(SO_4^{2-})_3$ and an analysis of peak areas gave a measure of the relative concentrations of Fe^{2+} and Fe^{3+}

Another area in which Mössbauer spectroscopy has proved particularly useful is in determining oxidation states after nuclear reactions. Thus[4] irradiation of $MgSnO_3$ with thermal neutrons produces appreciable amounts of Sn^{II} which can subsequently be removed by oxidative annealing in air. There is now an increasing amount of work being published on the use of Mössbauer spectroscopy for the study of radiation damage in solids and for the investigation of radioactive decay after-effects on the submicrosecond time scale[5].

The second hyperfine interaction from which information can be obtained is the quadrupole splitting, Δ. Any nuclear state with a spin quantum number $I > \frac{1}{2}$ has a quadrupole moment Q, which can interact with an electric field gradient,

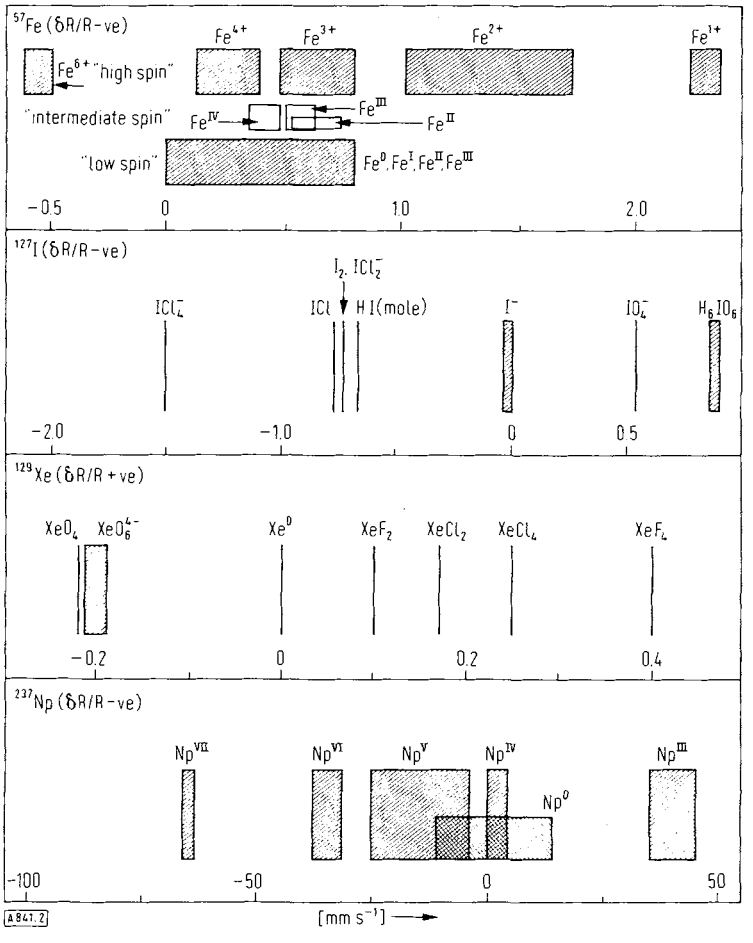

Fig. 2. Range of chemical isomer shift for ^{57}Fe, ^{127}I, ^{129}Xe, and ^{237}Np as a function of oxidation state and spin multiplicity.

Likewise the unusual blue color of the readily synthesized compound of ideal composition $FeTi(SO_4)_3$ was traced to the presence of both Fe^{2+} and Fe^{3+} in the compound which should be formulated[3] $(Fe^{2+}_{1-y}Fe^{3+}_y)$ $(Ti^{3+}_yTi^{4+}_{1-y})$

q, to lift the degeneracy of the state. In the simplest case of a transition between $|\pm\frac{3}{2}\rangle$ and $|\pm\frac{1}{2}\rangle$ in an axially symmetric electric field gradient the quadrupole splitting, Δ, is directly proportional to both Q and q. In general, it has been found

that Δ is an extremely powerful probe of local site symmetry and its magnitude has been found to depend on:

1. Electronic configuration of the atom, including
   (a) oxidation state
   (b) spin multiplicity
2. Site symmetry, including effect of
   (a) coordination number
   (b) *cis-trans* isomerism
   (c) ligand-field distortions *etc.*
3. Contributions from neighboring charges (atoms or ions)
   (a) asymmetric withdrawal of p and d electrons for bonding
   (b) polarizable atoms in covalent assemblies
   (c) lattice terms in ionic crystals

The third hyperfine interaction which influences the Mössbauer spectrum is the nuclear magnetic Zeeman splitting which arises when the nucleus is subject to an internal or an applied magnetic field. The extent of the energy separation depends both on the nuclear magnetic moments of the ground and excited states, and also on the magnitude of the magnetic field H. Thus in ^{57}Fe the $|\pm\frac{1}{2}\rangle$ ground state splits into two sublevels and the $|\pm\frac{3}{2}\rangle$ excited state splits into four sublevels; transitions between these are normally subject to the selection rules $\Delta m = 0, \pm 1$, so that six resonance lines will be seen. If an electric field gradient is also present then there is a perturbation which disturbs the even spacing of the lines and enables the mutual orientation of H and q to be determined.

2. Investigations on Metal Fluoride Systems

We have recently been using the above mentioned hyperfine interactions to study the details of structure and bonding in several fluoride phases having the rutile structure (Fig. 3). Thus, the Mössbauer spectra of FeF_2, Fe_2MgF_6, $FeMg_2F_6$, and $FeCoNiF_6$ all show a sharp quadrupole-split doublet with no indication of line broadening whatsoever[16]. This implies a statistical disordering of the various cations on the available cation sites. Further, as the cations have similar radii and identical charge, the positions of the six fluoride ions surrounding each metal remain unaltered; as the influence of this distorted octahedron on the high-spin Fe^{2+} d^6 configuration is the principal source of the electric field gradient in these compounds, the constancy of Δ and the sharpness of the lines can be understood. Below the Néel temperature these four compounds become antiferromagnetic and the spectra (Fig. 4) are characterized by a six-line pattern with two weak additional lines due to the usually forbidden transitions $|+\frac{3}{2}\rangle \rightarrow |-\frac{1}{2}\rangle$ and $|-\frac{3}{2}\rangle \rightarrow |+\frac{1}{2}\rangle$ which become allowed when magnetic and quadrupole interactions are mixed.

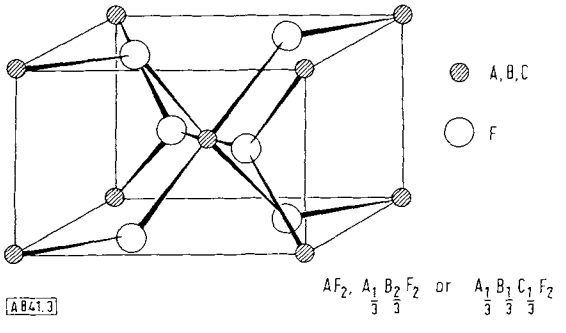

Fig. 3. The rutile structure of FeF_2 and several disordered ternary and quaternary fluoride phases such as Fe_2MgF_6, $FeMg_2F_6$, and $FeCoNiF_6$.

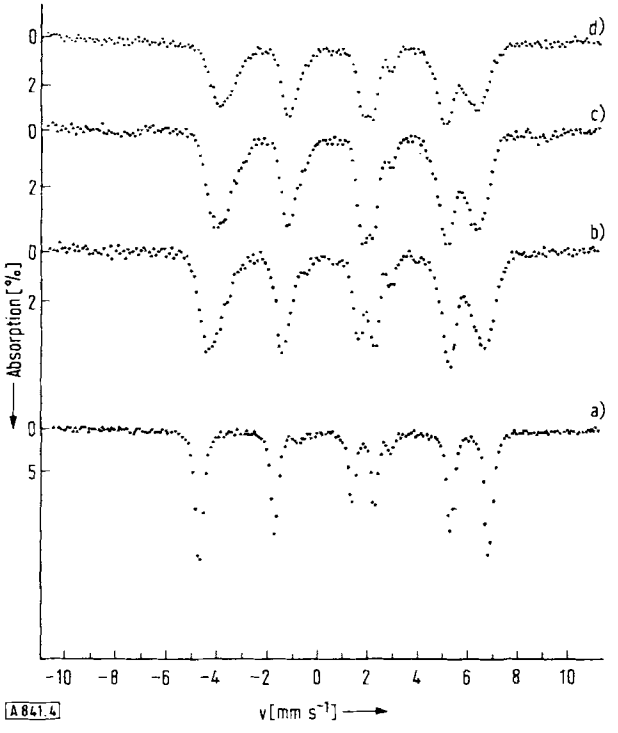

Fig. 4. Mössbauer spectra of a) FeF_2, b) Fe_2MgF_6, c) $FeMg_2F_6$, and d) $FeCoNiF_6$ at 4.2 K.

Another feature of these spectra is the appreciable broadening of the outer lines as compared with the spectrum of FeF_2 itself; this arises from a range of hyperfine magnetic fields which in turn reflects the range of (magnetic) local environments. The results indicate how fine a probe the technique is of local environment in the presence of statistical disorder.

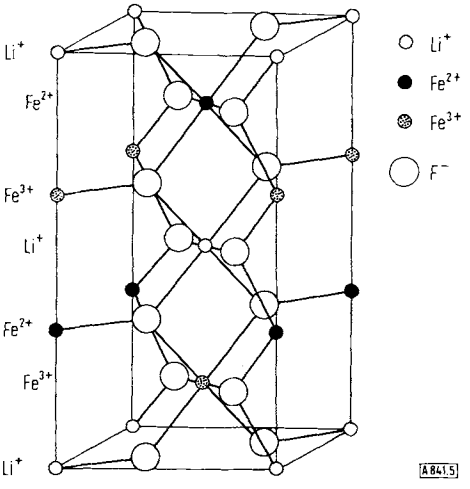

Fig. 5. The trirutile structure of $LiFe_2F_6$.

A particularly interesting compound of a related type is $LiFe_2F_6$. X-ray powder data had shown that the compound has the trirutile structure (Fig. 5) but was unable to distinguish between Fe^{2+} and Fe^{3+} and so left unanswered the question as to whether these ions were statistically disordered between the layers of lithium ions, or indeed whether the ions had a separate existence rather than being subject to rapid electron hopping or interchange. The Mössbauer technique is ideally suited to answer these questions and has yielded the following results[6, 7]:

(a) Fe^{2+} and Fe^{3+} give separate resonances at all temperatures up to the decomposition point of the compound (≈ 1000 K) indicating that there is no rapid electron hopping between the two species within the lifetime of the ^{57}Fe excited state (97 ns)

(b) The magnetic spectra below the Néel temperature of 102 K show two separate, sharp, magnetic hyperfine spectra arising from Fe^{2+} and Fe^{3+}, respectively. The sharpness of the lines implies that both the geometric and magnetic environments of each Fe^{2+} and Fe^{3+} ion are identical so that there is an ordering of all three cations Li^+, Fe^{2+}, and Fe^{3+} into every third layer respectively, as shown in Fig. 5.

(c) The Fe^{2+} and Fe^{3+} magnetic moments are aligned ferrimagnetically within each trirutile layer and the net moments are then aligned antiferromagnetically between successive layers.

3. Investigations of Metal Oxide Systems

If we now turn from fluoride systems to oxide systems we find that a vast range of problems has been studied by Mössbauer spectroscopy. Much of this has already been extensively reviewed[1, 5] and the resulting systematics have proved of considerable diagnostic value. The main observations are as follows:

(a) The chemical isomer shift of high-spin Fe^{3+} is substantially smaller than for high-spin Fe^{2+} by ≈ 0.8 mm s^{-1};

(b) The chemical isomer shift for iron in tetrahedral environments is somewhat smaller than for octahedral coordination; hence δ (tetrahedral Fe^{3+}) $< \delta$ (octahedral Fe^{3+}) $< \delta$ (tetrahedral Fe^{2+}) $< \delta$ (octahedral Fe^{2+});

(c) The quadrupole splitting, Δ, for both Fe^{3+} and Fe^{2+} in sites of accurately cubic symmetry is zero;

(d) For non-cubic sites $\Delta(Fe^{3+}) < \Delta(Fe^{2+})$;

(e) The magnetic hyperfine field $H(Fe^{3+}) > H(Fe^{2+})$.

Application of these generalizations has proved particularly valuable in studying the oxidation states, site occupancy, and degree of inversion of spinel phases[8]. Some of the results are summarized in Tables 1 and 2.

Table 1. Mössbauer spectra of ferrous spinels [*].

Spinel type	Site occupied	Example	Spectrum	Remarks
normal 2,3	A	$Fe^{2+}[Cr_2^{3+}]O_4$	single line $\Delta = 0.0$, $\delta = 0.83$	tetrahedral site has cubic symmetry; phase becomes tetragonal below 135 K ($\Delta \neq 0$) and ferrimagnetic below 69 K.
normal 4,2	B	$Ge^{4+}[Fe_2^{2+}]O_4$	two lines $\Delta = 2.80$, $\delta = 1.12$	large e.f.g. (q) from trigonal distortion on d^6; phase becomes antiferromagnetic below 11 K.
partly inverse 2,3	A and B	$Fe_x^{2+}\,Ga_x^{3+}[Fe_x^{2+}\,Ga_{2-x}^{3+}]O_4$	two pairs of lines $\Delta_A = 1.2$, $\delta_A = 0.83$ $\Delta_B = 2.9$, $\delta = 0.9$	non-cubic A site due to charge variations on B site; trigonal distortion at B site. Note A site has the smaller Δ and lower δ.

[*] δ in mm s^{-1} relative to iron foil; Δ in mm s^{-1}; H in kG.

Table 2. Mössbauer spectra of ferric spinels [*].

Spinel type	Site occupied	Example	Spectrum	Remarks
disordered 2,3	A	$Fe^{3+}[Ni^{2+}Al^{3+}]O_4$	two lines $\Delta = 0.53$, $\delta = 0.18$	cation disorder on B sites removes cubic symmetry of A sites
normal 2,3	B	$Zn^{2+}[Fe_2^{3+}]O_4$	two lines $\Delta = 0.36$, $\delta = 0.37$	e.f.g. (q) from trigonally distorted B site acting on spherical d^5
inverse 2,3	A and B	$Fe^{3+}[Cu^{2+}Fe^{3+}]O_4$ (tetragonal)	two superimp. six-line spectra A: $\delta = 0.33$, $H = 478$ $\varepsilon = 0.00$ B: $\delta = 0.50$, $H = 514$ $\varepsilon = 0.14$	only B site shows quadrupole effect ($\varepsilon = 0$ for A site may depend on alignment of e.f.g. (q) and H); A site has the smaller H and lower δ

[*] δ in mm s^{-1} relative to iron foil; Δ in mm s^{-1}; H in kG.

In favorable cases Mössbauer spectroscopy can be used to study not only the details of the static structure of a solid-state system but can also be used to investigate lattice dynamics, diffusion and reaction rates. Before con-

sidering specific examples it is necessary to realize that, depending on the timescale of the motions, vibration, diffusion, and jumping affect the Mössbauer resonance in different ways[9].

If the nucleus of interest is undergoing harmonic vibration about a fixed site at a frequency which is high compared with the inverse excited-state lifetime then this simply produces a reduction in intensity of the resonance without any line broadening, the decrease in the recoilless fraction f being given by the Debye-Waller formula

$$f = e^{-4\pi^2 x^2/\lambda^2}$$

where x^2 is the mean square amplitude of oscillation in the direction of observation of the γ-ray and λ is the wavelength of the γ-photon. This means that values of x of the order of 10 pm are conveniently measurable with Mössbauer isotopes having excited-state lifetimes similar to those of ^{57}Fe or ^{119}Sn.

A second limiting case arises if the nucleus of interest is undergoing continuous diffusion or Brownian motion. This leads to a broadening of the Mössbauer line with no reduction in overall recoilless fraction and no change in the basic Lorentzian line shape. This energy broadening, $\Delta\Gamma$, expressed as an increase in the linewidth at half height, is given by

$$\Delta\Gamma = 2\hbar\left(\frac{2\pi}{\lambda}\right)^2 D$$

where D is the self-diffusion coefficient. Values of D of the order of 10^{-15} m^2 s^{-1} give broadenings of the order of the natural linewidth for ^{57}Fe or ^{119}Sn resonances.

The third limiting case concerns jump diffusion. If the resonant nuclei jump instantaneously between fixed sites in such a way as to produce a random phase shift in the γ-ray wave train at each jump, then, as in the preceding case, the line is broadened without reduction in the recoilless fraction and without loss of the Lorentzian line shape; under these conditions the broadening is given by

$$\Delta\Gamma = 2\hbar/\tau_0 = 12\hbar D/l^2$$

where τ_0 is the mean resting time between jumps, D is the self diffusion coefficient and l^2 the mean square jump distance. Values of τ_0 equal to 280 ns and 53 ns give broadenings equal to the natural linewidth for ^{57}Fe and ^{119}Sn respectively.

An example of this last mechanism is afforded by the wüstite phase $Fe_{1-x}O$ at high temperatures and we have recently been studying this in some detail[7]. The work required the construction of a Mössbauer sample holder which could be held at various temperatures up to 1300 K under controlled partial pressures of oxygen down to 10^{-16} N m^{-2} whilst still being transparent to the 14.4 keV γ-rays[10]. Typical spectra are shown in Fig. 6 for various temperatures and compositions. The first spectrum which refers to a sample at the iron-rich phase boundary at 1168 K shows a resonance which can be resolved into two components: a narrow line, due to metallic iron above its

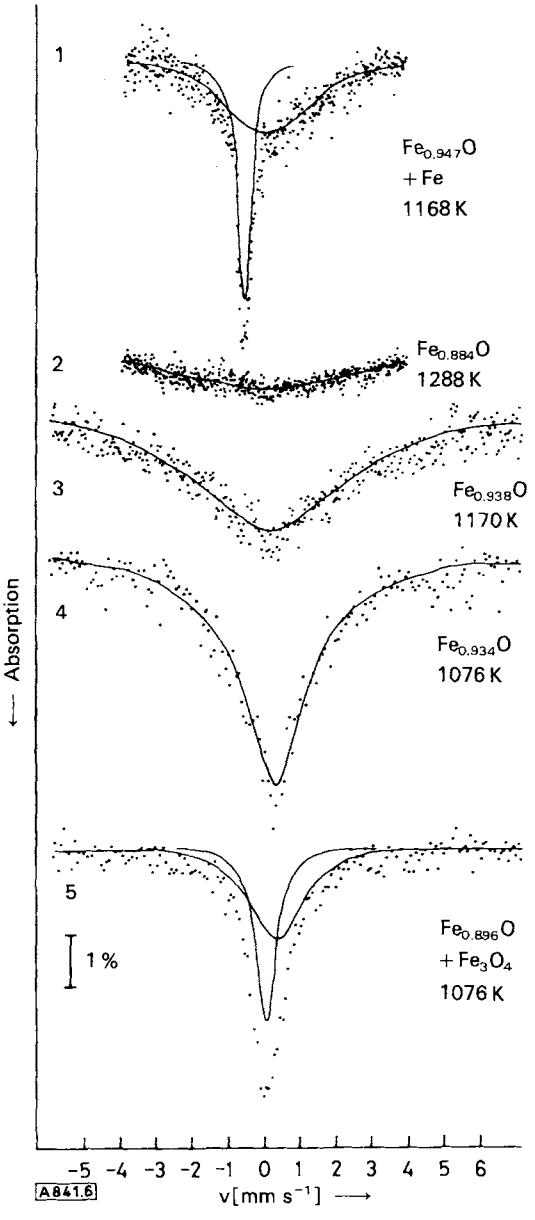

Fig. 6. Diffusion-broadened Mössbauer spectra of $Fe_{1-x}O$ under equilibrium conditions. At the phase boundaries sharp peaks due to Fe (sample 1) and Fe_3O_4 (sample 5) are also present.

Curie temperature, and a broad resonance due to the oxide phase. Spectrum 2 illustrates a typical resonance obtained from $Fe_{0.884}O$ at an even higher temperature 1288 K; the single resonance is now nearly 25-times the natural linewidth as a result of diffusion broadening. Spectra 3 and 4 illustrate the effect of temperature on samples of composition $Fe_{0.938}O$ and $Fe_{0.934}O$; the drop in temperature from 1170 K to 1076 K decreases the resonance linewidth by a factor of more than two. Finally, at the oxygen rich end of the wüstite phase field, spectrum 5 illustrates the resonance at 1076 K comprising a fairly narrow line due to Fe_3O_4 above its Néel temperature and a broadened resonance from $Fe_{0.896}O$. Several important results emerge from this study of $Fe_{1-x}O$. Firstly, the absolute values of the diffusion coefficients, when calculated from the theory of *Singwi* and *Sjölander*[11] were in excellent agreement with those reported from a previous study using the radioactive tracer technique[12]. The work therefore establishes the Möss-

bauer method as a valuable technique for studying diffusion in polycrystalline oxide samples at temperatures several hundred degrees below the melting point; previously the method had only been applied to diffusion in metals near the melting point. The technique is particularly valuable because it is independent of bulk transport, and because it is independent of other phases present as well as being independent of cracks or grain boundaries. Further, as the effect does not vary with time the sample can be fully equilibrated at the required temperature and pressure before measurements are begun.

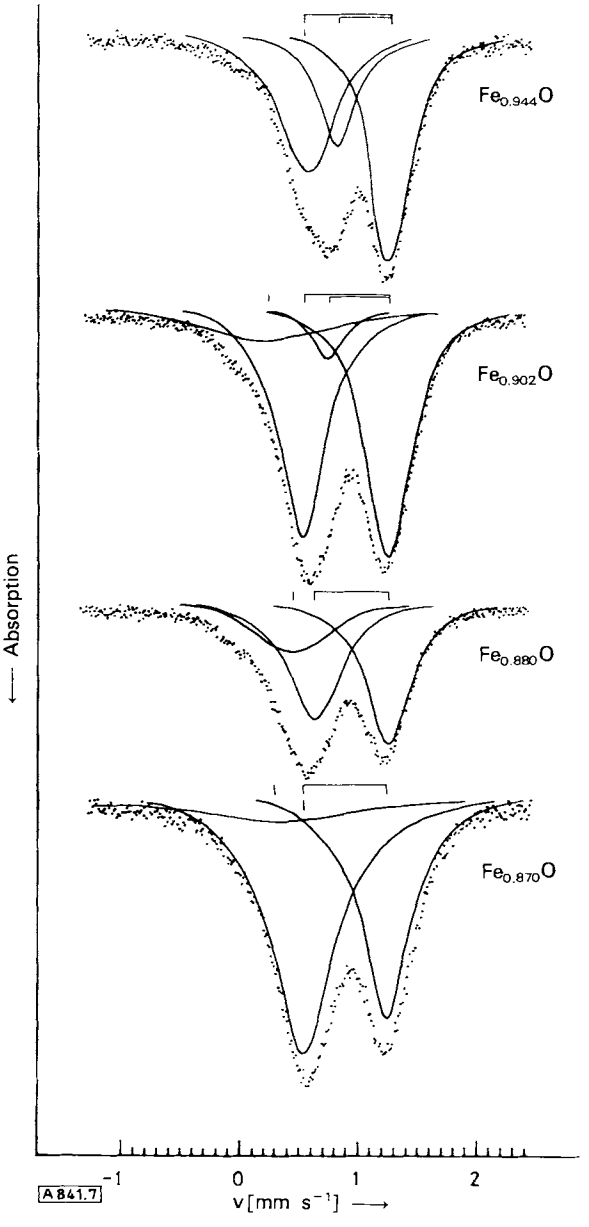

Fig. 7. Typical room-temperature Mössbauer spectra of quenched samples of $Fe_{1-x}O$ and proposed analysis in terms of two Fe^{2+} doublets and a broad Fe^{3+} resonance.

A second important result of the study was that at 1075 K the line broadening, and hence the diffusion coefficient were independent of composition (defect concentration). This implies an association of vacant cation sites and Fe^{3+} ions and has led to a detailed structure of the defect cluster in $Fe_{1-x}O$ at high temperatures[10]. At temperatures above 1100 K the line broadening becomes increasingly dependent on phase composition, implying a partial dissociation of the defect clusters.

When samples of $Fe_{1-x}O$ which have been equilibrated at high temperature are quenched very rapidly to room temperature the single broadened line splits into a partially resolved envelope of several overlapping resonances. Typical examples are shown in Fig. 7 for a variety of compositions. By studying the variation of line shape and intensity as a function of composition, and by doing a full statistical analysis of all possible model component spectra it was shown that the spectra were best considered as a pair of overlapping doublets from Fe^{2+} and a broader unresolved resonance from Fe^{3+}. There was no evidence for averaging of parameters by electron exchange between Fe^{2+} and Fe^{3+} and it is also significant that there was not a *range* of quadrupole splittings for Fe^{2+} at each composition but only two. The most obvious interpretation of these results is again in terms of defect clusters; it is then possible to assign the Fe^{2+} spectra respectively to Fe^{2+} adjacent to a defect cluster and Fe^{2+} further removed from the cluster, whilst the Fe^{3+} envelope embraces both tetrahedral and octahedral sites. This model not only gives the best statistical fit to the data but also gives concentrations of Fe^{2+} and Fe^{3+} which parallel the known composition over the whole range of samples from $Fe_{0.88}O$ to $Fe_{0.94}O$.

A further novel effect was also investigated during this study on quenched $Fe_{1-x}O$. When samples of the type discussed in the preceding paragraph are annealed for a few minutes at temperatures in the region of 500 K (or at temperatures above or below this) the broad quadrupole split Mössbauer spectra shown in Fig. 7 undergo a dramatic change—the linewidth progressively narrows to give a single sharp resonance approaching natural linewidth in the region expected for Fe^{2+} in a purely cubic environment. At the same time weaker components corresponding to the spectrum of Fe_3O_4 begin to appear (see Fig. 8)[10]. The position of the new narrow resonance is independent of

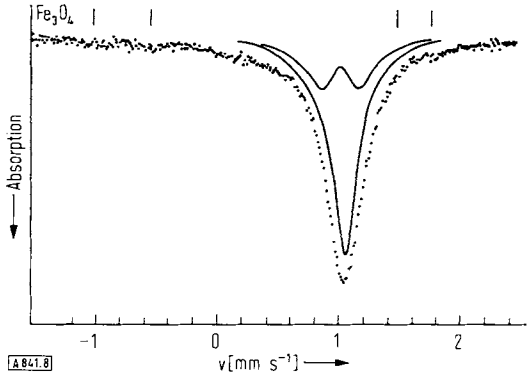

Fig. 8. Spectra of partly annealed (20 min at 300 °C) $Fe_{0.944}O$ showing the single sharp resonance of essentially stoichiometric FeO and the incipient emergence of the four inner peaks of Fe_3O_4 formed during disproportionation.

the original composition of the quenched wüstite phase but the relative intensities of this line and the Fe_3O_4 lines depend directly on the composition. This, in conjunction

with the implied precise cubic symmetry of the main Fe^{2+} site strongly implies disproportionation of the wüstite phase into essentially stoichiometric FeO and Fe_3O_4; this conclusion is confirmed by the measurement of the lattice constant a_0 of the new phase which corresponds precisely with the extrapolated value expected for a composition $Fe_{1-x}O$ in which $x = 0.00 \pm 0.01$. Thus

$$Fe_{1-x}O = (1 - 4x)\,Fe_{1.00}O + x\,Fe_3O_4$$

This is striking independent evidence for the formation of essentially stoichiometric FeO by a disproportionative mechanism as first proposed by *Hoffmann*[13]. Further evidence consistent with this view was obtained from the well resolved hyperfine field of Fe^{2+} in cubic environment below the Néel temperature. It is clear that this detailed study of quenched and annealed samples of FeO, as well as the equilibrium study of the wüstite phase field at high temperatures has added greatly to our understanding of this classic nonstoichiometric oxide.

4. Application of a Strong External Magnetic Field on Diamagnetic Tin Compounds

Another aspect of our recent work is the measurement and interpretation of ^{119}Sn Mössbauer spectra in the presence of applied superconducting magnetic fields at 4.2 K. Such work gives information about the sign of the quadrupole interaction and hence helps in the elucidation of the origin of this interaction in tin compounds. The problem is more complex than that of magnetic and quadrupole interactions in ^{57}Fe because the excited state of ^{119}Sn has a smaller quadrupole moment than that of ^{57}Fe whereas the nuclear magnetic moments of both the ground and excited state of ^{119}Sn are appreciably larger than those for ^{57}Fe. The data are in Table 3. One consequence of this, coupled with the rather large natural linewidth of the ^{119}Sn resonance,

Table 3. Nuclear quadrupole and magnetic moments [*] for the ground state and first excited state of ^{57}Fe and ^{119}Sn.

Nucleus	Q_g (barn)	Q_e (barn)	μ_g (μ_N)	μ_e (μ_N)
^{57}Fe	0	+0.33	+0.09024	−0.1547
^{119}Sn	0	−0.07	−1.046	+0.70

[*] 1 barn = 10^{-28} m^2
1 nuclear magneton = 5.050×10^{-27} A m^2

is that only limiting cases in which Δ is either zero or very large can be readily interpreted by simple perturbation theory. These two limiting cases are illustrated in Figs. 9 and 10 which show that when $\Delta \simeq 0$ mm s^{-1} as in SnO_2 an applied magnetic field gives rise to an unresolved doublet of triplets whereas when $\Delta = 4.2$ mm s^{-1} (as in Me_2SnMoO_4) the spectrum comprises a high field doublet and a lowfield quartet[14]. For intermediate cases (*e.g.* Me_2SnCl_2 for which $\Delta = 3.4$ mm s^{-1}) the pattern is more complex and the applied field cannot be treated as a simple perturbation of the quadrupole interactions. In such cases the total hyperfine interaction Hamiltonian must be in-

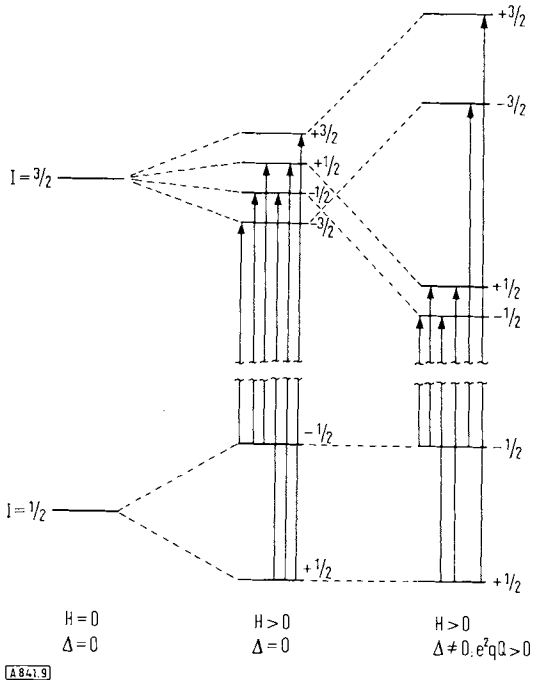

Fig. 9. Energy levels for the ^{119}Sn nucleus in the presence of magnetic and combined magnetic and quadrupolar interactions.

corporated into the treatment. Without this the experimental results are unintelligible, particularly for moderately small quadrupole splittings and applied magnetic fields. As an aid to the visual interpretation of such spectra *T. C. Gibb* in our Laboratories has computed an atlas of theoretical spectra to be expected for powdered samples in magnetic fields applied either perpendicular or parallel to the γ-ray direction and for a wide range of quadrupole

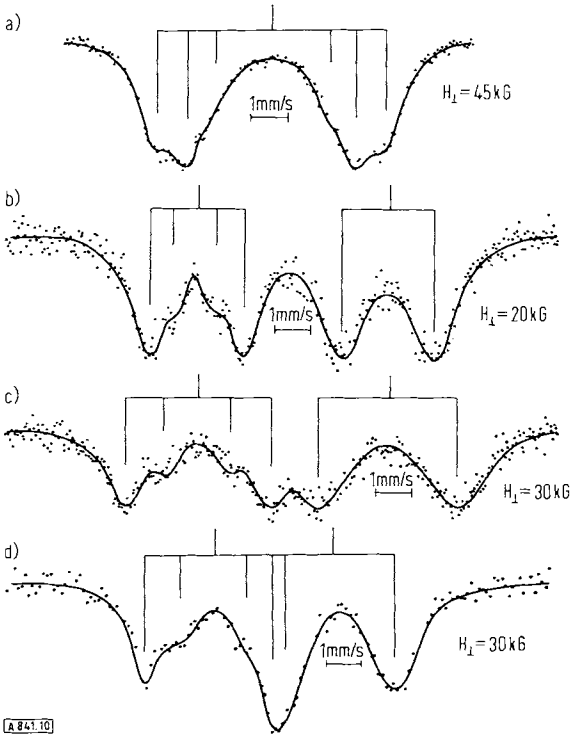

Fig. 10. Mössbauer spectra of tin compounds in the presence of an external magnetic field perpendicular to the direction of observation of the γ-rays: (a) SnO_2, (b) and (c) Me_2SnMoO_4, (d) Me_2SnCl_2.

splittings[15]. Typical spectra are shown in Figs 11 and 12. The results are particularly valuable in helping to design experiments since they indicate the optimum value of the magnetic field for a particular compound and also indicate the optimum setting for the velocity scan of the spectrometer. They also permit immediate visual determination of the sign of the electric quadrupole interaction e^2qQ and hence the sign and probable origin of the electric field gradient q. In this way we have shown[16] that e^2qQ is positive for the tin(II) compounds SnO, SnS, SnF_2, SnC_2O_4 and $Sn_3(PO_4)_2$ despite some contradictory claims in the literature; this demonstrates the dominating influence of the p_z character of the lone-pair electrons in these compounds. Likewise the *trans*-octahedral complex Me_2SnF_2 has positive e^2qQ whereas the trigonal pyramidal Me_3SnNCS and Me_3SnOH have negative e^2qQ because, in each case, of the dominating effect of the electrons in the Sn—C bonds when compared with the lower electron density near the tin atom in the bonds to electron-withdrawing groups such as F and OH[17]. Results on numerous other tin(IV) compounds in an applied magnetic field are consistent with these conclusions[17]

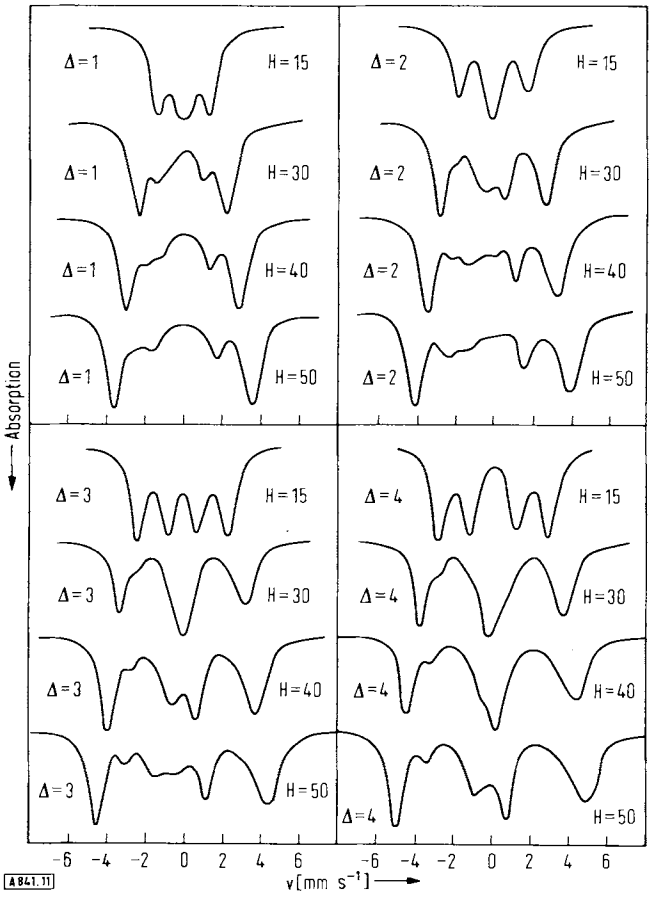

Fig. 11. Calculated spectra for ^{119}Sn with varying values of the quadrupole splitting Δ mm s^{-1} and magnetic field H (kG). In all cases H is parallel to the direction of observation, e^2qQ is positive, the asymmetry parameter $\eta = 0$, and the resonance linewidth has been taken to be 0.8 mm s^{-1}.

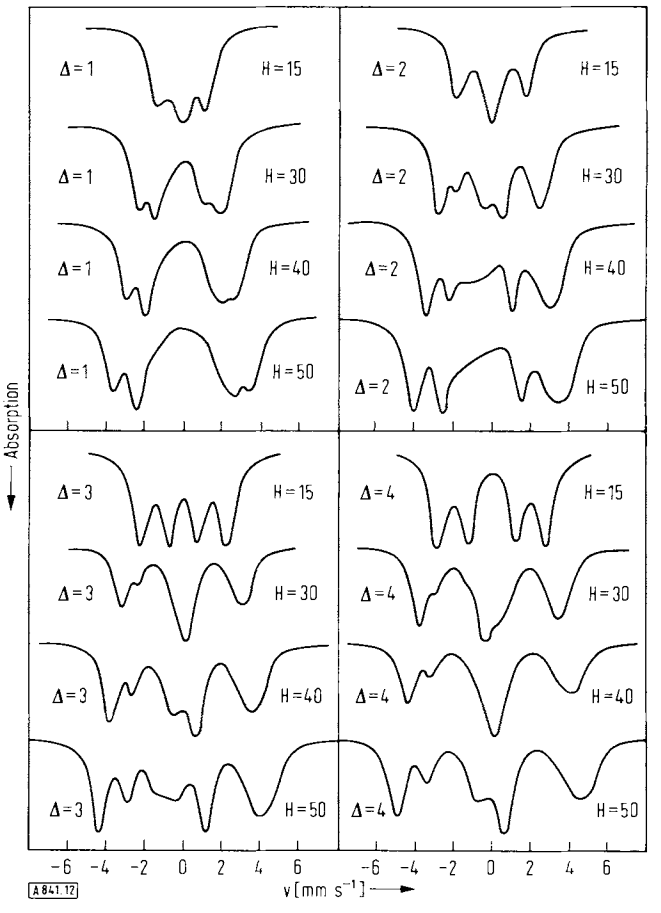

Fig. 12. Calculated spectra as for Fig. 11 but with H perpendicular to the direction of observation.

5. Investigations on Lunar Samples

In the last part of this article some recent work we have been doing on the application of Mössbauer spectroscopy to the analysis of the Lunar Samples returned by Apollo 11 and 12 last year will be outlined. Preliminary analysis[18] showed that the only Mössbauer isotope present in sufficient concentration in samples of the lunar regolith was ^{57}Fe. A typical spectrum of unseparated fines is reproduced

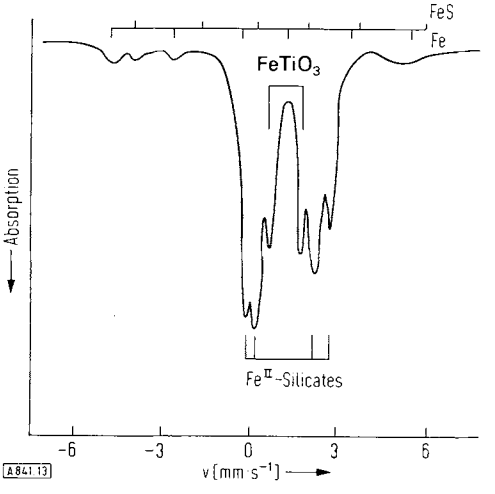

Fig. 13. Room-temperature Mössbauer spectrum of lunar microbreccia from the Apollo 11 mission.

in Fig. 13; it shows the presence of traces of metallic iron and troilite, and larger concentrations of ilmenite and Fe^{II} silicate phases, but there is no evidence for Fe^{III} or any other oxidation state of iron. More detailed work at various temperatures and under higher resolution led to the results in Table 4[19].

Table 4. Mössbauer data [*] and assignments for lunar fines (10084—13).

Chemical isomer shift (mm s^{-1}) [*]		Quadrupole splitting (mm s^{-1})		Assignment	% of resonance by area at
290 K	80 K	290 K	80 K		80 K
1.1	1.19	0.7	1.1	ilmenite (A)	20
1.2	1.21	2.0	2.1	glasses and site M 2 of clinopyroxenes (B)	75
1.2	1.31	2.5	2.9	olivines and site M 1 of clinopyroxenes (C)	
	0.0	($H = 330$ kG)		Fe (metal)	4
	0.9			FeS (troilite)	≤1

[*] With respect to metallic iron at 290 K as zero.

Phases definitely identified include native iron, troilite (stoichiometric FeS), ilmenite ($FeTiO_3$), clinopyroxenes [$Ca(Mg,Fe)Si_2O_6$], olivines [$(Mg,Fe)_2SiO_4$], and high spin Fe^{2+} in glassy silica phases. The data illustrate again the great range of information which can be obtained rapidly and nondestructively from small samples of unknown constitution. The results have been confirmed by other groups of workers[20], and have proved particularly valuable in helping to elucidate the complex magnetic properties of lunar minerals[21]. In addition a careful determination of the Néel temperature of lunar ilmenite showed it to be 57 ± 2 K in agreement with the known value for stoichiometric terrestrial ilmenite $FeTiO_3$[20].

Synthesis of Octakis(trifluorophosphane)-diiridium[1]

By *Thomas Kruck, Gerd Sylvester,* and *Inge-Petra Kunau*[*]

Mononuclear metal(0)-trifluorophosphane complexes $M(PF_3)_n$ of chromium, iron, nickel, and all their homologs have been synthesized in recent years[2]. Meanwhile only two homogeneous dinuclear complexes $[M(PF_3)_n]_2$ (M=Re: $n=5$; M=Rh: $n=4$) containing a direct metal-metal bond have been isolated for transition metals of odd atomic number[3,4], in sharp contrast to the situation in the chemistry of metal carbonyls. The reason for this behavior in the case of the cobalt group may be seen in the ease of formation of the highly stable hydrides $HM(PF_3)_4$ (M = Co, Rh, Ir); they are even formed under the conditions of reductive trifluorophosphanation of metal salts in the presence of slight traces of hydrogen-containing substances.

We have now succeeded in preparing and characterizing the first diamagnetic and thus dinuclear trifluorophosphane complex of iridium(0) by elimination of hydrogen from tetrakis(trifluorophosphane)iridium hydride *(2)*: Octakis-(trifluorophosphane)diiridium *(1)*, whose existence can be predicted by the noble gas rule, is formed in about 20% yield according to equation (1) on UV-irradiation of an ethereal solution of *(2)* for 17 hours.

$$\underset{(2)}{2\,HIr(PF_3)_4} \xrightarrow{\text{UV light}} \underset{(1)}{(PF_3)_4Ir{-}Ir(PF_3)_4} + H_2 \qquad (1)$$

The bright yellow crystals left on removal of the solvent melt at 105 °C and sublime at 20 °C/10^{-3} torr. They dissolve in all the common organic solvents and are stable for some time in air. IR spectroscopy showed that the prolonged action of even the slightest trace of moisture eventually leads to formation of the hydride *(2)*. The vapor-phase IR spectrum of *(1)* shows two sharp bands at 939 (w) and 900 (m) cm^{-1} which lie in the characteristic P—F stretching frequency range. As expected they are shifted to shorter wavelengths compared with *(2)*.

The ^{19}F-NMR spectrum (KIS-2, 84.7 MHz, dissolved in ether at 25 °C) shows only a doublet at $\delta = 5.85$ ppm (Cl_3CF as external standard); nor do any further signals appear at higher amplification, thus ruling out the presence of a PF_2 bridge such as is formed in the corresponding photolysis of $HCo(PF_3)_4$ to $(PF_3)_3Co(PF_2)(H)Co(PF_3)_3$[5]. The coupling constant $^1J_{P-F}$ of 1238 Hz lies in the usual region for terminal PF_3 groups.

The mass spectrum (Atlas CH 4, 20 and 70 eV) affords conclusive proof of the presence of an Ir—Ir bond. The molecular weight is apparent from the molecular peak at $m/e = 1088$. Fragmentation is characterized by two reactions: 1) Successive loss of PF_3 groups and 2) rupture of the Ir—Ir bond followed by loss of PF_3 from the two halves of the molecule. The higher the energy, the greater the role played by the second fragmentation route.

In line with the simple IR spectrum and the magnetic equivalence of the fluorine atoms, the following structure is proposed for *(1)*: The molecule is made up of two trigonal bipyramids, each Ir atom occupying the central position of one pyramid and the axial position of the other. Magnetic equivalence of the F atoms in this case results from structural isomerization or virtual coupling. We regard as unlikely a structure in which the Ir atoms occupy the apices of two square pyramids and are linked together such that the planes of the PF_3 groups are parallel to each other.

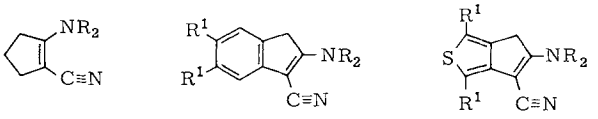
Transamination of Cyano Enamines[**]

By *Reinhard Helmers*[*]

Thorpe-Ziegler cyclization of dinitriles affords cyclic cyano enamines A whose tautomers—the imino compounds B—are hardly detectable[1]. Interest in these compounds was hitherto limited mainly to their hydrolysis reactions. As a hetero ketone analog, compound B should undergo proton-catalyzed condensation with secondary amines to give the enamines C, like the corresponding ketones.



Only two instances of this exchange reaction have so far been recorded in the literature. Thus 2-amino-3-cyano-indene[2] and 1-amino-2-cyano-1-cyclopentene[6] were treated either with benzylamine or aniline to give *N*-benzyl- and *N*-phenyl compounds. Otherwise cyclic *N,N'*-dialkyl cyano enamines were accessible only by acylation of enamines with cyanogen chloride[3]. After partly unsuccessful attempts to alkylate compounds of type A at the nitrogen,

[c] Coalescence at −23.2 °C; $\Delta G^{\neq} = 12.4$ kcal/mol.

the cyano enamines obtained on cyclization of dinitriles[4] were converted into *N,N*-dialkyl cyano enamines at elevated temperature and in the presence of small amounts of hydrochloride (see Table 1). Amines having high boiling points and the cyano enamines are refluxed with or without solvent; those having low boiling points are heated in autoclaves or bomb tubes.

The partial double bond character of the C—N bond in these cyano enamines is susceptible to quantitative analysis by low-temperature NMR spectroscopy[4].

1-Cyano-2-(N,N-dimethylamino)-1-cyclopentene (1a):

Dimethylamine (63 g, 1.4 mol) is passed into a solution of 1-amino-2-cyano-1-cyclopentene[5] (54 g, 0.5 mol) in dioxane (200 ml) and dimethylammonium chloride (1 g) is then added. The reaction mixture is heated to 165 °C for 24 h in an autoclave. After evaporation of the solvent, the product is vacuum distilled. Yield 54 g (79%) of *(1a)* as a colorless oil that solidifies at 33 °C.

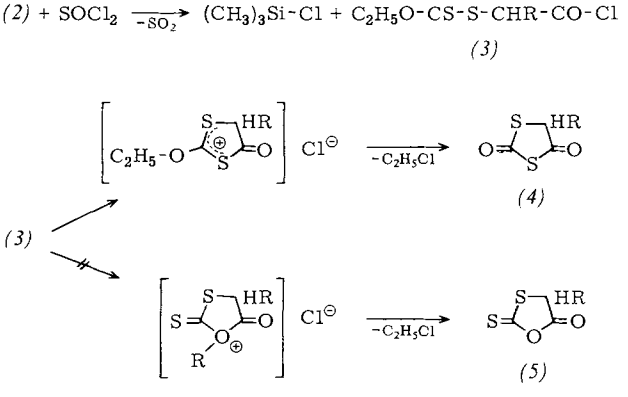
1,3-Dithiolane-2,4-diones



By *Hans R. Kricheldorf*[*]

The present communication describes the synthesis of the hitherto undescribed 1,3-dithiolane-2,4-diones *(4)*, R = H, CH_3, C_2H_5, which can be polymerized to polythiocarboxylic esters. The corresponding dioxolanediones also polymerize.

Reaction of sodium ethyl xanthate with 2-halo carboxylic acids yields the 2-(ethoxythiocarbonylthio)carboxylic acids *(1)*[1] which can be converted directly into the trimethylsilyl esters *(2)*. Compounds *(2)* can be distilled without decomposition.

Unlike the ethoxy compounds *(1)* and *(2)*, the corresponding methoxy compounds could not be isolated since they readily decompose with loss of COS. Reaction of the silyl esters *(2)* with thionyl chloride leads initially to the acyl chlorides *(3)* which cyclize at as low a temperature

R	*(2)* B.p. (°C/torr)	n_D^{20}	*(4)* B.p. (°C/torr)	n_D^{20}
a H	82—84/0.001	1.5110	68—70/0.1	1.6126
b CH_3	88—90/0.1	1.4985	53—55/0.1	1.5712
c C_2H_5	93—95/0.1	1.4920	64—66/0.5	1.5543

[*] Dr. H. R. Kricheldorf
Institut für makromoleculare Chemie der Universität
78 Freiburg, Stefan-Meier-Strasse 31 (Germany)

as 25 °C with elimination of ethyl chloride to give the 1,3-dithiolane-2,4-diones *(4)*.

There is no evidence for the formation of the isomers *(5)*. Thus the IR spectrum of the reaction products *(4)* exhibits a carbonyl band in the region 5.9—6.0 μm (1700 to 1670 cm^{-1}) like the thiazolidine-2,5-diones[2,3], whereas a carbonyl band at 5.4 μm (1850 cm^{-1}) would be expected for *(5)*, as found in the case of 2-thioxo-5-oxazolidones (and the oxazolidine-2,5-diones)[3,4].

1,3-Dithiane-2,4-dione, a homolog of the title compounds, could not be synthesized since the precursor of type *(3)* [3-(ethoxythiocarbonylthio)propionyl chloride] is stable (b. p. 78—80 °C/0.01 torr, $n_D^{20} = 1.5535$).

The 1,3-dithiolane-2,4-diones *(4b)* and *(4c)* are yellow, highly refractive liquids that can be vacuum distilled below 100 °C. *(4a)* melts at 44—46 °C. In the presence of basic catalysts and on prolonged heating, particularly above 100 °C, they polymerize with elimination of COS:

$$n\,(4) \longrightarrow n\,COS + (-S-CHR-CO)_n$$

1,3-Dithiolane-2,4-dione (4) via trimethylsilyl 2-(ethoxythiocarbonylthio)carboxylate (2):

A solution of sodium ethyl xanthate (1 mol) in ethanol (500 ml) is mixed with a solution of halo carboxylic acid (1 mol) in 4 N aqueous sodium hydroxide (250 ml) and left to stand at 25 °C for 24 h. The solution is then filtered, evaporated down *in vacuo*, diluted to a volume of 500 ml with water, and acidified to pH 1 with concentrated hydrochloric acid. The precipitated carboxylic acid *(1)* is dissolved in methylene chloride and the solution is dried over Na_2SO_4 and concentrated by evaporation. The residual acid is dissolved in THF (1 liter) and silylated by dropwise addition of trimethylchlorosilane (*ca.* 1 mol) and triethylamine (1 mol). The mixture is diluted with light petroleum, filtered with exclusion of moisture, and the product *(2)* is then isolated from the filtrate by vacuum distillation; yield 70—80%.

A silyl ester *(2)* (0.5 mol) is added dropwise to a warm solution of pure thionyl chloride (90 g) in chloroform (250 ml). The resulting solution is heated until evolution of gas has ceased (1—2 h) and then evaporated down *in vacuo*. The product *(4)* is isolated by vacuum distillation, the bath temperature not being allowed rise over 100 °C; yield 60—70%.—Results of C, H analysis of the new products agree with the calculated values (±0.3%).

Gram-Scale Purification of ^{244}Cm by Extraction Chromatography

By *K. Buijs, F. Maino, W. Müller, J. Reul*, and *Cl. Toussaint*[*]

Extraction chromatography, a technique combining the versatility of solvent extraction with the simplicity and good separation of chromatography, has been applied previously to the purification of mg-quantities of Cm[1,2].

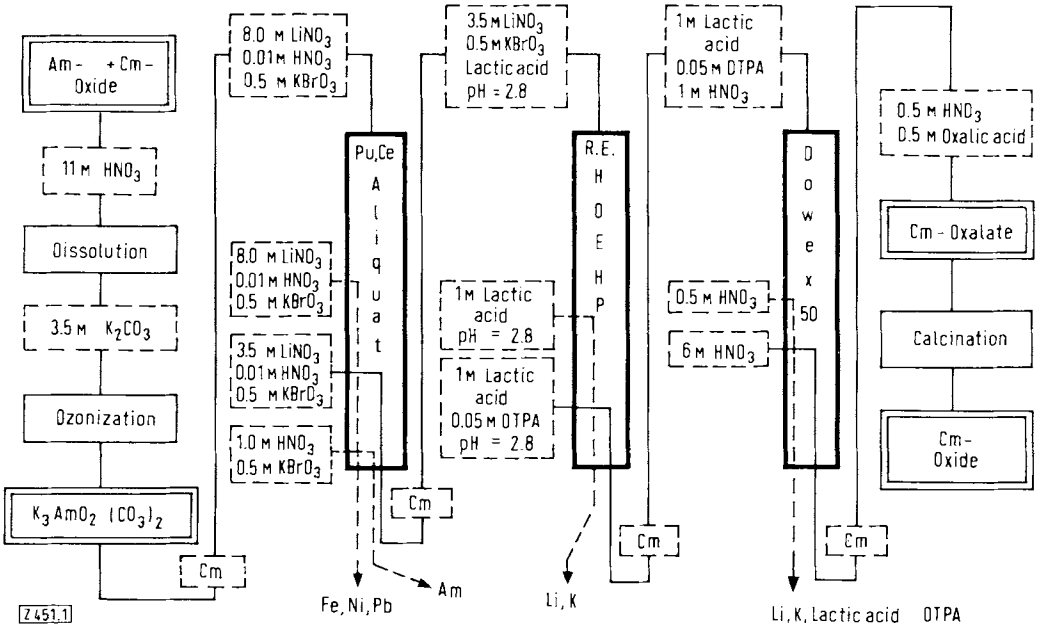

Fig. 1. Flowsheet for purification of ^{244}Cm by extraction chromatography.
R.E. = lanthanoids, DTPA = diethylenetriaminepentaacetic acid.

Extraction chromatography columns generally have a low specific capacity. The alpha-decay heat, which for ^{244}Cm corresponds to a thermal power of 2.83 W/g, therefore has less influence on the performance of extraction chromatography columns than on that of ion-exchange columns. Application of extraction chromatography to the purification of gram amounts of Cm was therefore thought feasible.

[*] K. Buijs, F. Maino, W. Müller, J. Reul, and J. Cl. Toussaint
Euratom, Institute for Transuranium Elements
P. O. Box 2266, 75 Karlsruhe (Germany)

An oxide mixture containing 5.9 g of ^{244}Cm and 5.1 g of ^{243}Am formed the starting material for the preparation of high-purity Cm oxide. A preliminary Am—Cm separation by two successive precipitations of $K_3AmO_2(CO_3)_2$ yielded a Cm fraction containing 2.7% of Am and an Am fraction containing 0.4% of Cm. The Cm fraction was then purified further by extraction chromatography and cation exchange as shown in the flowsheet (Fig. 1).

The whole purification process was carried out in nitrate medium which in comparison with chloride has the following advantages: less corrosion of glove-box equipment and less radiolytic decomposition of solutions. Furthermore, residual nitrate is decomposed during calcination of the oxalate.

Each of the extraction chromatography columns shown in the flowsheet had a volume of 1 liter and contained kieselgur as the inert supporting material. The weight ratios of tricaprylmethylammonium (Aliquat-336) nitrate and bis(2-ethylhexyl)phosphoric acid (HDEHP) to kieselgur were 0.25 and 0.11, respectively. During elution of the Cm fraction, the extraction chromatography columns were not affected by the passage of the solution of high power density, in contrast to the cation exchange column which, above the Cm-containing zone, was disturbed by gas bubbles. On all columns, the position of the Cm-fraction could be seen from the intense radioluminescence.

Analyses performed at Oak Ridge National Laboratory showed that the purification procedure reduced the inactive impurity content in the Cm from 7.8% to 0.65%; the residual Am content was 0.28%. The purification operation was carried out with master-slave manipulators in a glove-box which, for protection against neutrons from ^{244}Cm and gamma radiation from ^{243}Am (^{239}Np) and from traces of fission products, was installed behind a 25-cm shielding of water.

Reactions of 4,5-Dihydro-1,3,5-oxazaphosph(v)oles with Alkynes and Alkenes[**]

By *Klaus Burger* and *Josef Fehn*[*]

4,5-Dihydro-1,3,5-oxazaphosph(v)oles *(1)*[1] react with alkynes and alkenes at temperatures between 100—140 °C in solvents such as toluene and xylene with elimination of phosphoric acid esters to yield 1:1 adducts. The products of this [3+2] cycloaddition are assigned the structures of 2*H*-pyrroles *(2)* and pyrrol-1-ines *(3)* on the basis of IR, NMR, and mass spectra data.

Similarly to the 1,3-dipolar addition of imidochlorides in the presence of triethylamine to double- and triple-bond systems, the reaction should proceed *via* nitrile ylides[2–4]. Recent studies provide compelling evidence for the intermediacy of nitrile ylides in the transformation of 4-acyl-5-oxazolones and 2-acyl-2*H*-5-oxazolones into trisubstituted oxazoles[5]; occurrence of nitrile ylides in 1,3-dipolar addition of 2,2-disubstituted 5-oxazolones has been proved by adduct formation[6].

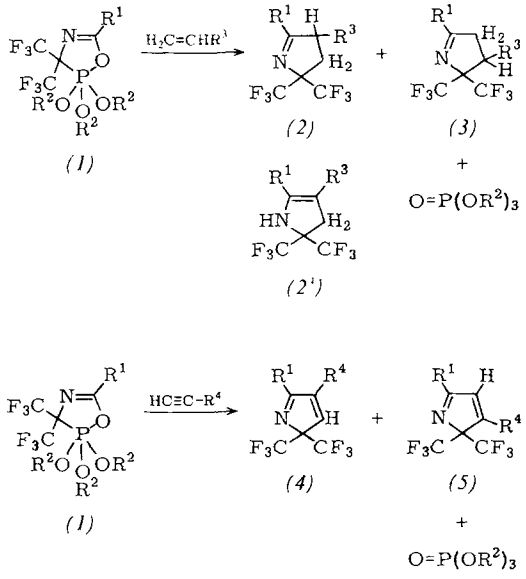
Orientation of Addition of Unsymmetrically Substituted Alkynes and Alkenes to 4,5-Dihydro-1,3,5-oxazaphosph(v)oles[**][1]

By *Klaus Burger* and *Josef Fehn*[*]

We recently reported on the reaction of 4,5-dihydro-1,3,5-oxazaphosph(v)oles *(1)*[2] with symmetrically substituted alkynes and alkenes leading to 2*H*-pyrroles and pyrrol-1-ines[1].

In all hitherto studied cases of the reaction of *(1)* and unsymmetrically substituted alkynes and alkenes both possible orientations were found. Table 1 lists isomeric ratios of compounds *(2)* or *(2')*:*(3)* and *(4)*:*(5)* respectively, as determined by NMR spectrometry, which were obtained in xylene at 120—140 °C (bath temperature). Examples for orientation in comparable reactions are given in ref. [3–6].

The mixtures *(2a)*/*(3a)*; *(2b)*/*(3b)*; *(2c)*/*(3c)*; and *(2d)*/*(3d)* obtained in the reaction *(1)*→*(2)*, *(3)* cannot be separated by distillation. Of the acids formed by alkaline hydrolysis and adjustment of the pH to 1—2, the β-keto acids derived from *(2)* undergo decarboxylation at room temperature[7]. Separation of *(6)* and *(7)* is now facile. The pyrrol-2-ine *(2'e)* is readily separable from *(3e)* by crystallization.



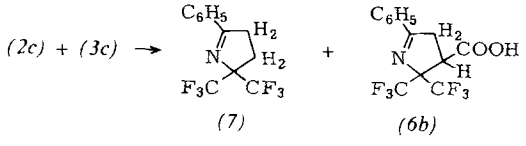


Table 1. Isomeric ratios.

Conformational Studies by Low Temperature ^{13}C-NMR Spectroscopy

By *Hans-Jörg Schneider, Roger Price*, and *Toni Keller*[*]

Low temperature ^{13}C-NMR spectra can be used to study chemical exchange processes in systems whose ^{1}H-NMR spectra are complicated by small shift differences and by coupling phenomena. The widely varying ^{13}C Larmor frequencies provide a wealth of information about the structure of the molecules concerned and about the energetics of their interconversions and permit measurement over a wide range of temperature; analysis is facilitated by the sole appearance of singlets in the ^{1}H-noise decoupled spectrum.

On inversion of *cis*-1,2-dimethylcyclohexane *(1)* into a chair conformation of equal energy the methyl groups change between equatorial and axial positions, causing all the C atoms to adopt corresponding stereoisomeric positions. This exchange process could be followed from the "frozen" equilibrium at 160°K to room temperature by pulse Fourier transform ^{13}C spectroscopy (see Fig. 1). The observed half-widths ranged from 87 Hz near the poorly defined coalescence point to about 0.5 Hz at 300°K; the limit of resolution is determined by the capacity of the computer storage. Evaluation of signal widths and, insofar as possible, of line separations too, of the 8 or 4 signals in the temperature range 200 to 270°K gave $\Delta H^{\neq} = 12 \pm 1$ kcal/mol, $\Delta G^{\neq}_{220} = 9.9$ kcal/mol. Analogous measurements on *cis*-1,4-dimethylcyclohexane *(2)* yielded $\Delta G^{\neq}_{220} = 9.3$ kcal/mol for the ring inversion barrier. These $\Delta G^{\neq}$ values agree to within an experimental accuracy of ± 0.5 kcal/mol with the inversion energies of cyclohexane and of 1,1-dimethylcyclohexane[1] determined by ^{1}H-NMR. The fact that substituents raise the inversion barrier by only a slight amount [compare *(1)* and *(2)* in particular] can be explained by ring deformation[1] or, alternatively, by a ground state of higher energy; moreover, the energy required is partly determined by the opening of the C—C angle which is affected only slightly by substituents.

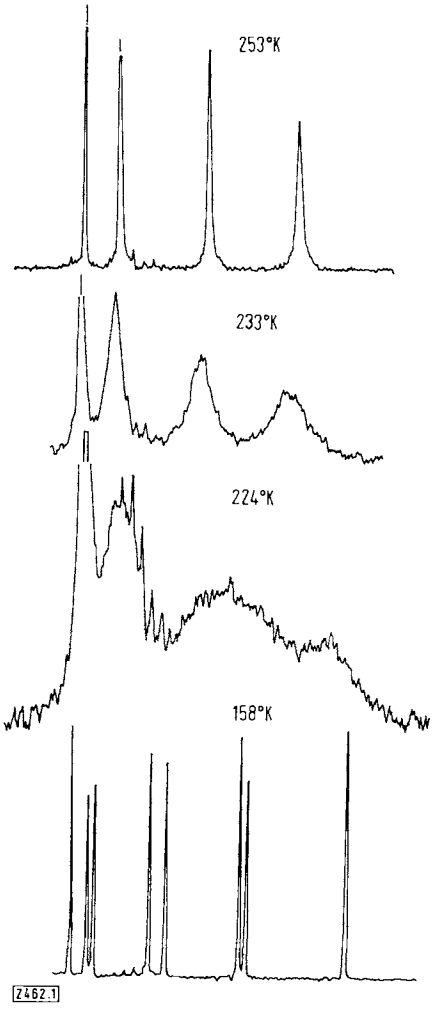

Fig. 1. ^{13}C-NMR spectra of *(1)* at different temperatures, measured in CCl_2F_2 + TMS (5:1) using $(CD_3)_2CO$ as lock.

The signals of *(1)* and *(2)* could be assigned unequivocally by their multiplicity in the off-resonance decoupled low-temperature spectrum and by application of known substituent rules[2, 3]. Comparison with the shifts calculated according to *Grant*[2] [see Figure 2] shows that the empirical shift parameters obtained from model substances will have to be corrected by the measurements on isolated conformers that have now become possible. The ^{13}C signal of an axial methyl is 5.9 ppm higher than that of an equatorial methyl group [see *(2)*, cf. [4]]. The upfield shift of a ^{13}C signal by γ substituents (by the diaxial γ protons in the case of an axial methyl group) must arise from both steric[2] and electronic effects[5, 6]. The difference in bonding between an axial and an equatorial methyl group is also

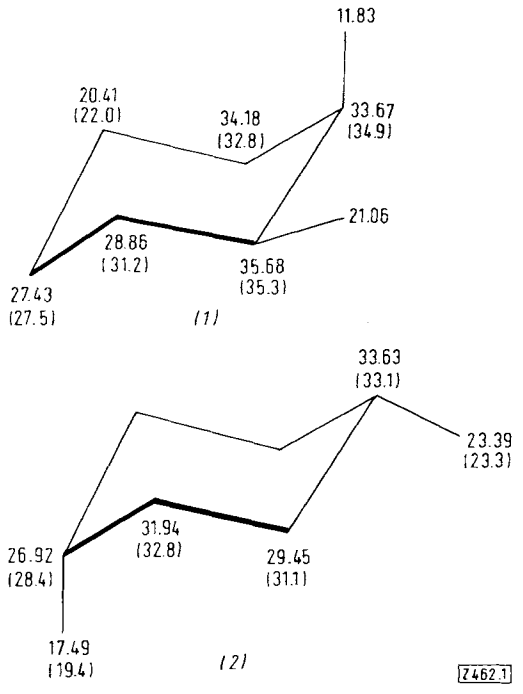

Fig. 2. ^{13}C-NMR shifts of *cis*-1,2-dimethylcyclohexane *(1)* at 158 °K and *cis*-1,4-dimethylcyclohexane *(2)* at 180 °K; solvent CCl_2F_2 + TMS (5:1). δ values in ppm downfield from TMS; values in parentheses shifts calculated according to *Grant* [2].

apparent from the diamagnetic shift of +5.7 ppm (resulting from mutual interaction of both groups in *(1)*) in the case of the axial group and of only +2.3 ppm for the equatorial group.

Identification of energetically unequal conformers and determination of their equilibria is facilitated by ^{13}C low-temperature spectroscopy[4]. The methyl signals of *cis*-4-methylcyclohexanol at 200 °K gave an equilibrium containing 7.7% with axial CH_3. The resulting energy difference of the conformers is $\Delta G = 1.07$ kcal/mol; this agrees with the value $\Delta G = 1$ kcal/mol obtained by addition of the conformational energies of CH_3 and OH groups, which indicates that the groups separated in the molecule exert no mutual interactions. This is confirmed by the shifts of the methyl group which, at $\delta_{TMS} = 23.5$ ppm or $\delta_{TMS} = 17.6$ ppm, do not differ from the values obtained for *cis*-1,4-dimethylcyclohexane *(2)* and for methylcyclohexane[4]. When evaluating ^{13}C-NMR spectra it should be borne in mind that the signal intensities can be falsified by differing relaxation times and Overhauser effects. That the relative abundances are correctly reproduced for identically substituted C atoms is shown, *e.g.*, by integration of the low-temperature spectrum of *(2)* to give area integrals for stereoisomeric (exchanging) C atoms having deviations of less than 0.5% for CH_3 and CH_2 and 4% for CH.

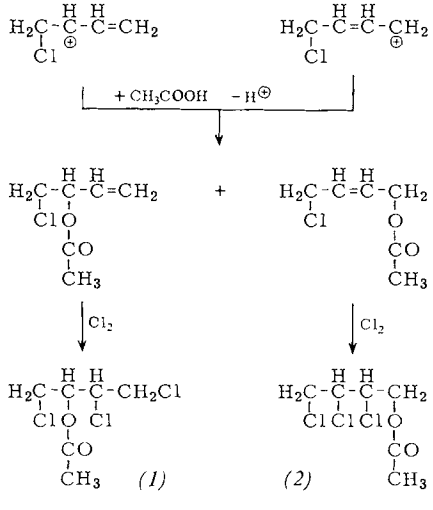
Elimination Reactions of Trichlorobutyl Acetates

By *Günther Maahs, Lutz Rohrschneider, Peter-Jürgen Frenzel,* and *Günter Peitscher*[*]

Dedicated to Professor Franz Broich on the occasion of his 65th birthday

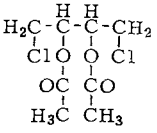


While the formation of chlorohydrin ethers and esters of monoolefins has been studied extensively[1], corresponding investigations on diolefins have received little attention[2]. In particular, reaction of diolefins and chlorine in the molar ratio 1:2 yields a rather complicated mixture of addition and substitution products. We have prepared trichlorobutyl acetates (chlorohydrinacetates of butadiene) and elucidated their elimination reactions.

Table 1. Results of combined GC/MS analysis (Perkin-Elmer Fractometer F 6/MAT mass spectrometer CH 4).

Peak No.	Overall ret. time (min)	Peak area (%)	Rel. intensities (%) *m/e* 43	49	61	73	169
1	10.9	9.1	100	2.8	3.1	0.2	0.5
2	11.3	52.3	100	2.6	2.9	0.2	0.7
3	11.9	15.1	100	3.1	5.1	16.2	0.02
4	13.3	23.5	100	2.9	3.8	18.7	0.01

Chlorine is passed into a solution of butadiene in glacial acetic acid (molar ratio $C_4H_6:Cl_2 = 1:2$) in the dark at 15—18 °C in the presence of traces of oxygen. (Alternatively, butadiene and chlorine can be passed simultaneously into glacial acetic acid.) Distillation at 75—78 °C/3 torr (116 to 120 °C/11 torr) gave a fraction (yield 25—35%; $n_D^{20} = 1.4783$) that could be separated into four components on a 50-m polyphenyl ether capillary column at 175 °C. Relevant GC/MS data are listed in Table 1.



According to Table 1, components 1 and 2 and 3 and 4 appear to be very similar in the mass spectra, although the two groups may readily be distinguished. The large proportion of fragments having mass number 73 ($-CH_2OCOCH_3$) in components 3 and 4 suggests the presence of the 1-acetate *(2)* since the 2-acetate cannot possibly give this fragment. Thus the reaction product consists of 61% of the trichloro-

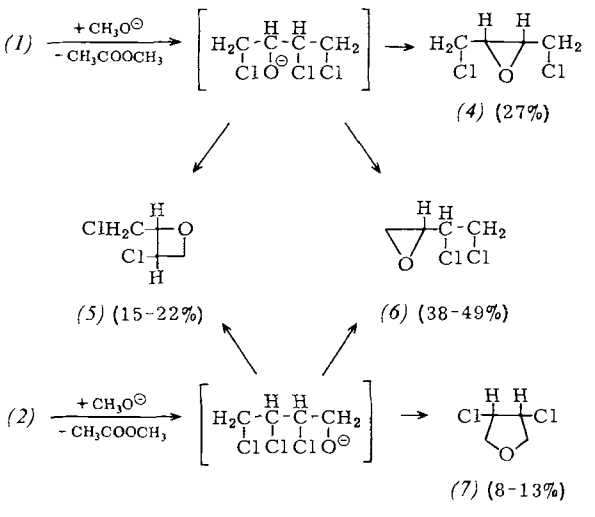
sec-butyl acetate [(1-chloromethyl-2,3-dichloropropyl) acetate] *(1)* and 39% of the trichloro-*n*-butyl acetate [2,3,4-trichlorobutyl acetate] *(2)* which are both composed of two diastereomers.



The other distillation fractions were not studied. A white solid crystallized from the high-boiling constituents (m.p.

(3)

115—116 °C from methylcyclohexane) which has the structure *(3)* according to its NMR and mass spectra.

The mixture of *(1)* and *(2)* was then treated in methanolic solution with an equimolar amount of sodium methoxide at room temperature. After the NaCl had been filtered off

and the solvent pumped off, the residue was distilled at 57—70 °C/10 torr (yield 60%, $n_D^{20} = 1.4790$).

The product was separated into four components on a preparative scale by gas chromatography. According to the mass spectrum, the components are isomers of composition $C_4H_6OCl_2$. The four cyclic structures *(4)*—*(7)* were assigned on the basis of the NMR and IR spectra. The methanol removed from the reaction mixture was also found to contain an equimolar amount of methyl acetate with respect to the product.

The nucleophilic substitution therefore seems to lead to an intramolecular elimination with ring closure. [The figures in parentheses represent the limiting percentages of product found for a variety of experimental conditions (reaction time 10—120 min, reaction temperature 20—65 °C, use of methanolic potassium hydroxide).]

1,3,6,8-Tetra-*tert*-butyl-9-carbazyl: A Crystalline Monomeric Aminyl Radical[1][**]

By *Franz A. Neugebauer* and *Hans Fischer*[*]

Direct linkage of two *ortho* positions in diphenylaminyl gives the 9-carbazyl system, a planar aminyl. In order to determine the properties of 9-carbazyl radicals we have synthesized the *tert*-butyl substituted carbazoles *(1a)* to *(1d)* and dehydrogenated them to give the 9-carbazyl radicals *(2a)*—*(2d)*.

Reaction of carbazole (1 mol) with *tert*-butyl chloride (6 mol) and $AlCl_3$ (1 mol) at room temperature gives 1,3,6,8-tetra-*tert*-butylcarbazole *(1a)* (m.p. 191—192 °C, 72%), 1,3,6-tri-*tert*-butylcarbazole *(1d)* (m.p. 136—137 °C, 5%), and 3,6-di-*tert*-butylcarbazole (m.p. 228—229 °C, 10%)[2, 3]. 1,8-Di-*tert*-butylcarbazole *(1b)* (m.p. 173—174 °C) is obtained from *(1a)* *via* 3,6-dinitro- (m.p. 289—290 °C), 3,6-diamino- (m.p. 254—255 °C), and 3,6-diiodo-1,8-di-*tert*-butylcarbazole (m.p. 230—231 °C)[3]. 1,3,8-Tri-*tert*-butylcarbazole *(1c)* (m.p. 131—132 °C) can be prepared similarly from *(1a)* by way of 3-nitro- (m.p. 227—228 °C),

(1) *(2)*

(a), $R^1 = R^2 = R^3 = R^4 = C(CH_3)_3$
(b), $R^1 = R^4 = C(CH_3)_3$; $R^2 = R^3 = H$
(c), $R^1 = R^2 = R^4 = C(CH_3)_3$; $R^3 = H$
(d), $R^1 = R^2 = R^3 = C(CH_3)_3$; $R^4 = H$

3-amino- (m.p. 159—160 °C), and 3-iodo-1,6,8-tri-*tert*-butylcarbazole (m.p. 135—136 °C)[3].

Addition of an equivalent of iodine oxidizes a solution of the lithium salt of *(1a)* in benzene to the deep blue (benzene: $\lambda_{max} = 660$ nm, $\log \varepsilon = 4.02$) species 1,3,6,8-tetra-*tert*-butyl-9-carbazyl *(2a)* which forms blue-black crystals (dec. p. 144—145 °C) from light petroleum. Hydrogenation of *(2a)* with $Pd/BaSO_4$ in pyridine indicates a radical content of 92%. The extremely strong ν(NH) band of the carbazole *(1a)* at 3520 cm^{-1} is just detectable in the IR spectrum of the radical *(2a)*. Oxidation of the carbazoles *(1b)*—*(1d)* with lead dioxide in benzene also gives blue 9-carbazyl

Table 1. Coupling constants and spin densities for 9-carbazyl.

Position	Exp. [a] $\lvert a_i[G]\rvert$	Exp. [a] $\lvert\rho_i^\pi\rvert$	Calc. [4] [b] ρ_i^π
1	3.8	0.16	0.189
2	0.9	0.038	−0.053
3	4.3	0.18	0.152
4	0.15	0.006	0.023
4a	—	—	0.073
9	6.9	0.24	0.284
9a	—	—	−0.026

[a] $a^H = -23.7\,\rho_C$ [5]; $a^N = 28.6\,\rho_N$ [6].

[b] $\beta_{CN} = 1.2\,\beta_{CC}$; $\beta_{C-4aC-4b} = 0.8\,\beta_{CC}$; $\alpha_N = \alpha_C + 1.2\,\beta_{CC}$; $\lambda = 1.2$.

[*] Doz. Dr. F. A. Neugebauer and H. Fischer
Max-Planck-Institut für Medizinische Forschung
Abt. Molekulare Physik
69 Heidelberg, Jahnstrasse 29 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

radicals which, however, are less stable and have not yet been isolated.

The carbazyls *(2a)*—*(2d)* give well resolved ESR spectra, *e.g.*, *(2a)* in benzene: $g=2.0033$; $a^{N}=6.86$, $a^{H_{2,7}}=0.93$, $a^{H}R^{2}$, $R^{3}=0.175$, $a^{H_{4,5}}=0.175$ G; *(2b)* in benzene: $a^{N}=6.97$, $a^{H_{2,7}}=0.89$, $a^{H_{3,6}}=4.3$, $a^{H_{4,5}}=0.14$ G. The ESR coupling constants show that the unpaired electron is largely delocalized over the planar π system. The experimental values found for the carbazyl derivatives *(2a)* to *(2d)* are in good agreement with the calculated spin densities for 9-carbazyl (Table 1). However, the sign of the calculated spin density in position 4 (sign of corresponding H coupling) still has to be determined experimentally (NMR).

The exceptional stability of the carbazyl *(2a)* stems from the steric shielding of the reactive aminyl nitrogen N-9 and the reactive positions C-1 and C-3 by the bulky *tert*-butyl substituents.

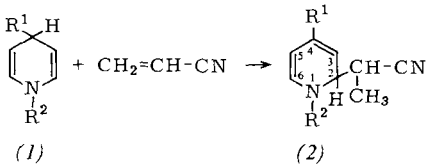
Addition of Acrylonitrile to Derivatives of 1,4-Dihydropyridine



By *Reinhard A. Sulzbach* and *Abul F. M. Iqbal*[*]

The 1,4-dihydropyridine system has hitherto attracted attention mainly because of its role as an intermediate in hydrogen transfer by pyridine nucleotides[1, 2]. The reactions carried out with 1,4-dihydropyridine compounds are limited to just a few examples[3–6].

We have now found that 1,4-dihydropyridines of type *(1)* undergo a surprising kind of reaction with acrylonitrile to give the 2-substituted 1,2-dihydropyridines *(2)*.

If the reaction is carried out with a molar excess of acrylonitrile, the Diels-Alder adduct of *(2)* and acrylonitrile can be isolated.

1,4-Dihydroquinolines react similarly with acrylonitrile to give 2-substituted 1,2-dihydroquinolines, as could be demonstrated in the case of 1,4-bis(trimethylsilyl)-1,4-dihydroquinoline.

(1) *(2)*

(a), $R^{1}=R^{2}=$ trimethylsilyl
(b), $R^{1}=H$, $R^{2}=$ 2,6-dichlorobenzyl
(c), $R^{1}=H$, $R^{2}=$ phenyl

In order that reaction may occur between a 1,4-dihydropyridine and acrylonitrile, an H atom must be present on C-4 of the dihydropyridine ring. After ten days' heating of 4-methyl-1,4-bis(trimethylsilyl)-1,4-dihydropyridine and acrylonitrile to 100 °C only unreacted starting material could be isolated. The 1,4-dihydropyridine system therefore shows no tendency to undergo reactions that are typical of enamines[7]. This observation is in accord with earlier findings that 1,4-dihydropyridines cannot be made to react with alkyl iodides in the manner expected for enamines[5, 6].

2-(1-Cyanoethyl)-1,4-bis(trimethylsilyl)-1,2-dihydropyridine (2a):

Acrylonitrile (5.3 g, 0.1 mol) is added slowly to 1,4-bis(trimethylsilyl)-1,4-dihydropyridine[8] (22.6 g, 0.1 mol) under argon in a 50-ml two-necked flask (thermometer, dropping funnel, magnetic stirrer). After 24 hours' reaction at room temperature, distillation gave *(2a)* (17 g, 61%) as a yellowish-green oil, b.p. 78 °C/10^{-3} torr; ^{1}H-NMR (C_6D_6): $\tau=6.38$ (H-2); 4.35 (H-3); 4.57 (H-5); 4.06 (H-6); 7.40; 9.18 (CH_3); 9.84 ($(CH_3)_3SiC$); 10.07 ($(CH_3)_3SiN$); $J_{2,7}=8.4$ Hz; $J_{3,2}=5.8$ Hz; $J_{3,5}=1.19$ Hz; $J_{6,5}=6.7$ Hz; $J_{6,2}=1.1$ Hz; $J_{7,8}=7.3$ Hz; M.W. (Simon/Tomlinson) = 277; correct elemental analyses.

Diethylaminotetrafluorophosphorane by Fluorolytic Cleavage of the P=N Bond[**]

By *Manfred Bermann* and *John R. Van Wazer*[*]

Phenyliminodiethylaminophosphorus(v) dichloride *(1)*[1] and an excess of antimony trifluoride do not give phenyliminodiethylaminophosphorus(v) difluoride but react further with splitting of the P=N bond to yield diethylaminotetrafluorophosphorane *(2)*[2].

$$\underset{(1)}{C_6H_5N{=}PN(C_2H_5)_2Cl_2} + SbF_3\ (\text{in excess}) \rightarrow \underset{(2)}{(C_2H_5)_2NPF_4} + SbCl_3 + Sb + \textit{by-products}$$

This behavior is unexpected, as the P=N bond in phenyliminodialkylaminophosphorus(v) dichlorides is usually quite inert. Thus, in general, HCl may not be added direct-

[**] This work was supported by the National Science Foundation, Grant GP-28698X.

ly[3] but only by the way of an ammonolysis[4], methyl iodide adds only slowly[5], and hydrolysis to the anilino group[6] also proceeds gradually. However, fluorolytic cleavage of the P=N bond is known for some phosphazo trichlorides: $RN{=}PCl_3$ ($R = F_2OP$[7], $ClSO_2$[8,9], FSO_2[7,10,11], CF_3SO_2[12], perfluoroalkyl-CO[13]).

The procedure described herein for the synthesis of diethylaminotetrafluorophosphorane *(2)* is carried out in three steps from commercially available reagents

$$2\,C_6H_5NH_2 + 2\,PCl_5 \rightarrow (C_6H_5N{=}PCl_3)_2$$

$$(C_6H_5N{=}PCl_3)_2 \rightarrow 2\,C_6H_5N{=}PN(C_2H_5)_2Cl_2 \quad (1)$$

$$2\,C_6H_5N{=}PN(C_2H_5)_2Cl_2 \rightarrow 2\,(C_2H_5)_2NPF_4 \quad (1) \quad (2)$$

This synthesis avoids the unpleasant and expensive utilization of PF_5 as in the case of the silazane cleavage of $(C_2H_5)_2NSi(CH_3)_3$[14] or the thermolytic decomposition of the adduct $(C_2H_5)_2NH \cdot PF_5$[15]. The compound $(C_2H_5)_2NPF_4$ cannot be obtained by fluorination of $(C_2H_5)_2NPCl_2$ with SbF_3[16].

Diethylaminotetrafluorophosphorane (2)

Finely ground SbF_3 (12 g) is added to *(1)* (13.5 g) (exothermic!) and the flask is immediately mounted on a distillation apparatus flushed with nitrogen. Distillation at 100—102 °C/756 torr (lit.[14] = 99—100 °C/760 torr) gives compound *(2)* (5.2 g, 59%) as a clear liquid. NMR spectra[17]: $\tau = 7.07$ (CH_2), 9.00 (CH_3), $J_{HH} = 7.3$ Hz, $J_{PNCH_2} = 2.0$ Hz; $\delta = +68.7$ ppm (P), $\delta = +65.1$ ppm (F), $J_{PF} = 859$ Hz [from ^{31}P-NMR], 853 Hz [from ^{19}F-NMR] (lit.[14,18]: +70.2 ppm, +66.5 ppm; 851, 863 Hz). $SbCl_3$ (3.4 g) is obtained on further distillation at 224—228 °C. The green-black residue contains elemental antimony as well as products which were not further characterized.

P,P-Diphenylethylenediphosphane[**]

By *R. B. King* and *Pramesh N. Kapoor*[*]

This communication reports the preparation of *P,P*-diphenylethylenediphosphane *(4)*, apparently the first known compound incorporating both the primary phosphane and tertiary phosphane functional groups. The synthesis of *(4)* provides the first example of the synthesis of a PCH_2CH_2P unit by the base-catalyzed addition of a phosphorus-hydrogen bond across the carbon-carbon double bond of a vinyl group bonded to a *four-coordinate* phosphorus atom. All previously reported[1,2] syntheses of this kind employed derivatives with vinyl groups bonded to *three-coordinate* phosphorus atoms.

$$H_2C{=}CH{-}\overset{\overset{O}{\|}}{P}(OC_2H_5)_2 + (C_6H_5)_2PH \rightarrow$$
(1) *(2)*

$$\left[(C_6H_5)_2P{-}CH_2{-}CH_2{-}\overset{\overset{O}{\|}}{P}(OC_2H_5)_2\right] \rightarrow$$
(3)

$$(C_6H_5)_2P{-}CH_2{-}CH_2{-}PH_2$$
(4)

$$P(CH_2{-}CH_2{-}P(C_6H_5)_2)_3 \quad (5)$$

A mixture of equimolar quantities of diethyl vinylphosphonate *(1)*[3] and diphenylphosphane *(2)* in tetrahydrofuran solution was boiled under reflux for 20 h in the presence of ≈5% potassium *tert*-butoxide catalyst. After cooling to room temperature the tetrahydrofuran and unreacted starting materials were removed by distillation up to 140 °C/0.8 torr. A non-crystalline viscous pasty residue remained which was presumably the expected adduct *(3)* but could not be purified by either crystallization or vacuum distillation. This residue was dissolved in tetrahydrofuran and reduced with a solution of $LiAlH_4$ in diethyl ether in the usual manner. After the reduction was complete, the reaction mixture was hydrolyzed cautiously with 6 N aqueous hydrochloric acid. The ether layer was separated, dried over anhydrous sodium sulfate, and distilled to give, after removal of the diethyl ether, a 21% yield of colorless very air-sensitive (sometimes pyrophoric) liquid *(4)*, b. p. 151—152 °C/0.5 torr. C, H analysis gave correct values.

The infrared spectrum (liquid film) exhibits a medium intensity ν(PH) frequency at 2294 cm^{-1}. The ^{1}H-NMR spectrum (neat liquid) shows a doublet of triplets ($J \approx 7$ Hz) centered at τ 7.35 arising from the PH_2 group, multiplets

centered at τ 7.87 and $\tau \approx 8.5$ arising from the two non-equivalent CH_2 groups, and multiplets around τ 2.65 and $\tau \approx 2.9$ arising from the phenyl groups. The ^{31}P-NMR spectrum (neat liquid) exhibits a singlet and a triplet ($J = 185$ Hz) arising from the tertiary phosphorus atom and the primary phosphorus atom, respectively, thereby providing unambiguous demonstration of structure *(4)*. The mass spectrum (70 eV) exhibits in addition to the molecular ion (*m/e* 246) the major fragment ions $(C_6H_5)_2PPH_2^{\oplus}$ (*m/e* 218), $(C_6H_5)_2PCH_2CH_2^{\oplus}$ (*m/e* 213), $(C_6H_5)_2PCH_2^{\oplus}$ (*m/e* 199), $(C_6H_5)_2P^{\oplus}$ (*m/e* 185), $C_{12}H_8P^{\oplus}$ (*m/e* 183), and $C_6H_5P^{\oplus}$ (*m/e* 108). Fragmentation processes supported by observed metastable ions include C_2H_4 elimination from the molecular ion and phosphorus elimination from $C_{12}H_8P^{\oplus}$

The compound *(4)* has two phosphorus-hydrogen bonds and thus should undergo base-catalyzed additions to appropriate unsaturated compounds. Reaction of *(4)* with two equivalents of diphenylvinylphosphane for 20 h in boiling tetrahydrofuran in the presence of potassium *tert*-butoxide catalyst gave an 84% yield of the known[1,2] tripod tetratertiary phosphane *(5)*, m.p. 129—130 °C (lit.[2] m.p. 131 °C) identified by its infrared spectrum in the 4000—600 cm^{-1} region. This conversion of *(4)* into *(5)* provides an unambiguous chemical demonstration of the structure of *(4)*.

Similar reaction sequences should be useful for converting $C_6H_5PH_2$ into $C_6H_5P(CH_2CH_2PH_2)_2$ and PH_3 into $P(CH_2CH_2PH_2)_3$. These compounds should in turn open up possible routes to new polytertiary phosphanes with PCH_2CH_2P units which are not accessible by previously developed techniques[1,2]. Unfortunately, the odor of *(4)* was so disagreeable, pervasive, and persistent that we have been forced to suspend our efforts to prepare the presumably still more malodorous derivatives $C_6H_5P(CH_2CH_2PH_2)_2$ and $P(CH_2CH_2PH_2)_3$.

Synthesis and Reactions of 1-Hydroxy-3-azabicyclo[4.1.0]hept-4-en-2-ones[1][**]

By *Walter Ried* and *Friedrich Bätz*[*]

Phenylcyclobutenedione and enamines react to afford substituted 3-hydroxy-2-pyridones *(4)*[2] by way of intermediates whose structure is elucidated below. The 1:1 adducts[2] obtained from phenylcyclobutenedione *(1)* and substituted 3-aminocrotonic esters *(2a)*—*(2c)* in benzene are found to be 1-hydroxy-4-methyl-2-oxo-7-phenyl-3-azabicyclo[4.1.0]hept-4-ene-5-carboxylic esters *(3a)* to *(3c)* of different configurations that are assigned by NMR spectroscopy.

IR spectra (KBr): *(3a)*, ν(OH) and/or ν(NH) = 3480, 3220, 3100, 2980 cm^{-1}, ν(CO) = 1700—1680 cm^{-1} (lactam and α,β-unsaturated ester); *(3b)* and *(3c)*, ν(OH) $\approx$ 3300 cm^{-1}, ν(C=O) = 1720 and ~1650 cm^{-1}. ^{1}H-NMR spectra (cf. Table): *(3a)* (in $CDCl_3$ and [D_6]-DMSO, TMS internal): an AB system with $\tau_A = 7.09$ and $\tau_B = 8.01$ ppm ($J_{AB} = 6.3$ Hz) occurs as well as the expected signals; *(3b)* (in $CDCl_3$ with a somewhat larger amount of hexamethyldisiloxane (HMDSO) as standard) gives a weakly split AB system (2H) ($J_{AB} = 10.2$ Hz); *(3c)* (in $CDCl_3$ against TMS) gives a weakly split AB system around $\tau_{AB} = 6.82$ ppm ($\tau_A = 6.76$, $\tau_B = 6.88$ ppm, calculated values), ($J_{AB} = 10.2$ Hz).

(a), R = H; *(b)*, R = CH_3; *(c)*, R = C_6H_5

The configurations can be determined from the coupling constants. According to these, *(3a)* exists as *(3a$_2$)* ($J_{trans} = 5$—7 Hz[3]), *(3b)* and *(3c)* exist as *(3b$_1$)* and *(3c$_1$)*, respectively ($J_{cis} = 9$—11 Hz[3]). (*cis* and *trans* refer to the arrangement of the H atoms on the cyclopropane ring.)

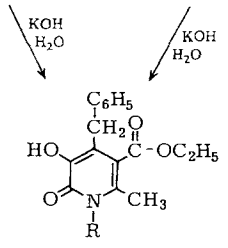
(3b$_2$) can be isolated as well as *(3a$_2$)*, *(3b$_1$)*, and *(3c$_1$)*. It can be obtained in about 2% yield from the mother liquor from the batch of *(3b$_1$)* by chromatographic separation on silica gel with methylene chloride as eluant. *(3b$_2$)* is obtained in *ca.* 25% yield if the reaction of *(1)* with *(2b)* is effected in dioxane saturated with dry HCl.

Comparison of the ^{1}H-NMR spectra of *(3a$_2$)*, *(3b$_2$)*, and *(3b$_1$)* can be regarded as further proof of the structures assigned (cf. Table). For *(3a$_2$)* the signal e' for the *endo*-proton appears at relatively high field strength because of ring current effects (cf. the ^{1}H-NMR spectrum of 2,5-diphenyl-3,4-diazanorcaradiene[4]). The signals e and e' of

Table. Comparison of the ^{1}H-NMR spectra of *(3a$_2$)*, *(3b$_2$)*, and *(3b$_1$)* (τ values in ppm against TMS).

Signal	*(3a$_2$)*	*(3b$_2$)*	*(3b$_1$)*	Number of H	Assignment
a	2.6–2.85	2.6–2.9	2.65–3.15	5	C_6H_5
b	3.59	6.45	4.29	1	OH
c	5.82	5.79	5.68	2	O—CH_2—CH_3
d	—	6.75	7.26	3	N—CH_3
e	7.09	6.84	6.85	1	CH—CH—C_6H_5
f	7.74	7.53	8.00	3	C—CH_3
e'	8.01	8.04	6.85	1	CH—CH—C_6H_5
g	8.72	8.69	8.62	3	O—CH_2—CH_3

(3a$_2$) and *(3b$_2$)* appear at approximately equal field strength. However, with *(3b$_1$)* the signals assigned to the C_{ring}-CH_3 and N—CH_3 group, respectively, are shifted by ring current effects from the corresponding signals of *(3b$_2$)*.



If treated with aqueous alkali hydroxides, the compounds *(3a$_2$)*, *(3b$_2$)*, *(3b$_1$)*, and *(3c$_1$)* rearrange to the substituted

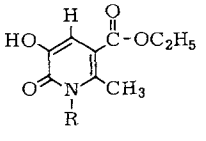
[**] Reactions of Cyclobutenediones, Part 22.—Part 21: *W. Ried* and *H. Kohl*, Chem. Ber., in press.

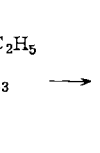
3-hydroxy-2-pyridones *(4)*[2]. Formation of the compounds *(4)* from the bicyclics *(3)* may occur analogously to the base-catalyzed ring opening of cyclopropanols[5].



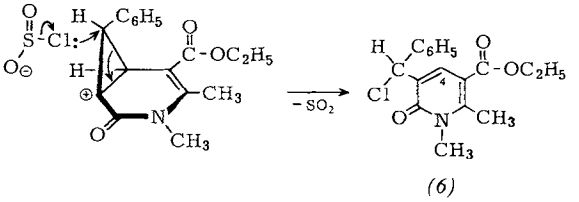
(3b₁), (3c₁) *(3a₂), (3b₂)*

(4a)-(4c)

On catalytic hydrogenation in presence of platinum, *(3b₁)* and *(3c₁)* absorb 4 molar proportions of hydrogen, affording 3-hydroxy-2-pyridones *(5b)* and *(5c)*, respectively; *(5b)*, m.p. 162—163 °C, yield ≈50%; *(5c)*, m.p. 184 to 185 °C, yield ≈40%. The NMR spectra, as well as the C=O stretching vibration bands at 1650 cm^{-1} (2-pyridone[6, 7]) serve as structural proof for *(4b)* and *(4c)*.



(3b₁) *(3c₁)* $\xrightarrow[[-C_7H_{14}]]{4\ H_2}$



(5b), (5c)

Treating *(3b₁)* with thionyl chloride affords 3-(α-chlorobenzyl)-5-(ethoxycarbonyl)-1,6-dimethyl-2-pyridone *(6)*, whose formation may be explained as due to an S_Ni' type attack by the thionyl chloride. Conversion of similar bicyclics into 2-pyridones has been described[8].

(3b₁) $\xrightarrow[-HCl]{SOCl_2}$

(6)

The C=O stretching vibration band at 1640 cm^{-1} in the IR spectrum of *(6)* can be assigned to the 2-pyridone portion[6, 7]. The ^{1}H-NMR signal at $\tau = 1.96$ ppm (H-4) appears at low field, as does the corresponding signal of 3-benzyl-5-(ethoxycarbonyl)-1-methyl-6-phenyl-2-pyridone[9] because of anisotropy effects of the benzene nucleus and the ester-carbonyl group ($\tau = 2.15$ ppm).

Ethyl 1-hydroxy-3,4-dimethyl-2-oxo-7-phenyl-3-azabicyclo-[4.1.0]hept-4-ene-5-carboxylate (3b₂)

Gaseous HCl is passed to saturation into a solution of *(1)* (1.58 g, 0.01 mol) in dry dioxane (about 80 ml). After addition of *(2b)* (2.2 g, 0.15 mol), the mixture is stirred at 20 °C for 7 h, the hydrochloride formed is filtered off, and the solvent is removed in a rotary evaporator. By chromatographic separation on silica gel (Woelm 0.05—0.2 mm) with benzene/ethyl acetate (3:1) as eluant first a fore-fraction is obtained and then a fraction from which *(3b₂)* crystallizes on removal of the solvent; recrystallization from benzene/cyclohexane gives a *ca.* 25% yield of material, m.p. 128—129 °C.

Reaction of Diphenylcyclobutenedione with Diazomethane[**]

By *Walter Ried, Walter Kuhn*, and *Arthur H. Schmidt*[*]

Reaction of diazoalkanes with small unsaturated carbocycles (cyclopropenes[3], cyclobutenes[4]) has been studied

[*] Prof. Dr. W. Ried, Dipl.-Chem. W. Kuhn [1], and Dr. A. H. Schmidt [2]
Institut für Organische Chemie der Universität
6 Frankfurt (Main), Robert-Mayer-Strasse 7—9 (Germany)

[**] Reactions of Cyclobutenediones, Part 23.—Part 22: *W. Ried* and *F. Bätz*, Angew. Chem. *83*, 763 (1971); Angew. Chem. internat. Edit. *10*, 735 (1971).

previously in detail, but nothing has so far been reported about the action of diazoalkanes on cyclobutenediones.

On reaction of diphenylcyclobutenedione *(1)* with an excess of diazomethane we obtained almost equal yields of 3a,6a-dihydro-4-methoxy-3a,6a-diphenylcyclopentapyrazol-6(3*H*)-one *(2)* and 2-methoxy-1,5-diphenylbicyclo-[3.1.0]hex-2-en-4-one *(3)*, which can be separated by virtue of their differing solubilities in CCl_4. The properties of the new compounds are reported in the annexed Table.

observed, and since the reaction of cyclones with diazomethane requires an extremely long time[8], we exclude any reaction mechanism by way of a cyclone. Comparison with the reaction of diazomethane with 2,4,5-triphenyl-4-cyclopentene-1,3-dione[9], which leads immediately to 3-methoxy-2,4,5-triphenylcyclopentadien-1-one, shows that a cyclopentenedione also does not occur as intermediate. We thus assume that in the reaction described above a 1,3-dipolar addition of the diazomethane to the double bond of the cyclobutenedione first occurs and only

Table. Some properties of compounds *(2)*—*(7)*. Satisfactory elemental analyses and UV and mass spectra have been obtained.

(5)	99–100 (CH_3OH)	2960, 2930, 2840, 900 (CH) 1610, 1580 (CC)	2.5–2.8 (10H/m) 3.48 (1H/s) 2.9 (1H/s) 6.26 (6H/s)	100 MHz $CDCl_3$
(6)	220–222 (dec) (CH_3OH)	3280 (NH) 2940, 2840 (CH) 1700 (CO) 1600 (CC)	2.77 (1H/s, D_2O-exchange) 2.9–3.45 (10H/m) 3.49 (1H/s) 4.18 (1H/s) 6.16 (3H/s)	100 MHz [D_6]-Acetone
(7)	229–231 (Benzene/ Cyclohexane)	2980, 2950, 2860 (CH) 1705, 1690 (CO) 1600 (CC)	2.8–3.6 (11H/m) 4.14 (1H/s) 6.06 (3H/s) 7.62 (3H/s)	60 MHz $CDCl_3$

When boiled in toluene, *(2)* loses nitrogen, passing into *(3)*, which rearranges into 6'-methoxy-*m*-terphenyl-4'-ol *(4)* on 12 hours' heating in xylene.

Methylation of *(4)* by dimethyl sulfate affords 4',6'-dimethoxy-*m*-terphenyl *(5)*[5], whose ^{1}H-NMR spectrum proves the positions of the substituents in *(5)* and *(4)*: the methoxy groups give a singlet (τ = 6.26), the proton in *o*-position thereto appears at τ = 3.48[6], and the *m*-proton appears at τ = 2.9. These two protons do not couple with each other, which indicates their *para* relation[6].

The pyrazoline derivative *(2)*, which also gives *(4)* on fairly long heating in xylene, isomerizes in a known manner[7] to 3a,6a-dihydro-4-methoxy-3a,6a-diphenylcyclopentapyrazol-6(1*H*)-one *(6)* when boiled in glacial acetic acid or methanol and also on chromatography on silica gel.

The pyrazolines *(2)* and *(6)* react with acetyl chloride to afford the 1-acetyl derivative *(7)*.

(2) and *(3)* are formed as soon as the components are brought together. Since the change of the yellow reaction solution to the violet color characteristic of cyclones is not

then is a CH_2 group inserted between the carbonyl groups. Enolization and methylation complete the reaction.

The exclusive formation of *(2)* accords with observations on the reaction of tetraphenylcyclone with diazomethane[8] and points to the differing stabilities of the two possible 1-pyrazolines.

An ESR Study of the Oxidation of Triethyl Phosphite by *tert*-Butoxy Radicals

By *Alwyn G. Davies, D. Griller*, and *B. P. Roberts*[*]

The radical reactions of phosphorus compounds are of considerable interest[1].

If di-*tert*-butyl peroxide Bu^tOOBu^t is photolyzed in the presence of a trialkylphosphane (R_3P with $R=CH_3$, C_2H_5, $(CH_3)_2CH$, $(CH_3)_2CH—CH_2$ or cyclo-C_6H_{11}), the *tert*-butoxyl radical brings about an S_H2 reaction at the phosphorus centre, and the displaced radical R· can be observed by ESR spectroscopy. When R = Me, the spectrum of the intermediate phosphoranyl radical *(1)*, $a_P = 618$ G is also apparent[2].

$$Bu^tO\cdot + PR_3 \rightarrow \underset{(1)}{Bu^tO\dot{P}R_3} \rightarrow Bu^tOPR_2 + R\cdot \qquad (1)$$

Under the same conditions, trialkyl phosphites [$(RO)_3P$ with $R=CH_3$, C_2H_5 or $(CH_3)_2CH$] were reported to show only the spectrum of the *tert*-butyl radical, and no intermediate phosphoranyl radical *(2)*[3] was detected[2].

$$Bu^tO\cdot + P(OR)_3 \rightleftharpoons \underset{(2)}{Bu^tO\dot{P}(OR)_3} \xrightarrow{k_2'} Bu^t\cdot + OP(OR)_3 \qquad (2)$$

We have studied the photolysis of di-*tert*-butyl peroxide in the presence of triethyl phosphite in cyclopentane, and have observed the ESR spectrum of both the phosphoranyl radical *(2)*, $R=C_2H_5$, and the *tert*-butyl radical; in dilute solutions, the spectrum of the cyclopentyl radical, which is formed in reaction (3), was also apparent.

$$Bu^tO\cdot + C_5H_{10} \xrightarrow{k_3} Bu^tOH + C_5H_9\cdot \qquad (3)$$

By monitoring the concentrations of these three radicals, Arrhenius parameters have been obtained for the overall reaction (2), and for the breakdown of the intermediate phosphoranyl radical.

The spectrum obtained by photolyzing a solution of di-*tert*-butyl peroxide (1.1 M) and triethyl phosphite (1.2 M) in cyclopentane at −85 °C in the cavity of an ESR spectrometer is shown in Figure 1[4]. The phosphorus-centered radical ($a_P = 891$ G, $g = 2.008$), to which we assign the structure *(2)*, $R=C_2H_5$, [**] shows no resolvable fine structure. Radical concentrations were measured against a ruby which was fixed in the ESR cavity[5].

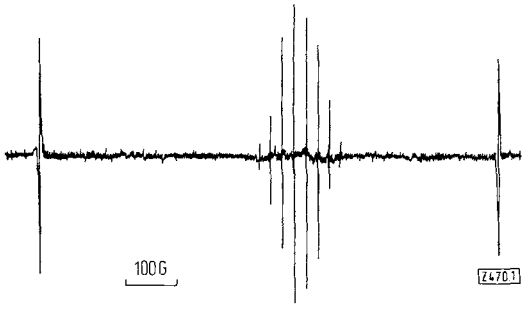

Fig. 1. ESR spectrum from irradiation of di-*tert*-butyl peroxide and triethyl phosphite in cyclopentane at −85 °C with UV light. Spectral parameters in the text have been corrected by the Breit-Rabi formula.

[*] Prof. A. G. Davies, D. Griller, and Dr. B. P. Roberts, Chemistry Department, University College London, 20 Gordon Street, London WC1H OAJ (England).

[**] The radical $Bu^t\dot{P}(OC_2H_5)_3$ is excluded because photolysis of 2,2′-azoisobutane in the presence of triethyl phosphite gave only the spectrum of the *tert*-butyl radical.

The rate constant (k_2) for the overall reaction (2) was determined relative to k_3 by the method we have recently described[6, 7], by measuring the relative concentrations of the *tert*-butyl and cyclopentyl radicals formed from dilute solutions of triethyl phosphite (0.07 M) in cyclopentane containing di-*tert* butyl peroxide (1.1 M). An Arrhenius plot of the results gives

$$k_2/k_3 = (0.83 \pm 0.01)\exp(2960 \pm 180)/RT$$

At 130 °C $k_2/k_3 = 190$. This is to be compared with a value of about 600 which can be estimated from Walling and Pearson's analysis of the products from the thermal decomposition of di-*tert*-butyl peroxide in a mixture of triethyl phosphite and cyclohexane[8].

If the value of k_3 is taken to be[7]

$$k_3 = 1.0 \times 10^9 \exp(-5200/RT)\ \mathrm{l\,mol^{-1}\,s^{-1}}$$

we derive

$$k_2 = 6.7 \times 10^9 \exp(-2240/RT)\ \mathrm{l\,mol^{-1}\,s^{-1}}$$

and

$$k_2(30°) = 1.6 \times 10^8\ \mathrm{l\,mol^{-1}\,s^{-1}}$$

Thus although the reaction proceeds through an intermediate complex, it is one of the fastest bimolecular radical-molecule reactions which are known.

By the steady state approximation,

$$k_2' = [Bu^t\cdot]/[(2)]\{2k_t[Bu^t\cdot] + 2k_t'[(2)] + 2k_t''[Bu^tO\cdot]\}\ \mathrm{s^{-1}}$$

where the last three terms refer to the removal of *tert*-butyl radicals by their reactions with the radicals $Bu^t\cdot$, *(2)*, and $Bu^tO\cdot$ respectively. The last term can be neglected because the value of $[Bu^tO\cdot]$ is very small.

There is as yet no information on the rate of the reaction of phosphoranyl radicals *(2)* with alkyl radicals[9][***], and

[***] It should be possible to evaluate this term by experiments at different light intensities and by monitoring the decay of the ESR signals by the CAT technique [10].

the second of these three terms might be similar in magnitude to the first[11]. If this second term is neglected, the reduced expression

$$k_2' = 2k_t[Bu^t]^2/[(2)]\ s^{-1}$$

gives an excellent Arrhenius plot which would correspond to

$$k_2' = (2.40 \pm 0.06) \times 10^{13} \exp(-9340 \pm 230)/RT\,s^{-1}$$

setting a lower limit to the value of k_2' at 30 °C of $4.4 \times 10^6\ s^{-1}$.

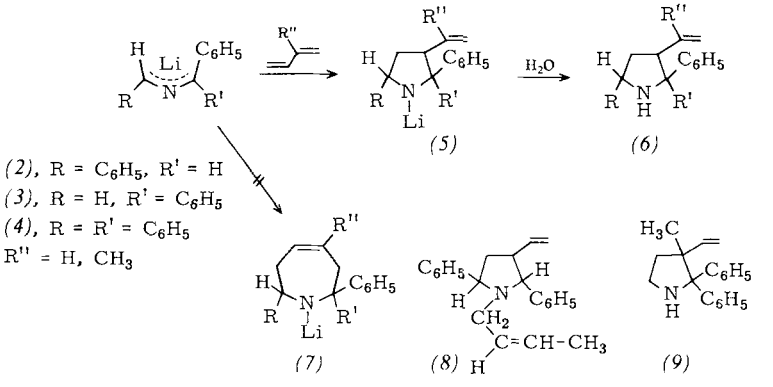
[1,3]-Anionic Cycloaddition of 2-Azaallyllithium Compounds to Dienes[1][**]

By *Thomas Kauffmann* and *Rudolf Eidenschink*[*]

2-Azaallyllithium compounds undergo cycloaddition in preparatively useful yields to CC[2], CN[3], and NN double bonds[3] as well as to CC and CN triple bonds[4] with formation of five-membered heterocycles. Analogous reactions have been observed for a 2-azaallylsodium[5], 2-azaallylpotassium[5], and 1,2-diazaallyllithium compound[6]. We propose the term [1,3]-anionic cycloaddition for this type of reaction, of which the first stage of the Baeyer test leading to *(1)* can be regarded as the oldest example[7].

As expected, 1,3-dienes can also act as [1,3]-anionophiles[8]: By reaction (conditions: [9]) of equimolar amounts of the three 2-azaallyllithium compounds *(2)*[2], *(3)*[2], and

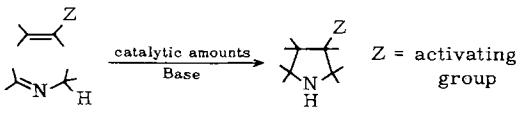


(1)

(4)[10] with butadiene or 2-methylbutadiene in THF/*n*-hexane (*ca.* 9:1) the pyrrolidines *(6)* listed in the Table were obtained *via* the cycloadducts *(5)*.

In the first experiment in the Table the yield of pyrrolidine of type *(6)* was decreased by further reaction of the cycloadduct to give the alkenylated product *(8)* (47%; *cis*- and *trans*-configuration of the *n*-butenyl group). In the fourth experiment the yield is decreased because cycloaddition of the 2-azaallyllithium compound to the electron-richer CC double bond of the 2-methylbutadiene leads to 3-methyl-2,2-diphenyl-3-vinylpyrrolidine *(9)* (13%) as well as to 3-(1-methylvinyl)-2,2-diphenylpyrrolidine [type *(6)*].

The structures of the new pyrrolidines obtained, which are oils whose yields are recorded in the Table, were proved by analyses and spectra (MS, NMR, IR), but the configuration of the substituents on the pyrrolidine ring is as yet uncertain. None of these products showed any sign of resolution into stereoisomers on gas chromatography, and the NMR spectra indicate sterically homogenous products. So the cycloadditions apparently occur stereospecifically. This and the non-appearance of seven-membered cycloadducts *(7)* signify a synchronous $[_\pi 4 + _\pi 4]$ process.



No.	2-Azaallyl-Li cpd.	Diene	Pyrrolidine deriv. *(6)*	Yield (%)	Salt	m.p. (°C)
1	*(2)*	1,3-Butadiene	2,5-Diphenyl-3-vinyl	36	Picrate	155
2	*(2)*	2-Methyl-1,3-butadiene	3-(1-Methylvinyl)-2,5-diphenyl	92	Picrolonate	234
3	*(3)*	1,3-Butadiene	2,2-Diphenyl-3-vinyl	91	Picrate	231
4	*(3)*	2-Methyl-1,3-butadiene	3-(1-Methylvinyl)-2,2-diphenyl	35	Picrate	171
5	*(4)*	1,3-Butadiene	2,2,5-Triphenyl-3-vinyl	35	Picrate	111

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The pyrrolidine *(6)* obtained in experiment 2 could be prepared, in 90% yield, also by treatment of one mol of the azomethine *N*-benzylidenebenzylamine in THF at 20°C with one mol of 2-methylbutadiene and a catalytic amount (0.05 mol) of lithium pyrrolidide. Apparently the lithium pyrrolidide formed in the addition process is able to metalate the azomethine smoothly. This base-catalyzed union of an azomethine *(10)* and an alkene, which is presumably not restricted to the special system discussed here, may lead to an industrially interesting process.

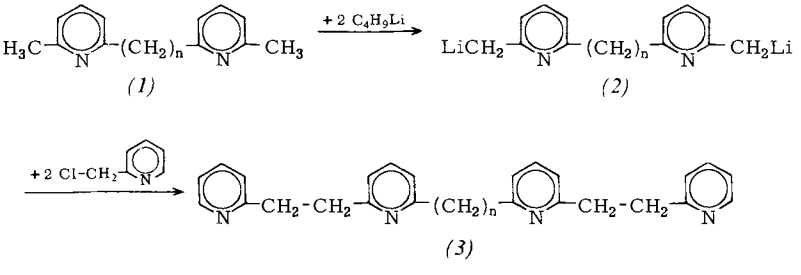
[9] The diene was always added at −65°C to a solution of the 2-azaallyllithium compound prepared at that temperature from the azomethine and lithium diisopropylamide, then warmed to 22°C. In experiment 5 only, the temperature was raised to 66°C.



[10] Preparation from *N*-benzylidene(diphenylmethyl)amine by treatment with lithium diisopropylamide in THF at −65°C (at this temperature only *ca.* 20% metalation).

has been introduced for cyclically bridged arenes[3], we propose the name protophanes (πρῶτος = first) for the open-chain (unbranched or branched) compounds. This usage, which is in line with the occurrence of protophanes as precursors in the synthesis of cyclic phanes, should not be applied to simple molecules such as 1,4-diethylbenzene or 1,2-di-(2-pyridyl)ethane, but should be restricted to molecules containing at least three arene units (= single rings or fused arene systems) separated by aliphatic groups.

Syntheses of protophanes containing three or four pyridine rings linked by ethylene bridges[2] has been possible because *(1)*, $n=2$, is metalated selectively at the methyl groups by *n*-butyllithium in THF at −70°C. Corresponding metalation of *(1)*, $n=3$, 5, 6, 8, has now been carried out (CH_3/CH_2 metalation = 95—100/5—0; total metalation 91—98%) and has been used for synthesis of protophanes: the dilithium compounds *(2)* obtained from *(1)*, $n=3$, 5, 6, 8[8] and 2 mol of *n*-butyllithium react with 2-(chloromethyl)pyridine in THF to afford the tetranuclear compounds *(3)*.

The monolithium compounds *(4)* obtained from *(1)*, $n=3$, 5, 6, 8, and one mol of *n*-butyllithium afford the tetranuclear protophanes *(5)* on treatment with CuCl. Compounds *(5)* are obtained also, but in somewhat lower yield, on reaction of compounds *(4)* with 1,2-dibromoethane. In these cases the hexanuclear protophanes *(6)* could also be isolated from the reaction mixtures, being formed from two molecules of the monolithium compound *(4)* and one molecule of the dilithium compound *(2)* which are in equilibrium with the unmetalated compound *(1)* in THF.

The protophanes mentioned were separated from higher-molecular by-products and cyclic phanes by column chromatography (Brockmann Al_2O_3, activity II—III), and their structures were proved by elemental analyses, molecular-weight determinations, and spectroscopy (NMR, MS). The Table sets out the reaction conditions, the yields, and the astonishingly sharp melting points.

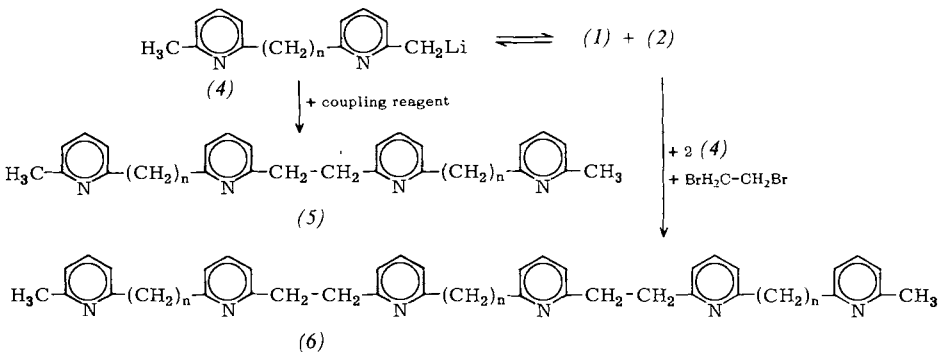
Pyridinoprotophanes with Alkylene Segments of Various Lengths[1][**]

By *Thomas Kauffmann, Gerhard Beissner,* and *Rüdiger Maibaum*[*]

Open chain bridged arenes such as *(3)*, *(5)*, and *(6)* and cyclically bridged arenes (= cyclophanes, phanes[3]) are related to one another in the same way as alkanes to cycloalkanes. It would therefore have been better to retain the name phanes for open-chain members and to name the cyclic ones all as cyclophanes. Since, however, "phane"



[*] Prof. Dr. Th. Kauffmann, Dipl.-Chem. G. Beissner, and R. Maibaum

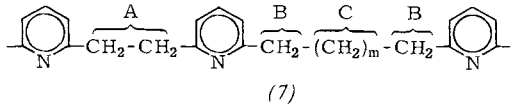
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The NMR spectra show in each case only three types of methylene proton, namely, for types *(3)* and *(5)/(6)*, respectively, in accord with representation *(7)*, H_A at $\tau=6.75$—6.90 or 6.78—6.90, H_B at $\tau=6.90$—7.39 or 6.90—7.46, H_C at $\tau=7.52$—8.84 or 7.56—9.18. Contrary to the case with protophanes of types *(5)* and *(6)* with $n=2$[9], here there is no resolution of the signals for methylene protons of the non-peripheral ethylene bridges.

IUPAC nomenclature is in practice inapplicable to complicated protophanes such as *(6)*. Such compounds can, however, be named easily and unambiguously if they are treated as alkanes in which individual carbon atoms have been replaced by arene rings or fused arene rings (*e.g.*, quinoline). The arene units could be denoted as phena (benzene), pyrida (pyridine), thiena (thiophene), *etc.* The ending "a" denotes a special nomenclature, so that there



would be no need for a particular class term (*e.g.*, phane) at the end of the name. Side chains of the "parent hydrocarbon" (considered to be the longest C chain), when containing arene rings, could be named analogously. The nomenclature described here only in principle[10] has a ter would have been [15](1.4)benzenocyclophane and [12](1.5)naphthalenocyclophane). *Vögtle* and *Neumann* [7] defined phanes in general as cyclically bridged arenes and would like to have cyclopolyarenes included in that class although they do not have the characteristic juxtaposition of aromatic ("ph" in phan) and aliphatic units ("an" in phan) and thus possess totally different chemical properties.

Protophanes Type	n	Yield (%)	M. p. (°C)	Reaction conditions
(3)	3	35—38	88	1. *(1)* +2 mol of *n*-BuLi in THF [a] at −70°C (30 min)

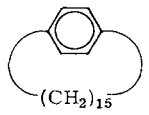
valued precursor in *Stelzner*'s a-nomenclature (*e.g.*, quinoline = 1-azanaphthalene) and would afford, *e.g.*, 1,12-di(2)-pyrida-4,9-di(2,6)pyrida-dodecane as the name for *(3)*, $n=4$.



Particularly valuable is that a few further rules would enable cyclic phanes and polyarenes to be named analogously.

Organometallic Syntheses of Thiophene-Pyridine Combinations[1][**]

By *Thomas Kauffmann, Ekkehard Wienhöfer*, and *Annegret Woltermann*[*]

Arene rings can be contained in fused systems (type A ring systems), linked directly by single bonds (type B ring combinations, IUPAC ring assemblies[3], polyarenes[4]), or bridged by means of atoms not belonging to the arene rings (type C, cf. Ref. [2]).

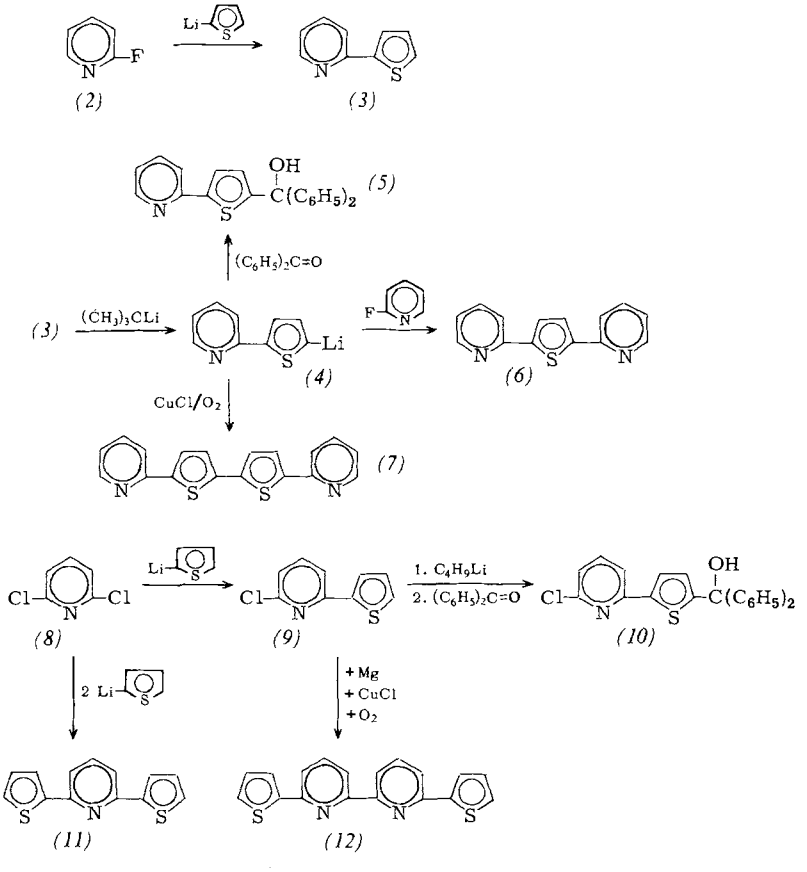
Ar—Ar—Ar Ar—(C)$_n$—Ar—(C)$_m$—Ar

B C



Whereas type A has been intensively studied, little is known about compounds of types B and C. This is surprising, particularly for type B; it should be extremely interesting to discover to what extent the arene systems of various structures (*i.e.* the cyclic atomic groups of organic chemistry distinguished by particularly low energy contents) can be connected in accordance with B to form longer unbranched or branched chains and into rings with various chain and ring members; and here it is noteworthy that polyarenes consisting homogeneously of benzene rings, pyridine rings (maximally 6[7]), or thiophene rings (maximally 7[8]) are thermally very stable.

(1)

We have first synthesized compounds of type B in which the possibility of mesomerism *(1)* should lead to a certain amount of exchange between π-electron-rich and π-electron-deficient nuclei and thus to alteration in the reactivities of the nuclei. (By π-electron rich we mean a system having an *excess* of π-electrons at the C atoms.)

Of the various ring combinations *(1)* in which X = O, S, or NCH_3, apparently only the thiophene derivative *(3)* (yield <4%[9]) is known. We were able to prepare this compound in 48% yield by treating 2-lithiothiophene *(2)* with one mol of 2-fluoropyridine. The chloro compound *(9)* was formed analogously from 2,6-dichloropyridine. These two biarenes were not attacked in the pyridine ring by *n*- or *tert*-butyllithium, but were metalated almost exclusively at the α-position of the thiophene ring[10]. Reaction of the lithium compound *(4)* obtained in this way with benzophenone gave the alcohol *(5)*, with 2-fluoropyridine gave the trisarene *(6)*, and with $CuCl/O_2$ gave the tetrakisarene *(7)*. Analogously the lithium compound

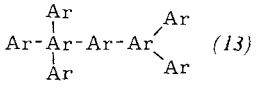
[f] B.p. 112—114°C/0.1 torr.

obtained from *(9)* gave, on reaction with benzophenone, the alcohol *(10)*. Treatment of *(8)* with an excess of 2-lithiothiophene leads to the trisarene *(11)*, while the action of a magnesium/CuCl mixture followed by O_2 on *(9)* gave the tetrakisarene *(12)* that is isomeric with *(7)*.

The Table records the reaction conditions, yields, and properties of the compounds prepared; their structures appear to be proved by elemental analyses, mass and NMR spectra, and the methods of preparation. None of the compounds in the Table has been reported before with the exception of *(3)*.

From the mass spectra of the tetrakisarenes *(7)* and *(12)* it follows that the bond between one pyridine and one thiophene nucleus is approximately the same strength as that between two pyridine or between two thiophene rings. This is to be expected since, like polyarenes built homogeneously from thiophene or pyridine rings[7,8], long-chain "mixed" polyarenes are also thermally very stable.



Received: July 5, 1971 [Z 473c IE]

[1] *Protophanes and Polyarenes*, Part 3. — Part 2: [2].

[2] *Th. Kauffmann, G. Beissner*, and *R. Maibaum*, Angew. Chem. *83*, 795 (1971); Angew. Chem. internat. Edit. *10*, 740 (1971).

[3] To differentiate them from ring systems (condensed) and to draw attention to the enormous possibilities of combination (*e.g.*, 81 combinations of one pyridine and two imidazole rings), we describe as ring combinations those molecules in which a small number of aromatic or non-aromatic rings are joined by single bonds.

[4] The nomenclature of polyarenes is unsatisfactory; if individual names [5, 6] are generalized, open-chain polyarenes are denoted as polyaryls or polyarenes, but cyclic ones as polyarylenes. "Polyarenes" appears to us the better designation for the open-chain compounds with more than two arene rings, since only this is neutral with regard to the bonding state of the arene ring; this can be very variable, as shown by *(13)* with 1-, 2-, 3-, and 4-bonded arene nuclei. Macrocycles whose ring members consist only of arene nuclei should be called cyclopolyarenes.

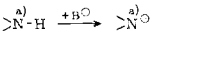
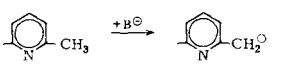
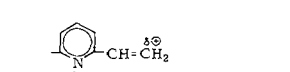
By *Thomas Kauffmann*[*]

Dedicated to Professor Adrien Albert







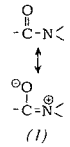
The extremely valuable division of arenes containing a hetero atom into π-electron-deficient and π-electron-rich arenes is due to *Albert*[3]. *Staab*[4] recognized that compounds with high acyl halide activity (azolides) are obtained by replacing the halogen of acyl halides by an azole group as in *(3)* of Table 2. We develop below a principle of wider application, whose value became apparent in studies of protophanes[5-7] and polyarenes[2,8].

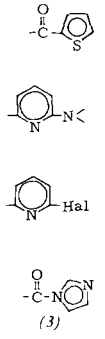
The Arenology Principle: Organic chemistry deals, not only with the classical functional groups, but also with a second set of functional groups consisting of the heterocyclic arene (heteroaromatic) nuclei. The latter are arene-analogous (arenologous) to the classical functional groups since they can fullfil analogous functions: they undergo analogous reactions (sometimes only under activation by strong bases[9]) and make it possible for attached groups to undergo analogous reactions (Table 1).

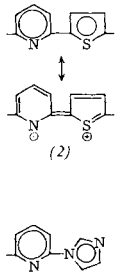
π-Electron-rich arenes (furan, thiophene, 1-methylpyrrole, *etc.*[10]) are comparable with functional *groups that have* $+M$ *and* $-I$ *effect*, and mobile hydrogen (—OH, —SH, $—NH_2$, *etc.*); π-electron-deficient arenes (pyridine, pyrimidine, *s*-triazine, *etc.*) are comparable with functional *groups with* $—M$ *and* $—I$ *effect* (C=O, >C=N—, —C≡N, *etc.*). Azoles containing more than one N atom bound by way of an N atom correspond to halogen and other good negative leaving groups.

Whilst the parallel with regard to the polarization of attached groups has been recognized, insufficient attention has been paid to the fact that other properties of certain heterocyclic arenes indicate their possible use as functional ("arenofunctional") groups. If this were not so, it would be unintelligible why no attempt has been made to make specifically arenologous[11] models of elementary or particularly useful organic structures such as acid amides, acid halides, di- and poly-carbonyl compounds, di- and poly-amines, Nylon, Perlon, *etc.*, or to carry out fundamental reactions such as esterification or the Claisen condensation *systematically with arenofunctional groups* (our attempts in this direction: [2,5-8]).

Table 1. Characterization of the functions of functional groups by examples. a) nucleophilic activity; b) electrophilic activity; c) X = good negative leaving group; d) Y = H or good negative leaving group.







Functional group	Arenofunctional group

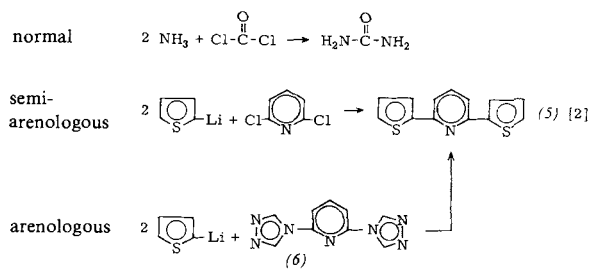
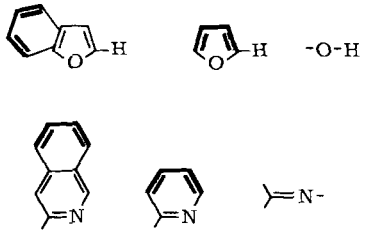
There are compound as well as simple functional groups, and from the former are derived semiarenologous and arenologous groups (Table 2). Although many semiarenologous groups are known and, in the case of the azolides [*(3)* of Table 2], are recognized as having functional activity, the arenologous type is as good as uninvestigated (cf. [2, 8]).

Table 2. Examples of compound functional groups and arenologs.

Normal	Semiarenologous	Arenologous
 *(1)*	 *(3)*	 *(2)*



The bond energy between the arenofunctional groups in *(2)* (the CC bond) is probably higher (cf. Ref. [2]) than that between the functional groups of the acid amide group *(1)*, and this could be advantageous for arenologous Nylon [*e.g. (4)*] and Perlon types, whose synthesis is therefore being studied[7].



(4)

The chemical reactions that functional groups undergo can be divided into three types (Table 3). So far only the synthesis of "arenologous urea" *(5)* from 2,6-dichloropyridine has been carried out[2], but as yet not that starting from *(6)*.

Table 3. Urea syntheses as example of the application of the arenology principle to reactions.

The arenofunctional groups mentioned above are monocyclic 6π-electron systems. It is apparent that corresponding bicyclic 10π- (*e.g.* quinoline, cf. Ref. [8]) or tricyclic 14π-electron systems could fullfil analogous functions. The relationship between 6π-arenofunctional and normal functional groups is similar to that between 14π-, 10π-, and 6π-arenofunctional groups.

Organometallic Syntheses of Thiophene-Quinoline Combinations[1][**]

By *Thomas Kauffmann, Jörg Jackisch, Hans-Joachim Streitberger*, and *Ekkehard Wienhöfer*[*]

Interaction of 2-thienylmagnesium iodide and pyridine in xylene at 130 °C gives 2- and 4-(2-thienyl)pyridine (together 4%[3]), but treatment with 2-thienylmagnesium bromide in ether at 35 °C (10%)[4] or with 2-lithiothiophene in THF at 60 °C (5%)[5] affords only the 4-isomer, for which chelate formation in the 2-adduct *(1)* is held responsible.

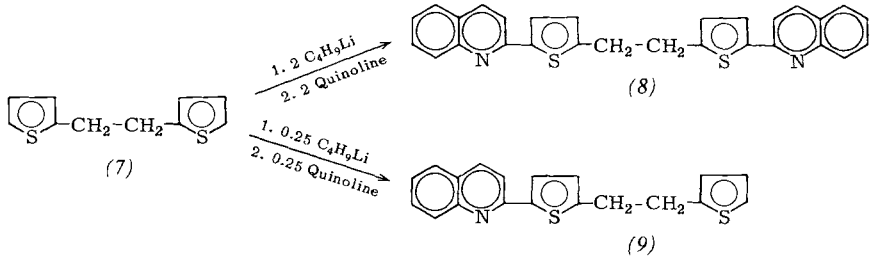
[9] Strong Lewis acids presumably can be used for activation in several cases.

[10] This order is not intended to state that the two types of functional groups correspond best when the heteroatoms correspond.



[11] In the sense of column 3 of Table 2, *i.e.* not semiarenologous.

[12] The pyridine nucleus reacts with nucleophiles analogously to a carbonyl group with good negative leaving groups. Only with bad negative leaving groups (aldehydes, ketones) does the carbonyl group behave differently (addition instead of substitution).

However, treating 2-lithiothiophene with quinoline at 20 °C by *Gilman*'s method[6] leads only to 2-(2-thienyl)quinoline *(2)* (38%), indicating steric hindrance of 4-addition by the *peri*-hydrogen atom of the quinoline. In the following reactions of the quinoline system with 2-lithiothiophene derivatives substitution is also only at the 2-position.

The yield of 2-(2-thienyl)quinoline *(2)* could be raised to 75% by causing the components to react at 45 °C [2 h in ether/*n*-hexane (2:1)], the 2-position of the thienyl group being provided by an analogous synthesis from 2-chloroquinoline instead of quinoline and by NMR spectroscopy. The lithium compound[6] obtained therefrom by *n*-butyllithium [yield 33% on the basis of the yield of alcohol (m. p. 221 °C) resulting from treatment with benzophenone] reacts with quinoline to give the trisarene *(3)* and with $CuCl_2$ to give the tetrakisarene *(4)*. As shown in the formula scheme and Table, compound *(4)* was accessible in higher yield by reaction of 2,2'-bithiophene and 2 mol of *n*-butyllithium with subsequent treatment with quinoline. The analogous reaction with one mol of the two reagents gave the trisarene *(6)* as main product.

Analogous methods afford compounds *(8)* and *(9)* which are homologs of *(4)* and *(6)* and of interest as starting materials for protophane syntheses[7]. Their preparation is possible because 1,2-di-(2-thienyl)ethane *(7)* (an "arenologous diamine", cf. Ref. [2]) is metalated by *n*-butyllithium in ether/*n*-hexane (9:1) only in the thiophene rings and not on the aliphatic bridge. The yield of *(8)* is considerably better than that of *(9)* since the monolithium derivative from *(7)* is in equilibrium with the dilithium compound and the unmetalated compound.

The Table records the reaction conditions, yields, and properties of the apparently new compounds prepared, their structures being proved by elemental analyses, mass and NMR spectra, and the method of their preparation.

Reaction	Treatment [a] of the metalated [b] product	Yield (%)	Product M. p. (°C)	Color
(2) → *(3)*	2 h, 35 °C	14	189—190	Yellow
(2) → *(4)*	3 h, 35 °C	14	250—251	Yellowish-red
(5) → *(4)*	1 h, 35 °C	37		
(5) → *(6)*	1 h, 35 °C	40 [c]	142	Yellow
(7) → *(8)*	2 h, 35 °C	57	189	Pale yellow
(7) → *(9)*	2 h, 35 °C	24 [d]	87	Pale yellow

[a] Solvent: diethyl ether (+ *ca.* 10% of *n*-hexane introduced with *n*-butyllithium); in the reaction *(2)* → *(4)* an additional 10% of THF.
[b] Metalation always with *n*-butyllithium at 0 °C (30 min).
[c] 26% of *(4)* formed as by-product.

Direct Transformation of the Second Excited Singlet State of Benzene into Dewar-Benzene

By *D. Bryce-Smith, A. Gilbert*, and *D. A. Robinson*[*]

We have found that the S_2 state of benzene (but not the S_1 state) can isomerize directly into Dewar-benzene (bicyclo-[2.2.0]hexa-2,5-diene) by a symmetry allowed process which appears to provide the first example of a non-dissociative photochemical reaction from an upper excited singlet state.

Irradiation of liquid benzene under nitrogen at 254 nm populates the S_1 state (^1B_2u) and thence the T_1 state (^3B_1u), and gives the benzene isomers fulvene[1] and benzvalene[2], but no trace of Dewar-benzene. On the other hand, this latter isomer is among those formed by irradiation of liquid benzene over the 160—210 nm range, a process which directly populates both the S_2 (^1B_1u) and S_3 (^1E_1u) states of benzene[3]. The interesting question arises whether Dewar-benzene is being formed by a hitherto unknown type of *direct* isomerization of the S_2 and/or S_3 states: such transformations would be symmetry allowed, as would that of the T_1 state, but would not be thus allowed from the S_1 or S_0 states[4]. It was therefore desirable to identify more precisely the state of benzene which transforms into Dewar-benzene.

[*] Prof. D. Bryce-Smith, Dr. A. Gilbert, and Dr. D. A. Robinson
Department of Chemistry, University of Reading
Whiteknights Park, Reading RG 6 2AD (England)

Use of a microwave-generated discharge in argon/iodine[5] as radiation source (λ 206 nm) has made possible the irradiation of liquid benzene specifically in the $S_0 \rightarrow S_2$ band (λ_{max} 203 nm) without direct population of the S_1 state. Such irradiation of liquid benzene under standardized conditions (20 °C, 90 min, 2-ml samples) led typically to concentrations of Dewar-benzene, fulvene, and benzvalene of 30 ± 3, 50 ± 5, and 150 ± 10 ppm, respectively (GLC retention times, UV-spectrum of fulvene, half-lives of Dewar-benzene and benzvalene). The amounts and proportions of these isomers were the same from both air-saturated and argon-saturated benzene[**]. Thus the S_2 state of benzene is clearly implicated at some stage in the formation of Dewar-benzene, but these results on their own do not exclude the intermediacy of S_0, S_1, or triplet states produced from the S_2 state by internal conversion. The intermediacy of the S_0 and S_1 states in the formation of Dewar-benzene is rendered improbable by the absence of this isomer from the products of prolonged irradiations (*e.g.* 48 h) of liquid benzene in the $S_0 \rightarrow S_1$ band, both at 254 nm and over the whole band. One could only reconcile the intermediacy of S_0 or S_1 states with this evidence by the rather strained postulation of the need for some critically high vibrational levels inaccessible by direct irradiation in the $S_0 \rightarrow S_1$ band, and, as noted above, the transformations would be symmetry forbidden. The idea of vibrationally excited intermediates also seems at variance with the observed need for a liquid- rather than a gas-phase[3].

The possible intermediacy of triplet states of benzene in the formation of Dewar-benzene was tested by comparison of the rate of formation of Dewar-benzene from pure benzene with that from dilute solutions of benzene in *cis*-cyclooctene and cyclooctane. *cis*-Cyclooctene acts as an energy acceptor from T_1 benzene, giving the *trans*-isomer[6], and other olefins are well known to behave similarly[7]. In fact, irradiation of 10% solutions of benzene in *cis*-cyclooctene at 206 nm as above surprisingly increased the rates of formation of Dewar-benzene, fulvene, and benzvalene approximately 20-fold in comparison with the rates from pure liquid benzene under comparable conditions, and a similar degree of insensitivity to dissolved air was observed[***]. A similar increase (22-fold) was found with the use of cyclooctane as medium, so the dilution effect is physical rather than chemical in nature. The greatly increased rate of formation of Dewar-benzene in the presence of the olefin rules out any appreciable contribution from triplet benzene as an intermediate. Thus the evidence leaves S_2 benzene as the only reasonable direct precursor of Dewar-benzene.

The question whether Dewar-benzene can also arise from S_3 (^1E_1u) benzene was investigated by the use of an oxygen lamp emitting over the range *ca.* 160—220 nm[3], and a filter of 0.98-M aqueous LiCl to isolate the $S_0 \rightarrow S_2$ band when necessary. It was found that Dewar-benzene can also arise from population of the S_3 state: the results are consistent with direct isomerization of this state or of some state (*e.g.* S_2 benzene) derived from it.

It is interesting that *Braun, Kato,* and *Lipsky* found that **the internal conversion** efficiency from upper electronic states to the S_1 state (which is normally unity for most organic molecules that have been studied in dilute solution) is significantly less than unity in the cases of benzene and some methylbenzenes[9]. The present results suggest that part at least of the discrepancy can be attributed to a tendency for 1,4-bonding in the S_2 state of benzene.

[**] The effect of the atmosphere on the process was examined for samples irradiated for 10 min since with the argon-saturated solutions significant amounts of an opaque polymer formed on the cell windows when the irradiation time was greater than *ca.* 30 min.

[***] The same mixture of cyclooctene-benzene 1,3-adducts was formed as is produced by irradiation at 254 nm, a result which suggests that higher excited states of benzene were not directly involved in the intermolecular cycloaddition process: cf. ref. [8].

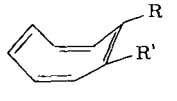
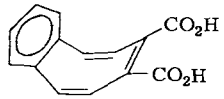
Inhibition of Bond Exchange in Cyclooctatetraenes



By *D. Bryce-Smith, A. Gilbert*, and *J. Grzonka*[*]

The [4*n*]annulenes so far studied exhibit (a) bond-alternation, and (b) bond-exchange[1-3]. Previous workers have shown that the rate of bond-exchange in the cyclooctatetraene ring tends to be decreased by mono- and 1,2-disubstitution, and that in the latter case the equilibrium favors the less overcrowded tautomer A[2-5]. We now report NMR and chemical evidence which, taken together, suggests that certain 1,2-disubstituted cyclooctatetraenes exist exclusively in form A.



Dimethyl cyclooctatetraene-1,2-dicarboxylate *(1)* shows an NMR spectrum (Table) which remains unchanged over the temperature range −40 to +200 °C, apart from minor

band shifts. The apparent lack of coupling between H_4H_5 and H_6H_7 is surprising, but another example of this is known[7]. The tabulated data are inconsistent with the presence of form B: cf. refs.[3, 7]. It is estimated that any contribution from form B greater than 2% would have been detected. Analysis of the NMR spectrum of the corresponding 1,2-dicarboxylic acid *(2)* leads to a similar conclusion (see Table).

Table. NMR spectra of compounds *(1)*, *(2)*, and *(6)* (interpreted as in refs. [2, 3, 6, 7]). The spectra are independent of temperature.

Compound, solvent	Signals (τ)	Assignment
(1)	2.94 (2H/d), $J = 3.0$ Hz	H-3, H-8, form A
CCl_4	4.02 (2H/d), $J = 3.0$ Hz	H-4, H-7, form A
	4.09 (2H) [a]	H-5, H-6, form A
	6.33 (6H/s)	methyl ester protons
(2)	2.88 (2H/d)	H-3, H-8, form A
$(CD_3)_2CO$	3.96 (4H/asym. m)	H-4—H-7, form A
	3.5 (2H/br. s)	carboxylic acid protons
(6)	2.85 (s) }	aromatic protons
CCl_4	2.79 (s) [b] } 6H	+H-3, form A
	3.75—4.40 (5H/m)	H-4—H-8
	6.58 (3H/s)	methyl ester protons

[a] Irregular singlet.
[b] Shoulder.

That none of form B is in fact present is also suggested by the reported inability of the dicarboxylic acid *(2)* to form a cyclic anhydride under normal conditions[8]. In contrast, benzocyclooctatetraene-7,8-dicarboxylic acid, which must exist solely in form *(3)*, readily forms a stable cyclic anhydride[6].

We now report that the acid *(2)* can be induced to form a cyclic anhydride in low yields when treated with ethereal dicyclohexylcarbodiimide. In contrast with the anhydride from acid *(3)*, this new anhydride is highly unstable and polymerizes rapidly. Yet fresh samples, obtained with difficulty, showed a parent peak in the mass spectrum and had IR and NMR spectra consistent with the presence of vinyl protons only (τ 3.7—4.45 in $C_6D_6/(CD_3)_2CO$). Since the properties appear to exclude the obvious structure *(4)*, we are obliged to consider the apparently more strained structure *(5)* as the only one consistent with the experimental observations. The apparent failure to stabilize by isomerization to form *(4)* is remarkable. The strong, apparently exclusive, preference for form A in the present examples may result more from steric than from electronic factors since the NMR spectrum (Table) of *(6)*[9] shows that it also occurs only in form A.

First Identification of a Steroid Carboxylic Acid *in* Petroleum[1]

By *Wolfgang K. Seifert, Emilio J. Gallegos,* and *Richard M. Teeter*[*]

In a recent publication[2], we reported forty new classes of carboxylic acids in a Californian petroleum of Pliocene age (10 million years old). We now wish to report the identification of 23,24-bisnor-5a-cholanic acid *(1a)* in the same oil.

(1a), R = COOH
(1b), R = CH_3
(1c), R = CH_2D
(1d), R = CH_2OH
(1e), R = CH_2-O-SO_2-$C_6H_4CH_3$
(1f), R = $COOCH_2(CF_2)_6H$
(1g), R = CH_2CH_2COOH

A narrow fraction of carboxylic acids (fraction D-4[3], representing 1.6% of all acids and 0.04% of the petroleum) was converted by parallel reductions to hydrocarbons and deuterium-labeled hydrocarbons (in the position of the original carboxylic acid group) *via* the alcohols and *p*-toluenesulfonates using $LiAlH_4$ and $LiAlD_4$ in the last step[4]. The hydrocarbon and deuteriohydrocarbon samples were then further fractionated in parallel by silica gel and gel permeation chromatography (GPC) using previously described techniques[4]. Gas chromatography (GC) of a selected GPC fraction (100-foot by 0.02-inch ID capillary column, coated with OV 17) in combination with mass spectrometry (AEI MS-9) led to the identification of compounds *(1b)* and *(1c)*, respectively, thus showing the acid to have structure *(1a)*.

Proof of structure was obtained by: 1. Synthesis of 23,24-bisnor-5α-cholane *(1b)* by Wolff-Kishner reduction of 3-oxopregn-4-ene-20β-carbaldehyde and subsequent catalytic hydrogenation with PtO_2 in acetic acid. The resulting mixture of *(1b)* and the stereoisomeric 5β-hydrocarbon was separable by preparative GC (6 m by 6 mm OD column, 3% OV 17 on Gas-Chrom Q) and the products distinguishable by mass spectrometry; 2. Synthesis of *(1c)* by chromic acid oxidation of 3β-hydroxy-23,24-bisnor-5α-cholanic acid to the corresponding ketone and subsequent Wolff-Kishner reduction to give acid *(1a)*; the latter was converted[4] to deuterium-labeled hydrocarbon *(1c)* *via* alcohol *(1d)* and *p*-toluenesulfonate *(1e)* with $LiAlD_4$. Mass spectral fragmentation patterns and gas chromatographic retention times of synthetic labeled *(1c)* and unlabeled *(1b)* hydrocarbons were identical with those obtained from the naturally occurring acid; 3. The mass spectrum of synthetic ester *(1f)* was identical with that obtain-

ed on GC-MS of the original acid fluoroheptyl ester mixture[5] at the retention time of ester *(1f)*.

In addition, two stereoisomeric C_{24}-steroid carboxylic acids were identified. Although structural proof is not complete, present results suggest that they are 5α- *(1g)* and 5β-cholanic acids.

The significance of this work is that these are the first polycyclic naphthenic carboxylic acids ever reported in petroleum as individual compounds; and on top of this they possess biological precursor hydrocarbon skeletons and, therefore, are geochemically significant. Animal bile acids are considered to be the most likely precursors.

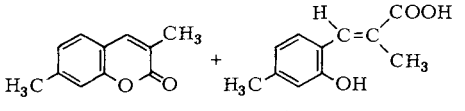
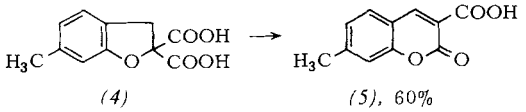
Ring Expansion in the Benzofuran Series



By *Bernard Libis* and *Ernst Habicht*[*]

2,3-Dihydro-6-methylbenzofuran-2-carboxylic acid[1] is converted into 2,3-dihydro-2,6-dimethylbenzofuran-2-carboxylic acid *(1)* (for procedure see Ref. [2]).

If compound *(1)* is treated with 2.2 mol. equiv. of lithium diisopropylamide at 0°C under N_2, the reaction mixture turns orange and a benzyl anion is formed. The dihydrofuran ring is cleaved between atoms 1 and 2, and acidification gives the known[3] coumarin *(2)* as the major product. The acid *(3)*, m. p. 200°C, whose stereochemistry precludes ring closure, appears as a minor product.



(1)

(2), 70% *(3)*, 10%

2,3-Dihydro-6-methylbenzofuran-2-carboxylic acid gives the dicarboxylic acid *(4)* when treated according to Ref. [2] and on adding CO_2. Reaction of *(4)* with 3.3 mol. equiv. of lithium diisopropylamide furnishes the known[4] coumarincarboxylic acid *(5)*.

(4) *(5)*, 60%

We consider it remarkable that an anion should be formed β to the COOLi group, which leads to destabilization of the ether linkage and thereby to a reversal of the Perkin coumarin-benzofuran ring contraction. The reaction probably represents a route to hitherto inaccessible coumarins and *o*-coumaric acid derivatives.

Elemental analyses, IR and NMR spectra were all compatible with the above formulations.

Diethylborylation and Determination of Water with Activated Triethylborane

By *Roland Köster, Klaus-Ludger Amen, Hans Bellut*, and *Wolfgang Fenzl*[*]

Protolyses of trialkylboranes to yield alkane and *O*- or *N*-alkylboryl derivatives according to

$$R_3B + H{-}X \longrightarrow R_2B{-}X + RH$$

R = C_2H_5, C_3H_7, $CH(CH_3)_2$, $CH_2CH(CH_3)_2$
X = O-alkyl, O-aryl, O-acyl, O—SO_2-alkyl, —O—SO_2-aryl, O—N=C-$alkyl_2$, O—N=C-$aryl_2$, N-$alkyl_2$, N-$allyl_2$, NH-aryl

proceed at differing rates, depending upon R and X. In general, trialkylboranes react with carboxylic acids[1] at about room temperature. In contrast, temperatures of 160—170°C are necessary for reaction of alcohols[2] or phenols[2], 170—200°C for dialkylamines[2], and about 100°C for alkane- and benzenesulfonic acids[3]. At these temperatures certain functional groups can be reduced by transiently formed B—H bonds (dehydroboronation) during the reaction.

We have found that protolyses of triorganoboranes can be considerably accelerated by catalytic amounts of pivalic acid or various pivalic acid derivatives:

$$(CH_3)_3C{-}COX,\ X = e.g.\ (C_2H_5)_2B{-}O > (CH_3)_3C{-}CO{-}O{-}CH_2{-}CH_2O \gg (CH_3)_3C{-}CH_2O > C_2H_5O$$

Triethylborane to which 0.1 to 1 mol-% of pivalic acid has been added reacts rapidly and quantitatively with water or alcohols at room temperature, one of its ethyl groups being eliminated as ethane.

$$2(C_2H_5)_3B + H_2O \xrightarrow{Cat.} (C_2H_5)_2BOB(C_2H_5)_2 + 2C_2H_6$$
$$Cat. = (C_2H_5)_2B{-}O{-}CO{-}C(CH_3)_3$$

This reaction can be utilized for a very simple determination of the water content of numerous hydrates of metal salts (see Table) with the aid of triethylborane/diethylboryl pivalate (b. p. 54°C/8 torr). The salts nearly always remain

Max-Planck-Institut für Kohlenforschung
433 Mülheim/Ruhr, Kaiser-Wilhelm-Platz 1

undissolved and can readily be isolated in the anhydrous state.

Like triethylborane, trimethyl-, tripropyl-, triisopropyl-, and triisobutylborane also react considerably faster with water, alcohols, or phenols on addition of pivalic acid.

Table. Determination [a] of water content of hydrates with triethylborane in the presence of diethylboryl pivalate.

Hydrate [b]	H_2O (%) [c]			$\frac{found}{calc.} \times 10^2$

[a] Volumetric determination of the ethane liberated.
[b] Commercial samples, water contents according to manufacturers' specifications.
[c] The determinations can be carried out much more rapidly and at lower temperatures (20—50 °C) in the presence of catalyst, cf. [d] and [e].
[d] Evolution of ethane is exothermic and is generally complete after 5 min. The reaction mixture is then heated to boiling. The values obtained are reproducible. The considerable deviations from the calculated H_2O contents are due to the impurity of the commercial hydrates.
[e] Values obtained after 1 to 2 hours' heating in boiling triethylborane.

However, the catalyzed protolyses of the trialkylboranes BR_3 proceed at varying rates, in the order:

$$R = C_2H_5 > C_3H_7 \gg CH(CH_3)_2 \gg CH_2CH(CH_3)_2$$

Whereas even at temperatures above 100 °C only one alkyl group of the trialkylboranes reacts with alcohols, triphenylborane in the presence of diethylboryl pivalate is already degraded to boric acid at about 100 °C.

We have used catalyzed protolysis to prepare a large number of alkoxy- and aryloxydialkylboranes, some of which have functional groups such as C=C or C≡C bonds or NO_2 groups in the organic residue RO. The dialkylboryl derivatives of alkane- and benzenesulfonic acids were also obtained in high yields.

Sulfuric acid, phosphoric acid, boric acid, and iodic acid are also esterified with the diethylboryl group in the presence of diethylboryl pivalate at room temperature. In the absence of catalyst the higher temperatures required for the reaction usually result in mixtures of boron-containing and the boron-free acid anhydrides being formed.

Diethylborylation of polyhydroxy compounds also proceeds particularly smoothly on addition of pivalic acid. The hydroxyl group content of soluble, and also of insoluble, compounds, *e.g.* starch and cellulose, can therefore be accurately determined. Introduction of *O*-diethylboryl protective groups into sugars and sugar derivatives is also of preparative interest. The per-diethylborylated monosaccharides and their derivatives, *e.g.* 1,2,3,4,5-pentakis(diethylboryl)-D-(+)-glucose (b. p. 136 °C/0.001 torr), 2,3,4,6-tetrakis(diethylboryl)-α-methyl-D-(+)-glucoside (b. p. 130 °C/0.001 torr), 2,3,5,6-tetrakis(diethylboryl)-L-(+)-ascorbic acid, which are readily soluble in hydrocarbons, can be vacuum distilled without decomposition. The diethylboryl groups can be removed quantitatively and under extremely mild conditions by treatment with methanol. The boron-free sugar is obtained after the azeotropic mixture of methoxydiethylborane (b. p. 88.8 °C/770 torr; $n_D^{20} = 1.3869$) and methanol [$CH_3OB(C_2H_5)_2$: CH_3OH = *ca.* 1:2.8; b. p. 59.7 °C/770 torr; $n_D^{20} = 1.3620$; $d_4^{20} = 0.7675$] has been distilled off.

Introduction of the diethylboryl group into numerous NH compounds is also facilitated by the presence of pivalic acid derivatives. In addition to pyrrole and its derivatives[4], ammonia, amines, hydrazines, and carboxamides and carbohydrazides all react under milder conditions than in the absence of catalyst. Aldo and keto phenylhydrazones as well as phenylosazones also react under relatively mild conditions with "activated" triethylborane. In general, NH compounds react at 50—80 °C in the presence of diethylboryl pivalate. Temperatures of about 140 °C are required for ammonia and some mono- and dialkylamines.

Bis(diethylboryl)sulfate:

Sulfuric acid (98%; 15.6 g, *i.e.* 345 mg-atom of $H^{\oplus}$) is added dropwise over about 2 h to triethylborane (79 g, 806 mmol) containing diethylboryl pivalate (*ca.* 0.5 ml). The temperature rises to about 50 °C. Ethane (7.32 l, 327 mmol) is evolved. A clear pink liquid results from which a small amount of dark solid precipitates. Vacuum distillation yields firstly 51 g of a mixture (triethylborane and tetraethyl diboroxide), b. p. up to 25 °C/15 torr, and then 30 g (81%)[5] of bis(diethylboryl) sulfate, b. p. 66—67 °C/0.001 torr; 1.9 g of residue was left in the distillation flask.

Borylation of Cellulose:

Triethylborane (6.3 g, 64.3 mmol) containing 0.1 ml diethylboryl pivalate is added dropwise to a stirred suspension of cellulose (2.7 g, 16.65 m equiv) in 40 ml heptane at 60—70 °C (bath) over a period of 70 min. 700 Nml of ethane are evolved during the addition. Following a further

1.5 hours at 70—80 °C a total of 1135 Nml (101%) ethane is evolved. The voluminous white solid is filtered off and washed three times with pentane before being vacuum dried (yield 5.85 g, 96%). Found 5.84% B (on C)[6], calc. 5.90% B (on C). The per-*O*-diethylborylated cellulose is insoluble in both aliphatic and aromatic hydrocarbons as well as in carbon tetrachloride.

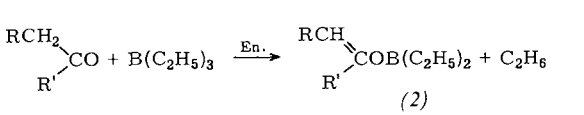
Reactions of Dialkyl Ketones with Triethylborane



By *Wolfgang Fenzl* and *Roland Köster*[*]

Enolizable aldehydes and ketones do not generally react with trialkylboranes below 100 °C. Above this temperature reduction (Red.) and enolysis (En.) compete with each other, depending upon the carbonyl compound and trialkylborane used. For example, diethyl ketone and triethylborane react at 150 °C to give an almost equimolar mixture of ethylene and ethane. The boron-containing products are 3-diethylboryloxypentane *(1a)* and 3-diethylboryloxy-2-pentene *(2a)* (see Table).

We have found that, like the protolysis of trialkylboranes with hydroxy compounds[1], the enolysis of trialkylboranes with certain carbonyl compounds can be greatly accelerated by pivalic acid derivatives $(CH_3)_3CCOOR$, *e.g.* with $R=BR'_2$ or $CH_2CH_2—O—CO—C(CH_3)_3$. Depending

(1)

(2)

upon the alkyl groups of the dialkyl ketones, the reaction furnishes substituted vinyloxydiethylboranes *(2)* (yield 60—98%), which are important for additions to nitriles[2].
