Nuclear Energy Reserves and Long-Term Energy Requirements[**]

By K. E. Zimen[*]

In this article the world's potential energy reserves are summarized on the basis of available estimates, and the future energy consumption is estimated with the aid of a working hypothesis relating to the growth of the world's population (P) and the energy consumption per capita (γ). According to this estimate, the energy requirements in 30 years will be about seven times and in 80 years about fifty times as high as they are today, and all the concentrated energy sources will be exhausted in about 120 to 160 years. – The energy requirements in the steady state (Pγ = const.) could be of the order of 10^{13} MWh per year and could be met out of magmatic rocks (U,Th) and sea water (U,D). High priority should be given to research and development work on the construction, reliability, and safety of breeder and fusion reactors, the chemical treatment and final disposal of radioactive waste, the extraction of uranium, thorium, and deuterium from the "primitive" raw materials, the relevant problems relating to protection of the environment, and the worldwide control of the excess birthrate.

1. The Problem

Man requires many goods and services to live. These needs must be met by some kind of energy, either in the form of mechanical power or manpower, and in the ultimate analysis, therefore, they find expression in a demand for energy (even money is a form of easily convertible energy[1]). Energy consumption per capita is a guide to the degree of industrialization and the standard of living. In order to view nuclear research and development in its proper perspective, we must ask ourselves how long our reserves of energy sources will be able to meet the requirements of the world's rapidly growing population. To answer this question, our potential energy resources must be compared with our present and future power requirements. The latter will depend on how much the population and the energy consumption per capita increase.

A distinction must be made here between *concentrated* energy sources, which will remain available for use in the near future, and the "primitive sources", which will be called upon to satisfy the long-term requirements of man. The latter consist of uranium and thorium in magmatic rocks, uranium and deuterium in sea water, and solar-radiation-based regenerative power sources. The first question to ask ourselves is how long the concentrated energy sources will be able to meet our demands. Here we find that man is rapidly approaching a steady state which will be characterized by the fact that the product of population and energy consumption per capita ($P \times \gamma$) is constant. Only the primitive raw materials will remain available to meet the energy requirements of man in this steady state, a point which is discussed in Section 5.

We know the following equations to be valid:

$$c = \gamma \times P \tag{1}$$

and

$$C_T = \sum_{}^{\Delta T} \gamma(t) \times P(t) \tag{2}$$

We want to find:

ΔT for $C_T = R$

where R = energy reserves (MWh), c = energy consumption per year (MWh/a), γ = energy consumption per capita per year (MWh $cap^{-1}a^{-1}$), C_T = cumulative energy consumption up to the year T (MWh), P_T = population in the year T (mid-year), T = year, (AD), ΔT = time (in years from 1970) for which the reserves will cover demand, and t = time.

2. Reserves of Concentrated Energy Sources

2.1. Recovery Factor and Efficiency

When considering energy reserves, a distinction must be made between reasonably assured resources (R_{ass}), calculated on the basis of investigations, and additional resources (R_{add}) estimated on the basis of the above and on the basis of general geological and geochemical considerations; the uncertainty regarding the latter is, of course, greater than that of the former. Furthermore, only a part of the available reserves can be recovered. The recoverable fraction of the assured and the estimated additional resources will be called the "potential resources" R (also "estimated ultimate recovery", EUR), and the factor r in

$$R = r(R_{ass} + R_{add})$$

will be called the recovery factor. The latter factor, and therefore also the extent of the potential resources, is dependent on the price that one can afford to pay. Thus, in the case of coal we are faced with the problem of how deep and narrow seams may be before they cease to be workable, and in the case of uranium and thorium of how poor the ores can be before they can no longer be processed. From a purely *technical* point of view there are practically no limits to the recovery of raw materials from very poor sources. An extreme example of this would be plutonium, which was initially separated from uranium in submicroquantities. From an *economic* point of view the richest ores are always exploited first, because they are the cheapest to process. Only when the rich sources are exhausted does it become financially viable to work the poorer sources, because then the materials will fetch high enough prices to cover costs. A decisive factor here is the competition between the energy sources on the market. *Theoretically,* the limit will be reached when the power required for extracting the fuel, *i.e.* for prospecting, recovery, transportation, and conversion of the raw material into the finished product, and conveying it to the place of utilization, in addition to the power equivalent of the total costs of the generating plant, is the same as the usable power that can be produced. The balance between the power expended in production and the power gained on utilization must remain positive, taking into account all losses. For the present purpose consideration should finally be given to the theoretical limiting value of the recovery factor (r_{lim}). This factor must always be less than 1 and may vary a great deal depending on the energy carriers and the deposits.

On average, r is nowadays taken to be ≈ 0.5 for coal and ≈ 0.4 for petroleum. For these raw materials, therefore, the ratio r_{lim}/r is certainly < 2 and thus can be neglected when considering orders of magnitude. The reserves of uranium ore are generally divided up into three price ranges: <25, 25–40, and 40–80 \$/kg U (roughly <10, 10–15, and 15–30 \$/lb U_3O_8). In competition with fossil fuels only the first price range is economically viable today. In the future the prices of the more expensive ores will also be competitive, so that here all three groups will be lumped together. Sources with higher recovery costs are discussed in Section 5; the estimation of r_{lim} will also be of interest in this connection.

As is well known, only a part of the energy content of an energy carrier can ever be used:

$$\text{usable energy} = \eta \times \text{primary energy content}$$

where η is the overall efficiency. Moreover, the efficiency varies depending on the energy carrier and the way in which it is utilized. Efficiencies of up to 80 % can be achieved if use is made of the heat of combustion of coal and oil, and, in the case of the production of electricity by means of water power, they may even exceed 90 %. In the conversion of the heat of combustion into electric power, η is governed essentially by the thermal efficiency which is about 35 %. If nuclear energy is used for the production of electric power, the conversion factor is also involved in the question of efficiency. In nuclear power stations with light-water reactors, the predominant type nowadays, essentially only the uranium isotope U-235 (relative abundance 0.72 %) is utilized; the overall efficiency relative to the total uranium is about 1 %. The development of breeder reactors, in which the bulk of the uranium (U-238, 99.28 %) and all the thorium (Th-232, 100 %) can also be used, is therefore an essential prerequisite for the future of nuclear energy. In breeder reactors the conversion factor is:

$$k = Q/Q_0 > 1$$

where Q_0 = initial quantity of fissionable material (U-235, Pu-239, U-233) in the reactor and the reprocessing plant, and Q = quantity of fissionable material left after a cycle in which the quantity Q_0 has been consumed; *i. e.* all of the uranium or thorium can be utilized. We estimate that, when the bulk of the (U,Th) ores are being used, full utilization will be made of the breeder process, so that the total efficiency, as in conventional power stations, will be governed essentially by the thermal ef-

Table 1. Energy equivalents and other conversion factors.

ficiency. (The power required for the reprocessing plants will cause a slight reduction in η. On the other hand it will be possible to increase η_{therm} slightly with time.)

Efficiency has been considerably improved over the years. *Putnam*[2] gives the mean global efficiency for all types of energy sources as 0.12 for 1900 and 0.22 for 1947; *Mandel*[3] states that it is now 0.30. This means that the consumption of usable energy has in the last 70 years increased 2.5 times more than the production of primary energy.

For the purpose of comparing the potential energy reserves with energy requirements, both quantities will be calculated in primary energy units, *i. e.* changes in η will not be taken into account, since there are no grounds for expecting an improvement in the present-day mean (0.3) that will have a significant effect on our calculations (factor 2). For thermodynamic reasons there can be no great improvement in thermal efficiency, and the proportion of the power requirements satisfied by electricity obtained from thermal power stations is rapidly increasing. Moreover, as already mentioned, in the case of uranium and thorium we are reckoning with the breeder process being put into use and are therefore taking into account the considerable increase in efficiency that it will bring with it (*Putnam*[2] calculates $\eta \approx 0.36$ for the year 2050 AD).

The unit of energy used throughout this article is the megawatt hour (MWh). Since many other units are encountered in the literature, relevant conversion factors are given in Table 1.

2.2. Estimates of Energy Reserves

Table 2 shows the most recent available estimates of global energy reserves.

The estimates of the oil reserves vary primarily on account of differing assumptions with respect to the recovery factor, which may be pushed up higher than 0.4 when the market situation changes. In particular the future recovery of oil from oil sands and oil shales is primarily a question of costs. For our purposes we have chosen – and this is also true of natural gas and coal – the highest of the estimates available for conversion into primary energy.

Table 2. Estimates of the global potential reserves of energy carriers. R_{ass} = assured reserves; R = potential reserves; r = recovery factor.

Raw material	units	Reserves R_{ass}	Reserves R	Primary energy (10^{12}MWh)	Ref.	Remarks
Crude oil	10^9 t	46	850		[6]	with oil-bearing sand and shale r = ?
		73			[7]	
		82	360		[8,9]	R without oil-bearing sand and shale; r = 0.4
			430		[8,9]	R with oil-bearing sand and shale; r = 0.4
			1200	13	[10]	R including 600 of oil-bearing sand and shale; $r \approx r_{lim}$
Natural gas	10^{12}m^3	38			[7]

			340	3	[8,9]	R, high estimate
Coal	10^9t h.c.e.	8600	7600	62	[8,9,11]	r = 0.5
Total				78		
U ores	10^6t U	2.3	5.0	113	[12-14]	< 80$/kg U
Th ores	10^6t Th	0.5	1.2		[12]	< 25$/kg Th
		0.5	1.5	35	[13]	< 25$/kg Th
Total				148		

The potential reserves of uranium and thorium have not yet been adequately investigated, and all data are more or less unreliable, particularly those for thorium. There are no literature data at all for many countries, including China, which together make up 44% of the Earth's solid surface. The actual reserves, particularly those in the higher cost category, may therefore be two to three times higher than the estimates in Table 2.

3. Consumption of Energy

Future energy requirements can be calculated from the increase in world population $P(t)$ and from the development in the average energy consumption per head, $\gamma(t)$.

3.1. Development of World Population

The historical growth in population is illustrated in Fig. 1. This graph clearly shows the rapid increase, often called the population explosion, that has occurred over the last 300 years and which coincides with the development of science and technology. At present the world population increases by 1.4 million per week, *i. e.* about 70 million per year. Figure 1 is not suitable for extrapolation into the future; a more detailed examination of population dynamics is required.

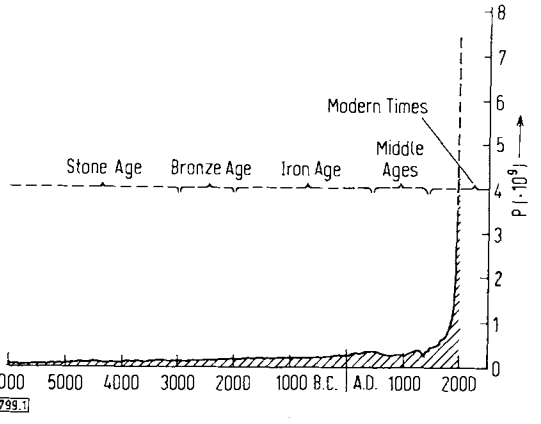

Fig. 1. Growth of world population P since 6000 BC [5].

The change in P (population) with time is expressed by the equation:

$$\frac{\Delta P/P}{\Delta t} = n - m = \varepsilon \qquad (3)$$

where n = natality (birthrate), m = mortality (deathrate), and ε = excess birthrate. Since ε varies with time, we may write $dP/P = \varepsilon(t)\,dt$ or

$$P_t = P_0 \times e^s \qquad (4)$$

$$s = \int_{\Delta t} \varepsilon(t)\,dt$$

Here s = area below the ε curve in the time interval Δt under consideration (dimensionless number). The following equation holds true for time intervals with ε = const:

$$P_t = P_0 \times e^{\varepsilon t} \qquad (5)$$

As an example of population dynamics, Fig. 2 shows the birthrate and deathrate figures for Sweden, an industrial country. Around 1750 the deathrate in Sweden began to fall, and a little later the birthrate also began to decline. The same is true of other western European countries. The graph also shows the corresponding curves for Mexico. Here the decline in the deathrate began at a much later date, but the mortality figures have now dropped to the same level as Sweden's – thanks to the imported "hygienic revolution" and the low average age – while the natality has remained at its previous level. All typical developing countries have been in this phase for about 30–50 years and have undergone a population explosion as a result.

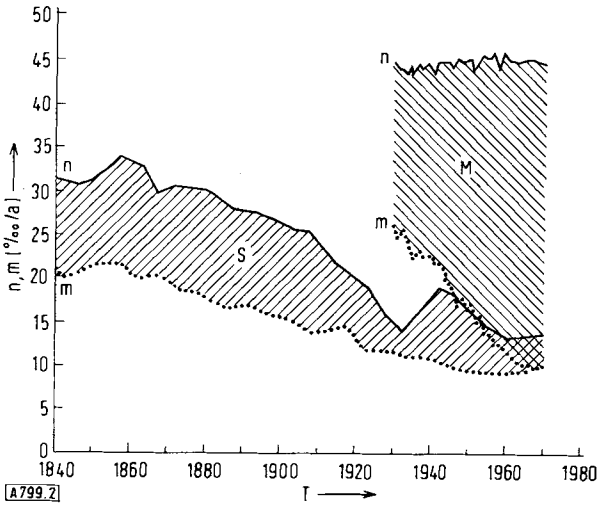

Fig. 2. Natality n (——) and mortality m (· · · ·) in S = Sweden (1840–1968) and in M = Mexico (1930–1968) [15].

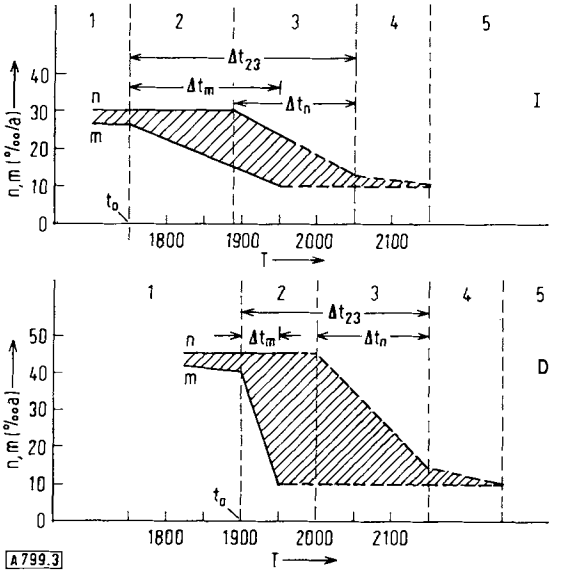

Fig. 3. The phases in population dynamics (schematic). I: industrialized country; D : developing country; natality n, mortality m (see Table 3).

Viewed schematically and as a whole, changes in population can be seen to occur in five phases. These phases are shown in Fig. 3 and Table 3.

Before attempting to anticipate future developments the following must be stated: the population explosion will very soon have to come to a standstill. With ε at its present value of 2%/a the population of the world would be 540×10^9 in 250 years, *i.e.* there would be 4000 in-

Table 3. The phases in population dynamics (see Fig. 3).

Phase no.	Designation	Natality n	Mortality m	Excess birth rate $\bar{\varepsilon}$
1	primitive	high	high	low
2	expansion [a]	high	rapidly falling	rapidly rising
3	regression [a]	falling	falling or low	high and falling
4	prestatic	low and falling	low	low and falling
5	static	constant	constant	constant

[a] Phases 2 and 3 are jointly designated "rationalization phase".

habitants per km^2, a figure typical for present-day cities, and in only 500 years there would be one human being for every square meter of the solid surface. It is obvious that, somehow or other, the population of the world will have to become stationary. The $P(t)$ curve, therefore, like all growth curves in nature will take the form of a sigmoid logistic curve:

$$y = a/(b + e^{-cx})$$

In order to make a prognosis for the future, it is obviously necessary to consider the industrialized and developing countries separately. The expansion phase begins (time t_0) about 150 years later in developing countries than in industrialized countries. The period during which the deathrate declines (Δt_m), however, is reduced from about 200 to about 50 years. It is an open question whether, and if so by how much, the rationalization phase Δt_{23} is also reduced.

A working hypothesis, which allows quantitative predictions, has been postulated by *Fucks*[16]. In order to extrapolate the excess birthrate curves for the developing countries, *Fucks* assumes that the area s under the $\varepsilon(t)$ curve for the developing countries will become equal to the area under the $\varepsilon(t)$ curve for European countries. (This is obviously not the case in Fig. 3, where the area between the n and m curves is considerably greater for the developing countries than for the industrialized countries; taking the *Fucks* hypothesis as a basis, the period of birthrate decline (Δt_n) would have to be very much shorter for the developing countries.) For the area under the ε curve for Europe between AD 1740 and 2020 *Fucks* obtains $s = 1.85$, and hence, using eq. (4), $P_t/P_0 = 6.4$. If the population of the other countries at time t_0 is multiplied by the same factor, then, in accordance with *Fucks*' "hypothesis of equal areas", the world population for the years 2000 and 2050 will be : $P_{2000} = 6.6 \times 10^9$ and $P_{2050} = 9.5 \times 10^9$.

W. Fucks' hypothesis seems to us to be overoptimistic. It is, of course, true that the existence of the old industrial states and effective communications between all countries have considerably shortened the period of deathrate decline Δt_m, but it is unlikely that the expansion and regression phases, *i.e.* the period Δt_{23}, will be similarly shortened. Education is much more difficult to import than hygiene, and the extremely rapidly growing excess birthrate in the expansion phase of developing countries has a feed-back effect which impedes both industrialization and the spread of information and education in family planning.

On account of this, we shall use another working hypothesis to estimate the course of the population growth for the next 130 years. This hypothesis does not take the ε curve for Europe as its starting point; instead, Europe, Asiatic USSR, North America, and Oceania[*] are considered together as industrialized areas. Since North America, Australia, and New Zealand were settled mainly by European emigrants, Europe and these countries must be taken together in order to get an idea of the development of industrialized areas. Asia excluding the USSR, Africa, and Latin America are regarded as developing areas.

Table 4. World population (P) and mean excess birthrate ($\bar{\varepsilon}$) from 1650 to 1970 and distribution on the basis of developing areas (Asia, Africa, Latin America) and industrialized areas (Europe + asiatic USSR, North America, Australia and New Zealand); see Fig. 4.

statistical material in its present form, these details are not taken into account, since they have no significant influence on the results.

Table 4 gives the corresponding distribution of the global population figures and the mean excess birthrate figures for 1650–1970; the variations of the latter with time are shown in Fig. 4.

As can be seen the $\bar{\varepsilon}$(I) curve has not yet clearly passed its maximum – a result at variance with that obtained by applying *Fucks*' hypothesis – so that the corresponding s(I) value can also be obtained only arbitrarily. Our basis for the extrapolation into the future will therefore be as follows (cf. Table 5):

Table 5. Hypothetical values for $\bar{\varepsilon}$ between 1970 and 2120 for industrialized and developing countries and the resultant population figures P (see also Fig. 5).

AD	Industrialized areas $\bar{\varepsilon}$ (%/a)	Industrialized areas P ($\times 10^9$)	Developing areas $\bar{\varepsilon}$ (%/a)	Developing areas P ($\times 10^9$)	World P ($\times 10^9$)	Remarks
1970		0.960		2.660	3.620	cf. Table 4
2000	1.3	1.4	2.8	6.1	7.5	after ref. [19]
2030	1.1	2.0	2.0	11.0	13.0	
2060	0.9	2.6	1.4	16.7	19.3	calculated on basis of assumed $\bar{\varepsilon}$ values, cf. text
2090	0.7	3.2	0.8	21.3	24.5	
2120	0.5	3.7	0.5	24.7	28.4	

1) For the period up to the year 2000 the latest estimates from the Demographic Center of the United Nations[17] will be used (high estimate).

2) For the period after the year 2000 it will be assumed that the birth excess curves of both the industrialized and the developing countries will fall steeply, namely from their maximum at about the end of this century to $\varepsilon \approx 0.5\%$ at the end of the next (cf. Fig. 4 which, for the sake of simplicity, shows this decrease in step form, the difference between each step being the same).

For reasons given above, this "hypothesis of equal periods" (from the maximum of the $\bar{\varepsilon}(t)$ curves to the beginning of the prestatic, or fourth, stage) seems more plausible to us than the "hypothesis of equal areas". The resultant decrease in the $\bar{\varepsilon}$(D) curve after the year 2000 is very steep, but much less steep – and therefore more realistic – than it would be if it were assumed that the areas under both $\bar{\varepsilon}$ curves had to be the same. As a rational, if only qualitative, basis for the "hypothesis of equal periods" mention should be made of the ever-improving techniques of communication which, of necessity, will lead to a leveling out of the differences. Furthermore, the time available for this leveling process is probably not much shorter but also not much longer, than a hundred years.

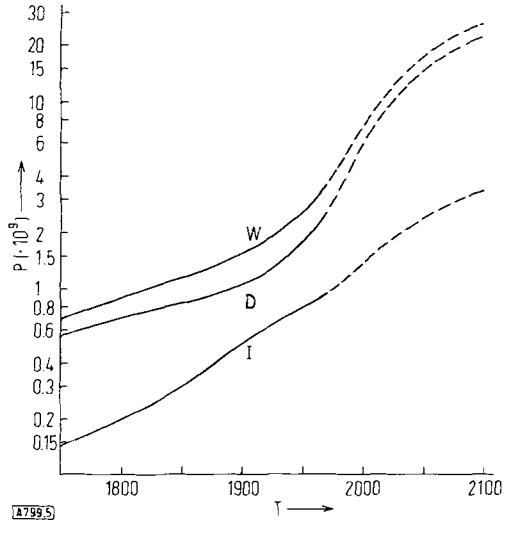

Fig. 5. Growth of the population P for the world, industrialized and developing countries from 1750–1970, and hypothetical extrapolations (cf. text).

On the basis of the above arguments, the world population will be 18×10^9 in the middle of the next century and 26×10^9 at the end of it (Table 5 and Figure 5). The enormous increase in population (to double the present figures in the next 30 years) means that there is also bound to be a rapid growth after the year 2000, since the people maturing sexually after 2000 will be born in rapidly increasing numbers in the 30 years up to the turn of the century. Furthermore, in a rapidly growing population the relative number of women of childbearing age also increases. At present, for example, the proportion of the population under 15 years of age amounts to 25% in Europe, while in Asia it is 35% and in Africa and Latin America it is as high as 43%. Examination of earlier estimates on population development (Table 6) shows that these estimates are invariably rather low.

3.2. The Development of Energy Consumption per Capita

As Figure 6 shows, there is a close correlation between the annual energy consumption per capita of the population (γ) and the gross national product. A large difference can be seen between the industrialized and the developing countries. The average consumption of commercial energy per head in the USA in 1961 was 70 MWh, *i.e.* 100 to 200 times more than in the areas with the lowest per capita consumption (0.4 to 0.8 MWh). The developing countries therefore have a lot

[23] *R. Pearl* and *L. J. Reed* in *R. Pearl:* Studies in Human Biology. Williams and Wilkins, Baltimore 1924.

[25] World Population Projections 1965-2000. Popul. Bull. (Washington, D.C.) *21,* No. 4 (1965).

of ground to cover in order to catch up. The average world consumption per capita per year is at present about 14 MWh[18].

The growth rate $\delta = \Delta\gamma/\Delta t$ of world energy production between 1947 and 1968 was 5.1% per year. while the per capita energy consumption between 1953 and 1968 increased by 3.0% per year[18].

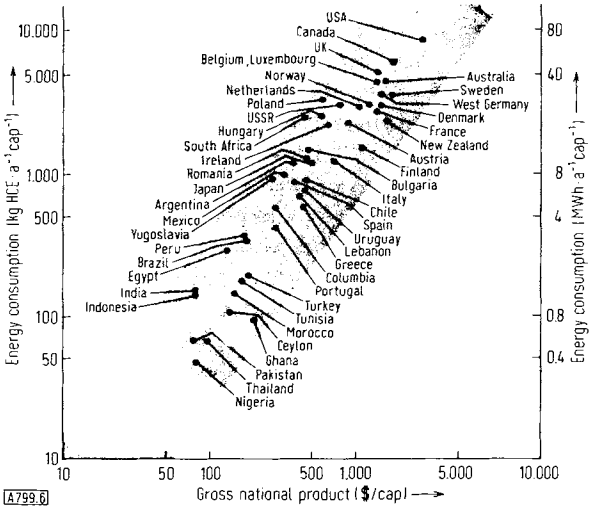

Fig. 6. Consumption of commercial energy per head in comparison with the gross national product in 1961 (after [26], supplemented by the right ordinate in rounded values).

As far as the future is concerned, we must assume that similar growth rates can only be maintained for a relatively short time. With δ at its present value of 3%/a and a population increase of 2%/a the consumption in only 100 years would be 10^{13}MWh per year and in 150 years it would be in excess of 10^{14} MWh/a. All the energy reserves mentioned in Table 2 would then cover only one year's demand. It is clear, therefore, that the growth rate in energy consumption per head, like the growth in population, will have to be reduced in the future. As a working hypothesis for the assessment of this inevitable development, it will be assumed here that the growth rate δ, like the growth rate ε for population on the basis of the "hypothesis of equal periods", will also decrease successively over the next hundred years to values of less than 1%/a, so that the prestatic phase will be reached. For the remaining 30 years of the twentieth century, however, the δ values will probably continue to rise. The high growth rates of the developing countries, arising as a result of their urgent needs (see above), are bound to have a marked effect on the global growth rate, since these countries account for a large proportion of the world's population (72% in 1963 and perhaps more than 80% in 2000).

The δ values given in Table 7 represent a plausible version of this working hypothesis. The world energy consumption per head per year works out at 45 MWh for

Table 7. Hypothetical values for the mean global growth rates of energy consumption per head per year, δ, from 1970 to 2120 and the resultant energy consumption γ, c and C_T.

AD	δ (%/a)	γ (MWh cap^{-1}a^{-1})	c (10^9MWh/a)	C_T (10^{12}MWh)
1970		14	50	4.3
2000	3.9	45	340	10
2030	2.7	100	1300	35
2060	1.8	170	3300	100
2090	1.3	240	5900	240
2120	0.7	300	8500	460

2000 AD. Earlier estimates for the year 2000 have already been corrected upward: *Searl*[27] reckoned on 27, *Bhabha*[28] on 35, and *Mandel*[3] on 43 MWh cap^{-1} a^{-1}. The figure estimated for the USA in the year 2000 is 175 MWh per head per year. After the turn of the century the postulated δ values gradually become lower, indicating a quite considerable decrease in the growth rate of energy consumption and therefore also of industrialization. The resulting γ values are given in Fig. 7. These figures are probably too low rather than too high. Finally from $P(t)$ (Figure 5) and $\gamma(t)$ (Figure 7), we obtain the global yearly energy consumption $c(t)$, as given in Table 7 and Figure 7.

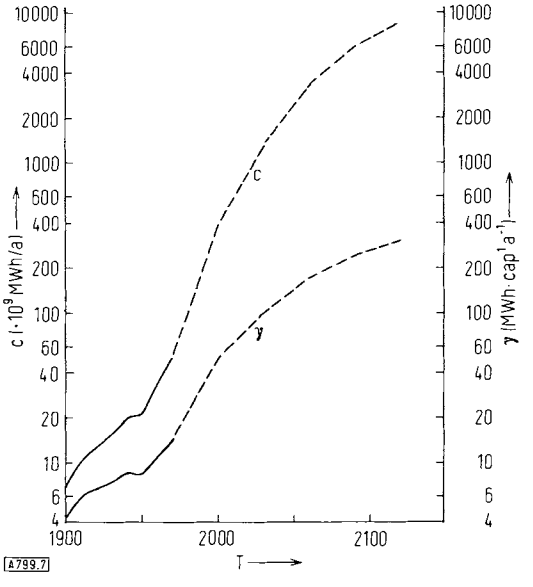

Fig. 7. Energy consumption per head and year, γ, and global annual energy consumption, c, from 1900 to 1970, with extrapolations (cf. text).

4. Comparison of Energy Reserves and Energy Demand

Figure 8 shows the potential energy reserves of the various energy carriers (Table 2). It also shows the cumulative energy consumption as a function of time, as obtained from $c(t)$ (eq.2). In order to normalize the curve, the value of 3.8×10^{12} MWh was chosen, corresponding to the amount of energy which, according to *Mandel*[3], had been consumed up to 1960. (*Putnam*[2] has estimated 6–9 Q, *i.e.* (1.8–2.6) $\times 10^{12}$ MWh for the time from AD 0 to 1860 and a further 4 Q, *i.e.* 1.2×10^{12}MWh, up to 1950 (the energy consumed up to 1860, however, derives mainly from wood and agricultural waste, *i.e.* regenerative energy sources.)

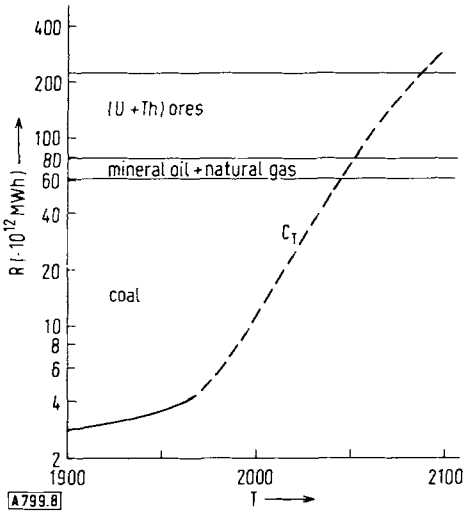

Fig. 8. Potential energy reserves R and cumulative energy consumption C_T (data on global energy consumption: 1900–1950 [2]; 1950–1968: [18]; from 1970 on cf. Table 7).

Comparison of reserves and demand on the basis of Figure 8 leads to the following conclusions:

In the next 30 years man will consume more energy than in all the years since the dawn of human history. The reserves of fossil fuels would suffice, if they alone were used, until 2050, *i.e.* for about 80 years from now.

The estimated potential reserves of uranium and thorium will move this date up to about 2090, *i.e.* they will increase the period only by about 40 years. ΔT, therefore, amounts to about 120 years.

The question posed in Section 1 has thus been answered. We should now ask: How large is the margin of error in this estimate?

It must first be stated that every estimate of ΔT can be meaningful only when based on a reasonably constant further development of the world. Global catastrophes must, therefore, be left out of consideration, even if they are considered likely. Famine and nuclear war apart, however, all predictions for the future, including the present estimates for raw material reserves and our hypotheses relating to $P(t)$ and $\gamma(t)$, must, of course, entail a great deal of uncertainty; they can never be anything more than informed guesses. The result from Figure 8, however, shows that the question posed on the time it will take until all the concentrated reserves are consumed can probably be answered more accurately than to within an order of magnitude, in spite of all uncertainties. On account of the steepness of the $C(t)$ curve an incorrect assessment of the reserves causes only a relatively small change in the period ΔT. If, for example, with a maximum recovery factor, twice the amount of energy carriers could be recovered, *i.e.* 450×10^{12} MWh of primary energy, ΔT would be increased only by 40 years, *i.e.* from 120 to 160 years. Only if the actual reserves exceeded the values used here for potential reserves by one order of magnitude would there be any considerable change in ΔT.

Furthermore, it should be stressed that all three factors were estimated optimistically, in contrast with the normal physical procedure involved in the transmission of errors. In the case of reserves the highest estimates of the potential resources have been used, and the upward correction of the values for uranium and thorium reserves that will probably have to be made will not cause any major changes in the picture. In the case of $P(t)$ the length of the rationalization phase for the developing countries has probably been assessed optimistically. The conjectured decrease in the excess birth rate after the turn of the century presupposes a thorough-going process of enlightenment and measures so rigorous and far-reaching that today they seem scarcely possible in view of all of the opposing factors of a religious, political, and economic nature and the world-wide failure to recognize the problem because of lack of information. Only if the rationalization process succeeds in the coming decades will the prestatic phase be reached in the second half of the next century so that in this period there is not another doubling of the world population. Finally, the prognosis for the energy consumption is probably extremely conservative. It presupposes a quite considerable deceleration in the growth rate of energy consumption per head and therefore in the standard of living after 2000 AD while at present consumption and production are increasing more and more rapidly, both in the planned and in the market economy systems. Furthermore, as is the case with reserves, a change in consumption by a factor of 2 or 3 causes relatively little change in the time ΔT.

Thus, unless the values used for energy reserves and energy consumption prove to be wrong by more than one order of magnitude, ΔT will remain in the order of magnitude of 100 years. Failure to take into account the enormous increase in energy demand as a result of the population explosion and as a result of the even faster growth in the energy demand per head is obviously the reason why ΔT has often been put at thousands or tens of thousands of years and the energy situation has been assessed unrealistically.

5. Energy Requirements and Energy Reserves in the Steady State

As shown above, the present explosion in population and in energy consumption will have to change drastically after the turn of the century and the prestatic phase will have to be reached in the course of the twenty-first century. The estimates of world population in the steady state are all fairly close to each other. Thus, for example, *Watson-Watt*[29] calculates that the figure will probably be 27×10^9 and *Clark*[30] has 45×10^9. Extrapolation of the $P(t)$ curve in Figure 5 indicates a population of between 30 and 40×10^9.

When estimating the energy requirement per head in the steady state, account must be taken of the fact that at this time all the concentrated raw-materials reserves

[29] *R. Watson-Watt*, cited in Internat. Sci. Technol. *1963*, No. 23, p. 98.

[30] *C. Clark* in: Man and his Future. Ciba Found. Sympos., Churchill, London 1963.

of the majority of metals will be exhausted. On the time scale of past and future human evolution the consumption by man of all the raw materials concentrated in ores is only a short episode. After this mankind will have to resort to the very large deposits in the sea and in rocks, which contain metals in very low concentrations. Furthermore, the indications are that desalinated sea water will form the basis of the water supply and that we shall be depending on maximal utilization of the land and sea for food purposes. The energy demand is therefore bound to increase even more. According to Table 7, 100 MWh $cap^{-1}a^{-1}$ will probably be reached in about 60 years and 300 MWh $cap^{-1}a^{-1}$ in about 150 years. With γ_{stat} = 300 MWh $cap^{-1}a^{-1}$ and $P_{stat} = 35 \times 10^9$ the energy demand will be of the order of

$$c_{stat} = 10^{13}\ \text{MWh/a}$$

In comparison, the total energy supplied through solar radiation amounts to 27×10^{13} MWh/a. After the concentrated fossil and fissionable raw materials have been exhausted the "primitive" raw materials mentioned at the beginning of this article will be left to cover the energy demand.

The regenerative energy sources based on solar radiation, according to present estimates (cf. Table 8), can supply some 10^{11} MWh of usable energy, which would only correspond to a few percent of the demand in the steady state.

Uranium and thorium are found as residual crystallization elements in fairly homogeneous distribution in granites and pegmatites at concentrations of 2.7 and 9.6 ppm[31] respectively, *i.e.* about 12 g (U + Th) per ton of rock. To give an example, there is 4.3×10^{12} t (U + Th) in a 1-km thick layer of the crust. According to *Mandel*[32], about 30×10^6 t U and 40×10^6 t Th, *i.e.* a total of about 10^8 t (U + Th), are recoverable (for < 1000 \$/kg U). In the example this would correspond to a recovery factor of 10^{-5}. In terms of primary energy reserves, this amounts to about 10^{15} MWh (Table 9).

The uranium concentration of sea water, according to *Wilson's* measurements[33], amounts to 3.3 μg/l (3.3 ppb), independently of the depth. Local variations are known to occur, and the total number of measurements is small, but the order of magnitude of 1–10 ppb is probably the best estimate for the mean concentration at present available. Since the total volume of sea water is 1.2×10^{18} m^3[34], it follows that the total reserves of uranium in the sea should be those given in Table 9. The thorium content, on the other hand, is so low that it can be ignored. According to *Gupta*[35], there are grounds for hoping that the uranium can be recovered from the sea relatively economically (< 200 \$/kg), perhaps in the way suggested by *Spence et al.*[36]. With the recovery factor value taken as an example in Table 9, the primary energy would be of the order of 10^{13} MWh.

Finally, the total content of deuterium in sea water can be deduced from the accurately known concentration, 156 ppm[37]. Thus, with the very hypothetical value given for *r*, we obtain a value of 10^{18} MWh for the potential primary energy (Table 9).

From the data in Table 9 it follows that the largest resources to meet the long-term requirements of man lie in the uranium and thorium in magmatic rock and, in particular, in the deuterium content of sea water. With the anticipated requirement of 10^{13} MWh/a in the steady state, these reserves could in fact suffice for thousands

Table 9. Reserves of "primitive" raw materials for the production of energy.

Source of energy	Power/m^2 or concentration. resp.	Total reserves (t)	Corresponding energy reserves (MWh)	Maximum recovery factor	Potential useful energy reserves (MWh)
Solar radiation	0.24 kW/m^2	-	2.7×10^{14} p.a.		10^{11} p.a.
U + Th in 1km of earth's crust	12 ppm	4×10^{12}	1×10^{20}	10^{-5}	10^{15}
U in sea	3 ppb	4×10^9	1×10^{17}	10^{-4}	10^{13}
D in sea	156 ppm	1.9×10^{14}	1.3×10^{22}	10^{-4}	10^{18}

of years. Some important reservations should, however, be made:

Firstly, it is doubtful whether the recovery factors in Table 9 represent realistic values. Furthermore, in the case of deuterium, the total efficiency cannot yet even be estimated in terms of orders of magnitude, since the question of the technical realization of fusion reactors remains open.

Secondly, it must be borne in mind that adequate working of magmatic rock and the extraction of deuterium from the sea in sufficient quantities are bound to mean changes in the ecological systems of our environment which cannot yet be visualized. Waste also presents a problem. It seems probable that the heating caused by the $^2/_3$ of the 10^{13} MWh/a evolved as heat for thermodynamic reasons, or the effects on the environment caused by fission products (10^5 t/a for 10^{13} MWh/a) arising from the use of nuclear energy, will set the limit at a considerably lower c_{stat} value.

Thirdly, and most important, the steady state characterized by $P \times \gamma = \text{const.}$ must persist. If P or γ were to increase only by a small amount, not even the enormous reserves of uranium, thorium, and deuterium could cover the energy requirements of man over a long period of time.

From the point of view of energy, therefore, it is imperative that the steady state with a constant population and constant standard of living can be reached. An increasing energy requirement arising from increased difficulties in obtaining raw materials or for the purpose of increasing the standard of living will then be possible only if it is compensated by a reduction in world population.

6. Conclusions

The energy demand in 30 years will be roughly seven times greater and in 80 years roughly 50 times greater than it is today. The potential fossil fuel reserves will suffice – if they are used exclusively – for about 80 years, and the potential concentrated uranium and thorium reserves for roughly another 40–80 years. Thus, optimistic estimates of the potential reserves and conservative estimates of the energy consumption lead to a figure of 120–160 years for the time that will elapse before the reserves of concentrated energy raw materials are used up.

Man is rapidly approaching a steady state characterized in that the population will be restricted by the availability of food and other factors and that the standard of living will be limited by the amount of energy available. The energy requirement in this steady state could be about 10^{13} MWh per year. To cover this demand in the long term it will be necessary to resort to the sources solar and geothermal energy, magmatic rocks, and above all deuterium from the sea.

The bases for these conclusions, namely the estimates of the potential energy reserves, the growth of population, and the development of per capita energy consumption, should be regarded with due caution, and they are offered for criticism. New data on these magnitudes and improved methods of extrapolation (cf., for example, ref.[40]) will from time to time permit improved predictions.

These reflections reach forward to a time which, measured by our own life expectancies, lies far in the future. In fact, however, the estimates have an important bearing on the present: The practice of using the reserves of fossil fuels for the production of heat and electricity should be abandoned as soon as possible, since if enough coal and oil were burned to satisfy the demand it would make the problem of environmental protection almost insurmountable and would probably have prohibitive ecological consequences. Furthermore, these reserves are more valuable, and sometimes indispensable, for other purposes, *e.g.* the manufacture of chemicals and pharmaceuticals, the running of aircraft and automobiles. The development of breeder reactors is an essential prerequisite for the adequate utilization of nuclear fission. Furthermore, the problems of reactor safety must be solved so that nuclear power stations can be operated economically in densely populated areas. This is also true of the chemical problems involved in the treatment and final disposal of the enormous quantities of radioactive waste.

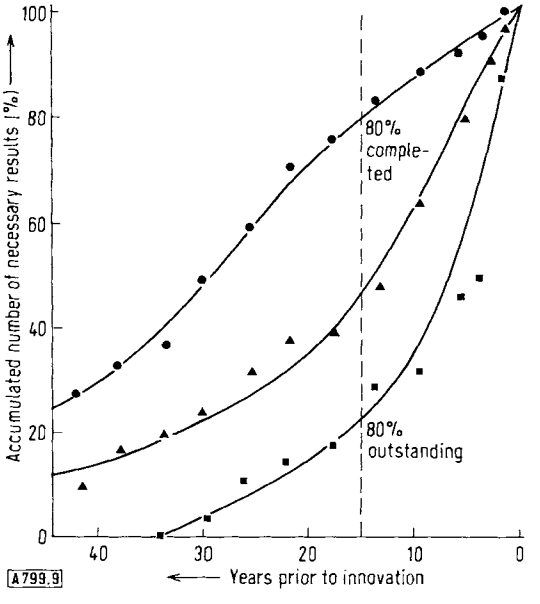

Fig. 9. Number of years of basic research (●), applied research (▲) and development (■) necessary for the realization of innovations (after [41]).

Research and development is of pressing importance for the extraction of uranium, thorium, and deuterium from the primitive raw materials and for the realization of fusion reactors. It takes many years to develop basic innovations, *e.g.* fusion, into technically and economically viable processes (cf. Fig. 9).

[40] United Nations: Future World Energy Needs, IAEA Conference Paper SM-146/50, Aug. 1970.

[41] *G. Friborg*, Forskning och Framsteg (Stockholm) *1969*, No. 3 p. 2.

High priority must be given to all relevant problems of environmental protection, which will probably be the limiting factors in future energy production. Above all, the turning point of the logistic population curve will have to be reached in the coming decades, something which, with all its implications, can scarcely be envisaged today.

Population and energy problems must be solved more quickly than is generally thought. Whether a rational solution is possible depends on what we do or do not do in the next few decades.

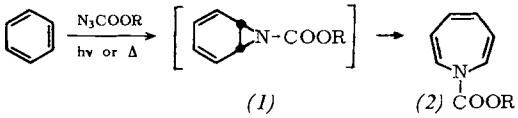
Valence Isomerism in Selected Heterocyclic Systems

By Leo A. Paquette[*]

Valence isomerization and the phenomenologically related principle of valence tautomerism, as they apply to several nitrogen-containing heterocyclic systems, are discussed herein. Attention is called first to 1H-azepines and the reluctance of such substances to isomerize to azanorcaradienes. The role of homo-1H-azepines in this context is then briefly outlined. Azocines (azacyclooctatetraenes) are seen to occupy an interesting position in the sense that pronounced shifts in the position of equilibrium (from almost entirely monocyclic to virtually completely bicyclic) occur with substitutional alterations of various types. The capability of azabullvalenes for degenerate valence isomerization is the next presented, and contrast is made with the properties of benzazabullvalenes and an azasemibullvalene derivative.



1. Introduction

Valence isomerizations, *i.e.*, those multicenter processes that occur *via* the synchronous (or at least nearly simultaneous) shift of σ and/or π electrons without the intervention of ionic or free radical intermediates, or the migration of atoms or groups, hold a very special position in organic chemistry. By their very nature, such transformations are sensitive to temperature effects, but not to catalytic agents or to wide changes in solvent structure and polarity. When the isomers in question are interconvertible by the surmounting of a relatively low energy barrier, the term valence tautomerism more properly applies. Because of the presence in cyclic polyenes of favorable geometric factors for bond reorganization, such systems commonly exhibit a fascinating propensity for valence tautomerism. Of theoretical significance is the question dealing with the nature of the causative factors that control the various positions of equilibrium as the structure of a given molecule is gradually altered. Customarily, however, a total dissection of the combined structural, electronic, and steric influences is difficult to achieve; as a result, quantitative data for an even wider variety of structural types must continue to be obtained in order to provide a fund of information which will permit the eventual development of sound theoretical principles[1].

In particular, knowledge of the effect resulting from the introduction of a nitrogen atom into various cyclic π-electron networks promised to uncover meaningful information concerning the principles of valence tautomerism. In this review, the behavior of such molecules will be discussed and compared with related hydrocarbon and heterocyclic structures.

2. 1*H*-Azepines

The synthesis of 1-substituted 1*H*-azepines such as *(2)* can be accomplished readily by the photolysis[2,3] or

pyrolysis[4–7] of azidoformates in benzene solution. Because singlet nitrenes appear to be involved in the thermal reactions[8], a concerted cycloaddition mechanism leading to intermediate *(1)* is believed to be operative in those cases. The major drawback of the nitrene insertion route is the relative lack of selectivity of nitrenes in their reaction with monosubstituted benzenes. Usually, a mixture of 2-, 3-, and 4-substituted 1*H*-azepines is produced which, in general, defies preparative scale gas chromatographic separation[9–11].

These difficulties can be obviated by means of a synthetic sequence based on the reaction of readily available 1,4-dihydrobenzenes with iodine isocyanate[12]. For example, treatment of 1,4-cyclohexadiene with silver cyanate and iodine in ether, and finally with methanol, produces iodocarbamate *(3)*. Reaction of *(3)* with aqueous potassium hydroxide leads to aziridine *(4)* which has been converted to a variety of functionalized derivatives such as *(5)*. Bromination and dehydrobromination of compounds of type *(5)* provides access to a wide variety of 1-substituted-1*H*-azepines *(6)*.

(3) *(4)*

(5) *(6)*

The isomeric 2-, 3-, and 4-methyl-1-carbomethoxy-1*H*-azepines were likewise obtained in good yield by an identical sequence of reactions commencing with the appropriate 1,4-dihydrobenzene derivatives[12]. Additional studies have shown that the dehydrohalogenation of 3,4-dibromo-7-azabicyclo[4.1.0]heptanes provides a simple scheme for synthesizing many 1*H*-azepines[1f].

The NMR spectrum of 1-ethoxycarbonyl-1*H*-azepine *(2)* (R = C_2H_5) displays a multiplet at δ = 5.3-6.1 due to the six ring protons. The presence of more powerful electron-withdrawing substituents on nitrogen generally results in the appearance of the vinyl protons at lower field[12]. *Günther* and *Hinrichs*[13] have reported a detailed analysis of the spectrum of *(2)* (R = C_2H_5). In Table 1, the spectral parameters for this azepine are contrasted with those for cycloheptatriene.

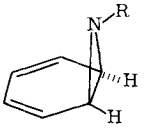

Table 1. NMR/Spectral parameters for *(2)* (R = C_2H_5) and cycloheptatriene [13].

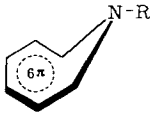
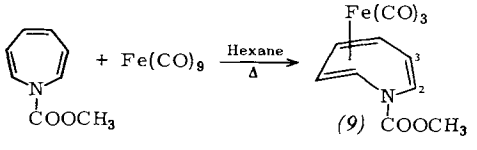
Compound[a]	$\nu_0\delta$[b]	$J_{4,5}$	$J_{3,4}=J_{5,6}$	$J_{4,6}=J_{3,5}$	$J_{3,6}$
(2), R = C_2H_5	35.74	11.44	5.43	0.65	-0.03
Cycloheptatriene	24.42	11.04	5.58	0.68	-0.12



[a] 20 vol % in CCl_4. [b] Relative chemical difference (in Hz) between protons H-4, H-5 and H-3, H-6.

The remarkably close correspondence serves to emphasize the gross structural similarities of the two molecules. Especially noteworthy is the observation that the NMR spectra of a number of 1*H*-azepines remain invariant over a substantial temperature range (−90° to +130°C)[12]. This constancy points to the absence of valence tautomerism of the 1*H*-azepine-azanorcaradiene type.

This conclusion was confirmed by a three-dimensional X-ray study of *(6)* (R = $-SO_2C_6H_4$-*p*-Br)[14]. The molecule clearly exists in a boat conformation; the double bonds are localized at C-2–C-3, C-4–C-5, and C-6–C-7 and the four atoms comprising each double bond and its immediate neighbors are coplanar. Additional molecular dimensions denote substantial sp^2 character for the nitrogen atom. The azepines are therefore true polyenes which exhibit little tendency to exist in the tautomeric azanorcaradiene form *(7)* or as azahomoaromatic entities such as *(8)*.



(7)

(8)

The 1*H*-azepines retain their monocyclic character when coupled to an iron tricarbonyl residue such as in *(9)*[12,15,16]. X-ray analysis of *(9)*[14] revealed bond distances which are consistent with a localized double bond at C-2–C-3 and delocalization in the remaining carbocyclic portion of the seven-membered ring. The geometry of the complex is simulated in formula *(9)*.

(9)

The 1*H*-azepine–azanorcaradiene equilibrium is weighted so heavily in the direction of the 8π-electron seven-membered ring that the bicyclic valence tautomeric form is not detected in *(10)* where the positions 1 and 6 are bridged by a tetramethylene chain[12]. Reversal of the equilibrium is seen only when the methylene bridge consists of three members as in *(11)*[12]. These observations

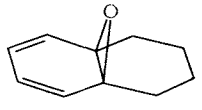
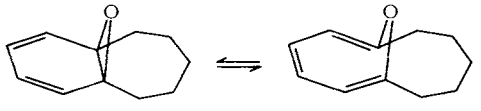
parallel closely the valence tautomeric behavior of bridged norcaradiene derivatives; for example, *(12)* exists exclusively in the cycloheptatriene form[1d,17].

(10)

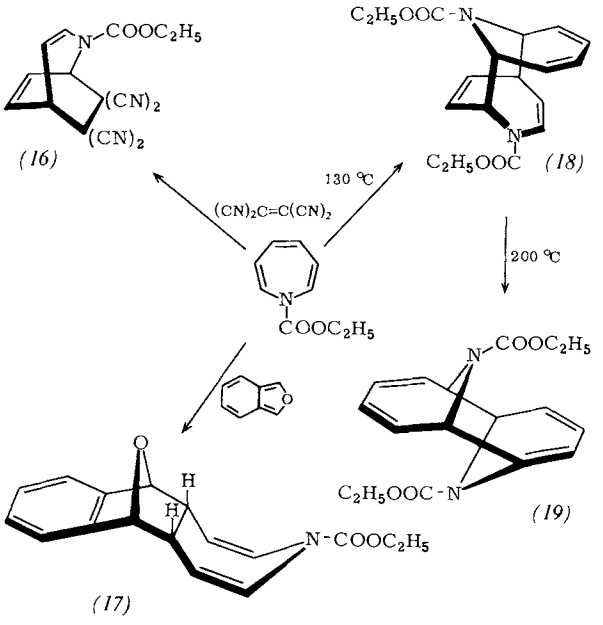


(11)

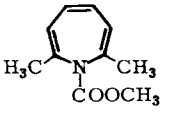


(12)

In contrast, annelated oxepins display concentrations of tricyclic isomers which vary substantially from the above. The substance with a tetramethylene bridge *(13)* exists exclusively in the arene oxide form, whereas the homologous molecule displays spectral properties consistent with the presence of comparable concentrations of *(14)* and *(15)*[1d].

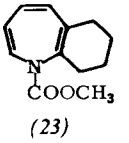


(13)

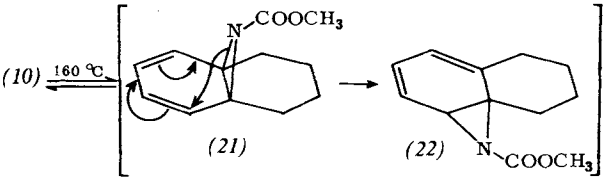


(14) *(15)*

At this point, it becomes very important to single out a significant difference in the chemical properties of 1*H*-azepines, oxepins, and cycloheptatrienes. Whereas oxepins and cycloheptatrienes are capable of ready disrotatory cyclization to the corresponding arene oxides and norcaradienes, respectively, especially in the course of chemical reactions[1d,e,18], 1*H*-azepine derivatives are particularly reluctant to form their related azanorcaradiene counterparts and will do so only as a last resort. For example, cycloaddition reactions and thermal dimerizations of 1*H*-azepines all proceed by way of the seven-membered ring structure except in those instances where steric inhibition precludes normal reaction[19–22].

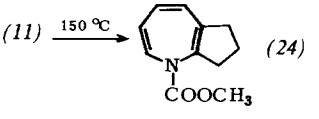


(16) *(18)* *(19)* *(17)*



The effect of internal strain on azepine reactivity is perhaps best exemplified by 1-methoxycarbonyl-2,7-dimethyl-1*H*-azepine *(20)* which withstands prolonged heating (24 h) at 200 °C without noticeable dire effects[21]. Thus, although in a formal sense *(20)* contains three conjugated double bonds and is entirely azepine-like in its spectral characteristics, it shows no tendency to dimerize and is not converted to a benzenoid isomer

(20)



(23)

(21) *(22)*

at elevated temperatures. On the other hand, the closely related annelated azepine *(10)* is cleanly rearranged to the isomeric 1*H*-azepine *(23)* in the vicinity of 160 ° C. Since this behavior is shared by azanorcaradiene *(11)*, the transformation is most readily interpreted on the

(24)

$\Delta H^{\neq}$ = 4.38 kcal/mole

$\Delta S^{\neq}$ = 24.6 e. u.

basis of valence tautomerism of *(10)* to *(21)* which is subject to 1,5-sigmatropic shift of the nitrogen atom and Cope rearrangement as shown[21]. In the absence of such polymethylene brackets, however, 1*H*-azepines exhibit no tendency for 1,5 nitrogen shift.

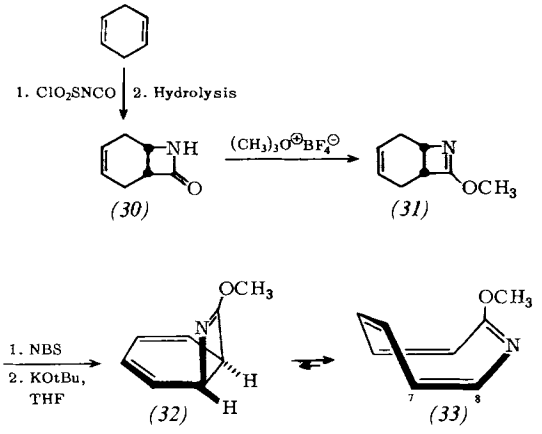
3. Homo-1*H*-azepines

Treatment of excess cycloheptatriene with an alkyl azidoformate at 125 °C produces a mixture of 1:1 adducts consisting chiefly of *(27)* and *(28)*[23, 24]. These homo-1*H*-azepines are presumably formed by valence isomerization of the initially produced aziridines *(25)* and *(26)*, respectively. The temperature-invariant NMR spectra of *(27)* and *(28)* (40–170 °C) attest to the fact that the internal cyclopropyl bond in these structures is not prone to delocalization or to valence-bond tautomerism. If equilibria of type *(25)* ⇄ *(27)* and *(26)* ⇄ *(28)*

are operative, the concentrations of *(25)* and *(26)* do not rise above the detection limits of the spectrometer (≈ 3%). By comparison, bicyclo[5.1.0]octa-2,5-diene *(29)* is subject to structurally degenerate Cope rearrangement which proceeds rapidly at room temperature[25]; no homooxepin has yet been synthesized.



The instability of aziridine isomers *(25)* and *(26)* relative to their homoazepine counterparts parallels the facility with which the thermal valence isomerizations of *cis*-divinyl substituted three-membered rings occur. It is now recognized that the thermal lability of such systems decreases in the order carbon > nitrogen > oxygen > sulfur, with a sizeable gap existing between carbon and nitrogen on the one hand, and oxygen and sulfur on the other[25–28].

The strong bias toward structures *(27)* and *(28)* may be the result of delocalization of the nitrogen electron pair which can only be made manifest in the homoazepines.

4. Azocines

According to *Anderson*'s terminology[29], 1*H*-azepines are considered to be π-excessive nitrogen analogs of cyclooctatetraene. The heteroatom may also be incorporated in π-equivalent fashion, in which case azocines result. In view of the blatant nonaromaticity and marked propensity for unusual structural rearrangement associated with the cyclooctatetraene molecule, unconventional physical and chemical properties can almost certainly be expected to be associated with such monoheterocyclic congeners of this polyene.

Because of the very real possibility that the parent azocine molecule would be so labile as to preclude ready examination of its chemical and physical properties, efforts in this laboratory have been directed to the preparation of 2-alkoxyazocines *(33)*. Such molecules are readily available by way of a highly versatile synthetic scheme based again on the concept of valence isomerization and involving, in its early stages, the monocycloaddition of chlorosulfonyl isocyanate to 1,4-dihydrobenzene derivatives[30–32]. *O*-Alkylation of the resulting β-lactam [*e.g., (30)*] with Meerwein's reagent gives a 1-azetine such as *(31)*, allylic bromination (with *N*-bromosuccinimide (NBS)) and dehydrobromination (with potassium *tert*-butoxide) of which provides the desired 2-methoxyazocines *(33)*.

The NMR spectra of the 2-methoxyazocines are characterized particularly by a low field (δ ≈ 6.5) doublet due to H–8 (when present) and a high field (δ = 4.9–5.1) absorption for H–7. Additionally, the placement of methyl groups on the azocine nucleus does not exert an influence which significantly favors one or more of the possible bicyclic valence tautomeric forms. All of the azocines examined to date exhibit temperature invariant (−75 to 185 °C) NMR spectra which fail to provide any suggestion of the presence of isomeric imidates[33,34]. These observations, in conjunction with the excellent correspondence of their ultraviolet spectra with that of cyclooctatetraene, suggest that these heteroanalogs likewise exist in the strain-free puckered "tub" confor-

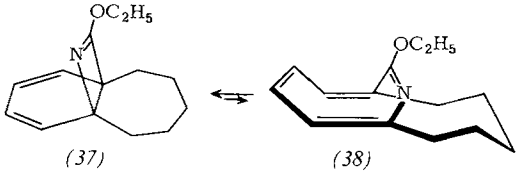
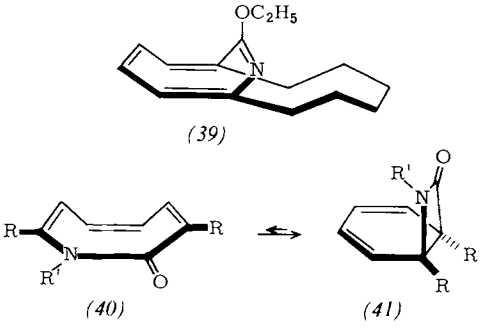
mation known to be preferred by the hydrocarbon[35,36]. Azetine tautomers such as *(32)* are the reacting species in a number of transformations exhibited by the azocines. For example, exposure of *(33)* to potassium *tert*-butoxide for extended periods results in base-induced conversion to benzonitrile[30,32]. Also, cycloaddition of *N*-phenylmaleimide to *(33)* in refluxing toluene leads exclusively to adduct *(34)*. A reversible equilibrium be-



(33) *(34)*

tween the two tautomers *(32)* and *(33)* must therefore exist. Evidently, the 2-methoxyazocines are sufficiently stabilized that the proportion of valence tautomer in equilibrium is below the spectroscopic detection limit ($\leq 3\%$). *Huisgen et al.*[37] have determined that the concentration of bicyclo[4.2.0]octatriene in cyclooctatetraene at 100 °C is 0.01%; there exists, therefore, a parallelism between the two systems.

Because of intensifying interest in the effect of steric influences on valence isomerism, attention was turned to the preparation of a number of annelated 7-azabicyclo[4.2.0]octatrienes. With but one exception[38], the tautomeric capability of unsaturated propellanes possessing a diatomic central bridge has not previously been studied. Taking into account our earlier discussion, it was expected that *(35)* and *(36)* would be totally tricyclic and this was observed[31,32]. Azetine *(37)* was also found to be uniform at room temperature, its spectral properties providing clear evidence for the indicated tricyclic



(35), n = 1
(36), n = 2

(37) *(38)*

formation. However, contrary to the behavior of *(35)* and *(36)*, the pentamethylene-bridged heterocycle exhibits a temperature-dependent NMR spectrum. Such changes (which are completely reversible) denote a substantial displacement of the azabicyclooctatriene–azocine equilibrium in favor of bridged azocine *(38)* at the elevated temperatures. Given this information, it was not unexpected to find that imidate *(39)* differed substantially from *(35)–(37)* in its spectral characteristics. Instead, the NMR, UV, and IR absorptions of *(39)* were markedly similar to those of the monocyclic azocines. Thus, it would seem that, when the central bridge of an unsaturated propellane derivative is a small diatomic sp^2-hybridized unit, a chain of six methylene units is required to arrive at a strain-free uniform substance.

Contrary to the behavior of 2-methoxyazocine, 1,2-dihydroazocin-2-one *(40a)* exists predominantly (97–98% at 60 ° C) as bicyclic tautomer *(41a)*[33,34]. Lactam *(40b)* behaves similarly; by comparison with *(40a)*, however, the percentage of monocyclic form was relatively larger

(39)

(40) *(41)*

(a), R = R' = H; *(b)*, R = CH_3, R' = H; *(c)*, R = R' = CH_3

(20%). The effect of a methyl group on the lactam nitrogen of *(40b)* influences the position of equilibrium to an amazing extent. Thus, the NMR spectra of *(40c)* indicated the substance to be entirely bicyclic [*i.e.*, as *(41c)*] over a substantial temperature range.

The presence of an amide function in *(40)*⇄*(41)* has several consequences. First, the strain in the β-lactam portion of *(41)* is not as great as in a 1-azetine ring. Secondly, if one considers the electropositive nature of the carbonyl carbon, a preference for bonding to sp^3 rather than sp^2 hybridized carbon is anticipated for reasons of electronegativity. These factors, in conjunction with a certain amount of stabilization resulting from an increase of diene π-orbital overlap in *(41)*, lead to the prediction that *(41)* should be favored. However, the reasons for this preference are very probably more subtle than outlined, especially when one considers the fact that 1,3,5-cyclooctatrienone is only 7% bicyclic at 60 ° C[39]. Dreiding models of *(40)* do indicate that the amide linkage in the medium-sized ring is somewhat distorted from planarity, thereby causing a reduction in resonance interaction. In tautomer *(41)*, the planar conformation enforced on the β-lactam ring results in restoration of total delocalization and accordant stabilization. Since cyclooctatrienone enjoys no such prerogative, the strain associated with the cyclobutanone ring in the bicyclic form may emerge as the dominant destabilizing factor.

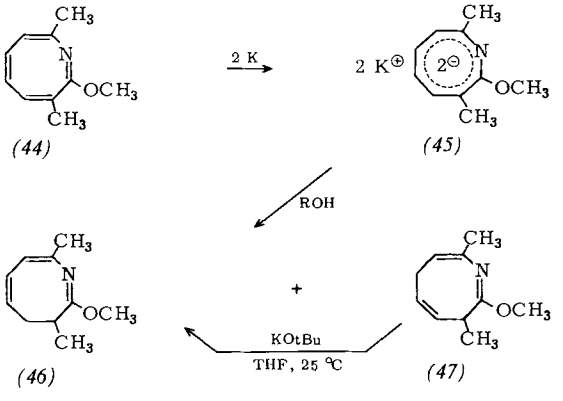
[37] *R. Huisgen, F. Mietzsch, G. Boche,* and *H. Seidl:* Organic Reaction Mechanisms, Spec. Publ. Chem. Soc. (London) *19,* 3 (1965).

[38] *L. A. Paquette* and *J. C. Philips,* Chem. Commun. *1969,* 680.

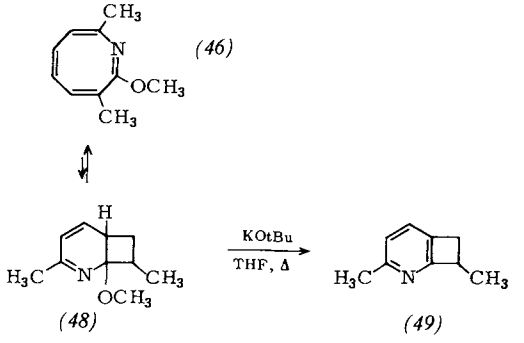
[39] *R. Huisgen, G. Boche, A. Dahmen,* and *W. Hechtl,* Tetrahedron Lett. *1968,* 5215.

Interestingly, sulfonamides *(42a)* and *(42b)* also exist only as azabicyclooctadienes *(43)*[33,34]. Notably, therefore, replacement of the carbonyl function of a dihydroazocinone by a methylene group and the corresponding alteration in the hybridization at that position from sp^2 to sp^3 does not reverse the position of tautomeric



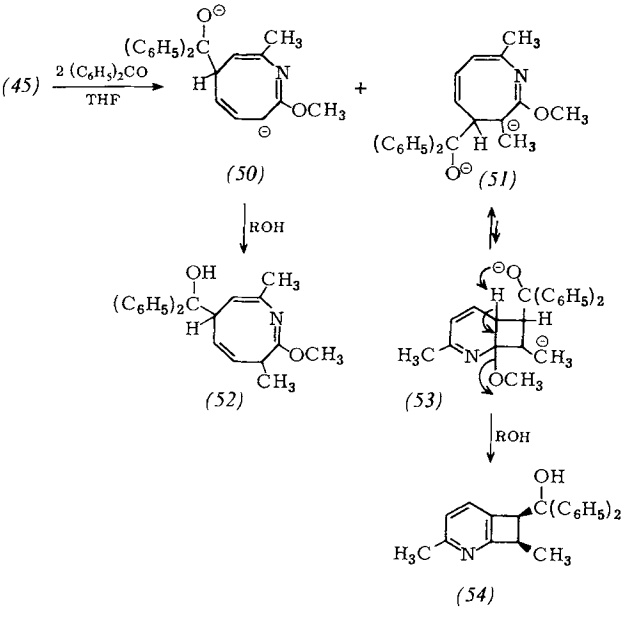
(42) *(43)*

(a), R = $SO_2C_6H_4CH_3$-*p*; *(b)*, R = SO_2CH_3



equilibrium. The bicyclic forms may be heavily favored because the appreciably wider bond angles in the four-membered rings lead to a substantial reduction in destabilizing non-bonded interactions. In *(41c)*, this effect would result in relief of the steric interference between *N*-methyl and carbonyl oxygen, whereas in *(43a)* and *(43b)* sulfonyl oxygen/methylene hydrogen interactions would be minimized.

When 2-methoxyazocine *(33)* and a number of its methylated derivatives such as *(44)* are treated with potassium metal in tetrahydrofuran, dimethoxyethane, or liquid ammonia, conversion to the corresponding aromatic 10π-electron dianion [*e.g., (45)*] occurs[40–43]. On protonation with various active hydrogen sources, the formation of 3,4- [*e.g., (46)*] and 3,6-dihydroazocines *(47)* is seen to be preferred. Potassium *tert*-butoxide in



(44) *(45)* *(46)* *(47)*

tetrahydrofuran at room temperature transforms *(47)* into its more extensively conjugated counterpart *(46)* Not unexpectedly, *(46)* does not exhibit a temperature-dependent NMR spectrum; in this instance, valence tautomerism would necessarily lead to *(48)* with attendant disruption of the imino ether function. However, the capability of *(46)* to produce *(48)* in low concentration is revealed by the observation that *(46)* is transformed readily in high yield to cyclobutenopyridine *(49)* when refluxed in tetrahydrofuran solution containing potassium *tert*-butoxide[44]. The passage from *(48)* to *(49)* is undoubtedly assisted by the driving force arising from the incipient aromaticity.

(46) *(48)* *(49)*

Novel intramolecular variants of the above reaction have been uncovered[44]. For example, alkylation of dipotas-

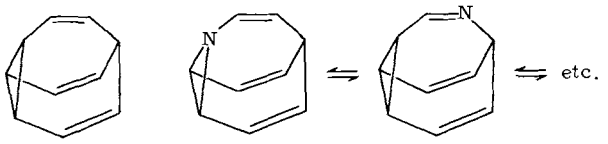
(45) *(50)* *(51)* *(52)* *(53)* *(54)*

sium 3,8-dimethyl-2-methoxyazocinediide *(45)* with two molar equivalents of benzophenone in anhydrous tetrahydrofuran at 25 ° C gives rise to triene *(52)* (1.6%) and 2,3-cyclobutenopyridine *(54)* (46%). The unusual conversion of *(45)* to *(54)* can be rationalized on the premise that alkylation of the azocinyl dianion at C-4 proceeds normally to afford an alkoxide [*e.g., (51)*], followed by valence isomerization of *(51)* to its bicyclic valence tautomer *(53)*, and intramolecular 1,5-proton abstraction with concomitant ejection of methoxide ion and aromatization. This particularly facile synthesis of the previously unknown 2,3-pyridocyclobutene ring system continues to be explored.

5. Azabullvalenes and Benzazabullvalenes

As a consequence of the dynamic fluxional nature of bullvalene *(55)*, all ten constituent carbon atoms find themselves in an ever-changing relationship to each other as

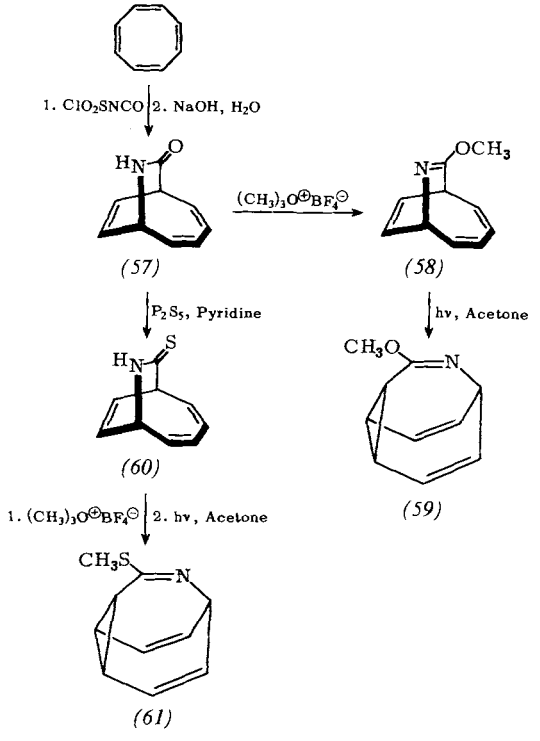
[40] *L. A. Paquette, T. Kakihana,* and *J. F. Hansen,* Tetrahedron Lett. *1970,* 529.



[41] *L. A. Paquette, J. F. Hansen, T. Kakihana,* and *L. B. Anderson,* Tetrahedron Lett. *1970,* 533.

[42] *L. B. Anderson, J. F. Hansen, T. Kakihana,* and *L. A. Paquette,* J. Amer. Chem. Soc., in press.

[43] *L. A. Paquette, J. F. Hansen,* and *T. Kakihana,* J. Amer. Chem. Soc., in press.



[44] *L. A. Paquette* and *T. Kakihana,* J. Amer. Chem. Soc., in press.

the molecule undergoes interconversion to each of 1,209,600 identical structural arrangements[25,45,46]. *A priori*, azabullvalene *(56)* can be expected to display the same remarkable features as *(55)*, but only if the nitrogen atom is not protected by sufficiently high energy barriers from entering into the various bond reorganizations. In this connection, a remarkably simple synthetic entry into the azabullvalene system has been devised[47–50].

(55) *(56a)* *(56b)*

Thus, cycloaddition of chlorosulfonyl isocyanate to cyclooctatetraene, followed by aqueous hydrolysis, results in 1,4 cycloaddition to the eight-membered ring to afford lactam *(57)*. Acetone-sensitized photoisomerization of the derived imino ether *(58)* leads directly to 2-methoxyazabullvalene *(59)*. The sequenze to methylthioazabullvalene *(61)* proceeds from lactam *(57)* and phosphorus pentasulfide in pyridine through thioamide *(60)* to its thiomethyl imino ether and ultimate photolysis[49].

(57) *(58)* *(60)* *(59)* *(61)*

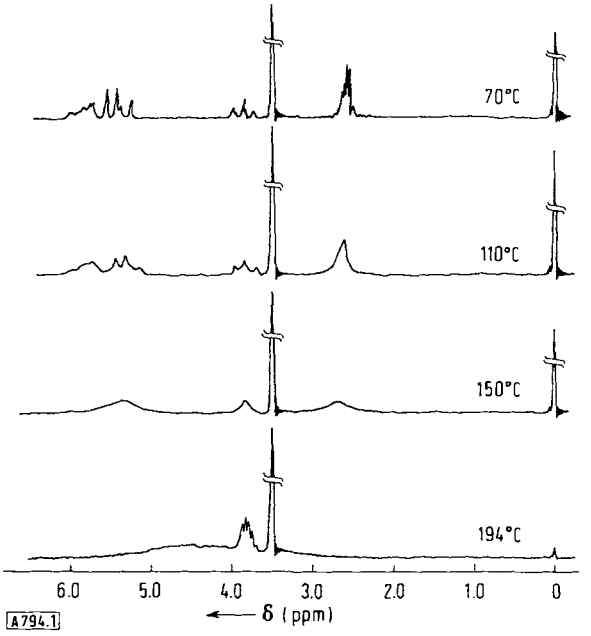


Fig. 1. 60-MHz NMR spectra of *(59)* in $Cl_2C{=}CCl_2$ solution at 70, 110, 150 and 194 °C.

Although the low temperature NMR spectra of *(59)* and *(61)* merely scramble signals within each separate absorption region (indicative of variations in concentration levels of non-degenerate isomers), elevated temperatures cause coalescence of the various proton signals with the exception of the one-proton 3.8–4.1 ppm absorption (the changes are completely reversible). These spectra are reproduced in Figures 1 and 2.

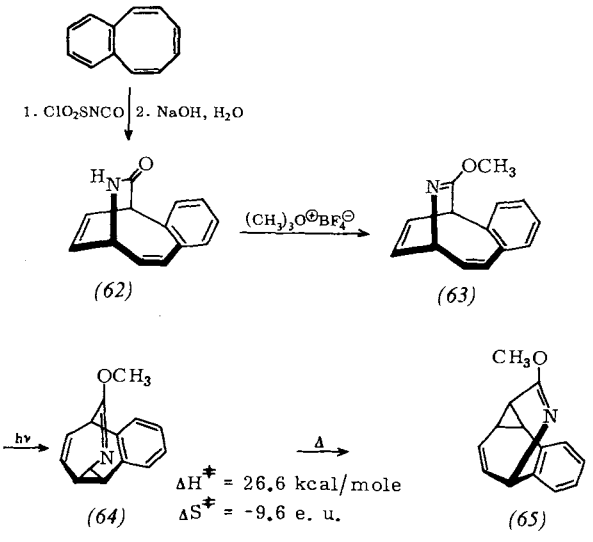
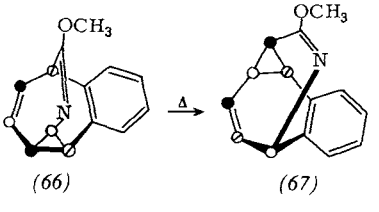
Since the ambient temperature spectra reveal the presence of three cyclopropyl and four vinyl protons in addition to the nonexchanging proton, the latter proton must occupy the bridgehead position, there must only be one such proton, and it must be positioned adjacent to nitrogen (chemical shift considerations). The NMR spectra impose the added stringent condition that the favored interconversion routes must preserve the positional integrity of the bridgehead proton and thereby insulate it from the scrambling that occurs among the other protons. The only averaging process that can give rise to the observed behavior is the sequential combination of two Cope rearrangements illustrated in Figure 3. The two-step conversion amounts formally to a rotation of the inner triatomic "spoke" on the outer "rim" by $2\pi/7$ radians (note wheel in Figure 3), it being

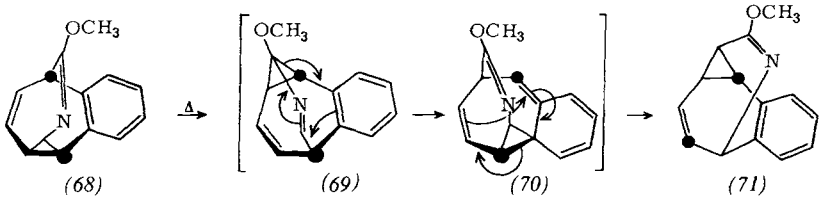


[A 794.3]

Fig. 3. The sequential Cope rearrangements in *(59)* and *(61)* showing the averaging of the seven peripheral hydrogens coupled with retention of the structural integrity of the triatomic "spoke".



evident that continued repetition of such a process would average the rim positions and exclude the spoke. Each of the seven equivalent structures thus generated is connected by a second Cope rearrangement to a more stable isomer (positioned on the outer periphery of the wheel)[51].

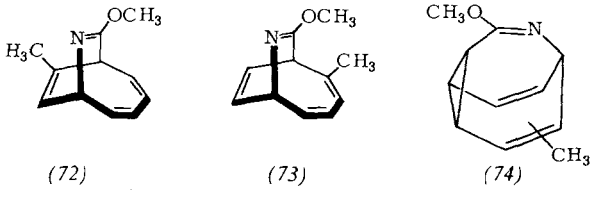


The reason that such a relatively simple averaging process occurs is apparently the strong preference of the nitrogen atom for participation in a double bond. By precluding any rearrangement path that places the heteroatom in the three-membered ring or at the bridgehead position, the integrity of the skeletal atoms constituting

the spoke is maintained and the number of accessible structural arrangements is limited to the 28 shown. The Cope rearrangement which necessitates placement of the methoxyl or methylthio substituent at one of the cyclopropyl positions with simultaneous disruption of the imino ether functionality is very likely rate-determining. The lower coalescence temperature exhibited by *(61)* [relative to *(59)*] denotes that it is somewhat less energetically demanding in the case of $-(CH_3S)C=N-$ than of $-(CH_3O)C=N-$, in agreement with the greater stability of the latter functionality. The decided preference of *(59)* and *(61)* to exist in the ground state as the outermost structures in Figure 3 has been attributed to an electronegativity effect[49].

In contrast, methoxybenzazabullvalene *(64)*, available from benzocyclooctatetraene as shown below, undergoes an irreversible reaction at 125–150 °C with the formation of a different methoxybenzazabullvalene *(65)*[49, 51a].

● = fully deuterated; ∅ = partially deuterated



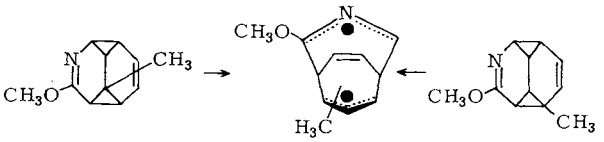
[51] There exists no spectral evidence for the presence of the seven valence tautomers which occupy the inner sphere of the wheel.

[51a] *L. A. Paquette* and *J. R. Malpass*, J. Amer. Chem. Soc. *90*, 7151 (1968).

[52] *L. A. Paquette, J. R. Malpass* and *G. R. Krow*, J. Amer. Chem. Soc. *92*, 1980 (1970).

Appropriate deuterium labeling studies show that the photorearrangement of *(63)* to *(64)* proceeds exclusively by way of a di-π-methane rearrangement involving vinyl-vinyl bonding in its initial stages[52]. More pertinent to the present discussion is the conclusion founded upon the thermal rearrangement of two differently labeled benzazabullvalene A's [*(66)* and *(68)*], that the formation of benzazabullvalene B's *(65)*, *(67)*, and *(71)* is the result of a Cope rearrangement sequence[52]. It is particularly significant and informative that this mechanistic pathway is followed since the first step [*i.e.*, *(68)*→*(69)*] requires disruption of the imino ether functionality, and the second step [*i.e.*, *(69)*→*(70)*] necessitates loss of aromatic character in the benzene ring.

Lastly, consideration should be given to the detailed mechanism which can account for the selectivity in methyl scrambling noted in the pyrolysis of *(72)*-*(74)* (600° C, flow system)[53,54]. Under these conditions, *(72)* and *(73)* suffer loss of methanol and afford in > 95% yield all the possible monomethylquinolines except 2-methylquinoline (Tab. 2). Pyrolysis of *(74)* afforded also a mixture of methylquinolines (95% yield), but in contrast, 2-methylquinoline was now the major product.



(72) *(73)* *(74)*

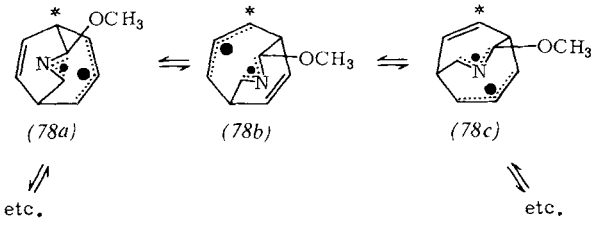


Table 2. Product data for the pyrolysis of *(72)*, *(73)*, and *(74)*.

Products	Substrate pyrolyzed *(72)*	*(73)*	*(74)*
	Composition (%)		
8-Methylquinoline	13	19	11
7-Methylquinoline	25	19	16

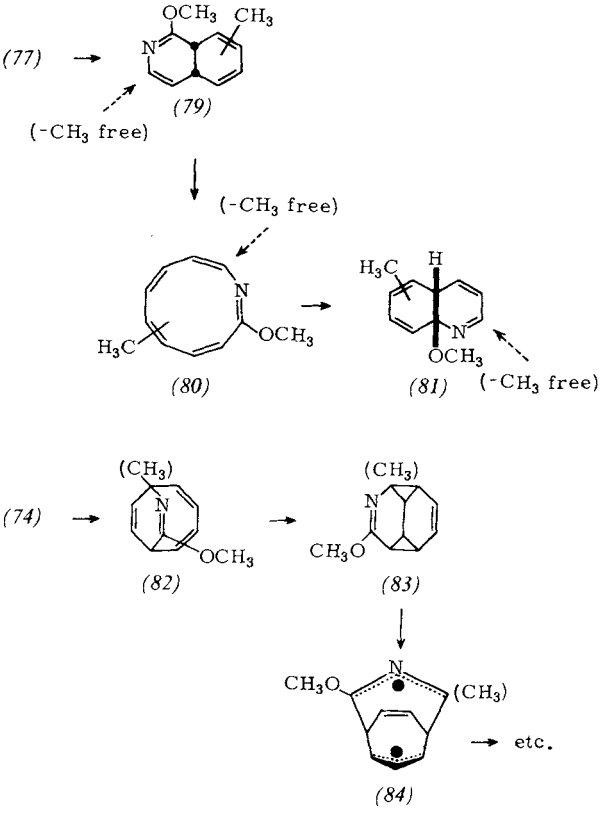
5-Methylquinoline	21	15	12
4-Methylquinoline	25	15	11
3-Methylquinoline	5	15	9
2-Methylquinoline	0	0	32
	100	100	100

It has been proposed[54] that *(72)* and *(73)* first undergo (4+2)π cycloaddition to give the two structurally distinguishable azatetracyclo[4.4.0.0^{2,10}.0^{5,7}]deca-3,8-dienes *(75)* and *(76)*, respectively. Reverse (3+3+2) cycloaddition of these intermediates give the same biradical *(77)*. The most obvious way to preserve the structural integrity of the triatomic nitrogen-containing bridge while allowing for scrambling of the methyl substituent among the remaining seven positions is to invoke a rotation of the heteroatomic bridge about the seven atom rim. In the parent series, this rotation would be totally degenerate [cf *(78)*]; in the case of *(77)*, scrambling of the methyl substituent to all the rim positions occurs with preservation of the absence of alkyl labeling on the carbon atom of the pivoting bridge. Eventually, *(77)* is converted to products by cyclization to *(79)* which aromatizes by ring opening to azacyclodecapentaene *(80)*, recyclization to *(81)*, and ejection of methanol.

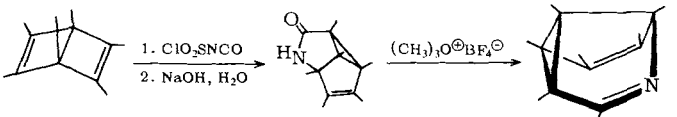


(75) *(77)* *(76)*

(78a) *(78b)* *(78c)*

Azabullvalene *(74)* yields considerable 2-methylquinoline because the methyl substituent has already found its way to the pivoting bridge due to earlier migration. The first step, namely thermal conversion of *(74)* to *(82)* can be experimentally realized at *ca.* 500 °C.

(79) *(80)* *(81)* *(82)* *(83)* *(84)*



Although the pirouetting effect associated with *(77)* and *(84)* results in a scrambling phenomenon somewhat related to that observed with the azabullvalenes, it is the first example to be encountered in a diradical species.

6. Azasemibullvalenes

As already noted, the consequence of rigidly locking a divinylcyclopropane moiety into an all-*cis* conformation as, for example, in methoxyazabullvalene is manifested in a marked acceleration of the Cope rearrangement. This fact, and the other considerations developed above, led us to undertake the synthesis of an azasemibullvalene derivative. At issue was the question of whether this ring system would exhibit valence tautomerism.

(85) *(86)* *(87)*

The azasemibullvalene derivative *(87)* has been synthesized in a three-step reaction commencing with hexamethyl (Dewar benzene) *(85)*[55,56]. Treatment of *(85)* with chlorosulfonyl isocyanate in cold methylene chloride solution and subsequent mild hydrolysis affords lactam *(86)* in excellent (87%) yield. *O*-Methylation of *(86)* with trimethyloxonium fluoroborate readily gave *(87)*. The NMR spectrum of *(87)* remained unaltered from $-40°$ to $+150°C$. Clearly, therefore, the restrictions imposed by the imino ether grouping on the possible Cope rearrangement parallel those observed with methoxyazabullvalene.

We wish to express our appreciation to the National Science Foundation, the National Institutes of Health, and Eli Lilly and Company for their support of the work performed at The Ohio State University in cooperation with my most able colleagues Larry Anderson, James Barrett, Thomas Barton, Robert Haluska, John Hansen, Tsuyoshi Kakihana, John Kelly, Grant Krow, Donald Kuhla, Louis Leichter, John Malpass, J. Christopher Philips, and Earl Whipple.

Progress in the Hetaryne Field[1]

By Thomas Kauffmann and Rolf Wirthwein[*]

Dedicated to Professor Wilhelm Klemm on the occasion of his 75th birthday

During recent years, instead of concentrating on the detection of the intermediacy of new hetarynes, as they did between 1958 and 1964, workers in this field have been more concerned with the critical sifting and checking of the earlier work. Special interest has been shown in the relation between structure and reactivity in the hetarynes. It has been shown that in addition to the elimination-addition mechanism (EA; hetaryne intermediate), other reaction paths (anomalous addition-elimination mechanism [AE_a] and "Reinecke mechanism") are possible for nucleophilic cine-substitutions on hetaryl halides. The use of deuterated hetaryl halides has proved very valuable for the elucidation of the mechanism of nucleophilic substitutions. Even where substitution mechanisms are superimposed on one another the occurrence of a hetaryne intermediate can be detected by a technique known as the "base competition method". A five-membered hetaryne (4,5-didehydro-1-methylimidazole) has been detected for the first time by this method with a probability that borders on certainty. Selectivity determinations have shown that the replacement of a CH group in 1,2-didehydrobenzene and in 1,2-didehydronaphthalene by an N atom distinctly increases the reactivity to bases. According to EHT (Extended Hückel Theory) calculations, the as yet hypothetical 2,3-didehydropyridine is richer in energy than 3,4-didehydropyridine; this agrees more closely with the experimental findings than the opposite result obtained from simple MO calculations. Besides cine-substitution (1,2 shift), tele-substitution (1,3-shift) has also been observed on reaction of hetaryl halides (pyridine, quinoline, and pyrimidine systems) with bases. An EA mechanism (via m-didehydrohetarenes) and an AE_a mechanism are considered as alternatives for the tele-substitution.

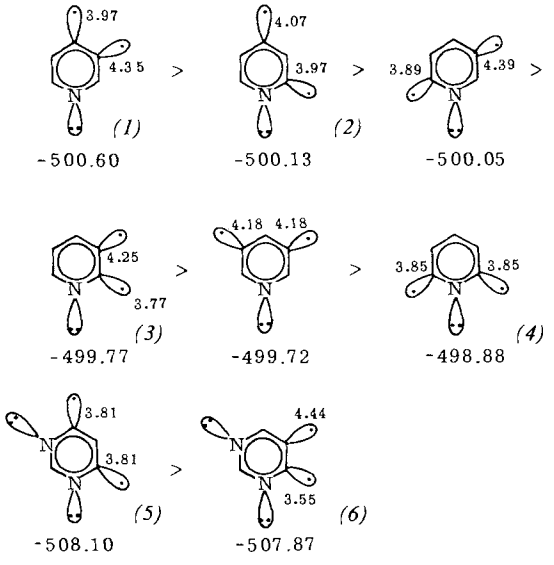
[1] Hetarynes, Part 15. – Part 14, see ref. [15].

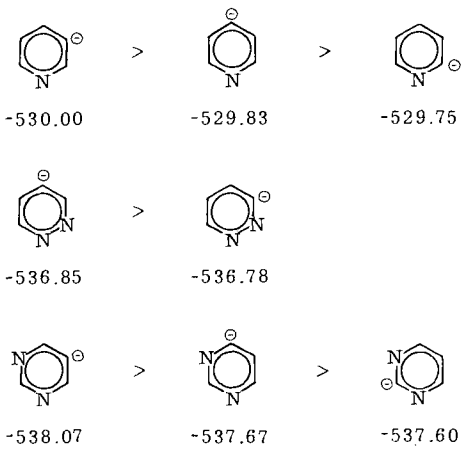
1. Introduction



Hetaryne chemistry, which developed rapidly after the discovery of 3,4-didehydropyridine (1959–1961) has already been the subject of four reviews covering the entire field [2–4]; nevertheless, the present article seems justified by new important findings. It also reports hitherto unpublished results obtained in our own research group by the base competition method. Five-membered hetarynes containing one hetero atom will be dealt with in least detail, since the latest position of investigations in this field has been adequately summarized in the two most recent reviews [2b, 4].

2. Six-Membered Hetarynes

2.1. EHT Calculations



R. Hoffmann et al. [5] have carried out EHT calculations for six-membered didehydrohetarenes and for deprotonated six-membered hetarenes, which may be taken as models for anionic didehydrohetarene precursors. The results (Tables 1 and 2) lead to a better understanding of earlier experimental observations, and will therefore be presented first.

Table 1. Total energies in eV (figures under the formulas) [6] and total valence electron densities (figures beside the orbitals) of the didehydropyridines *(1)–(4)* and of 4,5- and 4,6-didehydropyrimidines *(6)* and *(5)* [5].

Whereas simple Hückel calculations (MO theory)[7] indicated that the o-didehydropyridine *(1)* is richer in energy than *(3)*, EHT calculations lead to the opposite result. The hypothetical 2,6-didehydropyridine *(4)*, to which a relatively high stability was formerly ascribed because of the possibility of delocalization of the electrons of the extra orbitals over three atoms[7], is the least stable of all the possible didehydropyridines according to the EHT calculations, and 2,4-didehydropyridine *(2)*, whose 6-ethoxy derivative has recently been considered as an intermediate in a tele-substitution[8] (cf. Section 4), is situated even higher than 2,3-didehydropyridine *(3)* on the stability scale.

Table 2. Total energies of hetarene anions [5] in eV [6].

A higher stability is now also predicted for 4,6-didehydropyrimidine *(5)* than for 4,5-didehydropyrimidine *(6)*. On the whole, the EHT calculations contradict the previously assumed[7] stabilization by delocalization of the extra electrons over three adjacent ring atoms, and indicate, on the contrary, that pronounced destabilization of a didehydrohetarene results if the orbital of the lone pair of electrons of an N atom is immediately adjacent to the extra orbitals of the aryne bond (cf. also[9]).

Similarly, the lone pair of electrons of a nitrogen atom appears to have a destabilizing influence on *anions of six-membered hetarenes* if the anionized C atom is adjacent to the N atom (cf. Table 2).

The calculated stability sequences and total valence electron densities are in good agreement with experimental observations. For example, they explain why the action of strong bases on 3-halogenopyridines leads only to 3- and 4-substituted, but not to 2-substituted pyridines[2,3], since it must be assumed from Tables 2 and 1 that the intermediate anion *(7)* is poorer in energy than *(8)*, and that the hetaryne *(1)* is poorer in energy (by 0.83 eV or 19 kcal/mole) than *(3)*. The calculated values agree with the fact that the base-catalyzed H/D exchange in 3-chloropyridine takes place much more easily in position 4 than in position 2[10].

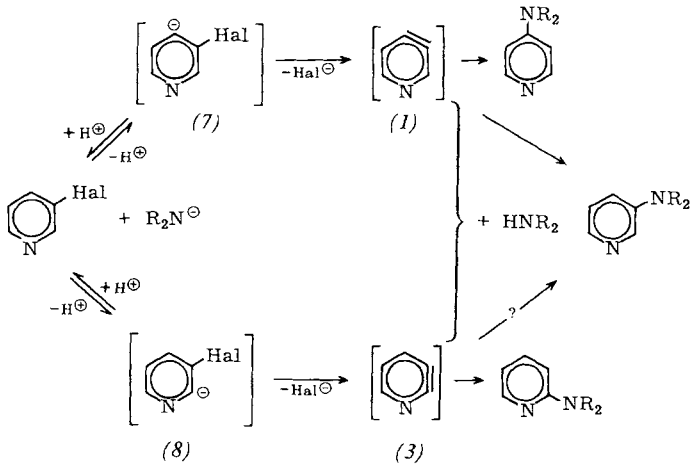
[5] *W. Adam, A. Grimison*, and *R. Hoffmann*, J. Amer. Chem. Soc. *91*, 2590 (1969); the total valence electron density on the atoms of the extra bond in 1,2-didehydrobenzene was found to be 4.20.



[6] The values for the total energy are comparable only within the group of compounds having the same number of nitrogen atoms. Of the compounds in Table 1, only *(1)* and *(6)* have been definitely detected.

[7] *H. L. Jones* and *D. L. Beveridge*, Tetrahedron Lett. *1964*, 1577.

[10] *J. A. Zoltewicz* and *C. L. Smith*, J. Amer. Chem. Soc. *88*, 4766 (1966); *89*, 3358 (1967).

The results of EHT calculations for the anions of diazines (Table 2), which may also be taken as models for anionic hetaryne precursors, again agree with experimental findings since the following relative rates were found in H/D exchange studies (in *O*-deuteriomethanol at 165 °C)[11]:

Further criteria are provided by the orientation phenomena in the addition of nucleophiles to hetarynes. It can be assumed from the calculated electron densities (Table 1) that a nucleophilic attack on 3,4-didehydropyridine will take place preferentially in position 4. Ammonia[2] and (much less definitely) secondary amines[12, 14b] are in fact added preferentially in position 4. Similarly, in the addition of amines to 3,4-didehydroquinoline *(9)* (in comparison with 1,2-didehydronaphthalene), the α-C atom of the extra bond (C-4) is distinctly favored over the β-C atom (C-3) (cf. Table 5), again in agreement with the results of the EHT calculations[5].

Finally, according to the EHT calculations, 2,3-didehydropyridine *(3)* and 4,5-didehydropyrimidine *(6)* should add nucleophiles preferentially in positions 2 and 4 respectively. Though nothing certain is known as yet about the regiospecificity of the addition of bases to *(3)* and *(6)*, there is considerable evidence (cf. Sections 2.3.3 and 2.4) to suggest that these predictions are correct. It will merely be mentioned that SCF (self-consistent field) calculations for hetarynes[13] show that the ground state of these molecules is a singlet state.

2.2. Selectivity Toward Bases

Extensive studies have been devoted to the question how hetero atoms influence the reactivity of the arynes[14, 15]. These investigations have been carried out by competition experiments such as were used earlier by *Huisgen et al.*[16] to compare the reactivities of 1,2-didehydrobenzene, 1,2-didehydronaphthalene, and 9,10-didehydrophenanthrene.

The competition constants found in these earlier measurements with the base pair phenyllithium/lithium piperidide for the carbocyclic arynes mentioned were $K = 4.4$, 5.8, and 12.8, respectively. On the basis of bond lengths of 1.39 Å for the CC bond in benzene (X-ray analysis), 1.365 Å for the 1,2 bond in naphthalene (X-ray analysis), and 1.352 Å for the 9,10 bond in phenanthrene (calculated value)[17], it was concluded that the increasing selectivity and decreasing reactivity indicated by the competition constants were due to increasing overlap of the extra orbitals in the order 1,2-didehydrobenzene, 1,2-didehydronaphthalene, 9,10-didehydrophenanthrene[16].

2.2.1. Competition Constants

The base pair phenyllithium/lithium piperidide used in competition experiments with carbocyclic arynes[16] is unsuitable for use with hetarynes such as 3,4-didehydropyridine or 5,6-didehydroquinoline, since undesirable side reactions[3] occur. Diethylamine and diisopropylamine were therefore used as the base pair for the competition experiments with hetarynes, in which only aryl halides were used that react entirely by the EA mechanism under the reaction conditions (for detection cf.[15]).

To produce the aryne, a solution of phenyllithium in ether is added dropwise to a solution of an aryl halide and the two amines (used in various proportions) in ether (molar ratio aryl halide : phenyllithium : Σ amines = 1 : 1 : 10). The amines are metalated by the phenyllithium to form lithium amides. These convert the aryl halide into the aryne and are themselves continuously consumed, so that their concentration is always low in relation to the concentration of the amine. Check experiments[15] have confirmed that essentially only the free amines are added to the aryne intermediates.

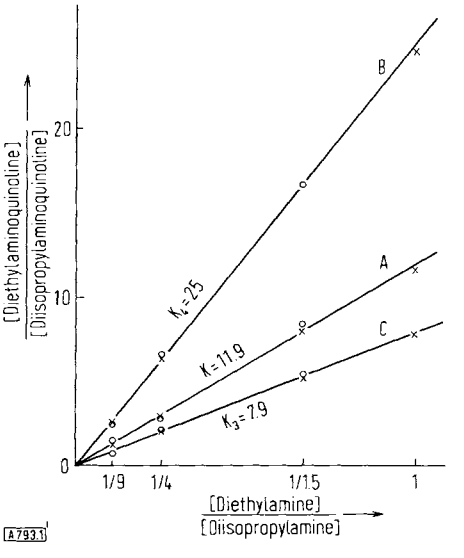

Fig. 1. Determination of the competition constant K (line A) and of the partial competition constants K_3 (line C) and K_4 (line B) in the competitive addition of diethylamine/diisopropylamine to 3,4-didehydroquinoline [25, 26]. amine, the result was a straight line (*e.g.* A in Fig. 1), the slope of which corresponds to the competition constant:

$$K = \frac{[\text{diethylaminoarenes}]}{[\text{diisopropylaminoarenes}]} \times \frac{[\text{diisopropylamine}]}{[\text{diethylamine}]}$$

of the aryne. Competition constants found in this way are given in Table 3.

Hal = Cl, Br; DA = $N(C_2H_5)_2$; DI = $N(i\text{-}C_3H_7)_2$

Table 3. Competition constants in competition experiments with diethylamine/diisopropylamine.

The competition constants show the following:

1) The replacement of a CH group that is not adjacent to the extra bond in 1,2-didehydrobenzene or 1,2-didehydronaphthalene by a nitrogen atom considerably decreases the selectivity toward bases[18], since additions to the hetarynes *(1)*, *(9)*, and *(15)* are much less selective than additions to the corresponding carbocyclic arynes *(16)* and *(17)*. Since the presence of nitrogen as a hetero atom in aromatic systems results in a system having fewer π electrons, the increased electrophilic activity of hetarynes is understandable.

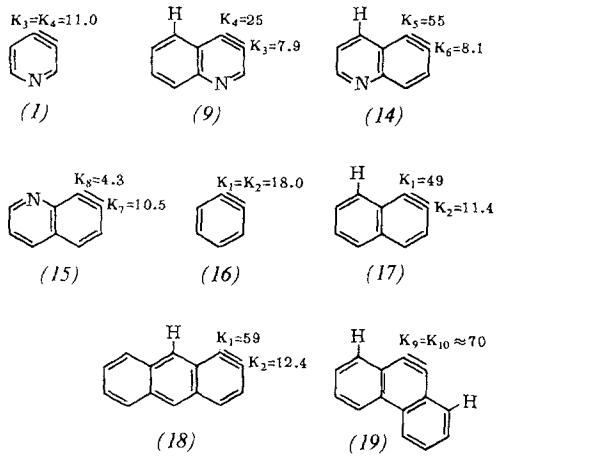
2) Fusion of a benzene or pyridine ring onto the 3,4-bond of 1,2-didehydrobenzene also leads to a decrease in selectivity.

3) In agreement with *Huisgen*'s results[16], fusion of a benzene ring onto 1,2-didehydrobenzene on each side of the extra bond [9,10-didehydrophenanthrene *(19)*] greatly increases the selectivity.

2.2.2. Partial Competition Constants

A base normally adds to an aryne in both possible orientations. In an aryne that is unsymmetrical with respect to the extra bond (as is normal in heterocyclic arynes), therefore, it is possible to distinguish two addition reactions, *e.g.* addition of the base residue to C-3 and C-4 in 3,4-didehydroquinoline *(9)*. In competition experiments (cf. Section 2.2.1), therefore besides the competition constant K, which refers to both orientations of the addition of the base (line A in Fig. 1), one can also determine "partial competition constants" (K_1, K_2, K_3, *etc.*) for the two partial reactions[14b, 15], which are defined in the same way as K (lines B and C in Fig. 1). For 3,4-didehydroquinoline *(9)* and the base pair diethylamine/diisopropylamine, for example,

$$K_3 = \frac{[\text{3-diethylaminoquinoline}]}{[\text{3-diisopropylaminoquinoline}]} \times \frac{[\text{diisopropylamine}]}{[\text{diethylamine}]}$$



$$K_4 = \frac{[\text{4-diethylaminoquinoline}]}{[\text{4-diisopropylaminoquinoline}]} \times \frac{[\text{diisopropylamine}]}{[\text{diethylamine}]}$$

The partial competition constants (Table 4) show the selectivity at the two C atoms of the extra bond, and are therefore often more informative than the competition constants K. In unsymmetrical arynes whose extra bond is in the α,β position in relation to a fused aromatic ring, the α-C atom of the extra bond exhibits a particularly high partial competition constant, *i.e.* the system has a high "α-selectivity", if there is an H atom in the peri position with respect to the α-C [arynes *(9)*, *(14)*, *(17)*, and *(18)*]. This may be assumed to be partly or entirely due to steric hindrance of the addition of diisopropylamine. Thus steric hindrance of the addition of the bulky diisopropylamine to the α-C atom because of the H atom in the peri position has been found for 1,2-didehydronaphthalene *(17)*[19], 3,4-didehydroquinoline *(9)*, and 5,6-didehydroquinoline *(14)*[15], whereas the addition of diethylamine is unhindered (cf. Table 5). The extremely low α-selectivity of 7,8-didehydroquinoline *(15)*, in which there is no steric hindrance to the addition to the α-C atom, because of the absence of an H atom in the peri position, is further evidence that steric hindrance is a cause of high α-selectivity. In this case the β (7) position should be more strongly screened than the α (8) position, since the orbital of a lone pair of electrons on the nitrogen should take up less space than an H atom (cf. Table 5).

[18] *Kauffmann* and *Nürnberg* [3], on the other hand, found a higher selectivity for 3,4-didehydropyridine ($K = 1.5$) than for 1,2-didehydrobenzene ($K = 1.0$) in competition experiments with piperidine/diethylamine. Later investigations showed, however, that the results of competition experiments with this base pair are not very conclusive; cf. [14, 15].

[19] *R. Huisgen* and *L. Zirngibl*, Chem. Ber. *91*, 2375 (1958).

Table. 4. Partial competition constants in competition experiments with diethylamine/diisopropylamine.

The extremely high selectivity of 9,10-didehydrophenanthrene *(19)* is evidently due to the fact that double the "α-selectivity" is found in this case since the C atoms of the extra bond both correspond to the α-C atom of *(17)* as far as the neighborhood of a peri-H atom is concerned[20].

Table 5. Addition of the base residue to the two C atoms of the extra bond in the addition of bases to 1,2-didehydronaphthalene and aza analogs.

Aryne	Reaction with	Addition (%) to C-α[a]	to C-β[a]	Ref.
1,2-didehydronaphthalene *(17)*	piperidine	31	69	[22]
	diethylamine	39	61	[22,15]
	diisopropylamine	13	87	[19,15]
	dicyclohexylamine	7	93	[19]
	phenyllithium	36	64	[23]
	lithium piperidide	25	75	[15]
3,4-didehydroquinoline *(9)*	piperidine	51	49	[24]
	diethylamine	51	49	[14b,25]
	diisopropylamine	25	75	[14b,25]
	dicyclohexylamine	27	73	[26]
	KNH_2/NH_3	56	44	[27]
5,6-didehydroquinoline *(14)*	piperidine	28	72	[28]
	diethylamine	31	69	[14b,15]
	diisopropylamine	5-6	94-95	[14b,15]
7,8-didehydroquinoline *(15)*	piperidine	36	64	[15]
	diethylamine	40	60	[15]
	diisopropylamine	62	38	[15]

[a] Based on the undehydrogenated aromatic nucleus.

[20] Steric hindrance is presumably also responsible for the high selectivity of 9,10-didehydrophenanthrene in the competitive addition of phenyllithium and lithium piperidide [16] (both are dimeric in ether [21]), since lithium piperidide is added to a smaller extent than phenyllithium in the sterically hindered α position of 1,2-didehydronaphthalene (cf. Table 5).

[26] *R. Wirthwein,* Dissertation, Technische Hochschule Darmstadt 1969.

In the bicyclic arynes *(9), (14),* and *(17),* as well as in *(18),* on the other hand, the high α-selectivity is less noticeable in the overall behavior of the arynes, since it is offset by the lower selectivity of the β-C atom. This "β-selectivity" is much more strongly dependent on electronic factors than the α-selectivity, and so provides more information about effects of that kind (cf.[15]). The overall impression conveyed by the data in Tables 3 and 4 is that, apart from steric factors, *the situation in the arynes is similar to that in the corresponding arenes;* in both cases the reactivity toward bases is increased by replacement of ring C atoms by N atoms and by fusion of aromatic rings.

2.3. EA/AE_n Competition in Nucleophilic Substitutions on Hetaryl Halides

Since there is as yet no method by which hetarynes can be produced in reasonable quantities, except by the action of bases on hetaryl halides, the main importance of the hetarynes still lies in their occurrence as intermediates in nucleophilic substitutions on hetaryl halides by the EA mechanism. In these reactions, the substitution by the EA mechanism is frequently (much more so than in the carbocyclic series) accompanied by substitution by the normal addition-elimination (AE_n) mechanism. This is often an undesirable situation from the preparative point of view, but the EA or the AE_n mechanism can be favored as desired by suitable choice of the conditions.

2.3.1. Factors that Determine the EA/AE_n Ratio

Whereas earlier investigations on EA/AE_n competition in the action of bases on halides of six-membered hetarenes had yielded abundant information (cf. "Mechanism Maps"[3]) about the influence of the proton affinity of the nucleophile (lithium amide and free amines) and the position of the halogen on the aromatic system, the topics studied in recent years have been the effects of the bulkiness of the nucleophile and of the nature of the halogen[29]. Investigations of this nature were possible for 4-halogenopyridines following the discovery, in reactions of 3-halogenopyridines (Cl, Br) in boiling ether with lithium piperidide/piperidine[12], lithium diethylamide/diethylamine[29], and lithium diisopropylamide/diisopropylamine[29], that 3,4-didehydropyridine formed as an intermediate under these conditions reacts in a constant "aryne ratio" of 48:52 to form the 3- and 4-substituted pyridines[30].

The same substitution products were formed in similar reactions with 4-chloropyridine. However, the aryne ratio of about 48:52 was found only when the very bulky

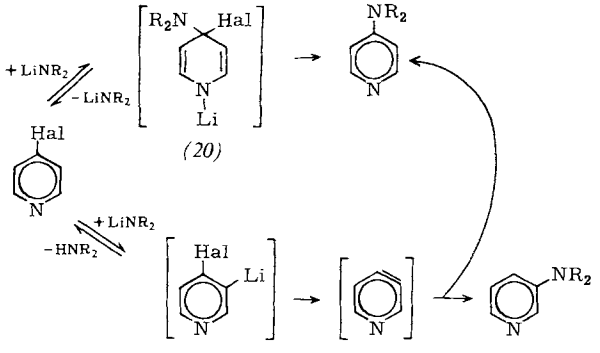
[28] *Th. Kauffmann, J. Hansen,* and *R. Wirthwein,* Liebigs Ann. Chem. *680,* 31 (1964).

[29] *Th. Kauffmann* and *R. Nürnberg,* Chem. Ber. *100,* 3427 (1967).

[30] There is very much more free amine than lithium amide present under the experimental conditions. The hetaryne thus probably reacts almost exclusively with the free amine [20].



lithium diisopropylamide was used[29]. With the other lithium amides, the increased formation of the 4-isomer (cf. Table 6) showed the participation of the AE_n mechanism. With lithium piperidide as the base, the AE_n mechanism almost completely displaced the EA mechanism. Table 6 shows similar situations in corresponding reactions with 4-chloroquinoline, 3-fluoroquinoline, and 8-chloroquinoline.

Table 6. Influence of the bulkiness of the nucleophile on the mechanism of nucleophilic substitutions on hetaryl halides (in ether, 35 °C).

Hetaryl halide	Base [a]	AE_n (%)	EA (%)
4-chloropyridine [29]	LiPip/HPip	97	3
	LiDA/HDA	19	81
	LiDI/HDI	0	100
4-chloroquinoline [26]	LiPip/HPip	91	9
	LiDA/HDA	20	80
	LiDI/HDI	0	100
3-fluoroquinoline [26]	LiPip/HPip	100	0
	LiDA/HDA	12	88
	LiDI/HDI	0	100
8-chloroquinoline [26]	LiPip/HPip	98	2
	LiDA/HDA	65	35
	LiDI/HDI	no substitution reaction	

[a] Pip, DA, DI = piperidino, diethylamino, and diisopropylamino residues.

The increasing participation of the AE_n mechanism in the order lithium diisopropylamide < diethylamide < piperidide can be best explained by the assumption that with decreasing bulkiness the amines react more rapidly with the hetaryl halides listed in Table 6 to form an adduct of the type *(20)*. In the EA mechanism, which begins with *o*-metalation of the halide, the bulkiness of the base, as expected, is less important.

The dependence of the EA/AE_n ratio on the nature of the halogen had been recognized in reactions of 3-halogenopyridines[12] with lithium piperidide/piperidine, since the fluoro compound, unlike the other 3-halogenopyridines, reacted exclusively by the AE_n mechanism. The reactions listed in Table 7 for 4-halogenopyridines and 4-halogenoquinolines show that even the replacement of chlorine by bromine can have a decisive effect on the EA/AE_n ratio.

Since less bulky base residues favor the AE_n mechanism in relation to the EA mechanism, it seems reasonable to attribute the increasing participation of the AE_n mechanism in the order I < Br < Cl < F to the decreasing bulk of the halogens, since the adduct formation is increasingly facilitated. However, other explanations are also offered by the difference in the polarizabilities of the halogen atoms[29].

Table 7. Influence of the halogen in hetaryl halides on the mechanism of the nucleophilic aromatic substitution (in ether, 35 °C).

Base	Hetaryl halide	AE_n (%)	EA (%)	Ref.
LiPip/HPip	4-fluoropyridine	100	0	[29]
LiPip/HPip	4-chloropyridine	97	3	[29]
LiPip/HPip	4-bromopyridine	10	90	[29]
LiPip/HPip	4-iodopyridine	4	96	[29]
LiPip/HPip	4-chloroquinoline	91	9	[26]
LiPip/HPip	4-bromoquinoline	16	84	[26]
LiDA/HDA	4-chloropyridine	19	81	[29]
LiDA/HDA	4-bromopyridine	0	100	[29]

[a] Pip, DA = piperidino and diethylamino residues.

If it is desired to avoid the EA mechanism, which generally leads to an isomer mixture, it is therefore advisable to use less bulky bases and a fluoro or chloro compound of the hetarene in question. If, on the other hand, one wishes the formation of a hetaryne, *i.e.* if one wishes to promote the EA mechanism, relatively bulky bases should be allowed to react with the appropriate bromide or iodide; however, reductive dehalogenation tends to occur as a side reaction when bromides are used, and this tendency is further increased with iodides.

2.3.2. Detection of Hetarynes when EA and AE_n Mechanisms Occur Concurrently ("Base Competition Method")

The carbocyclic or heterocyclic aryne formed in the EA mechanism usually adds bases in both possible orientations. Where an unsymmetrical aryne intermediate occurs, therefore, an "unrearranged" substitution product and a "rearranged" product are normally formed. In a pure EA mechanism, the ratio of these products is determined only by the rates of addition of the base to the aryne in the two orientations. The occurrence of an aryne intermediate and reaction exclusively by the EA mechanism can therefore be conclusively demonstrated if the isomer ratio can be shown to be constant when the halogen in the starting compound is varied[31]. The validity of this method depends on two conditions:

1) Two substitution products must be formed.

2) No other mechanism of nucleophilic aromatic substitution may occur in addition to the EA mechanism.

If one of these two conditions is not satisfied (superposition of two or three mechanisms of nucleophilic aromatic substitution is shown, if two substitution products are formed, by the inconstancy of the isomer ratio when the halogen is varied), the "base competition method"[25,32] may be used for the detection of arynes (only with reservations where three mechanisms occur). This is particularly important in the heterocyclic series, since an additive mechanism is then often superimposed

[31] *R. Huisgen* and *J. Sauer*, Chem. Ber. *91*, 1453 (1958).

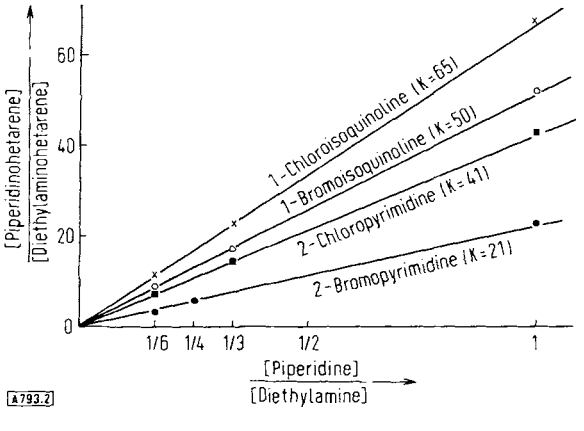
[32] *Th. Kauffmann, R. Nürnberg, J. Schulz*, and *R. Stabba*, Tetrahedron Lett. *1967*, 4273.

on the EA mechanism; moreover, the detection of heterocyclic arynes by interception with dienes has proved very unreliable[4,33].

In the "base competition method", two aryl halides that differ only in the nature of the halogen atom are allowed, in separate experiments, to react with *two* bases (competition experiments, cf. Section 2.2). The molar ratios of the "unrearranged" and/or "rearranged" substitution products as found by gas chromatography are plotted on graphs against the molar ratio of the competing bases. It is generally possible to recognize, from the resulting diagram, which substitution mechanisms (EA, AE_n, AE_a) occur.

If the aryl halides are sufficiently reactive to react with free secondary amines, the competition experiments are carried out in an autoclave at 130–180 °C without the addition of phenyllithium (method A). For less reactive halides, phenyllithium is added (method B), as described in connection with the selectivity determinations (cf. Section 2.2).

The "base competition method" derives from the fact that in a pure AE_n mechanism the competition constants found in the competition experiments are distinctly dependent on the halogen of the starting compound (cf. Fig. 2), whereas no dependence on the halogen is found in a pure EA mechanism (cf. Fig. 1), since the competition constants in this case are determined only by the rates at which the competing bases add to the common halogen-free aryne intermediate. This characteristic of the EA mechanism is also valid for the partial competition experiments (cf. Fig. 1); it can therefore be used for the detection of the EA mechanism in cases of EA/AE_n (or EA/AE_a) superposition, since only one of the two[34] partial competition constants determined by the EA mechanism will be affected by the superposition.



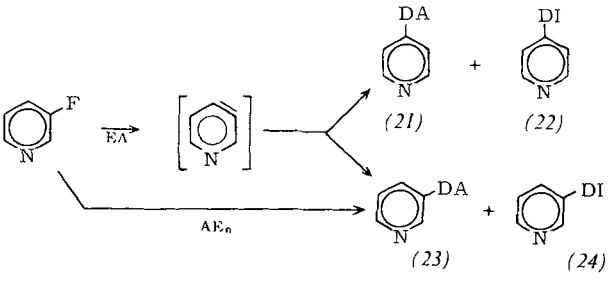


Fig. 2. Dependence of the competition constant on the halogen in nucleophilic substitution reactions with a pure AE_n mechanism. Reaction with piperidine/diethylamine (2-halogenopyrimidines by method A, 1-halogenoisoquinolines by method B). Since there is no H atom *o* to the halogen, the EA mechanism *via* a hetaryne intermediate is impossible here.

This can be illustrated by a concrete example. In competition experiments with diethylamine/diisopropylamine (by method B), 3-fluoropyridine reacts partly by the EA mechanism and partly by the AE_n mechanism, as is shown by the ratio of the 3- and 4-substitution products (cf.[29]). The "rearranged" substitution products *(21)* and *(22)* are formed exclusively by the EA mechanism; consequently, in the competition experiments,

the partial competition constant K_4 is the same as in corresponding competition experiments with 3-chloropyridine and 3-bromopyridine (cf. Fig. 3). The 3-substituted pyridines *(23)* and *(24)*, on the other hand, are formed by both the EA and the AE_n mechanisms. This is shown by the non-linear dependence of the ratio of the 3-substitution products obtained on the ratio of the bases. A non-linearity of this nature is often observed when mechanisms are superimposed (cf. Sections 2.4 and 3.2). It is evidently a typical phenomenon and in the elucidation of substitution mechanisms it therefore provides additional information, which is particularly valuable when *three* mechanisms are superimposed on one another.

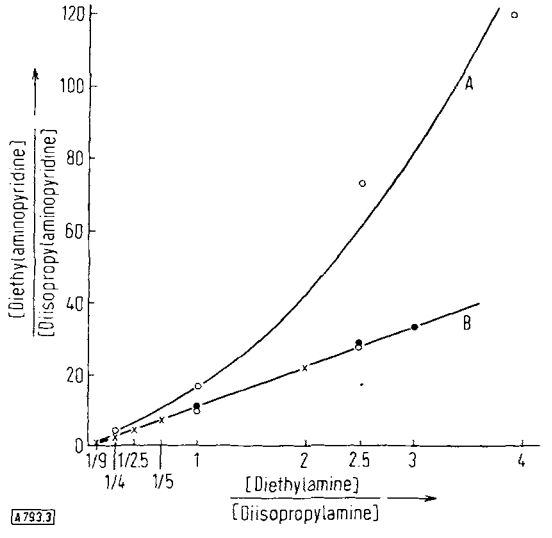

Fig. 3. Competition experiments with 3-fluoropyridine (○) and diethylamine/diisopropylamine by method B [25] (EA/AE_n superposition; evaluation of the 3- and 4-substituted pyridines) and corresponding experiments with 3-chloropyridine (●) and 3-bromopyridine (×) (pure EA mechanism; evaluation only of the 4-substituted pyridines). Curve A: evaluation of the 3-substituted pyridines; line B: evaluation of the 4-substituted pyridines.

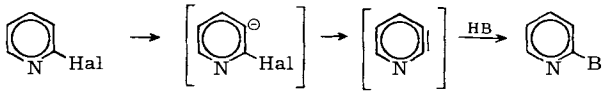
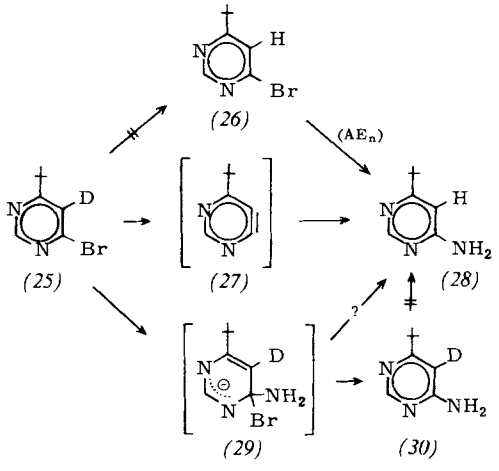
As will be shown in Sections 2.3.3 and 2.4, the "base competition method" is also suitable for the detection of AE_n and AE_a mechanisms.



2.3.3. EA/AE_n Competition in Hetaryl Halides with Imidoyl Halide Structures

Halides of six-membered hetarenes having imidoyl halide structures such as 2-halogenopyridines and 2-halogenoquinolines give only 2-substituted hetarenes on reaction with secondary halides or their lithium compounds or even with KNH_2/liquid NH_3 provided that no resinification or tele-substitution (cf. Section 4) occurs.

[33] *G. Wittig* and *M. Rings*, Liebigs Ann. Chem. *719*, 127 (1968).



[34] It is assumed here that two positionally isomeric substitution products are formed, as is usual in the EA mechanism.

By analogy with the mechanism of the Chichibabin reaction[35] therefore, these reactions have been assumed to proceed by the AE_n mechanism. However, they could also proceed by an EA mechanism.

According to EHT calculations (cf. Section 2.1), this mechanism is not unlikely, since the 3-pyridyl anion (model of the anionic hetaryne precursor) is relatively poor in energy and 2,3-didehydropyridine is electron-deficient on C-2, which could explain the exclusive uptake of the nucleophile in position 2.

The exclusive formation of the nondeuterated 4-amino compound *(28)* has in fact been observed in the comparable reaction of 4-bromo-6-*tert*-butyl-5-deuteriopyrimidine *(25)* with KNH_2/liquid NH_3 at −75° C; this points very strongly to the EA mechanism *via (27)*[36, 37].

The final elucidation of this problem should be possible by the base-competition method (cf. Section 2.3.2). Unequivocal results were obtained by competition experiments with 2-halogenopyridines (Hal = Cl,Br) using method A[25] and with 2-halogeno-4-methylquinolines (Hal=F,Cl,Br) using method B[39,40], with piperidine/diethylamine as the base pair; as in the corresponding experiments with halogenopyridines and halogenoisoquinolines (see Fig. 2), the product ratio was found to exhibit a strictly linear dependence on the base ratio, and the competition constants were strongly dependent on the halogen (cf. Fig. 4). This rules out a pure EA mechanism in these cases, and suggests a pure AE_n mechanism.

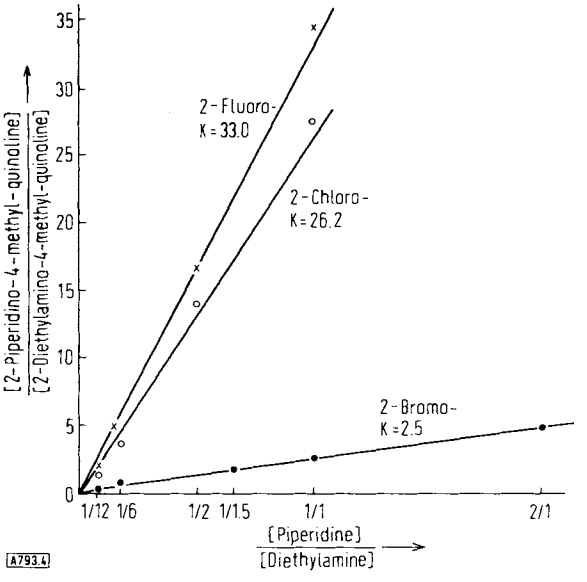


Fig. 4. Competition experiments with 2-halogeno-4-methylquinolines and piperidine/diethylamine (by method B) [39].

With the relatively bulky base pair diethylamine/diisopropylamine (the EA mechanism should be favored by the use of bulky bases, cf. Section 2.3.1), competition experiments on 2-halogenoquinolines (method B, Fig. 5)[41] gave a strictly linear dependence of the product ratio on the base ratio and a high competition constant only for Hal = F, for which the AE_n mechanism is most likely (cf. Section 2.3.1).

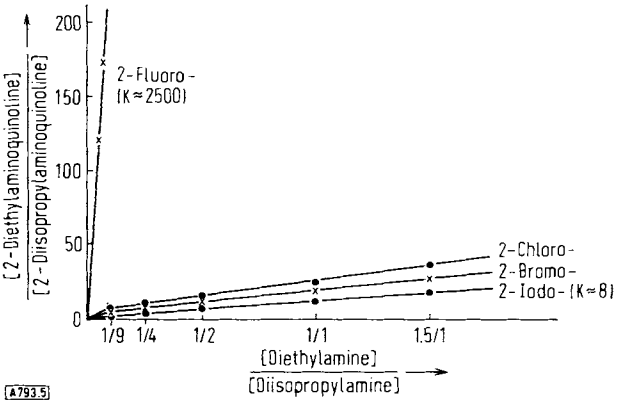

Fig. 5. Competition experiments with 2-halogenoquinolines and diethylamine/diisopropylamine (by method B) [41].

For Hal = Cl, Br, and I, the dependence of the product ratio on the base ratio was not perfectly linear, and the competition constants found were very similar to one another and of the same order of magnitude as in selectivity determinations carried out in the same manner on hetarynes (Tables 3 and 4). This suggests an EA/AE_n superposition with predominance of the EA mechanism for Hal = Cl, Br, and I, but cannot be taken as conclusive proof of the participation of the EA mechanism, the as-

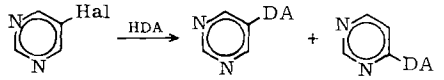
sumption of which also implies the exclusive uptake of the nucleophile in position 2 of the hypothetical 2,3-didehydroquinoline.

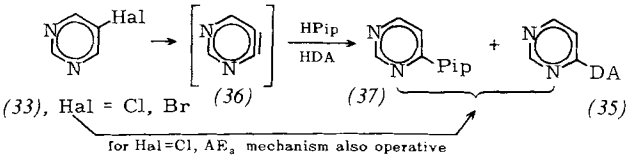
2.4. EA/AE$_a$ Competition in Nucleophilic Substitutions



The observation of cine-substitutions on reaction of hetaryl halides with bases has led in several cases to the discovery of a hetaryne. Reactions of this type are not, however, a reliable indication of the occurrence of a hetaryne intermediate, since 2-bromobenzo[*b*]thiophene *S*,*S*-dioxide reacts with piperidine in ethanolic solution by an anomalous addition-elimination mechanism (AE$_a$) to give the 3-piperidino compound[42].

On theoretical grounds (see below), it seemed probable[3] that the AE$_a$ mechanism also plays a part in the cine-substitution reactions observed by three groups of workers in 1964 with 5-halogenopyrimidines (cf.[38]). Two of these reactions have been investigated more closely.

Van der Plas et al.[36] studied the reaction of 5-bromo-6-*tert*-butyl-4-deuteriopyrimidine *(31)* with KNH_2/liquid NH_3. The resulting cine-substitution product *(28)* contained no deuterium, and the starting compound *(31)* and the deuterated amino compound *(30)* did not undergo D/H exchange under the experimental conditions. If it is assumed that no D/H exchange takes place in *(32)*, this means that the cine-substitution proceeds *via* the hetaryne *(27)* and not *via* the anomalous adduct *(32)* (intermediate of the AE$_a$ mechanism)[43].



Kauffmann et al.[38, 44] allowed 5-halogenopyrimidines *(33)* (Cl, Br) to react with diethylamine at 130 °C (autoclave) to form *(34)* and *(35)*. The ratio of *(34)* to *(35)* was found to vary with the halogen (82/18 for Hal = Cl; 40/60 for Hal = Br), ruling out a pure EA mechanism. The strong predominance of the "unrearranged" compound *(34)* points to the probable participation of the AE$_n$ mechanism in the reaction of 5-chloropyrimidine[45]. The participation of the EA mechanism was deduced from interception experiments with aniline and the inhibition of the cine-substitution *(33b)* → *(35)* by ethanol[38], which will be discussed below.

(33a), Hal = Cl *(34)* *(35)*
(33b), Hal = Br

To study the cine-substitutions further, the halides *(33a)* and *(33b)* were allowed to react with piperidine/diethylamine in competition experiments (method A; Section 2.3.2). The cine-substitution products *(37)* and *(35)* were formed in addition to other compounds[38].

If these were formed exclusively by the EA mechanism, the experimental points in Figure 6 should lie on a single straight line (cf. Section 2.3.2).

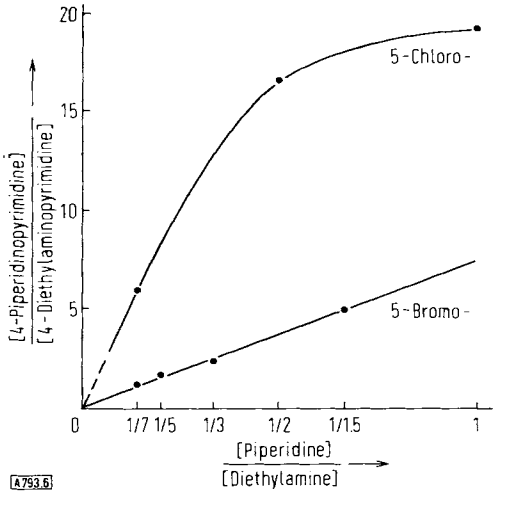


Fig. 6. Competition experiments with 5-halogenopyrimidines and piperidine/diethylamine (130 °C); evaluation of the cine-substitution products [38].

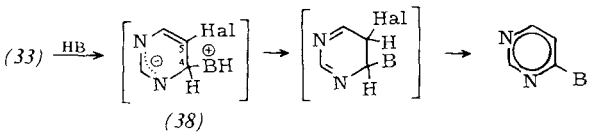
Since this is not so, a second cine-substitution mechanism must also be involved; this second mechanism must operate in the case of 5-chloropyrimidine, since the dependence of the *(37)*/*(35)* ratio on the molar ratio of the competing secondary amines was distinctly nonlinear in this case (typical of the superposition of two mechanisms; cf. Section 2.3.2). The second mechanism is probably the AE$_a$ mechanism, for which the conditions are particularly favorable in the 5-halogenopyrimidines, since the addition of a base in position 4 leads to an anomalous adduct *(38)*, in which, unlike in the normal adduct (base residue on C-5), the negative charge in-



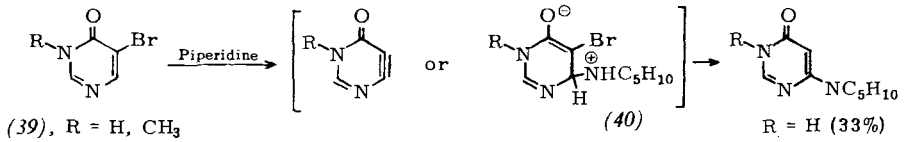
[42] *F. G. Bordwell, B. B. Lampert,* and *W. H. McKellin,* J. Amer. Chem. Soc. *71,* 1702 (1949).

[43] According to *H. C. van der Plas,* Tetrahedron Lett. *1965,* 555, a small quantity of 5-amino compound is formed as well as the 4-amino compound (4-isomer/5-isomer ratio 93:7) in the reaction of 5-bromo-6-*tert*-butylpyrimidine with KNH_2/liquid NH_3.

[44] *Th. Kauffmann, R. Nürnberg,* and *K. Udluft,* Angew. Chem. *80,* 614 (1968); Angew. Chem. internat. Edit. *7,* 617 (1968).

[45] AE$_n$ mechanism more favored in chlorides as compared with bromides (cf. Section 2.3.1).

troduced is taken over by two N atoms; this explains the intermediate occurrence of *(38)* (Hal = Cl) in addition to the energy-rich hetaryne *(36)*.



(38)

An additional and important argument in favor of the EA mechanism in the case of the bromo compound *(33b)* and the participation of the AE_a mechanism in the case of the chloro compound *(33a)* is the observation[38] that the cine-substitution in *(33b)* is completely suppressed by the *addition of ethanol* (protonation of the anionic hetaryne precursor), whereas practically no inhibition occurs in the reaction of *(33a)*[46].

Thus 5-chloropyrimidine very probably reacts with the secondary amines used by EA + AE_n + AE_a, whereas the bromo compound reacts by EA or EA + AE_n.

Good possibilities for the AE_a mechanism are theoretically also offered by hetaryl halides with a carbonyl group in the ring α to the halogen, since corresponding anomalous adducts, *e.g. (40)*, should be relatively poor in energy.

However, in the more intensively studied nucleophilic cine-substitutions of 3-halogeno-2-quinolones (reaction with piperidine at 180° C), in which a group of this type is present, only evidence of the EA mechanism was found (including constancy of the isomer ratio when the halogen is varied)[47]. Further investigations on the mechanisms of similar reactions of 3-chloro-1-methyl-2-pyridone[38], 5-bromouracil[3,48], 4-halogeno-1-methyl-2-phenylpyridazine-3,6-diones[49], and *(39)*[50] are necessary.

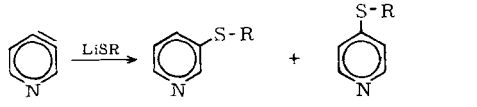
R = H (33%)

R = CH_3 (62%)



2.5. New Hetaryne Interception Reactions

9,10-Didehydrophenanthrene formed in ether by the action of lithium piperidide on 9-bromophenanthrene can be smoothly intercepted with lithium thiophenolate, since this reagent adds to the aryne much more rapidly than lithium piperidide[51]. In attempts to intercept 3,4-didehydropyridine *(1)* (formed in the same manner from 3-chloropyridine) with lithium thiophenolate, the expected thio ethers *(43a)* and *(44a)* could not be detected in the reaction mixture[52]. The reason for this may be that the addition products of lithium thiophenolate with *(1)* [*e.g. (41)*] either readily decompose further [*(1)* would then be removed from the equilibrium by irreversible addition of lithium piperidide] or cyclize with loss of lithium hydride to form thiophene derivatives [*e.g. (42)*]. Analogies are known for both possibilities[53].

(41) *(42)*

It was recently found[54] that the reaction of 3-bromopyridine or 4-chloropyridine with $NaNH_2$/liquid NH_3 in the presence of sodium methanethiolate (sixfold ex-

(1) *(43a)*, R = C_6H_5 *(44a)*, R = C_6H_5

(43b), R = CH_3 *(44b)*, R = CH_3

cess) yields *(43b)* and *(44b)* (molar ratio 1:1) in addition to 3- and 4-aminopyridines. Since the weakly basic sodium methanethiolate is unable to react with these two halogenopyridines, the products must result from interception of the hetaryne intermediate. Sodium methanethiolate may be regarded in general as a promising reagent for the interception of hetarynes.

On addition of furan to a solution of the lithium compounds *(45)* (R = NC_5H_{10}, OCH_3) in ether, the adducts *(47)* are formed in yields of 45%[55] and 35%[56] respectively. These reactions point to the intermediate formation of the 2,3-didehydropyridine derivatives *(46)*.

[46] The fact that the addition of ethanol causes practically no inhibition of the cine-substitution in the case of 5-chloropyrimidine, though the EA component should be suppressed by ethanol when EA and AE_a mechanisms occur together, can be explained by promotion of the AE_a mechanism by ethanol.

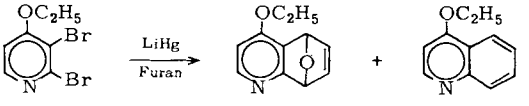
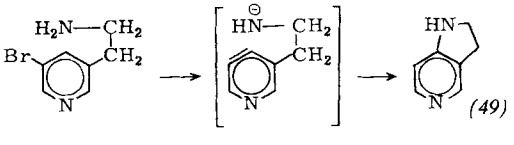
However, caution is necessary in view of the findings (cf. Section 3.1) with five-membered hetaryl halides. These reactions can therefore be accepted as showing the occurrence of *(46)* only if the conceivable routes *via (48a)* and *(48b)* can be experimentally ruled out.

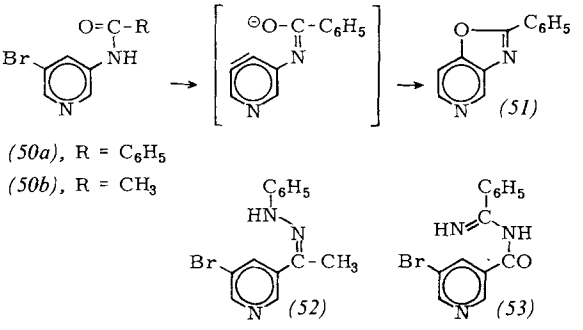


(45) *(46)* *(47)* *(48a)*



(48b)

Similar uncertainty exists in connection with the course of the reaction of 4-ethoxy-2,3-dibromopyridine with lithium amalgam and furan[57], as well as similar reactions that have been known for some time[58,59].



2.6. Side-Chain Cyclization

Some 100 examples (cf.[4]) of the cyclization of a side chain by intramolecular addition of a nucleophilic center to the aryne bond are known in the carbocyclic series. The application of this principle to hetarynes could be very useful for the synthesis of new heterocycles. It appears, however, that only two reactions of this type are known at present: Reaction of three equivalents of phenyllithium and 1.2 equivalents of diethylamine in boiling ether with 3-(β-aminoethyl)-5-bromopyridine leads to 2,3-dihydro-1*H*-pyrrolo[3,2-*c*]pyridine *(49)*[60] in 56% yield. Similarly, the action of an excess of lithium piperidide on 3-benzamido-5-bromopyridine *(50a)* in boiling ether gave 2-phenyloxazolo[4,5-*c*]pyridine *(51)* in 8% yield[60]; the low yield is partly due to the fact that *(51)* is unstable under the reaction conditions. No cyclization products could be isolated in similar reactions with *(50b)*, *(52)*, and *(53)*[60].

(51) *(52)* *(53)*

3. Five-Membered Hetarynes

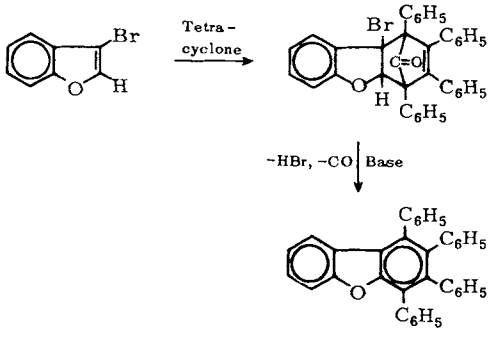
3.1. Containing One Hetero Atom

After careful analysis of the existing results on five-membered hetarynes, *R. W. Hoffmann*[4] concluded in 1967 that: "in fact no unambiguous evidence is as yet available for the formation of dehydro-derivatives of five-membered aromatic heterocycles". This situation has not changed in the meantime for five-membered hetarynes containing *one* hetero atom.

The reasons for the evident lag in relation to the chemistry of six-membered hetarynes are as follows:
1) *o*-Metalated five-membered hetaryl halides of the types *(54)*-*(56)* and related compounds that were promising hetaryne precursors have proved to be surprisingly stable. In their thermal decomposition, moreover, they always follow reaction paths that avoid a five-membered hetaryne intermediate[4,33].

(54) *(55)* *(56)*

2) The only method used so far for the attempts to detect five-membered hetarynes containing one hetero atom is interception with dienes. However, the corresponding hetaryl halides whose *o*-alkali metal or *o*-mercury compounds were used can often react with dienes, as in the example below. Since these hetaryl halides are formed from the *o*-alkali metal and *o*-mercury compounds by protolysis or thermal decomposition in the reaction mixture, this sometimes gave the impression of the occurrence of five-membered hetarynes, while in other cases it casts doubt on previous assumptions of five-membered hetaryne intermediates[4,33].



To clarify the mechanism, the cine-substitutions indicated below should now be investigated by methods that have been successful in the detection of six-membered hetarynes [checking for

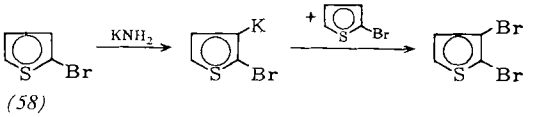
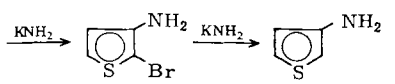
X = S; B = Piperidine, 250 °C [63]

[4]



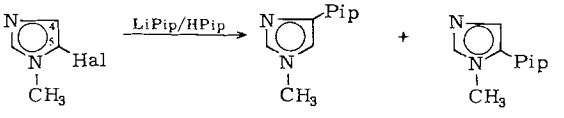
[42, 64]



(57)

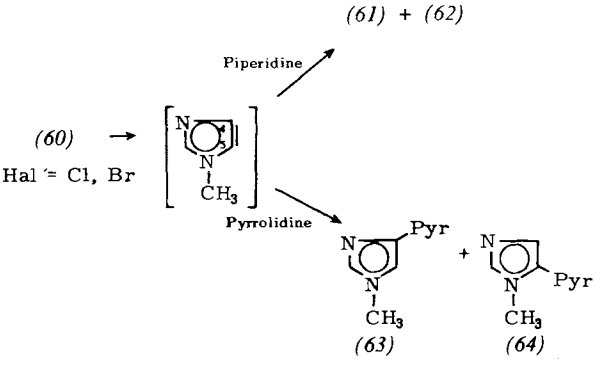
Owing to the high stability of lithium compounds of the types *(54)* and *(55)*, which is partly due to the inductive effect of the hetero atom in the ring, and because of the expected strong ring strain in five-membered hetarynes, the prospects for the AE_a mechanism in the cine-substitutions formulated above would be good[4]. On the other hand, unlike the N atom of the pyridine system or the $-SO_2-$ group in 2-bromobenzo[*b*]thiophene *S,S*-dioxide *(57)* (AE_a mechanism in ethanol[42]), the hetero atoms O,S, and N in five-membered hetarenes lead to an excess of π electrons on the C atoms of the heterocyclic ring, which must make nucleophilic additions introducing an AE_a (or AE_n) mechanism more difficult.

It is interesting in this connection to note that convincing evidence has been accumulated in favor of a "Reinecke mechanism" for the nucleophilic cine-substitution *(58)*→*(59)*[65] which significantly avoids both a five-membered hetaryne intermediate and an anomalous addition to the excess π-electron system.



(58)

(59) (59%)



3.2. Containing Two Hetero Atoms

Cine-substitutions on five-membered hetarenes containing two hetero atoms have only recently been discovered[32]. 5-Halogeno-1-methyl-imidazoles *(60)* (Hal = Cl, Br) react with lithium piperidide/piperidine in ether at 35 °C to give 4- *(61)* and 5-piperidino-1-methylimidazole *(62)*. The very clear dependence of the *(61)*/*(62)* ratio on the halogen in the starting compound (9/91 for Hal = Cl and 36/64 for Hal = Br[66]) rules out a pure EA mechanism. The strong preference for the formation of the "unrearranged" isomer points to the participation of an AE_n mechanism in the case of the chloro compound.

(60a), Hal = Cl *(61)* *(62)*
(60b), Hal = Br

In competition experiments with pyrrolidine/piperidine (method B, cf. Section 2.3.2), the substitution products *(61)*–*(64)* were formed.

(61) + *(62)*

Hal = Cl, Br

(63) *(64)*

The fact that the partial competition constant $K_4 = 2.2$ (line A in Fig. 7) is independent of the nature of the halogen (Cl, Br) leaves little doubt that the rearranged substitution products *(61)* and *(63)* are formed exclusively by the EA mechanism *via* 4,5-didehydro-1-methylimidazole.

For the formation of the substitution products *(62)* and *(64)* from the 5-chloro compound *(60a)* (curve B in Fig. 7), the non-linear dependence of the *(62)*/*(64)* ratio on the ratio of the competing secondary amines points to the superposition of the EA and a second substitution mechanism (presumably AE_n). The formation of the unrearranged substitution product from the bromo compound *(60b)* (line C in Fig. 7), on the other hand, also appears to proceed exclusively by the EA mechanism, in view of the linear dependence of the product ratio on the base ratio.

[64] In benzene this cine-substitution does not proceed exclusively *via* the anomalous adduct mentioned in Section 2.4 [42].

[65] *M. G. Reinecke* and *H. W. Adickes*, J. Amer. Chem. Soc. *90*, 511 (1968).

[66] Molar ratio halide : lithium piperidide : piperidine = 1 : 2.2 : 2.8.

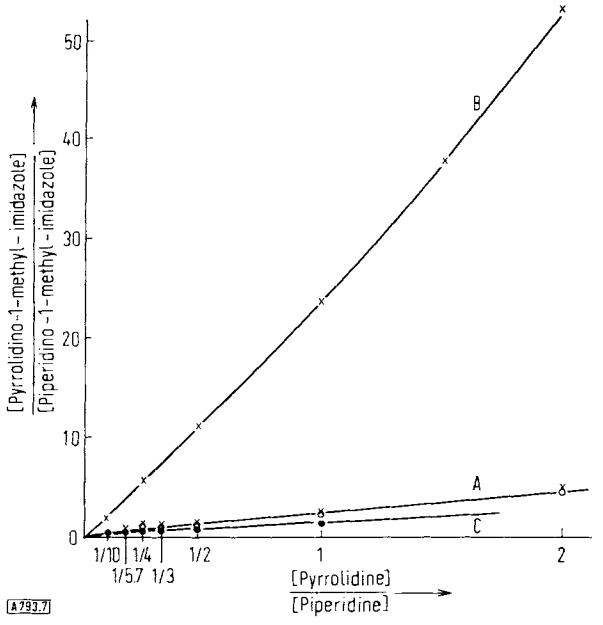

Fig. 7. Competition experiments with 5-halogeno-1-methylimidazoles *(60)* and pyrrolidine/piperidine (by method B) [32]. Line A: 4-substitution products *(61)* and *(63)* formed from *(60a)* (×) or *(60b)* (○); Line B: 5-substitution products *(62)* and *(64)* formed from *(60a)*; Line C: 5-substitution products *(62)* and *(64)* formed from *(60b)*

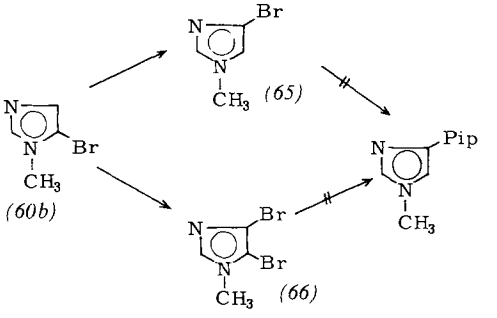
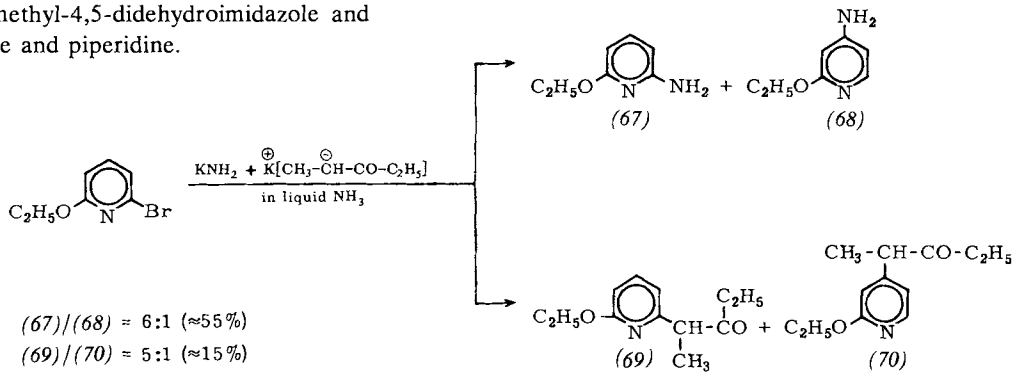


This is also indicated by the fact that the ratios (Table 8) of the quantities of isomeric pyrrolidino compounds *(63)/(64)* and of the piperidino compounds *(61)/(62)* are largely independent of the pyrrolidine/piperidine ratio. The isomer ratios found (approx. 68:32 and 72.5:27.5, respectively) apparently correspond to the aryne ratio for 1-methyl-4,5-didehydroimidazole and the bases pyrrolidine and piperidine.

Since 5-bromo-1-methylimidazole *(60b)* gives the 4-bromo compound *(65)* (yield 30%) on reaction with KNH_2/liq. NH_3[67], it seemed not unreasonable to assume

Table 8. Competition experiments with the 5-halogeno-1-methylimidazoles *(60)*; isomer ratios of the resulting pyrrolidino compounds *(63)* and *(64)* and piperidino compounds *(61)* and *(62)*.

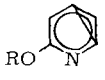


Halogen	[Pyrrolidine] / [Piperidine]	*(63)* : *(64)*	*(61)* : *(62)*
Cl	1:1	30:70	72:28
	1:2	18:82	60:40
	1:3	17:83	59:41
	1:4	16:84	54:46
Br	1:1	70:30	74:26
	1:2	67:33	72:28
	1:3	67:33	73:27
	1:4	67:33	71:29

that the above cine-substitutions, as formulated below for the piperidino compound, proceed *via* 4-halogeno-1-methylimidazoles. However, 4-chloro-1-methylimidazole and 4-bromo-1-methylimidazole do not react with lithium piperidide/piperidine in boiling ether to form 4-piperidino-1-methylimidazole[41]. Since the same is true of 4,5-dibromo-1-methylimidazole *(66)*, a cine-substitution mechanism involving an *o*-dihalogeno intermediate, as postulated by *Reinecke* for the thiophene system[65], may be ruled out, at least for 4-bromo-1-methylimidazole.

4. The Problem of *m*-Didehydrohetarenes

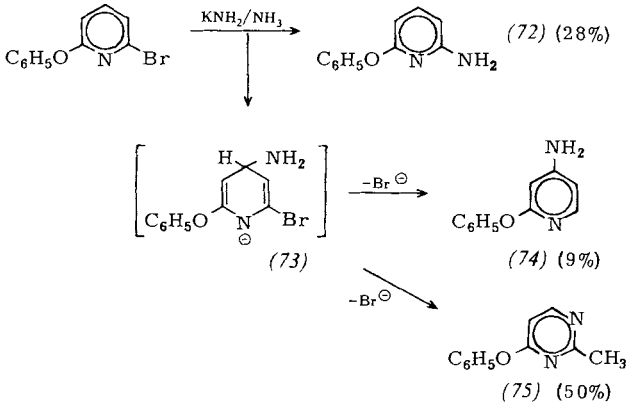
Though *m*-didehydrohetarenes are not hetarynes (= *o*-didehydrohetarenes) it seems appropriate to mention these compounds, which are purely hypothetical at present. According to EHT calculations[5] (Table 1), the hypothetical 2,4-didehydropyridine *(2)* is richer in



energy than 3,4-didehydropyridine, but poorer in energy than 2,3-didehydropyridine, for whose occurrence as an intermediate there are many indications[2-4]. It is therefore interesting to observe that in reactions of 2-bromopyridines containing a substituent ($-OCH_3$, $-OC_2H_5$, $-OC_3H_7$, $-C_6H_5$) in position 6 with KNH_2/liquid NH_3, *den Hertog et al.*[8,68,69] isolated tele-substitution products in which the new substituent occupies position 4, as in *(68)* and *(70)*. as well as "unrearranged" substitution products.

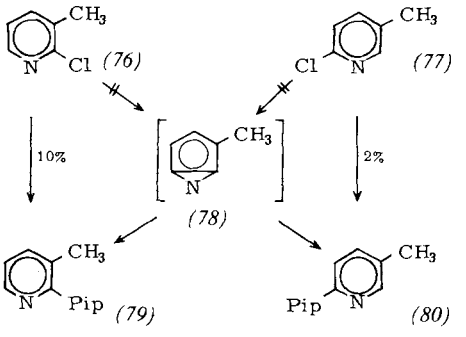
[67] *D. A. de Bie* and *H. C. van der Plas*, Recl. Trav. Chim. Pays-Bas *88*, 1246 (1969); references given there for similar halogen migrations in halogenobenzenes, halogenopyridines, halogenothiophenes, and halogeno-3-methylisothiazoles.

[68] *M. J. Pieterse* and *H. J. den Hertog*, Recl. Trav. Chim. Pays-Bas *80*, 1376 (1961).



[69] *J. W. Streef* and *H. J. den Hertog*, Tetrahedron Lett. *1968*, 5945.

An EA mechanism *via* 2,4-didehydropyridine intermediates *(71)* has been proposed for these reactions[8], since *(70)* was obtained as well as *(67)–(69)* on reaction of 2-bromo-6-ethoxypyridine with KNH_2 and potassium oxopentanide, whereas only the "unrearranged" substitution product *(69)* was formed with potassium oxopentanide alone.



(71)

These tele-substitutions can be readily explained by an AE_a mechanism *via* an anomalous adduct of the type *(73)*[70], since it is well known that potassium amide adds readily to C-4 of the pyridine system if C-2 and C-6 are substituted otherwise than with hydrogen. That one of

the substituents in these positions may be halogen is shown by the ring transformations observed for 2-halogenopyridines and 2-halogenoquinolines[27,69,71] which are introduced by the addition of the amide ion to position 4. In the reaction of 2-bromo-6-phenoxypyridine with KNH_2/liquid NH_3, for example, the ring transformation to form the pyrimidine derivative *(75)* competes with the substitution to give *(72)* ("normal") and *(74)* ("tele"). It seems plausible to assume the common intermediate *(73)* for the tele-substitution and the ring transformation.

The intermediate occurrence of 2,6-didehydropyridine and its methyl derivatives [*e.g. (78)*] was proposed[3] as a reason for the surprising observation that 2-chloropyridine and its 3- and 5-methyl derivatives resinify on reaction with lithium piperidide/piperidine (ether, 35 ° C), and give only a very small yield of the corresponding 2-piperidinopyridine[3], whereas the 2-piperidino compound is formed in 75% yield from the 6-methyl derivative[3] and in 95% yield from 2-chloroquinoline[26]. Since it has been found[72] since then that the tele-substitutions *(76)→(80)* and *(77)→(79)* fail to occur under the same conditions, and since 2,6-didehydropyridine, according to EHT calculations, is the richest in energy of all the didehydropyridines[5], it now seems very unlikely that the above resinification reactions involve 2,6-didehydropyridine intermediates.

T.K. is deeply grateful to his scientific co-workers in these investigations, J. Albrecht, H. Fischer, K. Forberger, Dr. R. Nürnberg, Dr. A. Risberg, Dr. M. Schönfelder, R. Stabba, Dr. K. Udluft, and Dr. R. Wirthwein, and to technical assistants H. Abshagen-Schrecken, J. Schulz, and M. Vestweber. Thanks are also due to the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung (Nordrhein-Westfalen), and the Fonds der Chemischen Industrie for their very valuable financial support of these investigations.

1,4-Benzodiazepines. Chemistry and Some Aspects of the Structure-Activity Relationship

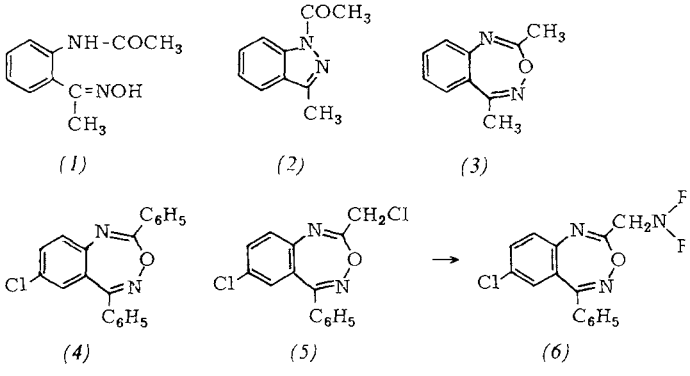
By Leo H. Sternbach[*]

Numerous clinically used compounds having favorable tranquilizing and toxic properties possess the 1,4-benzodiazepine skeleton. This group of active substances is readily accessible, e.g. by ring enlargement of quinazoline derivatives, by ring contraction of benzoxadiazocines, and by synthesis from aminobenzophenones, constructing the seven-membered ring in many cases in one step. The relationships between type and position of substituents and the pharmacological properties are illustrated using 1,3-dihydro-5-phenyl-1,4-benzodiazepin-2-ones as examples.

1. General Introduction

This review is meant to give a short outline of the history of the discovery and further development of the chemistry of tranquilizers of the 1,4-benzodiazepine type. It will be limited with very few exceptions to published and also unpublished work carried out in our laboratories[**]. It will concern itself mainly with the most important synthetic routes leading to pharmacologically and clinically interesting types of 1,4-benzodiazepines, and will contain also a short discussion of the pharmacological properties of these compounds.

In view of this, the main subject will be 5-phenyl-1,4-benzodiazepine derivatives which are the most extensively studied group. It should, however, be pointed out that most of the reactions have been used for the synthesis and transformations of 1,4-benzodiazepine derivatives bearing substituents other than phenyl on C-5.

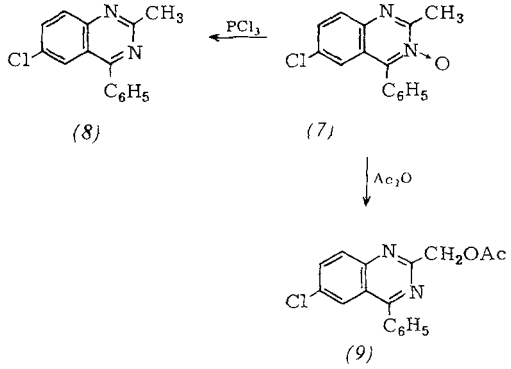


2. Introduction

In the search for a new class of drugs possessing tranquilizing properties similar to those of meprobamate and chlorpromazine, it was decided in the middle 1950's to investigate new types of heterocycles which might ultimately lead to compounds showing the desired properties. As a rather neglected group of chemically interesting compounds, we selected the benzheptoxdiazines, as they were called in the German scientific literature.

The first compounds of this type were obtained in 1891 by *von Auwers* and *von Meyenburg*[1] by dehydration of *o*-acylamino ketoximes *(1)* or aldoximes with a Beckmann mixture. At that time they were considered to be acylindazoles *(2)*.

These compounds were further studied in 1893[2] and reinvestigated in 1924[3] when it was agreed upon that they are best represented by structure *(3)*.



In the mid thirties, a few further members of this class of compounds were prepared, specifically compound *(4)*[4] and close analogs thereof. They were relatively easy to synthesize, crystallized very well, and were easy to purify. These were the reasons which made this group of heterocycles so attractive for further exploration. Derivatives to which basic substituents could be attached, as illustrated by conversion of *(5)* into *(6)*, appeared to be particularly interesting.

(1) *(2)* *(3)*

(4) *(5)* *(6)*

Closer chemical study of these compounds led to the conclusion that the so called "benzheptoxdiazines" did not have the structure originally assigned to them, but were in fact quinazoline 3-oxides of type *(7)*. The transformations shown below illustrate the structural proof[5]. The *N*-oxide oxygen could be readily removed by treatment with phosphorus trichloride or by catalytic hydrogenation to yield the quinazoline *(8)*. On the other hand, treatment with acetic anhydride resulted in the

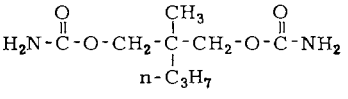
formation of the acetoxy derivative *(9)*, a transformation analogous to that of picoline *N*-oxide[6]. The interesting novel structure of these compounds lending itself to a variety of transformations led to intensified studies. These resulted first in the synthesis of a number of quinazoline 3-oxides of the general formula *(10)* and their transformations with various amines. Secondary amines generally yielded normal substitution products of type *(11)*, which showed no particularly interesting biological properties. The reaction with primary amines or ammonia, however, resulted in the formation of pharmacologically very attractive compounds.

(10) *(11)*

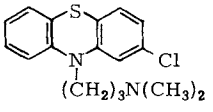
3. Ring Enlargement of Quinazoline 3-Oxides by Treatment with Amines

The products obtained on treatment of compounds of type *(10)* with primary amines were the result of an unusual, novel ring enlargement. Scheme 1 shows the first compound *(14)* thus obtained, and gives a short outline of the structural proof[7].



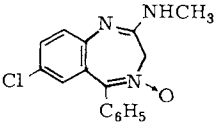
Scheme 1.

Compound *(14)* had the expected composition, was monomolecular, contained an *N*-oxide function and a secondary methylamino group. The UV and IR spectra indicated, however, that the quinazoline 3-oxide molecule must have undergone very profound changes and that the reaction product could not be *(13)*, the simple substitution product. This was confirmed by chemical studies which showed ultimately that the compound had the structure of a 1,4-benzodiazepine 4-oxide *(14)*, and was a representative of a novel group of heterocycles.



The structure was established by classical methods before the widespread use of NMR and mass spectroscopy became commonplace. It consisted in the acid hydrolysis of the deoxy derivative *(15)* which gave an excellent yield of the aminobenzophenone *(16)*. In addition, glycine and methylamine were formed, which, after benzoylation, were isolated from the hydrolysis mixture in over 60% yield. The normal substitution product *(13)*, on oxygen removal and hydrolysis, would have yielded *N*-methylglycine and ammonia in addition to the aminobenzophenone (see Scheme 1).

4. Pharmacology of Chlordiazepoxide



This compound *(14)*, which later obtained the generic name chlordiazepoxide was, as mentioned above, the first product to show desirable pharmacological properties. It was a sedative, muscle relaxant, and anticonvulsant resembling in many respects meprobamate and chlorpromazine, the then most used tranquilizers. Extended pharmacological and later, clinical studies confirmed these properties and led to its introduction in 1960 as the active ingredient of the specialty Librium®. Table 1 shows the comparison of its pharmacological properties and toxicity with those of the two aforementioned tranquilizers.

Meprobamate

Chlorpromazine

(14)

The top row shows the primary tests which were and are generally used in our Pharmacology Department to demonstrate sedative and "tranquilizing" properties. The first test (Inclined Screen) indicates sedation and muscle relaxation in mice, the second (the fighting mice test) a taming effect, and the third measures muscle relaxation in cats. The antimetrazole (Cardiazol) shock test is a measure of sedation and anticonvulsant activity, whereas the two electroshock tests indicate pure anticonvulsant properties[8]; the last column shows the toxicity. The figures in the table indicate the amounts of material (mg/kg) needed to achieve the desired effect. Therefore, small numbers indicate high potency and high numbers low activity[*].

[7] *L. H. Sternbach* and *E. Reeder*, J. Org. Chem. *26*, 1111 (1961).

[8] *L. H. Sternbach*, *L. O. Randall*, *R. Banziger*, and *H. Lehr* in *A. Burger:* Drugs Affecting The Central Nervous System. Marcel Dekker, New York 1968, Vol. 2, Chap. 6.

[*] All the pharmacological data reported subsequently will be presented in the same manner in tables containing the same tests in the same order. The toxicity data will be omitted since all benzodiazepine derivatives of the type discussed show a very low toxicity. In view of the wide variations found in biological tests, differences of ± 50% are meaningless. For detailed descriptions of the tests see [8].

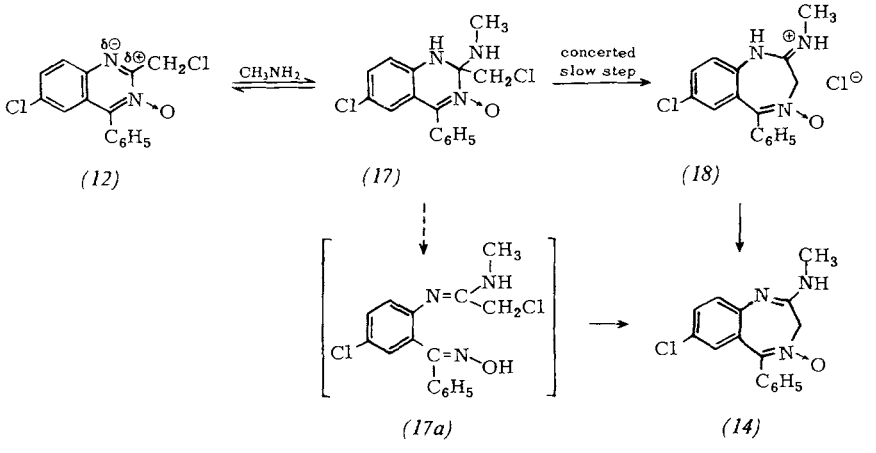

Table 1. Pharmacological and toxic properties of meprobamate, chlorpromazine, and chlordiazepoxide. For explanation see text.

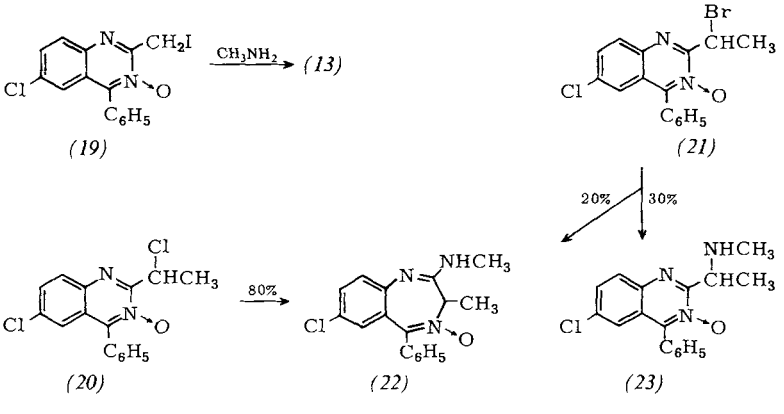
Compound	Incl. Screen	Fighting Mice	Cat	Anti-Met.	Electroshock Max.	Min.	LD_{50} p.o.
Meprobamate	250	250	100	150	200	167	1450
Chlorpromazine	17	20	2.5	42	150	600	75
Chlordiazepoxide	100	40	2	18	92	150	620

As can be readily seen, the new compound was, across-the-board, more potent than meprobamate and resembled chlorpromazine in many of the tests. In addition, it showed, on further study, a very pronounced taming effect on Rhesus monkeys. The interesting properties of this substance started intensive activity with this, at that time quite unexplored, group of heterocyclic compounds. It resulted in the development in our laboratories of a number of new synthetic approaches and in the synthesis of nearly 1500 benzodiazepines of various types, and about 4000 intermediates.

5. Mechanism of Ring Enlargement

The study on the first method for the synthesis of pharmacologically active 1,4-benzodiazepines, *i. e.* the ring enlargement, suggested the mechanism shown below.



Compound *(12)*, which carries a partial positive charge on C-2 of the quinazoline nucleus, reacts with the nucleophile to form an adduct of structure *(17)*, the reaction being in reversible equilibrium. This adduct in turn, in a concerted reaction, as indicated in formulas *(17)* and *(18)*, undergoes fission between C-2 and N-3, elimination of the chlorine, and formation of a new bond between the exocyclic methylene and the *N*-oxide nitrogen. A short-lived intermediate of structure *(17a)* could also be postulated, which in turn would undergo cyclization to *(14)*. The existence of such an intermediate is suggested by the results of other reactions which will be discussed later.

Further studies showed that we were faced here with two competing reactions, normal substitution and ring enlargement. Good leaving groups, steric hindrance, and substituents in the aromatic nucleus which decrease the positive charge on C-2 led to formation of the normal substitution products. The selection of solvents also affected the course of the reaction. Polar solvents resulted in normal substitution whereas non-polar solvents favored ring enlargement.

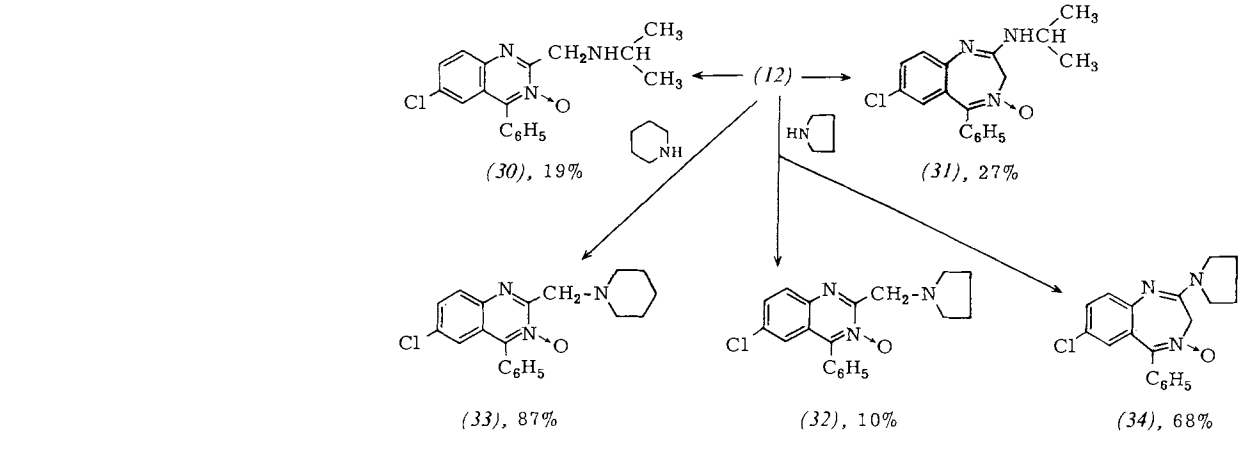
5.1. Effect of Leaving Groups[9]

The above effect is well illustrated by the difference in the course of the reaction as determined by the character of the halogen group on the exocyclic methylene group.

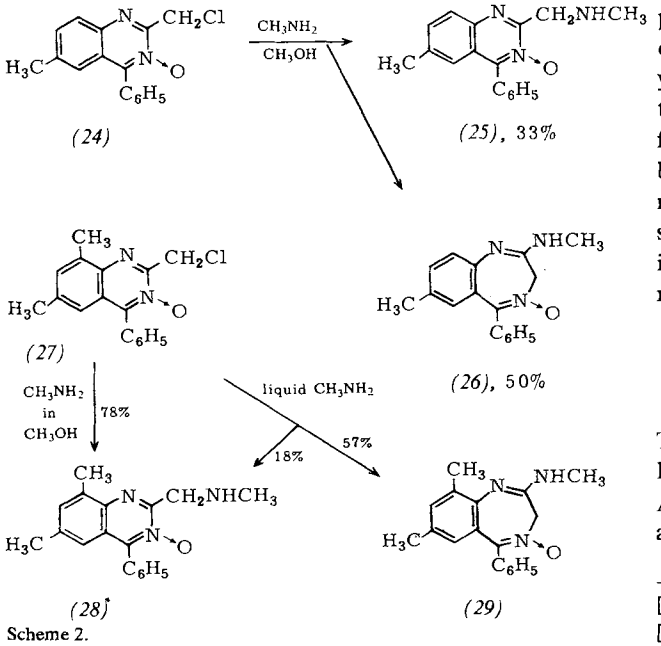
The chloromethylquinazoline derivative *(12)* gives, as already mentioned, the ring enlarged benzodiazepine *(14)* in almost quantitative yield. The corresponding iodo derivative *(19)* (obtained readily by treatment of *(12)* with sodium iodide), on the other hand, yields prevalently the normal substitution products *(13)*. The "intermediate" bromo derivative gives, as might be expected, both the normal substitution product *(13)* and the ring enlarged product *(14)*, which were isolated in yields of 30 and 20% respectively. In order to exclude a possible steric effect, caused by the exocyclic methyl group, the behavior of the chloro derivative *(20)* was also studied, and this showed almost quantitative ring enlargement.

In order to obtain comparable data, these reactions were all carried out under identical conditions (methanol as solvent, room temperature, large excess of methylamine). In every case the yields indicate the amounts of isolated crystalline material.

5.2. Effects of Substituents and of Solvents[9]



Whereas electron withdrawing substituents (Cl, NO_2, CF_3 *etc.*) on C–6 of the quinazoline nucleus favor ring enlargement, almost to the complete exclusion of normal substitution, electron releasing substituents have the opposite effect. Due to the decrease of the partial positive charge on C–2, the normal substitution offers strong competition, as shown in Scheme 2.



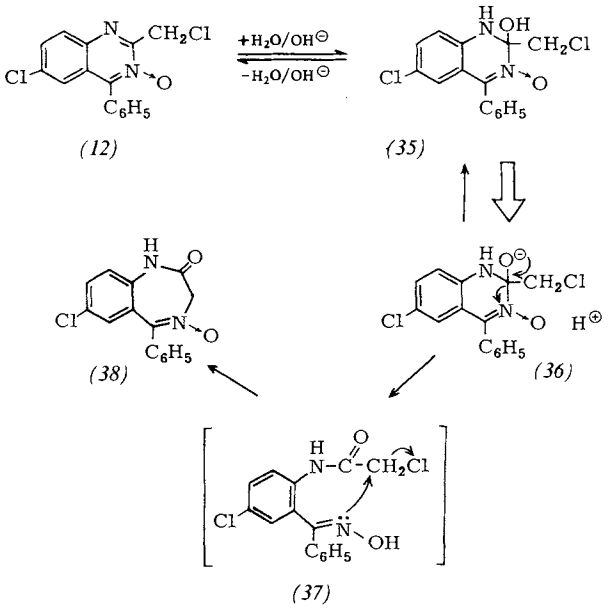
The presence of one methyl group on C–6 of the quinazoline nucleus *(24)* results in the formation of both the normal and the ring enlarged products *(25)* and *(26)*, which were isolated in the indicated yields. Even more pronounced is the additive effect of two methyl groups on C–6 and C–8. The predominant reaction product is the quinazoline 3-oxide *(28)* which is formed in very high yield under standard conditions.

The effect of the solvent is apparent when the reaction is carried out in aprotic liquid methylamine; ring enlargement is highly favored and the main reaction product is the benzodiazepine derivative *(29)*. This course of the reaction is not due to the low temperature as was established by parallel experiments in methanol.

5.3. Steric Effects[9]

The following examples illustrate the influence of sterically hindering substituents on the nucleophile. The bulky isopropylamine causes the formation of both products *(30)* and *(31)*; the even more hindered piperidine[7] results in almost quantitative substitution to yield *(33)*. On the other hand, it is interesting to note that pyrrolidine gives a result which differs considerably from that obtained with piperidine. The ring enlarged benzodiazepine *(34)* is the main reaction product and the normal substitution product *(32)* is formed only to a small extent. This parallels to some degree the difference in the behavior of pyrrolidine and piperidine in enamine reactions.

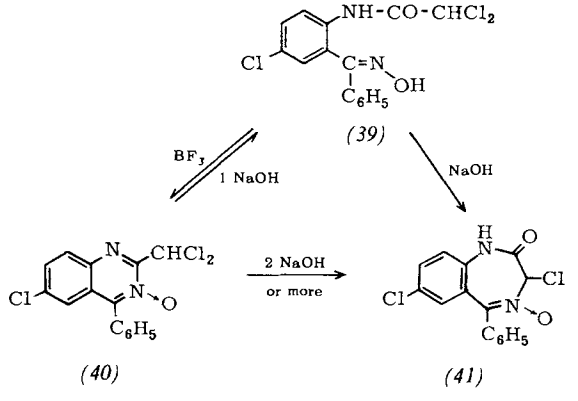
Scheme 2.



6. Ring Enlargements by Hydroxide Ions

The chloromethylquinazoline 3-oxide *(12)* reacts with hydroxide ions in a manner similar to primary amines. A ring enlargement takes place[10] which results in an almost quantitative conversion to the benzodiazepinone

[9] *G. F. Field* and *E. Reeder*, unpublished results.



[10] *L. H. Sternbach* and *E. Reeder*, J. Org. Chem. *26*, 4936 (1961).

(38), as shown below. Normal substitution, *i.e.*, replacement of the exocyclic halogen by a hydroxy group was never observed, even with compounds bearing electron releasing substituents in the benzene ring.

This can be explained as indicated above. The first reaction is, in analogy to the reaction with methylamine, addition of OH^- at C–2 of the quinazoline nucleus and formation of the equilibrium intermediate *(35)*. In this intermediate the OH hydrogen has strongly acidic character. This causes immediate ionization to form *(36)*, which cannot revert *via (35)* to *(12)*, but must undergo further reactions, possibly through *(37)*, to *(38)*.

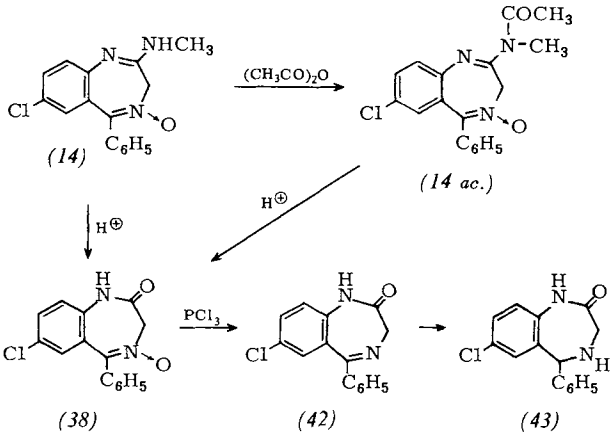
The study of the analogous ring enlargement of the "dichloromethylquinazoline" *(40)*[11] made it plausible that the open compound *(37)* is indeed an intermediate of the reaction *(12)*→*(38)*.

Treatment of *(40)* with 1 mole of alkali yielded the analog of *(37)*, the dichloroacetyl derivative *(39)*, which in this case could be readily isolated. Further treatment of this open compound *(39)* with alkali then gave an excellent yield of the benzodiazepinone *(41)*. Due to the lower reactivity of the chlorines in compound *(39)*, the cyclization to *(41)* does not occur with the speed which made it impossible to isolate the monochloro derivative *(37)* postulated as an intermediate in the preceding reaction. Another indication that in the "monochloromethyl" case the reaction proceeds as formulated is the ease of transformation of the intermediate *(37)* – prepared by unequivocal methods – into *(38)* on treatment with alkali[10].

7. Transformations of Chlordiazepoxide

The interesting biological properties of chlordiazepoxide *(14)* led to intensive study of its chemistry. These investigations were concerned initially with the structure determination [*(14)*→ *(15)*→ *(16)*[7]], but later the study of the effect of structural changes on the pharmacological properties became our main objective[8].

It was found that the readily accessible acetyl derivative of chlordiazepoxide *(14 ac.)* could be converted in excellent yield into the *N*-oxide *(38)*[10] and the simple 5-phenylbenzodiazepin-2-one *(42)*. It was of great interest that the benzodiazepinones *(38)* and *(42)* were pharmacologically at least as active as chlordiazepoxide, as can be seen in Table 2. Hydrogenation of *(42)* in the presence of a platinum catalyst led to a tetrahydro derivative *(43)* with considerably decreased pharmacological activity. This latter finding proved to be a general rule and was confirmed in all cases in which 4,5-dihydrobenzodiazepine derivatives were compared with the corresponding unhydrogenated compounds.



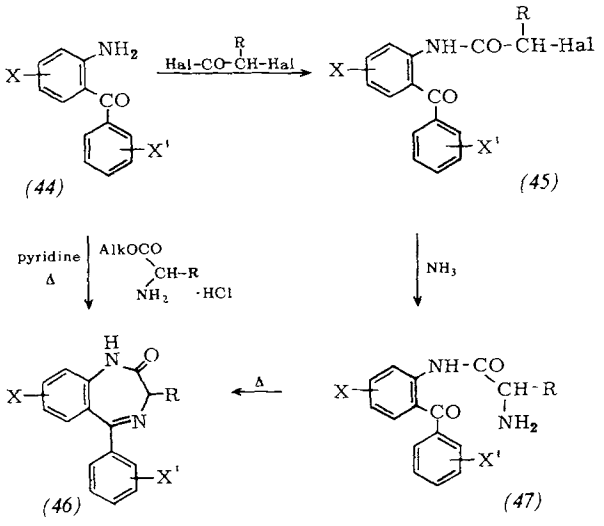


Table 2. Pharmacological properties of a few 1,4-benzodiazepine derivatives.

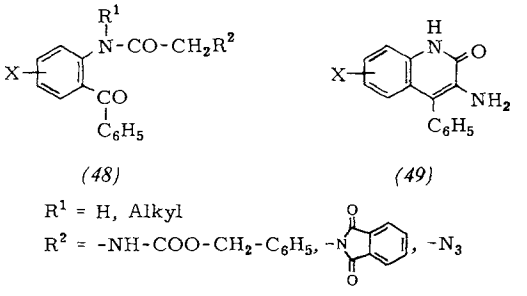
Compound	Incl. Screen	Fighting Mice	Cat	Anti-Met.	Electroshock Max.	Min.
(14)	100	40	2	18	92	150
(14 ac.)	100	20	2	15	150	150
(38)	75	40	1	6	52	400
(42)	75	20	1	6	25	61
(43)	300	40	10	9.2	36.7	106

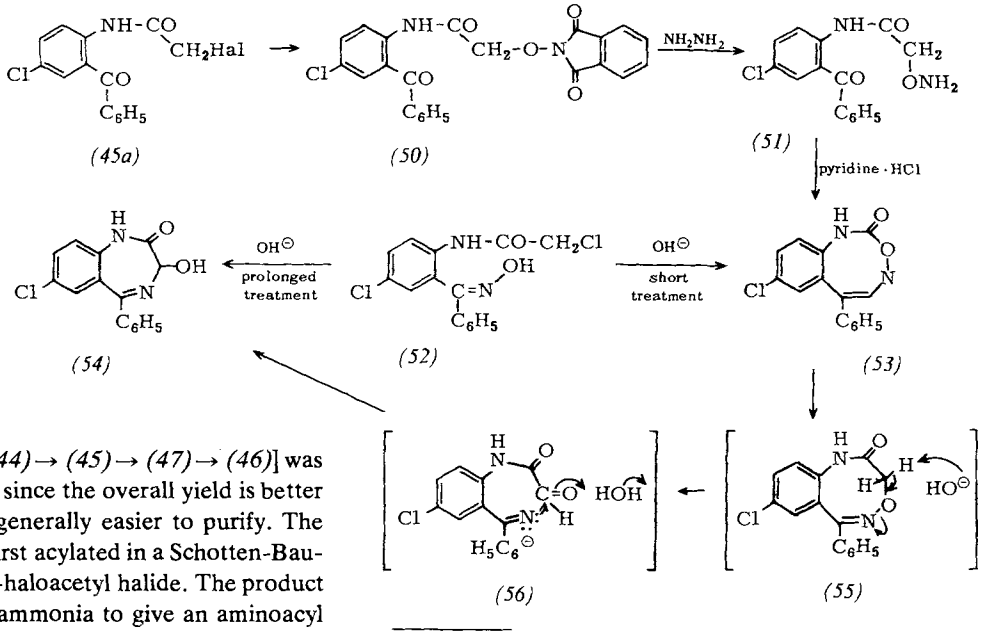
8. Methods for the Synthesis of 1,3-Dihydro-1,4-benzodiazepin-2-ones

The benzodiazepine 4-oxides of type *(38)* were relatively readily accessible by treatment of quinazoline 3-oxides such as *(12)* with alkali. This led to a fairly extensive pharmacological investigation of members of this group of compounds bearing different substituents in the phenyl rings.

[11] *A. Stempel, E. Reeder,* and *L. H. Sternbach,* J. Org. Chem. *30,* 4267 (1965).



More attractive, however, were benzodiazepinones of type *(42)*, which, as mentioned before, possessed even more pronounced pharmacological activity. Their simple structure induced the search for less involved synthetic approaches and resulted in alternative methods which enabled us to prepare a large number of compounds of this type[12]. The only limiting factor was the accessibility of the 2-aminobenzophenones or 2-aminoacetophenones which were used as starting materials. Our one-step method involves the treatment of an aminobenzophenone *(44)* with glycine ester hydrochloride in pyridine and results in the formation of the benzodiazepinone of type *(46)*, generally in yields of about 50%.

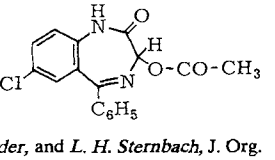


The multistep method [*(44)* → *(45)* → *(47)* → *(46)*] was preferable in most cases, since the overall yield is better and the end-product is generally easier to purify. The aminobenzophenone is first acylated in a Schotten-Baumann reaction with an α-haloacetyl halide. The product of acylation reacts with ammonia to give an aminoacyl derivative which can be readily cyclized. The overall yield in these three steps frequently exceeds 70%. These two methods made the 1,3-dihydro-1,4-benzodiazepin-2-ones the most readily accessible members of this group of heterocyclic compounds.

Another approach used *N*-protected glycine derivatives such as the benzoxycarbonyl[13], the phthaloyl[14] or azido[15] derivatives for the synthesis of intermediates of type *(48)* and the subsequent construction of the seven membered ring.

The ease of formation of this seven membered ring is quite remarkable. Competitive reactions, such as *e. g.* the formation of the aminopyridones[12] of type *(49)* were observed only in rare cases.

Another method for the synthesis of benzodiazepinone derivatives consists in ring contraction of a benzoxadiazocine *(53)*[16a] by treatment with alkali. It leads to 3-hydroxy derivatives such as *(54)*, a class of compounds which was first described by *Bell* and *Childress*[16b][*].



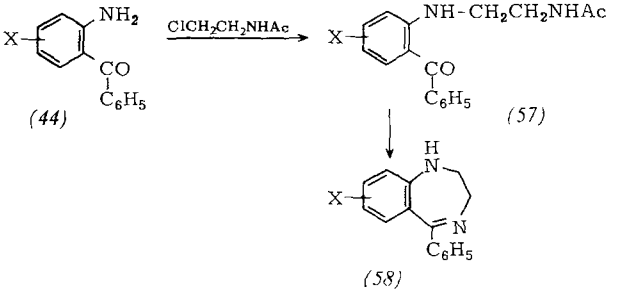
[12] *L. H. Sternbach, R. I. Fryer, W. Metlesics, E. Reeder, G. Sach, G. Saucy,* and *A. Stempel,* J. Org. Chem. *27,* 3788 (1962).

[13] *S. C. Bell, T. S. Sulkowski, C. Gochman,* and *S. J. Childress,* J. Org. Chem. *27,* 562 (1962); *A. Stempel* and *F. W. Landgraf, ibid. 27,* 4675 (1962).

[14] Netherlands Patent 6500446 (1966), Delmar; Chem. Abstr. *64,* 5120 (1966).

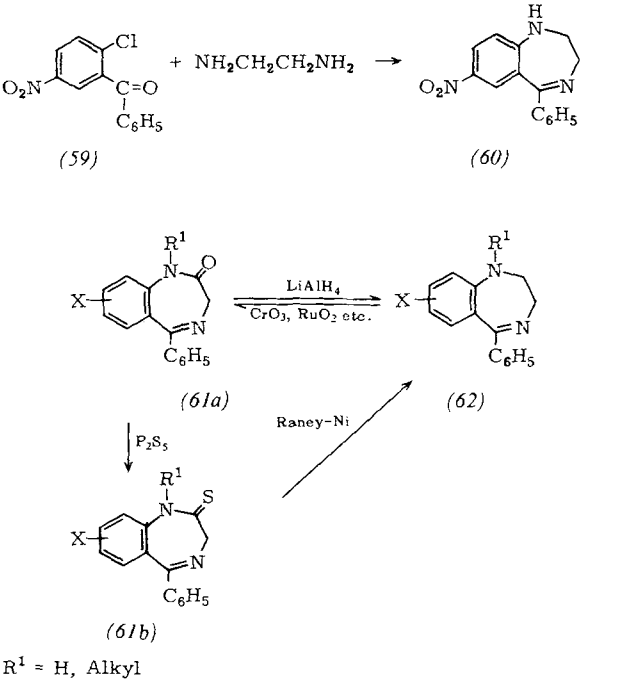
[15] *J. B. Petersen* and *K. H. Lakowitz,* Acta Chem. Scand. *23,* 971 (1969).

[*] *Bell* and *Childress* used as starting material the *N*-oxide *(38)*, which after subjection to a type of Polonovsky rearrangment and hydrolysis of the 3-acetoxy derivative is converted into *(54)*.



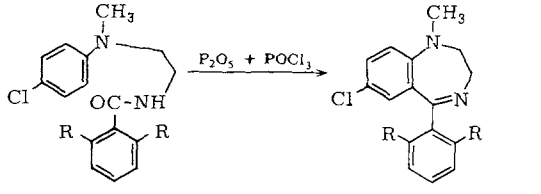
[16] a) *A. Stempel, I. Douvan, E. Reeder,* and *L. H. Sternbach,* J. Org. Chem. *32,* 2417 (1967); b) *S. C. Bell* and *S. J. Childress, ibid. 27,* 1691 (1962).

Two methods for the synthesis of the starting material *(53)* are outlined above. One approach, the transformation of *(50)* and related benzophenone derivatives, *via (51)*, into compounds of type *(53)* served as an unequivocal proof for the structure of *(53)*. Another method consists in the alkali treatment of *(52)* under mild conditions. On prolonged treatment with alkali, compound *(52)* was directly converted into *(54)* in about 60% yield. The mechanism indicated, *via (55)* and *(56)*, explains this transformation. It is interesting to note that under practically the same reaction conditions, the isomeric *anti* oxime derivative *(37)* gives the *N*-oxide *(38)* in excellent yield.



9. 2,3-Dihydro-1*H*-1,4-benzodiazepines

Further studies in the benzodiazepine series led to compounds of type *(58)*. The finding that these products also possessed valuable pharmacological properties resulted in a number of synthetic approaches.



The simplest route consisted in the introduction of the acylaminoethyl moiety into the *o*-aminobenzophenone molecule to yield *(57)*[17], which on hydrolysis gave the desired product *(58)*. The unsubstituted aminoethylamino ketone was not isolated in these cases since it cyclized immediately to form the very stable benzodiazepine derivative *(58)*.

Another method for the synthesis of benzodiazepine derivatives of this type is by reaction of an appropriately substituted *o*-halobenzophenone with ethylenediamine[18]. The yield in these reactions is generally very good. The nitro group in compound *(60)* could be reduced to the amino group, which, *via* Sandmeyer transformations, led to a variety of 7-substituted benzodiazepines. Another method for the preparation of benzodiazepines is the reduction of the 2-one *(61a)* or desulfurization of the thione *(61b)*[17,19][*].

R^1 = H, Alkyl

A Bischler-Napieralski type cyclization proved very useful[21]. This method led in some cases to compounds which were otherwise difficult to synthesize, *e. g.* compound *(66)*[9]. The yields in most cases were very good.

10. 1*h*- and 3*H*-1,4-Benzodiazepines

Compounds of this type are most readily accessible by ring enlargements of 1,2-dihydroquinazoline 3-oxides. In this connection it is amusing to mention how our first dihydroquinazoline *N*-oxide[22] was discovered. At the beginning of our studies when only small quantities of aminobenzophenone oximes were available, attempts were made to recover the last amounts of crystalline material from the oxime mother liquor – which consisted of a dark syrup. A variety of solvents was tried without success. Finally, when in despair we used acetone, a solvent we had previously always gingerly avoided, a large amount of a beautiful yellow crystalline material was obtained, which, however, was quite definitely not the desired oxime.

Closer investigation showed that an unexpected reaction had occurred: the oxime had condensed with the acetone to yield the dihydroquinazoline derivative *(67)*. Further studies showed that the reaction was quite general and that *anti*-oximes of type *(68)* react very readily with aldehydes or ketones to yield dihydroquinazolines[22].

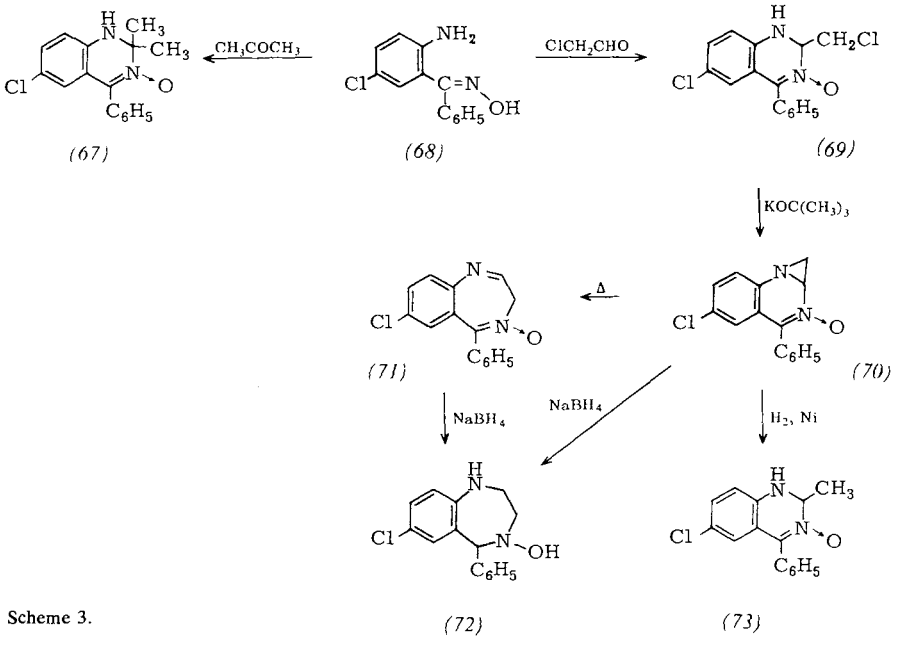
[19] *G. A. Archer* and *L. H. Sternbach,* J. Org. Chem. *29,* 231 (1964).

[*] Compounds of type *(62)* could be reoxidized to *(61a)* by various oxidizing agents [20].

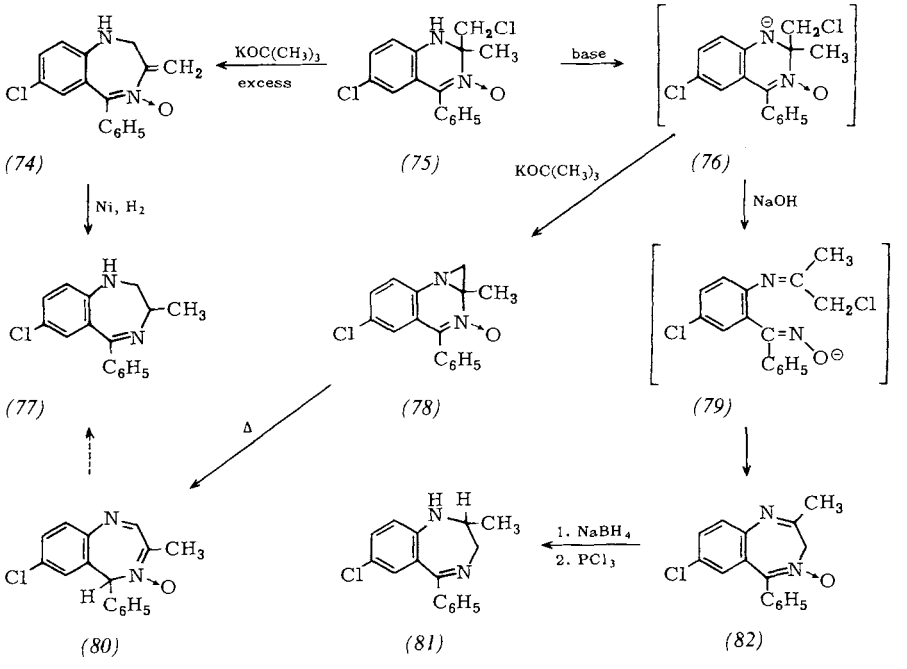


[20] *R. I. Fryer, G. A. Archer, B. Brust, W. Zally,* and *L. H. Sternbach,* J. Org. Chem. *30,* 1308 (1965); *A. M. Felix, J. V. Earley, R. I. Fryer,* and *L. H. Sternbach,* J. Heterocyclic Chem. *5,* 731 (1968).

[21] *H. H. Kaegi,* J. Labelled Compounds *4,* 363 (1968).

[22] *G. F. Field, W. J. Zally,* and *L. H. Sternbach,* J. Org. Chem. *30,* 3957 (1965).

Further study of these compounds showed that dihydroquinazoline derivatives containing exocyclic halogens undergo ring enlargements similar to those studied in the quinazoline 3-oxide series.

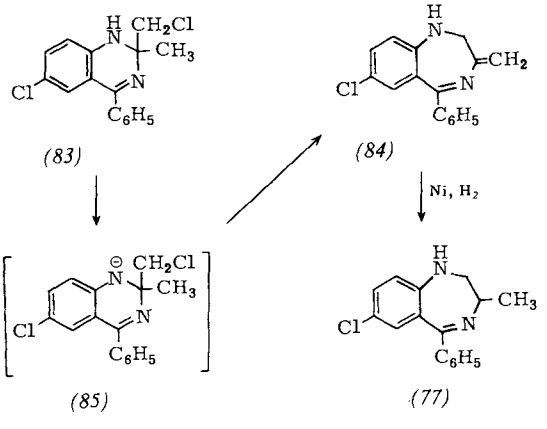


Scheme 3 shows reaction sequences leading to 3*H*-1,4-benzodiazepine derivatives[23]. On treatment of compound *(69)* with potassium *tert*-butoxide the first reaction product is compound *(70)*.

Scheme 3.

The presence of the three-membered ring in *(70)* is shown by the results of reduction experiments. Hydrogenation with Raney nickel as catalyst leads to hydrogenolysis of the bond between the 1-position and the methylene group to yield the 2-methyl-dihydroquinazoline *(73)*. On the other hand, reduction with $NaBH_4$ gave a good yield of the known tetrahydrobenzodiazepine derivative *(72)*. Heating converted compound *(70)* into the valence tautomer *(71)* which could again be reduced in excellent yield to compound *(72)*. The structural assignment for compound *(71)* is based on very convincing spectral evidence (IR, NMR) and is confirmed by the ease of transformation into the known *(72)*.

Investigation of the ring enlargement of a quinazoline 3-oxide *(75)* bearing two substituents on C-2 showed that the course of this reaction depends on the character of the base used and results in the formation of isomeric benzodiazepines. The sequence shown represents an explanation of these reactions. Ion *(76)* is in every case the primary reaction product. If dilute alcohol is used as solvent and sodium hydroxide as base, ring opening occurs to yield a postulated compound *(79)* [similar to *(37)*], which undergoes cyclization to *(82)*. In this reaction sequence the quinazoline *(75)* gives the benzo-



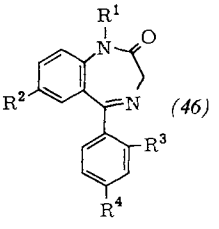
[23] *G. F. Field, W. J. Zally,* and *L. H. Sternbach,* J. Amer. Chem. Soc. *89,* 332 (1967).

diazepine *(82)* (~80% yield), whose structure was indicated by its UV and NMR spectra and confirmed by transformation into the known compound *(81)*.

The reaction of *(75)* with potassium *tert*-butoxide in an aprotic solvent proceeds somewhat differently. The primary reaction product, *i.e.* the ion *(76)*, undergoes intramolecular alkylation to form an aziridino-quinazoline *(78)* whose presence can be easily demonstrated and which on heating transforms into the benzodiazepine *(80)* [*(75)* → *(80)* = 42% yield], the isomer of *(82)*. The structural assignment is based on physicochemical data, UV and NMR spectra (signal for the methyl group) and on the stepwise chemical conversion into the known compound *(77)*.

Ring enlargement of the 2-disubstituted quinazoline 3-oxide under discussion can also take place *via* a third route[9]. When an excess of potassium *tert*-butoxide is used for the protonation of *(75)* an orange compound having an exocyclic methylene group is formed in 25% yield. It has the structure *(74)*. The mechanism of this reaction is not quite clear, but is certainly dependent on the excess of base which abstracts a proton from the exocyclic methyl group. The structure of *(74)* was proved by its NMR spectrum and its transformation by hydrogenation into the known 3-methylbenzodiazepine derivative *(77)*. Thus, three isomers – namely *(74)*, *(80)*, and *(82)* – can be formed on treatment of *(75)* with base.

Whereas the fully aromatic 2-chloromethylquinazolines underwent normal exchange reactions and needed the 3-oxide function in order to undergo ring enlargements, the 1,2-dihydroquinazolines behaved differently[9].



Treatment of *(83)* with a strong base (potassium *tert*-butoxide) resulted again in the formation of an ion of type *(85)*, which then underwent ring enlargement, possibly *via* an oxazirino compound, to yield the benzodiazepine *(84)*. The transformation of *(83)* to *(84)* is relatively clean and occurs with a yield of 60%. The structure of compound *(84)* was established by its physicochemical properties (NMR) and its chemical transformation into the known benzodiazepine derivative *(77)*.

11. Structure-Activity Relationship

Before concluding, a few examples will be given which illustrate some of the rules which could be established in the course of our studies regarding the relation of structure to activity[8].

The 1,3-dihydro-5-phenylbenzodiazepin-2-ones of type *(46)* lent themselves best to these investigations. One reason for this was the ready accessibility of these compounds; more important, however, was the fact that they are the most potent types of benzodiazepines and show,

(46)

Table 3. Pharmacological properties of 1,4-benzodiazepinones.

Cmpd.	R^1	R^2	R^3	R^4	Incl. Screen	Fighting Mice	Cat	Anti- Met.	Electroshock Max.	Min.

(46b)	CH_3	Cl	–	–	30	10	0.2	1.4	6.4	64
(46c)	–	Cl	Cl	–	100	40	0.1	0.4	13	115
(46d)	–	Cl	–	Cl	>500	>100	–	>800	300	>800
(46e)	–	NO_2	–	–	15	5	0.1	0.5	8.4	132
(46f)	–	CH_3	–	–	>500	>100	–	175	175	>800
(46g)	CH_3	NO_2	F	–	1	0.8	0.02	0.12	12	345

therefore, also the widest variations in activity. They are in this respect more interesting than the 2-amino derivatives of type *(14)*, the tetrahydro-2-ones of type *(43)*, the dihydrobenzodiazepines of type *(62)*, and the last discussed 1*H*- and 3*H*-benzodiazepines.

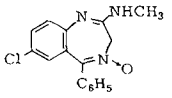

Table 3 shows some compounds of type *(46)* and their pharmacological properties. The substituent on C-7 was found to be of paramount importance, but also substitution on N-1 and in the 5-phenyl ring had a decisive effect on the activity.

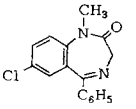
Electron withdrawing substituents on C-7 generally imparted high activity, whereas electron donors had the opposite effect.



A methyl group on N-1 potentiated the activity, as did a halogen in the *o*-position of the phenyl ring; a substituent in the *p*-position, however, decreased the activity dramatically. The additive character of these effects allowed us to synthesize custom tailored compounds such as, for example, *(46g)* which contained all the features known to impart high pharmacological activity. *(46g)* is indeed the pharmacologically most potent benzodiazepinone known to us.

12. Closing Remarks

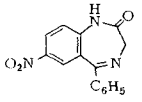


Table 4. 1,4-Benzodiazepines in clinical use.

These studies and those of other investigators resulted ultimately in the production of seven 1,4-benzodiazepine derivatives which are now in clinical use as tranquilizers or sleep inducers. Table 4 shows the formulas, the generic names, and also the names of the specialties containing these products.

Additional compounds are being studied and it is to be expected that the number of clinically used 1,4-benzodiazepine derivatives will increase considerably within the next few years.

I wish to acknowledge the dedicated work of my co-workers who contributed so greatly to the development of the chemistry of 1,4-benzodiazepines; in particular, I thank Mr. E. Reeder, Drs. G. Archer, G. Field, R. Ian Fryer, W. Metlesics, G. Saucy, N. Steiger, and A. Stempel. I also want to express my appreciation to the Director of our Pharmacology Department Dr. L. O. Randall and his co-workers for their close co-operation which resulted in the efficient biological evaluation of these compounds.

Preparative Solid State Chemistry: The Present Position[1,2]

By Harald Schäfer[*]

Dedicated to Professor Wilhelm Klemm on the occasion of his 75th birthday

Two types of reaction are distinguished in solid state chemistry: those in which high mobility of the reactants is aimed at (which can be achieved by the use of high temperatures, by the introduction of defects, by the promotion of surface diffusion, or by means of chemical transport phenomena), and those reactions in which the nature of the products is determined by existing structural elements or lattice defects of the reactants. The importance of paying more attention than hitherto to reaction pathways in preparative solid state chemistry is pointed out.

1. Introduction

The distinction between organic and inorganic chemistry has a historical basis. In some respects it is more meaningful to divide the subject into molecular chemistry and solid state chemistry, a classification that is also useful from the preparative point of view. Theories of reaction mechanism and their practical application are more fully developed in molecular chemistry than in solid state chemistry, for the following reasons:

Molecular chemistry is primarily chemistry in solution. The molecules or ions are so close together in the solution that the diffusion paths (of the order of 10 Å) are of no importance to the course of the reactions, and moreover the diffusion constants are relatively large ($\approx 10^{-5}$ cm^2/sec). Kinetic mechanisms, involving relatively small

[1] In memory of my late friend *A. D. Wadsley*, of Melbourne, who died on January 7, 1969, and to whom we owe our basic knowledge of the structure relations of the so-called Hägg-Magnéli phases.

[2] Expanded version of an address given at the Colloquium on Preparative Solid-State Chemistry on April 1, 1969 in Aachen (Philips Central Laboratories).

complexes, determine the rate at which such reactions take place, if the latter are thermodynamically possible.

In solid state chemistry the conditions are quite different, especially in the case of reactions between powdered solids: for a reaction between two grains in contact, A + B→AB, the rate is determined by the mobility of the reactants in the solid state. The diffusion paths are long (grain diameter *e. g.* 10^5Å) and the diffusion constants are small. This necessitates the use of high temperatures, and as a rule the products are what one would expect from thermodynamic considerations. In such cases it is not necessary to understand exactly the reaction mechanism in order to achieve a particular aim. Such syntheses appear to be trouble-free:

In the simplest case the solid starting materials, in the form of a mixture of powders or as pellets, are heated sufficiently strongly and for a sufficient length of time for the stable products to be formed. In some cases it may be necessary to conduct the reaction in a sealed tube because of the volatility of one component, but there is no essential difference between this situation and the first.

The preparative procedure so outlined is only the first step for the solid state chemist, and one to which he does not usually give too much attention. The real problem begins with the physical investigation of the product, determination of its crystal structure, its electrical and magnetic properties, light absorption, and so on. This means that more and more work is being published on the physical properties of materials whose early history is either unpublished or unknown.

If any generalization can be made about the work of others, it is that at times one has the impression that the wider development of physical techniques and their increasing claims on the researcher are accompanied by a neglect of the preparative methods.

There is no doubt that many important aspects of the chemistry are lost by the use of such primitive methods of preparation:

a) One cannot control or exploit a reaction without a knowledge of its mechanism.

b) Purely solid state reactions involve no purification effect. Incidental processes (evaporation, reaction with the walls of the vessel) disturb them, because they alter the desired proportions of the reactants in unforeseeable ways.

c) Only in exceptional cases can one obtain single crystals, which are suitable for X-ray structure analysis.

d) Attempts are sometimes made to correct mistakes by the expenditure of much physical and mathematical effort. Since these mistakes arise because insufficient care has been taken in the methods of preparation, such corrections are in principle meaningless.

e) All those compounds which are only stable at lower temperatures are lost.

f) The no less important metastable compounds as a rule remain inaccessible.

In the following we shall examine two limiting cases: the preparation of thermodynamically *stable compounds* by increasing the atomic mobility and the preparation of *metastable compounds* by making use of existing structural elements of the starting materials.

2. Increasing the Mobility of the Reactants

2.1. Solid Diffusion. Defect Concentration

The nature and concentration of imperfections (vacant lattice sites, interstitials, and dislocations) are important factors affecting diffusion in monocrystalline solid materials. The equilibrium concentration of imperfections increases exponentially with rising temperature. In polycrystalline solids diffusion along the grain boundaries must also be taken into consideration.

Pure solid state reactions take place in a finite time if the diffusion constants are at least around 10^{-12}cm^2/sec. This corresponds in principle to Tammann's rule, according to which a useful degree of conversion (*e.g.* in reactions of oxides) will only be obtained if the reactant mixture is so strongly heated that at least one of the components reaches 2/3 of its melting point on the absolute scale.

The concentration of imperfections can be substantially increased by the addition of small quantities of ions with another charge number (doping), but this method is seldom employed for preparation because of the resulting contamination of the materials.

More important is the thermal decomposition of mixed precipitates, solid solutions, or suitable complexes.

Examples:

$(Nb_2O_5, TiO_2, nH_2O) \xrightarrow{T} TiNb_2O_7$ [3] (1)
(X-ray amorphous precipitate)

$(NH_4)_2Mg(CrO_4)_2 \cdot 6\,H_2O \xrightarrow{T} MgCr_2O_4$ [4] (2)

Similarly, spinels MCr_2O_4 were obtained from complexes, where M = Zn, Cu, Mn, Fe, Co, Ni [4]

$(M, Fe_2)(C_2O_4)_3 \quad 6\,H_2O \xrightarrow{T} MFe_2O_4$ [5] (3)
(solid solution)

M = Mg, Ni, Co, Zn, Mn

Thus, for the reaction of a mixture of two oxides (TiO_2 + Nb_2O_5 *etc.*) not only have the diffusion pathlengths been reduced to the order of atomic dimensions, but also many imperfections and large surfaces have been created by the liberation of gaseous decomposition products. This is also true in the case of reactions of solids with gases.

Examples:

The formation of CuO by heating Cu turnings in a stream of oxygen proceeds beyond the Cu_2O stage only very slowly at 1000 °C on account of the considerable length of the diffusion paths through the protective layer. However, CuI changes readily into CuO at 300 to 400 °C in the presence of oxygen[6].

[3] *R. Gruehn* and *H. Schäfer*, Naturwissenschaften *50*, 642 (1963).
[4] *W. Whipple* and *A. Wold*, J. Inorg. Nucl. Chem. *24*, 23 (1962).
[5] *P. Kleinert* and *A. Funke*, Z. Chem. *1*, 155 (1961).
[6] *H. Schäfer* and *M. Rönspiess*, unpublished results (1963).

A similar situation is observed in the case of IrO_2. The oxidation of Ir with O_2 remains quite incomplete at 800 to 1000 °C. In contrast, $IrCl_3$ is completely converted into IrO_2 at 600 °C in a stream of O_2[7].

The reaction of a mixture of $BaCl_2$ and $NiCl_2$ with F_2 (300 °C) leads to a mixture of BaF_2 and NiF_2. On the other hand, $Ba[Ni(CN)_4]$ gives the ternary fluoride $BaNiF_5$[8] on treatment with F_2.

The preparation of $NiPbF_6$ from the oxides PbO and NiO in a stream of F_2 is difficult (if not impossible). However, it proceeds smoothly by the reaction of a mixture of $(NH_4)_2PbCl_6$ and $Ni(NH_3)_6Cl_2$ in a stream of F_2 (on heating from room temperature to 500 °C)[9].

The best way of synthesizing MnF_3 is by the reaction of $(NH_4)_2[MnF_5]$ with F_2 (350 °C)[10].

Seven stable structurally related phases appear at 1300 °C in the NbO_2–$NbO_{2.5}$ system[11,12]. The formation of the respective equilibrium phases takes place more quickly, in a suitable H_2/H_2O atmosphere, the greater the difference in composition (and therefore in structure) between the starting and the final states[12]. This means that the breakdown of one structure and the formation of another proceeds more quickly, because of the available defects and surfaces, than a rearrangement, through solid diffusion. "It is easier to knock an old house down completely and to build a new one, than to achieve the same result by stepwise conversion."

2.2. Surface Diffusion

The phenomenon of surface diffusion is well known through the classic work of *Volmer*[13], who showed that, in the growth of a mercury crystal from the gas phase at low pressures, Hg atoms are first of all adsorbed anywhere on the crystal surface, and reach their final resting place by surface diffusion[14]. Another important contribution was the measurement of the diffusion of benzophenone on glass surfaces[15]. The considerable part played by surface diffusion in the transport of material in finely porous substances has been demonstrated by the work of other authors[16–19]. Today it is well known that surface diffusion plays an important role in adsorption and chemisorption, in crystal growth, in the 'decoration' of crystal surfaces (*e.g.* by the condensation of gold[20,21]) and in heterogeneous catalysis (*e.g.* hydrogen migration on heterogeneous catalysts: "spillover"[22])[23]. However, the part played by surface diffusion in solid reactions has not been consciously emphasized or utilized.

Surface diffusion requires a considerably lower activation energy than solid diffusion, and consequently it is operative at lower temperatures. The diffusion constants for surface diffusion correspond in magnitude to those in solutions and in melts.

Returning to the basic question, let us consider the *thermal decomposition of a solid* with liberation of a gaseous component:

$$AB\ (s) \rightarrow A\ (s) + B\ (g) \qquad (4)$$

Two principal reaction pathways are possible: In the first of these, B splits off leaving the phase AB supersaturated with respect to A; the nuclei of A which are formed at the next step can only grow by *solid diffusion,* since they are in the body of the AB phase and are completely surrounded by it. In the other pathway B splits off from the surface of AB, and the formation and growth of A nuclei take place by *surface diffusion.*

Evidently the second way is frequently decisive, especially if the decomposition takes place not in vacuum but in the presence of a gas phase. As an example we may cite reaction (5):

$$3\ FeOCl\ (s) \rightarrow \alpha\text{-}Fe_2O_3\ (s) + FeCl_3\ (g)\ (^1/_2\ Fe_2Cl_6\ (g)) \qquad (5)$$

The following proposal for the reaction mechanism seems plausible: at a sufficiently high temperature we shall have mobile Fe^{3+}, O^{2-}, and Cl^- ions on the surface of the FeOCl crystal. In this surface film the environment of the Fe^{3+} ions is always changing, with the best possible electrostatic compensation (as in a solution or melt). In this way three Cl^- ions can become attached to an Fe^{3+} ion, and the molecule so formed can escape into the gas phase. As a result of such a process an increased concentration of O^{2-} and Fe^{3+} ions builds up in the surface film which leads, at suitable places, to the formation of nuclei and to the building up of an α–Fe_2O_3 lattice. Obviously such a process must be susceptible to *outside influences* through changes in the composition of the surface film. A good example of this is the thermal decomposition of VI_3[24].

$$VI_3\ (s) \rightarrow VI_2\ (s) + {}^1/_2\ I_2\ (g) \qquad (6)$$

Contrary to thermodynamic expectations, the decomposition of VI_3 takes place at a higher temperature in

vacuum than under 1 atm. of argon (Fig. 1). This observation can be taken to mean that in the argon atmosphere a certain pressure of iodine vapor builds up over the substance. There will be a corresponding concentration of iodine in the surface film, which will make the vanadium mobile by the chemical transport action of the halogen in the surface film. The steady loss of iodine to the gas phase promotes the formation of nuclei on the surface and thus leads to the building up of the VI_2 lattice.

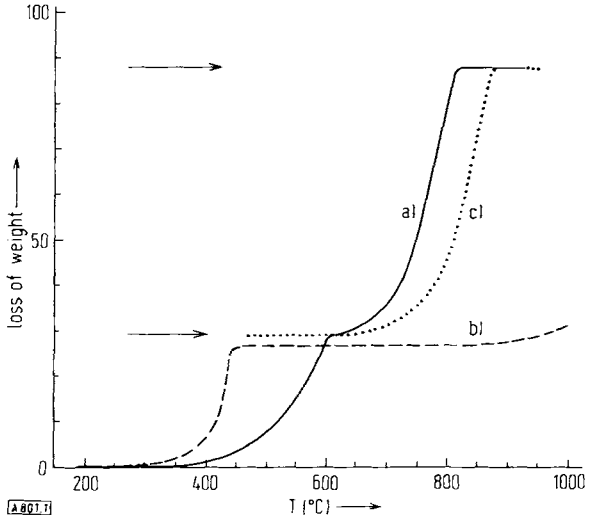

Fig. 1. Decomposition of VI_3 and VI_2 on the thermal balance. Temperature rise 2.7 °C/min. The arrows show the step heights corresponding to the elimination of iodine.

(a) VI_3; vacuum ($< 10^{-3}$ torr), (b) VI_3; 1 atm. of argon, (c) VI_2 (red), well crystallized; vacuum ($< 10^{-3}$ torr).

Comparison of curves (a) and (c) shows further that the VI_2 originating from the VI_3 in vacuum (a) is less well ordered and therefore decomposes at a lower temperature than the well-crystallized material (c).

This reaction mechanism cannot work under vacuum, because the necessary surface film cannot be formed. The thermal decomposition can only proceed rapidly in that case when the solid diffusion is rapid enough, *i.e.* at higher temperatures.

In accordance with this interpretation, it is found from X-ray photographs that the VI_2 obtained in the first case is well crystallized and well ordered, while that obtained by decomposition in vacuum contains many imperfections. In agreement with this, it is also found, on raising the temperature further, that the VI_2 obtained from the vacuum decomposition decomposes at a lower temperature (Fig. 1).

It seems logical to go one step further and to try to influence the composition of the surface film by the *addition of appropriate foreign substances;* in connection with the chemical transport of a solid by a *gas phase,* we must also bear in mind the *mineralizing effect* of the gas phase[25].

Ni recrystallizes strongly when it is heated to about 1000 °C in the presence of a trace of iodine[26], and the same is true for Fe_2O_3[27] in the presence of HCl, and for NbO_2 in the presence of I_2[28].

Up to now these phenomena have been interpreted only as gas-phase transport reactions involving reversible heterogeneous equilibria[25], but we have to remember that surface diffusion with breakdown and build-up of the crystal phases are important steps in normal chemical transport processes over long distances *via* the gas phase. Thus, it seems clear that for the above mentioned mineralizing effect of the transport agent surface diffusion other than *via* the gas phase can also be important.

It is obviously possible to suppress the influence of the gas phase and to isolate the effects of surface diffusion if the reaction is carried out in a *rapid stream of gas.* Consider a system for which chemical transport in the gas phase is possible; if the crystal phase is heated in a rapid gas stream, then the molecules escaping into the gas phase will be carried away without being able to undergo a back reaction on the starting place. Even if this involves considerable recrystallization of the solid phase (which would not happen in the absence of the transporting gas phase at the same temperature) then surface diffusion – *"chemical transport in the surface film"* – must be of decisive importance. A typical example of this is the recrystallization of the Pt catalyst gauze in the industrial combustion of ammonia: platinum is chemically transportable at a temperature of 1000 °C in the presence of oxygen[29] and also in a stream of NO[30]:

$$Pt + O_2 \rightarrow PtO_2\,(g) \qquad (7)$$

$$Pt + 2\,NO \rightarrow PtO_2\,(g) + N_2 \qquad (8)$$

$$PtO_2 \rightarrow Pt + O_2 \qquad (9)$$

Equations (7) and (8) show how the platinum volatilizes (as PtO_2) in the combustion of ammonia. Surface diffusion, *i. e.* chemical transport in the surface film corresponding to equations (7)–(9) is obviously responsible for the extensive recrystallization of the platinum gauze (Fig. 2). During this process the PtO_2 is mobile in the surface film.

Exact investigations of systems in which transport is possible in the surface film but not in the gas phase are of special interest. In this connection we may recall the observation[32] that silver condensed onto graphite recrystallizes readily at room temperature, *if an adsorbed film of water* is present. We may also remember that many reactions that were formerly regarded as typical solid-solid processes are now known to occur at the

stated temperatures only if water vapor (and CO_2?) is not excluded. This is true, for example, for reaction (10) at a temperature of 200 °C:

$$2\,BaO\,(s) + 4\,AgI\,(s) \rightarrow 2\,BaI_2\,(s) + 4\,Ag\,(s) + O_2 \quad [33] \quad (10)$$

With respect to the diffusion process surface diffusion can be compared to the processes which go on in the molten state. In fact melts are of great significance for the synthesis of solids and for crystal growth. We need only recall the dissolving power of fluoride melts for oxides. We cannot go further into this wide field in the present article, nor can we enlarge upon the use of small quantities of fluxes as mineralizing agents.

To sum up, considerable preparative advances are made possible by systematic control and utilization of surface diffusion.

2.3. Chemical Transport in the Gas Phase[25]

If *one* of two reacting solid substances is chemically transportable *via* the gas phase by means of a heterogeneous equilibrium this may have important *advantages:*

1) The transformation of solid starting materials into a solid product is usually accompanied by a decrease in volume, which means that the mechanical contact between the reactants becomes worse as the reaction progresses. If, however, the first of the starting materials is mobile by chemical transport, the second will so to speak interact with the 'gaseous solution' of the first:

$$A(s) + B(s) \rightarrow AB(s) \quad (11)$$

$$A(s) + X(g) \rightleftarrows AX(g) \quad (12)$$

$$AX(g) + B(s) \rightarrow AB(s) + X(g) \quad (13)$$

If the reaction product AB is not chemically transportable the solid diffusion of A or B in AB still plays an important role, being as a rule rate-determining. However, because of the transport process the substance A is available for reaction over the whole surface of the B grain, and not only at touching points as in purely solid-solid reactions.

2) The substances A and B will also react, even if they are widely separated, in the presence of a transport agent. This means that it is unnecessary (and usually inappropriate) to use A and B in exactly stoichiometric proportions. The *isothermal* transport ceases automatically when one of the starting materials is used up. It is convenient to use an excess of the transportable material. In this way the synthesis occurs with a selection of materials, and the analysis of the reaction products has some definite significance, in contrast to the case of purely solid state reactions.

Examples:

a) $$2\,CaO + SnO_2 \xrightarrow{900\,^\circ C} Ca_2SnO_4 \quad [34] \quad (14)$$

$$SnO_2(s) + CO \rightleftarrows SnO(g) + CO_2 \quad (15)$$

The formation of Ca_2SnO_4 is markedly accelerated by the addition of CO or H_2, since the SnO_2 can then be transported in the form of SnO(g).

b) $$NiO + Cr_2O_3 \xrightarrow{1100\,^\circ C} NiCr_2O_4 \quad [35] \quad (16)$$

$$Cr_2O_3(s) + 3/2\,O_2 \rightleftarrows 2\,CrO_3(g) \quad [25] \quad (17)$$

In the presence of oxygen, the reaction takes place even if the reactants are separated spatially; in this case the Cr_2O_3 migrates to the NiO.

c) $$11\,Nb + 3\,SiO_2 \xrightarrow{1000\,^\circ C} Nb_5Si_3 + 6\,NbO \quad [36] \quad (18)$$

Nb can be heated in a quartz tube under high vacuum without the thermodynamically favored reaction (18) taking place. On the other hand, if traces of H_2 are present the reaction proceeds to completion: the SiO_2 migrates from the walls of the vessel to the niobium:

$$SiO_2(s) + H_2 \rightleftarrows SiO(g) + H_2O \quad (19)$$

When iodine is used as the transport agent the migration takes place in the opposite direction; the niobium is now transported to the walls of the vessel,

$$Nb + 2\,I_2\,(g) \rightleftarrows NbI_4\,(g) \quad (20)$$

and reacts there with the quartz to form Nb_5Si_3 and NbO[37].

Quartz reacts similarly with tantalum (forming Ta_2Si and Ta_2O_5)[38] and with vanadium (forming V_3Si and VO)[39], if a transport agent is present.

When the reactants are heated to above 600 °C in quartz ampoules, traces of water vapor are liberated from the walls. Often it is these small amounts of water that make the reaction possible, due to their chemical transport action in the gas phase and/or in the surface films. Since the kinetics of the reactions were not generally investigated, we are free to speculate:

[39] *K. E. Spear, P. W. Gilles,* and *H. Schäfer,* J. Less-Common Metals *14,* 69 (1968).

d) The interaction of CdO with VO, V_2O_3, and VO_2 at 700 °C in quartz ampoules[40] leads to the formation of CdV_2O_4, $CdVO_3$ and CdV_3O_7. Additional CdO was introduced into the ampoules in the form of pellets, to compensate partly for the loss of CdO by reaction with the quartz. Since this proved effective, it can only mean that the gas phase is involved in the reaction. Gaseous molecules: H_2O, H_2, Cd; transport of Cd according to equation (21):

$$CdO\ (s) + H_2 \rightleftarrows Cd\ (g) + H_2O \qquad (21)$$

This transport process has already been observed in a temperature gradient[41].

Partial oxygen transport by means of H_2/H_2O has a bearing upon this question of the effectiveness of traces of water. For example, the reaction

$$Nb + NbO_2 \rightarrow NbO \qquad (22)$$

is not perceptible at 900 ° C under high vacuum, but takes place rapidly and completely in a quartz ampoule on the addition of a trace of H_2 or H_2O. The H_2/H_2O gas phase reduces the NbO_2 to NbO and oxidizes the Nb to NbO[28].

There are *additional advantages* if the *reaction product is also chemically transportable*:

3) Solid diffusion no longer plays a part. No troublesome protective layers are formed, because the product is carried away within the temperature gradient. This is also true if one of the starting materials is gaseous; see example (e).

4) The system is then effectively in a state of reversibility. The nature of the starting materials is of little significance, and so the cheapest and most easily available can be used.

5) As a rule single crystals of the product are obtained, without having to take special precautions, and these are at least of a size suitable for X-ray analysis, and are often $\geq$ 1 mm along the edge.

6) Heterogeneous reaction products can often be separated by chemical transport. This is particularly true if one of the products is transported by an *endothermic* reaction and the other by an *exothermic* one. They will then migrate in opposite directions in a temperature gradient.

7) By means of a "buffered gas phase", it is possible to prepare substances of certain desired composition, if complicated phase relationships or homogeneity ranges exist[42].

Examples:

e) Aluminum reacts only very slowly at 800 °C with gaseous sulfur to give Al_2S_3 (quartz ampoule; Al in an Al_2O_3 boat). The liquid aluminum becomes coated with a film of Al_2S_3 which acts as a diffusion barrier. If the same experiment is carried out in the presence of a little iodine and in the same temperature gradient 800 → 700 ° C, then Al_2S_3 separates in large colorless crystals in the 700 °C zone[43]. No Al_2S_3 coating is formed in this case, because the Al_2S_3 is carried away by the iodine.

$$Al_2S_3 + 3\ I_2\ (g) \rightleftarrows 2\ AlI_3\ (g) + 3/2\ S_2\ (g) \qquad (23)$$

It is in the nature of such reversible systems that they tell us nothing about the actual reaction path. Presumably the reaction sequence is:

$$2\ Al\ (l) + 3\ I_2\ (g) \rightarrow 2\ AlI_3\ (g)\ (Al_2I_6) \qquad (24)$$

$$2\ AlI_3\ (g) + 3/2\ S_2\ (g) \rightarrow Al_2S_3\ (s) + 3\ I_2\ (g) \qquad (25)$$

$$2\ Al\ (l) + 3/2\ S_2\ (g) \rightarrow Al_2S_3\ (s) \qquad (26)$$

Analogous relationships are observed if zinc or cadmium are treated with sulfur, with or without iodine as the transport agent[44].

f) Recently it has been observed[45,46] that numerous sulfides (*e.g.* TiS_2, "$VS_{1.7}$", NbS_2, TaS_3, TaS_2, Cr_2S_3, MoS_2, WS_2, FeS_2, CoS_2, NiS_2, PdS, PtS) are chemically transportable under a moderate pressure of sulfur (5–10 atm.), obviously because volatile sulfides are involved. Such processes could play an important, and hitherto unnoticed, role in the synthesis of sulfides from the elements in quartz ampoules.

g) As a further example of the action of small quantities of water vapor (originating *e.g.* from the walls of the quartz vessel), we may consider the reaction of In_2O_3 with W + WO_3 in the temperature gradient (1100 → 1050 ° C)[47]. Here crystals of $In_2(WO_4)_3$ and In_xWO_3 separate out side by side. The gas phase probably contains the molecules H_2O, H_2, In_2O, $WO_2(OH)_2$, and W_3O_9.

h) The possibility of separating the products of a reaction by Taking advantage of the different direction of transport has been referred to several times[25]. Typical examples are shown in Table 1.

Table 1. Chemical transport separations in a temperature gradient.

Deposition product at T_1	at T_2	Temperature gradient (°C) T_1/T_2	Transport agent	Ref.
CrTe	Cr	850/1025	I_2	[25]
Cu	Cu_2O	600/900	HCl	[49]
CuO	Cu_2O	700/800	HCl	[43, 46]
(NbO_2) [48]	NbO	950/1100	I_2	[28]
$Nb_{12}O_{29}$	(NbO_2) [48]	650/750	I_2	[28]
$NbAs_2$	NbAs	850/1050	I_2	[37]

2.4. Comments

There are several different ways of "increasing the mobility of the reactants" in solid state processes, such as *improving the solid diffusion* or *making use of surface diffusion* or of *chemical transport via the gas phase*. The frequently used method of reacting the solid substances

at a sufficiently high temperature is by no means always the best method of synthesis. One should always try, in the synthesis of solids, to understand what course the reaction will follow, as in this way one could learn how to alter this course in a purposeful manner.

3. Influence of Structural Elements of the Starting Material on its Reaction Behavior

In the type of reaction that we have been considering in Section 2, a knowledge of the structure and bonding of the solids is not as a rule very helpful. The thermodynamically stable end-product is obtained because of the increased mobility of the reactants, regardless of the structure of the starting materials. If the structure of the reactants is to have any influence on the course of the reaction and on the nature of the products, then we must avoid giving too large a degree of mobility to the particles – in contrast to the previous type of reaction. This means that we must avoid using excessively high temperatures and must exclude solvent and transport effects. With these conditions, the structure of the starting materials can have a considerable effect upon the reaction:

Structural elements of the starting materials can be taken over into the product (without decomposing in the meanwhile);
the processes which take place at the crystal surface, *e.g.* the formation of nuclei of new phases, can be influenced; lattice imperfections, which may possibly be characteristic for a certain type of structure, can have an effect upon the course of the reaction.

We find ourselves in the domain of *topochemical reactions* in the widest sense. *Pseudomorphs* too belong here, if it is not only the external habit but also the form and structure of the primary crystallite that are influenced by the starting materials.

3.1. Structural Elements of the Starting Material Are Preserved in the Reaction

This basic principle of molecular chemistry has been known for some time in solid state chemistry. We are especially concerned here with *intercalation compounds* in the narrow kinetic sense. The classic case is that of *graphite compounds* which are formed in such a way that the original layers of the graphite structure are preserved, and *e. g.* atoms of potassium or metal chloride molecules of a certain kind are sandwiched between them[50]. This type of reaction is shown also by other layer structures (*e. g.* MoS_2, WS_2[51]). The swelling and cation-exchange capability of certain layer silicates (*e. g.* montmorillonite)[52] are analogous processes. Their behavior can be plausibly explained in terms of the layer-structures of the starting materials. This is also true for intercalation in existing tubular cavities. Intercalation is also known for structures that do not seem quite so predestined for it. New examples of this kind are the *lower oxides of niobium and tantalum* (M_6O, M_4O, M_2O), which are thermodynamically unstable and are formed from the metal and oxygen at a moderate temperature ($< 600°$ C)[53,54]. The oxygen is obviously taken up, and is incorporated into the metal lattice in an ordered manner, with little deformation of the lattice. It is important to notice that the mobility of the oxygens is in this case considerably greater than that of the metal atoms. A similar effect is observed in the case of the higher niobium oxides. The blue-black compounds $Nb_{12}O_{29}$ (corresponding to $NbO_{2.417}$), $Nb_{22}O_{54}$ ($NbO_{2.453}$) and others, all of which are well characterized, are oxidized by air at a relatively low temperature (*e. g.* 650° C) to the colorless Nb_2O_5 without changing their basic structure. The changeover into the stable structure (the high-temperature modification *H*-Nb_2O_5), with the corresponding rearrangement of the niobium atoms, only takes place at a considerably higher temperature ($\approx 1100°$C)[55].

The greater mobility of the oxygen relative to the niobium is unexpected. Normally the smaller cations diffuse much more quickly than the larger anions (compare for example AgI, Ag_2S, Cu_2O, and many scaling processes). One would also expect that to be the case for the higher oxides of niobium, to judge from the ionic radii ($r_{Nb^{5+}} = 0.69$ Å, $r_{O^{2-}} = 1.32$ Å). Possibly the niobium is more firmly fixed than the oxygen on account of its higher charge. Anyway, it is to be assumed that the low-temperature uptake of oxygen by the above oxides of niobium is due to a peculiar, hitherto unexplained, mechanism.

Anderson and *Wadsley*[56] have proposed a model for oxidation and reduction processes which is applicable to compounds with closely related structures derivable from the ReO_3 type. The oxides of the elements W, Mo, and Nb fall into this class. Starting from the ReO_3 structure with its $ReO_{6/2}$ octahedra connected by the corners, it is possible to describe other compounds, not so rich in oxygen, containing blocks of the ReO_3 structure with boundaries in which the octahedra are connected not by the corners but by the edges. The size of the ReO_3 blocks, or the frequency of occurrence of planes with edge-joins (shear planes), determines the composition of the compound. The composition of the whole crystal can be changed in this way, by uptake or loss of oxygen at the crystal surfaces, the shear planes migrating throughout the structure in stepwise fashion, *i.e.* in jumps corresponding to the length of an octahedral edge. The compounds $W_{20}O_{58}$ and WO_3 for example, are theoretically interconvertible in this way. Experimental proof of the model is still lacking.

Experiments with labeled atoms[57] have shown, however, that another mechanism must be even more important: in single crystals of *H*-Nb_2O_5 the oxygen is found to diffuse preferably in a direction parallel to the (mutually perpendicular) shears planes.

[57] *J. S. Sheasby* and *B. Cox,* J. Less-Common Metals *15,* 129 (1968).

Finally, mention should be made of an as yet incomplete investigation: the oxide-fluorides NbO_2F and TaO_2F, which crystallize in the ReO_3 structure, are found to absorb considerable quantities of HF at slightly elevated temperatures, without losing their single-crystal character[58]. It is to be assumed that the HF goes into the "perovskite holes" of the starting structure. It is unlikely that the HF molecules first adsorbed on the crystal faces themselves migrate into the body of the crystal. More probably the incoming HF molecule displaces an F^- ion from its place in the lattice; and it is this F ion which, along with the H^+, finds its way into the next "perovskite hole". By a repetition of this process, all the perovskite holes could be filled reversibly with HF ("step mechanism").

The most important aspects of this Section have been, of necessity, only roughly outlined. It would be desirable if the available information were critically sifted, and more work done. We should aim at devising a "structural-kinetic" theory, which would predict the relationships between structure and reaction mechanism.

3.2. The Influence of Lattice Defects

The significance of lattice imperfections – especially dislocations – for the kinetic capability of a reaction is illustrated *e. g.* by the classical etch-pit method used to detect lattice defects. The latter can also be important in ordering processes, as shown by the following example: In the thermodynamically stable system of the niobium oxides, seven phases[12] (see Fig. 3) appear at 1300 °C in the region NbO_2–$NbO_{2.5}$. Even at 1300 °C the equilibrium between the crystal phases and the H_2/H_2O gas phase is achieved only slowly (*ca.* 20 h).

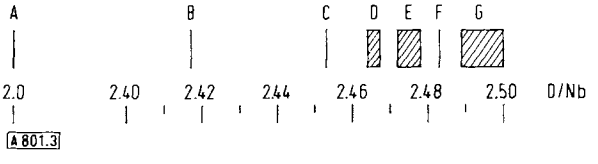

Fig. 3. Niobium oxide phases which are thermodynamically stable at 1300 ° C [12].

All these phases, with the exception of C, can also be obtained at lower temperatures (≈ 1100 °C). The attainment of equilibrium between the crystal phases and the H_2/H_2O gas phase is however strongly retarded at 1100 °C, and it is interesting that this retardation is much more marked in the case of $NbO_{2.5}$ single crystals than in the case of $NbO_{2.5}$ powder (in both cases the *H*-modification).

The reduction of the *powder* leads to the region of phases B to F (Fig. 3), where poorly-ordered material is often obtained. In this way the phase D was first observed[3,59].

The reduction of *single crystals*, in contrast, does not lead to phases in the region B to F, but the single-crystal character remains down to the composition $NbO_{2.44}$[60]. The range of phase G is thus considerably enlarged (metastable, of course). On stronger reduction the lattice breaks down and the NbO_2 phase, which is stable in the presence of the gas phase, is built up.

The single crystals can evidently change their composition, by a still unexplained mechanism, without causing a general rearrangement with formation of the stable phases. In the powder the atoms are much more mobile, a fact that is due not only to the larger surfaces but also to the lattice imperfections.

In this section we must also mention the phenomenon described by *Hüttig*[61] as the *"memory of solid materials"*. According to this, the reaction product "remembers" something about the starting materials, and this memory is manifested in its further reaction behavior. For example, Nb_2O_5 in the T-crystal modification on further heating gives different products, depending upon whether it has been obtained (a) from NbO_2 by oxidation with atmospheric oxygen, (b) from NbO_2 by reaction with chlorine, or (c) by heating of "niobic acid"[55]. Evidently it is sometimes not the ideal structure of the reacting substance, but its characteristic lattice imperfections that represent the true controlling factor of the reaction.

It is clear that we must be careful, in this field, to distinguish between the influence of true structural elements and that of the imperfections.

Turning to materials with distorted lattices one comes across *"active substances"*. Much work in this field has been done by *Fricke* and his associates. These active substances are important because they are especially good starting materials for solid-solid reactions, and also because they can be used to prepare substances that are not otherwise obtainable. A new example of this is the reversible (!) decomposition of "active" Al_2O_3 at 500 °C in vacuum to the black $Al_2O_{2.96}$[62].

4. Concluding Remarks

The solid-state chemist concerns himself at present mainly with structural principles and types of bonding in solids, and their corresponding physical properties. The question of the reaction mechanism is left in the background. Many interesting synthetic pathways are thus left unexplored and unused. The purpose of the present contribution was to point out the unsatisfactory state of affairs, in the hope that these critical reflections will stimulate some action in this direction.

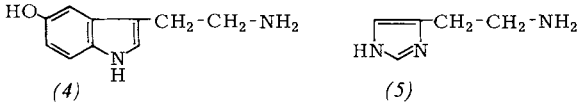
Biochemistry and Function of Biogenic Amines in the Central Nervous System

By Nikolaus Seiler, Lothar Demisch, and Herbert Schneider[*]



A number of amines are of the utmost importance to the normal function of the nervous system; numerous relationships also exist between certain diseases of the nervous system and the metabolism of these amines. Noradrenaline, serotonin, and histamine are taken as examples to offer some idea of the possibilities and methods of biochemical research that help to elucidate the physiological and pathological processes in the nervous system. The article shows that our knowledge of the functioning of the nervous system, even in a field that has been studied as thoroughly as the transmission of nerve stimuli at synapses, is still in its infancy.

1. Introduction

Biogenic amines are defined as amines that are formed in the course of any metabolic reaction in any organism. This general view, which was advocated *e.g.* 20 years ago by *Guggenheim* in his book on the subject[1], leaves the boundary between the biogenic amines and the alkaloids undefined. During recent years, general interest has been so strongly concentrated on a few particular amines that the majority of the amines present even in the animal organism have receded even farther from the field of view. In most of the publications that have appeared during the past few years, accordingly, only the catecholamines dopamine *(1)*, norepinephrine *(2)*, epinephrine *(3)*, and serotonin (5-hydroxytryptamine; 5-HT) *(4)*, histamine *(5)*, and possibly also acetylcholine are treated as biogenic amines, while *e.g.* the polyamines spermine and spermidine, which are present in nearly

(1) *(2)* *(3)*

(4) *(5)*

all tissues in very much higher concentrations than the catecholamines[2,3], as well as simple β-phenylethylamines, indolamines, and aliphatic monoamines and diamines are often completely ignored. This is because the great importance of catecholamines and serotonin to many physiological functions is already known, whereas our knowledge about the functional importance of other amines has many gaps or is totally inadequate.

The work carried out in recent years has been directed mainly toward the investigation of the function of the amines in the central nervous system. In this article, which will be confined to the amines in the central nervous system, we shall be concerned almost exclusively with dopamine, norepinephrine, serotonin, and histamine, and only these will be covered by the term "biogenic amines". Acetylcholine, in spite of its outstanding importance, must be omitted from our discussions, which would otherwise cover too wide a field. There has, however, been a recent trend back to the broader use of the term "biogenic amines". This is partly because sufficiently sensitive methods have been available for a long time for the detection of the catecholamines, serotonin, histamine, and acetylcholine, whereas the methods required for a successful experimental investigation of the other amines were largely lacking.

2. Methods of Detection and Determination

The concentration of the biogenic amines in the brain, as in most organs, is very low. It can be seen from Table 1 that it is generally less than 1000 ng/g of moist tissue. This means that very sensitive analytical methods are required for their determination, particularly since the quantities of tissue available are usually limited.

Some methods make use of the biological actions of the amines, *e.g.* their action on the blood pressure or on the contraction of smooth muscle (uterus, small intestine). These methods are characterized by high sensitivity, and the biogenic amines (catecholamines, serotonin, histamine, acetylcholine) were discovered with their aid. However, it is difficult to distinguish between different substances having a similar action by biological methods, and these methods have therefore been replaced over the years by more specific chemical methods. For this

reason, the biological methods will not be discussed in detail, and the reader is referred instead to comprehensive descriptions elsewhere[4,5].

2.1. Nonspecific Methods for General Use

Color reactions or coupling with colored or fluorescent molecules generally allow the use of optical methods for the determination of amines. The most commonly used reagents are still Ninhydrin for primary and secondary amines and the Dragendorff reagent for secondary and tertiary amines[6,7]. However, the scope of these colorimetric methods is limited by their relatively low sensitivity. Nevertheless, *Perry et al.*, for example, were able to identify a series of amines in tissues and excreta by a combination of ion-exchange chromatography and two-dimensional paper chromatography with Ninhydrin for staining[8–12]. *Honegger* used thin layer electrophoresis for the separation of brain amines[13].

As in the analysis of amino acids, numerous coupling reagents that form colored reaction products with primary and secondary amines have been suggested[14–23]. The most important of these reagents is 2,4-dinitrofluorobenzene (DNP-F), which forms yellow derivatives with amines. After separation by column chromatography, the amines are treated with DNP-F as described by *Dubin* and determined spectrophotometrically[24]. The DNP derivatives can be detected on chromatograms in quantities as small as 5 nmole.

It was found that the detection sensitivity could be increased by a factor of about 100 by the use of 5-dimethylaminonaphthalene-1-sulfonyl chloride (DANS-Cl)[25] and of 4-chloro-7-nitrobenzol[*c*]-[1,2,5]oxadiazole (NBD-Cl)[26] as coupling reagents. [^{131}I]-*p*-Iodobenzenesulfonyl chloride (pipsyl chloride) has also been used for the determination of histamine[27]; the resulting derivatives can be detected even in small quantities because of their radioactivity.

The detection methods described so far are nonspecific by their nature, in that they merely show the presence of a sufficiently basic primary or secondary amino group in a molecule. Moreover, most of the reagents mentioned also react with phenols. They can be used to advantage only if the mixture of amines (*e.g.* from a tissue extract) or of their derivatives can be separated.

All the usual chromatographic and electrophoretic techniques, particularly paper and thin layer chromatography, have been used for the separation of the amines. Thus *Lockhart* separated the DNP derivatives on paper chromatograms[28], while *Parihar et al.*[29] and *Zeman* and *Wirotama*[30] separated them on thin layer chromatograms. *Seiler* and *Wiechmann* have described systems for the separation of many DANS-amides by thin layer chromatography[31–33]. DANS derivatives can also be successfully separated on paper[34,35]. *Reisch et al.* have recently separated a number of NBD derivatives by thin layer chromatography[36]. The DNP and DANS derivatives are very well suited for the mass-spectrometric identification of the amines[30,37–40].

Since the general methods described so far have only occasionally been used specially for the determination of the catecholamines, serotonin, and histamine, no details will be given here. It is appropriate, however, to point out that the problem of the quantitative determination of colored or fluorescent substances separated by thin layer or paper chromatography has been solved in principle[41–44].

2.2. Gas Chromatography

Though the technique of gas chromatography is very highly developed, this method has not been widely used for the determination of biogenic amines. The gas chromatography of the free amines is obviously associated with special difficulties[45,46].

The detection of the trimethylsilyl ethers of the catecholamines with flame ionization detectors has proved to be relatively insensitive[47–49]. The best method appears at present to be the separation of the trifluoroacetyl derivatives of the biogenic amines in a capillary column combined with an electron capture detector or by direct coupling of the gas chromatograph and the mass spectrometer and recording of the total ion current[50–52]. The gas chromatographic separation of DNP amines was recently also described[53].

2.3. Mass Spectrometry

The high sensitivity and the separating power of the mass spectrometer are utilized by *Boulton* and *Majer* for the determination of amines in crude tissue extracts[54]. In this method, the integrated ion current of the molecule-ion is measured under standardized conditions (integrated ion current technique).

2.4. Specific Fluorometric Methods

By far the majority of the investigations on the distribution and metabolism of the biogenic amines were carried out by methods that made use either of the fluorescence of serotonin at certain pH values or of special reactions of the amines with formation of fluorescent derivatives[55]. The determination of serotonin in the brain and other tissues by measurement of the fluorescence of this amine in 3N HCl at 550 nm is due to *Bogdansky et al.*[56]. *Jepson* and *Stevens*[57] were the first to observe that serotonin reacts with Ninhydrin to form an intensively fluorescent product. *Vanable*[58], and later *Snyder et al.*[59], used this reaction as the basis of specific determination methods that are eight times as sensitive as *Bogdansky*'s method. According to *Snyder et al.*, the detection sensitivity of the method is 10 ng of serotonin. In more recent variants of these methods, only the extraction and separation methods have been changed, and the technique of the fluorescence measurement has been improved[60–63].

The fluorescence of the catecholamines in acidic solution is too nonspecific to be used for their determination in the brain, and is used only for the measurement of the total content of catechol derivatives in adrenals[64]. The determination of the catecholamines is based on two principles, *i.e.* conversion into trihydroxyindole derivatives (adrenolutin and noradrenolutin) and condensation with ethylenediamine. The trihydroxyindole method appears to be the more specific. Numerous oxidizing agents used under various reaction conditions have been suggested for the oxidation of the catecholamines[55, 65]. The most important at present are $K_3[Fe(CN)_6]$ and iodine. With potassium hexacyanoferrate (III), norepinephrine and epinephrine can both be oxidized at pH = 6.5, and epinephrine alone at pH = 3.5, whereas dopamine, 3-*O*-methylnorepinephrine (normetanephrine), and 3-*O*-methylepinephrine (metanephrine) do not react under these conditions[66]. On oxidation with iodine, dopamine is also converted into a lutin, and can be determined in the presence of norepinephrine and epinephrine on the basis of the different activation and fluorescence maxima[67–69]. The 3-*O*-methyl derivatives of the catecholamines can also be determined by the trihydroxyindole method[70,71].

The ethylenediamine method is based on the work of *Weil-Malherbe*[72–74] and of *Harley-Mason* and *Laird*[75]. The course of the condensation reaction has not yet been entirely elucidated[55]. The condensation products of epinephrine and norepinephrine can be distinguished by their different fluorescence maxima. This method is also suitable for the determination of dopamine[76], and has been used for the detection of the catecholamines on chromatograms[7].

Methods used for the concentration and separation of the catecholamines include extraction[77,78], adsorption on Al_2O_3[79], and above all chromatography on cation exchange columns[80,81]. The number of variants published in recent years, which relate not only to the concentration and separation, but in particular also to the stabilization of the lutins with ascorbic acid[55], sodium sulfite[82], sodium tetrahydridoborate[83], dimercaptopropanol (BAL)[84], and other antioxidants, as well as to the conditions of the oxidation and of the condensation with ethylenediamine, is so large that *Häggendal* stated in his review[81] that practically every laboratory concerned with catecholamine determinations appears to have developed its own method.

The catecholamines can be determined fluorometrically in the nanogram range by using smaller volumes and microcells. The

most recent efforts have been aimed at the determination of as many amines as possible in a single sample of tissue[85–88] and the automation of the methods [89–91].

The fluorometric determination of histamine is nearly always preceded by condensation with phthalaldehyde as described by *Shore et al.*[92]. The fluorescent product of this reaction has not yet been definitely identified. Histidine, spermidine, and other substances[93] also give fluorescent derivatives with phthalaldehyde. Due consideration was not given to this point in very many determinations of histamine in the brain and other tissues, and the results obtained in earlier histamine determinations were consequently much too high. This also made failure inevitable in the attempted histochemical demonstration of histamine in brain sections with phthalaldehyde. The only value of the method was for the demonstration of histamine in the mast cells of the small intestine, where it is present in very high concentrations[94, 95]. The method first reported by *Kremzner* and *Wilson*[96] for the separation of interfering substances by ion exchange chromatography has been improved to such a degree in recent years[97–100] that as little as 25 ng of histamine can now be reliably determined.

2.5. Radiochemical Methods

A specific enzymatic method for the determination of histamine has been developed by *Snyder, Baldessarini,* and *Axelrod*[101]. A small quantity of [^{3}H]-histamine and *S*-adenosylmethionine having a ^{14}C-labeled *S*-methyl group are added, together with

Scheme 1. Radiochemical determination of histamine. Ad-Rib = adenosyl.

histamine *N*-methyltransferase, to the tissue sample. The enzyme converts histamine specifically into [1-^{14}C]-methyl-4-histamine (Scheme 1). The ^{14}C/^{3}H ratio in the extracted methylhistamine is directly proportional to the quantity of histamine in the tissue sample. As little as 2 ng of histamine can be detected in this way.

The method devised by *Engelmann et al.*[102] is also based on the same principle of enzymatic labeling and measurement of the ^{14}C/^{3}H ratio; in this case, the ^{14}C-labeled *S*-methyl group from *S*-adenosylmethionine is transferred to the 3-OH group of the catecholamines by catecholamine *O*-methyltransferase (COMT) (see Scheme 2). *Franklin* and *Majer*[103] added [^{14}C]-catecholamines to the samples and then acylated the hydroxyl groups with [^{3}H]-acetic anhydride. After separation of the labeled products, the ^{3}H/^{14}C ratio is determined. The advantage of the double labeling methods is that the isolation and purification of the substances to be determined need not be quantitative, since the isotope ratio is a direct measure of the quantity of the substance that was present in the tissue. Any desired number of purification steps may therefore be included.

The rate of the enzymatic [^{14}C]-*N*-methylation of norepinephrine by phenylethanolamine *N*-methyltransferase is utilized by *Saelens et al.*[104] for the specific quantitative determination of norepinephrine in the presence of physiological concentrations of the other catecholamines.

2.6. Histochemistry

The conversion of indole derivatives into the intensely fluorescent β-carbolines by condensation with formaldehyde in the presence of acid has been in use for a long time in *Procházka*'s reaction[105] for the detection of indoles on chromatograms. A series of ring-substituted β-phenylethylamines can also be converted into fluorescent isoquinoline derivatives by condensation with formaldehyde[106].

As was first observed by *Falck* in 1962, the condensation of the catecholamines and of serotonin with formaldehyde gas proceeds even under very mild conditions in the presence of proteins or certain amino acids, with formation of intensely fluorescent 3,4-dihydroisoquinolines or the β-carboline deriva-

tive[107,108]. The reaction products are partly bound to the proteins, possibly *via* methylene bridges, so that they cannot be extracted with organic solvents. These observations formed the basis of the method that has been used with outstanding success over the last eight years for the cellular localization of the catecholamines and of serotonin in tissue sections. The method has been described in detail by *Falck* and *Owman*[109] and by *Corrodi* and *Jonsson*[110]. It is possible to distinguish norepinephrine, dopamine, and serotonin in the cells by measurement of the excitation and fluorescence spectra of the formaldehyde condensation products with the aid of a microspectrofluorometer[111–115]. Treatment of catecholamines and indolamines with formaldehyde gas also allows the detection of these substances on silica gel G layers[116,117].

3. Metabolism

3.1. Biogenesis

It can be seen from Schemes 2–4 that the reactions that lead to the formation of the biogenic amines and that cause their degradation or physiological inactivation in the mammalian organism are formally identical for the catecholamines, serotonin, and histamine. They involve biosynthesis by decarboxylation of the corresponding amino acids, and inactivation by oxidation and methylation. All the enzymes associated with the metabolism of the biogenic amines have been detected in the brain[118].

For the biosynthesis of dopamine and serotonin, the immediate precursors of the amines *i.e.* L-3,4-dihydroxyphenylalanine (dopa) and L-5-hydroxytryptophan (5-HTP), must first be produced by hydroxylation of tyrosine and of tryptophan. The hydroxylation appears in both cases to be the rate-determining step of the reaction sequence, which is inhibited by the final products (feedback), and so regulates the catecholamine and serotonin syntheses[119–127].

Tyrosine hydroxylase can use only L-*p*-tyrosine as the substrate. Fe^{2+} and tetrahydropteridines act as cofactors[127]. On the other hand, tryptophan hydroxylase, which also requires Fe^{2+} and tetrahydropteridines as cofactors, is a relatively unspecific enzyme, and can hydroxylate several aromatic amino acids in the benzene ring. However, the enzyme isolated from brain, unlike that from peripheral organs, cannot convert phenylalanine into tyrosine[128–130].

Dopa and 5-hydroxytryptophan are decarboxylated in the brain by the same enzyme to the corresponding amines, as has been shown by numerous observations. Dopa decarboxylase, which was first detected in kidney by *Holtz*[133], is not very specific, so that in addition to 5-hydroxytryptophan and dopa, a number of other aromatic amino acids, *e.g. o-* and *m*-tyrosine, are suitable substrates for the enzyme from brain. The enzyme requires pyridoxal 5-phosphate as a cofactor[134, 135]. The decarboxylation of the amino acids cannot be the rate-determining step of the amine biosynthesis, since the reaction rate is 75 times as high for dopa decarboxylase as for tryptophan hydroxylase[132]. Though histidine can also be decarboxylated by the unspecific decarboxylase for aromatic L-amino acids[134], there is still no agreement as to whether the histamine in the brain is formed physiologically by this or by a more specific enzyme[136].

The final step in the biosynthesis sequence of norepinephrine is the hydroxylation of the ethylamine side chain of dopamine by dopamine β-hydroxylase. The hydroxylation proceeds in the presence of ascorbic acid and oxygen[140]. In addition to dopamine, many other β-phenylethylamines are converted into β-hydroxy derivatives by this enzyme[141].

The distribution of the hydroxylases and of the decarboxylases in the various regions of the brain is substantially similar[131]. The highest dopa decarboxylase and histidine decarboxylase activities were found in the nucleus caudatus, the putamen (corpus striatum), and the hypothalamus[137–139]. The topographic distribution of the amines also corresponds in general to the distribution of the enzymes that synthesize them. However, norepinephrine is a striking exception. Whereas a high dopamine β-hydroxylase activity can be detected in the corpus striatum *in vitro*[142], only a little norepinephrine is found in this region together with a large quantity of dopamine (cf. Table 1 and Fig. 1). The *in vivo* activity of the hy-

droxylase must therefore be low in the corpus striatum. This means that either the dopamine and the enzyme are located in different metabolic compartments of the cells of the corpus striatum, or cofactors that are essential to the full activity of the β-hydroxylase are absent from these cells[143, 144].

Owing to the great practical difficulties, opinions differ as to the quantity of epinephrine that is present in the central nervous system, which is very small in any case. On the other hand, the enzyme that methylates norepinephrine to form epinephrine, *i.e.* phenylethanolamine *N*-methyltransferase, has been definitely detected in the brain. The methyl group donor in this reaction, as in many biological methylations, is *S*-adenosylmethionine[145]. Epinephrine can also be demethylated to form norepinephrine.

3.2. Degradation

According to the current view, catecholamines liberated from the nerve cells by nerve stimuli or by substances having a sympathomimetic action are physiologically inactivated either by an active re-uptake mechanism or by 3-*O*-methylation[146]. Catecholamine *O*-methyltransferase (COMT) transfers the methyl group of *S*-adenosylmethionine onto a series of catechol derivatives, the ratio of 3- to 4-*O*-methylation being strongly dependent on the structure of the side chain of the catechol derivative[147]. The 4-*O*-methylation plays only a very minor part *in vivo*.

Histamine is also methylated to a large extent on N-1 in the brain (cf. Scheme 4)[148, 149], whereas the physiological inactivation of serotonin by methylation is of no importance. On the other hand, the methylation of *N*-acetylserotonin by *N*-acetylserotonin *O*-methyltransferase in the pineal body is an important step in the synthesis of melatonin (cf. Scheme 3)[150].

The second path for the physiological inactivation of the amines, *i.e.* oxidative deamination by amine oxidases, leads first to the aldehydes, which cannot generally be detected directly. These are then either dehydrogenated to form the acids or reduced to the alcohols. The phenylacetic acids are generally formed preferentially from β-phenylethylamine derivatives, and the ethylene glycols from β-phenylethanolamines. The main product of norepinephrine metabolism found in the brain is accordingly 4-hydroxy-3-methoxyphenylethylene glycol, which was detected in the form of its 4-*O*-sulfate[151], whereas the norepinephrine in peripheral organs is mainly converted into 4-hydroxy-3-methoxymandelic acid (cf. Scheme 2). Dopamine is oxidized in the brain and in the peripheral organs to homovanillic acid (4-hydroxy-3-methoxyphenylacetic acid) and to 3,4-dihydroxyphenylacetic acid. There is evidence that the 3,4-dihydroxyphenylacetic acid is formed first, and is later 3-*O*-methylated[152, 153]. However, 3-methoxytyramine has also been detected in the brain, so that part of the dopamine can undoubtedly also be inactivated by direct methylation[143, 154].

Norepinephrine as well as dopamine is degraded, mainly by oxidation, in the corpus striatum[144]; the dopamine-rich cells of the corpus striatum differ very clearly in this respect from the nerve cells of the cerebral cortex.

In addition to 5-hydroxyindolylacetic acid, a small quantity of the corresponding alcohol, 5-hydroxytryptophol, is also formed from serotonin (cf. Scheme 3)[155, 156]. It is not yet possible to estimate the importance *in vivo* of the inactivation of serotonin by a sulfotransferase system that has recently been detected in the brain[157, 158].

The monoamine oxidases (MAO), which are located in the mitochondria[118], are partly responsible for the regulation of the amine concentration in the cells. These are flavoproteins[159, 160] containing Cu^{2+}. Mitochondria preparations exhibit an MAO activity toward all monoamines. The activity of the monoamine oxidases de-

creases in the order tyramine > dopamine > tryptamine > serotonin > norepinephrine; they have no stereospecificity[161,162].

Though the monoamine oxidases have been known for more than thirty years, it was only recently that their heterogeneity was detected directly. Four enzymes having different substrate specificities from brain and liver mitochondria were separated from one another electrophoretically[163–168]. The importance of these various monoamine oxidases to the catabolism of monoamines in the central nervous system cannot be decided until it is known whether different monoamine oxidases are located in different mitochondria or whether all mitochondria have the same enzyme pattern. A monoamine oxidase also catalyzes the oxidation of 1-methyl-4-histamine to 1-methylimidazolylacetic acid (cf. Scheme 4). The direct oxidation of histamine, which is effected in the peripheral organs by a diamine oxidase[169], probably does not occur in the brain, since the diamine oxidase activity in this organ is very low. The main path for the physiological inactivation of histamine is thus methylation on the imidazole nitrogen by the histamine *N*-methyltransferase[148]. Dimethylhistamine is observed only after administration of large quantities of histamine[170].

3.3. Storage and Liberation

A starting point for the intensive study of the biogenic amines in the brain, apart from their nonuniform distribution (cf. Table 1), was the observation that the concentrations of several amines in the brain are increased by monoamine oxidase inhibitors and reduced by reserpine and reserpine-like substances, the changes in the amine concentration in the brain being accompanied by pronounced changes in mood, affect, and behavior[171]. To gain an understanding of the chemical, biological, and pharmacological relationships, it was necessary first to localize the amines within the organism, in the individual organs, and finally in certain cells and cell elements.

Norepinephrine, dopamine, and serotonin were detected in the nerve cells of numerous regions of the brain and in the nerve fibers with their terminal arborizations, as well as in the endings of the sympathetic nervous system, by the histochemical fluorescence method (cf. Section 2.6). Evidence that the biogenic amines in the brain are located in specific neurons was also found[172–176]. It was also shown by electron-microscopic autoradiography that [^{3}H]-norepinephrine that had been injected into a ventricle of the brain was stored in the nerve cells and terminals[177].

Particularly significant clues to the functioning of the biogenic amines have been obtained from their localization within the synapses, the junctions between two nerve cells. Thus by centrifugation of the crude mitochondria fraction from brain homogenate in density gradients, it was possible to separate particulate fractions that could be identified by electron microscopy as the

Table 2. Distribution of the biogenic amines and some enzymes connected with their metabolism in the submitochondrial fractions from brain homogenate. (The numerical values in the table are relative concentrations or relative activities, *i. e.* the percentage of amine or enzyme activity found in the fraction in question divided by the percentage of protein found.)

severed endings of the nerve cells[178,179]. As can be seen from Table 2, the amines and also the enzymes that are associated with the metabolism of the amines were found in these nerve endings, and it must therefore be concluded that the synapses are not only morphological but also biochemical units.

Figure 2 shows an electron micrograph of central synapses. Apart from the mitochondria, which are regularly found in the synaptic apparatus, and the thickened presynaptic and postsynaptic membranes, the numerous vesicles are particularly striking. In addition to clear, round vesicles having a diameter of 400–600 Å, granulated vesicles having a diameter of 800–1200 Å are observed. Smaller granulated vesicles are typical of peripheral sympathetic nerve endings.

De Robertis was able to detect directly the storage site of biogenic amines in vesicles by bursting the membranes of the severed nerve endings by an osmotic shock, separating the vesicles from the other membrane fractions by centrifugation in a density gradient[180–184], and demonstrating the presence of the biogenic amines in the vesicle fraction. It was also shown that radioactively labeled biogenic amines are taken up by the vesicles[185–190].

Uchizono[191] was the first to draw attention to clear oval vesicles having a diameter of 400–600 Å. These are regarded by this author as the vesicles of the inhibitory neurons, and are thought to contain γ-aminobutyric acid as the transmitter substance. However, it has not yet been possible to separate the vesicles of various types from one another, and it is by no means certain whether a synapse stores the same amine or various substances in its various kinds of vesicles.

The outstanding importance of the discovery of the amine-storing vesicles is evident in the light of the views developed concerning the manner in which the biogenic amines function as neurochemical transmitter substances, and particularly of *Katz*'s hypothesis[192], according to which the transmitter substances are liberated from the synaptic store not as single molecules but simultaneously in large numbers. The vesicles could be regarded as the morphological equivalent of this quantum hypothesis.

Synapses are also found on the surface of dendrites, on the cell bodies themselves, and on the axons. A potential of about −70 mV is normally maintained by the nerve cells between the interior of the cell and the external medium. If this membrane potential is reduced sufficiently at any point of the cell membrane by some suitable means, it collapses entirely. A pulse of electricity is formed and spreads out in all directions. The height of the pulse, the velocity with which it spreads out, and its time course are determined by the anatomical details of the nerve cell in question. The pulse passes through the axon to the synapses of other nerve cells. A distinction is made between excitatory and inhibitory neurons. The pulse coming from an excitatory neuron acts through the corresponding synapses to produce a partial depolarization of the neuronal membrane, and so facilitates the formation of an electric pulse; inhibitory neurons, on the other hand, cause hyperpolarization of the neuronal membrane. They thus inhibit the formation of a pulse. Since both excitatory and inhibitory synapses terminate on the nerve cells in large numbers (possibly as many as 50000), and since these can act simultaneously or successively in a certain time sequence on the nerve cell, very fine control can obviously be exerted on the nerve cells by this means.

Apart from *T. R. Elliott*'s classic discovery (1905) that the action of epinephrine is equivalent to that of a sympathetic impulse and the experiments by *O. Loewi* (1923), in which the liberation of acetylcholine in the heart of a frog on stimulation of the vagus nerve and the production of a nerve impulse by the liberated acetylcholine were detected, physiological arguments in particular have been responsible for the development of the view that the transmission of stimuli from one nerve cell to another at the synapse proceeds essentially by a chemical mechanism:

1. The synapse presents a high resistance to electric current in both directions.

2. Whereas the axon can conduct an impulse in both directions, the conduction at the synapse is strictly unipolar, *i.e.* only those electric impulses that come from the presynaptic fiber are conducted.
3. The conduction of the impulse at the synapse is delayed by somewhat less than 1 ms. It may be assumed that this delay corresponds to the time required for the liberation of the transmitter substance and its transport to the receptor.

The transfer of stimuli is purely physical only in ephaptic junctions[*], which are rare in the animal kingdom.

The hypotheses developed at first were concerned mainly with the mode of transmission of stimuli at the synapses for acetylcholine as the transmitter substance, particularly on the basis of investigations of the muscle end plates and certain ganglia. These views were later applied to the action of norepinephrine and serotonin[193]. The most important of these views are shown schematically for norepinephrine in Figure 3.

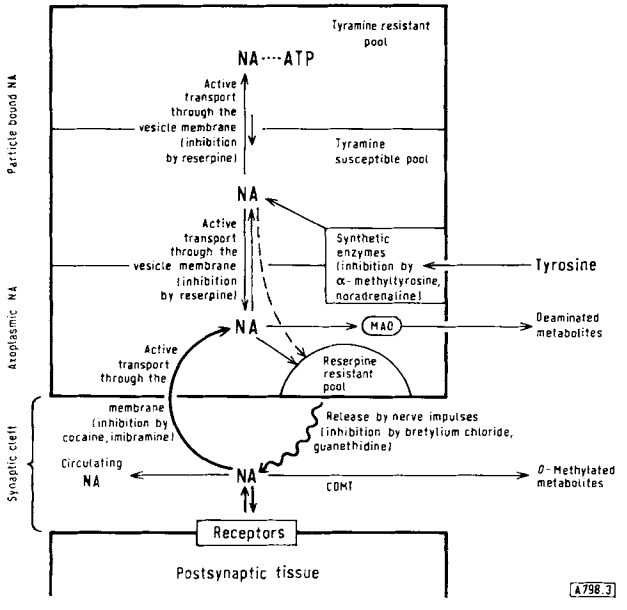

Figure 3. Scheme of the views on the mode of action of a noradrenergic synapse (based on [201]). NA = norepinephrine, MAO = monoamine oxidase, COMT = catecholamine *O*-methyltransferase, imipramine = *N*-(3-dimethylaminopropyl)-10,11-dihydro-5*H*-dibenz[*b*,*f*]azepine hydrochloride, bretylium chloride = ethyl-*o*-bromobenzyldi-methylammonium chloride, guanethidine = 2-(octahydro-1-azocinyl)ethylguanidinium sulfate.

From the synthesis of an amine molecule until it exerts its physiological action and is finally converted into a physiologically inactive derivative, its life cycle consists essentially of the following stages[194]:

1. Active transport of the amino acids (tyrosine, tryptophan, histidine) through the blood-brain barrier and through the neuronal cell membrane. This step is catalyzed by permeases.

2. Stepwise biosynthesis by hydroxylation and decarboxylation. The final step in the synthesis of norepinephrine, *i.e.* the β-hydroxylation of dopamine, takes place on the vesicle membrane[195,196]. It has recently also been shown that the amine-degrading enzyme monoamine oxidase, which is normally localized in the outer mitochondrial membrane, is probably also present in the norepinephrine-storing vesicles of the heart[197].

3. Uptake of the amine into a storage vesicle by active ATP- and Mg^{2+}-dependent transport and its association with binding substances in the vesicle[198–200]. In this form, the amine is physiologically inactive. It is in dynamic equilibrium with other storage forms, the morphological equivalent of which has not yet been ascertained.

4. Physiological liberation of the amine by a nerve impulse. In this active form, the amine can combine with the receptor protein or other specific proteins (*e.g.* monoamine oxidase).

5. Dissociation of the amine from the receptor protein and termination of the physiological action.

[^{3}H]-Norepinephrine injected into the blood stream is preferentially stored in the vesicles of the endings of the sympathetic nervous system. Two storage forms of [^{3}H]-norepinephrine have been distinguished in these endings by application of tyramine. One form is resistant to tyramine, and the norepinephrine in this form is complexed with ATP; the other form can be readily depleted by tyramine, and is in equilibrium with the norepinephrine in the extragranular fluid. The position of the equilibrium between the axoplasmatic norepinephrine and that bound to particles is determined by the uptake and liberation of the amine by the vesicles and its metabolic transformation by the monoamine oxidase.

An impulse arriving through the presynaptic nerve fiber presumably releases norepinephrine from a small pool, which cannot be emptied either by tyramine or by reserpine[201]. It diffuses from this store into the synaptic cleft and to the receptor. The combination of the amine with the receptor protein causes a specific change in the permeability of the neural membrane to ions, and hence in its polarization.

[*] Ephaptic or electronic junctions, like the synapses, are interphases provided for the transmission of stimuli, but have a relatively low electrical resistance. They occur mainly in the nervous systems of lower animals. They have not so far been observed in the central nervous systems of mammals.

[201] *L. L. Iversen*: The Uptake and Storage of Noradrenaline in Sympathetic Nerves. Cambridge University Press, Cambridge 1967.

The action of the amine on the receptor is terminated *e.g.* in the case of norepinephrine by active re-uptake, which takes place in the axonal membrane. The amine passes very rapidly from the axoplasm into the storage granules. A small proportion of the norepinephrine liberated by the nerve impulse is inactivated by 3-*O*-methylation. This reaction is catalyzed by catecholamine *O*-methyltransferase.

Our views on the mode of action of an adrenergic synapse (*i.e.* a synapse in which norepinephrine appears to act as the chemical transmitter substance) agree with numerous pharmacological experiments, which cannot be discussed in detail here. They can also be applied to the mode of action of a central noradrenergic synapse, and probably also in principle to the mode of action of dopamine, serotonin, and histamine in special synapses, though experimental observations on these amines are few. Apart from a few differences, these views are also applicable to the mode of action of acetylcholine at a cholinergic ending[202]. Acetylcholine, like norepinephrine, is bound in granular form in stores that differ in the ease with which they can be emptied, and a small proportion is also present in the axoplasm. Unlike norepinephrine, however, the acetylcholine liberated by a nerve impulse and associated with the receptor is hydrolyzed into choline and acetic by the acetylcholine esterase bound in the postsynaptic membrane[118,179], and its physiological action is thus terminated. The active reuptake of the choline into the synapse formally corresponds to the transport system that is responsible for the termination of the action of norepinephrine.

Norepinephrine is thought to be the transmitter substance not only in the noradrenergic neurons of the central nervous system but also in the endings of the postganglionic fibers of the sympathetic nervous system, while acetylcholine is regarded as the transmitter substance of the preganglionic fibers of this system and of the parasympathetic nervous system. However, acetylcholine esterase[203] and acetylcholine[204] have now also been found in sympathetic ganglia. These and many other pieces of evidence[205], which were first gathered together by *Burn* and *Rand*[206,207], led to the development of an interesting hypothesis, which is partly placed in doubt by the above picture of the mode of action of norepinephrine.

This hypothesis says in essence that the acetylcholine initially liberated by the nerve impulse in a cholinergic synapse liberates a further quantity of acetylcholine in a second step, and that this further acetylcholine is responsible for the transmission of the stimulus. Similarly, primarily liberated acetylcholine would cause the liberation of norepinephrine in a noradrenergic synapse.

The processes that take place between the arrival of a nerve impulse and the liberation of the transmitter substance of a synapse are not yet known. Our knowledge about the chemical nature and the mode of action of the receptors is also still unsatisfactory. Initial studies indicate that the receptor molecules in the postsynaptic membrane may be proteolipids[208]. Speculations on the structure of the adrenergic receptors and the importance of adenyl cyclase as an adrenergic receptor will not be discussed here (cf.[209–213]).

3.4. Turnover

The turnover of an amine in the brain is a measure of the rate at which the entire pool present is replaced. The amine is supplied to the pool by synthesis, and leaves it by metabolic transformation and to a small extent with the blood stream. It is uncertain, however, what proportion of the amine disappears from the pool because of metabolic transformation within the neuron and what proportion has been liberated by the neuronal activity and then transformed metabolically. Thus a high turnover rate cannot be equated directly to a high physiological activity.

The turnover rates of the amines in the brain can in principle be determined as follows: measurement of the decrease in the amine metabolite concentration after inhibition of the degradation of the amine, *e.g.* by monoamine oxidase inhibitors[214]; measurement of the rate of accumulation of the amine metabolites after inhibition of their transport out of the brain, *e.g.* by probenecid (*p*-dipropylsulfamoylbenzoic acid)[214–216]; determination of the decrease in the amine concentration after inhibition of the rate-determining step of the synthesis, *e.g.* by inhibition of the hydroxylation of tyrosine by α-methyl-*p*-tyrosine[217,218]; measurement of the rate of accumulation of radioactivity in the amine pool after constant perfusion (or after a single injection[219,220]) with the substrate of the rate-determining step of the amine synthesis. If it is assumed that injected amine can enter freely into equilibrium with the endogenous pool, the turnover rate can also be determined by measurement of the decrease in the radioactivity of the amine pool after equilibration of the pool with exogenous radioactive amine[220].

The measurements have shown surprisingly long half-life times for the biogenic amines in the various regions of the brain. Thus a half-life time of two hours was found

for norepinephrine with a turnover of 58 $ng.g^{-1}h^{-1}$ in the cerebellum and 4 h with a turnover of 328 $ng.g^{-1}h^{-1}$ in the hypothalamus[221]. It must be understood that the turnover measurements, in addition to their shortcomings, reflect only the turnover of a large population of neurons. The measurements do not provide an insight into the different turnover rates of small active amine pools, in which it is now thought that the amine synthesis proceeds, and which are also preferentially involved in the transmission of stimuli at the synapses, but which undergo only a slow exchange with the amine stored in the other pools. Nevertheless, turnover measurements give important indications of changes in the physiological state of the nervous system[217]. Thus by electric stimulation of the sympathetic nervous system, the rate of the norepinephrine synthesis can be increased by a factor of 5 to 6 with no increase in the amine concentration[225]. The absorption of exogenous norepinephrine in the endings of the sympathetic nervous system is in fact reduced under these conditions[226].

According to observations made so far, serotonin and dopamine have higher turnover rates in the central nervous system than norepinephrine[143,214].

The amine-storing vesicles, which are presumably formed in the cell body and transported along the axon to the endings at a speed of 0.5–10 mm/h, have a very much longer half-life time than the amine pool, *i.e.* 5–10 weeks[222–224].

4. Biogenic Amines and Behavior

4.1. Temperature Regulation and Biological Rhythms

The strong influence of the environmental temperature on the turnover rate of norepinephrine and serotonin in the brain and on the concentration of these amines[220,227] led to hypotheses regarding the importance of the biogenic amines to the regulation of the body temperature, particularly since the greatest changes in the turnover rates were observed in the hypothalamus, which has been regarded, since the classic investigations by *Magoun* and *Ranson,* as the site of the temperature regulation center. Another argument favoring the participation of the amines in the temperature regulation was provided by the observation that injections of norepinephrine and serotonin into the third ventricle of the cerebrum, *i.e.* into the neighbourhood of the hypothalamus, lead to changes in the body temperature[227–230].

Nearly all rhythms in mammals are controlled by internal biological clocks, with whose operation the biogenic amines frequently appear to be connected. Most of these rhythms with a period of about 24 hours are matched to the daily cycle of light and darkness, but they are retained even when the animals are deprived of the ability to perceive the change in light. These rhythms are described as circadian. An example of such a rhythm is the waking and sleeping rhythm. This is accompanied by a pronounced change in the serotonin concentration in the brain, while the norepinephrine concentration changes only slightly[231,232]. Recent electrophysiological and pharmacological studies have provided important insights into the importance of serotonin and norepinephrine to the sleeping and waking cycle[233]. The most important discovery was the fact that inhibition of the serotonin synthesis by *p*-chlorophenylalanine at the tryptophan hydroxylation stage causes insomnia, which can be eliminated by injection of 5-hydroxytryptophan. Insomnia has also been produced by total destruction of the serotoninergic neurons in the raphe system (an extensive network of fibers in the brain stem, cf. Fig. 1). Monoamine oxidase inhibitors cause complete suppression of paradoxical sleep and prolong synchronized sleep (slow wave sleep).

According to recent physiological results, sleep comprises these two forms, which can be very clearly distinguished and quantitatively determined by the difference in the electrical activity of the brain, in the tone of the neck musculature, and in the frequency of eye movements. It should be noted that dreaming occurs only during paradoxical sleep.

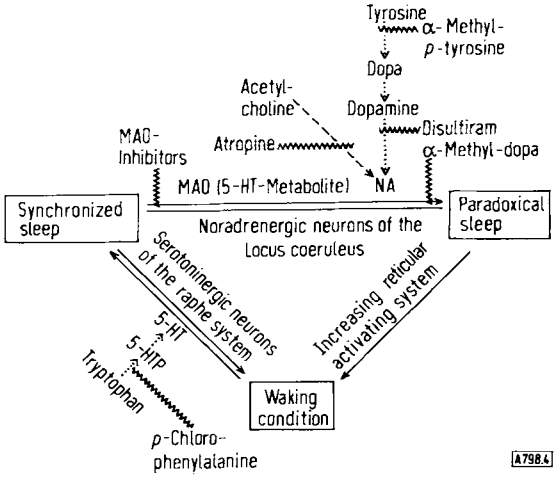

Figure 4. Scheme illustrating the relationships of the forms of sleep and of the waking state to one another and the serotoninergic and noradrenergic mechanisms that could be involved in the sleeping-waking rhythm (based on [233]). NA = norepinephrine, MAO = monoamine oxidase, 5-HT = serotonin (5-hydroxytryptamine), 5-HTP = 5-hydroxytryptophan, disulfiram = tetraethylthiuram disulfide.

Figure 4 shows a scheme of possible relationships between the forms of sleep and the aminergic mechanisms that control them. The transition from the waking state to synchronized sleep is the responsibility of groups of neurons that are controlled by synapses with serotonin as the transmitter substance. The next step in the cycle requires both certain serotonin metabolites, whose formation can be suppressed by monoamine oxidase inhibitors, and norepinephrine for the initiation process. The corresponding nerve cells have been located in the locus coeruleus (cf. Fig. 1). The norepinephrine-initiated processes that are necessary for the transition from synchronized sleep to paradoxical sleep can be inhibited at several points in the norepinephrine metabolism as well as by "false transmitter substances" (*e.g.* α-methyldopa). Atropine also prevents the final step to paradoxical sleep, presumably by inhibiting an acetylcholine-dependent trigger mechanism.

A striking rhythmic variation of the concentration of the biogenic amines in the pineal body is directly controlled by the action of light on the retina. The pineal body appears in turn to be functionally linked with rhythmic endocrine variations (*e.g.* the menstrual cycle)[234]. A rhythmic variation of the catecholamine concentration that parallels the menstrual cycle has also been observed in the nerve cells of the hypothalamus[235].

4.2. Ontogenetic and Pharmacological Aspects

In view of the idea that the biogenic amines function as neurochemical transmitter substances, one should expect normal amine concentrations in the brain to be fundamentally necessary for normal brain function and hence for normal behavior. This statement must not be taken to mean that certain average concentrations of the amines in the brain could be explained by certain types of behavior or moods. This type of thinking would be inadmissible in connection with such a highly differentiated organ as the brain. Nevertheless it frequently has to be used as a first step along the road to an understanding of the complex relationships, since the individual functional units cannot always be analyzed *per se*, for experimental reasons.

Newborn guinea pigs (which are nidifugous animals) have substantially the same amine contents in the brain as the adult animals, and their behavior is accordingly comparable with the adult behavior. On the other hand, rats, which are nidicolous, have lower percentage amine contents in the brain at birth than as adult animals. These low contents correspond to their immature behavior patterns[118,236–238]. However, these observations are by no means general for all nidifugous and all nidicolous animals (cf.[239]).

As was mentioned earlier, very pronounced changes in behavior are produced by certain drugs that can alter the concentration of the biogenic amines by interfering with their metabolism. The best-known example is the strongly sedative action of reserpine and related substances, which cause a decrease in the norepinephrine, dopamine, and serotonin concentration in the brain. The sedative action of these substances can be cancelled by injection of dopa, the precursor of the catecholamines, but not by injection of 5-hydroxytryptophan, the precursor of serotonin[240,241]. These observations show that the sedation is associated with the decrease in the catecholamine concentration, but not with the decrease in the serotonin level[242]. With the decrease in the amine concentration, the granulated vesicles (dense core vesicles) disappear from the central noradrenergic synapses[194,243,244] and from the endings of the sympathetic nervous system[245]. The action of reserpine appears to result from inhibition of the uptake of the amines into the vesicles (by blockage of the ATP- and Mg^{2+}-dependent transport). Substances that selectively inhibit the biosynthesis of the catecholamines, such as α-methyltyrosine, like reserpine, cause sedation and related behavioral changes[224].

The strongly tranquilizing action of chlorpromazine and related phenothiazines, however, is not due to a decrease in the norepinephrine concentration. Among its very numerous biochemical effects, that which best explains this action is probably the decrease in the permeability of some cellular and subcellular membranes to amines[173]. The hypothermia observed on treatment with chlorpromazine is probably also a result of the reduced response of the receptors in the hypothalamus to norepinephrine[194]. Chlorpromazine also blocks the dopaminergic receptors[224].

It was recognized a few years ago that the serotonin concentration in the brain can be selectively reduced with the aid of *p*-chlorophenylalanine. This compound acts *in vivo* as an irreversible inhibitor of the hydroxylation of tryptophan[246]. A decrease in the serotonin concentration to 10% of the normal value surprisingly causes only very small changes in the overall behavior, apart from an increase in irritability[194], so that very little can be said at present about the importance of the serotonin concentration to behavior. It must be assumed that the remaining 10% of the serotonin is sufficient to fulfil its function as a transmitter substance for the serotoninergic neurons, just as the small quantity of catecholamines that are stored in a reserpine-resistant form is sufficient to maintain the transmitter function[194].

The concentration of the biogenic amines in the brain cannot be increased by injection of the amines into the blood stream, since they cannot pass through the blood-brain barrier. Their concentration can however be significantly increased by injection of their precursors (amino acids) and by inhibition of the catabolic reactions of the amine metabolism. Monoamine oxidase inhibitors have been in use for a long time in the treatment of depressions, since the increase in the amine concentration in the brain after inhibition of the monoamine oxidase is followed by an increase in activity and drive. After a 50% inhibition of the enzyme, the serotonin concentration in the brain of the rat increases by about 100%. Dopamine generally behaves very similarly to serotonin, whereas the concentration of norepinephrine increases very much less. The reason for this is its increased 3-*O*-methylation[173].

It cannot be concluded directly that the increase in drive and the antidepressant action following the inhibition of the monoamine oxidase is due to the increased dopamine or serotonin content, since the concentration of tyramine and possibly of many other amines that have not yet been considered, but which could be responsible for the changes in behavior just as are dopamine, serotonin, norepinephrine, or histamine, is also increased. It should be pointed out here that many amines such as bufotenine, dimethyltryptamine, mescaline, and amphetamine that are structurally very close to serotonin or the catecholamines have a strongly excitatory or hallucinogenic action even in very small concentrations.

The increased motor activity and the antidepressant action of imipramine and related substances are not due to an increase in the total amine concentration. On the contrary, imipramine inhibits the active re-uptake of norepinephrine and serotonin in the synapses (cf. Fig. 3), and so prolongs the action of these substances on the receptor. Desipramine has a similar effect on noradrenergic neurons, but does not inhibit the neuronal serotonin pump. The imipramine group as a whole appears to have no action on dopaminergic neurons[224].

Even these few examples show that a similar gross behavior can result from very different molecular processes. As was indicated earlier, the action of biogenic amines on the behavior is due to the fact that monoaminergic neurons innervate practically all parts of the central nervous system, and are therefore involved in the central regulation of autonomic, motor, and endocrine functions, as well as of integrative mechanisms such as conditioned avoidance response, mood, and drive. The aminergic neuron systems can act more or less as a unit *e.g.* by modification of the excitability of large parts of the brain. However, each aminergic neuron system can also respond separately to certain stimuli, particularly under the action of certain drugs that have different effects on the various types of receptors[224].

[249] *O. Hornykiewicz,* Pharmakopsychiatrie, Neuro-Psychopharmakologie *1,* 6 (1968).

5. Neurological and Psychiatric Disturbances

An excellent example of the effect of the absence of a certain monoaminergic neuron system is the Parkinson syndrome. From the standpoint of pathological anatomy, this disease is characterized by the loss of cells in certain parts of the extrapyramidal motor system, particularly in the substantia nigra[247]. The strikingly low dopamine content in structures of the corpus striatum (nucleus caudatus, putamen, globus pallidus) of sufferers from Parkinson's disease[143] and many other observations indicate the importance of this amine to the occurrence of the abnormal movements of the patients. This assumption was confirmed by the action of L-3,4-dihydroxyphenylalanine, which leads to the disappearance of the serious clinical symptoms of parkinsonism, *i.e.* akinesia and rigor. On the basis of electrophysiological and pharmacological studies, it is assumed that the cholinergic fibers leading to the corpus striatum (striopetal system) activate the striatal cells, whereas a dopaminergic system has an inhibiting action on these cells. Because of the dopamine deficiency in the corpus striatum of parkinsonian patients, the cholinergic system becomes unbalanced and initiates the motor disturbances *via* descending fibers[248, 249]. The causes of the dopamine deficiency in the striatal system of parkinsonian patients have not yet been fully elucidated.

The influence of changes in the amine concentrations in the brain on mood and drive, as well as the knowledge of substances that can produce states very similar to those observed in endogenous psychoses, led at a very early stage to speculations on the role of the biogenic amines in the causality of these mental deteriorations, manic-depressive psychoses, and schizophrenias.

The catecholamine hypothesis (*J. Harley-Mason, J. R. Smythies,* and *H. Osmond,* 1952) is based on the close structural relationship of norepinephrine, dopamine, and mescaline (β-3,4,5-trimethoxyphenylethylamine), an effective hallucinogen. This led to the assumption that abnormal methylation products of norepinephrine or of dopamine with psychotoxic properties could be formed in the schizophrenic organism.

The pharmacological antagonism between serotonin and LSD-25 (D-lysergic acid diethylamide) led to the assumption that the serotonin metabolism could be abnormal in schizophrenia (*J. Gaddum* and *D. W. Woolley,* 1954; serotonin hypothesis). The discovery of the hallucinogenic action of *N*-methylated tryptamines led *Szara* to apply the hypothesis of abnormal methylation products to tryptamine derivatives (tryptamine hypothesis). The fourth hypothesis, which was proposed by *S. S. Kety et al.,* is closely related to the others. Following from plausible assumptions based on observations of the action of tryptophan and methionine on the behavior of schizophrenics, it is assumed that the schizophrenic organism carries out abnormal transmethylations (transmethylation hypothesis).

These hypotheses stimulated very many investigations on the amine metabolism in healthy and diseased organisms. It would be beyond the scope of this review to fol-

low even only the most important of these investigations in broad outline (cf. *e.g.*[250]). Neither a biochemical cause nor a biochemical correlate of endogenous psychoses has so far been found[251], though the relation between disease and amine metabolism appears to be obvious in the case of the endogenous depressions. Thus the symptoms of the depression are modified by measures that affect the amine metabolism in the brain. Monoamine oxidase inhibitors and substances of the imipramine type have an antidepressant action, while treatment with lithium chloride leads to an improvement of the symptoms[252] and causes an increase in the turnover of norepinephrine in the brains of experimental animals as well as increased metabolic transformation of this amine by the monoamine oxidase[253–255]. Depressions that are frequently indistinguishable from endogenous depressions can be produced again by treatment with reserpine[256]. There are also numerous observations that point to differences in the amine metabolism of diseased persons as compared with healthy subjects, but no conclusions can be drawn as yet from these observations on critical examination[257].

There are many reasons why our knowledge about the biochemistry of mental diseases is still very limited despite great efforts, quite apart from whether the approach *via* the amine metabolism, which is only one of the many possible approaches to the understanding of these diseases, does in fact lead to the desired result. One of the most important reasons seems to us to be as follows. To be able to recognize pathological modes of reaction, it is necessary to know the physiological processes for comparison. However, the biochemistry of the central nervous system is still largely unknown, even in a field that has been studied as intensively as that of the biogenic amines.

6. Closing Remarks

The function of some biogenic amines as transmitter substances at certain synapses can now be regarded as certain, though their precise mode of action is not yet known and very many questions remain to be answered in connection with the functioning of the synapses. The undeniably significant expansion of our knowledge concerning the biogenic amines during the past few years is an excellent example of the fact that progress in biology can only be achieved by the combined efforts of workers in a wide range of disciplines, *i.e.* biologists, morphologists, physiologists, pharmacologists, and chemists.

Oxidative Addition of Nitroalkanes to Tetrakis(triphenylphosphane)platinum(0): a Simple Route to Complex Metal Fulminates

By *Wolfgang Beck, Karl Schorpp,* and *Franz Kern*[*]

Dedicated to Professor Walter Hieber on the occasion of his 75th birthday

Complex metal fulminates have hitherto been synthesized by treatment of alkali-metal fulminates [accessible from $Hg(CNO)_2$ and the alkali-metal amalgam] with metal salts[1,2]. Although fulminatometalate anions with bulky cations, and complexes containing phosphanes, are not explosive and are relatively stable[2], work with the starting materials [NaCNO and $Hg(CNO)_2$] requires particular care.

We have now found that reaction of tetrakis(triphenylphosphane)platinum(0) with nitromethane provides a convenient and completely safe method of preparing difulminatobis(triphenylphosphane)platinum(II)[3].

$$Pt(PPh_3)_4 \rightleftharpoons Pt(PPh_3)_2 + 2\ PPh_3$$

$$Pt(PPh_3)_2 \xrightarrow[C_6H_6/C_2H_5OH/H_2O]{CH_3NO_2/80\,^\circ C} \left[\begin{array}{c} Ph_3P \quad CH_2 \\ H\text{-}Pt \quad N \\ Ph_3P \quad O \quad O \end{array}\right]$$

$$\xrightarrow[2.\ -\,2\ H_2O;\ -\,H_2]{1.\ +\ CH_3NO_2} O\text{-}N{\equiv}C\text{-}\underset{\displaystyle PPh_3}{\overset{\displaystyle PPh_3}{Pt}}\text{-}C{\equiv}N\text{-}O$$

We assume that nitromethane reacts as a compound containing an acidic CH group in this process, primarily by oxidative addition, analogously to the reaction of $Pt(PPh_3)_4$ with other protonic acids[4]. Accordingly, the reaction medium is decisive for formation of fulminate: whereas no fulminate can be detected

after 70 hours' heating under reflux in benzene/nitromethane, the fulminato complex is formed in 80% yield in ethanol/-water/benzene/nitromethane (1:1:1:3)[7] [cf. the acidity of nitromethane: pK (in H_2O) = 10.2[5]; pK (in an aprotic medium) = 15.96[6]].

If a large excess of triphenylphosphane is used, the cyano complex is the main product, fulminate being reduced to cyanide by the phosphane as in the reaction of organic nitrile oxides[8].

Reactions of $Pt(PPh_3)_4$ with nitroethane or 2-nitropropane do not lead to fulminates with loss of methanol or dimethyl ether, respectively, but instead the dinitro complexes $(PPh_3)_2Pt(NO_2)_2$ can be isolated.

Difulminatobis(triphenylphosphane)platinum(II)

$Pt(PPh_3)_4$ (1.25 g, 1 mmole) is heated under reflux in benzene/ethanol/water/nitromethane (1 : 1 : 1 : 3) (60 ml) under N_2 and with exclusion of light. Above 60 °C the solvent mixture forms one phase in which the platinum(0) complex dissolves completely within a few hours. After 50 hours the fulminato complex is partly precipitated even in the hot; it is filtered from the cooled reaction mixture and recrystallized from chloroform/light petroleum, forming colorless crystals that contain 1 mole of chloroform per formula unit of the complex (yield 0.75 g, 80%). IR: $2\nu_s(CNO)$ = 2325 cm^{-1}, $\nu_{as}(CNO)$ = 2190 cm^{-1}, $\nu_s(CNO)$ = 1153 cm^{-1}[3].

Sensitized Chemiluminescence on Thermolysis of Phthaloyl Peroxide in the Presence of 9,10-Diphenylanthracene

By *Karl-Dietrich Gundermann, Manfred Steinfatt*, and *Helmut Fiege*[*]

As was recently described[1], weak chemiluminescence occurs when potassium *tert*-butoxide reacts with phthaloyl peroxide in dimethyl sulfoxide in the presence of fluorescein. We have now found that warming phthaloyl peroxide (1.5×10^{-2} mole/l) with 9,10-diphenylanthracene (10^{-5} – 10^{-3} mole/l) in dimethyl or diethyl phthalate for *ca.* 10 min at 50–70 °C causes a relatively strong blue chemiluminescence (λ_{max} = 435 nm) which reaches *ca.* 5% of the maximal intensity and 6–7% of the quantum yield of luminol emitting in the same spectral region.

The emission spectrum is identical with the fluorescence spectrum of 9,10-diphenylanthracene; this is thus a case of sensitized chemiluminescence due to transfer to the diphenylanthracene of the excitation energy liberated on decomposition of the phthaloyl peroxide. The latter is partly converted by the reaction into yellow, non-fluorescing products. When the concentration of diphenylanthracene used is less than that given above, the chemiluminescence ceases prematurely, but it can be restarted by addition of further diphenylanthracene. Investigation of the obviously complex mixture of products is in progress (for thermolysis of phthaloyl peroxide in benzene see[2]).

We did not find any chemiluminescence from these two components in other organic solvents. The luminescence is appreciably catalyzed by addition of a little water to the phthalic esters: it then begins already at 25 ° C, although it reaches only about 1/3 of the intensity, but the same quantum yield is obtained in 20 min as in the reaction without water. Glacial acetic acid has a strong quenching action. Oxygen[2] was not found to be inhibitory, but it does not appreciably increase the light emission.

Dibenzoyl peroxide affords no chemiluminescence under the above conditions.

Hercules et al.[3] recently studied the role of energy transfer processes in the chemiluminescence of compounds such as 3,6-diphenyl-1,2,4,5-tetroxane (dibenzylidene diperoxide), also in the presence of diphenylanthracene. The sensitized chemiluminescence occurring in that reaction is ascribed to triplet benzaldehyde and/or singlet oxygen as primary excited particles (species which do not come into consideration for phthaloyl peroxide) and is weaker by several orders of magnitude than that now reported for the first time.

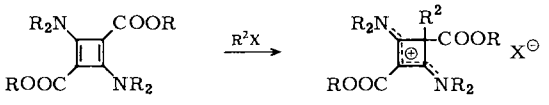
Addition of Electrophiles to Diethyl 2,4-Bis(diethylamino)cyclobutadiene-1,3-dicarboxylate[**]

By *Rudolf Gompper* and *Günter Seybold*[*]

Owing to the known stability of cyclobutenecyanine salts, the "push-pull" substituted cyclobutadiene *(1)*[1] should be a strong nucleophile and thus make possible a study of the hitherto unknown reactions of electrophiles with cyclobutadienes.

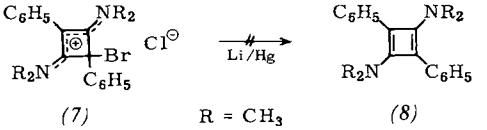


On reaction with strong acids such as HBF_4 in ether, compound *(1)* is converted quantitatively into protonated products, *e.g.* *(2a)*, from which it may be regenerated by treatment with sodium hydride[1].

Weak acids such as methanol add momentarily to *(1)*: initially formed cyclobutenecyanine cation immediately combines with methoxide ion to give cyclobutane derivative *(3)*, which escapes isolation by rearrangement to the stable butadiene derivative *(4)* [colorless oil, $n_D^{23} = 1.5282$][2]. The proposed structure *(4)* is based on the ^{1}H-NMR spectrum [in $DCCl_3$: $\tau = 5.25$ (1H/S); $\tau = 5.9$ and 6.6 (15H/M); $\tau = 8.8$ (18H/M)] and the IR spectrum [1680, 1550 cm^{-1}]; according to ^{1}H-NMR *(4)* is probably present as a mixture of geometric isomers. The finding that *(2a)* quantitatively yields the butadiene *(4)* on treatment with sodium methoxide in methanol supports the intermediacy of *(2b)*.

Compound *(2a)* reacts with $NaBH_4$ in acetonitrile at room temperature to give the butadiene *(5)* [colorless crystals, m.p. 53–55 °C] whose structure is confirmed by the ^{1}H-NMR spectrum [in $DCCl_3$; $\tau = 2.5$ (1H(-CH=)/S); $\tau = 5.25$ (1H(-CO-CH=)/S); $\tau = 5.9$ (4H(O-CH_2)/split Q); $\tau = 6.75$ (8H(N-CH_2)/M); $\tau = 8.8$ (18H (CH_3)/M)] and the IR spectrum [1700, 1605, 1560 cm^{-1}][3].

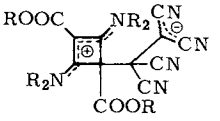
Compound *(1)* adds bromine very rapidly to form the 1:1 adduct *(6a)*, which crystallizes very poorly. On replacement of bromide ion by perchlorate ion (silver perchlorate in water/ethanol), a perchlorate is obtained that crystallizes very well [colorless needles, m.p. 111 °C] and whose IR spectrum [vCO = 1750, 1700, vC=C = 1605 cm^{-1}], UV spectrum [in $HCCl_3$; $\lambda_{max} = 289$ nm, log $\varepsilon = 4.49$], and ^{1}H-NMR spectrum (see Table) are compatible only with structure *(6b)*.



(1) R = C_2H_5 — *(6a), (6b), (9)-(11)*

Cpd.	R^2	X	^{1}H-NMR [b] OCH_2 (8H)	NCH_2 (8H)	CH_3 (18H)	R^2
(6a)	Br	Br				
(6b)	Br	ClO_4	5.32 (Q) [a]	5.96, 5.28 (Q)	8.68 (M)	
(9)	$COCH_3$	ClO_4	5.6, 5.7 (Q)	5.95, 6.40 (Q)	8.65 (M)	7.45 (3H/S)
(10)	CH_3	I	5.6, 5.7 (Q)	6.2 (Q) [a]	8.6 (T)	8.1 (3H/S)
(11)	2,4,6-Cycloheptatrien-1-yl	ClO_4	5.6 (Q) [a]	6.1, 6.5 (Q)	8.7 (M)	3.5 (4H) 4.85 (2H/T) 7.15 (1H/T)

[a] Split.
[b] TMS as internal standard, τ values in ppm, $DCCl_3$ as solvent.



(6a) loses bromine very readily, even on heating in a melting-point tube. Its mass spectrum[4] corresponds to that of the cyclobutadiene *(1)*.

Reaction of *(6b)* with sodium hydride in toluene at about 70 ° C yields a yellow solution in which *(1)* can be detected by the diphenylcyclopropenone test[5]. Cyclobutadiene *(1)* is liberated from *(6b)* by treatment with lithium amalgam in toluene; *(1)* can then be intercepted by dimethyl acetylenedicarboxylate[6]. Attempts to remove halogen from *(7)*[7] under similar conditions and to detect the cyclobutadiene *(8)* have so far been unsuccessful.

(7) R = CH_3 *(8)*

Compound *(1)* adds equivalent amounts of acetyl bromide at temperatures as low as −40 ° C to give a colorless oil that crystallized after replacement of Br^- by ClO_4^-. The properties of the salt *(9)* [m.p. 71–72 ° C; IR spectrum (1740, 1720, 1595, 1090 cm^{-1}); ^{1}H-NMR spectrum, see Table] are in agreement with the proposed cyclobutenecyanine structure *(9)*. Analogous compounds are formed from *(1)* and methyl iodide [*(10)*, m.p. 110–112; IR spectrum (1738, 1698, 1603 cm^{-1}); ^{1}H-NMR spectrum, see Table] and tropylium perchlorate [*(11)*, m.p. 125–126 °C; IR spectrum (1735, 1710, 1585, 1090 cm^{-1}); ^{1}H-NMR spectrum, see Table].

(12)

Tetracyanoethylene and *(1)*, dissolved in toluene at −80 ° C, furnish a deep violet solution whose color is probably attributable to a charge-transfer complex. At −40 °C an almost colorless precipitate is formed which – when rapidly filtered off with suction – is stable for a few days at room temperature [colorless needles, m.p. 97–107 ° C (decomp.)]. In solution, however, rapid decomposition occurs with yellow coloration. Elemental analysis, ^{1}H-NMR spectrum [in SO_2 at −40 ° C: $\tau =$ 5.6 (4H(O-CH_2)/Q split); $\tau = 6.2$ and 6.5 (8H(N-CH_2)/Q); $\tau = 8.7$ (18H)/M], and particularly the IR spectrum [in $HCCl_3$; vCN = 2175, 2130, vCO = 1740, 1715, vC=C = 1585 cm^{-1}] establish the dipolar structure *(12)* of the reaction product. In contrast to the dipolar intermediate obtained from *(1)* and *p*-nitrobenzylidenemalodinitrile[6], no reaction products of definite composition could be isolated after the decomposition of *(12)* in methylene chloride. Isolation of the dipole *(12)* warrants particular attention in view of the reaction[8] of 1,2-diphenylcyclobutadiene with tetracyanoethylene.

General procedure:

A solution of the electrophile in a small volume of toluene is added to a solution of *(1)*, prepared in accordance with ref.[1], at low temperature in a Schlenk tube. After completion of the reaction the product is filtered off or isolated by evaporating the solution. Yields are almost quantitative in all cases.

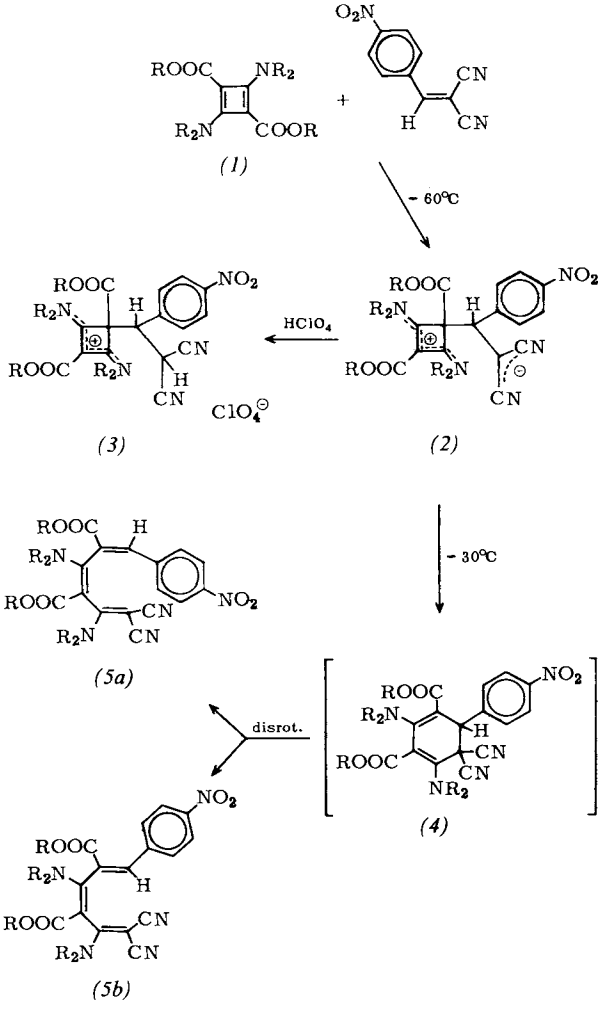
Cycloaddition to Diethyl 2,4-Bis(diethylamino)-cyclobutadiene-1,3-dicarboxylate[**]

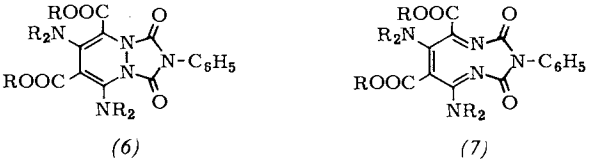


By *Rudolf Gompper* and *Günther Seybold*[*]

Cyclobutadiene is characterized by the pronounced readiness with which it undergoes cycloaddition with acetylenes, olefins, and other multiple bond systems. On stabilization by complex

formation with transition metals it completely loses this property. It was therefore of interest to establish whether, and if so to what extent, the "push-pull" stabilization in *(1)* affects the ability of this cyclobutadiene, which is stable at room temperature[1], to undergo cycloadditions.

Whereas *(1)* is inert towards the reactive but nonpolar CC double bond of norbornene, it reacts surprisingly well with electrophilic cycloaddends, even at low temperatures. The rapid reaction of *(1)* with simple electrophiles (HX, Br_2, CH_3I, CH_3COBr, and tropylium perchlorate)[2] and the stability of the resulting cyclobutenecyanine salts suggested the intermediacy of dipoles in cycloadditions to *(1)* in cases where the negative charge is sufficiently stabilized.

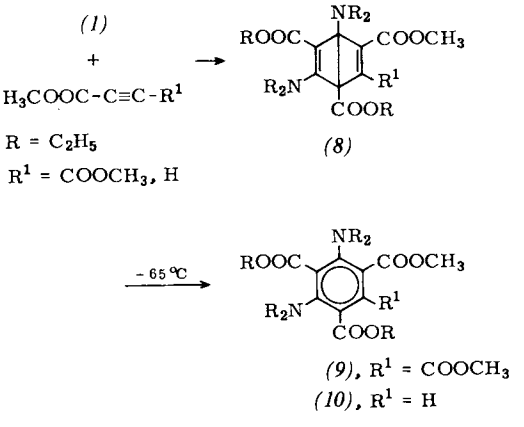


In fact, *p*-nitrobenzylidenemalodinitrile, which has already proved effective in forming dipoles in reactions with enamines[3] and ketene *S,N*-acetals[4], is found to react with *(1)* at −60° C to form a deep red solution from which an orange-yellow crystalline product can be precipitated with ether, whose properties, especially its low solubility in nonpolar solvents and its ease of protonation, indicate the dipole structure *(2)*. Protonation of *(2)* with anhydrous perchloric acid gives a quantitative yield of the colorless stable perchlorate *(3)* [correct elemental analysis; IR spectrum: νCO 1735, 1725, νC=C 1590 cm^{-1}].

R = C_2H_5

If a suspension of *(2)* in ether is warmed to −30° C, a yellow solution is obtained which yields an orange-yellow precipitate at room temperature. Repeated column chromatography of the precipitate furnishes two isomeric 1 : 1 adducts [of *(1)* and *p*-nitrobenzylidenemalodinitrile]; their IR spectra differ only slightly. A detailed study of the spectra shows (NMR) that the chemical shift of a signal due to a single proton at τ = 2.3 (in $DCCl_3$) and (IR) the stretching frequency of the cyano group at 2198 cm^{-1} and of the CC double bond at 1530 cm^{-1} are compatible only with the hexatriene structures *(5a)* and *(5b)*. Precise assignment of the isomers is not possible on the basis of the spectra alone. When the reaction mixture is warmed very slowly (3–4 h from −30° C to room temperature) the thermodynamically apparently more stable isomer is formed (yellow crystals, m.p. 144–146° C). In contrast, rapid warming gives mainly the less stable isomer (orange-yellow needles, m.p. 120° C) which quantitatively yields the yellow isomer on prolonged heating.

4-Phenyl-1,2,4-triazoline-3,5-dione combines with *(1)* at −80° C to give a crystalline, colorless 1 : 1 adduct [*(6)* or *(7)*].

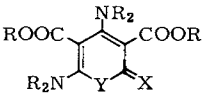


(6) *(7)*

R = C_2H_5

(7) would be expected to absorb in the visible region. Since the adduct is colorless (λ_{max} = 282 nm), we assign to it structure *(6)*. Attempts to convert *(6)* into *(7)* by heating were unsuccessful.

(1) also adds *N*-phenylmaleimide to give a 1 : 1 adduct (lemon-yellow needles, m.p. 140° C) whose structure probably corresponds to that of *(6)*.



Reaction of *(1)* with acetylenes offers a route to "push-pull" substituted Dewar benzenes. If dimethyl acetylenedicarboxylate is added to a solution of *(1)* in THF at −65° C, the solution becomes deep red for a few seconds and then pale yellow. A yellowish oil can be isolated in 89% yield (n_D^{23} = 1.5033) which is shown to be a 1 : 1 adduct by elemental analysis and osmometric molecular weight determinations. Its thermal stability (it withstands prolonged heating to 100°C) and the ^{1}H-NMR spectrum (the ester ethyl groups differ only slightly from each other) would indicate structure *(9)*.

Similarly, *(1)* reacts with ethyl propiolate. The chemical shift of the ring-proton signal [τ = 2.0 (in $DCCl_3$)] reveals the aromatic character of the reaction product *(10)*. It may further be deduced from the ^{1}H-NMR spectrum that the adduct contains two equivalent ester groups and two equivalent diethyl amino groups and must therefore possess the structure *(10)*. It follows that the propiolate adds uniformly to *(1)*, and this in turn strongly suggests a dipolar intermediate or a highly polar transition state if steric effects are considered insignificant. – The symmetry of the adduct *(10)* provides further proof of the fact that the two diethylamino groups and the two ester groups in the cyclobutadiene *(1)* are not adjacent but occupy the 1,3 and 2,4 positions, respectively.

The Dewar benzene intermediate *(8)* could not be detected by NMR spectroscopy, even at as low a temperature as −46° C. The unusual instability of *(8)* compared to other Dewar ben-

zenes again underlines the limited value of orbital symmetry considerations for polar systems. The rapid valence isomerization of *(8)* to *(9)* can be explained by an HMO model developed by *H. U. Wagner*[5]. At room temperature *(1)* reacts with heterocumulenes to form six-membered cyclic 1 : 1 adducts *(11)*.

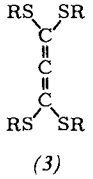
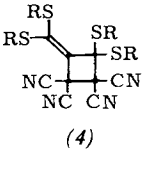
Detection of Dipoles in Cycloadditions to Allenes

By *Rudolf Gompper* and *Dietrich Lach*[*]

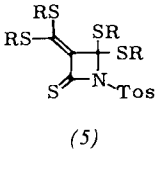
In conjunction with attempts[1] to detect and isolate dipoles of types *(1)* and *(2)* as intermediates of cycloadditions to allenes



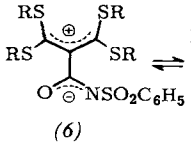
(1)



(2)



and heterocumulenes, we have studied the reaction of tetrakis(ethylthio)allene[2] *(3)*, as well as other "electron-rich" allenes, with tetracyanoethylene and with sulfonyl isocyanates and isothiocyanates. Since the adduct of tetramethoxyallene and tetracyanoethylene has recently been described[3], it is fitting that some of our experiments with *(3)* should also be reported. With the reactants mentioned above we obtained the 1 : 1 adducts *(4)–(8)* (see Table).



(3)

[a] TMS as internal standard, τ values in ppm, $DCCl_3$ as solvent ($DCCl_3/CF_3CO_2D$ for *(9)*).

The spectra of compounds *(4)* and *(5)* are consistent with the four-membered ring structure. The IR spectrum of the product of *(3)* and benzenesulfonyl isocyanate would also suggest a cyclic structure, *i. e. (7)*. However, such an assignment is contraindicated by the ^{1}H-NMR spectrum which shows only one quadruplet and one triplet for the ethylthio groups. If a solution of the product in $CDCl_3$ is cooled to −60° C, the quadruplet is replaced by two weakly structured signals at τ = 6.82 ppm and τ = 7.67 ppm (intensity ratio 1 : 1), the methyl proton peak at τ = 8.80 ppm becoming diffuse. It may therefore be concluded that at −60° C the four-membered ring *(7)* is present and at room temperature a fast equilibrium is set up between *(6)* and *(7)*, the mixture containing predominantly *(7)*. The solvent dependence of the ^{1}H-NMR spectrum of *(6)* + *(7)* indicates that the rate of interconversion *(6)*⇌*(7)* decreases in nonpolar solvents.

Acids protonate *(6)* + *(7)* to *(9)*; on treatment with pyrrolidine, ethanethiol is eliminated and the new dipole *(10)* results (see Table for spectra). Formation of *(10)* can be explained in terms of improved stabilization of the positive charge compared to *(6)*.

(9) *(10)*

R = C_2H_5

Action of chlorosulfonyl isocyanate on *(3)* gives only the dipole *(8)*, thus reflecting the superior stabilization of negative charge compared to the situation in *(6)*.

Diphenylaminyl[1]

By *Franz A. Neugebauer* and *Stephan Bamberger*[*]

Tetraphenylhydrazine dissociates into diphenylaminyl radicals *(1)* at 100° C or on irradiation with UV light[2]. Although the formation of *(1)* has been established by trapping with NO and triphenylmethyl[2], a well resolved ESR spectrum of this radical has hitherto not been obtained[3]. We have now recorded such a spectrum on irradiation of a 0.2 M solution of tetraphenylhydrazine in benzene with a 1000-W high-pressure mercury vapor lamp in a flow system (Fig. 1). The ESR spectra of the diarylaminyls *(2)* (Fig. 2), *(3)*, and *(4)* were also recorded under the

(1), $R^1 = R^2 = H$
(2), $R^1 = C(CH_3)_3$, $R^2 = H$
(3), $R^1 = H$, $R^2 = C(CH_3)_3$
(4), $R^1 = H$, $R^2 = CH_3$

Fig. 1. ESR spectrum of diphenylaminyl *(1)* in benzene (above); simulated spectrum (below) (line width 0.35 G).

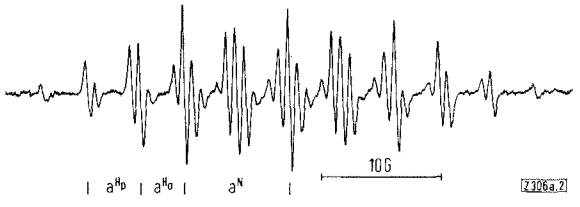

Fig. 2. ESR spectrum of bis(3,5-di-*tert*-butylphenyl)aminyl *(2)* in benzene.

same conditions. The ESR spectrum of *(4)* is identical with that obtained by thermal dissociation (90 °C) of tetra-*p*-tolylhydrazine[1].

Table 1. Coupling constants (in gauss) of the aminyls *(1)*, *(2)*, *(3)*, and *(4)* in benzene.

Cpd.	a^N	a^{H_o}	a^{H_m}	a^{H_p}
(1)	8.9	3.70	1.49	4.34
(2)	8.8	3.66	–	4.37
(3)	8.7	3.7	1.5	–
(4)	8.7	3.6	1.4	4.7 (H_{CH_3})

It may be calculated from the ESR coupling constants (Table 1) of diphenylaminyl[4,5,6] that the unpaired electron in diphenylaminyl is delocalized to the extent of about 60% into the phenyl groups (Table 2). In diphenylmethyl, the carbon analog of diphenylaminyl, about 66% of the spin density is localized on the methyl carbon[7]. This surprising result can be interpreted to some extent as a result of the higher electronegativity of the aminyl nitrogen. A quantitative interpretation is currently under investigation.

Table 2. Spin densities in diphenylaminyl *(1)*.

Diarylamine Radical Cations[1]

By *Franz A. Neugebauer* und *Stephan Bamberger*[*]

Oxidation of diarylamines in CF_3COOH with 0.5 equivalents of lead tetraacetate frequently gives intensely blue-colored solutions of diarylamine radical cations *(1)*, which we have now studied by ESR spectroscopy (Table). Because of the short lifetime of the diphenylamine radical cation *(1a)* its ESR spectrum was recorded in a flow apparatus (Fig. 1).

(1)

(2)

Table. Coupling constants of diarylamine radical cations *(1)* in CF_3COOH (in gauss).

Cpd.	Ar, substituents on phenyl	a^N	$a^{N_{NH}}$	a^{H_o}	a^{H_m}	a^{H_p}
(1a)	–	9.17	11.14	3.51	1.36	4.88
(1b)	4-CH_3	8.70	10.50	3.28	1.06	6.10 (CH_3)
(1c)	4-$(CH_3)_3C$	8.69	10.44	3.25	1.05	0.24 [$C(CH_3)_3$]
(1d)	3,5-$[(CH_3)_3C]_2$	8.64	10.50	3.36	–	5.15
(1e)	4-OCH_3	8.06	9.56	2.72	0.40	1.06 (OCH_3)
(1f)	2,6-$(CH_3)_2$, 4-OCH_3	7.05	8.61	1.73 (CH_3)	0.24	1.05 (OCH_3)
(1g)	2, 4, 6-$(OCH_3)_3$	7.41	9.15	0.59 (OCH_3)	0.43	0.76 (OCH_3)

The ESR spectrum of *(1e)* had already been observed upon dissolving bis(*p*-methoxyphenyl) nitroxide in CF_3COOH, but was assigned to the protonated nitroxide[2]. The observed $a^N/a^{H_{NH}}$ ratio of 0.84 provides support for our assignment. (For comparison: protonated 2,2,6,6-tetramethylpiperidine *N*-oxide: $a^N/a^{H_{NOH}} = 6.6$[3], *p*-phenylenediamine radical cation:

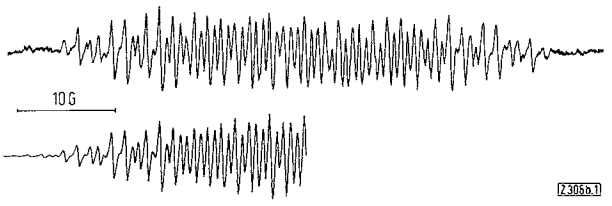

Fig. 1. ESR spectrum of diphenylamine radical cation *(1a)* in CF_3COOH (above); simulated spectrum (line width 0.3 G) (below).

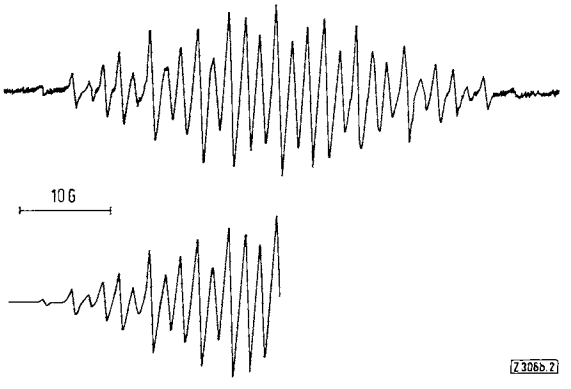

Fig. 2. ESR spectrum of bis(3,5-di-*tert*-butylphenyl)amine radical cation *(1d)* in CF_3COOH (above); simulated spectrum (below) (line width 0.5 G).

$a^N/a^{H_{NH}} = 0.9$[4], and $H_3\dot{N}^{\oplus}$: $a^N/a^{H_{NH}} = 0.73$[5].) Bis(*p*-methoxyphenyl) nitroxide disproportionates[6] in CF_3COOH and forms, among other products, the radical cation *(1e)*.

The diarylamine radical cations studied are representatives of a new series of secondary amine radical cations. They possess the same π-electron system as the diarylaminyls and can be regarded as protonated diarylaminyls. This is demonstrated by the ESR coupling constants of the parent systems diphenylaminyl[1] and *(1a)*, which differ only slightly from each other The calculated spin density distribution in diphenylaminyl[1] can also be used for *(1a)*.

Electron-donating substituents in the *para*- or *ortho*-position enhance the delocalization of the unpaired electron in *(1)* and decrease a^N. Bulky *ortho* substituents, which do not permit the π-system to achieve true planarity, have the opposite effect. In *(1f)* the electron-donating properties of the methyl group are more important than the opposing steric effect and the spin density on the nitrogen is lower than in *(1e)*. If the *o*-methyl substituents are replaced by the larger methoxy group then the steric effect predominates [*(1g),(1f)*].

Diarylamine radical cations are derivatives of the extensively studied triarylamine radical cations *(2)*[7–11]. The coupling constants a^N of *(1)* are approximately 10% smaller than those of the corresponding *(2)* derivatives; the coupling constants of the ring substituents in *(1)*, however, are considerably larger than in the case of *(2)*[8]. In total, there is more spin density in the two aryl groups of *(1)* than in the three aryl groups of *(2)*. This apparently is due to an extensive twisting of the aryl groups of *(2)* about the N–C substituent axes.

The Hydration Kinetics of 2-Methylbutyraldehyde

By *Marie-Luise Ahrens* and *Günter Maass*[*]

In aqueous solution many carbonyl compounds are in equilibrium with their hydrates[1]:

(1) *(2)*

(a), R^1 = H
R^2 = CH_3-CH_2-$CH(CH_3)$

A knowledge of the hydration behavior of simple carbonyl compounds, *e.g.* aliphatic aldehydes, permits conclusions to be drawn regarding the hydration behavior of more complex substances containing carbonyl groups.

Here, we report on the hydration behavior of 2-methylbutyraldehyde *(1a)*. Particularly useful information about the kinetics of hydration can be gained from a study of temperature jump – relaxation processes[2,3]. The change in absorption intensity of the characteristic carbonyl band can be used for the optical detection of the reaction *(1a)*$\rightleftharpoons$*(2a)* and for the determination of its equilibrium constants and their temperature dependence.

Equilibrium measurements: The ε_0^{max} of the 295 nm n-π^* band was determined for 2-methylbutyraldehyde in very dry tetrahydrofuran. Absorption obeyed the Beer-Lambert law and a molar extinction coefficient of $\varepsilon_0^{max} = 18.0\ l.mole^{-1}cm^{-1}$ was obtained. This value was used uncorrected for the investigations in aqueous solution. The absorption signal decreases because of hydrate formation; the equilibrium constant $K_{hydr.}$ = [hydrate]/[free aldehyde] can be determined from

$$E_{295} = \frac{\varepsilon_0^{max}}{1 + K_{hydr.}}\, c_0$$

(E_{295} = measured extinction at λ = 295 nm, c_o = concentration by weight of aldehyde). Measurements at T = 22.0° C gave $K_{hydr.} = 0.43 \pm 0.05$.

The temperature dependence of the equilibrium *(1a)*$\rightleftharpoons$*(2a)* was determined by evaluation of the amplitudes of relaxation diagrams at various temperatures, these measurements were carried out with a temperature-jump apparatus for reactions in the seconds range[3]. A temperature jump ΔT causes a change ΔE in the extinction, and if a temperature independent value of ε_0^{max} is assumed, the following expression is valid:

$$\frac{d\ln K_{hydr.}}{dt} = \frac{\Delta H}{RT^2} = -\frac{(1 + K_{hydr.})}{K_{hydr.}} \cdot \frac{1}{\Delta T}\frac{\Delta E}{E_{max}} \qquad (1)$$

Measurements at T = 22.0° C yielded a value of $\Delta H = (-4.8 \pm 0.1)$ kcal/mole for the heat of hydration.

Kinetic measurements: The reaction

(1a) *(2a)*

is of pseudo-first order. The reciprocal relaxation time is given by the expression

$$1/\tau = \vec{k} + \overleftarrow{k} = \overleftarrow{k}\,(1 + K_{hydr.}) \qquad (2)$$

The measured rate of the hydration-dehydration reaction of 2-methyl-α-butyraldehyde is strongly dependent on the hydrogen ion and hydroxide ion concentration of the solution and on the concentration of any Lewis or Brönsted-type acids or bases that may be present. In this case a general acid-base catalysis occurs where the rate constants are given by:

$$\begin{aligned}\vec{k} &= \vec{k}_o + \vec{k}_H c_H + \vec{k}_{OH} c_{OH} + \sum_i \vec{k}_i c_i \\ \overleftarrow{k} &= \overleftarrow{k}_o + \overleftarrow{k}_H c_H + \overleftarrow{k}_{OH} c_{OH} + \sum_i \overleftarrow{k}_i c_i\end{aligned} \qquad (3)$$

The subscripts denote the catalysts (i = Lewis- or Brönsted-type acids or bases); k_o takes into account the contribution from possible intramolecular catalysis and catalysis effected by the solvent. The experimental conditions for the determination of the individual constants were chosen such that, in each case, one of the terms in eq. (3) was larger than the remaining terms. Two regions of linear dependence, corresponding to H^+ and OH^- catalysis (Fig. 1) respectively, are obtained on plotting log $1/\tau$ against pH from measurements carried out in presence of H^+ and OH^- ions and in the absence of general acids and bases.

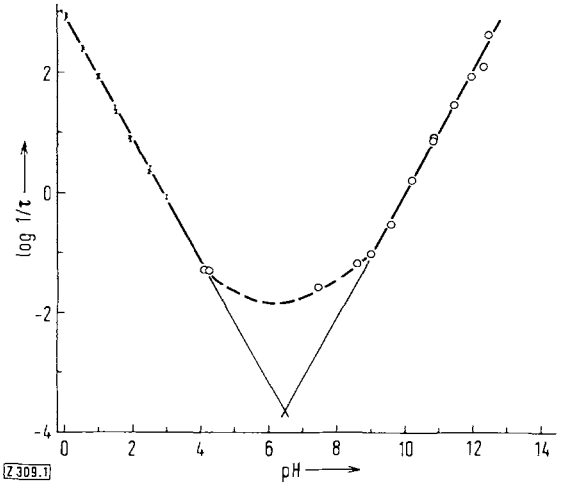

Fig. 1. Dependence of the relaxation time τ of the reaction *(1a)⇌(2a)* on pH. Adjustment of pH by addition of small amounts of HCl (x) or NaOH (o).

From these values the catalytic rate constants k_H and k_{OH} were determined with a mean error of 20% at $T = 22.0°$ C:

	hydration	dehydration
H^+catalysis:	$\vec{k}_H = 2.4 \times 10^2$ (l mole^{-1}s^{-1})	$\overleftarrow{k}_H = 5.7 \times 10^2$ (l mole^{-1}s^{-1})
OH^- catalysis:	$\vec{k}_{OH} = 4.5 \times 10^3$ (l mole^{-1}s^{-1})	$\overleftarrow{k}_{OH} = 1.2 \times 10^4$ (l mole^{-1}s^{-1})

Only limiting values can be given for k_0:

7.2×10^{-5} (s^{-1}) $\leq \vec{k}_0 \leq 0.4 \times 10^{-2}$ (s^{-1})

1.7×10^{-4} (s^{-1}) $\leq \overleftarrow{k}_0 \leq 1.1 \times 10^{-2}$ (s^{-1})

The following rate constants were determined for the acetic acid catalysis at $T = 22.0°$ C:

$\vec{k}_{Ac} = 0.5$ (l mole^{-1}s^{-1}) and $\overleftarrow{k}_{Ac} = 0.35$ (l mole^{-1}s^{-1})

The activation energies of hydration and dehydration as a function of temperature were obtained from kinetic measurements at pH = 4.22. Arrhenius plots (Fig. 2) of log $\vec{k}_H$ and log $\overleftarrow{k}_H$ against $1/T$ gives the following values for the activation energies $\vec{E}_A$ and $\overleftarrow{E}_A$ respectively: $\vec{E}_A = 6.9$ kcal/mole and $\overleftarrow{E}_A \approx 11.7$ kcal/mole.

Tellurium Tetrachloride-Olefin Addition Compounds

By *H. J. Arpe* and *Herbert Kuckertz* [*]

Tellurium chlorides are the active components in catalyst systems for the oxychlorination and chlorination of olefins[1–3]. In this connection the most noteworthy reaction is the particularly smooth formation of allyl chloride from propene, which can be looked upon as a direct substitution reaction since 2-chloropropane and 1,2-dichloropropane are not formed as intermediates[1].

Addition of $TeCl_4$ to propene to give an analog of compound *(1)*, which is formed by reaction of $TeCl_4$ with ethylene, can be presumed as the primary step.

We have now checked whether similar addition compounds of propene and of butadiene exist and whether their thermal behavior reflects the result of oxychlorination of these olefins in the gas phase on tellurium catalysts.

Introduction of propene or butadiene into a 30% suspension of $TeCl_4$ in CCl_4 at 20–60°C leads to dissolution of $TeCl_4$ and separation of a yellow oil. Separation is complete on cooling the mixture to 0° C. Pure *(3)* and *(4)* (Table) can be isolated from the crude products in 20–30% yield by recrystallization from CCl_4. The reaction with ethylene is more sluggish and necessitates separation of the crystalline compounds *(1)* and *(2)* from unreacted $TeCl_4$ by CCl_4 extraction.
Supporting evidence for the composition of compounds *(1)–(4)* was provided by C,H,Cl,Te elemental analysis and by ^{1}H-NMR and IR spectroscopy. The X-ray structure analysis of *(2)* has

Table. Tellurium tetrachloride-olefin addition compounds.

No.	Adduct	M.p. (°C) (dec., uncorr.)
(1) [4]	$Cl_2Te(CH_2\text{-}CH_2Cl)_2$	111
(2)	$Cl_3Te\,CH_2\text{-}CH_2Cl$	116
(3) [5]	$Cl_2Te(C_3H_6Cl)_2$	100
(4)	$Cl_2Te(CH_2\text{-}CH{=}CH\text{-}CH_2Cl)_2$	83

already been carried out[6] whereas that of *(3)* has not, so a decision between the alternative structures $Cl_2Te(CH_2\text{-}CHCl\text{-}CH_3)_2$ and $Cl_2Te(CH(CH_3)\text{-}CH_2Cl)_2$ for *(3)* cannot as yet be made.

The adducts *(1)–(4)* are thermally unstable even below their melting points. The same products of thermolysis are formed as in the tellurium-catalyzed gas-phase process: *(1)* and *(2)* yield, alongside $TeCl_4$ and metallic tellurium, substantial amounts of ethylene and 1,2-dichloroethane and small amounts of vinyl chloride and HCl. Mainly allyl chloride, HCl, propene, and 2-chloropropane and a little 1,2-dichloropropane are formed in the decomposition of *(3)*. Compound *(4)* decomposes with formation of butadiene, HCl, butenyl chlorides, and high-boiling chlorohydrocarbons. There was no indication of chloroprene having been formed. Likewise, no free chlorine could be detected in the pyrolysis of *(1)–(4)*.

A further reaction affording olefin – analogous to a heterolytic fragmentation[7] – is the hydrolysis of *(1)–(4)* with dilute alkali or acid. It possibly limits the conversion of olefin in the gas-phase process[1].

(1)–(4) can be titrated with 0.5N NaOH and the liberated olefins determined volumetrically.

$$TeCl_4 \cdot (olefin)_n + 4NaOH \longrightarrow TeO_2 + 2H_2O + 4NaCl + n\ olefin$$

X-Ray Crystallographic Investigations of Tellurium Tetrachloride-Olefin Adducts

By *D. Kobelt* and *E. F. Paulus*[*]

Passage of olefins such as ethylene or propylene through suspensions of $TeCl_4$ in CCl_4 at 20–60° C leads to an addition of one or two molecules of olefin, depending on the reaction conditions, to one molecule of $TeCl_4$[1]. We have determined the crystallographic data of $TeCl_4 \cdot 2C_2H_4$ *(1)* and $TeCl_4 \cdot 2C_3H_6$ *(3)* and carried out a three-dimensional X-ray structure analysis of $TeCl_4 \cdot C_2H_4$ *(2)*. 958 reflections were observed with a computer-controlled Siemens single-crystal diffractometer with MoK_α radiation according to the method proposed by *W. Hoppe*. After solving the structural problem and refining the parameters by the usual heavy atom method, an *R*-factor of 4.5% was obtained.

The Figure shows a projection of two $ClC_2H_4TeCl_3$ units on the *a/c* plane. The crystal contains polymer chains, whose structure is determined by mirror planes, glide planes, and two-fold axes. The tellurium atom has the coordination number 5. The ligands are at the corners of a pyramid having an approximately four-fold axis, the tellurium atom being situated very nearly in the center of the basal plane of the pyramid. The distance of the tellurium atom from the "best plane" through Cl-1, Cl-1′, Cl-2, Cl-2′ is 0.10 Å. The C-1–Te–Cl angles are 92.7 and 82.5°.

Table. Crystallographic data of tellurium tetrachloride-olefin addition compounds.

Compound	Cell constants						V (Å^3)	Z	$d_{x\text{-ray}}$ (g/cm^3)	Crystal system	Space group
	a(Å)	b(Å)	c(Å)	α(°)	β(°)	γ(°)					
$TeCl_4 \cdot 2C_2H_4$ *(1)*	7.87	12.50	10.51	90	106.5	90	991	4	2.18	monoclinic	$P2_1/c$

$TeCl_4 \cdot 2C_3H_6$ *(3)*	11.71	9.82	5.83	95.0	108.3	102.3	613	2	1.913	triclinic	P1 or $P\bar{1}$

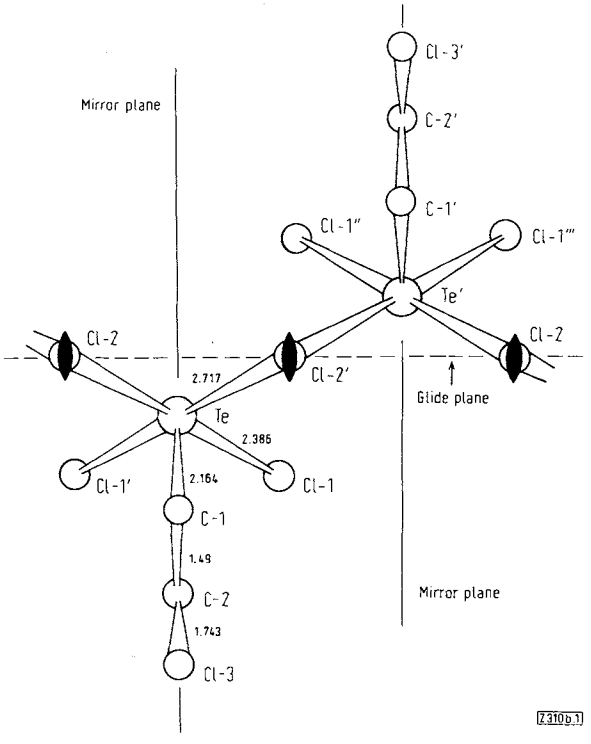

Fig. Crystal structure of β-chloroethyltellurium trichloride: Projection on the *a/c* plane. Standard deviation σ: Te-Cl 0.003, Te-C 0.013, C-C 0.02, C-Cl 0.014; lengths in Å.

The bridging chlorine atoms are about 0.3 Å further away from the tellurium than the terminal ones. This is much more pronounced in $TeCl_4$ (0.6 Å), which is tetrameric in the crystalline state and has a cubane-type structure with Te having a coordination number 6[2]; the Te-Cl distances of the terminal chlorine atoms have a value of 2.31 Å, and those of the bridging chlorine atoms 2.93 Å. A uniform value of 2.51 Å[3,4] was determined for the Te-Cl distance in $(CH_3)_2TeCl_2$, which crystallizes as monomer. To a good approximation one can assume the ions $TeCl_3^+$ and Cl^- in the case of $TeCl_4$[2] and four predominantly covalent bonds in the case of $(CH_3)_2TeCl_2$.

Compound *(2)*, having one Te-C bond, lies between $TeCl_4$, which has no Te-C bonds, and $(CH_3)_2TeCl_2$ which has two Te-C bonds; this explains the average Te-Cl distance of 2.38 Å for the terminal Cl atoms. According to this, Cl^- ions (on two-fold axis) and $ClCH_2$-$CH_2TeCl_2^+$ ions (on mirror plane) alternate along the polymer chain. Thus we find similar bonding characteristics as in TeF_4[5]. Separation into TeX_3^+ and X^- ions, however, seems to be indicated more prominently in our case. It appears to us to be unjustified to speak of a predominantly ionic lattice.

A Convenient Synthesis of 2',3',5'-Tri-*O*-acetyladenosine and -uridine

By *F. J. M. Rajabalee*[*]

A new method is described for the synthesis of 2',3',5'-tri-*O*-acetyladenosine *(1b)* and -uridine *(2b)*, *via* the boron trifluoride-catalyzed acetylation of adenosine *(1a)* and uridine *(2a)* respectively.

(1a), R = H
(1b), R = Ac

(2a), R = H
(2b), R = Ac

In a typical procedure, boron trifluoride-diethyl ether is added dropwise to a suspension of the nucleoside (1 part) in acetic anhydride (10 parts): the nucleoside soon dissolves in an exothermic reaction. The reaction mixture is allowed to stand at room temperature (adenosine: 1–2 h; uridine: 30 min)[1] after which it is co-evaporated with methanol (80 parts). The resulting syrup is dissolved in water (100 parts) and carefully neutralized with solid sodium bicarbonate. The filtered solution is then allowed to crystallize at 0 °C, giving after a few hours the chromatographically homogeneous triacetate *(1b)* or *(2b)*. *(2b)* can be recrystallized from absolute ethanol. *(1b)*, m.p. 166–167 °C, was thus obtained in 73–75% yield; *(2b)*, m.p. 129–130 °C, in 74–78% yield. Their identity was further confirmed by their undepressed melting points when admixed with authentic samples[2,3] and by their identical R_f values[1] and IR, UV, and NMR spectra.

The synthesis of *(1b)* and *(2b)* by the present method offers certain advantages over the pyridine-catalyzed method[2,3]: it is faster, gives a purer product (even the "crude" acetylated product obtained is chromatographically homogeneous whereas recrystallization is always required in the pyridine-catalyzed procedure) and yields are higher. Nucleoside acetates *(1b)* and *(2b)* are useful intermediates; they are, for instance, excellent substrates for reaction with triethyloxonium tetrafluoroborate (Meerwein reagent) in dichloromethane (both being soluble in that solvent), leading to *N*-ethylated nucleosides, which command interest in cancer research.

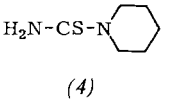
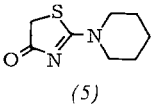
Removal of the Chloroacetyl Group from *N*-Chloroacetyl Derivatives of Amino Acids and Peptides by Means of 1-Piperidinethiocarboxamide[**]

By *Wolfgang Steglich* and *Hans-Georg Batz*[*]



It has recently been found that the *N*-chloroacetyl group can readily be removed with thioureas[1,2]. However, the amines are often obtained from the *N*-chloroacetyl-peptide derivatives in only unsatisfactory yields owing to a secondary reaction that we have studied in the case of the methyl ester of *N*-chloroacetyl-L-valine. If this compound is treated with thiourea in the usual way, thin layer chromatography of the product indicates the presence of not only the methyl ester of valine and *(1)* but also compounds *(2)* and *(3)*, which are also formed on reaction of *(1)* with valine methyl ester hydrochloride in boiling water[3,4].



(1)

(2) *(3)*

This secondary reaction can be avoided if an *N*, *N*-disubstituted thiourea, such as 1-piperidinethiocarboxamide (*N*, *N*-pentamethylenethiourea) *(4)*[5] is used in place of thiourea. The *N*-chloroacetyl residue is then removed quantitatively after several hours' boiling in ethanol without any reaction occurring between the resulting 2-piperidinothiazolin-4-one *(5)* and the amine.

(4)

(5)

This reaction greatly enhances the utility of the *N*-chloroacetyl group as a protecting group for peptide syntheses. Thus *N*-chloroacetyl-Val-Val-OtBu (m.p. 132–134 °C; [α] = –65.1 °[6]) affords *N*-chloroacetyl-Val-Val-Val-OtBu (m.p. 210–211 °C; [α] = –89.6°) in 91% yield after removal of the chloroacetyl group with *(4)* and reaction with *N*-chloroacetyl-Val by the dicyclohexylcarbodiimide/hydroxysuccinimide method[7]. Similarly, *N*-chloroacetyl-Ile-Val-OtBu (m.p. 100–103 °C; [α] = –68.3°) affords TFA-Ile-Leu-Val (yield 69%; m.p. 220–222 °C; [α] = –84.6°) after removal of the protecting group, coupling with TFA-Ile, and removal of the *tert*-butyl group with trifluoroacetic acid. According to the ^{19}F-NMR spectrum the compound is optically pure[8].

The *N*-chloroacetyl group is also well suited for protection of the ω-amino functions of ornithine and lysine. N^{α}-TFA-N^{δ}-chloroacetyl-Orn-Leu-OtBu (m.p. 149–152 °C; [α] = –38.8°) is converted into N^{δ}-chloroacetyl-Orn-Leu-OtBu (yield 98%) by treatment with $NaBH_4$/ethanol[9]; this compound then gives TFA-Ile-N^{δ}-chloroacetyl-Orn-Leu-OtBu (yield 58%; m.p. 194–197 °C; [α] = –61.5°) on reaction with TFA-Ile-OSu. Treatment with *(4)* and removal of the ester group with trifluoroacetic acid furnishes TFA-Ile-Orn-Leu (as trifluoroacetate: yield 73%; m.p. 191–193 °C; satisfactory amino acid analysis). The dipeptide derivative obtained from *N*-chloroacetyl-Val and Val-OtBu according to the dicyclohexylcarbodiimide/hydroxysuccinimide method showed no racemization in the Weygand test[10] after removal of the chloroacetyl group with *(4)* and conversion into the TFA-dipeptide methyl ester.

Procedure:

N-Chloroacetyl-peptide ester (10 mmoles), compound *(4)* (12 mmoles), and glacial acetic acid (0.5 ml) are refluxed for 2–5 h in anhydrous ethanol. After addition of methyl chloroacetate (2.5 mmoles) the reaction mixture is boiled for a further hour in order to convert the excess of *(4)* into *(5)*, the ethanol is removed under vacuum, and the residue is partitioned between saturated aqueous K_2CO_3 solution and ethyl acetate. The organic phase is washed three times with water, dried, and evaporated down. Compound *(5)*, which does not interfere with the next peptide coupling step, is subsequently removed by extraction with acid.

3-Oxobenzo[*d*]isothia(IV)-azole 1-Oxides

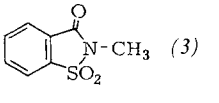
By *Peter Stoss* and *Gerhard Satzinger*[*]

The reaction of sulfoxides with hydrazoic acid leads to sulfoximides[1,2].

If esters of 2-sulfinylbenzoic acids *(1)* are used as starting materials then ring closure occurs simultaneously to give cyclic sulfoximides. These 3-oxobenzo[*d*]isothia(IV)-azole 1-oxides *(2)* are representatives of a new heterocyclic system.

(1) *(2)*

	R^2	R^3	R^4	*(1)* [a] m.p. (°C)	yield (%)	*(2)* m.p. (°C)	yield (%)	IR (cm^{-1}) in KBr NSO
(a)	CH_3	H	H	66-67	88	210-211	85	1227, 1124, 995
(b)	*n*-C_4H_9	H	H	oil	80 [b]	119	14	1247, 1220, 1124, 98
(c)	C_6H_5	H	H	84-85	68	127-128	37	1232, 1205, 1105, 97
(d)	CH_3	Cl	H	86	70	194	23	1235, 1205, 1124, 98
(e)	CH_3	Cl	Cl	oil	84 [b]	215	15	1245, 1227, 1000



[a] $R^1 = CH_3$.
[b] Crude product.

The conversion of *(1)* into *(2)* is carried out under the conditions of the Schmidt reaction. Polyphosphoric acid is suitable both as acid catalyst and as solvent. Toluene, chlorobenzene, and dichloroethane, as well as other solvents, may, however, also be used as diluents.

The sulfoxides *(1)* can be obtained by oxidation of the corresponding sulfides with sodium periodate.

The new ring system exhibits exceptional chemical stability. For example, compound *(2a)* is unaffected by hot concentrated sulfuric acid and by 48 hours' refluxing with 1N ethanolic KOH.

The carbonyl frequencies of compounds *(2)* (1675–1686 cm^{-1}) are remarkably low compared to those of 2-methyl-3-oxo-1,2-dihydrobenzoisothiazole 1,1-dioxide *(3)* (1730 cm^{-1}). The typical sulfoximide bands (NSO frequencies) occur at about the same wavelengths as those of *N*-alkyldiphenylsulfoximides[3]. The UV spectra of *(3)* and, *e. g.*, *(2a)* are very similar:

(3)

(3) (CH_3OH): $\lambda_{max}(\varepsilon) = 295$ (905); 285; 253 nm;
(2a) (CH_3OH): $\lambda_{max}(\varepsilon) = 294.5$; 285 (1300); 278.5 nm.

1-Methyl-3-oxobenzo[d]isothia(IV)-azole 1-oxide (2a)

Methyl 2-methylsulfinylbenzoate *(1a)* (99 g, 0.5 mole) is added to a mixture of 85% phosphoric acid (500 g) and phosphorus pentoxide (250 g) and the whole is heated to 80° C. Sodium azide (39 g, 0.6 mole) is then added to the reaction mixture at this temperature with vigorous stirring over a period of 2 hours. Stirring is continued for another 4 hours at the same temperature and the mixture is then cooled, diluted with water (500 ml), and neutralized with aqueous potassium hydroxide. The product *(2a)* can then be filtered off with suction (yield 77 g, 85%, recrystallized as colorless crystals from water).

Bis(tri-2-biphenylphosphite)nickel

By *M. Englert, P. W. Jolly,* and *Günther Wilke*[*]

In continuation of our studies on the chemistry of coordinatively unsaturated nickel complexes[1–3] we wish to report the preparation and some reactions of bis(tri-2-biphenylphosphite)-nickel, *(1)*.

It has been previously reported that the reduction of bis(2,4-pentanedionato)nickel(II) (nickel acetylacetonate, $Ni(acac)_2$) in the presence of tri-2-biphenylphosphite (hereafter referred to as L) by a large excess of trimethylaluminum leads to formation of $L_2Ni(CH_3)_2$[4]. Using a stoichiometric amount of trimethylaluminum the reaction takes a different course and *(1)* may be isolated as an orange solid in over 90% yield.

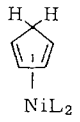
$$Ni(acac)_2 + 2\ P(OC_6H_4\text{-}o\text{-}C_6H_5)_3 + 2\ Al(CH_3)_3$$

$$+ 2\ (CH_3)_2Al(acac) + 2\ CH_4$$

(1)

The composition of *(1)* is confirmed by the reaction with monoolefins to give the corresponding olefin complexes[5] and by the absorption of two molecules of CO per molecule of complex with formation of $L_2Ni(CO)_2$.

In solution (toluene) *(1)* is dissociated and shows the expected catalytic activity with butadiene[6]. If the reaction with *(1)* is carried out below room temperature the butadiene complex *(2)* may be isolated. *(2)* is also formed by the thermal rearrangement of the olefin complex *(3)* formed from *(1)* and methylenecyclopropane.



(2) *(3)*

(1) trimerizes allene forming 1,2,4-trimethylenecyclohexane *(4)* and a bis-π-allyl-C_9 NiL compound. A complex containing an open chain dimer is obtained from the corresponding reaction with dimethylallene.

Reaction of *(1)* with cyclopentadiene yields the complex *(5)*, which, in contrast to the corresponding bis(tricyclohexylphosphane)nickel derivative[3], shows no tendency to form a cyclopentadienylhydridonickel complex. This is also the case

(4)

(5)

for the reaction with acetic acid from which a derivative of nickel(I) – $L_2Ni^{I}OC(O)CH_3$ – is obtained with the simultaneous evolution of one equivalent of hydrogen.

Other less sterically demanding phosphanes add to *(1)* forming mixed nickel phosphane complexes. For example tricyclohexylphosphane adds to form the bright red $L_2Ni(P(C_6H_{11})_3$ which may also be formed by reacting bis(tricyclohexylphosphane)-nickel[1,2] with tri-2-biphenylphosphite.

Attempts to prepare other bis(ligand)nickel complexes have so far met with no success and we attribute the formation of the molecule *(1)* to steric factors and to a shielding of the central atom by the six *o*-phenyl groups which can be clearly seen from molecular models.

Experimental

$Al(CH_3)_3$ (20 mmole) in pentane (5 ml) is dropped slowly into a solution of $Ni(acac)_2$ (5.1 mmole) and tri-2-biphenylphosphite (10.2 mmole) in ether (200 ml) cooled to −60 °C. The mixture is allowed to reach room temperature and stirred for 14 hours. The resulting bright orange precipitate is filtered off and washed with ether in which it is insoluble. Yield > 90%.

CONFERENCE REPORTS

Triplet Biradicals in Cycloaddition

By *Paul D. Bartlett*[*]

Photosensitized cycloaddition is known to originate in energy transfer from an excited triplet state of the sensitizer to that participant in the cycloaddition with the most favorable triplet excitation energy. Such a reaction can serve as a reference model of the behavior of a biradical intermediate.

Losses of configuration from an alkene during cycloaddition are the result of rotations occurring about single bonds during the lifetime of an intermediate biradical. Even in singlet biradicals extensive configuration loss occurs while a conformation suitable for ring closure is being approached; in triplet biradicals the lifetime of intermediate biradical. Even in singlet biradicals extensive configuration loss occurs while a conformation suitable for ring closure is being approached; in triplet biradicals the lifetime is further increased by the need for an electron spin inversion before a bond can be formed.

Thermal cycloaddition of *cis*- or *trans*-2-butene to cyclopentadiene yields 1,4-addition products stereospecifically; photosensitized reaction yields a mixture of three 1,4- and four 1,2-cycloadducts.

Complete identifications an quantitative analyses have been made of the product mixtures from *cis*- and *trans*-2-butene *(B. D. Kramer)*, *cis*- and *trans*-1,2-dichloroethylene *(O. A. Wersel)*, *cis*- and *trans*-1,2-dichloro-1,2-difluoroethylene *(R. Wheland)*, and *cis*- and *trans*-1-chloropropene *(L. A. Hull)*, in photosensitized addition to cyclopentadiene. Extensive loss of configuration occurs in all cases, but the product mixtures from *cis* and *trans* olefins remain different in serveral respects:

(1) The diastereomeric biradicals are formed to a greater extent in the *threo* configuration from the *trans* than from the *cis* alkenes;

(2) *Trans* alkenes produce consistently higher proportions of 1,4- to 1,2-adducts than do their *cis* isomers (with 2-butene this is not apparent at 30 °C but becomes so at −15 °C);

(3) In six out of ten cases, pairs of 1,2-cycloadducts formed competitively from the same biradical show a "crossover" phenomenon such that the *cis/trans* ratio is higher from *trans* alkene than from *cis*- by factors up to 4. The "crossover" being absent in the 1,4-adducts, it is proposed that

(a) the most favored initial conformation of the biradical is that appropriate to 1,4-ring closure, and retains the original configuration of the olefin,

(b) rotation from this conformation to that preceding 1,2-ring closure is coupled with an inversion from *cis* to *trans* or vice versa,

(c) there is a net flow of biradicals from the 1,4- to the 1,2-conformation, which superposes a net "crossover" on the general stereochemical equilibration resulting from the long life of the triplet biradicals. The coupling of rotations may be mechanical and highly specific, or it may have a general orbital basis analogous to the compulsory inversion in a 1,3-sigmatropic rearrangement.

Chiral Bornadiene: Its Synthesis and Rearrangement

M. R. Willcott, III and *C. J. Boriack*[*]

Bornadiene (1,7,7-trimethylbicyclo[2.2.1]hepta-2,5-diene) is converted to 3,7,7-trimethyltropilidene (3,7,7-trimethyl-1,3,5-cycloheptatriene) and *p*-cymene in the gas phase between 220 and 300 °C. Trimethyltropilidene is formed in a first order process with the rate $k = 10^{13.94} e^{-40.6/RT} s^{-1}$. Since these parameters do not give any accurate indication of the mechanism, a study of chiral (-)-(7*R*)-8-deuteriobornadiene *(1)* was undertaken. The chiral compound was prepared from (+)-camphor *(2)* in 11 steps in good overall yield. The most likely racemization step in the synthesis, the conversion of [D]-bornylene *(3)* to [D]-1,5,5-trimethylcyclopentadiene *(4)*, was monitored by the appearance of deuterium in the allylic methyl group. At a later point in the synthesis, the optical purity of [D]-bornadiene is determined in a simple NMR experiment from intensity measurements of the CH_3 and CH_2D groups. In this way, [D]-bornadiene was shown to be 82% enantiomerically pure.

Pyrolysis of [D]-bornadiene in the gas phase produced a [D]-trimethyltropilidene *(5)* of unknown optical purity. After a number of unsuccessful attempts to measure the optical purity, we found that conversion of the 3-methyl group to the hydratropyl ester derivative *(6)* from optically pure acid made a molecule in which the two 7-Methyl groups were measurably diastereotopic. Determination of the amount of deuterium in each methyl resonance permitted us to conclude that the [D]-trimethyltropilidene was racemic.

The mechanism of the rearrangement must involve either a symmetrical transition state, or a symmetrical high energy intermediate. It is possible that the role of the *p*-cymene can help in deciding between the transition state and the intermediate.

The Influence of the Complexed Metal Ion on the Mass Spectra of Organic Metal Complexes

By *Herbert Budzikiewicz*[*]

The fragmentation behavior of analogous organic compounds differing only in the nature of a hetero atom is influenced by this hetero atom. There are similar differences in the degradation reactions of organometal complexes and those of the uncomplexed ligand which may depend further upon the metal present in the complex. To explain this various factors have been invoked, such as

a) the nature of the bond (*e.g.*, metallocenes),

b) charge localization in the molecular ion on the ligand or on the metal (*e.g.*, benzenetricarbonylchromium derivates or pentanedionates),

c) possible change of valency of the complexed metal (*e.g.*, pentanedionates),

d) steric factors.

In order to investigate the importance of these various factors porphyrin complexes as well as model compounds were used. Simple porphin derivatives fragment – both starting from M^+ and from M^{2+} – preferentially in a way that even electron daughter ions are formed. This mode of fragmentation is retained with all metal complexes investigated and one may conclude that the positive charge and hence the radical site in the molecular ion is stabilized by the aromatic π-system and not by the complexed metal so that possible changes of valency are of no major importance. This conclusion is confirmed by the observation that the fragmentation behavior of the analogous metal complexes of 2-butyl-8-hydroxyquinoline, which exhibits a less extended π-system than the porphyrins, depends upon the ability of the complexed metal to change its valency. These quinoline complexes occupy an intermediate position between those of porphin derivatives and pentanedionates. The fragmentation pattern of more highly substituted porphyrins and chlorins may differ greatly from that of their complexes, which can be explained by assuming differing interatomic distances as well as changed steric relationships in the overcrowded part of the molecule.

Adsorption of Oxygen on Gold and its Effect on the Kinetics of Electrochemical Reactions

By *Gerhard M. Schmid*[*]

At potentials greater than 1.25 V the adsorption of oxygen on gold in 1 M H_2SO_4 or 1 M $HClO_4$ increases linearly with potential, monolayer formation being complete (two electrons per surface atom) at 1.45 V. At 1.70 V a second monolayer has formed. The adsorption exhibits hysteresis: oxygen that has been adsorbed between 1.25 and 1.70 V is only removed from the surface at potentials $\leq$ 1.25 V. Moreover, no difference could be detected between the first and the second monolayer. In acidic solutions containing chloride ion, the dissolution current of gold going into solution as $AuCl_4^-$ is directly proportional to the oxygen-free surface area. On formation of an oxygen monolayer dissolution ceases and the electrode is passive. On the other hand, the adsorbed oxygen reduces the apparent rate constant of the Ce^{III}/Ce^{IV} reaction in 1 M H_2SO_4 only from 12×10^{-4} cm/s (free surface) to 3×10^{-4} cm/s (monolayer). The rate constant remains unchanged when the coverage is increased to two monolayers. The charge transfer coefficient, $\alpha = 0.65$, is independent of the oxygen coverage. The change in the rate constant can be explained by a change of the potential drop in the inner double layer by 8mV. It would appear that the adsorbed oxygen is incorporated into the metal lattice, is a good electron conductor, and has only a slight effect on the potential conditions in the inner double layer.

Lecture at Mainz on September 15, 1970 [VB 258 IE]

SELECTED ABSTRACTS

Surface tension and compressibility of liquids near their triple points conform to a simple relation according to *P. A. Egelstaff* and *B. Widom*. On inspection of 30 liquids (*e.g.*, K, Ag, NaBr, N_2, H_2O, chlorobenzene) it was observed that while the surface tension and the compressibility separately vary by a factor of 150 their product varies only by a factor of about 3; its value always amounts to some tenths of an ångström unit. With the aid of a statistical model it is shown that this product, apart from a constant factor, corresponds to the "surface layer thickness", *i.e.* the depth below the surface where the intensive properties of the liquid no longer differ from those in the bulk. Apparently this distance is only weakly dependent on the nature of the intermolecular forces./J. Chem. Phys. *53*, 2667 (1970)/–Hz.

[Rd 259 IE]

The dipole moments of the diatomic IV/VI molecules (*e.g.*, CO, GeSe) are reported comprehensively by *J. Hoeft, F. J. Lovas, E. Tiemann,* and *T. Törring*. The dipole moments were evaluated mostly from Stark effect measurements on rotational transitions in the microwave spectrum. A plot of dipole moments *versus* internuclear distances reveals that molecules with one common atom are located on straight lines; this relation allows the prediction of internuclear distance and dipole moment for molecules not yet investigated, *e.g.*, for SiTe. This simple relation between dipole moment and internuclear distance in this class of molecules is in clear disagreement with the corresponding data of the alkali metal halides. For SnS, the dipole moments of the four lowest excited vibrational states are also reported./J. Chem. Phys. *53*, 2736 (1970)/–Hz.

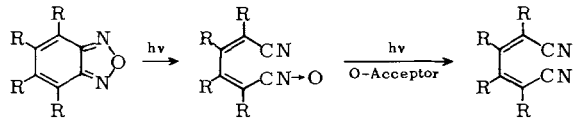
[Rd 260 IE]

The vibrational frequencies of adsorbed SO_2 are reported by *M. A. K. Phillips* and *R. C. Seymour*. The low frequency IR spectra were measured by Fourier analysis of interferograms. CsCl films were prepared by evaporation of CsCl onto polyethylene sheets at −196 °C and subsequent annealing at −78 °C. Specific surface areas of these films were found to be in excess of 200 m^2/g. On adsorption of SO_2 at a pressure of 0.1 torr a broad absorption band centered at 220 cm^{-1} appears. Its intensity increases with increasing SO_2 pressure. At 1 torr, a second band appears at 308 cm^{-1}. On evacuation, the 220 cm^{-1} band disappears rapidly, whereas the 308 cm^{-1} band requires continuous pumping for several hours to vanish. The band at 220 cm^{-1} is considered to be due to the vibration of physically adsorbed SO_2 molecules perpendicular to the surface, whereas the 308 cm^{-1} band is ascribed to a chemisorbed species formed by interaction of SO_2 with ions in the surface./Chem. Phys. Lett. *6*, 553 (1970)/–Hz.

[Rd 261 IE]

***N-tert*-Butyliminoacetonitrile** *(3)*, the first representative of a new group of compounds, the iminoacetonitriles RN=CHCN, has been synthesized by *J. H. Boyer* and *H. Dabek*. *N-tert*-Butylaminoacetonitrile *(1)* is converted by reaction with *tert*-butyl hypochlorite into *N*-chloro-*N-tert*-butylaminoacetonitrile *(2)*, whose dechlorination by triethylamine affords compound *(3)* (b.p. 28–29 °C/3 torr) in 46% yield. Catalytic reduction of *(3)*

$$\underset{(1)}{tBu\text{-}NH\text{-}CH_2CN} \longrightarrow \underset{(2)}{tBu\text{-}NCl\text{-}CH_2CN} \longrightarrow$$



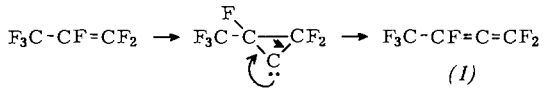
$$\underset{(3)}{tBu\text{-}N{=}CHCN} \xrightarrow[SiO_2]{HCN} tBu\text{-}NH\text{-}CH(CN)_2 \xrightarrow[SiO_2]{(3)}$$

$$tBu\text{-}NH\text{-}\overset{\overset{CN}{|}}{\underset{\underset{CN}{|}}{C}}\text{—}\overset{\overset{H}{|}}{\underset{\underset{CN}{|}}{C}}\text{-}NH\text{-}tBu \quad (4)$$

with W-2 Raney nickel gives *N-tert*-butylethylenediamine. *(3)* can be partly converted on a silica gel column into 1,2-di-*tert*-butylamino-1,1,2-tricyanoethane *(4)*, which is probably formed from HCN and two molecules of *(3)*./Chem. Commun. *1970*, 1204/-Ma.

[Rd 262 IE]

The preparation of 1,2-dinitriles from furazanes by UV irradiation in the presence of a reducing agent (triethyl phosphite) is the subject of a report by *T. Mukai* and *M. Nitta*. The nitrile oxide group formed in the intermediate is reduced to the nitrile group. Benzofurazane *(1)*, R = H, gives *cis,cis*-1,4-dicyano-1,3-butadiene *(2)*, R = H (80% yield), along with the *cis,trans* and *trans,trans* isomers (in 2% and 3.5% yields resp.). Naphthofurazane affords *cis*- and trans-*o*-cyanocinnamonitriles in 45% and 35% yields resp. Phenanthrofurazane is converted into 2,2'-

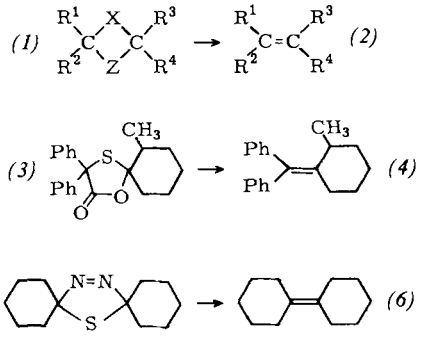


(1) (2)

dicyanobiphenyl. The photocleavage possibly proceeds *via* the singlet state of the furazane. / Chem. Commun. *1970,* 1192/-Ma.

[Rd 263 IE]

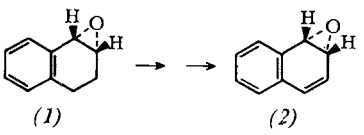
Fluorinated allenes, which have previously only been accessible by multistep syntheses, have been prepared by *M. J. McGlinchey, T. Reynoldson,* and *F. G. A. Stone* by reaction of carbon vapor (generated in an electric arc) with compounds $CF_2=CFX$ (X = CF_3, Cl, Br). For example, perfluoropropene gives perfluoro-1,2-butadiene *(1),* b.p. −5° C, in 20% yield;



(1)

chlorotrifluoroethylene analogously gives $ClFC=C=CF_2$, b.p. 12.6°C, in 10–15% yield. Reaction of bromotrifluoroethylene with carbon vapor leads to only *ca.* 5% $BrFC=C=CF_2$ along with 1-bromo-2,3,3-trifluorocyclopropene. The allene formation presumably proceeds *via* cyclopropylcarbene intermediates. / Chem. Commun. *1970,* 1264/-Ma.

[Rd 264 IE]

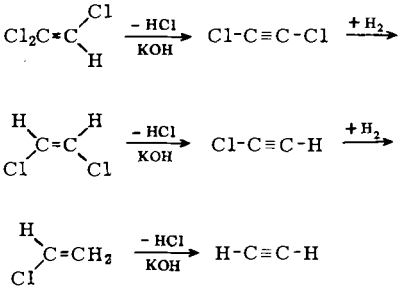


A novel method for olefin synthesis by double elimination has been developed by *D. H. R. Barton* and *B. J. Willis,* namely *(1)*→ *(2),* in which R^1, R^2 ... are alkyl, aralkyl, aryl, *etc.* and X and Y are residues that are easily eliminated. The CC double

bond is formed intramolecularly. The method is suitable for the synthesis of sterically hindered olefins. Thus, *e.g.,* the 1,3-oxathiolan-5-one *(3)* obtained by condensation of thiobenzilic acid, $Ph_2C(SH)COOH$, with 2-methylcyclohexanone is converted into the olefin *(4)* to the extent of 81% on being heated in presence of tris(diethylamino)phosphane. A further example is the synthesis of bicyclohexylidene *(6)* by heating *(5)* in presence of triphenylphosphane. Photolysis of the thiadiazole *(5)* does not yield olefin. / Chem. Commun. *1970,* 1225, 1226/-Ma.

[Rd 265 IE]

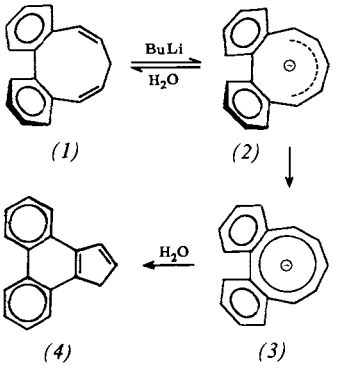
Optically active 1,2-naphthalene oxide *(2)* has been synthesized by *D. R. Boyd, D. M. Jerina,* and *J. W. Daly* from 1,2-epoxy-1,2,3,4-tetrahydronaphthalene *(1)* by conversion into the 4-bromo derivative, from which HBr was subsequently eliminated. (−)-*(1)* gave (−)-*(2)* in about 10% optical purity. Compound *(2),* which rapidly isomerizes to naphthol in methanol at 50° C, is optically and chemically stable at −80° C; at 20° C it can be kept for 25 h in $CHCl_3$ and for 8 h in CH_3OH. Addition of a trace of acetic acid to a methanolic solution of *(2)* leads



(1) (2)

to complete loss of optical activity within 1.5 h and to formation of naphthol; addition of a little methanolic KOH effects racemization without isomerization to naphthol. / J. Org. Chem *35,* 3170 (1970)/-Kr.

[Rd 266 IE]

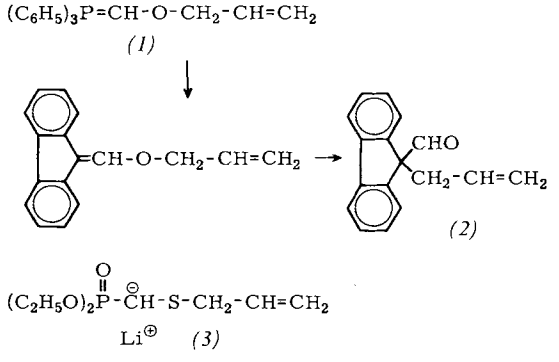


A safe synthesis of dichloroacetylene is described by *J. Siegel, R. A. Jones,* and *L. Kurlansik;* the reaction is carried out in ethylene glycol as solvent instead of in a dry combustion tube filled with NaOH as previously. Moreover, an excess of ether, which is known to delay the autoxidation of dichloroacetylene, is present throughout the reaction. The formulas illustrate the

formation of Cl–C≡C–Cl and indicate possible modes of by-product formation. The acetaldehyde found could arise from the ether or from the ethylene glycol. / J. Org. Chem. *35,* 3199 (1970)/-Kr.

[Rd 267 IE]

The anions of dibenzo[c,e]cyclononene *(1)* are the subject of a paper by *P. J. Garrat* and *K. A. Knapp.* A solution of *(1)* in THF is converted, by treatment with *n*-butyllithium in hexane at room temperature *in vacuo,* into a deep red solution whose NMR spectrum indicates the presence of the non-planar, non-aromatic anion *(2).* Addition of water regenerates *(1).* When

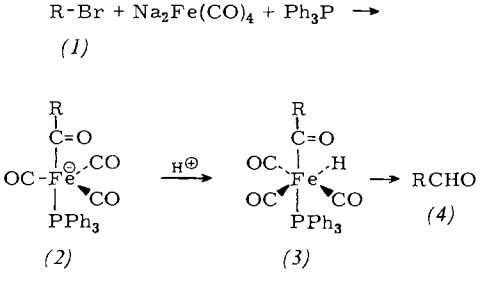


the solution of *(2)* is left to stand it forms the planar, aromatic anion *(3)* (detected by NMR spectroscopy), which yields *(4)* on treatment with water. Assuming the conversion of *(2)* into *(3)* to be a first order reaction, ΔF is 8.9 kcal/mole between 30 and 52° C and K (30° C) is 7.6×10^{-5} s. ΔF affords a measure of the lower limit of the delocalization energy of *(3).* / Chem. Commun. *1970,* 1215/-Kr.

[Rd 268 IE]

The ESR spectrum of di-*tert*-butyl nitroxide in water – lipid emulsions (coconut oil) has been investigated by *B. L. Bales* and *M. E. Baur*. Distinctly different resonances for the radical in water or lipid environment were found. Intensities of the corresponding spectral lines were used to determine the partition coefficient of the radical between aqueous and lipid phases. The partition coefficient is not constant at high lipid concentration; this can be explained by a perturbation of water structure near the oil droplets. The aim of this model investigation was to study the possibility of incorporating a "spin label" into biological structures and receiving information about the properties of the environment by analysis of the ESR spectrum of the label (anisotropy, line broadening). / Chem. Phys. Lett. *7*, 341 (1970)

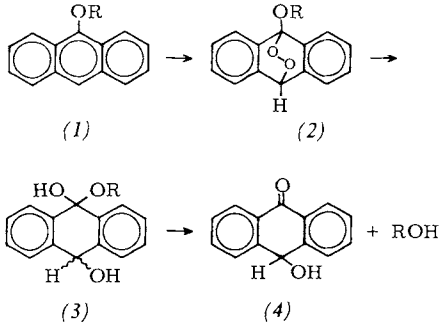
[Rd 270 IE]



α-Allylcarbaldehydes have been obtained in two ways from ketones by *E. J. Corey* and *J. I. Shulman*. The ylide *(1)* prepared from allyloxymethylphosphonium chloride reacts with aromatic aldehydes and ketones, *e. g.* fluorenone, to give an enol ether which on thermolysis affords the α-allylcarbaldehyde *(2)*. Re-

action with the lithium salt *(3)*, which can be obtained from diethyl allylthiomethylphosphonate, is suitable for alicyclic and enolizable ketones. The allyl vinyl sulfide thus obtained is converted on thermolysis in the presence of red mercuric oxide into the α-allylcarbaldehyde. / J. Amer. Chem. Soc. *92*, 5522 (1970) / –Kr.

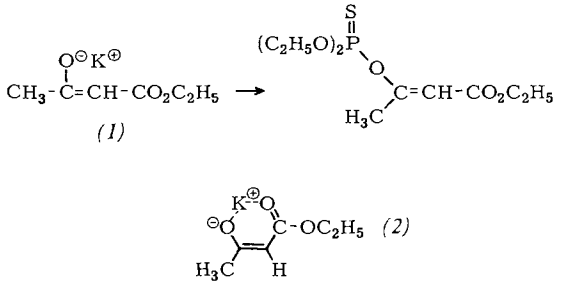
[Rd 273 IE]



Conversion of alkyl bromides into aldehydes by reaction with disodium tetracarbonylferrate(–II), which can be prepared from sodium amalgam and pentacarbonyliron in THF, is the subject of a report by *M. P. Cooke, Jr.* Addition of triphenylphosphine renders the reagent ready for use. After addition

of the alkyl bromide *(1)* the mixture is stirred for a few hours and then treated with glacial acetic acid. It is suggested that *inter alia* the intermediates *(2)* and *(3)* are formed in the reaction leading to the aldehydes *(4)* containing one more C-atom. Examples: *(4)*. R = *n*-C_9H_{19} (yield 91 %); $C_6H_5(CH_2)_2$ (86%); $(CH_3)_2C{=}CH(CH_2)_2$ (81%); *n*-C_6H_{13}-$CH(CH_3)$ (50%). / J. Amer. Chem. Soc. *92*, 6080 (1970) / –Ee.

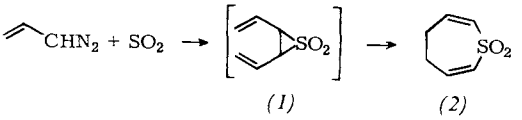
[Rd 274 IE]



The 9-anthroxy group is suitable for the protection of hydroxy functions according to *W. E. Barnett* and *L. L. Needham*. For introduction of the protecting group the alcohol is first converted into its tosylate which then reacts with the 9-anthrolate ion to give the ether *(1)*. The cleavage involves singlet-oxygen

oxidation of the ether *(1)* at –30 °C to give the peroxide *(2)* followed by mild catalytic reduction of the O–O bond. The initial reduction product is presumably a hemiacetal *(3)* which spontaneously decomposes to 10-hydroxyanthrone and the alcohol that was protected (*e.g.* hexadecanol). / Chem. Commun. *1970*, 1383 / –Ma.

[Rd 276 IE]



The structures of carbanions and factors determining the geometries of reactions of enolate anions have been investigated by *B. Miller, H. Margulies, T. Drabb, Jr.*, and *R. Wayne*. For example, *O*-phosphorylation of the potassium enolate *(1)* gave predominantly *cis*-isomers from reaction in non-polar solvents

and predominantly *trans*-isomers from reaction in polar solvents (in benzene: *cis/trans* = 40:1, in DMSO: 1:9). The authors present evidence that formation of the *cis*-isomers proceeds *via* chelate intermediates such as *(2)*, while formation of *trans*-isomers is due to reaction of "free" anions in which the normal repulsions between the polar groups is the geometry-deciding factor. / Tetrahedron Lett. *1970*, 3801, 3805 / –Kr.

[Rd 272 IE]

4,5-Dihydrothiepin 1,1-dioxide *(2)* has been prepared by *W. L. Mock* from 3-diazopropene and sulfur dioxide. Compound *(2)*, m. p. 111.5–112.5 °C, is possibly formed *via* the *cis*-divinylthiirane1,1-dioxide *(1)*, which subsequently undergoes a Cope rear-

rangement. On refluxing in benzene/triethylamine, compound *(2)* isomerizes quantitatively to 2,7-dihydrothiepin 1,1-dioxide. / Chem. Commun. *1970*, 1254 / –Ee

[Rd 271 IE]

Gas contents of salts from the Upper Permian formation (Germany) are reported by *H. D. Freyer* and *K. Wagener*. Samples of sylvinite, halite, and kieserite were investigated; their total gas contents are in the order of 10^{-3} cm^3 NTP/g. By comparison of different methods of disaggregation (grinding, dissolution, melting) of samples it can be concluded that the gases are molecularly dispersed in the lattice. Probably they were in equilibrium with the components of the solution when the salt was deposited. Consequently, gas analyses can supply information about the atmospheric composition at the time of salt formation. Mass spectrometric gas analyses are reported of N_2, O_2, Ar, CO_2, CH_4, H_2, and sometimes, H_2S./Z. Naturforsch. *25a*, 1427 (1970) / –Hz [Rd 269 IE]

BOOK REVIEWS

Catalysis by Nonmetals. Rules for Catalyst Selection. By *O. V. Krylov.* In the series: Physical Chemistry. A Series of Monographs. Academic Press, New York-London 1970. 1st Edit., x, 283 pp., $ 14.00.

This book is an English translation of the well-known Russian author's work. It deals with the catalytic properties of oxides, sulfides, solids with acid or basic surface groups, and other one-component nonmetals. Thus, at first glance the book can be seen to be the counterpart of the widely read monograph by *G. C. Bond* "Catalysis by Metals" which was published by Academic Press in 1962. The main object of *Krylov*'s work is to give rules for the choice of catalysts for certain reactions such as oxidations, hydrogenations, dehydrogenations, hydrations, dehydrations, exchange and decomposition reactions, isomerizations, cracking, alkylations, and polymerizations.

The book is divided into two sections, the first of which is reserved for a description of the correlations between the catalytic activity of solids – selectivity is unfortunately not considered – and their physico-chemical properties (for example, type of conduction, charge-carrier concentration, doping, width of the forbidden zone, electron work function, ionic radius and valence, electronegativity of the atoms, acidic or basic surface groups, dielectric constant, crystal type, and lattice constant). In this connection, due attention has also been given to theoretical discussions of reaction mechanisms. The second part of the book summarizes and describes the reactions for which catalysts can be found by applying the principles discussed. Finally, an appendix summarizes the major physicochemical parameters of a large number of solids. The list of references extends essentially as far as 1964.

The book will appeal primarily to physical chemists engaged in catalyst research and development.

Ernst-Günther Schlo [NB 918 IE]

Modern Reactions in Organic Synthesis. Edited by *C. J. Timmons.* Van Nostrand-Reinhold Company, London 1970. 1st Edit., vi, 311 pp., numerous formulas, bound £ 5.10.

The title of this book is too ambitious. The editor himself states in the foreword: "This book reviews, within chosen fields some of the synthetic methods recently developed or applied that seem important in the views of the contributors."

In seven chapters the book's eight authors discuss the following topics: reduction and oxidation methods; the use of free radicals in syntheses; electrochemical and photochemical methods; and the synthesis of aromatic and heterocyclic compounds. The references cited cover the period from 1960 to 1967/68. One wonders why the book has only just been published since, in spite of the lavish use of structural formulas, its careful preparation, and the detailed index, it should not have taken so much time to produce.

The individual chapters contain many relevant references (more than 1100 in all). However, in the case of oxidations with ozone, for example, no mention is made of the useful tetracyanoethylene variant [Chem. Ber. *96*, 1564 (1963)] and, in the case of the acyloin reaction in the section on radicals, there ist no reference to the valuable modified method in the presence of trimethylchlorosilane [Chem. Ber. *100*, 3820 (1967); Tetrahedron Lett. *1968*, 586].

The book should be kept in libraries for students in the final stages of their degree courses but it is of limited value to teachers and research workers.

Dieter Seebach [NB 919 IE]

The Radiation-Induced Decomposition of Inorganic Molecular Ions. By *E. R. Johnson,* Gordon and Breach, New York-London-Paris. 1970. 1st Edit., ix, 144 pp., Bound £ 18.–.

Comprehensive monographs on specialized topics from the large field of radiation chemistry have long been appearing in the English-speaking world. Thus, the present book, which attempts to give a comprehensive survey of the action of high-energy radiation on inorganic crystalline solids, is aimed at the specialist. Basic concepts of radiation chemistry are mentioned in a few introductory sentences. Somewhat more space is devoted to necessary information on solid-state physics (natural defects) and crystal-lattice defects caused by high-energy radiation. After a short description of the crystal properties that change under the effect of radiation and of the factors that cause these changes, three-quarters of the book is devoted to the results of the radiation-induced decomposition of inorganic salts (nitrates, chlorates, perchlorates, bromates, azides, sulfates, carbonates, and permanganates). Attention is also paid to the radiolysis products with their G values, the electronic absorption spectra, and the ESR spectra of the irradiated crystals.

In the case of the more thoroughly investigated nitrates, chlorates, bromates, and perchlorates, the kinetics and mechanisms of radiation-induced decompositions are discussed. A critical appraisal of the results, some of which are controversial, is given at the end of every relevant chapter.

Typically, only three of the 182 references (ranging up to 1968/9) cited in this successful book come from German journals. This cannot be dismissed with the usual explanation, namely that Americans read only English literature, since Russian journals, for example, are often quoted.

Hans Güsten [NB 921 IE]

Mensch und Arbeit im Chemiebetrieb (Man and Work in the Chemical Industry). General editor *W. Schneider.* Verlag Mensch und Arbeit, Munich, 1970. 1st Edit., 10 pp., ring binder, DM 16.80.

Society has changed considerably in the course of this century, not least in the sphere of working life. An employee in industry can no longer be regarded as a mere subordinate or as mere work power – he is developing more and more into an actively participating individual. Comprehensive professional training and further education are constantly improving the employee's ability to understand his sphere of work and to act fruitfully

on his own initiative. The employee is increasingly assuming the character of a coworker.

This change means that a new style of management is needed in industry and that, in particular, the old authoritarian principles must be abandoned. Many employers have already come round to this new way of thinking, often by force of circumstances.

The working group of the industrialists associations of the German chemical industry has for many years been attempting, by suitable training at middle management level, to take account of the changing circumstances. In this connection it has been running, among other things, business management courses and seminars for young graduates at Rech an der Ahr. This group also regularly produces two publications: "Informationsbrief für Führungskräfte in der Chemischen Industrie" (Information Sheet for Management Personnel in the Chemical Industry) and "Blätter für Vorgesetzte" (Notes for Managers).

The working group has now further supplemented its efforts in this field with the publication of the manual "Mensch und Arbeit im Chemiebetrieb". This appeared for the first time in 1966 as a pocket book under the title of "Mensch und Arbeit" (Man and Work) and, with more than 20000 copies, it has proved its worth as an organ of information for employers and as a reference book for everyday work in industry.

In separate chapters this manual deals with a very wide variety of practical problems, giving explanations, hints, and guidelines. A wide range of problems, which it would take too long to enumerate in full, are broached: design of the working area and its surroundings, wages systems, average productivity as a function of working time, question of health and safety, the management of men, information, assessment of staff, grading according to performance, training, fundamentals of industrial law and regulations, and information on the chemical industry. Many sections are supplemented and clarified with tables and statistics. It is obvious that trouble has been taken to provide employers with a compendium of relevant information which should make their work easier. It is openly admitted that there is no universal formula for solving managers' problems or for evolving management methods. Thus the book is made up in the form of a file in which the individual "chapters" are arranged as separate entities. By changing old material or adding new the manual can easily be kept up to date. It will best fulfil its task of giving advice and help to the reader if, as recommended in the introduction, it is not put into a bookcase but is left instead on the desk or workbench; if this is done, "it will certainly not be long before you find cause to use it". If such frequent use is made of it, its value will soon become obvious to the reader.

Hermann Reis [NB 922 IE]

Albert Einstein/Arnold Sommerfeld: Briefwechsel. (Exchange of Letters between Albert Einstein and Arnold Sommerfeld.) Ed. and annotated by *A. Hermann.* Schwabe & Co., Basel-Stuttgart 1968. 126pp., linen DM 18.80.

The editor describes this outwardly modest collection as "sixty letters from the Golden Age of modern physics". It provides what is probably the most stimulating reading in this field. Cleverly and skilfully annotated, these letters give a unusually vivid impression not only of the personalities of these two great physicists and of the intellectual conflict behind their achievements but also of the times – fickle and finally disastrous – which (by chance?) gave a home to these achievements. It is moving to see how personal quarrels arising from external or internal misunderstandings stand in stark contrast with scientific and theoretical discussions which time and again bridge the gap between these two men whose thoughts and feelings are in many respects so different.

One does not need to be interested in the history of physics to derive pleasure from this volume. The letters will be richly rewarding if one merely recalls that even the highest scientific achievements are the achievements of a human being.

Helmut Grünewald [NB 915 IE]

Handbook of Chemistry and Physics. Ed. by *R. C. Weast* and *S. M. Selby.* The Chemical Rubber Co., Cleveland 1970. 51st Edit., 2423 pp., bound DM 99.80.

After celebrating its jubilee, the fiftieth edition in 56 years, this great handbook has now appeared in a new edition for the 51st time. When it was first published people were acquainted with electrons, protons, and neutrons but knew practically nothing about them. Today the book has seven pages on these three elementary particles alone. Similar is the situation with chemical bonding (now twelve pages with data on bonding forces) and with superconductivity (fourteen pages of tables).

The size of the book, which increases with each edition, gives cause for concern. It now contains 2423 pages, 2100 of which (*i.e.* 87% of the whole book) are given over to tables which are important for the chemist. It must be said, however, that the editors know how to make the user very quickly forget the size of the book by their excellent arrangement and layout.

As always, numerous tables in this edition have been supplemented and brought right up to date. As always, too, a strip of gold foil is supplied with the book. Its purpose? On the cover there is a blank, deep red area, which is offset against the surrounding blue by a broad gold border, where one can put one's initials – in 23 carat gold. Not an everyday opportunity, but one which is thoroughly in keeping with the value of the work.

Helmut Grünewald 916 IE]

Taschenbuch für Chemiker und Physiker (Handbook for Chemists and Physicists). Ed. by *K. Schäffer* and *C. Synowietz.* Vol. III: Properties of Atoms and Molecules. Springer-Verlag, Berlin-Heidelberg-New York 1970. 3rd Edit., viii, 670pp., 112 figures, bound DM 48.–

This volume contains data on the physics and chemistry of atoms and molecules. Six sections give a survey of atomic nuclei, their most important properties and reactions, information on atomic and molecular spectra and the data that can be obtained from them, and tables of ionic radii, ionization potentials, effective cross sections, polarizabilities, and dipole moments. The relationships between molecular and directly observable macroscopic properties are also dealt with, and finally there is a table of spectral lines. Most tables are introduced by basic textual material which serves not only to clarify the tables but also to give a brief recapitulation of the most important relevant theoretical points. These introductions make the book more than a mere compendium of tables. They skilfully give the reader the help he needs to find his way through the wealth of data.

The arrangement of the tables, the dimensional data, and the explanation of the abbreviations and symbols are exemplary. Only the formulas occasionally leave something to be desired (dots instead of dashes). One cannot check at a desk the accuracy of the immense amount of data given in a handbook. One can only hope that such a book has as many readers as it deserves, so that the editors are rewarded for the enormous amount of work the have put into it.

Helmut Grünewald [NB 917 IE]

Biochemistry. The Molecular Basis of Cell Structure and Function. By *A. L. Lehninger.* Worth Publ. Inc., New York 1970. 1st Edit., xii, 833pp. with numerous figures, bound, *ca.* DM 65.–.

There is no lack of good American textbooks on biochemistry, but the present book by *A. L. Lehninger,* well known for his descriptive powers, will occupy a special place among them. It is not a summary of the structure and metabolism of biologically important compounds, nor is it built up simply on ideas about the dynamics of all molecules; instead, it is based on the concept that the conformity of molecular interactions with physical and chemical laws forms the basis of structure and function, and on the "molecular logic of living organisms". The cell forms

an open self-reproducing system consisting of numerous consecutive and interconnected chemical reactions catalyzed by organic molecules present in the cell.

Logically, the book begins with the various classes of biological molecules and their physicochemical behaviors, the principles of separation and analysis procedures being discussed wherever relevant. The author then moves on to an analysis of enzyme reactions, their arrangement into reaction chains and metabolic cycles, and the regulatory mechanisms within the cellular environment. He next deals with the flow of substances and particles through the channels of this machinery and with the question of how chemical energy becomes free and available in the form of ATP, enabling the occurrence of the energy-consuming reactions and physiological work of the cells, like movement, replication, and differentiation, with their complexity and high degree of organization. In this way the reader never sees the substances in isolation but alway as parts of a complete interacting system. The picture is admirably completed with a consideration of the origin and evolution of life.

The above patterns of thought and the extensive knowledge and teaching experience of the author combine to make this book unusually stimulating. The style is often rather stilted and apodictic but this does not detract from the work's excellent coverage of the topic and its didactic and esthetic qualities: figures, schemes, and underlinings break up the subject matter, clarifying it and making it easy to remember; the clear print and good layout make it a dependable and practical textbook.

Apart from the nowadays obligatory references (what student has ever used them?), each chapter contains a short summary of the subject matter, problems, and exercises. These are sometimes rather difficult, particularly since they are often not very clearly formulated. The appendix with the solutions, however, makes it possible to work them backwards. The interlinking of the chapters by cross references often leaves something to be desired, and a few cases of didactic license are superfluous. However, these are mere trifles compared with the overall impression of a thoroughly successful piece of work. It is a book which, both from the point of view of composition and layout, one would have liked to have had in one's own student days, or to have written oneself. All universities where students of medicine and biology receive a thorough training ought to have copies in their libraries.

L. Jaenicke [NB 925 IE]

Adsorption. Introduction to Physisorption and Chemisorption. By *G. Wedler*. Volume 9 of "Chemische Taschenbücher", edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie, Weinheim/Bergstr. 1970. 1st Edit., vii, 224 pp., 75 figures, 9 tables, paperback, DM 24.–.

This book, which is described as an introduction to adsorption, is intended less to give a theoretical and systematic survey of this field than to provide an experimentally oriented description of phenomena that occur during adsorption of gases on solid surfaces. Arranged according to methods of investigation, the book describes the effects occurring both in the adsorbent and in the adsorbate during adsorption and their measurement. Well-chosen examples of applications of these measurement techniques are used to show what information can be obtained from such investigations, and numerous references are given.

Since the majority of the methods discussed are "modern" techniques of surface investigation, this work constitutes a valuable addition to the existing textbooks dealing with this subject. However, there is no mention of methods like Auger spectroscopy and ellipsometry, and one wonders whether the author should not have striven for completeness of the experimental methods discussed to comply with the aim of the series "Chemische Taschenbücher", namely to supplement and enlarge upon the material contained in the basic textbooks.

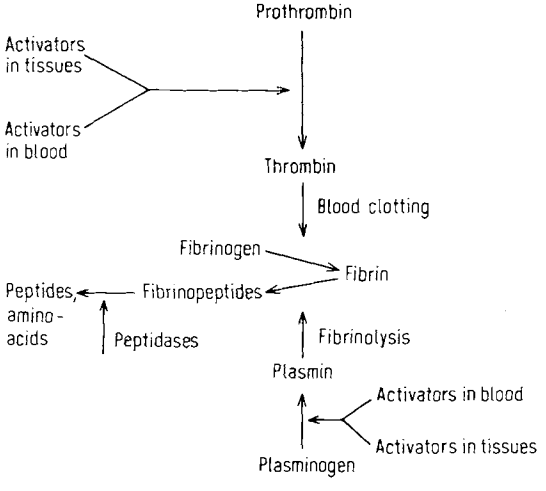
Blood Coagulation and Fibrinolysis



Norbert Heimburger and Heiner Trobisch[*]

As a result of advances in protein chemistry it is now widely accepted that blood coagulation proceeds via a series of reaction steps of the nature of enzyme-substrate reactions catalyzed by phospholipids. This also applies to the compensatory process of fibrinolysis. The factors taking part in both mechanisms as well as the inhibitors regulating the equilibrium have been shown to be proteins, some of them with a high carbohydrate content. Modern diagnostic methods and therapy are based on this knowledge.

1. Introduction

One of the most important physiological properties of blood is its ability to coagulate, and even to become completely solid and liquid in turn. In principle, both phenomena are manifestations of enzymatic reactions of a plasma protein, fibrinogen. The conversion of the soluble fibrinogen, present at a concentration of 0.2–0.4% in human plasma, into an insoluble, easily polymerizable derivative, fibrin, characterizes the process of blood clotting, while dissolution of the crosslinked fibrin marks the process of fibrinolysis. Coagulation and fibrinolysis succeed each other under physiological conditions. Such interplay guarantees that fibrin is produced when required for hemostasis and is degraded when it has fulfilled its biological function after the wound has healed. Hence, fibrinolysis can be considered as a further stage in the coagulation of blood.

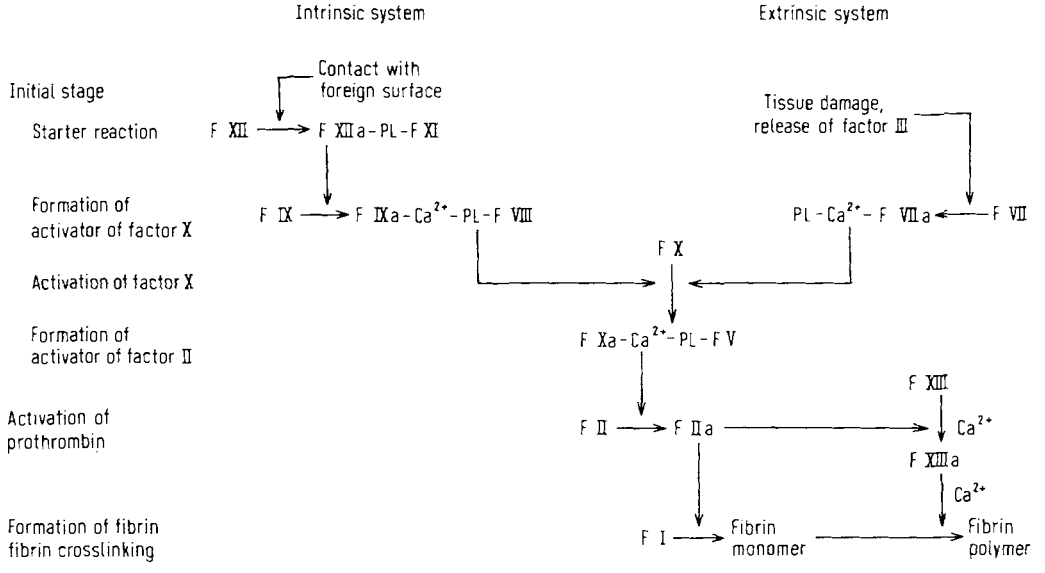
Coagulation and fibrinolysis are under enzymic control. Thus thrombin catalyzes the change of fibrinogen into fibrin and plasmin the hydrolysis of fibrin. Both enzymes, which are endopeptidases, possess no strict substrate specificity. The body is protected by a safety measure ensuring that under physiological conditions these enzymes circulate in the blood not in their activated form but as proenzymes. The activation of the proenzymes is also under enzymatic control. Thus some enzyme activators must first be generated from their precursors present in the blood. The factors required are often separated from the bloodstream by a cell or tissue barrier, which may also hold the activators back. Such an arrangement ensures that they are formed and released only when tissues are damaged or the surface of cells and especially of blood vessels is altered. This sequence of events guarantees that thrombin and plasmin are generated only locally and only in response to a real physiological need.

Scheme 1. Blood coagulation and fibrinolysis.

The reactions participating in blood clotting and fibrinolysis are very similar, although they exert opposite effects (Scheme 1). In each process the biological activity is associated with a proteolytic enzyme, thrombin or plasmin, which exists as inactive proenzyme in the blood and is activated by activators localized both in blood and in

[*] Dr. N. Heimburger and Dr. H. Trobisch
Behringwerke AG
D-355 Marburg/Lahn (Germany)

tissues. In a healthy organism clotting and fibrinolysis are in dynamic equilibrium. If the enzyme reactions overshoot in one or the other direction, the results may be fatal. Hemorrhage, thrombosis, and vascular disease can be the biological consequences, and arteriosclerosis may also ensue from a disturbance of this dynamic equilibrium[1].



Disturbances of the hemostatic equilibrium can nowadays be diagnosed and treated appropriately thanks to the knowledge gained from research on blood clotting. This means that the factors that determine the state of the coagulation and fibrinolysis system are known and can be measured.

2. Blood Clotting

As many as twelve factors present in the plasma and additional components derived from thrombocytes and cells are involved in the process of coagulation, which extends over several reaction steps. The plasma factors are predominantly proteins, some of which have enzymatic properties and which circulate in the form of inactive precursors in the blood; they can be characterized by techniques customary in protein chemistry, but only a few have so far been isolated in pure and biologically active states. The cellular factors active in the clotting process are phospholipids, a class of substances widely distributed as components of cell membranes. These lipids have been shown to catalyze important steps of enzyme activation during the process of clotting. This fact could explain why cellular disintegration inevitably leads to hypercoagulability.

The process of blood clotting can be initiated along two different pathways, both of which lead to the activation of factor X and hence to the formation of the prothrombin activator[7,8] (Scheme 2). The site of the stimulus governs the sequence of reaction steps, which lie either on an extrinsic[2] or an intrinsic[3] pathway. The intrinsic system is the more complicated; it involves several reaction steps, and since it incorporates several safety measures it tends to be relatively sluggish. In contrast, the extrinsic system reacts spontaneously. It can maintain the blood volume constant in an emergency, thus fulfilling what is probably its most important function. Platelets and vessels mutually assist the blood clotting system: a traumatic stimulus produces arterial contraction; an annular layer of muscle in the arterial wall regulates vascular tone; vaso-active peptides and biogenic amines affect muscular tension. These pharmacological substances, either vasoconstrictors or vasodilators, are produced by a kind of side reaction during coagulation and fibrinolysis.

A damaged vessel whose surface is foreign to the blood activates the intrinsic clotting mechanism. This applies, in particular, to collagen, which forms the supporting matrix of blood vessels, for blood platelets adhere to the collagen fibers, form aggregates on the unphysiological surface, and fuse into a viscous, white plug that effects a preliminary, mechanical closure of the wound[4,5]. The thrombocytes release their ADP which acts directly on the platelet membranes and catalyzes aggregation[6].

Scheme 2. Clotting mechanism (schematic; see also Table 1). PL = phospholipid.

During this viscous metamorphosis intracellular coagulant substances are released among which platelet factor 3, a phospholipid, and antiheparin, platelet factor 4, are the most important[6].

Table 1. Factors participating in the clotting process. They have been numbered with Roman numerals in the order of their discovery by a decision of the International Committee on Nomenclature. F IV is Ca^{2+}, F VI is not an independent factor but is probably identical with F V. Activated factors indicated by "a".

Factor	Synonyms	Source of preparation	Electrophoretic mobility/ Molecular weight	Function and special properties	Plasma concentration	Site of formation
I	Fibrinogen	Human plasma	β_2-Globulin 360000 (φpeak)	β_2-Glycoprotein, split by F IIa at two specific arginyl sequences to give fibrin monomers	200-400 mg/ 100 ml	Liver
II	Prothrombin	Human plasma	α_2-Globulin 52000	Proesterase activated by F Xa to an endopeptidase which is relatively fibrinogen-specific [32]	10-15 mg/ 100 ml	Liver, dependent on vitamin K [35, 36]
IIa	Thrombin		34000 [55]			
III	Thromboplastin, thrombokinase	Human and animal organs, preferably lung and brain.	Up to 3×10^6	Tissue factor, released on injury together with phospholipids [29, 30]	Normally not present in plasma	Cells
IV				Ca^{2+}		
V	Accelerin, accelerator globulin, labile factor	Bovine plasma [54]	β-Globulin Unknown	Very sensitive protein, stabilized by Ca^{2+}. Catalyzes in conjunction with phospholipids and Ca^{2+} the activation of prothrombin by F Xa [42, 43, 54]	Unknown	Liver?
VII	Proconvertin	Bovine plasma [31]	β-Globulin [31] 63000	Proenzyme, activation by contact with cell fragments; cofactor of F III to form activator of F X [31]	Unknown	Liver, dependent on vitamin K [31]
VIIa	Convertin		48000 [31]			
VIII	Antihemophilic globulin A, antihemophilic factor	Human, bovine, porcine, and rabbit plasma	β_2-Globulin [23] Unknown	No proof of enzyme character, stabilized by Ca^{2+}, substrate of F IXa [24]	Unknown	Spleen, RES [a]
IX	Christmas factor, antihemophilic globulin B	Human and bovine plasma	β_2-Globulin Unknown		Unknown	Liver, dependent on vitamin K
IXa			Unknown	Present in a complex with F VIII, Ca^{2+}, and phospholipids to form activator of F X [21]		
X	Stuart-Prower factor	Bovine plasma [32]	α_1-Globulin 50000	Proesterase, converted by endogenously or exogenously formed activators to arginine esterase [9, 32]	10 mg/100 ml	Liver, dependent on vitamin K
Xa			34000 [32]			
XI	Plasma thromboplastin antecedent	Not yet isolated	β_2-Globulin Unknown	Substrate of F XIIa; both form a complex with phospholipids catalyzing activation of F IX	Unknown	RES? [a]
XII	Hageman factor, contact factor [13, 14]	Bovine plasma [16]	β_2-Globulin [16]	Proesterase, activation on foreign surfaces to give arginine esterase (F XIIa) [16]	1 mg/100 ml [15]	RES? [a]
XIIa			*ca.* 240000 [14-16]			
XIII	Fibrin stabilizing factor, fibrinase	Human plasma	β_2-Globulin 290000	Transglutaminase, activated by thrombin; links fibrin monomers through peptide bonds into a firm network	1-2 mg/100 ml	Liver
XIIIa	Plasma transglutaminase					

[a] RES = reticuloendothelial system.

Table 1 lists the factors involved in the process of coagulation, showing their most important properties. Several of the factors are enzymes. Thrombin (F IIa) and the activated factors X and XII (Xa and XIIa) are esterases, and factor XIII is a transamidase in its activated form (XIIIa)[8]. The biochemical nature of most of the factors has not yet been clarified. There are indications that factors II, VII, IX, and X are related to one another. According to *Seegers*[9], they do not exist as individual proteins but are dissociation and association products of prothrombin (F II). Since clotting factors are particularly labile this question has not yet been finally answered; even the most modern techniques do not prevent denaturation and inactivation. The function of coagulant proteins naturally requires that they should be highly sensitive (see Section 2.1.1).

2.1. The Intrinsic Pathway

2.1.1. Initial Stage

In the starter reaction contact of blood with nonphysiological surfaces, such as skin, cellular debris, collagen fibers, and arteriosclerotic layers initiates the clotting process. At the same time, the Hageman factor (F XII), a proesterase, is changed into an active arginine esterase[10–17]. Other proteins acting as protective colloids pre-

vent an accidental activation of the Hageman factor in the blood. The technique used for enrichment and isolation makes use of the high affinity of the proenzyme for foreign surfaces[17]; however, the activated Hageman factor (F XIIa) obtained in this way is not stable indefinitely[18]. That is probably why the physicochemical properties of the Hageman factor are not yet fully known. A deficiency of factor XII does not apparently constitute a hemorrhagic disease, as may be seen from the clinical history of the first patient, by name of *Hageman*, with a hereditary deficiency of factor XII[22]. However, if factor XII is activated inside the body disseminated intravascular coagulation will occur, with fatal results. Since the Hageman factor also catalyzes the conversion of kallikreinogen into kallikrein, the kallikrein-kinin system (and indirectly also fibrinolysis) is activated at the same time as the intrinsic clotting mechanism[19, 20] (Scheme 4).

Factor XII once activated (F XIIa) forms an enzyme-substrate complex with factor XI in the presence of phospholipids; the starter reaction consists essentially in the formation of this complex, which then catalyzes the activation of factor IX, the most important component of the intrinsic system activating factor X[21].

The chemistry of factor XI is almost unknown: it has hitherto defied all attempts at isolation. However, its existence is demonstrated by a rare hereditary hemorrhagic disease caused by its deficiency in or absence from the blood.

When factor IX in its activated form (IXa) combines with another plasma protein, factor VIII, and with phospholipids in the presence of calcium ions, the complex thus formed constitutes the activator of factor X. No conclusive proof for this enzymatic step has yet been obtained because factor IX has not hitherto been isolated or characterized in any way.

Factor IX appears to possess neither protease nor esterase properties, because its action is not affected by diisopropyl fluorophosphonate to which esterases having serine in the active site are sensitive. Calcium ions catalyze the activation of factor IX, heparin blocks it. The synthesis of factor IX which takes place in the liver is dependent on vitamin K. A deficiency of factor IX which is inherited is responsible for hemophilia B, the second most frequent hemorrhagic disease.

Factor VIII, antihemophilic globulin A (AHG–A), is one of the best known clotting factors. Its inherited absence or deficiency is the cause of the most frequent familial hemorrhagic disease, *i.e.*, hemophilia A. The term "antihemophilic globulin A" derives from the fact that its administration represents the only effective treatment of hemophilia A. This globulin, which is probably synthesized in the spleen, belongs to the group of β_2-globulins of the plasma and has a relatively high molecular weight[23, 24].

It has not been possible to prepare AHG–A in a pure state, because it is very labile. Chelating agents inactivate it irreversibly by removing calcium ions which may stabilize AHG–A; alternatively, factor VIII may be a complex made up of several individual proteins or subunits. Neither theory has yet been proved. The most useful procedure for preparing therapeutically active concentrates is also the simplest, *i.e.* cryoprecipitation, where use is made of the differential solubilities of plasma proteins on freezing and thawing.

Activation of factor X is the first step in the cascade-like sequence of reactions common to the intrinsic and extrinsic mechanism of clotting and yet catalyzed by activators of different composition (Scheme 2). Enzymes catalyze the transformation of factor X to yield an arginine esterasé (F Xa) with a high affinity for calcium ions[28], which is evidently an important prerequisite for the formation of the prothrombin activator from factor Xa, calcium ions, phospholipids, and plasma factor V.

The intrinsic and extrinsic mechanisms converge at the point where the prothrombin activator is formed; details will therefore be discussed in the appropriate Section in order to facilitate an understanding of the subsequent activation of prothrombin.

2.2. The Extrinsic System

2.2.1. Initial Stage

When a wound is inflicted, blood will rush out of the injured capillary vessels into the surrounding tissue. Simultaneously substances differing in chemical nature and capable of promoting blood coagulation will be washed out of the damaged cells. Such substances are often still bound to cellular components; they are present in particularly large amounts in microsomes. This fraction of cell particles is called tissue thromboplastin or factor III[29, 30]; its release may be regarded as the starter reaction.

The interaction between tissue factor III and a plasma cofactor (F VII, proconvertin), which is carried by the blood to the wound, is the next step in the formation of the activator of factor X. The activation of factor VII to give F VIIa, which occurs on contact with factor III, is accompanied by a reduction of the molecular

weight[31], as investigations on isolated factors obtained from bovine plasma and serum have shown[31]. The difference in the molecular weights between the inactive and activated forms of F VII may indicate that activation is enzymatic, but no experimental evidence has yet been obtained[33,34].

An enzyme, factor Xa, arising on activation of factor X catalyzes the hydrolysis of *N*-substituted arginine esters[25-27]. It is liberated from the proesterase enzymatically; the reaction is catalyzed by trypsin or Russel viper venom *in vitro*. The activators formed either endogenously or exogenously catalyze this activation in a comparable manner *in vivo*[9].

Factor X was prepared in high purity for the first time from bovine plasma[32]. The isolation is carried out by adsorption onto $BaSO_4$ or $Ca_3(PO_4)_2$, fractional elution from these adsorbents, chromatography of the eluates on cellulose ion exchangers, and final separation on a molecular sieve. A uniform preparation is obtained under these conditions only if diisopropyl fluorophosphonate is added to the buffers[32]; this inhibitor prevents an enzymatic degradation and inactivation during the isolation. The molecular weight is decreased and the electrophoretic mobility altered as a result of activation[32]. Factor Xa is the enzymatic and also the most important component of the prothrombin activator complex.

The prothrombin activator catalyzes the transformation of prothrombin (F II) to thrombin (F IIa). Several components of the prothrombin activator take part in the reaction: factor Xa and factor V, which is a plasma globulin of uncertain nature, phospholipids, and calcium ions. The phospholipids provide the reaction surface on which the enzymatic conversion of prothrombin by factor Xa takes place. Since factor V determines the reaction rate, it is referred to as accelerator globulin. It is assumed that factors V and Xa are held inside the lipid micelles in such a way that both come into close contact with the prothrombin molecule[42-44], thus satisfying an essential condition for activation, *i.e.* a partial hydrolysis.

2.2.2. The Activation of Prothrombin

Although prothrombin (F II) is one of the trace proteins in human plasma, its presence in plasma can be detected by modern electrophoretic techniques as well as by biological tests.

When human plasma is subjected to electrophoresis in agarose gel containing fibrinogen, a turbidity arises in the α_2-globulin region if tissue thromboplastin (F III) and calcium ions are allowed to diffuse from a slot parallel to the direction of migration. The turbidity occurs in the electrophoretic position of prothrombin where it encounters the tissue thromboplastin diffusing in, so that thrombin could be formed. The turbidity in the plate is due to the formation of fibrin. This biological test can be combined with an immunological assay using a specific antiserum against prothrombin but not a multivalent antihuman serum. The concentration of prothrombin in plasma can be determined quantitatively in this manner. It is 10–15 mg/100 ml, and thus of the same order of magnitude as that of human plasminogen[37].

The synthesis of prothrombin (F II), which depends on vitamin K, occurs in the liver together with that of factors VII, IX, and X[35,36]. The prothrombin complex thus comprises four protein factors. Serious diseases of the liver upset the synthesis of these proteins. This also applies to vitamin K deficiencies caused by partial or complete elimination of the intestinal flora, *e.g.* in diarrhea, after treatment with non-absorbable antibiotics, or in cases of obstructive jaundice when fats are not readily reabsorbed and vitamin K is not taken up at all.

The dependence of the synthesis of factors comprising the prothrombin complex on vitamin K is pharmacologically important because the dicoumarols and indandiones, being antagonists of vitamin K, can be employed successfully in the prophylaxis of thrombosis and the treatment of cardiac infarction[35,36]. Recent findings on the effects of these long-acting anticoagulants contradict the original idea of a total inhibition of synthesis. These drugs act not so much by affecting the rate of synthesis of the prothrombin complex as by inducing the formation of a biologically unusable prothrombin molecule which will react with the prothrombin activator but not give rise to any thrombin[35-38].

In principle, the same techniques are applied to the isolation of prothrombin as to the preparation of factor X. Since the two proteins have such similar properties, they can be separated only with difficulty even when using the most varied methods of fractionation. It has not been possible to obtain a uniform preparation satisfying all purity criteria of proteins, because autocatalytic inactivation cannot be prevented entirely[39-41].

Prothrombin, which has a molecular weight of 52000, breaks up during activation into at least three components, one of which is identical with thrombin (mol. wt. = 34000)[25-27].

The prothrombin activator, a complex of phospholipids with factors Xa and V and with calcium ions, catalyzes the transformation of prothrombin to thrombin; the reaction appears to be a specific proteolytic hydrolysis, which is also catalyzed by trypsin and which proceeds autocatalytically in a 25% solution of sodium citrate[9]. Factor Xa on its own catalyzes the reaction only inadequately, although it cleaves arginine esters[32]. The reaction proceeds very sluggishly in a purified system containing prothrombin, but once factor V, phospholipids, and calcium ions are added, the rate of the reaction increases 1000-fold without simultaneous enhancement of ester hydrolysis. This result shows that factor V ac-

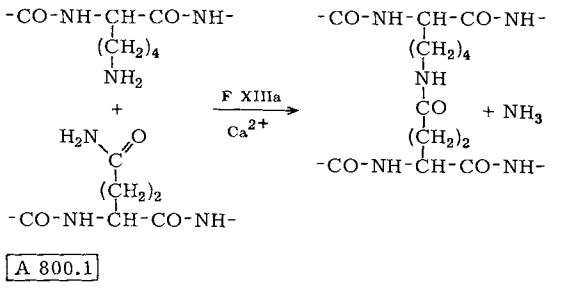
celerates the activation of prothrombin specifically, but only in a medium containing phospholipids. For this reason it is assumed that the activation of prothrombin takes place on the surface of the lipid micelles[42–44]. Such a concept would also explain the effect of prolonged-action anticoagulants on the organism: competitive blocking of the complex of factors Xa and V and of lipid (prothrombin activator) by pathologically modified prothrombin greatly reduces the rate of reaction[35].



Thrombin (F IIa) is a highly specific protease whose most important function is to catalyze the coagulation of fibrinogen. However, thrombin loses this property progressively from the moment of its formation while retaining its ability to hydrolyze esters for a relatively long time[118]. An acetyl derivative of thrombin has been described which, though not catalyzing coagulation, cleaves synthetic esters as well as thrombin (thrombin-E)[45].

Prothrombin and factor X have much in common: the site of formation, the methods of isolation, and properties such as their enzymatic nature. These facts may justify the notion that factor X is a subunit of prothrombin from which it is generated together with thrombin or as a by-product, according to the prevailing conditions[9].

2.2.3. Formation and Crosslinking of Fibrin

The transformation of fibrinogen (F I) into fibrin monomers and their subsequent crosslinking mark the last stage of the clotting process. Both reactions are catalyzed by enzymes, *i.e.* thrombin (F IIa) and factor XIIIa, a transglutaminase.

First of all thrombin removes two relatively acidic peptides, referred to as fibrinopeptides A and B, from fibrinogen, thus generating fibrin monomers which in turn polymerize into long strands with the diameter of one fibrinogen molecule. Fibrin filaments are formed by lateral aggregation of double strands of fibrin polymers[46]. A freshly formed fibrin network is not held together by covalent bonds but is stabilized by hydrogen bonds and hydrophobic forces. Hence it is soluble in denaturing agents. Covalent crosslinking is effected by the plasma transglutaminase (F XIIIa) which thrombin sets free from factor XIII in the presence of calcium ions (see Scheme 2). The ε-amino groups of lysine and the γ-glutaminyl groups are then linked *via* amide bonds, mainly between the fibrin monomers of a double strand[47–49, 51] (Fig. 1).

A 800.1

Fig. 1. Reaction mechanism of plasma transglutaminase (factor XIIIa).

This covalent crosslinking completes the clotting process. Fibroblasts enter the clot, where factor XIIIa promotes their growth[50], and synthesize collagen which increasingly replaces fibrin; the latter is now no longer required and will be degraded. The healing of a wound has entered its final stage[52, 53].

3. Fibrinolysis

The fibrinolytic pathway is simpler and more comprehensible than the clotting pathway: the plasminogen activators are available directly and do not have to be first formed from a series of plasma factors with participation of cellular components. All the factors involved in fibrinolysis are proteins which can be characterized by customary methods of protein chemistry.

3.1. Human Plasminogen (Proactivator Plasminogen[*]) and Plasmin

Human plasminogen differs in one important respect from that of many animals: the action of streptokinase, a metabolite of β-hemolytic streptococci, converts it into plasmin. This interaction yields an intermediate complex which has the same biological effect as intrinsic activators (see Section 3.2). Hence we also apply the term proactivator plasminogen (PP) to human plasminogen[56].

Plasmin is the predominant protease circulating as an inactive precursor in blood. The concentration of the proenzyme is 15–20 mg/100 ml human plasma[57]. Since human plasma contains 7–8g of protein/100 ml isolation of the proenzyme therefore represents a 350-fold enrich-

ment. Starting material for the preparation from human plasma is Cohn fraction III which is obtained by stepwise precipitation with alcohol; it may be extracted either with mineral acids[58] or with buffers containing lysine and ε-aminocaproic acid[59].

These amino acids are then also used for elution from ion exchange columns[60].

These basic amino acids, which enhance the solubility of human plasminogen but simultaneously inhibit activation, probably form salt linkages with the plasminogen molecule[56]. Use of buffers containing these amino acids in support media for electrophoresis has proved useful since many plasminogen preparations are poorly soluble under physiological conditions.

The sedimentation coefficient of highly purified human plasminogen measured in the gravitational field of the ultracentrifuge is $S_{20,w}=4.1$. A molecular weight approaching 90000 may be calculated on the basis of a diffusion coefficient of $D_{20,w} = 3.96$ and a partial specific volume of 0.72. In an electric field human plasminogen migrates uniformly, with a mobility corresponding to that of the β-globulins of human plasma. Human plasminogen is detected and estimated quantitatively in plasma by immuno-electrophoresis and by use of a univalent antiserum.

Human plasminogen migrates in several bands under the conditions of polyacrylamide gel electrophoresis, in which proteins are separated according to their charge and molecular shape and size (Fig. 5). The reason for this can be sought in the slight differences existing in the charge or in the molecular size and shape, due possibly to structural changes in the molecule induced by pH shifts. It can be shown by reaction with the activators and with homologous antisera that all the bands have the same specificity. When an unstained pherogram of human plasminogen is covered by a thin agar film, an immune precipitate is formed if the antiserum is allowed to migrate against the components that have diffused from the polyacrylamide gel into the agar. This precipitate extends over the whole region in which the bands are observed. Human plasminogen bound to serum migrates to the same electrophoretic position when this technique is applied.

Human plasminogen is composed almost entirely of amino acids[61]; it contains only 1.4% of carbohydrate. The polypeptide chain is held together by 22 disulfide bridges; its N-terminal amino acid is lysine and the C-terminal one is asparagine[63].

There are two additional terminal groups in plasmin, the activated molecule: N-terminal valine and C-terminal arginine (Fig. 2). Interestingly, the activation of human plasminogen is characterized by cleavage of an arginine-valine bond but the two resulting peptide chains separate only after one of the 22 disulfide bridges has been reduced. Obviously, large peptides are not removed on activation. However, the shape of the molecule is changed: its sedimentation coefficient increases and the coefficient of friction decreases. The changes in these physical properties and the appearance of the two additional end groups appear to be largely independent of the mode of activation. This has been demonstrated for autocatalytically activated plasmin as well as for the following activators: pig-heart activator, urokinase, streptokinase, and trypsin.

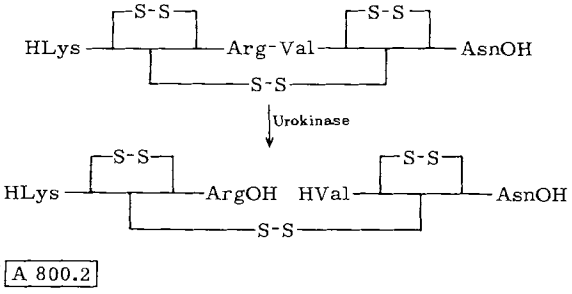

Fig. 2. Activation of plasminogen (top) by urokinase to form plasmin (bottom), schematic. Only three of the 22 disulfide bridges present are shown [63].

Since plasmin is an endopeptidase, its activity may be determined by measuring the rate of hydrolysis of fibrin, casein, or synthetic esters of lysine or arginine. However, plasmin catalyzes the hydrolysis not only of fibrin but also of other plasma proteins including certain clotting factors such as fibrinogen (Scheme 4). This reaction is of particular physiological importance because it can account for a pathological increase in fibrinolysis.

3.2. Activation of the Fibrinolytic System

The fibrinolytic system can be activated by three different mechanisms.

1) Direct conversion of the proenzyme by intrinsic activators and also by certain proteases.

2) An activator produced as an intermediate in a two-step reaction has the same biological properties as the intrinsic activators. Streptokinase is one of the relatively rare proteins having this action.

3) Some compounds of widely differing structures can have an indirect effect on the mechanism[62].

3.2.1. One-Step Activation

Natural activators are widely distributed throughout the body. As enzymes can be detected by their ability to hydrolyze synthetic esters of lysine and arginine but not high-molecular proteins such as fibrin[65]. Apart from this latter feature, their substrate specificity resembles that of trypsin which, too, is capable of activating human plasminogen in catalytic amounts. This fact is consistent with the finding that activation of the proenzyme is characterized by the hydrolysis of an arginine-valine linkage[64] (Fig. 2).

Different amounts of activator are present in various tissues[66]: Uterus, adrenals, lungs, and prostate are rich,

[66] *O. K. Albrechtsen*, Acta Endocrinol. *23*, 207 (1956).

and the testicles and spleen poor in the activator; the liver contains none at all. A high content of activator ensures that the blood maintains its fluidity. This explains why menstrual blood remains liquid or is reliquified.

Numerous problems are encountered in the isolation of pure tissue activators, because the active principle is often bound to structural elements. It can be extracted with concentrated thiocyanate solution but will reprecipitate in physiological saline. So far, two activators have been isolated from animal tissues, one from the heart muscle[67], the other from pig ovaries[65,68]; the latter has a molecular weight of 58000 and its properties as a protein and as an enzyme resemble those of urokinase obtained from human urine. Neither of the tissue activators is very soluble under physiological conditions.

Thrombocytes and erythrocytes are some of the blood corpuscles in which activators have been demonstrated; the active principle from erythrocytes, a pure erythrokinase, has already been obtained[69]. Certain body fluids and secretions are relatively rich in activators, *e. g.* urine (urokinase), amniotic fluid, and human milk, but activators are also found in lacrimatory fluid, saliva, and semen. In fact, the body makes them plentifully available wherever body fluids and secretions flow through capillaries liable to be endangered by occlusion.

One of the soluble activators is urokinase, which has been prepared in analytical purity from human urine. A volume of 2300 liters gave 29 mg of crystalline substance, the yield being 24%[70]. Urokinase, which is formed in kidney cells, has a molecular weight of 53000[71]. Like all intrinsic activators, it is an esterase that does not attack fibrin. A modified immunoelectrophoresis technique using an agar film containing fibrin as the supporting medium can demonstrate this very clearly[72]. The opalescent gel is a sensitive indicator for protease activity: clear areas appear on the agar plate wherever enzymes are located or are being generated following electrophoresis of enzyme or activator samples. Urokinase and other activators do not attack the fibrin film themselves. However, when human serum is permitted to diffuse at right angles to the migration of the activators in the fibrin film, an arc-like area of lysis is formed upon confluence as the result of proenzyme activation to plasmin. A result such as this illustrates the organization of the fibrinolytic system: neither activator nor human serum alone has fibrinolytic activity; the activators must be liberated before plasmin can be formed (Fig. 3).

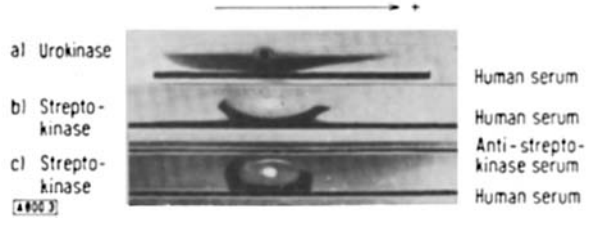

Fig. 3. Detection of plasminogen activators by electrophoresis on fibrin-agar plates and activation of the plasminogen system in human serum (a + b) with simultaneous immunological demonstration (c).

It should be mentioned again that human plasminogen changes to plasmin autocatalytically and that the activation of plasminogen can also be catalyzed by trypsin[73]. However, these reactions are of no biological interest.

3.2.2. Two-Step Activation

In addition to the intrinsic activators, which are esterases and convert plasminogen directly into plasmin, certain substances of biological origin are capable of changing proactivators into activators which in turn catalyze the formation of plasmin in a further reaction.

Although the animal organism makes little use of this mechanism, which should therefore be regarded as an exceptional case of plasminogen activation, it is of great interest therapeutically. A kinase having these properties has hitherto only been isolated from ascites cells[74]. The mode of action of streptokinase, one of the many metabolites of β-hemolytic streptococci has been more extensively investigated than that of this lysokinase. For several years streptokinase has been manufactured on an industrial scale by modern fermentation techniques for use in fibrinolytic therapy.

Streptokinase is a protein and has been characterized by the usual methods. It is homogeneous in an ultracentrifuge; it migrates uniformly like an α_2-globulin of human serum during free electrophoresis, immunoelectrophoresis, and polyacrylamide gel electrophoresis. The molecule (molecular weight = 47000) consists of a single peptide chain in which the amino acids are arranged without any intramolecular stabilization afforded by disulfide bridges, because cysteine is absent[57,75,76].

3.2.3. The Mode of Action of Streptokinase

According to the available evidence, streptokinase is not an enzyme: it is neither an esterase like the intrinsic activators nor a protease. Also, it is not affected by treatment with diisopropyl fluorophosphonate[77]. Hence its mode of action must differ from that of urokinase or other intrinsic activators. The fact that animal plasminogen, *e.g.* bovine plasminogen, is not activated by streptokinase agrees with the finding that it is largely specific for human plasminogen[78,79].

A definite amino-acid sequence and conformation of the plasminogen molecule therefore appear necessary for interaction with streptokinase. The activator is the initial product of the reaction between human plasminogen and streptokinase; plasmin is generated only during a second reaction. The activator, which has the physical characteristics of a complex between human plasminogen and

streptokinase, catalyzes the conversion of human and animal plasminogen in a manner comparable with natural activators[56,75] (Scheme 3). For this reason we have proposed the functional term "proactivator-plasminogen" to describe human plasminogen.

Scheme 3. Activation of animal and human plasminogen with endogenous activators and with streptokinase.

Measurement of the rate of hydrolysis of a fibrin clot, prepared by adding thrombin to a solution of fibrinogen, is the basis for assays of activator and plasmin. Clots of bovine fibrin are employed for the estimation of activator. Bovine plasminogen is adsorbed in relatively large quantities by fibrin prepared by the usual methods; activators but not streptokinase convert it into plasmin, as emphasized above. Plasmin, a proteolytic enzyme, is assayed by its hydrolysis of casein or of clots prepared from plasminogen-free fibrinogen. The dilution at which the clot is lyzed in the test solution within 15 min affords a measure of the activity of the activator or plasmin; its reciprocal value is used in the calculation.

The relative amounts of activator and plasmin formed by the catalytic action of streptokinase on human plasminogen can easily be appreciated[80]. Figure 4 is a plot of the results of a series of experiments showing how the activator and plasmin activities are affected by reaction of varying amounts of streptokinase (SK) with a constant amount of human plasminogen (PP). It can be seen that a relatively low proportion of streptokinase is sufficient for catalyzing a maximum formation of plasmin. It is important to realize that with increasing streptokinase concentrations the capacity of the activator increases to the same extent that the plasmin yield decreases. Quantitative stoichiometric evaluation of these results shows that the optimum for plasmin formation is at a molar ratio of plasminogen:

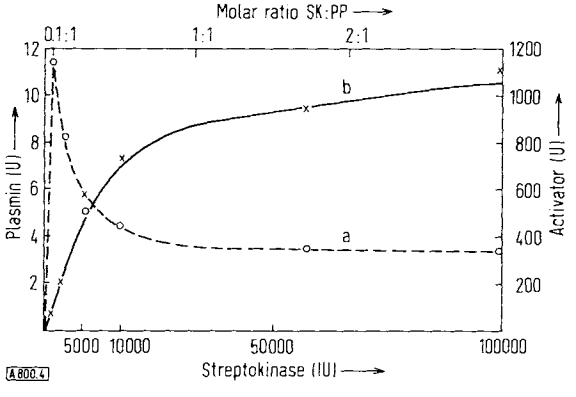

Fig. 4. The capacity of a constant quantity of human plasminogen for plasmin and activator formation as a function of the units of streptokinase used for activation. Determination on clots from pure bovine fibrinogen (a, plasmin) and plasminogen-containing bovine fibrinogen (b, activator). U = units.

streptokinase = 1:0.1, but the activator yield reaches its maximum only when the components are present in equimolar amounts. It might be added that the activator is only weakly proteolytic, in contrast to plasmin. The values obtained under the same conditions by measuring the hydrolysis of casein agree with the above figures[80]. On the basis of these findings we have developed a working hypothesis according to which plasmin loses its proteolytic activity but retains its ability to hydrolyze esters once it is bound to streptokinase to form the activator[57,81].

To prove this hypothesis it is essential that plasmin can be shown to combine with streptokinase in an activator complex. The technique of fibrin-agar electrophoresis enables us to demonstrate this clearly. Streptokinase is first subjected to electrophoresis on a fibrin-agar plate and plasmin that has been prepared by reacting streptokinase and human plasminogen at a molar ratio of 0.2:1 is then allowed to diffuse into the gel from a slit parallel to the direction of electrophoretic separation. An inhibition of the fibrinolytic activity of plasmin may be observed within the zone of migration of the streptokinase. If a solution of bovine serum, which does not react with streptokinase, is dropped onto this inhibition zone a clear halo indicating hydrolysis will appear. This result is not surprising, since the molar ratio of streptokinase to plasminogen reaches a value of 1 where plasmin (molar ratio of the components = 0.2:1) meets streptokinase. Here the conditions for activator formation are optimal, so that only residual proteolytic activity can be detected with casein or plasminogen-free bovine fibrinogen as the substrate (Fig. 4). Such activity cannot be ascribed to the activator with certainty because it is relatively labile and decomposes with the release of plasmin.

Plasmin and activator, which arise by the interaction between human plasminogen and streptokinase, can be

[80] *N. Heimburger* in: Sympos. d. Dtsch. Gesellsch. f. Angiologie, München. Schattauer-Verlag, Stuttgart 1967, p. 7.

[81] *N. Heimburger*, 16th Annual Sympos. on Blood. Detroit, Wayne State Univ., January 1968; Thrombos. Diathes. Haemorrh. *19*, 598 (1968).

characterized by the usual methods of protein chemistry. Polyacrylamide gel electrophoresis is an efficient tool to achieve a clear separation (Fig. 5).

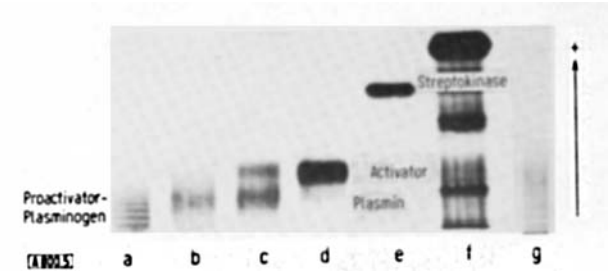

Fig. 5. Polyacrylamide gel electrophoresis. a, human plasminogen (proactivator plasminogen). b, human plasminogen activated by urokinase. c, human plasminogen activated by streptokinase; molar ratio 1 : 0.2. d, human plasminogen activated by streptokinase, molar ratio 1 : 1. e, streptokinase. f, human serum. g, human plasminogen activated by streptokinase, molar ratio 1 : 1, in 8 M urea.

It has been mentioned above that human plasminogen migrates in several bands on polyacrylamide gel electrophoresis although it behaves as a homogeneous protein on paper and immunoelectrophoresis and in the ultracentrifuge. In contrast, plasmin appears almost homogeneous when it has been prepared by activating human plasminogen with urokinase. The electrophoretic pattern of a reaction mixture of streptokinase and human plasminogen (molar ratio = 0.2:1) contains a component with the same mobility as well as a faster one. Since it is known that urokinase only catalyzes the formation of plasmin, the slower moving band can obviously be attributed to plasmin and the faster one to the activator, particularly since an activation mixture consisting of equimolar quantities of the components gives rise to only this one component, which migrates almost exactly between human plasminogen and streptokinase. Plasminogen as well as streptokinase can be demonstrated in this band by immunological methods. This means that the activator behaves like a complex of the two reactants[56]. The molecular weight calculated from sedimentation analysis corresponds to the sum of the molecular weights of plasminogen (or plasmin; cf. Fig. 2) and streptokinase[82].

The activator is a relatively labile intermediate product; for that reason traces of plasmin always appear, whatever its composition. Moreover, the complex remains stable for several days at 0 °C but disintegrates within a few hours at 37 °C[83]. The plasmin formed catalyzes the degradation of the activator by hydrolyzing streptokinase.

The complex is bound together only by physical forces; it disintegrates under conditions where hydrogen bonds are broken, *e. g.* in concentrated solutions of urea. During this dissociation a relatively large amount of plasmin is formed within a short time, which leads to total hydrolysis of streptokinase to form numerous by-products.

All the available evidence supports our concept of the mode of action of streptokinase: the intermediate product of the activation of human plasminogen is a complex held together by hydrogen bonds and hydrophobic forces. As far as its specificity is concerned, it may be compared with the intrinsic activators (Scheme 3); nevertheless, it is not stable but is catalytically decomposed by plasmin in a temperature-dependent reaction. Plasmin and streptokinase combine in the cold to form the activator. Human plasminogen that has previously been inactivated with diisopropyl fluorophosphonate will still bind streptokinase but is no longer biologically active. This indicates that the plasmin and the activator have the same active site, *i.e.* a reactive serine residue[84]. It follows that the activator is actually a modified plasmin which has lost its broad proteolytic action by association with streptokinase, but at the same time has acquired the specificity of intrinsic activators. How this complex is formed from the proenzyme is not yet clear, because streptokinase appears to possess no enzyme activity.

3.2.4. Indirect Activation

Fibrinolysis can be stimulated by many chemically defined substances, with often varying pharmacological efficacy. Such an effect is exhibited by heparin and its derivatives, a wide range of salicylic and nicotinic acid derivatives, hormones including their anabolic forms, and certain antidiabetic drugs[62]. All these have a mode of action about which little is known. They are regarded as indirect fibrinolytic agents, because some of them are not active *in vitro*. Heparin and its derivatives are used extensively in the prophylaxis and therapy of thromboembolic diseases; the nature of the fibrinolytic action of heparin has not yet been discovered. Derivatives of nicotinic acid act by mobilizing endogenous factors, and those of salicylic acid either activate plasminogen or block antiplasmins. The salicylic acid derivatives have widely varying structures and display activities measurable *in vitro*[57,85–87]. It may be assumed that metabolic stimulation and a shift in the metabolic equilibrium constitute the basis of the action of the hormones including their anabolites, and also of antidiabetic drugs[88–91].

4. Inhibitors of Blood Clotting and Fibrinolysis

Both blood clotting and fibrinolysis are under the control of inhibitors that are capable of blocking activation at various stages.

According to a no longer contemporary classification, human serum contains six antithrombins[116], all of them proteins (Table 2). Only two of them are thrombin in-

hibitors in the strictest sense. The functional relationships can be recognized from the nomenclature of the antithrombins.

Table 2. Antithrombins of human serum.

Antithrombin	Origin or action
I	Fibrin (adsorption effect)
II	Heparin cofactor
III	Progressive antithrombin [a]
IV	Reaction product of prothrombin activation
V	Pathological increase of immunoglobulins: antibody
VI	Degradation products of fibrinogen

[a] See also Table 3.

Fibrin has been called antithrombin I because it is capable of binding relatively large amounts of thrombin[92]. Degradation products arising from the action of plasmin on fibrin and fibrinogen are classified as antithrombin VI[93]. Their presence constitutes a diagnostic aid because they are found in blood in cases of pathologically raised fibrinolytic activity. These hydrolysis products act by inhibiting the polymerization of fibrin. It is of particular physiological interest that plasmin is able to split off an antithrombin substance from fibrin, for clotting and fibrinolysis are linked through this reaction in compensatory fashion. Antithrombin IV is set free during prothrombin activation[94] in proportions related to the quantity of thrombin generated. This neutralization of thrombin is based on a feedback mechanism. Antithrombin V[117] is a pathological factor probably identical with an antibody against thrombin.

Antithrombin III[95] and α_2-macroglobulin[96] are the most potent inhibitors found in blood; they are thrombin inhibitors in the strict sense. They were isolated only a few years ago and found to be glycoproteins (Table 3); in Table 2 they are still listed under a general name (antithrombin III or progressive antithrombin), because they could not previously be estimated separately. Together they are capable of inhibiting amounts of thrombin four to five times that present in the blood[97]. It may be recalled that these substances belong to the type of progressive inhibitors which do not neutralize thrombin immediately but progressively at a rate of inactivation that is constant during the first few minutes. Heparin accelerates the neutralization of thrombin by antithrombin very considerably by catalysis. In Table 2 this effect is listed as antithrombin II or heparin cofactor; originally it had been ascribed to another protein before we were able to show that antithrombin II and III are identical proteins[95].

The following proteinase inhibitors present in human serum, listed together with their physical and chemical properties in Table 3, have antiplasmin action: α_1-antitrypsin, antithrombin III, the $C\bar{1}$-inactivator, and α_2-macroglobulin. All these received their names from the most important or the first biological property discovered (Table 4).

Table 4. Enzymic specificity of inhibitors.

Inhibitors	Enzymes inhibited					
	trypsin	chymotrypsin	plasmin	thrombin	kallikrein	$C\bar{1}$-esterase
α_1-Antitrypsin	+	+	+	–	+	–
α_1-Antichymotrypsin	–	+	–	–	–	–

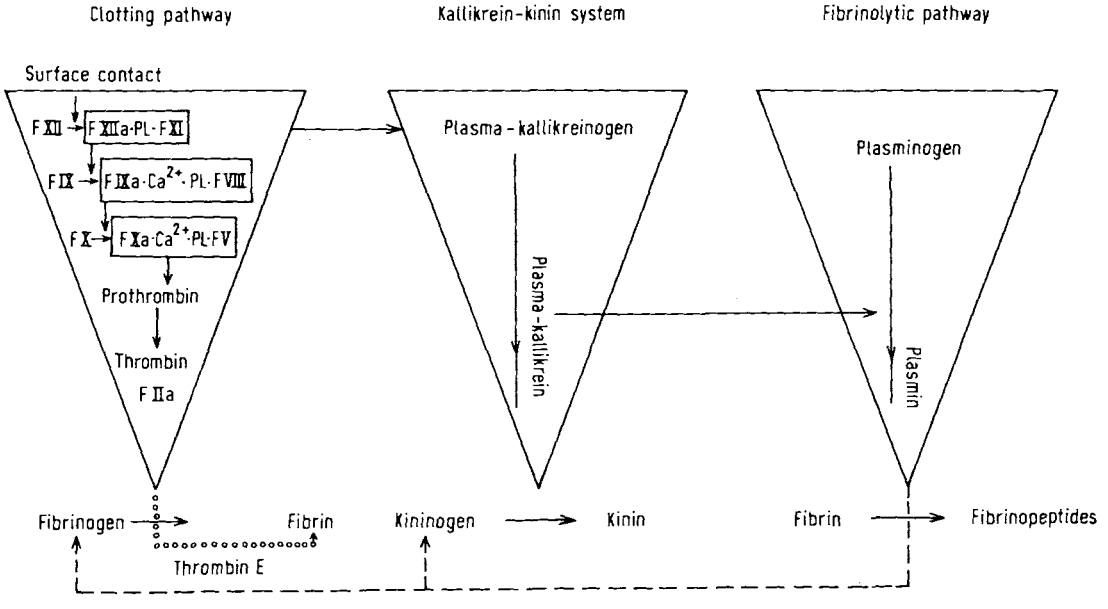
hibiting 30 times as much antiplasmin activity as potential plasmin activity.



Two of the plasmin inhibitors, α_2-macroglobulin and antithrombin III, also possess thrombin specificity, an observation which is of particular physiological interest. Hence these two proteins are able to control the equilibrium between clotting and fibrinolysis: the quantity expended during an increased release of thrombin is compensated by its not being available as an antiplasmin. The biological result is an increase in fibrinolysis.

The lack of specificity of proteinase inhibitors present in the blood is a phenomenon exploited by the body for the regulation of other proteolytically controlled reactions. These proteinases have many amino-acid sequences in common, including those at the active site, thus making them broadly specific[99]. This fact applies to trypsin, thrombin, chymotrypsin, and elastase; a phylogenetic relationship is obviously expressed. Therefore, it appears only logical that the reactions regulated proteolytically in the blood are also linked through these enzymes.

It can be seen in Scheme 4 that the Hageman factor (F XII) activates not only the coagulating but also the fibrinolytic mechanism[100,101] and the kallikrein-kinin system[102–106]. Neither thrombin nor plasmin are strictly specific enzymes: thrombin converts fibrin into fibrinogen and hydrolyzes fibrin as thrombin E[45,118]. Plasmin is known to hydrolyze fibrin and fibrinogen while at the same time setting free antithrombin VI which blocks the polymerization of fibrin. Finally, plasmin is capable of catalyzing the liberation of kinins from kininogen, an α_2-globulin of human plasma[107]. Here too the reaction product is biologically highly active, since it is a vasodilator, increases capillary permeability, and promotes the migration of leukocytes[108]. These events characteristic of inflammations demonstrate how a narrowly circumscribed biological phenomenon can express itself through many complicated chemical reactions. It should be mentioned that clotting factors I, V, and VIII are initially inactivated when fibrinolysis overshoots, but antiplasmins prevent the attack by plasmin on other plasma proteins or biological factors.

Inactivation and also generation (antithrombin VI) of clotting factors should be looked upon as biological measures designed to prevent reclotting after fibrinolysis. Finally, it should be stressed once more that the broad specificity of proteinases in blood is apparent in all these reactions.

Various drugs may intervene in the processes just described. Prothrombin synthesis may be influenced by vitamin K antagonists of the dicoumarol type, and complexing agents can prevent clotting because the calcium ion is the essential catalyst of the most important stages of the clotting mechanism.

5. Biochemical Aspects of Thrombolysis Therapy

Heparin is administered in the conventional treatment of thrombosis. It is known to accelerate catalytically the neutralization of thrombin by antithrombin III, and thus prevent reclotting following fibrinolysis. A lipoprotein lipase with the functional name of "clearing factor" is released following an injection of heparin[109–113]. The nature of the effect of heparin on the fibrinolytic mechanism is still unknown.

The fact that thrombosis is a vascular occlusion consisting predominantly of fibrin and therefore accessible to proteolysis suggests the following therapeutic possibilities: local application of enzymes to hydrolyze the clot; infusion therapy with enzymes; infusion therapy with fibrinolysis activators.

For local application the clot should be compact and accessible, so that the activator or enzyme solution can reach it through the catheter, thus by-passing inhibitors in the plasma. The reason why activators by themselves are so effective is the relatively large quantity of plasminogen that is adsorbed on the fibrin of the clot. Intrinsic substances such as plasmin are most suitable as enzymatic hydrolyzing agents, because immunologically foreign enzymes may stimulate the production of antibodies.

Treatment of thrombosis by injecting proteases at a distant site has little chance of success. The level of proteinase inhibitors in blood is too high, and it would not be sound biological sense to take a gamble. A generalized proteolysis would be the result, because proteinases are not sufficiently specific.

Infusion therapy with activators has been well tested clinically; in fact, the mechanism is found in the body. At first the obvious attempt was made to use endogenous urokinase for treatment, but experiments have shown that as much as 400 liters of urine yield only a single dose for treatment. Thus preparation of urokinase requires the manipulation of large volumes of urine which, owing to the limited stability of urokinase, must be processed fairly quickly and by applying complicated methods. These procedures make urokinase very costly and it is not yet available in amounts sufficient for therapy. In the meantime, the use of streptokinase has been developed. Now, ten years later, the necessary experimental and clinical experience is available for using streptokinase in treatment[114]: the indications and contraindications are known; with the exception of a few special cases, the dosage has been largely standardized and with it supervision of treatment.

Acute arterial and venous occlusions have proved to be sure and early indications. There are now pointers that so-called chronic arterial occlusions, several months old, can be treated by hydrolyzing the clot[115] (Fig. 6). Recent heart infarctions promise to become another important indication.

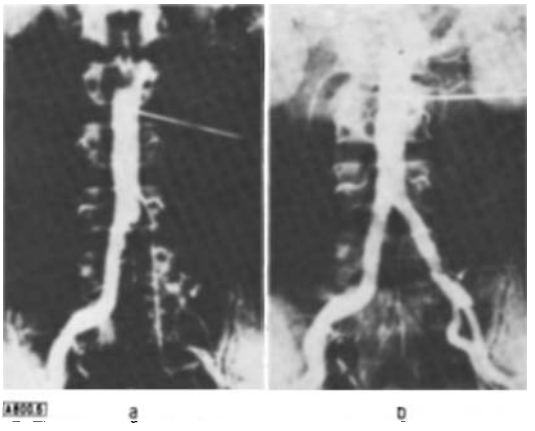

Fig. 6. Chronic obliteration of the common iliac artery and the femoral artery (left) a) before and b) after treatment with streptokinase (X-ray photograph by Dr. *M. Martin*, Aggertalklinik, Engelskirchen, Germany).

The dose of streptokinase is chosen so that the activator is the predominant product. Application is by infusion through continuous drip lasting several days. The advantage of this method of administration is that the hemostatic equilibrium remains largely undisturbed. A short period of plasminemia occurs at the beginning of the treatment, until the plasminogen and streptokinase are present in equimolar proportions. That is why a prolongation of the plasma thrombin time may be observed shortly after the onset of thrombolysis, which has been caused by the release by plasmin of antithrombin VI from fibrinogen. When the thrombin time becomes normal again after 4–6 h, the fibrinolysis is known to proceed smoothly.

Research on fibrinolytic agents tends toward finding oral prophylactics against thrombosis in the hope of bringing these endeavors to a successful conclusion.

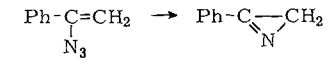
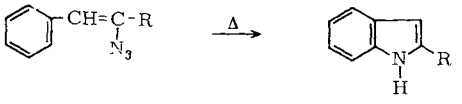
New Methods for the Synthesis of Vinyl Azides



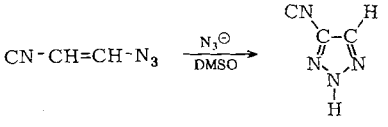
By Gerrit L'abbé and Alfred Hassner[*]

A critical survey of synthetic approaches to vinyl azides is presented, focusing especially on stereo- and regiochemical problems. The combined procedure of azidohalogenation of olefins followed by dehydrohalogenation, leads to regiospecific and, in the case of ionic additions, also to stereospecific formation of vinyl azides. Nucleophilic substitutions by azide ions on activated olefinic halides result in β-azidovinyl ketones, esters, nitriles, etc., and proceed predominantly with retention of configuration about the C=C bond. The known synthetic methods leading to α-azidovinyl ketones and esters give rise to the thermodynamically more stable trans-vinyl azides.

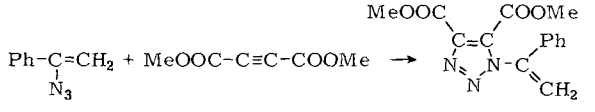


1. Introduction

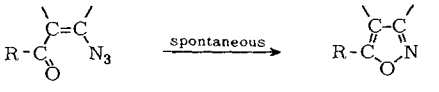
During the last few years unsaturated azides have acquired considerable importance as intermediates in organic syntheses and new methods for their preparation have been devised. It is remarkable that vinyl azide (CH_2=CHN_3), the simplest of this class of unsaturated azides, was first described in 1910[1], yet most of the knowledge concerning the synthesis and reactions of these compounds has been gained during the past five years. The reason for interest in this class of compounds is the high reactivity of the azide function which is susceptible to photolysis, pyrolysis, cycloadditions and attack by nucleophiles as well as by electrophiles[2]. The presence of a neighboring double bond accentuates the reactivity of the azide group and provides additional intramolecular pathways for reaction. A few examples are shown below.

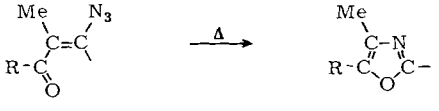


Among the recently studied transformations of vinyl azides are their pyrolysis[3] and photolysis[4] which serve as a general method of synthesis of azirines, a heretofore rare class of heterocycles.

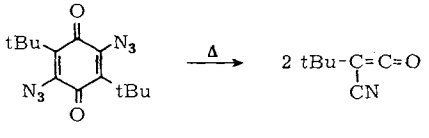


Pyrolysis of some vinyl azides has furnished indole derivatives[3b,5].





Examples of intramolecular[6] and of intermolecular[7] cycloadditions have been reported.



Formation of the heterocycles isoxazoles and oxazoles can likewise be accomplished *via* unsaturated azides[8].

The most recent synthetic application of vinyl azides is the synthesis of a reactive ketene in pure form[9].

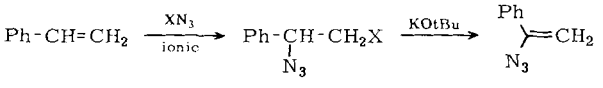
A few remarks about nomenclature are in place here. Though the term vinyl azide strictly applies to $CH_2=CHN_3$, it has been generally adopted, and hence is used in this review to denote any α,β-unsaturated azide. In addition to these two terms, that of enazide has been employed on occasion.

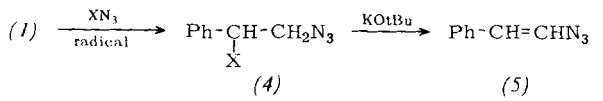
In this review we will discuss methods leading to the synthesis of vinyl azides. For convenience the topics have been divided according to the type of substituents present on the double bond.

Another aspect that will be emphasized is the stereochemistry and regiochemistry of these compounds. The *stereochemistry* refers to the configuration of substituents about the C=C bond, *i.e. cis* and *trans* compounds are to be differentiated.

trans



cis



Regiochemistry refers to directional preference in bond making or breaking[10] and in the case under study indicates the point of attachment of the azide function on the C=C bond, *i.e.* $R-CN_3=CH_2$ and $R-CH=CHN_3$ are *regioisomers.*

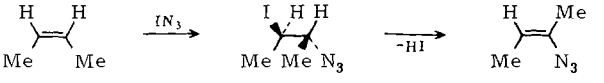
2. Simple Vinyl Azides[*]

A general synthetic method for vinyl azides, discovered by *Hassner et al.*[11], involves the addition of halogen azides to olefins, followed by treatment of the resulting β-haloalkyl azides with a base such as potassium *tert*-butoxide, sodium methoxide, or 1,4-diazabicyclo[2.2.2]-octane. The addition of halogen azides can occur by either an ionic or a free radical process and leads to regioisomeric vinyl azides as illustrated below in the case of styrene [*i.e. (1)* → *(2)* → *(3)* or *(1)* → *(4)* → *(5)*].

(1) *(2)* *(3)*

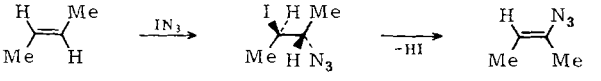
(4) *(5)*

An ionic pathway in the XN_3 addition is favored in a polar medium (*e.g.* acetonitrile, nitromethane, DMF) and in the presence of oxygen (a free radical inhibitor), whereas a free radical pathway is enhanced in a solvent of low polarity (*e.g.* pentane), in the presence of light, and in the absence of oxygen. Furthermore, it has been shown that the preference of the halogen azides for homolytic cleavage increases in the order: $IN_3 < BrN_3 < ClN_3$. Hence the conditions for an exclusive ionic or free radical reaction can be readily adjusted in the case of BrN_3, whereas IN_3 reacts preferentially by an ionic path and ClN_3 by attack of the N_3 radical on the double bond.



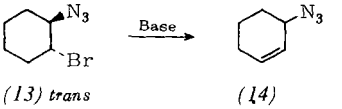
[*] By simple vinyl azides we designate those compounds lacking functional groups such as C=O, CN, F, *etc.*

2.1. Ionic Addition

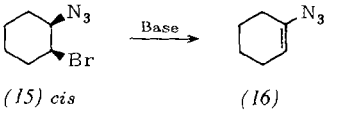


The ionic additions of IN_3 to olefins occur stereospecifically *anti*[*] *via* a cyclic halonium ion *(6)*, as was clearly shown by the exclusive formation of the *threo-(8)* and *erythro*-2-azido-3-iodobutane *(11)*, respectively, from *cis-(7)* and *trans*-2-butene *(10)*[11a].

(6)



(7) cis *(8) threo* *(9) trans*

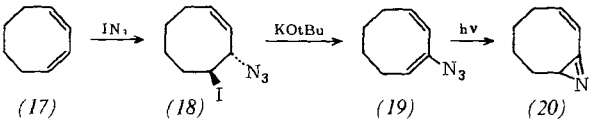


(10) trans *(11) erythro* *(12) cis*

cis- and *trans*-Stilbene gave similar results, cyclohexene was transformed into the *trans* adduct, and 2-cholestene afforded the *trans*-diaxial adduct. The *threo*- and *erythro*- adducts *(8)* and *(11)* are dehydrohalogenated in an *anti* fashion by potassium *tert*-butoxide to give the *trans*- and *cis*-vinyl azides *(9)* and *(12)*, respectively. In most cases the transition state for *anti*-dehydrohalogenation to the vinyl azide is of lower energy than that leading to the allyl azide; hence regiospecific elimination of HX to the vinyl azide is usually observed. An exception is provided by *trans*-halocycloalkyl azides (in rings with less than eight members) which lead to allyl azides, *i.e. (14)*. The *cis*-isomer *(15)* furnishes *(16)*. In eight-membered rings *syn* elimination to a vinyl azide occurs.

(13) trans *(14)*

(15) cis *(16)*



The regiochemistry of most ionic additions is controlled by electronic effects operating in the cyclic intermediate *(6)*. Thus 1,3-cyclooctadiene *(17)* adds IN_3 to give adduct *(18)* in 72% yield. Elimination of HI from *(18)* oc-

[*] The terms *cis* and *trans* are used for configurational assignments, and *syn* and *anti* for describing transformations during chemical processes.

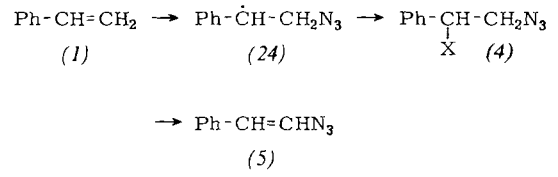
Chem. *33*, 2686 (1968); c) *A. Hassner* and *F. Boerwinkle*, J. Amer. Chem. Soc. *90*, 216 (1968); d) *A. Hassner* and *F. Boerwinkle*, Tetrahedron Lett. *1969*, 3309; e) *A. Hassner, F. P. Boerwinkle*, and *A. B. Levy*, J. Amer. Chem. Soc. *92*, 4879 (1970); f) *A. Hassner*, Accounts Chem. Res., in press.

curs regiospecifically and *syn*, yielding the *cis,cis*-azidocyclooctadiene *(19)*. Photolysis of *(19)* leads to the fused azirine *(20)*[4b].

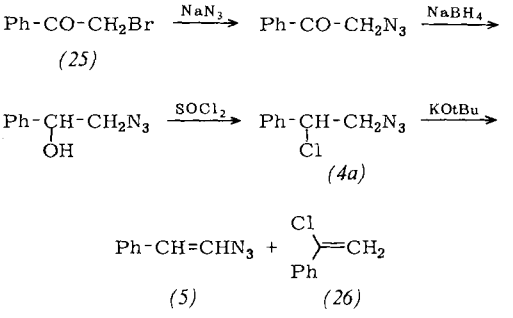
(17) *(18)* *(19)* *(20)*



An exception to the generally observed mode of addition (electronic control) is the IN_3 addition to 3,3-dimethyl-1-butene *(21)*, where a pure steric effect accounts for the exclusive formation of 1-azido-2-iodo-3,3-dimethylbutane *(22)* which, on treatment with potassium *tert*-butoxide, furnishes the 1-azide *(23)*[11b].

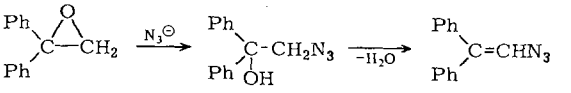
(21) *(22)* *(23)*

2.2. Radical Addition



The radical additions of halogen azides occur *via* a free radical intermediate such as *(24)* (for styrene) with the result that no stereospecific addition to *cis*- and *trans*-olefins can be expected.

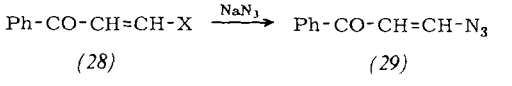
(1) *(24)* *(4)* *(5)*



Indeed, the addition of BrN_3 to 2-cholestene under free radical conditions led to a mixture of two 1:1 adducts, one *trans*-diaxial and the other *cis*. Another example is the ferric ion catalyzed radical addition of ClN_3 to cyclohexene for which a *trans : cis* ratio of 70/30 is reported[12].

Previous to the discovery of the free radical method, *trans*-β-azidostyrene *trans-(5)* was only available by a more expensive and time-consuming sequence starting from phenacyl bromide *(25)* with the formation of *(26)* as a side product[13].

(25) *(4a)* *(5)* *(26)*



Finally, another method that has been used in the synthesis of some vinyl azides involves the opening of an epoxide by NaN_3, followed by dehydration, as exemplified for 2-azido-1,1-diphenylethylene *(27)*[3b,14].

(27)

3. β-Azidovinyl Ketones, Esters, Nitriles, *etc.*

It is well known that simple vinyl halides are extremely resistant to nucleophilic substitution. However, when the vinylic halide is activated by an electron-withdrawing group in the β-position, halide substitution occurs readily[8,15]. Therefore, β-halovinyl ketones *(28)* are suitable starting materials for the synthesis of β-azidovinyl ketones *(29)*[16].

(28) *(29)*

X = Cl, Br, $\overset{\oplus}{N}H_3Cl^{\ominus}$, NO_2

X ≠ $SO_3^{\ominus}$, CN

Nesmeyanov and *Rybinskaya*[8,17] found that the substitution proceeds predominantly with retention of configuration about the CC double bond[18]. The stereochemical results are compatible with a conjugate addition of the azide ion to the X-carrying carbon of *(28)*, followed by a fast elimination of X^-. The two alternative possibilities — addition of HN_3 followed by elimination of HX or elimination of HX followed by addition of HN_3 — are excluded since the stereochemical results of the reaction would be independent of the configuration of the starting olefin.

It is noteworthy that the *cis*-β-azidovinyl ketone [*cis-(29)*] cannot be isolated in the free form from the reaction of the *cis*-β-halovinyl ketone [*cis-(28)*] and NaN_3, since it decomposes spontaneously to the isoxazole *(30)*. 1-Acetyl-2-chloro-1-cyclopentene *(31)*, which obviously has both substituents in the *cis*-position, is like-

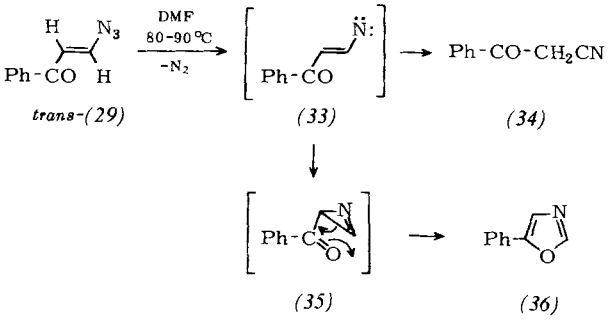
[18] The mechanism explaining retention of configuration in nucleophilic substitution on olefinic halides is discussed by: *E. L. Eliel,* "Stereochemistry of Carbon Compounds", McGraw-Hill Book Company, Inc. New York, 1962, p 369.

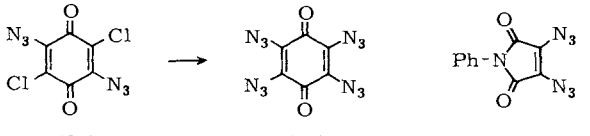
[19] *S. Maiorana,* Ann. Chim. (Rome) *56,* 1531 (1966).

wise converted by NaN_3 to the isoxazole *(32)*[19]. Whether isoxazole formation proceeds *via* a nitrene or by a concerted mechanism [as shown for *cis-(29)*] has not been established.



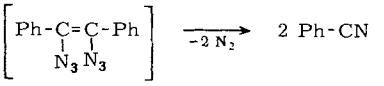
cis-(29) *(30)*

(31) *(32)*



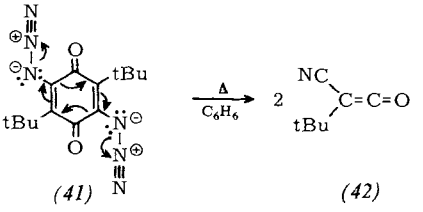
Unlike their *cis*-analogs, *trans*-β-azidovinyl ketones [*e.g. trans-(29)*] are stable under ordinary conditions and only decompose on heating into nitriles *(34)* and oxazoles *(36)*[20]. The reaction probably proceeds *via* a nitrene *(33)*, which is converted either to the nitrile *(34)* or *via* an azirine *(35)* to the oxazole *(36)*:

trans-(29) *(33)* *(34)* *(35)* *(36)*



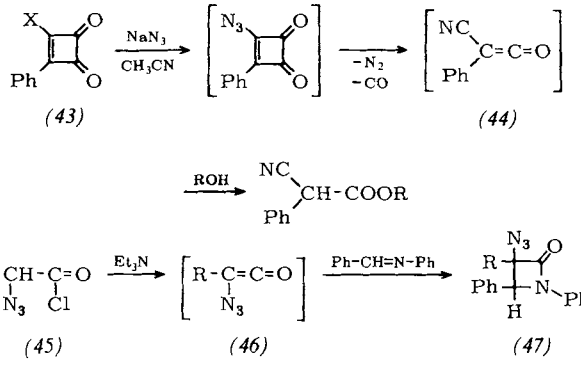
The formation of different products in the decomposition of *cis*- and *trans*-β-azidovinyl phenyl ketones *(29)* (isoxazoles *versus* nitriles and oxazoles) was used by *Nesmeyanov* and *Rybinskaya*[8, 17] as a criterion for elucidating the geometrical structure of the vinyl azides *(29)*.

Azidoquinones[21] [*e.g. (37)* and *(38)*] and azidomaleimides[22] [*e.g. (39)*] are structurally related to *trans*-azidovinyl ketones and are therefore readily prepared from the corresponding chloro derivatives.



(37) *(38)* *(39)*

Unlike their cyclic analogs, the open-chain vinyl α, β-bisazides, *e.g. (40)*, are unstable and decompose to nitriles[23].



(40)

2,5-Bisazido-3,6-di-*tert*-butyl-1,4-benzoquinone *(41)* undergoes a thermal fragmentation in refluxing benzene to give two molecules of the thermally stable, yet very reactive, *tert*-butyl cyanoketene *(42)*[9]. The decomposition reaction is comparable to the formation of phenyl cyanoketene *(44)* by reacting 3-halo-4-phenylcyclobutenedione *(43)* with NaN_3 in acetonitrile[24]. Ketene *(44)*, however, was only prepared *in situ* and was subsequently trapped by hydroxylic compounds. It is also noteworthy that azidoketenes *(46)* can be prepared *in situ* by dehydrohalogenation of *(45)* and can be trapped with Schiff bases to give azetidinones *(47)*[25].

(41) *(42)*

(43) *(44)* *(45)* *(46)* *(47)*

Modena and *Todesco*[26] reported that the reaction of both *cis*- and *trans*-β-chlorovinyl arylsulfones *(48)* with NaN_3 proceeds with retention of configuration and follows a second order rate law. Their kinetic results clearly indicate that the reaction rate is only slightly influenced by the geometrical structure of the starting olefin. Substituents in the phenyl ring, on the contrary, affect the rate profoundly and to the same extent for *cis*- as for *trans*-olefins. A plot of log k_2 *versus* σ gives two parallel lines with a ρ-value of +1.84, thereby demonstrating the accelerating effect of electron-withdrawing substituents.

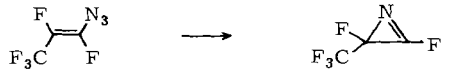
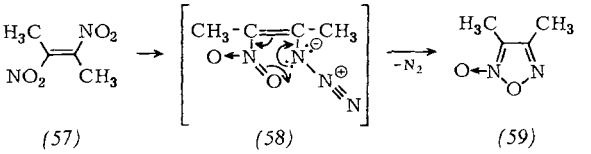
(48) (49)

Meek and *Fowler*[27] investigated the reaction of *cis*- and *trans*-1,2-ditosylethylene *(50)* with NaN_3 in several solvents, and their stereochemical findings [retention of configuration for *(50)*→*(51)*] agree with those of *Modena* and *Todesco*. In addition they found that *cis-(51)* is formed from *cis-(50)* in the early stage (3 min) of the reaction in DMSO, but it isomerizes into *trans-(51)* within 30 minutes. On standing for a longer time (24 h) in DMSO under the basic conditions (N_3^-), *trans-(51)* cyclizes to the triazole *(52)*. Evidently, the acidic hydrogen atom α to the sulfone in *trans-(51)* is removed under the basic reaction conditions, resulting in cyclization to the aromatic triazole *(52)*.



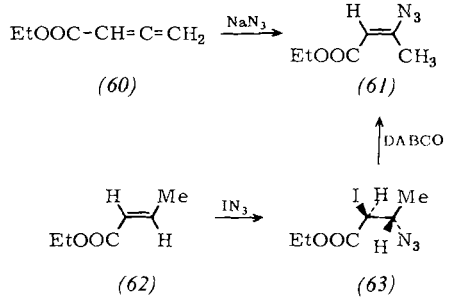
cis-(50) *cis-(51)* *trans-(51)* *(52)*

The generality of the synthetic method described in this section is further substantiated by the facile conversion of β-halovinyl nitriles[28] and fluorides[29] into the corresponding azides, *e.g. (53)* and *(55)*, at 0° C. Both *(53)* and *(55)* decompose at room temperature, the former yielding a ketenimine *(54)* and the latter an azirine *(56)*. The ketenimine was not isolated in the free form but its presence was inferred from trapping experiments.



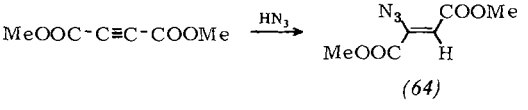
(53) *(54)*

R = H, Me, Ph HX = HCl, EtOH, $PhNH_2$



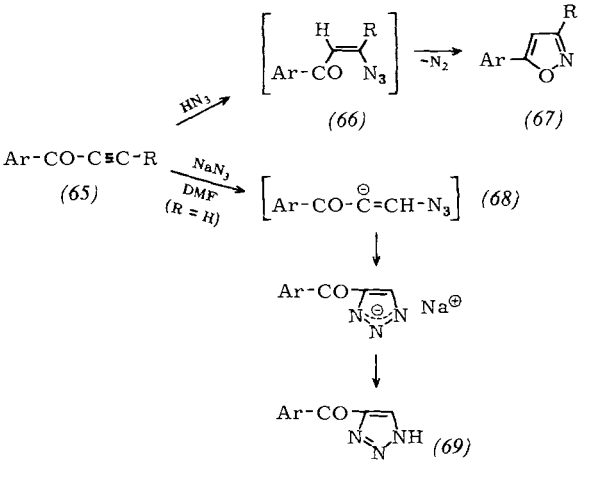
(55) *(56)*

When the β-position is activated by a nitro group as in the case of α-nitro-β-iodoolefins or α,β-dinitroolefins, the corresponding α-nitro-β-azidoolefins, *e.g. (58)*, are not isolated but instead give rise to furoxanes in high yields[30]. The conversion of *trans*-2,3-dinitro-2-butene *(57)* by NaN_3 into 3,4-dimethylfuroxane *(59)* is a typical example.



(57) *(58)* *(59)*

Recently, β-azidovinyl esters [*e.g. (61)*] and amides were prepared by treating allenic esters [*e.g. (60)*] and amides with an excess of NaN_3[31]. Although the stereochemistry of the reaction was not elucidated by the authors, structure *(61)* is suggested since the same product was obtained by *Hassner*'s method from ethyl crotonate *(62)*[11b] (DABCO = 1,4-diazabicyclo[2.2.2]octane).



(60) *(61)* *(62)* *(63)*

vic-Triazoles[32] and isoxazoles[33] normally result from the addition of HN_3 and NaN_3 to acetylenes, and only in a few cases[33,34], *e.g.* methyl azidofumarate *(64)*, have vinyl azides been obtained.

(64)

The isoxazoles *(67)* are obtained when acetylenic ketones *(65)* are treated with HN_3, and their formation is probably a result of decomposition of *cis*-β-azidovinyl

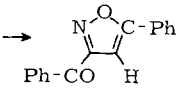
ketones *(66)*, produced initially. Interestingly, when the acetylenic ketones *(65)* are allowed to react with NaN_3 in an aprotonic solvent, such as DMF, no isoxazoles, but triazoles *(69)*, are obtained in high yields. This is logical if one considers the reaction as proceeding *via* the carbanionic intermediate *(68)* which, in the absence of a proton source, cyclizes to the stable aromatic triazole ring *(69)*. This result is similar to that discussed above for vinyl sulfones. Further support for this interpretation is provided by the fact that *trans-(29)* is also converted by NaN_3 in DMF *via (68)* into benzoyl-1,2,3-triazole *(69)*[19]

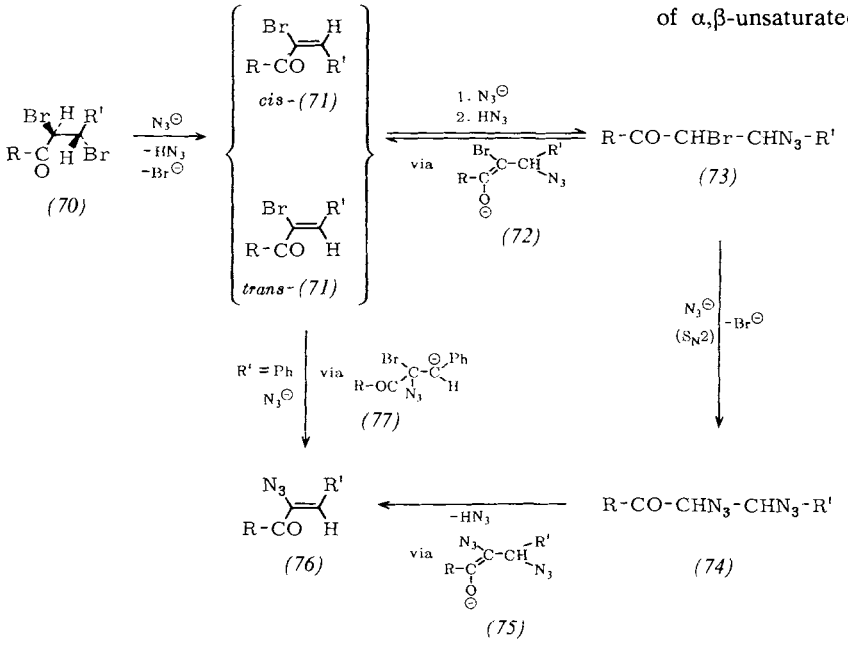
4. α-Azidovinyl Ketones and Esters



A general synthetic method for α-azidovinyl ketones *(76)* involves the reaction of α,β-dibromoketones *(70)* with two equivalents of NaN_3 in DMF at room temperature[35,36]. A detailed mechanistic study on three α, β-dibromoketones, using NMR techniques, revealed that the reaction proceeds through pathway *(70)→(71)→(73)→(74)→(76)*. Sodium azide in DMF eliminates HBr from *(70)* to give *cis*-bromovinyl ketone *(71)* which isomerizes more or less readily to the *trans*-isomer under the reaction conditions. Both geometrical isomers are converted to the bromo azide *(73)*, *via* intermediate *(72)*, by NaN_3 in the presence of the proton source HN_3. Compound *(73)* then undergoes further nucleophilic substitution by azide ion to give the unstable bis-azide *(74)*, which, on elimination of HN_3, yields the thermodynamically most stable *trans*-α-azidovinyl ketone *(76)*. It was further observed that when R' = Ph, the direct conversion of *(71)* to *(76)* *via* intermediate *(77)* competes with the sequence *(71)→(73)→(74)→(76)*. Both the activation of the α-carbon in *(71)* by the carbonyl group and the stabilization of the negative charge in *(77)* by the phenyl group provide the driving force of the competing reaction *(71)→(76)*.

From the mechanism outlined above, it is obvious that α-bromovinyl ketones *(71)* and the BrN_3 or IN_3 adducts of α,β-unsaturated ketones, *e.g. (73)*, are also starting materials for the synthesis of the α-azidovinyl ketones *(76)*[36]. All three synthetic methods afford *(76)* in high yields.

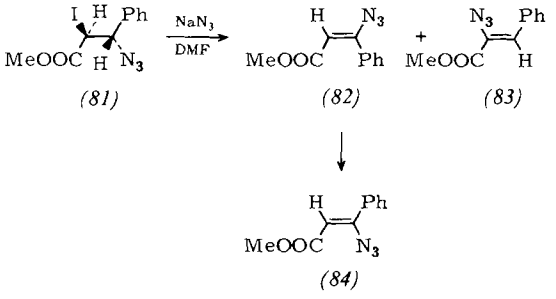
Under the same reaction conditions, *meso*-1,2-dibenzoyl-1,2-dibromoethane *(78)* gives 3-benzoyl-5-phenylisoxazole *(80)* exclusively[36a]. This product apparently results from decomposition of vinyl azide *(79)*, which has both the α-azido- and β-carbonyl groups in a *cis*-configuration.



(78) *(79)*

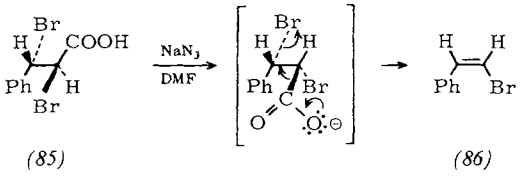
(80)

Unlike in the case of *(70)*, treatment of the dibromides of α,β-unsaturated esters (*e.g.* cinnamate dibromide) with NaN_3 gives a mixture of α- and β-azidovinyl esters[37]. Similar results are obtained with the corresponding iodine azide adducts[37]. Thus *(81)* reacts with one equivalent of NaN_3 in DMF to give, among other products (such as an azirine), both regioisomers *(82)* and



[35] a) *W. A. Kusmin* and *S. G. Friedmann*, Mem. Inst. Chem. Ukrain. Akad. Sci. *2*, 55 (1935); German Edit. *2*, 66 (1935); Chem. Abstr. *31*, 4660[5] (1937); b) *W. A. Kusmin* and *N. J. Semliansky*, *ibid. 2*, 183, 191 (1935); German Edit. *2*, 190, 194 (1935); Chem. Abstr. *31*, 3467[1] (1937); c) *W. A. Kusmin* and *N. J. Semliansky*, *ibid. 3*, 61 (1936); Chem. Abstr. *31*, 4978[9] (1937); d) *S. G. Friedmann*, *ibid. 3*, 587 (1936); Chem. Abstr. *31*, 7861[4] (1937).

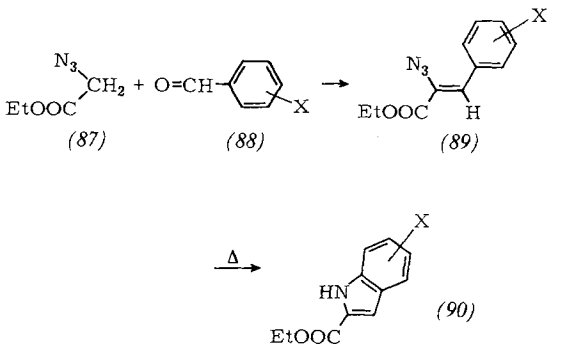
[36] a) *G. L'abbé*, *M. J. Miller*, and *A. Hassner*, J. Amer. Chem. Soc. in press; b) *G. L'abbé* and *A. Hassner*, J. Org. Chem. in press.



[37] *G. L'abbé*, *M. J. Miller*, and *A. Hassner*, Chem. and Ind. *1970*, 1321.

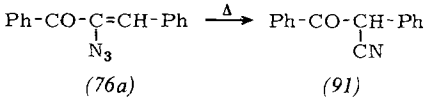
(83). Typically, when the reaction is carried out with an excess of NaN_3, *(82)* is formed first but isomerizes in the presence of NaN_3 to the more stable *trans* isomer *(84)*. Dehydroiodination of *(81)* with DABCO leads to the β-azidovinyl ester *(82)* exclusively[11b].

(81) *(82)* *(83)* *(84)*



On treatment of the *erythro*-dibromide of cinnamic acid *(85)* with NaN_3, CO_2 evolution occurs and *cis*-β-bromostyrene *(86)* is obtained[37,38].

(85) *(86)*



The examples cited above clearly indicate that the three pathways leading to α-azidovinyl ketones in high yields are not convenient for the synthesis of α-azidovinyl esters.

A series of α-azidocinnamates *(89)* were prepared recently[39] by the condensation of azidoacetate *(87)* with substituted benzaldehydes *(88)* in the presence of sodium ethoxide. In order to minimize the well known base-induced decomposition of the α-azidoester *(87)*[40], the reactions must be carried out under well defined conditions of temperature and time. Although the *trans*-configuration of *(89)* is to be expected on thermodynamic grounds, the NMR method proposed for the configurational assignment in these systems has been criticized[36a].

(87) *(88)* *(89)* *(90)*

The use of azidoacetophenone instead of *(87)* led to the synthesis of α-azidochalcones[41] for which a *trans* structure [*(76)*, R = phenyl, R′ = aryl] was proven in other work[36a]. In contrast to the α-azidocinnamates *(89)* which decompose thermally to indoles *(90)*[5b], the α-azidochalcones *(76)* rearrange on thermolysis to α-keto phenylacetonitriles *(91)*[42].

Influence of Ligands on the Activity and Specificity of Soluble Transition Metal Catalysts

By G. Henrici-Olivé and S. Olivé[*]

Dedicated to Professor G. V. Schulz on the occasion of his 65th birthday

The reaction of a covalently σ-bonded ligand (alkyl group, hydrogen) with a molecule (olefin, CO) attached to the transition metal by a coordinate bond is the essence of many catalytic processes. The influence of the other ligands in the complex on this reaction is discussed in the present article. Various ways in which the ligands can act, e.g. by electronic effects via the σ and π electron systems of the complex and by steric effects, are first described separately and then illustrated by examples.

1. Introduction

The expression "catalyst tailoring" is commonly used for the processes and efforts whose results and future prospects are to be discussed here.

What is catalyst tailoring? Over the past few decades, soluble transition metal complexes have become extremely important as catalysts for a wide range of reactions. The starting point of this development was probably the discovery by *O. Roelen*[1] in 1938 of the reaction of olefins with carbon monoxide and hydrogen to form aldehydes (the "oxo process" or hydroformylation), which takes place on a soluble cobalt carbonyl complex. Many reactions were subsequently discovered, some of the most important of which are the oxidation of ethylene to acetaldehyde on a palladium complex ("Wacker process")[2], the specific hydrogenation of double bonds on a series of transition metal compounds[3], hydroformylation on rhodium complexes[4], the cyclooligomerization of acetylene[5] and conjugated diolefins[6] on nickel, and the polymerization[7] and oligomerization[8] of olefins on soluble Ziegler-Natta catalysts.

The species that effected the catalysis were at first mostly definite complexes, *e. g. Vaska's*[9] complex $IrCl(CO)[(C_6H_5)_3P]_2$ as a hydrogenation catalyst, *Wilkinson's*[4] $RhH(CO)[(C_6H_5)_3P]_3$ in hydroformylation, and the system $TiCl_4/(CH_3)_2AlCl$ for the oligomerization of ethylene[8]. However, two fields of chemistry that also developed very rapidly at the same time led homogeneous catalysis in a new and extremly interesting direction. On the one hand, transition metals attracted growing interest in preparative coordination chemistry and many new compounds were discovered *(Wilkinson, Chatt, E. O. Fischer,* to name only a few schools), while on the other, important advances in theoretical inorganic chemistry (particularly the ligand field theory) influenced the thinking of catalysis chemists. The result was that more attention was devoted to the significance and the effects of ligands in the transition metal complex. Consequently, the ligands of a complex that was recognized as a catalyst were systematically modified to bring about specific changes both in the rate of the catalyzed reaction and in the final product, in an effort to understand which physical magnitudes (*e.g.* electron density on the metal, orbital energies, steric hindrance) are involved.

We are obviously still at a very early stage in these developments, and we are far from being able to design a homogeneous catalyst in advance for a given purpose (*e.g.* for the addition of molecular nitrogen to olefins). This is a long-term objective, which probably cannot be achieved without a precise knowledge of the kinetic and thermodynamic principles underlying every step of the catalytic reactions. Though research on these principles is being carried out in various places[10–13], procedures in practical catalysis are still semiempirical at best. It nevertheless seems a convenient time to review what has been achieved, one very important reason for this being in order to attract more interest in this young branch of catalysis chemistry, which should have an important future both in scientific and in industrial research.

2. Some Concepts in Homogeneous Catalysis

In most of the known cases of homogeneous catalysis on transition metal complexes, the catalytic reaction takes place between a covalently σ-bonded ligand R (alkyl group, hydrogen) and a substrate molecule (olefin, CO) coordinated to the metal M, the substrate molecule being inserted between the metal and R by a four-center reaction (concerted reaction). This is shown schematically for an olefin in formula (1).

(1)

(L_x) in this formula stands for all the other ligands in the complex. The same process may then be repeated (polymerization, see Sections 4.2 and 4.3), or the catalyst may be restored to its original state by hydrogenolysis or homolysis (cf. Section 4.1). The transition metal itself, the stability of the M–R and M-olefin bonds, and the possibility of influencing these bonds through the other ligands L are therefore of the utmost importance.

2.1. The Transition Metal

Transition metals are characterized in that the $(n-1)$d orbitals have energies similar to those of the ns and np orbitals of the valence shell, and so participate in bond formation. The special symmetry of these d orbitals is responsible for a particular type of bond between the transition metal and the ligand, which does not occur with other metals, and which therefore raises the chemistry of transition metals out of the plane of metal chemistry in general. This is the retrodative π bond (back donation). For symmetry reasons, some of the five d orbitals cannot participate in the normal σ bonds between the metal and the ligands. In an octahedral complex, for example, the orbitals d_{z^2} and $d_{x^2-y^2}$ point in the directions of the six ligands, but the "loops" of maximum electron density in the d_{xy}, d_{xz}, and d_{yz} orbitals lie between these directions. However, these orbitals can overlap with empty antibonding orbitals of suitable symmetry, such as occur in the most important coordinated ligands in catalytically active transition metal complexes, *e. g.* in olefins and CO. This may be illustrated by the well-known Dewar-Chatt-Duncanson model of the metal-olefin bond (Fig. 1).

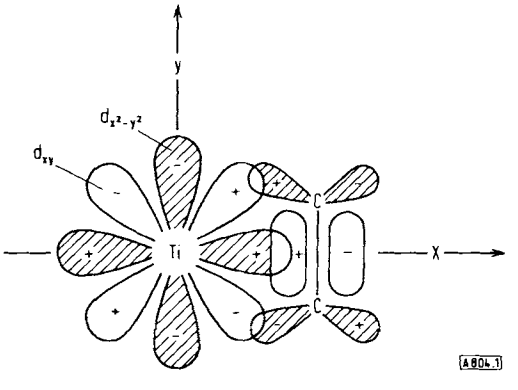

Fig. 1. Coordination of an olefin (ethylene) to a transition metal (titanium); schematic representation of the relevant orbitals in the x–y plane of an octahedral complex. Shaded: empty (acceptor) orbitals.

The bonding π orbital of the olefin, which contains two electrons, has σ symmetry[*] with respect to the axis of the metal olefin bond. It can overlap with an empty dσ orbital of the metal, with formation of a coordinate σ bond. The empty antibonding π* orbital of the olefin has π symmetry[*] with respect to the axis of the bond. If the dπ orbital of the metal that lies in the same plane is occupied, a π bond is also formed. The metal and the olefin can thus form a sort of double bond between them. *Via* the σ bond electron density passes from the olefin to the metal, while *via* the π bond electron density passes from the metal into the antibonding π* orbital of the olefin. Both effects lead to destabilization of the double bond of the olefin, and the distance between the two carbon atoms is increased. This is equivalent to activation of the molecule. The relevance to catalysis is obvious.

The same is true of the coordination of a CO molecule to the metal. A lone pair of electrons on the carbon supplies the σ bond in this case, while the retrodative π bond is formed with the aid of an antibonding π* orbital[14]. In contrast with the case of the olefin, however, the metal, the carbon, and the oxygen lie on the bond axis in this case.

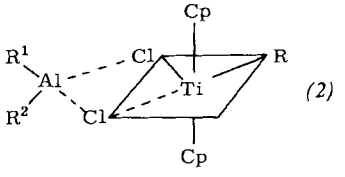
It is not yet possible, in general, to predict which metal is most effective for which catalysis situation. However, certain trends are evident. In the catalysis of polymerization, for example, it is known that catalyst systems containing metals of group VIII of the Periodic System (particularly Co and Ni) are generally favorable for conjugated diolefins, but as far as is known at present they do not polymerize either ethylene or α-olefins. Transition metals situated farther to the left in the Periodic System (Ti, V, Cr) on the other hand, have proved particularly suitable for the polymerization of these compounds.

Soluble complexes of Rh, Ir, Ru, and Co are particularly important in the homogeneous hydrogenation of olefins[3]; Co[1], and Rh[4] have proved particularly suitable for hydroformylation, whereas nickel is the preferred catalyst at present for the cyclooligomerization of butadiene[6].

Some reasons for this "specialization" of the metal complexes will be discussed below.

---

[*] σ symmetry is characterized in that the underlying wave functions retain their sign on rotation through 180° about the axis of the bond. In π symmetry, on the other hand, a single change of sign occurs.



[14] See *e. g. F. A. Cotton* and *G. Wilkinson:* Advanced Inorganic Chemistry. Interscience, New York 1966, p. 728.

2.2. Stability of the M–R Bond

The transition metal-carbon bond is generally not very stable. Many organometallic compounds of transition metals can be prepared or isolated only at low temperatures. It was recognized as early as the 1950's, however, that ligands that build up a strong ligand field around the central atom can stabilize alkyl and aryl compounds of the transition metals. With tertiary phosphanes as ligands, it was possible to isolate stable complexes of the type $(PR_3)_2Pt(CH_3)X$ (R = alkyl or aryl; X = halogen) at room temperature[15]. Carbonyl and π-cyclopentadienyl ligands have also been found to have a stabilizing effect[16], and a whole series of very stable organo-transition metal complexes are now known.

It is obvious that excessive stability of the M–R bond is unfavorable to the catalytic activity. The bond must open readily in the course of the reaction and reform with a new R [cf. *(1)*]. It must therefore have just the correct stability.

It has been found that very fine adjustment of the stability of the M–C bond is possible by means of ligands having relatively small differences in their electron donor-acceptor properties. Let us consider as an example the soluble complex *(2)*[17,7], which is formed from Cp_2TiRCl and R^1R^2AlCl, and which catalyzes the pol-

(2)

Cp = π-Cyclopentadienyl, R = Alkyl, R^1, R^2 = Alkyl or Cl.

ymerization of ethylene. It was possible in this case to follow this fine adjustment by direct measurement, since cleavage of the Ti–R bond results in the conversion of a diamagnetic Ti(IV) complex into a paramagnetic Ti(III) complex (measurement of the magnetic susceptibility as a function of time in absence of ethylene). It was found that the destabilization of the Ti–R bond increases in the order $R^1, R^2 = Cl < R^1 = Cl, R^2 = CH_3 < R^1 = Cl, R^2 = C_2H_5 < R^1R^2 = C_2H_5$. The stronger the donor properties of the ligands R^1 and R^2, the stronger is the destabilization of the Ti–C bond.

Though direct measurement is not always as simple as this, the principle of adjusting the stability of the M–R bond by varying the ligands is probably generally applicable. However, the stability of the R–M bond also depends on R itself. Thus for the titanium complex *(2)* with R^1 and R^2 kept constant, the stability varies with R in the order[7]. $CH_3 > CH_2{-}CH_3 > CH_2{-}(CH_2)_n{-}CH_3$.

The same trend has been found in the carbonylation reaction on the manganese complex *(3)*[18]:

$$RMn(CO)_5 + CO \rightarrow RCMn(CO)_5 \quad (3)$$

It was found that the rate of the reaction depends on R, and M–R is most stable (least reactive) for R = methyl, and least stable (highest rate) for R = propyl.

2.3. Coordination of the Substrate

The importance of the coordination on the transition metal to the catalytic process was discussed in connection with Figure 1: the energy barrier to the cleavage and reformation of bonds to the olefin is lowered.

Before an olefin can possibly be coordinated, space must obviously be available in the coordination sphere of the metal. In the case of the titanium/aluminum catalyst *(2)*, the empty coordination site is made available by a change in the symmetry on the central atom on complex formation with the ligand alkylaluminum. The starting substance Cp_2TiRCl is tetrahedral; in this symmetry the metal is saturated coordinately by four ligands. On the approach of the alkylaluminum (*e.g.* $C_2H_5AlCl_2$), the Cl requires a site in the coordination sphere of the Ti in order to form the very stable bridge structure (three-center bonds) between Ti and Al. This forces the central atom to change from tetrahedral to octahedral symmetry[7,17]. (The term "octahedral" here is not quite accurate, since the ligands are not all alike; however, it facilitates discussion and representation by drawings.) We may picture the "vacant site" as being truly vacant or as being occupied by a solvent molecule. However, it is also conceivable *e.g.* that the pentacoordinated complex *(2)* more closely resembles a trigonal bipyramid, and changes into the octahedral structure only on the approach of an olefin.

In other cases the free coordination site is formed by dissociation of a relatively weakly bonded ligand in solution. It is usually assumed that its place is taken by a solvent molecule S, which can be relatively easily displaced by the substrate (olefin). An example is the hydrogenation catalyst chlorotris(triphenylphosphine)-rhodium(I) *(4)*[19,3].

This reaction sequence again involves a change of symmetry, this time from square-planar to octahedral (Scheme 1). Unlike in the complex *(2)*, however, the symmetry change here is associated with a change in the valency of the metal from Rh(I) to Rh(III), and results from the oxidative addition of hydrogen. This process, which is important to the catalytic hydrogenation of olefins, was first observed by *Vaska*[20] in an iridium complex. Square-planar complexes of group VIII metals with the d^8 configuration have a particularly strong tendency to undergo this oxidative addition, in which they change into the d^6 configuration. These complexes are therefore particularly suitable for use as hydrogenation catalysts.

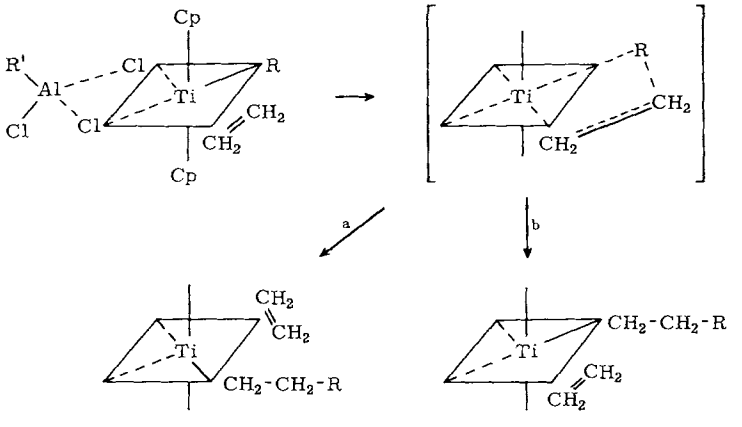
Scheme 1. S = solvent, P = $(C_6H_5)_3P$

Whether the olefin acts predominantly as a σ donor or as a π acceptor depends on the olefin itself, the metal, and the other ligands. Where the olefin has strong acceptor substituents ($F_2C{=}CF_2$, NC−CH=CH−CN), the electron flux is probably directed predominantly from the metal to the olefin. For ethylene and other simple olefins, spectroscopic studies on iridium complexes[10] and dipole measurements on platinum complexes[21] indicate that the olefins have a basic character toward these metals. Ethylene also acts predominantly as a donor toward the titanium complex *(2)*. This is deduced from the observation that the rate of the reduction Ti(IV) → Ti(III) is increased by the presence of unpolymerizable olefins[7]. The M–R bond is evidently destabilized by the coordination of the olefin (cf. the influence of the donor ligands R^1 and R^2, Section 2.2).



Excessive stability of the coordinate metal-olefin bond is undesirable, for obvious reasons. The absolute values and the relative σ and π bond components must be finely adjusted within narrow limits in order to activate the olefin for catalytic reactions. It must be borne in mind that the requirements imposed on the catalyst in this respect will vary from olefin to olefin. In the kinetic investigation of the S_N1 reaction[22]:

$$CpMn(CO)_2\,(olefin) + L \rightarrow CpMn(CO)_2L + olefin$$

it was found that the coordinate bonding of ethylene to the metal is very much more stable than that of propylene or of 1-pentene. These observations agree *e. g.* with the fact that the rates of polymerization of ethylene, propylene, and 1-butene on the same catalyst[*] are related as 50:5:1[23]. This may be due to steric factors and to the energy of the olefin orbitals that are responsible for the bonding.

2.4. Insertion versus *cis*-Migration

Formula *(1)* was intended to show that the coordinated olefin is "inserted" between M and R. The term "insertion" is used particularly in connection with polymerization reactions. However, it has not yet been possible to establish whether the situation shown results from insertion at the coordination site of the ligand R or from a *cis*-migration of the ligand to the adjacent olefin[24]. Both possibilities are illustrated in Scheme 2 (a: *cis*-migration, b: insertion)[7] for the growth step on the polymerization of ethylene.

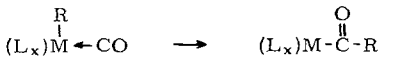
Scheme 2

In carbonylation reactions on a managanese catalyst (R = CH_3, coordinated substrate = CO), however, the question seems to have been answered in favor of the *cis*-migration[25,26]. This conclusion is based on the decarbonylation of *trans*-$(CH_3CO)Mn[(C_6H_5)_3P](CO)_4$.

[21] *M. A. Muhs* and *F. T. Weiss*, J. Amer. Chem. Soc. *84*, 4697 (1962).

[22] *R. J. Angelici* and *W. Loewen*, Inorg. Chem. *6*, 682 (1967).

[*] This was in fact a heterogeneous Ziegler-Natta catalyst, but the problem of the coordination of the olefin to the transition metal is the same.



[23] *H. Schnecko*, private communication.

[25] *R. J. Mawby, F. Basolo*, and *R. G. Pearson*, J. Amer. Chem. Soc. *86*, 5043 (1964).

[26] *K. Noak* and *F. Calderazzo*, J. Organometal. Chem. *10*, 101 (1967).

According to the law of microscopic reversibility, it is to be expected that the same reaction path will be followed (but in the opposite direction) as in the carbonylation, in which CO is "inserted" between the metal and an alkyl group.

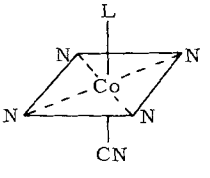
Owing to the phosphane ligand in the *trans* position, the products of decarbonylation by the two paths should be stereoisomers. The fact that *cis*-$CH_3Mn[(C_6H_5)_3P](CO)_4$ is formed shows that the probable mechanism is *cis*-migration, and not insertion.

3. Influences of the Ligands L

The ligands L [cf. *(1)*] may be ions (Cl^-, CN^-, H^-, *etc.*) or neutral molecules (phosphanes, phosphites, amines, CO, NO, *etc.*). A number of concepts have been used to interpret the influence of such ligands on the stability of the M–R and M–olefin bonds, and hence on the catalytic activity. These include the σ-donor ability or basicity of the ligands[6,7,27], the π-acceptor strength of the ligands[13], the *trans* effect[28], the inductive effect[29] and the resonance effect[30], the electron density on the metal[13,7], and the influence on the energies of the orbitals[15,17,31]. These concepts stem in part from different theories of chemical bonding (the valence bond theory, the MO theory, the ligand field theory), but they are all basically descriptions of the same thing: a change in the electronic structure, *i. e.* a decrease in the electron density in certain regions of the complex, an increase in others, and a consequent change in the bonding.

With few exceptions[7,27,29], however, no clear relationships have yet been discovered between continuously variable properties of a ligand (*e. g.* the basicity of phosphanes[27] and phosphites[29] or alkyl ligands[7]) and catalytic activity. This is probably because the catalytic processes are mostly complicated reaction sequences, in which the activation of different steps may place entirely different requirements on the ligands. To destabilize the M–R bond the σ-electron system must be influenced, while the activation of the coordinated substrate (retrodative π bonding) may occur preferentially *via* the π-electron system; a ligand L must frequently be dissociated in order to make a coordination site available, and the important factor then is strength of the M–L bond itself. There is therefore no reason to expect a simple relationship between electronic structure and reactivity. An attempt will nevertheless be made here to discuss the various factors separately.

3.1. Effects Acting *via* the σ-Electron System



Let us first consider an undoubtedly greatly simplified electrostatic picture in which the central transition metal ion is positively charged[*], and all the bonds between the metal and the ligands, including R and olefin, must be regarded as more or less polar:

If a ligand L^1 is now replaced by another ligand L^2 that is a better electron donor (*i. e.* is more basic, or has a lower electron affinity, or however one may express it) than L^1, the positive charge on the metal is reduced, with the result that the bonding between the metal and all the other ligands is weakened. However, this weakening generally affects only the relatively unstable M–R bond sufficiently, so that it consequently becomes reactive.

A similar result regarding the weakening of the σ bonding to all the other ligands follows from a MO calculation (extended Hückel MO) on *trans* and *cis* effects in square-planar Pt(II) complexes of the type $PtCl_2(L)(NH_3)$[32]. The more strongly σ bonding the ligand L ($H > PH_3 > CH_3 > H_2S > Cl > NH_3 > H_2O$), the lower is the electron density in the overlap region of the corresponding atomic orbitals between the metal and all the other ligands, *i.e.* the weaker are these bonds. It is interesting to note that it was found that contrary to general belief, the *cis* bond is weakened almost as much as the *trans* bond. Experimental evidence of this based on IR spectroscopic studies (bond force constants) has already been reported[33].

IR spectroscopic studies on cobalt(III) corrinoids *(8)*, which are complexes related to vitamin B_{12}, show that theses effects are not confined to square-planar complexes, as the cobalt in these complexes is hexacoordinated[34,35].

(8)

The four N atoms shown represent the corrin system, and L is the ligand to be varied. The bonding to all the other ligands becomes weaker with increasing donor strength of L ($CH_3–CH_2 > CH_3 > CH_2 = CH > CH \equiv C > CN > OH$); the ligand that is most strongly affected is the CN group in the *trans* position.

The σ-donor strengths (basicities) of phosphanes and phosphites *etc.* decrease in the following or-

ders[27,29,36,37]: $(C_2H_5)_3P > (CH_3)_3P > (C_2H_5)_2P(C_6H_5) > (C_2H_5)P(C_6H_5)_2 > (C_6H_5)_3P$; $R_3P > (RO)_3P$; $(CH_3OC_6H_4O)_3P > (C_6H_5O)_3P > ClC_6H_4O)_3P$; $R_3P > R_3As > R_3Sb$.

Another possible influence of a ligand L *via* the σ-electron system should be mentioned. This concerns the oxidative addition of H_2 to square-planar complexes, a reaction that plays an important part in many catalytic hydrogenations (cf. Scheme 1). It was found that for the compound *trans*-$IrL(CO)[(C_6H_5)_3P]_2$ (L = halogen ligand), the rate of additions decreases considerably in the order I > Br > Cl[12].

The electronegativities of the halogen atoms decrease in the reverse order; thus iodine attracts the σ electrons less than the other two halogens, *i. e.* the central atom is less positive when L = I. According to the above discussion, this means that all the other ligands are less strongly bound than in the complexes with L = Br or L= Cl. It may be imagined that this weaker bonding will facilitate the "flip" from the square-planar to the octahedral structure. (Since the two H atoms are added in the *cis* position, one ligand must move out of the x–y plane and enter into bonding with the d_{z^2} orbital.)

3.2. Effects Acting *via* the π-Electron System

In the case of ligands that have orbitals of the appropriate symmetry available (antibonding π*-orbitals in olefins and CO, d orbitals of the phosphorus in phosphanes, *etc.*), the influence of the π electrons is superimposed on the action *via* the σ-electron system. A ligand that can act as a π acceptor can withdraw electrons from the π bonds to other ligands; the dπ orbitals of the metal act as a "conductor" for the electrons. This is illustrated schematically in Figure 2 for a metal complex with a CO and a phophorus ligand. The possible effect on the metal-CO or metal-olefin bond in catalytic processes is obvious.

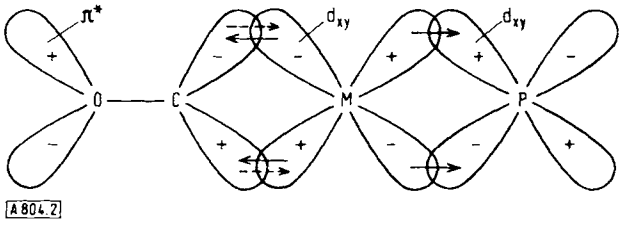

Fig. 2. Retrodative π bond between metal and CO on the one hand and between metal and phosphane on the other. The π bond to the CO is weakened by the presence of the phosphane (σ orbitals not shown).

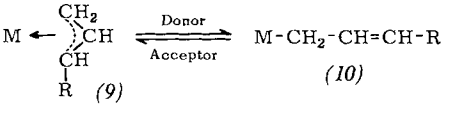

This effect is again determined experimentally by IR spectroscopy. In carbonyl complexes, for example, the CO stretching frequency ν_{CO} depends on how much electron density passes into the antibonding π* orbital of the CO by retrodative π bonding from the metal to the CO; the greater this quantity, the weaker is the bond between C and O, and the lower is ν_{CO}[*]. If electron density is withdrawn from π*(CO) by a π acceptor at another point in the complex, ν_{CO} is increased. NO can be used in a similar manner as a "diagnostic ligand". By investigations on complexes of the type $ML(CO)X_n$ or $ML(NO)X_n$ in which the metal (M) and the other ligands (X_n) are kept constant while L is varied, it is possible to arrange the ligands L in order of their π-acceptor strength[13,38-40]. The following series are obtained: NO ≈ CO > PF_3 > PCl_3 > $PCl_2C_6H_5$ > $PCl(C_6H_5)_2$ > $P(C_6H_5)_3$ > $P(C_2H_5)_3$; $PCl_2(OC_2H_5)$ > $P(OC_6H_5)_3$ > $P(OC_2H_5)_3 \approx P(OCH_3)_3 > P(CH_3)_3 > P(C_2H_5)_3$; $PR_3 \approx AsR_3 \approx SbR_3$.

Halide ions have no appreciable influence on ν_{CO}. They do not appear to act either as π acceptors or as π donors[38]. Their influence on catalytic reactions is probably due to effect acting via the σ-electron systems.

3.3. "σ−π Equilibrium" of Carbon Ligands

The delocalized π-electron systems of allyl ligands allows them to form bonds with the metal of a type that resembles those formed by olefins[41]. A σ bond is formed by the occupied bonding allyl orbital and an empty σ orbital of the metal, and the π bonding takes place between a dπ orbital of the metal and the half-occupied nonbonding allyl MO. However, the π-bonding is less important than *e. g.* in the case of ethylene. This is shown by the fact that the plane of the three carbon atoms of the allyl group forms an angle of more than 100° with the plane defined by the metal and the other ligands[42].

Under the influence of basic ligands (σ donors, *e. g.* phosphanes), this configuration can change with formation of a localized σ bond between the metal and the carbon *(10)*[6,43], whereas the "π complex" *(9)* is favored in the presence of acceptor ligands (*e.g.* Cl).

(9) *(10)*

Processes of this type often occur in reactions involving conjugated diolefins, *e. g.* in the dimerization or

[*] However, the stretching frequency ν_{CO} is also affected *via* the σ bonding. The contributions of the two effects to the measured result is not yet certain (see [38] and literature cited there).

cyclooligomerization of butadiene (cf. Section 4.4) or its codimerization with ethylene[44]. A similar equilibrium probably also occurs in the polymerization or oligomerization of ethylene, *e.g.* on Ti(IV) catalysts (cf. Section 4.2).

The relative frequency of this β-hydrogen transfer depends on the electron affinity of the metal, *i. e.* on the donor-acceptor behavior of the other ligands in the complex. If the electron affinity of the Ti is reduced (donor ligands), the hydrogen transfer occurs less frequently, *i. e.* the polymer molecules become longer.

To understand these processes, one must bear in mind that the σ-bonded carbon ligand supplies only one electron to the complex, whereas the π-allyl group or the combination of π-olefin and hydrogen ligand contributes three.

3.4. Bond Strength of the Ligand L

Reactions in which the vacant coordination site must be formed by dissociation of a ligand also depend on the strength with which this ligand is bonded.

The bonding strength for a series of ligands in octahedral chromium complexes has been estimated by measurement of the rate of replacement of L by CO[45]:

$$(phen)Cr(CO)_3L + CO \rightarrow (phen)Cr(CO)_4 + L$$

(phen = *o*-phenanthroline, a bidentate ligand). Since this process may be assumed to proceed by a dissociative mechanismen, the rate may be taken, to a first approximation, as a measure of the bond strength. The stability was found to decrease with L in the order $P(n\text{-}C_4H_9)_3 > P(OC_2H_5)_3 > CO > P(OC_6H_5)_3 > P(C_6H_5)_3 > PH_2(C_6H_5)$. A similar order has been found for tungsten complexes[46].

The order of the ligands varies in the same manner as the basicity rather than as the π-acceptor strength. The strength of the bond in this case thus appears to depend mainly on the σ-bonding. In an octahedral ruthenium complex in which the ligand L is situated *trans* to a hydrogen ligand, however, it was found that $L = (RO)_3P$ is more strongly bonded than $L = R_3P$[47]. The strong σ donor H evidently weakens the *trans* σ bond (cf. Section 3.1), to such a degree that the retrodative π bond from the metal to the phosphorus becomes the deciding factor for this bond.

3.5. Steric Effects

Bulky ligands can influence a catalytic process by allowing coordinative addition of the substrate only in a certain orientation; the result may be stereospecific catalysis. A typical example is the syndiotactic polymerization of propene on soluble vanadium catalysts at low temperatures[48]; chlorine ligands and the methyl group of the last propene molecule incorporated into the growing chain form a sort of rigid frame (matrix), which predetermines the direction of addition of the monomer. (Stereospecific polymerization on heterogeneous catalysts is based on the same principle.) This matrix formation on transition metal catalysts can even be used for the synthesis of optically active substances[49,50]. Thus optically active ligands such as (+)methylphenylpropylphosphane or (+)-phenylethylformamide have been used in rhodium complexes for the hydrogenation of α-ethylstyrene to (+)-2-phenylbutane (7–8% optical yield) and of methyl 3-phenyl-2-butenoate to optically active methyl 3-phenylbutyrate (50% optical yield).

The direction of a catalytic reaction can sometimes be changed by blockage of coordination sites. For example, cyclooctatetraene is formed from acetylene on Ni(II) chelates [*e.g.* bis(2-alkyliminomethylphenolato)nickel(II)][5,51]. It is assumed that the two chelating ligands can be displaced by the acetylene so that they each occupy only one coordination site. Four acetylene molecules then complete an octahedral structure and assume a steric arrangement that favors the formation of cyclooctatetraene. If a basic ligand that is too strongly bound to be displaced by acetylene [$P(C_6H_5)_3$, in a ratio of 1 : 1 with respect to the nickel compound] is introduced into the system, one site is blocked and only three acetylene molecules can now be added. Instead of cyclooctatetraene, therefore, the main product is benzene[51].

4. Examples of the Specific Modification of the Catalytic Activity

4.1. Hydrogenation of Olefins

Wilkinson et al.[19,27] studied the effect of varying the ligand in catalysts of the type $(R_3El)_3RhX$ on the rate of hydrogenation of olefins. The components that were varied were El(P, As, Sb), R(alkyl and aryl groups), and X(Cl, Br, I). Kinetic measurements showed that the reaction mechanism is probably as indicated in Scheme 1 (Section 2.3), *i. e.* dissociation of a ligand R_3El and replacement by a solvent molecule S, oxidative addition of H_2, replacement of S by the olefin, and transfer of the hydrogen to the olefin. A competing reaction in which S is replaced by olefin before the oxidative addition of H_2 does not lead to hydrogenation of the olefin. According to the views discussed here, the reason for this may be that the σ-donor strength of the olefin is not enough to ensure the "flip" into the octahedral complex (cf. Section 3.1).

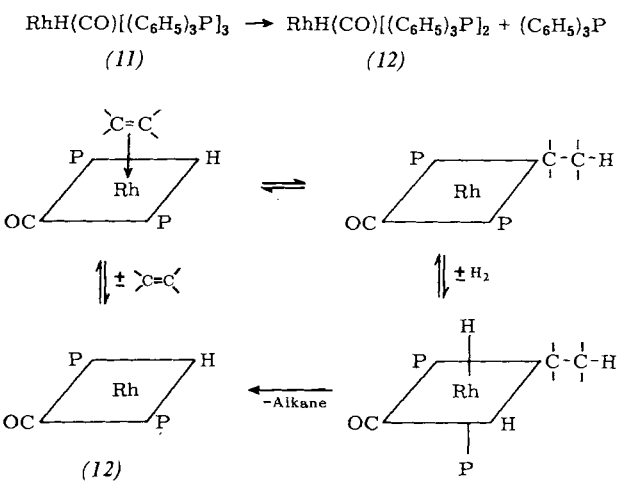
[48] *J. Boor Jr.* and *E. A. Youngman,* J. Polymer Sci. *A-1, 4,* 1861 (1966).

[49] *L. Horner, H. Büthe,* and *H. Siegel,* Tetrahedron Lett. *1968,* 4023.

[50] *P. Abley* and *F. J. McQuillin,* Chem. Commun. *1969,* 477.



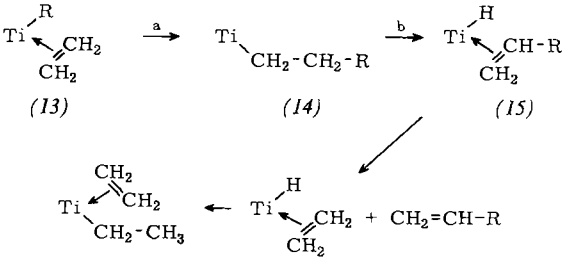
[51] *G. N. Schrauzer,* Angew. Chem. *76,* 28 (1964); Angew. Chem. internat. Edit. *3,* 185 (1964).

In the series with El=P, the activity increased with variation of R in the order *p*-Cl-C_6H_4 (1.6) < *p*-F-C_6H_4 (5.8) < C_6H_5 (40) < *p*-CH_3-C_6H_4 (85) < *p*-CH_3O-C_6H_4 (100). The figures in parentheses are the relative rates of hydrogenation of cyclohexene. The basicity of the phosphanes increases in the same order. It may be assumed that the accelerating effect is due to greater ease of the oxidative addition of H_2 and/or to weakening of the M–H and M–olefin σ bonds in the complex *(7)*, as described in Section 3.1.

A similar trend is shown by the observation that the rate is greatly reduced on replacement of $(C_6H_5)_3P$ by $(C_6H_5)_3As$, and becomes practically zero with $(C_6H_5)_3Sb$. As was mentioned in Section 3.1, the basicity (σ-donor strength) decreases in the same order. This picture is also in agreement with the discovery that when X is varied, the rate decreases in the order I > Br > Cl.

The σ-donor argument, however, cannot be applied in the same way to the series $(C_6H_5)_3P$ (36) ≈ $(C_6H_5)_2PC_2H_5$ (37) > $C_6H_5P(C_2H_5)_2$ (3.4) > $P(C_2H_5)_3$ (1). (Once again relative hydrogenation rates are given.) Here the reactivity and basicity of the phosphane obviously do not run parallel. We recall however that alkylphosphanes are more firmly bound to the metal than are arylphosphanes (Section 3.4). Replacement of a phosphane ligand by solvent with formation of the complex *(5)* thus appears to be the rate-determining step. This is also indicated by the fact that an excess of phosphane leads to a reduction in the rate[19]. Presumably the bond strength does not differ substantially within the series of *p*-substituted phenylphosphanes mentioned above, so that in this case the inductive effect of the *p*-substituents of the phosphane ligands remaining in the complex predominates.

An interesting ligand effect is also found on comparison of the hydrogenation catalysts $RhCl[(C_6H_5)_3P]_3$ *(4)* and $RhH(CO)[(C_6H_5)_3P]_3$ *(11)*[52]. The rates of hydrogenation under comparable conditions are related as 2:1 for the two catalysts, but complex *(11)* is specific for 1-olefins, whereas complex *(4)* hydrogenates different positional isomers at approximately the same rate. *Wilkinson et al.*[52] found that *(11)* acts by a different reaction mechanism. After the dissociation of a phosphane ligand, olefin is first coordinated and is then inserted into the metal-H bond (see Scheme 3). According to the workers who studied this system, this is possible only for 1-olefins, on steric grounds. It should also be remembered, however, that the strong π-acceptor ligand CO makes the coordination of the olefin difficult (weakening of the retrodative π bonding), and allows it to occur only under the most favorable conditions (1-olefins). The CO ligand is probably also responsible for the decrease in the rate.



Scheme 3

Finally, mention should be made of a ligand effect in hydrogenation with a Ziegler-Natta system[53]. The combination $CoCl_2$ + AlR_3 hydrogenates both 1-olefins and conjugated diolefins. If a phosphane or phosphite is added, conjugated diolefins are hydrogenated preferentially. The explanation of this effect is that only the dienes are able to displace the phosphane from the complex and so to approach the catalytically active species.

4.2. Oligomerization of Ethylene (1-Olefins)

The influence of ligands is clearly shown by a comparison of the two Ziegler-Natta systems $Cp_2TiRCl/RAlCl_2$ (Cp = cyclopentadienyl, R = alkyl)[7,17] and $TiRCl_3/RAlCl_2$[8]. Whereas solid polyethylene is obtained with the first of these catalysts, the second gives liquid oligoethylenes consisting mainly of 2-ethyl-1-olefins (vinylidene end groups). However, a certain influence of the solvent (toluene or CH_2Cl_2) and the temperature (0 and −70 °C) must be taken into account.

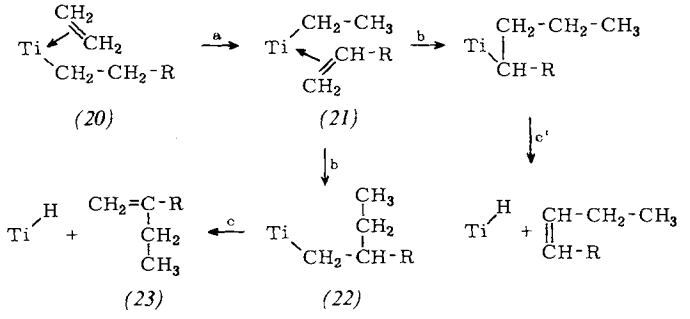
Scheme 4. For the sake of clarity, only the processes at the two coordination sites of the titanium in which we are interested are shown.

The great difference in product composition that is achieved by modification of only two ligands on the titanium led to the hope that by systematic variation of the ligands (with simultaneous temperature control), it would be possible to reach a region yielding linear 1-olefins in a molecular weight range that would be of interest for many applications (C_6–C_{40})[54]. Two opposing tendencies were observed. On the one hand, the chain length depends on the electron donor-acceptor properties of the

[52] *C. O'Connor* and *G. Wilkinson*, J. Chem. Soc. *A 1968*, 2665.

[53] *Y. Tajima* and *E. Kunioka*, J. Catalysis *11*, 83 (1968).

[54] *G. Henrici-Olivé* and *S. Olivé*, Angew. Chem. *82*, 255 (1970); Angew. Chem. internat. Edit. *9*, 243 (1970).



ligands. The greater the electron affinity of the titanium, the more important does the β-hydrogen transfer (reaction b, Scheme 4) become in relation to the chain growth reaction (reaction a), *i. e.* the lower does the molecular weight become (cf. Section 3.3). This tendency is clearly shown by Table 1.

Table 1. Dependence of the molecular weight of the ethylene polymer obtained on the ligands at the titanium. Al component: $C_2H_5AlCl_2$; Al/Ti = 5; solvent: benzene; $T = 5°C$; $p_{C_2H_4} = 1$ atm.

System	Ti component	Oligomers [a] (%)	Polymers (%)
(16)	$(C_2H_5O)_4Ti$	31	69
(17)	$(C_2H_5O)_3TiCl$	56	44
(18)	$(C_2H_5O)TiCl_3$	77	23
(19)	$TiCl_4$	92	8

[a] The oligomer is taken to be the part that is soluble in benzene at room temperature.

On the other hand, a high electron affinity of the titanium also allows an undesirable side reaction to take place; this reaction is indicated by the reaction sequence *(20)* to *(23)* in Scheme 5. The β-hydrogen

Scheme 5

transfer with conversion of the Ti–C σ bond into the π complex (Scheme 4, reaction b) occurs not only when the adjacent coordination site is vacant, but also when it carries a monomer. The normal growth is then replaced by transfer of hydrogen to the ethylene (Scheme 5, reaction a), and the growth step (b or b') leads to an ethyl or propyl branch. If this is again followed immediately by β–H transfer (c or c') a vinylidene end group or an inner double bond is formed. With the system that favors low molecular weight [*(19)* in Table 1], the content of 1-olefins is only about 5%, whereas with the system *(16)*, the oligomeric part consists mainly of 1-olefins at comparable conversions.

By lowering the temperature, however, the average molecular weight can be reduced without deterioration of the ratio of the principal reaction to the undesirable side reaction (Scheme 4/Scheme 5). [Since the polymerization rate is reduced to approximately the same degree, the effect is probably due to a decrease in the rate of the normal growth step *(13)* → *(14)*.] Thus it was finally possible, with the system *(17)* at −20 °C, to obtain a product containing 75% of 1-olefins having molecular weights in the range ≤ 300[54].

4.3. Oligomerization of Propene

Propene undergoes cationic oligomerization in the presence of Lewis or Brönsted acids to give oily to waxy oligopropene[55,56]. However, the growing chain end (carbonium ion) also reacts with the tertiary hydrogen atoms of the polymer chain (hydride transfer), with the result that highly branched products are formed.

The Ziegler-Natta systems listed in Table 2 were tested in an attempt to prepare unbranched polypropene having a relatively low molecular weight[57]. The object was to shift the place of polymerization from the solution (polymerization of free cations) to a coordination site in a titanium complex. In coordinative polymerization on a transition metal center[17], no free cations occur; on the contrary, the growing chain end carries a certain negative charge because of the polarization of the metal-carbon bond:

$$\overset{\delta\oplus}{Ti}\ldots\ \overset{\delta\ominus}{CH_2}\text{-}CH(CH_3)\text{-}R$$

The undesirable chain branching can therefore be suppressed. The result of these efforts was checked by IR spectroscopy. A band at 1155 cm^{-1} is characteristic of the grouping $-CH_2-CH(CH_3)-CH_2$[58]. Since the tertiary hydrogen is lost on branching, this band provides a measure of linearly incorporated propene (column 8 in Table 2).

The linearity of the product increases, *i.e.* the cationic initiation is suppressed, with the depression of the Lewis-acid character (decrease in the electron affinity of the

Table 2. Effect of ligands on the linearity of oligopropene [57] [Ti] = 20.10^{-3} mole/l; $T = 5°C$; solvent: benzene.

System	Ti component	Al component	Al/Ti	$p_{C_3H_6}$ (atm.)	Propene uptake (mole $l^{-1}h^{-1}$)	$\bar{M}_n$[a]	Linear growth (%)

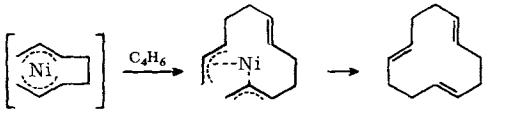
[57] *G. Henrici-Olivé* and *S. Olivé,* J. Polymer Sci. *B–8,* 205 (1970).

[58] *G. Natta, A. Valvassori, F. Ciampelli,* and *G. Mazzanti,* J. Polymer Sci. *A–3,* 1 (1965).

titanium) by donor ligands. It is assumed from analogy that the titanium complex that allows the coordinative polymerization has a structure similar to that of the octahedral complex *(2)* (Section 2.2).

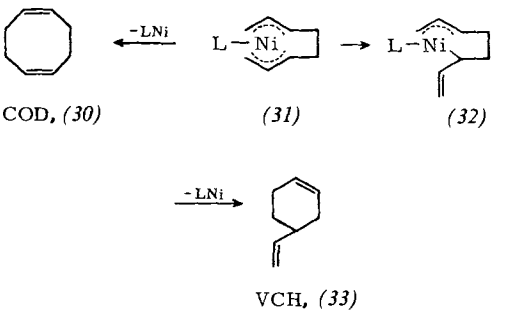


R = C_2H_5 or growing chains, X^1 = Cl or C_2H_5O, X^2 = Cl or C_2H_5.

It can bee seen in Table 2 that ethyl ligands on the Al exert a stronger influence *via* the bridge bond than C_2H_5O ligands attached directly to the titanium [cf. *e.g.* systems *(17)*, *(19)*, and *(24)*]. The reaction rate is considerably slower in coordinative polymerization than in polymerization *via* free cations [cf. systems *(16)*, *(17)*, and *(19)*]. This can be partly balanced by the use of higher propylene pressures [systems *(24)* and *25)*], but the molecular weight then also increases. Almost ideally linear growth was achieved with the system *(26)*.

4.4. Cyclooligomerization of Butadiene

The catalytic cyclotrimerization of butadiene to form cyclododecatriene (CDT) *(29)*[6,59,60] and the cyclodimerization to form cyclooctadiene (COD) *(30)*[43] on Ni(0) catalysts were discovered by *Wilke et al.*



Reduction of soluble nickel salts with alkylaluminum in presence of butadiene yields atomic nickel, which is held in solution by ligands formed from butadiene. The complex *(27)*, in which two butadiene molecules linked to form a C_8 chain are bonded to a nickel atom by two π-allyl groups, is assumed to occur as an intermediate. If no other ligands are present in the system, *(27)* takes up a further molecule of butadiene to form *(28)*. The trimer is displaced from the complex as cyclododecatriene *(29)* by fresh butadiene molecules, with formation of *(27)* once more.

(27) *(28)* CDT *(29)*

Scheme 6

One coordination site on the nickel can be blocked by addition of a ligand L (triarylphosphane or triaryl phosphite) in a ratio of 1:1 with respect to the nickel. Dimer is then displaced from the intermediate *(31)* (which can be isolated at low temperatures) by further butadiene either as cyclooctadiene *(30)* or as vinylcyclohexene (VCH) *(33)*. Some cyclododecatriene *(29)* ist always also formed.

COD, *(30)* *(31)* *(32)*

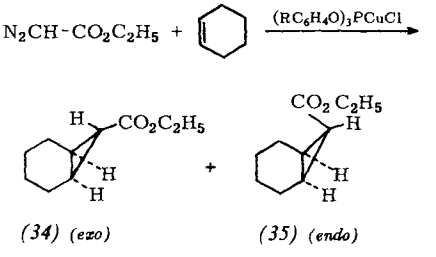
VCH, *(33)*

The ratio of the yields of *(30)*, *(29)*, and *(33)* is strongly dependent on the electron donor properties of the ligand L, as is shown by Table 3.

Table 3. Cyclooligomerization of butadiene; dependence of the composition of the reaction product on the ligand L. T = 80 °C; normal pressure, 3 hours (after [43]).

L	COD(%)	VCH(%)	CDT(%)	$>C_{12}$(%)
$(C_6H_5)_3As$	17	5.8	60	14
$(C_6H_5)_3P$	64	27	6	2.8
$(C_6H_{11})_3P$ [a]	41	40	14	4.8
$(C_6H_4O)_3P$	81	7.4	9.2	2.3
$(o\text{-}CH_3\text{-}C_6H_4O)_3P$	92	5.7	1.4	0.6
$(o\text{-}C_6H_5\text{-}C_6H_4O)_3P$	96	3.1	0.2	0.2

[a] Tricyclohexylphosphane.



Electron acceptors such as triaryl phosphites stabilize the nickel-bis(π-allyl) complex *(31)*, which preferentially forms cyclooctadiene. Electron donors (alkylphosphane > arylphosphane), on the other hand, apparently cause the conversion of a π-allyl into a σ-allyl group [complex *(32)*], with the result that the linkage of C–1 with C–6 to form vinylcyclohexene *(33)* is favored (cf. Section 3.3).

o-Substituted triphenyl phosphites increase the yield of cyclooctadiene. Since the electronic properties of the *o*-substituent are of no appreciable importance, this is assumed to be due to a steric effect.

In the presence of triphenylarsine, however, the reaction proceeds predominantly as shown in Scheme 6, in agreement with the fact that $(C_6H_5)_3As$, stands at the lower end both of the series of σ donors (Section 3.1) and of the series of π acceptors (Section 3.2), so that no appreciable interaction with the metal is to be expected.

4.5. Addition of Diazoalkanes to Olefins

The addition of ethyl diazoacetate to cyclohexene with chloro(triaryl phosphite)copper(I) as the catalyst has been studied by *Moser*[29]. The reaction proceeds in accordance with Scheme 7.

(34) (exo) *(35) (endo)*

Scheme 7

[59] *H. Breil, P. Heimbach, M. Kröner, H. Müller,* and *G. Wilke,* Makromol. Chem. *69*, 18 (1963).

[60] *B. Bogdanović, P. Heimbach, M. Kröner,* and *G. Wilke,* Liebigs Ann. Chem. *727*, 143 (1969).

The two isomeric cyclopropane derivatives *(34)* and *(35)* are formed in a yield of 30–70% together with diethyl fumarate and diethyl maleate. The ratio of *exo* compound to *endo* compound depends on the substituent R in the phosphite ligand, and decreases as R varies in the order o-CH_3 > m-CH_3 > p-H > p-Cl > p-CH_3CO. This result is interpreted by *Moser* as follows. The better the acceptor properties of the phosphite ligand on the copper, the greater is the positive charge on the metal, and the stronger, therefore, is the bonding with all the other ligands. The decrease in the bond lengths leads to steric hindrance between the reactant (coordinated cyclohexene) and the phosphite ligand. It is plausible on the basis of a model of the transition state, that this will favor the formation of the *endo* form.

For the *o*- and *m*-substituted phenyl phosphites, a linear relation exists between the ratio log*(exo/endo)* and the Hammett σ values for the substituents R. This indicates that the effects observed are purely electronic in origin. Nevertheless, they ultimately act *via* the steric hindrance of one of the two possible transition states. The author speaks of stereo-electronic effect. In the case of *o*-substitution, the values found for *(exo/endo)* are lower than those expected from the Hammett lines. This purely steric effect shows again that steric hindrance places the *exo* form *(34)* at a disadvantage in relation to the *endo* form *(35)*.

5. Conclusion

The number of systematic studies that have been carried out on the influence of the ligands on the catalytic activity of a transition metal catalyst is still relatively small. As long as a broad experimental basis is lacking, one cannot entirely rule out the possibility of occasional misinterpretations. In this sense, the present review is intended mainly to stimulate interest. We would be content if it led to the initiation of a few systematic studies that might help to deepen our understanding of these relationships, which are so important to the entire field of catalysis on transition metals.

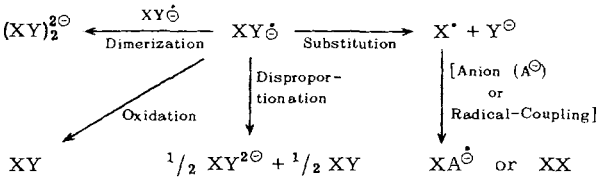
Radical Anion Intermediates in Organic Chemistry[**]

By N. L. Holy and J. D. Marcum[*]

Radical anions are reactive intermediates in a variety of organic reactions. They make possible several unique synthetic conversions and provide an opportunity for investigating structural relationships. Examples of such reactions are given and current mechanistic views are discussed.

1. Introduction



A radical anion results from chemical, electrolytic, or photolytic reduction:

$$XY + e^{\ominus} \rightarrow XY^{\dot{\ominus}}$$

The minus sign appearing in this symbol indicates the presence of a negative charge characteristic of an ion, and the dot indicates that the new species possesses an odd number of electrons and therefore a radical nature.

The most thoroughly studied electron-accepting systems are those of aromatic compounds; then alkyl halides, alkenes, azo compounds, diones and triones. While reactions involving radical anion intermediates were investigated as early as 1867 by *Berthelot*[1], it is only recently that they have been recognized as such.

This article surveys reported reactions in which a radical anion is an intermediate. Radical anion production has been reviewed extensively elsewhere[2,3]. Radical anion intermediates undergo the types of reactions shown in the following scheme:

2. Radical Anions as Intermediates in Substitution Reactions

Most radical anion substitution reactions center upon the chemistry of nitroaliphatic and nitroaromatic compounds. For example, it has been known for some time that aromatic nitro groups promote unique reactions. In 1949 investigation of the reaction of various *para* substituted benzyl halides with the lithium salt of 2-nitropropane[4] revealed that *p*-nitrobenzyl chloride effects *C*-alkylation to give *(1)*. Benzyl halides substituted in the *para* position by CN, CF_3, $\oplus N(CH_3)_3$, CH_3CO, CH_3OCO, Br, or CH_3 undergo oxygen alkylation to *(2)*, which subsequently converts into the aldehyde.

Not only does *C*-alkylation depend upon the presence of a nitro group, but further, it occurs only if the nitro group is *ortho* or *para* to the benzyl position. Thus, when *p*-nitrobenzyl chloride is treated with 2-nitropropyllithium compound *(1)* is obtained in 83–95% yield[4–8]; *o*-nitrobenzyl chloride leads to formation of *C*-alkylation product in 46% yield[4]. On the other hand, *m*-nitrobenzyl chloride gives no *C*-alkylate, producing instead, *m*-nitrobenzaldehyde[4]. *p*-Nitrobenzyl bromide and iodide give *C*-alkylation products in 17 and 7% yield respectively[5,7].

Scheme 2.

[5] *N. Kornblum, P. Pink*, and *K. V. Yorka*, J. Amer. Chem. Soc. *83*, 2779 (1961).

The *C*-alkylation reactions of *o*-and *p*-nitrobenzyl chloride are now understood to be radical anion reactions[7,8]. *O*-alkylation, on the other hand, arises *via* a S_N2 pathway. The mechanism for the reaction of *p*-nitrobenzyl chloride with the 2-nitropropyl anion is shown in Scheme 2[9]. (For corresponding iodides and bromides the competing S_N2 process predominates and leads to *O*-alkylation.)

The nitro group in *(3)* serves to lower the reduction potential (Table 1) and promotes the formation of the radical anion *(4)*. Loss of chloride from *(4)* yields a resonance-stabilized free radical *(5)*. The chain nature of the mechanism is established by the observation that introduction of a small amount of a more easily reduced nitroaromatic compound, such as *p*-dinitrobenzene (Table 1), suppresses *C*-alkylation. Presumably this occurs as a result of removal of the electron from *(4)* by dinitrobenzene. The transfer of an electron between nitroaromatics is known to be often rapid[10].

p-I	1.050	*p*-NO	0.525		

Reactions in which S_N2 substitution does not compete with the radical anion process have proven especially fruitful. Substitution reactions at the tertiary C-atom of cumyl chlorides preclude the S_N2 process since few, if any, authentic S_N2 displacements involving tertiary halides are known[12]. However, *p*-nitrocumyl chloride *(7a)* and α,*p*-dinitrocumene *(7b)* undergo facile substitution at the tertiary carbon with a variety of nucleophiles[13]. The reactions for *p*-nitrocumyl chloride and *p*-dinitrocumene are illustrated by the following scheme and the results listed in Table 2.

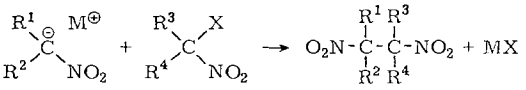
(8g)	see above		70
(8h)	OPh		66
(8i)	CH_3NH_2	91	

Dependence of the substitution reaction on the presence of a *para* nitro group is again demonstrated by the failure of carbon substitution to occur in the comparable compounds lacking the *p*-nitro group[13]. For example, the analog of *(7a)* without a *p*-nitro group reacts to give α-methylstyrene, and whereas α-nitrocumene is not attacked by thiophenoxide, reaction with α, *p*-dinitrocumene *(7b)* to give compound *(8)* is complete in twenty minutes.

The radical anion substitution mechanism is consistent with these results. It is further substantiated by the importance of the *para* nitro group in forming a radical anion intermediate and accounts for other observations: light speeds the reaction by facilitating electron transfer from $A^{\ominus}$ to *(3)*; the dimer *(9)* is isolated in 1–5% yields; small amounts of *p*-dinitrobenzene or oxygen dramatically retard the substitution reaction[13].



(9)

The importance of oxygen as a mechanistic probe in these reactions warrants further note. In the presence of oxygen yields from both *p*-nitrocumyl chloride *(7a)* and α,*p*-dinitrocumene *(7b)* are sharply reduced. For example, treatment of α,*p*-dinitrocumene with the anion of *n*-butylmalonic ester in the absence of oxygen leads to the *C*-alkylation product *(8d)* in 98% yield, while in the presence of oxygen this product is completely suppressed and *p*-nitrocumyl alcohol is formed in 80% yield[13]. These data support the intermediacy of a free radical[15].

A nitro group in the *meta* position offers an interesting study since it apparently cannot stabilize an intermediate benzylic free radical. Accordingly, there is no indication that *m*-nitrobenzyl chloride reacts by a radical anion pathway. However, *m*-nitrocumyl chloride and α, *m*-dinitrocumene result in high yields of tertiary substitution products which seem to arise *via* a radical anion process[16]. These reactions are slower than those with the nitro group in the *para* position. Since the *m*-nitrocumyl system, unlike *m*-nitrobenzyl chloride, cannot undergo S_N2 displacement, the radical anion substitution proceeds.

Some substitution reactions of nitroaliphatic compounds have also been investigated as possible radical anion reactions. Reactions of the 2-nitropropyl anion with 2-chloro- and 2-bromo-2-nitropropane, are known to be consistent with this mechanism[17]. *Russell* found that the reactions can be initiated photochemically or can be inhibited by hexaphenylethane or *p*-dinitrobenzene. The products in all cases are the *C*-alkyl derivates of the 2-nitropropyl anion. Earlier work has shown this dimerization to be a general one as long as R^1, R^2, R^3 and R^4, are alkyl and not hydrogen[18].

R^1-R^4 = Alkyl

3. Disproportionation

Aromatic hydrocarbons of sufficient electron affinity react with alkali metals to form mono-or divalent salts[19]. These salts are frequently observed to be in equilibrium, as shown in eq. 1.

$$2\ [R_2C{=}CR_2]^{\ominus}M^{\oplus} \rightleftharpoons [R_2\ddot{C}\text{-}\ddot{C}R_2]^{2\ominus}\ 2\ M^{\oplus} + R_2C{=}CR_2 \quad (1)$$

K is dependent upon structure, solvent, and cation. Furthermore, the radical anions in these equilibria are intermediates in dimerization and reduction reactions.

The effect of the cation and the solvent is interwoven, since the nature of the cation may exert controlling influences on the details of solvation[20–25]. As an example,

K values for the equilibrium between tetraphenylethylene (T) and various alkali metals are shown in Table 3[25c]. The variations in K indicate that the equilibrium should include the effects of cation association or aggregation.

Table 3. Equilibrium constants (disproportionation constants) K for the equilibrium

$2[Ph_2C{=}CPh_2]^{\ominus}\ M^{\oplus} \rightleftarrows [Ph_2\ddot{C}\text{-}\ddot{C}Ph_2]^{2\ominus}2M^{\oplus} + Ph_2{=}CPh_2$ at 25 °C.

If K is dependent on concentration the upper and lower limits are given.

M	In diglyme	In DME	In THF
Li		0.3–1.3	0.7–1.2
Na		0.05–0.3	8–30
K	9–12	40–50	6000
Cs	200–400	2700	large

From Table 3 it is seen that K decreases as the solvent polarity increases from THF < DME < diglyme. The phenyl groups in the radical anion $T^{\dot{\ominus}}$ are not coplanar[3,26]; thus, the counterion cannot approach close to the negative charge. On the other hand, coplanarity of the phenyl groups in the dianion is permitted through rotation about the central C-C axis to form a skewed conformation which allows for close approach of the counterions to the CPh_2 centers. Whereas the $T^{2\ominus}$, $2M^{\oplus}$ forms contact ion pairs, the $T^{\dot{\ominus}}M^{\oplus}$ forms solvent-separated pairs. The salt of the radical anion is therefore more sensitive to solvation effects than the salt of the dianion[27,28] and is favored by increasing solvent polarity.

The disproportionation shown in eq. 1 is dependent upon the structure of the radical anion. Radical anion disproportionation increases with increasing steric strain in arylethylenes. Table 4 shows that tetraphenylethylene and stilbene differ in K values by more than 10^4. By one interpretation[25a] disproportionation is accompanied by relief of steric strain because dianions are presumed to form skewed conformations while the ethylene structure of the radical anions are constrained to planarity. According to an alternative interpretation[27] the electron-electron repulsions in the stilbene dianion are greater

Table 4. Equilibrium constants (disproportionation constants) K [a] of arylethylenesodium compounds in 2-methyltetrahydrofuran at 25 ° C [25].

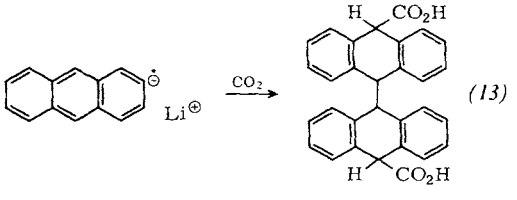
Hydrocarbon	K
α-Methylstilbene	1000
Stilbene	0.09
Triphenylethylene	36
Tetraphenylethylene	1000

[a] K is the equilibrium constant for disproportionation of ion pairs according to eq. 1. The concentration of ionic species ranged from *ca.* 10^{-5} to *ca.* 10^{-3} mole/l; K is concentration independent through this range.

than those of tri- or tetraphenylethylene (the phenyl groups promoting charge dispersal), so the radical anion side of the equilibrium is favored in the stilbene system.

The former argument seems preferable since methyl substitution of stilbene results in at least a 10^4 fold increase in K. It is anticipated that the effect of methyl substitution on electron-electron repulsion would be greater in the dianion than in the radical anion, but this implies a decrease in the value of K, the opposite of what is observed. Thus, the result of methyl substitution is best viewed as a steric effect reflecting a change in geometry accompanying disproportionation.

The effect of the cation upon K is dependent upon the ethylene structure. Disproportion of radical anions derived from stilbene increases as the size of the cation decreases. This trend is the reverse of that observed in tetraphenylethylene systems. It is likely that the radical anion of stilbene, as well as its dianion, forms a contact pair[3]. Ion pairing favors disproportionation because the binding of two counterions by a dianion is more than twice as powerful as the attraction of the radical anion and its partner. Thus, the stronger binding of a small counterion would lead to greater disproportionation. In the tetraphenyethylene system the radical anion forms a solvent-separated pair, whereas the dianion remains a contact pair. Solvation of the cation contributes to the stability of the radical anion and becomes increasingly important with small cations.



Coupling and/or reduction are possible reactions of the radical anion. When tolan is treated with an excess of sodium naphthalenide in THF[29], an initial rapid electron transfer occurs with formation of the radical anion *(10)*, followed by formation of either the dimer *(11)* or the monomer dianion *(12)*.

$$Ph\text{-}C{\equiv}C\text{-}Ph \xrightarrow{Naph^{\dot{\ominus}}} Ph\text{-}C{\equiv}C\text{-}Ph^{\dot{\ominus}} \qquad (10)$$

$$2\ Ph\text{-}C{\equiv}C\text{-}Ph^{\dot{\ominus}} \longrightarrow Ph\text{-}\ddot{C}{=}\underset{\underset{Ph}{|}}{C}\text{-}\underset{\underset{Ph}{|}}{C}{=}\ddot{C}\text{-}Ph \qquad (11)$$

$$Ph\text{-}C{\equiv}C\text{-}Ph^{\dot{\ominus}} \xrightarrow{Naph^{\dot{\ominus}}} Ph\text{-}\ddot{C}{=}\ddot{C}\text{-}Ph \qquad (12)$$

When an excess of tolan is present *(12)* does not form though *(11)* does. Formation of *(11)* is analogous to the coupling of anthracene radical anion *(13)* reported earlier[30]. Other examples are reviewed by *Birch*[31].

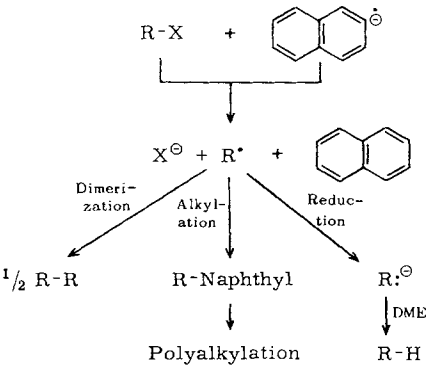
In the Birch reduction the intermediacy of a radical anion is well supported[32]. The mechanism for the reduction of anisole *(14)* is just one example[33].



14)

4. Radical Anions of Aromatic Hydrocarbons

It has been known for more than 100 years that aromatic hydrocarbons may react with alkali metals. The first real description (though not expressed in modern terms) is attributed to *Schlenk*[34]. More recently the formation and reactions of these adducts have been interpreted in terms of radical anion intermediates.

On treating naphthalene with metallic sodium a salt is formed that exhibits a variety of reactions: substitution, equilibrium, and oxidation-reduction. Often these processes occur simultaneously. For example, treatment of sodium naphthalenide with alkyl halides in 1,2-dimethoxyethane (DME) leads to oxidation-reduction[35,36], alkylation[37,38], and dimerization products[35] (see Schemes 3 and 5).

Scheme 3.

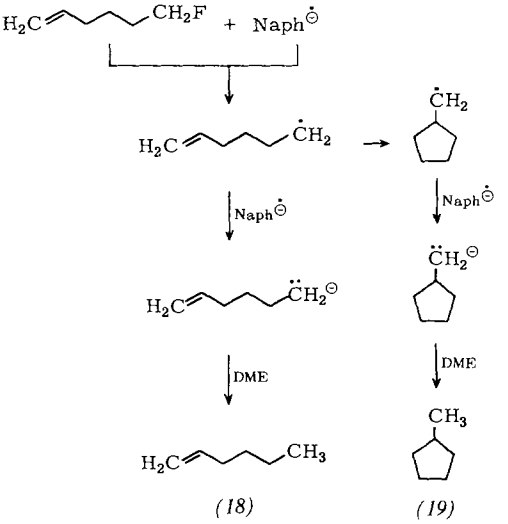
Table 5. Yield of aliphatic hydrocarbons in the reaction of sodium naphthalenide with RCH_2CH_2X [35].

X	R	Yield (%) of $R(CH_2)_4R$	RCH_2CH_3	$RCH=CH_2$
Cl	$CH_3(CH_2)_2$	0	44	0
Br	$CH_3(CH_2)_2$	5.0	29	0
I	$CH_3(CH_2)_2$	56	17	3.7
I	$CH_3(CH_2)_4$	50	22	6

Obviously no more than part of the reduction products can be accounted for by a disproportionation of the radical *(15)*. Two mechanisms [*via* the anion *(16)* and the radical *(17)*] have been suggested[35].

$$2\ RCH_2CH_2^{\bullet} \longrightarrow RCH{=}CH + RCH_2CH_3$$
(15)

$$RCH_2CH_2^{\bullet} + Naph^{\ominus} \longrightarrow RCH_2CH_2{:}^{\ominus} + Naph$$
(15) *(16)*



$$RCH_2CH_2{:}^{\ominus} \xrightarrow{DME} RCH_2CH_3 + CH_3OCH{=}CH_2 + {}^{\ominus}OCH_3$$

$$RCH_2CH_2^{\bullet} \xrightarrow{DME} RCH_2CH_3 + CH_3OCH_2\dot{C}HOCH_3$$
(15) *(17)*

$$CH_3OCH_2\dot{C}HOCH_3 \xrightarrow{Naph^{\ominus}} CH_3OCH_2\ddot{C}HOCH_3 \longrightarrow CH_3OCH{=}CH_2 + {}^{\ominus}OCH_3$$

Alkyl halide reduction products (R-H) arise through disproportionation or successive electron-transfer reactions. Reaction of sodium naphthalenide with *n*-propyl and *n*-pentyl halides[35], like other halides[36], results in a rather large difference in yield between the reduction and oxidation products. (Table 5).

Studies on 5-hexenyl fluoride are helpful in choosing between *(16)* and *(17)*. *Garst* found that the reduction of

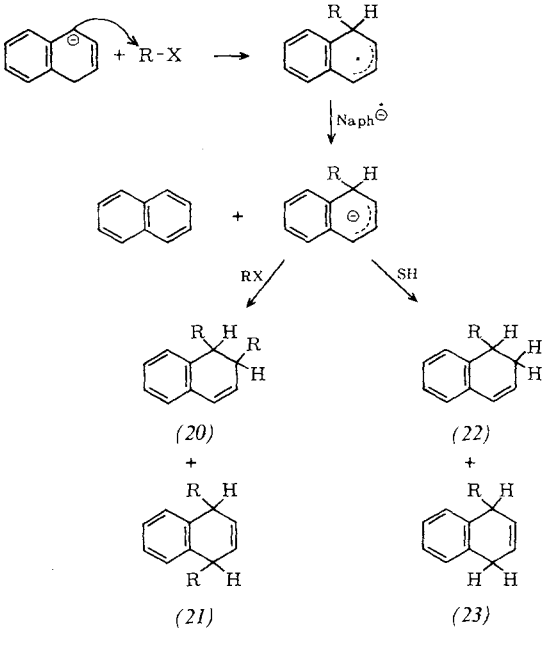
[38] *N. D. Scott* and *J. F. Walker,* US-Pat. 2 150 039 (1939).

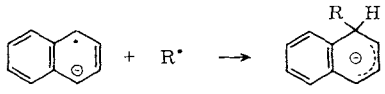


5-hexenyl fluoride with sodium naphthalenide yielded 1-hexene *(18)* and methylcyclopentane *(19)*; the reaction path given in Scheme 4 has been suggested[36b].

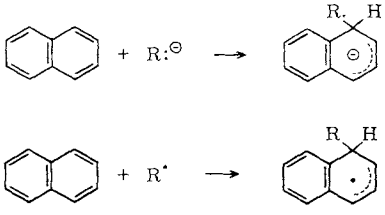
With an excess of sodium naphthalenide the ratio 1-hexene:methylcyclopentane is as much as 40:1; it never falls below 2:1. Consequently, the reaction path *via (17)* is less likely than that *via (16)* because it is known that cyclization of these radicals is much faster than hydrogen atom transfer[36a,39].

Dimerization of the alkyl moiety conceivably could occur either by the coupling of free radicals or through displacement. To determine the origin of the dimer a mixture of *n*-propyl and isopropyl iodides was treated with sodium naphthalenide. The hexanes produced were isolated in statistical yields[35], a result consistent with a coupling process, but not with displacement[40–43].

Another interesting facet of the dimerization process is the observation that dimer formation is significant only for alkyl iodides. Apparently, because the reactions of alkyl iodides are very fast, the concentration of radical is sufficient to render dimerization competitive with other processes. With fluorides, chlorides, and bromides little dimer is formed and there is an increase in reduction products (Table 5).



Diverse mechanisms are suggested to account for the formation of alkylation products. *Lipkin* proposes an initial S_N2 attack on the alkyl halide by a nucleophilic radical anion[37] (Scheme 5).



Scheme 5. SH = solvent

Subsequent reduction of the resulting free radical leads to a carbanion, which can attack another molecule of alkyl halide to form the products *(20)* and *(21)* and/or abstract a proton from the solvent to form *(22)* and *(23)*.

Another mechanism proposes "free radical" type combination of an alkyl free radical with the aromatic radical anion as the initiation step by which alkylation takes place[44].

Two additional variations postulate attack by an alkyl radical or alkyl anion on naphthalene[44,45]. Both reactions lead to intermediates common to the other mechanisms.

Preliminary evidence is more in accord with the combination of two radicals as the mechanism by which the formation of alkylation product is initiated. Support for this view comes from three observations: 1) The yield of alkylation is independent of halide[46]. 2) From Table 6 it is seen that the yield of alkylation product follows the order, tertiary > secondary > primary[44]. Both of these observations would discount a displacement (S_N2) mechanism. The observation that the alkylation product is wholly insensitive to the presence of excess naphthalene[44] suggests that mechanisms in which naphthalene couples with either an alkyl radical or a carbanion are not product controlling.

Table 6. Product distribution from the reaction of sodium naphthalenide with alkyl iodides RI [44].

Products	Relative yield (%) from			
	$(CH_3)_3CCH_2I$	*n*-$C_5H_{11}I$	*sec*-$C_5H_{11}I$	*tert*-$C_5H_{11}I$

[41] The tacit but necessary assumption that both radicals are produced at the same rate is supported by data which suggest that the rate of reaction of both halides with sodium naphthalenide should be diffusion controlled; *D. J. Morantz* and *E. Warhurst,* Trans. Faraday Soc. *51,* 1375 (1955).

[42] Nucleophilic displacement reactions on *n*-propyl exceed rates on isopropyl by at least a factor of ten; *A. Streitwieser, Jr.*: Solvolytic Displacement Reactions. McGraw-Hill, New York 1962, pp. 11–13; Chem. Rev. *56,* 571 (1956).

[43] For nucleophiles of hard basicity the competing E2 elimination is more significant for isopropyl than propyl halides: See, for example, *M. L. Dahr, E. D. Hughes, C. K. Ingold,* and *S. Masterman,* J. Chem. Soc. *1948* 2055.

[44] *G. D. Sargent* and *G. A. Lux,* J. Amer. Chem. Soc. *90,* 7160 (1968).

[45] *G. J. Hoijtink,* Chemie-Ing.-Techn. *35,* 333 (1963).

[46] *J. F. Garst, J. T. Barbas,* and *F. E. Barton II,* J. Amer. Chem. Soc. *90,* 7159 (1968).

This observation is interesting, particularly in view of data to follow concerning reactions of alkyllithium with anthracene. In a system that is analogous to the reaction of sodium naphthalenide with alkyl halides, anthracene undergoes a photolytically catalyzed alkylation reaction with various alkyllithium reagents[47] (see Table 7).

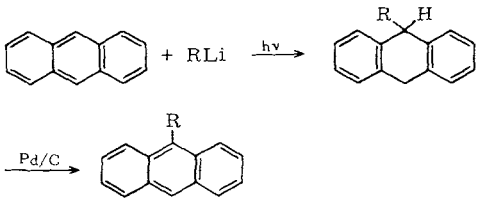

Table 7. Reaction of alkyllithium RLi with anthracene [a].

Solvent	R	Yield (%) of R-Anthracene	Yield (%) of 9,10-Dihydroanthracene
Ethyl ether	CH_3	0	0
THF	CH_3	0	37
THF	C_2H_5	74	0
THF	n-C_4H_9	66	0

[a] The fate of all alkyl moiety is not clear. Dimer formation is not reported.

Evidence does not point to attack by alkyllithium on the anthracene radical anion. With *n*-butyllithium no ESR evidence is found for a 9-butylanthracene radical anion. (The anthracene radical anion is present.) Also, if lithium anthracenide is prepared independently and treated with *n*-butyllithium there is less alkylation and more 9,10-dihydroanthracene formation. The dihydroanthracene possibly derives from dianion, which would be more probable here than under normal alkylation conditions. Photolyses performed on other hydrocarbons in the presence of *n*-butyllithium show that the reactivity of the hydrocarbon decreases in the order anthracene, phenanthrene, naphthalene, biphenyl[47]. This may be a consequence of differences in absorption of the UV light used to catalyze the reaction, or of the variations in electron affinity of these hydrocarbons[48].

It is tempting to view the process as one involving the transitory existence of a radical anion formed by electron transfer from alkyllithium to anthracene in a solvent cage, followed by collapse of the two species. Such a process would be consistent with the best supported mechanistic proposal for the reaction of sodium naphthalenide with alkyl halides. This route, however, seems unlikely in view of the results of other photonucleophilic aromatic substitution reactions. Such reactions include hydroxylation[49,50], amination[50,51], cyanation[52], halogenation[53], and alkoxylation[54]. These reactions apparently proceed by aromatic excitation to the S_1 state followed by coupling with the nucleophile rather than an electron transfer process[55].

Another process shown to have a radical anion pathway is the reaction of sodium naphthalenide with alkyl toluenesulfonates[56], which leads to alcohols in good yield (see Table 8).

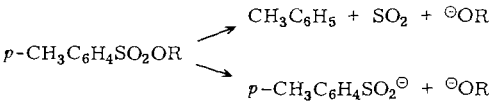

Table 8. Cleavage of toluenesulfonates p-$CH_3C_6H_4SO_2R$ with sodium naphthalenide to alcohols ROH [57].

R	Yield of ROH (%)
Cyclohexyl	100
Cyclopentyl	98
cis-4-Cyclooctenyl	98
Menthyl	98
trans-2-Phenylcyclohexyl	93
Cholesteryl	95
Phenyl	99
Stearyl	99
Neopentyl	85

Other arene radical anions may be used. Phenanthrene-sodium appears to be quite suitable, whereas anthracene-sodium reacts much more slowly and gives poorer yields (*ca.* 50% with cyclohexyl toluenesulfonate). Sodium diphenylketyl does not reduce sulfonates even though the reduction potential of benzophenone ($-E_{1/2}$ = 1.22 V)[58] is comparable to that of anthracene ($-E_{1/2}$ = 1.46 V)[59]. Reduction of toluenesulfonates by sodium in ammonia[60] and sodium amalgam in ethanol[61] also produces alcohol, conceivably *via* a radical anion route.

Phenyl radical anions show a rather small neighboring group effect. It is conceivable that a phenyl radical anion could participate either directly or as an electron transfer agent (Scheme 6, above and below)[62].

Cram found[62] that upon treatment of *threo*-2-phenyl-3-pentyl methanesulfonate with potassium in DME 94% of the product was 2-phenylpentane and 6% was 3-

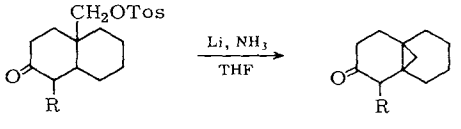
Scheme 6



phenylpentane (the product of phenyl migration). Treatment of *threo*-3-phenyl-2-pentylmethane sulfonate with sodium in liquid ammonia gave 75% 3-phenylpentane and 3% 2-phenylpentane (the product of phenyl migration). Conceivably rearrangement could also result from phenyl migration to a carbon radical or organometallic compound. But aryl radical anion participation seems more appropriate in view of the fact that 1,2-phenyl migration to carbon radicals[63] or to carbon bonded to metal[64] occur only in systems widely different than the above.

A result which seems to confirm electron transfer as a neighboring group effect is the reduction of 1,1-dideuterio-1-methoxy-2-(1-naphthyl)ethane *(24)* with potassium. Reduction occurs *readily* and without rearrangement. Reduction of *threo*-2-phenyl-3-methoxypentane *(25)*, by comparison, is extremely slow. These experiments demonstrate the necessary role of the naphthyl group in the reduction process and imply neighboring group participation by electron transfer.

(24) *(25)*

There is one other example of a reaction in which a radical anion might have served as a neighboring group; this involves the conversion of *(26)* to *(27)*[65].

(26) *(27)*

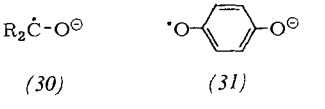
5. Azo Radical Anions

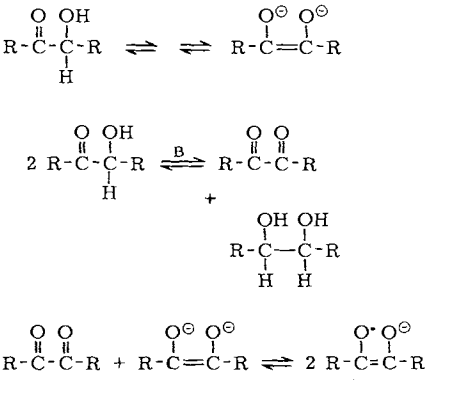
The existence of a 1:1 adduct of sodium with azobenzene was recognized by *Schlenk*[66]. However, he formulated the product *(28)* rather than the radical anion *(29)*.

(28) *(29)*



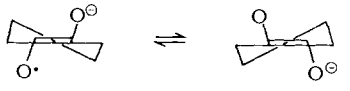
The intermediacy of radical anions can be inferred from work showing that the "di-Grignard" reagent of hydrazobenzene readily reduces benzoin and that azobenzene oxidizes many organometallic compounds[67]. For example, azobenzene is reduced to a salt of hydrazobenzene when treated with phenyllithium or phenyl magnesium bromide, both of which undergo coupling to biphenyl[68]. *Gilman* and *Adams*[69] showed that the formation of biphenyl did not involve triphenylhydrazine anion as an intermediate.

Wittig[70] described a crystalline salt of a radical anion prepared by the reaction of azobenzene with the lithium salt of azobenzene, though it is now known that the equilibrium lies far to the left.



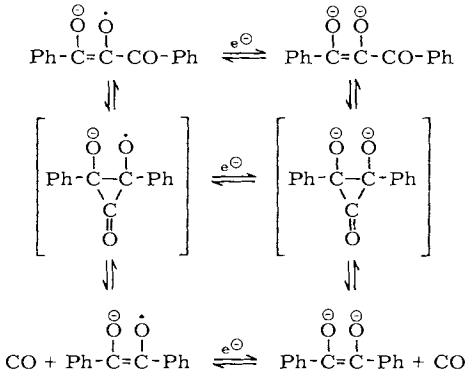
6. Diones and Triones

The chemistry of ketyl *(30)* and semiquinone *(31)* radical anions is well known. Ketyls are intermediates in the pinacol reaction; semiquinones are particularly important as electron carriers in certain biological systems. Less well known are the reactions of semidiones and semitriones.



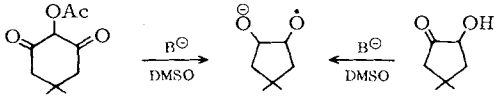
(30) *(31)*

Radical anions of diones are produced by electrolytic reduction or reaction of the appropriate α-hydroxy ketones in DMSO containing an excess of potassium *tert*-butoxide[71]. These radical anions have been shown to have considerable stability even when R is alkyl or hydrogen.



The study of semidiones has largely centered in the area of conformational analysis. For example, *Russell* has examined the semidiones of various cycloalkanes[72]. The effect of temperature on the population in the equatorial (more stable) and axial conformations of the methylcyclohexanesemidiones yields enthalpy differences of 0.7 and 1.4 ($\Delta S = 0$) for the 3- and 4-methyl substituents. Cyclohexanesemidione *(32)* undergoes the interconversion of half-chair conformations with an enthalpy of activation of 4.0 kcal/mole, entropy of activation +1 eu.

(32)



Semitriones are produced by polarographic and electrolytic reductions. Reduction of a triketone often leads to a rearrangement. For example, 1,3-diphenyl-1,2,3-propanetrione loses carbon monoxide and is converted to the semidione (in equilibrium with the dianion) most likely according to the reactions given in Scheme 7[73].

Scheme 7

This route is supported by the fact that ^{14}C-labeling at C-1 and C-3 yields carbon monoxide devoid of radioactivity[74].

Ring contraction is known to occur in at least one case[73]. Reaction of 2-acetoxy-5,5-dimethylcyclohexane-1,3-dione or 4,4-dimethyl-2-hydroxycyclopentanone with potassium *tert*-butoxide in DMSO yields a five-line sextet consistent with four equivalent hydrogen atoms, a_H = 12.8 gauss.

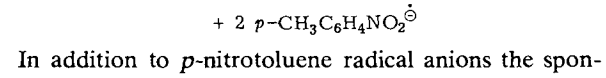
7. Other Reactions of Nitro Compounds



In section 2 it was noted that nitroaromatic systems are good electron acceptors. Reactions other than substitution are known to proceed through a reactive radical anion intermediate. For example, treatment of *o*- and *p*-nitrotoluene with base, and the resultant disproportionation products have been studied by a number of earlier workers[75].

A more recent investigation with potassium *tert*-butoxide in *tert*-butyl alcohol or with dimethyl sulfoxide (DMSO), has shown formation of the *p*-nitrotoluene radical anion in the absence of oxygen[76,77]. This process is spontaneous and derives from reduction of the parent nitrotoluene by ionization products of the nitrotoluene.

(33)

In addition to *p*-nitrotoluene radical anions the spontaneous disproportionation (in the absence of oxygen) of *p*-nitrotoluene in basic *tert*-butyl alcohol produces *p,p'*-dinitrobibenzyl *(34)* and insoluble products (Table 9)[77].

Table 9. Spontaneous dimerization of *p*-nitrotoluene in *tert*-butanol/potassium *tert*-butoxide at 25 °C.

Reaction time (min)	Yield of *(34)* (%)	Recovered *p*-nitrotoluene	Benzene-insoluble materials (%)
5	21	69	0
10	37	56	0.4
20	41	51	1.5
30	47	a	+
60	57	a	++

[a] Not measured.

p-Nitrotoluene in a mixture of 80% DMSO and 20% *tert*-butyl alcohol, however, yields additional products, namely *p,p'*-dinitrostilbene and its radical anion. Stilbene derives from the bibenzyl product and is apparently connected with the fact that *p,p'*-dinitrobibenzyl is soluble in DMSO but not in *tert*-butyl alcohol.

In the presence of oxygen, treatment of *p*-nitrotoluene with potassium *tert*-butoxide in *tert*-butyl alcohol yields *p,p*'-dinitrobibenzyl plus *p*-nitrobenzoic acid *(35)*[78]. Molecular oxygen can replace the un-ionized *p*-nitrotoluene as an electron acceptor. It also converts the *p*-nitrotoluene radical anion into *p*-nitrotoluene, so that higher ultimate yields of dimer can be achieved in the presence of oxygen than in its absence. The *p*-nitrobenzoic acid is formed in a competing process whose rate is dependent upon oxygen pressure.

$$p\text{-}NO_2C_6H_4\overset{\ominus}{C}H_2 + O_2 \longrightarrow p\text{-}NO_2C_6H_4CH_2OO^{\ominus}$$
$$\downarrow$$
$$p\text{-}NO_2C_6H_4CO_2^{\ominus} \quad (35)$$

Mechanisms involving the coupling of *p*-nitrobenzyl radicals in the presence of molecular oxygen can be excluded by the known rapidity of the reactions of molecular oxygen with alkyl radicals, including those of the *p*-nitrobenzyl type.

A similar type of behavior is shown in the reactions of aliphatic polynitro compounds. Formation of unstable radical anions of tri- and tetranitromethane by electron transfer from a number of carbanions is followed by loss of a nitro group in each case[79]. $[(NO_2)_2CH]^{\cdot 2\ominus}$ is eventually detected from trinitromethane and $[(NO_2)_3C]^{\cdot 2\ominus}$ is the decomposition product of tetranitromethane. Treatment of the related nitroalkane, 1,1,1-trinitroethane, with butyl thiolate and 2-nitropropyl anions leads to the dimers of the anion in yields of 71 and 87% respectively[80].

Organic reaction pathways involving radical anions are numerous and varied. This review has not exhausted the extant applications; additional examples are likely, as are further investigations into the aspects cited here.

The authors are grateful to Professors W. G. Lloyd, J. W. Reasoner and R. D. Farina for their aid in preparing this manuscript.

COMMUNICATIONS

Myrmicacin, The First Insect Herbicide[**]

By *Hermann Schildknecht* and *Knut Koob*[*]

The leaf-cutting ants, *e.g. Atta sexdens* from South America, demonstrate a uniquely effective way of establishing and maintaining their "fungus gardens" as a source of food. Until now the mechanism by which this is accomplished – under growth conditions favorable to many microorganisms – has not been resolved. Equally mysterious was the method by which harvest ants succeeded in preserving gathered grain in storerooms for long periods of time without sprouting.

From the metathoracic glands of Myrmicine ants we have isolated and identified β-indolylacetic acid (IAA)[1] and phenylacetic acid (PAA)[2]. *Martin*'s[3] investigation of leaf-cutting ants revealed – contrary to *Weber*'s suggestion[4] – neither the presence of growth regulators nor of antibiotics.

Thin-layer chromatography of the secretion of the metathoracic glands followed by treatment with concentrated sulfuric acid revealed a previously unidentified substance, which we called Myrmicacin, between the PAA- and IAA-spots. Again, all the usual reactions indicated a carboxylic acid. We succeeded with its micro-preparative isolation gas-chromatographically after silylation of the thin-layer band. From the molecular weight of the silylated Myrmicacin (332.229271), obtained by mass spectrometry, we deduced the formula $C_{10}H_{20}O_3$. For structural analysis, using a combination of mass spectrometry and gas chromatography, we prepared the methyl ester with diazomethane. We found the fragment mass 103 to be a key fragment, which indicated a β-hydroxy ester. After subtraction of this key fragment there remained a C-7 fragment, which was easily detected in the mass spectrum of the silylated carboxylic acid. Thus, as the result of mass spectral analysis we found the β-hydroxydecanoic acid *(1)* and also – as further analysis of the secretion showed – β-hydroxyoctanoic *(2)* and β-hydroxyhexanoic acid *(3)*; see Table 1. Myrmicacin *(1)* was found to be the levorotatory D-acid with $[\alpha]_D^{20} = -3°$ (in $CHCl_3$).

Table 1. Concentrations of the acids in the metathoracic glands of the leaf-cutting ants *(A. sexdens)*.

Acids		Conc. (μg/gland)
Phenylacetic acid	PAA	1.3 - 3.0
Indolylacetic acid	IAA	0.01 - 0.1
D-β-Hydroxydecanoic acid (Myrmicacin)	*(1)*	2.0 - 3.5
β-Hydroxyoctanoic acid	*(2)*	0.5 - 5.0
β-Hydroxyhexanoic acid	*(3)*	<0.1

$CH_3\text{-}(CH_2)_6\text{-}CHOH\text{-}CH_2\text{-}COOH$
(1)

$CH_3\text{-}(CH_2)_4\text{-}CHOH\text{-}CH_2\text{-}COOH$
(2)

$CH_3\text{-}(CH_2)_2\text{-}CHOH\text{-}CH_2\text{-}COOH$
(3)

The carboxylic acids in Table 1 were also detected in other ants by gas-chromatographic techniques; see Table 2.

Table 2. Acids from the metathoracic glands of ants.

Kind of ant	Myrmicacin	PAA	IAA	*(2)*	*(3)*
Atta sexdens	+	+	+	+	+
Messor barbarus L.	+	+	–	–	–
Myrmica laevinodis Nyl.	+	+	+	–	–
Acromyrmex sp.	+	–	+	–	–

The occurrence of hydroxy acids together with the bioregulators IAA and PAA suggested that they too may be growth regu-

lators. Since the seed-storing ant *Messor* does not have the growth regulator IAA but does produce Myrmicacin, the hydroxy acids could be expected to have a germination-inhibiting effect. In support of this hypothesis the fungicide test[5] showed that Myrmicacin in a concentration of 0.015% has an effectiveness of 25% for growth inhibition of *Altenaria tennis* and *Botrytis cinerea*, and in a concentration of 0.03%, it is 90% effective. The fungicidal activity of Myrmicacin can be demonstrated very vividly by adding 20 mg of the latter to 100 g of plum puree. For three weeks the puree was not attacked by fungi or fruit flies, while in the same time the control puree lacking Myrmicacin was completely overgrown with microorganisms.

Thus we conclude that the harvest ants prevent the gathered grass seeds from sprouting and the leaf-cutting ants prevent the intruding spores from sprouting by using Myrmicacin as a herbicide. Additional preliminary experiments show that PAA inhibits bacterial growth in the garden, and IAA supports the growth of the mycelia[6]. Thus only the symbiotic fungus is able to thrive at the founding of a new nest because it is brought as mycelia by queen ants after their nuptial flight[7]. All the other fungi which intrude as spores remain undeveloped. Whether or not the bulbous thickenings which are formed under the care and control of the ants at the ends of the mycelia and which are used as food for the ants and whether their young develop with the help of the compounds secreted by the metathoracic glands is still being investigated.

Complexes of Phosphirane

By *R. Bausch, E. A. V. Ebsworth*, and *D. W. H. Rankin*[*]

Attempts to add or remove a proton from the phosphorus atom in the small ring compound phosphirane, $(CH_2)_2PH$, have not been successful. Reaction with protonic acids is rapid, and leads to liberation of ethylene[1]; with potassium in liquid ammonia there is a complicated reaction to give the anions of different phosphanes without liberation of hydrogen. Similarly, reaction of phosphirane with methyllithium in ethers leads to decomposition. The compound is not deprotonated by KPH_2 in dimethyl ether.

Treatment of the *N*-methylpyridinium salt of $[Mo(CO)_5I]^-$ with phosphirane in CH_2Cl_2, however, gives the solid complex pentacarbonylphosphoranemolybdenum(0), $[(CH_2)_2PH]Mo(CO)_5$; the species $[(CH_2)_2PH]_2Mo(CO)_4$ and $[(CH_2)_2PH]_3Mo(CO)_3$ have been obtained from phosphirane and tetracarbonylnorbornadienemolybdenum or tricarbonylcyclohexatrienemolybdenum. The complexes have been characterized spectroscopically and by analysis, and the ^1H and ^{31}P-NMR spectra of $[(CH_2)_2PH]Mo(CO)_5$ have been obtained and analyzed, as have those of phosphirane itself[2].

The ^{31}P-NMR spectra are essentially first order, with $J(PH)$ equal to 333 Hz in the complex, compared with 155 Hz in phosphirane; the values obtained from the ^1H-NMR spectra are 330.2 Hz and 157.7 Hz, respectively. The magnitudes of the two couplings $J(HCP)$ have been obtained from the ^{31}P spectra, but the signs and magnitudes are found in the full analysis of the ^1H spectra. The values of $+2.2$ and -8.8 Hz for the complex compare with those of $+16.5$ and -2.2 Hz for free phosphirane. The only other couplings to change significantly on complexing are the two couplings $J(HCPH)$.

Pentacarbonylphosphiranemolybdenum reacts with KPH_2 in dimethyl ether, with liberation of 80% of the phosphane expected for the reaction:

$$[(CH_2)_2PH]Mo(CO)_5 + PH_2^- \longrightarrow [(CH_2)_2PMo(CO)_5]^- + PH_3$$

The resulting yellow salt reacts with trimethylchlorosilane with precipitation of a white solid; the IR, NMR, and mass spectra of the soluble products indicate the formation of the complex $[(CH_2)_2PSiMe_3]Mo(CO)_5$. There is a similar reaction with monobromosilane.

6,11-Methanocyclobutabenzo[1,2-*a*][10]-annulene, a Biphenylene Analog Containing a Carbocyclic 10π-Electron Ring

By *P. J. Garratt* and *K. Peter C. Vollhardt*[*]

Biphenylene is one of the few examples of a polycyclic system composed of planar $4n$ and $(4n+2)$ π-electron rings, and as such has considerable theoretical interest[1,2]. The replacement of one of the benzene rings by a charged[3] or heterocyclic[4] 6 π-electron system has recently been reported, but no compounds are known in which a ring has been replaced by an annulene containing ten or more π-electrons[5]. We now report the synthesis of 6,11-methanocyclobutabenzo[1,2-*a*][10]annulene *(3)*, a compound formally derived from biphenylene by replacement of a benzene ring by 1,6-methano[10]annulene[6].

(1) *(2)* *(3)* *(5)* *(4)*

The addition of a solution of 1,3,5-cycloheptatriene-1,6-dicarboxaldehyde *(1)*[7] in THF to an equimolar solution of preformed 1,2-dihydro-1,2-bis(triphenylphosphoranylidene)-cyclobutabenzene *(2)*[8] in ether : benzene (3 : 1) at room temperature under nitrogen led to an immediate discharge of the red color and the formation after several minutes of a dark green mixture. After stirring for 2 hours, chromatography on alumina and subsequent preparative thin-layer chromatography on silica of the hydrocarbon fraction gave *(3)* as yellow crystals, mp 166–167° C, in 1% yield.

The structure is based on the molecular formula (*m/e* 216), and the spectral and chemical properties; electronic spectrum: (C_2H_5OH) λ_{max} = 223 (ε 15200), 280 (53600), 320 (31200), 388 (2800), and 398 nm (2800). This spectrum resembles that of 1,6-methano[10]annulene[6], except that the maxima are increased to longer wavelength and differ in relative intensity. The NMR spectrum (CCl_4, 100 MHz) has signals centered at τ = 3.06 (2H) and 3.30 (8H), and an AB-system at τ = 7.55 and 9.71 (*J* = 10 Hz).

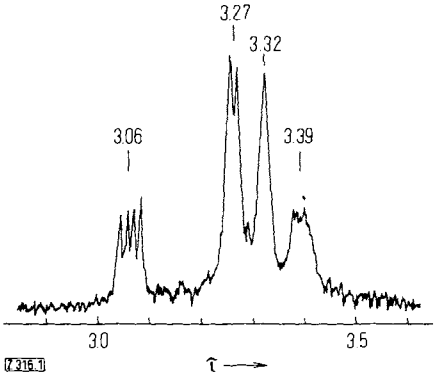

Fig. 1. The low field region of the 220 MHz NMR spectrum of *(3)* in CCl_4.

The low field region of the 220 MHz NMR spectrum of *(3)* is shown in the Figure [an AA'BB' system at τ = 3.06 and τ = 3.39 (H^8, H^9 and H^7, H^{10} respectively), an AA'BB' multiplet at τ = 3.27 (H^1–H^4), and a 2-H pseudosinglet at τ = 3.32 (H^5, H^{12})]. Irradiation (100 MHz) of the AB-signal at τ = 9.71 causes the pseudosinglet to sharpen, and irradiation of the AB-signal at τ=7.55 causes a change in the signals due to H^7, H^{10}. Since it is known that in 1,6-methano[10]annulenes the ring protons are more strongly coupled to the methylene proton which has the *anti*-orientation[9], the signal at τ=7.55 is attributed to H^a and that at τ=9.71 to H^b.

Hydrogenation of *(3)* over Pd/C in ethyl acetate gave the decahydro derivative *(4)* as a liquid.

The assignments of the ring protons are further supported by deuteration studies[6]. Treatment of *(3)* with CF_3CO_2D/D_2SO_4 in ether caused the disappearance of the proton signals in the order τ = 3.39, 3.32, and 3.27; the hexadeuterio compound *(5)* is eventually formed, which in the NMR spectrum has two singlets at τ=3.06 and 3.27 (1:1).

The positions of the ^1H and ^{13}C-NMR signals in biphenylene[2] and the ^1H-NMR signals in cyclobutabenzo[1,2-*c*]thiophene[4] have been attributed to the shielding effect of a paramagnetic ring current arising from the $4n$ π-electron 4-membered ring. The benzene protons in *(3)* show an upfield shift when compared to those in *(4)*, indicating that *(3)* also exhibits a paramagnetic effect. The chemical shift of the H^a methylene proton, at unusually low field for a delocalized bridged [10]annulene system[6,10], suggests that this proton is experiencing *paramagnetic deshielding* and must occupy a position inside the deshielding cone of the 4-membered ring.

Derivatives of 1,3,4,2,5-Triazadiborolidine

By *Dieter Nölle* and *Heinrich Nöth*[*]

1,3,4,2,5-Triazadiborolidine *(1a)*, which is isoelectronic with cyclopentadiene, is unknown. Until now only two of its derivatives have been described, namely *(1b)*, which is formed on partial aminolysis of the corresponding 1,2,4,5,3,6-tetrazadiborine *(2)* with cyclohexylamine[1], and *(1c)*, which is formed from *N,N'*-dimethylhydrazine and $[(CH_3)_2N(C_6H_5)B]_2NH$[2]. We found the scope of both methods of preparation to be severely limited.

The fact that the equilibrium (1) can be shifted in favor of the BN compound opens up a new, simple route to compounds of type *(1)*. Although the diborylamine $[(CH_3)_2B]_2NH$ can be obtained from $(CH_3)_2BSCH_3$ and NH_3[3], reaction of 2 moles of $CH_3B(SCH_3)_2$ with 1 mole of NH_3 under mild conditions leads not to $[CH_3(CH_3S)B]_2NH$ but exclusively to the borazine $(CH_3BNH)_3$, which is obtained quantitatively when the reactants are used in the molar ratio 1:1[4]. This affords additional evidence for the kinetic instability of diborylamines of type $[R(X)B]_2NR'$[3]. On the other hand, reaction of 2 moles of $RB(SCH_3)_2$ with 1 mole of the hydrazines R'NH-NHR' under suitable conditions furnishes preferentially compounds of type *(3)* as well as *(2)* as a minor product. However, *(2)* is the major product when the reactants are present in a molar ratio of 1:1. Compound *(3)* readily reacts with NH_3 and primary amines to

$$\geq B\text{-}SR + H_2NR' \rightleftharpoons \geq B\text{-}NHR' + HSR \qquad (1)$$

(2)

give derivatives of *(1)*. It seems that the reaction also involves *(2)*, which appears to be in equilibrium with *(3)* according to Scheme (2), since *(2)* can no longer be detected by ^{11}B-NMR spectroscopy after reaction with the primary amine has reached completion. Small amounts of borazine derivatives are also formed [cf. Scheme (2)].

The method described above is suitable for the synthesis of many derivatives of *(1)* and of other boron heterocyclics[5].

	R	R'	R''	M.p. (°C)	B.p. (°C/torr)	δ^{11}B [a] (ppm)	Yield (%)
(1a)	H	H	H	-	-	-	-
(1b)	C_6H_5	CH_3	C_6H_{11}	101	-	-30.5	-
(1c)	C_6H_5	CH_3	H	110	-	-29.6	75
(1d)	CH_3	CH_3	H	37	93/130	-30.6	72
(1e)	CH_3	CH_3	CH_3	-	28/2.5	-31.8	63
(1f)	CH_3	CH_3	$N(CH_3)_2$	-	62/12	-31.0	60
(1g)	CH_3	C_6H_5	H	85	-	-34.4	70
(1h)	CH_3	C_6H_5	CH_3	88	-	-34.8	65

[a] Standard: $BF_3 \cdot O(C_2H_5)_2$, external.

Procedure:

A solution of *N,N'*-dimethylhydrazine (3 g) in diethyl ether (50 ml) is added during 24h to a stirred solution of $CH_3B(SCH_3)_2$ (13.2 g) in diethyl ether (40 ml) at 0 °C. If dry ammonia (1.27 g) is condensed into the solution at −70 °C a precipitate is formed that dissolves when warmed. Ether and methanethiol are then distilled off, first at 600 torr and finally at 400 torr, using a 50-cm spinning band column. Fractionation of the residue affords 2,4,6-trimethylborazine *(4)* (b.p. 58–68 °C/130 torr; 0.38 g), an intermediate fraction consisting of *(4)* and *(1d)*, and then *(1d)*, which suddenly solidifies to a mass of needle-shaped crystals.

1,4-Bis(trimethylsilyl)-1,4-dihydropyrazine by Reductive Silylation of Pyrazine

By *Reinhard A. Sulzbach* and *Abul F. M. Iqbal*[*]

The 1,4-dihydropyrazine system, which contains an interesting arrangement of two enamine structures, has hitherto received very little attention. This might be due to the lack of simple,

(1)

selective methods for synthesizing 1,4-dihydropyrazines. We have found that the 1,4-dihydropyrazine system can be prepared very easily by reductive silylation of pyrazine with alkali metals and halogenosilanes. Thus, if pyrazine is allowed to react with lithium and trimethylchlorosilane the yellow 1,4-bis(trimethylsilyl)-1,4-dihydropyrazine *(1)*, which is extremely sensitive to oxidation, is formed in almost quantitative yield.

Analogously to the reductive silylation of benzene[1] and pyridine[2] this reduction may proceed *via* radical anions of pyrazine.

Procedure:

A solution of pyrazine (20 g, 0.25 mole) in THF (75 ml) is added dropwise over a period of 1h at 0 °C to a mixture of lithium (5.2 g, 0.75 g-atom; particle size 1–10 μm), trimethylchlorosilane (81.5 g, 0.75 mole), and THF (75 ml). Unreacted lithium and precipitated lithium chloride are then filtered off. After removal of excess trimethylchlorosilane from the filtrate by distillation there remains a solid yellow residue. Recrystallization from diethyl ether yields *(1)* as yellow needles. Yield 50 g (88%); m. p. 65 °C; NMR: τ = 5.34 (H ring), 10.03 ($-CH_3$). Since *(1)* decomposes spontaneously in the presence of air all operations must be carried out in an inert atmosphere.

The Thiazyl Cation $[NS]^+$

By *Oskar Glemser* and *Wolfgang Koch*[*]

Simultaneous introduction of sulfur nitride fluoride NSF (p = 1 torr) and the pentafluoride AsF_6 (p = 1 torr), or SbF_5 (p = 1 torr), into a quartz flask at room temperature[1] leads to products having the molecular composition $NSF \cdot XF_5$ (X = As or Sb), which according to spectroscopic findings, can be formulated as ionic compounds $[NS]^+[XF_6]^-$, *i.e.* as compounds containing the hitherto unknown thiazyl cation.

Proof of structure was afforded by the Raman spectrum of $[NS]^+[AsF_6]^-$, which exhibited the following bands (cm^{-1}; rel. intensity in brackets): 1437 (6), 684 (10), 557 (3), 368 (4). The bands at 684, 557, and 368 cm^{-1} can be assigned unequivocally to the $[AsF_6]^-$ ion: cf. *e.g.* $Cs[AsF_6]$[2]: $\tilde{\nu}_1$ 685, $\tilde{\nu}_2$ 576, $\tilde{\nu}_3$ 372 cm^{-1} and $[SF_3][AsF_6]$[3]: $\tilde{\nu}_1$ 676, $\tilde{\nu}_2$ 551, $\tilde{\nu}_3$ 366 cm^{-1}. The signal at 1437 cm^{-1} corresponds to the wave number of the NS vibration; as is to be expected it is higher than in the case of NSF ($\tilde{\nu}_{NS}$ = 1372 cm^{-1}). The same is true for the NS valence force constants[4] and NS bond orders[5] calculated from these results:

$f_{[NS]^+}$ = 11.85 mdynes/Å; bond order $N_{[NS]^+}$ = 2.6

$f_{NS}(NSF)$ = 10.71 mdynes/Å; bond order $N_{NS}(NSF)$ = 2.4

The ^{19}F-NMR spectra of the substances dissolved in AsF_6 confirm their ionic character: no SF signals appear between +350 and −440 ppm ($CFCl_3$ as external standard); exchange of fluorine between the anions and AsF_6 was not observed.

Chromium Trichloride-Tris(aluminum trichloride)

By *Keith Lascelles* and *Harald Schäfer*[*]

We have observed that solid chromium(III) chloride can be chemically transported by gaseous aluminum(III) chloride in a temperature gradient (500 → 400 °C). There is therefore a reversible endothermic reaction by which the $CrCl_3$ is taken into the gas phase at 500 °C, and after an appropriate gas movement (diffusion, flow) is deposited again in the zone at 400 °C. An adequate concentration gradient of the chromium-containing molecule between the reaction spaces is necessary for a measurable transport effect. The equilibrium given in eq. (1) cannot be responsible since at 500 °C it still lies very much to the left; with $p(Al_2Cl_6) = 1$ atm, calculation gives $p(CrCl_4) \approx 10^{-11}$ atm[1,2].

$$4\ CrCl_{3,s} + Al_2Cl_{6,g} \rightleftarrows 4\ CrCl_{4,g} + 2\ AlCl_g \qquad (1)$$

On the basis of other known volatile $AlCl_3$ complexes $NaCl \cdot AlCl_3$[3,4], $CaCl_2 \cdot Al_2Cl_6$[5], $NdCl_3 \cdot 3\ AlCl_3$[6], $UCl_4\ 2\ AlCl_3$[7], and $UCl_5 \cdot AlCl_3$[7] we investigated the existence of a volatile compound of $CrCl_3$ and $AlCl_3$ responsible for the observed transport. In these experiments, carried out with the special exclusion of moisture, equilibrium spaces V_1 and V_2 were heated in metal block ovens at 400 and 500 °C respectively. They contained $CrCl_{3,s}$ and $Al_2Cl_6/AlCl_3$ and were connected by a diffusion path 80 mm long and 6 mm diameter. The same total pressure thus prevailed throughout the whole system. The partial pressures of Al_2Cl_6 and $AlCl_3$ in spaces V_1 and V_2 depended on the initial amount of $AlCl_3$ and the known dissociation equilibrium $Al_2Cl_6/AlCl_3$[2]. The partial pressure of $CrCl_3.x\ AlCl_3$ was neglected in the calculation of the total pressure.

In the range of measurements used, the total pressure Σp lay between 0.15 and 5.18 atm, the Al_2Cl_6 pressure in space V_2 between 0.067 and 4.49 atm, and the transport yield m/t between 10 and 84 mg $CrCl_3$/5 days. The analysis showed that the transport is caused by the formation of $(CrCl_3 \cdot 3\ AlCl_3)_g$ according to equilibrium (2):

$$CrCl_{3,s} + 1.5\ Al_2Cl_{6,g} \rightleftarrows (CrCl_3 \cdot 3\ AlCl_3)_g;\ Kp \qquad (2)$$

This conclusion was reached as follows:
The partial pressure of the initially unknown volatile chromium compound is represented as $p(Cr)$. The transport by diffusion between the equilibrium spaces V_2 and V_1 is, by the well-established relationships, proportional to $\Delta p(Cr) = p_2(Cr) - p_1(Cr)$, and inversely proportional to Σp[8]. It was found experimentally that $p_1(Cr) \ll p_2(Cr)$. The following is therefore true:

$$m/t \propto p_2(Cr)/\Sigma p$$

By introduction of the equilibrium constant for reaction (2), it follows that

$$m/t \propto p^{1.5}(Al_2Cl_6)/\Sigma p$$

The measured values were in good agreement with this relationship. Other formulas $CrCl_3 \cdot x\ AlCl_3$ with $x = 1$, 2 or 4 for the volatile complex are excluded unequivocally.

The *structure* of the compound $CrCl_3\ 3\ AlCl_3$ was not investigated, but a clear possibility is one in which the Cr is octahedrally, and the Al tetrahedrally surrounded by Cl. Such a molecule can exist in mirror isomerism.

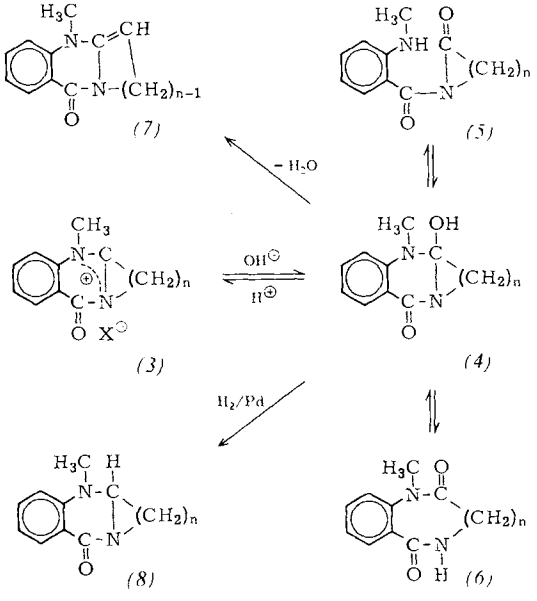
Synthesis of an Azacyclol[1][**]

By *Manfred Rothe, Tibor Tóth,* and *Dieter Jacob*[*]

Bicyclic, *N*-acylated orthodiamides containing a free OH group *(1)*, "azacyclols", are of interest as nitrogen analogs of the peptide part of the ergot alkaloids *(2)*. In addition they represent examples of the unstable tetrahedral intermediates in carbonyl reactions of acid amides with amines and amides, whose existence had hitherto been postulated only on the basis of the reaction kinetics.



(1)

(2)

We have now synthesized a previously unknown type of azacyclol *(1)*. As in oxa-[2] and thia-cyclols[3] a fused benzene ring should increase the stability of the cyclol and render its unequivocal spectroscopic identification much easier.

The synthesis of the azacyclol *(4)*, $n = 3$, was accomplished by reaction of the acylamidinium salt *(3)* ($n = 3$, X = I) – which was prepared by *N*-methylation of 2,3-propano-4-quinazolone – with NaOH. In contrast to the representatives having a larger lactam ring[4], the azacyclol *(4)*, $n = 3$, is isolable and comparatively stable. Its structure was established unequivocally from elemental analysis, spectroscopic data, and from results of chemical reactions. The tautomeric structures *(5)* and *(6)* which have been taken into consideration as stabilization possibilities for cyclols – at least in equilibrium[2,3] – could be definitely ruled out.

(7) *(5)* *(3)* *(4)* *(8)* *(6)*

The UV spectrum with $\lambda_{max} = 223$ nm ($\varepsilon = 36500$) is in accord with the cyclol structure *(4)*, in contrast to the cyclodipeptide *(6)*, $n = 7$, which absorbs at $\lambda_{max} < 200$ nm. The structure *(5)* of the *N*-acylamides that absorb in the same region (*N*-benzoylpyrrolidinone: $\lambda_{max} = 228$ nm), could be ruled out on the basis

of the NMR spectrum (in [D_7]-DMF): The CH_3 signal would have to be split into a doublet by the NH proton, but only the singlet ($\tau = 6.87$ ppm) expected for *(4)* was found. Further characteristics are (i) the neighboring aromatic proton shifted downfield ($\tau = 2.18$ ppm) by the magnetic anisotropy of the carbonyl group, indicating coplanarity of the benzene ring and the heterocycle, and (ii) the OH signal occurring as a sharp singlet at $\tau = 6.68$ ppm (in [D_6]-DMSO) which establishes the presence of a tertiary OH group. In the IR spectrum the broad band at 3247 cm^{-1}, the unsplit carbonyl absorption (1631 cm^{-1}), and the very intense aromatic vibration at 1595 cm^{-1} give further evidence for the cyclol structure. In the mass spectrum the weak molecular peak at *m/e* 218 and the intense peak at M^+-18 [loss of water to give *(7)*] are also in complete agreement with this structure.

Chemical reactions affording proof of structure *(4)* are the formation of the acylamidinium salt *(3)* on treatment with dilute HCl, the catalytic hydrogenation to the deoxycyclol *(8)*[5], and the thermal elimination of water with formation of the anhydroazacyclol *(7)*, whose structure was deduced from the bromine addition reaction and from IR, UV, NMR, and mass spectra.

On attempting to synthesize the homologous azacyclol *(4)*, $n = 4$, from *(3)*, $n = 4$, by treatment with alkali, only the anhydroazacyclol *(7)*, $n = 4$, (m.p. 71 °C) could be isolated. Its structure was determined similarly to that of the cyclol; the olefinic double bond was established by IR ($\tilde{\nu} = 1656$ cm^{-1}) and NMR spectroscopy ($\tau = 6.11$ ppm, in $CDCl_3$). Both anhydroazacyclols are unstable and discolor on standing in air for a short time; this instability indicates their keteneaminal structure.

9a-Hydroxy-9-methyl-1H-2,3,3a,4,9,9a-hexahydropyrrolo-[2,1-b]quinazolin-4-one (azacyclol*(4)*, $n = 3$):

N NaOH (10.5 ml) is added dropwise with stirring over a period of 20 min to an ice-cold suspension of acylamidinium iodide *(3)*, $n = 3$, X = I, (3.28 g, 0.01 mole) in water (30 ml). The mixture is then stirred for an additional 30 min at 0 °C. The precipitate, which forms immediately, is filtered off, washed with ice-cold water (100 ml), and finally dried and stored in a refrigerator. Yield 1.71 g (79%), chromatographically pure, m.p. 91–92 °C.

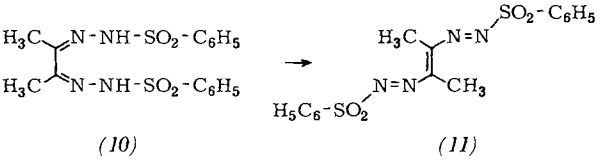
The Oxidation Products of Bisacylhydrazones of α,β-Diketones

By *Helmut Bauer, A. J. Boulton, W. Fedeli, A. R. Katritzky, A. Majid-Hamid, F. Mazza,* and *Alessandro Vaciago*[*]

Petersen and *Heitzer*[1] have recently "reinterpreted" the oxidations of the title compounds *(1)*, originally supposed[2] to give dihydrotetrazines *(2)*, as leading to "mesoionic"[3] triazoles *(3)*. As they appear to be unaware of the previous work, both by *Curtin* and *Alexandrou*[4–6] and by us[7,8] on this problem, and of the uncertainty which, despite this additional work, still surrounds the structure of these fascinating oxidation products, we feel that it is necessary to set the record straight so that further confusion may be avoided.

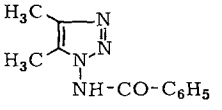
(1) *(3)* *(4)* *(5)*

(2) *(6)* *(7)* *(8)*



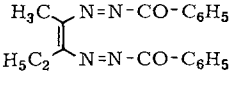
(a): R = R' = CH_3, Ar = C_6H_5
(b): R = H, R' = CH_3, Ar = C_6H_5
(c): R = CH_3, R' = C_2H_5, Ar = C_6H_5

It is clear that the known[2,4] conversion of the bishydrazones *(1)* into diacylaminotriazoles *(5)* involves two intermediates *(3)* and *(4)* of which only one can be isolated. Work by *Curtin* and *Alexandrou*[4] showed that the compound previously thought to be a dihydrotetrazine *(2)* was one of these intermediates, and they favored the structure *(4)*. Independent work by us[8] had led us initially to postulate the *N*-acylimide structure *(3)*. Unfortunately, despite much further work it is still not clear whether structures of type *(3)* or *(4)* are correct:



(i) Attempts to synthesize *(4a)* independently – by treating *(9)* successively with $SOCl_2$ and sodium benzoate – have so far failed.

(ii) The coupling constant of the methyl protons to the triazole ring protons in the ^{1}H-NMR spectrum of *(5b)* was the same (0.8 Hz) as that in the spectrum of the isolated intermediate, which favors structure *(4b)* with a similar 4,5-bond order, but is not conclusive.



(iii) We found that the sulfonylhydrazone *(10)* was oxidized to a true bisazo compound *(11)*: this again tends to favor structures of type *(4)* over *(3)* for the acyl analogs since the sulfonyl derivative could give a compound analogous to *(3)* but not to *(4)*. On the other hand, cyano compounds with structures analogous to *(3)* are known in the bicyclic series[9].

(10) *(11)*

(9)

(12)

(iv) Oxidation of the unsymmetrical bishydrazone *(1c)* gave two products. Had they possessed structures *(3c)* and *(6c)* it might have been possible to interconvert them *via (12)* (cf. the corresponding interconversion of furoxanes[10]). However, each of these isomers is converted thermally only to the corresponding *(5c)* or *(8c)*: again negative evidence for the isolable intermediates existing as *(4c)* and *(7c)*.

(v) Infrared and ultraviolet spectra[4,5,11] and mass spectra[6] are not conclusive but, on the whole, favor the formulation *(4)*.

(vi) The obvious solution is to use X-ray crystallography. We prepared[7] the *para*-chloro-, *meta*-chloro-, *para*-bromo- and *meta*-bromo-substituted compounds *(3)* or *(4)* for this purpose, but unfortunately each one crystallized in a manner which made it unsuitable for X-ray examination[12]. We are at present trying to solve the more difficult problem of X-ray analysis of the parent compound *(3a)* or *(4a)* without a "heavy" atom.

We conclude that the problem of the structure of these oxidation products is as yet unsolved, although the balance of evidence at present favors the "amidotriazole enol ester" structure of type *(4)*.

Addendum: The X-ray analysis referred to in (vi) above has now been completed (December 15, 1970); the results confirm that the isolable intermediate of the conversion of the bishydrazones *(1)* into diacylaminotriazoles *(5)* has the "amidotriazole enol ester" structure *(4)*.

Compound *(4a)* crystallizes in the monoclinic system, space group $P2_1/c$, $a = 5.94$, $b = 10.76$, $c = 27.31$ Å, $\beta = 100.8°$, $Z = 4$.

The structure was solved by direct methods and refined to a current R value of 0.10, using 1576 independent reflections estimated visually from Weissenberg photographic records. The standard deviations of the bond lengths and bond angles, which define structure *(4a)*, are 0.01 Å and 0.6° respectively.

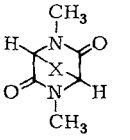
Synthesis of 2,5-Piperazinediones Having Sulfur-Containing Bridges between C-3 and C-6[**]

By *Hans Poisel* and *Ulrich Schmidt*[*]



Gliotoxin[1], the virus inhibiting antibiotics of the aranotin type[2], the physiologically highly active sporidesmins[3], and the cancerostatic antibiotic chaetocin[4] all contain a 2,5-piperazinedione ring with a 3,6-epidithio bridge *(1)* as characteristic structural unit. One of the aims of our synthesis carried out in this series has been the direct introduction of sulfur functions into the 2,5-piperazinedione ring by nucleophilic substitution.

[a] Against TMS as internal standard. [b] In $CDCl_3$. [c] In CF_3COOH. [d] In $(CD_3)_2SO$.

Treatment of 3,6-dibromo-1,4-dimethyl-2,5-piperazinedione *(2)* with methanolic methanethiolate solution leads to rapid formation of a *cis-trans* mixture of the dimethylthio compound *(3)*. Treatment with ethanethiolate leads exclusively to one isomer. Stereospecific introduction of *cis* sulfur functions into the 3,6-positions is achieved by reactions with dianions *via* bridge formation; thus, reaction of *(2)* with sodium trithiocarbonate *(6)* and with sodium tetrasulfide leads to the very stable compound *(5)* (in the model the diketopiperazine nucleus is planar and all interplanar angles in the tetrasulfide bridge are *ca.* 90°) in 67% yield. The tetrasulfide *(5)* can be reduced with sodium tetrahydridoborate to the *cis*-dithiol *(4)*, which, on treatment with S_2Cl_2 in absence of base regenerates the tetrasulfide *(5)* and on reaction with phosgene gives the dithiocarbonate *(7)* that can also be obtained by reaction of the trithiocarbonate *(6)* with mercuric acetate.

Trown has reported on the preparation of the dithiol *(4)* by reaction of the dibromide *(2)* with potassium monothioacetate followed by hydrolysis of the bis(monothioacetate)[5]. We have not been able to reproduce the dehydrogenation of the dithiol *(4)* to the epidithio compound (72% yield) with 3,3'-dinitro-5,5'-dithiodibenzoic acid reported by this author[6]. Under such conditions we have obtained only small amounts of a reaction product consisting primarily of the tetrasulfide *(5)*, a little epidithio compound, and some unknown reaction products.

Dehydrogenation of *(4)* with Fe^{3+}/O_2 leads to a crystalline oligomeric disulfide whose molecular weight cannot be determined osmometrically or mass spectrometrically. For the recording of its mass spectrum an inlet temperature of 100° C is necessary and decomposition (formation of S_8) occasionally takes place at the same time. The 20 eV spectrum affords evidence of a depolymerization to the epidithio compound. The epidithio compound *(8)* occurs in good yield and high purity in the dehydrogenation of the dithiol *(4)* in a two-phase system (dithiol in chloroform/aqueous KI_3 solution). The mass spectrum can be recorded at 30° C. 1,4-Dimethyl-3,6-epidithio-2,5-piperazinedione *(8)* is purified by high-vacuum sublimation and recrystallization. Its structure is confirmed by mass spectroscopy, vapor pressure-osmometric molecular weight determination, and NMR spectroscopy.

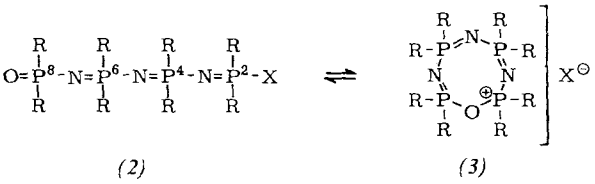
Cycloisomerization of Tetraphosphorus Nitride Oxide Derivatives: Octaphenyloxatriazatetra-P^V-phosphocinium Salts[1]

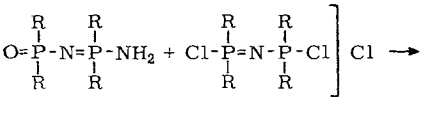


By *Alfred Schmidpeter* and *Karl Stoll*[*]

The routes (A) and (B) offer themselves for the formation and the stepwise extension of the chain of a phosphorus nitride oxide chloride:

Attempted use of route (A) for $n = 0$ (in this and in the following examples, R = C_6H_5)[2] led not to *(1)*, $n = 1$, but to a compound corresponding to *(1)*, $n = 3$, in its composition, and which was also designated as such[2], as major product. Meanwhile we have prepared *(1)*, $n = 1$, by another method and used it for route (B); surprisingly, the second step again gave a product whose analysis and properties agree with those of the compound described by *Paciorek*[2]. It is characterized by a very high melting point and a low solubility in nonpolar solvents.

While the favored formation of the P_4 chain *via* both routes (A) and (B) is striking and the properties of the product are unusual for a compound of type *(1)*, they are readily explained in terms of cyclic ionic isomers and by the justifiable assumption that in the case of $n = 3$, *i. e.* for the eight-membered ring *(3)*, X = Cl, the cyclic form will be particularly stable.



(2) *(3)*

The ^{31}P-NMR spectrum of $(R_2P)_4N_3OCl$ shows only two signals of equal intensity, thus confirming a high symmetry which is consistent only with the cyclic form. Moreover, the ionic structure is also apparent from the fact that the chlorine can be replaced by another anion (with $NaB(C_6H_5)_4$, $(C_5H_5N)_2AgClO_4$, $AgSbF_6$)[3] or incorporated into a chloro anion (with $SbCl_5$) without causing any change in the IR and ^{31}P-NMR spectrum of the rest of the molecule, *i.e.* of the cation (see Table).

In contrast, more powerful nucleophiles replace the chloride ion with concomitant ring cleavage; ammonia, monomethylamine, and diethylamine afford compounds *(2)*, X = NH_2, $NHCH_3$, and $N(CH_3)_2$, respectively, which unlike *(3)* melt at low temperatures and are readily soluble in benzene. Each one of the four phosphorus atoms gives rise to a signal whose shift is dependent upon X; the sum of the shifts amounts to -27 ± 1.7 ppm which is much higher than in the case of the ring compound (approx. –75 ppm). The azide and phenoxide[2] also appear to be represented by the covalent formula *(2)*, X = N_3, OC_6H_5. Hydrolysis of *(3)*, X = Cl, gives *(2)*, X = OH.

The cation in *(3)* is the first representative ($n = 3$) of a series $[(R_2P)_{n+1}N_nO]^+$ that is isosteric with the cyclophosphazenes. A phosphorus nitride oxide cation containing a six-membered ring has previously been formulated as a reaction intermediate[8].

Compound *(3)*, X = Cl, is best prepared by reaction of the amide of tetraphenylimidodiphosphinic acid with its trichloride:

2 HCl + *(3)*, X = Cl

Equimolar amounts of the components react in boiling tetrachloroethane within about 8 h. When the solvent is distilled off there remains a paste-like residue which is extracted with boiling benzene. The product then crystallizes and can be recrystallized from nitromethane; yield *ca.* 50%.

Table. Chemical shifts $\delta^{31}P \times 10^6$ of octaphenyltetraphosphorus nitride oxide derivatives. (Positive values signify that the signals appear upfield from H_3PO_4.)

	X	M.p. (°C)	P^2+P^8		P^4+P^6		Solvent
(3)	Cl	339-340 (338-345 [2])	−25.7		−11.5		CH_2Cl_2
(3)	BPh_4	202-204	−25.4		−11.6		CH_2Cl_2
(3)	ClO_4	303-305	−25.7		−11.3		CH_2Cl_2
(3)	SbF_6	285-290	−25.0		−10.4		CH_3NO_2
(3)	$SbCl_6$	308-313	−27.6		−13.1		$C_2H_2Cl_4$
			P^2	P^4	P^6	P^8	
(2)	NH_2	77-83	−15.2	−10.4	−1.0	+1.3	CH_2Cl_2
(2)	$NHCH_3$	171-175	−19.5	− 9.7	+0.2	+2.0	CH_2Cl_2
(2)	$N(CH_3)_2$	130-136	−22.5	− 6.5	+0.2		CH_2Cl_2

The NMR signals of *(3)* (Table) are assigned to the two halves of the ring on the basis of the following comparison of the ^{31}P shifts:

	Y = S	O	$N^{\oplus}_{1/2}$	
$Y=R_2P-N=R_2P-Y^{\ominus}$	−35.6[4]	−12.7[5]	−11.5	*(3)*, P^4+P^6
$Y=R_2P-O-R_2P=Y$	−79.3[6]	−33.1[7]	−25.7	*(3)*, P^2+P^8

In the case of *(2)* the assignment is based on the expectedly relatively low shielding of the amino-substituted P^2 atom, which decreases further on methylation, and its competition with the shielding of P^4, which is characteristic for PNP systems[4].

New Preparation of Isocyanides[1][**]

By *Rolf Appel, Roland Kleinstück,* and *Klaus-Dieter Ziehn*[*]

Isocyanides can be obtained by elimination of water from monosubstituted formamides. According to *Ugi* and *Meyr*[2] phosphorus oxide trichloride has proved to be a most effective dehydrating agent for this reaction. It reacts rapidly in the presence of pyridine or potassium *tert*-butoxide to give good yields in some cases (25 to 95%).

In conjunction with our studies on the ternary system phosphane/CCl_4/ammonia derivatives we have now found that isocyanides *(1)* are formed very readily by the joint action of triphenylphosphane, CCl_4, and triethylamine on monosubstituted aliphatic and aromatic formamides:

$$R\text{-}NH\text{-}CHO + Ph_3P + CCl_4 + (C_2H_5)_3N \longrightarrow$$

$$R\text{-}\overset{\oplus}{N}\equiv\overset{\ominus}{C}: + Ph_3PO + HCCl_3 + [(C_2H_5)_3NH]\,Cl$$

(1)

Use of a 20% excess of triphenylphosphane gives an approximately 90% yield of isocyanide.

(1)	R	Solvent	B.p.(°C/torr)	Yield (%)	Light petroleum (bp., °C)
(a)	*n*-C_4H_9	CH_2Cl_2	119/760	90	35-50
(b)	C_6H_5	$ClCH_2CH_2Cl$	54/12	91	60-95
(c)	C_6H_5-CH_2	$HCCl_3$	90-92/10	89	60-95

The elimination of water proceeds stepwise. An adduct is formed initially from the phosphane and CCl_4 which, as in the corresponding synthesis of nitriles from carboxamides[3] and carbodiimides from urea[4], phosphorylates the formamide at the oxygen. Chloroform is first liberated and then HCl.

Experiments with formamides deuterated at the nitrogen showed that the proton of the chloroform comes exclusively from the N–H bond.

$$Ph_3P + CCl_4 \longrightarrow [Ph_3PCl]CCl_3 \xrightarrow{OCH\text{-}NH\text{-}R}$$

$$[Ph_3\overset{\oplus}{P}\text{-}O\text{-}CH{=}NR]\,Cl^{\ominus} + HCCl_3$$

$$[Ph_3\overset{\oplus}{P}\text{-}O\text{-}\overset{H}{C}{=}N\text{-}R]\,Cl \xrightarrow[-[(C_2H_5)_3NH]Cl]{+(C_2H_5)_3N} Ph_3PO + \overset{\ominus}{:}C{\equiv}\overset{\oplus}{N}\text{-}R$$

(1)

General procedure:

Equimolar amounts of monosubstituted formamide, carbon tetrachloride, triethylamine, and triphenylphosphane (20% excess) are dissolved in 1,2-dichloroethane, dichloromethane, or chloroform (0.1 mole in 100 ml of solvent) and heated to 60 °C for 2.5 h. The solvent is distilled off at slightly reduced pressure and the residue is extracted five times with light petroleum. The residue left on removal of the light petroleum is then fractionated.

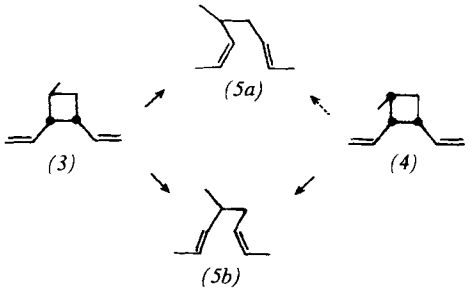
Stereoelectronically Controlled Reductive Ring Cleavage of *cis*-1,2-Divinylcyclobutanes

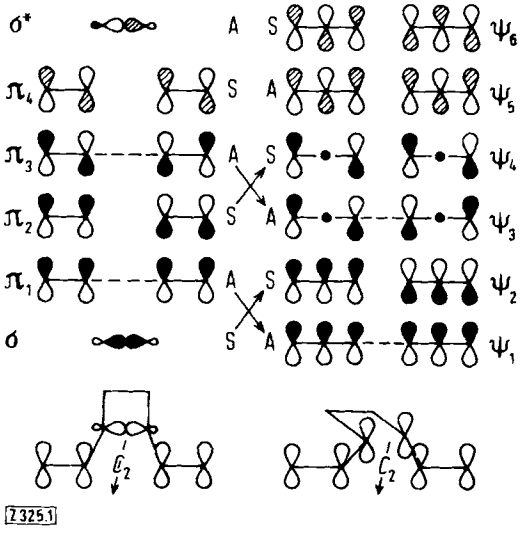
By *Hansjörg Hey*[*]

Reduction of *cis*-1,2-divinylcyclobutane *(1a)*[1], which is readily accessible *via* a catalytic reaction, with alkali metals in liquid ammonia results in ring cleavage to give *cis,trans*-2,6-octadiene *(2a)* in 69% yield. The *trans,trans* isomer is formed in only 5.7% yield and the *cis,cis* isomer in 4.6% yield.



(1a), R = H *(2a)*, R = H
(1b), R = CH_3 *(2b)*, R = CH_3

Reduction of dimethyldivinylcyclobutane *(1b)*[2] under the same conditions gives 4,5-dimethyl-*cis,trans*-2,6-octadiene *(2b)* in 72% yield.



The reduction of the two isomeric 3-methyl-*cis*-1,2-divinylcyclobutanes *(3)* and *(4)*[3] yields different products for steric reasons. The *trans*-3-methyl compound *(3)* affords both possible methyloctadienes *(5a)* and *(5b)* as an approximately 1 : 1 mixture in an overall yield of 73%. However, compound *(4)* gives a 1 : 4 mixture of *(5a)* and *(5b)* in 81% yield.

The structures of *(2a)* and *(2b)* were assigned on the basis of the IR and ^{1}H-NMR spectra. In the case of *(5a)* and *(5b)* the structures were determined from the spectra and the retention behavior. The retention times are characteristic of allyl-substituted *trans*- and *cis*-2-alkenes respectively[4].

The first step in the reduction of the divinylcyclobutanes probably involves radical anions whose radical part is also transformed to an anion in the next step. During reduction the four-membered rings undergo cleavage between C–1 and C–2 (cf. ref.[5]). The divinylcyclobutanes afford allyl anions which are then protonated in such a way that thermodynamically favorable compounds having disubstituted double bonds are formed.

The surprisingly high stereospecificity of the reaction becomes readily understandable when it is regarded as a stereoelectronically controlled process in which conrotatory ring opening forms two anions having a *cis*- and a *trans*-allyl group. Fig. 1 shows a correlation diagram for this process.

Z 325.1

Fig. 1. Correlation diagram for the conrotatory opening of *(1a)* to *(2a)*.

A total of four molecular orbitals of *cis*-1,2-divinylcyclobutane participate in the rearrangement. The symmetry properties of the molecular orbitals with regard to a twofold symmetry axis C_2 are shown in the diagram. C_2 passes through the molecule perpendicular to the reacting σ orbital and to the π orbitals and is conserved with respect to the molecular orbitals taking part in the reaction, as is required for a conrotatory process.

The examples studied cannot be classed as electrocyclic reactions since no rearrangement of a cyclic compound into its conjugated polyene isomer takes place. A formal similarity to, *e.g.*, conrotatory opening of *cis*-3,4-disubstituted cyclobutenes to give *cis, trans*-2,4-dienes[6,7] nevertheless exists. In both cases the σ bond participating in the reaction occurs in the four-membered ring and the uppermost occupied π orbitals are of the same symmetry. Steric effects also play a role in determining the absolute rotation on conrotatory opening of the substituted *cis*-1,2-divinylcyclobutanes *(3)* and *(4)*, thus leading to an unequal distribution of the isomers *(5a)* and *(5b)* on reductive ring cleavage.

General procedure:

cis-1,2-Divinylcyclobutane (11.9 g, 0.11 mole) is dissolved in a mixture of liquid ammonia (approx. 100 ml) and ether (10 ml), and sodium metal (6.3 g, 0.274 mole) is added to the solution. The resulting blue solution is allowed to react for about 4 h at −33 °C. After the ammonia has evaporated overnight through a reflux condenser cooled to −25 °C, 50 ml of pentane is added and the reaction mixture is filtered. The solvent is distilled off and the residue analyzed by gas chromatography.

Photochemical (2π+6π)-Cycloadditions. Novel 1,4-Cycloaddition with Formation of the Bicyclo-[2.2.2]octadiene System

By *Gerhard Hesse* and *Peter Lechtken*[*]

On irradiation with a high-pressure mercury vapor lamp[1] dichlorovinylene carbonate[2] adds to aromatic compounds if a Duran filter is used. The formation of a 1 : 1 adduct is established by elemental analysis and mass spectrometry. When benzene is used as substrate a molecular peak at *m/e* = 232 (Cl = 35) is obtained resembling a pattern typical of a dichloro compound. NMR and UV spectra show that the addition must have taken place in the 1,4 position.

(1a), R = H

(2a), $R^1 = R^3 = H$; $R^2 = R^4 = CH_3$
(2b), $R^1 = R^2 = R^3 = R^4 = CH_3$
(2c), $R^1 = R^3 = H$; $R^2 = R^4 = OCH_3$

Cpd.	Rel. RR[a]	Quantum yield Abs. [b]	Rel.	M. p. (°C)	Yield (%) [c]
(1a)	1.00	0.007	1.00	116	11
(1b)	5.57	0.036	5.15	90	50
(2a)	1.89	0.011	1.57	117	44
(2b)	12.33	0.087	12.40	109	63
(2c)	5.25	0.038	5.43	99	42

[a] Reaction rate.
[b] Information regarding the irradiation performance of the TQ150 lamp as a function of wavelength and burning time was taken from the manufactures specifications. The quantum yields are valid for the first 100 mins' irradiation.
[c]Analytically pure product; referred to dichlorovinylene carbonate.

This 1,4 addition fits in with the series of 1,2 and 1,3 cycloadditions[3–5] found previously. The only example reported so far of a photochemical cycloaddition in the 1,4 position is the reaction of butadiene with benzene to give the bicyclo[4.2.2]-decatriene derivative[6], but only fair yields were obtained.

The 1,4 additions carried out by us by direct irradiation of *ca.* 10% solutions of dichlorovinylene carbonate in aromatic compounds gave relatively good yields and could be accelerated by a factor of about 40 by addition of acetone or acetophenone. A purely thermal addition to the hydrocarbon does not occur after 48 hours' heating at 150°C.

By way of example, proof for the structure of *(1b)* was obtained from the following data: NMR: τ = 4.40 (2 vinyl H/M); 6.28 (1 bridgehead H/T); 8.09, 8.11 (2 vinyl CH_3/D); 8.37 (1 bridgehead CH_3/S). UV: λ_{max} = 208 nm (ε = 1950). This absorption indicates unequivocally the presence of a bicyclo[2.2.2]octadiene system, for 1,3-cyclohexadiene absorbs at 258 nm (ε = 1600)[7] and values of 220 nm (ε = 3000) were found for 1,3 addition compounds[4]. The analogous norbornadiene, on the other hand, absorbs at 205 nm (ε = 2100)[8]. IR: the position of the carbonyl vibration at 1835 cm^{-1} indicates that the cyclic carbonate remained unchanged.

2,6-Dichloro-7,9,10-trimethyl-3,5-dioxatricyclo[5.2.2.$0^{2,6}$]-undeca-8,10-dien-4-one (1b)

Dichlorovinylene carbonate (8 g, 51.6 mmole) is dissolved under N_2 in anhydrous mesitylene (80 ml) and UV-pure acetone (10 ml) and then irradiated for 65 hours through a Duran filter. After removal of acetone and excess mesitylene a viscous oil is obtained which is then sublimed at 80–100°C/0.5 torr. The crystals thus obtained are pressed on an unglazed plate to remove any residual oil and recrystallized from petroleum ether. Yield 7.0 g (50%), m.p. 90°C, analytically pure.

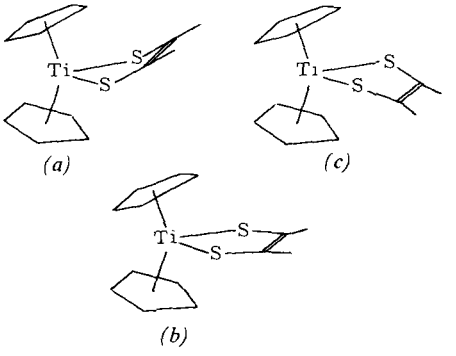
Conformational Studies on Enedithiolate Chelates[**]



By *Hartmut Köpf*[*]

Although *cis*-1,2-enedithiolate (or α-dithiodiketone) complexes of transition metals nowadays number among the most thoroughly investigated *S*-coordinated chelate complexes[1] nothing has hitherto been reported regarding the possible conformations and inversion processes of the five-membered MS_2C_2 chelate rings in solution.

It is, however, to be expected that an insight into the spatial structure of metallocene enedithiolate chelates[2] will be provided by the ^{1}H-NMR spectrum of the cyclopentadienyl ligands, as in the case of metallocene polychalcogenide chelates[3]. In fact, the titanocene 1,2-enedithiolates *(1)*[4], *(2)*[5], and *(3)*[5]

(1) *(2)*, R = H *(3)*, R = CH_3

give spectra exhibiting a reversible temperature dependence of the C_5H_5 proton resonance[6], which is independent of the solvent and which is in the same sense for compounds *(1)*–*(3)*, while the signals of the groups C_2H_2, C_6H_4, and $C_6H_3CH_3$, respectively, remain unchanged in the temperature range studied. This observation can be interpreted in the following manner:

1) At −50°C the occurrence of two sharp singlets of equal intensity indicates the presence of the identical conformers *(a)* and *(c)* in which the magnetic equivalence of the two freely rotating cyclopentadienyl ligands of each molecule is canceled by a folding of the chelate rings along the S · · · S axis[7]. The nonplanar chelate rings are rigid; no measurable conformational transitions take place.

2) When the temperature of the sample is raised the signals broaden and finally coalesce between +10 and +20° C. This would indicate that the mutual interconversion *(a)*⇌*(c)* is now occurring at a detectable rate, probably *via (b)* as excited state[7]. The coalescence temperature T_c and the signal splitting $\Delta\nu$ afford the free energy of activation $\Delta G_c^{\neq}$ of this inversion process.

3) At normal measuring temperature (+36°C) a single sharp singlet appears, as would be expected for a rapid conformational

interconversion of the now mobile, "dynamically planar" chelate rings.

For unbridged 1,2-enedithiolates containing no other kind of ligand attached to the central ion approximately planar chelate ring structures have been found in the solid state[1]; however, there are cases in which the ring is known to be folded[8]. The above results for solutions of *(1)–(3)* together with the analogous chelate ring folding in crystalline $(C_5H_5)_2MoS_2C_6H_4$[2] demonstrate that the planar structure *(b)* recently proposed[1] for metallocene enedithiolate chelates cannot be regarded as generally valid.

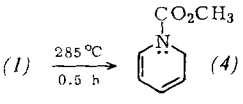
Synthesis and Thermolysis of *N*-Methoxycarbonyl-2,3-homopyrrole[1,2]

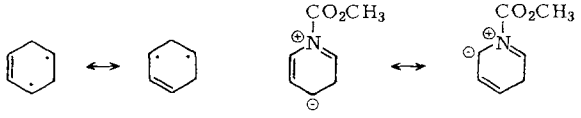
By *Frank W. Fowler*[*]

We report that the cuprous chloride catalyzed decomposition of diazomethane in the presence of *N*-methoxycarbonylpyrrole produces mainly *N*-methoxycarbonyl-2,3-homopyrrole (*N*-methoxycarbonyl-2-azabicyclo[3.1.0]hex-3-ene) *(1)* in addition to smaller amounts of the bishomopyrroles *(2)* and *(3)* (3:1:0.6).



R = CO_2CH_3 *(1)* *(2)* *(3)*

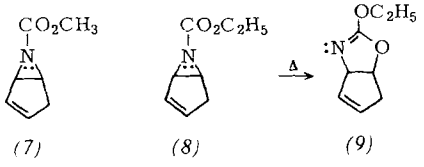
The NMR spectrum ($CDCl_3$) of *(1)* shows τ = 3.60 (1H/broad,s), 4.53–4.70 (1H/m), 5.83–6.28 (1H/m), 6.22 (3H/s), 7.75–8.00 (1H/m), 8.98–9.37 (1H/m), and 9.83–10.08 (1H/m). This spectrum remains essentially unchanged from room temperature to 170 °C except that the vinylic hydrogen adjacent to the nitrogen atom appears as a doublet at high temperature and a broad singlet at room temperature. This observation is attributed to hindered rotation of the methoxycarbonyl group at room temperature.



Previous studies have shown that the copper catalyzed decomposition of diazo compounds in the presence of pyrrole and its *N*-methyl derivative yields only substitution products[3] The formation of addition rather than substitution products with *N*-methoxycarbonylpyrrole is attributable to the known ability of the *N*-methoxycarbonyl group to cause pyrrole to behave as a diene[4].

Pyrolysis of *(1)* in the gas phase at 285 ° C produced a nearly quantitative yield of *N*-methoxycarbonyl-1,2-dihydropyridine *(4)*. The NMR spectrum ($CDCl_3$) is similar to that previously reported for *N*-phenyl-1,2-dihydropyridine[5]. Reduction of *(4)* ($LiAlH_4$) gives the known *N*-methyl derivative[6].

(1) *(4)*



A comparison of the thermal isomerization of *(1)* with the carbocyclic analog indicates that the heterocycle rearranges more readily. Whereas the thermolysis of bicyclo[3.1.0]hex-2-ene to 1,3- and 1,4-cyclohexadiene has a half-life of 30 min at 339.4 °C[7] the isomerization of *(1)* proceeds to completion within 30 min at 285 °C. If a similar mechanism is assumed for the isomerization of *(1)* as has been proposed for bicyclo[3.1.0]hex-2-ene then the greater ease with which *(1)* rearranges is consistent with a greater stability of the delocalized intermediate *(6)* compared to the biradical *(5)*.

(5) *(6)*

Attempts to detect the aziridine *(7)* that should result from the presumably even more facile vinyl-cyclopropane rearrangement[8,10] have been unsuccessful. Carrying out the reaction at 245 ° C gave only a 30% conversion to the dihydropyridine *(4)*. No other product could be detected.

It is possible that aziridine *(7)* is thermally less stable than cyclopropane *(1)* and its equilibrium concentration is too small to detect. We believe this is unlikely and doubt that *(7)* is ever being formed. This conclusion is based on the known fact[9] that heating *(8)* gives the oxazoline *(9)* and neither the corresponding homopyrrole nor dihydropyridine. Orbital symmetry considerations also suggest that the interconversion of *(6)* with *(1)* should be more favorable than *(6)* with *(7)* which is consistent with our observations[11].

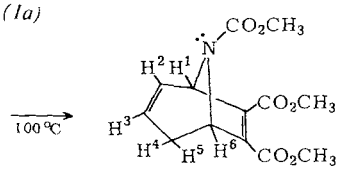
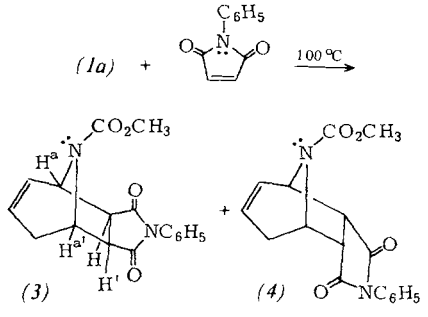
Cycloadditions of *N*-Methoxycarbonyl-2,3-homopyrrole[1,2]



By *Frank W. Fowler*[*]

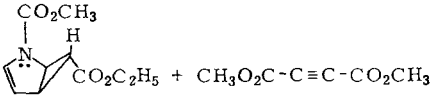
N-Methoxycarbonyl-2,3-homopyrrole (*N*-methoxycarbonyl-2-azabicyclo[3.1.0]hex-3-ene) *(1a)*[3] reacts with dimethyl acetylenedicarboxylate to give the cycloadduct *(2)*[4] [NMR

spectrum ($CDCl_3$): $\tau = 3.50 - 3.83$ (H^2/m), 4.25 – 4.61 (H^3/m), 4.90 (H^6/d, $J = 5.5$ Hz), 5.11 (H^1/d, $J = 5.0$ Hz), 6.18 (6 methyl-H/s), 6.27 (3 methyl-H/s), and 7.55 (H^4, H^5/center of broad AB)].



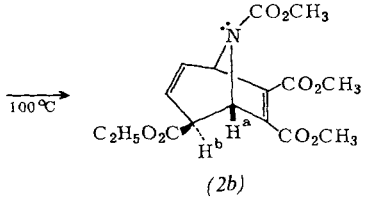
(1a)

(2a)



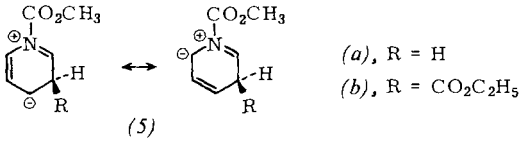
The above assignments were deduced from double resonance experiments. It is interesting to observe that H^6 occurs as a doublet suggesting zero coupling between H^6 and either H^4 or H^5. Dreiding molecular models and a comparison with the carbocyclic system[5] indicate that the bond to H^6 forms an angle of approximately 90° with the adjacent bond to the *endo* hydrogen. This would suggest that zero coupling occurs between H^6 and the *endo* hydrogen H^5.

N-Phenylmaleimide also reacts with *(1a)* to give two isomeric adducts in the ratio 2:3 which could be separated by preparative layer chromatography. The product *(3)* is assigned the *exo* configuration since the bridgehead hydrogens H and H′ appear as an AB pattern showing zero coupling to the bridgehead hydrogens H^a, and $H^{a'}$. Hydrogenation of *(3)* gives a symmetrical structure where the hydrogens that were responsible for the AB pattern now appear as a singlet. This result is consistent with the above assignment.



(3) *(4)*

The reaction of the homopyrrole with *N*-phenylmaleimide is first order with respect to both the homopyrrole and dienophile and shows almost no solvent dependence ($k_{CCl_4} = 1.36 \pm 0.11 \times 10^{-2}$ l mole^{-1}s^{-1} and $k_{CH_3C\equiv N} = 1.17 \pm 0.30 \times 10^{-2}$ l mole^{-1}s^{-1} at 75.08 °C).



(1b)

(2b)

The reaction of DMAD with homopyrrole *(1b)*[6] follows an interesting course. There are two possible stereoisomers obtainable from this reaction. Only isomer *(2b)* is formed which readily rearranges on silica gel to the conjugated isomer. The stereochemical assignment of *(2b)* is based on the NMR spectrum. The bridge hydrogen H^a appears as a broad singlet indicating nearly zero coupling to the adjacent hydrogen H^b It follows from the above discussion that H^b must occupy the *endo* position.

(5)

These results can be explained in terms of dipole *(5)* which can be formed by a thermally allowed disrotatory ring opening of *(1)*. *(5b)* can undergo a 2+4 cycloaddition from the sterically unhindered side to give the observed product *(2b)*.

A concerted mechanism requires that the dienophile approach the homopyrrole from the *endo* direction. Molecular models indicate that electronically this type of attack is most favorable. That is, the cyclopropane bond that is being broken can be more nearly colinear with the p-orbital of the dienophile when attack occurs from the *endo* direction[7].

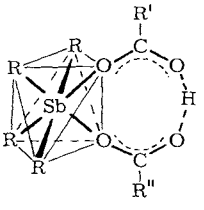
Hydrogendicarboxylate Ions as Hydrogen Bonded Chelate Systems in Organoantimony Compounds[1]

By *Hubert Schmidbaur* and *Karl-Heinz Mitschke*[*]

It was observed during systematic studies on the coordination chemistry of antimony in compounds of type R_4SbX[2] that the acceptor strength of the central atom is reduced considerably by the inductive effect of four organic groups R. Many of these compounds are consequently found to exist as monomeric, covalently bonded molecules; only in some cases are weak intermolecular interactions detectable and then only in the solid state (X = F, OH). Adducts of the type R_4SbXL in which L represents a monofunctional donor are largely unknown[3]. However, we have now found that a R_4SbXL adduct can exist when X and L are additionally linked by a *hydrogen bond*. We wish to report on the first representatives of this type of compound in the present communication.

The tetramethylantimony carboxylates *(1)*[4], which may be obtained from equimolar amounts of pentamethylantimony and a carboxylic acid R′COOH with elimination of methane, are volatile monomeric compounds containing pentacoordinated antimony: they are readily soluble in nonpolar solvents. Addition of a further mole of carboxylic acid leads to stable 1 : 1 adducts *(2)* which crystallize readily and whose acid content can easily be determined by titration. Elemental analysis provides confirmatory evidence for their composition. According to cryoscopic and ebullioscopic molecular weight determinations in benzene

the compounds *(2)* all exist in the form of monomers and, like *(1)*, they may therefore be regarded as molecular compounds.

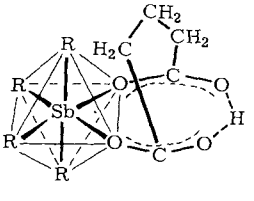


$$Sb \xrightarrow[-RH]{+R\,COOH} R_4SbOC(O)R' \xrightarrow{+R''COOH} R_4SbOC(O)R \quad R\,COOH$$

(1) *(2)*

$= CH_3$

The IR spectra of Nujol emulsions of *(2)* exhibit characteristic absorptions for the $(CH_3)_4Sb$ and R'COO moieties but none that can be attributed to a free hydroxyl group, thus indicating the presence of strong hydrogen bonds O...H–O. This assumption was confirmed by the highly informative ^{1}H-NMR spectra which exhibit, in addition to the $(CH_3)_4Sb$ singlet[5] and the signals due to two equivalent carboxylate groups, a sharp singlet in the extreme low-field region that is reserved for the resonances of strongly acidic hydrogens and those participating in hydrogen bonds (Table).



These findings are consistent only with the proposed structure *(3)* which provides the possibility of chelate interaction between the tetramethylstibonium ion and hydrogen bonded hydrogendicarboxylate ions. For steric reasons formation of a *cis*-chelate at the antimony atom is most likely. The gain in energy from the hydrogen bond on formation of an eight-membered ring system (without significant loss of entropy) adds to the small amount of energy resulting from the carboxylate coordination at the Sb atom thereby endowing the complex with sufficient stability[6].

(3)

In addition we were able to show that the eight-membered ring system can also be formed from two different carboxylic acids ($R' \neq R''$; $R' = CH_3$, $R'' = C_6H_5$).

It is apparent from a consideration of models that a linkage of the two carboxylic acids by way of their groups R' and R'' only becomes possible when the bridging chain of carbon atoms has reached a certain length. Thus reactions of $Sb(CH_3)_5$ with the *di*carboxylic acids oxalic acid, malonic acid, and succinic acid do not lead to products of low molecular weight; such a product is however obtained with *glutaric* acid. The resulting compound probably has the bridgehead structure *(4)* in which the bicyclic ring system is again closed *via* a hydrogen bond.

(4)

Table. Properties of compounds of type *(2)*, *(3)*, or *(4)*, respectively.

R	R'	R''	m.p. (°C)	NMR: τ(ppm), TMS, external ≙ 10 R	R' R''	H bond	solvent
CH_3	H	H	39	8.22	1.33 (s)	−6.25	CH_2Cl_2
CH_3	CH_3	CH_3	85-86	8.43	8.32 (s)	−4.31	CH_2Cl_2
C_6H_5	CH_3	CH_3	112-113	2.33	8.20 (s)	−1.50	CH_2Cl_2
CH_3	CH_3	C_6H_5	58-59	8.40	8.0 (s) | 2.3 (m)	−5.00	CH_2Cl_2
CH_3	C_6H_5	C_6H_5	80-81	8.40	2.3 (m)	−2.83	CH_2Cl_2
CH_3	$(CH_2)_3$		92-93	8.73	8.2 (m)	−4.90	CD_3CN

Molecular weight determinations, elemental analyses, and IR and NMR spectra again confirm the composition of the compound and the existence of the hydrogen bond. Corresponding structural features have meanwhile also been found in other organometallic systems.

Pentachalcogenide Chelates of Vanadium[**]

By *Hartmut Köpf, Alexander Wirl,* and *Werner Kahl*[*]

Metallocene polychalcogenide chelates having an element of subgroup IV[1] or subgroup VI[2,3] as central atom have already been reported. We have now been able to prepare the first polychalcogenide chelates of a subgroup V element[4] and, at the same time, the first paramagnetic complexes of this type, namely the pentachalcogenide six-membered ring chelates containing the d^1 central ion V^{IV}, $(C_5H_5)_2VS_5$ *(1)* and $(C_5H_5)_2VSe_5$ *(2)*. Their preparation was accomplished by reaction of dichlorobis-(π-cyclopentadienyl)vanadium(IV)[6] with ammonium pentasulfide and sodium pentaselenide in acetone respectively:

$$(C_5H_5)_2VCl_2 + M^I_2X_5 \longrightarrow (C_5H_5)_2V\begin{matrix}X\text{-}X\\ \diagup\quad\diagdown\\ X\quad\ X\\ \diagdown\quad\diagup\\ X\text{-}X\end{matrix} + 2\ M^ICl$$

(1), X = S
(2), X = Se

The black crystals of *(1)* and *(2)* are stable towards air (decomposition at 180 °C) and are soluble in all the usual organic solvents; however, the solutions of *(1)*, and in particular those of *(2)*, are rapidly decomposed by even a trace of atmospheric oxygen. Compounds *(1)* and *(2)* can be crystallized from dimethylformamide (DMF) in an inert atmosphere. The composition $(C_5H_5)_2VX_5$ was established by elemental analysis; the molecular weights determined cryoscopically in benzene show that *(1)* and *(2)* are also present in the monomeric chelate form in their solutions.

As derivatives of quadrivalent vanadium in solution (DMF), compounds *(1)* (*g*-value 1.976) and *(2)* (2.006) show, as they do in the solid state (see Figure), an intense ESR signal[7], while the C_5H_5-^{1}H-NMR signal (in DMF solution) remains absent.

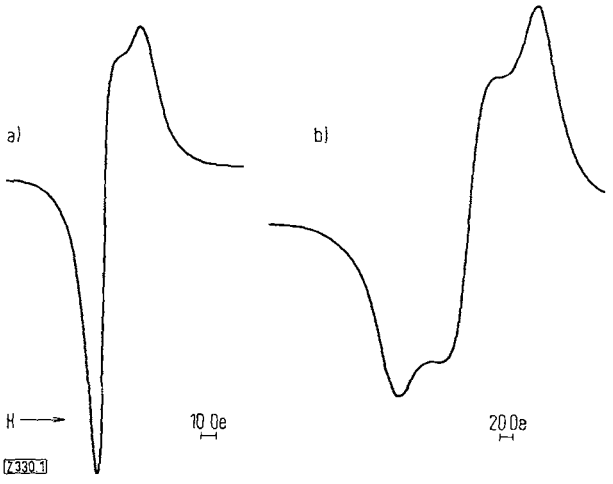

Fig. Solid-state ESR spectra of a) *(1)*, ampl. 1, and b) *(2)*, ampl. 8 at room temperature.

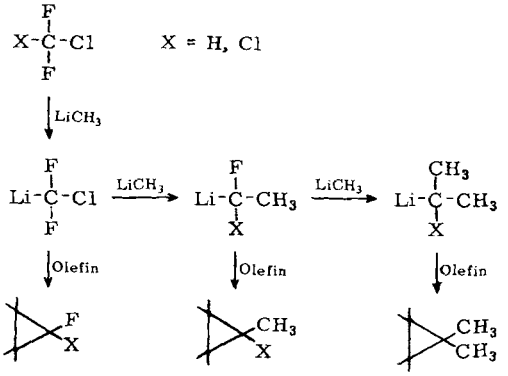
The IR spectra of *(1)* and *(2)* recorded on KBr disks are almost congruent with those of $(C_5H_5)_2TiX_5$[1] in the region where the vibrations of the π-C_5H_5 ligands occur. The S–S stretching mode of *(1)* appears, like that in $(C_5H_5)_2TiS_5$[1] and $[Pt(S_5)_3]^{2-}$[8], as a weak double band (478 and 455 cm^{-1}), while in five-membered chelate rings of type MS_4[2,3,9] it occurs as a single peak of medium intensity.

Bis(π-cyclopentadienyl)pentasulfidovanadium(IV) (1) and -pentaselenidovanadium(IV) (2):



The preparation and all investigations of *(1)* and *(2)* in solution must be carried out in air-free solvents and in an argon atmosphere. For the preparation of $(NH_4)_2S_5$ and Na_2Se_5 solutions cf. Ref. [3]. – A suspension of $(C_5H_5)_2VCl_2$[6] (0.50 g, 2 mmoles) in acetone (20 ml) is poured with stirring into an aqueous solution (0.8 ml) of $(NH_4)_2S_5$ (2.5 mmoles/ml) or added dropwise to a solution of Na_2Se_5 (2 mmoles) in acetone (20 ml) and stirred for 2 h at 60 °C. After cooling the black precipitate is filtered off, washed with cold ethanol/water (3 : 1), and dried under vacuum. It is then dissolved in hot DMF (60 °C) and crystallized at −30 °C. Washing with cold absolute ethanol and drying under vacuum yields 0.51 g (74%) of *(1)* as black needles, or 0.18 g (16%) of *(2)* as a black crystalline powder respectively.

Alkyl/Halogen Substitution in Carbenes (Carbenoids): A Route to New Cyclopropane Derivatives[**]

By *Manfred Schlosser* and *Le Van Chau*[*]

Treatment of chlorodifluoromethane or dichlorodifluoromethane with methyllithium leads to formation of a short-lived intermediate (carbene, carbenoid, or carbenoid complex[1]), which reacts with olefins to give difluorocyclopropanes *(1)* and – to a lesser extent – chlorofluorocyclopropanes *(2)*. However, the intermediate chiefly reacts with further organometallic compound with replacement of one or two halogen atoms by methyl groups[2]. The 1-fluoro-1-methylcyclopropanes *(3)*, 1-chloro-1-methylcyclopropanes *(4)*, and the 1,1-dimethylcyclopropanes *(5)* can be isolated as final reaction products (see Table). The reaction scheme has been simplified as far as possible.

(1), X = F *(3)*, X = F *(syn+anti)* *(5)*
(2), X = Cl *(syn+anti)* *(4)*, X = Cl *(syn+anti)*

	Reaction conditions [a]	Olefin	Yields (%)					
			(1)	*(2)*	*(3)*	D-ratio [b]	*(4)*	*(5)*
$CHClF_2$	A, −78 °C	Cyclohexene	[c]	2	23	(2.7:1)	2	8
$CHClF_2$	B, −50 °C	Cyclohexene	[c]	< 1	8.3	(3.5:1)	1.5	4
CCl_2F_2	B, −50 °C	Cyclohexene	[c]	< 1	8.5	(3.5:1)	1.8	3.5
CCl_2F_2	B, −78 °C	Cyclohexene	[c]	< 1	8.5	(1.8:1)	3	2
CCl_2F_2	C, −78 °C	Cyclohexene	[c]	< 1	8	(2.2:1)	2	3
CCl_2F_2	B, −50 °C	2-Methyl-2-butene	9	–	15	(2.3:1)	1 [d]	2 [d]
CCl_2F_2	B, −50 °C		12 [e]	–	12 [e]	(1.5:1)	–	1

[a] See also the general procedure. Variants:
A: The methyllithium, after removal of as much ether as possible under vacuum, was suspended in cyclohexene and then treated with the halogenomethane; B: The ethereal methyllithium solution was added dropwise over a period of 2 h to the halogenomethane/olefin mixture; C: As in B, but duration of addition reduced to 5 min.

[b] D-ratio = ratio of diastereoisomers; presumably there is a preponderance of the diastereoisomer whose halogen atom takes up the *trans* position to the greater number of vicinal alkyl residues.

[c] No detectable amounts (<0.3%).

[d] Structural assignment on the basis of gas-chromatographic retention times only.

[e] Isolated as ketone after acid hydrolysis.

1-Butylfluorocyclopropanes are obtained analogously when *n*-butyllithium is used as metalating agent (*e.g.* 6% *syn*- and *anti*-7-butyl-7-fluoronorcarane from cyclohexane). With phenyllithium, only tetraphenylethylene was formed – presumably *via* α,α'-difluorostilbene. If, however, the stationary concentration of the organometallic compound is diminished by ate-complex formation with pentaphenylantimony[3], approximately 1% difluoronorcarane can be detected.

General procedure:

A solution of organolithium compound (0.20 mole) in petroleum ether or diethyl ether is added dropwise over a period of 15 minutes to a mixture of dichlorofluoromethane (or chlorodifluoromethane) (40 ml) and olefin which is kept at −40 to −50 °C. The reaction mixture is then allowed to warm to room temperature and the excess of halogenomethane allowed to evaporate. The mixture is hydrolyzed with dilute acid, washed, and dried. After evaporation of the lowest boiling constituents the mixture is fractionated, if necessary under vacuum, with a spinning band column. The reaction products usually have to be purified by gas chromatography.

CONFERENCE REPORTS

Investigation of the Self-Diffusion of Small Molecules in a High-Molecular Environment

By *Robert Kosfeld*[*]

Self-diffusion is a translatory motion in which the molecules move in any direction with respect to their immediate environment in accord with statistical laws. This molecular-kinetic process depends on the intermolecular interactions between the molecules that determine the structure of the relevant system. The characteristic parameter of self-diffusion is the self-diffusion coefficient (SDC). Accurate knowledge of this coefficient as a function of the temperature, pressure, particle concentration of individual components, and the duration of measurement affords an insight into the structure of the system under investigation.

Particular interest attaches to the study of the translational motion of small molecules in a polymeric environment since both synthetic and biological polymers often contain components of low molecular weight (for example as plasticizers). Not only will the polymeric part of the system exert an effect on the mobility of the solvent molecules but the solvent molecules in turn will have a profound influence on the properties of the polymeric part of the system.

The spin-echo technique is well suited for the study of molecular-kinetic processes, and offers several distinct advantages over conventional methods for the determination of the SDC. Thus the molecules or even parts of molecules are labeled in that the relevant atoms acquire a certain phase difference with respect to one another. Compared with the tracer technique the system is far less perturbed; consequently the results obtained represent a better approximation to the processes occurring in the unperturbed system.

In multicomponent systems in which several self-diffusion processes are taking place the individual events can be detected simultaneously and independently of one another.

Whereas the usual spin-echo technique for determination of the SDC employs field gradients of the same sign that are either constant with respect to time or, as in the method devised by *Tanner* and *Stejskal*[1], applied as pulses, we have developed a method utilizing alternating field gradient pulses[2]. This technique permits determination of the SDC in the wide range between 10^{-10} and 10^{-3} cm^2s^{-1}. The shortest diffusion time measured so far with our apparatus is 80 μs. The minimum time that can be measured using field pulses of the same sign is about 2000 μs. The method has been used for diffusion-time dependent SDC measurements on the sintered glass membrane/benzene system and the effect of hindered diffusion has been studied more closely.

More attention was devoted to the study of the temperature dependence of the SDC of polystyrene (PST) in a solution containing 85.7 mole-% of deuterated benzene. Between 40 and 100 °C the diffusion process can be described by an Arrhenius equation with an activation energy of $\Delta E = 3.7$ kcal $mole^{-1}$. In the case of pure benzene the activation energy for the diffusion process was found to be $\Delta E = 3.0$ kcal $mole^{-1}$.

The temperature and concentration dependence of the SDC of benzene in crosslinked and non-crosslinked PST was the subject of a detailed investigation. An Arrhenius plot also gave a linear relationship for the SDC of benzene in both crosslinked and non-crosslinked PST. The activation energy increases with the polymer concentration from 3 kcal $mole^{-1}$ to 12 kcal $mole^{-1}$ in a system containing 25 wt.-% of benzene. The concentration dependence of the SDC of benzene above 60 wt.-% of benzene is described adequately by a simple exponential relation. Evaluation of the numerical results according to the Doolittle-Fujita theory[3] permits determination of the relative free effective volume f and the SDC D_{so} of pure PST:

T (°C)	30	40	50	60	70
$f \times 100$	5.9	6.1	9.5	7.9	7.9
D_{so} ($cm^2 s^{-1}$)	2.2×10^{-11}	4.6×10^{-11}	9.0×10^{-8}	1.8×10^{-9}	1.6×10^{-9}

T (°C)	80	90	100
$f \times 100$	8.6	9.6	10.1
D_{so} ($cm^2 s^{-1}$)	4.6×10^{-9}	2×10^{-8}	7.3×10^{-8}

Other authors[4] have obtained a value of 0.13 for the free volume from pressure- and temperature dependent volume meas-

urements at 90°C. In this case the free volume is regarded as the total volume less the volume of the molecules in closest packing. It should however be noted that an additional volume is taken up by intermolecular interactions between molecules of polymer and of benzene which is no longer available to the benzene molecules in the self-diffusion experiments. This would offer at least a qualitative explanation of the difference in the free volumes determined by the two methods.

In conclusion, attention is drawn to the fact that a "discontinuity" is observed at 50°C in the plot of the temperature dependence of the SDC of pure PST which can be attributed to rearrangement of the phenyl rings.

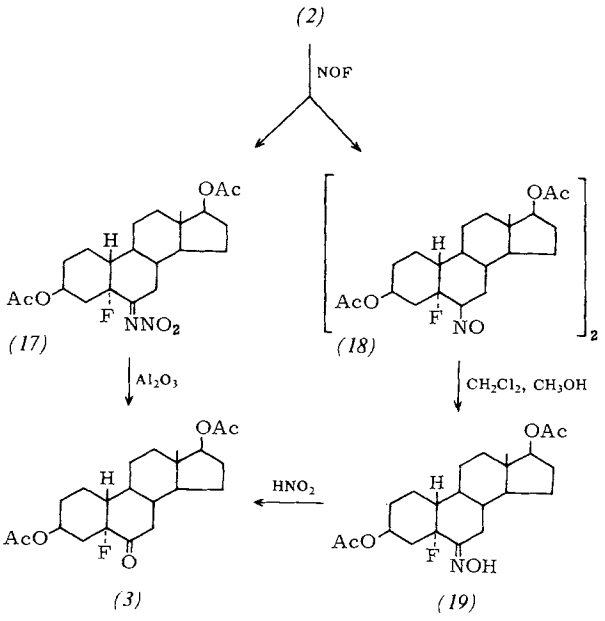
Synthesis, Chemistry, and Biological Properties of Some Novel Hormonal Fluorosteroids



By *G. A. Boswell, Jr.* (Lecturer), *A. L. Johnson*, and *J. P. McDevitt*[*]

Previous investigations into the effect of 6,6-difluoro substitution of steroids on their hormonal activity showed that in certain progestational steroids activity was considerably enhanced[1]. It was of interest to establish if such a modification would increase the biological activity of the clinically important 17α-ethynyl-19-nortestosterone (norethindrone). Introduction of the two fluorine atoms onto C-6 of the 19-norsteroid nucleus was accomplished using nitrosyl fluoride and sulfur tetrafluoride as the key reagents (Schemes 1 and 2).

Treatment of 3β,17β-diacetoxy-5(6)-estrene *(2)* with NOF in CH_2Cl_2 gave a separable mixture of 3β, 17β-diacetoxy-5α-fluoro-6-nitroiminoestrane *(17)* and the dimer of the 5α-fluoro-6β-nitroso derivative *(18)*[2]. The latter on standing reverted to the monomer, and tautomerized to the 5α-fluoro-6-oxime *(19)*, which was deaminated with nitrous acid to give the 5α-

Scheme 1. Synthesis of 17α-ethynyl-6,6-difluoro-19-nortestosterone *(13)* and derivatives from 19-nortestosterone *(1)*.

Scheme 2. Details of the reaction of nitrosyl fluoride with 3β,17β-diacetoxy-5(6)-estrene *(2)*.

fluoro-6-one *(3)*. *(3)* could also be obtained from the nitroimine *(17)* by treatment with neutral alumina (activity III). Mild treatment of the fluoroketone *(3)* with SF_4 and HF in CH_2Cl_2 gave 3β,17β-diacetoxy-5α,6,6-trifluoroestrane *(4)* in high yield which was then converted to the key intermediate 6,6-difluoro-4-estrene-3,17-dione *(7)* by mild acid hydrolysis, oxidation with CrO_3 in acetone followed by dehydrofluorination with alumina. Reduction of *(7)* afforded the diol *(8)*, which was selectively oxidized with dichlorodicyanobenzoquinone (DDQ) to give 6,6-difluoro-19-nortestosterone *(9)*. Conversion of *(9)* to the ketal *(10)* with ethylene glycol and oxalic acid catalyst in benzene followed by oxidation with CrO_3 in pyridine gave the 17-ketone *(11)* which was ethynylated using sodium acetylide in dimethyl sulfoxide solution. Treatment of the ethynylated ketal *(12)* with 90% acetic acid at room temperature yielded 17α-ethynyl-6,6-difluoro-19-nortestosterone *(13)*. *(7)* can also be converted directly into *(11)*.

The 6,6-difluoro modification enhanced both the oral progestational and oral anti-uterotrophic activity of 17α-ethynyl-19-nortestosterone[3].

Rearrangements of Nitrogen Compounds Having Electronegative Substituents

By *Albert Heesing*[*]

Base-catalyzed rearrangement of guanidines bearing electronegative substituents leads, in the presence of quinones, to quinone semicarbazones. The action of acids or bases on quinone semicarbazones – and generally on derivatives of aryldiazenecarboxylic acids – leads essentially to the corresponding phenol (or to the aromatic hydrocarbon). Hydrazobenzene derivatives are also formed: *via* the aryldiimine intermediates. A variety of mechanisms have been proposed (see *e.g.* Ref. [1]) for this condensation, during which nitrogen is eliminated.

In our studies of the formation of hydrazobenzenes from deuterium- and ^{15}N-labeled compounds we have found three different reaction routes:

1) Two molecules of *p*-tolyldiimine react in acid solution *via* a concerted mechanism (A), eliminating N_2 without N–N bond cleavage, to give the hydrazo derivative.

2) In an acid medium, *p*-nitrophenyldiimine decomposes, with cleavage of the N–N bond, the β-nitrogen being liberated as N_2 (B).

3) In alkaline solution the N–N group remains intact in all cases. This reaction proceeds stepwise (C): aryldiimine and aryl radical react to give the final product.

On the basis of these findings it could be shown that:

a) In the Meerwein reduction of diazonium salts the aryl radicals[2] are not formed *via* the aryldiimine oxidation stage since no hydrazo compound is formed. While aryl radicals could be trapped in crossover experiments no aryldiimine could be intercepted.

b) Likewise, reduction of diazonium salts with H_3PO_2 does not involve aryldiimines. The aryl radicals detected in this reaction[3] could not be intercepted in crossover experiments (with *p*-tolyldiimine; reaction type A), thus affording additional proof of the concerted nature of reaction A in acid solution.

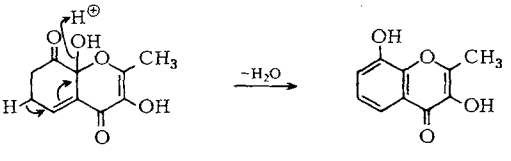
A photooxidation of alkanes by nitrobenzene takes place (under nitrogen) on irradiation with a high-pressure mercury arc lamp according to a report by *J. W. Weller* and *G. A. Hamilton.* Alcohols and carbonyl compounds are formed in good yields, *e. g.* cyclohexanol and cyclohexanone in 50% yield (w.r.t. O content of used nitrobenzene) from cyclohexane. Investigation of the photooxidation of 2-methylbutane showed that the relative reactivity of primary, secondary, and tertiary hydrogens using a pyrex filter is 1:19:300; using a vycor filter this ratio is 1:7:110. The photooxidation of either pure *cis*- or pure *trans*-1,2-dimethylcyclohexane leads to the same ratio (1.6:1) of *cis*- and *trans*-tertiary alcohols. The reaction involves initial hydrogen atom abstraction from the alkane and subsequent reactions of the alkyl radical with nitrobenzene. / Chem. Commun. *1970,* 1390 / –Ma.

[Rd 275 IE]

A photochemical sigmatropic 1,7-shift of hydrogen in a semicyclic triene, 1-vinylcyclopenta-1,3-diene *(1),* has been observed for the first time by *L. J. M. van de Ven, J. L. M. Keulemans-Lebbink, J. W. de Haan,* and *H. Kloosterziel.* UV irradiation of *(1)* in 2,2,4-trimethylpentane or ether at −5° C

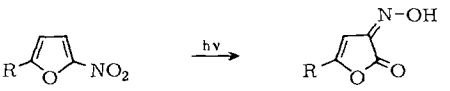


(1) *(2)*

(high-pressure mercury arc lamp) affords 6-methylfulvene *(2)* almost quantitatively. The shift presumably proceeds suprafacially. 1,7-Sigmatropic shifts have hitherto been observed only in cycloheptatriene and its derivatives. / Chem. Commun. *1970,* 1509 / –Ma.

[Rd 277 IE]

The formation of aromatic compounds from D-glucuronic acid and D-xylose under weakly acid conditions has been investigated by *T. Popoff* and *O. Theander.* The following compunds have been identified alongside the known reaction products furan-2-aldehyde, reductic acid, and furan-α-carboxylic acid after treatment of D-glucuronic acid in aqueous solution (pH = 3.5–4.5, 96°C, 48 h): pyrocatechol, 2,3-dihydroxytoluene, 2,3-



(1) *(2)*

dihydroxybenzoic acid, 2,3-dihydroxyacetophenone, 3,8-dihydroxy-2-methylchromone *(2)* and its precursor *(1).* The latter three compounds are also formed from D-xylose. The complex formation reaction involves fragmentation and recombination of carbohydrate fragments. / Chem. Commun. *1970,* 1576 / –Ma.

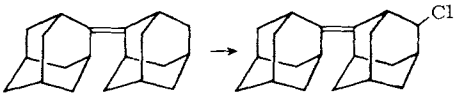
[Rd 278 IE]

The photorearrangements of 2-nitrofuran and 2-nitropyrrole have been investigated by *R. Hunt* and *S. T. Reid.* Irradiation of 2-nitrofuran in methanol or acetone with a medium-pressure mercury arc lamp gives 3-hydroxyimino-2-oxo-2,3-Dihydrofuran *(1),* m. p. 132°C. 5-Methyl-2-nitrofuran affords the methyl derivative. 2-Nitropyrrole analogously yields 3-hydroxyimino-2-oxo-2,3-dihydropyrrole, m. p. 210°C (dec.). The photoreaction presumably involves initial rearrangement to nitrite followed by thermal or photochemical cleavage to a furyl-

(1)

oxyl radical and NO and subsequent radical recombination at C-3. Correspondingly, 2-nitrofuran behaves like conjugated nitroalkenes (rearrangement of β-methyl-β-nitrostyrene to 1-phenyl-1-hydroxyiminopropan-2-one). / Chem. Commun. *1970,* 1576 / –Ma.

[Rd 279 IE]



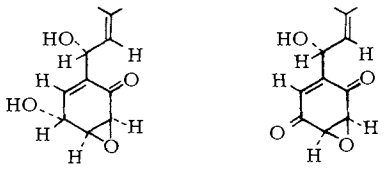
The structure of the aluminate ion in alkaline solutions has been investigated by *R. J. Moolenaar, J. C. Evans,* and *L. D. McKeever.* They measured IR, Raman, ^{23}Na and ^{27}Al NMR spectra at concentrations of 0.5 to 6 mole/l in H_2O and D_2O solutions. The spectra at low Al concentrations are consistent with the predominant existence of tetrahedral $Al(OH)_4^-$. At concentrations above 1.5 mole/l the vibrational spectra show new bands and the ^{27}Al resonance is broadened. These phenomena are interpreted as being due to condensation of $Al(OH)_4^-$ to $Al_2O(OH)_6^{2-}$. No evidence for AlO_2 occurring in the solutions was found. / J. Phys. Chem. *74,* 3629 (1970) / Hz.

[Rd 280 IE]

Molecular motions in crystalline *o*- and *m*-carboranes have been studied by *R. H. Baughman* using NMR, X-ray diffraction, and calorimetric techniques. Both molecules are nearly regularly icosahedral. At 25°C the ^1H resonance line second moment is 0.71 G^2 for *o*-carborane and 0.82 G^2 for *m*-carborane; a rigid lattice would require theoretically 34 G^2, rapid isotropic reorientation 0.63 G^2. The *o*-isomer was also studied at lower and higher temperatures: at about +4° C a phase transition with a transition enthalpy of 0.84 kcal mol^{-1} and an entropy of 3.0 e. u. was detected. Below this transition, molecular reorientation still proceeds relatively fast. Down to −130° C no further phase transition was found, indicating that either an order-disorder transition lies below −130° C, or the entropy is different from zero at 0°K. At about +200° C translational motions of molecules in the lattice effect a further decrease in NMR line width. / J. chem. Physics *53,* 3781 (1970) / –Hz.

[Rd 281 IE]

The anomalous chlorination of adamantylideneadamantane *(1)* is the subject of a report by *J. H. Wieringa, J. Strating,* and *H. Wynberg.* Compound *(1),* a reactive though strongly sterically hindered olefin, reacts *e.g.* with bromine to give the bromonium bromide. Reaction with chlorine at room temperature, on the other hand, yields only a polychlorinated product. At

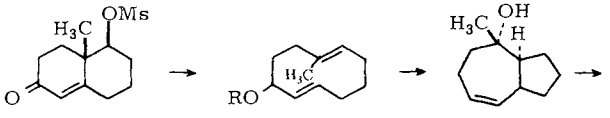


(1) *(2)*

−20° C a powder could be isolated, which, on the basis of its insolubility in non-polar solvents, could be a chloronium chloride. On warming it loses chlorine and HCl; the crystals remaining behind consist of starting material *(1),* 4e-chloroadamantylideneadamantane *(2),* and a little disubstituted material. Tetrahedron Lett. *1970,* 4579 / –Ee.

[Rd 282 IE]

The structures of panepoxydone and some related metabolites produced by the fungi *Panus rudis* and *P. conchatus (Basidiomycetes, Agaricaleae)* have been elucidated by *Z. Kis, R. Closse, H. P. Sigg, L. Hruban,* and *G. Snatzke:* panepoxydone *(1),* panepoxydione *(2),* neopanepoxydone, isopanepoxydone, 7-



(1) (2)

deoxypanepoxydol, neopanepoxydol. The absolute configurations were deduced from CD measurements and by comparison with structurally related compounds such as epoxydone, terreic acid, and terremutin. Compounds (*1*) and (*2*) inhibit the propagation of the mast cell tumor P-815 in mice. / Helv. Chim. Acta *53*, 1577 (1970) / –Ma.

[Rd 283 IE]

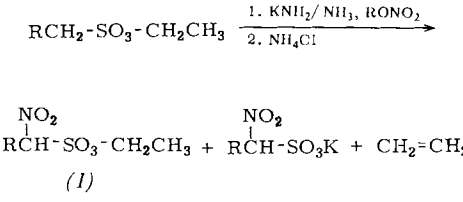
A new synthesis of hydroazulenes by stereochemically selective transannular cyclization of cyclodecadienyl derivatives has been reported by *J. A. Marshall* and *W. F. Hufman*. Reaction of the unsaturated keto mesylate (*1*) with diborane in THF and subsequent treatment with $NaOCH_3$ in methanol affords the cyclodecadienol *(2)* in 60% yield. Solvolysis of the *p*-nitrobenzoate *(3)* in dioxane/water leads to hydroazulenol *(4)* (70%), which

(*1*) (*2*), R = O (*4*)

(*3*), R = p-$NO_2C_6H_4CO$

on hydrogenation yields the alcohol *(5)*. *(5)* can also be obtained from *trans*-hydroazulene. / J. Amer. Chem. Soc. *92*, 6358 (1970) / –Ma.

[Rd 284 IE]

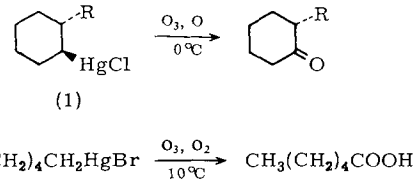


Novel light-sensitive protecting groups have been reported by *A. Patchornik, B. Amit,* and *R. B. Woodward*. Irradiation of amino acid derivatives, whose amino function is blocked by the 6-nitroveratryloxycarbonyl or 2-nitrobenzyloxycarbonyl group, with light of wavelength > 3200 Å (concentration: 10^{-2} – 10^{-3} mole/l; duration: 1–24 h; solvent: dioxane, $CHCl_3$, THF, dimethoxyethane, alcohols, ethanol/water, or ether/water) leads to quantitative cleavage of the groups without influencing even light-sensitive amino acids such as tryptophan. The yield of amino compound, however, is not quantitative since an intermediary aldehyde probably reacts with the amino compound. The amino compound (amino acid, peptide) is quantitatively liberated only on addition of aldehyde reagent during the photoreaction. 2,2'-Dinitrobiphenylylmethoxycarbonyl amino acid derivatives exhibit the best deblocking effect. The COOH function blocked by 2,2'-dinitrobiphenylylmethanol is liberated quantitatively on irradiation without addition of other compounds. / J. Amer. Chem. Soc. *92*, 6333 (1970) / –Ma.

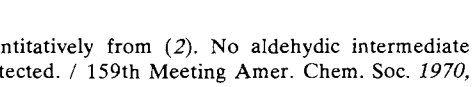
[Rd 285 IE]

Ozonization of a secondary amine has been studied by *P. S. Bailey, J. E. Keller,* and *T. P. Carter jr.* 2-Methyl-2-nitropropane, *tert*-butylammonium chloride, and derivatives of the *tert*-butyl group liberated on formation of the nitro compound were identified as major products of ozonization of di-*tert*-butylamine. In contrast to the ozonization of *tert*-butylamine no ozonate anion radical was formed. A primary product of ozonization is di-*tert*-butyl nitroxide which is apparently formed, together with di-*tert*-butylammonium ion, by reaction of initially produced amine-ozone adduct with a second molecule of amine. Formation of all other products can be explained by ozonization of the nitroxide. / 159th Meeting Amer. Chem. Soc. *1970*, ORGN 61 / –Ma.

[Rd 287 IE]



The synthesis of aliphatic α-nitro sulfonic esters *(1)*, a new class of compounds, has been described by *H. Feuer* and *M. Auerbach*. Aliphatic sulfonic esters react with KNH_2 and alkyl nitrates in liquid NH_3 to give (*1*). Reaction of the neopentyl ester yields (*1*) as sole product. Reaction of the ethyl ester with, *e.g.*, butanesulfonate affords not only ethyl 1-nitro-1-butanesulfonate but also the potassium salt of 1-nitro-1-butanesulfonic acid. The latter compound is formed by β-elimination in the ester part of the molecule during nitration. The



nitration was also used successsfully for the production of tertiary α-nitro sulfonic esters. / 159th Meeting Amer. Chem. Soc. *1970*, ORGN 101 / –Ma.

[Rd 288 IE]

Ozonolysis of organic mercurials has been studied by *P. E. Pike, P. G. Marsh,* and *W. L. Waters*. Primary and secondary alkylmercury compounds were ozonized in CH_2Cl_2 at about 0° C. Compounds (*1*), R = OCH_3 and (*1*), R = H, gave the corresponding ketones (about 60% isolated). *n*-Hexanoic acid was

(1)

formed quantitatively from (*2*). No aldehydic intermediate could be detected. / 159th Meeting Amer. Chem. Soc. *1970*, ORGN 62 / –Ma.

[Rd 289 IE]

Improved specific enzyme electrodes for urea and amino acids have been produced by *G. G. Guilbault* and *E. Hrabankova*. The urea electrode consists of urease in a polyacrylamide matrix that was covered with an ammonium ion electrode. The amount of NH_4^+ produced at the surface by the urea-urease reaction serves as a measure of the urea present in a sample of body fluid (in the range 0.01–10‰). The amino acid electrode contains amino acid oxidase immobilized in polyacrylamide gel. L- or D-amino acid specificity is ensured by use of the respective enzyme. / 159th Meeting Amer. Chem. Soc. *1970*, ANAL 86 / –Ma.

[Rd 286 IE]

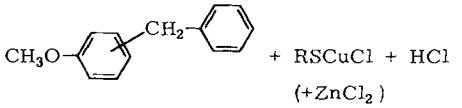
The photoconductivity of liquid nitrobenzene has been investigated by *G. Brière* and *F. Gaspard*. Two types of experiments were carried out: firstly, the time dependence of the photocurrent generated by continuous illumination (436 nm) and low voltage pulses was measured. Secondly, with a continuous voltage applied across the cell, the current-time behavior was followed after switching on or off the light source. In both experiments the liquid was stirred. The first experiment showed that after a time of the order of 10^3 sec a saturation current is developed which is independent of voltage over a wide range: this means that the same amount of ions disappear per unit time as are generated photochemically. If a high enough voltage is chosen for the second experiment recombination can be neglected compared with elimination of ions by discharge at the electrodes. Combination of the results of both experiments yields values of $k_R = 2.6 \times 10^{-7} cm^3 sec^{-1}$ and $k_D = 5.8 \times 10^{-13} sec^{-1}$ respectively for the ion recombination and dissociation rate constants. For comparison, ion recombinations in aqueous solutions are faster by a factor of about 10^{10}. In addition to photodissociation and ion recombination, irreversible processes also take place in the system. / Chem. Phys. Letters *7*, 537 (1970) / –Hz. [Rd 291]

Rates of formation and decomposition of oxonium hydrates have been evaluated by *C. E. Young, D. Edelson,* and *W. E. Falconer.* The authors used an ion drift tube attached to a time-of-flight mass spectrometer. Argon-water mixtures with 0.5–1.8% water vapor partial pressure were investigated at total pressures of 0.6–3.0 torr at 337° K. Analysis of the flight times as functions of the drift tube pressure and accelerating potential can be used to evaluate the kinetics of the reactions

$$H_3O^+(H_2O)_{n-1} + H_2O + Ar \underset{k_{-n}}{\overset{k_n}{\rightleftharpoons}} H_3O^+(H_2O)_n + Ar$$

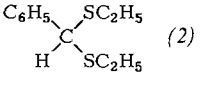
For n=1,2,3, the rate constants are $k_1=6\times10^{-28}$; $k_2=6\times10^{-28}$; $k_3=2\times10^{-28}$ cm^3sec^{-1}. The rate constants of the reverse reactions are of the order of 10^{-13} cm^3sec^{-1}. / J. Chem. Phys. *53,* 4295 (1970) / –Hz.

[Rd 290 IE]



Ionization constants of water in mixtures with organic solvents are reported by *E. M. Woolley, D. G. Hurkot,* and *L. G. Hepler.* The difference between the EMF values of cells with glass and Ag/AgCl electrodes containing acid and alkaline solutions was evaluated. With the same solvent composition and at low ionic strengths which are approximately equal for the solutions compared, liquid junction potentials can be considered very nearly equal. p$K(H_2O)$ values are given for mixtures of water with ethanol, *n*-propanol, isopropanol, *tert*-butanol, ethylene glycol, acetone, and 1,4-dioxane containing up to 60 wt% of the organic component. Generally, pK values increase with increasing organic concentration, with the exception of glycol-water mixtures. The anomalous behavior of glycol can not, as yet, be explained. / J. Phys. Chem. *74,* 3908 (1970) / –Hz.

[Rd 292 IE]



The benzylation of aromatic compounds with benzyl sulfides in the presence of $CuCl_2$ and $CuCl_2/ZnCl_2$ has been investigated by *T. Mukaiyama, K. Maekawa,* and *K. Narasaka.* Compounds of type *(1)* [*e.g.*: R=CH_3 (76% yield); 4,5-dihydro-2-thiazolyl (57%); 4-pyridyl (79%)] and *(2)* react with aromatic compounds such as anisole, *m*-xylene, toluene, or benzene in the presence of $CuCl_2/ZnCl_2$ (equimolar amounts) to give the corresponding benzyl derivatives. If the reaction is carried out in

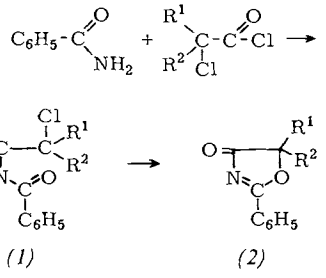
(1)

(+$ZnCl_2$)

(2)

the presence of $CuCl_2$ alone the yields of benzylation product are low. $CuCl_2$ reacts with the sulfide to form a complex which is activated by $ZnCl_2$ but not by $AlCl_3$, $SnCl_4$, $FeCl_3$ or ether-BF_3. / Tetrahedron Lett. *1970,* 4669 / –Ma.

[Rd 293 IE]



Methyl and *n*-alkylketones have been synthesized by *G. H. Posner* and *C. E. Whitten* from carboxylic acid chlorides and lithium diorganocopper reagents:

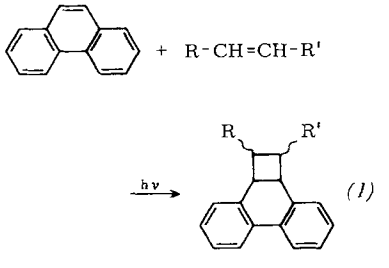
$$R'\text{-}COCl + R_2CuLi \rightarrow R'COR$$

The reagents are readily obtained by reaction of methyl-, ethyl-, or *n*-butyl-lithium with CuI (molar ratio 2:1) in ether at 0° C under N_2; the alkylations, which require 15 min were performed at −78° C with 3 mmoles Cu reagent per mole of acid chloride. Functional CO groups and halogen atoms of the acid chloride are not attacked under the extremely mild conditions. Yields are high; for example: *n*-$C_5H_{11}COCl$, R=CH_3, 81%; R=*n*-C_4H_9, 79% yield: cyclo-$C_6H_{11}COCl$, 86%, 80%; $(C_6H_5)_2CHCOCl$, 93%, 90%; *tert*-C_4H_9COCl, 84%, 90%; 3,5-$(CF_3)_2C_6H_3COCl$, 92%, 75–80%; *p*-$O_2NC_6H_4COCl$, 50%. / Tetrahedron Lett. *1970,* 4647 / –Ma.

[Rd 295 IE]

A novel synthesis of 4(5*H*)-oxazolones is reported by *Y. Shyamsunder Rao* and *R. Filler.* α-Chlorodiacylamines *(1),* which are prepared by heating equivalent amounts of benzamide and α-chlorocarboxylic acid chloride, afford the 4(5*H*)-oxazolones *(2)* in 50–70% yield when treated with NaH in dry benzene.

(1) *(2)*



/ Chem. Commun. *1970,* 1622 / –Ma.

[Rd 296 IE]

Pentafluorobenzenesulfenyl chloride *(1)* is, according to a report by *P. Sartori* and *A. Golloch,* a suitable reagent for introduction of the pentafluorophenylthio group. The authors prepared *(1)* in yields greater than 90% *via* a new route, namely by chlorination of C_6F_5SH, $C_6F_5SSC_6F_5$, or $Hg(SC_6F_5)_2$ in CCl_4. *(1),* b.p. 48°C / 1 torr, is thermally very stable. When heated under vacuum in a flow system at temperatures between 700 and 750°C it is converted quantitatively into chloropentafluorobenzene and elemental sulfur. *(1)* can be oxidized to the sulfonyl chloride; it can be converted *e.g.* into the sulfenyl piperidide by reaction with piperidine and into the amide $C_6F_5S\text{-}NH\text{-}SC_6F_5$ by reaction with NH_3 in ether. Reaction with KCN leads to the thiocyanate C_6F_5SCN. / Chem. Ber. *103,* 3936 (1970) / –Ee.

[Rd 297 IE]

Photocycloaddition of olefins to phenanthrene have been observed by *T. Miyamoto, T. Mori,* and *Y. Odaira.* Irradiation of phenanthrene with a high pressure mercury arc lamp under nitrogen at room temperature in the presence of a) *cis*-dichloroethylene, b) *trans*-dichloroethylene, c) dimethyl maleate, d) acrylonitrile in ether or ethanol leads to tetrahydrocyclobuta-

(1)

phenanthrenes *(1).* Addition occurs at the 9,10 position. In examples a) and b) the *cis,trans,trans-*, *cis,cis,cis-*, and *cis,trans,cis*-adducts are obtained in 22, 7, 3 and 25, 32, 0.6% yields respectively while in c) the *cis* adduct is formed in 62% yield and in d) the *syn*- and *anti*-adducts in 78% and 20% yield respectively. / Chem. Commun. *1970,* 1598 / –Ma.

[Rd 294 IE]

Table of Ion Energies for Metastable Transitions in Mass Spectrometry. By *J. H. Beynon, R. M. Caprioli, A. W. Kundert* and *R. B. Spencer.* Elsevier Publishing Company, Amsterdam-London-New York 1970. 1st Edit., 506 pp., bound, Dfl. 70.00.

"Metastable ions", *i.e.* ions which decompose on the way from the ion source to the collector, play an important role in the investigation of mass-spectrometric decomposition processes because they yield information on cleaved-off particles. Metastable ions lead to the formation of relatively broad bands in the corresponding mass spectra. However, the low intensity of such bands makes them difficult or impossible to detect.

To facilitate the task of detecting metastable ions *Beynon*, one of the authors, has evolved an elegant method: normal ions from the ion source of a double-focusing apparatus pass through the field-free space with a kinetic energy E into the electrostatic sector field. In contrast, metastable ions, which are decomposed in the field-free space, carry only the fraction $F = Em_2/m_1$ of the kinetic energy of the parent ions, m_1 being the mass of the parent ions and m_2 that of the daughter ions. These ions can only pass through the retarding potential if the voltage V in the electrostatic sector field is reduced to the value Vm_2/m_1. If the voltage is continuously changed from 0 to V, one obtains a spectrum of the kinetic energies of all metastable transition processes. Since in this case there is no overlap with the normal spectrum, this technique constitutes a very sensitive method for investigating metastable ions.

With the aid of the present tables the corresponding metastable transition processes can easily be determined from the kinetic energy values, which can be read off directly. This book will therefore be an indispensable and time-saving tool for all laboratories in which IKE (ion kinetic energy) spectra are used for the study of metastable ions.

Spiteller [NB 923 IE]

Disinfection. Edited by *M. A. Bernarde.* Marcel Dekker, Inc. New York 1970. 1st Edit., xiii, 466 pp., $ 24.50.

This book demonstrates that disinfection still belongs to an underdeveloped area of research. In many cases ultraconservatism – "disinfection rituals" – stands in the way of the few new possibilities in the field of disinfection. In practice, disinfection is primarily a question of money and of suitable staff.

The book is aimed at all people working in research, hygiene, and the foodstuffs industry who are interested in new discoveries in the field of disinfection. Nineteen authors have contributed to the book, most of them giving detailed reports on specialized fields. The collaboration of the team of authors, however laudable in itself, sometimes leads to overlapping and unnecessary repetition.

One is inclined to divide the book into a theoretical and a practical and technical part. The first part would have been improved by condensing some parts and expanding others. Bacterial metabolism and mechanisms of action should perhaps have been put in one chapter and the sites of action of the common disinfectants and (in somewhat more detail) those of some antibiotics could have been included in the metabolism and biosynthesis schemes. A few basic theoretical aspects could also have been transferred from the practical and technical section into the theoretical section which is rounded off with chapters on disinfection kinetics, the destruction of resistant bacterial spores and viruses, the scope for the application of gas disinfection, and the disinfection problem *per se* (American hospitals).

Further reports on disinfection procedures in hospitals (Japan, USSR) form the transition to the practical and technical section. From this point on the book assumes something of the character of a practical manual (which the editor wanted to avoid). Disinfection in the milk industry is treated in too much detail; there is also a lot of information on the disinfection processes in the foodstuffs, fish, and drinks industries.

The layout of the book is attractive. Some points of confusion and a few printing errors should have been avoided.

Progress in Molecular and Subcellular Biology. Vol. 1. By *B. W. Agranoff, J. Davies, F. E. Hahn, M. G. Mandel, N. S. Scott, R. M. Smillie,* and *C. R. Woese,* edited by *F. E. Hahn.* Springer-Verlag, Berlin-Heidelberg-New York 1969. 1st Edit., vii, 237 pp. 32 figures, bound, DM 58.–.

Molecular biology has pleged itself, like a kind of religious society, to a "central dogma" according to which DNA alone regulates all life processes; it is always seeking new frontier regions in which to carry out its mission and establish regularities that can be explained by physical phenomena. The law that derives from the central dogma is that of the "information flow" (nothing is added to the clarity of this concept by the fact that it is used so loosely and its meanings are so obviously varied), controlled according to time, place, and quantity by membranes, hormones, and nerve cells. Thus, after molecular genetics and many other things, the study of nervous processes has now caught the interest of molecular biologists.

The series "Progress in Molecular and Subcellular Microbiology" begins in a very promising way. The editors have commissioned several skilled and knowledgeable authors to write within a wide, general framework. In a very well constructed section *C. R. Woese* deals with what intellectual and heuristic implications the solution of the genetic code had for molecular biology. *B. W. Agranoff* has contributed a stimulating chapter on the role of macromolecules in the cerebral function. He comes to the conclusion that the higher animals have a natural behavior repertoire which is "learnt" in a similar way to immune body formation. A typical chapter on subcellular biology is that which deals with the autonomic biosynthesis of chloroplasts, written in lucid detail by *R. M. Smillie* and *N. S. Scott.* An information molecule controls the formation of a complex structure: taking 5-fluorouracil as an example, *H. G. Mandel* describes what happens when artificial blockages and defects are incorporated into such information molecules, while *J. Davies* investigates the natural band width of the replication mechanisms.

All of these sections are informative and well presented, although many doubts remain as to the persuasive power of so many ephemeral arguments. However, it is only recently that exceptions to the central dogma and to the reliability of the translation mechanisms have become known. The present book is successful in its intention and will also serve to familiarize the chemist with the thinking and the problems of the molecular biologist.

L. Jaenicke [NB 924 IE]

Quantenmechanik und Theorie des Molekülbaues (Quantum Mechanics and the Theory of Molecular Structure) By *W. M. Tatewski.* Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., 126 pp., numerous figures, stitched, DM 19.50.

The title of this book is misleading; it is not an introduction to current theory on chemical bonds and the electronic structure of molecules. The author has instead set out to show, on the basis of quantum mechanics, how well founded the concepts and laws of classical structure theory are and where they can be applied. He comes to the conclusion that at present it is not possible in the case of polyatomic molecules to derive either exactly or even approximately the concept of chemical bonding

or the structural formula from the general principles of quantum mechanics. The only generally valid theoretical criterion for the stability or instability of the states of a system of nuclei and electrons is the presence of a minimum in the corresponding energy surface.

The usual concepts of theoretical chemistry, for example valence electrons, electron pair bonding, σ-π-separation, and localization or delocalization of electrons, naturally have no place in such a strict quantum theory of molecular structure. This argument is presented in a very convincing manner, but it will be of little help to the chemist in his attempts to understand the relationships between the structure and properties of molecules.

Martin Klessinger [NB 930IE]

Lehrbuch der anorganischen Chemie (Textbook of Inorganic Chemistry). By *A. F. Hollemann* and *E. Wiberg*. Walter de Gruyter & Co., Berlin 1971. 71st – 80th Edits., xxxii, 1209 pp., bound, DM 58.–.

Holleman's textbook of inorganic chemistry, which in the fourth decade of this century, having seen 21 editions, had been on its last legs, was given an entirely new form by *Egon Wiberg* in 1942. Teachers and students alike received the new work with enthusiasm. It pointed the way for teaching in inorganic chemistry and in less than 30 years appeared in another 50 editions.

Hitherto (21st–70th editions[1]) the scope and content of the work have been oriented primarily toward chemistry students preparing for their preliminary examinations in inorganic chemistry. It also provided adequate information for those working in other fields of chemistry and preparing for their diploma and doctorate examinations. In the present editions (71st–80th) a wish long cherished by *Wiberg* has at last been fulfilled. The textbook has been revised and, above all, expanded in such a way that it can now also be used profitably by advanced inorganic chemists. Thus, the text has been extended to cover 1209 pages instead of the previous 766, the index of names has been increased by a further 600 entries, and 6300 new keywords appear in the subject index. Introductory and comparative surveys, figures, tables, molecular and lattice structures, three-dimensional diagrams, short biographies, etymological derivations, and many other things besides have been considerably extended. An extremely valuable feature is the inclusion of 450 references to collective reviews and monographs: this gives interested readers easier access to sources without further increasing the size of the textbook. The concentration on problems of inorganic chemistry has unfortunately meant that many technological processes have fallen the victim of abridgement. These were a strong point of the earlier editions. The author used a total of 25,000 personal index cards. It is difficult to believe that one person could be capable nowadays of preparing such a comprehensive work covering the whole field of inorganic chemistry.

It would be impossible for such a book to be without any faults. The critic should bear in mind, however, that this work is written for inorganic specialists. A person who looks at inorganic chemistry *e.g.* from the point of view of an expert in bond theory, molecular dynamics, or structural clarification will find little to satisfy him. It is difficult to suit everyone. In the ultimate analyses every critic should write a textbook for his own private use.

Time will tell whether it was wise to expand the textbook so much in one volume. I myself think that it would have been better to have two 700-page volumes, an introductory one and an advanced one. Young people who carry pleasure as their banner and not work, who leave school incapable of independent academic work, who cling to the apron strings of their tutors and instructors, and who have to have their knowledge predigested for them will not be able to manage this book if their teachers do not break down the factual content into much smaller units and build up the students' knowledge step by step. Although the price of the book is fairly reasonable, some features are to be deplored. The covers of the two copies sent to the reviewer were already torn when they were unpacked, one of the pairs of red-green spectacles was faulty, and many bond lines were incorrectly printed (pp. 396, 397, 409, 414, *etc.*). The pop colors of the cover (orange on sky blue) are regrettable. It is also surprising that the publishers should publish 10 editions at once instead of taking into account the suggestions for corrections received from readers after one or two editions. As it is, errors will be perpetuated over many years.

It should also be pointed out that the index of names could cause confusion as to the scientific significance of the entries, although the frequency of the citations is governed mainly by the output (monographs) of the authors quoted, and that the chronological table on the history of inorganic and general chemistry is made up, doubtless to the regret of all inorganic chemists that have been working on research in the past few decades, almost exclusively of discoveries in the field of physics (preservation of parity, the first reactor built in West Germany, the discovery of the antineutrino and of the Ω particle, construction of the ruby laser, *etc.*).

The reader might be inclined to take these criticisms as an indication that the reviewer is concerned much more with the faults of the book than with its good points. This could not be further from the truth. If I were asked whether I could name a better textbook on inorganic chemistry my unhesitating answer would be no.

50 Years of Hydrogen Bond Theory[**]

By Maurice L. Huggins[*]

The "hydrogen bond" or "hydrogen bridge" concept has proved to be one of the most useful structural concepts in modern science. The properties of substances containing hydrogen bonds depend on the strength, symmetry, and polarity of these bonds. These characteristics, in turn, are related to the effective electronegativities of the bridgehead atoms, the distance between these atoms, and the degree of coupling with other hydrogen bonds. Symmetrical hydrogen bonds exist in the FHF^- and $H_5O_2^+$ ions and in some acidic compounds. Coupled hydrogen bond systems exist, for example, in ice, liquid water, hydroquinone clathrates, starch, cellulose, polypeptides, nucleic acids, KH_2PO_4, and silicate hydrates. It is suggested that systems of coupled, nearly symmetrical, hydrogen bonds should be interesting subjects of further research.

1. Introduction

It is my prejudiced belief that, except for electron-pair bonding between atoms and Coulombic attractions and repulsions between ions, the most important structural principle in chemistry and biology is that of hydrogen bonding. Hydrogen bonding is also of great importance in physics, crystallography, mineralogy, geology, meteorology, and various other "-ologies". I therefore take pride in the fact that I was the first to introduce the hydrogen bond concept: the idea that a hydrogen atom can be bonded at the same time to two other atoms[1–6]. That was just 50 years ago.

It seemed reasonable to me that a nonbonding electron pair – a "lone pair", as I called it – should have a considerable attraction for a positively charged proton, even if that proton is already bonded to another atom.

2. Early Applications

This idea was first used to explain tautomerism in acetoacetic acid esters and similar compounds, the interaction of ammonia with water, the structure of sulfuric acid, and similar phenomena. Soon thereafter, *Latimer* and *Rodebush*[6] used the concept very effectively in discussing the behavior of polar compounds in water solution.

I first found definite evidence for the existence of hydrogen bonds in the crystal structure of ammonium

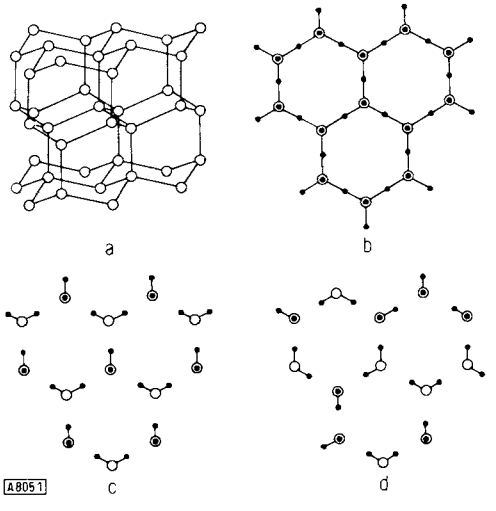

Fig. 1. The structure of ice: a) Arrangement of oxygen atoms. b) Distribution of hydrogen and oxygen atoms in a section of the structure, assuming (incorrectly) that the hydrogen bonds are symmetrical. c, d) Two of the many ways of distributing the hydrogen atoms with unsymmetrical hydrogen bonds.

[*] Dr. Maurice L. Huggins
Arcadia Institute for Scientific Research
135 Northridge Lane
Woodside, Calif. 94062 (USA)

[**] Adapted from a lecture delivered before the Royal Swedish Academy of Sciences at Stockholm on October 8, 1969, and at six other institutions.

chloride[4]. In this compound the hydrogen atoms must be located on the centerlines between nitrogen and chlorine atoms. I predicted that ice would be found to have a structure in which each oxygen is surrounded tetrahedrally by four other oxygen atoms, with the hydrogens presumably on the centerlines between oxygen atoms. Before long, *W. H. Bragg*[7] showed that the structure is actually like this (Fig. 1a).

Since then, studies by X-ray diffraction, neutron diffraction, infrared spectroscopy, and other techniques have confirmed the existence and importance of hydrogen bonds in thousands of compounds.

3. Symmetrical and Unsymmetrical Hydrogen Bonds

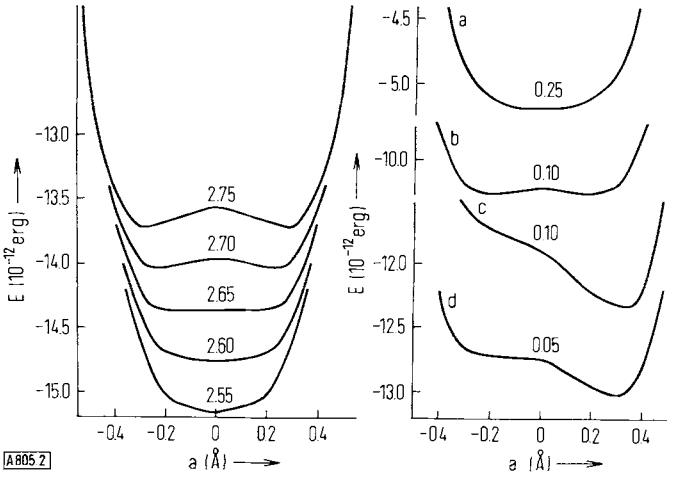
At first I considered a hydrogen bond between two like atoms to be symmetrical (see Fig. 1b). Later[8], chiefly because of the relatively small shifts of infrared band frequencies when a compound containing hydroxyl groups goes from the gaseous state to the liquid or solid state, I concluded that they are usually unsymmetrical (Fig. 1c and 1d). Now that the hydrogen positions can be precisely located by X-ray and neutron diffraction studies, we know that this is the case.

The conclusion that the hydrogen bonds are unsymmetrical in such substances as water was independently arrived at by *Bernal* and *Fowler*[9] at about the same time. In a number of instances, however, the hydrogen bonds between like bridgehead atoms are definitely symmetrical, with the hydrogen atom in the middle of the bridge in each case. The first such bridge to be identified was that in the FHF^-ion[10]. Some others will be discussed presently.

4. Potential Energy Curves

With the aim of achieving a better understanding of the properties of hydrogen bonds, I calculated[11] potential energy curves for the hypothetical motion of a hydrogen atom along the centerline between two bridgehead oxygens. As an approximation, I assumed that the energy of interaction between the hydrogen and each oxygen depends on the interatomic distance in the same way as in the OH molecule. (Errors in this assumption would not affect the qualitative conclusions drawn from comparisons of the different curves.) The graphs obtained (Fig. 2, left) show how the shape of the potential energy curve changes as the oxygen-to-oxygen distance changes. For the distances usually observed there are two minima, indicating an unsymmetrical hydrogen bond. For somewhat shorter oxygen-to-oxygen distances only a single minimum is found, meaning that the hydrogen bridge is symmetrical. In agreement with this result, all known symmetrical bridges have very short O · · · O distances.

The effect of altering the effective negative charges on the bridgehead oxygens was examined by adding a Coulombic term to the previously calculated energies. This of course modifies the shapes of the curves symmetrically, if the change is made for both oxygens, and unsymmetrically, if made for only one (see Fig. 2, right).



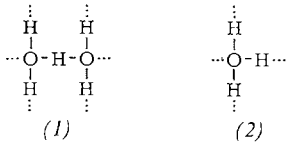


Fig. 2. Theoretical potential energy curves for OHO hydrogen bonds, showing (left) the dependence on the distance between the bridgehead oxygens (numbers on curves, in Å) and the effect of adding a Coulombic attraction term α (right, curves a and b) to both O-H interactions and (right, curves c and d) to only one O-H interaction (α is given by the numbers on the curves).

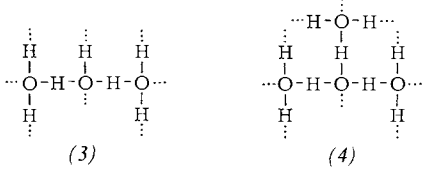
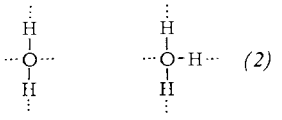


5. Hydrogen and Hydroxide Ions

Consideration of the model curves in Fig. 2 suggested[11] that hydrogen ion in water solution might consist essentially of a proton at the center of a short, strong, symmetrical hydrogen bond joining two H_2O groups together, as shown in *(1)*, instead of the H_3O^+ unit *(2)* usually assumed[*].

(1) *(2)*

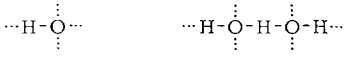
There is no *a priori* reason for eliminating the possibility of $H_7O_3^+$ *(3)* or $H_9O_4^+$ *(4)* or larger ions, but the stabilization of the short, single minimum, hydrogen bonds by the excess positive charge should become less as the average excess charge per oxygen atom decreases.



(3) *(4)*

The composition and structure of the cation in acidic aqueous solutions are not yet known. In some crystals of known structure H_3O^+ moieties have been found. In others, $H_5O_2^+$ units, with short, symmetrical hydrogen bonds, exist[12–14]. These units have also been found in acidic solutions in dimethyl sulfoxide[15].

The formation of symmetrical hydrogen bonds in $H_5O_2^+$ ions can be rationalized in the following way: Comparing



[*] The positive charge has been omitted from all formulas of this kind.

the oxygens in a water molecule and a hypothetical H_3O^+ ion *(2)*, the latter would have a smaller effective negative charge. It would attract the close protons less and so the hydrogen bonds formed by these close protons would be more nearly symmetrical. If one of these protons forms a symmetrical hydrogen bond, however, that increases slightly the effective negative charge on the oxygen under consideration, perhaps enough to prevent the other two close hydrogens from also forming symmetrical hydrogen bonds.

(2)

Comparing similarly the oxygens in a water molecule and a hypothetical OH^- ion *(5)*, the latter would have a larger effective negative charge. It would thus have a greater attraction for each of the more distant bridging hydrogen atoms and tend to make them more nearly symmetrical. If this tendency is great enough, one or more symmetrical hydrogen bonds may be formed, giving a structure that can be represented by the formula *(6)* or a more complicated structure.

(5) *(6)*

In this discussion the effect of the changes in effective negative charges on the oxygen-to-oxygen distance has been neglected. For the hydrogen ion this effect would decrease this distance and so favor the formation of a symmetrical hydrogen bond. For the hydroxyl ion the oxygen-to-oxygen distance would be increased and a symmetrical hydrogen bond made less likely. The actual situation must be determined by future experiments.

The mechanism of conduction, by either hydrogen ion or hydroxyl ion, presumably involves a Grotthuss chain process[11,16], with protons passing over an energy hump from one side of an unsymmetrical hydrogen bond to the other or with unsymmetrical hydrogen bridges changing to symmetrical ones, and *vice versa*.

6. Effective Charges

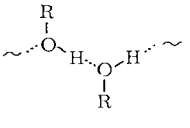
Since the potential energy curves showed the importance of the effective negative charges on the bridgehead atoms, I attempted to estimate these charges, as functions of the kinds and numbers of atoms to which the bridgehead atoms are attached[17]. Recently, in connection with a study of hydrogen bonding in certain silicate hydrates[18], I have made similar estimates for the types of bridgehead oxygens in these crystals.

These rough estimates, for the effective bridgehead atom charges exclusive of the contribution of the hydrogen atom of the bridge being considered, are calculated as follows: To a charge of -2 for the "oxide ion", I add $+1$ for a silicon neighbor, $+1/6$ for a sodium neighbor, $+3/4$ for a close hydrogen of a hydrogen bridge, and $+1/4$ for a distant hydrogen of a hydrogen bridge. The charges so calculated are listed in Table 1.

Table 1. Estimated effective charges on bridgehead oxygen atoms in certain hydrated silicates.

Structon formula [a]	Calculated charge
O(H··,··H,··Na)	− 0.83
O(H··,2··H)	− 0.75
O(Si,2··Na)	− 0.67
O(Si,··H,··Na)	− 0.58
O(Si,2··H)	− 0.50
O(Si,2··H,··Na)	− 0.33
O(2H··,··Na)	− 0.33
O(Si,3··H)	− 0.25
O(2H··,··H)	− 0.25
O(Si,H··,··Na)	− 0.08
O(Si,H··,··H)	0.00

[a] The hydrogen of the bridge for which the calculation is made is not included in the expression in parentheses.



For the first five types listed in Table 1, the hydrogens of the bridges being considered are at the close ends of the bridges, near the oxygens for which the charge calculation is made. The total calculated charge, including the contribution of the bridging hydrogen, is thus 0.75 units more positive than the value listed, in each case. For the last 6 types, the bridging hydrogen is at the far end of the bridge in each case; hence the total calculated charge is 0.25 units more positive than that given. As would be expected, the calculated total charges are never very far from zero. (Table 1 of Reference[18] gives the calculated total charges for the oxygens in $Na_2(H_2SiO_4) \cdot nH_2O$ and $Ca_3(HSiO_4)_2 \cdot 2H_2O$ crystals.)

Until more quantitative methods become available, estimates of effective charges on the bridgehead atoms should be useful in comparing dissymmetries and energies of different hydrogen bonds.

It may be noted, incidentally, that some of the oxygens in these silicate hydrates, in addition to being bonded to a silicon atom, are at the weak ends of *four* hydrogen bonds. Since an oxygen atom has only four electron pairs in its valence shell, this shows that, as previously assumed, the hydrogen-to-oxygen attractions at the weak end of an unsymmetrical OHO hydrogen bridge are largely Coulombic.

7. Coupled Hydrogen Bonds

Crystals of organic hydroxyl-containing compounds invariably contain chains or rings of hydrogen bonds, with each oxygen atom a bridgehead for two H-bonds:

(7)

(See Fig. 3 to 5).

In cellulose, one hydroxyl group of each ring probably makes a hydrogen bond to the oxygen atom in the next

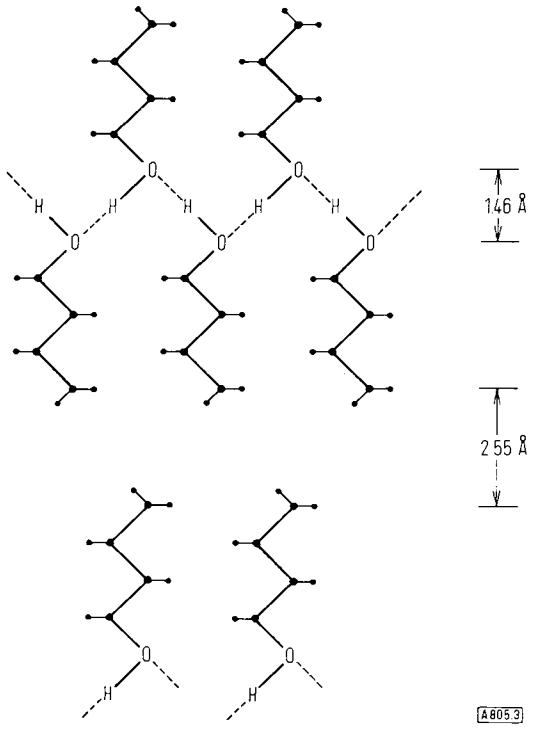


Fig. 3. Diagrammatic representation of the structure of a crystalline alcohol [17].

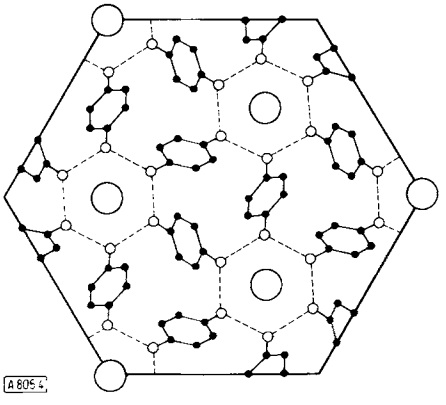

Fig. 4. Projection of the structure of a hydroquinone clathrate [19]. Hydrogen bonds are represented by dashed lines. The large circles indicate sites for guest molecules.

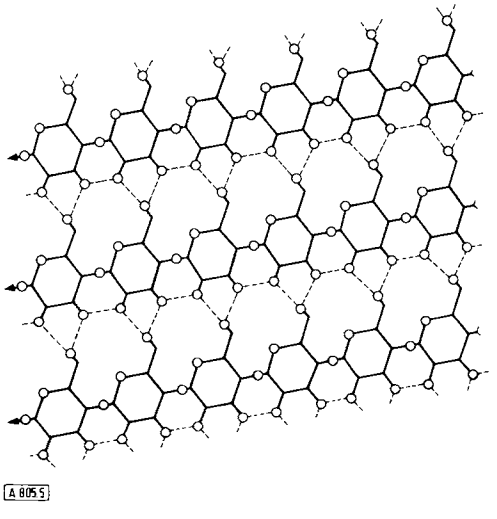

Fig. 5. Proposed spiral structure for a form of amylose starch [20–22]. Dashed lines denote hydrogen bonds. (Imagine that the pattern has been drawn on a paper cylinder and that this cylinder has been slit parallel to its axis and then flattened.)

ring. The other hydroxyl groups, I believe, form chains of hydrogen bonds, stitching adjacent molecules together in approximately the same way as successive turns of the helix are stitched together in the postulated model for amylose starch[22,23].

Crystals of carboxylic acids also contain chains or rings of hydrogen bonds, connected together through the carboxyl groups (Fig. 6).

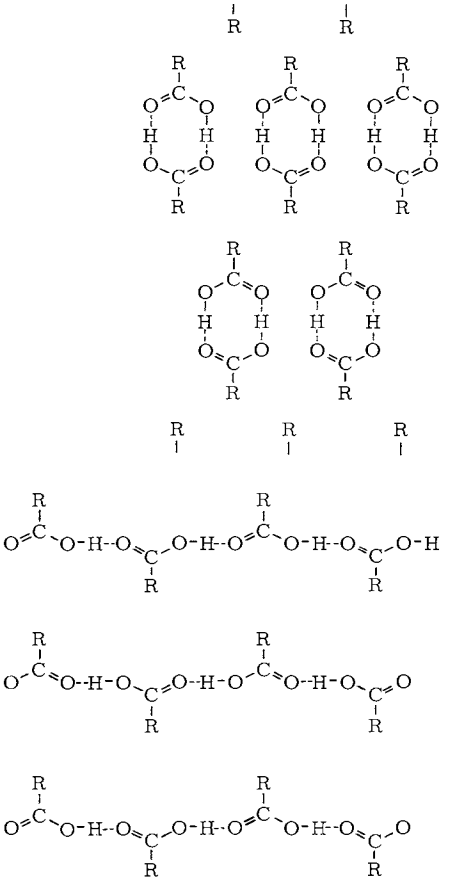

Fig. 6. Diagrammatic representations of two types of structures in crystalline fatty acids [17].

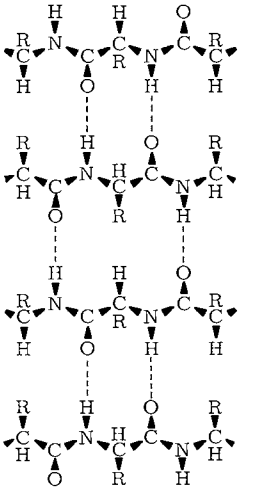

Fig. 7. NHO hydrogen bonding between chains in fibrous proteins and polypeptides [17, 23–25].

A similar situation exists in proteins, polypeptides, and other compounds containing CO-NH groups (see Fig. 7 and 8).

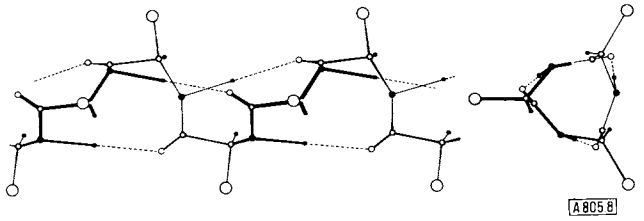

Fig. 8. Two projections of one of a series of helical structures with NHO hydrogen bonds, proposed for proteins and other polypeptides [25–27].

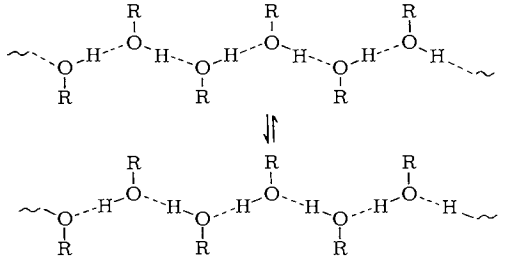
With reference to protein and polypeptide structures, it may be noted that the concepts of NHO hydrogen bonding, parallel and antiparallel extended chain structures, helical structures, and the planar peptide unit were introduced by me (contrary to many statements in the literature) over 30 years ago[17,23–25,27]. At that time it was impossible for me to determine which of a number of helical structures actually exist in proteins. That decision could only be made after X-ray diffraction data on synthetic polypeptides became available.



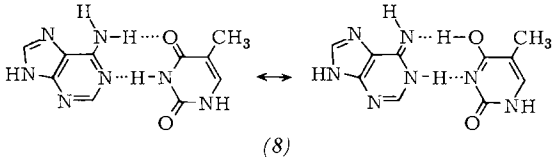


Fig. 9. Reversal of polarization in a chain of coupled unsymmetrical hydrogen bonds.

In a chain or ring of hydrogen bonds connecting hydroxyl groups, as depicted (for a chain) in Figure 9, one would expect some electron resonance between the two oppositely polarized structures shown. This resonance would be small for very unsymmetrical hydrogen bonds, but should become large and important in systems of H-bonds that are symmetrical or nearly so. This resonance increases the stability of the system and makes each hydrogen bridge more nearly symmetrical than it would be without the resonance. Similar resonance should occur in the carboxylic acid and amide chains and rings, since the hydrogen bonds are connected together through conjugated bond systems. The two "extreme states" differ by interchange of the lines and dots in the hydrogen bond formulas and by interchange of the single and double bond lines in the O=C–O and O=C–N formulas.

Another kind of resonance[28], which I believe to be equally important, can be described as the synchronized oscillation of the hydrogens of the hydrogen bridges in the chain or ring and the electron clouds in the oxygen atoms or OCO or OCN groups between the hydrogen bridges. This should be more important the broader and less steep the potential energy curve near its minimum, hence more important the closer that curve approaches the single minimum type (*i.e.*, the more symmetrical the hydrogen bond when the bridgehead atoms are alike). This synchronized oscillation resonance, like electron resonance, tends to make each hydrogen bond more nearly symmetrical (or closer to the single potential energy minimum type) than it would otherwise be.

The hydrogen bonding within the "base pairs" in nucleic acids is often referred to, but the important stabilization of these bonds by electron resonance and synchronized oscillation resonance is rarely mentioned. With regard to the electron resonance, two of the contributing extreme states are those indicated in formula *(8)* for the bonding between adenine and thymine.

(8)

Other zwitterion states doubtless also contribute importantly, as do (in my opinion) the synchronized oscillations of the atoms, especially the hydrogens, and electron clouds around the ring.

Coupling between hydrogen bonds can also exist if they are suitably connected in a two- or three-dimensional net structure. This situation exists, for example, in crystals of KH_2PO_4 and some other ferroelectric materials[22] (Fig. 10).

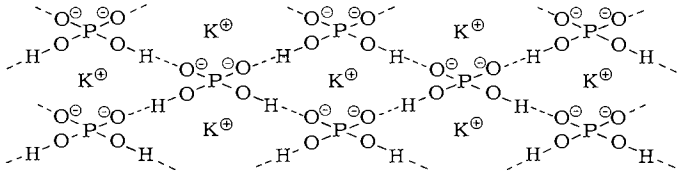

Fig. 10. Diagrammatic representation of the structure in a domain of a KH_2PO_4 crystal [22]. Note the polarization, which can be reversed by shifting of each hydrogen from one side of its hydrogen bond to the other side.

Within a domain, the polarization of all the hydrogen bonds, and likewise that of all the intervening phosphate groups, is presumably uniform. By changing the external electric field, this polarization can be reversed, indicating (as could also be inferred from the short oxygen-to-oxygen distance for the hydrogen bonds) that the hydrogen bonds are nearly symmetrical, with a very small potential energy hump between the two minima.

A similar reversal of polarity, by external means or by chemical alteration of the chain ends, should be possible for chains of coupled hydrogen bonds, if the energy barriers are small enough. I suggest that it should be possible, with the aid of the principles that I have outlined, to design and synthesize many substances with strongly coupled hydrogen bridges and very low energy barriers, even at room temperature. It should prove interesting to study the properties of such systems, as dependent on structural factors, the kinds of atoms or groups con-

necting the hydrogen bridges together, the kinds of other atoms or groups attached to the bridgehead oxygens or nitrogens, the presence of proton donors or acceptors or electron donors or acceptors, *etc.*, at the ends of the chains or the surfaces of the domains, and the external electric field. In some cases it should be possible to transmit pulses or waves across the system or to set up standing wave patterns. I predict that the synthesis and study of such systems will prove very exciting, perhaps leading to models for the transmission of nerve impulses[29] or for brain activity, including memory retention.

8. Conclusion

In concentrating, in this article, on the aspects of the subject in which I have myself been most interested, I have not intended to belittle the great contributions to the development and application of hydrogen bond theory made by thousands of others. Much fine work has been done and yet much more obviously remains to be done.

The Synthesis of Physiologically Active Peptides[**]

By Rolf Geiger[*]

In addition to the classical protective groups and linkage methods for the synthesis of peptides, there are now a number of new techniques that allow the synthesis of fairly long peptide chains without racemization. In the present progress report, the diagnostic and therapeutic importance of the analogs obtainable by chemical synthesis is illustrated by some examples, particularly from the field of the peptide hormones secreted by the neurohypophysis, oxytocin and vasopressin, as well as corticotropins and releasing hormones. With the advance of synthesis technique, it will become possible to include fairly complicated molecules, such as insulin and even enzymes in such considerations.

1. Introduction

We know of no physiological process that takes place without the participation of proteins. For example, all enzymes belong to this class of substances, and enzymes are the catalysts for the synthesis, transformation, and degradation of organic material in nature.

From the chemical standpoint, proteins are peptides, *i.e.* compounds in which amino acids are joined to one another by amide linkages to form molecules that are often extremely large[1].

[*] Dr. R. Geiger
Farbwerke Hoechst AG

[**] Based on a lecture delivered before the Gesellschaft Deutscher Naturforscher und Ärzte at Düsseldorf on October 6, 1970.

The distinction between peptides and proteins is historical, and has now become problematic. The limit chosen was the size of molecule up to which these compounds pass through a natural dialysis membrane. This corresponds to a molecular weight of about 10000. According to this definition, peptides consist of up to approximately 100 amino acid residues, whereas proteins or macropeptides contain more than about 100 amino acid residues.

The chemist seeks to bring proteins within the scope of the more general term "peptides". The biologist, on the other hand, looks on a protein rather as a molecule that, unlike the smaller peptides, can have a certain autonomous reactivity as well as characteristic physical properties. This reactivity is seen *e.g.* physically in the ability of fibrous proteins to contract, or chemically in the catalysis of specific reactions by enzymes.

The properties of the proteins are encoded in the sequence of the amino acids in the peptide chain, *i. e.* the primary structure. The genetic information for the amino acid sequence is contained in the base sequence of the deoxyribonucleic acids (DNA) in the gene.

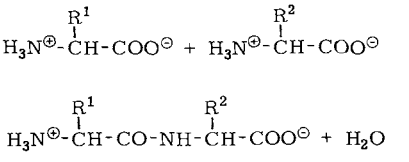
The activation of a gene section triggers off the biosynthesis of the corresponding protein. It begins with the transcription of the information into a ribonucleic acid (RNA), which acts as a messenger and ultimately effects the translation of the information into the amino acid sequence at the site of protein synthesis.

This is where extreme difficulties arise for the chemist who is concerned with the analysis of proteins or peptides, and who is trying to obtain these molecules by synthesis. Though the growth of the number of proteins whose amino acid sequences have been established is becoming steadily faster, it is only a short time since the first venture was made into the synthesis of a protein, this protein being the enzyme ribonuclease.

Over the past 15 years, the true domain of the synthetic worker has been peptides up to a chain length of about 40 amino acids. Many hormones having high physiological activities and fascinating properties were discovered in this field.

In the organism such substances are synthesized in a matter of seconds. A team of experienced chemists, on the other hand, takes weeks, months, or even years for such a synthesis. It thus seems uneconomical at first sight to try to compete with nature in this field. This unfavorable light changes, however, when one considers that the completion of a gene mutation involving the replacement of a single amino acid within a protein takes *e. g.* 7 to 10 million years in the case of hemoglobin[2], whereas once a scheme has been developed, the chemist can apply it to the synthesis of many similar peptides within a short time.

The synthesis of peptides thus allows the study of structure-action relationships. Such investigations are possible only within very narrow limits by chemical or enzymatic modification of naturally occurring peptides.



A further incentive to synthesis may lie in the difficulty of obtaining many peptides having comparatively simple structures. These often occur only in small concentrations even at the site of their formation, *e. g.* in a gland or in the serum. It is only by synthesis that they can be made available in sufficiently large quantities for biological research or for medicinal use.

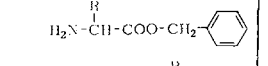
Finally, even in this class of substances, a clear synthesis provides proof of a proposed structure.

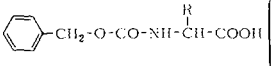
Parallel with the synthesis of a growing number of peptides, the arsenal of methods and technical experience has also grown during the past 20 years.

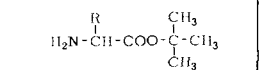
2. Protective Groups and New Condensation Methods

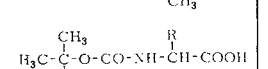
It is well known that peptides formally result from the condensation of amino acids with elimination of water. Scheme 1 shows the principle of this reaction for the synthesis of a dipeptide.

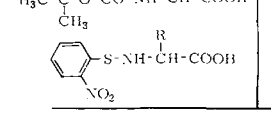
Scheme 1











If the reaction is to yield a single product, there must be only one free amino group and one free carboxyl group; in other words, the functional groups that are not to react must be blocked by protective groups. The situation is complicated by the fact that side chains R may also contain reactive groups, and these must then also be blocked.

We thus need two types of protective groups, *i. e.* one type that intermittently protects the α-amino and carboxyl groups and liberates them again selectively, and another type that blocks the other functional groups throughout the synthesis. All these protective groups must be capable of being removed at the end of the synthesis under conditions that do not affect the sensitive final product.

Though many protective groups have been recommended, only a few have found general and extensive use. Since most peptides are reasonably stable in acidic media, combinations of protective groups having graded acid labilities are preferred nowadays.

Three important types are shown in Table 1. These are the benzyl type, the *tert*-butyl type, and the phenylsulfenyl type[1]. Benzyl ester groups protecting carboxyl groups can be removed by

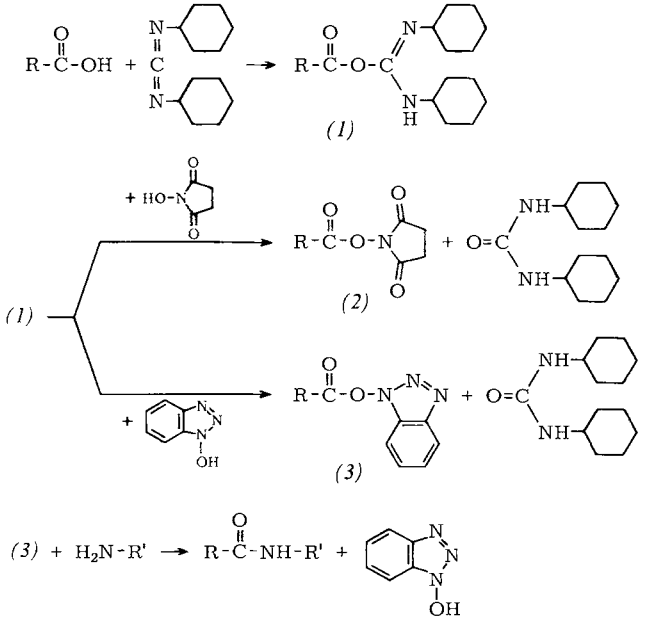
Table 1. Protective groups for amino acids during peptide synthesis.

Amino acid + protecting group	Name	Symbol	Removal
	Benzyloxy (benzyl ester)	OBzl	HBr, HF, hot trifluoroacetic acid, catalytic hydrogenation
	Benzyloxycarbonyl	Z	
	*tert*-Butoxy (*tert*-butyl ester)	OBu^t	*e.g.* cold trifluoroacetic acid
	*tert*-Butyloxycarbonyl	Boc	
	2-Nitrophenylsulfenyl	Nps	*e.g.* weak acid + indole

catalytic hydrogenation. It was discovered only later that protonic solvolysis of benzyl esters can also be accomplished with acids such as hydrogen iodide or hydrogen bromide in glacial acetic acid, as well as hydrogen fluoride or hot trifluoroacetic acid.

To protect the amino group, the benzyl residue cannot be attached directly to the nitrogen since the C-N bond is too stable. So that the benzyl residue will again be attached by an ester linkage, a urethane is prepared. After the removal of the benzyl residue, the carbonic acid escapes as CO_2, and the amino group is again in the free state.

The *tert*-butyl residue is used in a similar manner to protect amino and carboxyl groups. *tert*-Butyl esters are resistant to alline hydrolysis and to catalytic hydrogenation, but are rapidly attacked by acids even under conditions such that benzyl residues are still stable, *e.g.* by cold trifluoroacetic acid.



A further increase in acid sensitivity is achieved with the nitrophenylsulfenyl residue. However, this can only be used for the protection of the amino group. The S-N bond can be broken merely by a nucleophilic attack in dilute acid but, because this reaction leads only to an equilibrium, and since the nitrophenylsulfenyl group is readily transferred to the indole ring of tryptophan, an "interceptor", *e.g.* indole, is also added to take up the sulfenyl residue and to bind it irreversibly[3].

More or less practicable solutions, mostly based on the benzyl and *tert*-butyl types mentioned above, have also been discovered for the masking of hydroxyl, mercapto, and guanidino groups, which can also occur as constituents of amino acids[1].

Another central problem of peptide chemistry is the condensation of amino acids or peptide fragments without racemization.

The formation of a peptide linkage between an amino group and a carboxyl group with elimination of water requires energy. This energy is supplied through the chemical activation of the carboxyl group. In this high-energy state, the optically active amino acids readily undergo racemization. This usually results in loss of biological activity. The most pressing requirement for any condensation method is therefore the prevention of racemization.

Only one of the "old" techniques fully satisfied this requirement; this was the azide method, which was developed by *Curtius*[1]. It ultimately also became possible to reduce racemization to a minimum in the carbodiimide method[1], which has been known for a long time (Scheme 2).

Scheme 2

Dicyclohexylcarbodiimide (DCC) first adds on to the carboxylic acid to give an isourea derivative, which is extremely reactive and hence liable to suffer racemization. This compound is very rapidly attacked by certain *N*-hydroxy compounds that are added to the reaction mixture. This leads *e.g.* to the activated carboxylic acid derivatives *(2)* and *(3)*[4,5]. In the final step, *i.e.* the slow formation of the peptide linkage by aminolysis of *(2)* or *(3)*, the amine now reacts with this activated derivative, which is resistant to racemization despite its high reactivity, instead of with the readily racemized primary addition product.

It has recently been shown that the synthesis of peptides *via* mixed anhydrides with half-esters of carbonic acid[1] can also proceed without racemization under certain conditions[6].

A more recent variant of the synthesis technique still remains to be mentioned. This is *Merrifield*'s solid state synthesis[7] in which the amino acid is reversibly attached by the carboxyl end to a synthetic resin. The further steps in the synthesis now take place on this insoluble support, which is suspended in and swells in the solvent. After each reaction, excess reagents are simply washed out by solvent. Since the steps involved in the successive incorporation of the amino acids are repetitive, the synthesis can be automated. Though the results obtained so far by this interesting method have fallen short of expectations in many cases, it now allows the preparation of peptides containing up to about 12 amino acid residues with a considerable saving of time if satisfactory facilities are available for the purification of the initial crude peptide mixture and if knowledge and experience of the application of purity criteria are available.

We shall now discuss considerations that guide the synthesis of physiologically active peptides with the aid of a few selected examples.

3. The Hormones of the Neurohypophysis

Hormones have no autonomous reactivity such as is possessed *e. g.* by enzymes; they are messengers that trigger off a reaction or reaction chain only after being bonded to specific receptors at the site of action. Thus if we make changes in the amino acid sequence of a peptide hormone in order to study structure-action relationships, we are simultaneously exploring the receptor, though this method cannot provide particularly accurate information about its nature and topography.

The two hormones of the neurohypophysis, *i. e.* the labor-inducing oxytocin *(6)* and the antidiuretic and pressor substance vasopressin [Arg^8 vasopressin *(8)* and Lys^8 vasopressin *(9)*], for example, are recognized by the receptor only in their steric structure as determined by the cyclic form. Simple cleavage of the ring formed by a disulfide bridge or even a small increase in the ring size leads to disappearance of the homone action. A whole series of modifications are nevertheless possible.

Out of more than 150 known natural and synthetic peptides having analogous structures[1], a few are listed in Table 2. We recognize arginine vasotocin *(7)* which is assumed to be the parent hormone of this family. It is found in cold-blooded animals and in the pineal gland of higher vertebrates[8]. Starting from this compound, it is possible to imagine the differentiation into the oxytocin and the vasopressin series by stepwise gene mutation after gene reduplication[9].

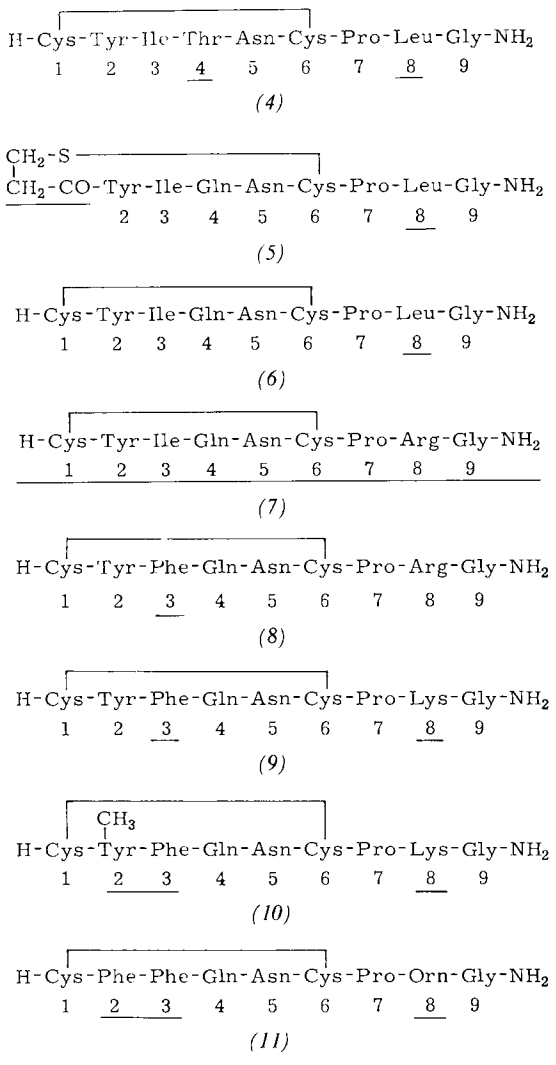


Table 2. Biological activities of the hormones of the neurohypophysis and its analogs (in I.U./mg).

Hormone or analog	Oxytocin effect (rat uterus)	Vasopressin effect: blood pressure (rat)	Vasopressin effect: antidiuretic action (rat)	Ratio blood pressure: antidiuretic action
Ile[4] Oxytocin *(4)* (synthetic)	900	0.4	3	1 : 7.5
Deaminooxytocin *(5)* (synthetic)	900	1	15	1 : 15
Oxytocin *(6)* (natural)	450	5	5	1 : 1
Arg[8] Vasotocin *(7)* (natural)	155	245	250	≈ 1 : 1
Arg[8] Vasopressin *(8)* (natural)	16	400	400	1 : 1
Lys[8] Vasopressin *(9)* (natural)	5	270	250	≈ 1 : 1
Methyl Tyr[2] Lys[8] vasopressin *(10)* (synthetic)	0.02	2.4	275	1 : 115
Phe[2] Orn[8] Vasopressin *(11)* (synthetic)	1	120	0.5	240 : 1

Alongside these natural hormones, synthetic peptides are now taking their place. Elimination of the amino group on the cysteine leads in the oxytocin series to deaminooxytocin *(5)*, which has a stronger biological action than the natural product.

To explain this phenomenon we must consider the biological breakdown of the peptides. Peptides are formed and broken down again in the body within a short time. It is therefore probably no accident that the body uses this very class of compounds for the sensitive, fast-acting, and also rapidly discontinuing "fine adjustment" of physiological processes, a very rapidly adjustable equilibrium being achieved by increasing or decreasing the supply.

Aminopeptidases break down the peptides from the amino end, and carboxypeptidases break them down from the carboxyl end. The rupture of certain bonds within the molecule, which is important in proteins, becomes less important in lower peptides.

Deaminooxytocin *(5)* is no longer susceptible to attack by the specific aminopeptidase for the breakdown of oxytocin. The molecule thus has a longer lifetime than the natural hormone. This is seen experimentally as an increased activity, provided that, as in the present case, the change in the structure does not appreciably reduce the bonding by the receptor.

The highly active threonine[4] oxytocin *(4)*, the synthesis of which was recently described by *Manning*[10], provided something of a surprise. Whereas more than 80 oxytocin analogs have been synthesized over the past 15 years, the only one that showed biological activity was deaminooxytocin, and the increase in that case was indirect, as it resulted from the longer lifetime of the molecule. In threonine[4] oxytocin, on the other hand, it appears that the bonding to the receptor and thus the as yet unknown primary effect of the hormone on the receptor is strengthened. In this respect, the natural hormone has now been dethroned by a synthetic "mutant".

The vasopressins are characterized above all by two physiological effects. They promote the reabsorption of water in the distal section of the renal tubules, *i. e.* they have an antidiuretic action. They also strengthen the contraction of the arterioles and capillaries, and so increase the blood pressure.

The vasopressins thus have several receptors. In view of the close structural relationship between the hormones, it is not surprising that the vasopressins also have a certain affinity for oxytocin receptors. Conversely, oxytocin also has a certain vasopressin action.

Variations within the peptide chain influence the vasopressin effects to varying degrees. This is particularly noticeable when the tyrosine in position 2 is slightly changed. Methylation of the phenolic OH group of tyrosine, as in *(10)*, leads practically to disappearance of the pressor action, whereas the antidiuretic action is slightly increased. Replacement of the tyrosine by phenylalanine, *i.e.* elimination of the OH group, on the other hand, leads to almost total disappearance of the antidiuretic action, while the pressor effect is less strongly influenced. This tendency is intensified by additional variation in position 8, as in *(11)*. Whereas the pressor action and the antidiuretic action, expressed in international units per mg, are balanced by definition in vasopressin, slight modification of the molecule is sufficient to increase the specificity of action by several orders of magnitude (see the last column in Table 2). A vasopressin with specific pressor activity is finding practical use in gynecology, where it should replace epinephrine as an additive in local anesthetics.

Shifts of the action spectrum have also been observed in the case of oxytocin, which induces milk ejection as well as contraction of the uterus; however, the changes in specificity observed here so far are not so pronounced.

4. Adrenocorticotropic Hormone[1]

Whereas only those changes that left the size of the molecule unchanged lead to highly active analogs in the case of the hormones of the neurohypophysis, an additional possibility is offered by shortening of the chain in the case of adrenocorticotropic hormone (ACTH, corticotropin).

The hormone consists of a chain of 39 amino acids (Scheme 3). It is formed in the adenohypophysis, *i.e.* the anterior lobe of the pituitary gland, and when bound by a receptor on the adrenal cortex it induces the secretion of the corticosteroids.

sequence 6–10 is common to both peptides, this small fragment must be essential for the initiation of the ACTH effect.

It is interesting to note that the same sequence is also responsible for the action of the melanophore-stimulating hormone (MSH)[1] and of the lipotropic hormone (LPH)[12]. It is only the sequences attached on either side of this fundamental unit that determine the receptors to which the active section will be bound, and so decide whether its action will be mainly corticotropic, melanophore-stimulating, or lipolytic.

The binding sequences also contribute to the biological activities. Even peptides consisting of 13–15 amino acids are almost as active as natural corticotropin, provided that the amino and carboxyl ends are protected against enzymatic breakdown (Table 3)[11].

However, the biological activity increases suddenly at a chain length of 17 amino acids to reach a value of about

Scheme 3. Human corticotropin *(12)* (top) and principle for the determination of the shortest biologically active sequence (bottom) on synthetic ACTH analogs (activity: 0.4 and 7 I.U./mg respectively).

Only a part of the molecule can be responsible for the hormone action, since even peptides containing about 20–24 amino acid residues, counted from the amino end, retain the full biological activity. Further shortening of the peptide chain results in a fast, but not yet abrupt, decrease in the ACTH activity. This alone suggests that the actual active region could be much smaller, and is enclosed by sequences that effect the bonding of this active region to the receptor.

To test this hypothesis, two peptides having severely shortened ACTH sequences were compared (Scheme 3)[11]. The boxed region common to the two peptides is assumed to be the active sequence. The other parts of the molecule would then be responsible for bonding the sequence to the specific ACTH receptor. The terminal residues were so chosen that they protect the molecule against enzymatic degradation from the amino and carboxyl ends.

As the experiment showed, both peptides have a small but clearly measurable ACTH activity. Since only the 800 I.U./mg, which is approximately four times the activity of the natural hormone. Similar observations have been made on a peptide containing 18 amino acids, in which the amino end was blocked by D-serine and the carboxyl end by an amino group[13].

Table 3. Constitution and ACTH activity of synthetic ACTH analogs. The sequence 5–16 of the four analogs corresponds to that in the natural hormone [cf. *(12)*].

Compound [a]	No. of amino acids	ACTH activity [b]
ß-Ala-Tyr-Ser-Met-Glu-····-Lys-Lys-R 1 2 3 4 5 16 17	17	807 (533-1360)

X-Ser-Met-Glu-····-Lys-Lys-R 3 4 5 16 17	15	149 (82-250)
X'-Glu-····-Lys-Lys-R 5 16 17	13	92 (70-120)

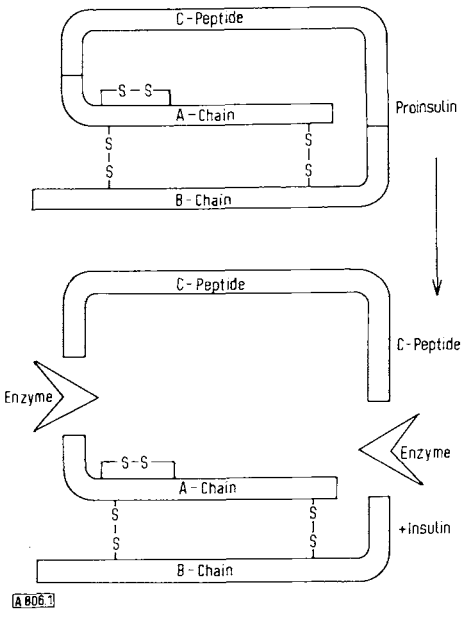
[a] R = NH–$(CH_2)_4$–NH_2; X = *p*–HOC_6H_4–CH_2–CH_2–CO; X' = H_3C–$(CH_2)_3$–O–CO.

[b] Values in I.U./mg; determination in rats after blockage with Dexamethasone®; 3rd Internat. Standard. $P = 0.95$.

The significance of these short-chain, biologically highly active corticotropins lies in their ability to penetrate mucous membranes more readily than the natural hormone because of their comparatively low molecular weight. Unlike the natural hormones, therefore, they can be applied sublingually or intranasally. Their increased duration of action, which extends over a few hours with suitable doses, tends toward an ideal ACTH therapy, which takes the diurnal rhythm into account. The time-action relationship of these new synthetic corticotropins corresponds to the rapid increase in the ACTH blood level in the morning and the slow return to the normal low value.

5. Insulin and Ribonuclease

Chemical synthesis no longer presented any fundamental difficulties in connection with the hormones discussed so far, and it was possible to concentrate entirely on the study of structure-action relationships. Insulin, on the other hand, which is one of the most extensively discussed peptide hormones from the medicinal point of view, still presents many problems not only to the physiologist but also to the chemist. Chemically speaking, insulin is an embodiment of a new type. It consists of two peptide chains linked to each other by two disulfide bridges. Another disulfide bridge exists within the A chain (Scheme 4).



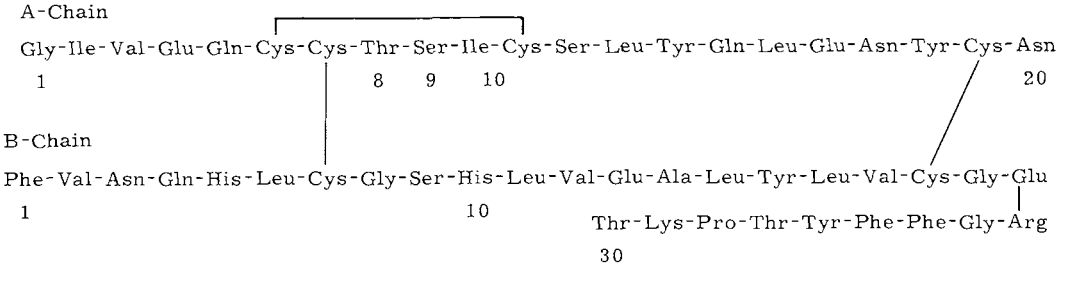


Fig. 1 Formation of insulin from proinsulin.

In the case of ribonuclease, which is an enzyme consisting of a peptide chain of 124 amino acids and containing four disulfide bridges (Fig. 2), reductive cleavage followed by reformation of the four disulfide bridges leads, not to the 105 possible monomolecular isomers, but to

Scheme 4. Human insulin. Bovine insulin contains Ala-Ser-Val in positions 8–10 of the A chain, and in both bovine and pig insulin, the B chain ends with Ala instead of Thr.

It has long been a puzzle how the body synthesizes such a molecule. *Steiner* discovered proinsulin[14], a single-chain precursor in which we again find the two chains of insulin. In this case they are joined by an intervening link, the connecting peptide or C peptide. When this C peptide has fulfilled its function of bringing the two parts of the chain into the appropriate position for the formation of the disulfide bridges, it is split off enzymatically and undergoes degradation (Fig. 1).

Though the chemical synthesis of insulin has already been accomplished[15], we are still far from finding a satisfactory solution to the problems associated with it. The synthesis of the two peptide chains presents greater difficulties than the synthesis of other peptides of comparable chain length. However, the limiting step is the specific combination of the two chains to form insulin. a quantitative yield of a single isomer, *i. e.* the fully active enzyme. The two insulin chains, on the other hand, lack the inherent directing force of ribonuclease. A mixture of many isomeric and polymeric compounds is therefore obtained.

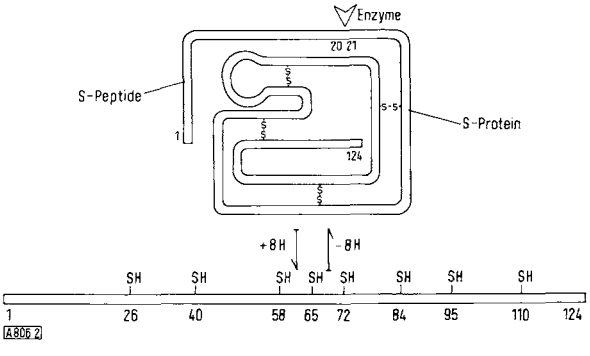

Fig. 2 Top: Oxidized (enzymatically active) and bottom: reduced ribonuclease.

Proinsulin, the one-chain precursor of insulin, behaves more like ribonuclease. About 70% recombination in accordance with the formula is obtained at high dilutions, though the yields under preparative conditions, *i.e.* at higher concentrations, are lower.

The parallels between ribonuclease and insulin or proinsulin can be followed still further. Ribonuclease is specifically cleaved by the enzyme subtilisin at a single point, *i.e.* between amino acids 20 and 21[16]. The enzymatic action of ribonuclease is retained, despite the breakage of the peptide chain at this point, and disappears only if the two fragments, the S peptide and the S protein, are separated from each other. If the two fragments are then reunited in solution, the strong intermolecular forces between the two peptides cause them to recombine immediately in the correct conformation to give the structure having the full enzymatic activity (Fig. 2).

The knowledge gained with ribonuclease was also applied to proinsulin. Attempts were made to reoxidize reduced proinsulin that had already been ruptured enzymatically at one or both cleavage points. However, the recombination yield was no higher than in the combination of A and B chains, *i.e.* these fragments of proinsulin also lack the directing forces that are inherent in the two fragments of ribonuclease.

However, reservations are necessary regarding the information obtainable from this experiment. The enzymatic cleavage of proinsulin is not confined to the elimination of the C peptide. There are two basic amino acids at each of the linkage sites, which are also entirely or partly eliminated in this reaction. The product that is finally isolated as the C peptide is not the actual fragment, but the intermediate link with four basic amino acids less.

There is thus a possibility that it is these basic amino acids that are responsible for the full development of the attractive forces between the three sections.

Since this question could not be answered using natural C peptide, it was necessary, in a synthesis consisting of about 120 steps, to synthesize a C peptide that had these four basic amino acids at the two ends[17]. Since the addition of this synthetic fragment had no effect on the yield in the recombination of A and B chains[18], we can expect no further help with the synthesis of insulin from this line of enquiry.

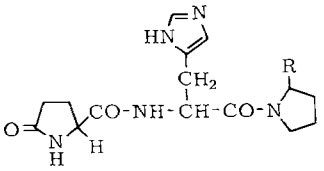
Moreover, synthesis *via* proinsulin is not very attractive from the economic point of view. In addition to the effort of synthesizing a peptide having more than 80 amino acids instead of two chains of 21 and 30 amino acids respectively, the method suffers from the unsatisfactory formation of the disulfide bridges. The elimination of the C peptide by an enzyme that we have not yet isolated and the loss of this sequence, which could no longer be used for another synthesis, suggest that a preparatively satisfactory insulin synthesis by this route is likely to be unattainable.

It still remains to examine the successive formation of the disulfide bridges by specific reactions for the preparation of asymmetric disulfides. Corresponding methods are known in principle, and have already been applied to model peptides having a partial insulin sequence[19].

Despite the uncertainty of this situation, studies on structure-action relationships have been started even for insulin. Though the need to use unsatisfactory synthetic routes has prevented the establishment of precise information about the biological action of insulin analogs, it is hoped that by exchange of amino acids, it will be possible to learn which amino acids or functional groups are essential to the action of insulin. The picture found for insulin is similar to that for oxytocin and vasopressin. Extensive replacement of amino acids has even less influence on the biological action, both quantitatively and qualitatively, than in the case of the hormones of the neurohypophysis. On the other hand, trifling modifications in the A chain, perhaps affecting the steric structure of insulin, are not permissible[20].

Insulin brings us very close to the old boundary between peptides and proteins; this boundary was passed for the first time with the syntheses of ribonuclease[21] and of ribonuclease S-protein[22]. However, the methods used in these cases were the same as those used in the synthesis of lower peptides, a further reason for paying more attention to the peptide nature of the proteins.

The trend toward increasingly bold syntheses of ever-larger peptides is unmistakable. In the very year in which the first synthesis was achieved, however, interest was also focused back on a group of lower peptides, *i.e.* the releasing hormones[23].



6. Releasing Hormones

The releasing hormones are formed in the hypothalamus, and migrate by a portal system into the anterior pituitary lobe, where they specifically effect the release of a hormone, each of these anterior pituitary hormones apparently being subordinate to a releasing hormone (and possibly also an inhibiting factor).

The importance of the releasing hormones is primarily in the diagnostic field. Just as the anterior pituitary hormones can be used to test the function of the target organs, *e.g.* of the gonads or of the adrenal cortex, it should be possible to test the function of the pituitary gland with the aid of the releasing hormones, and differential diagnosis of the types of cells involved in the production of a certain anterior pituitary hormone would then also be possible.

Releasing hormones may be of therapeutic use where subordinate anterior pituitary hormones obtained from animal material are inactive in man because of their species-specificity. The treatment of hormonal disturbances with releasing hormones would thus be equivalent to treatment with anterior pituitary hormones of the same species, provided that the anterior pituitary lobe is intact and that the releasing hormone lacks species-specificity. The structure of only one of these hormones, the thyrotropin-releasing hormone (TRH), is known at

present[24]. This substance is pyroglutamylhistidylprolinamide *(13)*. The story of the discovery of this hormone illustrates the unimaginable difficulties encountered in the investigation of this class of substances.

(13), R = $CONH_2$
(14), R = H

Even highly purified extracts from hundreds of thousands of hypothalami gave too little material for elucidation of its structure, and even this was not chemically uniform. The amino acids found in the hydrolyzate were regarded for a time as impurities, and no further thought was given to the peptide nature of these hormones.

It was only when the three amino acids histidine, proline, and glutamic acid were found in equimolar quantities in sufficiently pure preparations that the synthesis of the six possible isomeric tripeptides was started. These compounds were biologically inactive. However, the problem was nearer solution than the negative results indicated. When attempts were made to acetylate these peptides, Glu-His-Pro gave a product having a high TRH activity[25]. At the same time, it was deduced elsewhere[26] that pyroglutamic acid, which can be formed together with other products on acetylation of glutamic acid, is present. These observations finally led to the synthesis of pyroglutamylhistidylprolinamide, which was found to be identical with natural TRH[24]. The synthesis of this hormone and the determination of its constitution were thus achieved simultaneously.

The course of this structural elucidation presumably provides the model for the discovery of other releasing hormones, since all these compounds are isolable only in such small quantities, and are so difficult to obtain with the purity required for determination of their constitution, that confirmation by synthesis is necessary at a very early stage. Moreover, the availability of these hormones in sufficient quantities for diagnosis and therapy will also be dependent on synthetic preparation. The specificity of constitution of TRH is high. Even small changes in structure lead to loss of its biological activity. The amide group, however, is not essential to its action. Elimination of this group leads to a dipeptide-amide *(14)*, which, though less active, is just as specific as the natural hormone[27]. So far as we know, this dipeptide-amide is the first and at present the only dipeptide with such a strong and specific hormone action.

7. Closing Remarks

If one looks back on the work of past years, it is surprising at first to note that peptide chemistry in its present sense did not exist 20 years ago.

Though *Emil Fischer* laid the foundations in this field as early as the first decade of the present century, the superstructure was slow to assume its present shape. And though the discovery of the benzoxycarbonyl protecting group by *Bergmann* and *Zervas* in 1932 opened up a new phase in peptide synthesis, even in 1950 only a few naturally occurring dipeptides and tripeptides were known and had been synthesized.

Between 1944 and 1954, however, the analytical situation was made ripe for the purification, isolation, and constitutional elucidation of higher peptides, and *du Vigneaud* showed in 1953, with the synthesis of oxytocin[1], that the preparation of such substances in the retort was no longer a dream. This achievement broke the "spell", and the last decade has brought an undreamed-of advance in peptide chemistry, with the syntheses of corticotropin, insulin, glucagon, and calcitonin, and finally with the first synthesis of an enzyme and a releasing hormone.

The chemistry of peptides is methodically integrated with organic chemistry. Its objects, on the other hand, arise from biochemical problems. It thus constitutes one of the strongest and most active bridges between chemistry and biology, and it is surely reasonable to hope that medicine will participate to an increasing extent in this alliance.

Lac Repressor

By Benno Müller-Hill[*]

Repressors are proteins that interact with inducers and operators to regulate the synthesis of enzymes in the cell. Lac repressor ensures that sufficient β-galactosidase is available to the bacterium Escherichia coli, depending upon the amount of lactose present in the culture medium. It has proved possible to isolate lac repressor from E.coli. The present progress report describes how these discoveries were made, as well as the formation and mode of action of the repressor.

1. Introduction

Some of the mechanisms which limit and control protein synthesis in bacteria have become known over the last few years. The bacterium *Escherichia coli* is particularly suited for such an analysis, since its chromosome is able to code for a total of only 3000 proteins. They are all formed according to the "central dogma" of molecular biology:

$$\text{DNA} \xrightarrow[\text{Transcription}]{} \text{RNA} \xrightarrow[\text{Translation}]{} \text{Protein}$$

Coli-DNA is transcribed in discrete pieces, covering one to twenty genes. The starting points, and presumably the stopping points, of transcription are fixed. The signals which indicate "start of transcription" have been called promoters; their base sequence, however, is so far unknown.

It is clear that only a few protein-synthesizing systems can be fully operative at one and the same time, otherwise the cell would be filled with unneeded proteins, grow more slowly, and lose out in evolution. An *E.coli* cell grown in the presence of glycerol, for example, needs enzymes to break down glycerol but has no need for the enzyme which breaks down lactose, β-galactosidase. It harbors only a few copies of this protein. But when grown for a few generations in the presence of lactose, the β-galactosidase level increases 500 fold: about two percent of the soluble protein become β-galactosidase. Similar drastic changes in amount of protein are found in many catabolic enzyme systems which break down sugars, amino acids, or lipids and many anabolic systems which synthesize amino acids or nucleic acid precursors.

In 1961 *Jacob* and *Monod* proposed a negative control system for the lactose system[1]. The biochemical realization of the negative control is simple: reversible steric hindrance of the process to be controlled is all that is needed. It can be exerted at any stage of the process. Intuitively, hindrance of the earliest step of the process of protein synthesis seems the most likely, but inhibition at later stages is also possible. *Jacob* and *Monod* proposed that the structural genes of the lactose system had a very efficient but negatively controlled starting site for transcription. For this, two separate control elements are needed: 1.) a diffusible gene product (the repressor), which is able to interact with a signal (the inducer), and 2.) a DNA site (operator), near the promoter, with which the repressor interacts so that the start or the progress of transcription might be blocked. The negative control by steric hindrance, and the distinction between the regulatory apparatus and the proteins to be regulated, are the most fundamental aspects of the model. This theory has been proved in all its elements to be correct.

2. The i Gene and the Lac Repressor

2.1. The System

The lactose system has been very extensively studied over the last 25 years[2]. Figure 1 shows a schematic map of the lactose system in *E.coli*. The system consists of three closely-linked structural genes, z, y, and a, which code for β-galactosidase (z), lac permease (y), and transacetylase (a), respectively. The genes are transcribed in one molecule of messenger RNA (m-RNA)[1] and the direction of reading is from z to a[1,3]. Between the

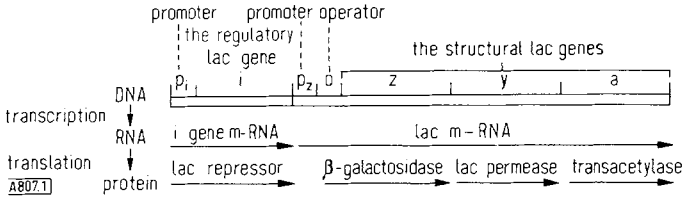

Fig. 1. The lactose system of *E.coli* DNA makes RNA, RNA makes protein – that is the dogma of molecular biologists. The regulatory i gene makes i gene messenger RNA which is translated into repressor protein. The structural lac genes make their own messenger RNA which is translated into three proteins: β-galactosidase, lac permease, and transacetylase. The promoter sites (p) are the starting sites of transcription. The operator site (o) is where synthesis of lac messenger is regulated. Fig. 1 to 3 are not drawn to scale.

starting site of transcription, the promoter (p_z), and the beginning of the z gene, lies a stretch of DNA to which the repressor binds in the absence of inducer (Fig. 2)[4]; this locus is called the operator (o). If repressor is bound to the operator, no transcription of the lac structural genes occurs. Promoter, operator, and the structural genes form one operon. The repressor is coded by a gene, the i gene, which attaches itself to the left on the promoter

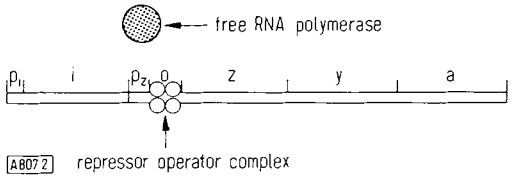

Fig. 2. Repression: Repressor sits on the operator DNA. The RNA polymerase molecules cannot sit properly on their starting site p (promotor) to make messenger RNA from the structural lac genes. There is also no RNA polymerase molecule on the promoter of the i gene; it is considered a bad promoter. Only rarely is transcription of the i gene successfully started. The cap protein [65] and cyclic AMP [64] are omitted in Fig. 2 and 3 (see below).

p_z. The i gene is also transcribed from left to right, so that its promoter (p_i) (starting site of transcription) is on its far left[5]. The sequence of all lac loci is thus p_i, i, p_z, o, z, y, a.

The i gene product, the lac repressor, inhibits the start and/or progress of the transcription of the structural lac genes in the absence of inducer. In the presence of an inducer, the repressor can no longer interact efficiently with the operator, and transcription can proceed (Fig. 3). The repressor exists in two forms: one form (R) is able to bind inducer (I) but no operator DNA (O); the other (R') can bind operator DNA (O) but no inducer (I). Since induction occurs rapidly, both forms must be in a rapidly forming equilibrium:

$$OR' \rightleftharpoons O + R'$$
$$R' \rightleftharpoons R$$
$$R + I \rightleftharpoons RI$$

This is the classical interpretation of the mechanism of induction. As we will see later, it is only partially true: ternary complexes (ORI) also play an important role.

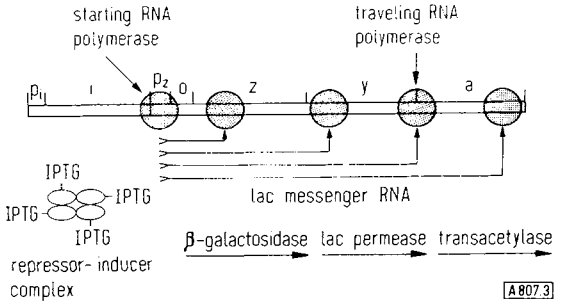

Fig. 3. Induction: Inducer has been added. All repressor molecules swim around as repressor-inducer complexes. This complex cannot bind to the operator site; the operator is free. An RNA polymerase molecule is about to start from the promoter site of the structural genes. It then begins its journey along the DNA and transcription has started. Before the polymerase reaches the end, other polymerase molecules hop on. The long threads of the transcribed messenger RNA hang from the RNA polymerase molecules. These in turn make the three structural proteins.

2.2. Properties of the Wild-Type i Gene Product: Specificity of Induction.

Lactose enhances the rate of β-galactosidase synthesis in *Escherichia coli*. The presence of the product of the y gene (lac permease) is necessary for the entry and accumulation of lactose into the cell[6]; that is, a y^- mutant cannot be induced by lactose. After the lactose has entered the cell, it is still unable to induce[7]; it has first to be converted into the real inducer by the few molecules of β-galactosidase present in the uninduced cell. β-Galactosidase not only breaks down lactose into galactose and glucose, but also transfers the galactose moiety of lactose to suitable acceptors[8]. Such acceptors can be molecules having aliphatic hydroxy groups. Among these

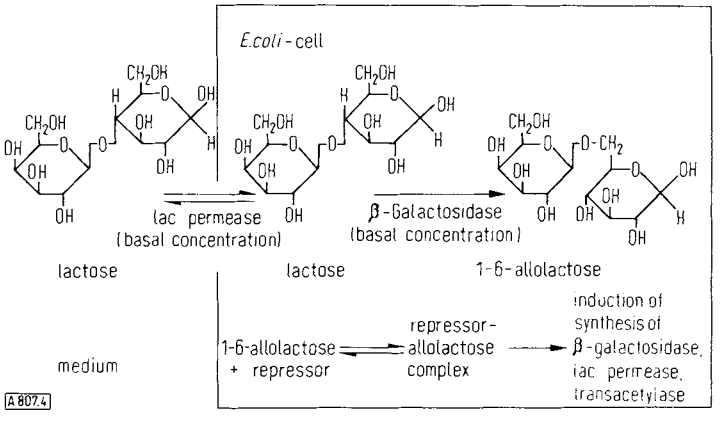

Fig. 4. The induction process with lactose: Lactose has first to enter the cell. This only happens in the presence of lac permease. There are always a few molecules of permease around, even in uninduced cells. Now it has to hit a β-galactosidase molecule. Uninduced cells contain several β-galactosidase molecules. Here it is either hydrolyzed or converted into one of the various lactose isomers (1-2, 1-3, 1-6 allolactose). Only the 1-6 allolactose is able to bind to lac repressor.

transfer products, the 1–6 lactose isomer (allolactose) and galactosido-β-D-glycerol are active as inducers of the lac system[7,9]. The other lactose isomers, which are also formed, have been tested and have been found inactive. The whole chain of events is depicted in Fig. 4.

To circumvent this double complication in the laboratory, galactosides have been synthesized which can enter the cell in the absence of permease, which are inducers without prior interference from β-galactosidase, and which are not hydrolyzed by β-galactosidase[10,11]. The most effective of these synthetic sugars is isopropyl-1-thio-β-D-galactopyranoside (IPTG). It induces at the lowest concentration of all known lac inducers, and leads, under saturating conditions, to the highest maximal rate of β-galactosidase synthesis.

Any analysis of the concentration dependence of induction implies that the concentration of the inducer *inside* the cell is known. The inside concentration does not necessarily equal the concentration in the medium, since the inducer might be accumulated by the cell. Such is the case[12] with 1-β-D-galactosidoglycerol, which for some time was thought to be the most effective inducer of the lac system[7].

Among the synthetic sugars, a whole set has been found which are not only non-inducers, but also induction inhibitors[9]. The most prominent member of this class of anti-inducers is *o*-nitrophenyl-β-D-fucopyranoside (ONPF). It is reasonable to think that it acts by binding to the form of repressor which sticks to the operator[13], thereby stabilizing the operator-repressor complex. It isn't surprising that several sugars have been found which fall into both classes: they induce weakly and they inhibit induction weakly. They have been called paradoxical compounds[14]. The structural differences between inducers, anti-inducers, and inert compounds are rather small (see Table 1).

Table 1. Specificity of induction and antiinduction.

Inducers:
1-6-*O*-β-D-galactopyranosyl-D-glucose [7,9]
isopropyl-1-thio-β-D-galactopyranoside [11]

Antiinducer:
o-nitrophenyl-β-D-fucopyranoside [9]

Weak inducer and weak antiinducer:
p-aminophenyl-1-thio-β-D-galactopyranoside [14]

Inert analogs:
1-4-*O*-β-D-galactopyranosyl-D-glucose (lactose) [7,9]
p-nitrophenyl-β-D-fucopyranoside [9]
o-nitrophenyl-1-thio-β-D-fucopyranoside [9]

2.3. Mutants of the i Gene

The i gene is characterized by a large variety of mutants with different phenotypes (Table 2). They fall into two main classes: mutants that no longer repress, and mutants that have altered inducer-binding capacity.

Mutants of the first class, in which the i gene product is unable to bind efficiently to the operator, are constitutive, that is, they produce under all circumstances

Table 2. Mutations in the i gene.

Genotype	Biological Phenotype (i z^+y^+)	Molecular Phenotype	Ref.
i^+	Wild-type; inducible; grows on lactose	About 10 molecules of normal repressor per cell	[1]
i^-	Constitutive; grows on lactose	The mutated repressor is unable to bind to operator and to stop transcription of the lac structural genes	[1]
i^{-d}	Constitutive; transdominant; grows on lactose	i^{-d}Repressor is able to form mixed i^+i^{-d} oligomers; they are unable to bind to operator	[15, 16]
i^s	Normal basal level of β-galactosidase; is not induced by low concentrations of inducer; transdominant over i^+; does not grow on lactose	Repressor binds to operator but only badly to inducer	[23]
i^r	Constitutive; β-galactosidase synthesis is repressed by some galactosides	Not well analyzed	[20, 21]
i^{TL}	Constitutive at high temperature; wild-type at low temperature; grows on lactose	Repressor is temperature-sensitive	[22]
i^{TSS}	Constitutive at high temperature; wild-type at low temperature; grows on lactose	Repressor subunits are temperature-sensitive; tetrameric repressor is stable	[22]
i^i	Induced by subnormal IPTG concentrations; grows on lactose	Binds IPTG tighter	[16]
i^q	Wild-type; grows on lactose	About 200 molecules of normal repressor per cell	[16]
i^{superq}	Wild-type; grows on lactose	About 1000 molecules of normal repressor per cell	[19]

("constitutively") large amounts of β-galactosidase[1]. They are called i^- (the minus sign signifies the absence of functional i gene product). Two classes of such i^- mutants have been found: recessives[1] and transdominants (i^{-d})[15,16]: "recessive" means that the introduction of a second functional i^+ gene into a cell which already carries an i^- gene leads to repression. The new i^+ gene produces functional repressor which is not influenced by the existence of possible products of the i^- gene; "transdominant" means that the constitutive character of the i^- dominates over the i^+ character of the other i gene. To the recessives belong: a) the nonsense i^- mutants[17,18], in which only the amino terminal piece of the i gene product is made; b) some, but not all, i gene deletions (mutants whose i gene is missing either in part or completely), and c) some, but not all missense mutations, in whose i gene product one amino acid is exchanged for another. Among the transdominants, not only three missense mutations[15,16] but also three deletions[19], all cutting into the amino terminal end, have been found. Their behavior can be explained by negative complementation[16] (*i.e.* the formation of mixed i^+i^{-d}oligomers): the i^{-d}character of one subunit "spoils" all the "good" i^+ subunits. This is quite possible, since normal repressor has been shown to be a tetramer (see below). Further, i^{-d} repressor could also bind to operator without repressing.

There are also i mutants in which the repressor binds to the operator after the addition of various synthetic sugars such as IPTG, ONPF or TDG (thiodigalactoside)[20,21]. They have been called i^R. In most of these cases, repression is not quantitative.

Two classes of temperature-sensitive i^- mutants have been isolated[22]: mutants in which the i gene product itself is temperature-labile (i^{1L}), and mutants in which a precursor (presumably the subunit) of the repressor is temperature labile (i^{TSS}).

There are a variety of mutants in which IPTG or lactose do not induce at the usual concentration. The phenotype of such mutants is lac^-; that is, they cannot grow on lactose. They are transdominant. They map in the i gene and are called i^s[23]. They are rather rare; only 0.4% of independent lac^- has this genotype. One might assume that the binding of inducer to repressor has become weaker, or, less likely, that the binding is still strong but that the repressor binds to the operator even in the presence of inducer. Revertants of these mutants which can grow on lactose are almost exclusively i^- or o^c (see below), since it is much easier to destroy the i gene by mutation than to revert just the one base pair which made an i^s from the original i^+. A rare mutant has been isolated (i^t) in which the binding of repressor to IPTG is tighter than normal[24].

Only a few of the i^- mutants mentioned have been mapped by three factor crosses[15]. Deletion mapping of sixteen i^s and two i^{-d} mutants has been carried out[25] (see Fig. 5).

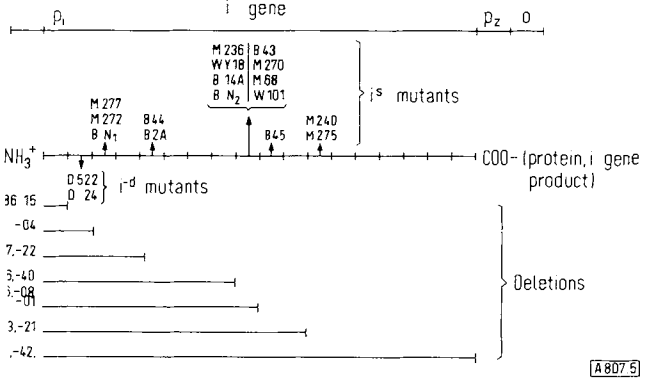

Fig. 5. Genetical map of the i gene: 16 i^s and 2 i^{-d} mutants have been mapped. They have been ordered with 18 tryp-TonB-i deletions in the transposed lac strain. The deletions X8600 are from the collection of *J. Miller*. Strains No. 68, 101, 236, 240, 270, 272, and 275 are from the collection of *B. Müller-Hill*. Strains No. N1, N2, 2A, 14A, 43, 44, and 45 are from the collection of *S. Bourgeois*. Strain y18 is from *C. Willson* and strains 24 and 522 are from *J. Davies*. The mapping has been done by *M. Pfahl*. Details will be given elsewhere[25].

Although the number of mutations and deletions investigated is too small in order to make definite conclusions there are indications that the i^{-d} and i^s mutations occur in clusters at definite sites of the genome. One might hope to obtain through mapping of such mutations and sequence analysis of the corresponding repressor (see below) a picture of the active sites of the repressor.

2.4. Mutants of the i Gene Promoter

Starting from a temperature-sensitive i gene mutation of the i^{TSS} type[22], a mutation of the i gene has been isolated which overproduces lac repressor[16]. It has been called i^q (q for quantity). The overproduction was at first estimated to be about tenfold. This was based on data obtained from the original strain that overproduced temperature-sensitive repressor. Since then, the TSS mutation has been crossed out, resulting in a strain that overproduces presumably wild-type repressor[26]. Recent data using this strain suggest that the increase in repressor is more likely twenty fold. Starting from this strain, it has been possible to isolate an even better overproducer[26]. This strain, called i^{superq}, makes five to ten times more repressor than the i^q strain (see Table 3). These strains have been used to isolate enough repressor (4g) for a sequence analysis (see below). The q mutation has been mapped at the left side of the i gene[19].

Table 3. Lac repressor levels in various strains.

Genotype	lac repressor molecules per cell	
	i gene on the chromosome	i gene on the phage [b]
i^+	10	300
i^q [a]	200	6000
i^{superq} [19]	1000	20000

[a] i^q is the strain overproducing wild-type repressor. The originally[16] present TSS mutation has been crossed out[19].
[b] "On the phage" means after heat induction of cells carrying the prophage $\lambda h80c_{1857}t68dlac$[16], a phage in which part of the phage genome is replaced by the lac genes.

2.5. Changing the Number of Copies of the i Gene in the Cell

E.coli contains, under normal conditions, only one copy of each gene per chromosome. It has been known for a long time that doubling the number of copies of uncontrolled genes leads to a doubling of the gene products in question[22]. Strains having three sets of lac genes can be constructed[27] by using lac transducing phage. They yield, as expected, an approximately threefold increase of the i gene product. An elegant way of introducing many copies of one particular gene into *E.coli* is to use a multiplying specific transducing phage which carries this gene. Such a phage is available for the lac system[27]. It has been made more useful by the introduction of two additional mutations: one which allows the multiplication of the phage to start by means of a short heat treatment of the bacteria (the phage has a temperature-sensitive repressor; the mutation is called c_{1857}), and another mutation which prohibits lysis of the bacterial cells after the phage is induced (the nature of the lysis inhibition is not clear; the mutation is called t68[28]). The use of this phage yields a 30 fold increase in amount of repressor made[16] (see Table 3).

2.6. Consequences of the Low Amount of Repressor in Wild-Type Strains

The repressor is made in only a few copies per cell. An accurate estimate of the amount is difficult since repressor cannot be determined accurately in the crude extract of the wild-type strain. A reasonable estimate is that there are about 10 molecules present per cell[24]. A likely explanation for the low amount of repressor is that the promoter of the i gene (its starting site for transcription) is very inefficient[16]. One or two copies of i gene messenger RNA per division cycle could be sufficient for the amount of repressor found, since one messenger RNA molecule can be translated several times before it decays. The assumption of a slow rate of i gene messenger synthesis can be used for the interpretation of several phenomena:

It has been observed that β-galactosidase is made at a fast rate over 60 minutes if a male (F' or Hfr) i^+z^+ strain is allowed to mate a female strain harboring a lac deletion[29] (Fig. 6). The β-galactosidase z^+ genes are no

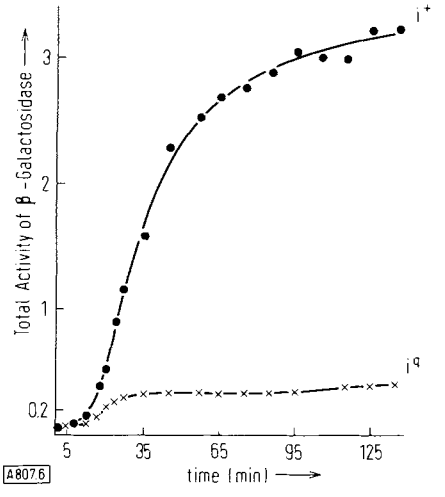

Fig. 6. Onset of repression in a mating experiment: The experiment which had been already performed with ambiguous outcome with a $F'i^{qTSS}$ male [16] has been repeated with an $F'i^{q+}$ male. At time $t = 0$, Sm^s male cells growing exponentially at 37 °C and carrying either the $F'i^+z^+$ or the $F'i^qz^+$ episome were mixed with a two fold excess of Sm^r female cells carrying the RV lac deletion. After 10 minutes of further growth at 37 °C in the casamino-acid-M56[10] glycerol medium, mating was interrupted by vortexing and adding of 30γ/ml of sodium dodecyl sulfate. Streptomycin (250γ/ml) was added to stop further growth of the male cells. Samples were withdrawn at 10 minute intervals, to measure β-galactosidase[9]. The efficiency of transfer of the lac character was determined by plating. It was between 15 and 20%. The β-galactosidase levels are given in arbitrary units normalized to equal transfer after subtraction of a male cell blank. ·–·–· $F'i^+z^+$ males, ×–×–× $F'i^qz^+$ males. The data have been taken from the dissertation by *M. Pfahl*. Universität Köln.

longer repressed after they have been transferred into the female cell. They function constitutively for quite a while in the new environment. Before the first i gene messenger RNA is made, β-galactosidase is produced at maximal speed. The synthesis of repressor messenger RNA occurs statistically at different times in different cells, but after a certain time half of the cells should have had one i gene messenger RNA made, which would make several repressor copies within a few minutes. This should lead to an almost complete shut-off of β-galactosidase synthesis in these cells. If the logarithm of the relative rate of β-galactosidase synthesis is plotted against time a straight line is obtained (Fig. 7). On inspection of the data for the wild-type F'lac $i^+z^+y^+$ we find that the decay of the rate of β-galactosidase synthesis is exponential over 60 minutes. After 24 minutes the rate has fallen by a factor of 1/e. If our interpretation is correct this means that one i gene messenger is made every 24 minutes. The existence of the i^q mutation gives us an internal control for the experiment. If the i^q mutation is a promoter mutation, that is, if it increases the occurrence of the start of transcription of the i gene, we can make a clear prediction for a similar experiment

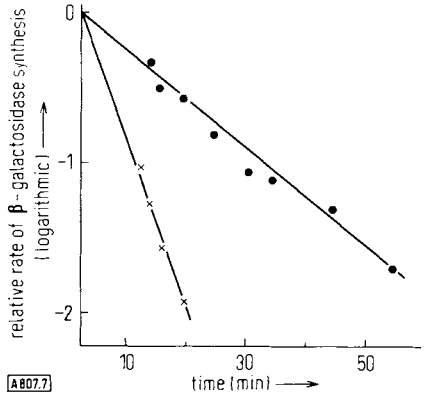

Fig. 7. Onset of repression in a mating experiment: The data from Fig. 6 have been replotted. The logarithm of the rate of β-galactosidase synthesis (in arbitrary units) is plotted against time. The straight lines indicate exponential decay of this capacity (·–·–· $F'i^+z^+y^+$, ×–×–× $F'i^qz^+y^+$). We interpret this as an indication of rare i gene transcription in the wild-type, and more frequent transcription in the i^q mutant[16].

using an $F'i^qz^+y^+$: the decay of the rate of β-galactosidase synthesis should be correspondingly faster. Figure 6 contains the experimental data; Fig. 7 shows that in the case of the i^q the rate of β-galactosidase synthesis decays at least 3 times faster than in the wild-type. This would indicate that the frequency of transcription is three times higher in the i^q than in the i^+ strain. One might wonder why it is not found to be even higher, since 20 times more repressor is made – at the moment we can offer no simple explanation.

Methyltryptophan was used in order to stop protein synthesis in such a mating experiment and thus to test whether the assembly of the repressor precursors takes a long time[30]. The same exponential decrease in the rate of β-galactosidase synthesis was observed as under normal conditions. It may be concluded that it is actually the process of m-RNA synthesis which is rate-determining, and that the assembly of the repressor is rather fast[16].

The small amount of repressor made in wild-type cells is the cause of another interesting phenomenon: escape synthesis of β-galactosidase after UV[31] or heat[32] induction of lac transducing phage. The replicating lac genes $i^+o^+z^+y^+$ escape repression control: β-galactosidase is synthesized constitutively after phage induction. It has been concluded that escape synthesis is due to the lack of sufficient repressor to titrate all operators of the replicating DNA. Particularly clean results have been ob-

tained using the heat-inducible $\lambda c_{I857}h80t68dlac$ phage[32]. Escape synthesis occurs for exactly ten minutes, and then stops completely while phage DNA replication proceeds. If one uses a phage which carries the i^q gene, no escape synthesis is observed. Enough repressor is synthesized at all times to titrate all operators.

Another consequence of the existence of only a few repressor molecules per cell is the time curve of β-galactosidase production after heat induction of an i^{TTS} strain[22]. The "turning-on" of β-galactosidase synthesis by a shift to high temperature has been called heat induction. The repressor already formed in the i^{TSS} strain seemed to be stable at high temperature whereas no new functioning repressor seemed to be assembled under these circumstances. If an i^{TSS} strain is grown for several cell generations at low temperature, and if the temperature is then raised to 43 °C, β-galactosidase synthesis begins to accelerate before the cells have doubled. The first explanation of this phenomenon has been that since already-formed i^{TSS} repressor was stable in the absence of growth it was unstable in the presence of growth. Under growing conditions, it was supposed to have a halflife of 1/10 to 1/5 of a generation[22]. A more plausible explanation is that the i^{TSS} repressor is somewhat temperature labile itself: at very low repressor levels, small differences in repressor concentration in different cells can lead to vastly different rates of β-galactosidase synthesis. Two lac operators and two repressor molecules lead to complete repression, whereas two lac operators and one repressor allow one lac promoter to function at optimal speed. A Poisson distribution would describe the situation. According to this interpretation, rather soon after the temperature shift some cells would contain less repressor than operator. In order for the proposed mechanism to be proven, the inhomogeneity of the cells in regard to β-galactosidase content has to be demonstrated experimentally; this has not yet been done.

2.7. The Nature of the i Gene Product

At the time when the Jacob-Monod model was published, and the existence of messenger RNA had just been proved, it seemed quite reasonable that the repressor might be a nucleic acid[35], that is, presumably the messenger RNA from the i gene. This was actually proposed on the basis of a faultily-interpreted mating experiment in which chloramphenicol was supposed to have completely stopped the synthesis of new protein, but in which new repressor seemed to have been made[34]. On the other hand, it was difficult to believe that an RNA molecule should be able to interact specifically with a small molecule such as IPTG. The known facts about inducer specificity[7,9,10] suggested that the repressor was a protein. The first experiment which made this seem rather likely was the finding of temperature-sensitive i gene mutants[22]. In the two types of temperature-sensitive mutants which were found, either the repressor itself was temperature-labile, or the precursor of the repressor was temperature-labile. Since temperature-sensitive RNA molecules were not known at the time, it made good sense to assume that the repressor was a protein. The same mutants also gave excellent proof of the fact that the inducer binds directly to repressor: IPTG influences the stability of the temperature-sensitive repressor[22]. Furthermore, from the concentration dependence of the heat lability of the repressor in the i^{TSS} strain, it was concluded that the repressor might be a tetramer or another oligomer[22]. More rigorous proof of the protein nature of the repressor was given a few years later. The i^- mutants obtained from i^{s}[17] or i^{+}[18] strains were found to be suppressed by nonsense suppressors. Since nonsense suppression acts on the level of translation by prohibiting chain termination in the nonsense codon, this clearly showed that the translation of the i gene messenger RNA was necessary for the synthesis of functioning repressor.

2.8. *In vitro* Tests of the Lac Repressor

Two types of tests are available for the assay of lac repressor: they measure its binding to inducer IPTG[24,36] or to lac operator containing DNA[37,38]. A sensitive way to determine small amounts of repressor is by equilibrium dialysis with ^{14}C labeled IPTG[24]. The extract to be tested is transferred to a dialysis sac and dialyzed against a 10^{-7} molar solution of ^{14}C labeled IPTG. After equilibrium is reached an equal volume is taken from the outside solution and from inside of the sac, and counted. A more elegant and faster method makes use of the fact that the lac repressor binds to nitrocellulose (millipore) filters, and when bound there, binds IPTG tightly[36]. The latter method is limited by the amount of protein that can be put through the filter: the filter becomes saturated at about 10 to 100 micrograms of protein. Other methods, such as precipitation of the complex with ammonium sulfate[39] (the Farr test from immunology[40]) and phase partition have been used[21].

The binding of lac repressor to lac operator (see below) can be followed rather laboriously using glycerol gradients with $\lambda h80dlaco^+$ DNA and ^{35}S labeled repressor[37] or, more easily, using the filter-binding technique with cold repressor and ^{32}P labeled DNA[38].

2.9. *In vitro* Tests of Mutant Lac Repressor

The original test for lac repressor[41] relied on the IPTG binding capacity of the repressor[24]. The proofs of the isolation of the lac repressor relied on the use of i gene mutants. The physico-chemical behavior of the repressor has to agree with the predictions of the properties of mutants. The simplest correlates are negative ones. Thus one would expect the absence of IPTG binding material in extracts made of strains which harbor i gene deletions. IPTG binding was indeed found to be absent in several i deletion strains, but since in some of these strains the deletion passed the borders of the i gene, this was not a very good control. A more rigorous control was the absence of IPTG binding material in extracts from one i^- nonsense mutant, since one would probably not expect a repressor fragment to bind IPTG. (Later

studies [see below] showed that some deletions which only cut small pieces from the amino-terminal end or from the carboxy-terminal end, still have IPTG binding capacity[19].) One might also expect i^s mutants not to exhibit good IPTG binding. Indeed, in the one i^s strain which was originally studied, no binding was found[24].

All these proofs are strictly negative; better proof that the IPTG binding was caused by the i gene product was provided by the following positive correlations between the extract behavior and the mutants genotype: the IPTG dissociation constant was found to be two times smaller in an extract made from the i^t strain than in one from wild-type[24]. Another positive correlation was found with temperature-sensitive i^{TL} and i^{TSS} mutants[42]. As expected, the IPTG binding activity of the i^{TL} extract was more heat-labile than in the wild-type. The i^{TSS} extract was also found to be heat-labile. This was somewhat unexpected at the time; it now actually serves for the interpretation of the growth instability of the repressor (see above). The binding of lac repressor to operator (see below) gives the final proof that the i gene product is the repressor. Recently, the weakened inducer binding of i^s repressors has been demonstrated in a convincing manner[43]: the stronger the i^s character the weaker the interaction with IPTG *in vitro*.

2.10. Purification of the Lac Repressor

In most purifications of the lac repressor, only IPTG binding has been followed. The repressor is very stable in this respect. Operator binding, on the other hand, tends to disappear rapidly during purification of the lac repressor. It is likely, but not proven, that the repressor is simply very labile and denatures partially during the purification procedure, like many other allosteric proteins. But it is not excluded that an essential part of the repressor is lost during the purification procedures. Pure lac repressor can be obtained in two steps using the extract from a strain carrying the i^q gene[44] on the $\gamma h80c_{I857}t68dlac$ prophage. The phage is induced to multiply by a short heat treatment of the bacteria. The i^q genes which are multiplied with the phage then make about 1% of the soluble protein of the bacteria repressor. The bacteria are centrifuged and frozen for storage. They lyze when they are put into buffer (pH = 7.6). The debris are spun down. Ammonium sulfate precipitation between 20 and 30% and chromatography on phosphocellulose are sufficient to obtain pure repressor (Table 4). Chromatography on DEAE cellulose and on sephadex has also been used successfully[36,46]. In the crude extract of the heat-induced nonfrozen phage-carrying i^q strain the repressor has a sedimentation constant of 7S. It has a tendency to aggregate during purification and to precipitate out of solution[44,36]. Our investigations show that the sedimentation constant of 7S is not appreciably changed if repressor is centrifuged in the presence of 10^{-3} M IPTG or 10^{-3} M ONPF. The molecular weight of the 7S species has been determined by equilibrium centrifugation to be 150000[45]. In electrophoresis on sodium dodecyl sulfate (SDS) acrylamide gels, a single band is seen. The location of the band indicates a molecular weight of 39000[45]; the molecular weight of the monomer, calculated from the amino acid analysis, is 40000[46]. The form in which the repressor seems to be most stable is tetrameric. But under extreme conditions, such as after freezing, freeze-thawing, in very high tris or salt concentrations, monomers, dimers, and higher aggregates have been observed[46]. The amino acid composition is normal: the repressor contains all amino acids normally occurring in proteins[46] (Table 5). It is an acidic protein (the isoelectric point is 5.6)[45].

Table 4. Purification of lac repressor from 100 g frozen cells ($\lambda h80c_{I857}t68dlaci^q$)[44].

		Specific activity [a] (%mg^{-1}ml^{-1})	Recovery (%)	Total amount of repressor (mg)
Step I	Total extract	14	100	61
Step II	Supernatant after first ammonium sulfate precipitation (0–15%)	19	98	60
Step III	Dialyzed ammonium sulfate precipitate (15–33%)	112	88	54
Step IV	Phosphocellulose chromatography: peak	1 300	54	33

[a] The specific activity of the lac repressor is determined by equilibrium dialysis against ^{14}C labeled IPTG[24]. Per cent/mg/ml means excess of IPTG inside the dialysis sac expressed in per cent, divided by the protein concentration (mg/ml).

Table 5. Amino acid composition of lac repressor (i^q) from *E.coli*.

Amino acid	µmole/100 µmole	Calculated amino acid residues per 40 000
Lysine	3.67	13
Histidine	1.69	6
Arginine	4.80	17
Aspartic acid	9.04	32
Threonine	5.37	19
Serine	7.34	26
Glutamic acid	12.43	44
Proline	3.95	14
Glycine	7.34	26
Alanine	11.58	41
Cysteine [a]	0.58	3
Valine	8.19	29
Methionine	2.25	8
Isoleucine	5.65	20
Leucine	10.73	38
Tyrosine	2.26	8
Phenylalanine	2.26	8
Tryptophan [b]	0.56	2

[a] Determined as cysteic acid.
[b] Data from enzymatic and alkaline hydrolysis.

Chemical analysis of pure repressor has provided no evidence for the presence of reducing sugar or of nucleic acids[44]. The ratio of absorption at 280 nm to that at 260 nm has been found to be as high as 1.8 in pure tetramer preparations (Table 6). In aged preparations, where the repressor has started to aggregate, the OD ratio can drop appreciably due to light scattering and thereby falsely suggest the presence of nucleic acids.

The number of IPTG binding sites has been accurately determined (Fig. 8). There is exactly 1.0 binding site per subunit[46].

Table 6. Properties of lac repressor (i^q) from *E.coli*.

		Method of determination	Ref.
Rel. molecular weight	150000	High speed equilibrium method	[45]
Rel. molecular weight of subunit	40000	Dodecyl sulfate polyacrylamide gel electrophoresis. Amino acid analysis	[45, 46]
Sedimentation value tetramer monomer	 7.2 2.7	Glycerol gradient	[24, 36, 46]
Isoelectric point	pH 5.6	Isoelectric focusing	[45]
DNA content RNA content	< 1.2% <0.2%	Dische reaction Orcinol reaction	[46]
Binding sites for IPTG per mol. weight 150000	4.2	Equilibrium dialysis	[46]
Binding constant for IPTG in TMS 4°C	1.8×10^{-6}M	Equilibrium dialysis	[24, 36, 46]
$O.D._{280}$ 0.1%, 1 cm	1.38		[46]
$O.D._{280} : O.D._{260}$	1.8		[46]
Amino terminus Carboxyl terminus	Methionine Lysine	DNP-, Dansyl-method, Edman degradation Carboxypeptidase B, Hydrazinolysis	[45, 46] [46]

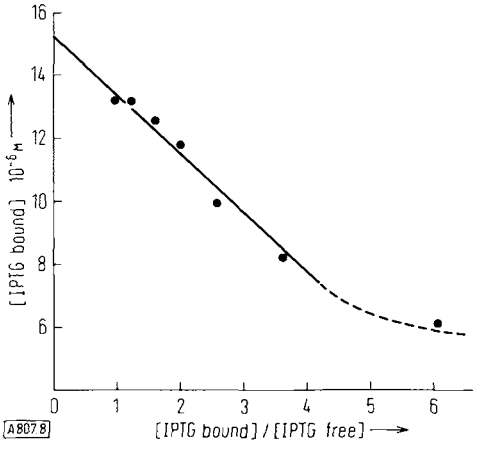

Fig. 8. Inducer binding sites of the lac repressor. Bound IPTG is plotted against bound IPTG over free IPTG. The concentration of repressor in this experiment was 3.6×10^{-6}M. The curve extrapolates to four sites per one repressor molecule of a molecular weight of 150000[46].

Tryptic fingerprints (*i.e.* paper chromatograms of the protein after cleavage with trypsin) have been made[46]; they give the approximate number of spots (29) one expects from the arginine and lysine content (30). This, together with the genetical data, strongly suggests that the repressor consists of four identical subunits. Methionine has been shown to be the N terminal amino acid[45,46]; the sequence at the C terminal is Arg-Lys[46].

2.11. Properties of Repressor Isolated from Various i Gene Mutants

Only a few i gene mutants have been analyzed for the biochemical or physical properties of their repressors. Rather surprisingly, it has been found that many i^- mutants still contain IPTG binding capacity. Such is the case with one i^{-d} mutant (i_{24}^{-d})[46], one transdominant deletion[19,46], which cuts from the tryptophan operon into the first part of i, and the deletion LI[19], which cuts from the carboxy-terminal end of the lac repressor into the lac promoter. The protein in the latter case has been isolated and the molecular weight of the subunit has been determined by SDS acrylamide gel electrophoresis to be 38000[19].

2.12. Dominance of the Lac i Gene Mutants

When *Jacob* and *Monod* proposed their model, the dominance relationship of the i gene seemed to be simple and clear. Presence of the repressor (i^+) was dominant over the absence of repressor (i^-)[1]. Presence of a mutant repressor, which was unable to interact effectively with inducer (i^s), was dominant over both i^+ and i^-[23]. The finding of transdominant i^{-d} mutants posed the first problem[15,16]. Do they act by negative complementation (by forming mixed oligomers which are unable to bind to the operator) or does their repressor still bind to the operator but remain unable to stop transcription? If, as seems most likely, negative complementation is the explanation for the dominance, the subunits of the i^{-d} repressor must aggregate very slowly. Since repressor mRNA is only made every twenty minutes no complementation could otherwise occur. (We assume that the tetramers, once they are formed, are stable and cannot exchange subunits.)

The existence of mutants which overproduce wild-type repressor leads to further complications: i^q is dominant over i^s[16]. The simplest explanation is certainly complementation, that is, the formation of normally functioning mixed oligomers between i^s and i^+ repressor subunits. The halflife of free i^s repressor subunits can be rather short, since in the i^q strain lac messenger is made every six minutes. The mixed oligomers can be induced by IPTG to fall off the operator.

All the dominance relationships are summarized in Table 7.

Table 7. Dominance relationships.

Genotype	dominant over	Ref.
i^+	i^-	[1]
i^s	$i^+; i^-$	[23]
i^{-d}	i^+	[15, 16]
i^q	$i^s; i^{-d}$	[16]

Table 8. Repressor operator interaction. The bacteria were grown in minimal medium M56 [10] with glycerol at 37 °C. β-Galactosidase was determined as in [9].

Genotype	Specific activity of β-galactosidase
$i^+o^cz^+$	2000
$i^+o^cz^+/F'i^+o^+z^+$	1200
$i^+o^cz^+/F'i^qo^+z^+$	300
$i^+o^cz^+/F'i^{superq}o^+z^+$	130
$i^+o^+z^+$	15

3. The Operator and the Mode of Action of the Repressor

3.1. Mutations of the Operator Locus

Genetic analysis shows that the product of the i^- gene reacts in *trans* with the operator[1]: it sits not only on operators which lie next to the i gene but also on distant lac operators such as on an F′ or a prophage. The operator is characterized by operator constitutive mutations (o^c). They are *cis* dominant mutations in which the repressor-operator interaction is weakened: the synthesis of β-galactosidase (in *cis:* that is from the z gene which is *directly* connected with the operator) is no longer one thousand fold repressed; it has become partially constitutive. By the addition of inducer it can be fully induced. No operator constitutives have been found so far which totally abolish repression. The strongest o^c's are still eight fold repressed. It has been claimed[47] that all o^c mutants are deletions, but this is questionable, since the most important property of deletions, their non-revertibility, cannot be easily checked. The frequency of occurrence of o^c's, after the use of specific mutagens, has also to be interpreted cautiously since the alleged o^c's have been isolated from i^si^s diploids, and complications such as the existence of transdominance or increased homozygosis after mutagenesis will obscure the results.

3.2. Estimate of the Binding Constant between Repressor and Operator from Data Obtained *in vivo*

The introduction of an $F'i^+$ episome (F′ = an independently replicating piece of DNA consisting of an F factor and bacterial DNA, in this case the lac genes) into a cell carrying an $i^+o^cz^+$ genotype reduces the rate of operator constitutive β-galactosidase synthesis by a factor of 2 to 2.5[1]. Since the repressor level is doubled by the introduction of a second i gene, one can state that the speed of β-galactosidase synthesis varies inversely with the first power of repressor concentration[22]. We have tested this further by the introduction of an $F'i^q$ into the same $i^+o^cz^+$ strain. The level of repressor then increases ten to twenty fold; the β-galactosidase level decreases by a factor of 7 (see Table 8). This indicates that there is a simple mass action relationship between repressor and operator.

$$R + O \rightleftharpoons RO$$

$$\frac{[R]\ [O]}{[RO]} = K_o$$

If we make the reasonable assumption that the synthesis of β-galactosidase is proportional to the concentration of free operator[22], the concentration of free operator has to decrease as the concentration of repressor increases. This is also true for the wild-type o^+ basal level. That is, the basal level goes down by a factor of two, if an $F'i^+o^+z^-$ is introduced into an $i^+o^+z^+$ strain[48]. Now we might calculate the binding constant between repressor and operator: the volume of an *E.coli* cell is 0.7×10^{-12} cm^3; Avogadro's number is 6×10^{23}. This means that the solution of one molecule in one *E.coli* cell is about 10^{-9} molar. In a normally dividing *E.coli* cell, the lac operator concentration would be 2×10^{-9} molar, and the lac repressor concentration (assuming 10 molecules/cell) 10^{-8} molar. If one assumes that the observed ratio 1 : 1000 in β-galactosidase levels between the uninduced and the induced state is totally due to repression, then the concentration of free operator in an uninduced cell should be 2×10^{-12} M. The concentration of operator-repressor complex practically equals the concentration of total operator, 2×10^{-9} M. The concentration of free repressor is also practically unchanged, 10^{-8} M. From these data we can calculate the binding constant:

$$K_o = \frac{[R]\ [O]}{[RO]} = \frac{10^{-8} \times 2 \times 10^{-12}}{2 \times 10^{-9}} = 10^{-11}\ \text{M}$$

3.3. Determination of the Binding Constant of the IPTG-Repressor Complex

The dependence of the induction on the concentration of the inducer in an $i^+o^cz^+y^-$ and an $i^+o^+z^+y^-$ strain gives a direct measure of the binding constant of the inducer towards repressor[23, 24]. The dependence of the inducer concentration is not first order, but third order. If we disregard this for the moment, we have the following two alternative models. Either it takes just the same amount of IPTG to double the basal level in the o^+ as in the o^c, or it takes the same amount of inducer to get half maximal induction in both strains. Since the former is true[23], the following equation holds:

$$K_i = \frac{[I]\ [R]}{[IR]}$$

If we assume that the speed of β-galactosidase synthesis is proportional to free operator, it follows directly that the inducer binding constant is numerically equal to the

concentration of IPTG that is necessary to double the basal rate in an i^+o^+ or an i^+o^c strain; that is, K_i equals 2×10^{-6} M. The binding of repressor to IPTG has been determined *in vitro*. Binding was found to be anticooperative with repressor from i^+ cells; pure i^q repressor showed no cooperativity in binding to inducer. The experimental conditions (temperature, *etc.*) do not correspond to the *in vitro* conditions; still, how can this be reconciled with the third order kinetics of induction? No quantitative theory which accommodates all the facts has been worked out. It suffices to say here that one IPTG molecule bound to the repressor might be enough to weaken its binding to the operator sufficiently to lead to induction.

3.4. *In vitro* Measurements of the Repressor-Operator Binding

The binding of repressor to operator DNA has been measured using two assay systems. One uses centrifugation of the complex through glycerol gradients[37], the other adsorption of the complex on nitrocellulose (millipore) filters[38]. DNA from lac o^+ transducing phages has been used as a source of operator DNA. This has the advantage that 70 times less DNA has to be used than would be the case if one used *E.coli* DNA. Moreover, the phage DNA is uniform in size. The large difference between the sedimentation constant of the $\lambda h80c_{1857}t68dlac$ DNA (40S) and of the repressor (7S) makes it possible to follow radioactively-labeled repressor which is bound to operator DNA through a glycerol gradient. Such studies have yielded the following information[37,49]: the repressor binds to operator with a dissociation constant that is in the range of the expected one, 10^{-11} to 10^{-13} M. The strength of the binding constant is dependent on the concentration of salt; increasing salt concentration weakens the binding. The DNA has to be native; the repressor does not bind to denatured DNA. The interaction is specific, as shown by the fact that the repressor does not bind to $\lambda h80$ DNA. Inducer (IPTG) is able to prohibit the binding. This effect is specific; the anti-inducer ONPF, for example, does not lead to a weakening of the binding.

It has been verified *in vitro* that the binding of repressor to o^c DNA is weaker than that to wild-type DNA. Two o^c's have been used; their behavior was in qualitative agreement with expectations: the stronger the o^c character, the weaker the binding[37,38].

3.5. Physical Consequences of the Tight Binding of Repressor to Operator

The dissociation constant of the repressor-operator complex (K_o) is also defined as the ratio of the backward (k_b) to the forward (k_a) rate constants.

$$K_o = \frac{k_b}{k_a}$$

The repressor has to diffuse to the operator. With the given volume of the cell (10^{-12} cm^3), only seconds are needed until the repressor hits its operator. The conformational changes in the repressor and in the operator may have to occur before the complex is formed. The conformational changes might be fast. The forward rate has been determined to be as high as 7×10^9 mole^{-1} sec^{-1}[50]. This is at least one order of magnitude higher than one would expect. A possible explanation might be one-dimensional diffusion; that is, repressor that hits the DNA not too far from the operator is able to slide along the DNA very rapidly until it hits the operator.

The decay rate of the repressor-operator complex[50] has also been measured: it is as slow as 5×10^{-4} sec^{-1}. The dissociation of half of this complex takes half an hour or so. However, *in vivo* the actual induction process only takes a few seconds[51]. (The two reports which seem to give opposite evidence are probably wrong[52,53].) We are thus left with the fact that *in vivo* in the presence of IPTG, repressor falls off the operator very rapidly. The existence of a ternary complex between operator, repressor and IPTG would solve this problem. The strength of the repressor-operator interaction could drop appreciably and thereby lead to fast dissociation *in vitro* and induction *in vivo*. Experiments which prove this have been done *in vitro*, using the filter binding technique[50]. In the presence of IPTG, the decay rate of the repressor-operator complex is so fast that it cannot be measured[54]. The existence of the ternary IPTG-repressor-operator complex is not so astonishing as it might at first seem. It has been known for a long time that not all inducers give maximal levels of induction at the highest inducer levels. With one inducer, methyl-1-thio-β-D-galactopyranoside (TMG), a close analog of IPTG, the maximal level of induction is lower by 20% than with IPTG[55]. This can be easily explained by a strong binding of the TMG repressor complex to the operator; at the highest TMG concentration, 20% of the operator is inactive because it forms the ternary complex. In the same kinetic study[54] it was shown that the ternary repressor-ONPF-operator complex was more stable than the binary repressor-operator complex.

3.6. The Size of the Operator

One can try to deduce the size of the operator by simple reasoning. If the operator has no secondary structure, and if the repressor has to bind only to the operator site and to no other site of the DNA in *E.coli*, it has to be at least twelve base pairs long. If:

A = the number of base pairs in an *E.coli* chromosome
B = the number of different bases
n = the number of base pairs whose sequence occurs only once on the chromosome,

then we have:

$$A = B^n$$
$$3.5 \times 10^6 = 4^n$$
$$= 11 \text{ to } 12$$

There are some hidden assumptions in this calculation: the DNA must be a random polymer, or more specifically, operators in general may not share common se-

quences. The close linkage between the operator and the promoter could speak against such an assumption. If the sharing of common structures in operators is maximal, the number of base pairs to which the repressor actually binds specifically could be appreciably less. Repeating structures[50] which accommodate all subunits and secondary structure in the operator[56] have been discussed, yet there is no *a priori* reason to invoke their existence. Inspections of the space model of DNA suggest that a protein can "see" the base pairs in the large groove. One turn in the helix takes ten base pairs. The physical dimension of 12 base pairs in this arrangement is not too large to be touched by one subunit of the repressor. If every base pair contributes one to two kilocalories to the binding energy, the binding of the repressor to the total structure can become as tight as observed.

Unfortunately, purely genetic measurements do not help in this discussion. The length of the operator could be determined by recombination frequencies between o^c mutants[57], or from the mutation rate of o^c mutants[58]. Recombination frequencies between different o^c mutants have been measured; they give the rather large number of 200 base pairs[57]. They suffer, as do all recombination data for closely-linked markers, from influences from other effects which obscure the actual marker distance. The measurement of frequencies of o^c mutations *versus* i^- mutations has also been attempted[58]. The rather high mutation rate observed for o^c mutants seems to indicate at first glance that the structure is large. It should however be recalled that mutational "hot spots" might completely obscure the data.

Attempts to determine the size of the operator directly by isolating its physical structure are in progress. Operator-containing pieces which contain only 1/20th of the DNA of the λh80dlac phage have been purified[59]; they are 2500 base pairs long and, consequently, substantially larger than the operator itself. Recently, the isolation of a piece of operator DNA 20–23 base pairs long has been reported[60]. ^{32}P labeled $\lambda C_{I857}S7$ plac DNA has been digested with DNAse in the presence of repressor and the shielded pieces have been isolated on nitrocellulose filters.

3.7. Repression *in vitro*

Repression might be tested in two different ways *in vitro*. One might try to measure the repression of an isolated transcription system, or the repression in a protein-synthesizing system. Both have been tried. λh80dlac DNA can be transcribed with RNA polymerase *in vitro*. Lac messenger can be differentiated from the other RNA through a special hybridization test; thus repression can be tested. No repression has been found in a system consisting exclusively of DNA, RNA polymerase, and repressor. It seems that additional factors are necessary. Recently, success has been claimed by the addition of crude ribosomes[61]. The *in vitro* synthesis and repression of β-galactosidase has been claimed several times[62–64]. In the first two cases the results were incorrect; in the third case[64] the results seem to be well substantiated. An interesting fact emerges from these experiments: to function, the system needs a protein (the cap protein) which is common to all catabolite-repressed systems[65,66]. Only the presence of this protein plus cyclic AMP allows effective synthesis of the lac structural proteins.

3.8. Mechanism of Action of the Repressor

How does the repressor act? That is, which process is actually inhibited when repressor is bound to the operator? There are two possible processes with which the repressor might interfere: the start of transcription or RNA chain elongation. If we assume start of transcription, this might be either prohibiting the RNA polymerase from "sitting" on the promoter, or prohibiting the starting reaction of the RNA polymerase.

There is some biological evidence that the repressor might interfere with the start of transcription[67]. A deletion has been isolated which cuts from one of the tryptophan genes into the (transposed) lac promoter. The lac structural genes are now controlled by the tryptophan repressor. The lac operator is far away from the tryp promoter where the transcription of the lac genes now starts. If one turns the tryptophan system on, and if one introduces into this strain an i^+ gene on an episome, the β-galactosidase level in the constitutive tryptophan strain goes down by a factor of 3. This has been taken as evidence that the repressor interferes with RNA chain elongation rather than start of transcription[67]. I would like to interpret the data differently: the three-fold repression of the RNA chain elongation seems to be too weak to be the general mode of action of repressor. If the effect of the repressor is in the steric hindrance of the start of transcription, then o^c mutants might be found which are actually due to insertions between the promoter and the operator. The existence of such o^c mutants will certainly make the mapping of the operator difficult.

4. Evolution of the Control of the Lac System

The lac operon and its regulatory gene are closely-linked. This situation is not the normal one in *E. coli*. In most negative control systems, structural and regulatory genes do not map closely together. What has brought them together in the lac system? To pose the question is to ask for the path of evolution of the lactose system. The product of a regulatory gene must obviously be able to bind a small molecule which is sterically related to at least one of the substrates or products of the enzyme the synthesis of which is to be controlled. It is possible, but not necessary, that the regulatory gene might have arisen by duplication of one of the structural genes to be controlled. That is, the i gene might be related in its structure to parts of the z y a genes. What the "repressor-precursor" needed to learn further was to bind effectively to the chromosome very near the promoter of the structural genes. Duplications seem to map in tandem[68], *i.e.* they lie next to each other. This might be an explanation for the close linkage observed between the

i gene and the structural genes. We can't think of any other reason to bring a regulatory gene, which has arisen elsewhere, into close linkage with the structural genes. We have looked for similarities in the structures of lac repressor and β-galactosidase using immunological methods[46] and have found no cross reaction between repressor and β-galactosidase and their antibodies in an Ouchterlony test. This makes a close structural relationship between the two unlikely.

It is not known during which time span the evolution of the lac genes occurred. In *Shigella* (a closely related bacterium) the y gene is lacking[69]. Has it been lost or has *Shigella* never acquired a transport system for lactose? The i^+z^+ genes alone are not useless: *Shigella* cannot grow on lactose but it can grow on methylgalactoside or galactosidoglycerol, since these are transported by a different transport system. It has been pointed out[12] that lactose occurs only in mammals, and that *E.coli* must be older in origin than the mammals in which it now lives. Galactolipids are extremely frequent in plants; it might be that the lac system has to be traced back to times when galactolipids were the original substrate for *E.coli*. Alternatively the lac system may be of rather recent origin; this could explain the close linkage between structural and regulatory genes: the lac genes have not yet had the time to separate as have the very old regulatory and structural genes which are involved in the production of amino acids.

5. How General is Negative Control of Protein Synthesis?

At the time when *Jacob* and *Monod* proposed their model, it looked as if it were the only one operating in *E.coli*. In the meantime, more systems have been analyzed extensively. In particular, the λ and $i_{434}c_I$ control systems are fully analogous to the lac system: λ and $i_{434}c_I$ product is oligomeric [70] and binds to operator DNA[71,72]. About half of all the systems in *E.coli* seem to follow the Jacob-Monod scheme in every respect but the other half seem to operate differently. Here we have the characteristics of positive control: in the absence of the product of a regulatory gene, none of the products of the structural genes are made. Genetical analysis makes it appear rather unlikely that behind these apparently positive control systems other still unidentified negative control systems are lurking. Yet there is a way in which they might be reduced to negative control systems. Prevention of normal stop might be the basis of these control systems. If this happens to occur at the transcriptional level, then only in the presence of the product of the regulatory gene would transcription proceed to the structural genes. Alternatively, sigma factors[73] which give the RNA polymerase specificity towards promoters may be involved. The biochemical analysis, which alone can prove these mechanisms, has yet to be performed.

I wish to thank the "Stiftung Volkswagenwerk" for providing the equipment for the sequence work and the "Deutsche Forschungsgemeinschaft" for their support of the research. I also thank my colleagues from the Institute of Genetics for their critical reading of this manuscript, and all the people who have made unpublished information available to me.

The Mechanism of Contact Elimination, A Contribution to Understanding the Function of Polar Catalysts

By Heinrich Noller, Paulino Andréu, and Manfred Hunger[*]

The current ideas of organic chemists based on the work of Ingold and his school are applied to heterogeneous catalytic eliminations (mostly from haloalkanes and aliphatic alcohols). It is deduced from the activity of the catalysts, the reactivity of the substrates (reactants), and the primary product distribution that these eliminations proceed by a heterolytic mechanism similar to that involved in the liquid phase. The activity of the catalysts (salts and oxides) increases with increasing charge and decreasing radius of the cations and with increasing basicity of the anions. The reactivity of the substrates behaves in much the same manner as in the liquid phase. In contrast with the liquid-phase reaction, the cis-olefins are frequently favored as primary products. The stereospecificity of the reaction is determined from the relative strengths of the interactions between the catalyst cation and the leaving group X^-, and between the catalyst anion and the leaving proton. Only trans elimination has so far been found in the concerted mechanism.

1. Introduction

This article will be concerned exclusively with β-eliminations, mostly from haloalkanes and aliphatic alcohols[1,2]. The reactants in every case will be gaseous (at the reaction temperature), and the catalysts will be solid. The reaction takes place on the surface of the solid.

$$X\text{-}C_{\alpha}\text{-}C_{\beta}\text{-}H \longrightarrow C{=}C + HX$$

In some respects, contact elimination (elimination over catalysts) occupies an intermediate position between eliminations in the liquid phase and in the gas phase. Elimination in the liquid phase is generally regarded as a heterolytic process. *Maccoll*[3] also assumes a heterolytic or, to put it more cautiously, "quasi-heterolytic" course for the gas phase reaction (see also ref. [1], p. 182ff). In our opinion, contact elimination also follows a heterolytic mechanism. Experimental evidence in favor of this assumption is the observation that this type of reaction is catalyzed only by polar substances (salts and oxides), and not by metals. The kinetics, the activity of the catalysts, the reactivity of the substrates, and the primary product distribution were studied in order to obtain information about the mechanism. The reactivity includes the kinetic isotope effect, and the primary product distribution the distribution of isotopes in the products.

2. Kinetics

In contact eliminations, as in the liquid phase, it is necessary to differentiate between E1, E2, and E1cB eliminations. These possibilities are shown in Scheme 1.

Scheme 1.

In the E1 mechanism, the reaction begins with the abstraction of X. Since X is generally more electronegative than H, this first step yields a carbonium ion, which has a definite lifetime and loses a proton in the second step. The potential energy profile has two maxima separated by a minimum, which corresponds to the carbonium ion.

The E1cB mechanism (cB = conjugated base) begins with the cleavage of C–H bond. The energy profile again has two maxima; the intervening minimum corresponds to the carbanion.

In the E2 mechanism, which is also described as a concerted or multi-center process, H and X are removed simultaneously. However, the process will be truly synchronous only in exceptional cases, if at all, and the reaction will normally begin with the lengthening of only one bond. Before the rupture of this bond is complete, the other bond begins to break. Thus the rupture of the two bonds has proceeded to different extents in the activated complex[1,2]. The concerted reaction thus covers a broad range of possibilities with tendencies toward E1 or E1cB. The essential feature is that the energy profile has only one maximum.

In the liquid phase, the criterion of an E1 mechanism is taken to be a reaction order of 1 with respect to the reactant, the reaction being independent of the base concentration, while the criterion of the E2 mechanism is a reaction order of 2, *i.e.* the reaction is first order with respect to the reactant and the base. Since the function of the base is taken over in the contact reaction by the anions of the catalyst, the concentration of which does not change, both the carbonium ion mechanism (E1) and the concerted mechanism (E2) should give a reaction order of 1. With certain reservations, this is in fact the result obtained in the investigations so far.

For the catalytic elimination of HCl from ethyl chloride, *Cremer* and *Baldt*[4] found a reaction order of 1 with respect to the reactant up to a conversion of about 50%. This was confirmed by *Schwab* and *Noller*[5]. *Noller* and *Wolff*[6] were then able to show that deviations from the first order are due to the influence of the reverse reaction, *i.e.* the addition. The simple equation:

$$R = k_{el} p(C_2H_5Cl) \qquad (1)$$

must therefore be replaced by an equation that takes the reverse reaction into account:

$$R = k_{el}\, p(C_2H_5Cl) - k_{ad}\, p(C_2H_4) p(HCl) \qquad (2)$$

(R = reaction rate; k = rate constant; el = elimination; ad = addition; p = pressure). This equation was also used by *Simkovich* and *Wagner*[7].

The importance of the second term depends on the position of the equilibrium. *Heinzelmann*[8] used conditions of practically complete elimination (ethyl chloride at about 300 °C, pressures below 50 torr, flow apparatus, carrier gas He, catalysts $MgSO_4$ and Al_2O_3). Under these conditions, eq. (1) is satisfied up to conversions of more than 80%. However, the constant k_{el} decreases with increasing initial pressure. At a given (initial) pressure, the elimination itself (*i.e.* without interference from the addition) is of 1st order (unimolecular reaction).

Unlike in the liquid phase reaction, it is difficult to draw any further conclusions from the kinetics.

3. Activity of the Catalysts

There is no generally accepted measure of catalyst activity. We use the reaction rate *(R)* in some cases and the activation energy *(AE)*[*] in others.

3.1. Effect of the Cations

A preliminary survey is provided by Table 1. The alkaline earth metal ions are more active than the alkali metal ions. This may be thought of as resulting from the stronger electric field of the bivalent cations or from their more strongly electrophilic properties, which amounts to the same thing here. Within each of the two groups, the activity decreases from top to bottom of the periodic table, *i.e.* with increasing radius, which again corresponds to the strength of the electric field (the electrophilic properties).

The result is also influenced by the anion. *Schwab* and *Karatzas*[13] found that with C_2H_5Cl as the reactant,

[*] *I.e.* the Arrhenius activation energy, which we regard as equivalent to the Eyring activation enthalpy (cf. [12]).

Table 1. Activities (activation energies, *AE*) of alkali metal and alkaline earth metal chlorides and sulfates.

Reactant	Catalyst	*AE* (kcal/mole)	Temp. (°C)	Measuring technique	Ref.
2-Chloro-propane	LiCl	20	242 – 271	flowing	[9]
	NaCl	25	362 – 393		
	KCl	46	295 – 315		
2-Chloro-propane	$CaCl_2$	18	116 – 189	static	[6]
	$SrCl_2$	20	128 – 171		
	$BaCl_2$	28	82 – 142		
	$CaSO_4$	17	72 – 132		
2-Chloro-butane	$MgSO_4$	13	150 – 300	pulsed	[10, 11]
	$CaSO_4$	16	180 – 320		
	$BaSO_4$	22	250 – 400		

$Ba[MnCl_4]$ with its bivalent anion gave a lower activation energy (13 kcal/mole) than $BaCl_2$ (21 kcal/mole) or $MnCl_2$ (28 kcal/mole) (temperature range 330–380 °C). (For the effect of the anions, see Section 3.3.)

Table 2. Activity of the cations in sulfate catalysts: order of activities, activation energies *(AE)*, temperature ranges, and cation radii [14] (reactant: 2-bromobutane; pulse technique [11]).

Activities [a]	Mg^{2+} >	Ba^{2+} >	Be^{2+} >	Al^{3+} >	Li^+ >	K^+
Radius of cation (Å)	0.65	1.35	0.31	0.50	0.60	1.33
AE (kcal/mole)	30	16	24	5	26	15
Temp. (°C)	90-120	100-160	120-220	150-250	200-330	170-380

[a] The reaction rate was used as a measure of the activity

A fundamental difficulty in the comparison of activities is that more than one of the properties (nature, size, and charge of the ions and crystal structure) change when the catalyst is changed. If we consider the values for catalysts with cations of roughly equal size in Table 2[14], we find that the order of the activities of the cations is similar for 2-bromobutane, 2-chlorobutane, 1-chlorobutane, and 1-bromobutane[14]. The monovalent cations are again less active than those with higher valencies. Mg^{2+} is the most active, whereas Al^{3+} should be more active if the activity was determined purely by the size and the charge. Another factor presumably involved is lack of accessibility, *i.e.* shielding *e.g.* by anions, which is relatively pronounced in the case of small cations (Be^{2+}) and with an unfavorable ratio of the number of cations to the number of anions (Al^{3+}). $AlPO_4$, which has a more favorable cation to anion ratio, is in fact more activity than $Al_2(SO_4)_3$[15]. The reaction rate was used here as a measure of the activity.

The effect of the cations is also clear in the case of zeolite catalysts. As was found by *Venuto, Givens, Hamilton,* and *Landis*[16] the Linde molecular sieves X and Y[16a] in the lanthanide, Na, Ni, H, and Ag forms are more active for the elimination of HCl from ethyl chloride than the cracking catalyst 46 AI (silica alumina) of the Socony Mobil Oil Company (activity measure: reaction rate at 260 °C).

Similar patterns are found in the dehydration of alcohols. *Galitsch et al.*[17] obtained the following sequence of activities (reaction rates) with 1-butanol on zeolites (molecular sieves): LiNaX > NaX > KNaX > RbNaX. *Scharf et al.*[18] found the sequence HNaY > ZnNaY > MgNaY > ZnNaX > MgNaX > NaY > NaX with 1-pentanol (measure of activity: reaction rate in the temperature range 170 to 400 °C). The activity of the cations is again determined largely by their charge (valency) and size.

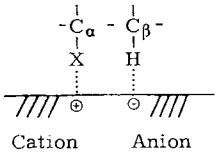
3.2. Relationship between Catalytic Elimination and Cracking

This relationship is revealed in the work of *Rabo et al.*[19], who like the present authors, regard the electric field (which depends on size and charge) as the factor that decides the catalytic action of the ions. The order of the activities of various forms of Linde molecular sieves X and Y[16a] for the cracking of hexane is as follows: NaX ≈ NaY ≈ silica alumina (cracking catalyst) < BaY < MgX < SrY < CaY < MgY. The Y series is more active than the X series, showing that the "anion" has some influence. A corresponding activity sequence was found for the cracking of cumene (isopropylbenzene): NaY < BaY < SrY < CaY ≈ MgY ≈ BeY. LaY has a much higher cracking activity than NaY (reactant: butane, measure of activity: reaction rate in the temperature range between 360 and 500 °C).

3.3. Effect of the Anions

The effect of the anions (Table 3) is not so clear as that of the cations. There seems to be a certain parallelism with the basicity. The important quantity is presumably not so much the basicity as the rate of combination of the base and the proton, which is sometimes referred to as the nucleophilicity[2].

Table 3. Activity of the anions of lithium salts [20]: order of activities, activation energies *(AE)*, and temperature ranges (reactant: 2-chlorobutane; pulse technique [11]). The reaction rate was used as a measure of the activity.



Activities	PO_4^{3-} >	SO_4^{2-} >	F^- >	CO_3^{2-} >	Br^- >	Cl^-
AE (kcal/mole)	25	16	18	25	26	25
Temp. (°C)	150-260	170-375	160-440	190-400	200-400	290-420

3.4. Views on the Catalyst Action

The division of the catalyst action into a cationic and an anionic component corresponds to the distinction usually made in liquid-phase reactions between cationoid (Lewis acid, electrophilic) and anionoid (basic, nucleophilic) components of the reaction medium. The fact that the eliminations in question are catalyzed only by polar substances, and not by metals, shows that this dual action of the catalyst is important[21].

The activities found for the cations and anions indicate that the cation removes the halogen from the alkyl halide in the form of a halide ion, whereas the anion takes up a proton from C_β. As was suggested by *Schwab* and *Karatzas*[13], the interaction between the catalyst and the reactant can therefore be formulated as shown in *(1)*, steric aspects being disregarded.

The action of the cation frequently appears to be more decisive than that of the anion, *i.e.* the attack of the electrophilic centers of the catalyst (cations) on the C–X bond seems to be more effective than the attack of the nucleophilic (basic) centers (anions) on the C–H bond.

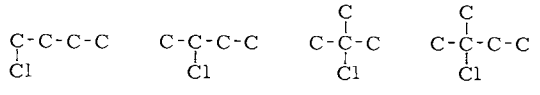
(1)

Since, with X=halogen, the rupture of the C–X bond is easier than that of the C–H bond, the process seems to follow the obvious principle that the reaction begins with the attack of the catalyst on the weakest part of the molecule.

For the application of the semiconductor theory of catalysis to elimination reactions, see [7,22].

4. Reactivity

4.1. Ease of Removal of the Group X



For 1-X-butane and 2-X-butane over the sulfate catalysts[14] of Table 2 and over calcium sulfate and calcium phosphate[23], the following sequence was found for the ease of removal.

X	Br ≈ Cl > OH > NH_2 > C_6H_5				
Homolytic dissociation energy[24] of the C–X bond in C_2H_5–X (kcal/mole)	65	82	93	78	94

Thus the ease of removal (measured by the reaction rate in the temperature range between 200 and 350 °C) does not vary parallel with the homolytic dissociation energy.

4.2. Primary, Secondary, and Tertiary Carbon Atoms

The ease of removal of a substituent X also depends on whether it is attached to a primary, a secondary, or a tertiary carbon atom. As in the liquid phase, the ease of removal increases in the above order. The following activation energies (in kcal/mole) were found on $CaCl_2$ between 100 and 350 °C[25]:

The reactivity series for cracking on silica alumina is[26]: *tert*-butylbenzene > *sec*-butylbenzene > cumene (isopropylbenzene) > *n*-butylbenzene. The similarity of elimination and cracking is again clear. This is also true of the cracking of aliphatic compounds. The relative reactivities of primary, secondary, and tertiary carbon atoms in hexane were found to be related as 1 : 2 : 20[27]. *Dohse* found this reactivity sequence as early as 1931[28] for the dehydration of alcohols on bauxite (Table 5).

4.3. Effect of Substituents

The following activation energies *(AE)* were obtained for a series of 1-chloro-*n*-alkanes on $BaSO_4$ between 160 and 400 °C[29]:

Number of C atoms	2	3	4	5	6	7
AE (kcal/mole)	17	12	19	15	10	10

The activation energy does not show a monotonic variation with the chain length (β-substitution by alkyl groups). The result is presumably due to a complex interplay of neighboring-group and inductive effects. The inductive effect of the alkyl group itself acts in opposite directions. On the one hand, it favors removal of X^-, while on the other it hinders the removal of the proton (C_β also carries a greater negative charge, and so holds the proton more strongly). The latter effect is more pronounced in the E2 mechanism than in the E1. According to *Bunnett*[2], β-alkyl groups displace the mechanism toward E1 (Table 11).

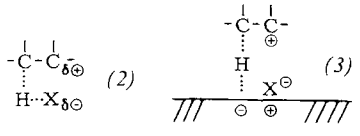
The effects of electronegative substituents in the β position (which, according to *Bunnett*[2], displace the reaction course toward E1cB) are shown in Table 4. There is a clear difference in behavior here between the catalysts $MgSO_4$ and K_2CO_3. $MgSO_4$ is an E1 catalyst, while K_2CO_3 is an E2 catalyst[*] (for further details see Section 5.4). In the E1 mechanism, the β-chlorine atom hinders the (rate-determining) removal of the chloride ion and the formation of the carbonium ion; this hindrance also occurs in the E2 mechanism, but is more than compensated by the greater ease of removal of the proton and the conjugation of the p electrons of the remaining chlorine with the double bond being formed.

A phenyl group in the β position acts in the same manner as an electronegative substituent (see Table 7).

Table 4. Activation energies [30] (in kcal/mole) determined between 160 and 350 °C for ethane with electronegative substituents (chlorine).

Reactant		Cl-C_α-C	Cl-C_α-C_β-Cl	Cl-C_α(Cl)-C	Cl-C_α-C_β-Cl	Cl-C_α(Cl)-C
Catalyst (E1)	$MgSO_4$	23	very high	33	very high	21
Catalyst (E2)	K_2CO_3	24	16	24	14	33

α-Substitution by a methyl group considerably increases the reactivity (Table 5). The effect is similar in its magnitude to that found by *Maccoll*[1,3] and earlier by *Barton*[31] for the homogeneous reaction in the gas phase. In both the homogeneous and the contact reactions, the activation energies vary in the same manner as the energies of the heterolytic rather than of the homolytic dissociation. *Maccoll* concluded that the gas phase reaction is a (quasi)heterolytic process, like the E1 process in the liquid phase. We believe that the same is true of



[*] Statements of this type are always intended to be taken relatively, since the mechanism also depends on the reactant. In the present case, therefore, we mean that K_2CO_3 favors the E2 mechanism more than $MgSO_4$. If, on the other hand, $MgSO_4$ gave an E2 mechanism (a situation that did not occur with our substrates), K_2CO_3 would give a shift toward E1cB (cf. [2]).

the contact reaction. The activation energies for the dehydration of alcohols on bauxite vary in the same manner[28] (Table 5).

Table 5. α-Substitution by electron-donating substituents (methyl), activation energies *(AE)* for the contact reaction on LiCl, and the homogeneous reaction; also energies of the homolytic and heterolytic dissociation *(D)* (all in kcal/mole). For comparison: Activation energies of the dehydration of alcohols on bauxite (values based on *AE* measured between 150 and 400°C).

	X-C-C	C-C-C (X)	C-C(C)-C (X)
Catalyst LiCl[9] (X=Cl) *AE*	25	20	16
Homogeneous reaction[1, 3] (X=Cl) *AE*	60	51	41
D (R-Cl)	81	82	78
D ($R^{\oplus}$-$Cl^{\ominus}$)	193	166	150
Catalyst Bauxite[28] (X=OH) *AE*	31	25.5	20

Banthorpe[1] thought it probable that the addition in the gas phase (homogeneous reaction) involved the transition state *(2)*. On the basis of the principle of microscopic reversibility, he also suggested this same transition state for the elimination in the gas phase[1].

A similar transition state *(3)* seems probable for the contact reaction in the E1 case. The activated complex *(3)* evidently requires less energy for its formation than *(2)*, and this is the basis of the catalyst action.

The action of the catalyst is comparable to that of a solvating solvent. As was shown by *Gutmann*[32], the ability of such a solvent to heterolyze covalent bonds and to stabilize the resulting ions is a phenomenon of coordination chemistry. Similarly, the polar catalyst causes the heterolysis of the bonds that have to be broken in the reaction by stabilizing the ionic structures that occur in the transition state through coordination. The effect of the catalyst, which consists in a decrease in the activation energy, may therefore also be regarded as a phenomenon of coordination chemistry. Differences are, however, seen in the fact that no "all-round solvation" occurs in catalysis and that the transition states are unstable structures along the reaction coordinate.

Electronegative substituents in the α position hinder the E1 elimination (catalysis by $MgSO_4$, Table 4) since the second chlorine atom makes it more difficult for the first to take the electrons with it. The E2 elimination, on the other hand, is not affected (catalysis by K_2CO_3, Table 4). Though the removal of the electrons with the first chlorine atom is still made more difficult, this is offset by the conjugation of the remaining chlorine with the double bond being formed.

A second additional chlorine atom (1,1,1-trichloroethane, Table 4) probably causes a transition toward E2 over $MgSO_4$ (since the removal of the chloride is now even more difficult, whereas that of the proton is easier, so that the rupture of both bonds is roughly equally difficult), and the activation energy of the E2 elimination may be less than that of the E1 process because of the possibilities of conjugation. On K_2CO_3, on the other hand, there is a further increase in the difficulty of removal of the chloride, which evidently cannot be offset by the conjugation of the resulting double bond with two chlorine atoms.

Mochida[33] found the reactivity sequence given in Table 6 on several catalysts. This sequence is similar to that on $MgSO_4$ (Table 4). The same sequence is given by *Venuto, Givens, Hamilton,* and *Landis*[16] for a lanthanide-loaded molecular sieve (REX in Table 6).

Table 6. Effects of electronegative substituents in the α and β positions.

Catalyst	Order of reactivities [a]	Ref.
SA-1 [b], A-B-1 [c], Mg-10X [d]	Cl_3C-C > Cl_2C-C > Cl_2C-CCl_3 (→ ClC=CCl) > Cl_2C-CCl_2 > ClC-CCl > Cl_2C-CCl (→ Cl_2C=C)	[33]
Cr_2O_3	Cl_3C-C > Cl_2C-C > Cl_2C-CCl_2 > Cl_2C-CCl (→ClC=CCl)>ClC-CCl > Cl_2C-CCl (→ Cl_2C=C)	[33]
REX [e]	Cl_3C-C > Cl_2C-C > ClC-CCl	[16]

[a] The reaction rate at 300°C was used as a measure.
[b] Silica alumina (13% Al_2O_3).
[c] Alumina boria (10% B_2O_3).
[d] Linde molecular sieve 10X, Mg form.
[e] Linde molecular sieve 13X, loaded with a mixture of lanthanides.

Table 7. Effects of methyl and phenyl substitution. Expected sequence of activation energies *(AE)* and experimental activation energies (in kcal/mole) measured between 100 and 450°C.

Expected order of *AE* for E1	Cl-C(C$_6$H$_5$)-C	<	C-C(Cl)-C	<	Cl-C-C-C	<	Cl-C-C-C_6H_5	<	Cl-C-C
Found *AE* on $MgSO_4$	–		6		9		11		19
Found *AE* on $BaSO_4$	–		8		10		15		–
Expected order of *AE* for E2	Cl-C(C$_6$H$_5$)-C	≈	Cl-C-C-C_6H_5	<	C-C(Cl)-C	<	Cl-C-C-C	<	Cl-C-C
Found *AE* on K_2CO_3	–		17		24		38		–
Found *AE* on K_3PO_4	–		9		13		18		–

If ethyl chloride is substituted in the α and β positions with methyl or phenyl groups[34], the sequences indicated in Table 7 are to be expected for the activation energies,

depending on whether the process is E1 or E2[34]. Chloroethane reacts so reluctantly that it has only been studied in one case. 1-Chloro-1-phenylethane, on the other hand, reacts so readily that the activation energy could not be determined. The (E1-like) homogeneous reaction is so strongly supported by the α-phenyl group that it is complete even at about 100 °C.

The sequences found on $MgSO_4$ and $BaSO_4$ (E1 catalysts) agree with those expected. On K_2CO_3 and K_3PO_4 (E2 catalysts), though 1-chloro-2-phenylethane has the lowest activation energy, as expected, the difference between 1-chloropropane and 2-chloropropane should be smaller. The great difference found presumably means that the dissociation of the C–Cl bond has progressed much farther in the transition state than that of the C–H bond, *i.e.* that the reaction is a concerted process with a tendency toward E1[1,2].

4.4. Kinetic Isotope Effect

The reaction rates were determined for the following series on magnesium sulfate and magnesium phosphate: CH_3-CHCl-CH_3 (D_0), CH_3-CDCl-CH_3 (D_1), CD_3-CHCl-CD_3 (D_6), CD_3-CDCl-CD_3 (D_7). The rate of D_0 is practically equal to that of D_1, and that of D_6 is equal to that of D_7. The ratio $k(D_{0,1})/k(D_{6,7})$ of the rate constants is 1.7 on magnesium phosphate at 320 °C[35] and 3 on magnesium sulfate at 160 °C[36].

Isotope effects of this magnitude are compatible with an E1 mechanism[1] such as is to be expected for both catalysts (see Section 5.4).

With the C_β-deuterated alcohols isobutanol $(CH_3)_2CD$-CH_2OH, *sec*-butanol, C_2D_5-CH(OH)-CH_3, and *tert*-butanol $(CD_3)_3COH$ on Al_2O_3, *Knözinger* and *Schegli-la*[37] found an isotope effect (k_H/k_D) of between 3.95 (*sec*-BuOH at 120 °C) and 1.7 (*iso*-BuOH at 200 °C). They deduce an E2-like dehydration mechanism, which tends toward E1 with rising temperature.

No secondary isotope effect was observed. On introduction of a D atom on C_α, though the conversion of the deuterated reactant is always slightly less than that of the undeuterated material, the differences are less than 10% (CH_3-CDCl-CH_3 on $MgSO_4$, $BaSO_4$[10]; CH_3-CDCl-C_2H_5 on $CaCl_2$[38]; CH_3-CDOH-C_2H_5 on $CaSO_4$[39]).

5. The Primary Product Distribution

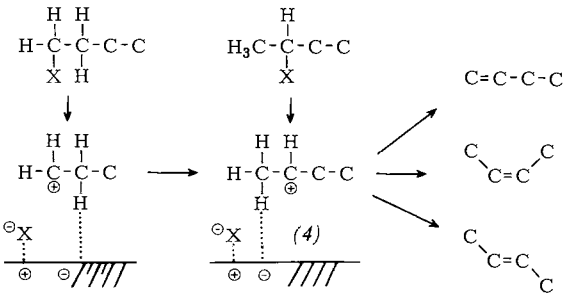
The determination of the primary products is a particularly important means of obtaining an insight into the mechanism of a reaction. Whereas the equilibrium distribution is determined by the difference in the free energies (enthalpies) (thermodynamic control), the primary product distribution depends on the difference in the free activation energies (enthalpies) (kinetic control). The primary product distribution should therefore generally be different from the equilibrium distribution, the only exceptions being the extremly rare cases in which the two energy differences are equal. Kinetic control should therefore always be found. If, however, it is thought that "thermodynamic control" has been detected, this may be taken either as a sign of secondary reactions that lead to an equilibrium or as an indication that the reaction temperature is too high to allow the difference in the two energy differences to become effective.

5.1. Orientation

In contact eliminations from compounds that can form several olefins, Saytzeff orientation has nearly always been found so far. Thus, the olefin with the greater number of alkyl groups predominates. This is true not only with 2-halobutanes[23,25,38–41], 2-halopentanes[42], and *tert*-amyl chloride[42] on various salt and oxide catalysts, but also for 2-butanol[37,39,43,43a]. The Saytzeff orientation is also favored with 2-aminobutane[43b] and 2-phenylbutane[26] on silica alumina. It is generally accepted[1,2] that the Saytzeff orientation is characteristic of E1 and possibly E2, but less so for E1cB.

It is interesting to note that the Hofmann orientation is found in the dehydration of alcohols on thorium oxide. 2-Butanol thus gives mainly 1-butene[44], and even 3-methyl-2-pentanol gives about 80% of 3-methyl-1-pentene at 360 °C[45].

5.2. Wagner-Meerwein Rearrangement



Though 1-X-butane always reacts less readily than 2-X-butane in contact eliminations, the products are the same and the product distributions are frequently similar, particularly with X=Cl, Br. 2-Butene usually predominates[23,25,40–42]. Some examples are shown in Table 8. This presumably means that both reactants form the same 2-butyl cation *(4)*; in the case of 1-X-butane, this cation is formed by Wagner-Meerwein rearrangement of the initially formed 1-butyl cation.

Table 8. Similarity of the product distribution with 1-chlorobutane and 2-chlorobutane as reactants, and examples of preferred formation of *cis* olefin [41].

Catalyst	Temp. (°C)	Reactant	Conversion (%) [a]	1-Butene (%) [b]	*trans*-2-Butene (%) [b]	*cis*-2-Butene (%) [b]
$MgSO_4$	240	1-Cl-Butane	80	10	60	30
$MgSO_4$	240	2-Cl-Butane	100	13	59	28
$BaSO_4$	245	1-Cl-Butane	70	21	36	43
$BaSO_4$	130	2-Cl-Butane	34	7	32	61
$BaSO_4$	180	2-Cl-Butane	97	9	46	45
Li_2SO_4	390	1-Cl-Butane	10	100	–	–
Li_2SO_4	270	2-Cl-Butane	10	15	27	58
Li_2SO_4	330	2-Cl-Butane	39	19	32	49
Li_2SO_4	390	2-Cl-Butane	100	22	40	38

[a] Based on the reactant as 100%.
[b] Based on the sum of the butenes as 100%.

This similarity of the product distribution is further evidence in favor of an E1 mechanism with a carbonium ion as the intermediate. In addition to hydride shifts,

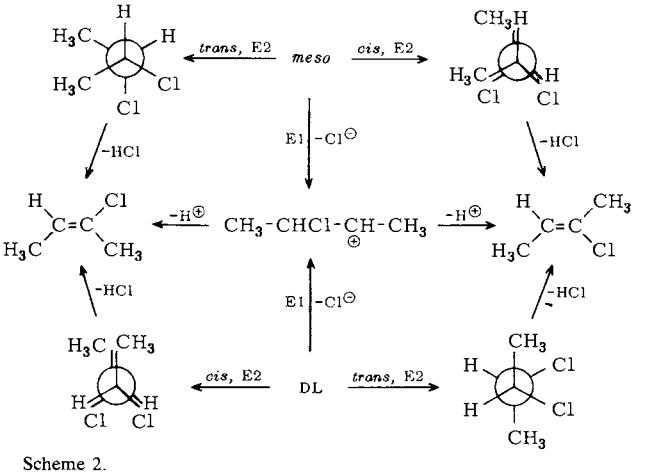
rearrangements of the carbon skeleton are also observed. Neopentyl bromide on Al_2O_3, even around 100 °C, gives 2-methyl-2-butene (principal product) and 2-methyl-1-butene[42]. The only catalysts that allow the preferential formation of 1-butene from 1-halobutanes are lithium salts[20,41,46] (Table 8). If the halogen is replaced by a substituent that is more difficult to remove, displacement of the mechanism toward E2 is to be expected. It is in fact found that 1-butyl acetate on $MgSO_4$, which is a pronounced E1 catalyst for haloalkanes, gives between 50 and 60% of 1-butene. $BaSO_4$, which is also an E1 catalyst for haloalkanes, though less so than $MgSO_4$, leads to the exclusive formation of 1-butene[47].

5.3. Preferential *cis*-Olefin Formation

An interesting characteristic of contact eliminations is that the (thermodynamically less stable) *cis*-olefin is frequently favored over the *trans*-olefin in the primary products (Table 8). The *cis*-olefin is nearly always formed in a quantity greater than that corresponding to the equilibrium[20,23,25,38–41]. *Knözinger* and *Bühl* recently found the extremely high *cis/trans* ratio of 10:1 with 2-butanol on Al_2O_3[43].

This characteristic is particularly pronounced on lithium salts[20], while it is weaker or even absent on very active catalysts (particularly selective catalysts such as lithium salts are often only moderately active). The distribution approaches equilibrium with rising temperature.

5.4. Stereoselectivity and Stereospecificity



We use the term stereoselectivity with respect to the catalyst, and the term stereospecificity with respect to the reaction in general.

One method of obtaining information about stereoselectivity and stereospecificity is the use of cyclic compounds. In the investigation of the dehydration of menthol or neomenthol on Al_2O_3, *Pines* and *Pillai* came to the surprising conclusion that this reaction must be a *trans*-elimination[48]. A similar result was obtained by *Blanc* and *Pines*[49] with other alkyl- and phenyl-substituted cyclohexanols, again on Al_2O_3. This observation of *trans*-elimination was recently confirmed by *Blanchard* and *Canesson*, who investigated the dehydration of 2-methyl-1-cyclohexanol on thorium oxide[50]. The present authors obtained a similar result in the contact elimination of HCl from menthyl chloride and neomenthyl chloride on $CaCl_2$ and other salt catalysts[51].

Another possibility is the use of substances in which the starting positions of H and X are fixed from the outset with respect to each other, *e.g. cis*- and *trans*-chlorostilbenes, both of which give tolan. Investigations using numerous salt and oxide catalysts have shown[40,52] that both isomers react, the *cis*-isomer usually more readily than the *trans*-isomer. However, this must not be taken directly as an indication that the *cis*-elimination is preferred, since *cis*-chlorostilbene has undoubtedly a higher energy than *trans*-chlorostilbene (the difference in the case of *cis*-stilbene and *trans*-stilbene is 9.5 kcal/mole[53]). *cis*-Chlorostilbene is thus presumably closer in energy to the activated complex than *trans*-chlorostilbene, though the two complexes need not be identical. The results show that both elimination mechanisms are fundamentally possible.

The best method for the recognition of stereoselectivity and stereospecificity is probably use of compounds with asymmetric α- and β-C atoms. We have made considerable use of 2,3-dichlorobutane[54,55,55a], as well as of 2,3-dibromobutane[56] and 1,2-dichloro-1,2-diphenylethane[57].

Scheme 2 shows what one should expect from the various mechanisms in the case of 2,3-dichlorobutanes. The decisive information is provided by the ratio of *cis*- to *trans*-2-chloro-2-butene and from the difference in this ratio according to whether the *meso* or DL form of the reactant is used.

Scheme 2.

In the case of a concerted *cis*-elimination (E2), the *meso*-form gives the *trans*-olefin, while the DL-form gives the *cis*-olefin; the result is reversed in a concerted *trans*-elimination. If the mechanism is E1, both forms give the same carbonium ion, and this logically gives the same *cis/trans* ratio of the olefins.

Table 9 shows a list of catalysts in order of decreasing stereoselectivity. The stereoselectivity was measured by the difference in the ratios of *cis*- to *trans*-2-chloro-2-butene obtained from the *meso*- and DL-forms. It increases with decreasing charge and increasing radius of the cation, as well as with increasing basicity of the anion.

This principle is obvious if one bears in mind the adsorption [as in *(1)*, Section 3.4] and interaction between

the reactant and the catalyst that has already been mentioned several times. If the cation-X interaction predominates, X is removed in the first step, corresponding to an E1 mechanism. This is so on most catalysts with polyvalent cations, *i.e.* the more active catalysts. If the cation-X and anion-H interactions are (roughly) equal in strength, an E2 mechanism occurs. With decreasing electrophilicity of the cation and increasing nucleophilicity (basicity) of the anion, therefore, the mechanism is displaced from E1 to E2, and presumably further to E1cB, though this seems to be more difficult. Strengthening of the C–X bond and weakening of the C–H bond should have the same effect.

It is surprising to note that in the E2 process, the *trans* mechanism is favored in the contact elimination, just as in the liquid-phase reaction. It is not yet certain how the proton, which is probably directed away from the surface of the catalyst in the activated complex, reaches this surface. It must be assumed that it is more mobile than is commonly believed (tunneling?)

Aluminum oxide exhibits partial stereoselectivity in the elimination of HCl[55a]. No other oxides have been tested. The *trans*-mechanism has recently also been confirmed in the dehydration of open-chain compounds. *Hall*[58] found it with [3-D]-DL-*erythro*-2-butanol and [3-D]-DL-*threo*-2-butanol on aluminum oxide. *Narayanan* and *Pillai*[45] obtained a similar result in the dehydration of *threo*-3-methyl-2-pentanol both on aluminum oxide and on thorium oxide.

Table 9. Order of stereoselectivities of some catalysts, indicated by the ratio (*cis*+*trans*=100) of *cis*- to *trans*-2-chloro-2-butene obtained from the *meso*- and the DL-forms of 2,3-dichlorobutane (see Scheme 2). The three groups of catalysts correspond to different investigations.

	KBO_2 ≈ K_2CO_3	> K_3PO_4	> K_2SO_4	> $BaCO_3$	> $Ca(BO_2)_2$	> $Ba_3(PO_4)_2$ >
meso	97/3	92/8	93/7	86/14	87/13	46/54	69/31
DL	9/91	7/93	11/89	11/89	19/81	19/81	25/75

	$CaCl_2$	K_2CO_3	> Na_2CO_3	> Li_2CO_3	$CaCl_2$[a]	≈ $Ca_3(PO_4)_2$[a]
meso	17/83	98/2	75/25	10/90	22/78	17/83
DL	17/83	35/65[b]	40/60[b]	10/90[b]	23/77	14/86
Temp. (°C)	200	330	330	350	220	220

[a] Reactant: 2,3-dibromobutane.
[b] The DL-form contained more than 10% of the *meso* form.

The elimination of acetic acid from 1-butyl acetate on $BaSO_4$ and $MgSO_4$ was mentioned in Section 5.2. From Table 9, the elimination from 2,3-dichlorobutane should be expected to follow a mixed mechanism on $BaSO_4$ and a pure E1 mechanism on $MgSO_4$. Since the C–O bond is stronger than the C–Cl bond, the elimination from 1-butyl acetate on $BaSO_4$ proceeds almost completely by the E2 mechanism, as is shown by the absence of 2-butene. The olefin distribution in the elimination on $MgSO_4$, on the other hand, points to a mixed mechanism. An increase in the strength of the C–X bond displaces the mechanism toward E2.

In these studies on stereospecificity, we again find the rule that more active catalysts are less selective.

The selectivity generally decreases with rising temperature, again in agreement with the rule, since the catalyst becomes "more active" with rising temperature, and the mechanism shifts from E2 toward E1.

5.5. Is the Reaction really a β-Elimination?

Eliminations of this type are generally tacitly assumed to be β-eliminations, though this should really be checked. Studies by *Schwab*[59] on the dehydration of CH_3-CD_2OH on various catalysts have shown that in most cases (about 80%) hydrogen from the methyl group is removed together with the OH group, *i.e.* that β-elimination at least predominates. Table 10 shows the results of similar studies on [2-D]-2-chloropropane and on [2-D]-2-butanol.

Table 10. The question of β-elimination (loss of deuterium on complete conversion; pulse technique).

Catalyst	Reactant	D content [a]	Temp. (°C)	Product(s)	D content [a]	Ref.
$CaSO_4$	CH_3-CDCl-CH_3	98	320	Propene	94	[10]
$BaSO_4$	CH_3-CDCl-CH_3	98	400	Propene	95	[10]
$MgSO_4$	CH_3-CDCl-CH_3	97	220	Propene	97	[36]
$CaSO_4$	CH_3-CDOH-C_2H_5	96	430	1-Butene+	96	[39]
				trans-2-Butene+	88	
				cis-2-Butene	80	

[a] The values show the percentage of molecules having the number of D atoms that corresponds to the formula.

About 90% of the deuterium present in the reactant is frequently found in the products. In the case of [2-D]-2-butanol on $CaSO_4$, the loss of D in the three butenes

varies[39]. Thus the formation of 1-butene must have been a pure β-elimination. Though slight α-elimination cannot be ruled out in the case of the 2-butenes, it is equally conceivable and compatible with the other findings that the loss of D is connected with the structure of the intermediate carbonium ion.

The loss of D is also relatively small in the elimination of HCl from CH_3-CDCl-CH_3 on $MgSO_4$, $CaSO_4$, and $BaSO_4$.

The results justify the assumption that β-elimination predominates to a great extent.

6. The Factors that Determine the Mechanism

The mechanisms in most of the cases investigated are E1 and E2. The E1cB mechanism has not so far been detected with absolute certainty, though evidence in this direction has been found[60]. This mechanism should occur in systems with strong anion-H interaction and weak cation-X interaction and/or a strong C–X bond and a weak C–H bond.

Bunnett[2] has described how changes in the reaction system alter the mechanism of the elimination in the liquid phase. However, his discussion was confined to the range of the concerted mechanism. We believe that the argument can be confidently extended into the E1 and E1cB regions.

Table 11 shows a modified form of *Bunnett*'s scheme adapted for the contact reaction. Entries 1–5 and 11 need no comment. The effect of electron-attracting β-substituents under 6 is lacking from *Bunnett*'s scheme. Such a substitution should hinder the removal of X and facilitate that of the proton. However, no definite conclusion can be drawn from the few experimental observations, *e.g.* those in Tables 4 and 6.

Table 11. Influence of various factors on the mechanism of contact elimination. For explanations see text.

No.	Factor	E1	E2	ElcB
1.	α-Aryl group	←	—	—
2.	α-Alkyl group	←	—	—
3.	β-Aryl group	—	—	→
4.	β-Alkyl group	←	—	—
5.	Electron-attracting α-substituent	—	—	→
6.	Electron-attracting β-substituent	—	—	→
7.	More readily removed group X	←	—	—
8.	Facilitation of removal of the proton	—	—	→
9.	Higher cation charge	←	—	—
10.	Greater cation radius	—	—	→
11.	Higher anion basicity	—	—	→
12.	Higher shielding of the cation by the anion	—	—	→
13.	Increase of temperature	←	—	—

The item "more readily removed group X" under 7 refers simply to the energy required for the heterolytic dissociation of the C–X bond. It may be assumed that the energy in the transition state shows a corresponding trend. *Bunnett* had included as a further factor the inductive electron attraction of the leaving group, which displaces the mechanism toward E1cB. We have omitted this factor, since we believe that it is difficult in contact elimination to compare reactants that differ only in this respect and not also in the dissociation energies.

The difficulty of removal of the proton (see under 8) is undoubtedly determined by the factors indicated above, but certainly not all the many variations of molecular structure that can affect the ease of removal of the proton have been covered.

The entries under 9 and 10 are not necessarily valid for transition metals. Little is known at present about how empty d orbitals affect the elimination activity. Moreover, it is assumed that the shielding (masking) of the cations by anions is the same. The cations are often smaller than the anions. Such cations are situated slightly deeper in the surface than the anions (see under 12). The more this is so, the smaller is the action of the cation on the reactant, firstly because of the greater distance and secondly because of the stronger shielding by the electron clouds of the anions.

In the case of entry 13 the only experimental observations made so far show that an increase in temperature displaces E2 toward E1[37,54,55,55a] and we do not believe that it can be inferred that E1cB is displaced toward E2; the arrow has therefore been drawn only from E2 to E1. We are of the opinion that the E2 mechanism is always displaced toward one of the ionic mechanisms (carbonium ion or carbanion) by an increase in temperature, but that the direction of the displacement possibly depends on its character at the lower temperature. If this were the case then we would have a further criterion for deciding whether an E2 mechanism had E1 or E1cB character.

We are grateful to the Deutsche Forschungsgemeinschaft, the Verband der Chemischen Industrie, the Juan-March Foundation (Spain), and the Consejo Científico y Humanístico de la Universidad Central de Venezuela, for their support of our work in this field. The investigations were carried out in various locations: the Physikalisch-Chemisches Institut der Universität München, the Escuela de Química de la Universidad Central de Venezuela, Caracas, and the Centro Experimental de la Universidad de Carabobo, Valencia (Venezuela). Many colleagues participated in the work, and we are grateful to all of them. Their names will be seen from the references. Mention should also be made of H. Kober, D. Moronta, L. Picott, A. Schwab, and K. Seyffarth. Many other colleagues have assisted us in various ways. The investigations have also been supported for a certain time by Dr. Luis B. Tugues.

Arguments Concerning the Orbital Sequence in Borazine[1]

By *Hans Bock* and *Werner Fuss*[*]

MO calculations taking account of all valence electrons[2–5] result in an orbital sequence for borazine that is at variance[6] with its photoelectron spectrum[5]; in particular, the highest occupied molecular orbital is calculated to be a σ type orbital. The following considerations and experimental data favor a different assignment:

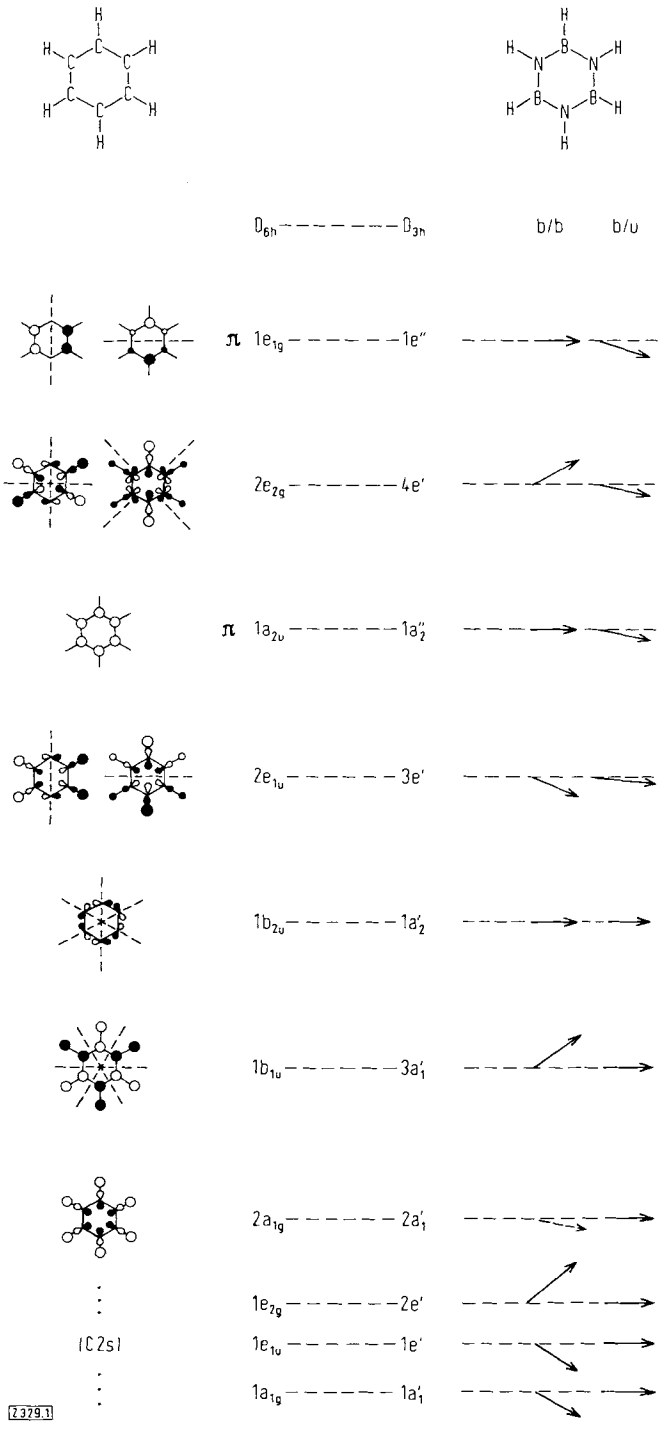

Fig. 1. Qualitative energy level shifts on transition from benzene to borazine.

1) The completely assigned[7] photoelectron spectrum of benzene, a molecule that is isoelectronic with borazine, leads to the sequence of energy levels characterized in Fig. 1 by orbital diagrams and irreducible representations of the corresponding molecular orbitals. On changing from D_{6h} to D_{3h} symmetry, the irreducible representations e_{2g} and e_{1u} coincide in e′ and the irreducible representations b_{1u} and a_{1g} in a_1'[8]. If a perturbation of symmetry D_{3h} is introduced by an alternate raising and lowering of the nuclear charge of the ring atoms then the molecular orbitals of the same irreducible representation will become mixed: The smaller the energy difference between two levels, the greater their "mutual repulsion". The energy level shifts resulting from interactions between occupied molecular orbitals are shown qualitatively in Fig. 1 by the arrows b/b, and additional changes due to the unoccupied molecular orbitals by the arrows b/u. Whether the orbital sequence is altered within this benzene→borazine correlation can be decided experimentally by the assignment of individual bands in the photoelectron spectrum.

2) Six bands (at least) can be distinguished in the PE spectrum of borazine (Fig. 2) up to energies of 21.21 eV[9]. The first band at 10.09 eV is readily assigned to a π ionization on account of its recognizable vibrational fine structure: The progression of 1360± 100 cm^{-1} can only arise from a ring vibration E′ (IR spectrum of borazine: ν_{13} = 1465 or ν_{14} = 1406 cm^{-1}[10]) and, as in the case of benzene, indicates a degenerate level; the progression of 800 ± 40 cm^{-1} corresponds to a ring vibration A_1'

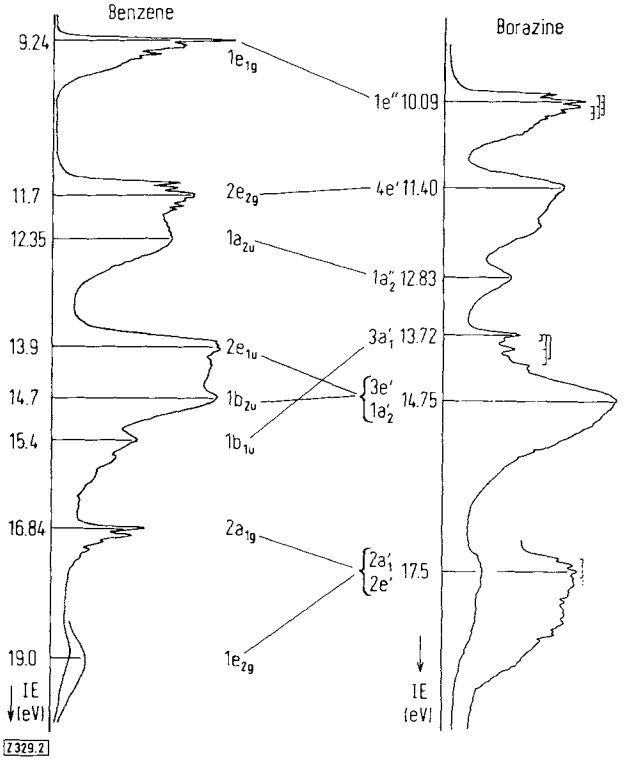

Fig. 2. Correlation of the photoelectron spectra of benzene and borazine [9].

(Raman spectrum of borazine: ν_3 = 944 or ν_4 = 842 cm^{-1}[11]) and is therefore to be assigned to the "ring bonding" π orbital 1e″. For the σ orbital 4e′, which is hardly involved in B/N bonding, there remains only the structureless second band at 11.40 eV. Moreover, the band at 13.72 eV can be assigned to the "strongly B/H bonding" orbital $3a_1'$ on account of its vibrational fine structure: This is confirmed primarily by the appearance

of the B/H stretching vibration 1880 ± 100 cm^{-1} of species A_1' (Raman spectrum of borazine: ν_2 = 2442 cm^{-1}[11]) which, like the C/H stretching vibration of the $1b_{1u}$ band in the photoelectron spectrum of benzene, is drastically lowered by ionization[7]. On the basis of the qualitative orbital correlations (Fig. 1) and the approximate intensity ratios 2:2:0.7:0.7:5:(1), the remaining bands of the borazine photoelectron spectrum are tentatively assigned in the sequence of degenerate and nondegenerate molecular orbitals $e''/e'/a_2''/a_1'/(e' + a_2')/(a_1' + e')$ . . . (Fig. 2).

3) Further arguments supporting the π assignment of the highest occupied borazine molecular orbital arise from the photoelectron spectra of methyl and halogeno derivatives whose first ionization potentials are shown in Fig. 3.

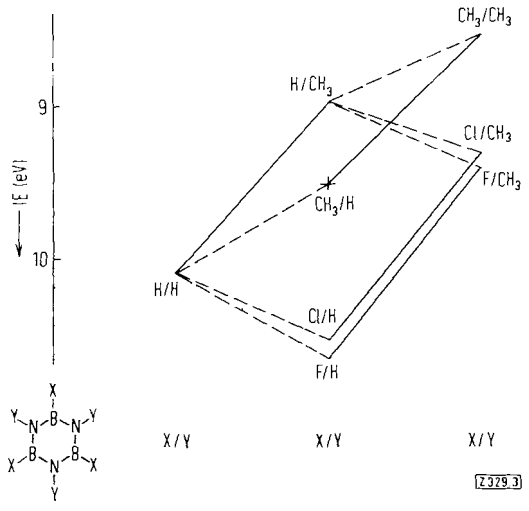

Fig. 3. First ionization potentials of borazine and some of its methyl and halogeno derivatives.

Halogeno substituents X = F,Cl should lower the highest occupied σ level considerably while in a π system the resonance effect of X will oppose the inductive effect[12]: The first band in the photoelectron spectrum of *B*-trifluoroborazine at 10.66 eV and that of *B*-trichloroborazine at 10.55 eV therefore clearly correspond to a π ionization. It also follows from the slight perturbation of the π system that it is the first of the two photoelectron bands of borazine at 10.09 and 11.40 eV (Fig. 2) that has to be assigned to a π orbital.

Methyl groups should have the effect of raising the highest occupied orbital in borazine and its derivatives. According to first order perturbation theory the change in orbital energy

$$\delta\varepsilon_J = \sum_{\varrho} c_{J\varrho}^2 \, \delta\alpha_{\varrho}$$

is given by the perturbation term $\delta\alpha_{\varrho}$ and the square of the orbital coefficient $c_{J\varrho}^2$ at the perturbed center ϱ. Additivity can be expected in the case of several perturbations: As can be seen from Fig. 3, the first ionization potential is altered by the same amount on *N*-methylation (——), independently of the *B*-substituents, and on *B*-methylation or *B*-halogenation (– – –), independently of the *N*-substituents. Such an additivity is not to be expected for σ orbitals, particularly in the case of *B*-halogenoborazines.

Assuming a constant perturbation $\delta\alpha_{\varrho}$ (CH_3), it is also possible to calculate the ratio of the squares of the *B*- and *N*-orbital coefficients: Insertion of the measured mean orbital energy changes $\delta\varepsilon_J(B\text{–}CH_3)$ = 0.55 ± 0.05 eV and $\delta\varepsilon_J(N\text{–}CH_3)$ = 1.1 ± 0.1 eV into the perturbation formula yields $\sum_B c_{JB}^2 : \sum_N c_{JN}^2$ ≈ 1:2 for the highest occupied π orbitals of the borazine derivatives listed in Fig. 3[**].

Alkaline Earth Metal Halide Hydrates: Use of IR Spectra for Phase Analysis and Determination of Possible Structural Types[1]

By *Heinz D. Lutz, Hans-Jürgen Klüppel,* and *Georg Kho*[*]

Investigations of the lattice vibrations of alkaline earth metal hydroxides have shown[1–3] that IR spectra are much more suitable for the identification and characterization of hydroxides and hydroxide-hydrates than X-ray patterns, which usually contain many lines and, without measurements on single crystals, are only difficultly interpretable. It can now be shown, using alkaline earth metal halide hydrates as example, that lattice vibration spectra also afford a means of classifying compounds having the same stoichiometry into particular structural types and thus considerably simplify the indexing of powder photographs.

Thus it follows from the spectra, and in particular from the number and position of the stretching (3000–3600 cm^{-1}) and bending (1600–1700 cm^{-1}) modes and the librations (300–800 cm^{-1}) of water of crystallization, that the strontium halide hexahydrates $SrCl_2 \cdot 6H_2O$ and $SrBr_2 \cdot 6H_2O$, have, as noted from X-ray crystallographic data[4], the same structure and that the monoclinic barium and strontium halide dihydrates $SrCl_2 \cdot 2H_2O$[4], $BaCl_2 \cdot 2H_2O$[4] and $BaBr_2 \cdot 2H_2O$[5], and $BaI_2 \cdot 2H_2O$[6] belong to three different structural types (Fig. 1).

According to their IR spectra (Fig. 2) the monohydrates of the alkaline earth metal halides, of which we have been able to prepare $SrBr_2 \cdot H_2O$, $SrI_2 \cdot H_2O$, and $BaI_2 \cdot H_2O$ for the first time, are, with the exception of $SrI_2 \cdot H_2O$, all isotypic. The crystallographic data subsequently recorded by us for these compounds, which, according to electron diffraction measurements on $BaCl_2 \cdot H_2O$[7], crystallize in the space group Pnma, are given in the Table.

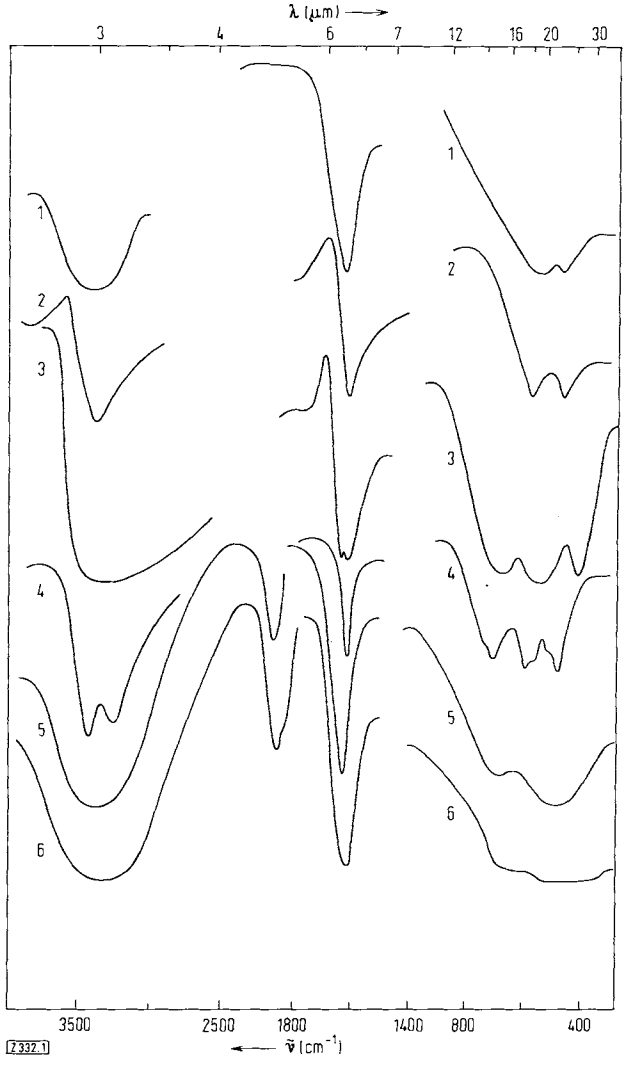

Fig. 1. IR spectra of $BaI_2 \cdot 2H_2O$ (1), $BaBr_2 \cdot 2H_2O$ (2), $BaCl_2 \cdot 2H_2O$ (3), $SrCl_2 \cdot 2H_2O$ (4), $SrCl_2 \cdot 6H_2O$ (5), $SrBr_2 \cdot 6H_2O$ (6).

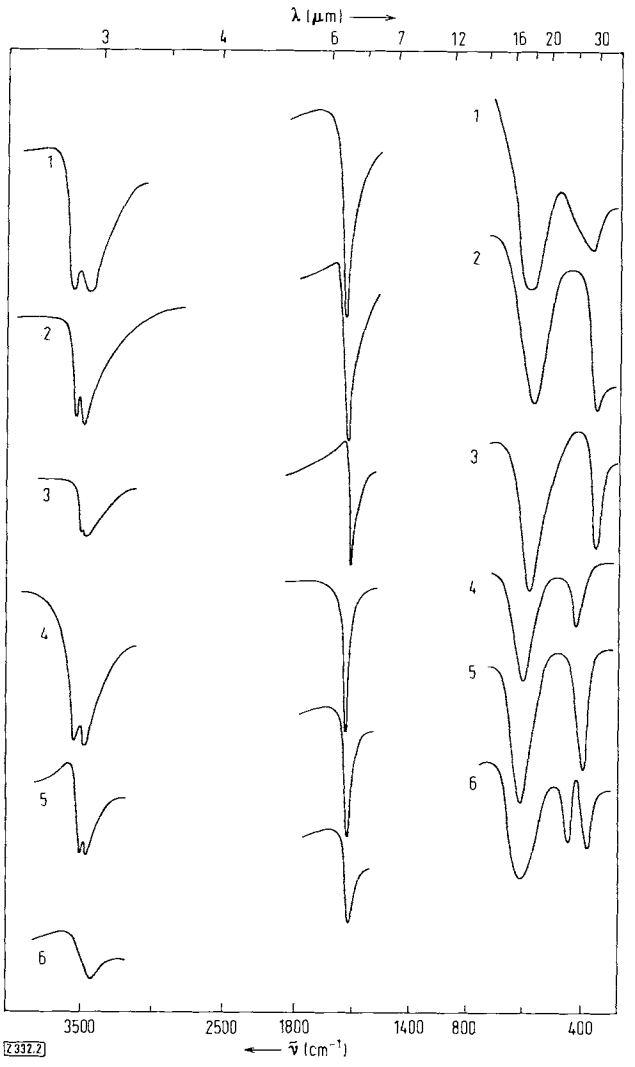

Fig. 2. IR spectra of $BaCl_2 \cdot H_2O$ (1), $BaBr_2 \cdot H_2O$ (2), $BaI_2 \cdot H_2O$ (3), $SrCl_2 \cdot H_2O$ (4), $SrBr_2 \cdot H_2O$ (5), $SrI_2 \cdot H_2O$ (6).

$SrCl_2 \cdot H_2O$ and $SrI_2 \cdot H_2O$ could not be identified X-ray crystallographically. Thus, as has already been established in the case of alkaline earth metal hydroxides[2], compounds of the above type that cannot be identified by X-ray crystallography can be unequivocally characterized by their IR spectra. Just the close range order of a few cells apparently suffices for observation of the lattice vibrations of a structure.

The alkaline earth metal halide monohydrates were prepared by dehydration of hexa- or dihydrates in vacuum at 75–100°C. The preparation of samples for IR spectroscopic measurements (nujol, KBr; Beckman IR 10) and X-ray (powder) crystallography ($Cu_{K\alpha}$) was carried out in a dry-box because some of the compounds are very hygroscopic.

Table. Crystallographic data of alkaline earth metal halide monohydrates (Å).

$MX_2 \cdot H_2O$	*a*	*b*	*c*
$BaCl_2 \cdot H_2O$[7]	4.51	9.02	11.28
$BaBr_2 \cdot H_2O$[7]	4.59	9.41	11.59
$BaI_2 \cdot H_2O$	4.73	9.92	12.15
$SrBr_2 \cdot H_2O$	4.88	8.96	11.47

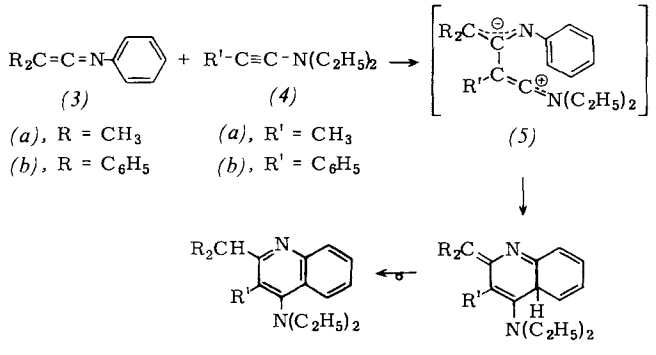
Cycloadditions of Keteneimines to Ynamines[**]

By *Léon Ghosez* and *Cécilia de Perez*[*]

Experience[1] has well substantiated *Woodward* and *Hoffmann*'s suggestion [2] that ketenes *(1a)* owe their reactivity in

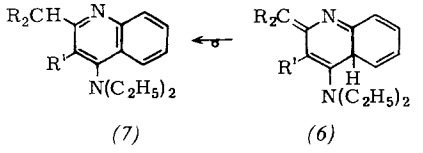
(2+2) cycloadditions to their ability to behave electronically as "pseudo" vinyl cations *(2a)*.



(1) *(2)*

(a), X = O; *(b)*, X = N-R

Substitution of a nitrogen atom bearing various substituents *(1b)* for the oxygen atom in the ketene molecule would offer the interesting possibility of varying the vinylium character of the cumulene *(2b)* and studying the consequences on its behavior in cycloadditions.

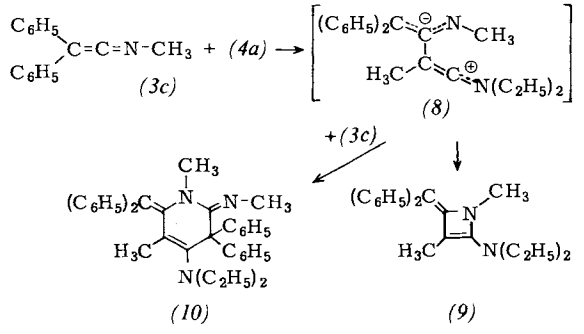


This preliminary report describes the stepwise polar cycloaddition of *N*-aryl and *N*-alkyl-substituted keteneimines to the strongly nucleophilic aminoacetylenes. We have found that *N*-phenylketeneimines *(3a)* and *(3b)* cycloadd to ynamines *(4a)–(4b)* at room temperature to yield the 4-aminoquinoline derivatives *(7a)* to *(7d)* as the sole isolable adducts. This provides a simple synthetic route toward these heterocyclic systems. In contrast the reaction of *N*-methyl-diphenylketeneimine *(3c)* with *(4a)* in acetonitrile is sluggish (7 days) and yields both 1 : 1 and 2 : 1 adducts for which structures *(9)* and *(10)* are proposed mainly on the basis of mass spectral data.

(3) *(4)* *(5)*

(a), R = CH_3 *(a)*, R' = CH_3

(b), R = C_6H_5 *(b)*, R' = C_6H_5



(7) *(6)*

(a), R = R' = CH_3

(b), R = C_6H_5; R' = CH_3

(c), R = R' = C_6H_5

(d), R = CH_3; R' = C_6H_5

(3c) *(8)* *(10)* *(9)*

(7b)	137–139 (67)	380(M^+)	322 (5.2) 309 (4.17) 234 (52.7)	1.01(6 Methyl-H/t); 2.38(3 Methyl-H/s); 3.30(4 Methylene-H/q); 5.92(1 Methine-H/s); 7.45(12 arom. H/m); 8.0(2 arom. H/m)
(7c)	156 (61)	442(M^+)	322 (4.5) 234 (54.2)	0.92(6 Methyl-H/t); 2.87(4 Methylene-H/q); 5.45(1 Methine-H/s); 7.00-8.3(19 arom. H/m)
(7d)	69.4 (52)	318(M^+)	320 (4.33) 230 (46.4)	0.95(6 Methyl-H/t); 1.23(6 Methyl-H/d); 2.90(4 Methylene-H + 1 Methine-H/m; ≈ 7.40 (7 arom. H/m); ≈ 8.10 (2 arom. H/m)
(9)	137.3 (35)	318(M^+) 207 205 113	–	0.83(6 Methyl-H/t); 2.13(3 Methyl-H/s); 3.20(4 Methylene-H/q); 3.26(3 Methyl-H/s); ≈ 7.30(10 arom. H/m)
(10)	180.8 (34)	525(M^+) 455 318 207	–	0.50(6 Methyl-H/t); 1.66(3 Methyl-H/s); 2.30(2 Methylene-H/q); 2.70(3 Methyl-H + 2Methylene-H/s + q); 3.22 (3 Methyl-H/s); 6.80–7.70(20 arom. H/m)

[a] B.p. 140–142°C/0.7–0.9 torr.
[b] λ_{max}(nm), $\varepsilon \times 10^{-3}$ (in cyclohexane).
[c] δ values, TMS internal standard (in $CDCl_3$).

In each case, solvents with high dielectric constant were shown to accelerate the reaction: monitoring the reaction by IR showed that, in ether, the formation of *(7d)* required about 3 days, whereas in acetonitrile it was essentially completed after 6–7 h. It is worth noting that these cycloadditions proceed much more slowly than the corresponding reactions involving ketenes[3]. Roughly, it can be said that the reactivity sequence parallels the "vinylium" character of the cumulene:

C=C=O≫C=C=N–aryl > C=C=N–alkyl.

Our observations are consistent with a cycloaddition mechanism involving the initial formation of a stabilized 1,4 dipole *(5)* or *(8)* which either cyclizes to 6 or 4 membered rings *(6)* or *(9)*, or is trapped by a second molecule of keteneimine to yield *(10)*.

2-Benzhydryl-4-diethylamino-3-phenylquinoline (7c). A mixture of *(4b)* (0.329g, 1.9 mmole) and *(3b)* (0.431 g, 1.6 mmole) in acetonitrile (10 ml) was allowed to stand under nitrogen at room temperature; after 10 hours, 0.318 g of crystalline *(7c)* could be filtered off. A further crop of *(7c)* was obtained by evaporation of the filtrate and recrystallization of the resulting residue from ether/pentane. Total yield 0.431 g (61%).

Anions Derived from PH_3 Complexes: Deprotonation by PH_2^-

By *Gerd Becker* and *E. A. V. Ebsworth*[*].

The complexes $(PH_3)_2Mo(CO)_4$ and $[P_2H_4Mo(CO)_4]_x$ react with potassium in liquid ammonia, giving products which appear to contain anions of the type $[(PH_2)_2Mo(CO)_4]^{-2}$, but in the former case at least the reactions are complicated and the products are difficult to characterize. We have found, however, that phosphane complexes can be deprotonated by potassium phosphide in dimethyl ether. The complex pentacarbonylphosphanemolybdenum(0), for example, reacts quantitatively with KPH_2 in $(CH_3)_2O$ at 0 °C over a period of an hour; phosphane is evolved, and the salt $K[PH_2Mo(CO)_5]$ can be isolated from the resulting solutions as a yellow solid.

$$PH_3Mo(CO)_5 + PH_2^- \rightarrow [PH_2Mo(CO)_5]^- + PH_3$$

The compound has been characterized by its IR and NMR spectra [J(HP) = 160.5 Hz; τ_{PH} = 10.36 in $(CH_3)_2O$] and by analysis. An excess of $PH_3Mo(CO)_5$ yields the binuclear anion complex μ-phosphido-bis(pentacarbonylmolybdate(0))[1]:

$$PH_3Mo(CO)_5 + [PH_2Mo(CO)_5]^- \rightarrow [(CO)_5MoPH_2Mo(CO)_5]^- + PH_3$$

The NMR spectrum of the dimeric anion has been recorded [J(HP) = 249.3 Hz; τ_{PH} = 8.69 in $[D_6]$-acetone]. Signals of minor intensity in the spectrum we assign to a compound like $[PH_3Mo(CO)_4PH_2Mo(CO)_5]^-$ which is formed with the evolution of a small amount of CO.

The salt $K[PH_2Mo(CO)_5]$ reacts slowly with CH_3Cl, giving 50% of the expected yield of $CH_3PH_2Mo(CO)_5$ (characterized spectroscopically by comparison with spectra of authentic samples); reactions with trimethylchlorosilane and with acetyl chloride lead to the formation of a mixture of products $R_nPH_{3-n}Mo(CO)_5$ [R = $(CH_3)_3Si$- or CH_3CO-].

The monomethylphosphane complex $CH_3PH_2Mo(CO)_5$[2] is also deprotonated by KPH_2; 83% of the calc. amount of PH_3 is evolved together with some CH_3PH_2 (17%):

$$CH_3PH_2Mo(CO)_5 + PH_2^- \rightarrow [CH_3PHMo(CO)_5]^- + PH_3$$

An excess of $CH_3PH_2Mo(CO)_5$ yields the bridged anion $[(CO)_5MoPH(CH_3)Mo(CO)_5]^-$. Similar results have been obtained with $(PH_3)_2Mo(CO)_4$ and KPH_2.

Reactions of Disulfur Difluoride with Fluorosulfonic Acid, Oleum, Boron Trifluoride, and Arsenic Pentafluoride

By *Fritz Seel, Volker Hartmann, Imre Molnar, Rudolf Budenz,* and *Willy Gombler*[*]

Both isomers of disulfur difluoride, SSF_2 and FSSF, dissolve in fluorosulfonic acid and in anhydride-containing sulfuric acid (30% oleum was used) at low temperature with development of a deep yellow color that does not change on prolonged storage at −80 °C. On warming the solution first becomes green before reaching room temperature, then deep blue, and finally, after one hour at room temperature brownish red. UV and ESR spectra indicate that both the blue and the brown solutions contain species made up of sulfur cations as found in solutions of elemental sulfur in oleum[1–7]. Such solutions cannot be prepared in 100% sulfuric acid or from S_2Cl_2. Moreover, it was also found that reaction of S_2F_2 with HSO_3F gives *disulfuryl fluoride* and *thionyl fluoride,* which are also formed by reaction of SF_4 with HSO_3F.

Table. Data for complex cations of sulfur.

$\tilde{\nu}_{max}$(cm^{-1})		g-factor in oleum	Assignment, color	
10600 } 13900 }	[7]	2.0260 [1, 2, 5, 7]	S_n^+,	brownish red [7]
17000	[3, 4, 6, 7]	2.0131 [1, 2, 5, 7]	S_4^+,	deep blue [7]
25000	[4, 7]		S_8^{2+},	yellow [7]
30000	[3, 4, 6, 7]		S_4^{2+},	colorless [6, 7]

IR spectra show SSF_2 and BF_3 to be stable together as gases but not so FSSF and BF_3. A compound *(1)* that is stable only at low temperature could be prepared on a liquid-nitrogen cooled AgCl disk by condensation of S_2F_2 and BF_3; the compound exhibits the IR bands of the tetrafluoroborate ion at 1040 to 1080 cm^{-1} and a characteristic band at 830 cm^{-1}. AsF_5 reacts with S_2F_2 even below −100 °C in the molar ratio 1:1 to give compound *(2)*, which also gives a new IR band at 850 cm^{-1} and the bands characteristic of AsF_6^-. Compounds *(1)* and *(2)* thus appear to have the salt-like structures $S_2F^+\ BF_4^-$ and $S_2F^+\ AsF_6^-$. Further support for this concept comes from the observed catalysis of the conversion of FSSF into SSF_2 by BF_3:

$$FSSF + BF_3 \rightarrow S_2F^+ + BF_4^- \rightarrow SSF_2 + BF_3$$

Remarkably, the band $\tilde{\nu}_3$ (F_{1u}) of the AsF_6^- ion is split into two component bands at 691 and 662 cm^{-1}: This would indicate a lowering of the symmetry of the ion by fluoro bridging. Additional evidence is provided by the width of the band at 850 cm^{-1} which is apparently attributable to the S-F stretching vibration of the S_2F^+ ion. This broad intense band probably masks the S-S frequency. (The maxima of the SF and SS stretching bands of SSF_2 are separated by only 8 cm^{-1}.)

On warming *(2)* is first discolored to ocher yellow. When heated to 100 °C or at room temperature in the presence of AsF_5 it becomes deep blue and on stronger heating finally turns deep red. With regard to their appearance and their intense absorption the blue ($\tilde{\nu}_{max}$ = 17000 cm^{-1}) and the red product resemble the compounds $S_8[AsF_6]_2$ and $S_{16}[AsF_6]_2$ prepared by *Gillespie* and *Passmore*[8] by reaction of sulfur with AsF_5.

They are however mixtures in which $SF_4 \cdot AsF_5 = SF_3^+AsF_6^-$ *(3)* ($\tilde{\nu}_{SF} = \tilde{\nu}_3(E)$ = 926 cm^{-1}; δ_{FS} = −30 ppm from $CFCl_3$ in SO_2 solution) can be detected by IR and NMR spectrometry, and the blue and brownish red radical ion of sulfur by ESR spectrometry. Decomposition of *(2)* thus differs from the disproportionation of disulfur difluoride into sulfur and SF_4 in that complex sulfur cations are formed instead of molecular sulfur because the initially formed negative charge carrier AsF_6^- is extremely stable. The finding that decomposition of *(2)* does not give free AsF_5 indicates that $S_4[AsF_6]_2$ *(4)* is formed as main decomposition product together with *(3)*.

$$12\ (2) \rightarrow 3\ (3) + 3\ (4) + S_8[AsF_6]_2 \text{ or } 2\ S_4[AsF_6]$$

In liquid SO_2 reaction of S_2F_2 with AsF_5-proceeds just as fast as the reaction with fluorosulfonic acid; after initial red coloration a deep blue solution is formed. ^{19}F-NMR signals indicate unstable intermediates, which rapidly exchange fluorine, and the presence of the end products SF_3^+ and AsF_6^-.

P–N Cleavage in Tris(dimethylamino)phosphanecarbonyl Complexes of Molybdenum(0)[1]

By *Mathias Höfler* and *Wolfgang Marre*[*]

The P–N bonds in $(PF_3)_xNi(PF_2NR_2)_{4-x}$ (x = 0,1,2,3) can be cleaved by HCl to give the corresponding PF_2Cl complexes[2]. Since trisaminophosphanes are excellent complexing ligands (their complexing behavior is similar to that of triphenylphosphane[3]), it was considered of interest to investigate the applicability of such reactions to aminophosphanemetal carbonyls. As model compounds for the investigation we chose $Mo(CO)_5P(NMe_3)_3$ *(1)* and *trans*-$Mo(CO)_4[P(NMe_2)_3]_2$ *(2)* (Me = CH_3).

(1) was treated with liquid HCl in an autoclave at 20 °C without addition of solvent: purification of the reaction products by chromatography afforded a colorless crystalline product in *ca.* 60% yield which was identified by elemental analysis and IR spectroscopy as pentacarbonyltrichlorophosphanemolybdenum(0) *(3)*.

$$\underset{(1)}{Mo(CO)_5P(NMe_2)_3} + 6HCl_{(g)} \rightarrow \underset{(3)}{Mo(CO)_5PCl_3} + 3[H_2NMe_2]Cl\ (A)$$

Introduction of HCl gas into a pentane solution of the complex *(1)*, on the other hand, led to a mixture of *(1)*, $Mo(CO)_5PCl(NMe_2)_2$, $Mo(CO)_5PCl_2NMe_2$, and *(3)*. The cleavage reaction (A) could also be used for the analogous synthesis of *trans*-$Mo(CO)_4(PCl_3)_2$ from *(2)*.

In order to check whether the cleavage reaction – which was carried out for the first time on phosphane-substituted metal carbonyls – could also be used for the preparation of PBr_3 and PI_3 complexes we investigated the reaction of *(1)* with HBr and with HI. The reaction with HBr according to the method (A) afforded $Mo(CO)_5PBr_3$ in *ca.* 50% yield; reaction with HI in pentane at −20 °C gave a disubstitution product in 30% yield.

$$(1) + 4HI \longrightarrow \underset{(4)}{Mo(CO)_5PI_2NMe_2} + 2[H_2NMe_2]\,I$$

If the reaction temperature is increased to −5 °C, a mixture of substances can be isolated after 4 hours that consists of 70% of *(4)* and 30% of $Mo(CO)_5PI_3$ *(5)*. However, since the PI_3 complex *(5)* decomposes in solution at room temperature, attempts to obtain pure *(5)* by further reaction at an increased temperature have so far failed.

The reactivity of the halogen hydracid HX increases in the series HCl < HBr < HI. That the reaction with HI – in contrast to HCl and HBr – is not quantitative is mainly due to steric hindrance.

The spectroscopic and physical properties of the PX_3 complexes prepared by us are in agreement with those reported by other authors[4, 5].

Of such PX_3 complexes, those with X = Cl are the most suitable for the synthesis of further phosphane complexes because of the reactivity of the P–Cl bond and the low nucleophilicity of the chloride ion. They react with moderately weak and very weak bases with replacement of Cl. Thus, reaction of *(3)* with water-free methanol proceeds as follows:

$$(3) + 3CH_3OH \longrightarrow \underset{(6)}{Mo(CO)_5P(OCH_3)_3} + 3HCl$$

However, the reaction is not complete until after 3 hours and is thus considerably slower than the methanolysis of free PCl_3.

Since aminophosphane complexes in general are readily accessible and stable they open up a new route for the synthesis of PX_3 complexes (X = Cl,Br,I), which can be used for the preparation of other phosphane complexes.

Conformation of the Arabinonucleoside 1-β-D-Arabinofuranosyl-4-thiouracil

By *Wolfram Saenger* and *Volker Jacobi*[*]

In connection with studies of the behavior of thiopyrimidine nucleotides toward various polymerizing enzymes[1] our interest has been directed to the properties[2] of 1-β-D-arabinofuranosyl-4-thiouracil *(1)* and its phosphorylated derivatives. *(1)* differs from 4-thiouridine[3] only in the position of the 2'-hydroxyl group.

The conformation of the arabinose residue in *(1)* was found to be not unusual.

(1)

Fig. Structure of 1-β-D-arabinofuranosyl-4-thiouracil *(1)*, projection along the crystallographic *a* axis.

Compound *(1)* crystallizes from water in the form of thick plates of monoclinic space group $P2_1$ and unit cell dimensions a = 4.787, b = 15.060, c = 8.661 Å; β = 73.0°. The density of the crystals indicated that the nucleoside was in the form of its monohydrate. The intensities of approximately 2000 reflections were measured on an automatic diffractometer (Mo radiation) and corrected for geometric factors. The position of the C4-S vector could be obtained from a sharpened Patterson synthesis with removed origin; once this information had been

obtained, the complete structure (Fig. 1) could be derived from two Fourier syntheses. The atomic parameters were subjected to isotropic full-matrix refinement by the method of least squares until an R factor of 9% was reached. At this stage the following features became apparent (see Fig. 1):

a) In *(1)* the dihedral angle C2'-C1'-N1-C6[3] is −80° (*i.e.* the bond N1-C6 is rotated by 80° in an anticlockwise direction with respect to the bond C1'-C2'). Hitherto, all pyrimidine nucleosides apart from 4-thiouridine have been found to have this *anti* conformation[4] in which the O2 atom points away from the sugar.

b) As in 4-thiouridine, 3'-*O*-acetyl-4-thiothymidine[5], 2,4-dithiouridine[6], and 1-methyl-4-thiouracil[7], the 4-thiouracil residue is in the keto, keto form. The atoms of the heterocycle are substantially coplanar.

c) In nucleosides the sugars usually have an "envelope" configuration with C2' or C3' displaced about 0.5 Å from the plane through the other four atoms of the five-membered ring. In the arabinose present in *(1)*, C3' is about 0.6 Å away from the plane and on the same side as C5' – the sugar residue thus has the C3'-*endo* conformation.

The *cis*-diol group in ribosyl residues of comparable C3'-*endo* conformation has a dihedral angle O2'-C2'-C3'-O3', of about +50°. In the arabinose residue, however, this angle is about −80°, *i.e.* the C3'-O3' bond is rotated in an anticlockwise direction relative to the C2'-O2' bond.

The dihedral angle N1-C1'-C2'-O2' is also an important factor in any comparison between the structures of the ribose and the arabinose residues. In the C3'-*endo* ribonucleosides this angle is about −140°; however, in *(1)* it is only −29°, *i.e.* in the former case the C1'-N1 and C2'-O2' are *"trans"* (*trans*-planar or -*anti*-clinal (-ac)[8], and in the latter case they are *"cis"* (*cis*-planar or -*syn*-periplanar (-sp)[8]).

The position of O5' relative to the arabinose is given by the dihedral angles O5'–C5'–C4'–O1' and O5'–C5'–C4'–C3'[9] which are *ca.* −55° and 62° respectively in the present case. The atom O5' thus lies above the sugar residue, a position that is preferred in ribonucleosides.

Complex Bonding of a Vinylcyclopropane Group of Bullvalene to a Transition Metal *via* a π-Allyl and a σ Component[1]

By *Rudolf Aumann*[*]

Reaction of cyclopropane with H_2PtCl_6 yields a brown complex[2] containing a C_3Pt ring[3]. Analogous ring systems incorporating rhodium are also known[4]. Vinylcyclopropane *(3)*[5] and methylenecyclopropane[6] form stable π-allyl-palladium complexes, apparently by ring opening of the postulated edge-coordination complexes[7]. The action of $Fe_2(CO)_9$ on cyclopropylstyrene[8] and spiro[2.4]hepta-4,6-diene[9] furnishes substituted diene-$Fe(CO)_3$ complexes. Manganese, rhenium, iron, and iridium have been reported to give very stable cyclopropylcarbonyl complexes, the manganese compound affording a π-allyl derivative on decarbonylation[10].

The present communication reports on the first example *(2)* of complex formation by a vinylcyclopropane group *(3) via* a π-allyl and a σ component *(4)* with a $Fe(CO)_3$ unit.

(3) *(4)* *(5)*

Previous investigations[8] on this topic led to the isolation of substituted butadiene-$Fe(CO)_3$ complexes *(5)*. An intermediate *(4)* was mentioned. System *(4)* proves to be stable if C^5 is the bridgehead C atom of a polycyclic system as in complex *(2)*. The halflife of *(2)* on thermal decomposition at 135 °C in *n*-octane is about 20 h. Complex *(2)*, m.p. 133–134 °C, is the major product of the reaction between bullvalene *(1)* and $Fe_2(CO)_9$[11], in which six isomeric complexes of composition $C_{10}H_{10}Fe_2(CO)_6$ and a complex $C_4H_4Fe_2(CO)_6$ are also formed as minor products.

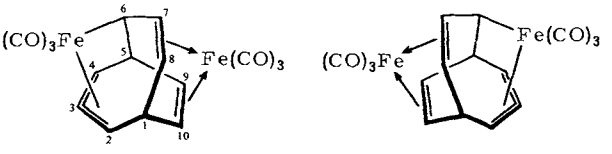

Fig. 1. The enantiomers of compound *(2)*.

Since *(1)* contains both an unconjugated diene unit and a vinylcyclopropane group in a position favorable for complex formation, it can form both 1,4-diene complexes and vinylcyclopropane complexes, depending upon the metal system used. Thus the 1,4-diene partial structure bonds to $Mo(CO)_4$ or $W(CO)_4$ groups, leaving the cyclopropane ring intact[12], while cleavage of the cyclopropane ring occurs on bonding to metal systems such as $Fe(CO)_3$ that are richer in electrons.

Perturbation calculations on a simple Hückel model of butadiene show that an increase in the distance C^4–C^6 in *(4)* leads to a decrease in the energy of the antibonding orbitals, and an increase in energy of the bonding orbitals. This would indicate more extensive back donation from metal to ligand in *(2)* than in butadiene-$Fe(CO)_3$ *(6)*. This effect can be detected experimentally by an increase in the ν_{CO} frequency in the IR spectrum of *(2)* compared to that of *(6)*:

ν_{CO} in cm^{-1} (hexane as solvent)

(6): 2054, 1989, 1979
(2): *(a)* 2054, 1996, 1992;
(b) 2024, 1980, 1964.
a = 2,3,4,6-*tetrahapto*-$Fe(CO)_3$
b = 7,8,9,10-*tetrahapto*-$Fe(CO)_3$

The CH skeleton of *(2)* was determined by ^{1}H-NMR analysis, including double resonance and tickling experiments, on the basis of the observed coupling pattern[13]. Since the relative positions of the resonance signals are strongly dependent upon the solvent the measurements were carried out both in CS_2 and in C_6H_6 solutions.

The protons H^2,H^3,H^4 form an allyl system whose chemical shifts[14] $H^2 = 5.15\,\tau$, $H^3 \approx H^4 = 5.4\,\tau$[15] correspond to those found in similar complexes[16]. H^2 is strongly coupled to H^1 = 6.13 τ ($J_{1,2} \approx 8.5$ Hz), and $H^{3,4}$ to $H^5 = 7.13\,\tau$. $H^{9,10} = 6.95\,\tau$

and H^1, H^5 give an AA'CX system ($J_{5,9}$ = 7.2 Hz; $J_{9,10}$ = 4.8 Hz; $J_{5,10} = J_{1,9} = -1.2$ Hz; $J_{1,5}$ = 2.4 Hz)[17]. The measured coupling constants $J_{6,7} = J_{7,8} = J_{1,8}$ = 7.5 Hz (H^7 = 6.68 τ, H^8 = 6.29 τ) are in good agreement with the values expected. $J_{5,6}$ = 11.5 Hz indicates a small dihedral angle between H^5 and H^6 and thus also a close proximity of C^6 and the allyl system. As expected, H^6 = 8.58 τ is strongly shielded by the metal.

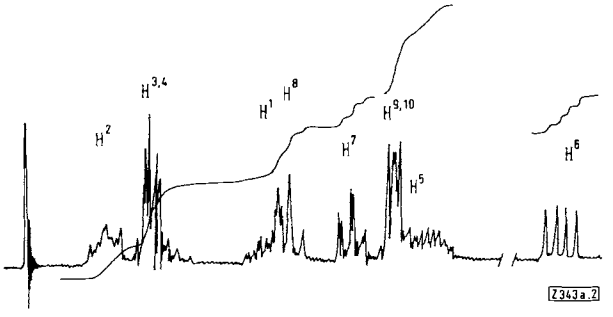

Fig. 2. ^{1}H-NMR spectrum of *(2)* in CS_2 solution; 100 MHz; CH_2Cl_2 = 4.70 τ as internal standard.

The enantiomers of the racemate formed on synthesis of *(2)* are configurationally stable on the NMR time scale.

A Stable Bis(tricarbonyliron) Complex of Tetracyclo[4.4.0.0^{5,7}.0^{2,10}]deca-3,8-diene and Its Dynamic Behavior in Solution[1]

By *Rudolf Aumann*[*]

Tetracyclo[4.4.0.0^{5,7}.0^{2,10}]deca-3,8-diene *(1)* has been postulated by *Schröder* as an intermediate in the thermally induced conversion of bullvalene *(2)* into naphthalene[2], and has recently been enriched to 40–50% in the photostationary mixture of hydrocarbons formed on low-temperature photolysis of *(2)*[3,4].

(2) *(1)* *(4)*

The present communication reports on a stable iron complex *(3)* derived from *(1)* by complex bonding of the two vinylcyclopropane partial structures[1]. Complex *(3)*, m. p. 172 °C, is formed in the thermal reaction of *(2)* with $Fe_2(CO)_9$ along with six isomeric compounds of composition $C_{10}H_{10}Fe_2(CO)_6$ and a compound $C_4H_4Fe_2(CO)_6$[1].

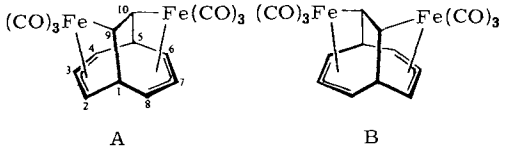

Fig. 1. The enantiomers A and B of compound *(3)*.

The CH skeleton of *(3)* was analyzed by ^{1}H-NMR employing double resonance and the usual calculations. Mössbauer measurements showed both iron atoms to have the same s-electron density at the nucleus (IS = 0.215 ± 0.003 mm/s) and the same field gradients (QS = 0.761 ± 0.003 mm/s)[6], thus establishing the identity of the chemical environments of both iron atoms.

As a result of the C_{2v} symmetry of the molecule, the NMR parameters of *(3)* show a pairwise equivalence: $H^4 = H^8$ = 5.29, $H^2 = H^6$ = 5.18, $H^3 = H^7$ = 5.66, $H^1 = H^5$ = 7.04, $H^9 = H^{10}$ = 8.08 τ[7]. H atoms 2,3,4 and 6,7,8 appear as a somewhat distorted allyl system in the ^{1}H-NMR spectrum recorded at 0 °C. Coupling constants $J_{2,3} = J_{6,7}$ = 8.0, $J_{3,4} = J_{7,8}$ = 7.0, $J_{1,2} = J_{5,6}$ = 7.0, and $J_{4,5} = J_{1,8}$ = 8.0 Hz, and the chemical shifts of the allyl protons in the NMR spectrum agree with the values found for similar iron complexes[1,5]. The

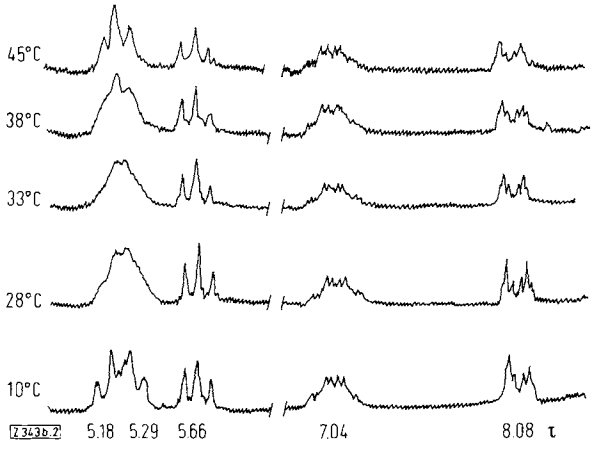

Fig. 2. ^{1}H-NMR spectrum of *(3)* at various temperatures (saturated solution in [D_2]methylene chloride; 100 MHz).

chemical-shift of $H^{9,10}$ can readily be explained for the given skeleton by assuming a coordination of C^9 and C^{10} to the metal, thus leading inevitably to the structure shown in Fig. 1.

The AA'XX' system formed by protons 9,10 and 1,5 was analyzed by computer. The strong vicinal coupling $J_{1,9} = J_{5,10} = 10$ Hz indicates a small dihedral angle between H^5 and H^{10}. Consideration of models clearly shows that this signifies spatial proximity of C^9 and $C^{2,3,4}$ and of C^{10} and $C^{6,7,8}$[8].

The ^{1}H-NMR spectrum of *(3)* recorded at 0 °C is a limiting spectrum since further lowering of the temperature causes no change in the shape of the signals. On warming, however, increasingly rapid exchange of the magnetic environments of $H^2 \rightleftharpoons H^4$ and $H^6 \rightleftharpoons H^8$ becomes evident from signal broadening. Above ≈ 45 °C these resonance signals are averaged (Fig. 2)[10].

This effect is tentatively interpreted as mutual interconversion of the enantiomers A and B (Fig. 1). Of all conceivable exchange processes, this would involve the minimum possible change in the relative spatial positions of all the atoms involved. Racemization entails inversion at C^9 and C^{10} (Fig. 1). The free energy of activation $\Delta G^{\neq}$ measured at the coalescence temperature in methylene chloride is 15.9 ± 0.5 kcal/mole[9]. A value of $\Delta G^{\neq} \approx 16$ kcal/mole was obtained for a similar racemization of a $C_{10}H_{10}$ skeleton attached to a $Fe_2(CO)_6$ group[5].

[6] The Mössbauer spectrum was kindly recorded by Dr. *B. Hentschel*, Münster.

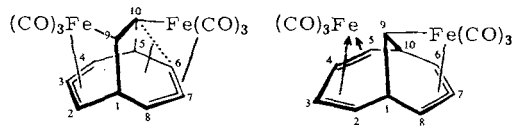
[7] Saturated solution of *(3)* in [D_2]methylene chloride; 100 MHz; reference signal CH_2Cl_2 = 4.70 τ.

[8] An X-ray structure analysis is currently being performed by Dr. *I. C. Paul*, Urbana, Ill.

[9] The calculation of errors is based on the assumption of an inaccuracy in the determination of the coalescence temperature of 33 ± 5 °C.

[10] An accidental overlap of signals due to the temperature shift was excluded by careful calibration of the temperature dependence of the chemical shifts.

Isobullvalenebis(tricarbonyliron)[1]



By *Rudolf Aumann*[*]

Isobullvalene *(1)* has recently been synthesized by *Masamune et al.*[2] and *Katz et al.*[3]. This communication reports on a metal complex *(4)* derived from *(1)* by complex bonding of the conjugated diene- and vinylcyclopropane units[4] to $Fe(CO)_3$ groups.

(1) *(2)*

(4), m.p. 123 °C, is formed quantitatively at 120 °C in the thermally induced skeletal rearrangement of a $Fe_2(CO)_6$ complex *(3)* of tetracyclo[4.4.0.0^{5,7}.0^{2,10}]deca-3,8-diene *(2)*[5].

(3) *(4)*

The CH skeleton of *(4)*, like that of the complex *(3)*, was determined from the ^{1}H-NMR spectrum. The coupling constants $J_{2,3} = J_{4,5} = 8.0$, $J_{3,4} = 5.0$ Hz calculated from the AA'XX' system of the protons 2,3,4,5 agree with the values expected for such a structure, as do $J_{1,2} = J_{5,10} = 8.0$ Hz[6]. The arithmetic mean $\bar{H} = 5.59$ τ of the chemical shifts[7] of $H^{3,4} = 4.80$ τ and $H^{2,5} = 6.38$ τ corresponds to the arithmetic mean of the chemical shifts of the allyl protons $H^{6,7,8} \approx 5.6$ τ[8]. As expected, $H^9 = 9.19$ τ is strongly shielded by the metal. The chemical shift of the bridgehead protons $H^{1,10} = 7.19$ τ do not differ appreciably from the value observed in the case of *(3)*[4].

Confirmatory evidence for structure *(4)* comes from the long-range coupling of H^6 and H^8 to H^9 ($J_{6,9} = J_{8,9} = 1.4$ Hz) and the absence of any such coupling of H^2 and H^5 to H^9 in the ^{1}H-NMR spectrum, as well as from the mass spectrum and elemental analysis.

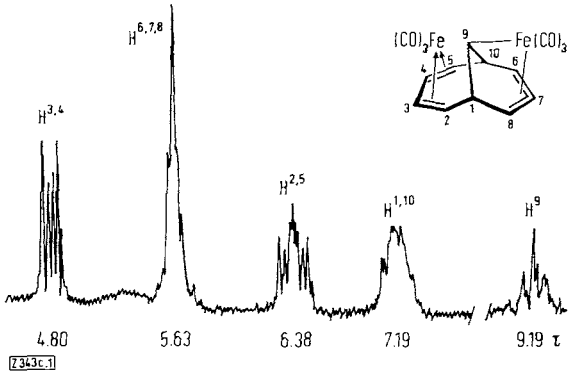


Fig. ^{1}H-NMR spectrum of *(4)*. Solution in $CHCl_3$; TMS as internal standard; 100 MHz.

Isomerization of *(3)* to *(4)* proceeds by way of a 1,2-rearrangement of the carbon skeleton, in which one of the two seven-membered rings is transformed into a six-membered ring that is coordinated to a $Fe(CO)_3$ group *via* the π-allyl system $C^{6,7,8}$ and a two-center bond (from C^9). No further 1,2-rearrangement to give a bond between C^2 and C^9, thus affording the known compound 9,10-dihydronaphthalene-[$Fe(CO)_3$]$_2$ *(5)*[9], was

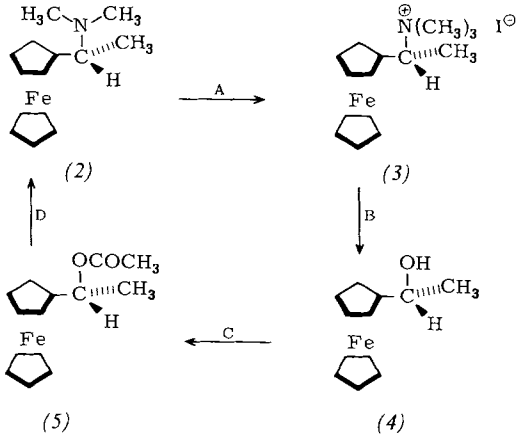
The Retentive Nucleophilic Substitution of (*R*)-α-Ferrocenylethyl Acetate

By *George W. Gokel* and *Ivar K. Ugi*[*]

It is well known that reactions of esters with nucleophiles proceed *via* an additive attack of the nucleophile on the ester carbonyl followed by elimination of the alkoxide moiety[1], leading to cleavage of the acyl-alkoxy bond. Recently, *Richards et al.*[2] demonstrated that ethanolysis of α-ferrocenylethyl acetate afforded 1-ethoxy-1-ferrocenylethane and acetic acid. This result indicates that the reaction proceeds by a mechanism other than that already known.

Our interest in the α-ferrocenylethyl system arises from its potential as a model system of optically active amine components for stereoselective four component syntheses of peptides[3]. This synthesis necessitates cleavage of the auxiliary group introduced by the amine component from the four component condensation product such that the chiral amine can be regenerated in its original configuration. The stereochemical integrity of the α-ferrocenylethylcarbonium ion[4] prompted the investigation reported here.

Since α-ferrocenylethyl compounds *(1)* with a strong leaving

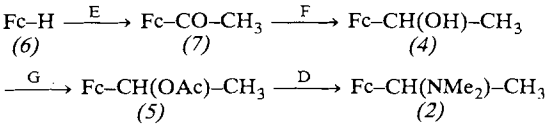


(1)

group, for example, X = Cl[5], have a pronounced tendency to eliminate HX leaving vinyl ferrocene, we attempted to find a suitable group, X, such that the transformation

(1), X = OH → *(1)*, X = NH_2

proceeds in good yield and is easy to carry out. We found that the reaction cycle A→D proceeds in good chemical yield at all stages and with complete configurational retention throughout the cycle.



(2): Preparation and resolution [6]: $[\alpha]_D^{25} = +14.1°$ (*c* = 1.5, ethanol); after reaction cycle: $[\alpha]_D^{25.2} = +14.0°$ (*c* = 2.3, ethanol).
(3): $[\alpha]_D^{24.2} = +40.8°$ (*c* = 1.2, methyl cellosolve) [5].
(4): $[\alpha]_D^{25} = -28.9°$ (*c* = 1.7, benzene).
(5): $[\alpha]_D^{25.4} = -27.1°$ (*c* = 1.4, ethanol).

A: Ref. [9]; B: Stir in 1:1 aqueous acetonitrile at *ca.* 20 °C for 15 hours [7] yield = 90%; C: Ref. [8]; D: Stir at *ca.* 20 °C with five equivalents of dimethylamine for 15–20 hours in aqueous methanol, yield = 84%.

The transformation *(4)*→*(5)*→*(3)* is also important for the synthesis of *(2)*, a key compound in the stereochemistry of ferrocene derivatives. To our knowledge, *(2)* is the only known ferrocene derivative whose racemate gives both antipodes in good yield, and which can be transformed with a high degree of stereoselectivity into ferrocene derivatives with a plane of chirality.

The substitution of the acetate by a dimethylamino group proceeds in excellent yield and provides for the synthesis of *(2)* from *(4)* by an alternative to the phosgene method[6].

Fc = $C_{10}H_9Fe$–; E: Acetyl chloride, aluminum chloride in dichloromethane for 2 hours at 0 °C [9], yield = 95%; F: Sodium bismethoxyethoxy aluminate [10] in benzene (1 M) for 1 hour, yield = 90%, G: boil with 5 equiv. acetic acid in benzene for 3 hours, yield = 96%

The replacement of the acetoxy group in *(5)* by ammonia proceeds in only 45% yield.

Pertinent experiments with other easily prepared esters of α-ferrocenylethanol are in progress.

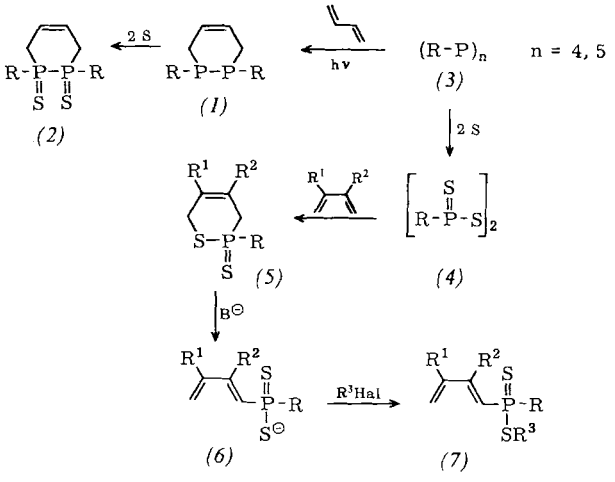
Cycloadditions of Phosphonodithioic Anhydrides; Formation of Dienephosphinodithioic Acids



By *Alfred Ecker, Immo Boie*, and *Ulrich Schmidt*[*]

In connection with our studies of the photochemical reaction between cyclophosphines and dienes[1,2] we have treated the reaction product with sulfur in order to characterize the resulting 3,6-dihydro-1,2-diphosphorins *(1)* as stable disulfides *(2)*. In so doing we found that unreacted cyclophosphine *(3)* forms a phosphonodithioic anhydride *(4)* that adds to an excess of diene to give the six-membered heterocyclic compound *(5)* in a reaction that proved to be almost universally applicable. To carry

out the addition, the dithioic anhydride (which is usually readily accessible from phosphonothioic dichloride and H_2S[3]) is heated for several hours with an excess of the diene in an autoclave at about 100 °C.

The structures of the adducts were deduced from their NMR spectra. *(5f)* in CCl_4: multiplet at δ 1.89 (3H), doublets (J = 13 Hz) at δ 1.99 (3H) and 2.80 (2H), a doublet with fine structure at δ 3.54 (2H), and a multiplet at δ 5.86 (1H). The absence of γ-coupling with the phosphorus indicates that the methyl group is in position 5. Coupling of this kind is observed for 4-methyl groups, *e.g.* in *(5c)* and *(5j)*.

On reaction with strong bases in aprotic solvents (*e.g.* NaH in diglyme) initial metalation is followed by ring cleavage to give the dienephosphinodithioic acids *(6)* which react *in situ* with alkyl halides to give the esters *(7)*.

(5)	R	R^1	R^2	Yield (%)	M.p. (°C)	B.p. (°C/torr)
(a)	Phenyl	H	H	65	70	
(b)	Phenyl	H	CH_3	88	33	
(c)	Phenyl	CH_3	CH_3	90	62

(k)	Isobutyl	H	H	97		135/0.4
(l)	Isobutyl	CH_3	CH_3	53		144/0.4

Synthesis of (5j):

Thiophene-2-phosphonodithioic anhydride[4] (30 g) and 2,3-dimethylbutadiene (50 ml) are heated together for 2 h at 100 °C in an autoclave. The product crystallizes on cooling of the reaction mixture. Recrystallization from ethyl acetate affords colorless crystals (36 g) having m.p. 85 °C.

Cleavage of (5j) with NaH and esterification of the butadiene-phosphinodithioic acid (6j):

Compound *(5j)* (5.2 g) and NaH (0.5 g) are stirred for 2 h at 75 °C in anhydrous 1,2-dimethoxyethane (60 ml). *p*-Nitrobenzyl bromide (4 g) in ether (50 ml) is then added to the reaction mixture and the resulting NaBr is filtered off immediately. The solution is evaporated down to a volume of 20 ml and the product filtered off with suction after standing for several days. Recrystallization from ether furnishes 3.8 g of *p*-nitrobenzyl-*P*-(2,3-dimethylbutadienyl)-*P*-(2-thienyl)phosphinodithioate *(7j)*.

ESR Investigations of an Oscillating Redox System[**]

By *Horst Frühbeis* and *Albert Röder*[*]

Periodic processes play an important role in biological systems[1]. In addition to oscillating enzymatic systems[2], several purely chemical systems have been described which oscillate in an homogeneous medium[3]. One of these – the oxidation of malic acid by bromate in acid medium, which is catalyzed by Mn^{2+} ions and occurs in a limited concentration range as an oscillating redox system[3] – was chosen by us as a model reaction on the following grounds:

1. Despite the unphysiological pH range (see below) and oxidation pool (bromate) two important biochemicals are involved (malic acid and Mn^{2+}).

2. In ESR spectroscopy we had a "probe" at hand for specific measurement of the concentration of the Mn^{2+} catalyst. Its characteristic six-line spectrum is not influenced under the conditions of the oscillating mixture, either by malic acid and bromate concentration or by the concentration of H^+ ions.

3. We found (Fig. 1) that the catalyst participates in the oscillation.

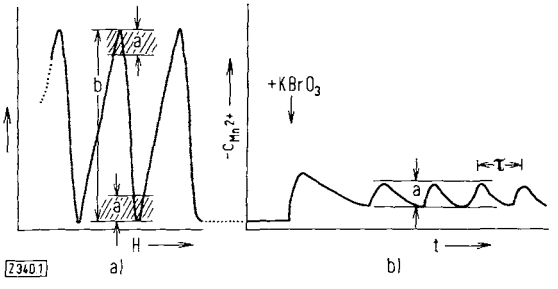

Fig. 1. Calculation of the oscillating portion of the Mn^{2+} ions (b = 100%, $2a$ = 25%). a) Derivation of the intensity of the ESR absorption line as a function of the magnetic field, b) concentration of Mn^{2+} as a function of time (magnetic field constant). Mixture: 20ml 10^{-2}M $MnSO_4$ in 2N H_2SO_4, 50ml 2N H_2SO_4, 40ml 1M malic acid and 40ml 0.25M aqueous $KBrO_3$ solution (see arrow). Varian x band spectrometer, Mod. 125, Amp. 1000, H_0 3155 gauss, rate of pen recorder 12.4 cm/min.

Measurements were carried out at the maximum (or minimum) of one of the six absorption lines of Mn^{2+} (Fig. 1a) at constant field; the Mn^{2+} concentration was recorded as a function of time (Fig. 1b). The reaction mixture was mixed outside the cuvet through which it was subsequently pumped by means of an all-teflon pump.

With this arrangement we were able to record the initial phase of the oscillation (Fig. 1b). It can be seen from the same figure that maximally about 25% of the Mn^{2+} ions occur in a higher oxidation state at the concentrations of the redox pool quoted. The length of the period τ is influenced by various reaction mixture parameters, the hydrogen ion concentration playing a significant role. The period is short at high H^+ ion concentration and long at low H^+ ion concentration. Under the experimental

conditions quoted below it varies between *ca.* 30 sec (on addition of 20 ml 8N H_2SO_4) and 10 minutes (on addition of 20 ml 1N H_2SO_4).

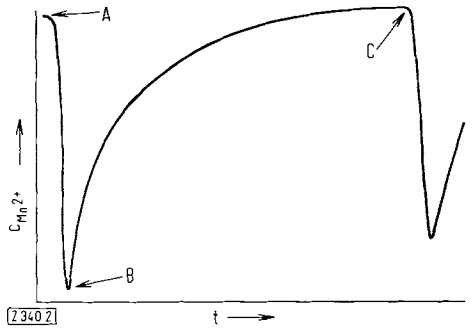

Fig. 2. Typical oscillation period of the bromate-manganese-malic acid oscillator. Mixture: 10ml 10^{-2}M aqueous $MnSO_4$ solution, 20ml 1N H_2SO_4, and 20ml 1M aqueous malic acid solution are mixed. The oscillation starts a little time after addition of 10ml of a 0.25M aqueous bromate solution. Mod. 250, Amp. 1000, H_0 *ca.* 3100 gauss.

We assume that the following reactions take place during a period of oscillation of the bromate – manganese – malic acid oscillator (Fig. 2, A→B→C):

1) A→B: Obviously the concentration of Mn^{2+} ions decreases, for they are oxidized by the bromate to an ESR-inactive oxidation state. The color of the solution (yellow to brown) indicates the presence of Mn^{3+} ions[4]. Reaction (1) probably dominates in this part of the oscillation period.

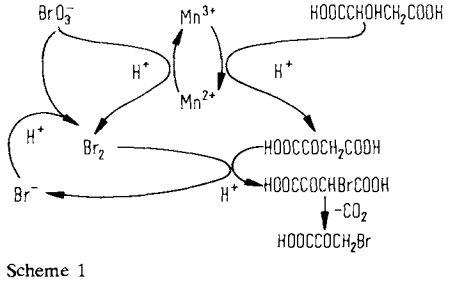
$$5\ Mn^{2+} + BrO_3^- + 6\ H^+ \rightleftharpoons 5\ Mn^{3+} + 1/2\ Br_2 + 3\ H_2O \quad (1)$$

2) B→C: The concentration of Mn^{2+} increases again, the Mn^{3+} formed by reaction (1) converting the malic acid to oxaloacetic acid in analogy with the oxidation of secondary alcohols[5]. Reaction (2) predominates.

$$2\ Mn^{3+} + HOOCCHOHCH_2COOH \rightleftharpoons 2\ Mn^{2+} + HOOCCOCH_2COOH + 2\ H^+ \quad (2)$$

The oxaloacetic acid formed according to Eq. (2), unlike malic acid, now reacts very rapidly with Br_2.

$$HOOCCOCH_2COOH + Br_2 \rightleftharpoons HOOCCOCHBrCOOH + H^+ + Br^- \quad (3)$$



The bromide formed in Eq. (3) is oxidized by bromate to bromine, which once again can undergo reaction according to Eq. (3).

$$BrO_3^- + 5\ Br^- + 6\ H^+ \rightleftharpoons 3\ Br_2 + 3\ H_2O \quad (4)$$

In strong acid medium (> 3N H_2SO_4) vigorous liberation of CO_2 was seen to take place after a short while; we explain this as being due to decarboxylation of the brominated oxaloacetic acid.

$$HOOCCOCHBrCOOH \xrightarrow{-CO_2} HOOCCOCH_2Br \quad (5)$$

The partial reactions (1) to (5) are grouped together in Scheme 1

Scheme 1

In analogous oscillating systems[3c, 3d] bromide occurs as inhibitor. This is also the case in the present system. After addition of bromate the oscillation starts once again. Conversely, the oxidation of Mn^{2+} is renewed by precipitation of the bromide with silver nitrate. After addition of silver nitrate the concentration of Mn^{2+} very rapidly reaches the minimum value. On addition of a larger amount of silver nitrate the corresponding maximum concentration of Mn^{3+} remains constant until the oscillation is renewed with an unchanged period after consumption of the Ag^+ ions.

The occurrence of oscillation in the system under consideration can be explained in the following way: After the components have been added together reactions (1), (2), and (3) start successively, the bromide formed in reaction (3) having an inhibiting effect on reaction (1). A noticeable inhibition of reaction (1) could be achieved at time B in Fig. 2. The Mn^{3+} present at time B is reduced according to Eq. 2 (B→C). The bromide is oxidized according to Eq. 4 to bromine, which once again reacts in Eq. 3, the overall effect corresponding to consumption of bromide. If the concentration of bromide reaches a sufficiently low value, reaction (1) is renewed and a new cycle begins. Thus a negative feedback by bromide ions occurs. As *Higgins*[6] and *Sel'kov*[7] have shown from mathematical models (system of ordinary first order differential equations), oscillations can occur under special conditions in a reaction system where feedback is present.

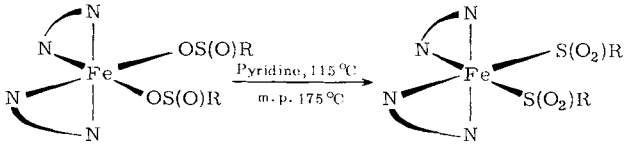
Bond Isomerism in Sulfinato Complexes of Transition Metals

By *Ekkehard Lindner, Ingo-Peter Lorenz,* and *Günter Vitzthum*[*]

We were recently able to show that sulfinato complexes are particularly suitable as model compounds for the detection of various phenomena of isomerism[1]. In a study of Fe^{II} complexes of this kind we have now observed the first example of a true bond isomerism of the ambivalent RSO_2^- ligand.

The reaction between $Fe(O_2SR)_2(OH_2)_2$ *(1)*[2] and 2,2'-bipyridine (= bipy) shows a marked dependence on the solvent: In tetrahydrofuran the reactants give exclusively $Fe(O_2SR)_2$bipy *(2)*[3]; in pyridine $Fe(O_2SR)_2(bipy)_2$ *(3)* is obtained; and in water the ionic compound $[Fe(bipy)_3](O_2SR)_2$ *(4)* is formed quantitatively.



$$(1) \xrightarrow{bipy} (2) \underset{-bipy}{\overset{+bipy}{\rightleftharpoons}} (3) \underset{-bipy}{\overset{+bipy}{\rightleftharpoons}} (4)$$

Sulfinato-*O,O'* Sulfinato-*O,O'* *(a)*, Sulfinato-*O*
(b), Sulfinato-*S*

R = p-$CH_3C_6H_4$

(3) is formed in pyridine at 115 °C as the sulfinato-*S* complex (yield 15%). If *(4)* is treated with boiling, anhydrous acetone under nitrogen in an extraction thimble with sintered disk until the acetone remains colorless (*ca.* 1 h), black-violet $Fe(OS(O)R)_2(bipy)_2$ *(3a)* remains on the disk in 93% yield, while the filtrate contains a 7% yield of the deep red bond isomer $Fe(S(O_2)R)_2(bipy)_2$ *(3b)*. Prolonged extraction results in reversible formation of paramagnetic blue *(2)*.

When heated to 115 °C in pyridine or to its melting point (175 °C), *(3a)* is converted irreversibly into the thermodynamically more stable *(3b)*, m.p. 75 °C.

(3a) *(3b)*

Composition and structure of *(3a)* and *(3b)* can be deduced from elemental analysis and IR and Mössbauer spectra. Evidence for the *O*- and *S*-linkage in these complexes is provided in particular by the position of the SO_2 stretching mode (cf. Table)[4].

Table. SO_2, Fe–O, and Fe–S stretching vibrations (in cm^{-1}) of the complexes *(3a)* and *(3b)*.

(3a)	*(3b)*
1054 vs ν(SO)	1219 vs } $\nu_{as}(SO_2)$
918 vs ν_{as}(SOFe)	1199 vs }
	1034 m } $\nu_s(SO_2)$
	1012 m }
448 m } ν(Fe–O)	368 w-m } ν(Fe–S)
354 m }	290 w-m }

The frequency splitting of ν_{as} and ν_s (SO_2) observed in the case of *(3b)* indicates *cis* bonding of the sulfinato ligand. The Mössbauer spectra show a quintet ground state for *(3a)* (normal magnetic behavior) and a singlet or triplet ground state for *(3b)* (anomalous magnetic behavior). Only a limited number of cases of true bond isomerism were hitherto known, *e.g.* in thio- and seleno-cyanato and nitrito complexes.

Tungsten Carbide as Anode Material for Fuel Cells

By *Detlef Baresel, Winfried Gellert, Jürgen Heidemeyer*, and *Peter Scharner*[*]

Pohl and co-workers[1] found that tungsten carbide (WC) is an excellent catalyst for the electrochemical oxidation of hydrogen in acid medium. *Sandstede et al.*[2] were able to carry out oxidations of formaldehyde, acetaldehyde, formic acid, hydrazine, and carbon monoxide on WC, but only at low current densities.

Instead of using powdered tungsten metal as starting material for the preparation of WC we used tungsten oxide, which was allowed to react with gaseous carbon-containing compounds, *e.g.* hydrocarbons (C_nH_{2n}, C_nH_{2n+2}) or carbon monoxide (CO). The tungsten oxide which was precipitated from aqueous solution had a large surface area and a high surface activity; it was mixed with powdered oxalic acid, pressed into the desired form, and finally carburized into WC electrodes within 2 to 8 h at temperatures below 750 °C. No support was necessary for the preparation of electrodes having diameters up to 25 mm; however, on increasing the surface area (>10 cm^2) and reducing the thickness (<1mm) the electrodes had to be fitted with a tungsten filament support. For the preparation of permeable electrodes, porous carbon disks were used into which powdered WC (as a suspension in acetone) could be easily deposited. The activity of the electrodes was determined at 70 °C in 3N sulfuric acid in a half cell arrangement by potentiostatic measurement of the current at 300 mV. An autogeneous hydrogen electrode was used as reference point and a carbon rod as counter electrode. The concentration of formaldehyde or formic acid was 6 mole/liter. Hydrogen was passed through the electrode at a pressure of 0.2 at. For all electrodes, the corrosion current (including any possible oxygen-reducing current) was determined in absence of fuel and subtracted from the current measured in the presence of fuel. The differences are quoted as "activity current".

Current densities achieved so far (recorded after 3 hours):

for hydrogen 500 mA/g
for formaldehyde 650 mA/g or 280 mA/cm^2
for formic acid 160 mA/g or 60 mA/cm^2

The current density for hydrogen cannot be quoted in mA/cm^2 because of the electrode construction.

The stationary potentiostatic current-voltage curves for WC electrodes and Raney platinum electrodes of the same size are compared in Fig. 1. It can be seen from the curves that WC is superior to Raney platinum for oxidation of formaldehyde in sulfuric acid in the potential ranges that come into consideration for fuel cell anodes. Appreciable conversion also occurs in the case of formic acid, which can be formed as an intermediate in the oxidation of formaldehyde or methanol.

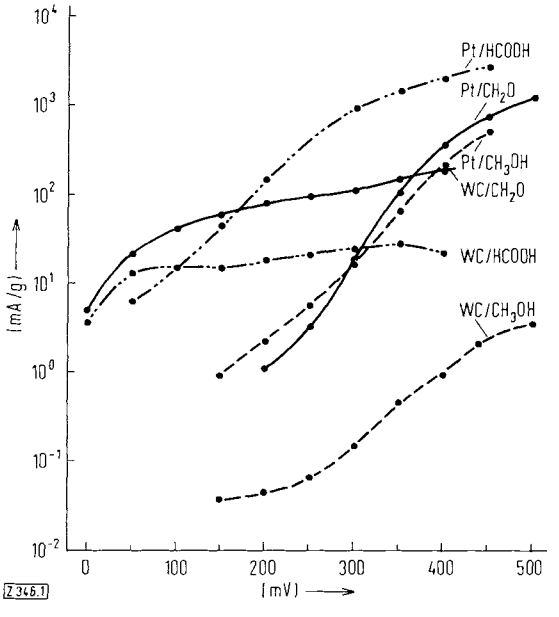

Fig. 1. Electrochemical oxidation of 6M CH_3OH, CH_2O, and HCO_2H on Raney platinum (Pt) and tungsten carbide (WC).

The internal surface areas of the electrodes were between 20 and 30 m^2/g and were determined by a dynamic BET method[3] before and after the electrochemical measurements. The current strengths were considered constant if their values varied by less than 3% over a period of 5 hours.

By using a slightly different technique for the fabrication of electrodes and the same method of preparation of WC much thinner electrodes (*ca.* 0.2 mm) can be prepared having a large surface area and almost the same activity.

Chromium as Catalyst in Ammonia Synthesis

By *Rudolf Brill, Johannes Kurzidim*, and *Ernst Ruch*[*]

Brill, Richter, and *Ruch*[1] were able to show that a) strong interaction occurs between N_2 and the (111) face of iron, and b) the action of metallic iron as NH_3 catalyst is due to the adsorption of N_2 molecules oriented perpendicular to the (111) face where a weakening of the N≡N bond, arising from overlapping of occupied π orbitals of N_2 with vacant surface orbitals of iron, permits reaction of the molecule with hydrogen. If this concept is correct, other transition metals having the same atomic symmetry and similar interatomic distances as the (111) face of iron should also be catalytically active. These conditions are fulfilled by the (111) face of chromium metal. The correctness of this prognosis has now been confirmed experimentally. The catalyst was prepared by decomposition of dibenzenechromium. Experimental results on a Cr surface of approximately 30 cm^2 are shown in the Table:

Table. NH_3 synthesis: catalyst Cr; T = 436.5 °C.

t	$x \times 10^2$	$k \times 10^3$
0.334	1.63	1.0
0.200	1.38	1.2
0.132	1.01	1.1
0.101	0.87_2	1.1

t = contact time (s); $x = p_{NH_3}/p_{NH_3(\text{equilibrium})}$; k = rate constant.

The rate constants of NH_3 formation for a given surface area are of the same order of magnitude as for iron. This confirms the mechanism of NH_3 synthesis derived from another series of experiments[2], according to which the initial product is N_2H; further hydrogenation and eventual dissociation yields NH_3.

Generalization of the Isosbestic Point

By *Ch. Chylewski*[*]

A simple graphical representation of spectrophotometric data permits similar conclusions to be drawn as the occurrence of isosbestic points while allowing freedom of choice of the wavelength.

The widespread view that the occurrence of isosbestic points (points of constant extinction) in families of absorption spectra proves the presence of only two absorbing components in the chemical system under study is erroneous[1]. *Schläfer* and *Kling*[2] have demonstrated the correct conditions: Isosbestic points indicate that the changes in concentration of all absorbing components are related *linearly* when one parameter such as pH, time, or temperature is varied. The linearity follows from the stoichiometry if the concentrations of all absorbing components are connected by a *single* reaction equation. Kinetically this means that the reaction has only *one* rate-determining step and the respective rate law can be expressed as a single first-order differential equation. Isosbestic points provide no information about the number of participating substances. Further reasoning assumes the validity of Beer's law. Moreover, all absorbing substances should exhibit linearly independent spectra, a condition that is not always satisfied in practice.

The wavelengths at which isosbestic points occur, if at all, depend upon the absorption spectra of the participating substances and are not known in advance in the case of a new reaction. They are therefore found by recording the absorption spectra over a whole range of wavelengths in the hope that at least one of the points sought is found within this interval. This restricts the application of the method to the study of slow reactions. In addition, isosbestic points sometimes lie in spectral regions in which measurements are inaccurate or even impossible with the equipment available, or in which traces of impurities or side reactions have a pronounced effect. Finally there is still a general lack of equipment for the direct superposition of spectra in such a manner that the isosbestic points are readily recognized; copying operations lead to a loss in accuracy and waste time.

To prove: The extinction of a system is measured at two wavelengths λ_1 and λ_2 and the measured values plotted against each other in a system of Cartesian coordinates. There results a point whose position depends upon the concentrations of all components absorbing at these wavelengths. If a parameter that affects the concentrations is varied continuously, this point moves on a *straight line* under the same condition for which isosbestic points occur.

Proof: The reaction equation is taken to be:

$$a_1A_1 + a_2A_2 + \ldots \rightarrow a_iA_i + a_{i+1}A_{i+1} + \ldots \quad (1)$$

where a_i are stoichiometric reaction coefficients, A_i are the species participating in the reaction (the subscript has a mathematical rather than a chemical significance). The concentration of species A_i is c_i, and the initial concentration is c_i^0. If the coefficients on the left hand side of equation (1) are regarded as being negative and a reaction variable X is introduced[3], the following equation applies throughout the reaction:

$$c_i = c_i^0 + a_iX \quad (2)$$

ε_i is the extinction coefficient for species A_i as measured for a sample of 1 cm thickness. If Beer's law is valid, the extinction of the whole system at any wavelength is given by

$$E = \sum_i \varepsilon_i c_i = \sum_i \varepsilon_i c_i^0 + X \sum_i \varepsilon_i a_i \qquad (3)$$

Substances whose concentration remains constant throughout the reaction (*e.g.* the solvent) can be accounted for formally by assignment of a reaction coefficient of zero.

E and ε_i depend upon the wavelength. They have the values E_1 and $\varepsilon_{i,1}$ and E_2 and $\varepsilon_{i,2}$ at the wavelengths λ_1 and λ_2 respectively:

$$\begin{aligned} E_1 &= \sum_i \varepsilon_{i,1} c_i^0 + X \sum_i \varepsilon_{i,1} a_i \\ E_2 &= \sum_i \varepsilon_{i,2} c_i^0 + X \sum_i \varepsilon_{i,2} a_i \end{aligned} \qquad (4)$$

Eq. (4) is the parametric representation of a straight line from which X can be eliminated:

$$E_1 = \frac{(E_2 - \sum_i \varepsilon_{i,2} c_i^0) \sum_i \varepsilon_{i,1} a_i}{\sum_i \varepsilon_{i,2} a_i} + \sum_i \varepsilon_{i,1} c_i^0 \qquad (5)$$

Thus it is established that E_1 and E_2 are connected by a linear relation.

In practice the converse of this proof is more important, *i.e.* deduction of the number of reaction variables from the linearity of the observed function. The converse applies when the slope of the line is negative. Provided that the spectra are continuous, this slope is a continuous function of λ_1 and λ_2. If, *e.g.*, λ_1 approaches λ_2, the slope assumes all values between a negative amount and one, and must therefore be zero at one wavelength at least. However, a straight line of zero slope corresponds to an isosbestic point whose existence is thus proved indirectly.

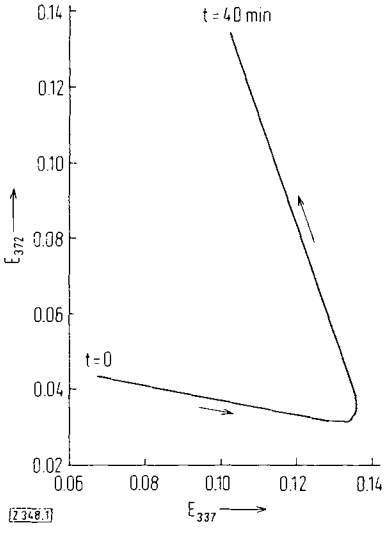

Fig. Example of a reaction that proceeds in two stages, each having one rate-determining reaction step (reduction of methyl orange by 1,2-dihydro-2,3-dimethylquinoxaline in excess at pH 0).

If the line observed has a positive slope, this suggests, but does not prove, that the reaction has only one reaction variable. The line is particularly uninformative if its extrapolation passes close to or through the origin. In such a case it is highly probable that it is mainly the same species that is absorbing at both the wavelengths chosen. A straight line then clearly results purely on the basis of Beer's law, independently of the stoichiometry of the reaction.

Measuring technique and applications: When the parameter to be varied is not the time, the successive measurement at two wavelengths gives rise to no difficulties. On the other hand, four possible methods are available for a kinetic study:

a) Simultaneous extinction measurements at two wavelengths. Suitable spectrophotometers are commercially available.

b) Alternate measurements at two wavelengths with interpolation of the missing values. This method has proved very effective in our laboratory. About 10 alternations are sufficient for the half-life of a reaction. With a Beckman DB–G instrument it is possible to switch over once every second provided that the two wavelengths are not too far apart. The interpolation can be carried out graphically or numerically.

c) Stopping the reaction. This method is of greatest interest for photochemical reactions where samples can be taken at regular intervals from the irradiation vessel, the reaction being interrupted in the samples themselves.

d) Repetition of the reaction. The extinction is first measured at one wavelength, and then at a second wavelength for a reaction mixture that is as similar as possible to the first. This is not recommended in the case of slow reactions since kinetic data are often not very accurately reproducible and poorer results are obtained than with method b) for double the experimental effort. We have successfully employed the technique for fast reactions which can be reproduced several times in a short period and for which it is impossible to switch over the monochromator.

Kinetic Spectrophotometry of Relaxation Systems Containing 7,8-Polyphenyl-Substituted *o*-Quinodimethane Derivatives[1]

By *Karl-Heinz Grellmann, Joachim Palmowski,* and *Gerhard Quinkert*[*]

o-Quinodimethanes have only a young history as experimentally confirmed intermediates. Kinetic[2] and stereochemical[3] investigations require, and low temperature ($< -180\,°C$) electronic spectra[4,5] establish, their part as kinetically unstable seco isomers of benzocyclobutenes of the appropriate constitution and configuration. Results of flash photolysis experiments at temperatures between -53 and $23\,°C$[6] provide information about other modes of formation, lifetimes, and reactions of these species.

(1) (2) (3) (4) (5) (6) (7) (8) (9) (10)

Thermal cyclization of 7,7,8,8-tetraphenyl-*o*-quinodimethane affords, depending on the temperature used, the cyclo isomers *(1)* or *(3)*, which have been interpreted as being the thermodynamically or kinetically determined products, respectively[4]. Flash photolysis of *(1)* and *(3)* (Fig. 1) reveals the presence of the common intermediate *(2)*; *(2)* rapidly cyclizes to *(3)* [$\tau = 3.6 \times 10^{-5}$ s at 23 °C; Arrhenius activation parameters: E = 15.3 kcal/mole, $A = 3.2 \times 10^{15}$ s^{-1} (measured between −53 and 23 °C)], while the formation of *(1)* from *(3)* is relatively slow.

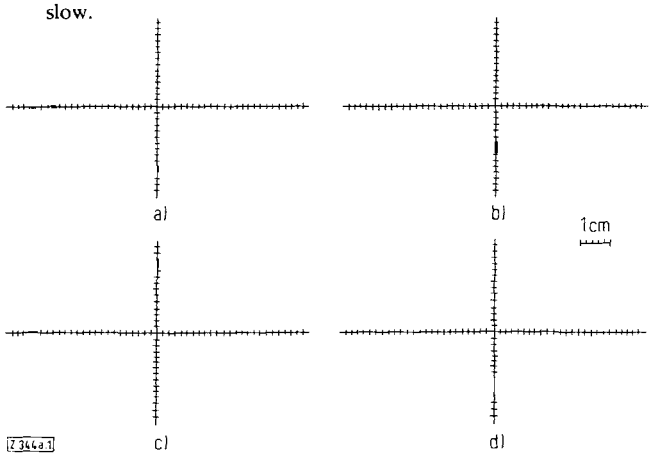

Fig. 1. Oscilloscopic traces after flashing a 1.66×10^{-5} M solution of *(1)* in methylcyclohexane [7a].

a) (T = 23 °C; t = 0.5 ms/cm; λ = 450 nm; S = 1.0 V/cm): The primary product *(2)* formed by light-induced cyclo/seco isomerization, which, unlike the reactant *(1)* absorbs at 450 nm [4], decays in a thermally induced first order seco/cyclo isomerization to give the secondary product *(3)* ($k_{(2)\rightarrow(3)} = 2.8 \times 10^4 s^{-1}$) which does not absorb above 300 nm [4].

b) (T = 23 °C, t = 0.05 ms/cm; λ = 400 nm; S = 5.0 V/cm): Light induced cyclo/seco isomerization of the reactant *(1)* leads to the primary product *(2)* which absorbs weaker at 400 nm and which undergoes a thermally induced first-order seco/cyclo isomerization to give *(3)* ($k_{(2)\rightarrow(3)} = 2.8 \times 10^4$ s^{-1}).

c) (T = 23 °C, t = 1000 ms/cm; λ = 400 nm, S = 0.5 V/cm): The secondary product *(3)* is completely reconverted in a two-stage first order reaction *via (2)* into the original reactant *(1)*; $k_{(3)\rightarrow(1)} = 0.385$ s^{-1}.

d) (T = −35 °C; t = ms/cm; λ = 400 nm; S = 0.5 V/cm): Compound *(3)* prepared from *(1)* by irradiation is kinetically unstable at room temperature [4] and is converted in a light-induced cyclo/seco isomerization into *(2)* which absorbs at 400 nm and shows the same spectral data [7b] as the primary product formed from *(1)* by light-induced cyclo/seco isomerization, and which regenerates *(3)* in a thermally induced first-order seco/cyclo isomerization ($k_{(2)\rightarrow(3)} = 57$ s^{-1}).

According to their electronic absorption spectra the light-induced ring opening of the configurationally isomeric benzocyclobutene derivatives *(4)* and *(5)* (with 254-nm light) at −189 °C proceeds non-stereospecifically, although stereoselectively[5]. All three configurationally isomeric *o*-quinodimethane derivatives *(6)*, *(7)*, and *(8)* participate in the reaction[8]; their relative proportions depend on the viscosity of the medium. Flash photolysis of *(4)* and *(5)* at 21.6 °C (Fig. 2) reveals three distinct decay processes. A comparison of the absorption spectra of those *o*-quinodimethanes[9] obtained either directly using low-temperature techniques at −186 °C or by point by point scanning at 21.6 °C using kinetic spectrophotometry indicates that *(6)* (τ = 19 ms; E = 15 kcal/mole) and *(7)* (τ = 690 ms; E = 17 kcal/mole) cyclize to the benzocyclobutenes *(5)* and *(4)*[5] in order of their decreasing rates; at 21.6 °C *(6)* and *(7)* are formed from *(4)* or *(5)* in 13 and 87% or 26 and 74% yield, respectively[10].

Electronic spectroscopic control experiments show[13] that the *o*-quinodimethane derivatives *(6)* and *(7)* also occur in the photodecarbonylation of the configurationally isomeric 2-indanone derivatives *(9)* and *(10)*[12] at −189 °C. According to flash photolysis experiments, the same is true for the light-induced CO elimination at 21.6 °C; *(6)* and *(7)* are formed from *(9)* or *(10)* in the ratios of 54:46 or 47:53 respectively[10] (Fig. 3).

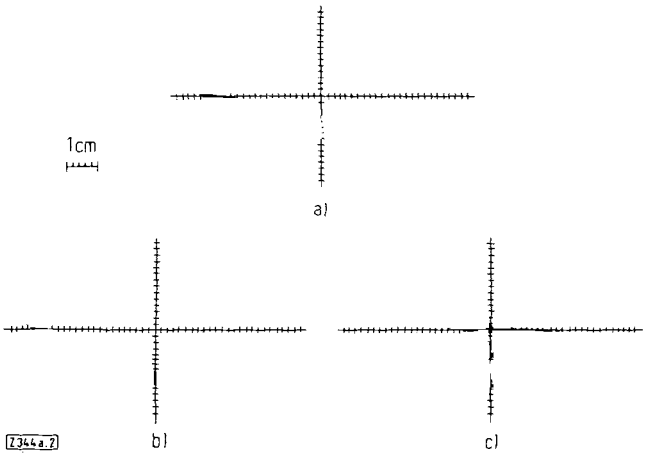

Fig. 2. Oscilloscope traces after flashing a 2.67×10^{-4} M solution of *(5)* in methylcyclohexane at 21.6 °C [7a].

a) (t = 10 ms/cm; λ = 440 nm; S = 1.0 V/cm): Light-induced cyclo/seco isomerization of *(5)* [11a] leads to formation of *(6)* which rapidly undergoes first order decay (k = 52.5 s^{-1}) [11b].

b) (t = 500 ms/cm; λ = 440 nm, S ≈ 0.5 V/cm): Compound *(7)*, which also decays with first order reaction kinetics, but slower (k = 1.5 s^{-1}) than *(6)*, is also formed [11b].

c) (t = 500 ms/cm; λ = 250 nm; S ≈ 0.5 V/cm): A third decay process of minor importance takes place which again proceeds *via* a first order reaction: the species formed, which cannot be detected by flash spectroscopy, has a halflife of about 20 s.

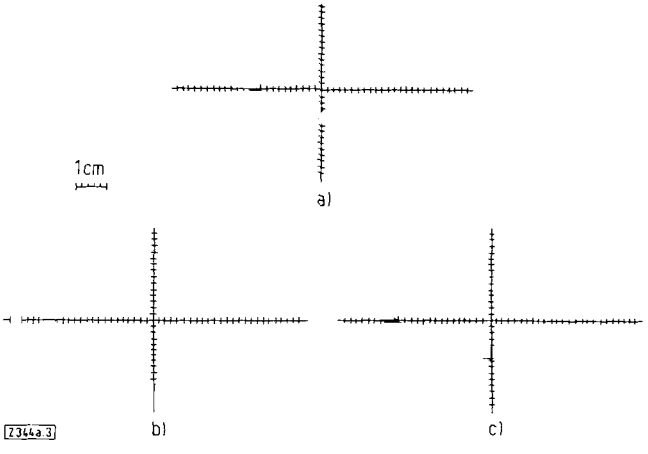

Fig. 3. Oscilloscope traces after flashing a 2.44×10^{-4} M solution of *(10)* (a and b) and a 3.49×10^{-4} M solution of *(9)* (c) in methylcyclohexane at 21.6 °C [7a].

a) (t = 10 ms/cm; λ = 440 nm; S = 0.5 V/cm): Decay curve (first order) of *(6)* formed from *(10)* by photodecarbonylation (k = 52.5 s^{-1}; E = 15 kcal/mole; λ_{max} = 450 nm).

b) (t = 500 ms/cm, λ = 440 nm; S = 0.2 V/cm): First order decay of *(7)* which is formed in practically the same amount as *(6)* (k = 1.5 s^{-1}; E = 17 kcal/mole; λ_{max} = 445 nm).

c) (t = 10 ms/cm; λ = 440 nm; S = 1.0 V/cm): First order decay of *(6)* formed from *(9)* by photodecarbonylation (k = 52.5 s^{-1}; E = 15 kcal/mole; λ_{max} = 450 nm) [14].

[7a] The first portion of the curve shows the position of the base line, upward (downward) deviations correspond to a decrease (increase) in the transparency. T = temperature; t = sweep rate of trace; λ = wavelength at which decay curve was recorded; S = sensitivity (V_0 = 10 V); $\tau = 1/k$. – The time-dependent photomultiplier signals V_0 (before flashing) and $V = V_t$ (at time t after flashing) are proportional to the intensity I of the signal. The change in optical density $\Delta E = \Delta E(t)$ is $\Delta E(t) = \log I_0/I_t = \log V_0/V_t$.

[7b] Low-temperature spectroscopic data [4]: λ_{max} (ε) = 284 (30600) and 519 nm (9170), $\varepsilon_{284}/\varepsilon_{519} = 3.34$; flash spectroscopic data of relative intensity: λ_{max} = 290 and 505 nm, $\varepsilon_{290}/\varepsilon_{505} = 3.3$.

[8] See footnote 14 in [5].

[9] The photo product obtained from *(4)* at −189 °C [5] has an absorption maximum at 465 nm (ε = 10600); warming to −178 °C results in an irreversible shift of the maximum to 455 nm without change in intensity. This observation concerns that portion of the *o*-quinodimethane derivatives able to photocyclize and is compatible with a *Z/E* isomerization of *(8)* to *(7)*.

[10] The quantitative results are based on the observation that the absorption of *(6)* at 455 nm has almost twice the intensity (20100) of that of the other configurational isomers.

[11a] The flash photolysis of *(4)* shows – apart from a slight participation of *(6)* – analogous behavior.

[11b] According to low-temperature spectroscopic (flash spectroscopic) data recorded in methylcyclohexane/3-methylpentane, 4:1 (methylcyclohexane), the long wavelength absorption maximum of the thermally most labile *o*-quinodimethane derivative *(6)* unable to photocyclize [5] appears at 455 nm [9] (450 nm at 21.6 °C); *(7)* shows a maximum at 455 (445) nm.

[12] *G. Quinkert, H.-P. Lorenz*, and *W.-W. Wiersdorff*, Chem. Ber. *102*, 1597 (1969).

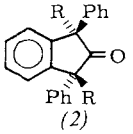
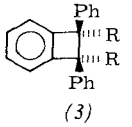
[14] In this case compound *(7)*, which occurs in the same way, was determined only flash spectroscopically (λ_{max} = 450 nm).



Non-Cheletropic Photodecarbonylation of 1,3-Diphenyl-Substituted 2-Indanone Derivatives[1]

By *Gerhard Quinkert, Joachim Palmowski, Hans-Peter Lorenz, Walter-Wielant Wiersdorff*, and *Manfred Finke*[*]



Unconjugated cyclopentenones undergo smooth decarbonylation, both in their electronic ground state[2] and after $\pi^* \leftarrow n$ excitation[3] to give butadiene derivatives. If the thermal decarbonylation proceeds in one step, the correlation diagrams demand a stereospecific, in the present case disrotatory, course[2b,4]. The stereochemistry of the corresponding photodecarbonylation, which has been discussed under different, in part contradictory, premises, is *a priori* unclear. Two shortcomings are responsible for this, *viz.* insufficient knowledge of the photoreactive state and lack of a conclusive theory of light-induced reactions.

(b), R = CH_3
(c), R = D

Photodecarbonylation of the symmetric 2-indanone derivatives *(1a)* and *(2a)*[5] in hydrocarbon mixtures at −189 °C with 313-nm light affords the 7,8-diphenyl-substituted *o*-quinodimethanes, *(5)*, *(6)*, and *(7)*, which, on the basis of their absorption spectroscopic properties have already been differentiated as photocyclizable [*(5)* and *(6)*] and non-photocyclizable *(7)* configurations[6]; the *o*-quinodimethane derivative *(7)* unable to photocyclize is formed from *(1a)* in 61.5% yield and from *(2a)* in 95% yield.

A stepwise monitoring of the reaction showed that the ratio of the two configurational types [*(5)* + *(6)* and *(7)*] formed from *(2a)* is independent of the progress of the reaction, whereas the composition of the product in the case of *(1a)* is a function of the irradiation time since a photostereomutation of the educt[7] takes place. In the latter case, extrapolation to zero time (t=0) shows that the initial products formed are almost exclusively *o*-quinodimethanes having the photocyclizable configuration. However, since no information is available as to whether *(5)* and/or *(6)* is initially formed from *(1a)*[8], a quantitative determination of the two configurational types in light-induced low-temperature decarbonylation does not afford conclusive details about the (one- or multi step) course of the reaction.

Table. Data of the decarbonylation of *(1a)*, *(1b)*, *(2a)*, and *(2b)* at 13±2 °C in ether with 313-nm light.

Educt	Conversion (%)	Hydrocarbon fraction [a] Ratio of isomers (%)	Ketone fraction [a] Ratio of isomers (%)
(1a)	50	*(3a)*: 8; *(4a)*: 92	*(1a)*: 87; *(2a)*: 13
	67	*(3a)*: 10; *(4a)*: 90	*(1a)*: 58; *(2a)* 42
	80	*(3a)*: 11; *(5a)*: 89	*(1a)*: 36; *(2a)* 64
(2a)	36	*(3a)*: 18; *(4a)*: 82	
	48	*(3a)*: 17; *(4a)*: 83	exclusively *(2a)*
	70	*(3a)*: 13; *(4a)*: 87	
(1b)	30	*(3b)*: 69; *(4b)*: 31	
	53	*(3b)*: 70; *(4b)*: 30	exclusively *(1b)*
	66	*(3b)*: 69; *(4b)*: 31	
	100 [b]	*(3b)*: 29; *(4b)*: 12; *(8)*: 59	
(2b)	25	*(3b)*: 8; *(4b)*: 92	
	41	*(3b)*: 10; *(4b)*: 90	exclusively *(2b)*
	50	*(3b)*: 9; *(4b)*: 91	
	100 [b]	*(3b)*: 1; *(4b)*: 67; *(8)*: 32	

[a] The irradiation products were analyzed by gas chromatography [5] and by NMR spectroscopy [12] after treatment with an excess of $LiAlH_4$ and chromatographic separation of the alcohols from the hydrocarbons; the presence of piperylene (0.75 M) showed no effect on the conversion and the product composition.

[b] Irradiation at −78 °C.

The Table contains data of the decarbonylation of *(1a)*, *(1b)*, *(a)*, and *(2b)*[5] in a merry-go-round apparatus[9]. In each case a mixture of configurational isomers of four-membered ring hydrocarbons *(3)* and *(4)* occur, the composition of which remains unaffected by the presence of the ketone triplet quencher piperylene. Simulation of a trivial non-stereospecificity by photostereomutation of the benzocyclobutene derivatives does not occur in direct irradiation or sensitization[10]; in contrast to *(1a)* a light-induced configurational isomerization of the ketonic reactants *(1b)*, *(2a)*, and *(2b)* does not come into consideration. Although it has been established, for example, that *(3a)*

and *(4a)* are formed stereospecifically[12] from the corresponding seco isomers also detected at room temperature[11], a thermal and/or photo configurational isomerization of the intermediate compounds under these conditions cannot be ruled out. The observed non-stereospecificity is therefore irrelevant for the course of the reaction in question. However, the fact that photostereomutation and photodecarbonylation in *(1a)* result from one and the same electronically excited singlet state verifies the stepwise, noncheletropic character of the light-induced CO elimination in the case of the cyclopent-3-en-1-one system investigated[13].

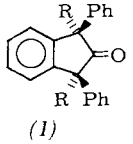
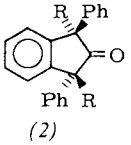
Increase in Selectivity of Photoelimination Products on Replacing the Liquid Phase by the Crystalline Phase[1]



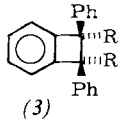
By *Gerhard Quinkert, Takao Tabata, Eckhard A. J. Hickmann,* and *Walter Dobrat*[*]

The observation that photodecarbonylation of 1,3-diphenyl substituted 2-indanone derivatives[2] does not take place in a single step[3] indicates an intermediacy of biradicals, which, because of internal rotations and inversion at radical centers comprise whole groups of subspecies. Experience has shown that in such cases the preparatively as well as mechanistically useful product selectivity increases with increasing viscosity of the medium[4]. The crystal lattice of a solid is expected to have a particularly strong influence on the rate, and possibly the direction, of molecular motion. Investigations carried out at the Weizmann Institute[5,6] suggest that the crystalline phase is a suitable medium for photoeliminations as it allows entry of light and escape of gaseous products.



A considerable increase of the cage effect, and consequently of the constitutional selectivity, is observed for the photodecarbonylation of 1,1,3-triphenyl-2-propanone[2a] by substituting the crystalline phase for the (benzene) solution. The extent of the cage effect given by the ratio:

$$a = \frac{^{2M}[1,1,2\text{-triphenylethane}]}{^{M}[\text{reactant}]} - 1;\ M = \text{mole equivalent.}$$



increases from the one limiting value $a = 0$ in solution (1,2-diphenylethane, 1,1,2-triphenylethane, and 1,1,2,2-tetraphenylethane occur in the ratio 1:2:1[2a]) to the other limiting value $a = 1$ in the solid (1,1,2-triphenylethane is formed exclusively). The constitutional selectivity for the photodenitrogenation of diphenylmethylazotoluene changes less drastically; practically only 1,1,2-triphenylethane occurs in the light-induced N_2 elimination in the crystalline phase at −196 °C[7], while on irradiation of a benzene solution at 27 °C *a* falls only to 0.28[8]. This finding is in accordance with the higher kinetic stability of an acyl radical relative to the isoelectronic diazoalkyl radical[9].

(a), R = H
(b), R = CH_3
(c), R = D

Table. Data of the decarbonylation of *(1a), (1b), (2a),* and *(2b)* in solution and in the crystalline phase.

Reactant \ Product	Percentage composition in	
	Solution [a]	Cryst. phase [b]
(1a)	*(3a)*: 11 *(4a)*: 89	*(3a)*: 95 *(4a)*: 5
(2a)	*(3a)*: 13 *(4a)*: 87	*(3a)*: 5 *(4a)*: 95
(1b)	*(3b)*: 69 *(4b)*: 31	*(3b)*: 90 *(4b)*: 4 *(5)*: 6
(2b)	*(3b)*: 9 *(4b)*: 91	*(3b)*: 14 *(4b)*: 86

[a] The products obtained by irradiation of an ethereal solution at 13 ± 2 °C with 313-nm light were analyzed by gas chromatography [12] and by NMR spectroscopy [2b] after treatment with an excess of $LiAlH_4$ and subsequent chromatographic separation of the alcohols from the hydrocarbons.

[b] Irradiation was carried out in a Rayonet reactor (300-nm lamp; Southern Ultraviolet Co., Middleton, Conn.) using a filter (2.5% aqueous solution of potassium hydrogen phthalate; layer thickness 8 mm) in a Duran vessel of wall-thickness 1 mm at 13 ± 2 °C. For a detailed analysis of the irradiation products see [a]; in none of the cases was a stereomutation of the educt observed.

As a result of the restricted internal mobility of the intermediate species formed from the configurationally isomeric ketone pairs *(1a)/(2a)* and *(1b)/(2b)*[12] on UV irradiation, the configurational selectivity of the subsequently isolated benzocyclobutene derivatives *(3)* and *(4)* increases considerably on changing from the solution to the crystalline phase as a reaction system and in one case even changes its direction.

CONFERENCE REPORTS

Present Trends in Polyurethane Chemistry

By *Helmut Piechota*[*]

The discovery of the diisocyanate polyaddition process for the production of macromolecular materials has led to a wide variety of valuable synthetic materials within a little more than 30 years: PUR elastomers, which can be cast or sprayed or, alternatively, injection molded or extruded, are commonly encountered nowadays. The same applies to urethane lacquers and varnishes, to PUR coatings for fabrics, to PUR synthetic leather, to adhesives, and to PUR synthetic fibers and foams. (PUR has become an accepted abbreviation for polyurethane.)

The production of PUR raw materials (polyisocyanates, polyethers, polyesters), which is nowadays carried out on a full industrial scale, requires an accurate knowledge of the structural parameters that determine the properties of the resulting polyurethane. The starting materials are made to react in one step or by the prepolymer process under strictly controlled conditions to give polyurethane. By suitable choice of raw materials and control of the reaction it is possible to determine the properties of the PUR product in advance: polyurethanes are "tailor made" plastics.

The most important PUR products are foams, which can be produced in all degrees of hardness. In 1970 world production exceeded 10^6 tons. Flexible PUR foams in the form of continuously produced slabs or foamed in place are used as upholstering materials, for mattresses, automobile seats, *etc.* Recent developments include foams that are self-extinguishing under defined test conditions, as well as "cold foams". The latter are used in the manufacture of molded materials having properties resembling those of latex foams. They have been rapidly accepted, *e.g.* for the production of automobile seats and arm chairs.

Rigid PUR foams are excellent insulating materials. Practically all European household refrigerators are insulated with such materials, as are also refrigerated vehicles, cold stores, district heating supply pipes, flat roofs of buildings, *etc.* In the future, the sandwich technique, *i.e.* the combination of rigid facings with a core of rigid PUR foam, will become increasingly important and many examples of its industrial application can already be given. Increasing use in building construction raises the question of fire prevention: Recent developments have resulted in the trimerization of polymeric diphenylmethane diisocyanate with simultaneous foaming. The polyisocyanurate foams thus produced are flame retardant and comply with the German industrial standard DIN 4102.

PUR structural foams are produced by foaming in place. By taking particular chemical and process-engineering measures it is possible to produce, from a single reaction mixture in a one-step operation, a molded article having a massive skin, which is gradually transformed towards the microporous core. Soft and semirigid structural PUR foams are widely used for automobile safety fittings (*e. g.* arm rests, crash pads, bumpers) and also for lightweight shoe soles that can be foamed directly onto the shoe shaft. Owing to their sandwich structure, rigid PUR structural foams represent novel materials of construction that are suitable for the production of large-surface, high-volume moldings. These materials have acquired an important position in the furniture industry, in the manufacture of casings, and in the sports equipment industry.

There is probably no other field in the plastics industry where chemistry and process engineering are so closely linked as in the polyurethanes. From the chemical point of view increasing attention is being devoted to other reactions of the isocyanate group (*e. g.* trimerization), while in process engineering new molding techniques are being sought (*e. g.* structural foams). This leads to new materials with novel properties for new applications (*e. g.* agricultural foams). 30 years of PUR chemistry clearly represents not a final goal but a milestone on the way of continuing progress.

Continuous Emulsion Polymerization

By *Heinz Gerrens*[*]

Several industrially important plastics such as butadiene-styrene rubbers and emulsion polyvinyl chloride are nowadays prepared by continuous emulsion polymerization. A trend towards increasing use of continuous processes can also be expected to parallel increased production in the case of plastic dispersions. The properties of the plastics, and particularly those of the dispersions, strongly depend on the process variables; consequently, a knowledge of the relevant reaction kinetics is most important on changing from batch to continuous processes.

The continuous emulsion polymerization of styrene and of methyl acrylate in a series of three continuous stirred tank reactors has been investigated[1]. The number of particles and over-all reaction rate were measured as a function of the emulsifier and initiator concentration, mean residence time, and temperature. The results obtained with styrene are in fairly good agreement with the theory proposed by *Gershberg* and *Longfield*[2]. Deviations from theory in the case of methyl acrylate can be qualitatively explained by the relatively high solubility of this monomer in water, which favors direct particle formation from the aqueous phase and transfer of radicals from one latex particle to another.

According to a theory put forward by *Matsuura* and *Kato*[3] one unstable and two stable stationary operating states can occur in an isothermally and continuously operating ideal stirred tank reactor if the reaction under investigation has autocatalytic character. Under certain conditions, a high self-acceleration due to the Trommsdorff effect is apparent in the emulsion polymerization of styrene. In continuous reactions carried out in the three-stage series of stirred tank reactors, six stable stationary operating points were found for the individual reactors and three stable operating states for the whole series[4]. The data obtained were in good agreement with the values expected theoretically from a time-conversion plot of the batch process. A changeover from one stable operating point to another in one of the reactors occurs if the monomer concentration is suddenly increased for a short time. Theoretically, in a series of n reactors a maximum of $n+n(n+1)/2$ stable and n unstable stationary operating points are possible in the individual reactors and $n+1$ stable operating states in the whole series.

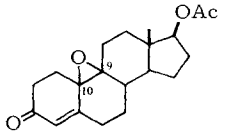
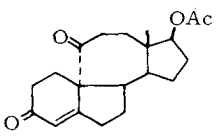
New Developments in the Field of Steroid Ketone Photochemistry

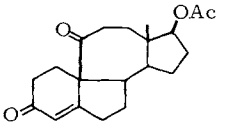


By *Kurt Schaffner*[*]

The steroids are a class of compounds which are easily modified chemically and which are suitable for studying the various structural aspects of photo-induced processes. In combination with investigations of smaller model compounds steroids often prove to be most convenient substrates for the stereochemical analysis of photoisomerizations.



The rearrangement of α,β-epoxyketones to β-diketones has been formulated as a photolytic cleavage of the C_α-O bond and subsequent β→α-alkyl migration[1]. The reversibility of the primary photochemical step was detected by the C_α epimerization of the exocyclic oxirane of the diastereoisomeric pulegone epoxide[2]. The stereospecific isomerization of the epoxyketones (+)-*(1)* and (−)-*(1)* to the enantiomeric spiroketones *(2)* now indicates however that the second step can be rapid enough to compete with rotation about the C_α–C_β bond in the primary product[3]. Results with 3-oxo-4,5-oxido steroids had



(+)-*(1)* ⟶ (−)-*(2)*
(−)-*(1)* ⟶ (+)-*(2)*

shown that the β→α-alkyl shifts are subject to a stereoelectronic control, which provides selectivity with respect to the migrating group and stereospecificity of the rearrangement[4]. The selective isomerizations *(3)→(5)* (at −65 °C) and *(4)→(6)+(7)* (at room temperature) apparently reflect the influence of such factors, which in the case of *(3)* at higher reaction temperatures may not be sufficient to prevent a transformation such as *(3)→(7)*, which presumably proceeds *via* an additional radical intermediate step[5].

Introduction of a 4α-CD_3 group can be used as a stereochemical probe for differentiating between a concerted $[_{\sigma}2+_{\pi}2]$ addition and a stepwise reaction sequence in the rearrangement of α,β-unsaturated δ-ketone *(8)* to the cyclopropyl ketones *(9)* and *(10)*. The different geminal methyl groups on C-4 in the product of type *(9)* and *(10)* resulting from labeled enedione were sterically equilibrated, while recovered starting material exhibited no such isomerization[6]. This finding rules out a concerted process and demands an intermediate product in which the steric equilibration is effected by rotation about the C-4–C-5 bond.

In the case of the bis-enone *(11)* the question arises as to which enone grouping is to be ascribed the excitation state which induces rearrangement to *(12)*. The reactions of *(8)* and *(11)* are quenched by suitable triplet energy acceptors. A combination of phosphorescence studies on *(8)* and *(11)* and ring-A and ring-B model enone compounds and the use of sensitizers and quenchers with various triplet energies showed that E_T (Ring A) < E_T (Ring B) and that the triplet energy of the reactive state of *(11)* is localized in the Ring A enone[7].

Lecture at Freiburg on December 18, 1970 [VB 267 IE]
German version: Angew. Chem. *83*, 180 (1971)

SELECTED ABSTRACTS

The photoisomerization of 1,2,4-trifluorobenzene in the vapor phase with light of wavelength 254 nm leads, according to *G. P. Semeluk* and *R. D. S. Stevens*, to two main products. After separation by gas chromatography, the products were identified by IR, NMR, and mass spectroscopy as 1,2,5-trifluorobicyclo[2.2.0]hexa-2,5-diene *(1)* and 2,3,5-trifluorobicyclo-[2.2.0]hexa-2,5-diene *(2)*. Quantum yields are low. Oxygen at 674 torr does not completely prevent formation of either compound, which can be regarded as trifluoro-Dewar-benzenes. This would suggest formation from the excited singlet state of 1,2,4-trifluorobenzene and not from the triplet state.

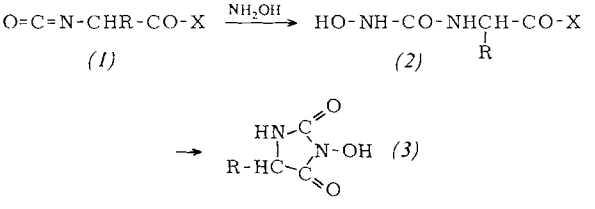
/ Chem. Commun. *1970*, 1720 / –Ma.

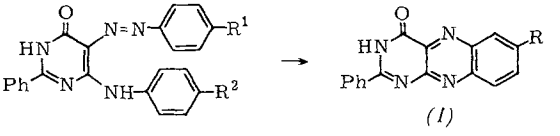
[Rd 301 IE]



A new sensitive and specific reaction for the detection of aldehydes is reported by *R. G. Dickinson* and *N. W. Jacobson*. 4-Amino-3-hydrazino-5-mercapto-1,2,4-triazole *(1)*, which can be easily prepared from hydrazine hydrate and numerous open-chain or cyclic thioureido compounds, condenses with the formyl group in 1 N NaOH to give the unstable, oxygen-sensitive tetrahydrotriazolo[4,3-*b*]tetrazine *(2)*, which is rapidly oxidized to the violet compound *(3)* by atmospheric oxygen. The color depends on the substituent R (absorption at 520–555 nm). Reaction is still detectable at concentrations as low as 10^{-4} mole/l. Ketones, esters, amides, hydrazines, hydroxylamines, quinones, aminophenols, urea, and formic acid do not give violet condensation products. / Chem. Commun. *1970*, 1719 / –Ma.

(1) *(2)* *(3)*

[Rd 302 IE]

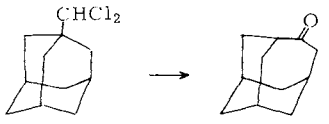


3-Hydroxyhydantoins *(3)*, **a new class of cyclic diacylated hydroxylamines,** are readily obtained by reaction of α-isocyanato fatty acids with hydroxylamine in dioxane-methanol according to a report by *P. Fankhauser* and *M. Brenner*. The reaction proceeds *via* an intermediate α-hydroxyureido fatty acid ester *(2)*. Assignment of structure follows from Exner correlations of the IR, NMR, and mass spectra. 3-Hydroxyhydantoins *(3)*, like hydantoins, are easily hydrolyzed. Examples: R = H, parent amino acid glycine, 90% yield, CH_3, DL-alanine, 85%; $C_6H_5CH_2$, DL-phenylalanine, 70%; $(CH_3)_2CHCH_2$, DL-leucine, 50%; $(CH_3)_2CH$, DL-valine, 60%. / Helv. Chim. Acta *53*, 2298 (1970) / –Ma.

(1) *(2)* *(3)*

[Rd 305 IE]

A new alloxazine synthesis is reported by *F. Yoneda, M. Ichiba, K. Ogiwara*, and *S. Nishigaki*. Heating of 6-anilino-4-hydroxy-5-*p*-nitrophenylazo-2-phenylpyrimidines with 10% sulfuric acid in glacial acetic acid (130–140 °C, 3 h) gives 2-phenyl-2-deoxyalloxazine *(1)* in 83% yield. No cyclization took place in the presence of acetic acid or trifluoroacetic acid alone. The 5-phenyl and 2-*p*-chlorophenylazo compounds could not be cyclized. Important factors affecting the reaction include the acid

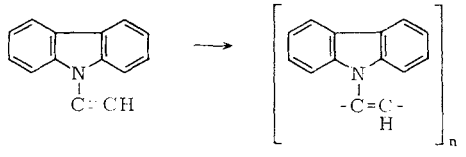


(1)

R^1 = NO_2, R^2 = H, Cl, Br R = H, Cl, Br (83,84,92%)

ity of the solvent (no reaction with 20% H_2SO_4) and the presence of a strongly electron-attracting group such as NO_2 in the 5-phenylazo substituent. / Chem. Commun. *1971*, 23 / –Ma.

[Rd 306 IE]

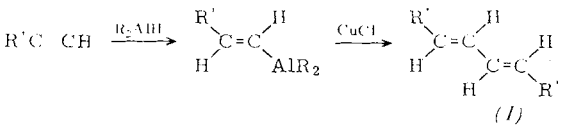


Dichloromethyladamantanes have been obtained by *I. Tabushi, Z. Yoshida,* and *N. Takahashi* by dichlorocarbene insertion into adamantane, methyladamantane, and dimethyladamantane. The hydrocarbon was allowed to react in aqueous NaOH/benzene in presence of trimethylbenzylammonium chloride with chloroform as source of dichlorocarbene (yield of 1-dichloromethyladamantane *(1)* 91% with respect to unchanged adamantane). The insertion reaction is also applicable to cyclic and acyclic hydrocarbons. When heated with 85% phosphoric acid at 110–130°C in an atmosphere of nitrogen, compound *(1)* undergoes hydrolytic rearrangement to give homoadamantanone *(2)* (69%) along with some 1-adamantanecarboxaldehyde (6%). At higher temperatures the latter is one of the main products. Formation of *(2)* probably proceeds *via* an intermediate carbonium ion. / J. Amer. Chem. Soc. *92*, 6670 (1970) / –Ma.

(1) *(2)*

[Rd 303 IE]

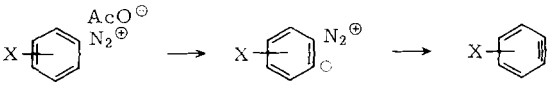
Synthesis and properties of *N*-ethynylcarbazole *(1)* and poly-*N*-ethynylcarbazole *(2)* are reported by *Y. Okamoto* and *S. K. Kundu*. *N*-Acetylcarbazole reacts with PCl_5 in boiling benzene or toluene to give *N*-(α,β-dichlorovinyl)carbazole, which affords *N*-ethynylcarbazole (m. p. 58°C, yield 31%) on treatment with $NaNH_2$ in liquid NH_3 followed by decomposition with NH_4Cl. Thermal polymerization of *(1)* in toluene or cyclohexane or without a solvent at 100–120°C in an evacuated sealed tube gave a dark brown polymer *(2)* having a molecular weight of 1530–1960 (*n* approximately 8–10). The conductivity of the



(1) *(2)*

polymer was 10^3 times as high as that of poly-*N*-vinylcarbazole; however, it possessed no photoconductivity. / J. Org. Chem. *35*, 4250 (1970) / –Ma.

[Rd 309 IE]

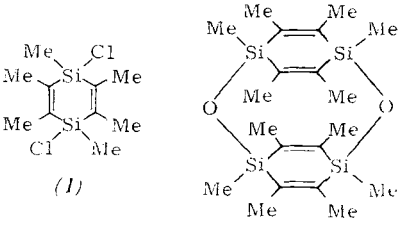


A novel stereoselective synthesis of 1,3-dienes from terminal alkynes is described by *G. Zweifel* and *R. L. Miller*. For example, when vinylalane, which is formed by the hydroalumination reaction from 1-hexyne and diisobutylaluminum hydride, is treated with CuCl in THF at 25°C copper precipitates out and coupling takes place to give isomer-free *trans,trans*-5,7-dodecadiene *(1)* (R' = C_4H_9) in 73% yield. Increasing the size of the alkyl group attached to the triple bond has little effect on the yield and stereochemistry of the diene formed. The coupling reaction with CuCl is also applicable to vinylalanes derived from disubstituted alkynes. The reaction probably proceeds *via* the vinyl-Cu(I) compounds. Examples: Alkyne: C_5H_{11}–C≡CH → 1,4-dicyclopentyl-*trans,trans*-1,3-butadiene, 68%; *tert*-butyl-C≡CH → 2,2,7,7-tetramethyl-*trans,trans*-3,5-octadiene, 67%; $C_2H_5C{\equiv}CC_2H_5$ → 4,5-diethyl-*trans,trans*-3,5-octadiene, 71%. / J. Amer. Chem. Soc. *92*, 6678 (1970) / –Ma.

(1)

[Rd 304 IE]

A simple one-step conversion of aniline into dehydrobenzene has been observed by *J. I. G. Cadogan, J. R. Mitchell,* and *J. T. Sharp*. Reaction of aniline, pentyl nitrite, and acetic anhydride with 2,3,4,5-tetraphenylcyclopentadienone in benzene at 80°C gave 1,2,3,4-tetraphenylnaphthalene in 32% yield. *m*-Bromo-, *m*-chloro-, *m*-methoxy-, and *m*-methylaniline behaved analogously. Reaction of aniline in the presence of anthracene as acceptor yielded triptycene in 10% yield. Better results were obtained with the system *p*-chlorobenzoyl nitrite/acetanilide



which gave the benzyne adduct in 50% yield. The reaction requires acetate ions. / Chem. Commun. *1971*, 1 / –Ma.

[Rd 307 IE]

The synthesis of 3,5-disubstituted cyclopentenes by ozonolysis of norbornadiene is described by *C. A. Grob* and *H. R. Pfaendler*. The ozonization product obtained at −70°C in methanol reacts with Ag_2O to give cyclopent-4-ene-*cis*-1,3-dicarboxylic acid, and on Lindlar reduction over a Pd-lead carbonate catalyst it gives the hitherto unknown cyclopent-4-ene-*cis*-1,3-dicarbaldehyde, which affords the saturated aldehyde on treatment with Pd/H_2. Reduction of the ozonization product with $NaBH_4$ leads to *cis*-1,3-bis(hydroxymethyl)cyclopent-4-ene. Reduction of its bis-tosylate with $LiAlH_4$ gives *cis*-3,5-dimethylcyclopentene. / Helv. Chim. Acta *53*, 2156 (1970) / –Ma.

[Rd 308 IE]

An organosilicon cyclophane *(2)* has been synthesized by *F. Wudl, R. D. Allendoerfer, J. Demirgian,* and *J. M. Robbins*. Treatment of 1,4-dichlorohexamethyl-1,4-disilacyclohexa-2,5-diene *(1)* with hydrazine gave a crystalline compound *(2)* (1–5% yield) alongside polymeric products. A further synthesis, which provided proof of structure, consists in the reaction of equimolar amounts of *(1)* and 1,4-dihydroxyhexamethyl-1,4-disilacyclohexa-2,5-diene in the presence of triethylamine in highly dilute, anhydrous solution in THF to give *(2)*, again alongside polymeric material. Compound *(2)*, which crystallizes as hexa-

(1)

gonal prisms from ether, is thermally stable and sublimes at *ca.* 268°C. NMR, mass, and IR spectra all confirm the structure. Additional proof is provided by the ESR spectrum of the green radical anion formed on reduction of *(2)* with potassium in dimethoxyethane at −80°C. / Chem. Commun. *1971*, 50 / –Ma.

[Rd 310 IE]

Methylchlorocarbene has been obtained by *R. A. Moss* and *A. Mamantov* by photolysis of methylchlorodiazirine (λ >300 nm) in tetramethylethylene, trimethylethylene, isobutene, *cis*-butene, and *trans*-butene. Addition to give the expected cyclopropanes occurred, and at 25–30°C the relative reactivities were 3.87, 2.44, 1.00, 0.74, and 0.52. The addition to *cis*-butene and to *trans*-butene was stereospecific. Vinyl chloride was formed simultaneously by rearrangement of methylchlorocarbene. / J. Amer. Chem. Soc. *92*, 6951 (1970) / –Ma.

[Rd 311 IE]

Atlas der Kunststoff-Analyse (Atlas of Plastics Analysis). Vol. I: High Polymers and Resins. Spectra and Methods of Identification. By *D. Hummel* and *F. Scholl*. Carl Hanser Verlag, Munich, and Verlag Chemie, Weinheim/Bergstr. 1968. 1st Edit. Part 1: Text. xi, 223 pp., 53 figures, 64 tables. Part 2: spectra, tables, index. 615 pp. with 1758 spectra. Plastic binding. Price for Volume I (2 parts) DM 228. The subscription price finishes on publication of Volume II. Volume I will then cost DM 260.

The Atlas of Plastics Analysis is intended as an aid to the rapid identification of polymers. To this end Part I describes methods of chemical analysis and Part II shows many IR spectra with a broad range of wavelengths. The book includes supplementary data on the thermal behavior, density, refractive index, solubility and dielectric constants of polymers and on special uses of gas chromatography, paper chromatography, thin-layer chromatography, and pyrolysis mass spectrometry. Nuclear resonance spectra are not given.

While the authors refer to more comprehensive descriptions of chemical analysis, they give only a brief account of the relevant principles. This is adequate for the specialist but is probably not informative enough for the beginner. The same is true of the separation processes. If importance is attached not only to the separation of fillers and plasticizers but also to the isolation of the anti-agers, accelerators, lubricants, antistatics, and catalysts, the separation processes prescribed for the substance classes have to be considerably altered in accordance with the problem and the polymer. Moreover, the separation methods developed for polymer analysis, *e. g.* fractionation processes, gel chromatography, and electrophoresis, are not described. The book limits itself mainly to identification of the substances and omits the physical methods that are usually important within the context of polymer analysis, *i. e.* the determination of molecular weights and their distributions, chemical nonuniformities and sequence length distributions, long-chain branching and microgel, coil, and particle sizes, crystallization characteristics, orientations, aggregations, and morphological structures, and network densities.

The book provides a broad and very useful basis for the identification of polymers.

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). 8th, completely revised edition. Edited by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in the Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH., Weinheim/Bergstr.[1]

System No. 61: Silver: Part A, 1.
History. Occurrence. Principal editor: *Karl-Christian Buschbeck*. 1970. iv, vii, 144 pp., linen, DM 180.–.

The introductory chapter (31 pp.) recounts the very long history of silver and its compounds. A particularly interesting feature is the description of the smelting processes, which vary with the nature of the ore and its source. Among the silver compounds, the nitrate, chloride, sulfate, and fulminate in particular have long histories. Almost a whole page is devoted to alchemical specifications for the preparation of the Arbor Philosophorum or the Arbor Dianae (experiments which work – The reviewer).

The following chapter is entitled "Cosmochemistry" and gives information on the occurrence of silver in stars and meteorites. A chapter on the geochemistry of silver is subdivided into sections on crystallochemistry, geochemical characteristics, and the frequency and occurrence of silver in the lithosphere and hydrosphere. There is also a section devoted to silver in the atmosphere, less perhaps for the sake of completeness than for the sake of curiosity: on June 14, 1956 there was a rain storm over München and the insoluble residues of the rain contained ^{111}Ag. A short section on the circulation of silver, which describes its route through the individual geospheres, concludes the chapter. A further chapter describes all silver-containing minerals, their paragenesis and their physical and chemical properties. The most important deposits and the relevant production figures are summarized in the final chapter "Production Statistics and Important Deposits".
The references in this volume go up to 1968 and in some cases even later.

System No. 61: Silver: Part A, 2.
Technology and Preparation. Isotopes. Atom. Molecules. Physical Properties of the Metal. Principal editor: *Franz Seuferling*. 1970. vi, xvi, 350 pp., 76 figures, linen, DM 421.–.
This volume is devoted entirely to elementary silver. 70 pages deal with the technology and preparation of the metal. In the main, pyrometallurgical processes are used for its extraction from silver-containing lead ores and from pure silver ores. The author describes these in detail. Hydrometallurgical processes, the most important of these being leaching with inorganic cyanides, are of minor importance in the total production of silver. The same is true of the amalgam processes. The extraction of crude silver from the anode sludge of electrolytic copper refining baths is of greater technological importance, since 18% of the world silver production is obtained from copper ores. A large number of techniques are used to process these ores, the choice depending on the nature and concentration of the admixtures.

A further section deals with the purification of crude silver. The largest part of this deals with the electrolytic separation of silver. Only the size of the section in question (about 20 pages) gives any indication of the technical importance of the recovery of silver from scrap, photographic baths, waste, *etc.* This is followed by two short sections giving exhaustive information on purity testing and the preparation of special forms of silver such as powder, sponge, wool, thread, mirrors, and films. The remainder of the book will interest the physicist more than the chemist. The chapter on the isotopes of silver deals with the preparation, separation, accumulation, and properties of Ag isotopes. The chapter entitled "Atom and Molecules" relates to work connected with electron configuration, wave functions, polarizability, atomic and ionic radii, and the optical and X-ray spectra of the atom and atomic ions.

This volume is also very up to date. The references are complete up to 1968 and some relate to works published after this date.

Ekkehard Fluck [NB 929 IE]

---

[1] Cf. Angew. Chem. internat. Edit. *9*, 913 (1970).

Quantenmechanik und Theorie des Molekülbaues (Quantum Mechanics and the Theory of Molecular Structure). By *W. M. Tatewski*. Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., 126 pp., numerous figures, stitched, DM 19.50.

The title of this book is misleading; it is not an introduction to current theory of chemical bonds and the electron structure of molecules. The author has instead set out to show, on the basis of quantum mechanics, how well founded the concepts and laws of classical structure theory are and where they can be applied. He comes to the conclusion that at present it is not possible in the case of polyatomic molecules to derive either exactly or even approximately the concept of chemical bonding or the structural formula from the general principles of quantum mechanics. The only generally valid theoretical criterion for the stability or instability of the states of a system of nuclei and electrons is the presence or otherwise of a minimum in the corresponding energy surface.

The usual concepts of theoretical chemistry, for example valence electrons, electron pair bonding, σ-π-separation, and localization or delocalization of electrons, naturally have no place in such a strict quantum theory of molecular structure. This argument

is presented in very convincing manner, but it will be of little help to the chemist in his attempts to understand the relationships between the structure and properties of molecules.

Martin Klessinger [NB 930 IE]

X. FATIPEC-Kongressbuch (10th FATIPEC Congress Report). 1970. Edited by the Scientific Committee of the 10th FATIPEC Congress. Verlag Chemie GmbH., Weinheim/Bergstr.: 1970. 1st Edit., 601 pp., numerous figures, bound, DM 98.–.

The two-yearly congress of the Fédération d'Association de Techniciens des Industries des Peintures, Vernis, Emaux et Encres d'Imprimerie de L'Europe Continentale (FATIPEC) is the largest and one of the most important scientific and technical conventions in the field of paints, lacquers, printing inks, and pigments. The 1970 FATIPEC Congress in Montreux had as its main themes the durability and decomposition of modern coatings as dependent on formulation, the preparation of the base and application, and the properties of printing inks as dependent on formulation, manufacture, the material to be printed on, and the printing process.

In addition to the ten general lectures, all the lectures (about 60) on pigments, vehicles, solvents and wetting agents, on the chemistry, physics, and structure of coatings, weathering, the effects of light and heat, corrosion and substrate, electrophoresis, mathematical statistics, optimization, and printing inks are reproduced in the book.

The lectures cover themes ranging from the theoretical to the practical end of the spectrum. It is easy to see that when the program was drawn up importance was attached to the scientific treatment of basic and practical themes alike.

The FATIPEC Congress report, as always, gives a comprehensive survey of the current problems and progress in this field of technology. Its completeness is almost unrivaled.

Werner Funke [NB 931 IE]

The Synthesis and Characterization of Inorganic Compounds. By *W. L. Jolly.* Prentice Hall International, Hearts 1970. 1st Edit., xi, 590 pp., bound, *ca.* DM 74.–.

The first three chapters of this book deal with the fundamentals of synthesis, preparative methods, and characterization of compounds, while the fourth gives procedures for the preparation of inorganic compounds.

The first chapter describes the thermodynamic and kinetic aspects of the synthesis of compounds. The second chapter deals with the methods commonly used in the laboratory: purification and drying of solvents, operations in inert atmospheres, in vacuum, and under pressure, measurements of low and high pressures, purification of compounds, high- and low-temperature techniques, *etc.*

The third chapter is devoted to the characterization of substances and to determination of their structures, greatest emphasis being placed on instrumental methods, such as IR, UV, NMR, ESR and mass spectroscopy. Procedures for the preparation of a large number of interesting inorganic compounds are given in the fourth chapter. The substances are so chosen that materials from the earlier sections can be used in later ones. The preparations are well chosen as representative of the whole range of inorganic chemistry and the most important working methods involved. Glass blowing, safety precautions, and first aid are reviewed in an appendix, and tables are given of things such as irreducible representations of important symmetry groups. Each chapter provides access to further information by means of literature references, and also a series of exercises.

This book thus contains all the information that a good preparative inorganic chemist must have at his command, and at the same time shows the high demands which are made on his versatility. The general appearance and printing are very attractive; the work is clearly divided up into sections, and easy to understand. It is particularly recommended to all those who have to organize inorganic practical work for advanced students, and to the students themselves. Even preparative chemists who are not working in the field of inorganic chemistry will find a wealth of valable information in this book.

Alois Haas [NB 941 IE]

Phase Diagrams, Materials, Science and Technology. Vol. I: Theory, Principles and Techniques of Phase Diagrams. By *A. M. Alper.* Academic Press, New York – London 1970. 1st Edit., xviii, 358 pp., numerous figures, bound $ 16.00.

This book, which is the first of three volumes, correlates in its opening sections the thermodynamic theory of phase diagrams with the results of recent computer investigations. In the main these chapters aim at drawing conclusions from thermodynamic data such as heats of fusion and heats of mixing on the structure of melting diagrams and phase diagrams or *vice versa, i.e.* at drawing conclusions on thermodynamic data of the type mentioned from diagrams obtained experimentally. The thermodynamic relationships necessary for this are set out very clearly, with the relevant diagrams in a section written by *Y. K. Rao.* The results of computer calculations on this thermodynamic basis are given in a contribution by *L. Kaufmann* and *H. Bernstein,* who deal in great detail with a large number of metal alloy systems.

Three larger sections follow on the experimental determination of phase diagrams *(J. Macchesney* and *P. Rosenberg),* the interpretation of experimentally obtained diagrams *(H. C. Yeh)* and their use in obtaining or preparing solid phases of a desired constitution *(W. A. Tiller).* These sections deal in detail with all modern experimental methods such as dilatometric and electrochemical investigations (EMF methods), conductivity measurements, thermogravimetric methods, X-ray analysis and the classical methods.

Two shorter sections on the very modern field of high pressure investigations *(A. Jayaraman* and *L. H. Cohen)* and on metastable systems and their application in the preparation of refractory systems *(T. P. Seward)* complete this first volume.

This book fulfils a valuable function with respect to solid state technology, particularly the technology of metal alloys, a subject which in recent years has become very important for many fields of endeavor (space technology, reactor technology, *etc.*) and can therefore be recommended to all who intend to work and carry out research in the newest fields of this branch of science.

Klaus Schafter [NB 933 IE]

Biologische Zerstörung der makromolekularen Werkstoffe (Biological Destruction of Macromolecular Materials). In the series Chemie, Physik und Technologie der Kunststoffe in Einzeldarstellungen, Vol. 15. By *H. H. M. Haldenwanger.* Springer Verlag, Berlin – Heidelberg – New York, 1970. 1st Edit., viii, 283 pages, bound, DM 58.–.

This "piece of writing", which is how *Haldenwanger* described his book, is the astonishing work of a blind author. After *Haldenwanger's* death the manuscript was skilfully revised and condensed by *G. H. Göttner.*

The book is arranged on the basis of the most important groups of pests. In the 16 chapters that this system of classification gives rise to, the most important organic materials and their resistance to biological attack are discussed. The detailed reproduction of test specifications saves the biologist the trouble of sorting through the original literature. The comparison of the various test results and the critical comments on these are extremely valuable.

A chemist might also have liked to see the book arranged along technological lines. The polyethylene specialist, for example, has to sort out the test results that interest him from each individual chapter. The short subject index is not very helpful either, since only general entries are included on polyolefins or polyvinyl compounds.

The comprehensive 43-page appendix of tables, twelve of which summarize formulas, the most important fungicides, biocides, insecticides, harmful organisms, and softeners for plastics, makes the book immensely clear and informative. Exhaustive

references are quoted for work published up to 1967. This excellent book would have been even more valuable if the chemical compounds mentioned had been cited not only by name, which is by no means a clear system and which in the present case has led to a few errors, but also in the form of structural formulas.

With the above reservations, however, the book as a whole can be recommended as a work of reference for biologists, chemists, and practical technologists alike.

H. Alberts [NB 934 IE]

Organosilicon Heteropolymers and Heterocompounds. By *S. N. Borisov, M. G. Voronkov,* and *E. Ya. Lukevits.* From the series Monographs in Inorganic Chemistry. Plenum Press, New York, 1970. 1st Edit., xx, 632 pp., bound, $ 40.00.

The present work is an English translation of a Russian monograph which was published in 1966. Of the authors, *M. G. Voronkov* ranks as one of the most active research workers in the field of organosilicon compounds, while *Borisov*'s premature death in an accident was a sad loss to science.

Stimulated by the success of organosiloxane chemistry, researchers have recently turned more and more toward the chemistry of organic silicon compounds containing hetero atoms, and Soviet research workers have been involved strongly in this trend. A summary of the current state of knowledge by Russian authors is thus to be welcomed, particularly in view of the difficulties posed by the Russian literature. Admittedly the term "current" is a relative one – the literature is covered up to May 1, 1965 – but this, as we know only too well, is a common failing with translations.

The book deals with low- and high-molecular compounds containing the groups ≡Si-M, ≡Si-O-M, ≡Si-N-M, and ≡Si-C-M. The method of preparation, physical properties, chemical behavior, and possible applications are described in each case. The known data on definite low-molecular compounds of the classes considered are summarized in numerous tables.

This is the first complete compilation of the material in this form. The amount of knowledge that has been accumulated in such a relatively short time will astound even the initiated. This is a reference book which will provide much needed help for the worker in the field of organometallic chemistry.

The fact that in the future many details in the material reviewed may require revision is surely only a reflection on the newness of the subject. In particular, as far as the practical aspects are concerned – *de facto* the technical significance of the organic heterocompounds of silicon is small outside the USSR – it will be necessary to go through many of the literature recommendations with a critical eye and sort the wheat from the chaff.

To a western reader it may seem odd, to say the least, to find the literature references (of which there are almost 1750) separated into those by Soviet and those by non-Soviet authors, and also to find all the authors' patents listed. As *Goethe* says, "There is no such thing as nationalistic art or nationalistic science. Both belong, like all else that is great and good, to the entire world".

Walter Noll [NB 935 IE]

Manual on Radiation Dosimetry. Edited by *N. W. Holm* and *R. J. Berry.* Marcel Dekker, Inc., New York, 1970. 1st Edit., xvi, 450 pp., numerous figures, bound, $ 24.50.

The editors' intention has been to create once and for all a handbook which in its shape and weight is genuinely a "hand-book", a book, in fact, which can easily be carried around. This book is intended for scientists, engineers, and technicians who are daily confronted with practical problems of dosimetry. The book is divided into two parts. The first part contains chapters on methods of dosimetry and on the various fields of application, such as radiation protection, radiation therapy, ^{60}Co and accelerator dosimetry. The second part gives 20 sets of precise instructions for the operation of the various dose measurement processes which can be used in experimental work. As in a larger "handbook", the individual chapters are written by experts of international renown in their fields, which of course results in a certain degree of unevenness both in the presentation and in the selection of references. The index helps one to track down all the mentions of a given topic which is covered in different chapters. The book is a veritable mine of information for anyone concerned with chemical dosimetry techniques in the widest sense, and the extensive tables contribute toward this, but anyone working on neutron or accident dosimetry in reactors will search in vain for his keywords. The book is undoubtedly a valuable addition to any library.

H. Kiefer [NB 943 IE]

Organic Peroxides. Vol. 1. Edited by *D. Swern.* John Wiley and Sons Ltd. New York – London 1970. 1st Edit., x, 654 pp., numerous figures, bound, £ 15.00.

The chemistry of the organic peroxides was discussed in 1961 in two extremely good but relatively short books by *Davies* and *Hawkins.* The present book is the first section of a three-volume work, written by a group of authors with personal experience in the field of peroxide chemistry.

While the introductory chapter (104 pp.) does not give much more information than the books mentioned above, the second chapter by *Benson* and *Shaw* on the thermochemistry of organic peroxides (35 pp., with numerous tables) contains novel and useful information. The next three chapters (125 pp. in all) deal with the rearrangements of peroxy radicals, the reactions of peroxides with nucleophiles, and the synthesis and decomposition of peroxy esters. The two chapters by *Swern* (195 pp.) on the preparation and the physical properties of peroxy acids are remarkable in their attention to minute experimental details. Three chapters by *Sosnovsky* (90 pp.) describe the base-catalyzed autoxidation and the metal ion-catalyzed decomposition of symmetrical peroxides and peroxy esters. A final short chapter is devoted to polymerization with the aid of peroxides and its kinetics.

In a work by a number of authors it is impossible to avoid a certain fluctuation in quality. Notwithstanding this, it is extremely valuable to have information on peroxides collected together into one place, in a form as up-to-date and as complete as possible. Indeed, it is almost too complete, because in the tables on pp. 31 and 241 we find the as yet undiscovered ozonide of tetramethylethylene, and the ozonide of fluorenone which was deleted from the literature some twenty years ago! However, too much emphasis should not be placed on these minor shortcomings. A critical evaluation will only be possible after the publication of the two remaining volumes, which it is to be hoped will take place as soon as possible.

Rudolf Criegee [NB 944 IE]

The Alkaloids. Edited by *R. H. F. Manske.* Academic Press, New York – London. Vol. XI: 1st Edit. 1968, xvi, 549 pp., numerous equations, bound $ 26.00. Vol. XII: 1st Edit. 1970, xvii, 637 pp., numerous equations, bound, $ 29.00.

In the 20 years since the appearance of the first volume, *Manske*'s "The Alkaloids"[1] has become a household word for all chemists concerned with natural products, even if its character has in part changed; from vol. XI onward "The Alkaloids" became principally a summary of progress in the chemistry of alkaloids from individual plant species. For the most part the articles refer back to others previously published in this collection.

Nine of the twelve chapters of vol. XI are devoted to indole compounds. In this balanced survey practically the whole range is considered; of the major groups, only the ergot alkaloids are not included. Further sections deal with the alkaloids of the Amaryllidaceae and colchicine with related compounds, and the last chapter is concerned with pyridine alkaloids, which throughout is an amplification of the corresponding chapters which appeared more than ten years ago in vol. VI.

The most interesting features of vol. XII are the two extensive chapters on diterpene alkaloids, since this is the area in which there has been considerable progress in the last few years. The present survey is in fact the first one in which it has been possible

to evaluate a large number of known structures. One minor failing is the unclear way in which the formulas are numbered, which could give rise to errors. The chapter devoted to the indole alkaloids of Alstonia species is a supplement to the first nine chapters of vol. XI. The chapters on the alkaloids of the Papaveraceae and of Senecio are very thorough and therefore very useful; they reflect the endeavor to use alkaloid chemistry for chemo-taxonomic purposes. The last chapter is devoted to the legal chemical aspects of alkaloid chemistry. Its social importance alone makes this chapter an essential part of the book.

The penultimate chapter, "Alkaloids Unclassified and of Unknown Structure", presents something of a problem. As a collection of all those compounds which could not be classified under any other heading due to lack of chemical information, it could have had some value. In its present form, however, it includes compounds whose classification presents no difficulties. In some cases, the same compound even appears in two places, once in this chapter and once in the appropriate chapter in the same volume (venoterpin, pp. 208 and 458; cassipourine, pp. 323 and 464). Part of the trouble is certainly due to the relatively long delay in publication; to judge from the references most of the reviews were written in 1967, since only in exceptional cases are articles published in 1968 considered.

In general, it must be said that the volumes under review, like all the previous volumes, represent an increase in our store of knowledge, and one which no library specializing in this subject can afford to be without.

Karel Bláha [NB 945 IE]

[1] Cf. Angew. Chem. internat. Edit. *6*, 192 (1967).

Tables for Use in High-Resolution Mass Spectroscopy. By *R. Bings, J.S. Littler,* and *R. L. Cleaver.* Heyden and Son Ltd., London 1970. 1st Edit., xx, 160 pp., numerous tables, DM 97.–.

The tables compiled by *Bings, Litter,* and *Cleaver* are intended to assist in the "peak matching" technique for mass determination with high-resolution mass spectrometers. The authors appear to have had AEI instruments chiefly in mind.

The first table gives the most important mass lines in the spectra of perfluorokerosene, perfluoromethyldecalin, perfluorodimethylcyclohexane, and heptacosafluorotributylamine, which are frequently used as reference components. The table also contains factors which enable the ion masses of the mass lines of a reference substance to be converted into the ^{13}C analogs. This is extremely helpful for people whose instruments do not have a digital mass indicator; users of more modern equipment will hardly ever use these factors.

Much the same situation is found with Table 2, which contains factors for the determination of further mass lines in the reference compound. Since factors of up to 1.5 are given, while for example Varian instruments (SM 1) only permit a mass difference of about 10%, this table again can only be used fully by the possessors of certain types of instruments.

The next table contains the corresponding values for fluothane. The final table simplifies the mass determination of compounds with hetero atoms, which are composed of different isotopes. It shows in graphic form the isotope ratios for chlorine, silicon, sulfur, boron, and bromine, for increasing numbers of hetero atoms, and also combinations of chlorine and bromine atoms. It can also be used to obtain the contribution of these hetero atoms to the precise ion mass. This table is thus very useful for the mass determination of compounds containing hetero atoms, particularly as such values are not given in other collections of tables for the determination of empirical formulas.

The book is completed by an appendix containing the tried and trusted "Henneberg Tables" for mass determination.

This collection of tables is thus an important aid, but principally for those laboratories carrying out precise mass determinations with instruments not fitted with digital mass indicators. Of this limited clientele, some will undoubtedly be frightened off by the high price. This appears to be due to the attractive binding (artificial leather) rather than the contents.

Gerhard Spiteller [NB 939 IE]

Coordination Compounds. From the series Studies in Modern Chemistry. By *S. F. A. Kettle.* Thomas Nelson and Sons Ltd., London 1969. 1st Edit., vii, 220 pp., £ 1.75.

The present series now includes a monograph on coordination compounds, written by a very notable English author belonging to the younger generation of theoretical chemists. The contents are divided into eleven chapters: 1. Introduction; 2. Nomenclature and geometrical structure of coordination compounds; 3. Preparation of coordination compounds; 4. Stability of coordination compounds; 5. Crystal-field theory of transition metal complexes; 6. Ligand-field theory of transition metal complexes; 7. Electronic spectra of transition metal complexes; 8. Magnetic properties of transition metal complexes; 9. Other methods of studying coordination compounds (vibration spectroscopy, resonance spectroscopy), 10. Thermodynamic aspects; 11. Reaction kinetics of coordination compounds. There is an appendix containing brief discussions of some applications of group theory, the Russell-Saunders coupling scheme, the significance of ligand group orbitals, and examples of Tanabe-Sugano diagrams. The text is supplemented by numerous clearly arranged tables and figures.

This very clearly written monograph attempts to bridge the gap between the standard textbooks and the almost unmanageably large number of publications in the field of coordination chemistry. The author is writing mainly for advanced students, and assumes an elementary knowledge of AO and MO theory, chemical kinetics, and thermodynamics. He is principally concerned with the coordination compounds of the transition metals, but in a number of places he also draws attention to complexes of the main group elements. It is pleasant to find numerous references to the analogy between the coordination relationships in solution and in the solid state, but regrettably, there is no discussion of the large number of coordination compounds in which the central atom is formally in a lower state of oxidation. Again, a monograph like this, which deliberately goes beyond the range of the elementary textbooks, ought to have references to the more important works in the literature (*e.g.* to review articles on important sub-topics). Despite these objections, however, the book can be thoroughly recommended to any chemist whose main interest is "classical metal complexes".

Helmut Werner [NB 940 IE]

Free-Radical Chain Reactions. By *E. S. Huyser.* John Wiley and Sons Ltd., New York – London 1970. 1st Edit., 387 pp., numerous figures, bound, £ 9.50.

The study of radical chain reactions has long ranked as a domain of physical chemistry; in lectures on organic chemistry this type of reaction is usually only mentioned in passing, with reference to a few reactions, such as the chlorination of methane. Today this topic is of importance in both preparative and full-scale industrial organic chemistry, and in the present work *E. S. Huyser* has undertaken to present the basic principles of the kinetics and mechanisms of these reactions clearly and in a manner understandable by any chemist. The complicated kinetic equations are derived in so detailed a manner that even those less experienced in mathematics should be able to follow them in every detail.

Chapters 1–4 deal with the fundamentals of the mechanisms, kinetics and the relationships between structure and reactivity. The following sections are concerned with the principal types of chain reactions: aliphatic substitutions (greatest emphasis being placed on halogenation), radical additions (the compound being added and the unsaturated substrate are separately and systematically dealt with), eliminations, and radical rearrangements. A separate chapter is devoted to the chemistry of in-

itiators, but chain-termination reactions, which today have been just as thoroughly investigated, are in the reviewer's opinion dealt with too briefly. The stimulating section on redox reactions is a little uneven and could profitably have been restricted to electron-transfer reactions. The section on autoxidation could easily have fitted into the section on aliphatic substitution, for example. The last chapter gives a general survey on polymerization which makes up in breadth of coverage what it lacks in depth. No account is taken of aromatic substitutions, some of which also involve radical chains.

The discussion is always a balanced account of the current state of the art, and is clarified by a generous allocation of equations. There are places where excessive use is made of the concept of radical stability in the interpretation of reactivity relationships and bond energies. It is pleasant to report that only a few errors (*e.g.* Equation 3–142 or in the derivation on p. 53) were found.

This is an outstanding work. Every library should have a copy, and it is heartily recommended to all those interested in radical chemistry.

Christoph Rüchardt [NB 938 IE]

Rodd's Chemistry of Carbon Compounds. Edited by *S. Coffey.* Vol. II, Part D: Steroids. Elsevier Publishing Company, Amsterdam – London – New York 1970. 2nd Edit., 550 pp., 42 figures, bound, Dfl. 95[1].

In three chapters this book, the first of two volumes on steroids, deals with sterols and bile acids, steroid hormones, and cardioactive steroids.

The introductory section discusses the nomenclature and stereochemistry of this class of substances and gives details of the usual physical methods of investigation. The references to comprehensive works are very useful.

The chapter on sterols and bile acids accounts for almost 50% of the book and is a mine of information for the chemist with historical interests.

The isolation, synthesis, and modification of estrogens, androgens, and progestative and adrenocortical hormones are discussed in the second section. No mention is made, however, of the recent developments in the stereoselective total synthesis of 19-norsteroids.

The comparisons of biological intensities of action are of absolute value only if the experimental conditions (*e.g.* animal species, application, dosage range, *etc.*) do not differ. The selection of the modified sex hormones discussed seems to be very random.

Detailed information is given on the structural determination of cardioactive cardenolides and bufadienolides, but the synthesis of these substances receives only incomplete treatment.

An appendix gives the latest IUPAC rules for steroid nomenclature.

The text, with its references and physical data, makes difficult reading. The work will be particularly useful to chemists and biochemists working in the field of Sterols and Steroids. It is not very suitable for teaching purposes.

Rudolf Wiechert [NB 936 IE]

Chemische Elementarprozesse (Elementary Chemical Processes). Edited by *H. Hartmann* in collaboration with *J. Heidberg, H. Heydtmann,* and *G. H. Kohlmaier.* Springer Verlag, Berlin – Heidelberg – New York, 1968. 1st Edit., xii, 487 pp., 86 figures, bound, DM 58.–.

The present book contains a collection of lectures delivered during the 1965 Constance theoretical chemistry summer school on the subject of elementary chemical processes. In accordance with the object of the course, this book sets out to introduce advanced students and scientists in other disciplines to the latest developments in the field of reaction kinetics. It deals both with the theoretical foundations of kinetics and with modern methods for investigating elementary processes in the gas and liquid phase. Subjects like reaction cross sections and rate constants, transition state theory, potential surfaces, nonadiabatic reactions, quantum statistics of chemical reactions, unimolecular reactions, intermolecular energy transfer, and Monte Carlo calculations are discussed; molecular beams, shock waves, flow systems, and flash photolysis are also explained. The authors also deal with structure and reactivity, heats of reaction, solution reactions at high pressure, nuclear magnetic resonance, and relaxation processes for rapid reactions in solution.

Since some of the articles go far beyond the bounds of introductory material they offer new points of view even for the reader who is more familiar with this field. In fact, the term introduction cannot be applied at all to some of the contributions. As a whole, the book gives an excellent survey of the very varied fields of modern reaction kinetics, and will be used widely both as an introduction and as an aid to further study.

Biogenic Substances in Sediments and Fossils[**]

By Pierre Albrecht and Guy Ourisson[*]

Most sedimentary rocks contain small concentrations of finely divided organic material. With the aid of modern analytical methods, samples of such rocks can be examined in detail, and conclusions can be drawn concerning the origin of the organic substances. Intact or modified biogenic compounds such as paraffins, isoprenoids, alcohols, ketones, carboxylic acids, steroids, triterpenes, and porphyrins have been isolated from the soluble fractions of the organic material of many sediments and from identified fossils of various geological ages. Even Precambrian rocks contain biogenic substances, so that life forms must have existed more than three billion years ago. The main component of the organic material is "kerogen", the complicated polymeric structure of which has not yet been established.

1. Introduction

It is the inorganic chemist rather than the organic chemist who is concerned with the analysis and chemistry of minerals and sediments. Organic substances, such as amber, ozocerite, and fichtelite, and naturally also petroleum and coal, are only rarely encountered in classical geochemistry.

The past ten years have seen an unexpected upsurge in the investigation of organic substances in a wide range of sedimentary rocks, fossils, and meteorites, arising from the original studies by *Treibs*[1]. This has only become possible through modern analytical methods, which allow determinations in the microgram to nanogram range.

These investigations have also led to close, friendly cooperation between geologists and organic chemists, two groups of scientists whose jargon, methods, and thought processes differ considerably.

"Organic geochemistry" is not confined to the practically important problems of the formation of petroleum, of oil shale, or of coal, but has a very comprehensive brief, which includes isolation and characterization of organic components in rocks, explanation of their origin and of the changes brought about by time and temperature as well as in reactions catalyzed by minerals (*i.e.* interpretation of their "diagenesis"), simulation of the diagenesis in the laboratory, comparison of the constituents of present-day plants and related fossils (paying due attention to their diagenesis), searches for signs of the earliest life forms or of extraterrestrial life, *etc.* Geologists, paleontologists, and chemists are particularly interested in the substances that occur intact in sediments and fossils, though also in those that are present in degraded or otherwise modified forms.

In this progress report we shall refer only briefly to the studies on meteorites and moon specimens, since these are still far from complete. We shall be concerned mainly with the organic geochemistry of the earth, and the methods and problems of this new discipline will be illustrated by relevant examples.

2. General

Most of the organic material on this earth is finely distributed in the sedimentary layers of its crust.

The total quantity of carbon on the earth is estimated to be approximately 6.4×10^{15} t, of which 5×10^{15} t is in the

[**] General literature: *I. A. Breger*: Organic Geochemistry. Pergamon Press, London 1963; *E. T. Degens*, Geochemistry of Sediments. Prentice Hall, London 1965; *B. Nagy* and *U. Colombo*, Fundamental Aspects of Petroleum Geochemistry, Elsevier, Amsterdam 1967; *P. H. Abelson*: Researches in Geochemistry. Wiley, New York 1967, Vol. 2; *M. Calvin*: Chemical Evolution. Oxford University Press, London 1969; *G. Eglinton* and *M. T. J. Murphy*: Organic Geochemistry. Springer, Berlin 1969; see also Advan. Org. Geochem. *1962*, *1964*, *1966* and *1968*.

sediments (particularly in the shales and carbonates) and about 1.4×10^{15} t in the metamorphic rocks. By comparison, the quantity of carbon in living organisms, *i.e.* 0.003×10^{15} t, is practically negligible[2]. Even coal and petroleum, estimated to account for 1/500 and 1/16000, respectively, of the total organic material in the sediments[3], seem insignificant by comparison. These results are based on thousands of analyses by many research groups.

According to *Welte*[2], the carbon cycle may be divided into two subcycles, *i.e.* the "biochemical" cycle, whose period can be measured in days, and the "geochemical" cycle, which takes millions of years (Fig. 1). This second cycle results from the fact that about 0.01% of the total organic products in the sediments "survives". Small as this proportion seems to be, a considerable quantity of organic material accumulates and is preserved in the sediments in the course of millions of years, and there it undergoes the second cycle.

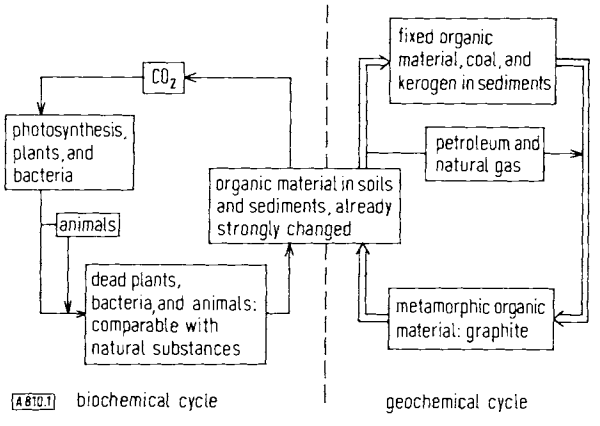

Fig. 1. Carbon cycle (after [2]). Oxygen is present in the biochemical cycle, but not in the geochemical.

The organic material occurs in the sedimentary rocks in two characteristic forms, one of which (average 10%) can be extracted with common organic solvents, while the other, known as kerogen (average 90%), is insoluble in such solvents.

Kerogen is a highly condensed polymer whose structure is still almost unknown. It can be obtained in a more or less unchanged form by dissolving the inorganic material of the rock in hydrochloric acid and hydrofluoric acid and washing it out. The kerogen forms a brown to black powder, depending on its source.

3. Methods and Analytical Procedures

An average 100-g sediment sample yields about 100–200 mg of extract, which usually has a very complex composition. Identification of the constituents may be complicated by contamination of the sample with traces of foreign substances during treatment, which necessarily involves several steps. Traces of amino acids and hydrocarbons have been detected in fingerprints[4]; plasticizers and silicones are also common contaminants in modern analytical chemistry[5]. *Hoering*[6] pointed out that many samples are wrapped in paper or in textile or plastic material for dispatch, and may therefore be contaminated even before they are received. Thus *Brandt*[7] has isolated traces of polychloro-biphenyls from a fossil fern. However, manufactured products of this nature are no longer found if the most rigorous precautions are always taken in geochemical work.

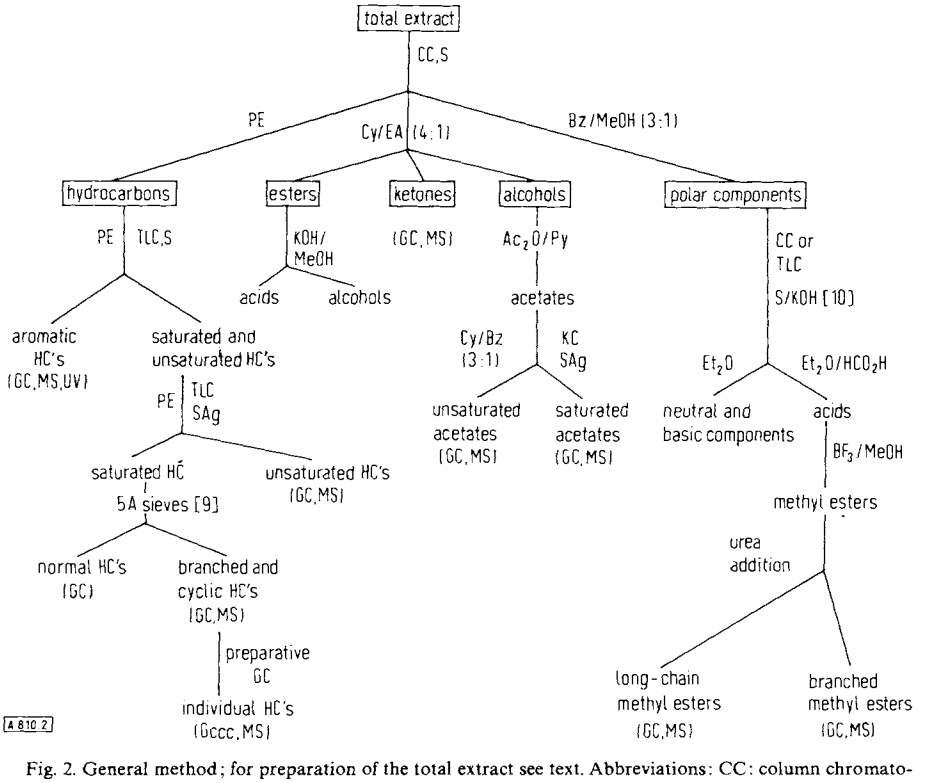

Fig. 2. General method; for preparation of the total extract see text. Abbreviations: CC: column chromatography; TLC: thin layer chromatography; S: silica gel; SAg: 10% of silver nitrate on silica gel; S/KOH: silica gel impregnated with KOH; GC: gas chromatography; GCCC: gas chromatography on capillary columns; MS: mass spectrometry; PE: petroleum ether; Cy: cyclohexane; Bz: benzene; EA: ethyl acetate; Py: pyridine; HC: hydrocarbons.

3.1. General Methods

The surface of the rock sample is first carefully scraped. The rock is then crushed into pieces measuring 2–3 cm, and is washed with 40% hydrofluoric acid, with water, and finally with benzene/methanol (3:1). The dried pieces are ground to a fine powder in a disk mill and then extracted in centrifuge tubes using ultrasound according to *McIver*[8], usually with benzene/methanol (3:1). This method is much faster and much more effective than continuous Soxhlet extraction.

After centrifugation, decantation, and evaporation of the solvent, the residue is separated chromatographically. The importance of chromatography on selected adsorbents and the significance of the 5-Å molecular sieves for the separation of linear and branched hydrocarbons can be seen in Figure 2.

The substances or mixtures isolated are characterized by the usual methods, *i.e.* UV (particularly for the aromatic compounds), IR (microcells, in some cases beam condenser), NMR (microcells, CAT), and usually mass spectrometry (preferably coupled with gas chromatography). The quantities of substance are generally only sufficient for such physical characterization, though useful guides to functional groups can be obtained *e.g.* by thin layer chromatography.

Hypothetical structures can often be deduced from such data, and can then be checked by comparison with reference substances. If no reference substance is available, X-ray structural investigations may be used. *Whitehead et al.*[11] determined the structures of some polycyclic saturated hydrocarbons from optically active petroleum fractions in this way.

4. Biogenic Substances in Sediments and Fossils (Survey)

The presence of biogenic substances in petroleum and in oil shales was first detected by *Treibs*[1] in his studies on porphyrins. Since then, nearly all classes of organic substances have been isolated at least once from sediment extracts (see Table 1). It must be expected, however, that certain biologically important macromolecules such as nucleic acids, proteins, polysaccharides, and enzymes will be extensively changed in the sediments.

Table 1. Presence of various classes of compounds in sediments and fossils.

Proteins	in fossil bones, shells [12]
Chitin	in a fossil insect [13]
Carbohydrates	present as traces in pre-Cambrian sediments [14]
Porphyrins, Amino acids, Saturated fatty acids, Alkanes	widely distributed components, also present as traces in the oldest pre-Cambrian deposits of the earth [15–18]
Triterpenes	in lignite [19]; in oil shale [20]; degradation products also in petroleum [21]
Sterols	in recent sediments [22], in oil shale [23], in lignite [24]
Carotenoids	only in recent sediments [25]; in reduced form also present in Green-River oil shale [26]

Proteins have been isolated from places that were well protected against diagenetic effects and from cavities of fossil shells and bones[12]. Chitin, a polymer of *N*-acetylglucosamine units with ether linkages, which is found in the exoskeleton of arthropods, has been isolated from a Cambrian fossil insect[13] (see Table 2).

Table 2. Geological time scale. Age of earth: 4.6×10^9 a.

Era	Formation	Divisions	Age in millions of years

	Ordovician	Upper Lower	500
	Cambrian	Upper Middle Lower	570
	Pre-Cambrian	–	

The saturated linear fatty acids and the porphyrins derived from organic pigments such as chlorophyll and hemin are best suited by their stability to withstand geological conditions without suffering excessive degradation. The alkanes also play a very important part, since these are the most stable organic compounds. They may be present in the sediment in their original form or as the final products formed from molecules that had formerly contained functional groups; alternatively, they may even be fragments of kerogen.

Substances occurring in sediments and fossils and having structures specific enough to allow the verification of their biological origin are aptly described by *Eglinton et al.*[27] as "biological markers". These may be intact or only slightly degraded biological compounds for which abiogenic synthesis appears extremely improbable.

These biological markers may provide valuable clues to the origin of the geological organic material, and may also very often be of great value as paleo-ecological markers. In the case of partly degraded products, correlation with biological precursors may allow one to build up a picture of the reactions in the sediment.

5. Former and Present-Day Biological Processes; Possibility of Paleochemotaxonomy

The organisms normally lose their original form by breakdown in the sediment, so that it is usually impossible to assign the organic material in the sediment to a certain life form. This material is very often derived from a large number of different plants and animals. In special cases, however, the organic matter of dead fauna and flora may be replaced by fine-grained rock or by minerals in such a way that the original morphology is preserved. In broad outline, this is the process by which fossils are formed.

It is conceivable that small traces of the most stable part of the original organic molecule from the plant or animal still remain in such cases.

On comparison of the organic material from very old sedimentary rocks with that from some more recent rocks, it is found (see Section 7) that the biochemical processes since the Precambrian are substantially similar to present-day processes.

To allow a direct correlation between former and present-day biochemical processes, however, it would be necessary to compare the organic substances from fossils and existing life forms of the same species or at least of a very closely related species. These comparisons are complicated by the fact that many fossil plant and animal species have now become extinct.

In a study of pigments of fossil crinoids (sea lilies) from the Jurassic period (170 million years old), *Blumer*[28] was able to isolate hydroxyquinones similar to those of present-day life forms that are related to the crinoids (see Section 6.2.2).

The Lower Triassic layers of the variegated sandstone (200 million years old) of the Vosges contain clay layers that are very rich in fossil plants. Samples containing only fossil "horse-tails" *(Equisetum brongnarti)* have been examined in some detail[29]. Since the genus *Equisetum* is still common among present-day flora, the constituents of the fossil can be compared directly with those of the fresh plant *(Equisetum silvaticum)*. The distribution of the alkanes is almost identical in both cases (Fig. 3). This similarity was also confirmed in studies by *Stransky et al.*[30] on another present-day species *Equisetum palustre*.

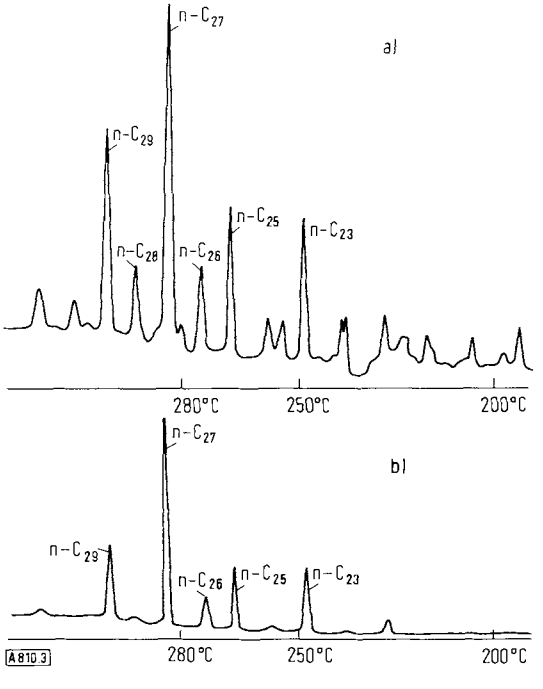

Fig. 3. Gas chromatograms of the saturated hydrocarbons from (a) fossil and (b) modern *Equisetum* (after [29]).

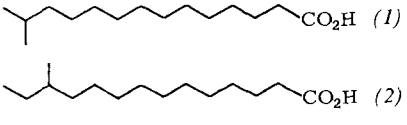
The *n*-alkanes are important constituents of the cuticle, and are synthesized in the present-day plants in definite proportions, though these vary from family to family. A chemotaxonomic classification is therefore possible in some cases[31]. The investigations mentioned above thus show that at least a small part of the original cuticle alkanes may persist in the fossil plants if these are not buried too deeply, *i.e.* at low temperatures and pressures; they therefore open the way to paleochemotaxonomy. This possibility is particularly interesting because intact plants are frequently not available for conventional taxonomy, and analyses of the type described can be carried out on incomplete specimens.



6. The Fate of Biological Substances under Geological Conditions

The organic material is exposed to numerous diagenetic attacks in the sediment. These attacks are evident in various stages of diagenesis, and can be divided into three main groups. Enzymatic and microbiological processes undoubtedly occur in the early stages of sedimentation. Physicochemical effects (acidic-basic and oxidizing-reducing conditions) operate in these and in subsequent stages ("early diagenesis"). Finally, during the sinking of a sediment, important changes are effected in the organic material by rising temperature, increased pressure, and catalytic effects of the rock.

6.1. Enzymatic, Microbiological, and Other Changes in the First Stages of Sedimentation

Enzymatic changes, particularly to complex biogenic polymers (proteins, polynucleotides, *etc.*), can take place shortly after the death of the organisms. Other "spontaneous" changes result from autoxidation. Amber, for example, about whose structure little is known, is probably a "spontaneous" polymer formed from the original resin acids by air oxidation and copolymerization. Autoxidation is possibly also involved in the formation of kerogen[32].

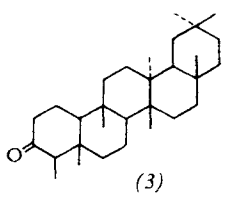
Microbiological decomposition undoubtedly also occurs in the upper layers of a sediment, but this can no longer be detected at a depth of a few meters. The free sulfur that is often present in sediments may be regarded as evidence of this process; the C_{12}—C_{18} iso- and anteiso acids *(1)* and *(2)* isolated from recent marine sediments may be assumed

to be residues of a bacterial organic material, since these compounds, which are rare elsewhere, are frequently found in present-day bacteria[33].

Arpino et al.[34] have detected long-chain methyl ketones containing odd numbers of carbon atoms as well as other long-chain compounds in a clay-rich limnic sediment from the Eocene (30% C) found at Bouxwiller (Alsace). These long-chain methyl ketones have not so far been found in the plant cuticle but have only been isolated from humous soils and peat[35]. They may be present in the sediment as a result of microbiological modification of fatty acids (β-oxidation followed by decarboxylation) or of *n*-alkanes (oxidation), such as has been found for compounds having lower molecular weights[36].

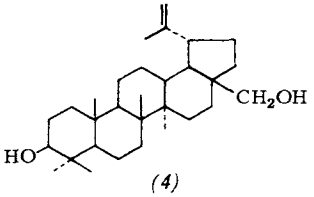
Microbiological decomposition processes of this type, the mechanism of which is largely unknown, are extremely important in the topmost layers of the sediments, and may play an important part in particular in the formation of kerogen.

6.2. Changes due to Physico-Chemical Effects in Early Diagenesis



Important changes in the original organic material can be brought about by the acidic-basic and oxidizing-reducing conditions prevailing in the sediment. The retention of molecular structures is known to be endangered most by acids and oxidizing agents. In the presence of reducing agents, on the other hand, the molecular skeleton generally remains intact, though partial or complete hydrogenation or hydrogenolysis may occur. However, even compounds containing functional groups may remain unchanged under favorable sedimentation conditions. Two possibilities must therefore be considered for the origin of some compounds, such as hydrocarbons.

If the compounds found can be compared with biological precursors, *i.e.* particularly in the case of "biological markers", it should be possible to draw certain inferences concerning the geological conditions.



6.2.1. Unchanged Biogenic Substances in Sediments and Fossils

It first became possible to identify unchanged, relatively sensitive, biologically important molecules as well as degradation products in studies on lignite (*i.e.* a sediment that is very poor in inorganic matter). For example, the triterpenes friedelin *(3)* and betulin *(4)*, which are of wide occurrence in the plant kingdom, have been isolated from a Czech Miocene lignite (25 million years old)[37].

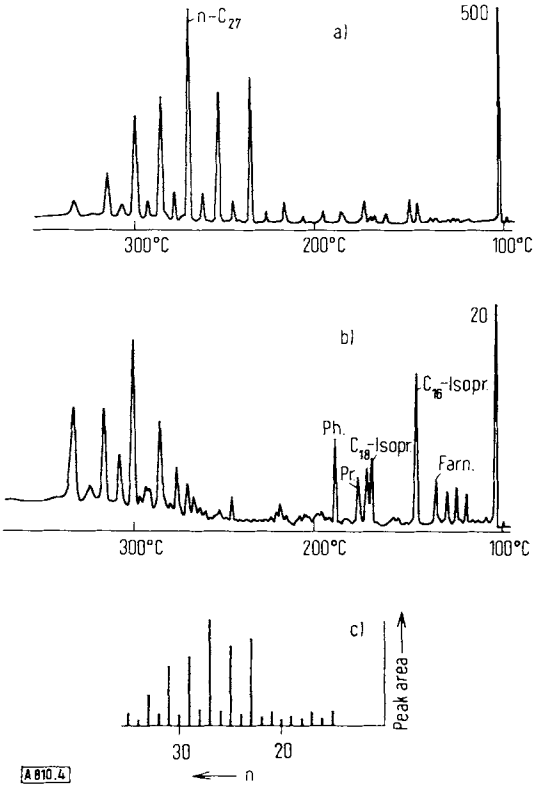
Our investigations on the organic material in the Eocene oil shale from Messel (near Darmstadt)[20] have shown that

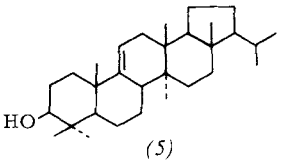
(3)

(4)

besides the alkanes and fatty acids, very sensitive biogenic substances containing functional groups can also survive unchanged for more than 50 million years. The Messel oil shale[38], which is famous for its fossil flora and fauna, is a limnic sediment deposited in small continental basins, which has never been buried more than 200–300 m deep[39]. The samples investigated consist of a finely layered shale containing water, with about 30% of carbon and 35% of a clay fraction consisting almost exclusively of montmorillonite.

The first indication of the continental origin of the organic material is provided by the distribution of the *n*-alkanes, which shows a strong predominance of the compounds with odd numbers of carbon atoms (Fig. 4). This feature is characteristic of the cuticle paraffins of higher plants, as was shown in the example of *Equisetum* (Section 5).





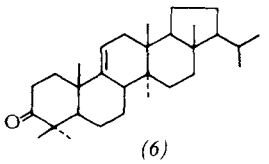


Fig. 4. Gas chromatograms of the saturated hydrocarbons of the Messel oil shale. (a) Total, (b) branches, (c) linear hydrocarbons. Column: 1.5% of SE30, 1,50 m. Pr. = pristane, Ph. = phytane, Farn. = farnesane, Isopr. = isoprenoid, n = number of C atoms. For the definition of isoprenoid see Section 6.2.3.

Further information is provided by the triterpene alcohol isoarborinol *(5)* and the ketone arborinone *(6)*, which occur together with other polycyclic alcohols and ketones in the Messel oil shale. A compound like isoarborinol is very susceptible to oxidation and reduction, as well as to attack by acids and heat. Its occurrence in the original form is indicative of mild conditions during diagenesis in the Messel sediments. It is not yet possible to establish the fossil plants in which these substances occur. The group of triterpenes of the arborane type was discovered fairly recently[40], and has so far been isolated only from tropical plants. Since the fossil flora found in the Messel oil shale is very closely related to the present-day plants of the

tropical regions[38,41], it should be possible to achieve a paleo-ecological approximation by studies on the organic compounds of certain sediments.

(5)

(6)

Extremely sensitive olefins and steroids from the Messel oil shale decompose rapidly in air after their isolation[42,43]. It is almost unbelievable that such substances could have survived in their original form in a sediment for millions of years, and suggests that the sediment is to some extent a sealed system.

The long-chain esters, which are extremely characteristic of plant cuticles, have been isolated from many lignites and coals[43]. They occur in the Messel oil shale and in the limnic sediments of Bouxwiller, and are undoubtedly unchanged biogenic substances[34,44].

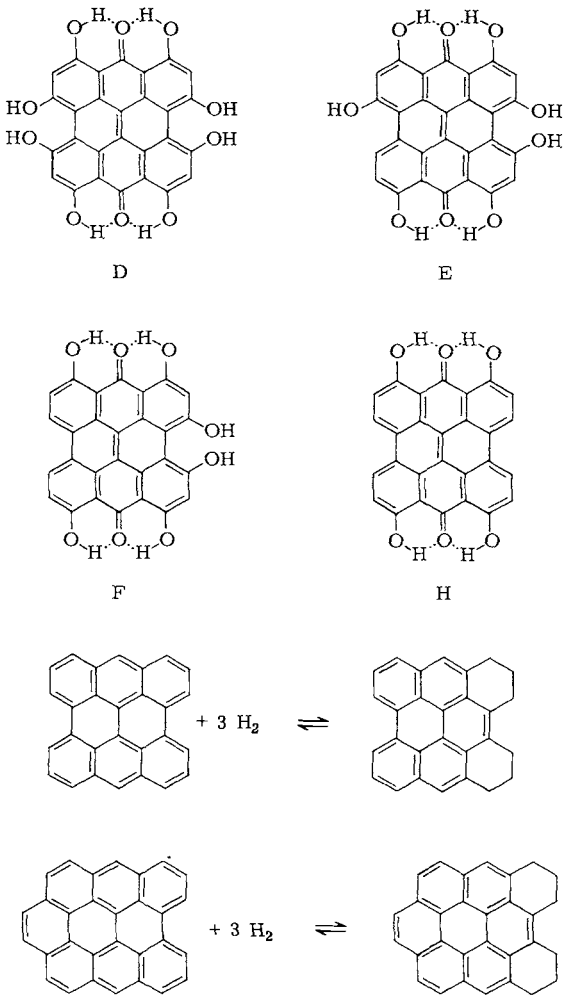
Unesterified free long-chain alcohols with even numers of carbon atoms, which are also found in the cuticles of higher plants, have been detected in the Bouxwiller sediment[34]. Other free alcohols have been identified in several recent and earlier sediments[45].

6.2.2. Degraded Biogenic Substances in Sediments and Fossils

Blumer's investigations[28] on fossil crinoids (sea lilies) point to a correlation between the polyhydroxyquinoid pigments and the aromatic hydrocarbons that occur in the same fossil as reduction products of the pigments. These substances appear to form an oxido-reduction series (Fig. 5). Though most of the reactions, particularly the reduction of functional groups containing oxygen to alkyl groups, are probably irreversible under the geological conditions, a few reactions, such as hydrogenation and dehydrogenation, seem to proceed reversibly under certain sedimentation conditions.

These arguments are supported by the great similarity of the distributions (GC, MS) of the polycyclic alcohols and of the polycyclic ketones in the Messel oil shale, which point to a possible equilibrium between these two groups of compounds. However, it is not yet possible to say whether this is due to a true equilibrium or to incomplete irreversible reactions under geological conditions[42].

Pigments containing four pyrrole groups, which result from the dehydrogenation of chlorophyll or of hemin, occur in many sediments and petroleums as nickel and vanadyl complexes. In his investigations on porphyrins in the Swiss oil shale of Serpiano (Triassic, 200 million years old), *Blumer*[28] was able to explain a number of degradation reactions brought about by the geological environment. It can be seen from Figure 6 that complete reduction by "degradative decarboxylation" of the carboxyl group and cleavage of C—C bonds as described by *Cooper* and *Bray*[46] occur as well as decarboxylation.



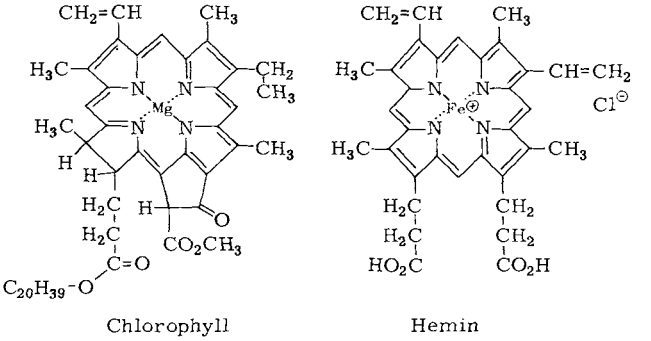


Fig. 5. Pigments (fringelites D, E, F, and H) and hydrocarbons from a fossil crinoid (sea lily) (after [28]).

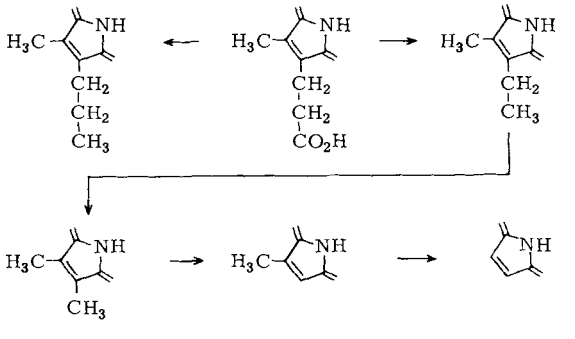

Fig. 6. Some diagenetic reactions of the pigments (after [28]).

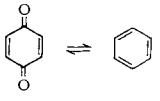
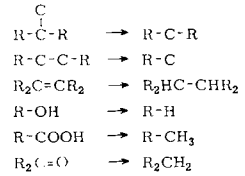
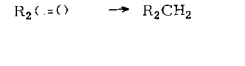
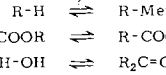
Since the reduction of such a carboxyl group to a methyl group occurs in the laboratory only under very vigorous conditions, it is surprising that reactions of this kind take place in the sediment at low temperatures and in the presence of water. Some irreversible and possible reversible geochemical reactions detected in particular in the study of fossil pigments are listed in Table 3.

Table 3. Irreversible and reversible geochemical reactions (after [28]).



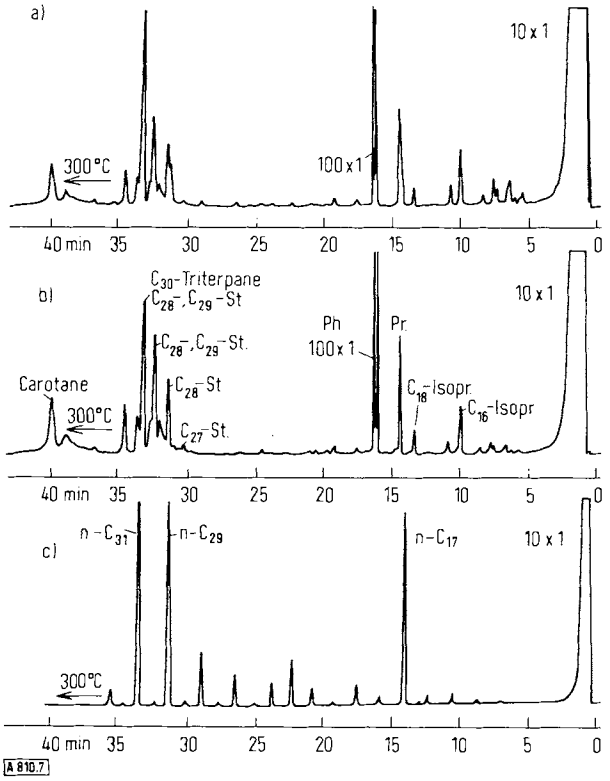


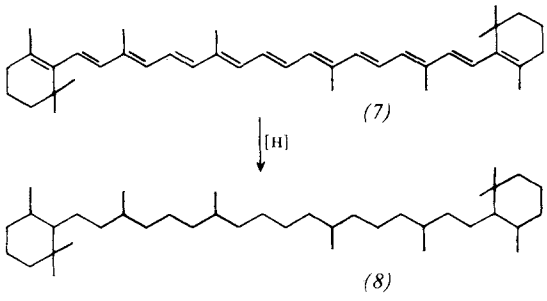


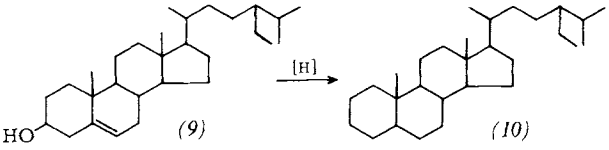


Irreversible processes	Reversible processes
R-COOH → R-H	
R-COOH → R-H + acids and hydrocarbons of low and of high molecular weight	
	
	
$R_2C{=}CR_2 \rightarrow R_2HC{-}CHR_2$	
R-OH → R-H	
R-COOH → $R{-}CH_3$	
$R_2C{=}O \rightarrow R_2CH_2$	$R{-}H \overset{?}{\rightleftharpoons}$ R-Metal
	R-COOR ⇌ R-COOH
	$R_2CH{-}OH \rightleftharpoons R_2C{=}O$

Figure 7 shows the composition of the alkanes from the extensively studied shale of the Green River formation, which is by far the most important oil shale reserve in the USA. This limnic sediment deposited in an inland sea is a finely layered shale containing about 25% of carbon, whose inorganic fraction is poor in clay but rich in carbonates.







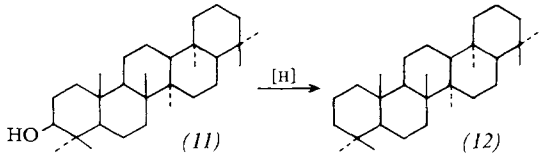


Fig. 7. Gas chromatogram of the saturated hydrocarbons of the Green River Shale. (a) Total, (b) branched and cyclic, (c) linear hydrocarbons (after [18]). Pr. = pristane, Ph. = phytane, St. = sterane, Isopr. = isoprenoid. For the definition of isoprenoid, see Section 6.2.3.

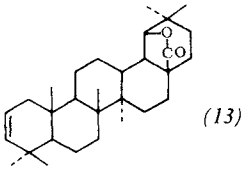
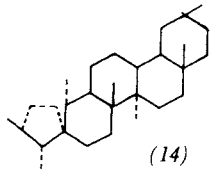
The compounds sitostane *(10)*, ergostane, cholestane, gammacerane *(12)*, and carotane *(8)* that occur in this shale[26, 47] are not present as biogenic substances in plants or animals, so far as is known. They were therefore most probably formed by reduction of the compounds β-sito-



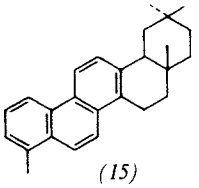
sterol *(9)*, ergosterol, cholesterol, gammacerin *(11)*, and β-carotene *(7)*, which occur widely in nature. Gammacerin has recently been detected in a protozoon.

Some petroleums also contain polycyclic compounds, which may be taken as evidence that not all of the organic material is of marine origin. Thus, *Barton et al.*[48] have detected the triterpene lactone *(13)* in an American petroleum; this compound may be regarded as a product of the acid-catalyzed degradation of the triterpene betulin *(4)*, which frequently occurs in the flora.



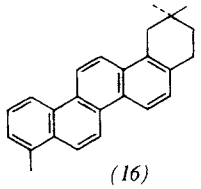
By capillary column gas chromatography and mass spectrometry, *Hills* and *Whitehead*[21] have isolated some polycyclic compounds, whose biological precursors are known in the present-day plant world in the form of alcohols, from optically active fractions of a Nigerian petroleum.

It may be assumed that such degradation reactions took place during earlier stages of diagenesis in the sediment before the migration in the petroleum formation.

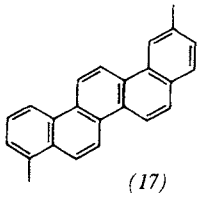


All these polycyclic, frequently saturated substances still contain enough information in their ring skeletons to serve as "biological markers" or even as "paleo-ecological markers". Their presence enables one to say whether the

organic material of a sediment is of marine or terrestrial, plant or animal origin. Such a classification could be made more precise if the distribution of all the oxygenated and unsaturated precursors in the present-day plants and animals were known. However, care is required since fundamental transformations are possible. For instance, a spirotriterpane has been isolated from a Nigerian petroleum [*(14)*, structure determined by X-ray crystallography]; such structures have not so far been detected in plants, and the compound in question is probably a rearrangement product formed by the catalytic action of clay[11].

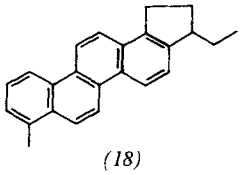


(14)

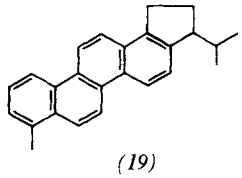


Partly dehydrogenated substances frequently also occur. These may be used as "biological" or "paleo-ecological labels" if their structures still contain sufficient information that points to biological precursors. Thus, *Jarolim et al.*[49]

(15)

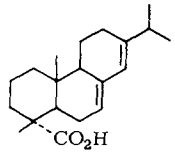


(16)

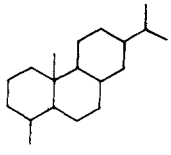


(17)

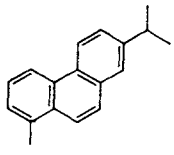
have isolated products of a dehydrogenation series of triterpene precursors [*(15)*, *(16)*, and *(17)*] from a Czech lignite. The compound *(17)* has also been found by *Carruthers* and *Watkin*[50] in an American petroleum. *Albrecht*[42] was able to identify small quantities of the dehydrogenated triterpenoid substances *(18)* and *(19)* in the Messel oil shale. It may be assumed that such compounds are formed in the sediment by disproportionation reactions.



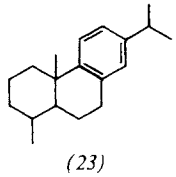
(18)



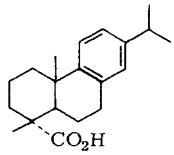
(19)



It is interesting to note that some compounds occur in hydrogenated forms and others in dehydrogenated forms in the same rock. Both types even occur together for some substances. Thus fichtelite *(22)* and retene *(21)*, which are undoubtedly formed from the same starting material [abietic acid *(20)*] by decarboxylation, and hydrogenation and dehydrogenation, respectively, have been isolated from a fossil wood[51]. Dehydroabietene *(23)*, another degradation product of abietic acid, occurs in large quantities (4.6%) in the soil of a Canadian pine forest[52], and dehydroabietic acid *(24)*, the simplest dehydrogenation product of abietic acid, has been found in the rosin lining the inside of the coffin of *Mary Ward*, a 16th Century English saint[53].



(20)



(21)

(22)

(23)

(24)

Little is known about the course of such degradation reactions of biogenic substances. It is not impossible that some of the reactions described were caused by microbiological processes.

6.2.3. Dual Origin of Some Groups of Compounds

"Dual origin" refers to the fact that a compound isolated from sediments or fossils was originally present both as such and as a precursor. Three groups that are of great biological significance have been selected as examples here. These are the long-chain isoprenoids and the linear alkanes and fatty acids.

Isoprenoid compounds: The long-chain saturated isoprenoids have attracted special interest in recent years. These compounds occur in nearly all geological sources, such as petroleum[54], lignite[55], coal[56], oil shales[57], and other sediments[18], usually without functional groups, but also in the form of acids and alcohols. The isoprenoids are mainly between C_{15} (2,6,10-trimethyldodecane = farnesane) and C_{20} (2,6,10,14-tetramethylhexadecane = phytane), but with little or no C_{17} isoprenoid; they frequently account for the greater part of the branched alkane fraction (*e.g.* 3.4% of the total benzene extract from Green River shale)[57].

Traces of C_{17} isoprenoid have been detected for the first time in Antrim shale, a 265-million-year-old shale from Michigan, by *McCarthy* and *Calvin*[58]. This substance is also found in the deeper Upper Cretaceous sediments of the Douala Basin (Cameroon)[42].

The C_{21} isoprenoid (2,6,10,14-tetramethylheptadecane) is also present in several sediments[59]. *Han* and *Calvin*[60] even detected traces of C_{22}—C_{25} isoprenoids in a Californian petroleum (Bell Creek oil).

Saturated C_{14}—C_{22} isoprenoid acids can be isolated together with linear saturated acids in the free form from several sediments and petroleums[61]. *Murphy et al.*[62] re-

cently reported the presence of traces of C_{18} isoprenoid acid (6,10,14-trimethylpentadecanoic acid) in Green River shale. *Burlingame* and *Simoneit*[63] showed that most of the acids in Green River shale are in the form of the calcium salts.

(25)

Sever and *Parker*[45] have been able to determine traces of dihydrophytol *(25)* in many recent and some older sediments.

The long-chain isoprenoids, which are of widespread occurrence in living nature as unsaturated compounds, very rarely occur as saturated substances. Pristane (2,6,10,14-tetramethylpentadecane) and phytane have been found in some algae and bacteria[64]. However, pristane is a relatively important component in marine zooplankton, in which it occurs together with monoolefins having the same carbon skeleton (zamenes) and with phytadienes; it is also present in fish oils and in whale oil[28]. In zooplankton and in the oils, these compounds together with the isoprenoid acids are probably the end products of a metabolic degradation pathway of the phytol side chain of the phytoplankton chlorophyll in the marine nutritional chain.

A strong dominance of pristane in an "immature" (*i.e.* not too deeply buried) sediment could, according to these results, indicate that the organic material is of marine origin, and pristane could thus be a "paleo-ecological marker". *Blumer* and *Snyder*[65] found pristane, but not phytane, in two recent marine sediments. This compound is also by far the most common branched alkane in the upper, relatively little diagenetically changed layers of the Upper Cretaceous of the Douala Basin (Cameroon) (see Section 6.3)[66]. This is also so in the French marine oil shale of Créveney (Jurassic) (Fig. 8), which is 180 million years old, and has never been very deeply buried[67]. In immature sediments of nonmarine origin, as in the case of the Green River shale (Fig. 7) or the Messel oil shale (Figs. 4 and 9), on the other hand, phytane or the C_{16} isoprenoid predominates. However, these results are in need of confirmation from a large number of suitable sediments.

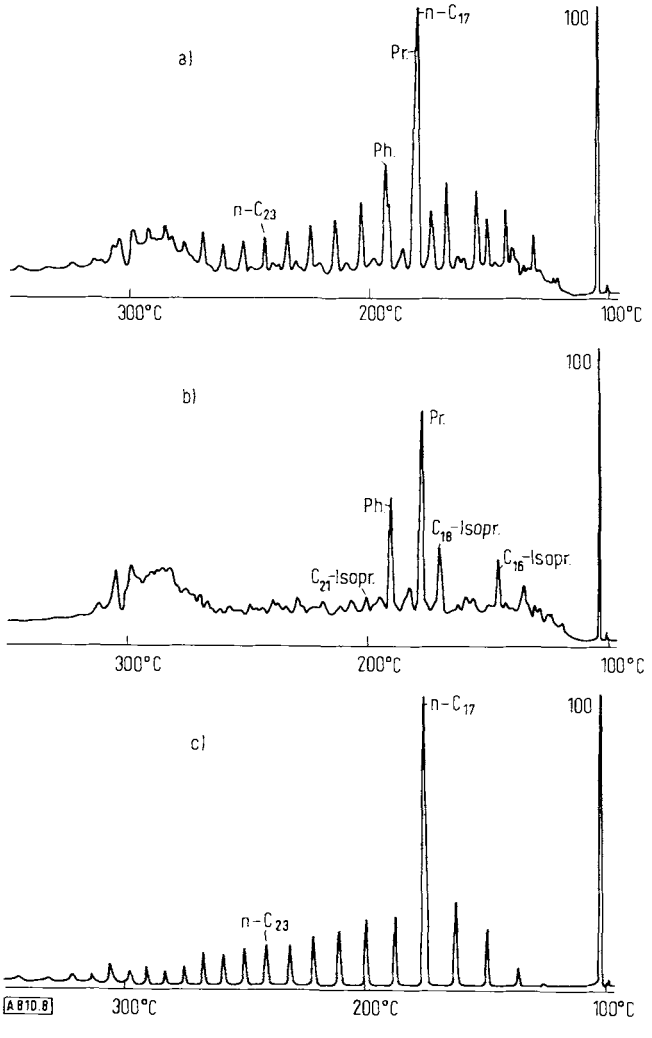


Fig. 8. Gas chromatogram of the saturated hydrocarbons of a marine oil shale (Créveney, Jurassic). (a) Total, (b) branched and cyclic, (c) linear hydrocarbons. For conditions and abbreviations, see legend to Fig. 4.

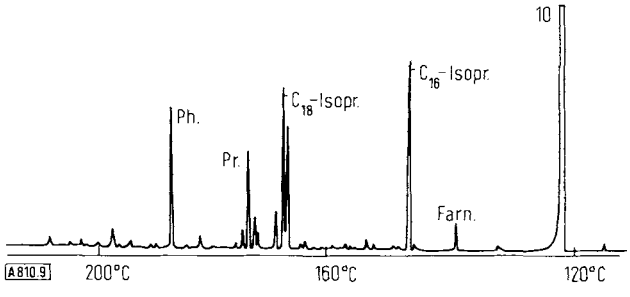

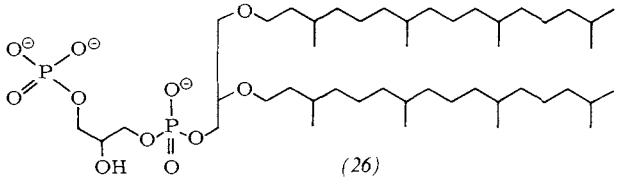

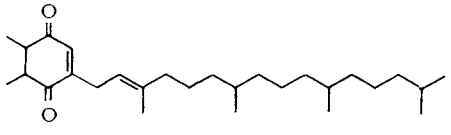

Fig. 9. Capillary column gas chromatogram of the low molecular weight branched alkanes of the Messel oil shale. Polyphenyl ether column 45 m × 0.25 mm.

Compounds with isoprenoid chains have been found in bacteria and algae[68], *e.g. (26)* in the halophilic bacteria *Halobacterium cutirubrum* and *(27)* in the fresh-water algae *Euglena gracilis*. However, chlorophyll is by far the most widely occurring compound with an isoprenoid side chain (Fig. 10); it may be assumed that a large proportion of the isoprenoids in fossils and sediments is derived from this substance through oxidation-reduction reactions, possibly also involving microbiological processes.

Phytane could be formed from phytol by hydrogenation and hydrogenolysis or by elimination of water and subsequent hydrogenation of the phytadiene. Reduction of

(26)

(27)

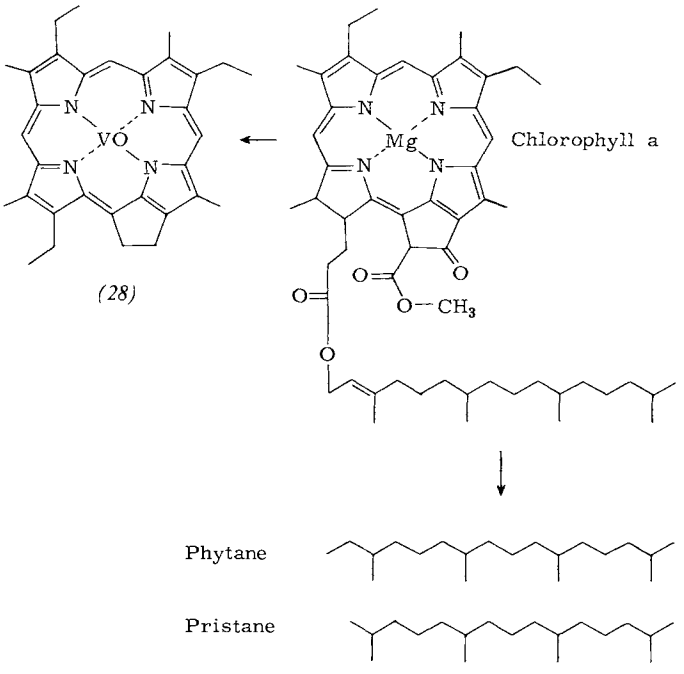

Fig. 10. Probable geochemical degradation reactions of chlorophyll with formation of vanadyldeoxyphylloerythroetioporphyrin *(28)*, phytane, and pristane.

phytol to dihydrophytol, which has been isolated from sediments, could lead after oxidation to phytanic acid, decarboxylation of which yields pristane. Isoprenoids with low molecular weights could then be formed by further "degradative decarboxylation" according to *Cooper* and *Bray*[47]. However, it is also possible that the hydrocarbons found are formed from the intermediate phytadienes and phytenes by cleavage of the CC double bonds and by reduction.

Isoprenoids in more deeply buried sediments may also be degradation products of kerogen or cracking products of the isoprenoid hydrocarbons (see Section 6.3).

n-Alkanes have been detected in nearly all sediments though sometimes only in small quantities. Like the isoprenoids, these compounds may be original biogenic substances or they may have been formed during diagenesis by reduction of molecules containing functional groups.

The *n*-alkanes can often be regarded as "paleo-ecological markers", particularly in immature sediments. Thus the predominance of *n*-alkanes with odd numbers of carbon atoms (between C_{23} and C_{35}) that is so characteristic of higher plants is found in terrestrial sediments, *e.g.* in Green River shale (Fig. 7) and in the Messel oil shale (Fig. 4), but also in many recent marine sediments, where they may serve as evidence of the supply of terrestrial organic material. This predominance is weak or absent in most marine organisms and in lower terrestrial plants[30,64b,69]; *n*-heptadecane is often the main component. The predominance of *n*-heptadecane is particularly pronounced in several immature marine sediments, *e.g.* in the Créveney oil shale (Fig. 8) and in samples of the topmost sediments of the Upper Cretaceous of the Douala Basin (see Fig. 14); between C_{23} and C_{35}, the alkanes with odd numbers of carbon atoms no longer predominate. The distribution in Green River shale probably points to a dual origin of the organic material of this sediment, which is partly derived from higher plants and partly from lower fresh-water plants.

Knoche et al.[70] have investigated the saturated hydrocarbons in a Lower Triassic fossil conifer, *Voltzia brongnarti*, that occurs in the variegated sandstone of the Vosges. Unlike the horse-tail mentioned in Section 5, these fossil remains, of which about 60% is made up of goethite (Fe_2O_3, H_2O), occur not in clay-rich inclusions but in the sandstone itself, as branches of varying thickness. The composition of the alkane fraction (3 mg from 2.6 kg of fossil) is remarkable, since it consists almost entirely of *n*-octacosane ($C_{28}H_{58}$). In view of the preference for alkanes with odd numbers of carbon atoms in the higher plants, this is probably a modification product. In the search for possible biological precursors, *Knoche et al.* analyzed the extracts for some conifers related to the species *Voltzia*, which is now extinct. The alcohol *n*-octacosanol, occurring in the leaf wax of *Taxodium distichum* Rich. and *Ginkgo biloba* L., is a possible precursor, since it could yield the saturated hydrocarbon on hydrogenolysis of the primary alcohol group in the sediment.

The slight preponderance of *n*-docosane ($C_{22}H_{46}$) in several sediments[71] could similarly be the result of reduction of docosanol. This compound is the main component *e.g.* of the alcohol fraction of Green River shale[45].

Decarboxylations, which have also been confirmed by *in-vitro* experiments[72], and complete reduction of the carboxyl groups of linear fatty acids[73] are further possibilities for "secondary" *n*-alkane formation in the sediments.

As a sediment sinks (see Section 6.3), the original distribution is partly masked by the dilution effect produced by the genesis of new hydrocarbons, and it is then more difficult to draw conclusions. Nevertheless, the compounds with odd numbers of carbon atoms may still predominate slightly in older, deeper sediments, and even in petroleums.

Linear fatty acids: These compounds may also be of "primary" or of "secondary" origin. They are often of great importance as "paleo-ecological markers". Thus the preponderance of linear saturated fatty acids with even numbers of carbon atoms between C_{22} and C_{32} in the Messel oil shale may be regarded with certainty as a contribution from the organic material of higher plants[44]. On the other hand, the fatty acids with even numbers of carbon atoms below C_{20} are usually most abundant in organisms of marine or lower terrestrial origin[74]. Thus tetradecanoic, palmitic, and stearic acids are the main components of the acid fraction in some recent marine sediments[33b]. There is often only a very slight preponderance of compounds with even numbers of carbon atoms in older, deeper deposits. Fatty acids with odd numbers of carbon atoms, among other compounds, appear to have been formed in these deposits during diagenesis. A correlation seems to exist between the distributions of *n*-alkanes and of *n*-carboxylic acids, particularly in older sediments[17]. However, this problem has not yet been finally settled.

A few words are appropriate at this point concerning the validity of the concept of "biological markers". The greater

part of the organic material that occurs in fossils and sediments is undoubtedly of biological origin. The few samples for which an abiogenic origin appears to be possible[75] (in Precambrian sediments and in meteorites) lack most of the "biological markers" mentioned in the above examples. Even the slight preponderance of *n*-alkanes with odd numbers of carbon atoms cannot be detected in these cases. Most is expected at present of the long-chain isoprenoids. However, some reservations are necessary here[76]. Polyisoprenoid chains can be synthesized stereospecifically by polymerization of isoprene with special catalysts, such as $Al(C_2H_5)_3$—VCl_3 (2:1)[77]; it is extremely unlikely, however, that such compounds have ever been available on earth as catalysts. On the other hand, a Fischer-Tropsch synthesis carried out by *Studier et al.*[78] with D_2 and with meteorite dust as the catalyst yielded, among other products, traces of deuterated C_9—C_{14} isoprenoids. Though no long-chain isoprenoids such as pristane and phytane were detected in this experiment, the result shows that abiogenic synthesis of certain long-chain isoprenoids over geological periods cannot be entirely ruled out.

McLean et al.[79] were able to separate diastereoisomers of esterified isoprenoid acids from Green River shale, and so to show that these acids are probably derived from chlorophyll. Separation of the diastereoisomers of phytane and detection of their optical activity could be an important step toward the solution of such problems.

6.3. Influence of Depth on the Organic Sediments

As a sediment becomes buried in a basin, it is subjected to a gradual rise in temperature and pressure. It loses most of its water, and both the inorganic material and the organic matter change. Laboratory experiments have shown that hydrocarbons can be produced by heating kerogen[3]. In most cases, however, experiments of this nature can give only a rough idea of reality, since they attempt to simulate the action of time, which plays a vital part in geology, by an excessive temperature rise.

A number of investigations have also been carried out on samples that have undergone natural diagenesis. Such experiments are of interest in connection with the problems of the origin and genesis of petroleum.

Louis and *Tissot*[80] have investigated the changes in the organic material of the Toarcian sediment layer (180 million years old) of the Paris Basin. This formation, which varies in its depth, appears on the surface at the edge of the basin, but is buried 2500 m down at the center. It thus provides samples of the same age, but from different depths. The ratio of alkanes to organic carbon begins to increase beyond a depth of 1400 m and at 60 °C. This increase, which signals the genesis of hydrocarbons, continues to the maximum depth of 2500 m (Fig. 11a).

Philippi[81] analyzed the hydrocarbons of various samples from the Californian basins of Los Angeles and Ventura. These samples reach, in the deepest layers, the Miocene deposits (12–15 million years old). Figure 11b shows a very pronounced increase in the hydrocarbon concentration in the Los Angeles basin at a depth of 2400 m and at 115 °C, continuing to 3500 m. The increase is accompanied by a change in the alkane distribution. The strong preponderance of compounds with odd numbers of carbon atoms between C_{27} and C_{33} above 2400 m, which is characteristic of the terrestrial influence, begins to decrease beyond this depth, and is insignificant beyond 3300 m, since the original hydrocarbons are now diluted with those formed later.

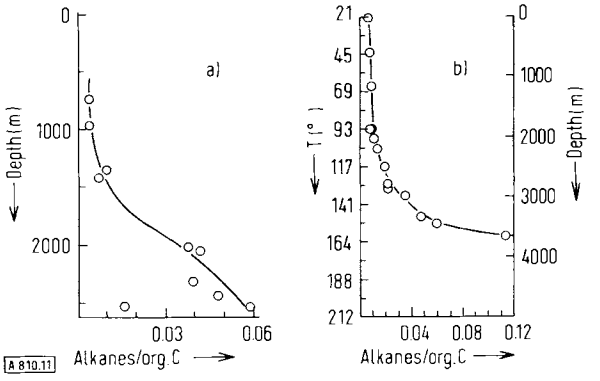

Fig. 11. Variation of the ratio of alkanes to organic carbon (org. C) with depth (a) in the Toarcian formation of the Paris Basin (after [80]), (b) in the Los Angeles Basin (after [81]).

We have investigated the hydrocarbons present in samples from the Upper Cretaceous sediments (80 million years old) of the Douala Basin (Logbaba, Cameroon)[66, 42]. Important characteristics of this series are shown by the geological history of the basin and by an accurate analysis of the inorganic material[82]. Because of the depth of the sedimentary series (4000 m), high temperatures (150 °C) and pressures (650 atm) are reached in the deepest layers. This geochemically homogeneous series, which was formed in a relatively short time (about 15 million years), consists of nearly horizontal sediment layers that are very rich in clay, sometimes interspersed with small sandstone lenses. The diagenesis of the clay fraction has been studied in great detail, and points to a gradual change in the clay minerals. In particular, the montmorillonite that mostly occurs in the upper layers changes beyond 1200 m into a montmorillonite-illite interstratified clay; this finally gives way, in the deepest part of the basin (3500 m), to illite, a non-swelling clay[82]. It was therefore assumed that this homogeneous series would be particularly suitable for studies on

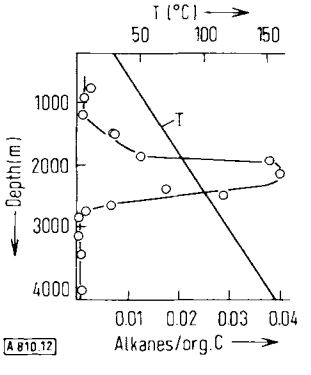

Fig. 12. Variation of the ratio of alkanes to organic carbon (org. C) with depth in the Upper Cretaceous sediments of the Douala Basin (Cameroon).

the organic material, and that changes could be interpreted as a consequence of diagenesis due to depth.

Figure 12 shows the depth variation of the ratio of alkanes to organic carbon (the total content of organic carbon in these sediments is 1–2%). A significant increase in the ratio at 1200 m confirms the results reported by *Louis* and *Tissot* and by *Philippi*. However, a correlation is also found between time and genesis temperature. In geologically younger basins such as that of Los Angeles (15 million years old), the genesis processes require much higher temperatures (115 °C) than in the older basins of Douala (80 million years old, 65 °C) and of Paris (180 million years old, 60 °C). The pressure appears to be of minor importance. Time and temperature are in fact to some extent interchangeable factors.

Because of the great depth and age of the Douala sediment series, other phenomena are also observed. At 2200 m (95 °C) the ratio of alkanes to organic carbon, after passing through a maximum, begins to decrease once more, and falls off to low values beyond 2800 m. This result, which is caused particularly by thermal effects, is undoubtedly the outcome of diagenesis due to depth, since the change in the ratio of alkanes to organic carbon is accompanied by a very regular variation of the distributions of the *n*-alkanes and of the branched alkanes (Figs. 13 and 14). C_R/C_T (carbon ratio), *i.e.* the ratio of the organic carbon that is non-volatile at 900 °C under nitrogen (C_R) to the total organic carbon (C_T) of the kerogen[83], increases steadily with depth, pointing to a gradual transition of the organic

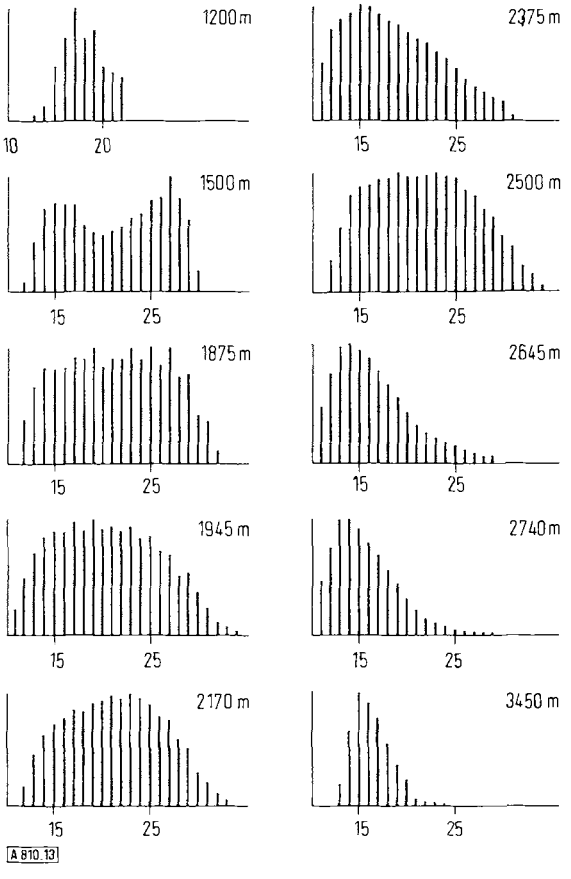

Fig. 13. Variation of the distribution of *n*-alkanes with depth in the Upper Cretaceous sediments of the Douala Basin (Cameroon). Ordinate: Signal area; abscissa: number of carbon atoms.

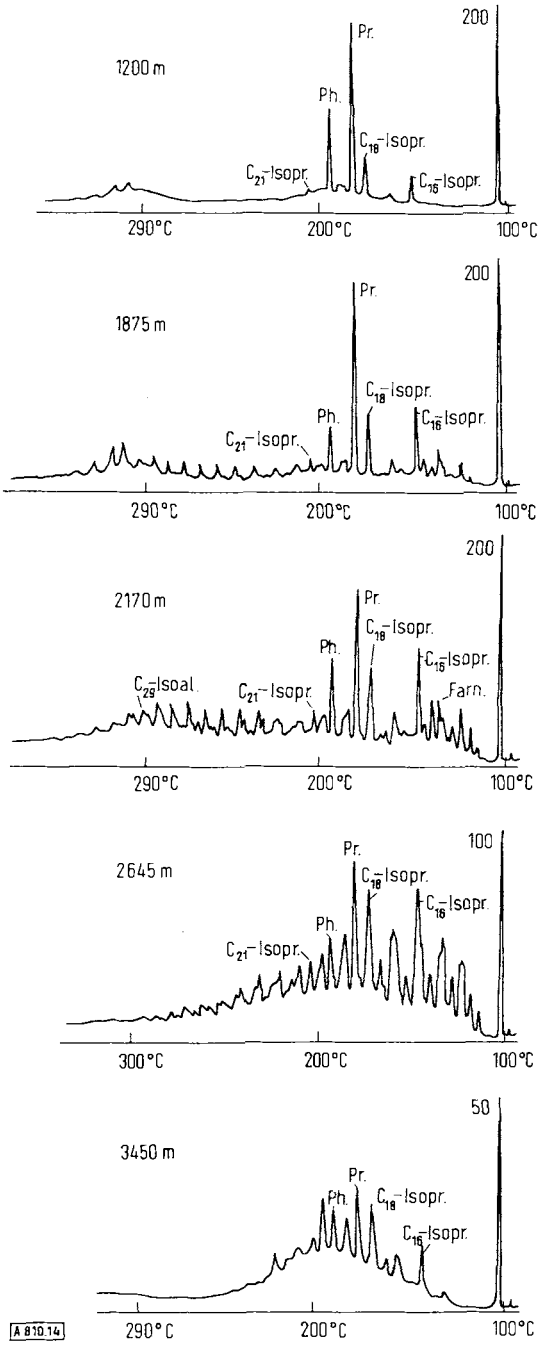

Fig. 14. Variation of the distribution of branched alkanes with depth in the Upper Cretaceous sediments of the Douala Basin (Cameroon). Gas chromatograms recorded under the same conditions as for Fig. 4; for abbreviations see legend to Fig. 7. Isoal. = isoalkane.

material into graphite[84]. The homogeneity of the original organic material is confirmed by the fact that the isoprenoids occur in practically the same proportions, irrespective of depth[85]; the pronounced dominance of pristane and the distribution of the *n*-alkanes in the uppermost sediment deposits point to a material of marine origin. Finally, the main results of the investigation have been confirmed by heating experiments carried out in the laboratory on the uppermost samples[42]. The newly formed hydrocarbons result partly from the removal of functional groups from the soluble fraction of the organic material and partly from the cleavage of bonds in the kerogen. Beyond 2200 m in the West African series of the Douala Basin, C—C bonds are also frequently cracked by the

higher temperature under the catalytic action of the clay. This is shown by the disappearance of high molecular weight in favor of low molecular weight compounds and the gradual appearance of an isomer mixture, which cannot be resolved by gas chromatography, in the series of branched alkanes. It is known that model reactions with dry clays as catalysts proceed by a carbonium ion mechanism[72], which favors branched compounds[72].

Such investigations are particularly interesting in connection with petroleum problems. Petroleum is probably formed in the finely divided organic material of the sedimentary rocks, which moves into porous reservoir rocks such as carbonates or sandstones during a migration process, where the oil phase separates from the water phase. It is generally assumed that this "primary" migration is usually restricted to short distances[86]. Fig. 15 shows a

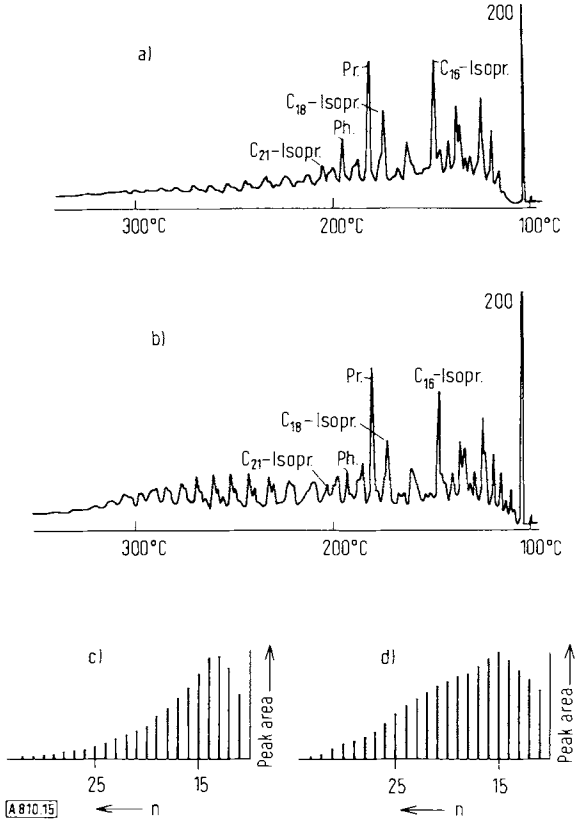

Fig. 15. Comparison of the alkane distributions of a petroleum and of a rock sample from under the reservoir rock (Upper Cretaceous of the Douala Basin, Cameroon). (a) Petroleum, branched alkanes, (b) rock, branched alkanes, (c) petroleum, *n*-alkanes, (d) rock, *n*-alkanes. For abbreviations, see legend to Fig. 7. n = number of carbon atoms.

comparison of the alkanes of a petroleum found in a sandstone lens at a depth of 2360 m in the sediment series of the Douala Basin with those of a lower-lying deposit (2364 m) whose organic material may have contributed to the formation of the oil. The very similar isoprenoid distributions confirm that the oil is probably related to the organic material of the neighboring sediment. The concentrations of higher *n*-alkanes and isoalkanes are lower in the oil than in the sediment, in agreement with the more recent migration theories, such as *Baker*'s micelle solubility theory[87] or the frontal chromatography process postulated by *Meinschein et al.*[88].

7. Investigations on Precambrian Sediments

According to *Darwin*'s continuity principle, a chemical evolution must have preceded biological evolution on earth. The transition from chemical to biological development could, *e.g.* according to *Oparin*'s theory[89], have occurred by formation of membranes around small droplets of organic substances, and would have led at a very early period to important changes in the composition of the organic material[90]. The investigations on Precambrian rocks were originally carried out in the hope of detecting such changes in the organic material of the sediments.

The ages of the Precambrian sediments investigated so far, which can be determined with good accuracy by isotope dating methods, range from one billion years for the North American Nonesuch shale to more than three billion years for the Fig Tree and for the Onverwacht series of South Africa. For comparison, the age of the earth is estimated to be about 4.6 billion years.

Only very few morphologically well-determined fossils from the period before the Cambrian are known. However, some microfossils, which correspond to present-day microalgae and bacteria, can be detected in Precambrian sediments[91]. Since it is often very difficult to determine the geological history of such old rocks, contamination with younger organic material, *e.g.* with younger petroleums, is one of the principal problems in the investigation of Precambrian deposits. Depending on the source of the organic material, the frequently used $^{12}C/^{13}C$ determinations show differences that, though small, can be easily measured with modern mass-spectrometric methods[92], and can be useful in the present case, since the $^{12}C/^{13}C$ ratio of the soluble fraction in most younger sediments is practically the same as that of the kerogen. If the kerogen is assumed to be an original polymeric material that cannot migrate, it can be shown by this method that some Precambrian sediments have probably been contaminated[16]. However, it is not certain that the isotope ratio has not been altered by external influences[90,93].

n-Alkanes and isoprenoids[94], as well as traces of fatty acids[95], porphyrins[96], and amino acids[97] have been detected in the small (but frequently investigated) soluble extracts. The kerogen fraction is very similar to that of younger sediments[6].

Though no transition from chemical to biological evolution has been found so far in the investigations on Precambrian sediments, it has been shown that biological material very probably existed on earth more than three billion years ago. Any transition from chemical to biological development must therefore have occurred even before this time, very soon after the formation of our planet.

8. Extraterrestrial Rock Samples

The investigations on extraterrestrial samples have so far been of interest particularly in connection with the possibility of extraterrestrial life. If such life had ever existed, it could also have been brought to earth. Some authors

believe that this is entirely possible, since the already complex biological processes detected in the older Precambrian sediments leave relatively little time for a chemical evolution[98].

Hayes has discussed this topic very critically[99]. Many of the extraterrestrial samples investigated are carbonaceous chondrites whose carbon contents are similar to those of terrestrial sediments; *n*-alkanes and the isoprenoids pristane and phytane have been detected in these meteorite samples[100]. Traces of aromatic compounds and biological compounds such as porphyrins, heterocyclic bases, and amino acids have also been found.

The impurities are again the main problem in such analyses. The difficulty here is not the determination of contamination, which can often be recognized by blank tests[101], but rather the impurities due to contact with the soil of the earth and in many cases to the long storage in museums (100 years in the case of the famous Orgueil meteorite). "Biological markers", the presence of which normally allows far-reaching conclusions to be drawn, can therefore not be used for the detection of extraterrestrial life. It is not impossible that part of the organic material in these samples was formed abiogenically *in situ*, since many substances identified in the meteorites can be synthesized abiogenically in the laboratory from simple organic and inorganic starting materials under the conditions of the primeval terrestrial atmosphere[99,102].

The analysis of the Pueblito-de-Allende meteorite, which landed in Mexico in February 1969, has led to a very remarkable result[103]. The determinations carried out in early March 1969 with a coupled apparatus for capillary column gas chromatography and mass spectrometry have shown that the soluble organic material is confined to the outermost layers of the meteorite, and no soluble substances can be detected in the interior. The organic material of the meteorite's crust, which is very similar to that of other meteorites, contains traces of *n*-alkanes and isoprenoids as well as saturated and unsaturated carboxylic acids.

This analysis thus shows that such samples very quickly become "contaminated"; it thus casts doubt on many earlier results, and shows the care that is necessary in studies in this field. It is possible that further help could be provided by an accurate analysis of the insoluble organic material in such samples[104].

The moon rock samples brought to earth by the Apollo expeditions have been analyzed with extreme precautions[105]. The first results indicate that these rocks contain only very small quantities, mostly in the contamination range, of organic material[106].

9. Kerogen

Kerogen is the name given to the insoluble polymeric organic part of the sediments. There is not just one kerogen, but many types. A rough classification by *Forsman* and *Hunt*[107] distinguishes between a coaly type and a non-coaly type of kerogen. Geomicrobiological studies have shown that at least part of the kerogen consists of various microbiological remains.

Though kerogen is the most abundant form of organic material on earth, very little is known about its structure or about its structural elements. As was mentioned in Section 6.3, it is the source of a substantial proportion of the hydrocarbons in the more deeply buried sediments, and hence also a large proportion of the petroleum. Hydrocarbons almost identical with those of petroleum have been prepared in the oil shale industry by heating kerogen to high temperatures. Kerogen is therefore a potential source of hydrocarbons.

Various attempts have been made to explain the formation of kerogen, which must occur in the early stages of sedimentation. According to *Abelson*[32], the cell membranes could change after the death of the plankton. The oxygen present may come into contact with reactive substances during the very slow sinking of such microscopic units. The formation of very reactive peroxides would then lead, as in the drying of linseed oil, to chain linkage. *Brooks* and *Shaw*[108] report a certain similarity between kerogen and sporopollenin, a component of the cell walls of pollen and spores. This polymer, which contains carotene esters among other compounds, yields substances similar to the kerogen of some sediments on oxidation. However, the problem is not that simple, since simple molecules also appear to be bound to the kerogen either chemically or as inclusions. *Blumer* and *Snyder*[109], for example, have shown that porphyrins are incorporated in the high molecular weight asphaltenes of the Swiss oil shale of Serpiano; such inclusions are undoubtedly also present in some way in the kerogen, as has been shown by the extraction of porphyrins by heating the kerogen of a recent sediment[110].

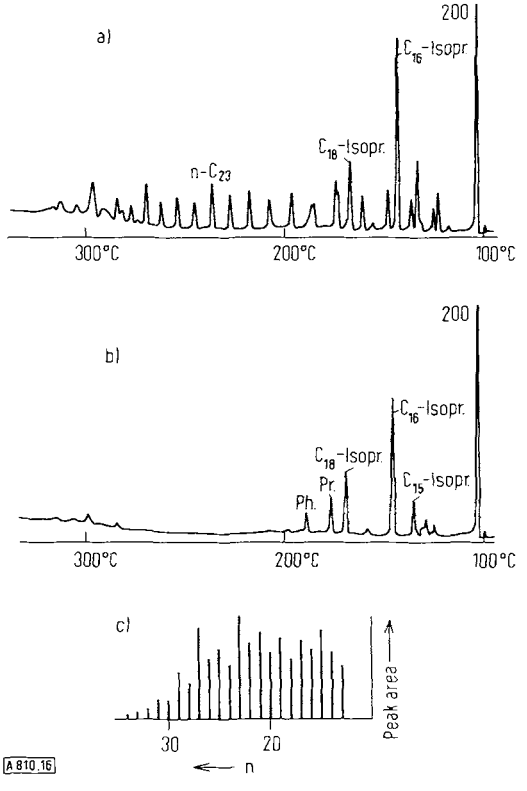

Fig. 16. Gas chromatogram of the alkanes formed by thermal degradation (40 h, 200 °C, under N_2) of the kerogen from the Messel oil shale. (a) Total, (b) branched and cyclic, (c) linear alkanes. For abbreviations see legend to Fig. 7. *n* = number of carbon atoms.

Numerous investigations have been carried out on the kerogen of Green River shale (65 %C) by thermal and chemical degradation[111]. *Burlingame* and *Simoneit*[112] managed to bring it into solution by oxidation for 48 hours with CrO_3. It was shown by mass spectrometry and gas chromatography that the main products are long-chain and isoprenoid acids. Even earlier, *Douglas et al.*[113] detected *n*-alkanes, olefins, and isoprenoids on thermal degradation of this kerogen. Hydrogenolysis at high temperatures, a procedure frequently used in the oil shale and coal industries, also brought 90 % of Green River shale into solution and led, *inter alia*, to the formation of saturated hydrocarbons with a strong preponderance of isoprenoids, particularly pristane[114].

The kerogen of the Messel oil shale (60 %C, 7 %H, 1.5 %N) yields long-chain *n*-alkanes on thermal degradation; when lower temperatures are used, a preponderance of alkanes with odd numbers of carbon atoms can be detected[39b]. With moderate heating (200 °C, 40 hours under N_2), in addition to *n*-paraffins, branched saturated hydrocarbons consisting exclusively of isoprenoids are also formed[42] (Fig. 16).

According to these preliminary results, the kerogen of this oil shale appears to be a polycondensed material with long straight and isoprenoid chains.

10. Conclusion

Investigations using the latest analytical methods have extended and deepened our knowledge of the composition and origin of the finely divided organic material of sediments and fossils. Because of the small quantities of organic substance, strict precautions are often necessary to avoid contamination in these studies.

The occurrence of original or degraded biological compounds in sediments and fossils shows that the organic material from these geological sources, with few exceptions, is of biological origin.

These "biological markers" can in many cases be used as "paleo-ecological criteria", since they allow the deduction of the origin of the organic substance with great certainty, and possibly its classification. They also provide valuable information about important degradation reactions of the biological material in the geological environment. In the topmost layers of the sediments, these processes are probably due to the action of microorganisms and oxidizing-reducing and acid-base effects of the environment. A better knowledge of the degradation mechanisms would be very welcome. As a sediment sinks in a basin, it is gradually exposed to rising temperatures and higher pressures. At a depth and temperature that depend on the age and lithology of the basin, bonds are broken in the soluble and insoluble organic fractions of the rock, with formation of new hydrocarbons, which can also be broken down later.

Petroleum comes from the finely divided organic material of sedimentary rocks, which collects in porous reservoir rocks during migration processes.

The biological processes have probably remained unchanged since the Precambrian. The presence of "biological markers" in the oldest sediments of the earth indicate, with a probability that borders on certainty, that life began more than three billion years ago, *i.e.*, geologically speaking, relatively soon after the formation of the earth. "Biological markers" in extraterrestrial rocks have also been closely examined in an effort to detect the existence of life outside the earth. However, no definite answer to this question can be given as yet.

Kerogen forms the greater part of the organic material in the sediments, and is thus the most general form of organic material on earth. Unchanged kerogen is a complicated polymer containing straight and isoprenoid chains, probably condensed, *e.g.* by ester and ether bridges.

When kerogen is heated, it undergoes degradation reactions that lead to new hydrocarbons. A better knowledge of its structure could help to explain its origin and the manner in which it was formed. This might lead to a better understanding of the hydrocarbon genesis that takes place during the sinking of sediments.

The arrangement of the organic and of the inorganic material in the sediments is also of great importance. It is interesting to contemplate how far the changes in the organic and inorganic materials during sedimentation are coupled.

Finally, the methods described here could also be useful in fields such as oceanography, soil research, and environmental science.

Our investigations were carried out as part of Research Program D.G.R.S.T. No. 64-FR-058. We are grateful to the Entreprise de Recherches et d'Activités Pétrolières, the Institut Français du Pétrole, and Ytong AG for supplying the samples from Logbaba (Cameroon) and from Messel (Germany). These investigations would not have been possible without the kind cooperation of the Institut de Géologie Strasbourg, under the direction of Professor Dr. G. Millot, as well as Professor Dr. J. Lucas, Professor Dr. G. Dunoyer de Segonzac, Dr. C. Sittler, Dr. J. C. Gall, and Mr. L. Grauvogel. We are also very grateful to our coworkers Dr. R. Brandt, Dr. H. Knoche, Dr. G. Mattern, Dr. O. Sieskind, Mr. P. Arpino, and Mrs. M. Vercaemer for their assistance and for the valuable discussions and the great enthusiasm with which they repeatedly overcame the many difficulties that arose. We also thank Dr. J. Connan, S.N.P.A., Pau, for his helpful discussions and for the analyses that he carried out. Finally, we thank Dr. Eglinton, Bristol University, for the time that one of us (P.A.) was allowed to spend in his laboratories.

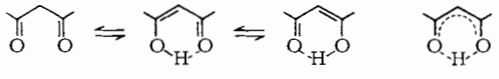
Bond Character of β-Diketone Metal Chelates

By Bodo Bock, Karsten Flatau, Helmut Junge, Manfred Kuhr, and Hans Musso[*]

The vibrational spectra of molecules labeled with ^{2}H, ^{13}C, and ^{18}O show that delocalization of double and single bonds in the six-membered ring is complete in all the metal chelates investigated of 2,4-pentanedione (acetylacetone), but not in 2,4-pentanedione itself. Mercury, on the other hand, is bonded to the central C atom of the ligands. The NMR spectra of the metal chelates of 3-mesityl-2,4-pentanedione and 3-anthryl-2,4-pentanedione show that the chelate rings have no magnetic anisotropy comparable with that of benzene. A critical appraisal is made of the questions whether it is at all justifiable to attribute any "aromatic character" to such molecules and why all comparisons with the chemical reactivity of benzene have so far led to controversial conclusions concerning the character of the bonding in the metal chelates of 2,4-pentanedione.

1. Introduction



At various stages of its development the concept of aromatic character has stimulated chemists to compare unsaturated ring systems that had either been known for a long time, or specifically prepared for this purpose, with benzene. Although one is attracted by the formal similarity and the desire to approach the ideal of this state, more or less pronounced differences in the chemical and physical properties are found in practice.

To cope with this situation, various qualified expressions such as benzenoid and nonbenzenoid aromatic systems, heteroaromatic systems, quasiaromatic and pseudoaromatic systems, nonclassical aromatic systems, and anti-

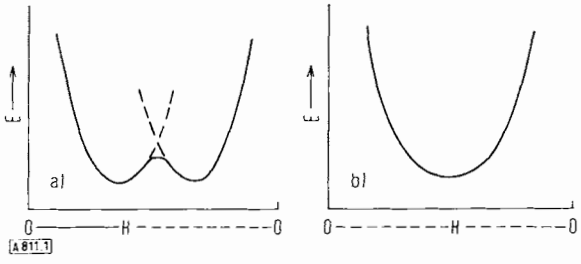
75 Karlsruhe 1, Postfach 6380 (Germany)

aromatic systems[1] were introduced. Alternatively, the aromaticity of a system is sometimes expressed in percentages[2]. Whether or not these terms are rigorously defined and based on theory, or are universally used and unambiguously understood, it is certainly of interest to know the experimental methods used in attempts to answer questions of bonding in such a molecule, as well as the results. The methods providing a relatively clear picture in the case of 2,4-pentanedione (acetylacetone) and its metal chelates will be described here.

The equilibrium between the keto and enol form of pentanedione [*(1)* and *(2)*] is established so slowly at room temperature that the two forms can be easily detected in each other's presence by their vibrational and NMR spectra. However, the two methyl groups of the enol form *(2)* give only *one* sharp signal in the ^{1}H-NMR spectrum, though their environments are different in the usual notation *(2)*[3], and it is very unlikely that the signals coincide by accident. Either the interconversion of the two tautomers *(2a)* and *(2b)*, which have equal energies, is very fast even at low temperatures (double minimum in the energy profile, Fig. 1) or the molecule has a symmetrical

(1) *(2a)* *(2b)* *(3)*

structure *(3)* in which the bonds between the acidic proton and the two oxygen atoms are of exactly the same length (only one broad minimum in the energy profile, Fig. 1).



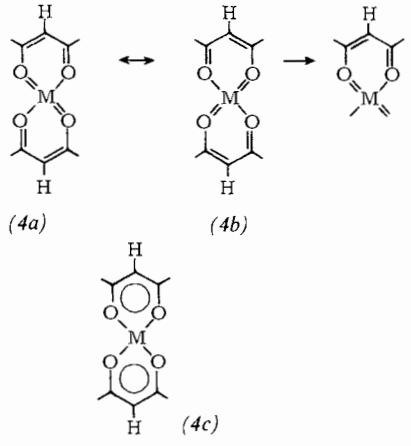


Fig. 1. Energy profile for (a) unsymmetrical and (b) symmetrical hydrogen bonds.

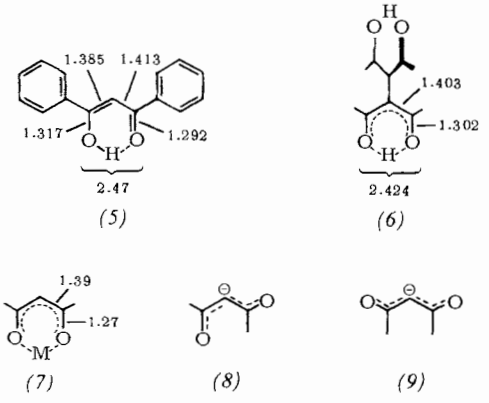
2,4-Pentanedione reacts with many metal ions to form complexes[4]. Those with chromium, cobalt, and rhodium are so stable that the central H atom on the chelate ring can be substituted as in benzene. They can be halogenated with *N*-bromosuccinimide or iodine chloride, acylated with acetic anhydride and boron trifluoride, formylated with phosphorus oxide chloride and dimethylformamide, converted into thiocyanates with dithiocyanogen and into thioethers with sulfenyl chlorides. Furthermore, they can be chloromethylated with chloromethyl ether, and nitrated with copper nitrate in acetic anhydride. The nitro compound can be reduced to amine; this gives a stable diazonium salt, which couples with β-naphthol, can be converted into the OH compound by heating, is reduced by ethanol, and can even be converted into the fluoro compound under the conditions of the Balz-Schiemann reaction[5].

Calvin[4] first tried to explain the stability of these chelates by a benzenoid resonance and represented it using resonance structures *(4a)*↔*(4b)* analogous to those used for benzene, the prototype aromatic compound. The similar-



(4a) *(4b)* *(4c)*

ity of their behavior to that of the benzene ring in electrophilic aromatic substitutions led *e.g. Collman*[5] and *Bayer*[6] to attribute an aromatic, quasiaromatic, and pseudoaromatic character [see *(4c)*] to these compounds, and experimental results repeatedly appear which seem to confirm these conclusions[7].

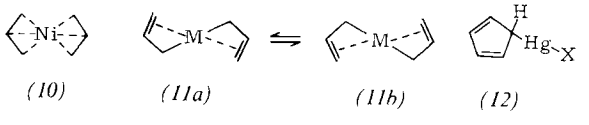
2. Structure of 2,4-Pentanedione and Its Metal Chelates

In the keto form *(1)* of pentanedione, the acetyl groups can rotate about the bond to the central C atom, whereas the enol form is fixed in the planar *cis* structure *(2)* by the hydrogen bond. So far as is known, no attempt has been made to establish the position of the proton between the O atoms in the enol form by X-ray analysis or neutron diffraction. The electron diffraction in the gas phase at about 100 °C appears to be compatible with the symmetrical position *(3)*[8], but the radial distribution curve cannot be interpreted completely and conclusively with respect to the exact position of the light hydrogen atoms[9]. In the case of 1,3-phenyl-1,3-propanedione *(5)*, the X-ray structure in the crystal shows different lengths for the C—O and C—C bonds[10], whereas it has been reported that the proton in the crystal of tetraacetylethane *(6)* is probably

(5) *(6)* *(7)* *(8)* *(9)*

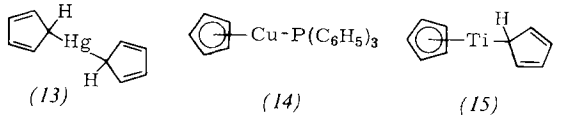
situated exactly midway between the O atoms[11]. Earlier structural analyses on metal chelates of 2,4-pentanedione show that, *e.g.* in the case of Cu, the lengths of the C—O and C—C bonds are slightly different[12], whereas the majority of recent investigations on many chelates of 2,4-pentanedione with a wide variety of metals (Mn, Zn, Cu, Ni, Cr, Al, Co, VO, Zr, Fe, Be, Ce[13], Co[14], Rh[15], Ni[16], Mn[17], Ce[18]) indicate a symmetrical electron distribution in the chelate ring; these investigations lead to the average values given in *(7)* for the C—O and C—C distances[13].

Slight deviations of the ligands from C_{2v} symmetry are rare (Zn[19], Fe[20], U[21], Cu[22]), and may be due to experimental errors, the particular arrangement in the crystal, or Jahn-Teller distortion[22]. The vibrational spectra indicate that the free anion prefers *trans* conformations *(8)* and *(9)* in solvents in which the complexes dissociate[23].



X-ray analysis, however, suffers from the following drawbacks in connection with this question:

1) The result refers to the crystal, in which the structure may be different from that in solution or in the gaseous state, owing to interaction with the neighboring molecules in the lattice.



2) It is extremely difficult to decide whether the ligands are truly symmetrical or whether they deviate slightly from C_{2v} symmetry, irrespective of whether they have a regular alternating arrangement, are randomly distributed, or are in a rapid equilibrium.

3) The X-ray analysis yields only distances, and provides no direct information as to whether the conjugation in the chelate ring passes cyclically through the metal ion, though the average C—C distance is 1.39 Å, as in benzene.

This problem of double or single minimum, which has been discussed here for 2,4-pentanedione, also arises with

(10) *(11a)* *(11b)* *(12)*

(13) *(14)* *(15)*

many other molecules, and is constantly being discussed in the literature, *e.g.* in connection with the carboxylate ion[24], nonclassical carbonium ions[25], and σ- and π-allyl metal complexes, where both cases appear to occur, depending on the central atom and the ligand. Allyl residues are bonded symmetrically to Ni and Pd *(10)*[26], and unsymmetrically to Rh and Ru; phosphanes or arsanes as additional ligands can favor the interchange in the allyl residue *via* equilibria between σ and π bonds [*(11a)*⇌*(11b)*][27]. Cyclopentadiene is σ-bonded to mercury halides and mercury as in *(12)* and *(13)*[28–31], and a fast equilibrium, which is catalyzed by traces of mercury salts[31], occurs between all five C atoms, and may give an incorrect impression of a symmetrical *pentahapto* bond, *e.g.* in NMR studies. With other metals, *e.g.* in cyclopentadienyltriphenylphosphanecopper *(14)*, such a bond has been verified by IR[32] and X-ray analysis[33]. In comparable titanium compounds, the σ- and *pentahapto*-π types appear to occur together at the same central atom *(15)* and are in rapid equilibrium[34].

If NMR spectroscopy responds too slowly to detect the tautomers or valence-isomeric structures separately, as in the case of 2,4-pentanedione, vibrational spectroscopy is more promising. Structures with lifetimes of down to 10^{-12} s should still be recognizable in the region of C—C, C—O, and O—H stretching vibrations. It is only when the energy barrier between the tautomers *(2a)* and *(2b)* (Fig. 1) decreases to the order of magnitude of the vibrational quanta that band broadening must be expected. If the energy barrier is lower than the first vibrational level, it is no longer meaningful, in terms of vibrational spectra, to discuss different structures, since then these structures are simply vibrational amplitudes of the symmetrical structure. In cases where a proton oscillates between two oxygen atoms, as in the enol form of pentanedione, the frequency for small O—O distances, because of the tunnel effect[35], can be as high as 10^{11}, and thus approach the time resolution limit of vibrational spectroscopy; however, electronic spectra may then provide further information (see Section 6[100, 102]).

3. Analysis of the Vibrational Spectra

To obtain information about the symmetry of a molecule from the vibrational spectrum, one must first assign all the bands. When we began our studies, no unambiguous assignment of the bands in the IR spectra of copper bis-(pentanedionate) (Fig. 2) and other chelates of β-diketones was to be found in the literature. We shall first discuss only the first four strong bands at 1578, 1527, 1397, and 1281 cm^{-1}.

Whereas *e.g. Collman*[36] and *West*[37] initially assigned the first band in the carbonyl region at 1578 cm^{-1} empirically to the C=O and the second at 1527 cm^{-1} to the C=C stretching vibration, *Nakamoto*[38] and his coworkers concluded from a normal coordinate analysis that the first band has 75% C=C and only 25% C=O character, while the second band arises from the same bonds with the proportions reversed. *Mecke* and *Funk*[39] avoid attributing these bands to discrete group frequencies, since localization of the vibrational energy in a certain bond cannot be expected if the vibrations are extensively coupled, and they suggest that these four bands should be regarded as characteristic stretching vibrations of the chelate ring as a whole, as in the case of benzene.

Uncertainties in the assignment of frequencies in the vibrational spectrum can be eliminated experimentally if individual atoms in the molecule under study are replaced by heavy isotopes. According to the vibration equation for a harmonic oscillator [eq. (1)], this leads to a displace-

$$\nu = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \qquad (1)$$

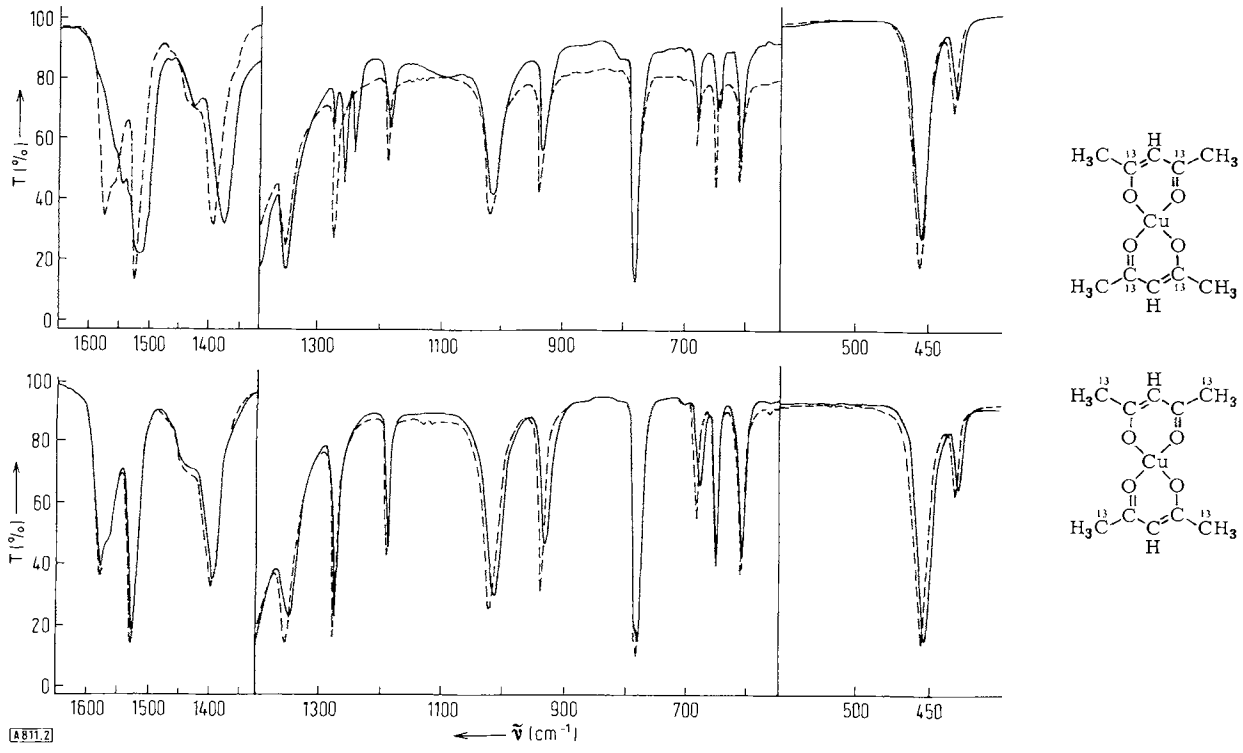


Fig. 2. IR spectrum of the copper bis(2,4-pentanedionate) complex, unlabeled ---, above [2,4-$^{13}C_2$]-labeled, below [1,5-$^{13}C_2$]-labeled.

ment of the absorption band to longer wavelengths, since the mass of the vibrating atoms is in the denominator in the square root. With only 50% labeling of the atoms, two bands appear in the spectrum (Fig. 3), and the difference

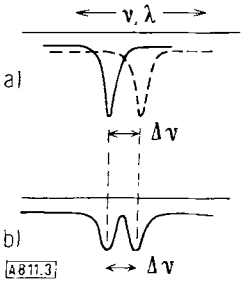

Fig. 3. (a) Frequency shift due to 100% incorporation of a heavy isotope ---; (b) vibrational spectrum of a molecule with 50% labeling with a heavy isotope.

between the vibrations of the unlabeled and of the labeled molecules can be calculated and is a measure of the extent of the movement of the labeled atom in the vibration. It is assumed here that the force constant does not change on isotopic substitution, an assumption that is sufficiently valid even for the greatest possible change, *i.e.* replacement of hydrogen by deuterium[40]. In the spectrum of a compound with many atoms (29 in this case), the equations become correspondingly complicated, and the vibrations are more or less strongly coupled, so that several bands are displaced at the same time[41]; however, one can see directly which frequencies in the spectrum are associated with a given atom[42]. If this atom does not move in a given vibrational mode of the molecule, the band in question will not be affected by isotopic substitution.

Consequently, as many of the atoms of 2,4-pentanedione as possible were replaced both singly and in the combinations shown in Fig. 4, by the isotopes ^{13}C, ^{18}O, and ^{2}H (more than 50% enrichment). The spectra of the complexes with various metals were recorded and numerous band shifts observed. The comprehensive results may be summarized and evaluated in the amplitude diagrams in Fig. 5[43,44].

If the magnitude of the shift of a given band is represented by a circle of corresponding size around the labeled atom in the formula, one can immediately see how strongly each atom participates in the vibration in question. The direction of vibration is deliberately omitted, since it is not immediately evident from the band shift. The band at

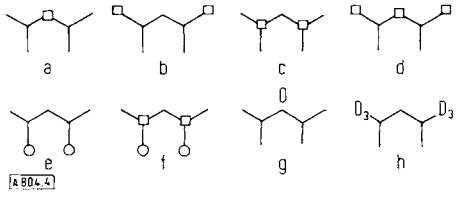

Fig. 4. List of isotopically labeled 2,4-pentanediones (a–h). □, ^{13}C 50% enriched; ○, ^{18}O 70% enriched; D, ^{2}H more than 90% enriched.

1578 cm^{-1} is displaced by −30 cm^{-1} toward longer wavelengths (Figs. 2 and 5) when C atoms 2 and 4 are exchanged for ^{13}C. If the atoms 1, 3, and 5 are substituted by ^{13}C, this band undergoes only an extremely small shift, whereas replacement of the O atoms by ^{18}O leads to a displacement of the same band by −26 cm^{-1} to lower frequencies. This band thus clearly has a high C—O stretching character, whereas the second band at 1527 cm^{-1} is the antisymmetric vibration of the C—C—C segment

of the chelate ring, and the fourth band at 1281 cm^{-1} is the corresponding symmetric vibration, in which C atoms 2 and 4 move in the same direction toward or away from C-3. The third band at 1397 cm^{-1} is again mainly a C—O vibration, and most of the other bands in the spectrum can be assigned in the same way. The bands due to deformational vibrations are located in the center of the spectrum (Fig. 2), and the metal-oxygen frequencies at longer wavelengths[44].

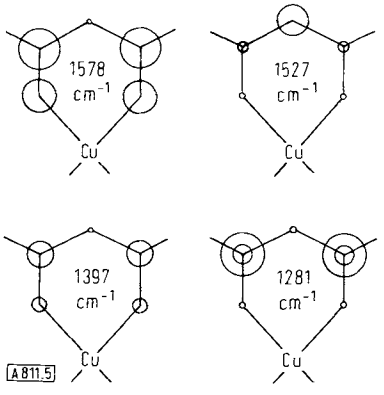

Fig. 5. Amplitude diagrams for some bands from the IR spectrum of copper bis(2,4-pentanedionate). The circles show the magnitude of the long-wave shift of the frequencies in question when these atoms are replaced by heavy isotopes.

The assignment discussed here, particularly of the C—O and C—C—C bands, was also deduced by other workers from ^{18}O-labeling experiments[45]. However, normal coordinate analyses do not lead definitely to the desired information for this molecule containing 29 atoms. More recent calculations for the Cu and Eu complexes[46] give the same result as the earlier calculations[38], but agreement with the experimental assignment given here was achieved by improvement of the force field used for the first calculation[47]. Measurements have recently also been carried out on pentanedionates highly enriched in heavy metal isotopes ($^{54}Fe/^{57}Fe$, $^{50}Cr/^{53}Cr$, $^{63}Cu/^{65}Cu$, $^{104}Pd/^{110}Pd$) to verify the assignment of the metal-oxygen vibrations[48].

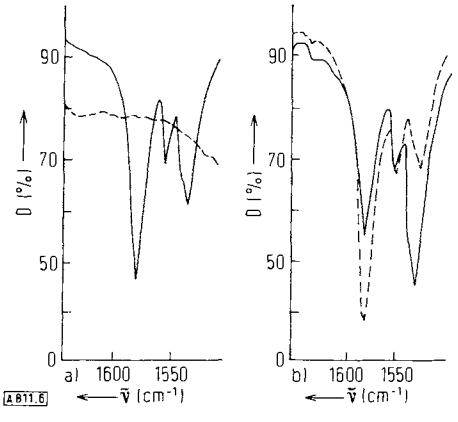

Fig. 6. (a) —— IR spectrum of copper bis(2,4-pentanedionate) in stretched polyethylene film, thickness 4×10^{-3} cm without polarizer against polyethylene film of thickness 4×10^{-3} cm. --- IR spectrum of a stretched polyethylene film of thickness 4×10^{-3} cm against air. (b) IR spectrum of copper bis(2,4-pentanedionate) in drawn polyethylene film of thickness 4×10^{-3} cm against polyethylene film of thickness 4×10^{-3} cm, with polarizer, ⊥ perpendicular —— and ∥ parallel --- to the stretching direction.

The question which of the two C—O vibrations is the antisymmetric and which the symmetric can be answered with the aid of the spectra of molecules oriented in stretched films with polarized IR light. The molecules are oriented with their longitudinal axes in the stretching direction, and the intensity of the bands is high when the plane of polarization of the radiation coincides with the direction of the transition moment of the vibration, and low when the two vectors are perpendicular to each other. It can be seen from Fig. 6 that the band at 1578 cm^{-1} is caused by the symmetric C—O vibration[44]. The organic chemist tends to accept that the antisymmetric vibration *e.g.* for the NH_2, NO_2, and $CO_2^{\ominus}$ groups has the higher frequency, but this is strongly dependent on the angle between the two vibrations.

4. Symmetry of the Chelate Ring

It can be seen that the symmetric stretching vibration of the C—C—C segment at 1281 cm^{-1} in the spectrum of the [2,4-$^{13}C_2$]-labeled Cu complex splits into three equidistant sharp bands with very different intensities, and the shifts are -16.5 and -33.5 cm^{-1}. Since this can provide considerable information about the symmetry of the complex, let us enlarge this pattern of bands in Figure 7 and analyze it in more detail.

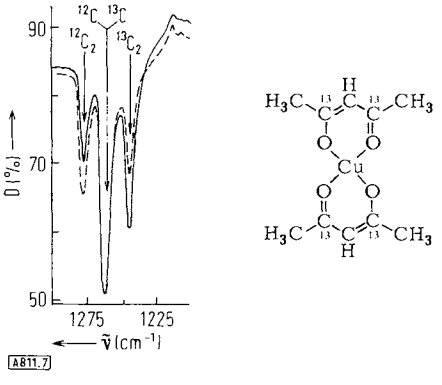

Fig. 7. Splitting pattern of the band at 1281 cm^{-1} for the copper bis(2,4-pentanedionate) complex at various levels of labeling with ^{13}C (——, 52.5% [$^{13}C_1$]acetic acid as starting material; ---43.9%).

The starting material for the synthesis of the complex was acetic acid in which the carboxyl group had been enriched in ^{13}C to 52.5%. The product thus consists of a mixture of 22.6% of unlabeled molecules, 49.9% of molecules containing only one ^{13}C atom in position 2 or 4, and 27.6% of molecules doubly labeled in these positions. Since the intensities of the three bands in the spectrum correspond to these percentages, the first band is assigned to the unlabeled complex, the second to the singly labeled complex, and the third to the doubly labeled complex. That this assignment is correct can be easily shown by starting with an acetic acid sample with 43.9% $^{13}C_1$; in this case the intensities of the three bands change in accordance with the calculated ratio to 31.5, 49.2, and 19.3%.

This band splitting is related to the symmetry of the molecule as follows. In a molecule A in which the bonds between

an atom M2 and two other atoms M1 and M3 of the same kind differ in strength (Fig. 8), replacement of the atom M1 by a heavy isotope will lead to a pronounced displacement of the stretching vibration ν_{M1-M2} (ν_2) and a small shift of the second stretching vibration ν_{M2-M3} (ν_1) because of

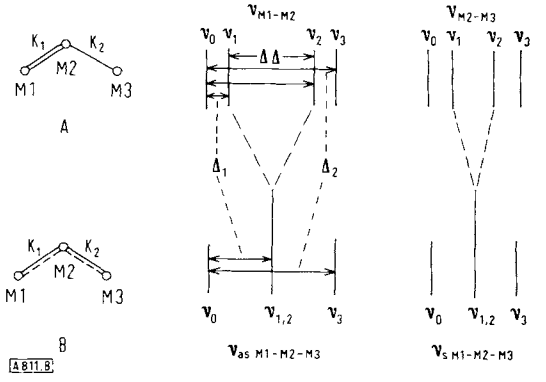

Fig. 8. Splitting of the stretching vibrations for the unsymmetrical case A and the symmetrical case B.

coupling, both displacements being to longer wavelengths. The same is true when atom M3 is labeled. If both M1 and M3 are replaced, both frequencies will exhibit an even greater shift (ν_3). The IR spectrum of a mixture of all three types of labeled molecules must therefore show three displaced partial bands (ν_1, ν_2, and ν_3) for both bands, as well as the component for the unsubstituted molecule ν_0. If the force constants of the two bonds are equal, as in B (Fig. 8, $K_1 = K_2$), the vibrational spectrum will also show two stretching vibrations, *i.e.* one antisymmetric and one symmetric. In contrast with A, the replacement of M1 is no longer distinguishable from that of M3, and the two middle frequencies ν_1 and ν_2 in the splitting pattern for the bands of the mixture coincide. Each band of B gives a triplet, and the ratio of the shifts for the components of each triplet Δ_1 and Δ_2 must be 1:2. If the shifts for an angular C—C—C system in which ^{12}C has been replaced by ^{13}C are calculated by starting with a single and a double bond (A, $K_1/K_2 = 2.0$) and making the force constants

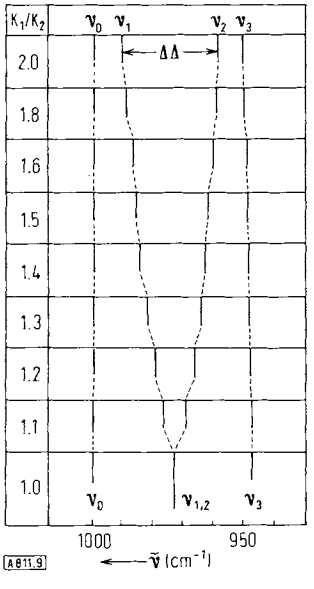

Fig. 9. Calculated splitting for various force constant ratios K_1/K_2.

between the atoms more and more similar until they are exactly equal as in B ($K_1/K_2 = 1.0$), one can see from Fig. 9 that the difference $\Delta\Delta$ between the middle components ν_1 and ν_2 decreases steadily. For a difference of 10% in the force constants ($K_1/K_2 = 1.1$), we obtain a splitting of 3.5 cm^{-1}. The experimental error of ± 1 cm^{-1} in the IR spectrum corresponds to a difference of 3% in the force constants. When converted into bond lengths, this corresponds to an accuracy of ± 0.01 Å for the difference or identity of the bond lengths, which is as good as, and in many cases better than, that of a careful X-ray analysis.

The IR spectrum of partly labeled products thus offers the possibility of a definite answer as to whether there is an equilibrium between tautomeric or valence-isomeric structures or only one structure with complete delocalization of single and double bonds (double or single minimum in the energy profile, Figs. 1 and 8). However, two important conditions must be satisfied. It must be possible to locate the corresponding bands with certainty in the spectrum, and the half-widths of the bands in the splitting pattern must be small in relation to their shift with respect to the unlabeled compound.

Table 1. Shift of the 1281 cm^{-1} band of copper bis(2,4-pentanedionate) on substitution of C atoms 2 and 4 with ^{13}C.

	Δ1	Δ2
Calculated:	17.2 cm^{-1}	33.3 cm^{-1}
Experimental:	16.5 ± 1 cm^{-1}	33.5 ± 1 cm^{-1}

These conditions are satisfied by many metal complexes of acetylacetone. The half-widths of the three partial bands (Fig. 7) in the spectra of the complexes with Cu, Li, Na, Mg, Be, and Pd agree to within ± 1 cm^{-1} both in the crystal and in solution. Thus the force constants between the C atoms of the chelate ring are equal, and the delocalization of the double bonds is complete[49, 50]. The observed

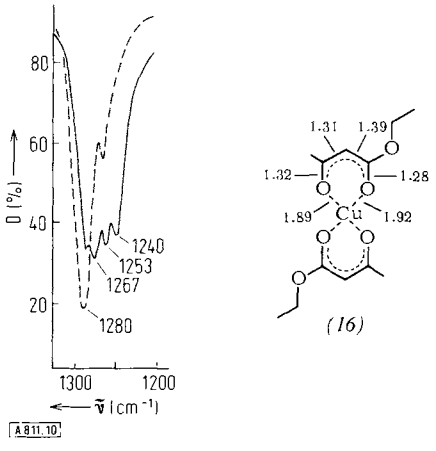

Fig. 10. Section of the IR spectrum of the [1,3-$^{13}C_2$]-labeled Cu complex of acetoacetic ester *(16)*; unlabeled ---.

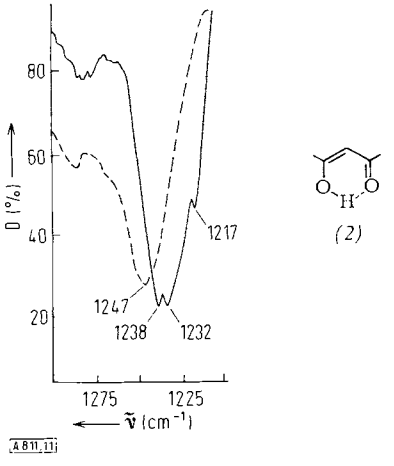
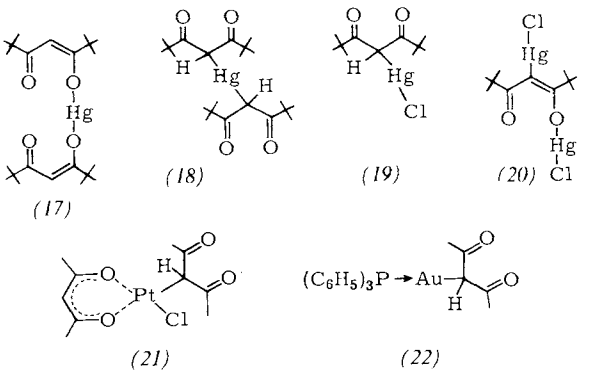
shift of the band at 1281 cm^{-1} agrees with the value calculated for the symmetrical molecule *(7)* (Table 1)[51] within experimental error.

In order to check this conclusion measurements were also carried out on the copper complex of [1,3-$^{13}C_2$]-labeled acetoacetic ester. According to X-ray analysis *(16)* the C—C distances in the ring are significantly different, and have values of 1.31 and 1.39 Å (±0.025)[52], corresponding to a force constant ratio of 1.3.

The spectrum (Fig. 10) does in fact show three displaced bands, and the shift difference $\Delta\Delta = 14\ cm^{-1}$ corresponds to a force constant ratio of 1.4 or a difference of 0.1 Å in the bond lengths[50].





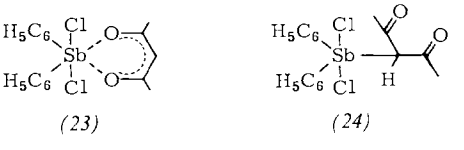


Fig. 11. Section of the IR spectrum of [2,4-$^{13}C_2$]-labeled pentanedione *(2)*; unlabeled---

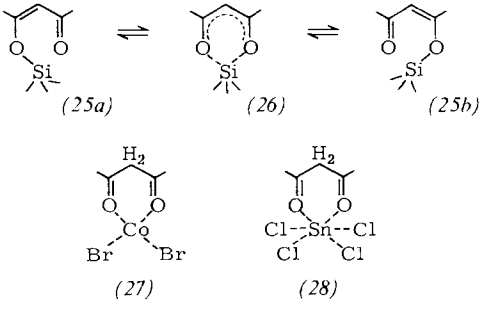
In the case of [2,4-$^{13}C_2$]-pentanedione, the IR spectrum at room temperature shows only one C—C—C band of the enol form at about 1240 cm^{-1}, with pronounced broadening toward longer wavelengths. For the crystalline enol, at −176 °C, the band is so much sharper that the splitting of the middle components ν_1 and ν_2 (6 cm^{-1}) becomes clearly recognizable (Fig. 11)[50]. The ratio of the force constants is thus 1.20. A normal coordinate analysis of the entire spectrum carried out by *Nakamoto*[53] gave $K_1/K_2 = 1.18$.



5. C-Bonded Heavy Metal Complexes of 2,4-Pentanedione

The IR spectra of very many metal complexes of 2,4-pentanedione all indicate the same type of bonding in the region between 1500 and 1600 cm^{-1}[54]. Force constants are given for the metal-oxygen bond[46], and the π-bonding mechanism is discussed[55]. A marked exception is mercury, which tends to arrange organic ligands in a linear manner[56], and whose very sparingly soluble complex with 2,4-pentanedione gives a sharp and intense C=O band at 1678 cm^{-1} in the IR spectrum. *Nonhebel*[57] has proposed the open enolate structure *(17)* for the more soluble complex of mercury with 2,2,6,6-tetramethyl-3,5-heptanedione which gives the same IR band. However, the NMR spectrum of this compound at −40 °C in $CDCl_3$ indicates an H—C—^{199}Hg coupling of $J = 221$ Hz in the signal for the proton on the central C atom at −4.86 ppm[58]. β-Diketone residues must therefore be bonded to the mercury by the C-3 atoms, as shown in *(18)*. The NMR spectrum also shows about 3% of enolate structures [*e.g. (17)*]. To rule out mercury salt catalyzed ligand exchange[31] during the NMR measurement, the β-diketones were treated with bis(hexamethyldisilylamido)mercury[60] according to the method used by *Lorberth*[59] for the preparation of pure dicyclopentadienylmercury *(13)*; the mercury compound formed from pentanedione in this way was obtained in an analytically pure state for the first time. All earlier methods give products that contain larger or smaller amounts of OH, acetate, or chloride[61,62]. C-Bonded structures have also been deduced for the mercury halide complexes from the IR spectra [*(19)*, C=O 1684 cm^{-1}; *(20)*, C=O 1668, C=C 1602 cm^{-1}][61-63]. According to IR[64], NMR[65], and X-ray analyses[66] in ionic platinum chloride complexes, one pentanedione is in the form of a chelate and the other is C-bonded *(21)*, as is also reported for the gold complex *(22)*[67]. In the dichlorodiphenylantimony complex, the equilibrium between the chelate *(23)* and the C—Sb form *(24)* is established so slowly that both forms can be recognized in the NMR spectrum[68].

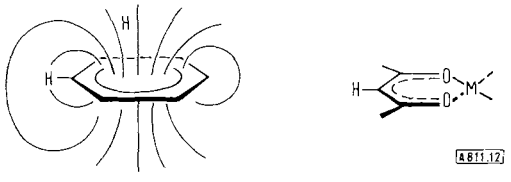
It is well known that boron is incorporated into the chelate ring as RB or F_2B[69-71]. Trialkylsilyl enol ethers of β-diketones form *cis-trans* isomers. A chelated transition state *(26)* with an activation energy of 13.8 kcal/mole is reported[72] for the fast equilibration of the trimethylsilyl group between the O atoms of the *cis* form *(25)*. Complexes of pentanedione with cobalt and bromine[73], tin, titanium, and zirconium tetrachlorides[74], and nickel[75]

have also been described, to which, on the basis of the IR spectra (bands 1700–1722 cm^{-1}), structures [*e.g. (27)* and *(28)*] are assigned in which the keto form is coordinated *via* the two oxygen atoms; some of these can be readily converted into chelates.

6. Magnetic Anisotropy of the Chelate Rings

It can be seen from the foregoing discussion that a chelate, an open enolate, and a C-bonded structure can be distinguished easily and with certainty on the basis of the vibrational spectrum. Complete equalization of the bonds and the symmetry of the ligands can also be established by an accurate analysis of the spectra of partly labeled products. It is asking too much of vibrational spectroscopy, however, to use it in attempts to compare the bonding in the chelate ring with that in benzene, even though the metal-oxygen bond should have some π character.

The effect of the magnetic anisotropy of an aromatic ring on the position of a proton signal in the NMR spectrum is well known[76, 77] (Fig. 12), and is nowadays accepted as perhaps the simplest experimental criterion of aromatic



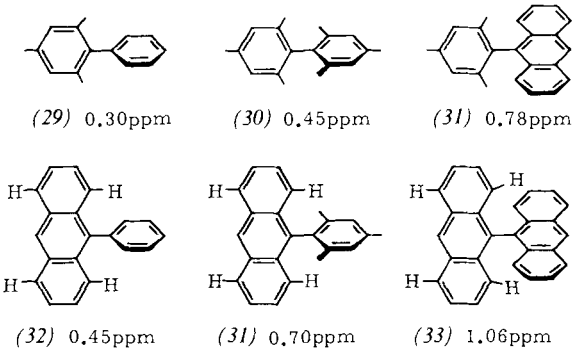


Fig. 12. Comparison of the magnetic anisotropy of the benzene and chelate rings.

character. Protons in the plane of the aromatic ring are shifted downfield, and protons above and below this plane to higher fields, and the magnitude of the shift can be calculated[77]. Impressive examples of the application of this concept are *ansa* compounds[78], cyclophanes[79], annulenes[80], bridged annulenes[81], *trans*-15,16-dimethyldihydropyrene[82], and polycondensed systems of the azulene type[83].

Numerous attempts to deduce the aromatic character of the metal chelates of 2,4-pentanedione from the chemical shift of the signal due to the proton bonded to the chelate ring in the plane of the ring were at first interpreted in very different ways[84]. Some authors argued in favor of aromaticity[85, 86], while others argued increasingly against it[70, 87, 88]. The position of these protons is evidently influenced by polar effects[89], and this is supported by calculations on the shift of the C—H signals and of the ^{13}C—H coupling with the aid of the electric field in the plane of the ring[90, 91].

To establish in some other manner whether or not cyclic conjugation of 6 electrons *via* the metal atom really does occur in these chelates and whether it produces a magnetic anisotropy effect comparable to that observed with benzene, pentanedionates were prepared in which protons are situated above and below the plane of the chelate ring[92, 93]. The NMR spectra of the model compounds *(29)* to *(33)* show the magnitude of the shifts to be expected for such protons in aromatic systems. The difference $\Delta\delta$ in the shifts of the *o*- and *p*-methyl groups in the NMR spectra of phenylmesitylene *(29)*, bimesityl *(30)*, and 9-mesitylanthracene *(31)* and of the 1,8- and 4,5-H atoms in 9-phenylanthracene *(32)*, *(31)*, and 9,9′-bianthryl *(33)* show that a difference of about 0.5 ppm should be observed if the system is truly aromatic. The differences in the case of the models (0.30–1.06 ppm) are due partly to the somewhat different average twisting angles of the two aromatic systems in relation to each other, and partly to the fact that the 1,8-anthryl hydrogen atoms are more firmly fixed

above the other ring than the hydrogen atoms of the rapidly rotating methyl groups, for which only average values are recorded for favorable and unfavorable positions with respect to the other ring. Finally, the electron densities in the phenyl, mesityl, and anthracene rings are naturally different. It should be mentioned that calculation of these shifts by the usual methods[77] leads to values that agree satisfactorily with the experimental values, even if the local contributions of the atoms to the total anisotropy are taken into account[94] [*e.g.* calc. 0.50 for *(30)*, 0.80 for *(30)*].

The NMR spectra of the corresponding mesityl- and anthryl-substituted acetylacetones [*(34)* and *(35)*] and their metal chelates give shift differences of 0.20 and 0.05 ppm, respectively, that deviate only very slightly within the limits of error ($\pm$0.02 ppm), regardless of whether the measurements are carried out on the free acids, the alkali metal salts with K, Na, and Li, which are more or less dissociated in dimethyl sulfoxide, or the chelates with Be, Al, Co, and Pd (Table 2). With increasing stability of the

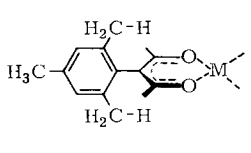

Table 2. $\Delta\delta$ values from the NMR spectra of *(34)* and *(35)*.

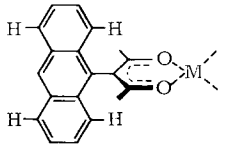
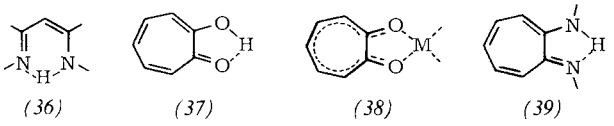
	(34)			*(35)*	
M	Solvent	$\Delta\delta$	M	Solvent	$\Delta\delta$
H	$CDCl_3$	0.20	H	$CDCl_3$	0.05
H	DMSO	0.19	H	DMSO	0.10
K	DMSO	0.17	K	DMSO	0.13
Na	DMSO	0.13	Li	DMSO	0.07
Li	DMSO	0.14	Be	$CDCl_3$	0.12
Be	$CDCl_3$	0.14	Pd	$CDCl_3$	0.08
Al	$CDCl_3$	0.13			
Co	$CDCl_3$	0.16			
Pd	$CDCl_3$	0.22			



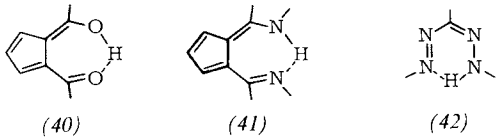
complex, there is no additional shift of the protons above the plane to higher magnetic fields, and the values for the anthryl derivatives *(35)* are smaller instead of greater than those for the mesityl compounds *(34)*. Thus at least the angular C—C—C part of these chelate rings has no mag-

netic anisotropy comparable with that of benzene, and if this is accepted as a criterion no argument can be deduced favoring aromatic bonding in the β-diketone metal chelates examined here[92].

Further chelates with other metals will naturally also have to be examined, and it would be interesting to use aromatic models in which the electron density in the ring is systematically varied by means of suitable substituents and in which the rings carry, *e.g.* positive and negative charges. It should also be pointed out that there is room for improvement in the accuracy of the Δδ values. The analysis of the spectra of the anthryl derivatives [*(31)–(33)* and *(35)*] is that of a frequently not very well resolved ABCDX spectrum[95]. The 2,3,6,7-tetramethylanthryl derivatives were prepared in some cases to facilitate the determination of Δδ from the spectrum[93].



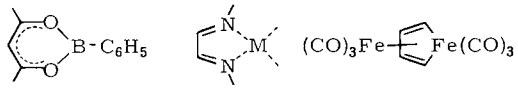
(34)



(35)

This result is contradicted by more recent studies, in which it is deduced from the electronic spectra and from NMR and ESR data for some heavy metal chelates of β-diketones that donor or acceptor π bonds of various strengths occur between the metal and the oxygen, depending on the metal[96, 97]. However, if one attempts to drive an electron around the chelate ring in accordance with the ring current model[77] it has to overcome a relatively high potential barrier at the metal atoms and falls into a relatively deep potential well at the oxygen, whereas this does not occur in a similar treatment for benzene[98, 99].

Daltrozzo[100, 101] independently reaches the same conclusion regarding the bonding in β-diketone chelate rings by analysis of the intensities in the fine structure of electronic spectra and from NMR spectra. According to this author, the amino-imino derivatives of β-diketones *(36)*, just like the enol form of 2,4-pentanedione *(2a)*⇌*(2b)*, are not symmetrical[102].



(36) *(37)* *(38)* *(39)*

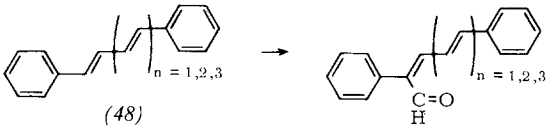
(40) *(41)* *(42)*

The same is true of tropolone *(37)*[103] and its amino-imino derivative *(39)*[104] and of the compounds *(40)*[105], *(41)*[106], *(42)*[107] for which symmetrical structures similar to *(3)* and the term "nonclassical aromatic systems" had formerly been proposed[104, 108, 109]. The bond delocalization is probably again complete in the anions and metal chelates, as is indicated by the X-ray analyses of the tropolonates *(38)*[110].

It now seems interesting to use the method described here to examine many other ring systems to which a more or less aromatic character has been attributed on the basis of

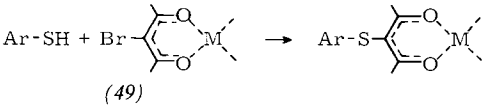
(43) *(44)* *(45)*

(46) *(47)*



the chemical shift of their protons in the plane of the ring or other criteria; examples of such systems are phenylboron chelates *(43)*[69, 70], metal complexes of glyoxal diimine *(44)*, butadienyliron carbonyls *(45)*[111], and many nitrogen, sulfur, and oxygen heterocycles, *e.g. (46)* and *(47)*[112].

7. Conclusion



Formerly, the only way in which a chemist could determine the character of a bond was by comparison of chemical reactions in which the bond, or else a bond in its immediate vicinity is broken or formed. The arguments involved were qualitative and frequently very approximate. Chemists have learned how to use quantitative physicochemical measurements for this purpose, such as interatomic distances from X-ray data, force constants from vibrational spectra, and differences in chemical shifts from NMR spectroscopy.

In comparing chelate rings with benzene on the basis of chemical reactivity, one should determine accurate kinetic parameters, and should above all be certain that the reaction used for comparison proceeds by exactly the same mechanism in both cases. This latter condition has not been verified in any case for the reactions mentioned earlier. Moreover, *e.g.* the Vilsmeier formylation also takes place in open-chain systems such as *(48)*[113], and a nucleophilic substitution that does not occur with benzene has recently been observed for the chelate ring *(49)*[114].

One could argue about what is aromatic and whether it is meaningful to look for such a character or for aromaticity in a compound. As long as this concept leads to new compounds and new information about properties, it may be regarded as useful. However, one thing that must be appre-

(48)

(49)

ciated is that the perfection of benzene is lost when any change is made to the molecule. Irrespective of the method of comparison used, benzene is always situated at one end of the scale, and an open-chain or partly hydrogenated system, which is defined as nonaromatic (Fig. 13), at the

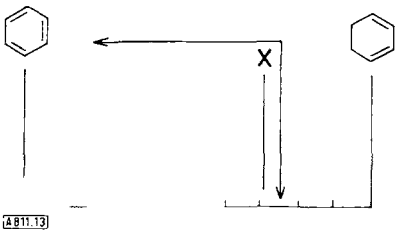


Fig. 13. Gradation of aromaticity from benzene to cyclohexadiene.

other. Anyone can then draw the line in the scale in such a way that his compound X under examination is on the left of the line, and so still appears to be aromatic.

Our own investigations were supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Prof. Dr. W. Lüttke, Göttingen, and Prof. Dr. H. Kuhn, Marburg, have contributed to the progress of this work by suggestions and discussions. We are sincerely grateful to them all.

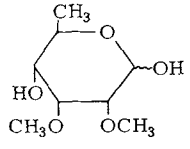
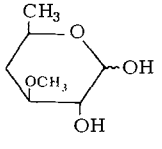
The Synthesis of Antibiotic Sugars[**]



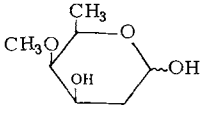
J.S. Brimacombe[*]

The term antibiotic sugar denotes the carbohydrate component of an antibiotic. Two alternative approaches are adopted for the synthesis of these neutral and amino sugars, many of which have unusual structures: One route starts from fairly simple non-carbohydrate precursors, the other depending upon the modification of a carbohydrate precursor.



1. Introduction

The term "antibiotic" was introduced[1] into the literature in 1942, although it had been realized for many years that certain microorganisms were able to exert antagonistic effects upon other organisms. In many cases, the antagonist was shown to produce an active, isolable substance (*i.e.*, the antibiotic) which was responsible for the biological activity. Early antibiotics such as gramicidin were effective[2] against pneumococcal and streptococcal infections in animals, and the first clinical use of an antibiotic (streptomycin[3]) was reported in 1944, although *Fleming*[4] had already suggested that penicillin could be used as a dressing for septic wounds.



The remarkably successful clinical application of antibiotics in the ensuing years has naturally aroused widespread interest in the organic compounds responsible for the biological activity, and has ensured the intensive investigation of antibiotic substances by structural organic chemists. It has been a particularly active period for carbohydrate chemists since many antibiotics contain sugars of unusual, and often unique, structures[5,6]. Some representative examples are found in the formulas *(1)* to *(18)*; it is notable that a large number of antibiotic sugars possess a 6-deoxy function.

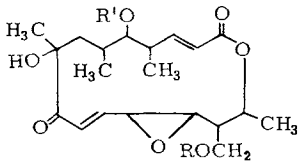
[**] The following abbreviations have been used in the present article: Ac = acetyl; Bz = benzoyl; DCCD = dicyclohexylcarbodiimide; DMF = dimethylformamide; DMSO = dimethyl sulfoxide; Ms = methanesulfonyl; NSB = *N*-bromosuccinimide; Ph = phenyl; Tos = *p*-toluenesulfonyl; Tr = triphenylmethyl (trityl).

There are two approaches that can be applied to the synthesis of these rare antibiotic sugars. One of them uses fairly simple non-carbohydrate precursors as starting materials, whereas the other depends on effecting transformations on carbohydrate precursors. The first approach will lead, of course, to a racemic product which must be resolved if the natural enantiomer is to be obtained. The second method has certainly been more popular, although this may merely reflect the carbohydrate chemist's preference to operate with familiar molecules. Examples of both approaches will be given.

The common sugars carry the highest density of functional groups of any natural product so that transformations on carbohydrate precursors can present some quite intriguing problems. The magnitude of the task can be visualized by comparing the formulas *(1)* to *(18)* with those of the more abundantly occurring sugars such as D-glucose *(19)*, D-galactose *(20)*, and L-rhamnose *(21)*. The validity of this comparison lies in the fact that most syntheses of antibiotic sugars commence from such readily available precursors.

(19), R = OH, R' = H; D-Glucose
(20), R = H, R' = OH; D-Galactose



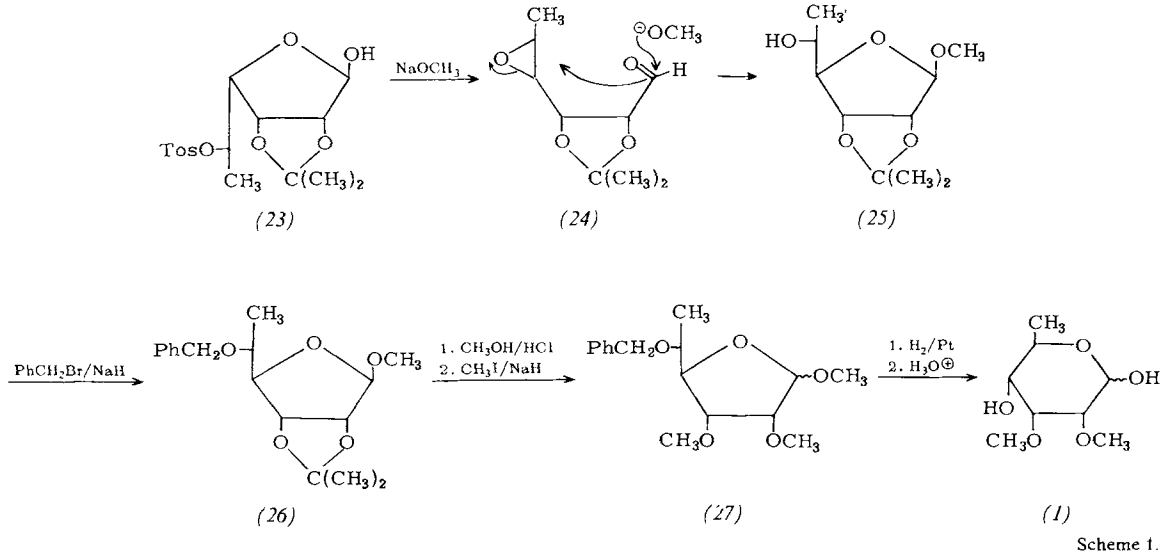
(21) L-Rhamnose

The following examples are fairly representative and were chosen to demonstrate the many diverse synthetic approaches that have been used; in many cases, other equally attractive and definitive syntheses are available.

2. Neutral Antibiotic Sugars

2.1. Mycinose *(1)*

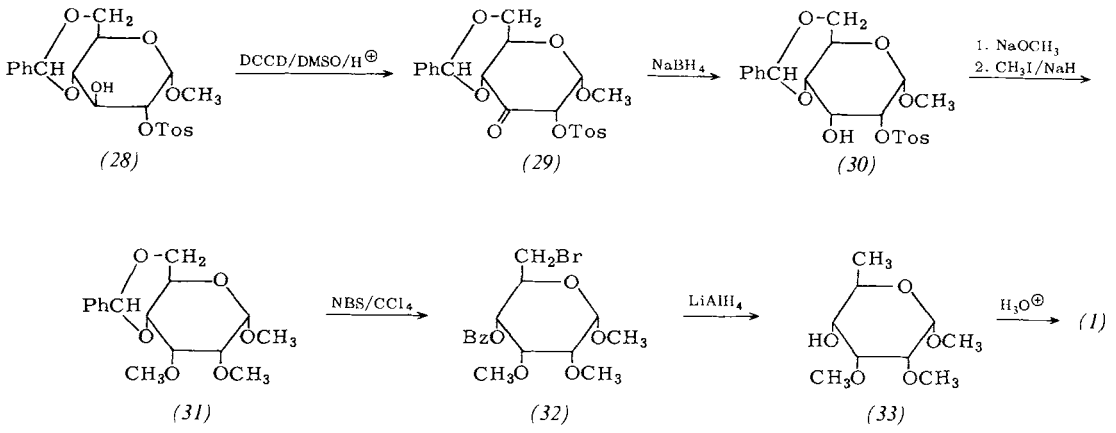
The macrolide antibiotic chalcomycin *(22)* contains two neutral sugars, mycinose[7] and chalcose[8]. Chemical and spectroscopic evidence had identified mycinose as 6-deoxy-2,3-di-*O*-methyl-D-allose *(1)*, an assignment that was verified by a synthesis[9] from 2,3-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-L-rhamnofuranose *(23)* (Scheme 1).



(22)

R = β-Mycinosyl
R' = β-Chalcosyl

Solvolysis of the sulfonate *(23)* with methanolic sodium methoxide converted it into methyl 6-deoxy-2,3-*O*-isopropylidene-β-D-allofuranoside[10] *(25)* by a reaction that involves[11] neighboring aldehyde-group participation in the opening of the intermediate epoxide *(24)*. The overall reaction results in inversion of configuration at both C-4 and C-5 of the initial L-rhamnose derivative, thus providing a ready means of entering the 6-deoxy-D-allose series. Benzylation of *(25)* gave *(26)*, which on sequential methanolysis and methylation yielded methyl 5-*O*-benzyl-6-deoxy-2,3-di-*O*-methyl-D-allofuranoside *(27)*. Catalytic debenzylation of *(27)* followed by acid hydrolysis liberated mycinose *(1)*.



An alternative synthesis of mycinose is available[12] (Scheme 2) whereby entry into the D-allose series was gained by inverting the configuration at C-3 of the D-glucose derivative *(28)* by an oxidation-reduction sequence [*i.e.*, *(28)* → *(29)* → *(30)*]. The oxidation of partially protected sugars has proved troublesome in the past but can now be accomplished[13] efficiently with such oxidants as ruthenium tetroxide[14], the Pfitzner-Moffatt reagent[15] (see Section 2.5), and acid anhydrides in dimethyl sulfoxide[16]. Desulfonylation of *(30)*, with methylation of the resulting diol, gave compound *(31)*. Conversion into the 6-deoxyalloside *(33)* was achieved by the action of *N*-bromosuccinimide in hot carbon tetrachloride on *(31)*, and reduction of the 6-bromo-5-benzoate *(32)* so formed with lithium tetrahydridoaluminate[17]. This procedure provides a very neat way of introducing a 6-deoxy substituent, and is more direct than previous methods which rely on the

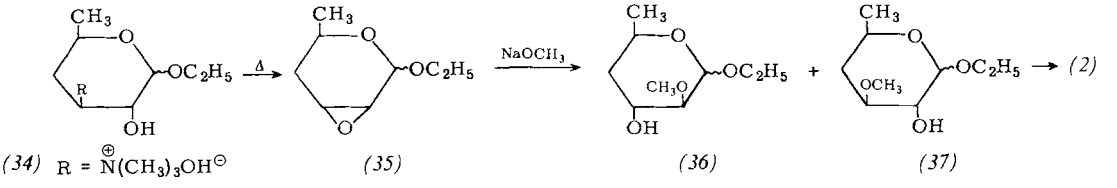
(23) *(24)* *(25)*

(26) *(27)* *(1)*

Scheme 1.

Scheme 2.

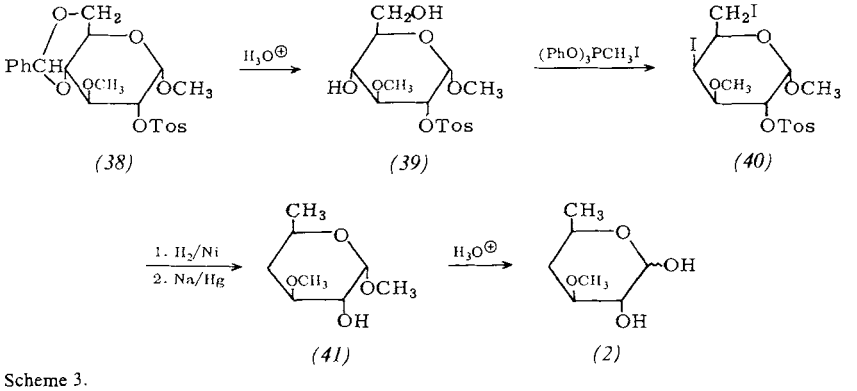
formation and subsequent displacement of a primary sulfonic ester group. Finally, acid hydrolysis of *(33)* afforded mycinose *(1)*.



2.2. Chalcose (Lankavose) *(2)*

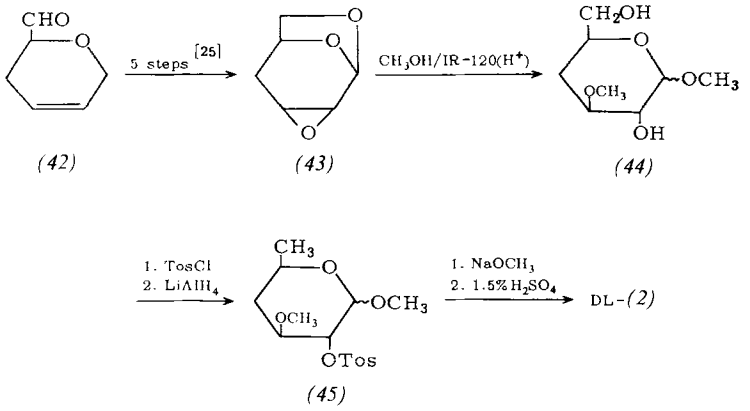
The structure of chalcose, a component of such antibiotics as chalcomycin *(22)*[18], lankamycin, and neutramycin, was deduced by *Woo et al.*[8,19] to be 4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose *(2)*. Evidence corroborating this structure was provided when it was shown[20] that chalcose could be configurationally related to desosamine *(12)*, an antibiotic sugar of known structure (see Section 3.1).

(Scheme 3) is particularly notable since it demonstrates an elegant way of introducing the deoxy functions.



Methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*O*-*p*-toluenesulfonyl-α-D-glucopyranoside[23] *(38)* was partially hydrolyzed to the diol *(39)*, which was treated with methyl triphenylphosphonium iodide to give methyl 4,6-dideoxy-4,6-diiodo-3-*O*-methyl-2-*O*-*p*-toluenesulfonyl-α-D-galactopyranoside *(40)*. Hydrogenolysis of *(40)* followed by cleavage of the sulfonate group with sodium amalgam yielded the 4,6-dideoxyglycoside *(41)*, which was hydrolyzed with acid to chalcose *(2)*.

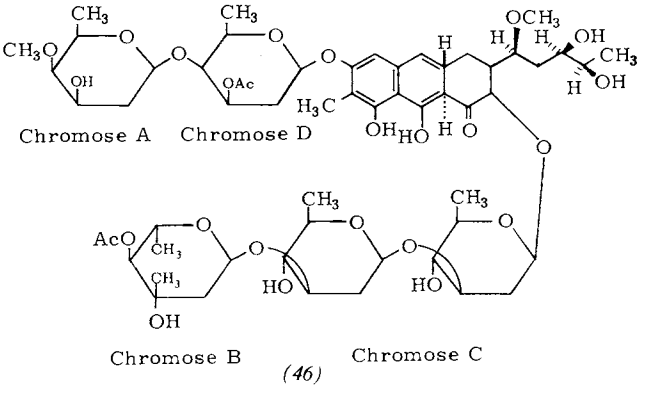
Racemic chalcose has been prepared[24] from non-carbohydrate precursors by the route outlined in Scheme 4. The key intermediate *(43)* for the synthesis was prepared[25]



This was achieved by pyrolysis of the desosaminide derivative *(34)* to give the epoxide *(35)*, which afforded a mixture of isomeric methyl ethers *(36)* and *(37)* on ring-opening with boiling sodium methoxide. Acid hydrolysis of one of these isomers *(37)* gave chalcose.

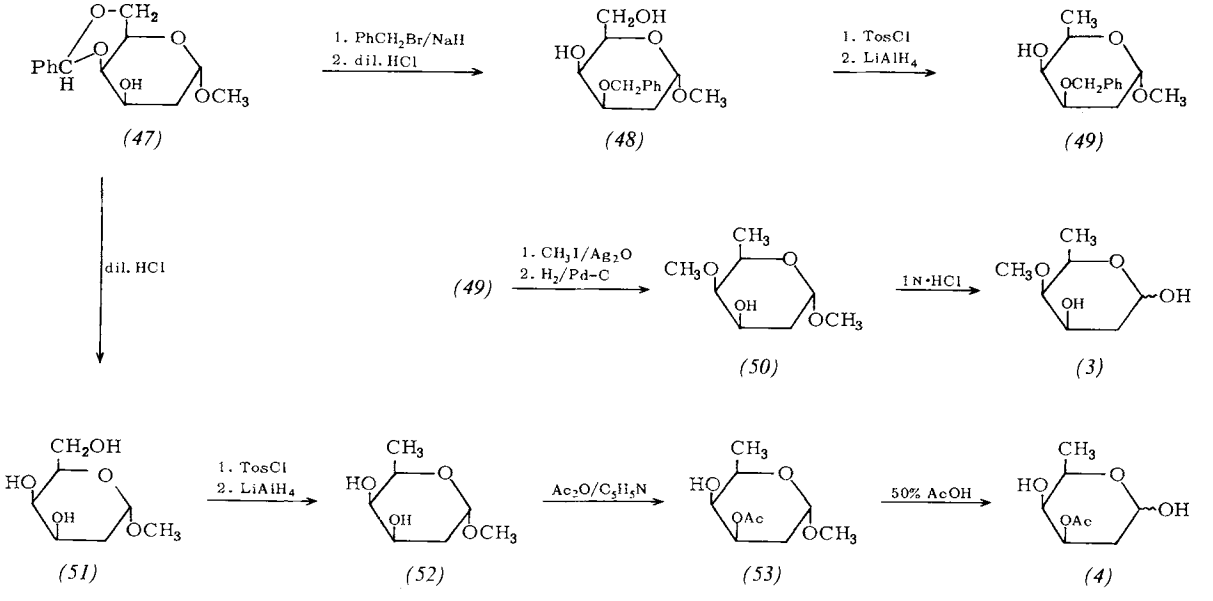
Several stereospecific syntheses of chalcose have been reported[21], but that developed by *Kochetkov* and *Usov*[22] from acrolein dimer *(42)*, and it underwent acid-catalyzed opening of the epoxide ring in boiling methanol to give a mixture of the anomeric methyl 4-deoxy-3-*O*-methyl-DL-*xylo*-hexopyranosides *(44)*. Thereafter, the 6-deoxy function was introduced using a conventional displacement of the 6-*p*-toluenesulfonate with lithium tetrahydridoaluminate. Successive treatments of the resulting 4,6-dideoxy derivative *(45)* with sodium methoxide and dilute sulfuric

Scheme 3.



Scheme 4. IR-120(H^+) is an ion exchanger in acidic form.

acid produced DL-chalcose, but resolution of the racemate was not attempted.

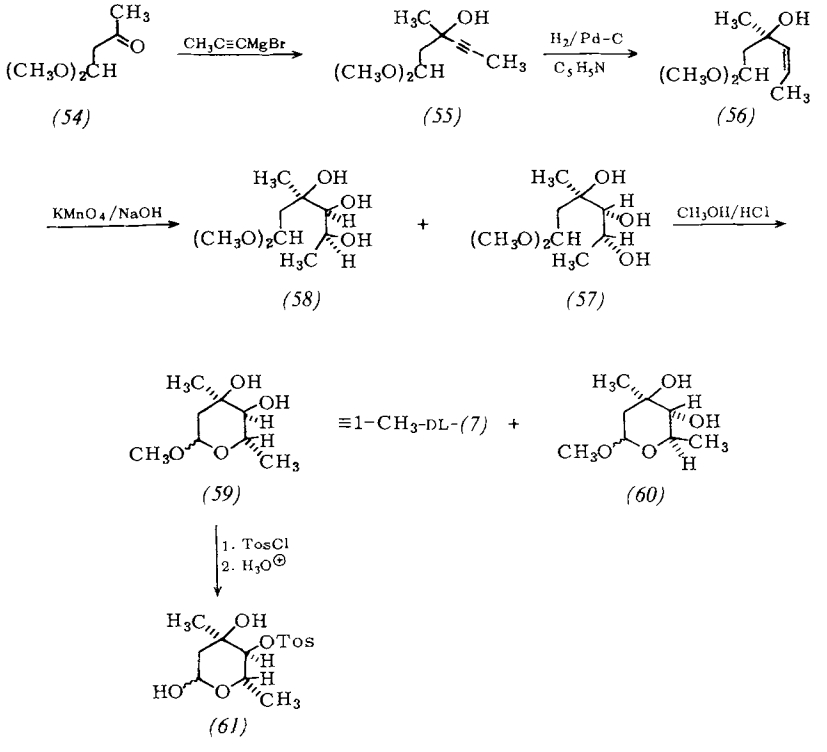


2.3. The Chromoses

Chromomycin A_3 is the principal constituent of a group of cancerostatic and antitumor antibiotics produced[26] by *Streptomyces griseus* No. 7; closely related antibiotics are aureolic acid, olivomycin, aburamycin, and mithramycin. The structure of chromomycin A_3 is probably that shown in formula *(46)*, although the configurations of the glycosidic linkages have not been settled beyond dispute. The four sugar components of chromomycin A_3 are[27] 2,6-dideoxy-4-*O*-methyl-D-*lyxo*-hexose [*(3)*, chromose A], 4-*O*-acetyl-2,6-dideoxy-3-*C*-methyl-L-*arabino*-hexose (chromose B), 2,6-dideoxy-D-*arabino*-hexose (chromose C or olivose), and 3-*O*-acetyl-2,6-dideoxy-D-*lyxo*-hexose [*(4)*, chromose D]; a fifth 2,6-dideoxyhexose having the structure 2,6-dideoxy-4-*O*-isobutyryl-3-*C*-methyl-L-*arabino*-hexose (chromose B') is encountered[26] in chromomycin A_2.

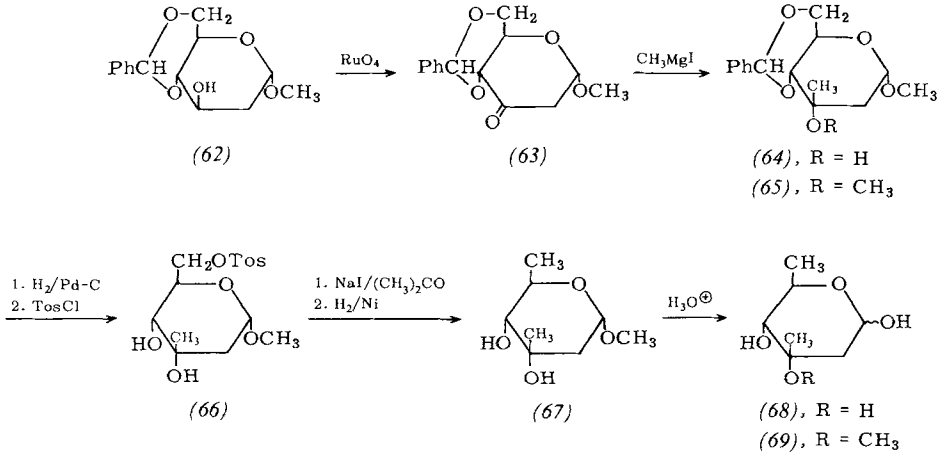
The assignments of structure to chromoses B and C were decided[27] on the basis of spectroscopic evidence and from comparisons with known compounds. The structure of chromose A *(3)* was confirmed[28] by a synthesis from methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*lyxo*-hexopyranoside *(47)*. The route used (Scheme 5) requires little detailed comment since, once the C-3 hydroxyl group had been protected by benzylation, the functionalities at positions 4 and 6 were introduced by straightforward reactions.

The synthesis of chromose D *(4)* posed a more interesting problem since it required the selective acylation of a *cis*-diol system. Unimolecular acetylation of the 6-deoxyglycoside *(52)* gave[29] mainly the required 3-acetate *(53)*, the product predicted on conformational grounds; this assignment was reinforced by an unequivocal synthesis[29] of the isomeric 4-acetate. Partial hydrolysis of *(53)* with hot 50% acetic acid liberated the free sugar *(4)*, which proved to be identical with chromose D. Deacetylchromose D has been discovered[30] recently in chromocyclomycin, a new streptomycete metabolite possessing antitumor activity.



Scheme 5.

2.4. Mycarose *(7)* and Cladinose *(8)*



The structure of mycarose, a component of antibiotics such as magnamycin, spiramycin, and tylosin, is now firmly established[31] as 2,6-dideoxy-3-*C*-methyl-L-*ribo*-hexose *(7)*. The antibiotic sugar cladinose *(8)* (from erythromycin) is the 3-methyl ether of mycarose, and is converted into mycarose on demethylation with boron trichloride[32].

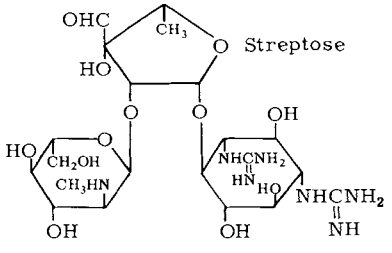
Preliminary investigation indicated[33] that mycarose was a branched-chain sugar which could be generally formulated as a 2,6-dideoxy-3-*C*-methylaldohexose. As there was no clear evidence for the relative configuration at the three asymmetric centers, *Woodward et al.*[34] devised a scheme which would lead to the four possible racemates; the reactions which eventually established the stereochemistry of mycarose are shown in Scheme 6. In brief, the acetal *(54)* was condensed with 1-propynylmagnesium bromide to give the acetylenic alcohol *(55)*, which was converted into the *cis*-alkene *(56)* following partial hydrogenation over a poisoned palladium catalyst. *cis*-Hydroxylation of *(56)* and cyclization of the resulting triols *(57)* and *(58)* gave a mixture of the racemic glycosides *(59)* and *(60)*. The relative configurations of the separated glycosides were elucidated by chemical means, and the relationship of racemic *(59)* to mycarose was demonstrated by its conversion into the *p*-toluenesulfonate *(61)*, which was spectroscopically indistinguishable from the corresponding natural sugar derivative.

(54) *(55)* *(56)* *(58)* *(57)* *(59)* *(60)* *(61)*

Scheme 6.

(62) *(63)* *(64)*, R = H *(65)*, R = CH_3 *(66)* *(67)* *(68)*, R = H *(69)*, R = CH_3

Scheme 7



Racemic *(59)* was resolved by means of the hydroxybornane sulfonic esters and, finally, the absolute configuration of mycarose was determined[34] by correlating the stereochemistry at C-5 with that of L-lactic acid.

The D-forms of both mycarose and cladinose have been synthesized[35] (Scheme 7) by way of a Grignard reaction on methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose *(63)*, prepared by oxidation of the 2-deoxyglycoside *(62)* with either chromium trioxide or ruthenium tetroxide. A crystalline branched-chain derivative isolated from the reaction was concluded to have the D-*ribo* configuration *(64)* from the existence of intramolecular hydrogen-bonding between the C-1 and C-3 substituents in dilute solutions of carbon tetrachloride; this evidence precluded the alternative D-*arabino* configuration. After catalytic debenzylidenation of *(64)*, the 6-deoxy function was introduced by means of an iodide displacement on the 6-sulfonate *(66)*, whereafter acid hydrolysis of the glycoside *(67)* liberated D-mycarose *(68)*.

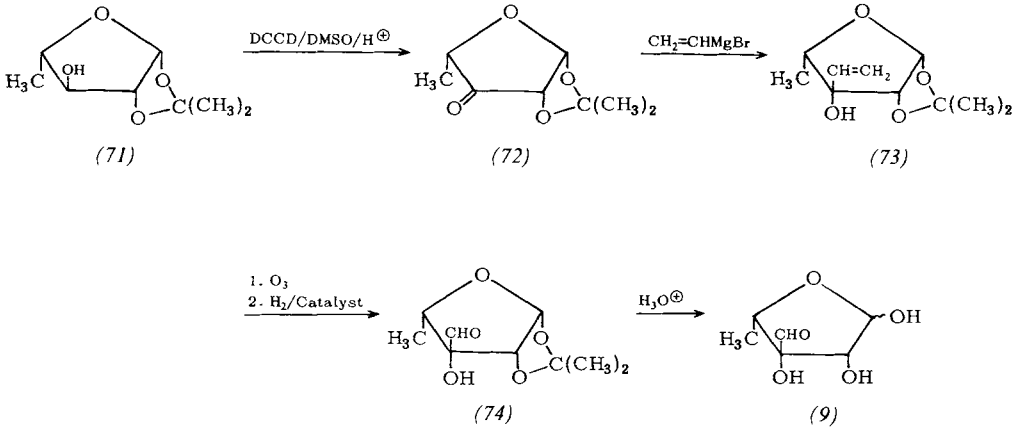
An analogous sequence of reactions performed on the methylated derivative *(65)* led ultimately to the synthesis[35] of D-cladinose *(69)*.

2.5. Streptose *(9)*

The component fragments of the antibacterial antibiotic streptomycin *(70)* are streptidine, 2-deoxy-2-methylamino-L-glucose, and the branched-chain sugar streptose[36].

2-Deoxy-2-methylamino-L-glucose Streptidine

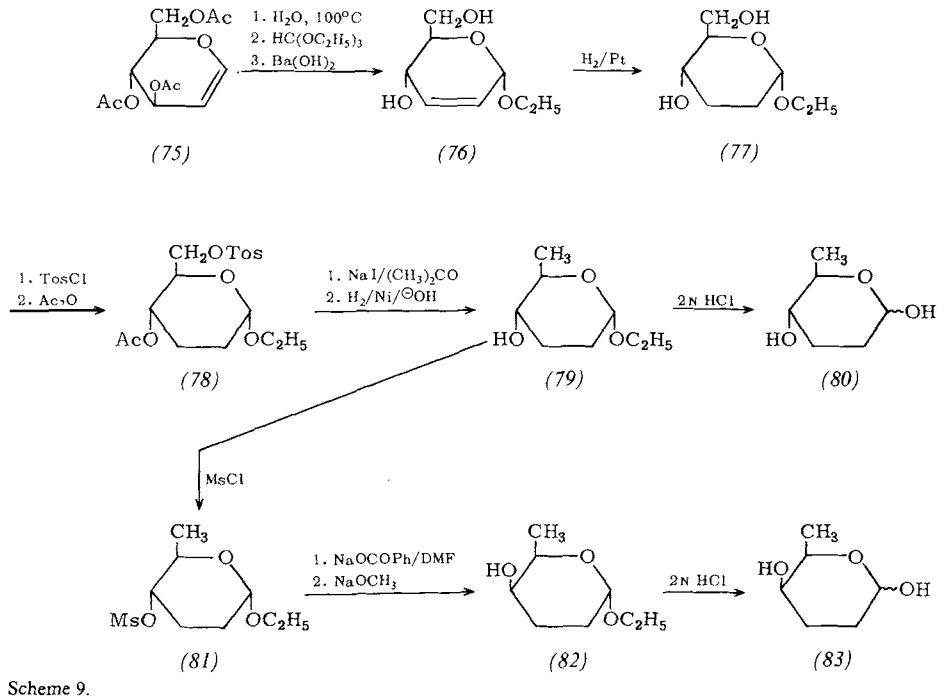
(70)



Whereas syntheses of the two basic components were achieved[37] by 1950, some fifteen years elapsed before a total synthesis (Scheme 8) of streptose [5-deoxy-3-*C*-formyl-L-lyxose, *(9)*] was reported[38], although its stereochemistry had been firmly established by other means[36].

Oxidation of 5-deoxy-1,2-*O*-isopropylidene-β-L-arabinofuranose *(71)*, using dicyclohexylcarbodiimide, pyridinium phosphate, and dimethyl sulfoxide (the Pfitzner-Moffatt reagent[15]), gave the ketone *(72)*, which underwent a stereospecific addition of vinylmagnesium bromide to yield 5-deoxy-1,2-*O*-isopropylidene-3-*C*-vinyl-β-L-lyxofuranose *(73)*. Catalytic hydrogenation of the ozonide of *(73)* gave the 3-*C*-formyl derivative *(74)*, which liberated streptose *(9)* on deacetonation with an acid resin.

2.6. Amicetose *(80)* and Rhodinose *(5)*

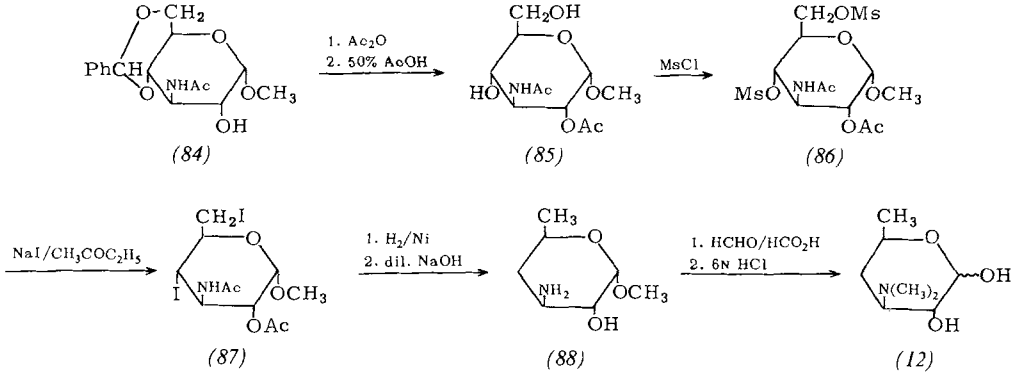


Both these sugars are 2,3,6-trideoxyaldohexoses. Amicetose [*(80)*, 2,3,6-trideoxy-α-D-*erythro*-hexose] is a constituent of the antibiotic amicetin[39], whereas rhodinose [*(5)*, 2,3,6-trideoxy-L-*threo*-hexose] is a constituent of rhodomycin[40] and streptolydigin[41]. The stereochemistry of amicetose was established by a synthesis[42] from the readily accessible D-glucal triacetate *(75)* (Scheme 9). The unsaturated sugar was transformed into ethyl 2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside[43] *(76)* which, after hydrogenation to the saturated glycoside *(77)*, was converted[42] into ethyl 2,3,6-trideoxy-α-D-*erythro*-hexopyranoside *(79)* by way of the 6-*p*-toluenesulfonyl and 6-iodo derivatives. Acid hydrolysis of *(79)* afforded a trideoxyhexose *(80)* identical with amicetose.

The 6-deoxyglycoside *(79)* was also used[42] to confirm the stereochemistry of rhodinose, which had been assigned the L-*threo*-configuration *(5)* from optical rotatory data. Inversion of the configuration at C-4 by means of a benzoate displacement reaction on the derived methanesulfonate *(81)* gave, after debenzoylation, ethyl 2,3,6-trideoxy-α-D-*threo*-hexopyranoside *(82)*. The sugar *(83)* liberated on acid hydrolysis of *(82)* was recognized as the enantiomer of natural rhodinose *(5)*.

(71) *(72)* *(73)* *(74)* *(9)*

Scheme 8.

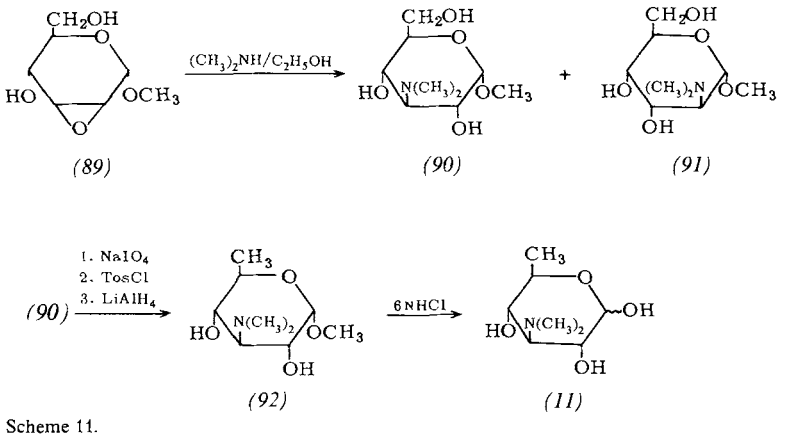


Scheme 9.

3. Antibiotic Amino Sugars

3.1. Desosamine *(12)*

The structure of desosamine was shown[44] by degradative and spectroscopic evidence to be 3,4,6-trideoxy-3-dimethylamino-D-*xylo*-hexose *(12)*. The glycosidically bound sugar is a component of several macrolide antibiotics such as erythromycin, narbomycin, picromycin, and oleandomycin. Non-specific syntheses of desosamine have been reported[45] but the stereospecific synthesis of desosamine outlined in Scheme 10 is due to *Richardson*[46].



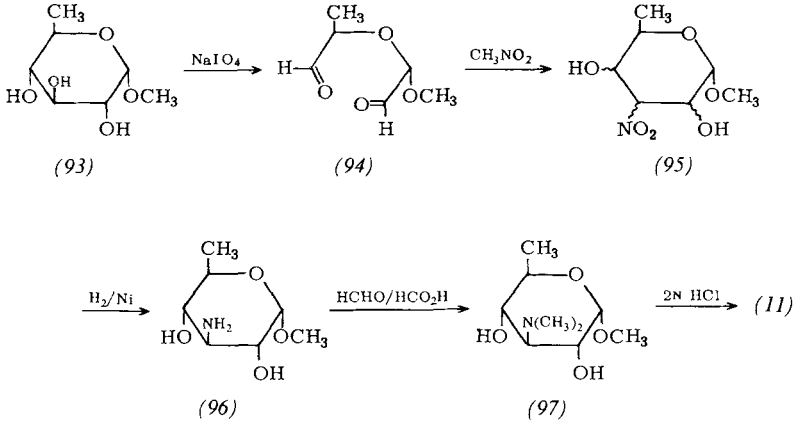
Scheme 10.

Partial acidic hydrolysis of the 2-acetate obtained by acetylation of methyl 3-acetamido-4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside[47] *(84)* converted it into the diol *(85)*. Treatment of the derived dimethanesulfonate *(86)* with sodium iodide in boiling butanone effected the displacement of *both* sulfonic ester groups to give a di-iodo derivative presumed to be *(87)*. Since secondary carbohydrate sulfonates are generally unreactive towards iodide ion under the conditions used, the displacement reaction undergone by *(86)* can be attributed to neighboring-group participation by the acetamido group and attack of iodide ion on the oxazoline intermediate. Hydrogenolysis of the di-iodide *(87)* over a nickel catalyst and deacetylation with strong base yielded methyl 3-amino-3,4,6-trideoxy-α-D-*xylo*-hexopyranoside *(88)*, which was converted into desosamine *(12)* following *N*-methylation, with the formic acid-formaldehyde reagent, and removal of the glycosidic substituent with acid.

3.2. Mycaminose *(11)*

This basic sugar is a component of antibiotics such as the leucomycins, the magnamycins, and members of the spiromycin group[5]. Mycaminose was identified[48] as a 3,6-dideoxy-3-dimethylaminohexose and, after some early

Scheme 11.

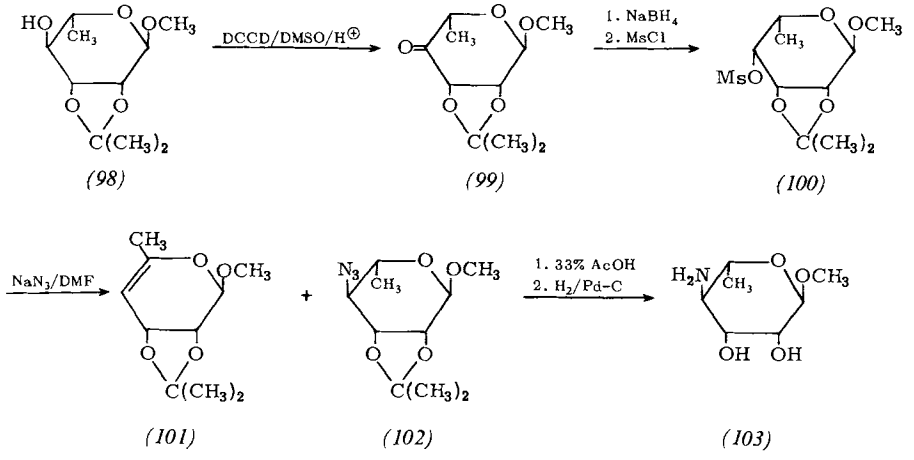


confusion, its absolute stereochemistry was finally decided by synthesis.

In the route used by *Foster et al.*[49] (Scheme 11), methyl 2,3-anhydro-α-D-allopyranoside *(89)* was heated with ethanolic dimethylamine to give an approximately equimolar mixture of the isomeric dimethylamino alcohols *(90)* and *(91)*. The D-*altro* isomer *(91)* was removed from the mixture by oxidation of the *vic*-diol system with sodium periodate and absorption of the resulting aldehydic fragment on to a strongly basic resin. The remaining D-*gluco* isomer *(90)* was converted, *via* the 6-*p*-toluenesulfonate, into the 6-deoxy derivative *(92)*, which was then hydrolyzed to 3,6-dideoxy-3-dimethylamino-D-glucose *(11)*. The hexosamine derivative—isolated as the hydrochloride monohydrate—was identical with natural mycaminose.

3.3. Perosamine *(13)*

4-Amino-4,6-dideoxyhexoses and their derivatives are constituents of a number of antibiotics[51]. The amino sugar component (perosamine) of the heptaenic antibiotic perimycin[52] was recognized[53] from chemical evidence as 4-amino-4,6-dideoxy-D-mannose *(13)*.



A relatively straightforward route to perosamine derivatives can be envisaged[51] by way of an azide displacement reaction on methyl 6-deoxy-2,3-*O*-isopropylidene-4-*O*-methanesulfonyl-α-D-talopyranoside *(100)*. An attempt to prepare the latter compound by a route involving nucleophilic displacements on the corresponding D-mannose sulfonate had to be abandoned when it was shown that ring-contracted products were formed[54].

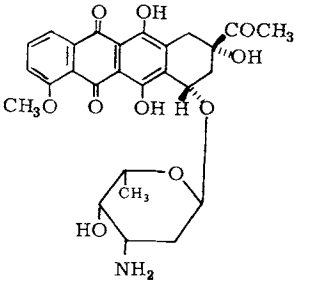
Scheme 12.

In an alternative synthesis[50] (Scheme 12), the 3-amino function was introduced by nitromethane cyclization of the dialdehyde *(94)* formed on periodate oxidation of methyl 6-deoxy-α-D-glucopyranoside *(93)*. Methyl 3-amino-3,6-dideoxy-α-D-glucopyranoside *(96)* was isolated in 24 % yield following reduction of the mixture of isomeric 3-nitropyranosides *(95)*, and was further converted into the di-*N*-methyl derivative *(97)*. Subsequent hydrolysis of *(97)* with hydrochloric acid yielded mycaminose *(11)*.

This difficulty was overcome—in the L-series—by effecting the desired inversion of configuration through the ketone *(99)* (Scheme 13)[55]. Reduction of *(99)* with sodium tetrahydridoborate in methanol proceeded virtually stereospecifically to yield the L-*talo*-alcohol. Unfortunately, considerable amounts of the unsaturated sugar *(101)* accompanied the formation of the 4-azido derivative *(102)* in the reaction between the methanesulfonate *(100)* and sodium azide in dimethylformamide. However, the L-*manno*-amine *(103)*, resulting from partial

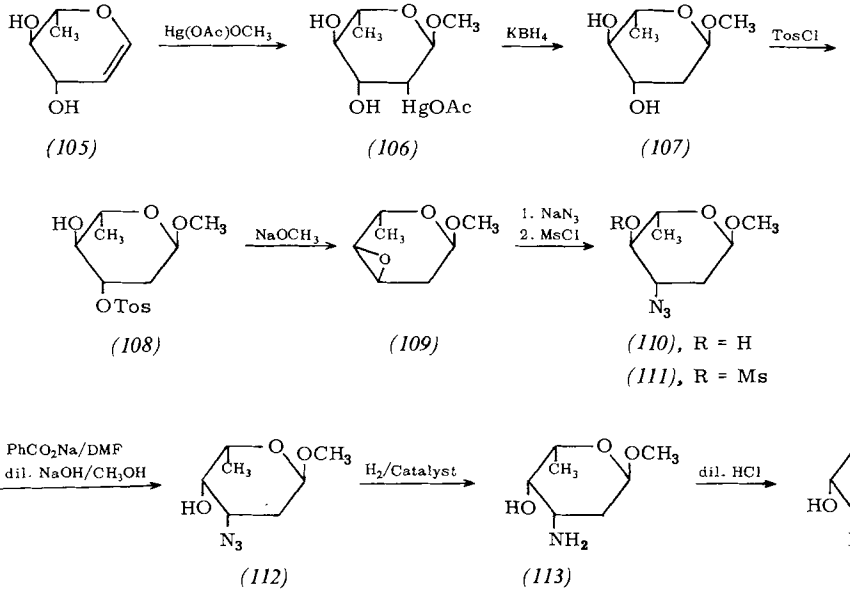
(98) (99) (100) (101) (102) (103)

Scheme 13.



hydrolysis and catalytic hydrogenation of *(102)*, was shown to be enantiomeric with methyl perosaminide, obtained on methanolysis of the antibiotic[53].

Ring-opening of either methyl 3,4-anhydro-6-deoxy-α-D-talopyranoside or its 2-benzoate with lithium azide and ammonium chloride in 2-methoxyethanol has been used[56] to prepare derivatives related to natural perosamine.



3.4. Daunosamine *(114)*

Daunomycin *(104)*[57] is a streptomyces metabolite possessing antitumor activity; the amino sugar component, named daunosamine[58], is 3-amino-2,3,6-trideoxy-L-*lyxo*-hexose *(114)*.

Two syntheses of D-daunosamine have been reported[59] but the quite elegant synthesis of *Goodman et al.*[60] yielded the natural L-sugar (Scheme 14). In this, methoxymercuration of L-rhamnal *(105)* provided an excellent route to the 2-deoxyglycoside *(107)*; the latter compound will also be recognized as the methyl glycoside of L-chromose C. Selective *p*-toluenesulfonylation of *(107)* gave the 3-sulfonate *(108)* which, after conversion into the epoxide *(109)*, was treated with sodium azide to yield the expected product, *viz.* methyl 3-azido-2,3,6-trideoxy-α-L-*arabino*-hexopyranoside *(110)*. A S_N2 displacement on the derived methanesulfonate *(111)* with sodium benzoate in dimethylformamide gave, after saponification of the ester group, methyl 3-azido-2,3,6-trideoxy-α-L-*lyxo*-hexopyranoside *(112)*. Catalytic reduction of *(112)* afforded the amino sugar glycoside *(113)*, which was hydrolyzed to daunosamine *(114)* with dilute hydrochloric acid.

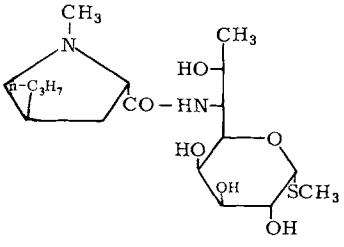
(105) (106) (107) (108) (109) (110), R = H (111), R = Ms (112) (113) (114)

Scheme 14.

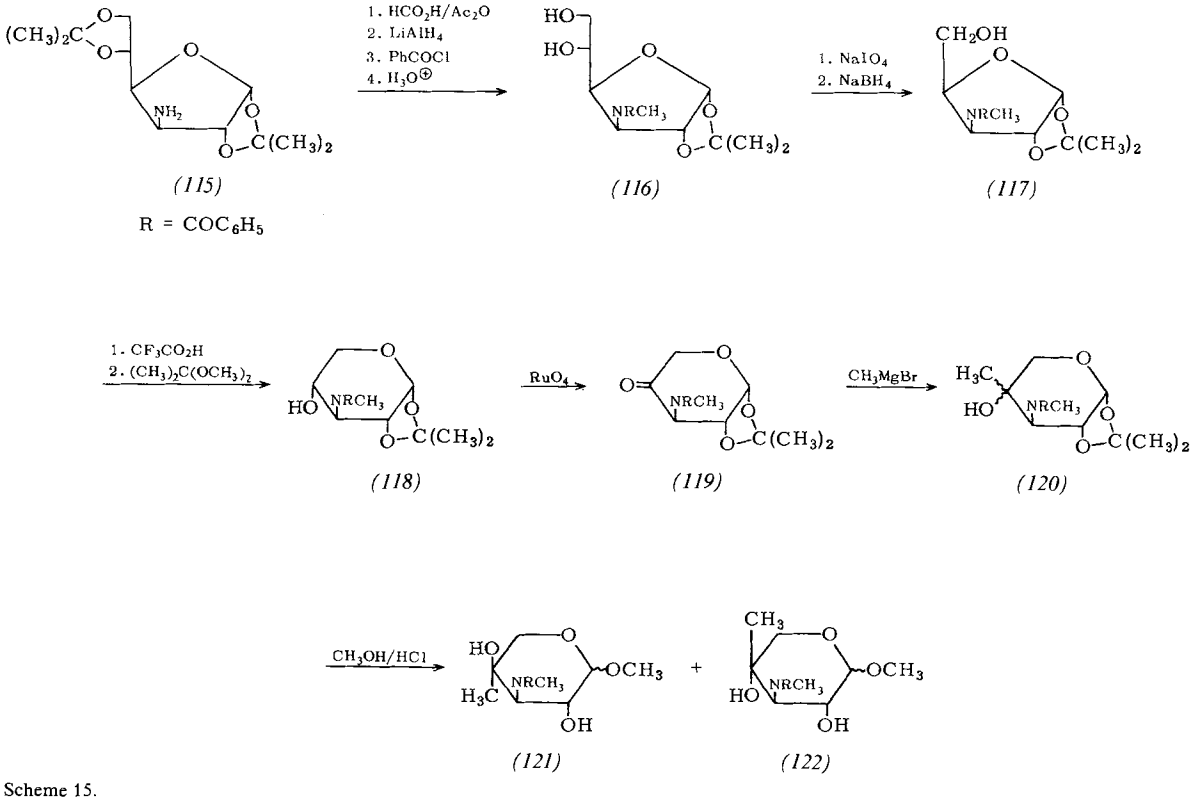


3.5. Garosamine *(17)*

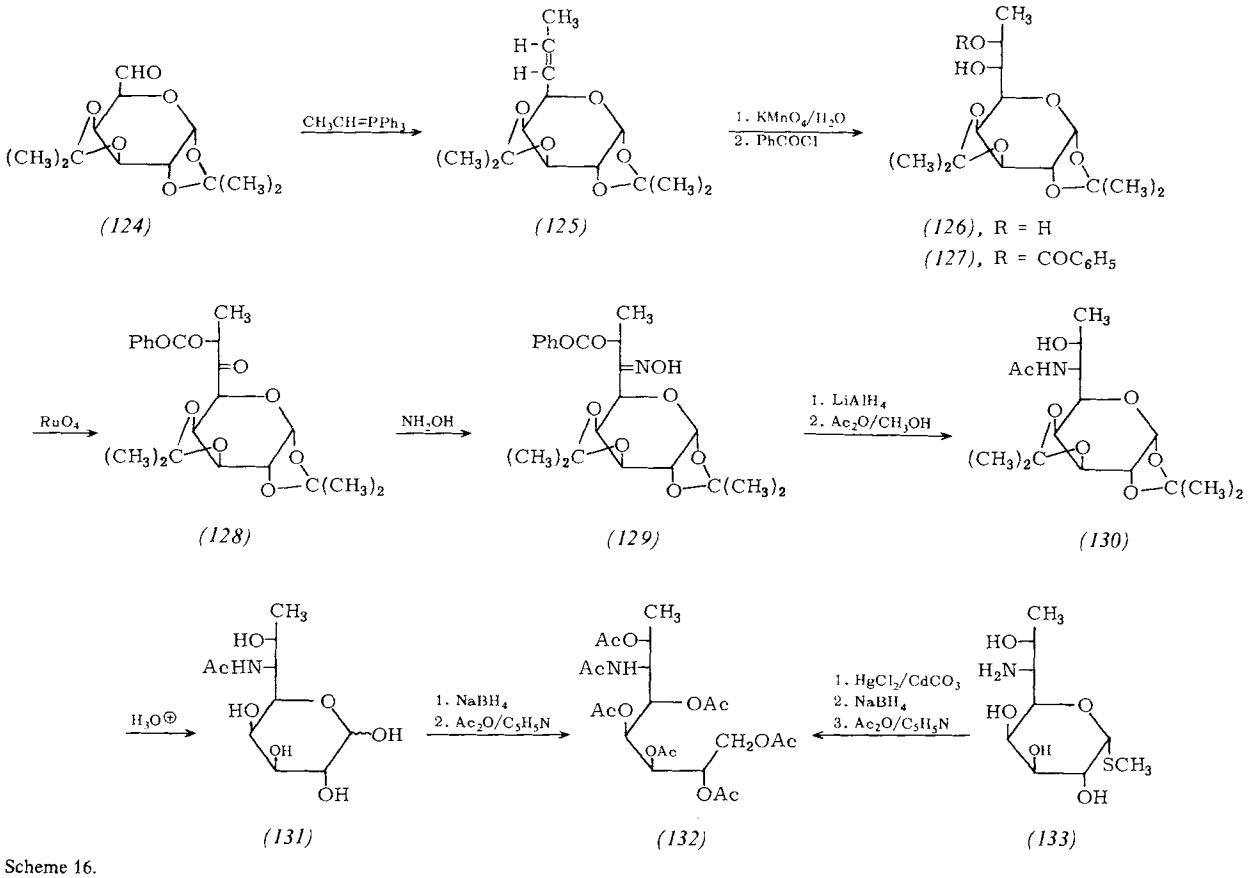
Methanolysis of the antibiotic gentamicin C, a broad spectrum antibiotic complex isolated[61] from fermentations of *Micromonospora*, yielded[62] an amino sugar glycoside (methyl garosaminide), which was shown to be either methyl 3-deoxy-4-*C*-methyl-3-methylamino-β-L-arabinopyranoside or the corresponding α-D-*xylo* derivative. A decision in favor of the L-*arabino* isomer *(17)* was claimed[63] after the synthesis of derivatives related to both isomers (Scheme 15).

The readily accessible 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose[64] *(115)* was transformed[63] by standard reactions into the monoacetal *(116)*, which was subjected to a chain-shortening process with sodium periodate to give, after treatment with sodium tetrahydridoborate, the 3-aminoxylose derivative *(117)*. Deacetonation of *(117)* and acetalation of the free sugar using 2,2-dimethoxypropane afforded the corresponding pyranose acetal *(118)*, which was smoothly oxidized to the ketone *(119)* with ruthenium tetroxide in the presence of potassium periodate. A mixture of the two possible branched-chain sugars *(120)* was obtained on the addition of methylmagnesium bromide to *(119)*, which after methanolysis gave the glycosides *(121)* and *(122)*. The structures of these compounds were deduced by examining the extent of intramolecular hydrogen-bonding exhibited by the pure anomers in dilute solutions of carbon tetrachloride, and from nuclear magnetic resonance spectroscopy. The physical properties of a crystalline glycoside assigned the β-L-*arabino* configuration [*(121)*, β-form] were comparable with those of a similar garosamine derivative.

3.6. Lincosamine *(18)*



The antibiotic lincomycin *(123)*, produced by *Streptomyces lincolnensis* var. *lincolnensis*, is active against gram-positive organisms[65]. It consists[66] of the methyl thioglycoside of an aminodideoxyoctose (methyl 6-amino-6,8-dideoxy-1-thio-D-*erythro*-α-D-*galacto*-octopyranoside) bound by an amide linkage to an amino acid (*trans*-1-methyl-4-*n*-propyl-L-proline).

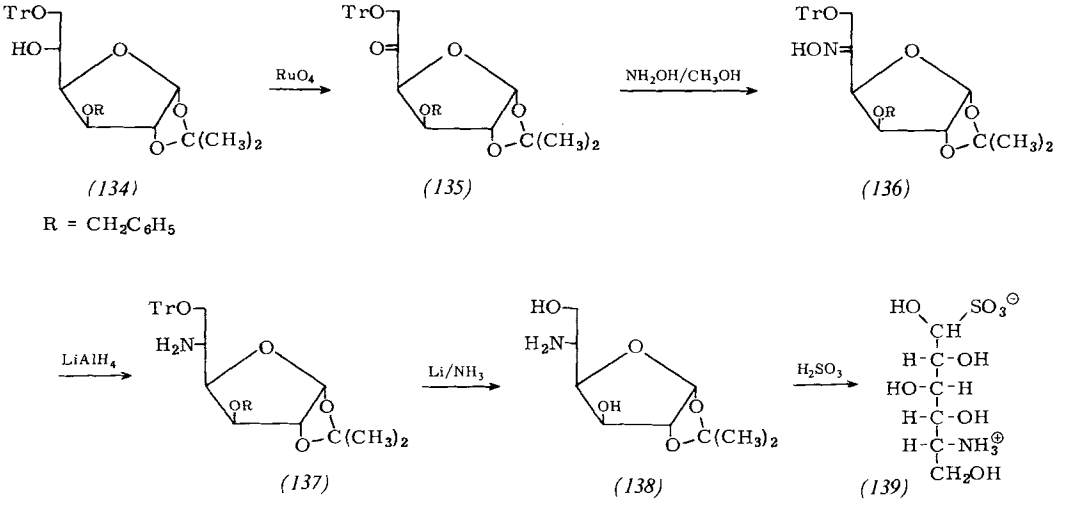


(123)

The main problem associated with the synthesis of lincosamine derivatives is the synthesis of the octose skeleton. This was achieved in a synthesis reported by *Howarth, Szarek*, and *Jones*[67] by means of a Wittig reaction between the D-galactose 6-aldehyde *(124)* and ethylidenetriphenylphosphorane. The resulting *cis*-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-6-enose *(125)* was converted into the *cis*-diol *(126)* by hydroxylation with potassium permanganate (Scheme 16).

Selective benzoylation of *(126)* gave the monoester *(127)*, which was oxidized to the ketone *(128)* with ruthenium tetroxide. Oximation of *(128)* afforded a mixture of both isomeric oximes *(129)* from which one of the pure isomers

Scheme 15.



Scheme 16.

was obtained by fractional crystallization. Reduction of this oxime with lithium tetrahydridoaluminate gave, after *N*-acetylation, a mixture of *vic*-acetamido alcohols containing *(130)* as the major component. Partial hydrolysis of *(130)* liberated the free sugar *(131)* whose structural relationship with the antibiotic sugar was established by their mutual conversion into the heptaacetate *(132)*. In the case of methyl thiolincosaminide *(133)*, this required desulfurization with aqueous mercuric acetate and cadmium carbonate, sodium tetrahydridoborate reduction of the free sugar, and acetylation.

3.7. Nojirimycin *(16)*

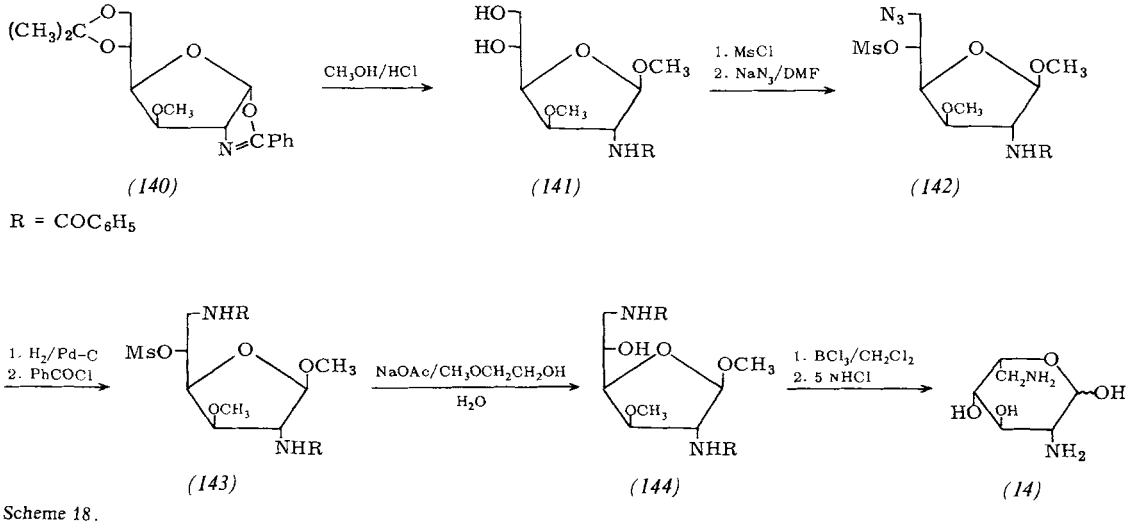
Fermentation broths of several strains of *Streptomyces* yield an antibiotic nojirimycin[68], which is endowed with remarkable biological activity against *Sarcina lutea*, *Xanthomonas oryzae*, and *Shigella flexneri*. Chemical and spectroscopic evidence[69] clearly pointed to nojirimycin being D-glucopiperidinose *(16)*—that is, a sugar containing a nitrogen heteroatom in the six-membered ring [5-amino-5-deoxy-D-glucopyranose *(16)*].

Scheme 17.

The structure of nojirimycin was confirmed by a nine-stage synthesis[69] (Scheme 17) from D-glucose, which was initially converted into 3-*O*-benzyl-1,2-*O*-isopropylidene-6-*O*-triphenylmethyl-α-D-glucofuranose[70] *(134)*, and thence, on oxidation with dimethyl sulfoxide and acetic anhydride[116], into the 5-ketone *(135)*. Reduction of the oxime *(136)* derived from *(135)* over Raney nickel in ammoniacal methanol (or with lithium tetrahydridoaluminate in ether) yielded the diastereoisomeric 5-amino derivatives to which structures were assigned on the basis of optical rotatory dispersion measurements on their *N*-salicylidene derivatives. Treatment of the major isomer *(137)*, shown to have the D-*gluco* configuration, with lithium in liquid ammonia converted it into *(138)*, which was deacetonated with sulfurous acid. The sugar was intercepted as the bisulfite adduct *(139)*, and this was shown to be identical with the corresponding nojirimycin derivative; the free sugar *(16)* could be regenerated by hydrolysis of the adduct with a basic resin.

3.8. Paromose (Neosamine B) *(14)*

The antibiotics paromomycin and neomycin B contain a 2,6-diamino-2,6-dideoxyhexose (paromose) which, from chemical and biogenetic considerations, was indicated[71] to have the L-*ido* configuration *(14)*. This assignment of stereochemistry was verified when a MacDonald-Fischer degradation on *N,N*-diacetylparomose diethyl dithioacetal gave[72] 5-acetamido-5-deoxy-L-xylose. A synthesis of paromose has been described by *Meyer zu Reckendorf*[73].



Careful treatment of the oxazoline[74] *(140)* (Scheme 18) with methanolic hydrogen chloride afforded methyl 2-benzamido-2-deoxy-3-*O*-methyl-β-D-glucofuranoside *(141)*, which gave the 6-azido-5-methanesulfonate *(142)* following treatment of the 5,6-dimethanesulfonate derivative with sodium azide in boiling dimethylformamide. Reduction of the azide group and *N*-benzoylation afforded methyl 2,6-dibenzoylamino-2,6-dideoxy-3-*O*-methyl-5-*O*-methanesulfonyl-β-D-glucofuranoside *(143)*, which underwent solvolysis to the L-idose derivative *(144)* in wet 2-methoxyethanol containing sodium acetate; the solvolysis is aided by participation of the neighboring benzoylamino group and results in inversion of configuration at C-5. Successive treatment of *(144)* with boron trichloride and dilute hydrochloric acid removed the protecting groups to give paromose *(14)*.

4. Future Developments

The constant search for new antibiotics continues to bring to light new sugars of unusual structure. The first naturally occurring nitro sugar (evernitrose) has been obtained[75] recently from everninomicin antibiotics, and the neutral macrolide aldgamycin E contains[76] two sugars, each possessing a cyclic carbonate group; the synthesis of these sugars presents a number of interesting problems. The challenge offered by the total synthesis of antibiotics that are entirely carbohydrate in nature has been accepted, and total syntheses of kanamycin A, B, and C were achieved[77] recently. Significant developments in this direction are likely to follow and, with a better understanding of the precise modes of action of these and related antibiotic substances, should lead to the synthesis of new and improved antibiotics.

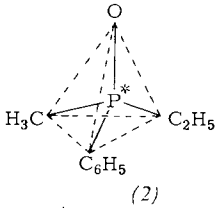
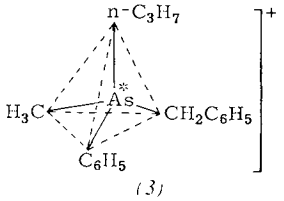
Optical Activity from Asymmetric Transition Metal Atoms

By Henri Brunner[*]



The preparation and resolution of asymmetric organometallic compounds of the transition series with four different ligands on the metal atom are described. Some of the optically active complexes retain their configuration, while others undergo racemization in solution. Their properties and reactions are discussed. Centers of asymmetry at transition metal atoms can also be detected on the basis of the magnetic nonequivalence of diastereotopic groups. Information about the configurational stability of such compounds can be obtained by investigation of the temperature dependence of the nuclear magnetic resonance spectra.

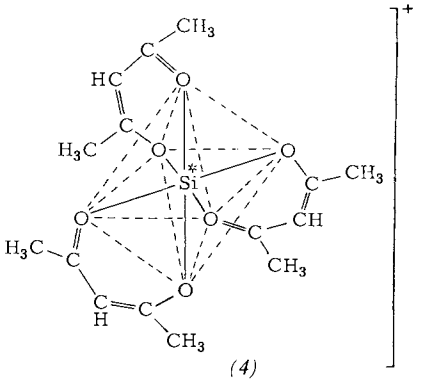
1. Introduction



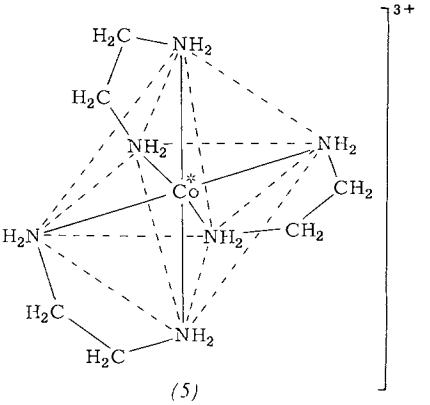
Compounds containing an asymmetric carbon atom C(a, b, c, d) can generally be resolved into enantiomers[1,2]. This is also true of other main-group elements, such as beryllium[3,4], boron[3,5], silicon[6-8], germanium[9-11], nitrogen[12,13], phosphorus[12,15-17], and arsenic[12,16], when they are situated at the center of a tetrahedron with four different substituents, as shown in the examples *(1)*[7],

(1)

(2)

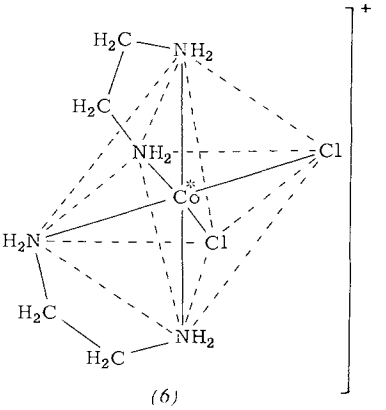


(3)



(2)[15,17], and *(3)*[16,18]. For compounds where optical activity has been measured, an asterisk marks the center of asymmetry in the present article. Only a few octahedral compounds of main-group elements have been obtained in optically active forms[19,20], an example being the cation $[Si(acac)_3]^+$ *(4)*[21].

On the other hand, there are many optically active octahedral chelates of transition metals[19,20]. The cobalt cations *(5)*[22-24] and *(6)*[25,26], which were isolated in the pioneering studies of *A. Werner*, are typical of this class of compound. However, optically active derivatives with tetrahedral structures are confined to a few complexes[27-30] of symmetry C_2 of the type *(7)* with unsymmetrical chelate ligands[27].



Chiral optically active transition metal compounds with four different substituents $M(L_1, L_2, L_3, L_4)$ *(8a)* and *(8b)*, corresponding to the optically active organic compounds with asymmetric carbon atoms, were previously unknown. Our aim was to prepare tetrahedral transition metal complexes $M(L_1, L_2, L_3, L_4)$ containing four different ligands, to separate the optical antipodes *(8a)*

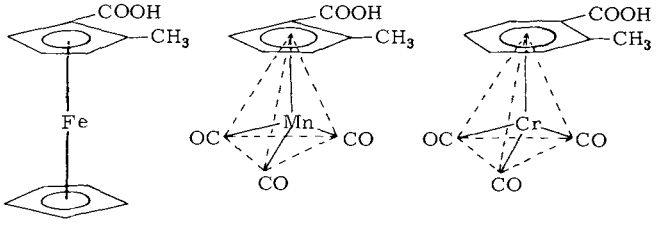
and *(8b)* of these compounds, and to carry out reactions with the optically active complexes in order to establish their stereochemical course.

(7)

(8a) *(8b)*

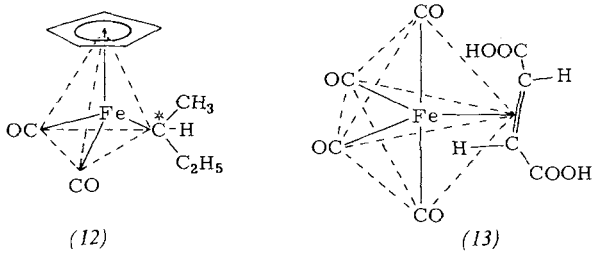
Either *cis-trans* isomers or enantiomers may be used for the investigation of the stereochemistry of substitutions of *octahedral* complexes. Information about the steric course of the reaction can be obtained from the structure of the end products. Only *cis-trans* isomers can be used in the case of *square-planar* complexes, since compounds of this type do not occur in optically active forms. *Tetrahedral* compounds, on the other hand, do not exhibit *cis-trans* isomerism. Only optically active derivatives are therefore available in this case for the investigation of the stereochemistry of substitutions. The manner in which these can be used for the elucidation of reaction mechanisms is shown by the classic investigations of *Ingold* and *Hughes* on nucleophilic substitutions on the sp^3-hybridized carbon atom[31] and by more recent work on reactions of silicon-[6] and phosphorus compounds[14]. Similar stereochemical results should be obtainable from the investigation of optically active tetrahedral transition metal compounds. The comparison of substitution reactions of tetrahedral compounds of main group elements and transition metals looks particularly interesting.



There are two main difficulties to be overcome in the preparation of tetrahedral transition metal complexes $M(L_1, L_2, L_3, L_4)$. Firstly, there are no suitable synthetic methods available by which complexes of this type can be "made to measure", as is possible in the case of organic compounds. Secondly, complexes of the type *(8a)* and *(8b)* are often kinetically unstable; they disproportionate with formation of a mixture of all possible products, as follows:

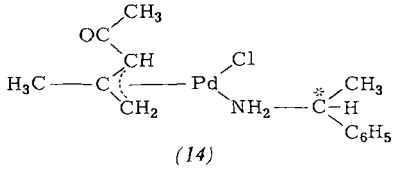
$$M(L_1, L_2, L_3, L_4) \rightarrow M(L_1)_4 + M(L_2)_4 + \cdots + M(L_1)_3L_2 + \cdots \quad (1)$$

"Scrambling" reactions of this kind have already been observed for many compounds of main group and transition elements containing several different ligands[32].



Organometallic compounds seem particularly suitable as a means of avoiding these difficulties, since the synthetic possibilities are greatest in this field of inorganic chemistry. Moreover, the σ-donor bonds from the ligands to the metal atom are strengthened in organometallic compounds by additional π back-bonding from the metal atom to empty antibonding orbitals of the ligands. This interaction of σ-donor and π-acceptor bonds should lead to a relatively stable bond framework, which should rule out disproportionation reactions in accordance with equation (1). This is essential for the isolation and subsequent resolution of derivatives with four different substituents.

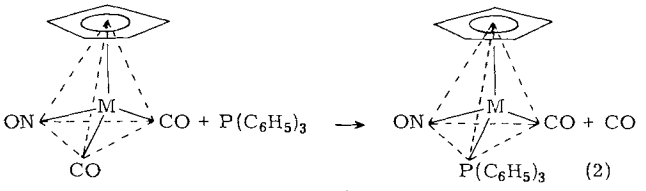
Optically active organometallic compounds of the transition series are in fact known, examples being derivatives of ferrocene[33–36], cyclopentadienyltricarbonylmanganese[33,36,38], and benzenetricarbonylchromium[33,39–41] with different substituents in positions 1 and 2 of the same ring, such as *(9)*[36], *(10)*[37,38], and *(11)*[37,41]



(9) *(10)* *(11)*

Unlike in the compounds $M(L_1, L_2, L_3, L_4)$ *(8a)* and *(8b)*, however, the metal atom is not the center of asymmetry in the complexes *(9)–(11)* or in the optically active alkyl-[42], olefin-[43–46], and allyl derivatives[47,48], *(12)*[42], *(13)*[44,45], and *(14)*[47,48]. The optical activity of these

(12) *(13)*

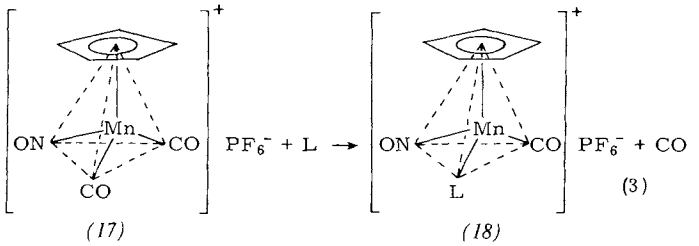


(14)

complexes is due to the dissymmetry of the ligands, and particularly their asymmetric C atoms. The plane of symmetry that is still present in the free ligands is lost on complex formation, and the compounds *(9)–(11)*, *(13)*, and *(14)* are therefore also described as exhibiting planar chirality[49].

2. Preparation of Transition Metal Complexes Containing Four Different Substituents

The cyclopentadienyldicarbonylnitrosyl complexes *(15)* of chromium, molybdenum, and tungsten[50] are readily obtainable compounds that already contain three different ligands. In the reaction of these compounds with triphenylphosphane, a CO group is replaced by the phosphane in accordance with

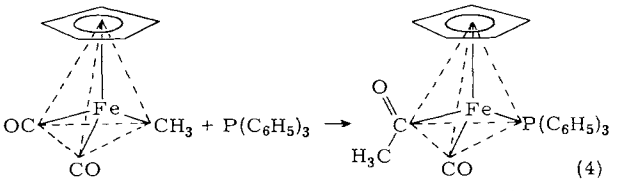


(15) *(16)* (2)

M = Cr, Mo, W

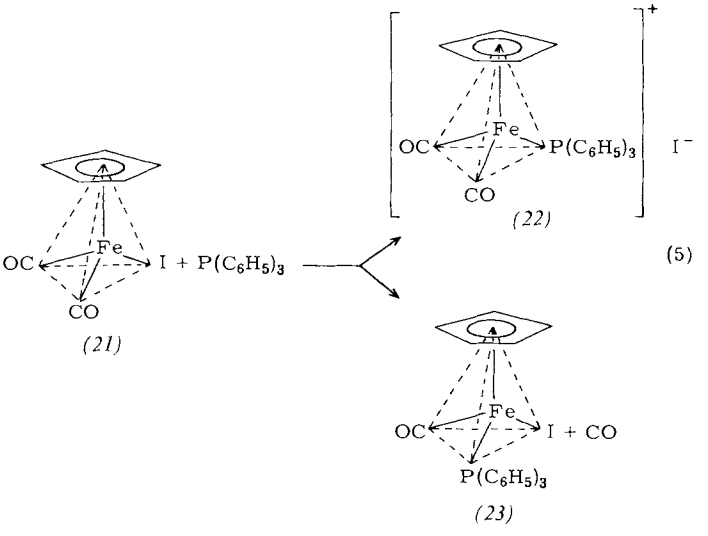
and the monosubstitution products *(16)* with four different ligands on the metal atom are formed[51,52]. On substitution of the strong π acceptor CO by triphenylphosphane, the electron density on the metal atom increases, with the result that the M→C back-bonding to the remaining CO group is strengthened. The CO ligand in *(16)* is consequently much more strongly bound, and hence more difficult to replace, than the CO ligands in *(15)*. The reaction therefore stops at the monosubstitution stage, even when an excess of triphenylphosphane is used[51].

It is usually assumed that the π-cyclopentadienyl ligand occupies three coordination positions on the metal atom. The compound *(16)* should therefore be classified as octahedral, and not as pseudotetrahedral. This view is not without its opponents[53]. However, since there are only four ligands on the metal atom, complexes of the type $C_5H_5M(L_1, L_2, L_3)$ only have the stereochemical possibilities of the tetrahedron, *i.e.* two opposite configurations, irrespective of how the cyclopentadienyl group is bonded.



Substitution experiments on $[C_5H_5Mn(CO)_2NO][PF_6]$[54,55] *(17)* have shown that the CO groups of the cation are more readily replaced by other ligands than those of the isoelectronic neutral complex $C_5H_5Cr(CO)_2NO$[56,57]. This is due to the positive charge of the Mn complex, which prevents strong back-bonding from the metal atom to the carbonyl groups. The CO ligands are therefore only loosely bound, and can be readily replaced by many donors L such as phosphanes, phosphites, arsanes, and isocyanides, in accordance with

(17) *(18)* (3)

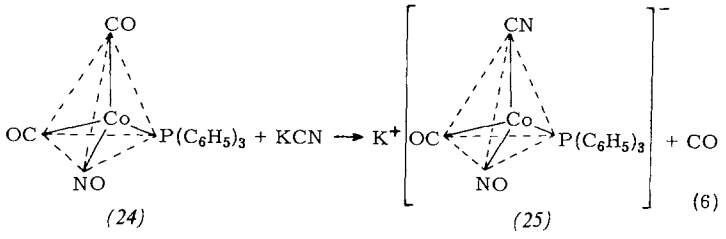


The monosubstitution products *(18)* are formed in this way at room temperature, and also the corresponding disubstitution products at higher temperatures[56-59]. However, the reaction can easily be stopped at the monosubstitution stage; this gradation of reactivity is a great help in the attempt to prepare transition metal complexes with four different substituents.

We have carried out these substitutions to obtain asymmetric complexes for resolution of the racemates. However, other reactions yielding compounds with four different ligands have also been described, though these were not used for stereochemical purposes. For example, cyclopentadienyldicarbonylmethyliron *(19)* reacts with triphenylphosphane in accordance with equation (4)[60,61].

(19) *(20)* (4)

The methyl group migrates from the iron atom on to the carbon atom of a carbonyl ligand to form an acetyl group in *(20)*. In the reaction of cyclopentadienyldicarbonyliodoiron *(21)*



(21) *(22)* *(23)* (5)

the ligands CO and I^- are replaced to roughly equal extents by triphenylphosphane[61]. The compound *(23)* formed on replacement of the CO also contains four different substituents on the iron atom.

The reaction of the readily obtainable complex *(24)*[62] with KCN yields the potassium salt of the carbonylnitrosyltriphenylphosphanecyanocobaltate ion *(25)*[63].

It can be seen from these examples that four different substituents can readily be incorporated into approximately tetrahedral molecules by the synthetic methods of organometallic chemistry, and that the products, with few exceptions[64], are kinetically stable and do not disproportionate in accordance with equation (1).

As has been predicted many times[63, 65–67], it should be possible to separate the enantiomers of compounds of the type *(16)*, *(18)*, *(20)*, *(23)*, and *(25)*. However,

(24) *(25)* (6)

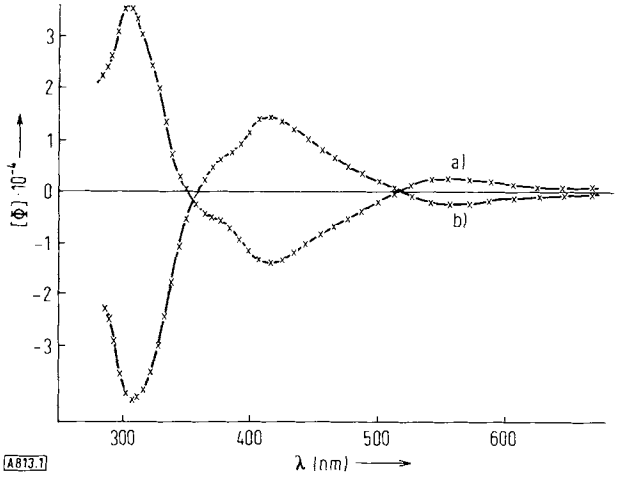
attempts to achieve such a separation with the anion of the salt *(25)* have so far been unsuccessful[67]. We shall now show how the examples of equations (2)–(6), stereochemically modified, can be used for the resolution of racemates or for the NMR-spectroscopic detection of centers of asymmetry on the metal atom.

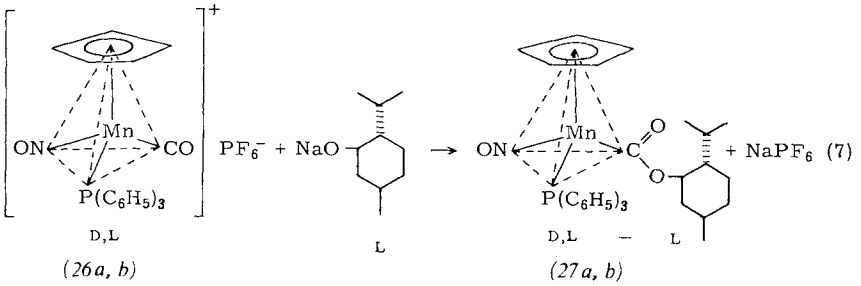
3. Diastereoisomeric Manganese Complexes

In the compound cyclopentadienylcarbonylnitrosyltriphenylphosphanemanganese hexafluorophosphate *(26a,b)*[56–59], the manganese atom is approximately tetrahedrally surrounded by four different ligands. The complex cations therefore occur in pairs of enantiomers, each being 50% in the D configuration and 50% in the L configuration. The symbols D and L are used only to distinguish the two opposite configurations. On reaction with an optically active component, enantiomers are converted into diastereoisomers which have different physical and chemical properties[1, 2]. A very suitable optically active substance in this case is the anion of the naturally occurring alcohol menthol, to which we shall assign the configuration L. The mentholate ion adds to the carbonyl carbon of the complex cation[68] to form an ester group. The product consists of the pair of diastereoisomers D,L/L,L *(27a,b)*. The two diastereoisomers *(27a)* and *(27b)* can be separated on the basis of their solubility differences. Whereas the dextrorotatory compound *(27a)* is soluble in pentane, the levorotatory *(27b)* is only sparingly soluble[68].

Both complexes are configurationally stable in the solid state; their optical rotations do not change at room temperature[68]. In solution, on the other hand, both *(27a)* and *(27b)* lose their high rotation values in a matter of hours. The equilibrium (8) is established between the two forms, since the configuration on the manganese atoms changes in solution[68, 73]. From both sides, the rotation reaches a constant equilibrium value $[\alpha_\infty]^{25}_{579} = +90°$ in benzene solution.

The diastereoisomers *(27a)* and *(27b)* can be interconverted by means of the equilibrium (8) if the different solubilities are taken into account. For example, when the more readily soluble dextrorotatory *(27a)* is heated in pentane, the sparingly soluble levorotatory *(27b)* eventually separates out in the pure state[68].





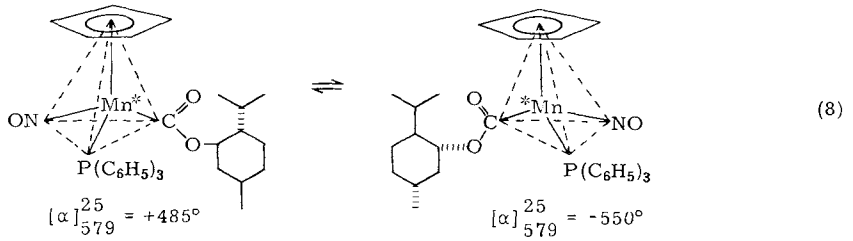


Fig. 1. ORD spectra of (a) *(27a)* and (b) *(27b)* in benzene.

The ORD and CD spectra of *(27a)* and *(27b)* are shown in Figures 1 and 2. Both compounds contain the same L-menthyl residue, but this does not absorb above 300 nm.

(26a, b) *(27a, b)*

(27a) *(27b)* (8)

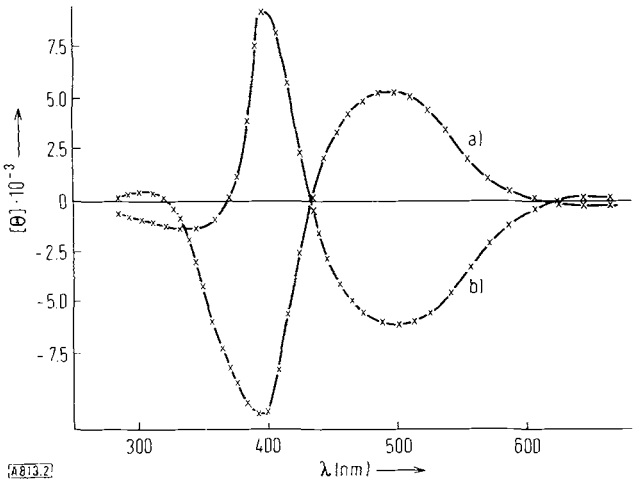

Fig. 2. CD spectra of (a) *(27a)* and (b) *(27b)* in benzene.

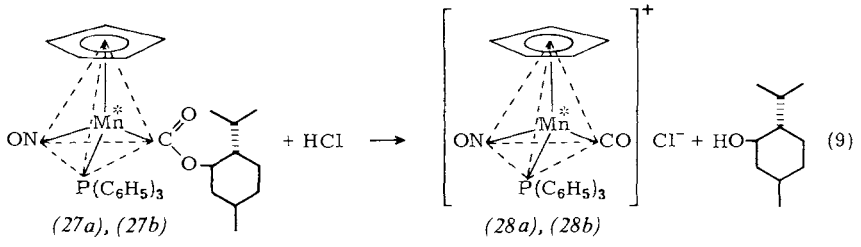
The bands in this region are therefore due only to the metal chromophore and its interaction with the ligands. Since the metal atoms in *(27a)* and *(27b)* have opposite configurations, the ORD and CD curves obtained are approximate mirror images.

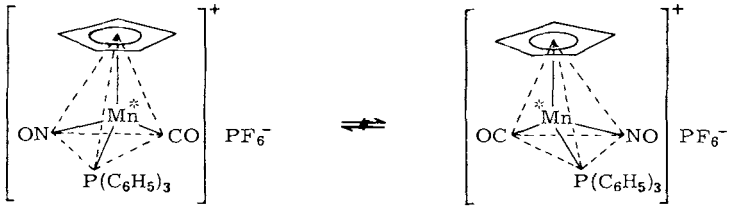
4. Enantiomeric Manganese Complexes

The preparation of the diastereoisomeric manganese compounds *(27a)* and *(27b)* from the racemic mixture of $[C_5H_5Mn(CO)(NO)P(C_6H_5)_3][PF_6]$ *(26a,b)* was described in Section 3. To complete the resolution of the racemate, the added optically active component, *i.e.* the mentholate ion, must be removed from the diastereoisomers *(27a)* and *(27b)*. This can be achieved by reaction with acids, which allows the removal of alkoxide from ester groups bonded to metals[69, 70].



If dry HCl is passed through solutions of the neutral ester derivatives *(27a)* and *(27b)* in toluene, preferably at −20 °C to prevent epimerization, the chlorides of the cyclopentadienylcarbonylnitrosyltriphenylphosphanemanganese cations *(28a)* and *(28b)* precipitate out within a few minutes[71]. The menthyl residue is eliminated in this way. The chlorides can be converted with NH_4PF_6 into the water-insoluble hexafluorophosphates *(26a)* and *(26b)*[71].

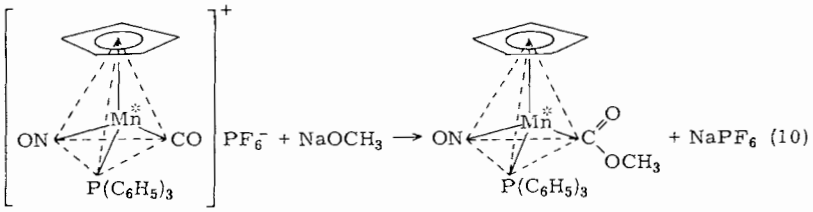
These reactions are stereospecific. The dextrorotatory diastereoisomer *(27a)* gives the (+) form of the salt *(26a)*, while the levorotatory *(27b)* gives the (−) form of the salt *(26b)*[71]. Since the reaction with HCl only involves the ligands, it does not affect the centers of asymmetry at the metal atoms. Both the two dextrorotatory compounds *(26a)* and *(27a)* and the two levorotatory compounds *(26b)* and *(27b)* therefore have the same relative configuration at the manganese atom[71]. The optical rotation values of the salts *(26a)* and *(26b)* agree except in sign to within the limits of accuracy, as is to be expected for enantiomers.



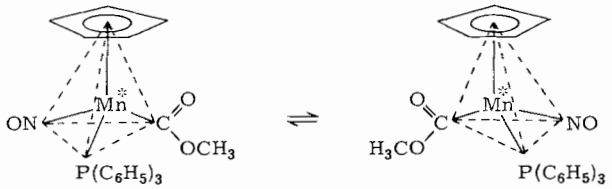
The optical activity of the diastereoisomers *(27a)* and *(27b)* is partly due to the three asymmetric carbon atoms in the menthyl residue. The salts *(26a)* and *(26b)*, on the other hand, no longer contain any asymmetric carbon atoms. Their optical activity is therefore entirely due to asymmetric metal atoms[71].

Unlike the diastereoisomers *(27a)* and *(27b)*, which epimerize in solution, the salts *(26a)* and *(26b)* are found to be configurationally stable. Their solutions in methylene chloride or tetrahydrofuran show no decrease in the rotation values on storage for several weeks even above room temperature[71]. There is also no change in the rotation values in the presence of an excess of triphenylphosphane. Backside attack of triphenylphosphane, which should lead to racemization by formation of S_N2-like transition states, therefore does not occur[71].

The optically active salts *(26a)* and *(26b)* can be used for the synthesis of other optically active compounds. For example, the reaction with sodium methoxide leads in accordance with the route shown in equation (10)



(27a), (27b) *(28a), (28b)*



$[\alpha]_{579}^{25} = +375°$ *(26a)*

$[\alpha]_{579}^{25} = -386°$ *(26b)*

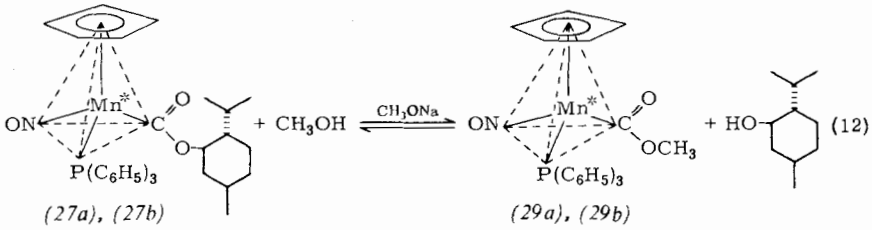
(26a), (26b) (29a), (29b)

(10)

$[\alpha]_{579}^{25} = +550°$ (29a)

$[\alpha]_{579}^{25} = -530°$ (29b)

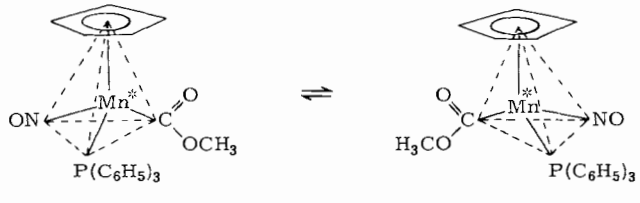
(11)



to the neutral methyl esters *(29a)* and *(29b)*[72]. The dextrorotatory *(26a)* yields the (+) form *(29a)*, and the levorotatory *(26b)* the (−) form *(29b)*. A mirror-image relation is again found for the rotation values of the optical antipodes[72].

The same methyl esters *(29a)* and *(29b)* are obtained by the action of sodium methoxide on the menthyl esters *(27a)* and *(27b)* in methanol.

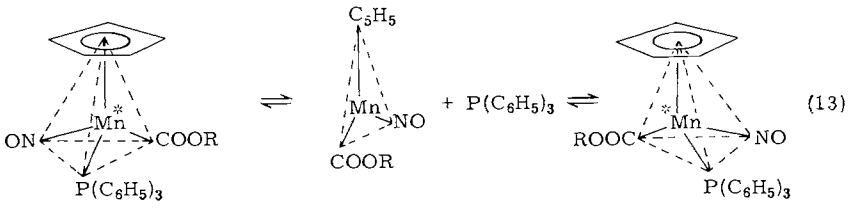
With methanol as the solvent, the equilibrium is completely displaced to the side of *(29a)* and *(29b)*[72]. The dextrorotatory diastereoisomer *(27a)* is converted in this reaction into the dextrorotatory methyl ester *(29a)*, and the levorotatory diastereoisomer *(27b)* into the levorotatory methyl ester *(29b)*[72].



(29a) and *(29b)* are configurationally stable in the solid state[72]. The racemization that occurs in solution can be investigated kinetically. The rotation values fall off exponentially with time from both sides, and ultimately reach 0 (Fig. 3)[73]. A plot of the logarithm of $[\alpha_t]$, *i.e.* rotation value at time *t*, against time yields a straight line whose slope can be used to find the rate constant for the approach to racemization equilibrium. The decrease in the rotation value is a first order reaction with a halflife of 170 min at 30 °C in benzene solution. The activation energy for the racemization is 31.1 kcal/mole, the entropy of activation 21.8 e. u.

Intramolecular and intermolecular mechanisms are conceivable for the change in configuration on the manganese atom. Highly positive values for the entropy of activation in reactions of organometallic compounds in nonpolar solvents are generally regarded as indicative of a dissociative mechanism[74, 75]. The activation parameters thus favor an intermolecular mechanism[73] such as (13).

(27a), (27b) (29a), (29b)



(12)

$[\alpha]_{579}^{25} = +550°$ (29a)

$[\alpha]_{579}^{25} = -530°$ (29b)

(11)

(29a) *(29b)*

Metal-cyclopentadienyl and metal-nitrosyl bonds are generally not broken at room temperature in complexes such as *(29a)* and *(29b)*. Also the fission of the ester-to-metal bond would lead to either energy-rich ions or radicals. Only the removal of triphenylphosphane in accordance with equation *(13)* gives a stable ligand molecule together with the coordinatively unsaturated

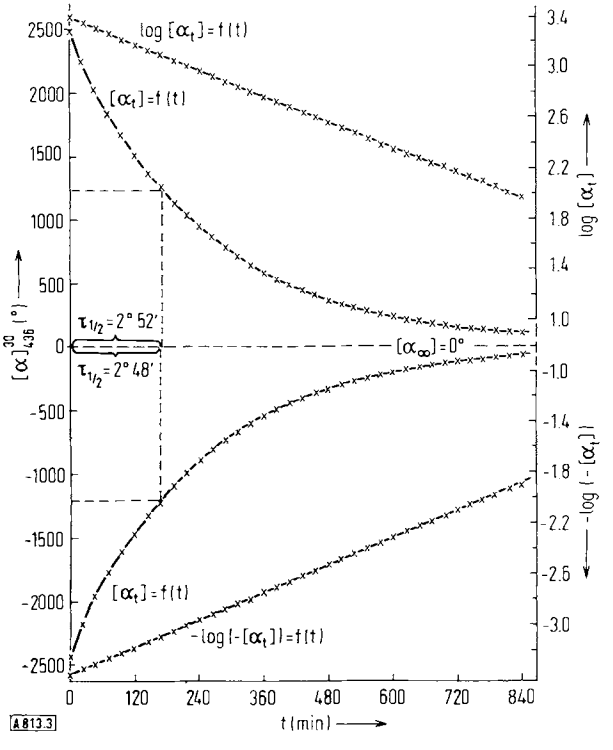


Fig. 3. Optical rotation values $[\alpha_t]$ of *(29a)* and *(29b)* as a function of time at 30 °C in benzene (left ordinate); log $[\alpha_t]$ as a function of time (right ordinate).

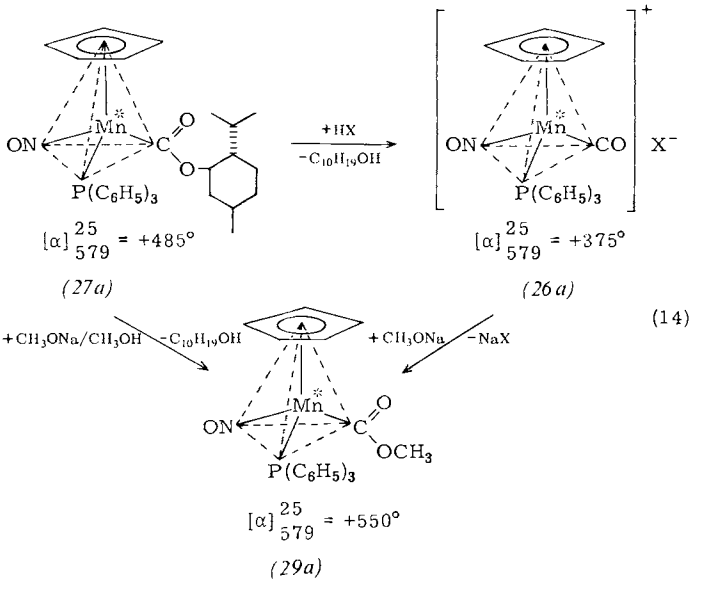


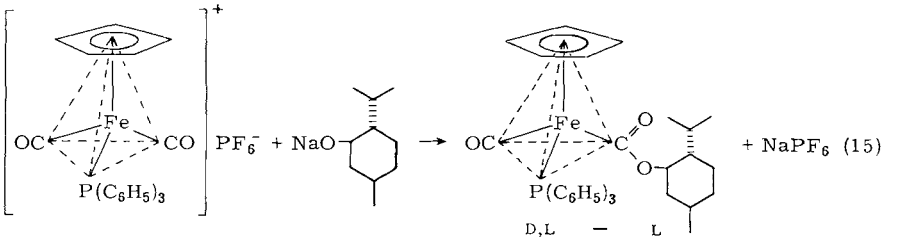
metal complex that is formed in every case. Since dissociations of $P(C_6H_5)_3$ from transition metal complexes are known[76], the cleavage of the Mn—P bond is the most likely process for the change in the configuration on the manganese atom[73], which must be the basis not only of the racemization of *(29a)* and *(29b)* but also of the epimerization of *(27a)* and *(27b)*.

The enantiomeric methyl derivatives *(29a)* and *(29b)* are of the same type as the menthyl derivatives *(27a)* and *(27b)*. A comparison of these compounds, which differ only in the alkyl residue of the ester group, should give an indication of whether electronic or steric effects are responsible for the change in configuration on the manganese atom. The electronic effects of the different OR groups on the cleavage of the Mn—P bond, which is some distance away in the molecule, should be approximately equal, whereas the steric effects of methyl and menthyl residues are very different. The menthyl group is much more bulky than the methyl group, particularly because of the isopropyl residue in position 2.

Kinetic measurements give almost the same results for the menthyl compounds *(27a)* and *(27b)* as for the methyl compounds *(29a)* and *(29b)*.

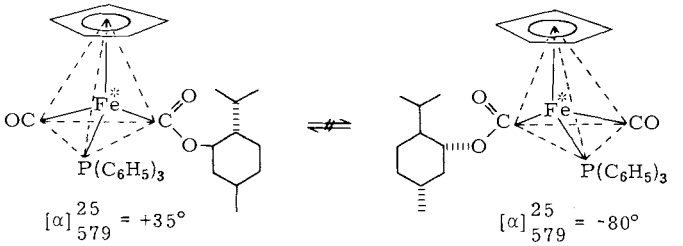
It may therefore be concluded that the steric effects do not play a very important part in the racemization. Whether the Mn—P bond is broken therefore depends mainly on the electron density on the metal atom.

Six optically active compounds have so far been prepared in the manganese series. The three dextrorotatory complexes *(26a)*, *(27a)*, and *(29a)* can be converted into one another, as indicated in scheme (14), as can the three levorotatory complexes *(26b)*, *(27b)*, and *(29b)*. Since these reactions involve only the ligands, both the dextrorotatory and the levorotatory complexes form series



with the same relative configuration on the manganese atom. The configurations *(27)* and *(29)* are labile; the products racemize in solution. The configurations *(26)* are stable; the optical rotation values of the complexes do not change in solution.

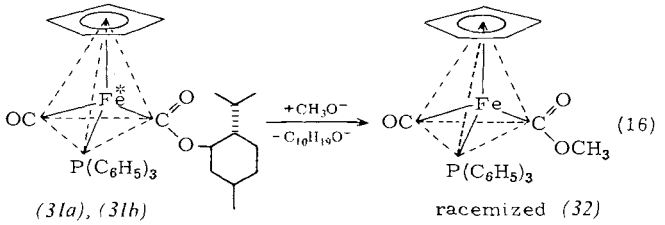
5. Diastereoisomeric Iron Complexes



Cyclopentadienyldicarbonyltriphenylphosphaneiron hexafluorophosphate *(30)*[61] serves as the starting material for another series of optically active organometallic com-

pounds. The cation in *(30)* is not chiral, since it contains two CO ligands, and hence a plane of symmetry. On addition of the mentholate ion to one of the two CO groups in accordance with equation (15), however, a center of asymmetry is produced at the iron atom[77].

Transesterification of the diastereoisomeric iron-menthyl compounds *(31a)* and *(31b)* in methanol should, as in the case of the manganese complexes *(27a)* and *(27b)*, lead to optically active enantiomeric iron-methyl derivatives. As is shown in scheme (16), however, the racemized



(30) *(31a, b)*

(31a) *(31b)*

The pair of diastereoisomers *(31a,b)* can again be resolved into the pure dextrorotatory and levorotatory diastereoisomers *(31a)* and *(31b)* on the basis of solubility differences[77]. The rotation values of the two complexes are very strongly dependent on temperature[78].

The iron compounds *(31a)* and *(31b)* correspond to the manganese complexes *(27a)* and *(27b)* according to the "nitrosyl shift principle"[79]. If the central metal in a compound is replaced by the element before it in the Periodic Table, which contains one electron less, while a CO ligand is simultaneously replaced by a NO ligand, which supplies one electron more, the same compound type is obtained. The similarity of the compounds *(27)* and *(31)*, which are analogous according to the nitrosyl shift principle, is so extensive that their IR spectra practically coincide apart from the differences in the CO and NO vibrations[78]. However, they differ in one other respect. The iron compounds are configurationally stable not only in the solid state but also in benzene solution[77], whereas the corresponding manganese derivatives racemize at room temperature with half lives of 2–3 hours[68,73].

(31a), (31b) racemized *(32)*

methyl ester *(32)* is always formed[78]. On dissolution of *(31a)* and *(31b)* in methanol, the optical activity decreases within a few seconds to the value for free menthol, and the racemized complex *(32)* separates out[78], whereas solutions of the complexes *(31a)* and *(31b)* in benzene do not lose their optical activity[77].

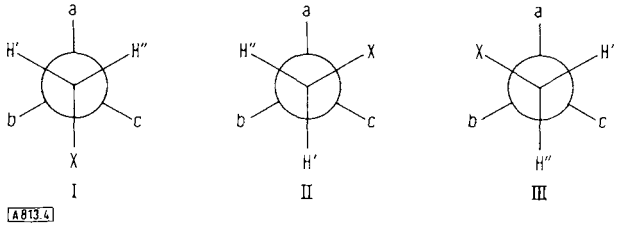
The transesterification of the manganese complexes *(27a)* and *(27b)* in accordance with equation (12), unlike that of the iron complexes *(31a)* and *(31b)*, does not take place in pure methanol, but proceeds only on addition of a base.

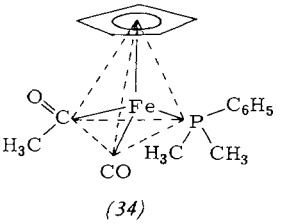
6. Detection of Centers of Asymmetry on the Basis of Magnetic Nonequivalence

Instead of optical activity, NMR spectroscopy may be used for the detection of centers of asymmetry on transition metal atoms. Because of the large contact shifts, paramagnetic complexes of the type *(7)* give well-resolved ^{1}H-NMR spectra[80,81]. If the ligands contain centers of asymmetry, the spectra show signals for all possible diastereoisomers including the various configurations on the metal atom.

It is convenient at this point to discuss more fully the detection of centers of asymmetry on transition metal atoms on the basis of magnetic nonequivalence, the principles of which are summarized below[82,83]. In compounds of the "ethane type", the protons of a methylene

group generally give only one NMR signal. The situation changes when the grouping CH_2X is attached to a center of asymmetry. In compounds of this type, the methylene protons are diastereotopic, and hence magnetically nonequivalent[82,83]. This is illustrated by the Newman projections of the three staggered conformations (Fig. 4). In I, the proton H′ is situated between the substituents a and b of the center of asymmetry, while H″ is between the substituents a and c. As in I, the environments of the two hydrogen atoms H′ and H″ are also different in the other two Newman projections II and III. The magnetic nonequivalence is not cancelled out by fast rotation about the central C—C bond. The methylene protons should therefore give different signals in the ^{1}H-NMR spectrum. Consequently, the CH_2X grouping may be used as a probe for centers of asymmetry[82,83]. This discussion is valid not only for the protons of a methylene group but also for diastereotopic *gem*-methyl groups in compounds of the type $Y—C(CH_3)_2X$ or $Y—P(CH_3)_2X$. *gem*-Methyl groups on the phosphorus can be introduced into transition metal complexes with phenyldimethylphosphane, which has already been used for the investigation of the structures of octahedral complexes with several substituents[84].





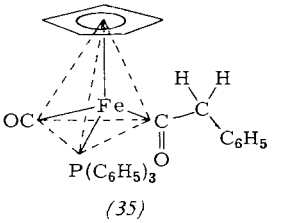


Fig. 4. Newman projections of the staggered conformations of the molecule type abcC—CH_2X.

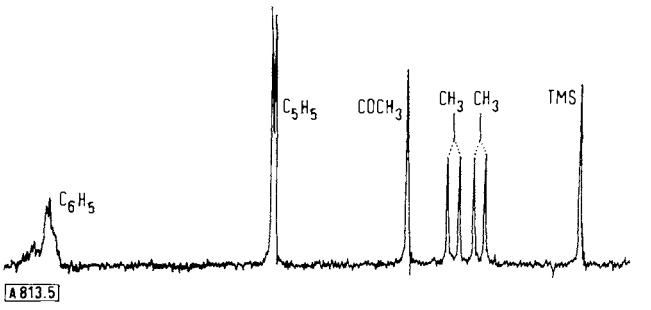
In a reaction similar to (4), $C_5H_5Fe(CO)_2CH_3$ *(19)* and $P(CH_3)_2C_6H_5$ give the product *(34)*, a compound with a center of asymmetry on the iron atom and *gem*-methyl groups on the phosphorus[85,86]. In addition to the signals of the phenyl protons of the phosphane, the cyclopentadienyl protons (which are split by the phosphorus), and the methyl protons of the acetyl group, the ^{1}H-NMR spectrum of this complex (Fig. 5) contains four practically equidistant signals, which can be assigned to the two magnetically nonequivalent methyl groups. The signals of the two different methyl groups are split here into doublets as a result of coupling with the nuclear spin of the phosphorus. The magnetic nonequivalence of the *gem*-methyl groups confirms the presence of a center of asymmetry on the iron atom in *(34)*[85,86].

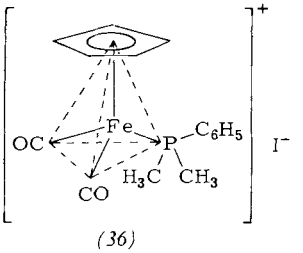
Like the methyl compound *(19)*, the corresponding benzyl compound $C_5H_5Fe(CO)_2CH_2C_6H_5$, which also contains

(34)

(35)

a probe for centers of asymmetry in the form of the grouping $CH_2C_6H_5$, can also react with triphenylphosphane[85,86]. There results the complex *(35)*, in which the methylene group is separated from the center of asymmetry





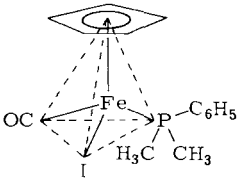


Fig. 5. ^{1}H-NMR spectrum of $C_5H_5Fe(CO)(COCH_3)P(CH_3)_2C_6H_5$ *(34)* in CS_2 solution.

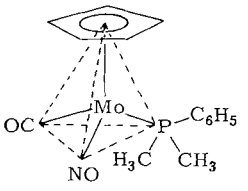
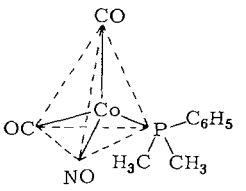
on the iron atom by a CO bridge. Nevertheless, a well resolved AB system is again observed for the two magnetically nonequivalent methylene protons[85,86]. $C_5H_5Fe(CO)_2I$ *(21)* reacts with $P(CH_3)_2C_6H_5$, as shown for $P(C_6H_5)_3$ in equation (5), to give a salt *(36)* and a neutral product *(37)*[85,86]. The cation of the salt *(36)* contains two CO groups, and hence has a plane of symmetry, which leads to magnetic equivalence of the *gem*-methyl groups on the phosphorus. The ^{1}H-NMR spectrum therefore contains only one methyl signal, which is split into a doublet as a result of coupling with the phosphorus[85,86]. This example thus shows that the magnetic nonequivalence of the *gem*-methyl groups in *(34)* is due only to the asymmetric metal atom.

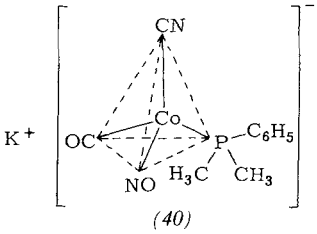


(36)



(37)

In the substitution product *(37)*, the iron atom is again surrounded by four different ligands. The magnetic nonequivalence of the two geminal methyl groups on the phosphorus demonstrates the presence of a center of asymmetry on the metal atom in *(37)*[85,86].



In the chiral iron complexes *(34)*, *(35)*, and *(37)*, the four different ligands differ considerably in each compound. In the complex $C_5H_5Mo(CO)(NO)P(CH_3)_2C_6H_5$ *(38)*, which can be prepared in a reaction analogous to equation (2), the carbonyl and nitrosyl ligands are extremely similar both in their linear structure and in the similar charge distribution. It was therefore interesting to consider whether the differences between the two ligands are sufficient to induce magnetic nonequivalence in the probe $P(CH_3)_2C_6H_5$. As can be seen from the ^{1}H-NMR spectrum in Figure 6, splitting is in fact present. However, it is much weaker than in *(34)*, *(35)*, and *(37)*.

(38)

(39)

(40)

The compound $Co(CO)_2(NO)P(CH_3)_2C_6H_5$ *(39)*[86] contains two CO ligands. The *gem*-methyl groups on the phosphorus are therefore magnetically equivalent, as in the complex *(36)*. In the product *(40)* of the reaction of

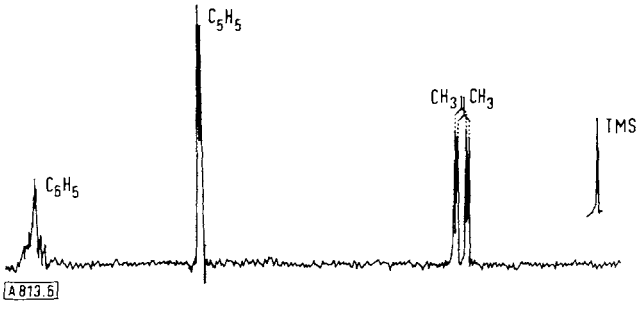


Fig. 6. ^{1}H-NMR spectrum of $C_5H_5Mo(CO)(NO)P(CH_3)_2C_6H_5$ *(38)* in CS_2 solution.

(39) with KCN [cf. equation (6)], on the other hand, the cobalt atom is surrounded by four different ligands, of which the CO, the NO, and the CN groups are very similar[86]. However, magnetic nonequivalence of the *gem*-methyl groups on the phosphorus is also found for this compound. The differences between the CO, NO, and CN ligands are thus large enough for the *gem*-methyl groups in the probe $P(CH_3)_2C_6H_5$ to show that the environment of the cobalt atom is asymmetric[86].

7. Temperature Dependence of the Nuclear Magnetic Resonance Spectra

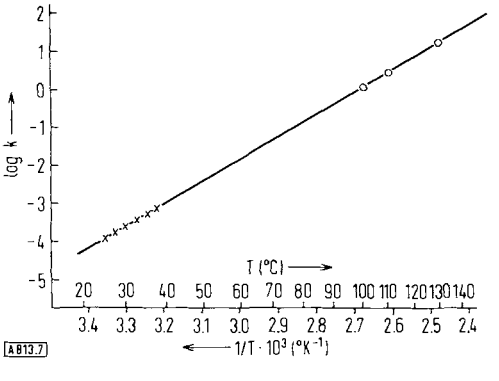
Besides showing the presence of centers of asymmetry, the NMR spectra can also provide information about the stability of the configuration at the transition metal atom through their temperature dependence. Thus fast ligand exchange *via* symmetrical intermediates, *e.g.* in accordance with equation *(17)*, which is similar to the racemization mechanism (13), should lead to the disappearance of the magnetic nonequivalence, and hence to the coalescence of the four signals in Figures 5 and 6 to form a pair. However, this does not occur either at or above room temperature. The temperature dependence has been investigated up to 100 °C for *(34)*, up to 110 °C for *(40)*, and up to 130 °C for *(38)*[86]. The complexes decompose at higher temperatures. Up to the temperatures indicated, however, even the line broadening that should precede the coalescence of the signals cannot be observed. The complexes thus exhibit surprising configurational stability[86].

However, the temperature dependence of the NMR spectra can also be used quantitatively. If signals coalesce with rising temperature, the rate constants of the reactions involved can be found from the spectra[87]. If the coalescence temperature is not reached, as in the cases of *(34)*, *(38)*, and *(40)*, it is still possible to give upper limits for the reaction rates, in this case for the change in configuration on the metal atoms[87,88]. Upper limits found in this way for the rate constants of the ligand exchange are shown in the left-hand side of Table 1[86].

Table 1. Rate constants (in s^{-1}) of ligand exchange and epimerization reactions.

T(°C)	Ligand exchange [a]	Epimerization [b]
100	70.3 *(34)*	1.7 *(27b)*
110	15.6 *(40)*	4.6 *(27b)*
130	12.5 *(38)*	30.2 *(27b)*

[a] Upper limits determined by NMR spectroscopy [86].
[b] Extrapolated to higher temperatures from the Arrhenius diagram [73, 86].



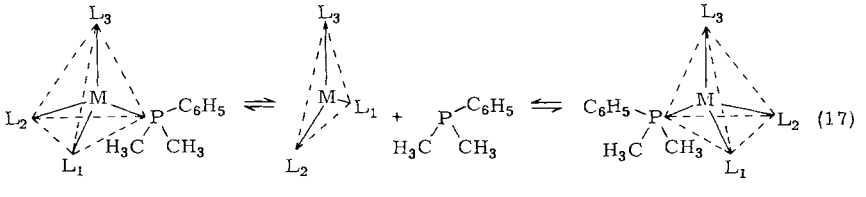


Fig. 7. Extrapolation of the Arrhenius diagram of *(27b)* to higher temperatures.

As was mentioned, the rate constants for the epimerization of the manganese compounds *(27a)* and *(27b)* have been determined in the temperature range 25–40 °C by polari-

(17)

metric kinetics[73]. Extrapolation to temperatures of 100–130°C in the Arrhenius diagram for *(27b)* (Fig. 7), assuming a constant activation energy, gives the rate constants shown in the right-hand side of Table 1[86], which cannot be measured polarimetrically, since *(27b)* decomposes thermally above 40°C[73]. These values may be compared with the upper limits of the rate constants for the ligand exchange in the complexes *(34)*, *(38)*, and *(40)* as found by NMR spectroscopy. The same process, *i.e.* the change in the configuration on the asymmetric metal atom, is measured in both methods. If it is considered that the values in the left-hand side of Table 1 give only upper limits, while the true rate constants are much smaller, it is found that the complex *(38)* and probably also *(40)* and *(34)* have greater configurational stability than the manganese derivative *(27b)*[86]. This means that the complexes *(34)*, *(38)*, and *(40)*, if they were to exist in an optically active form, would racemize more slowly than the manganese complex *(27b)*, which has already been prepared in an optically active form. This is a point that requires experimental verification.

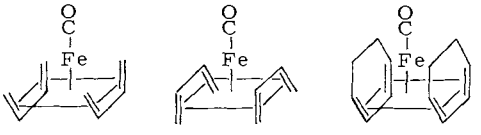
Photochemical Synthesis of Bis(1,3-diene)monocarbonyliron Compounds

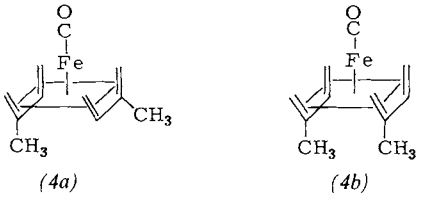
By *Ernst Koerner von Gustorf, Jürgen Buchkremer, Zorka Pfajfer*, and *Friedrich-Wilhelm Grevels*[*]



Thermal reaction of butadiene with iron carbonyls results in replacement of at most two CO ligands by butadiene[1]. Thus butadiene and $Fe(CO)_5$ react in an autoclave at 140 °C to give butadienetricarbonyliron *(1)* in 42 % yield[2].

The photochemical preparation of *(1)* at 20 °C[3,4] gives higher yields. During a study of this reaction we found that bis(butadiene)monocarbonyliron *(2)*, the first example of a new type of olefincarbonyliron complexes[5], is formed as by-product. Under appropriate conditions *(2)* becomes the main product (see experimental part). The complex crystallizes from pentane at −78 °C as orange-red tetragonal crystals of several centimeters length (m.p. 130–135 °C, decomp.). The crystals are stable in air at room temperature.

The structure of *(2)* follows from the ^{1}H-NMR spectrum, whose splitting pattern is superimposable with that[6] of *(1)*, thus establishing the symmetrical arrangement of the butadiene units. This assumption is confirmed by the space group $P\bar{4}2_1m$ found by X-ray structure analysis[5,7]. By analogy with the position of the butadiene[8] in *(1)*, the former of the two alternatives *(2a)* and *(2b)* appears the more probable.



Apart from the molecular ion, the mass spectrum of *(2)* shows fragments that arise from the successive loss of CO and two butadiene units. As expected, only one CO stretching mode at 1984.5 cm^{-1} (in *n*-hexane) is seen in the IR spectrum.

Under the conditions worked out for *(2)*, $Fe(CO)_5$ reacts photochemically with 1,3-cyclohexadiene to give a 40 % yield of bis(1,3-cyclohexadiene)monocarbonyliron *(3)* that also forms orange-red crystals (m.p. 134–136 °C; decomp.; $\tilde{\nu}_{CO}$ = 1964.5 cm^{-1}). The ^{1}H-NMR spectrum again exhibits coupling constants corresponding to those observed for 1,3-cyclohexadienetricarbonyliron[9]. X-Ray structure analysis[7] confirms a symmetric arrangement of ligands and shows that the CH_2—CH_2 groups of the cyclohexadiene are turned towards the carbonyl group. This substantiates the assignment of structure *(2a)* to compound *(2)*.

(2a) *(2b)* *(3)*

Irradiation of $Fe(CO)_5$ with isoprene affords bis(isoprene)monocarbonyliron *(4)* (m.p. 99–104 °C, decomp.; $\tilde{\nu}_{CO}$ = 1980 cm^{-1}). According to the ^{1}H-NMR spectrum the two CH_3 groups in *(4)* are chemically equivalent[10]. Of the two isomers *(4a)* and *(4b)* only one is apparently present; consideration of models indicates that *(4a)* is the more likely structure as it involves less interaction between the two isoprene units.

(4a) *(4b)*

The diene-iron bond, *e.g.* in *(2)*, can be cleaved again photochemically; in the presence of 1,3-cyclohexadiene compound *(3)* is formed as a result of ligand exchange.

The bis(diene)monocarbonyliron compounds are isosteric with the starting materials – such as, for example, bis(1,5-cyclooctadiene)nickel(0) – for the preparation of nickel catalysts used in the oligomerization of butadiene[11]. On coordination with CO iron becomes formally isoelectronic with nickel(0); bis(diene)monocarbonyliron complexes therefore also catalyze the oligomerization of butadiene. In the presence of n-donors such as phosphanes butadiene can be dimerized to 4-vinyl-1-cyclohexene and 1,5-cyclooctadiene by catalytic amounts of *e.g. (2)* or *(3)* at temperatures of about 100 °C. When no phosphane is present, trimerization to 1,5,9-cyclododecatriene and other butadiene trimers is observed[12]. The bis(diene) complexes of other transition metals of corresponding structure and electronic configuration should also fulfill the requirements for catalytic activity.

Procedure for the preparation of (2):

$Fe(CO)_5$ (0.05 mole) and butadiene (1 mole) in pentane (300 ml) are irradiated at −35 °C under argon for 48 h in an immersion-lamp apparatus with internal and external cooling using a high pressure mercury arc lamp, Philips HPK 125 W. The coolant is first passed through the external cooling mantle and then through the internal one. The temperature gradient causes the product *(2)* to crystallize at the outer wall of the reaction vessel. After irradiation, the solution is allowed to warm to room temperature whereupon *(2)* dissolves and can be freed from small amounts of brown decomposition products by inverse filtration. On renewed cooling of the filtrate to −78 °C, crystalline *(2)* of analytical purity is precipitated in 85–90 % yield (based on $Fe(CO)_5$).

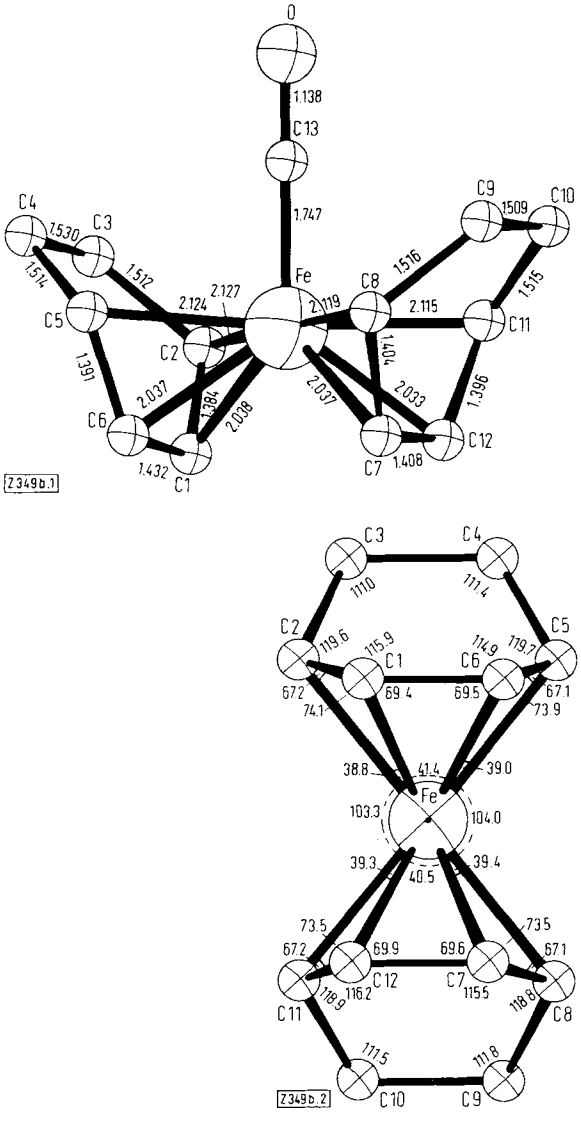
Molecular and Crystal Structure of Bis(1,3-cyclohexadiene)monocarbonyliron

By *Carl Krüger* and *Yi-Hung Tsay*[*]

Bis(1,3-cyclohexadiene)monocarbonyliron *(1)*[1], a compound of interest because it is isosteric with starting materials employed in the production of highly active nickel catalysts, crystallizes in the orthorhombic space group $P2_12_12_1$ along {001} with the following cell constants: $a = 17.089 \pm 0.0005$, $b = 8.495 \pm 0.0004$, $c = 7.545 \pm 0.0004$ Å; $Z = 4$; $d(\text{calc}) = 1.48$ g cm^{-3}.

The molecular structure was deduced by the heavy atom method from 1697 diffractometer data and, including the unequivocally located hydrogen atoms, refined anisotropically to an R factor of 3.3%.

Unlike bis(1,3-butadiene)monocarbonyliron[2] ($a = 7.76$, $c = 7.33$ Å), whose space group $P\bar{4}2_1m$ requires the molecule to have C_s symmetry, complex *(1)* is chiral and has only approximately m-symmetry. In spite of their fairly close contact to the carbonyl group, the C_6 rings are arranged as shown in Fig. 1; Fig. 2 shows a view along the Fe—CO axis.



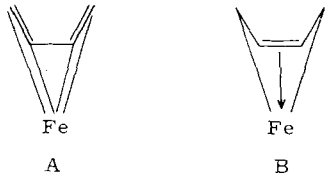


Fig. 1 (above) and 2 (below). Maximum estimated errors: lengths ±0.006 Å; angles ±0.5°.

The two rings differ in conformation and in their bonding to the iron by amounts that are too large to be accounted for by experimental errors. This may be due to slight predominance of the limiting structure A in ring 1 (C1–C6), and structure B in ring 2 (C7–C12). Both kinds of bonding have been considered for analogous diene complexes[3]. However, the observed distortions could only be induced

[*] Dr. Carl Krüger and Dr. Yi-Hung Tsay
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Lembkestrasse 5 (Germany)

by the asymmetry of the crystal field. The central atom lies 0.1 Å above the best plane through the atoms C2, C5 and C8, C11. The lines joining the atoms C2–C5 and C8–C11 respectively are twisted through 1°.

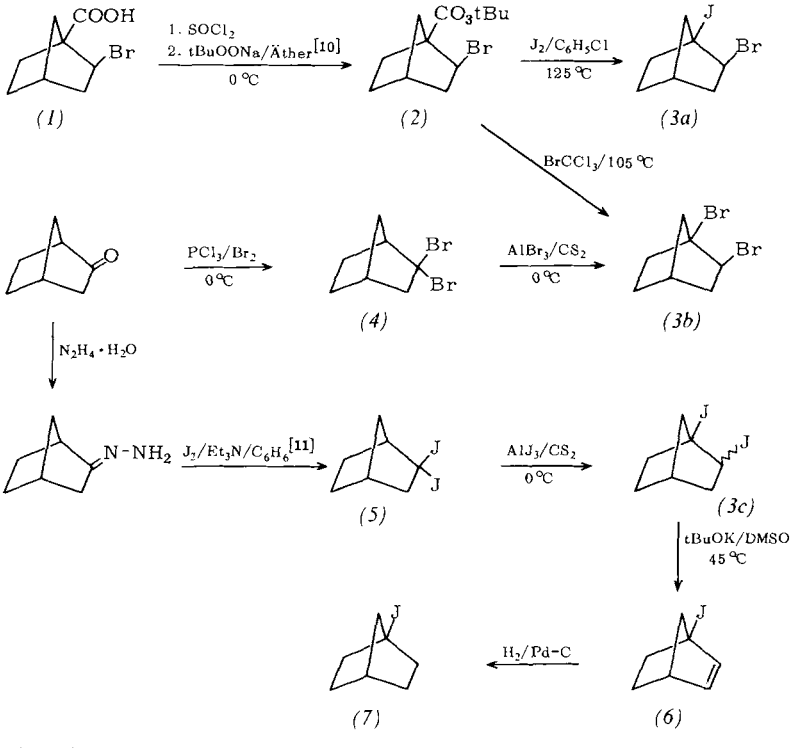
Concerning the Existence of 1-Norbornene

By *Reinhart Keese* and *Ernst-Peter Krebs*[*]

Bredt's rule categorically denies the possibility of a normal double bond at the bridgehead of the norbornane system[1]. However, it remains an open question whether bicyclo-[2.2.1]hept-1-ene *(8)* with its highly strained double bond[2] can be detected[3], possibly as a metastable intermediate.

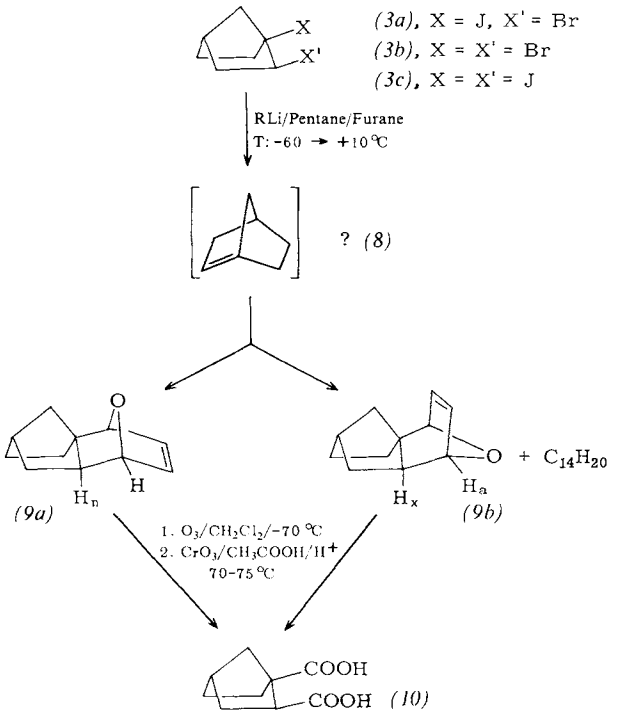


In the present communication we report the results of bis-dehalogenation of 1,2-dihalogenonorbornanes. The starting materials *(3a)–(3b)* were prepared as shown in Scheme 1[4].

Fragmentation of *(2)*[6a] in cumene at 130 °C gives 2-*exo*-bromonorbornane[7]; this supports both the *exo*- configuration of *(1)*[8] and that of *(3a)* [NMR: 4.15 (o, $J = 7.5$, 3.5, 1.5; 1 H), 2.8–0.7 (*ca.* 9 H); mass spectrum: 302/300 (M^+), 221 (M^+–Br)][9]. The constitution and configuration of *(3b)*[6b] are apparent from its formation on thermolysis of *(2)* in bromotrichloromethane [NMR: 4.15 (o, $J = 7.0$, 3.5, 1.8; 1 H), 2.7–1.0 (*ca.* 9 H); mass spectrum: 256/254/252 (M^+), 175/173 (M^+–Br)].

The constitution of *(3c)* [NMR: 4.30 (o, $J = 8.0$, 4.0, 1.5; 1 H), 2.8–1.0 (*ca.* 9 H); mass spectrum: 348 (M^+), 221 ($M^+ - I$)], which is formed almost quantitatively from *(5)*, is supported by *(7)*—obtained *via (6)* [NMR: 6.18 (d, $J =$ 5.5; 1 H), 5.88 (q, $J = 5.5$, 3.0; 1 H), 2.7–1.0 (7 H); mass spectrum 220 (M^+), 192 ($M^+ - C_2H_4$)]—whose IR spectrum is identical with that of 1-iodonorbornane[12] prepared by conventional means; the probable[13] *exo* configuration of *(3c)* remains to be confirmed.

The elimination of halogen from *(3a)*, which is induced by *n*-butyllithium and proceeds *via* lithium-iodine exchange[14], gives, in the presence of furan, the isomeric adducts *(9a)* and *(9b)*. Three saturated hydrocarbons of composition $C_{14}H_{20}$ whose structures are unknown were isolated as by-products (see Scheme 2 and Table).



The furan adducts *(9a)* and *(9b)* differ significantly in their NMR coupling constants. In *(9b)* H_x is *exo* to H_a ($J_{ax} = 4.0$ Hz), whereas H_n in *(9a)* is *endo* to the proton at the ether bridge and consequently is not coupled with it[15].

Scheme 1.

Ozonolysis and subsequent chromic acid oxidation of both isomers *(9a)* and *(9b)* affords the same 1,2-*exo*-norbornanedicarboxylic acid *(10)*[16]. The constitution

of this acid is confirmed by independent synthesis starting from the Diels-Alder reaction between methyl cyclopentadienecarboxylate[17] and allyl acetate.

All the trapping reactions so far carried out with furan give the same ratio of the adducts *(9a)* and *(9b)* (see Table). We regard this result as compelling evidence for the intermediacy of bicyclo[2.2.1.]hept-1(2)-ene *(8)*.

The question whether the highly reactive intermediate *(8)* is susceptible to detection at all and whether it is a triplet or a singlet molecule warrants further study. Experiments to detect bicyclo[2.2.1.]hept-1(7)-ene are also currently in progress.

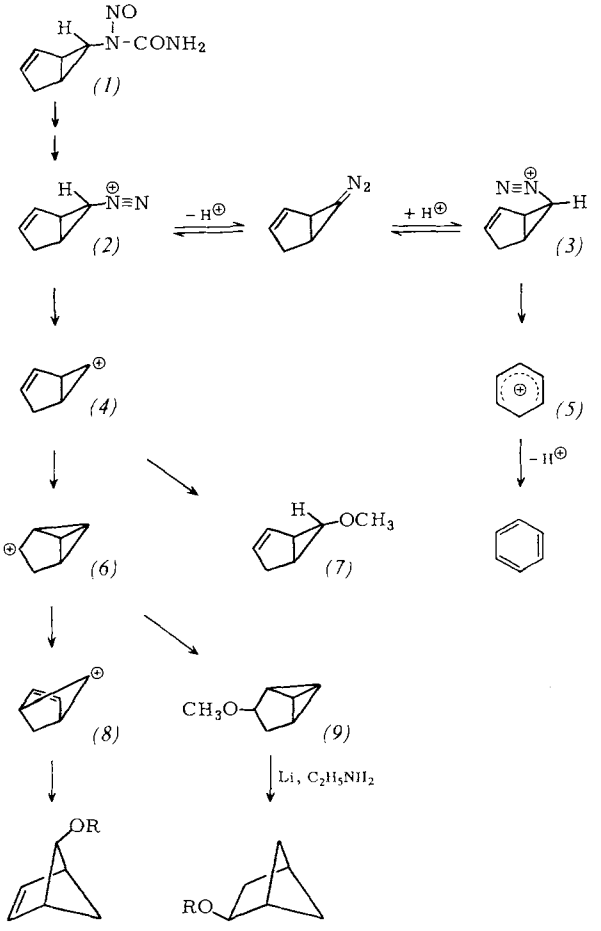
A New Route to Derivatives of Bicyclo[2.1.1]hexene and Tricyclo[3.1.0.0^{2,6}]hexane

By *Wolfgang Kirmse* and *Friedrich Scheidt*[*]

In conjunction with our work on bicycloalkyldiazonium ions[1] we have studied the decomposition of *N*-nitroso-*N*-*exo*-bicyclo[3.1.0]hex-2-en-6-ylurea *(1)*. Compound *(1)* was prepared, analogously to the saturated compound[1], from cyclopentadiene and ethyl diazoacetate. Alkaline cleavage of *(1)* with 2 mol. equiv. of sodium carbonate as base gave benzene as the sole product. Benzene is the product expected from deprotonation of the cyclohexadienyl cation *(5)* formed by a cyclopropyl-allyl rearrangement. However, the *exo*-diazonium ion *(2)* cannot be transformed into *(5)* in a concerted process (outward disrotation). We therefore assume that benzene formation is preceded by a base-catalyzed isomerization of the *exo*-diazonium ion *(2)* to the *endo* species *(3)*. This assumption is confirmed by the incorporation of deuterium in deuterated solvents.



Under less strongly alkaline conditions, benzene is accompanied by substitution products (Table). In methanol the reaction yields *exo*-6-methoxybicyclo[3.1.0]hex-2-

[*] Prof. Dr. W. Kirmse and Dr. F. Scheidt
Abteilung für Chemie der Universität Bochum
463 Bochum-Querenburg, Postfach 2148 (Germany)

ene *(7)* (identified by comparison with a product formed from methoxycarbenoid and cyclopentadiene[2]) and methoxytricyclo[3.1.0.0^{2,6}]hexane *(9)*. The structure of *(9)* is established by spectroscopic data [NMR: 60 MHz, ppm relative to TMS: 3.87 (1H/dd); 3.13 (3H/s); 2.45 (2H/m); 2.32 (1H/m); 2.1 (1H/m); 1.75 (2H/m)] and by the cleavage of the C-2—C-6 bond by lithium in ethylamine[3] to give 2-methoxybicyclo[2.1.1]hexane *(13)*. Compound *(13)* was prepared for comparison from the known compound bicyclo[2.1.1]hexan-2-ol[4].

Table. Reactions of *(1)*.

Solvent	Base (mol. equiv.)	T(°C)	Products (yield)
Methanol	none	40	*(7)* (23%)
	NaOCHO (2)	20	*(7)* (2–3%) *(9)* (35%) benzene (43%)
	$NaHCO_3$ (2)	20	*(9)* (18%) benzene (72%)
	Na_2CO_3 (2)	20	benzene (90%)
Water/dioxane (10:8)	NaOCHO (1.2)	20	*(11)* (20%) benzene (7%)
	$NaHCO_3$ (1.2)	0	*(10)* (14%) benzene (5%)
	$NaHCO_3$ (1.2)	20	benzene (55%)
Water/THF (1:1)	NaOCHO (1.3)	20	*(10)* (5%) *(11)* (23%) benzene (14%)

Reaction in water/dioxane gave *anti*-bicyclo[3.1.1]hex-2-en-5-ol *(10)* and, on use of sodium formate as base, the corresponding formic ester *(11)*. *anti*-5-Acetoxybicyclo[2.1.1]hex-2-ene *(12)* was obtained by deamination of *exo*-bicyclo[3.1.0]hex-2-en-6-ylammonium chloride in glacial acetic acid/sodium acetate at pH 4.7 in 24% yield. The spectral data of *(10)*–*(12)* agree with those given for *(12)* in the literature[5].

The transition *(2)*→*(9)* is a homoallyl-cyclopropylcarbinyl rearrangement and the conversion *(2)*→*(10)* is a homoallyl-homoallyl rearrangement. The cationic intermediates [*(4)*, *(6)*, and *(8)*] – formulated as classical ions in the reaction scheme – are probably bridged systems. This is suggested by the stereospecific formation of *exo*-*(7)* and *anti*-*(10)*. The rearrangement leads to products exhibiting greater strain than the starting materials: bicyclo[2.1.1]hexenes undergo thermal rearrangement to bicyclo[3.1.0]hexenes[5–7].

Preparation of 1,1-Dimethyl-5-oxo-4,5-dihydro-1,3,2,4,6-thia(VI)thiatriazine 3,3-Dioxide from Dimethyl Sulfone Diimine[1]

By *Manfred Haake*[*]

The novel heterocyclic compound 1,1-dimethyl-5-oxo-4,5-dihydro-1,3,2,4,6-thia(VI)thiatriazine 3,3-dioxide *(3)* has now been isolated after repeated purification from the products of the reaction between chlorosulfonyl isocyanate

[*] Dr. M. Haake
Institut für Pharmazeutische Chemie
und Lebensmittelchemie der Universität
355 Marburg, Marbacher Weg 6 (Germany)

(2) and dimethyl sulfone diimine *(1)*[1,2] in the presence of triethylamine.

Preparation of *(3)* by a modified route proved to be more favorable. Thus compound *(1)*, to which triethylamine has already been added, is first condensed with *N*-chlorosulfonylurethane *(5)* (which is readily accessible from *(2)* and methanol[3] and which forms reactive intermediates with triethylamine[4]) to give methoxycarbonylsulfamoyl dimethyl sulfone diimine *(6)* (yield 80%). Brief heating of *(6)* in boiling DMF affords *(3)* in almost quantitative yield.

Compounds *(3)* and *(6)* are readily soluble in water and, because they contain the SO_2—NH—CO group, they can be titrated as monobasic acids[3]. Their acid character is also demonstrated by reaction of *(3)* and *(6)* with diazomethane to give the *N*-methyl compounds *(4)* and *(7)*.

The structures of *(3)*, *(4)*, *(6)*, and *(7)* were confirmed by elemental analysis, molecular weight determinations (mass spectra), and IR and NMR spectrometric measurements (see Table).

	M.p. (°C)	IR: ν(cm^{-1}) NH	CO	NMR: δ(ppm) in [D$_6$]DMSO SO_2NH	SNH	$S(CH_3)$	OCH_3	NCH_3
(3)	182 (dec.)	3240	1667	11.2	—	3.70	—	—
(4)	190 (dec.)	—	1656	—	—	3.75	—	3.13
(6)	172 (dec.)	3320	1754	7	7	3.38	3.67	—
		3010	1742					
(7)	83	3290	1740	-	4.0	3.35	3.70	3.10

Attempts to convert the ester *(7)* into *(4)* by boiling in DMF were unsuccessful. This would suggest[5] that the facile condensation of *(6)* to form the compound *(3)* proceeds *via* an elimination-addition mechanism involving a sulfonyl isocyanate intermediate.

Procedure:

A solution of *(5)* (3.76 g) in dry methylene chloride (20 ml) was added dropwise to a vigorously stirred solution of *(1)* (2.0 g) and triethylamine (2.2 g) in dry methylene chloride (20 ml) within 30 min. After an additional 30 minutes' stirring, the precipitate was filtered off and washed thoroughly with methanol; yield 3.9 g (80%) of *(6)* (can be recrystallized from acetonitrile). A solution of *(6)* (0.75 g) in dry DMF (5 ml) was heated to boiling within 3 min under a current of dry N_2. The reaction mixture was then diluted with anhydrous ethanol (50 ml) and subsequently cooled in an ice bath for several hours. The crystals were filtered off under suction and washed with a little ethanol; yield 0.6 g (93%) of *(3)* (can be recrystallized from water/isopropanol).

N-Fluorosulfonyldichloroamine[1]

By *Herbert W. Roesky*[*]

Perfluorinated inorganic derivatives of dichloroamine are little known or unstable[2,3]. *N*-Fluorosulfonyl sulfur oxide imide reacts with chlorine monofluoride at room temperature with cleavage of thionyl fluoride to give *N*-fluorosulfonyldichloroamine *(1)* in high yield.

$$FSO_2N{=}S{=}O + 2ClF \rightarrow \underset{(1)}{FSO_2NCl_2} + SOF_2$$

(1) is a pale yellow liquid which can be distilled undecomposed at reduced pressure: b.p. 29—30°C/75 torr. On standing the compound slowly decomposes with formation of Cl_2, N_2, and FSO_2Cl. Its identification followed from elemental analysis and the mass spectrum: *m/e* 171, 169, 167 (molecular ion); 134, 132 (FSO_2NCl); 88, 86, 84 (NCl_2); 83 (SO_2F) and smaller fragments. The molecular weight was determined by cryoscopic measurements (in benzene) to be 165.

The IR spectrum (capillary film between AgCl plates) shows absorptions at (cm^{-1}): 1458 vs, 1222 vs, 1025 w, 844 vs, 790 vs, 630 m, 588 vs, 522 m, 482 m, 440 s. They are tentatively assigned to the following vibrations: ν_{as}(SO) 1458, ν_s(SO) 1222, ν(SF) 844, ν(SN) and ν(NCl) 790, 630, and 588 cm^{-1}. The ^{19}F-NMR spectrum contains a singlet at $\delta_F = -26.5$ ($CFCl_3$ as external standard). According to IR, NMR, and mass spectra the isomeric form $ClSO_2NClF$ is less probable. Compound *(1)* liberates iodine from aqueous potassium iodide solution, the first step of the hydrolysis being formation of hypochlorous acid:

$$FSO_2NCl_2 + HOH \rightarrow \underset{(2)}{FSO_2NClH} + HOCl$$

N-Fluorosulfonylmonochloroamine *(2)* could be isolated in the form of its amide by treatment with tetraphenylphosphonium or tetraphenylarsonium chloride:

$[(C_6H_5)_4P]^+ [FSO_2NCl]^-$; m.p. 200°C (dec.)
$[(C_6H_5)_4As]^+ [FSO_2NCl]^-$; m.p. 154°C (dec.)

Both salts are colorless and are soluble in acetone and methanol.

Experimental:

FSO_2NSO (0.1 mole) is placed in a 100 ml two-necked quartz flask fitted with a delivery tube, refluxing condenser, and T-piece for purging with dry nitrogen. ClF (0.25 mole) is fed into the flask, the internal temperature of which is not allowed to increase beyond 30°C. Finally, the flask is purged with nitrogen and the liquid phase is fractionally distilled twice at 75 torr. Yield of *(1)*: 13.5 g (81%). The highest boiling fraction contained, in addition to FSO_2NSO and *(1)*, a compound which according to the ^{19}F-NMR spectrum ($J_{F-F} = 13$ Hz) could be $FSO_2NS(O)ClF$, but it could not be isolated in pure form.

3-Chloro-1,3,5,2,4,6-thiadithia(IV)triazine 1,1,3-Trioxide[1]

By *Herbert W. Roesky*[*]

N-Fluorosulfonyl sulfur oxide imide, $FSO_2N{=}S{=}O$, reacts with boron trichloride in methylene chloride with replacement of fluorine by chlorine. *N*-Chlorosulfonyl sulfur oxide imide[2] *(1)* loses sulfur dioxide even at room temperature. The resulting bis(*N*-chlorosulfonylimido)-sulfur *(2)* cannot be isolated by distillation: after distilling off unreacted *(1)* there remains a solid, sublimable, yellow residue. The reaction can be formulated as follows:

SO_2 could be detected by IR and mass spectrometry. The structure of the reaction product *(3)* was deduced from the results of elemental analysis, molecular weight determinations, and from the IR and mass spectra. *(3)*, m.p. 105—108 °C, is soluble in benzene and acetonitrile and is readily hydrolyzed in the presence of traces of moisture.

The mass spectrum of the sulfur-nitrogen ring *(3)* shows, alongside the molecular ion at *m/e* 223 and 221, fragment ions at *m/e* 186 ($S_3N_3O_3$), 143 (NSOClSN), 110 (SO_2NS), 83 (SOCl), 80 (SO_2NH_2), 78 (SO_2N), 64 (SO_2), 63 (SONH), 62 (SON), 48 (SO), 46 (NS). The molecular weight was determined cryoscopically in benzene to be 236 and 240.

IR spectrum (NaCl and KBr region): 1350 (vs), 1175 (vs), 1125 (vs), 1078 (s), 1025 (m), 800 (s), 662 (m), 632 (s), 571 (s), 482 (w), 468 (w) cm^{-1}. The vibrations between 1000 and 1200 cm^{-1} are tentatively assigned to $\nu_s(SO)$, $\nu(SO)$, and $\nu(S{-}N)$, and the vibration at 1350 cm^{-1} to $\nu_{as}(SO)$.

Experimental:

A powerful stream of BCl_3 is passed through a solution of FSO_2NSO (1 mole) in methylene chloride (500 ml). The temperature of the reaction mixture increases to about 35 °C. After completion of reaction the solvent is removed by evaporation and the residue is purified by distillation under reduced pressure (oil pump): Compound *(1)* b.p. 40—42 °C/1.2 torr[2]; a small amount of *(3)* (2 g) is obtained as side product.

Exposure of *(1)* (0.5 mole) to daylight for 3 weeks, or irradiation under UV light[3] in a quartz flask for 12 h leads to evolution of SO_2. Compound *(3)* can be isolated from the liquid reaction product by distillation-sublimation (oil-pump vacuum), the bath temperature of the distillation-sublimation apparatus, however, should not be allowed to increase beyond 80 °C. The compound was purified by double sublimation at 60—70 °C/0.01 torr and finally separated from small amounts of insoluble decomposition products by dissolution in benzene. Yield: 5 g.

The Structure of Polymeric 2,4-Hexadiynylene-bis(phenylurethane)[1][***]

By *Erich Hädicke, E. C. Mez*, and *C. H. Krauch* and *Gerhard Wegner* and *Johannes Kaiser*[*]

Not only low molecular[2, 3] but also polymeric materials[4, 5] can be prepared structure-specifically and stereoselectively by topochemical reactions without using catalysts and by merely utilizing the packing properties of organic materials. For example, crystals of suitably substituted monomeric diacetylenes are converted into macroscopic polymer crystals by heat or by high-energy radiation[6]. On the basis of crystallographic and general crystallochemical considerations it had been predicted that the main chain of these polymers must be a completely conjugated system[6]. This prediction has now been confirmed by the X-ray structural analysis of the polymeric 2,4-hexadiynylenebis(phenylurethane).

For the three-dimensional X-ray structural analysis we used triclinic needles of the monomer which had been crystallized from dioxane/water, polymerized by UV irradiation ($\lambda > 240$ nm), and separated from unchanged monomer by extraction with dioxane[6]. Crystallographic data of the polymer: $a = 4.89_1$, $b = 12.53_4$, $c = 16.77_5$ Å; $\alpha = 69.3_8$, $\beta = 96.8_1$, $\gamma = 96.2_0°$; $d_{exp} = 1.37$ g cm^{-3}; space group $P\bar{1}$. The asymmetric unit contains one molecule $C_{20}H_{16}N_2O_4$ and $\frac{1}{2}$ molecule $C_4H_8O_2$ (dioxane) at the center of symmetry ($d_{calc} = 1.37$ g cm^{-3}). All reflections up to $\vartheta = 51°$ ($\vartheta/2\vartheta$ scan; 5 value measurements) were measured on a single crystal diffractometer with $Cu_{K\alpha}$ radiation. Of the 2035 reflections, only 86 were not observed ($J < 2\sigma$). 281 signs were determined from the 400 strongest reflections by triple product methods[7]. An E-Fourier synthesis using these values gave the positions of all 29 atoms ($R = 29.6\%$). Refinement by the method of least squares (full matrix) required overlapping cycles because of the large number of parameters. Isotropic refinement yielded an R factor of 12.6%. The anisotropic refinement converged to an R factor of 7.9%. We have found the majority of the expected hydrogen atoms in a difference Fourier synthesis.

Figure 1 shows the structure of a fundamental unit of the polymer chain. Comparison of this structure with the structures of the similarly polymerizable 2,4-hexadiynediacid[8] and 2,4-hexadiynediol[9] provides supporting evidence for the mechanism of polymerization suggested in previous publications[6]. As expected, the polymer chain is formed by 1,4-polymerization of the conjugated triple

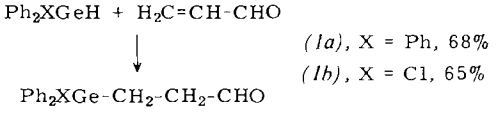
The X-ray crystallographic findings show that the main chain of the polymer is a planar conjugated system to which the plane of the two phenylurethane side-chains are inclined at angles of 73 and 89°. The position of the phenylurethane groups is determined by hydrogen bridges to neighboring molecules and to the dioxane. Since solvent-free modifications of the monomer do not polymerize[10], it appears that the dioxane is partly responsible for the suitable packing of the molecules of monomer.



The hydrogen bonds fix the side chains and bring the conjugated triple bonds in the monomer into a suitable position for the polymerization, such that solid-state polymerization can proceed without essential change of the crystal lattice and a polymer with all-*trans* structure is formed.

1-Germylallyl Alcohols and Germacycloalkanols

By *Pierre Rivière* and *Jacques Satgé*[*]

Substituted germanes can undergo addition to the C=C or the C=O double bonds of compounds such as acrolein. On radical initiation (UV or azoisobutyronitrile), triphenylgermane and diphenylchlorogermane add to the C=C double bond of acrolein to give 3-germylpropionaldehydes *(1a)* and *(1b)*, respectively. These reactions are inhibited by galvinoxyl and do not take place in nitromethane. In this polar solvent, the slightly positive character of the proton attached to germanium in Ph_2ClGeH is increased to such an extent that 1,2-dipolar addition to the carbonyl group to form the 1-germylallyl alcohol *(2a)* occurs in the presence of H_2PtCl_6. Under the same conditions, phenyldichlorogermane gives the 1-germylallyl alcohol *(2b)*. The clear polarization of the $\overset{\delta-}{Ge}—\overset{\delta+}{H}$ bond induced in $PhCl_2GeH$ by the combined electron-withdrawing effects of the chlorine atoms and the phenyl group favors the probably concerted dipolar addition mechanism.

The desired alcohol *(3)* could not be isolated after reduction of *(2b)* with $LiAlH_4$ at high dilution. However, in addition to polymeric products, we observed a small

Université Paul Sabatier
118 route de Narbonne, F-31 Toulouse (France)

quantity of 1-phenyl-1-germa-2-cyclobutanol *(4)* formed from *(3)* by intramolecular addition (see Table).

Phenyldichlorogermane reacts on heating with crotonaldehyde to give the monoadduct *(5)* and the diadduct *(6)*. In contrast to the reaction with 1-vinyl ketones, we observed no 1,4-addition[1]. In nitromethane and in the presence of H_2PtCl_6, 1,2-dipolar addition to the carbonyl group with formation of *(5)* is strongly favored (95 % yield) since the solvent inhibits the secondary radical reaction leading to *(6)*. The diadduct *(6)* can be isolated in high yield, however, if the reaction is carried out under free-radical conditions (UV irradiation).

On heating, *(6)* decomposes in the same way as analogous 1-chloro-germyl alcohols[2]. The alcohol *(5)* decomposes similarly at 80 °C. Phenylchlorogermylene (PhGeCl) was detected by interception with dimethylbutadiene[3,4].

[c] Yield determined by NMR spectroscopy.

Reduction of *(5)* with $LiAlH_4$ gives 1-phenylgermyl-2-butenol *(7)* (b.p. 78 °C/5×10^{-2} torr) which has been characterized by IR and NMR spectroscopy. Unlike *(2)*, the alcohol *(7)* does not polymerize on heating. However, it is converted into 4-methyl-1-phenyl-1-germa-2-cyclobutanol *(8)* on UV irradiation (Table); polymeric products are also formed.

An addition of the same type is observed with 10-undecenal. The unstable phenyldichlorogermyl alcohol *(9)* is reduced by $LiAlH_4$ to phenylgermyl alcohol *(10)*, which cyclizes at 100 °C in the presence of azoisobutyronitrile to give 1-phenyl-1-germyl-2-cyclododecanol *(11)* (Table).

Pyrimidines from *N,N*-Unsubstituted β-Enamino Carbonyl Compounds and Formamide

By *Eberhard Breitmaier*[*]

Not only *N*-alkyl and *N,N*-dialkyl β-enamino carbonyl compounds[1] but also *N,N*-unsubstituted β-enamino aldehydes and ketones (β-aminovinyl aldehydes and ketones) *(1)* undergo cyclocondensation with formamide *(2)* to give pyrimidines *(3)*. R may also be replaced by H or by part of a fused ring.

This reaction can be used for the synthesis of the pyrimidines *(3a)–(3j)* listed in the Table, of which *(3e)–(3j)* were hitherto inaccessible[2]. The heterocyclic compounds obtained were characterized on the basis of their identity with known pyrimidines and by elemental analysis and ^{1}H-NMR spectra. Thus, for example, the ^{1}H-NMR spectra of the 5-alkylpyrimidines *(3b)–(3g)* contain the peak due to the proton on C-2 at $\tau = 0.9$, and that due to the equivalent protons on C-4 and C-6 at $\tau = 1.35$ [in deuteriochloroform relative to tetramethylsilane as internal reference; intensity ratio: H-2: (H-4 + H-6) = 1:2]. These peaks are shifted upfield (H-2: $\tau = 1.0$–1.1; H-4: $\tau = 1.5$–1.6; intensity ratio: H-2:H-4 = 1:1) in the ^{1}H-NMR spectra of the bicyclics *(3h)–(3j)*.

(j)	2-aminomethylene-3-methyl-6-isopropylcyclohexanone [7] [a]	5-methyl-8-isopropyl-5,6,7,8-tetrahydroquinazoline [a]	78	135–138/11 98–101/1	—

[a] Mixture of stereoisomers and optical isomers.

The method opens up an effective synthesis of interesting and hitherto difficultly accessible pyrimidines, such as *(3h)–(3j)*. It also provides supporting evidence for the mechanism proposed by *Bredereck*, *Gompper*, and *Morlock* for the synthesis of pyrimidines from 1,3-diketones and 1,3-dialdehydes[1a,3] since *N*,*N*-unsubstituted β-enamino carbonyl compounds are suggested to be the key intermediates in that synthesis.

Procedure:

Compound *(1)*[4–6] (0.1 mole) and formamide *(2)* (18 g) are refluxed with piperidinium acetate for 12–14 h in an oil bath at 140 °C. After cooling, the resulting yellow oil is poured into chloroform (50 ml). The lower phase, consisting of chloroform and the pyrimidine *(3)* is separated off, and the upper layer, containing formamide and water, is extracted with three 25-ml portions of chloroform. The united chloroform solutions are dried over anhydrous magnesium sulfate, filtered, and vacuum distilled (for results see Table).

2-Hydroxymethylenecycloalkanones required for the preparation of 2-aminomethylenecycloalkanones *(1h)–(1j)*[6] can be obtained from the corresponding cycloalkanones[7].

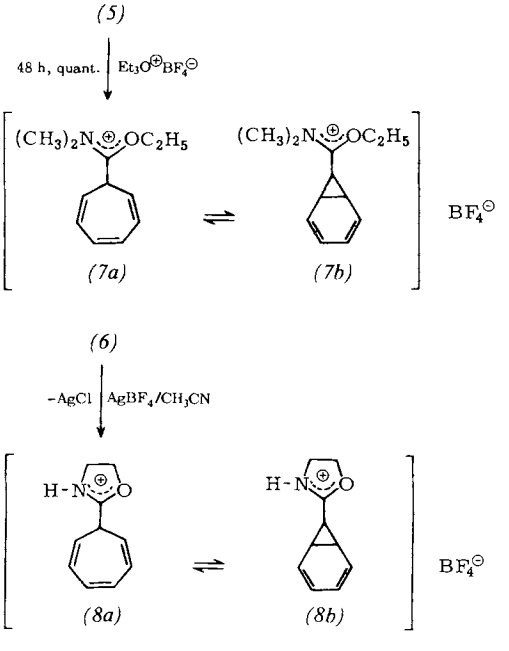
Stable 2,4,6-Cycloheptatrien-1-ylmethyl Cations[1]

By *Werner Betz* and *Jörg Daub*[*]

Studies of stable 2,4,6-cycloheptatrien-1-ylmethyl cations should permit conclusions to be drawn regarding the effect of the substituent at C-1 on the cycloheptatriene⇌norcaradiene equilibrium[2]. Stable 2,4,6-cycloheptatrien-1-ylmethyl cations have not previously been described in the literature. Reaction of such cycloheptatriene systems that could be formulated as proceeding *via* cationic intermediates mostly give ring-contracted benzene derivatives[3–6].



We have now been able to prepare 2,4,6-cycloheptatrien-1-ylmethyl cations, in which the positive charge is stabilized by an α hetero atom, from the carboxylic acid derivatives *(5)* and *(6)*, which are themselves accessible from 2,4,6-cycloheptatriene-1-carbonyl chloride *(4)* (Table 1). Our reaction route for preparation of *(3)* *via* compounds *(1)* and *(2)* has proved more effective than former methods[5,7,8].

(1) *(2)–(6)*

Reaction of *(5)* with triethyloxonium tetrafluoroborate or of *(6)* with $AgBF_4$ affords the oily complexes *(7)* and *(8)*, respectively.

The ^{1}H-NMR spectra (Table 2) furnish information concerning the structures of *(7)* and *(8)*. The τ values of the protons $H^{2,7}$ of *(7)* and *(8)*, which in both cases

Inversion of Secondary Cyclic Grignard Compounds[**]

By *Adalbert Maercker* and *Reinhart Geuss*[*]

Inversion at the α-carbon atom of primary Grignard compounds can be detected by NMR spectroscopy[1]. Particular attention has been devoted to 3,3-dimethylbutyl (neohexyl) Grignard compounds (RMgX) and the corresponding dialkyl compounds (R_2Mg)[1a−1c], as well as 2-methylbutylmagnesium compounds[1d]. In contrast, inversion has not yet been observed with secondary Grignard compounds in spite of many efforts to detect it[1a,2]. Neither the reason for the slow (NMR time scale) inversion process of secondary carbanion centers nor the mechanism of inversion is known; the latter has been considered both as a bimolecular[1a,1d] and as a unimolecular ionization-recombination process[1b].

It was noted in NMR studies on carbanion rearrangements of cyclic homoallyl Grignard compounds[3] that the peak due to the α proton of 3-cyclohexenylmagnesium bromide *(1)* in THF, which lies in the TMS range as expected, is remarkably broad and unresolved at room temperature, whereas well resolved signals exhibiting fine structure were obtained at lower and at higher temperatures (Fig. 1). The high temperature spectrum, which

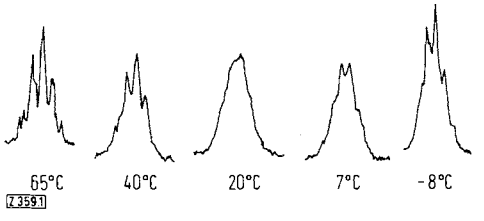

Fig. 1. Variation of the NMR signal (60 MHz) of the α proton of *(1)* with temperature; [D_8]-THF solution, 1.5 mole/l.

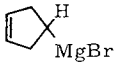
does not show any change above 70 °C (up to 110 °C), differed from the low temperature spectrum, which did not change below −10 °C. The occurrence of coalescence at 20 °C can only be explained by an inversion at the α carbon atom, *i.e.* this is the first example of a secondary Grignard compound whose α inversion is fast enough to be detectable by NMR spectroscopy. We assume that the inductive effect of the double bond between C-3 and C-4 enhances the electrophilicity of the magnesium, thus increasing the ease of replacement of the group in an S_E2 mechanism.



[*] Priv.-Doz. Dr. A. Maercker and Dipl.-Chem. R. Geuss
Institut für Organische Chemie der Universität Erlangen-Nürnberg
852 Erlangen, Henkestrasse 42 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The spectrum of the 3-cyclopentenyl Grignard compound *(2)* also supports this concept: The α proton gives a clear quintet at $\tau = 10.2$ ($J = 10$ Hz) in ether and in THF. Thus, unlike the alcohol and the bromide, there is only one coupling constant to all four neighbors. This again suggests rapid inversion, although conclusive proof has not yet been obtained because the Grignard compound *(2)* is precipitated below −20 °C before the coalescence temperature has been reached[4]. However, it is quite reasonable to suppose that the five-membered ring Grignard compound *(2)* should invert more rapidly than the six-membered ring compound *(1)*, since in the former case

(1)

(2)

the −I effect of the double bonds can act from both sides *via* only two single bonds. It is therefore understandable that the coalescence point has still not been reached at as low a temperature as −20 °C. It is unlikely that homoallyl resonance plays a very important role in comparison with the inductive effects, particularly since the anion of *(2)*, even if σ overlapping with the π electrons of the double bond were permitted by the stereochemistry, would be a "bishomoantiaromatic" system[5]. In this connection it is interesting to note that primary, open-chain homoallyl Grignard compounds do not invert significantly more rapidly than the corresponding saturated compounds[6].

The inversion of the cyclic compound *(1)*, like that of primary Grignard compounds, depends on the medium[1,6]. It is particularly noteworthy that the rate of inversion is lowered not only on going from diethyl ether to THF but also on changing to more dilute solutions. This observation makes an ionization-recombination mechanism appear unlikely for the inversion of these Grignard compounds.

Electrophilic Alkylation of α-Diazosulfones with Enamines

By *A.M. van Leusen*, *B.A. Reith*, *R.J. Mulder*, and *J. Strating*[*]

The course of reaction of diazo compounds with enamines seems to be determined mainly by the type of diazo compound involved. During a study of the photolysis of α-diazosulfones[1] it was found that, without irradiation, α-diazosulfones *(1)* add to enamines. Surprisingly, the diazo group is not involved directly in this reaction, since the adducts are α-alkylated-α-diazosulfones *(3)*.

(1) *(2)*

(3)

The alkylated diazosulfones *(3)* are obtained easily in high yields, either by reaction of *(1)*[2] dissolved in an excess of *(2)* (neat), or by reaction of equimolar quantities of *(1)* and *(2)* in acetonitrile, for 2–5 days at room temperature in the dark. After removal of the solvent the residue is crystallized from methanol or ether/pet.ether.

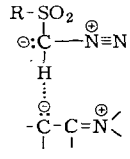
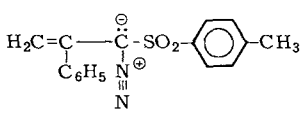
(3f)	82	84— 85	2076	1318, 1120



[a] NMR-Data (in $CDCl_3$) of *(3a)* [typical for the compounds *(3)*]: δ(R) = 2.43 (3 H/s), 7.73 (2 H/d), 7.33 (2 H/d), $J = 8$ Hz; δ(R^1) = 0.58 (3 H/d); δ(R^2) = 1.02 (3 H/d), $J = 6$ Hz; δ(H) = 1.1—2.3 (1 H/m); δ(R^3) = 2.95 (1 H/d), $J = 11$ Hz; δ(morpholino) 2.39 (4 H/m), 3.63 (4 H/m).

As far as diazo compounds are concerned, this is one of the very few examples in which an α-hydrogen becomes substituted by an alkyl group[3]. Moreover, the reaction can be considered as a nucleophilic addition at the C_α of an enamine. Such reactions are common for iminium salts, but not for the unprotonated enamines[4].



α-Diazoketones or α-diazoesters, bearing an α-hydrogen, react differently with enamines. Through a 1,3-dipolar cycloaddition involving the diazo function pyrazoles are formed eventually[5]. This difference may be explained as follows: The ability of the methine proton to act as a donor in hydrogen bonding presumably is larger in α-diazosulfones than in α-diazoketones[6]. In the case of α-diazosulfones some iminium salt character may be induced in the enamine through a hydrogen bond as indicated in *(4)*[7]. Thus, nucleophilic attack of the diazo carbon at the

[*] Dr. A.M. van Leusen, Drs. B.A. Reith, and Prof. Dr. J. Strating

Groningen University, Zernikelaan, Groningen (The Netherlands)
Dr. R.J. Mulder, present address:
Koninklijke Zwavelzuurfabrieken v/h Ketjen N.V.,
Amsterdam (The Netherlands)

enamine C_α might be facilitated more for α-diazosulfones than for α-diazoketones.

(4)

(5)

The properties of the products *(3)* are remarkable also. Whereas α-tosyldiazoethane[1b] is thermally unstable and highly reactive, *(3a)* for instance is very stable under a variety of conditions. The diazo group in *(3a)* can be displaced only with difficulty.

With HCl in ether a salt is formed (according to NMR, protonation occurs at the morpholino nitrogen), in which the diazo function is still present. On exposure to the air, the salt slowly releases HCl and *(3a)* is recovered unchanged. Salt formation apparently occurs also in aqueous 2N HCl in which the water-insoluble *(3a)* dissolves. On treatment with NaOH *(3a)* is liberated again. By treatment of *(3a)* with Cl_2 in 2N HCl, however, the diazo group is replaced by two Cl atoms; at the same time the enamine function is hydrolyzed to give 1,1-dichloro-3-methyl-1-tosyl-2-butanone (m.p. 87°–89°C, 69% yield).

The HCl salt of *(3d)* is obtained similarly. When dissolved in chloroform at room temperature, this salt splits off morpholinium chloride to give a new, unsaturated α-diazosulfone, 3-diazo-2-phenyl-3-tosyl-1-propene *(5)*, isolated as a yellow oil and characterized as its triphenyl phosphazine (m.p. 138°–140°C, 65% overall yield).

The diazo group in *(3a)* can be reduced with $NaBH_4$ in methanol to give 1-hydrazino-3-methyl-2-morpholino-1-tosyl-1-butene (m.p. 133°–135°C, 93% yield). This α-β-unsaturated hydrazine is isomerized to the corresponding hydrazone (m.p. 134°–134.5°C, 63% yield) by treatment with 2N HCl.

A Heavy Atom Effect in the Photoreaction of Maleic Anhydride with Acenaphthylene

By *Willy Hartmann* and *Hans-Georg Heine*[*]

The property of heavy atoms to relax the forbidden transition between singlet and triplet states has been known for some time in spectroscopy[1]. On the other hand, the change in course of a photochemical reaction as a result of this phenomenon has only recently been studied and so far only been observed in the dimerization of acenaphthylene *(1)*[2], the addition of acrylonitrile to *(1)*[3], and the Rhodamine B sensitized oxygenation of 2,5-dimethylfuran[4]. We have now found a further example in our investigations of the addition of maleic anhydride to *(1)*.

(1) *(2)* *(3)*

Irradiation[5] of solutions of maleic anhydride and *(1)* in dioxane, acetone, or acetonitrile leads to formation of a copolymer[6] and/or the dimers of *(1)*[7]. If an halogenated solvent is used, the reaction proceeds differently; under otherwise similar reaction conditions a further product, the cycloadduct *(2)* m.p. 235–236°C, is formed. The yield of *(2)* increases proportionally with the atomic number of the halogen, and at the expense of the copolymer (see Table).

Table. Solvent dependence of the product distribution in the combined irradiation[5] of maleic anhydride and acenaphthylene.

Solvent	Yield (%) *(1)*-Dimer [a] [b]	Copolymer [b]	*(2)* [b]	Conversion of *(1)* (%)
Dioxane	97	–	–	17
Acetone	61	29	–	50
Acetonitrile	35	51	–	53
Dichloromethane	11	25	56	49
Dibromomethane	12	18	70	47
Iodomethane	13	–	81	47

[a] Mixtures of stereoisomers of different composition.
[b] Referred to unchanged *(1)*.

The IR spectrum (KBr) of *(2)* shows the characteristic bands for a saturated cyclic five-membered anhydride at 1790 and 1870 cm^{-1}. The NMR spectrum (CD_2Cl_2) contains signals at $\tau = 2.0$–2.5 (aromatic protons), 5.46 (benzyl protons), and 4.55 (cycloaliphatic protons) in the intensity ratio 3:1:1. In agreement with the spectroscopic data, oxidative decarboxylation of the adduct with $Pb(OAc)_4$/pyridine[8] affords the cyclobutene derivative *(3)*, m.p. 117.5–118.5°C, whose hydrogenation (ethylacetate/5% Pd-carbon) leads to the known[9] 6b,7,8,8a-tetrahydrocyclobut[*a*]acenaphthylene, m. p. 78.5–79.5°C. The *anti* configuration of *(2)* follows from the results of ozonolysis, oxidative treatment, and esterification with diazomethane to *cis,trans,cis*-1,2,3,4-tetracarbomethoxycyclobutane[10].

anti-6b,7,8,8a-Tetrahydrocyclobut[a]acenaphthylene-7,8-dicarboxylic anhydride (2)

After irradiation[5] of compound *(1)* (8.5 g) and maleic anhydride (15 g) in anhydrous dibromomethane (150 ml), 0.35 g (9%) of the *trans* dimer of *(1)* was separated from the irradiated mixture by filtration. Evaporation of the filtrate gave a solid residue which was digested twice with anhydrous ether (2 × 75 ml) to remove unchanged *(1)* (4.5 g) and maleic anhydride. On extracting the ether in-

Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG
415 Krefeld-Uerdingen (Germany)

soluble part with boiling anhydrous benzene (150 ml), there remained 1.1 g (18%) of copolymer.

The benzene solution afforded, after concentration and multiple fractional crystallization from benzene or ethyl acetate, 4.3 g (70%) of *(2)*, m. p. 235–236 °C and 0.1 g (3%) of the *cis* dimer of *(1)* [yields based on 47% conversion of *(1)*].

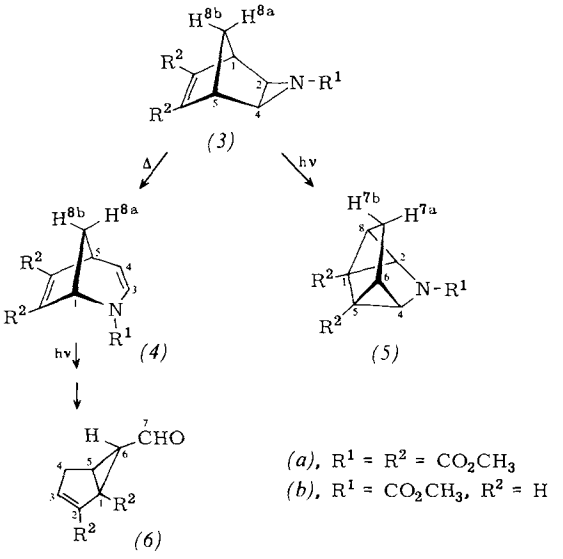
Photochemical Olefin-Aziridine Cycloaddition[1][**]

By *Michael Klaus* and *Horst Prinzbach*[*]

Intramolecular $[2\pi+2\sigma]$ photocycloadditions between ethylene units and cyclopropane or oxirane units to give cyclopentane derivatives $[(1a)\rightarrow(2a)]$[2] or tetrahydrofuran derivatives $[(1b)\rightarrow(2b)]$[3] are valuable synthetic steps in preparative chemistry[4].



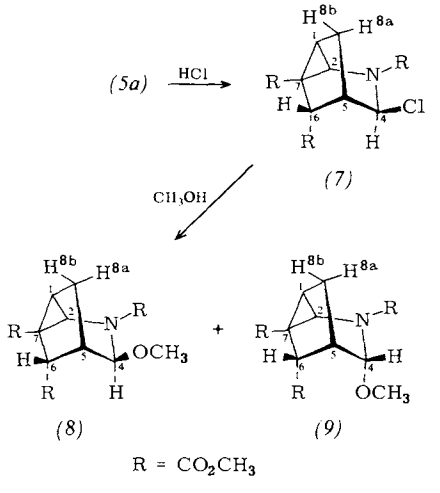
(1) *(2)*

(a), X = CH_2, CR_2
(b), X = O
(c), X = N-CO_2CH_3

Taking compound *(3a)* as an example, we shall now show that a similar type of valence isomerization between a CC double bond and an aziridine ring $[(1c)\rightarrow(2c)]$ can also be achieved photochemically[5].

The *exo*-aziridine *(3a)* is obtained *via* the triazoline by known methods from dimethyl bicyclo[2.2.1]heptadiene-2,3-dicarboxylate and methyl azidoformate[6]. Like the isocycle and oxaheterocycle, *(3a)* is rearranged on heating (160 °C, 3.0 g in 6.5 h) by cleavage of an exocyclic bond of the three-membered ring to give the bicyclic compound *(4a)*[7] (78% yield, colorless oil). Results of photolysis experiments are in accord with the structure deduced from spectroscopic data (cf. Table); after hydrolysis of the photoproduct, the aldehyde *(6a)* can be isolated. No di-π-methane rearrangement products could be detected.

A relatively rapid reaction takes place when *(3a)* is subjected to direct irradiation in O_2-free acetonitrile (−20 °C,



(3) *(4)* *(5)* *(6)*

(a), $R^1 = R^2 = CO_2CH_3$
(b), $R^1 = CO_2CH_3$, $R^2 = H$

5.0 g in 300 ml CH_3CN, 5.5 h) with vycor-filtered light from a high-pressure Hg vapor lamp; in addition to polymeric material and a small amount (3–5%) of hydrogenated products, the bishomopyrrole diester *(5a)* is formed as a colorless oil which crystallizes from ethyl acetate/pet. ether (50–55%). Conversion into *(5a)* has not been observed upon indirect excitation in acetone.

The tetracycle *(5a)* is thermally very stable and does not react with dimethyl acetylenedicarboxylate by addition to the bishomopyrrole moiety below 200 °C. On the other hand, it reacts almost instantaneously with HCl gas at room temperature to give *(7)*. On treatment with methanol a mixture of the isomeric compounds *(8)* and *(9)* (ratio ≈ 20:1) is formed.

(5a) *(7)* *(8)* *(9)*

R = CO_2CH_3

The structure of the photoproduct *(5a)* is evidenced by the chemical transformations to *(7)*, *(8)*, and *(9)* and confirmed by spectroscopic data. The stereochemistry of the addition of HCl and of methanol in *(7)* and *(8)* is apparent from $J_{5,6}$ and from the W-coupling $J_{4,8b}$ confirmed by double resonance. The absence of this W-coupling and the higher position of the H^{8a} signal compared to that of H^{8b} confirm the *endo* position of the methoxy group in *(9)*. Evidence for a primary excitation of the maleate chromophore in the isomerization $(3a)\rightarrow(5a)$ is provided by the finding that *(3b)* likewise affords *(4b)* thermally, but does not undergo a $[2\pi+2\sigma]$ cycloaddition to *(5b)* either upon direct or upon sensitized excitation.

Isocyanide Complexes of Thorium and Uranium Halides[**]

By *Franz Lux* and *U.-E. Bufe*[*]

In discussions of the bonding of actinoids particular interest attaches to the range of existence of their organometallic compounds. With one exception[1], the ligands in all the actinoid organometallic compounds hitherto described are in a negative oxidation state relative to the actinoid atom[2]. We have studied complexing with neutral ligands to form stable actinoid-carbon compounds and now report on the first isocyanide complexes of actinoids that contain no stabilizing π ligands such as are found in $(C_5H_5)_3U\cdot CNC_6H_{11}$[1].

Reaction of uranium tetraiodide (0.75 g, 1 mmole) with cyclohexyl isocyanide (1.25 ml, 10 mmoles) in anhydrous *n*-hexane at −5°C for 80 h, followed by filtration, washing of the residue with *n*-hexane (20 ml), and drying *in vacuo* (10^{-5} torr) – all operations being performed at −5°C – gave tetraiodotetrakis(cyclohexyl isocyanide)uranium(IV), $UI_4(CNC_6H_{11})_4$.

The compound is not noticeably sensitive to oxygen, but extremely so toward moisture. It can be kept for some time at 0°C, but gradually turns brown at room temperature. This aging process also results in a considerable reduction in solubility. The fresh complex is hardly soluble in *n*-hexane, moderately soluble in benzene, and dissolves readily in chloroform, acetone, methanol, *etc.* The initially yellow solutions gradually deposit a dark brown precipitate.

The instability of the compound in solution is also apparent from the following observations:

1) Reaction of uranium tetraiodide with a solution of cyclohexyl isocyanide in a small volume of benzene furnishes the compound directly in the solid state in the reaction mixture. However, owing to the partial decomposition of the portion dissolved in benzene the product

[*] Prof. Dr. F. Lux and Dipl.-Chem. U.-E. Bufe
Institut für Radiochemie der Technischen Universität München
8046 Garching bei München (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

obtained after filtration and washing in benzene is probably less pure than that prepared in hexane suspension.

2) Reaction of uranium tetraiodide with cyclohexyl isocyanide in chloroform rapidly yields an orange-yellow solution. The complex is precipitated by addition of carbon tetrachloride or *n*-hexane. These products are dark in color and not analytically pure.

The complex closely resembles $Pd(CNC_6H_{11})_2$[3] in its chemical and physical properties.

In the IR spectrum (KBr disk) the ν(NC) band appears at 2190 cm^{-1} and is thus shifted by 55 cm^{-1} toward higher wave numbers ($C_6H_{11}NC$: ν(NC) = 2135 cm^{-1}[4]), in full agreement with the general tendency of ν(NC) to be shifted toward higher frequencies or considerably less toward lower frequencies in isocyanide complexes having a positively charged metal atom than in metal(0) complexes[5]. This suggests that the uranium-carbon bond has considerable σ-donor character. In the limiting case of a pure σ-donor bond of isocyanide[6] in $(C_6H_5)_3B{\cdot}CNC_6H_{11}$ (ν(NC) = 2255 cm^{-1}[7]) the bond shift toward higher wave numbers amounts to 120 cm^{-1}. In $UI_4(CNC_6H_{11})_4$ the U—C bond therefore has a back-bonding component.

In agreement with the argumentation above, ν(NC) = 2160 cm^{-1} is shifted only 25 cm^{-1} toward higher wave numbers in $(C_6H_5)_3U{\cdot}CNC_6H_{11}$, which is a U^{III} complex. Thus, as suggested by the ready oxidation of U^{III} to U^{IV}, a relatively large contribution by uranium → isocyanide back bonding can be assumed[1].

If IR measurements are repeated on the same sample the intensity of the characteristic ν(NC) band decreases until the band finally disappears altogether. At the same time the KBr disk turns dark and loses its isocyanide odor.

Similarly, thorium tetraiodide, uranium tetrabromide[8], uranium tetrachloride, and uranyl chloride react with cyclohexyl isocyanide in *n*-hexane to give ivory-colored complexes having ν(NC) = 2194, 2193, 2196 and 2213 cm^{-1} respectively.

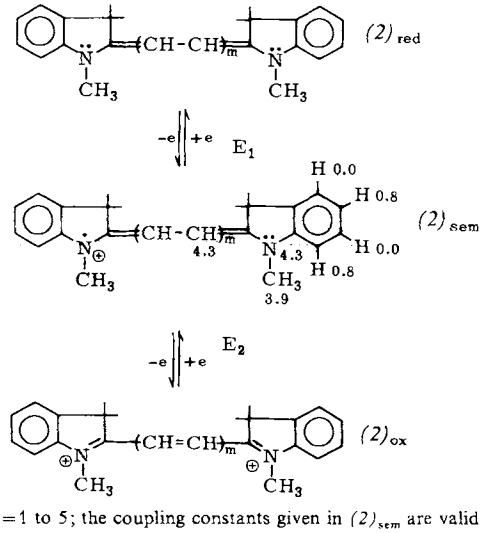
The Position of Equilibrium in Vinylogous Two-Step Redox Systems

By *Siegfried Hünig, Friedrich Linhart,* and *Dieter Scheutzow*[*]

Redox systems of general structure *(1)* allow one-electron transfers in two discrete steps[1-3], whereby the redox equilibrium [eq. (1)] can lie strongly on the side of the radical cation ("violene"[4]) $(1)_{sem}$ (*K* so far up to 10^9).

$$red + ox \rightleftharpoons 2\,sem$$
$$K = [sem]^2/[red][ox] \qquad (1)$$

Using previously estimated values[5] as a starting point for further examination of such systems, *P. Čársky* and *R. Zahradník*[6] have been able to detect a linear relationship between log *K* of vinylogous systems *(1)* and the change of π electron energy calculated according to



$$E_\pi^{ox} + E_\pi^{red} - 2\,E_\pi^{sem} = J_{mm}\ ^{[7]}$$

if it is assumed that solvation effects can be neglected.

This assumption holds true in the case of the previously investigated systems *(1)* ($n = 1$ to 3), in which X is a part of an (aromatic) ring[6].

In order to investigate the behavior of π systems which are not directly coupled to aromatic rings, we synthesized the vinylogous compounds $(2)_{red}$ and $(2)_{ox}$ ($n-1=m=1$ to 5) and produced $(2)_{sem}$ ($m = 1$ to 5) by comproportionation of $(2)_{red}$ and $(2)_{ox}$ in acetonitrile (Scheme 1)[8,9]. The species $(2)_{sem}$ ($m = 1$ to 5) show characteristic absorption and ESR spectra with pronounced hyperfine structure in the case of the lower members[8]. As expected the $>C(CH_3)_2$ group does not participate in the delocalization of the single electron. The ESR spectrum of $(2)_{sem}$ ($m = 1$) can be readily simulated using the quoted coupling constants without consideration of this group (Fig. 1)[9].

Thus *(2)* behaves as a pure vinylogous system, which, in addition, exists as the longest series known to date. For $m = 1$ to 3, *K* can be obtained from the polarogram[10]; for $m = 3$ to 5 it is obtained from the extinctions of the comproportionation solution[11]. As can be seen in the Table, log

Scheme 1. $m = 1$ to 5; the coupling constants given in $(2)_{sem}$ are valid for $m = 1$.

[a] E(mV) in CH_3CN; Ag/AgCl reference electrode.
[b] $E_m=(E_1-E_2)/2$. [c] J^{sem}_{mm} = Repulsion integral.

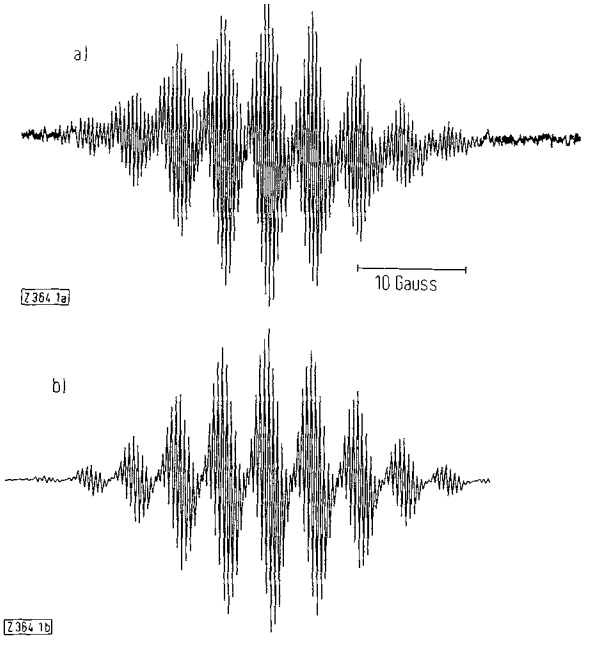

Fig. 1. a) ESR spectrum of $(2)_{sem}$ ($m=1$) in acetonitrile; b) simulated spectrum.

K, and consequently the thermodynamic stability of $(2)_{sem}$, rapidly decreases with increasing chain length, *i.e.* the difference between E_1 and E_2 becomes progressively smaller.

As in the case of previously investigated violenes[6], K is scarcely influenced by solvation effects, thus indicating the linear relation between log K of *(2)* and J^{sem}_{mm} for $m=1$ to 5.

The significance of these calculations for predictions about other redox systems of type *(1)* is thus more apparent than heretofore. In particular, it has been established that J^{sem}_{mm} should be greater than 4 eV if isolation of $(1)_{sem}$ in substance is desired (*i.e.* log $K>3$)[6].

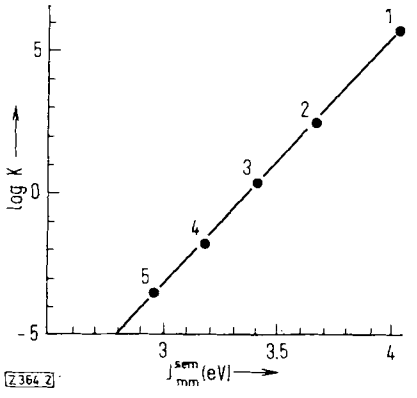

Fig. 2. Correlation between log K and J^{sem}_{mm} for *(2)*, $m=1$ to 5.

Preparation of Substituted 5-Vinylcyclohexa-1,3-dienes and Tricyclo[2.2.2.0^{2,6}]oct-7-enes

By *Paul Heimbach*, *Klaus-Jürgen Ploner*, and *Frank Thömel*[*]

In our last communication concerned with the mixed oligomerization of butadiene and alkynes[1] we mentioned, *inter alia*, the formation of 5-vinylcyclohexa-1,3-diene *(1a)* from phenylacetylene and butadiene (molar ratio 1:5 at start of reaction) at −10 °C in the presence of a nickel^0-triphenylphosphane catalyst in 25% yield[2].

We have now found[3] that butadiene reacts with alkyl- or aryl-substituted acetylenecarboxylic esters under the above conditions to give substituted 5-vinylcyclohexa-1,3-dienes *(1)–(4)*.

The various isomers are formed in the following ratios:

$$(1b):(2b) = 1.2:1.0$$
$$(1c):(2c) \approx 1:1$$
$$(1d):(2d):(3d):(4d) = 1.7:1.4:1.0:6.7$$

At 180 °C the 5-vinylcyclohexa-1,3-dienes *(b)–(d)* rearrange quantitatively to the tricyclo[2.2.2.0^{2,6}]oct-7-enes. This rearrangement has already been described for unsubstituted 5-vinylcyclohexa-1,3-diene[4,5] and for a derivative having a disubstituted vinyl group[6]. The equilibrium mixture of *(1a)* and *(5a)* contains the two components in the ratio 70:30 at 180 °C.

[a] Weak splitting.

The conditions of the catalytic reaction exert a considerable influence on the course of the reaction. If phenylacetylene, for example, is added dropwise at 40 °C to a benzene solution of the catalyst [Ni^0-$P(C_6H_5)_3$] that is saturated with butadiene, the yield of *(1a)* can be increased from 25 to 78%[2]. 1,4-Dimethoxy-2-butyne reacts with

(9)

(10)

butadiene in the presence of Ni^0-tricyclohexylphosphane-catalyst at 20 °C to give *(1e)* in 26% yield. In the presence of a nickel catalyst having no phosphorus-containing ligands[7], slow addition of butadiene to 2-butyne at 30 °C gives *(1f)* in about 20% yield.

Both the 5-vinylcyclohexa-1,3-dienes and the tricyclo-[2.2.2.0^{2,6}]oct-7-enes react with dienophiles. At 20 °C, *(1f)* reacts with maleic anhydride to give the adduct *(9)*. *(5f)* reacts at 40 °C with dimethyl acetylenedicarboxylate to give *(10)*; any possible intermediates have so far defied detection.

CONFERENCE REPORTS

Investigations of Reactions and Phase Transformations with a Novel X-Ray Camera

By *Arndt Simon*[*]

By suitable modification of the X-ray recording technique it is also possible to use the high resolution Guinier method for the investigation of substances that are extremely sensitive to air. The sample to be examined is fused in a Mark tube which is arranged parallel to the focal line of the monochromator on the focusing circle of the film chamber. With the aid of a sensitive control device, structural changes in the sample with temperature can be determined very accurately (±0.02 °C between −190 and 400 °C).

This method has been used in an investigation of the phase transformations occurring in solid halogen hydrides. With the modified apparatus it is possible, especially in the case of HBr, to detect all the transformations expected from the calorimetric behavior (orthorhombic ⇆ orthorhombic ⇆ cubic ⇆ cubic). Interpretation of the data obtained by X-ray crystallography would suggest that

[1] *E. Rengade,* Bull. Soc. chim. France (4), *5*, 994 (1909).

intermolecular interactions over a wide range play an important role in the course of these transformations.

The modified apparatus proved particularly useful for the investigation of the phases in alkali metal suboxides. With additional aid of a sensitive DTA arrangement, existence of all the suboxides designated by *Rengade*[1] as Cs_7O, Cs_4O, Cs_7O_2, and Cs_3O could be established. The presently found compositions deviate, in certain cases quite distinctly, from those previously reported in the literature; the Cs_3O phase has a wide range of homogeneity. The occurrence of such suboxides is not confined to cesium; well-defined suboxides of rubidium have also been observed. In the latter case, however, the investigation is rendered much more difficult by the peritectic formation of Rb_2O at *ca.* 40 °C. In order to gain more detailed information about the suboxide phases, we have begun a series of X-ray crystallographic investigations on single crystals.

Heterocycles from C_3 Systems and Sulfur

By *Friedrich Boberg*[*]

1,2-Dithiacyclopenten-ones, -thiones, -imines, and 1,2-dithiolium compounds can be prepared from allyl compounds and sulfur. 1,2-Dithiacyclopentenimines are also formed from 3-chloro-1,2-dithiolium compounds and *N*,*N*-dichloro compounds having electron attracting groups attached to the nitrogen (sulfonyl, alkoxycarbonyl, carbonyl) with elimination of chlorine. The systems are described by apolar and polar resonance structures (positive charge on the heterocycle, negative charge on the exocyclic heteroatom) in which electron shifts by substituents in position 5 have to be considered. Dipole moments of 1,2-dithiacyclopentenones and -thiones confirm these concepts. Information about the distribution of charge in the heterocycle is provided by chlorine exchange with $[^{36}Cl]$-$SbCl_3$ and $[^{36}Cl]$-$AlCl_3$, which, in the case of 3,4,5-trichloro-1,2-dithiolium chloride, preferentially takes place at the 3- and 5-positions.

1,2-Dithiacyclopentenones react with preservation of the heterocycle and with ring cleavage. The position of substitution is in agreement with theoretical concepts. S^{2-}, OH^-, RO^-, and R_2NH open the heterocycle between the carbonyl group and ring sulfur and reaction with Grignard compounds leads to ring cleavage at the disulfide bridge. The primary cleavage product reacts further to give various types of compounds, the substituents in the 4- and 5-positions of the 1,2-dithiacyclopentenone being of importance. The primary cleavage products from the reaction of RO^- with 1,2-dithiacyclopentenones containing Cl in position 4 or 5 undergo intramolecular or intermolecular elimination of Cl^- to give other sulfur heterocycles. The following products have been established: 1,2,5-trithiacycloheptadienes, 1,4-dithiacyclohexadienes, 1,2-dithiacyclohexadienes or the valence tautomeric dithioamides (unknown) and thiophenes from 4-chloro-1,2-dithiacyclopentenones; 1,2,4,5-tetrathiacyclohexanes, 1,2,4-trithiacyclopentanes, 1,3-dithiacyclobutanes, and 1,3-dithiacyclopentenes from 5-chloro- or 5-sulfonyl-1,2-dithiacyclopentenones[1]. The intermolecular mechanism is excluded in the case of the 1,2-dithiacyclohexadienes. The thiomalonic acid derivatives obtainable by reaction of 5-amino-1,2-dithiacyclopentenones with Grignard compounds are starting materials for the preparation of aminopyrazolinones and methylenebenzothiazoles.

Attempts to prepare the thiacyclopropene system were without success.

Electronic and Molecular Structure of Coordination Compounds of Transition Metals as Derived from Their Optical Properties

By *H.-H. Schmidtke*[*]

The gain in energy on formation of chemical bonding between central ions (electron acceptors) and ligands (donors) of a complex results from resonance properties of the electrons and from electrostatic interactions between the atoms and ions participating in the molecule. While the molecular orbital theory takes account of both effects, ligand field theory can only describe the electrostatic component of the bond. The ligand field theory satisfactorily accounts for the high- and low-spin behavior of the complexes that finds experimental expression in, for example, their magnetic behavior or their electronic spectra. However, the utility of the theory is limited once results are required that are not of a purely qualitative nature. For instance, no explanation is forthcoming of the existence of the spectrochemical series, in which some neutral ligands possess a stronger ligand field than charged ligands. The shortcomings of the theory are attributable to the overemphasis placed on electrostatic effects in the description of the electronic structure.

The angular overlap model, whose parameters are symmetry-orbital adapted and therefore better fitted to the molecular orbital theory, provides a better interpretation of experimental data. This model represents a semi-empirical theory which takes into account second order perturbation terms and which is of comparable quality to the Pariser-Parr theory. It is particularly suitable for the interpretation of spectra of low-symmetry coordination compounds with significantly covalent bonding and for the assignment of geometric isomers (*e.g.*, interpretation of the spectra of hydroxo complexes, assignment of the three geometric isomers of bis(L-histidinato) complexes). Mention should also be made of the assignment of linkage isomers, such as *S*- and *N*-bonded thiocyanate, on the basis of the electronic spectrum. Information about the mode of bonding is provided by both the ligand field theory and the charge transfer spectrum. The latter case is concerned with the transfer of ligand electrons to the d shell of the central ion. Assignment of linkage isomers is possible on the basis of differing optical electronegativities for *S*- and *N*-bonded thiocyanate.

The Chemistry of Learning

A one day symposium on "The Chemistry and Biology of Memory" was held at the 137th Conference of the American Association for the Advancement of Sciences (December 26—31, 1970 in Chicago) under the chairmanship of *W.L. Byrne.*

A. M. Golub (University of Waterloo, Ontario, Canada) reported on experiments performed on 45 rats which had been trained in an automatic one-way avoidance box designed by *Tenen.* RNA was extracted from the brains of trained animals with phenol and then analyzed by gradient centrifugation. Most of it was represented by ribosomal RNA, which in general contains no information. When these RNA preparations were injected into the recipient animals, significant transfer effects were observed between the second and fifth day after the injection: the recipient animals immediately used the escape route in a Tenen apparatus on occurrence of conditioning stimuli although they had never been subjected to an electric shock. The effect of the intracranial injection is dependent on dose; the effect is better after the application of 0.25 brain equivalents than after 0.5 equivalents. The results are more impressive when rest periods have been given to the animals during the training.

E.J. Fjerdingstad (Brain Research Institute, Memphis, Tenn.) uses a light avoidance shock procedure similar to that described by *Agranoff* in 1963 for the group training of goldfishes; the fishes have to learn to swim rapidly under a barrier into the other half of the training tank when a light signal appears, otherwise they receive an electric shock. After 12 days' training RNA was extracted from the brains of the fishes by a method described by *Golub.* 30 micrograms of RNA, corresponding to one brain equivalent, is injected intracranially into recipient fish; when twice as much material is injected into the recipients the results become rather doubtful.

A second study reported by *Fjerdingstad* concerned the transfer of audiogenic seizures. According to a report by *Henry* (1967), some mice suffer seizures on being subjected to sonication, which under certain circumstances can lead to death. A mouse strain resistant to audiogenic seizures can be made sensitive by a single sonication of 60 seconds duration on the 16th day after birth, which is assumed to be the first day of hearing in the animals' life. When such recipients are sonicated on their 21st day of life they immediately die from seizures. Spontaneously insensitive animals can be made sensitive to sonication by injecting them with 0.006 equivalents of brain homogenate from artificially sensitized animals. The question has been raised by the author whether this means a real learning rather than priming of new-born animals.

The lecture given by *G. Ungar* (Baylor College of Medicine, Houston, Texas) was the most exciting paper given at the symposium. Rats, which normally prefer a dark part of their cage to an illuminated area, have been trained by an electric shock procedure to avoid the dark. From 4000 trained rats, 5 kg of brain were collected. The intraperitoneal injection of a homogenate prepared therefrom into untrained recipients made these animals stay in the illuminated part of the cage. The transfer active material can be purified chromatographically. 300 micrograms of a peptide consisting of 15 amino acids have been obtained. *Desiderio* (Houston) has been able to determine the primary structure of it by mass spectrometry.

W. Parr (Tübingen and Houston) has used the Merrifield solid phase technique for the synthesis of this peptide which has been named "Scotophobin". The following peptide showed 100% of biological activity compared to that of the natural material isolated from trained brains.

Ser—Asp—Asn—Asn—Gln—Gln—Gly—Lys—Ser—Ala—Gln—Gln—Gly—Gly—Tyr—NH_2[*].

In order to gain more information about the chemical nature of such memory transferring peptides two new procedures have been started for mass training of animals: 3000 rats will learn the sound habituation procedure and 20000 goldfishes are to be trained for color discrimination by the procedure described by *Zippel* and *Domagk. Ungar* has found that goldfish are able to distinguish between green and blue colors when the maximum absorption differs by only 30 nm.

O. Wolthuis (Medical Biological Laboratory, Rijswijk, Netherlands) has trained rats in a fully automated system in which the animals drink only when a light or an acoustic stimulus is offered. Total brain homogenates prepared from such trained donors will change significantly the behavior of the recipient animals. A stimulus specific transfer of acquired information seems to be possible.

J. Daliers (UCB-DIPHA, Brussels, Belgium) has studied the phenomenon of memory with the aid of the spinal cord fixation time: When one hemisphere of the cerebellum of an anesthetized rat is removed, the rat will show an asymmetry of its hind legs; on the side of the removed hemisphere the hind leg shows a hypertonic flexion, whereas the contralateral side rests in hypotonic extension. This asymmetry disappears when the spine is dissected within 35 minutes after end of narcosis; if the dissection is carried out after 45 minutes or later the asymmetry will persist. Apparently the animal has learned something during this period. When brain extract—prepared by extraction with organic solvents—from donors which have spent a certain time in asymmetry is injected into animals at the onset of narcosis these recipient animals will exhibit persistent asymmetry of the hind legs even when the spine is dissected after 35 minutes. It is concluded that immediately after the lesion there is a progressive biosynthesis of one or more compounds in the brain, the intraperitoneal injection of which facilitates the production of asymmetry. The extract was found to be specific for a left side or right side lesion of the cerebellum. Injection of such extracts does not interfere with the recipient rats' learning in a watermaze.

G.F. Domagk (Louvain, Belgium) and *H.P. Zippel* (Göttingen, Germany) reported on the transfer of acquired information in goldfish experiments. Untrained goldfish show strong preference for red light whereas green light is disliked. On combining the two stimuli these effects are even enlarged. In a shock-free procedure, with feeding of Tubifex worms as the reinforcement, the fish can be trained to prefer green light even when the latter is offered with red light as a competing stimulus. Brain extract prepared from fish trained by this procedure is injected intraperitoneally into naive red-preferring fish. The recipients, who have never in their life received food together with green light, develop a rather strong preference for green which lasts for about a week; if no reinforcement is offered during this test period the memory decays.

[*] The terminal carboxy group is amidated.

Since training periods of up to five to seven weeks are required in order to get well trained donors other training procedures have been tried. It has been found that fish spontaneously prefer certain tastes, whereas other chemical compounds are strongly disliked. Quinine or acetic acid, both spontaneously disliked, have been used as the conditioning stimulus after the fishes were trained to react positive to either of these stimuli. Even when glucose is offered as a competing spontaneously preferred stimulus, the fish had learned after five days to react positive to either quinine or acetic acid. Brain extract prepared from either kind of donor made the recipients go specifically for the taste offered as the conditioning stimulus during the training period. It was shown that the acquired information is strictly related to the stimulus used during the training procedure. The memory for taste training lasts for about one week, whereas fishes that have learned the same tasks by active training can remember this task up to three months. Evidence is presented that "double transfers" are possible, *i.e* the donor fish can been trained to react positive to a color as well as to a taste stimulus.

J.H. Levan (Chicago, USA) reported on investigations with mice, which prefer a 1% saccharine solution to water if both are offered simultaneously. When after a certain observation period the animals are treated with x-ray or gamma radiation, they reverse their drinking habit: now water is strongly preferred to the simultaneously offered saccharine solution. This aversion towards saccharine could be induced in non-irradiated animals by the injection of brain extracts prepared from irradiated donors. Such a transfer effect was not observed after injection of extract prepared from blood but positive transfer has been seen with extracts prepared from liver and spleen tissues of trained donors. This latter observation raised an interesting discussion about the possible distribution of memory transfer factors over the whole body.

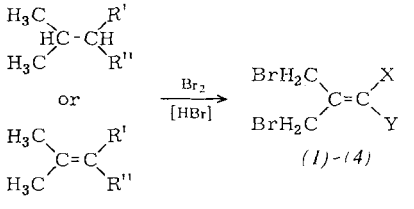
Trimethylsilyl- and Triphenylsilyl-Substituted Dyes

By *Heinrich Hopff*[*]

Trimethylsilyl- and triphenylsilyl-substituted aromatic compounds are now readily accessible *via* the Wurtz-Fittig synthesis. Permanganate oxidation of 3- and 4-trimethylsilyl-*o*-xylene leads to the previously unknown trimethylsilylphthalic acids which have been used for the synthesis of phthaleins, phthalocyanines, and quinophthalones. Introduction of the trimethylsilyl group causes a slight deepening in color, a noticeable increase in the solubility in organic solvents, and in certain cases, much better light-fastness. The advantage of such properties is particularly evident in the coloration of plastics and in "solvent dyeing".

Trimethylsilylindigo could only be obtained from the corresponding *o*-nitrobenzaldehyde by condensation with acetone in alkaline solution according to the method of *A. v. Baeyer*. 6,6'-Bis(trimethylsilyl)dithioxo-β,β'-isoindigo was prepared by reaction of trimethylsilylphthalodinitrile with hydrogen sulfide and ammonia. A larger number of trimethylsilyl-substituted mono-, di-, tri-, and tetracarboxylic acids were used for the synthesis of anthraquinone vat dyes. Trimethylsilyl-substituted anilidocyanuric chlorides were used for the preparation of triazinylaminoanthraquinone vat dyes.

Acid anthraquinone dyes were synthesized by condensation of bromaminic acid with aromatic aminosilanes.



Trimethylsilyl-substituted aromatic amines react with leucoquinizarin to give anthraquinone dispersion dyes. Comparison with *tert*-butyl substituted dyes revealed a distinct superiority of the trimethyl substitution as regards affinity, and stability toward light and chlorine. All the dyes and intermediates investigated showed the typical bands at 750, 835, 1250 cm^{-1} for $-Si(CH_3)_3$ and at 1095 and 1120 cm^{-1} for $-Si(C_6H_5)_3$ in their IR spectra.

Bromination in Liquid Bromine

By *Hermann Stetter* and *Erhard Tresper*[*]

The bromination of adamantane in liquid bromine has already been shown to proceed *via* an ionic mechanism that leads to a stepwise selective bromination of the tertiary hydrogen atoms. It has also been shown that defined bromination products can be obtained, sometimes in high yields, on bromination of aliphatic hydrocarbons with adjacent tertiary carbon atoms and in the case of tetraalkylated ethylenes. The reactions carried out may be summarized as follows:

(1)-(4)

(5)

	R'	R''	X	Y
(1)	CH_3	CH_3	CH_2Br	CH_2Br
(2)	C_2H_5	CH_3	$CHBr—CH_2Br$	CH_2Br
(3)	n-C_3H_7	CH_3	$CHBr—CHBr—CH_3$	CH_2Br
(4)	C_2H_5	C_2H_5	$CHBr—CH_2Br$	$CHBr—CH_2Br$

Photochemical *cis-trans* Isomerization of *n*-Octenes in the Presence of Organoaluminum Compounds

By *Siegfried Warwel, Heinz-Peter Hemmerich*, and *Friedrich Asinger*[*]

Pure *cis-trans* isomerization of an olefin can be effected by reversible radical addition at the olefinic double bond or *via* a photochemical route using UV light or γ-radiation; in the latter cases the presence of photosensitizers such as benzene or benzophenone is usually necessary.

We have now found that *n*-octenes containing an internal double bond also undergo *cis-trans* isomerization when subjected to irradiation with UV light or γ-rays if molar amounts of an organoaluminum compound ($HAlR_2$[1] or AlR_3) are present. This *cis-trans* isomerization, which under otherwise similar reaction conditions is not observed in the absence of the organometallic compound, proceeds without any shift of the CC double bond in the olefin molecule and leads, irrespective of the configuration of the olefin used, almost to the thermodynamically stable equilibrium mixture of the configurational isomers. Thus, *e.g.*, γ-irradiation (^{60}Co source, dose: 4.3×10^6 rad) of *cis-n*-4-octene for 37 h in presence of tri-*n*-butylaluminum (molar ratio 1:4) at 22 °C leads to an *n*-4-octene which consists of only 17.8% *cis*-, but 82.2% *trans-n*-octene. On irradiation of *trans-n*-4-octene the product of the isomerization reaction contained *cis* and *trans* isomers in the ratio 18.1:81.9.

Not only $Al(n\text{-}C_4H_9)_3$, but also $HAl(i\text{-}C_4H_9)_2$, $Al(i\text{-}C_4H_9)_3$, and $Al(n\text{-}C_8H_{17})_3$ effect a pure *cis-trans* isomerization; the extent of isomerization differs in each case, $Al(n\text{-}C_8H_{17})_3$ being considerably less effective than the other compounds.

The configurational isomerization is noticeably hindered if the organometal compound is complexed by electron donors. Triethylamine, tetrahydrofuran, and di-*n*-butyl sulfide hinder the isomerization almost completely. The mechanism of the isomerization reaction is as yet unknown, but it most probably involves the participation of metal-olefin π complexes as active intermediates.

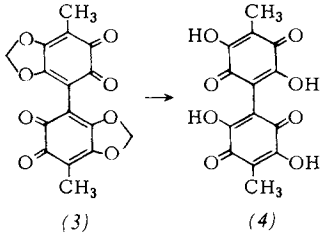
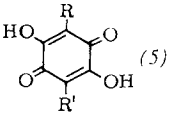
Substituted *o*-Benzoquinones[1]

By *Franz Dallacker, Zoltan Damó*, and *Gernot Löhnert*[*]



We have synthesized low molecular secondary plant substances by treating the compounds *(1a)–(1c)*, which are readily prepared by reaction of alkyl halides with 2,3-dimethoxy-5,6-methylenedioxyphenyllithium, with dilute nitric acid. Resonance stabilized 4,5-methylenedioxy-*o*-benzoquinones *(2a)–(2c)* are formed in good yields.

(1) (2)



R	R'	(1) M. p. (°C)	(1) Yield (%)	(2) M. p. (°C)	(2) Yield (%)
(a) $H_3C-(CH_2)_{10}$	H	43	72	110–111	74
(b) $H_3C-(CH_2)_{12}$	H	49–50	69	105–107	78
(c) $H_3C-(CH_2)_{18}$	H_3C	49–50	65	114	75

The ditoluene-di-*o*-quinone derivative *(3)* (dec. pt. 256 °C) can be prepared in 72% yield by the same method.

(3) (4)

When aqueous potassium hydroxide solutions of the quinones *(2a)–(2c)* and *(3)* (if necessary with addition of a few milliliters of ethanol) are acidified with hydrochloric acid, the natural substances embelin *(5a)*, rapanon *(5b)*, oosporein *(4)*, and the dehydromaesaquinone *(5c)* are precipitated in high yields.

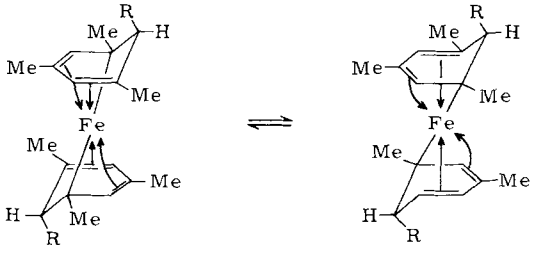
[1] Derivatives of Methylenedioxybenzene, Part 29.—Part 28: *F. Dallacker*, Monatsh. Chem. *100*, 742 (1969).

Preparation of larger sections of diamond-type lattice has been attempted by *H. Stetter* and *K. Komorowski*. Bicyclo-[3.3.1]nonan-3,7-dione is allowed to react with pyrrolidine to give the 2-oxaadamantane derivative *(1)*, which loses water and is converted into the bisenamine 3,7-dipyrrolidinobicyclo[3.3.1]nona-2,7-diene. Reaction of this bis-

(1)

(2)



enamine with ethyl α-bromomethylacrylate affords the pentacycle *(2)*. / Chem. Ber. *104*, 75 (1971) / –Ee.

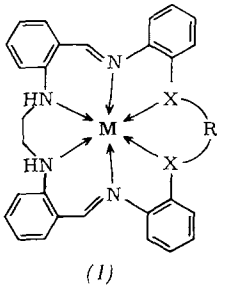
[Rd 312 IE]

The electron-induced topotactic decomposition reactions of SnS_2 and $Cu(OH)_2$ have been investigated by *J. R. Günter* and *H. R. Oswald*. The electron diffraction diagrams of thin lamellas of SnS_2 (CdI_2 type) show, even after short irradiation, reflections of elementary tin, which is present in three crystallographically equivalent orientations to the SnS_2. Holes are formed at the same time. The (001) layer is the structure-retaining element.—The thermal decomposition of SnS_2 follows a completely different course: it leads, *via* the intermediary Sn_2S_3, to formation of SnS. In the case of $Cu(OH)_2$ (chain structure) very small CuO crystals can be detected after a short irradiation time whose [110] axes are parallel to each other and to the [100] axis of $Cu(OH)_2$, but tilted. Further irradiation leads to formation of small crystals of Cu_2O. The structure is retained in the [100] chain. The majority of such reactions are controlled two-dimensionally or unidimensionally; in topotactic reactions the compounds taking part do not necessarily have to have related structures. / Chimia *24*, 421 (1970) / –Kr.

[Rd 313 IE]

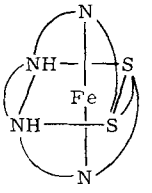
Pseudoferrocenes have been studied by *J. F. Helling* and *D. M. Braitsch*. Bis(6-*tert*-butyl-1,3,5-trimethylcyclohexadienyl)iron(II) *(1)* and the phenyl analog *(2)* prepared by reaction of bis(mesitylene)iron(II)hexafluorophosphate with *tert*-butyl or phenyllithium show temperature-dependent, simple NMR spectra indicative of fluxional behavior. The spectra allow either free rotation with respect to the ring-Fe-ring axis or lack of rotation but do not permit hindered

(1), R = $C(CH_3)_3$
(2), R = C_6H_5



rotation. *(1)* and *(2)*, m.p. 203–204 °C and 102–105 °C respectively, are stable toward air and water. At and above the temperature at which the high temperature limiting NMR spectra are found (+100 and +2 °C resp.), *(1)* and *(2)* are possibly present as homocyclopentadienide ion complexes, *i.e.* as "pseudoferrocenes". / J. Amer. Chem. Soc. *92*, 7207, 7209 (1970) / –Kr.

[Rd 314 IE]

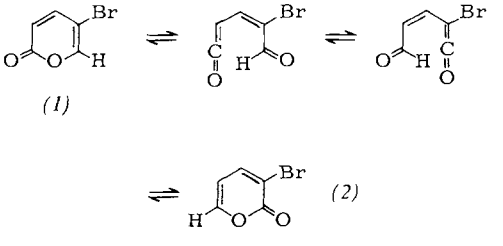


Hydridobis(π-cyclopentadienyl)phenyltungsten $(\pi\text{-}C_5H_5)_2WHC_6H_5$ has been prepared by *M. L. H. Green* and *P. J. Knowles* by reaction of dihydridobis(π-cyclopentadienyl)tungsten with benzene in the presence of dienes such as isoprene at 120 °C. The yellow, sublimable phenyl derivative is formed in 15% yield. If toluene is used instead of benzene only the *p*-derivative is formed. A similar addition of benzene has been postulated to occur in H/D exchange reactions of C_6D_6 with H_2 that are catalyzed by $(\pi\text{-}C_5H_5)_2TaH_3$. / Chem. Commun. *1970*, 1677 / –Ee.

[Rd 317 IE]

Metal complexes of new macrocyclic sexadentate ligands have been investigated by *P. A. Täsker* and *E. B. Fleischer*. Complexes such as *(1)* were prepared *in situ* from 2,2'-(ethylenediamino)dibenzaldehyde, the perchlorate of the desired metal (Fe^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}) and a diamine containing two additional donor sites. X-ray structure ana-

(1)

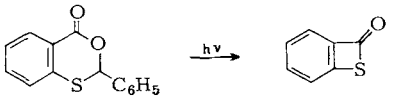


(2)

lysis of *(1)*, M = Fe, X—R—X = S—CH_2—CH_2—S, showed that all six donor atoms are arranged octahedrally about the central iron atom as in *(2)*. / J. Amer. Chem. Soc. *92*, 7072 (1970) / –Ee.

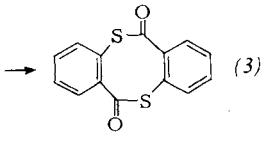
[Rd 315 IE]

Skeletal rearrangement with participation of 1,5-sigmatropic hydrogen shifts is reported by *W. H. Pirkle, H. Seto*, and *W. V. Turner* to be the underlying rearrangement *via* which the already well-known methyl migration occurs in the pyrolytic decarboxylation of 5-methyl-6-carboxy-2-pyrone to 3-methyl-2-pyrone and related reactions. To test



(1)

(2)



this hypothesis the authors pyrolyzed 5-bromo-2-pyrone *(1)* and found that the recovered material consisted of an approximately 50:50 mixture of 3-bromo-2-pyrone *(2)* and *(1)*. The postulated occurrence of ketene aldehydes as intermediates was supported by the low-temperature IR spectroscopic detection of the unsubstituted analog in the photolysis of 2-pyrone. / J. Amer. Chem. Soc. *92*, 6984 (1970) / –Ee.

[Rd 316 IE]

2-Thiobenzopropiolactone *(2)*, the thio analog of the unknown benzopropiolactone, has been synthesized by *O. L. Chapman* and *C. L. McIntosh* by irradiation of the

(1) *(2)*

(3)

benzoxothianone *(1)* at –196 °C in $CHCl_3$; presence of the new species was confirmed by IR spectroscopy (ν(C=O) = 1803 cm^{-1}). Warming of the irradiated sample to –40 °C gives rise to formation of the dimer *(3)* from *(2)*. When the irradiation of *(2)* is carried out in the presence of methanol methyl *o*-mercaptobenzoate is formed. / J. Amer. Chem. Soc. *92*, 7001 (1970) / –Ma.

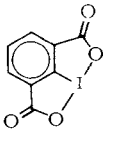
[Rd 318 IE]

A new method for the synthesis of *N*-oxides of polyhalogenated N-hetero aromatics is described by *G. E. Chivers* and *H. Suschitzky*. It involves oxidation with a mixture of concentrated sulfuric acid, H_2O_2, and acetic or trifluoroacetic acid. The principle of the reaction is nucleophilic attack of the amino nitrogen on the peroxide oxygen whose electrophilic character is enhanced by protonation of the peracid that is formed as intermediate. Examples: *N*-oxide from pentachloropyridine, 85% yield; 2,3,5,6-tetrachloropyridine, 80%; 2,6-dichloropyridine, 65%; 2,3,5,6-tetrachloro-4-nitropyridine, 67%; 2,3,5,6-tetrachloro-4-methylpyridine, 70%; pentabromopyridine, 85%; tetrachloropyrazine, 56%; tetrachloropyridazine, 50%. / Chem. Commun. *1971*, 28 / –Ma.

[Rd 319 IE]

The molecular structure of tetrasulfur dinitride (1,2,3,5,4,6-trithiathia$^{(IV)}$diazine) has been investigated by *J. Nelson* and *H. G. Heal*. After preparation by two methods and purification by chromatography and sublimation S_4N_2 proved to be a single substance. Its dipole moment is 1.74 ± 0.28 D; it was determined *via* the dielectric constants and refractive indices of CS_2 solutions. The ^{14}N-NMR spectrum shows a single resonance at 105 ± 1 ppm upfield from aqueous nitrate ion. The mass spectrum at low ionizing voltage contains only a signal for $S_4N_2^+$, thus establishing

(1)



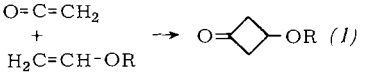
the molecular weight. The electronic spectrum shows three bands at 220, 377, and about 455 nm; the last one is ascribed to the n→π* transition owing to its solvent dependence. In addition, IR and Raman spectra were measured. The combination of all these physical data leads to *(1)* as the most probable structure among about 60 covalent formulas taken into consideration. At the present stage, however, no distinction is possible between planar, chair, or boat conformations of *(1)*. / J. Chem. Soc. *A 1971*, 136 / –Hz.

[Rd 320 IE]

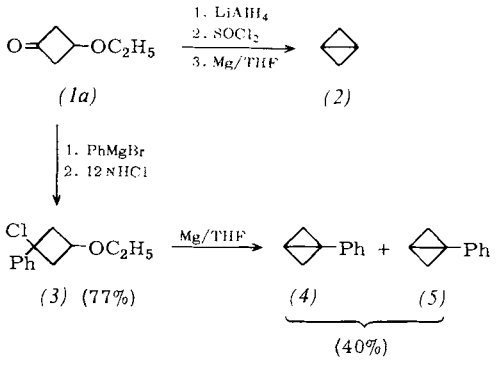
The adsorption of hydrogen halides on alkali-metal halides has been studied by *R. StC. Smart* and *N. Sheppard* by means of IR spectroscopy. Films of alkali-metal halides with high surface areas (around 200 m^2g^{-1}) were obtained by deposition from the vapor phase on cold (80 °K) carrier surfaces. The dominant surface species is most probably X—H··Y$^-$ (X, Y = halogen) with a hydrogen bond to a surface anion. In favorable cases it was possible to detect all of the three vibrational frequencies of this species; *e.g.*, for HCl on CsCl, 2110, 1160, and 218 cm^{-1}. The strength of the hydrogen bonds of HCl increases along the sequences LiCl < NaCl < CsCl and NaI < NaBr < NaCl. In mixed-halogen systems, halogen exchange is observed if X of HX has a higher atomic number than Y of the salt. / Proc. Roy. Soc. (London) *A 320*, 417 (1971) / –Hz.

[Rd 321 IE]

The ^{127}I Mössbauer spectra of aromatic compounds with polyvalent iodine have been investigated by *B. S. Ehrlich* and *M. Kaplan*. ZnTe with ^{127m}Te was used as the source for the 57.6 keV transition of ^{127}I; source and absorber were cooled to 4.2 °K. The compounds investigated were iodobenzene PhI, iodobenzene dichloride $PhICl_2$, iodosobenzene PhIO, iodoxybenzene $PhIO_2$, and the di-"lactone" of 2-iodoisophthalic acid *(1)*. The analysis of the quadru-



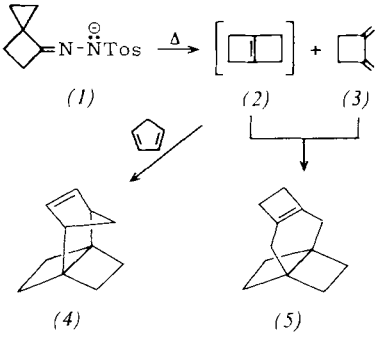
(1)



pole splitting, asymmetry parameter, and isomer shift revealed that in all compounds, with the exception of $PhIO_2$, only p orbitals of iodine participate in bonding. Accordingly, the C—I—O angle in PhIO is about 90°; compound *(1)* is approximately planar with a linear O—I—O group. In $PhIO_2$ the bonding orbitals show slight s hybridization; the angle O—I—O is predicted to be about 95°. / J. Chem. Phys. *54*, 612 (1971) / –Hz.

[Rd 322 IE]

3-Alkoxycyclobutanones *(1)*, **precursors of bicyclo[1.1.0]-butanes,** have been prepared by *J. B. Sieja* by addition of ketene to vinyl ethers at 100 °C:



The reactivity decreases along the series R = *tert*-butyl ≫ ethyl > methyl > benzyl (yield 20–87%). The 3-alkoxycyclobutanones serve as starting materials for many bicyclobutanes. The parent compond *(2)* is formed *via* the alcohol

(87%) and the chloride (70%) in 70% yield. 1-Phenyl *(4)*, 1-vinyl, and 1-cyano derivatives can be prepared similarly./ J. Amer. Chem. Soc. *93*, 130 (1971) / –Ma.

[Rd 323 IE]

The synthesis of bicyclo [2.2.0]hex-1(4)-ene *(2)*, from which the theoretically interesting hydrocarbons tricyclo-

[2.2.1.$0^{1,4}$]heptane and tricyclo[2.2.2.$0^{1,4}$]octane may prove preparable, has been described for the first time by *K. B. Wiberg*, *G. J. Burgmaier*, and *P. Warner*. Thermolysis of the Na salt of spiro[2.3]hexanone 4-tosylhydrazone *(1)* in a high vacuum [the volatile products being trapped in liquid nitrogen which is then allowed to evaporate at room temperature] yields 1,2-dimethylenecyclobutane *(3)* and the dimer *(5)*, which can be regarded as a Diels-Alder adduct of *(2)* and *(3)*. Compound *(2)* could be detected in the thermolysis products of *(1)* by addition of cyclopentadiene to the liquid nitrogen. The adduct *(4)* was formed on heating to room temperature. / J. Amer. Chem. Soc. *93*, 246 (1971) / –Ma.

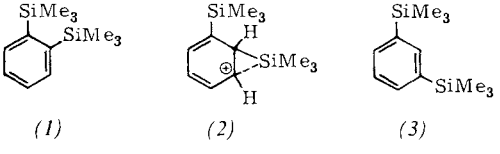
[Rd 324 IE]

Reactions of silicon difluoride with silanes and germanes have been studied by *J. L. Margrave*, *D. L. Williams*, and *P. W. Wilson*. These authors mixed gaseous SiF_2, prepared from SiF_4 and Si, with the relevant silane or germane in a flow system and subsequently condensed the gases as fast as possible at –196 °C. The volatile products were isolated after warming to room temperature. Under these conditions, SiF_2 does not react with $Si(CH_3)_4$ or $Ge(CH_3)_4$; with $Si(CH_3)_3Cl$ it forms $Si(CH_3)_3F$, presumably by halogen exchange. In contrast SiF_2 and $Si(CH_3)_3OCH_3$ react *via* insertion into the Si—O bond to give $Si(CH_3)_3F$, $(CH_3)_3Si—Si(CH_3)_2F$, CH_3OSiF_3, and a little $(CH_3)_3Si—SiF_3$. The initial product is probably $(CH_3)_3Si—SiF_2OCH_3$. Insertion into the CH_3—O bond is somewhat less likely. / Inorg. Nucl. Chem. Lett. *7*, 103 (1971) / –Ee.

[Rd 326 IE]

A new mercury ion, Hg_3^{2+}, has been detected by *G. Torsi* and *G. Mamantov* in acidic $NaCl/AlCl_3$ melts containing $HgCl_2$ or Hg_2Cl_2 to which metallic mercury had been added. Hg_3^{2+}, which renders the solution yellow, exhibits an asymmetric absorption band with $\lambda_{max} = 325$ nm. The ion can also be obtained by polarographic reduction of Hg^{2+} in acidic $NaCl/AlCl_3$ melts. Further indications of its existence have been afforded by the reactions of $HgCl_2$ or Hg_2Cl_2 with Hg in pure $AlCl_3$ melts. / Inorg. Nucl. Chem. Lett. *6*, 843 (1970) / –Kr.

[Rd 299 IE]



Alkyl nitrates can be prepared by deamination of primary amines with N_2O_4, according to *F. Wudl* and *T. B. K. Lee*. The reaction is strongly dependent on the solvent. It proceeds most satisfactorily at low temperature (*ca.* –60 °C) in THF and other ethers, which, as Lewis bases, can form strong complexes with N_2O_4:

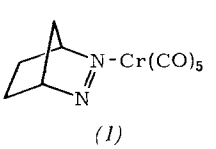
$$R—NH_2 + N_2O_4 \xrightarrow[-60\,°C]{THF} R—ONO_2 + N_2 + H_2O$$

Examples: $R = CH_3(CH_2)_3CH(C_2H_5)CH_2$, 65% yield; $C_6H_5CH(CH_3)$ 80%; $CH_3(CH_2)_5$, 20%. Extensive retention of configuration indicates an ionic mechanism./J. Amer. Chem. Soc. *93*, 271 (1971) / –Ma.

[Rd 325 IE]

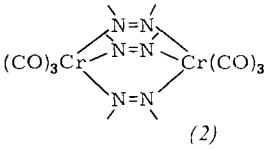
A new organosilicon rearrangement has been discovered by *D. Seyferth* and *D. L. White*. On reaction for 48 h in the presence of benzene and trifluoroacetic acid at 150 °C in mixture of *(1)* (2%), the *meta* isomer *(3)* (93%), and the *para* isomer (5%), alongside a small amount of trimethyl-

phenylsilane. The *meta* and *para* isomers undergo only very slight rearrangement under the same conditions. In the absence of trifluoroacetic acid all three isomers are stable. The authors assume that the rearramgement is similar to the 1,2-shift in dialkylbenzenes *via* intermediates such as *(2)*, which has been described by Olah[1]./J. Organometal. Chem. *26*, C15 (1971)/-Ee.



[Rd 327 IE]

[1] *G. A. Olah et al.*, J. Org. Chem. *29*, 2310, 2313, 2315, 2687 (1964).



Coordination compounds of 2,3-diazabicyclo[2.2.1]hept-2-ene have been prepared by *M. Herberthold* and *W. Golla*. The ligand gives three types of complex with carbonyl: metals: 1) In *(1)* [obtained from the bicyclic and photolyti-

cally produced $Cr(CO)_5$] it functions as a unidentate two-electron ligand. 2) In *(2)* [formed on heating of *(1)*] the bicyclic behaves like a bidentate four-electron ligand (although a structure having only one azo bridge and two chelating ligands cannot be dismissed altogether). 3) The bicyclic reacts with $Fe_2(CO)_9$ to give *(3)* in which the azo group can be formally regarded as a six-electron ligand. *(1)* to *(3)* and some similar compounds can be sublimed in high vacuum and are fairly stable toward air./J. Organometal. Chem. *26*, C27 (1971)/-Kr.

BOOK REVIEWS

Chemische Spektralanalyse (Seith–Ruthardt), Anleitung für die chemische Laboratoriumspraxis (Chemical Spectral Analysis, Introduction to Chemical Laboratory Practice) Vol. 1. By *W. Rollwagen*. Springer Verlag, Berlin-Heidelberg-New York 1970. 6th ed., xii, 185 pp., 84 Figs, and 1 Table, bound DM 48.—.

"Chemische Spektralanalyse" has for some decades been the most important German-language introduction to practical emission-spectral analysis. The fundamental principles formulated by *Seith* and *Ruthard* in their description of sample preparation, light sources, light conduction, spectral breakdown, radiation receivers, and particularly evaluation still deserve the attention of all those who wish to use emission-spectrochemical methods of analysis. *Rollwagen*, who revised and expanded the 5th edition (1959), has also made some additions in the present 6th edition. The section on photoelectric measurement has been expanded. The determination of gases in metals and calibration by the addition method are discussed. The new section on *Grimm*'s glow discharge lamp must obviously have been inserted at a time when knowledge of this interesting and important light source was inadequate. There are many instances where failure to revise the text is regrettable: this is so *e.g.* wherever a qualitative description is given for some point that could nowadays be presented more easily by means of a simple formula. The required slit width and systematic focusing steps are easier to calculate from the data for the spectral apparatus than to find by trial and error. These and other formulas are nowadays tools that should not be lacking from this book, which contains so much important information.

Hans Massmann [NB 950 IE]

The Chemistry of Inorganic Ring Systems, Parts 1 and 2. By *I. Haiduc*. John Wiley and Sons Ltd., New York 1970. 1st ed., vi, 1197 pp., £10.00.

In 1960, *Ionel Haiduc* wrote a remarkable book in Romanian on inorganic ring systems. He now spotlights this fascinating and fast-developing field of inorganic chemistry once again in a much more comprehensive work in English. The work is divided into two parts. The first deals with homocyclic inorganic ring systems and with heterocycles whose main component is an element of group III or IV. The second part covers heterocycles whose main component is an element of group V or VI and heterocycles that are coordination compounds containing metals. Since the assignment of the individual heterocycles to these groups cannot always be free from arbitrary choice, a good keyword index is helpful in finding one's way around. A list of contents precedes each chapter.

The work contains an abundance of material. The recent literature is taken into account. The literature coverage is admittedly not complete, and probably was not intended to be so; however, the selection is excellent. All the important inorganic ring systems and their principal chemical and physical properties are surveyed. The discussion of chemical behavior includes substitutions that proceed with retention of the ring system, together with their problems, as well as reactions in which the ring system is opened. The physical properties are collected in tables in many cases. The emphasis is always placed on the phenomenological. Mechanistic aspects are mentioned only briefly. In this way the reader is acquainted with the most important substances and their behavior. At the same time he is directed by numerous references (about 5000) to the original literature, from which he can obtain further information. It is felt, however, that the chapters on structure and bonding in inorganic rings and on inorganic ring systems in equilibrium might have been rather more detailed. The chapter on bonding theory contents itself with a superficial indication of the problems. The very stimulating chapter on inorganic rings in equilibrium, which was written by the author at the suggestion of and with the aid of *J.R. Van Wazer*, should have presented more qualitative description.

To summarize, it can be stated that this is an outstanding work offering an excellent introduction to the field of inorganic heterocycles, and showing how fluid the boundaries between inorganic and organic chemistry have now become. The inorganic heterocycles lie at a particularly interesting junction between these regions. The book, which is clearly and simply written, can be strongly recommended to chemists interested in this field as well as to students.

13. MAI 1971

Surfactant Biodegradation, Surfactant Science Series, Vol. 3. By *R. D. Swisher*. Marcel Dekker Inc., New York 1970. xxiii, 496 pp. bound $ 33.50.

The author, who is well known in the field of surfactant research, has undertaken the task of sorting through the vast literature on the biological degradation of surfactants and presenting its substance in the form of a monograph. He summarizes present-day knowledge in eight chapters. He first describes the introduction of the alkylbenzenesulfonates around 1950 and their first effects on water management, particularly on clarifying plants and rivers; general remarks on biological degradation pathways are also included. Then follow data on the physical and chemical properties and on the structures of anionic and nonionic surfactants. A long chapter is then devoted to the analysis of surfactants, which is difficult from the very point of view with which the book is concerned, *i.e.* the degradation of surfactants in very low concentrations. The author concentrates on the methylene blue method for anionic surfactants, while several methods are discussed for nonionic surfactants. Special physicochemical methods also allow an insight into the detailed structures and their modification during degradation.

Nonspecific methods based on measurement of the biological oxygen requirement or of the interfacial tension are also mentioned briefly. The microbiological questions of surfactant degradation are carefully discussed before a long chapter is devoted to the microbiological degradation test methods; practically all the methods used in laboratories and in practice are discussed here. The interactions between surfactant structure and microbial attack are then presented. Finally, existing knowledge about the metabolic pathways in the total degradation of surfactants is discussed. Tables covering 83 pages present the results reported by many research workers, showing surfactant structure, time, and analytical method. The work is completed by a 56 page bibliography and a 27 page subject index. It should be an important tool to all those who are concerned with surfactants, particularly their effect on water management.

Synthetic Paper

By Hans Lunk and Karl Stange[*]

Synthetic paper can be made either by forming a web from synthetic fibers or by extruding a film from thermoplastic polymers. With suitable starting materials and appropriate treatment it is possible to equal the properties of conventional cellulose paper; in some respects, as in wet strength and dimensional stability, the synthetic papers are clearly superior.

1. Introduction

Since the beginning of the 19th Century, the 2000-year-old craft of papermaking has developed into a highly technological industry with a world-wide production of over 120 million tons per year. This tremendous progress was due to the invention and further development of efficient machines for the continuous production of paper. The raw material itself has not changed; as in ancient times, cellulose fibers are still used.

[*] Dr. H. Lunk and Dr. K. Stange
Badische Anilin- & Soda-Fabrik
67 Ludwigshafen (Germany)

In the last few years, however, a development has started which deviates from this tradition: the application of plastics in place of the cellulose fibers. This development is not unusual; other natural products such as textile fibers, wood, and leather have been replaced to a considerable extent by synthetic polymers. In the case of paper, the use of plastics was delayed, partly for technical reasons, but mainly because of the relatively low cost of the conventional raw material and manufacturing process. This article is a description of the present state of development of synthetic paper; methods of preparation, properties, and possible applications will be described.

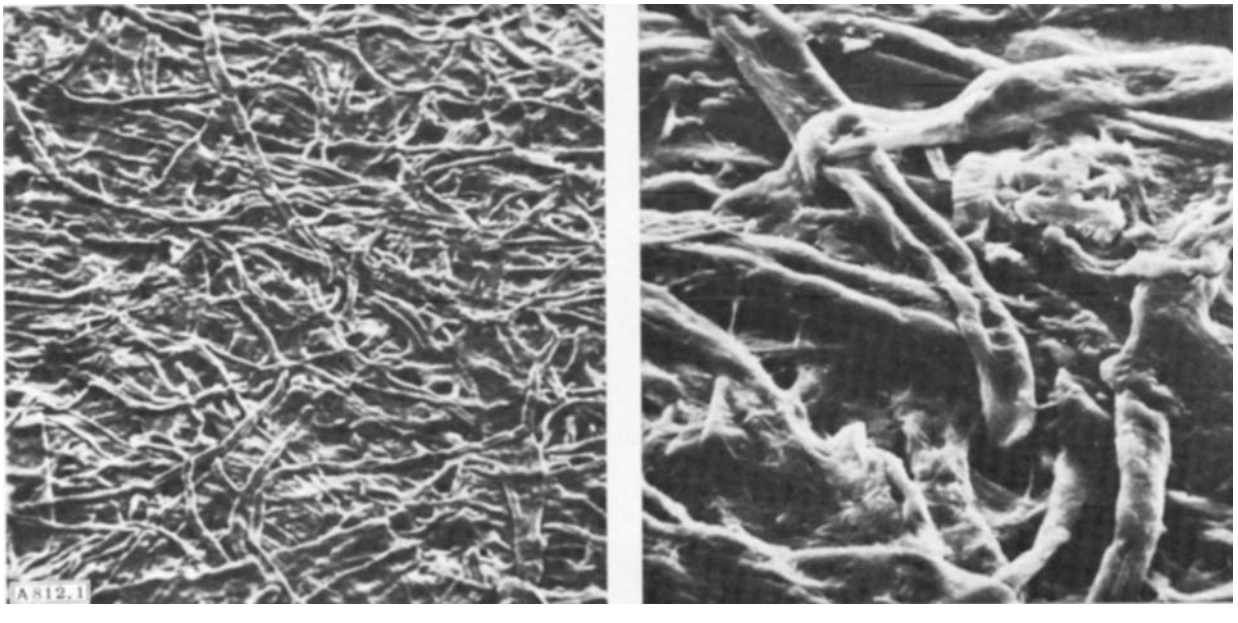

Fig. 1. Surface of a typewriter paper (Stereoscan picture). Enlargement: left, 100:1, right, 500:1.

Before discussing synthetic paper, it may be useful to say a few words about the production and the structure of cellulose paper. Today, paper is almost exclusively made from wood. A suspension of cellulose fibers, obtained from wood chips either by chemical treatment or by mechanical grating (groundwood), is poured onto a continuously moving sieve. Most of the water is removed here, and the resulting sheet is dried on a series of rolls and cylinders. Modern paper machines have working widths of up to 9 meters and speeds of about 600 to 800 meters per minute. The product of these machines is a mat of interlocked cellulose fibers as shown in Fig. 1. By adding fillers and size in the appropriate amounts, one obtains the different types of paper. The surface can then be further improved by application of a pigment coating.

Synthetic papers may be classified into two different types. The first one has a fibrous structure like cellulose paper, with synthetic fibers made from polyamides, polyester, or polyolefins replacing the cellulose fibers. Such synthetic fiber webs have excellent properties, but they are quite expensive because of the high cost of the raw materials. The other type of synthetic paper does not use fibers; rather, a film is directly extruded from a thermoplastic polymer. These products differ considerably in their structure from cellulose paper, and thus present a whole variety of different problems.

2. Paper-like Webs from Synthetic Fibers

2.1. Fabrication *via* the Paper Process

One method of making synthetic paper consists in replacing the cellulose fibers by synthetic fibers cut to the appropriate length. A suspension of such fibers is run through regular paper machines, taking advantage of the high production speed and uniform product thickness achievable with such equipment. The products have essentially the same structure as cellulose paper, and therefore possess good printability and ink absorbing qualities. Because of the different fibers, they also have properties which deviate from those of regular paper. Synthetic fibers generally exhibit lower water absorption than cellulose fibers; the webs made from them are therefore less sensitive to moisture, and possess greater wet strength and dimensional stability. The excellent mechanical properties of the synthetic fibers are reflected in the fiber webs. They have high tensile strength, tear strength, and above all, high folding endurance. Commercial papers made from synthetic fibers are shown in Table 1.

In place of spun fibers, one can also use fibers made in a different way. If olefins are polymerized with certain Ziegler-Natta catalysts under conditions of high shear, the polyolefin is obtained in the form of fine, mattable fibers. These can be used, either by themselves or in combination with other fibers, to make products quite similar to the fiber webs mentioned above[1]. This method is not yet used in practice, but has probably good chances for commercial success because of the relatively low cost.

2.2. Thermally Bonded Fibrous Sheets

Another process for the fabrication of synthetic fiber webs does not involve a suspension of staple fibers, but uses continuous filaments. During the extrusion, the filaments are placed on top of one another in an unordered array and at the same time thermally welded together (spunbonded). Commercially available products made from high density polyethylene, polypropylene, polyester, and polyamide are shown in Table 1 with trade names and producers.

The properties of these sheets are of course largely dependent on the kind of synthetic fiber used. Generally, they are between those of paper and woven fabrics. Since these materials are also intermediate in their prices, they are used as durable paper with especially good mechanical properties and also for disposable textile products.

Table 1. Synthetic fiber webs.

Trade name	Producer	Raw material	Process
Syntosil®	Zürcher Papierfabrik	polyamide	from staple fiber on conventional paper machines
Neobond®	Feldmühle	polyamide	
Tyvek®	DuPont	HD-polyethylene	continuous fibers, thermally bonded
Typar®	DuPont	polypropylene	
Reemay®	DuPont	polyester	
Bidim®	Rhodiaceta	polyester	
Viledon®	Freudenberg	polyamide	

3. Extruded Film

3.1. Fabrication

There are two different extrusion processes for the fabrication of film from thermoplastic materials. In both cases, the polymer is plasticated in the extruder, advanced by a rotating screw, and finally forced through the die.

In the cast film process (Fig. 2) the polymer melt is extruded through a slot die. After extrusion, the film is quenched on a water cooled chill roll and then wound up. The thickness of the film can be varied by adjusting the width of the die slot and the take-off speed. Usually it is necessary to trim the edges in order to obtain the desired width of the film and to remove material with differing film thickness.

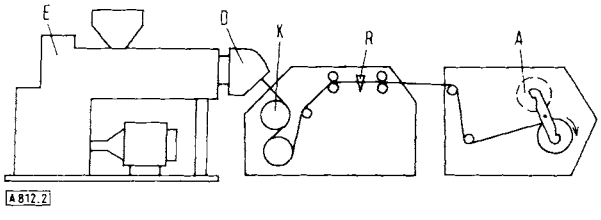

Fig. 2. Cast film process. E = extruder, D = die, K = chill roll, R = edge trimmer, A = windup.

In the blown film process (Fig. 3) the melt is forced through a circular die. The tubing thus formed is blown up to the desired diameter, air cooled for a certain distance, and then laid flat by means of two nip rolls. Both edges are trimmed and the two resulting layers of film are wound up separately.

The main advantage of the blown film process is that through high blow-up ratios relatively thin and broad films can be produced. On the other hand, the maintenance

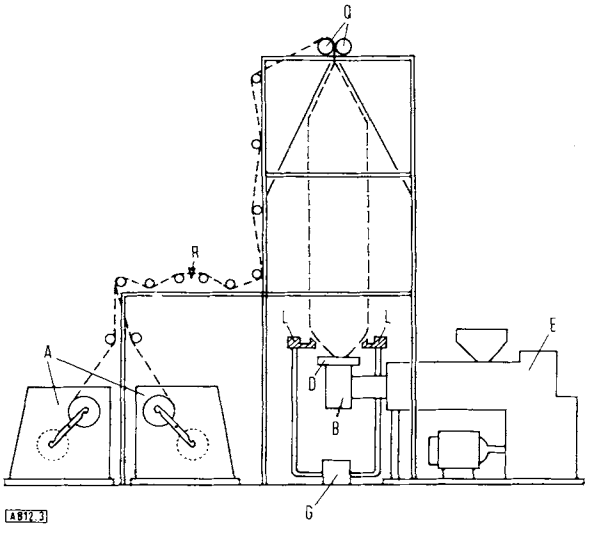

Fig. 3. Blown film process. E = extruder, B = blow head, D = die, L = air cooling ring, Q = nip rolls, R = edge trimmer, A = windup.

of constant thickness over the whole width of the film is somewhat problematic. Depending on the starting material and the intended application, both cast film and blown film processes are used in practice.

A variant of the blown film process is the extrusion of foamed film. Through the addition of blowing agents (usually low boiling hydrocarbons) it is possible to produce foamed film from a variety of polymers. Because of their special properties (thermal insulation and shock absorption) they are a valuable addition to the compact films.

3.2. Stretching

Frequently it is desirable to improve the mechanical properties of the film by stretching. By application of external forces the chain molecules can be oriented in such a way that the chain axes lie preferentially in the plane of the film. As a result, tensile strength, tear strength, stiffness, as well as some other properties are improved. Since it is desirable that the properties be equal in all directions of the plane of the film, the stretching has to be done biaxially, *i.e.* in two directions at right angles to each other. The stretching is usually carried out at a temperature in the thermoplastic region above the glass point, with crystalline polymers between glass point and melting point. It is important, especially with amorphous polymers, to freeze the orientation of the molecules by rapid quenching. The stretch ratio depends on the material and on the properties desired; usually it is between 2:1 and 4:1 in both directions, and for crystalline polymers frequently somewhat higher.

Two methods are used for the biaxial stretching of cast film: the simultaneous stretching process, in which the stretching is carried out in both directions at the same time, and the two-stage process, in which the two stretching operations are carried out consecutively. Fig. 4 illustrates the principle of a simultaneous stretching machine and the deformation of a unit element during the stretching process. As it comes from the extruder, the film is gripped by special clamps on two continuous chains. In the stretching zone, the two chains move away from each other, and at the same time the distance between the individual clamps is increased, resulting in a biaxial stretching of the film.

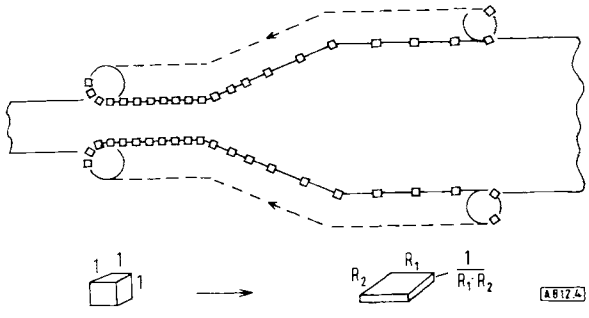

Fig. 4. Machine for simultaneous biaxial stretching of film. R_1 = stretch ratio "along", R_2 = stretch ratio "across".

The two-stage stretching unit is shown in Fig. 5. First, the film is stretched lengthwise on a series of rolls with increasing speed, then across in the second part of the machine. As in the simultaneous process, the film is gripped by two continuously moving chains with clamps. In the stretching zone, the chains move apart; the distance between the clamps, however, stays constant.

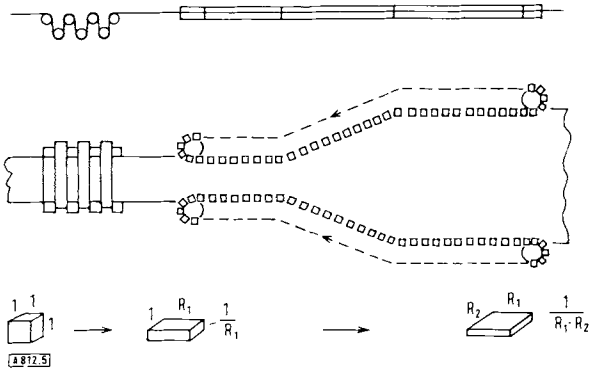

Fig. 5. Two-stage film stretching unit. R_1 = stretch ratio "along", R_2 = stretch ratio "across".

Apart from these methods of stretching cast film, there are also a number of methods for stretching blown film. Although it is possible to stretch blown film during extrusion and blow-up, the orientation achievable in the transverse direction is usually insufficient. The patent literature describes several procedures in which tubular film is stretched by blowing it up again after it has passed the nip rolls[3].

The process of stretching is expensive in each of the described variations. However, it improves the properties of the materials to such an extent that thinner films or less expensive raw materials can be used. Although the oriented film is weakened along a line perpendicular to its plane, this is not much of a disadvantage since the mechanical demands in this direction are rather small.

3.3. Properties

The differences in the mechanical behavior of cellulose paper and polymer films can best be seen in a stress/strain diagram (Fig. 6). Paper has a relatively low elongation at break, but a high tensile strength. The modulus of elasticity is also high, as can be seen from the slope of the stress/strain curve. Most papers have somewhat different properties in the machine direction (the direction in which the paper moves on the machine during fabrication) and in the cross direction. This difference arises from the preferred orientation of the cellulose fibers in the machine direction, which raises both tensile strength and tensile modulus as shown in Fig. 6.

Polymer films behave somewhat differently in the tensile test. After reaching a certain stress, the tensile yield stress σ_y, a plastic deformation takes place which is not recovered at room temperature. The tensile strength is frequently higher than the yield strength, but for comparison with paper the important property is the yield strength. Beyond it the film becomes permanently deformed, an intolerable condition for most applications. For the same reason, the relatively high elongation at break of the polymer films is of little use.

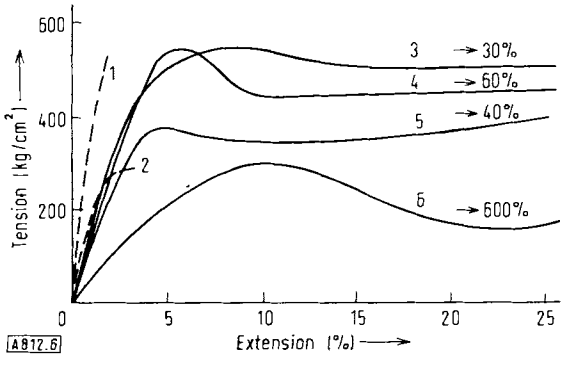

Fig. 6. Stress/strain diagrams of paper and polymer films: 1, paper (along); 2, paper (across); 3, high impact polystyrene (biaxially oriented); 4, polyvinyl chloride; 5, high impact polystyrene; 6, high density polyethylene.

Table 2 summarizes the important mechanical properties of those polymer films which are candidates for the preparation of synthetic paper. For comparison, two cellulose papers are included in this table. In spite of the structural differences between paper and extruded polymer film, the mechanical properties with the exception of the elongation at break are quite similar. It can also be seen that tensile strength and modulus of elasticity are improved considerably by biaxial stretching.

Table 2. Properties of extruded polymer film and cellulose paper.

	Density (g/cm^3)	Yield strength (kg/cm^2) DIN 53455	Elongation at break (%) DIN 53455	Young's modulus (kg/cm^2) DIN 53457	Tear strength (kg/mm) DIN 53363
Unoriented film					
High impact polystyrene	1.05	370	40	24000	1.3
High density polyethylene	0.95	300	600	10000	27
Polypropylene	0.90	320	650	12000	35

[a] MD = machine direction, CD = cross direction.

In contrast to cellulose paper, the polymer films are thermoplastic. They deform at elevated temperatures, especially if frozen-in stresses such as those present in stretched films provide a driving force for the deformation. This limits the applications involving high temperatures such as in copying machines. Upper service temperatures for the films listed in Table 2 range from 75 °C (polyvinyl chloride) to 120 °C (polypropylene). An advantage of the thermoplastic behavior is the possibility of melt sealing. By application of heat and pressure, films of the same or of different materials can be permanently bonded together.

With the exception of polyvinyl chloride, the thermoplastics in Table 2 are non-polar. They all have low water absorption, and do not change their properties in the presence of water. Because of the low water absorption, films made from these materials have a high dimensional stability. Depending on the moisture content of the air, cellulose paper absorbs varying amounts of water, which causes dimensional changes of up to two percent. This can be very problematic with multicolor printing, and with tracing paper. It is therefore necessary to store paper at a carefully controlled temperature and humidity if it is to be used for these applications. With films made from the above polymers this problem does not exist.

A disadvantage of the non-polar films is their tendency to acquire static charges, which can lead to difficulties in the printing process when the sheets are fed into the press. This can be overcome by adding suitable polar compounds of low molecular weight, or by post-treatment of the film, *e.g.* by application of a pigment coating. Fig. 7 shows the disappearance of electrostatic charges on films of high impact polystyrene (untreated, with antistatic additive,

and pigment coated). With the latter two, the charge quickly disappears; in this respect they resemble coated paper.

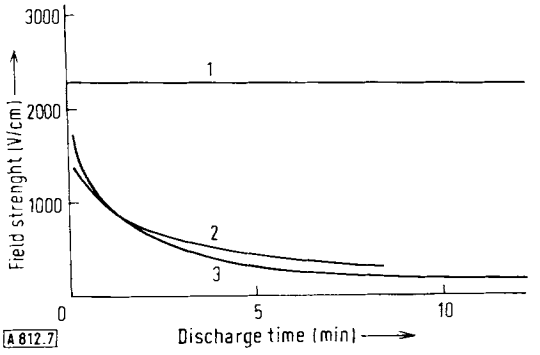

Fig. 7. Disappearance of electrostatic charges on polystyrene films: 1, high impact polystyrene; 2, high impact polystyrene with pigment coating; 3, high impact polystyrene with antistatic additive.

The optical properties of the polymer film depend on the raw material, the additives (*e.g.* pigments), and the fabricating conditions. With most thermoplastic films there are rather wide limits in which opacity, smoothness, and gloss can be adjusted. In contrast to paper, which frequently has a cloudy structure, the films can be made homogeneous. They are therefore better suited for the various photographic processes, provided they can stand the required temperatures.

3.4. Printing

Conventional printing inks and printing processes have been specially developed for paper since it has hitherto been the only printing substrate of significance. The synthetic fiber webs described in the first part of this article are very similar to paper in their structure, and it is generally possible to print or write on them by the usual methods. Not so with extruded films. These have a smooth surface which depends more on the state of the chill rolls than on the material itself. There are no cavities with capillary activity such as between the fibers of cellulose paper or synthetic fiber webs. This combination of smooth surface, low absorbing power, and non-polar structure frequently makes it difficult to print on polymer films: drying times are long, and the adhesion of the printing ink is poor.

In principle, these problems can be approached in two different ways. One can develop special printing inks for the polymer films, or one can treat the surface of the films to make it more receptive. The nature of the polymer as well as the selected printing process will determine which of the two approaches is more appropriate.

Commercial printing methods may be divided into two groups according to the printing inks used. The first group, comprising gravure and flexographic printing, is based on solvent-containing inks with low viscosity. Evaporation of the solvent leaves a film of pigment and polymeric binder; a porous surface is not required to absorb the ink. In the second group of printing methods, consisting of the letterpress and offset processes, paste inks made with linseed oil or similar drying oils are used. These inks do not dry by evaporation of a solvent, but by oxidative crosslinking of the unsaturated drying oil, a very slow process. Unless the printing ink can penetrate into the substrate, it will take a long time until the printed object can be handled. It is therefore necessary for the letterpress and offset printing methods to have a substrate with a porous surface, and polymer films must be modified accordingly.

One type of surface treatment to improve the printability is the application of a pigment coating. In the paper industry, the improvement of the surface of cellulose paper with a pigment coating has been known for some time. Typical binders for these coatings are casein, polyacrylates, or copolymers of butadiene and styrene. China clay, barium sulfate, chalk, or titanium dioxide are used as pigments. Coated papers are particularly well suited for art prints. In spite of their closed, smooth surface they are sufficiently absorptive for letterpress and offset printing because of their high content of mineral filler. Coated polymer films have similar properties; they can also be used for all printing processes, and the print quality is equal to that of coated papers.

Coatings for polymer films usually differ somewhat from those used for paper. The binders are the same, but less binder is used since it cannot penetrate into the film and is therefore fully available for the formation of the pigment coating. In some cases, particularly with polyolefins, the surface of the film must be oxidized by corona treatment or flaming to improve the adhesion of the coating. Conventional paper-coating machines can be used to apply the coating, but it may be necessary to modify the drying section because of the relatively low distortion temperatures of the polymer films.

There are also other methods through which the printability of film surfaces may be improved. In 1937, a patent was issued which describes a method to improve the printability of polystyrene through the action of solvents[4]. In the meantime, other patents have appeared[5-7] which are also concerned with the effect of solvents on polymer films. It is possible to produce porous surface layers which equal cellulose paper in their ability to absorb ink. Through variation of solvent and reaction time, one can adjust the depth of the porous layers as well as the pore size. Examples of possible applications of this method are shown in Fig. 8.

For gravure and flexographic printing it is not necessary to have a porous surface, since the printing inks dry through evaporation of the solvent. However, conventional printing inks, which were developed for paper, frequently adhere poorly to polymer films. This problem can sometimes be solved by the use of special printing inks. Another possibility is to increase the polarity of the polymer surface by oxidation, either with a corona discharge or by flame treatment. These methods have been used successfully for a number of years, especially with polyolefins. In practice, in-line units are used where the film is treated immediately after extrusion. Ink adhesion can also be improved by mechanical grinding which roughens the surface and enlarges the surface area.

Thus, in principle, all polymer films can be printed on, either with special printing inks or after surface treatment. If the proper method is selected, the polymer films equal or surpass cellulose paper in ease of printing and print quality.

3.5. Commercial Products

Extruded polymer films have been commercially available for some time, unoriented as well as biaxially oriented. Films specifically developed for use as synthetic paper, however, have only been marketed in recent years. The first product of this type was produced by Union Carbide Corporation under the trade name Ucar®. It is a film made from high density polyethylene with a high pigment content; similar products have more recently appeared under the names of Acroart® and Polyart®. Most of the recent developments of paper-like films come from Japan[8–10].

Table 3. Commercially available synthetic paper made by extrusion.

Name	Producer	Raw material	Printability through	Applications
Q'Kote®	Japan Synth. Paper Co.	polystyrene	pigment coating	art printing
Q'Per®	Japan Synth. Paper Co.	polystyrene	solvent treatment	writing and printing
Printel S®	Sekisui Chemical Co.	polystyrene	pigment coating	art printing
Ucar®	Union Carbide Corp.	HD-polyethylene	pigmentation	art printing
Acroart®	Mead Paper Corp.	HD-polyethylene	pigmentation	art printing
Polyart®	Bakelite-Xylonite Ltd.	HD-polyethylene	pigmentation	art printing
Finoplas®	C. K. Addison Ltd.	HD-polyethylene	pigmentation	tissue paper
HM-Folie®	Farbwerke Hoechst	HD-polyethylene	pigmentation	tissue paper
Tissuethene®	MGS Plastics Ltd.	HD-polyethylene	pigmentation	tissue paper

They are predominantly pigment coated biaxially oriented films made from high impact polystyrene (Q'Kote® and Printel S®) or solvent-treated films made from polystyrene (Q'Per®). Table 3 summarizes the most important commercial products; completeness is not claimed.

The cost of paper made from polymer film is still considerably (50–150%) higher than the corresponding cellulose paper[8], mainly because of the higher cost of the raw materials. It can be expected, however, that the more rapidly rising cellulose prices will change this situation in favor of the paper made from polymer film.

4. Applications

4.1. Packaging Materials

The rapid developments in the packaging field in the past few years have led to an increasing competition between packaging made from paper and from plastics. Important factors for using plastics are their complete indifference toward moisture, the availability of different degrees of transparency, and their resistance toward bacteria. A more recent application in the packaging field, in which the paper-like quality of the polymer films is more apparent, is synthetic tissue paper[11]. These extremely thin films, used mostly for wrapping flowers, shoes, and textiles, are made from high density polyethylene *via* the blown film technique. In feel and appearance they are quite similar to tissue paper made from cellulose. Since there is usually no need to print on them, a special treatment of the surface is not necessary.

Foamed film made from polystyrene has found acceptance for the packaging of eggs, meat, and fruit; it is also used for the production of drinking cups. Apart from its excellent thermal insulation and shock absorbing qualities, this film has the advantage that it can be given the desired shape by deep drawing.

4.2. Printing Substrates

By far the most interesting application of synthetic paper is as substrate for printing. It is simply a matter of price that has prevented its reaching greater economic significance in this area. Since all synthetic printing substrates, fiber webs as well as extruded films, are still considerably more expensive than cellulose paper, they are used only in applications where their special properties are needed and where they can command a higher price.

Synthetic fiber webs, the most expensive of the synthetic papers, are distinguished by their high tear strength, high folding endurance, resistance to yellowing, and high wet strength. Brochures of the manufacturers mention maps, identification papers, tags, and similar items as possible applications.

Extruded films for use as printing substrates have been available only for a short time. Because of several desirable properties, they have already found a number of applications. Their excellent dimensional stability makes them suitable for computer cards, recording paper for instruments, and other uses where constant dimensions are important. They can also be made with good transparency, which suggests their use as tracing paper.

5. Prospects

The technical problems in fabricating synthetic paper and making it printable have largely been solved. Further developments will deal mainly with the optimization of existing processes and with the reduction of costs by using larger production units. A problem which still remains to be solved is the disposal of synthetic paper waste. Waste cellulose paper is used to a large extent for the production of cheaper grades of paper and cardboard. Reusing synthetic paper will be difficult since it not only must be separated from cellulose paper, but also must be sorted according to the type of polymer used, such as polystyrene, polyethylene, *etc.* The only practical solutions may be combustion or deposition with solid refuse.

Of great interest, not only to the paper manufacturers, but also to the producers of the thermoplastic polymers is the potential share of the synthetic paper in the paper market. The only prognosis available comes from Japan. A much cited publication of the Resources Investigation Council, Science and Technology Agency[12] gives the figures shown in Table 4.

Table 4. Estimated share of synthetic paper in the total consumption of paper in Japan [12].

Application	1973		1978	
	Share (%)	Amount (10^3 t)	Share (%)	Amount (10^3 t)
Packaging	13	91	33	290
Cardboard	3	115	25	1480
Printing paper	3	42	23	420
Tracing paper	9	12	46	100
Others	6	36	30	230
Total		296		2520

The basis for this Japanese prognosis is the increasing shortage of wood and the ensuing increase in the price of cellulose, as compared to constant or even slightly falling prices for plastics. It is also assumed that the cost of manufacturing synthetic paper can be decreased by improvements in the processes and by large scale production. The combination of these factors, according to the above

forecast, will bring the price of synthetic paper close to that of cellulose paper.

The realization of the above figures for the production of synthetic paper would require not only a tremendous increase in the capacities for the production of thermoplastics, but also for the starting materials benzene, ethylene, and propylene. It would also require an acceptable solution to the disposal problem.

The question arises as to how far the Japanese prognosis can be applied to other countries. Regrettably, similar studies for Europe or America do not exist. However, it seems likely that, at least initially, synthetic paper will play a much smaller part in these areas. Cellulose prices are generally lower than in Japan, and there has been no development effort of comparable intensity. For most applications, synthetic paper will be too expensive, even if the still uncertain question of its cost is interpreted optimistically. Only the future can tell whether synthetic paper will find a substantial share of the market in some special applications.

We are indebted to Dr. H. Hendus for the stereoscan pictures.

Synthesis of Heterocyclic Ring Systems for Heat-Resistant Plastics from Polyisocyanates

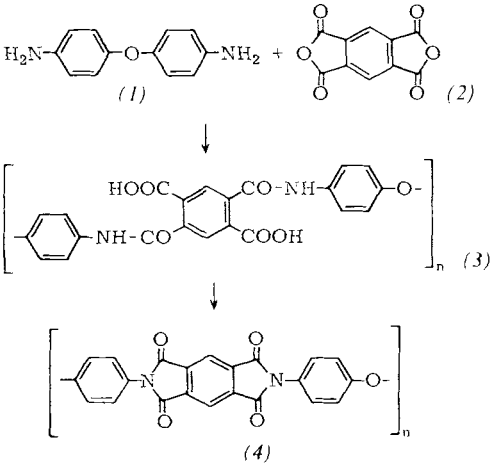
By Rudolf Merten[*]

Investigations on space flight and rockets carried out in particular in the United States have aroused great interest in plastics with enhanced thermal stability. It has become possible to pass far beyond the expected limits of thermal stability with organic plastics, and to synthesize plastics and polymers that can be used at temperatures between about 200 and about 500 °C, a range that formerly appeared to be the exclusive province of inorganic materials.

1. Introduction

The thermal stability of organic compounds is largely determined by the basic structural units. Polymers with recurring heteroaromatic units are extremely stable to heat, especially when these rings are fused to other aromatic systems. However, this structural feature is not essential for high thermal stability, as will be shown below.

The expression "heat resistance of plastics" can be construed in various ways. It may be taken to mean that the melting or softening point is high (above about 250 °C), that the decomposition point is high, or that a high stability up to high temperatures is found in differential thermal analysis or in thermogravimetric investigations. On the other hand, the mechanical and physical properties of plastics both after brief exposure to high temperatures and after prolonged aging are vital to their practical use (see Section 6). Reviews on these general questions have been published[1, 2].



The present progress report will deal with syntheses of heat-resistant plastics from polyisocyanates, with particular reference to practical applications in the field of electrical insulation.

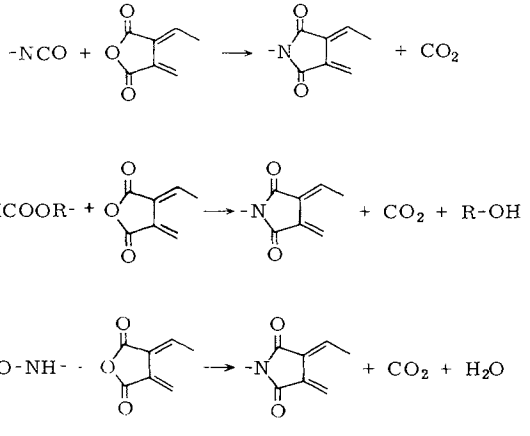
Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG
509 Leverkusen-Bayerwerk (Germany)

2. Polyimides

The first important contribution in the field of polymers with enhanced heat resistance was the polypyromellitimides, which were developed primarily by Du Pont. Pyromellitic dianhydride *(2)* reacts with 4,4'-diaminodiphenyl ether *(1) via* polyamidecarboxylic acids *(3)* to form polypyromellitimides *(4)*, which have found extensive use in various forms (Capton H as a film, Pyre ML as a paint component, and Vespel as a plastic).

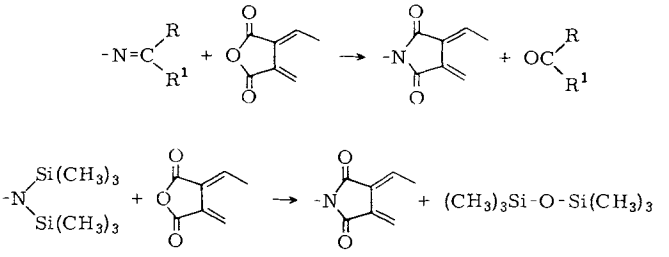
The difficulties associated with the synthesis of such plastics in practice are evident even in this system. Because



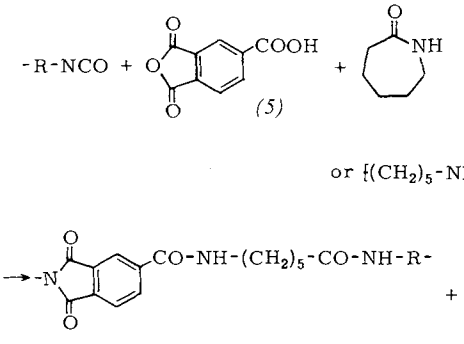
(1) *(2)* *(3)* *(4)*

of their high softening points (above 250 °C), these plastics can be processed by the methods used for thermoplastics only under very special conditions. Processing as solutions is more generally applicable, but this usually necessitates the use of precursors. The final polymers are practically insoluble in common industrial solvents; solubility in *e.g.* concentrated sulfuric acid or chlorosulfuric acid is of little practical interest.

Since the service properties, particularly the elastic behavior, are satisfactory only for products with high molecular weights, these precursors must be capable of being condensed to a sufficiently high degree; this is a problem that can often be solved only by expensive and complicated purification operations. Thus polypyromellitimide *(4)* is always converted into the final polymer only after molding in the amidecarboxylic acid state *(3)*. This presents complications because of the poor hydrolysis resistance of the intermediate *(3)* [and water is eliminated in the cyclization to form *(4)*] and because of the necessary purification of the starting material. Another disadvantage, the seriousness of which varies according to the field of application, is the rather high wastage rate during further processing, *e.g.* for film material, since the material is practically insoluble after cyclization.



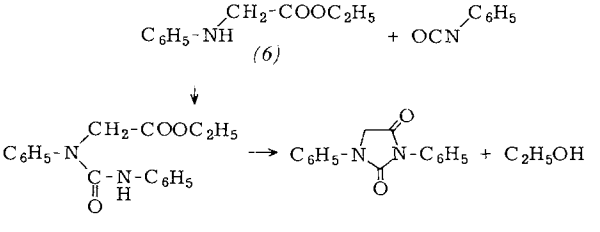
The use of "masked" amines offers considerable advantages in the synthesis of polyamide systems. Such "masked" amines are all less basic than the parent substance, and can be obtained more readily in the pure state. Moreover, they react much more slowly with the anhydride groupings, thus making stepwise reaction possible. Another advantage in some cases is the elimination of inert, volatile by-products, which cannot interfere with the reaction (see Section 6.2).



R = Aryl, Alkyl

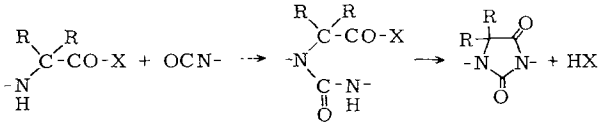
The most interesting variants of the "masked" amines are the isocyanates[3]. They react with an anhydride grouping with elimination of carbon dioxide as an inert component to form the imide; the reaction is readily controlled between 120 and 200 °C. Instead of the free isocyanates, compounds that react as isocyanates only at high temperatures and that may allow further variation of the course of the reaction in combinations can be used with equal or in some cases better success. Examples of such compounds are *O*-aryl and *O*-alkyl esters of carbamic acids or the ureas from which the isocyanates are derived.

Instead of as isocyanates, the amines can also be used in the form of aldimines or ketimines[4] or as *N,N'*-bis(trimethylsilyl)derivatives[5]. The condensation with the anhydrides proceeds with elimination of oxo compounds or of hexamethyldisiloxane.



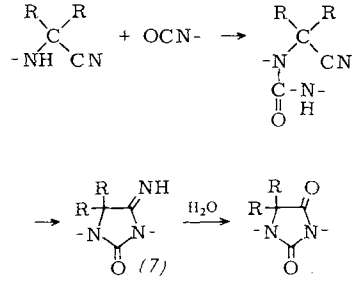
The above methods can be used to make a desired polymer containing imide groups while providing for further variation by incorporation of additional functional groups. The pure polyimides (obtained from pyromellitic acid), the polyamide-imides (from trimellitic anhydride), and such polymers modified by introduction of ester groups appear of especial interest. A variant of particular industrial significance results on use of caprolactam and its polymers in condensations between anhydrides and isocyanates or "masked" isocyanates[6]. The overall reaction is shown for trimellitic anhydride *(5)*.

3. Polyhydantoins



In the polyimide plastics and the other known heat-resistant systems, the heterocyclic units always possess aromatic character, and are also fused to aromatic systems. However, nonaromatic systems can also have high thermal stabilities, as we have been able to show in particular for polyhydantoins.

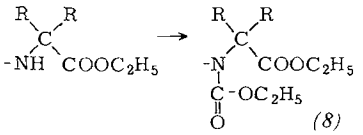
Several methods are now known for the synthesis of polyhydantoins[7,8]. Apart from the polymerization of *N*-vinylhydantoins[9], the addition of HCN to diisocyanates[10], and condensation of bishydantoins with formaldehyde[11],



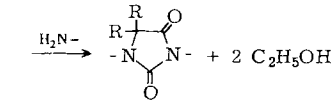
the reaction of *N*-phenylglycine esters *(6)* with phenyl isocyanate, which was described in principle by *Wheeler* and *Hoffman*[12] in 1911, now plays an important part[7, 8].

This reaction is of a general nature, and can be used for the synthesis of polymers from polyfunctional glycine esters and polyfunctional isocyanates (or their derivatives).

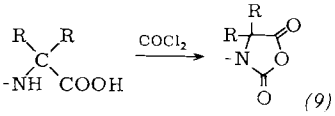
X = OCH_3, OC_2H_5, $N(CH_3)_2$, NH_2, OH



A variant of this method is the reaction of glycinenitriles with isocyanates[13]. The ureas obtained cyclize to form "iminohydantoins" *(7)*, which afford the hydantoins on hydrolysis. This path is particularly suitable for the preparation of low molecular weight hydantoins, which then react by means of functional groups to form polymers.

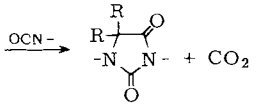


(7)

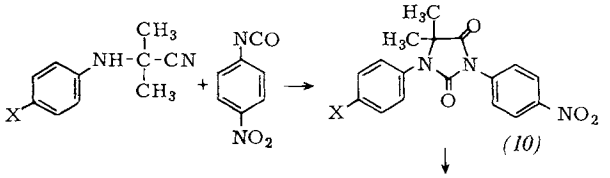


Further possibilities for the synthesis of the hydantoin ring are offered by the use of glycine-*N*-carboxylic acid derivatives, *e.g.* the esters *(8)*[14] and the anhydrides *(9)*, which also react with amines and isocyanates to give hydantoins. However, the last two methods have proved to be less suitable for the synthesis of high molecular weight compounds, since the polyfunctional starting materials are too difficult to obtain in the pure state.

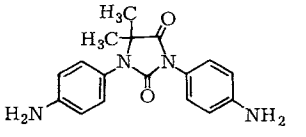
The above methods have been used for the preparation of many monomers and oligomers containing other reactive groupings, which allow the formation of polymers, besides



(8)

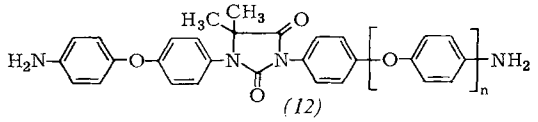


(9)



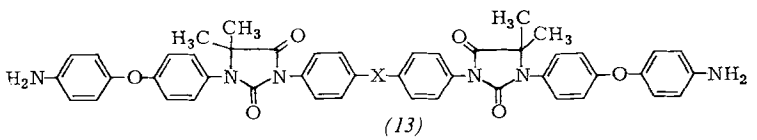
the hydantoin groups. Several possibilities of this type are indicated in the following formulas and in Scheme 1 (see also[13, 15]).

(10)



(10a), X = H; m.p. 214-215 °C
(10b), X = NO_2; m.p. 228-230 °C
(11) m.p. 279-280 °C

(11)



Other functional groups can be introduced *via* the isocyanates, *e.g.* by the use of isocyanates that also contain ester groups, unsaturated groupings, or even additional isocyanate groups.

Another variant of the preparation of oligohydantoins containing functional groups begins with esters of aspartic acid. Primary amines add smoothly to maleic and fumaric esters to form aspartic esters *(15)*; subsequent reaction with (poly)isocyanates again yields hydantoins containing ester groups. Polyfunctional derivatives are obtainable, *e.g. via* polyamines or polyisocyanates[16].

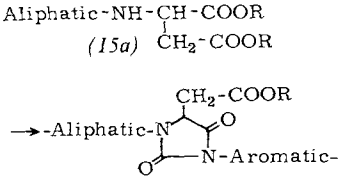
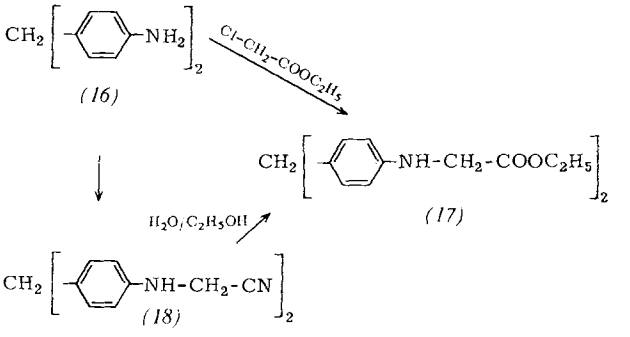
Scheme 1. Examples of heat-resistant oligohydantoins.

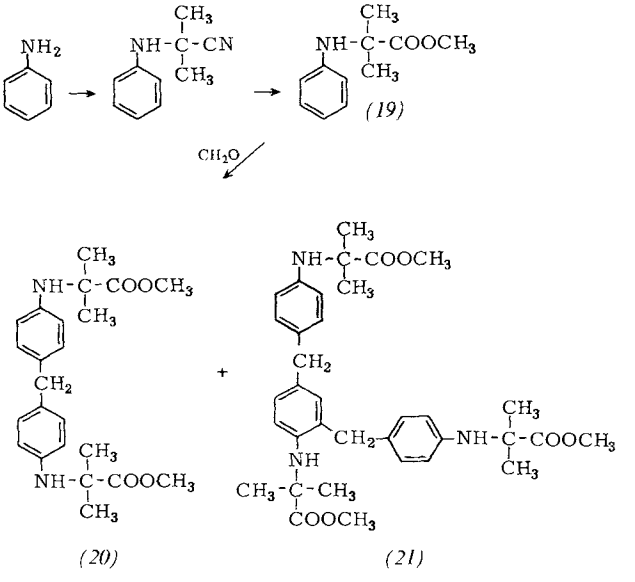


The synthesis paths described lead to more or less high molecular weight compounds containing hydantoin rings, which also contain functional groups that allow conversion into more highly polymeric systems. Polyamides and polyimides can be prepared in this way from these "oligohydantoins" containing free amino groups (*e.g.* with isophthaloyl chloride or pyromellitic dianhydride). Phosgenation of the aminooligohydantoins leads to polyfunctional isocyanates, which can be made to react further by the methods of polyurethane chemistry. Oligohydantoins containing carboxylic acid groups can be modified by esterification or aminolysis. Unsaturated compounds of this series can be homopolymerized or copolymerized.

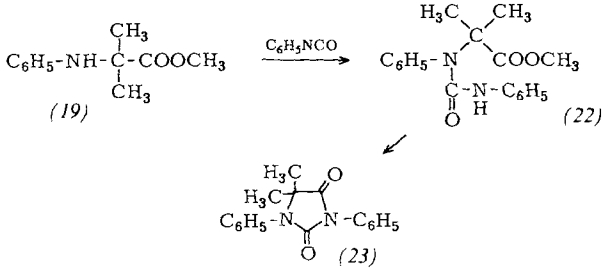


Polyhydantoins can also be obtained by a polymer-forming reaction of the addition-condensation type involving the reaction of compounds containing at least two glycine ester groups with polyisocyanates.

Two particularly useful methods for this purpose are the reaction of maleic (fumaric) esters with diamines and diisocyanates and the reaction of aromatic bisglycine esters with polyisocyanates.



The first method leads in the most favorable case to mixed aliphatic-aromatic polyhydantoins, whose heat resistance is reduced by the aliphatic components. (It is difficult to obtain sufficiently high yields in industry when aromatic diamines are used in the addition reaction, since these compounds do not add readily.) However, the method is fascinating in its simplicity. The amine component is added dropwise to the maleic ester in cresol; after the addition to form *(15a)*, the aspartic ester derivative, the diisocyanate is added and the compounds are condensed at the boiling point of cresol. The resulting solutions of polyhydantoin in cresol can be used directly for the preparation of electrically insulating varnishes with softening points above 330 °C.



The addition of diisocyanate to aromatic bisglycine esters leads to polyhydantoins with exclusively aromatic linkage. The starting compounds can be prepared by well-known methods; aromatic diamines *(16)* react with chloroacetic ester in the presence of bases such as $CaCO_3$ to form bisglycine esters *(17)*. The same compounds can be obtained by Strecker synthesis *via* the nitrile *(18)*, with subsequent hydrolysis.

Polyglycine esters derived from bis(aminophenyl)methane, such as *(20)*, can also be obtained from aniline *via* anilinoisobutyric ester *(19)* by condensation with formaldehyde. The simultaneously formed trisglycine esters *(21)* may be useful in the preparation of branched or crosslinked polyhydantoins.

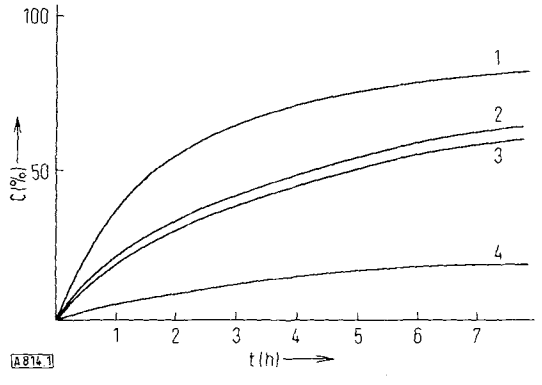
Difficulties arise in the reaction of glycine esters with isocyanate, since the amino group in the glycine ester reacts only slowly with the isocyanate. Moreover, it is necessary to avoid the cyclization of the urea intermediate *(22)* before the addition is complete, since there is otherwise a possibility of a competitive reaction with the liberated alcohol to form urethane. The desired molecular weights of *e.g.* more than 15000 for lacquer components and more than 25000 for films require 96 and 98% definite reaction, respectively, between the two components. These problems have been solved by the choice of catalyst and reaction medium.

(19) *(22)* *(23)*

The system phenyl isocyanate/anilinoisobutyric ester *(19)* was used for kinetic investigations. The results show that the usual views on the catalysis of isocyanate reactions are inapplicable (Table 1 and Fig. 1).

Table 1. Conversion of phenyl isocyanate in the reaction with methyl anilinoisobutyrate *(19)* (5 hours, 20°C, in dichloromethane) on addition of 1 mole-% of catalyst (in 1 N solution).

Catalyst	Conversion (%)	Catalyst	Conversion (%)
none	17	BF_3-ether	43
Iron(III) chloride (sublimed)	15	Phenol	62
		Formic acid	49
Boric acid	16	Acetic acid	88
Trifluoroacetic acid	21	Propionic acid	87
p-Toluenesulfonic acid	39	Benzoic acid	85



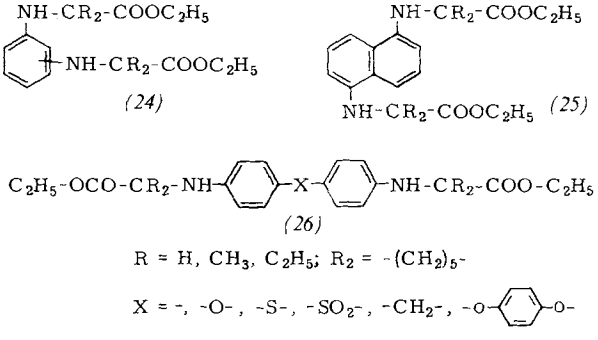


Fig. 1. Conversion of phenyl isocyanate in the reaction with methyl anilinoisobutyrate *(19)* (20°C, in dichloromethane) on addition of 1 mole-% of catalyst (in 1 N solution).
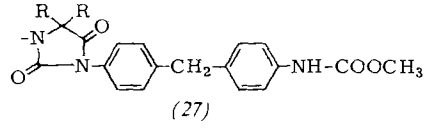
Catalysts: 1: acetic acid; 2: 1,4-diazabicyclo[2.2.2]octane; 3: phenol; 4: none.

A reasonable catalytic effect is observed only when compounds of "medium acidity" (carboxylic acids, phenols) are used, and this effect is sufficient only when these compounds are used as solvents. Because of the tendency toward ring closure when basic substances are used, as well as the side reactions of NCO groups in the presence of carboxylic acids or amines, phenols are practically the only "active" solvents left. The condensation reactions to form the aromatic polyhydantoins in the production of polymers are thus best carried out in phenol or cresol, particularly since the polymers are readily soluble in these solvents (they are not very soluble in other solvents, apart from CH_2Cl_2 and similar compounds).

With the aid of these precautions, numerous polyhydantoins have been prepared from polyglycine esters such as *(24)*, *(25)*, and *(26)* with polyisocyanates[17], and heterocycles may also be fused on[18].

By means of the methods described earlier for the introduction of functional groups, it is possible to prepare polymers having definite molecular weights and containing functional end groups, *e.g.* with urethane groups, ester groups, or polymerizable olefinic groups [by the use, either alone or otherwise, of more than or less than the equivalent molar



(24) *(25)*

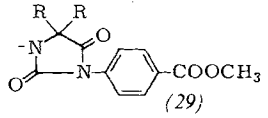
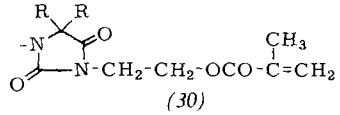
X = -, -O-, -S-, $-SO_2-$, $-CH_2-$, -o--o-

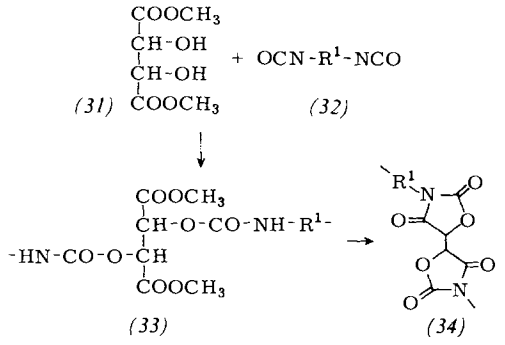


quantity of isocyanates, esters of isocyanato acids, or isocyanatoolefins; examples are *(27)–(30)*], which can then be condensed further or crosslinked by means of these functions, *e.g.* on application of the lacquer.

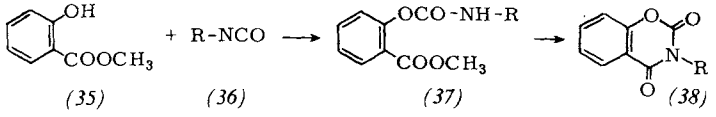


(27)

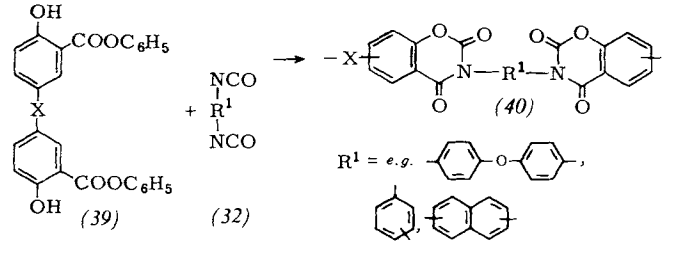
(28)



(29)



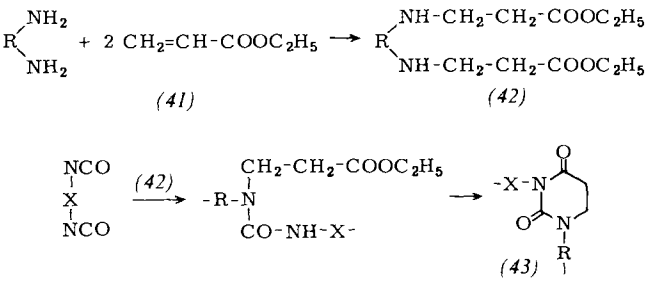
(30)

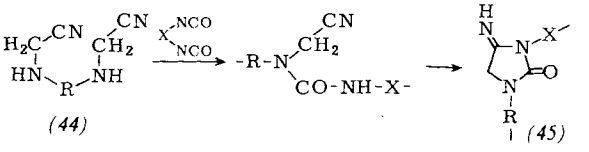


4. Polyoxazolidinediones, Polyquinazolinediones, and Polybenzoxazinediones

Instead of α-amino acids, esters of α-hydroxy acids can also be used for the preparation of heterocyclic polymers. The reaction of a tartaric acid ester *(31)* with a diisocyanate *(32)* can be used to obtain the polyoxazolidinedione *(34)* *via* the urethane intermediate *(33)*[19].

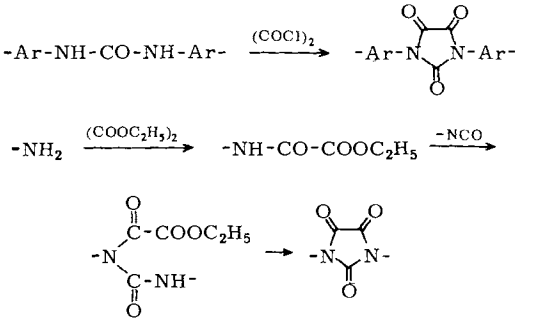
A similar reaction sequence can be applied to homologous systems in the aromatic series and used for the preparation of polyquinazolinediones[20] and polybenzoxazinediones such as *(40)*[21]. In this case, the heterocycles are condensed with an aromatic system, and the expected high heat resistances are obtained. Out of several methods that are available for the preparation of this class of substances, the reaction of an *o*-hydroxy acid ester *(35)* with an isocyanate *(36)* is particularly interesting; it leads to the benzoxazinedione *(38) via* the *O*-arylurethane *(37)*, which cannot always be isolated. The application of this reaction to polyfunctional *o*-hydroxy acid esters, such as the phenyl esters of methylenedisalicylic acid, 4,4'-dihydroxybiphenyl-3,3'-dicarboxylic acid, or 2,5-dihydroxyterephthalic acid [generally obtainable by Kolbe syntheses from phenols], *e.g.* *(39)*, and polyisocyanates such as *(32)* yields the polybenzoxazinediones *(40)*. The reaction is carried out in polar solvents such as dimethyl sulfoxide, generally with amine catalysts. On elimination of phenol, the polymer *(40)* can be isolated directly, *e.g.* by precipitation.





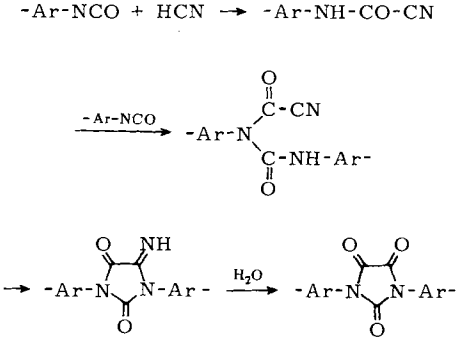
The final polymer can be *e.g.* cast from solutions in polar solvents such as dimethylformamide and dimethyl sulfoxide to form films, the solubility of which depends on the starting components.

5. Polydihydrouracils and Polyiminoimidazolidinones



The addition of acrylic esters *(41)* to polyamines followed by addition of polyisocyanate yields polydihydrouracils *(43)*. The results of such condensations were described in detail by *Dyer* and *Hartzler*[22]. These authors[22] have also

reviewed the synthesis of polyiminoimidazolidinones by reaction of polyfunctional α-amino nitriles *(44)* with polyisocyanates.



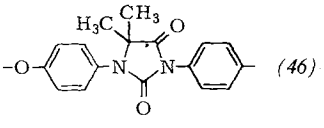
Also of interest are polymers containing parabanic acid linkages (polytriketoimidazolidines). They can be prepared by a variety of methods, *e.g.* by reaction of polyureas with oxalyl chloride[27] or by a route resembling the synthesis

of polyhydantoins from amines, diethyl oxalate, and isocyanate *via* an oxamic ester intermediate[28].

Furthermore, polyparabanic acids may also be prepared from polyisocyanates and hydrocyanic acid[29] in aprotic solvents and in the presence of cyanide ion as catalyst. The reaction proceeds *via* "iminoparabanic acid" intermediates.

6. Applications

6.1. Electrical Insulators



The possible uses of the heterocyclic systems mentioned will merely be outlined. Table 2 gives values[21, 23] for properties that are important in electrical insulators.

Table 2. Properties of heat-resistant plastics.

Product	Softening point (°C)	Heat shock [a] (°C)
Polypyromellitamide-imide	380–400	300
Polyhydantoin	380–400	280–300
Ester-imide (depending upon imide content)	285–360	180–260

[a] Heat shock (Brit. Standard 3160 5e, USA Standard C 9100 1968): A specimen of the coated wire is wound around a mandrel having the same diameter as the wire and heated for $^1/_2$ hour in order to determine the temperature at which no cracking occurs.

Polyhydantoins can also be used as insulating films, the advantages here being in the use of halogenated hydrocarbon solvents (methylene chloride). The hydantoin ring is resistant to temperatures up to 400 °C; to meet the requirements for insulating films, the hydantoin rings must be joined by heat-resistant and oxidation-resistant links. A group that has proved useful for this purpose is the 4,4'-disubstituted diphenyl ether residue, which leads to repeating units such as *(46)*. The same is true of polybenzoxaziniediones, which are sufficiently soluble to be processed in polar solvents such as dimethylformamide.

(46)

Long-term heat resistance tests lead to values between 165 and 180 °C, the polybenzoxaziniediones falling near the upper limits; polypyromellitimide (Capton H) withstands 210–250 °C. The dielectric and mechanical properties of both classes are practically constant up to temperatures far above 200 °C.

Experimental details in connection with the possibilities described may be found in the literature cited.

6.2. Heat-Resistant Foams

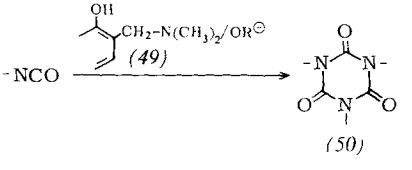
As was mentioned earlier, foamed plastics with high softening or melting points are gaining in importance, particularly since these products are all incombustible or nearly so.

The reaction of anhydride groupings and carboxylic acid groups with isocyanate groups (see Section 2) proceeds with liberation of carbon dioxide, which can in some cases be used as the blowing agent for the polymer being formed[24]. For example, by heating a mixture of trimellitic anhydride and diphenylmethane diisocyanate to about 200 °C, it is possible to start a slightly exothermic reaction, which leads to a foam containing amide and imide groupings. These foamed plastics have high thermal stabilities and are practically incombustible. The difficulty in this process for the production of imide foams lies at present in the high initiation temperature and the heat evolved, which makes the reaction difficult to control on a large scale.

Polyisocyanurate foams, *i. e.* foams consisting essentially of isocyanurate rings linked by aromatic structures, are more favorable in practice.

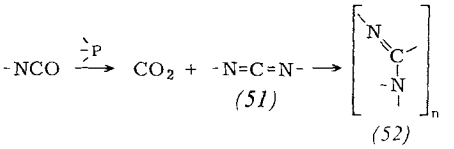
A rigid polyurethane foam is generally prepared by reaction of an isocyanate with a polyalcohol to form a urethane grouping *(47)*. The foam structure is produced by addition of low-boiling foaming agents such as chlorofluoromethane. In exceptional cases even water may be used; the product then contains urea structures *(48)*. Since the reaction leading to the urethane grouping *(47)* is reversible, the

(47)



heat stability of the resulting foams is limited because of decomposition into the polyol and the isocyanate (or its reaction products). Moreover, the resulting low molecular

(48)



weight fragments and their decomposition products make the polymer combustible. The polyol component plays a particularly important part in this respect.

These difficulties do not arise with the isocyanurate foams, which are obtained by polymerization of the isocyanate to form trimeric structures *(50)*. Despite the pronounced branching, the polymers are relatively elastic, owing to the absence of hydrogen bonds. In addition to this isocyanurate formation, there is some conversion of the isocyanate groups into carbodiimides *(51)*, which are converted more

(49)

(50)

(51)

(52)

or less rapidly into cyclic and linear polymerization products *(52)*. This last reaction contributes to the foaming process, and cannot be reversed by heat. Thus no decomposition into monomeric or low molecular weight fragments is possible when these foamed plastics containing isocyanurate and carbodiimide groups are heated. Though the isocyanurate formation is reversible at relatively high temperatures (250–300 °C), the resulting isocyanates evidently lose carbon dioxide under these conditions to form the carbodiimides and their reaction products, so that the polymer structure is retained.

The production of polyisocyanurate foams of this type requires the use of special catalysts[25]. These should initiate the polymerization even at room temperature without an incubation period, and the temperature coefficient of the reaction rate should be as low as possible. The foaming is also carried out in this case with the foaming agent (chlorofluoromethanes), which should evaporate slowly and uniformly. Several groups of catalysts are avail-

able, including alkali metal phenoxides and alkoxides or compounds such as *(49)* containing an *o*-dimethylaminomethylphenol grouping. The formation of carbodiimide groups can be catalyzed in the conventional manner[26] by phosphorus compounds, so that it is possible, by choice of the catalysts, to cause both reactions [with formation of *(50)* or *(52)*] to occur together.

Small quantities (5–20%) of high molecular weight polyols must sometimes be used as "internal plasticizers" to achieve adequate elasticity. However, these appreciably lower the softening points of the polymers obtained, and also increase their combustibility. The formulations are strongly dependent on the intended use (possible uses include insulating materials and building materials). The thermal stabilities attainable with various systems are indicated in Table 3.

Table 3. Hot bending strength of heat-resistant plastics according to the German Industrial Standard DIN 53424.

Product	Hot bending strength (°C)
Polyurethane	110
Polyurethane on cane sugar basis	110–130
Polyisocyanurate foam	
containing 10% of castor oil	190–210
containing 5% of castor oil	220
containing no additives	250

Some Aspects of Chemical Mutagenesis in Man and in Drosophila

By Günter Obe, Karl Sperling, and Hans J. Belitz[*]

Since mutations produced by chemicals are, like spontaneous mutations, generally transmitted by recessive factors, i. e. as they are only expressed after several generations, depending on the circumstances, it is extremely difficult to trace the true cause of such mutations, which are almost always unfavorable. However, it is possible to study the mutagenic action of chemicals in test systems, e. g. in Drosophila in vivo or in human chromosomes in vitro. Alkylating agents which damage DNA indirectly have a particularly severe mutagenic action. The present progress report contains, among other things, a comprehensive list of substances that produce aberrations in human chromosomes.

1. Introduction

To the geneticist the term "mutation" means changes in the genotype. Mutations occur spontaneously in all organisms, and those in the gametes can be transmitted to the descendants. The capacity to undergo mutation is an inherent property of genetic material, including both the genes themselves and also the chromosomes on which the genes are arranged linearly in a certain order. The significance of mutations can be considered from several aspects:

The individual development of an organism is "self-controlled", and its detailed construction is defined by genetic information in the DNA. Ontogenesis can thus be regarded as translation of the genetic code into the form of a living creature. However, the relationship of the living creature to its environment is also important if the significance of the capacity of organisms to undergo mutation is to be understood. It is only the environment that makes life possible, and at the same time it sets certain limits to the development of living creatures. The genes determine the normal response of an organism to its environment, and thus its capacity for some degree of adaptation to this environment. The adaptation of organisms is the result of their historical development and is based essentially on the effect of two evolutionary factors, the mutability and selection. The members of a species which inhabit a certain environment and thus belong to a reproducing community are called a population.

The individual members of a population certainly do not have the same genetic make-up, although they all have the same number of chromosomes and the same number of genes in each body cell. This apparent contradiction can be explained in the following way: an ovum capable of reproduction contains one set of species-specific chromosomes, it is haploid; the same applies to the male gamete (the spermatozoon). After fertilization the diploid zygote is formed, which thus contains a homologous set of paternal and maternal chromosomes. The diploid organism develops from the zygote in the course of normal cell divisions (mitoses). The haploid gametes are formed again in the gonads by reduction division (meiosis).

[*] Dr. G. Obe, Dr. K. Sperling, and Prof. Dr. H. J. Belitz
Institut für Genetik der Freien Universität
1 Berlin 33, Arnimallee 5–7 (Germany)

In man and *Drosophila* the females have two homologous X-chromosomes, while the males have one X-chromosome and the morphologically and genetically different Y-chromosome (sex chromosomes). The other chromosomes (autosomes) are the same in both sexes (Fig. 3).

Each autosome has a set of genes, which corresponds to the set of its homologous partner chromosome. However, two homologous genes do not have to be exactly the same. If the sequence of the purine and pyrimidine bases in the DNA of a gene is changed, then the function of this gene can be modified to a certain extent or it can even be made impossible. Such changes are recorded by the geneticist as gene mutations.

The different forms a gene can take are termed alleles. In diploid cells each gene locus is represented by two alleles. If both alleles are identical (homozygous), then their external characteristics become fully developed, *i. e.* their phenotype is shown completely. However, if they are different (heterozygous), then there are several possible ways their characteristics can be expressed. New gene mutations are as a rule recessive, *i. e.* their phenotypic effect is not produced in the heterozygous state. Recessive mutations in the X-chromosome of the male sex are exceptions to this rule. There is no normal allele accompanying a mutated allele in the X-chromosome, and thus the mutations can be expressed phenotypically "in a single dose". Dominant mutations also show their phenotypic effects in the heterozygous state.

Most mutations in the homozygous state decrease the viability of their bearer, very many act as lethals and lead to death, and only very few produce an improvement. This is understandable when one considers that the mutation process is random and that each change occurring by chance in a system that is generally optimally adapted to its environment is more likely to lead to a deterioration rather than an improvement. As a result of selection, the bearers of viability-depressing alleles are eliminated or they have a reduced probability of reproducing themselves. In this way the frequency of harmful alleles in natural populations is generally low.

If a new mutation has certain advantages, its bearers have a greater probability of reproducing themselves than normal members of their species. The new allele is favored by selection; its frequency increases from generation to gene-

ration, and finally the allele from which it developed is completely eliminated.

In addition to the above-mentioned gene or point mutations, there are chromosome mutations which also play an important role; three types of these must be briefly discussed here.

The term deletion is used for the loss of a chromosome segment

ABCD → ABD

As a rule the loss of such a segment (here segment C) is lethal.

The same applies to the replacement of parts of chromosomes by nonhomologous chromosomes (translocation):

ABCD + EFGH → ABGH + EFCD

In another type of chromosome mutation a section of a chromosome is inverted through 180° to its normal position (inversion):

ABCD → ACBD

Inversions are more frequently found in natural populations than the other aberrations mentioned above.

Disturbances in the course of mitosis or meiosis can cause an irregular distribution of the chromosomes in the daughter cells. Cells with a different number of chromosomes (aneuploids) are thus formed, which as a rule disturbs the gene balance. An aneuploidy occurring spontaneously in man is the trebling (trisomy) of the small chromosome no. 21 (cf. Fig. 7), associated with Down's syndrome (mongolism).

Another type of mutation, widely distributed in plants, is the multiplication of the diploid number of complete chromosome complements (polyploidy). Polyploidy does not play any great role in the animal kingdom.

The well-known works of *Muller*[1], *Auerbach*[2] and *Oehlkers*[3] have shown that both X-rays and chemicals can produce a drastic increase in the frequency of spontaneous gene and chromosome mutations. These discoveries resulted in the development of two extensive areas of research, radiation genetics and chemogenetics.

Some results will now be reported which it was possible to obtain in a genetic and a cytological test system used to investigate the mutagenic effects of chemical substances. The test systems will first be described in greater detail in the following sections.

1.1. Drosophila melanogaster

The classical tool used in mutation research is the fruit fly *Drosophila melanogaster*, on which *Muller*[1] demonstrated the mutagenic effect of X-rays in 1927. *Muller*, who was a master in developing special strains, used at that time the famous ClB strain to demonstrate sex-linked (*i.e.* situated on the X-chromosome) recessive lethals. Later he bred a

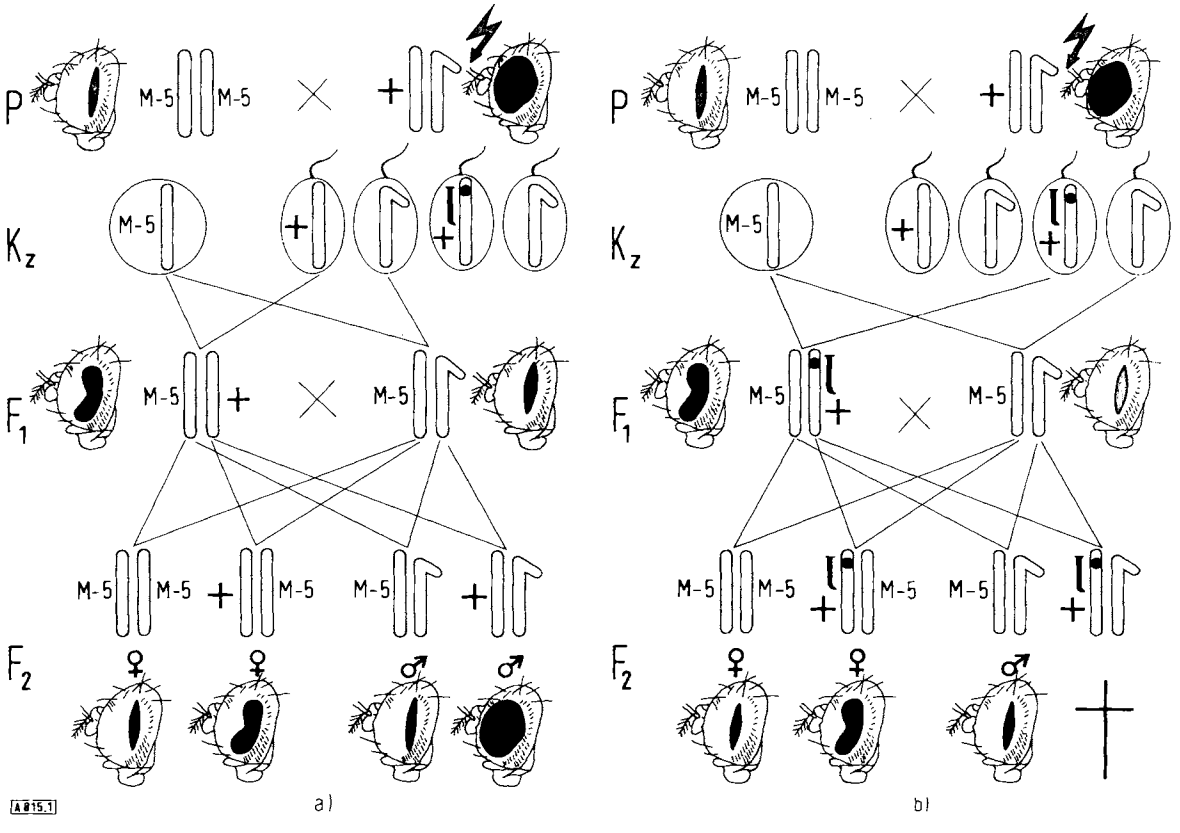

Fig. 1. The Muller-5 method for the detection of recessive sex-linked lethals in *Drosophila melanogaster*. a) Crossing with the participation of the normal X-chromosome; b) crossing with the participation of the X-chromosome with an induced lethal. The lines indicate the possible combinations at fertilization. P = parental generation; F_1, F_2 = first and second filial generations; K_z = gametes of the parental generation (the rod-like elements are X-chromosomes and the hook-like elements Y-chromosomes); M-5 = Muller-5 chromosome; + = X-chromosome of the wild type; l = recessive lethal factor; ϟ = treatment with X-rays or chemicals; † = non-appearance of normal males. (After charts of the Institute of Genetics of the Free University of Berlin.)

far better strain for the same purpose, and this has been the one generally used since 1948[4].

This special strain is known as Muller-5 (M-5) or Basc after the characteristic factors on its X-chromosome. Factor B (bar-eyes) is dominant, the two other factors (apricot-colored eyes and a bristle anomaly) being recessive. In addition, the M-5 chromosome contains two inversions.

When carrying out mutagenicity tests, normal males (with red, round eyes) are exposed to the action of X-rays or chemicals. Before the whole-body irradiation the flies are

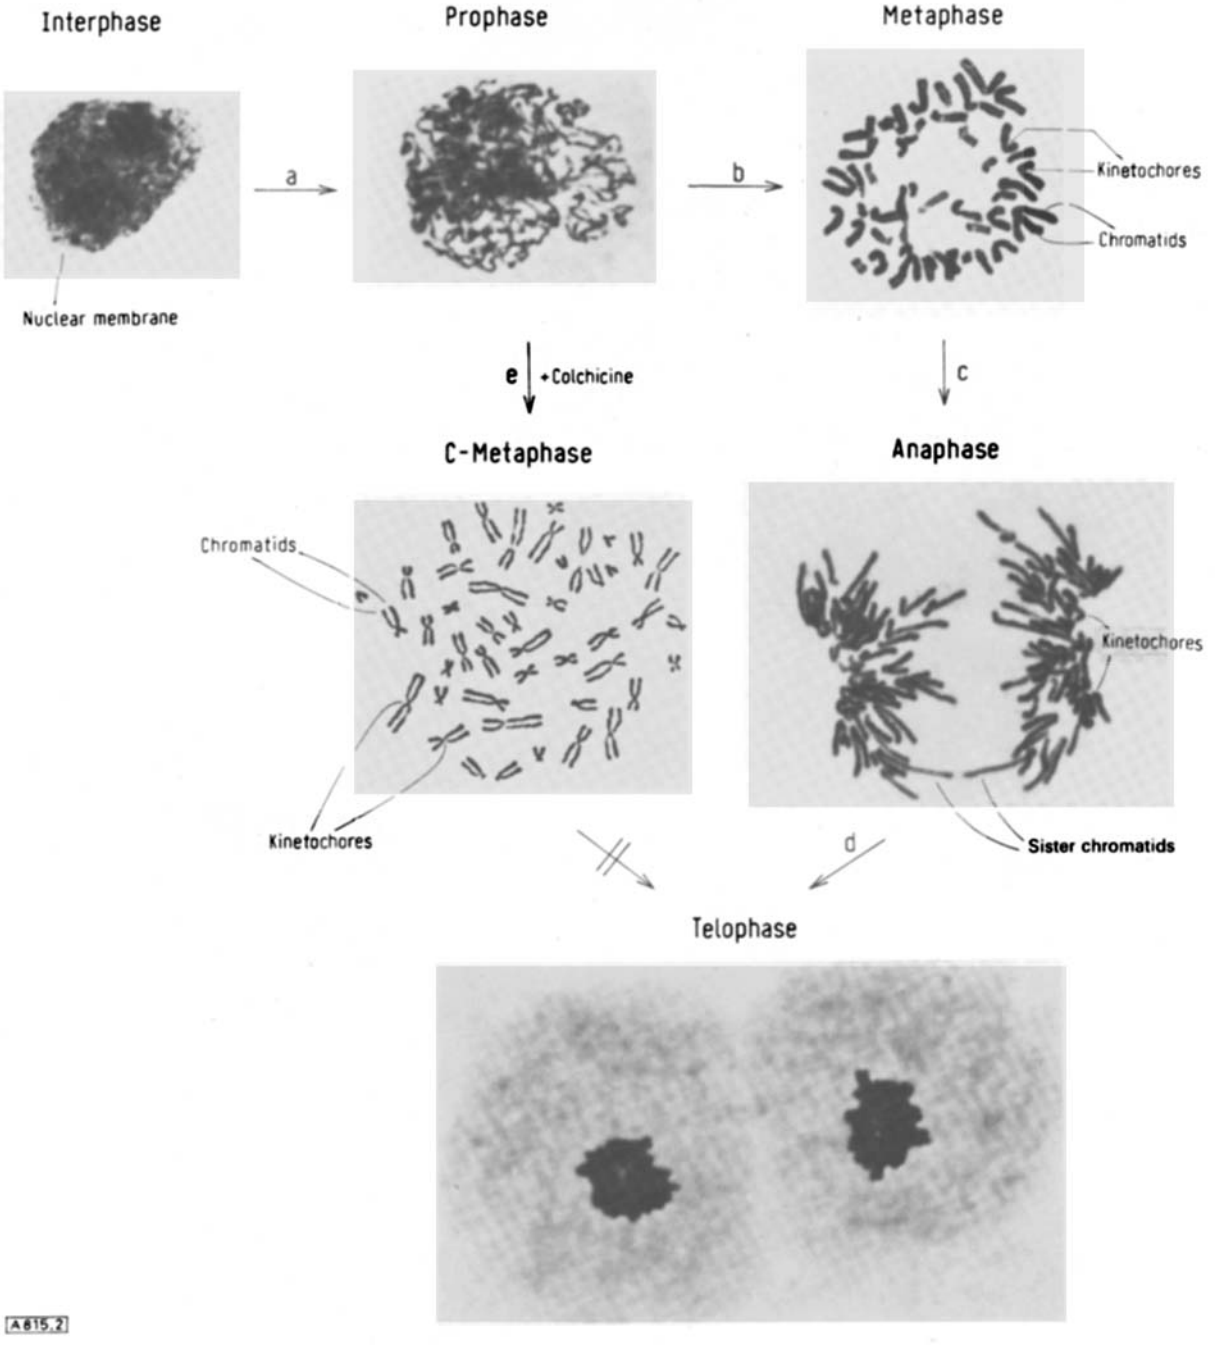

Fig. 2. Mitosis and C-mitosis (Colchicine-mitosis) of human cells *in vitro*. a→b→c→d: normal mitosis; a→e: C-mitosis.

Interphase: The chromosomes are mostly unfolded and separated from the surrounding cytoplasm by a nuclear membrane. The replication of the chromosomes occurs in a fraction of the interphase time called the synthesis phase (S-phase).

Prophase: Progressive folding up of the chromosomes makes them visible under a light microscope.

Metaphase: The nuclear membrane has disappeared. The considerably shortened chromosomes are arranged in the equatorial plane of the cell. The chromosomes are clearly seen to be composed of two chromatids connected in the region of the kinetochores. The chromosomes are arranged in a circle leaving a chromosome-free region in the middle of the equatorial plane.

Anaphase: With the kinetochores ahead, the longitudinal halves of the chromosomes move toward the opposite poles of the cell. The spindle fibers cannot be seen in these pictures. They join the kinetochore regions to the cell poles.

Telophase: The daughter chromosomes arrive at the cell poles. The daughter nuclei are formed. The plasma body divides itself in the equatorial plane.

C-Metaphase: The contraction of the chromosomes is more extensive than in a normal metaphase. Chromatids and kinetochores can be readily distinguished, especially after hypotonic treatment of the cell. The chromosomes are distributed over the whole equatorial plane.

enclosed in small gelatine capsules. The chemicals can be applied in various ways. The flies are often placed in glass filter crucibles saturated with solutions of the substances under test, and they then take the mutagen orally[5]. The dissolved substances can also be injected into the flies abdomen.

The treated males are mated individually with one or several females of the M-5 strain. The female progeny of the first generation obtain one of their X-chromosomes from their mother (M-5-X), while the other X-chromosome comes from the father and can be mutated. The males of this generation receive their single X-chromosome from their mother and look like their mother, as the Y-chromosome coming from the father contains practically no genes. The females have bar-shaped, but red eyes. Each female thus possesses *one* X-chromosome that had been treated in the initial male.

In this test system the fate of the autosomes cannot be followed further. Each female of the first generation is placed with a brother to produce the next generation, and the experiment can be evaluated 12 days later. Each culture now represents *one* X-chromosome treated in the initial males. If a lethal has been induced in one of these, then no males of normal appearance can be found in the affected culture, but only M-5 animals and heterozygous females (with bar-eyes). While the recognition of visible mutations largely depends on the experience of the investigator, the absence of a whole Mendel class cannot be overlooked (cf. Fig. 1). The overall frequency of the sex-linked recessive lethal factors can be determined very precisely with the M-5 strain.

The treated males come from laboratory strains with known spontaneous mutation frequencies. For the sex-linked lethal factors these lie between 0.07 and 1.0%, *i.e.* 7–100 new lethal mutations appear for every 10,000 gametes.

The order of magnitude of the effect of X-rays can be stated. The frequency of recessive sex-linked lethal factors in *D. melanogaster* increases to about 3% per 1000 R. However, no generalizations can be made concerning the chemical mutagens, which will be discussed in detail later.

1.2. Human Chromosomes

The chromosomes of the higher organisms undergo a characteristic change in shape during cell division (mitosis). Under a light microscope they can be examined best at the stage of maximum contraction (the metaphase). This condition is fulfilled best in the colchicine metaphase (C-metaphase)[6, 7]. Colchicine prevents the distribution of the chromosomes to the daughter cells, as the spindle fibers necessary for this purpose are not formed. The two identical split halves of the chromosomes, the chromatids (the replication of chromosomes occurs during the interphase stage when no division is taking place), remain connected to each other at the spindle fiber attachment site (kinetochore), as is shown with human chromosomes in Figure 2.

Colchicine does not inhibit the dissolution of the nuclear membrane, and the chromosomes are dispersed over the whole equatorial region of the cell. Treatment with a hypotonic salt solution (for example 0.9% sodium citrate) during the course of the preparation increases the dispersion process still further. Another advantage arising from the mode of action of colchicine is a concentration of the colchicine metaphases. Tissue culture is the method of choice for obtaining cell populations suitable for this technique. It was in this way that *Tjio* and *Levan*[8] in 1956 first determined the exact number of chromosomes in man as $2n=46$.

After culture the cells are fixed in a mixture of alcohol and acetic acid and are dropped onto cooled slides in this mixture. After spreading the cell suspension on the slide and drying off the fixation mixture, the chromosomes are stained with orcein. The metaphases can now be examined under a microscope.

The normal set of human chromosomes consists of 44 autosomes (22 pairs) and two X-chromosomes in the female and an X- and a Y-chromosome in the male. The chromosomes are classified schematically according to decreasing length, and are numbered from 1 to 22. The sex chromosomes are named as such. Figure 3 shows this classification for a female and a male metaphase.

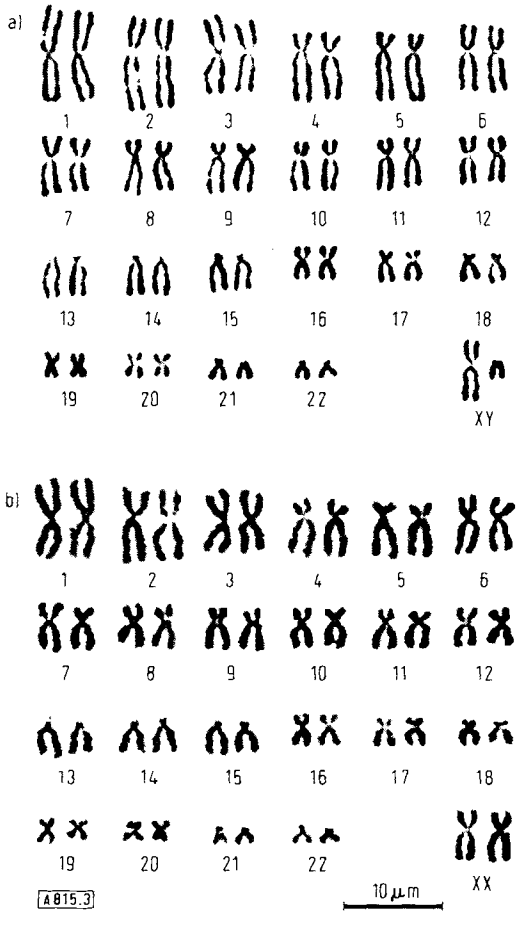

Fig. 3. Classified human metaphases: a) male, b) female. (Original from *Th. Lüers.*)

The substances to be tested for mutagenicity are added to the cell cultures at the desired concentrations some hours before processing. The metaphase chromosomes can then be examined for any damage.

A list of substances that have been found to be mutagenic *in vitro* in man is given in the table.

It is particularly important to note that chromosome mutations can be demonstrated not only after the action of mutagens *in vitro* but also after contamination *in vivo*, for example after chemotherapeutic treatment with cytostatics, after psychotropic drugs (*e.g.* LSD), and after inhaling polluted air (gasoline fumes). Such cases are marked with a cross in the "*in vivo*" column in the table.

2. Alkylating Agents[9–12]

Among the large number of mutagenic substances the alkylating compounds will be discussed here in greater detail. These compounds, which are considered to be some

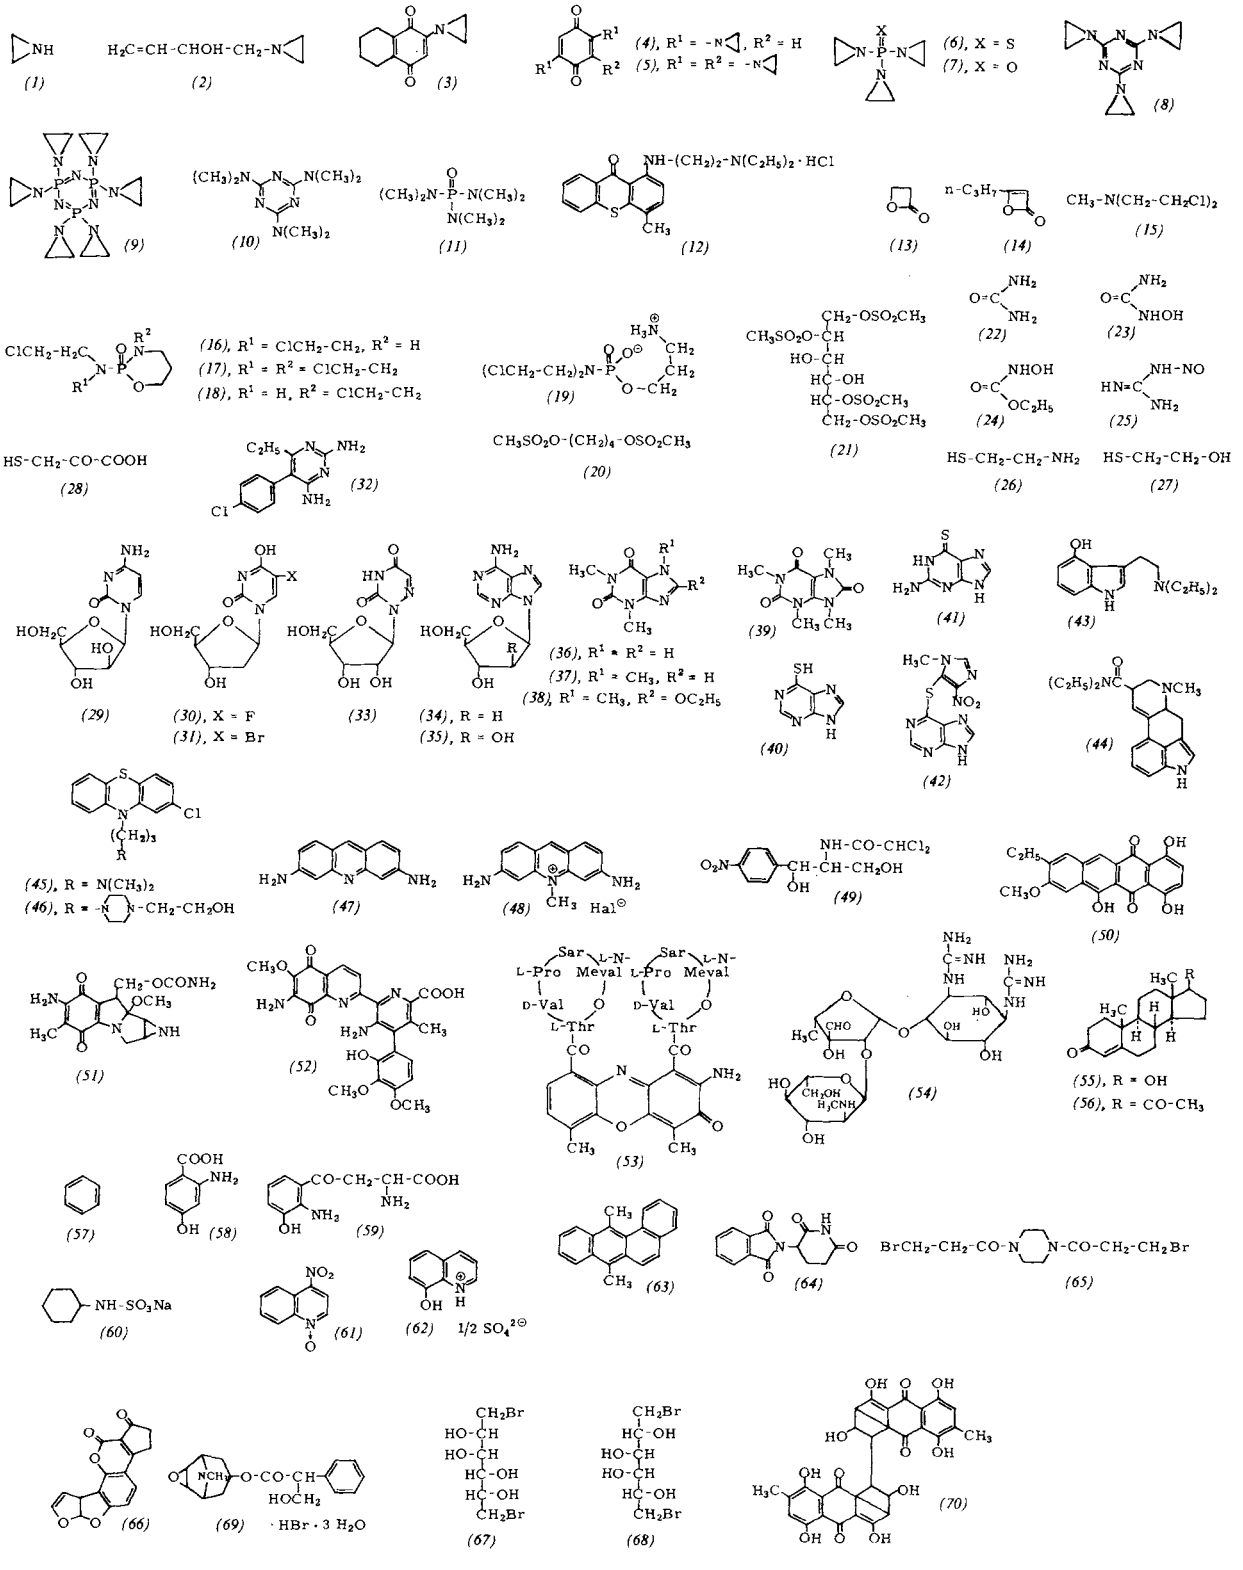

Table 1. Substances inducing aberrations in human chromosomes *in vitro* = after the action of the substance on cell cultures; *in vivo* = after ingestion or inhalation. (For a list of the formulas see page 306.)

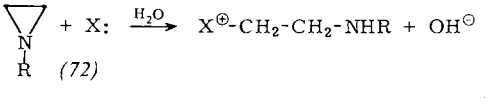

No. or formula	Name	Mutagen *in vitro*	Mutagen *in vivo*	Ref.
(1)	Aziridine, ethylenimine	+		[40]
(2)	1-Aziridino-3-buten-2-ol	+		[40b]
(3)	2-Aziridino-5,6,7,8-tetrahydro-1,4-naphthoquinone; A 137	+		[41]
(4)	2,5-Bis(aziridino)-1,4-benzoquinone; Quinone I	+		[39]
(5)	2,3,5-Tris(aziridino)-1,4-benzoquinone; Trenimon	+		[29, 42]
(6)	Tris(aziridino)thiophosphorane, Thio-TEPA, Tespa	+		[42]
(7)	Tris(aziridino)oxophosphorane; TEPA	+		[40b]
(8)	2,4,6-Tris(aziridino)-1,3,5-triazine; Triethylenemelamine, TEM	+		[42, 43]
(9)	2,4,6-Tris(aziridino)-1,3,5,2,4,6-triazatriphosphorine; Apholate	+		[40b]
(10)	Hexamethylmelamine; Hemel	+		[40b]
(11)	Hexamethylphosphoric acid triamide	+		[40b]
(12)	1-(2-Diethylaminoethylamino)-4-methylthioxanthone hydrochloride; Miracil D	+		[18]
(13)	β-Propiolactone	+		[44]

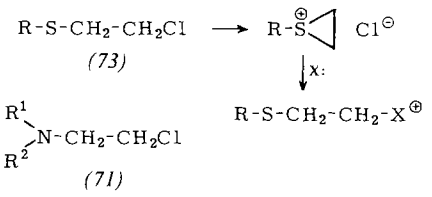
(69)	Scopolamine hydrobromide	+		[46d]
(70)	Luteoskyrin	+		[85]

of the most powerful mutagens known, are particularly used in therapy as cytostatics but they also play an important role as pesticides. In the textile industry they are needed in the production of dyestuffs as well as for the manufacture of fireproof and crease-resistant fabrics. It is particularly disquieting that they are also present in automobile exhaust fumes.

These compounds differ greatly in structure but they share the ability of transferring an alkyl residue to other atoms or molecules. In biologically active alkylating agents this alkyl residue is bound to the parent substance *via* an oxygen, nitrogen, or sulfur atom. An S_N2 reaction generally occurs in alkylation:

$$X: + RY \rightarrow X^+—R + Y^-:$$



in which X is the nucleophilic agent and R is the alkyl residue. For example, the alkylation of the methanesulfonic ester $ROSO_2CH_3$ takes place in this way. In functional groups with a ring structure such as aziridines *(72)*, epoxides, and β-lactones the alkylation is associated with opening of the rings.

(72)

As regards the cytostatic effect of aziridine, it may be noted that the hydrolytic cleavage of the ring occurs four times as quickly at the typical pH of cancer cells (6.5) as at the pH of healthy cells (7.2)[131].

The sulfur and nitrogen mustards *(73)* and *(71)* form another highly active group. These have an alkylating effect only after forming a ring, and the rate of the reaction is thus determined by the relative rates of the two steps.

(73)

(71)

The *N*-nitroso compounds include the dialkylnitrosamines *(74)* and the acyl-alkylnitrosamides *(75)*. A characteristic of these substances is that they are inactive as such. These "transport forms" are converted by enzyme-induced and spontaneously occurring changes in the cell into forms with alkylating action.

(74) *(75)*

It is not only in the *N*-nitroso compounds that transport and active forms are differentiated. Another well known example of this is the nitrogen mustard derivative known as Endoxan or Cytoxan *(16)* (see Table 1), which is used in cancer therapy, and whose alkylating activity only develops after hydrolytic splitting in the liver.

The nucleophilic groups in the cell are primary to tertiary nitrogen atoms as well as OH, SH, and sulfide groups. Many reactions can thus take place between the alkylating agents and the biological material, but in these the alkylation of DNA is of central importance. Permanent changes in the DNA are produced by even the smallest quantities of alkylating agents. In isolated DNA it can be demonstrated that it is the bases in particular that are alkylated. Pyridine-type nitrogen atoms are attacked preferentially, which is understandable when one considers that the free pairs of electrons on such nitrogens are not incorporated into the conjugated electron system of the heterocycle. The introduction of an alkyl residue at this site thus does not result in any damage to the conjugated system but only in a small lowering of resonance energy. It is more difficult to understand, however, why the N-7 atom of guanine is alkylated most frequently, while the N-1 atom of this base and the N-3 and N-7 atoms of adenine are affected more rarely. Presumably these differences are due essentially to spatial effects in the double helix of DNA. *In vivo* the circumstances are even more complicated, but here too an N-7 alkylation of guanine can be demonstrated after treatment with tritiated β-propiolactone.

Besides the bases being attacked, certain alkylating agents, such as the nitrogen mustard *(15)*, primarily attack the phosphate groups. Part of the phosphate ester thus formed is broken down hydrolytically and liberates an alkyl radical which can then react with a base. This process and direct alkylation of the bases thus lead to the same result. Following the formation of an alkylguanine and hydrolytic breakdown of the base and deoxyribose compound, the guanine can be eliminated and thus result in a break in the polynucleotide chain.

The biological activity of alkylating compounds with several functional groups is greatly superior to that of alkylating agents carrying only one functional group. This can be attributed to the formation of cross-linkages. Such cross-links can bridge the sister strands of the DNA double helix or two molecules within the same strand of the double helix. Bridges between different double helices can be shown by electron microscopy. Cross-links between chromosomal proteins and the DNA must also be taken into consideration. The severe toxic effect of polyfunctional alkylating agents is probably due to these linkages, which hinder or prevent correct replication of the DNA.

The damage to the DNA caused by alkylation is repaired for the most part by enzyme action. Occasionally resulting mistakes in the repair process alter the native base sequence and are thus undoubtedly a source of point mutations. How alkylation results in changes in the chromosomes that can be observed under the light microscope is still largely unknown. It will only be possible to solve this problem when the structure of chromosomes in higher organisms has been clarified.

The results can certainly be best explained if one assumes that a single chromosome in the nucleus of a non-dividing cell (an interphase nucleus) consists of only one continuous DNA double helix which, in association with proteins, acts as a matrix for the formation of sister chromosomes in the synthesis phase of the cell cycle. In the C-metaphase these appear as two chromatids still attached to the kinetochore (cf. Fig. 2). The contraction of the chromosomes could be interpreted as a progressive folding of the DNA protein fibrils of each chromatid (the folded fiber model of chromosome structure)[14, 15]. If the breaks occurring in a DNA strand of an interphase chromosome as a result of alkylation are not repaired, a break occurs in the fibrils of one of the chromatids found after replication. This concept is also in agreement with the fact that defects are only found in the chromatids in the first metaphase after the introduction of an alkylating agent (in the previous interphase). These chromatid aberrations can be transformed into chromosome aberrations after a further mitosis, but this is generally not observed because of their lethal effect. To obtain a true picture of the pattern of damage in the chromosomes it is thus important to detect the first mitosis occurring after the introduction of the alkylating agent.

Some results obtained with these two test systems will be compared and discussed in the following sections.

2.1. Achromatic Lesions (AL)

Achromatic lesions appear very frequently in human chromosomes. These are color defects in the longitudinal structure of the chromatids, and are not breaks in the chromatid structure. The chromatid areas distal to the achromatic lesion are not separated from the proximal section (near the kinetochore). The lesions are probably repaired again in the synthesis phase following their induction[16].

Of particular importance is the question whether the achromatic lesions should be considered as equivalent to mutations. Comparative observations on the mutagenic efficacy of the thioxanthone derivative Miracil D *(12)* (see Table 1) on *Drosophila*[17] and human chromosomes[18] indicate that this question can be answered in the negative. In *Drosophila* Miracil D has almost no effect at all, except that the frequency of chromosome changes is increased above that in controls. After addition of Miracil D the testicular spirals of *Drosophila* are stained and so it could be determined that the substance had actually accumulated here and had not, for example, been metabolized after administration and then excreted without producing any effect.

In human chromosomes there were, in addition to some translocations, over 40% of achromatic lesions 24 hours after the introduction of 1×10^{-5} mole/ml. If these were equivalents of mutations then the frequency of the sex-linked lethals in *Drosophila* would have to be increased, especially as the test concentrations used were of the same order of magnitude.

Further help in throwing light on this problem has been provided by studies on the action of antibiotics which are not mutagenic to higher organisms, *i.e.* streptomycin *(54)* (see Table 1) and dihydrostreptomycin, on human chromosomes *in vitro*[19]. Whereas streptomycin induced almost 40% of achromatic lesions, dihydrostreptomycin was completely inactive. The frequency of all the other types of aberrations was not increased by either antibiotic, apart from quite sporadic translocations occurring equally after streptomycin and dihydrostreptomycin. These antibiotics differ among other things in that streptomycin is linked ten times more strongly to polyanions than is dihydrostreptomycin[20]. The achromatic lesions could arise by such nonspecific linkages to chromosomal polyanions.

2.2. Chromatid Breaks (B′)

Chromatid breaks are true ruptures in chromatids. In the anaphase following their induction the broken segment is left behind and can, at the most, arrive passively in one of the developing daughter cells. This type of damage thus leads to the loss of terminal sections (deletions).

The loss of terminal sections occurs only rarely in man spontaneously (in about one out of 100,000 births) and causes very severe malformations. The loss of a section on the short arm of chromosome no. 5 results in the development of the cat cry syndrome (cri-du-chat syndrome)[21], named after the cat-like cries of the children, who also have many malformations.

2.3. Isochromatid Breaks (B″)

Isochromatid breaks form another type of aberration which can be detected in the cytogenetic test. This type consists of two breaks which occur at morphologically homologous sites on two sister chromatids. They lead to the formation of two chromatid sections without kinetochores and of a residual chromosome. An isochromatid break results in the loss of chromatid sections in both daughter cells.

Figure 4a shows a metaphase with achromatic lesions and chromatid and isochromatid breaks in addition to chromatid translocations. The damaged chromosomes are illustrated separately in Figure 4b.

Fig. 4. a) Metaphase with chromosome damage resulting from 32 hours' exposure to 0.02 µg/ml of Quinone I *(4)*. b) Composition of the damaged chromosomes. 1 = achromatic lesion; 2 = chromatid breaks; 3 = isochromatid breaks; 4 = chromatid translocations (after [39]).

2.4. Chromatid Translocations (RB′)

Chromatid translocations are the most easily recognized and the most obvious equivalents of mutations. They are the result of repair processes in which unrelated fragments

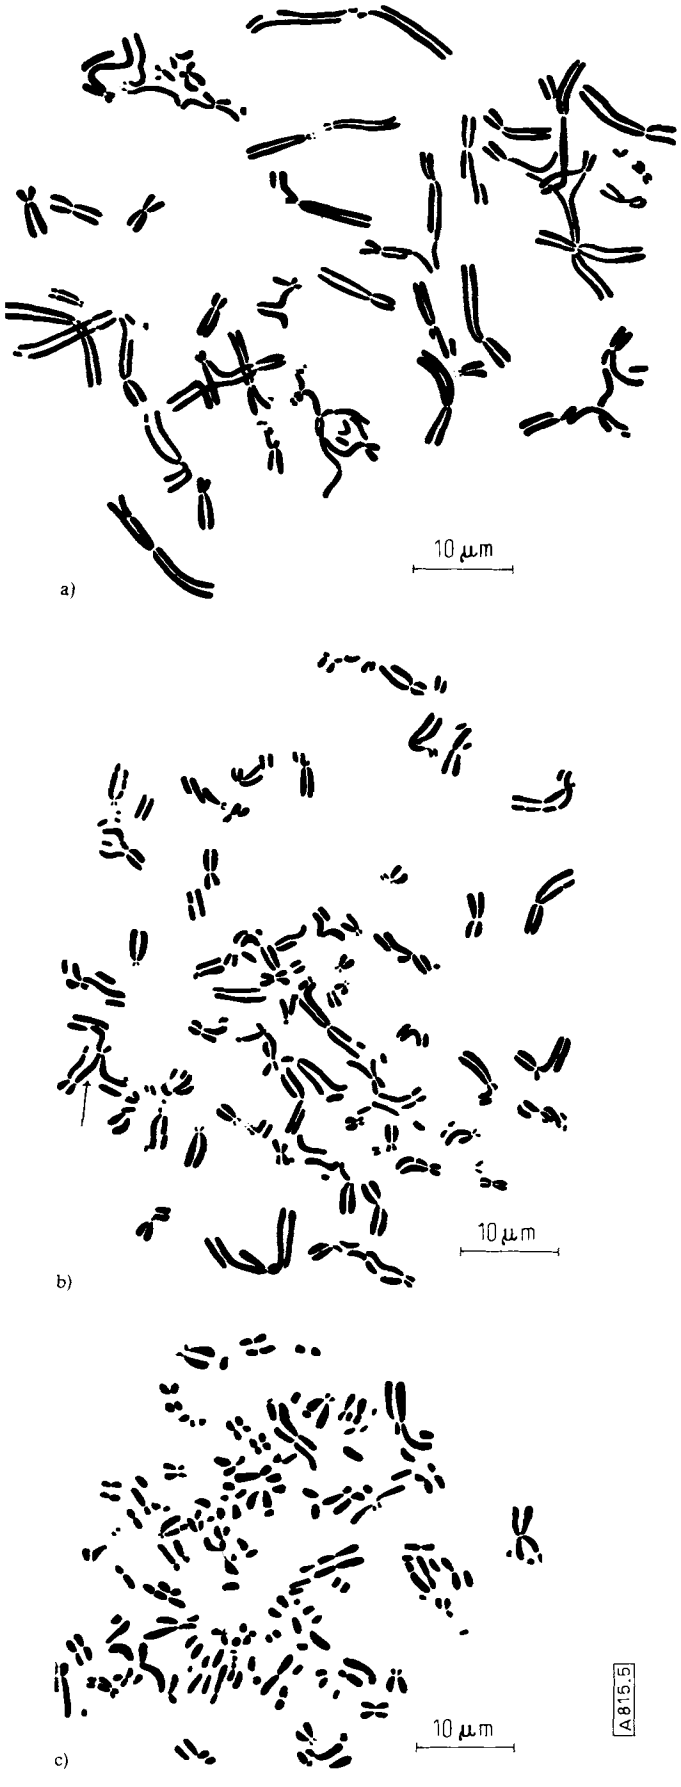


Fig. 5. Metaphases with damage of varying severity as a result of 24 hours' exposure to 5.0×10^{-7} mole/ml of Trenimon *(5)*. a) Numerous chromatid translocations; b) in addition to numerous breaks there is still only one chromatid translocation (arrow); c) completely disintegrated metaphase (pulverization) without any chromatid translocations (after [29]).

of different chromatids have been joined together. These translocations generally have the typical shape of a cross.

RB′ figures differ in the way they are jointed together; in some the kinetochores are not united with one another (symmetrical RB′), while in others the kinetochores are joined by chromatid bridges (asymmetric RB′), which in the following anaphase extend between the kinetochores migrating to the poles.

Translocations can be regarded as a visible expression of the repair processes taking place in the cell. The very severely disordered metaphases, which occasionally appear without any translocations, indicate a breakdown of the repair system in these cells. Figures 5a–5c show transitions ranging from severely disordered metaphases with translocations to those which appear completely "pulverized".

The intercellular distribution of the translocations and breaks also makes it possible to draw conclusions concerning repair processes in the cell[22]. If one assumes a random distribution of the primary defects in the cells investigated, then the chromatid breaks and translocations in each cell must fall into a *Poisson* distribution. However,

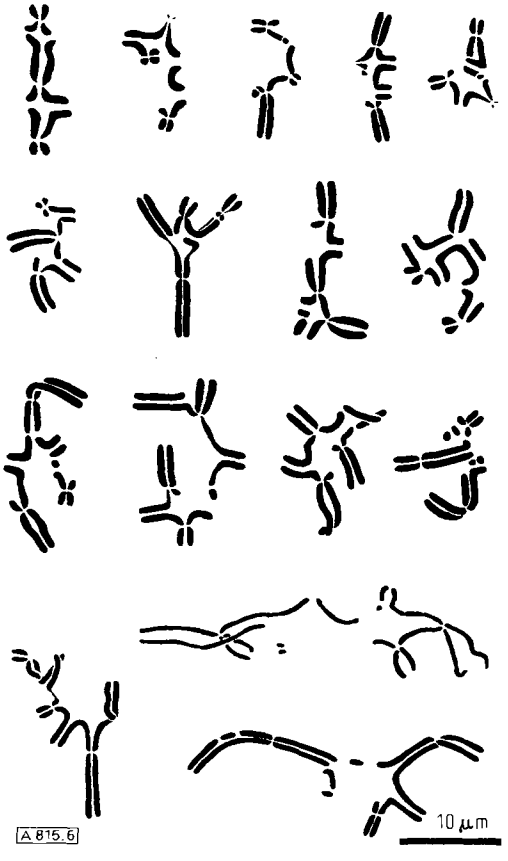

Fig. 6. Chromatid translocations (RB′) from three chromosomes after 24 and 32 hours of exposure to Quinone I *(4)* (after [39]).

after treatment with Quinone I *(4)* (see Table 1) there were too many cells in the 0-class, *i.e.* without chromosome aberrations; these are probably cells in which all the defects had been restricted.

Another question is the period within which healing of potential translocation-producing breaks can occur. X-ray experiments on human lymphocytes have given a period of 60–90 minutes[23].

The number of translocations formed can be reduced by inhibitors both of DNA and of protein synthesis[24–27], which indicates that such syntheses participate in the formation of translocations.

In addition to translocations involving two chromatids, translocations occur in mutation experiments in which more than two elements take part. Figure 6 gives some examples of translocations between three chromosomes.

In man, spontaneous translocations occur just as rarely as deletions. A translocation between chromosomes 13 and 21 leads to the formation of a new chromosome, whose short arm corresponds to chromosome no. 21 and whose long arm corresponds to chromosome no. 13. The short arms of the two affected chromosomes are lost during the translocation and appear to be of no genetic significance. The carriers of this translocation are phenotypically normal, but have only 45 chromosomes. Figure 7a shows the chromosome complement of a female carrier of this trans-

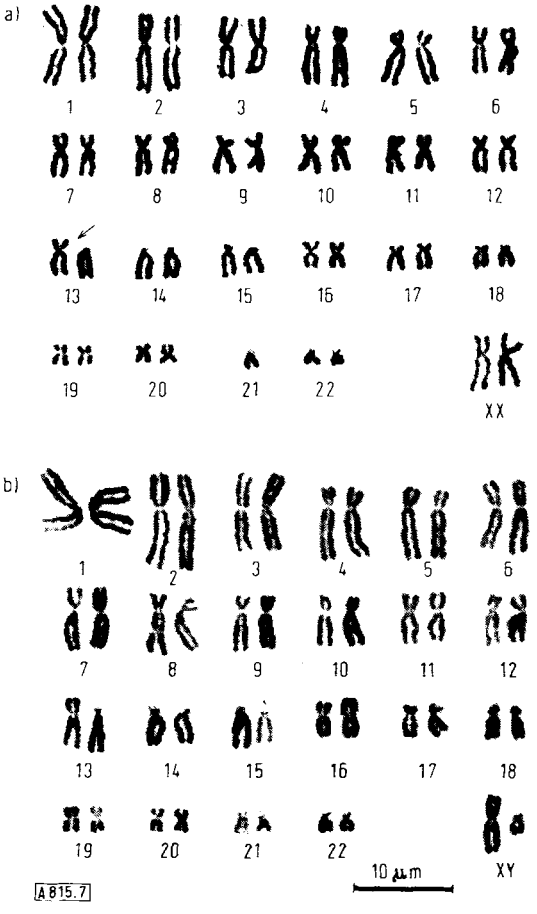

Fig. 7. Classified human metaphases with translocation chromosome 13/21 (arrow). a) Balanced state (45 chromosomes); b) combined with trisomy 21 (translocation mongolism, 46 chromosomes). (Original from *Th. Lüers.*)

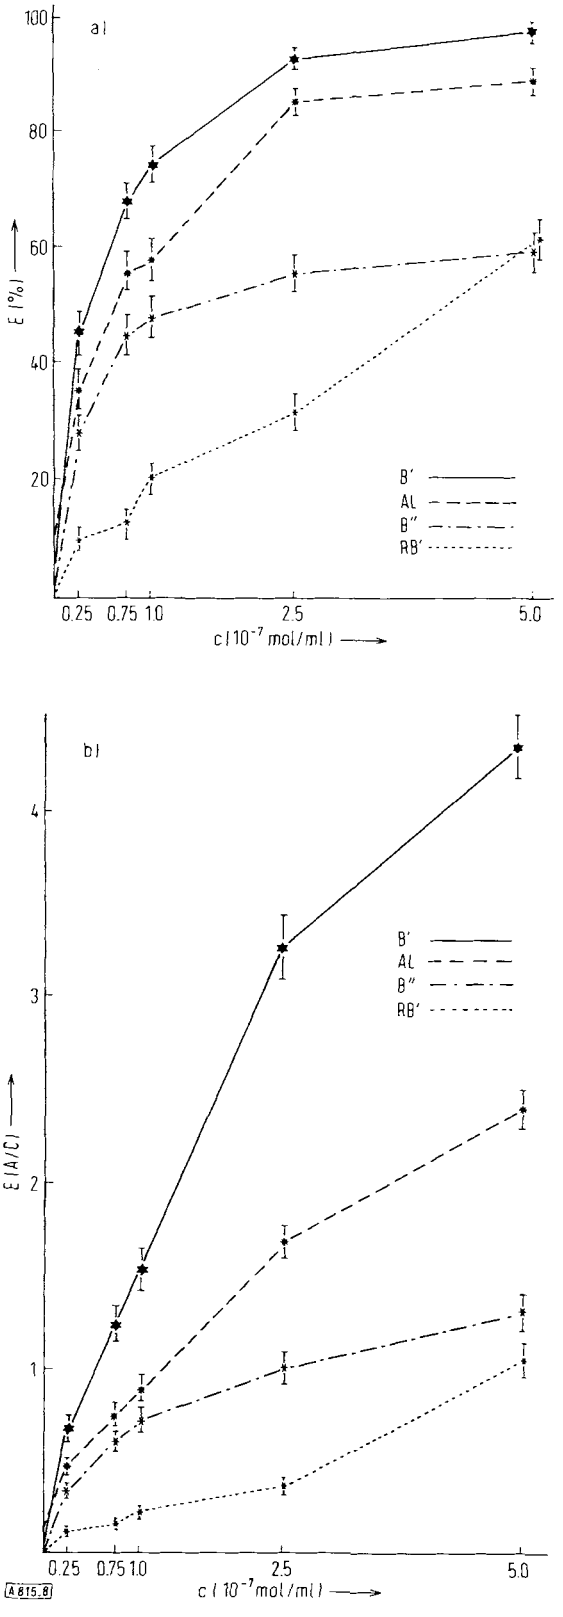
location. If the chromosome no. 21 and also the translocation chromosome attain one oocyte, then after fertilization with a normal spermatozoon there appears an organism with $2n = 46$ chromosomes, but one that has three times the gene dose for chromosome no. 21 and is thus affected with Down's syndrome (translocation mongolism)[28]. Figure 7b shows the chromosome complement of a male translocation mongol.

3. Dose-effect Relationships

All the aberration types mentioned (AL, B', B'', and RB') increase in frequency with increasing dose of the mutagen unter test. Figure 8 shows such dose-effect relations for the



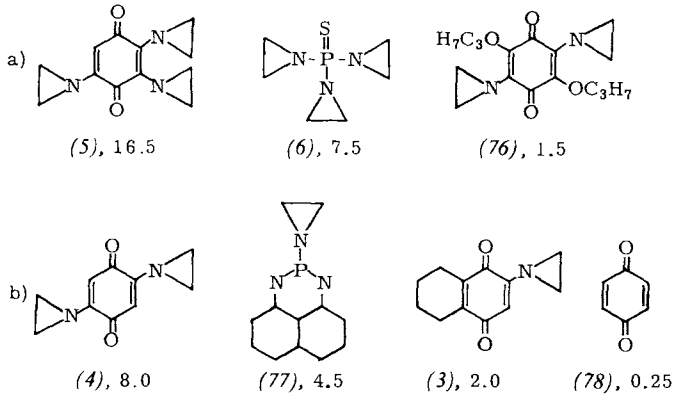


Fig. 8. Dose-effect relationships for achromatic lesions (AL), chromatid breaks (B'), isochromatid breaks (B''), and chromatid translocations (RB') as a result of 24 hours' exposure to Trenimon *(5)*. a) The effect (E) in percent; b) the effect in aberrations per cell (A/C) (after [29]).

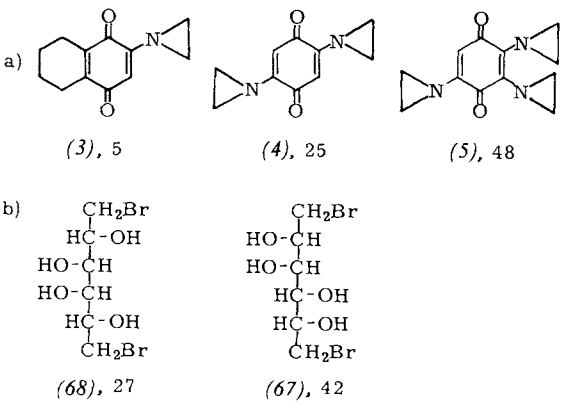
alkylating agent Trenimon *(5)*[29] (see Table 1). Dose-effect relationships are also shown in recessive lethal mutations of *Drosophila*, for example after the administration of increasing doses of triethylenemelamine *(8)*[30] and nitrogen mustard derivatives[31].

4. Chemical Constitution and Mutagenic Action

The connection between chemical constitution and mutagenic action will be discussed on the examples of some aziridines.

As regards the induction of recessive lethal mutations there is a positive correlation with the number of aziridine groups per molecule[32]. Thus, the trifunctional Trenimon *(5)* is 10 times more active than the bifunctional E 39 *(76)*, while the bifunctional Quinone I *(4)* is 3.5 times as mutagenic as the monofunctional A 137 *(3)* (Scheme 1). However, the parent substance of an alkylating agent also has an effect



Scheme 1. Frequency of recessive lethal mutations in the X-chromosome of *Drosophila melanogaster* as a result of three days' feeding of a) 2.3×10^{-4}% solutions of Trenimon *(5)*, thio-TEPA *(6)*, and E 39 *(76)* (2,5-bis(aziridino)-3,6-*n*-propoxy-1,4-benzoquinone) and of b) 2.3×10^{-2}% solutions of quinone I *(4)*, A 140 (2-aziridino-1,3-diaza-2-phosphaperhydrophenalene) *(77)*, A 137 *(3)*, and *p*-quinone *(78)*. The numbers under the formulas give the frequency (%) (according to values from [32]).

on its mutagenic activity. Trenimon *(5)* has twice the activity of Thio-TEPA *(6)*, although both substances are trifunctional aziridines.

The number of mutations occuring does not show a simple relationship with the number of reactive groups. An *in vitro* study on human chromosomes to compare the efficacy of 1×10^{-6} mole/ml of A 137 *(3)* (monofunctional), 0.5×10^{-6} mole/ml of Quinone I *(4)* (bifunctional), and 0.33×10^{-6} mole/ml of Trenimon *(5)* (trifunctional) showed that, in spite of the same number of aziridine groups per culture, Trenimon was considerably more effective than Quinone I, and the mutagenic effect of the latter was clearly superior to that of A 137[33].

Scheme 2 shows the results of this experiment with reference to the translocations. An effect is produced here by cross-linking, which can only occur with the polyfunctional and not the monofunctional alkylating agents.

Scheme 2. Frequency of chromatid translocations in human chromosomes as a result of a) 24 hours' exposure to 1×10^{-6} mole/ml of A 137 *(3)*, 0.5×10^{-6} mole/ml of Quinone I *(4)*, and 0.33×10^{-6} mole/ml of Trenimon *(5)* (according to values from [32]) and b) 40 hours' exposure to 1×10^{-5} mole/ml of dibromodulcitol *(68)* and dibromomannitol *(67)*. The numbers under the formulas give the frequency (%).

The difference in the efficacy of dibromodulcitol *(68)* and dibromomannitol *(67)* in inducing translocations (RB') indicates that the spatial structure of a compound has an effect on its mutagenic action (Scheme 2).

5. Localization of the Mutations

Using a very large amount of material, *Belitz* investigated the distribution of spontaneous recessive lethal factors and of those induced by Quinone I *(4)* and triethylenemelamine *(8)* on the genetic map of the X-chromosome in *Drosophila*[34]. The spontaneous mutations were most frequent in the distal section (32.4%), with a minimum (9.8%) in the proximal section near the kinetochore of the affected chromosome. After treatment with Quinone I, 14.4% of the lethal factors were found in the distal section, against 19.1% in the kinetochore region. These differences could be confirmed statistically. A characteristic distribution pattern is also shown by mutations induced by triethylenemelamine *(8)* (distal 20.5%, proximal 23.2%). Mutations thus clearly occur more frequently in certain regions of the X-chromosome.

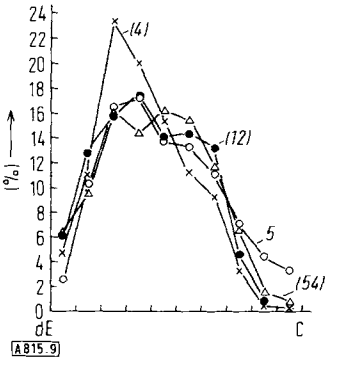


Fig. 9. Distribution of achromatic lesions and chromatid breaks in ten relatively equal sections of all the chromosomes of the human karyotype after exposure to Quinone I *(4)*, Trenimon *(5)*, Miracil D *(12)*, and streptomycin *(54)*, dE = distal end; C = kinetochore (according to values from [19, 29, 35, 36]).

The aberrations in human chromosomes are also not distributed at random. A similar distribution pattern is given by achromatic lesions (AL) and breaks (B') on ten sections of relatively the same length from all the chromosome arms after treatment with Trenimon *(5)* (AL+B')[29], Quinone I *(4)* (AL+B')[35], Miracil D *(12)* (AL+B')[36], and streptomycin *(54)* (AL)[19] (Fig. 9). The aberrations occur most frequently in the central region and decline greatly toward the distal end and the kinetochore region. Whereas in *Drosophila* the mutations are mainly concentrated at the distal end and in the kinetochore region, the achromatic lesions and chromatid breaks have precisely the opposite distribution in human chromosomes.

6. Concluding Remarks

We have attempted to give a brief and illustrative insight into chemogenetics on the basis of some results obtained with a genetic test system *(Drosophila)* and a cytological test system (cultured human cells). Today work on mutation occupies a very important position within genetics and is closely associated with other lines of research. Whereas the processes which lead to gene mutations are in principle well known, we still know relatively little about the processes which give rise to chromatid or chromosome aberrations[37]. Study of the repair processes is also part of the field of mutation research.

The techniques for producing mutations are extremely useful in other fields, for example developmental genetics, which can lead to significant inferences concerning the importance of a normal allele in the development of an individual from the abnormal action or lack of function of a mutated allele. On a larger scale, the population geneticist uses mutagenic agents to increase the genetic variation in artificial populations or to observe what happens to populations under increased mutation pressure.

The practical importance of mutation research is just as great as its scientific significance. Mutations are produced on a large scale in the breeding of cultivated plants and tested for their suitability for increasing quality and yield.

As is well known, most new mutations have an unfavorable effect. An especially important task for mutation research is developing from the constant contamination of our environment with a large number of materials whose genetic effects are known insufficiently or not at all. The increasing pollution due to the use of substances such as food additives, therapeutic agents, narcotics, contraceptives, and pesticides, as well as pollution of the oceans and the atmosphere, is rapidly becoming one of the most pressing problems of our time. The danger of such chemicals producing mutations in man is definitely greater than the risk of mutations caused by radiation.

Investigations on the possible mutagenic effect of such substances are thus of special importance. When a substance is recognized to be mutagenic it should be treated with extreme caution; whenever possible, it should be banned completely from our environment, as is shortly to happen in the United States with cyclamates, which are suspected of being mutagenic and carcinogenic[38].

While acute biological effects, such as signs of poisoning, are recognized immediately and the blame can generally be placed squarely on the toxic agent responsible, there is a much longer period between the mutation process and the manifestation of a genetically induced defect. Dominant mutations, which constitute the great majority of chromosome mutations, are as a rule lethal, and in man they probably lead mainly to early abortions. They are therefore not recognized as mutations. Dominant genetic defects leading to malformations occur relatively rarely among the whole range of mutations, and recessive autosomal hereditary changes can only be revealed in later generations.

As induced mutations do not differ qualitatively from natural (spontaneous) mutations, it is only possible to demonstrate an induced mutation statistically. However, if one were to wait for statistical proof of an increased incidence of mutations in man as a result of contamination with mutagens, then the damage already caused could be incalculable.

The only possible way of protecting mankind from mutagenic substances is the laboratory testing of all chemicals before they reach our environment. This is a gigantic task when it is realized that about 30,000 new chemical compounds are developed every year. A particular difficulty standing in the way of this undertaking is that of raising funds to prevent dangers whose extent is not immediately obvious to the general public.

In view of all this, the founding by American geneticists of an Environmental Mutagen Society (EMS), a European section of which was set up recently, is highly welcome. The German Research Association maintains a "Central Laboratory for Mutagenicity Testing" at Freiburg-im-Breisgau, where chemicals are tested for their possible mutagenic effects in close cooperation with the chemical industry.

Sulfinato Complexes

By Günther Vitzthum and Ekkehard Lindner[*]

Sulfinatometal complexes exhibit unusual features in their structure, preparation, and use, and have attracted rapidly growing interest. Their structures are determined by the ability of the RSO_2^- group both to act as a monodentate ligand (sulfinato-S or sulfinato-O) and to add to coordination centers as a bidentate ligand, either intramolecularly or intermolecularly, via the two oxygens atoms (sulfinato-O,O') or via the sulfur atom and one of the oxygens (sulfinato-O,S).

1. Introduction

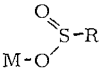
In 1858, *Hobson*[1] published an article "On the Action of Sulfurous Acid on Zinc Methyl". When dry SO_2 is passed into a solution of $(CH_3)_2Zn$ in ether, a colorless precipitate is formed; this was described as the "zinc salt of methylodithionic acid". However, the analytical data reported and the manner of preparation (insertion of SO_2) indicate that it is bis(methanesulfinato)zinc, the structure of which was not elucidated until 110 years later[2, 3]. The behavior of $(C_2H_5)_4Sn$ toward SO_2 was investigated by *Frankland* and *Lawrance*[4] in 1879. *Peters*[5] later allowed arenesulfinic acids to react with Hg^{II} salts. This reaction is used for the preparation of homogeneous mercury sulfinates having definite compositions[6]. Since 1937, aromatic sulfinic acids have been used in analytical chemistry for the quantitative determination of transition metals[7–9].

Wide industrial application of sulfinic acids followed from the observation[10, 11] that unsaturated organic systems containing sulfinic acids rapidly polymerize in the presence of transition metal salts[12–17]. Highly reflective nickel coatings can be deposited electrolytically from baths containing nickel salts of sulfinic acids[18]. Finally the bactericidal effect of benzenesulfinatosilver can be used for the production of antiseptic soaps[19].

Though numerous investigations on sulfinato complexes had been reported by 1964, little was known about their structure and bonding. The increased attention that has been devoted to these problems during the last six years is due in no small measure to the variety of ways in which the RSO_2^- ligands can be bonded to coordination centers.

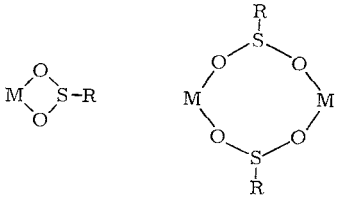
2. Problems of Structure and Bonding

2.1. Possibilities for the Coordination of the RSO_2^- Ligand



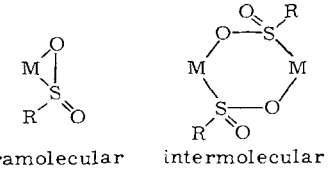
The bonding of a potential polydentate ligand such as carboxylate[20], nitrate[21], carbonate[20], sulfate[20, 22], sulfinate[23] or sulfolan[24] can very often be determined by IR spectroscopic investigations, since the corresponding CO_2, NO_3, CO_3, SO_4, and SO_2 stretching vibrations change on coordination. The stronger the bond between the metal and the ligand, the greater is the shift of the element-oxygen absorption bands to lower or higher frequencies. For oxo anions with D_{3h} (NO_3^-, CO_3^{2-}) or T_d (SO_4^{2-}) symmetry, we find frequency splittings of degenerate vibrations and the additional appearance of originally forbidden bands because of decreased symmetry. The greater the number of bonds formed between a polydentate ligand and a metal, the greater is the splitting of the degenerate element-oxygen absorptions.

For a sulfinato complex having the general, simplified composition RSO_2M (R = organic residue, M = central ion) there are four possibilities for bonding the RSO_2^- ligand to coordination centers[23]:



1. *Sulfinato-S complex*; the central ion is linked directly to the sulfur:

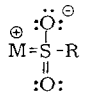
2. *Sulfinato-O complex*; the RSO_2^- group is linked to the coordination center by one oxygen atom:



3. *Sulfinato-O,O' complex*; the RSO_2^- ligand is coordinated to the central ion *via* both O atoms:

intramolecular intermolecular

4. *Sulfinato-O,S complex*; the RSO_2^- ligand can be coordinated *via* oxygen and sulfur:



intramolecular intermolecular

The frequencies of $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ show whether a complex is of the sulfinato-*S* or sulfinato-*O* type, and their

[*] Dr. G. Vitzthum and Priv.-Doz. Dr. E. Lindner
Institut für Anorganische Chemie der Universität
Erlangen–Nürnberg
852 Erlangen, Fahrstrasse 17 (Germany)

difference shows whether one or both O atoms are bonded to the central ion.

For a sulfinato-*S* complex, $\nu_{as}(SO_2)$ absorbs in the range 1250—1100 cm^{-1}, and $\nu_s(SO_2)$ between 1100 and 1000 cm^{-1}. In comparison with sulfones[25], the bands are shifted by 150—100 cm^{-1} to lower wave numbers, evidently because of a strong π interaction between the metal and the sulfur[26,27]:

In the sulfinato-*O* type, the "free" S—O stretching vibration absorbs between about 1100 and 1050 cm^{-1}, whereas ν_{as}(S—O—M) is shifted to lower frequencies in comparison with the longer-wave $\nu(SO_2)$ band of the free sulfinate ion; the frequency difference here is usually 100—200 wave numbers. The structures of two sulfinato-*O* complexes, *i.e.* $(p\text{-}CH_3C_6H_4SO_2)_2Cu(OH_2)_4$[28] and

$[\pi\text{-}C_5H_5Fe(CO)_2]_2Sn(O_2SC_6H_5)_2$[29,30],

have so far been established by X-ray studies. Only for the copper compound are the IR data[31] in conflict with the type of bonding found in the structural investigation.

For a sulfinato-*O,O'* complex, $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ are shifted to longer wavelengths in comparison with the SO_2 stretching vibrations of the free anion, with a frequency difference of 10 to 80 cm^{-1}.

The most problematic is doubtless the last type of linkage mentioned, *i.e.* the sulfinato-*O,S* type, which is relatively rare[32,33]. The intramolecular arrangement should be unlikely in any case because of excessive ring strain.

The dependence of the frequency difference between $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ on the angle is illustrated by the following example. In the *p*-dimethylaminobenzenesulfonylium ion[34], the sulfur is certainly sp^2-hybridized, and the O—S—O angle is therefore approximately 120°. Whereas the frequency difference here is 223 cm^{-1}, it decreases to only 66 cm^{-1} for the sulfinato-*O,O'* complex $[p\text{-}CH_3C_6H_4SO_2Ni(phen)_2]Cl$[32]. The difference becomes understandable when one considers that the O—S—O angle must be distorted because of the electrostatic influence of the Ni^{2+} ion on the sulfinate ion. Similar arguments are valid for the sulfolan coordination[24]. As the O—S—O angle becomes smaller, the vibrations of the sulfolan molecule should change, since the coupling of the symmetrical SO_2 stretching vibration depends mainly on the O—S—O angle[35].

2.2. Criteria for the Formation of Sulfinato-*S* and Sulfinato-*O* Complexes

The sulfinate ion can act in two ways as an electron donor, *i.e.* as a "soft" donor[36–38] *via* the S atom or as a "hard" donor *via* one or both O atoms. This allows the specific preparation of sulfinato-*S* or sulfinato-*O* complexes, according to whether a "soft" or a "hard" coordination center is offered to the RSO_2^- group.

2.2.1. Sulfinato-*S* Complexes

To prepare a sulfinato-*S* complex, the central ion must have a soft (b[38]) character. This requires the lowest possible oxidation number, a low positive charge, a large ionic radius, occupied outer orbitals, and high polarizability.

The other ligands bonded to the coordination center besides RSO_2^- must have primarily π-acceptor as well as donor properties. Because of its energetically favorable, empty d orbitals, sulfur itself is suitable for the acceptance of the negative charge of the central ion *via* a (d-d)π bond.

By suitable choice of ligands, it is possible to induce a soft character in a metal ion that is hard by nature. Typical examples of this are found among the sulfinato-*S* complexes of Co^{III}: $[Co(SO_2R)(CN)_5]^{3-}$[39], RSO_2Co(salen) (salen = *N,N'*-ethylenebis(salicylideneiminato))[40], and $[RSO_2\text{-}Co(dmgH)_2py]$ (dmgH = dimethylglyoximato)[41].

2.2.2. Sulfinato-*O* Complexes

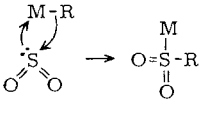
The conditions for obtaining a sulfinato-*O* complex are hard character of the central ion, *i.e.* higher oxidation number, higher effective charge, small ionic radius, low polarizability, and low oxidizability. The ligands coordinated besides RSO_2^- must be hard, *i.e.* they must have mainly donor properties.

A sulfinato-*S* complex may be converted into a sulfinato-*O* complex by ligand exchange or addition reactions[27,31]:

$$\underset{\text{sulfinato-}S}{CF_3SO_2Fe(CO)_4Cl} + 2\,THF \rightarrow \underset{\text{sulfinato-}O,O'}{CF_3SO_2Fe(THF)_2Cl} + 4\,CO \quad (1)$$

$$\underset{\text{sulfinato-}S}{(RSO_2)_2Hg} + 2\,H_2O \rightarrow \underset{\text{sulfinato-}O,O'}{(RSO_2)_2Hg(OH_2)_2} \quad (2)$$

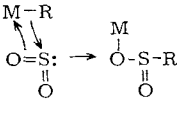
Thus hard ligands without π-acceptor properties cause rearrangement of the RSO_2^- group such that it becomes bonded to the central ion *via* the hard oxygen.



3. Preparation

The fundamental routes to obtain sulfinato complexes are as follows:

(a) *Insertion of SO_2 into the metal-carbon bond of organometallic compounds:*

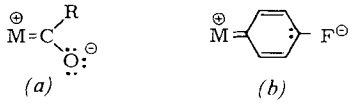


$$R\text{—}M + SO_2 \rightarrow RSO_2M \quad (3)$$

Investigations on the reaction mechanism[42–48] point to an electrophilic cleavage of the metal-carbon bond. Depending on whether SO_2 attacks the central ion nucleophilically *via* sulfur or oxygen, the result is a sulfinato-*S* [eq. (4)] or a sulfinato-*O* complex [eq. (5)].

(4)

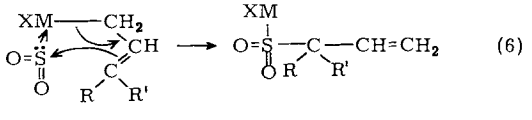
S_Ei



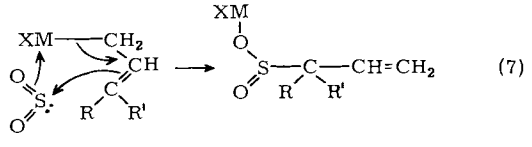
(5)

Transition metals in low oxidation states (soft character; cf. Sections 2.2.1 and 3.1.1) and some Hg compounds show a preference for path (4). With metals of hard character, such as Zn, Al, Ga, In, Tl, Sn, and Pb, on the other hand, the SO_2-insertion takes place in accordance with eq. (5). Except in the cases of organotin and organolead compounds, the cleavage of the metal-carbon bond by SO_2 becomes more difficult in the following order[26,48]:

$$CH_3 \sim C_2H_5 \gg C_6H_5 \sim CH_2C_6H_5$$



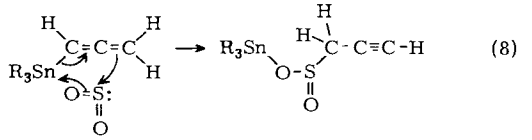
Acyl, perfluoroalkyl, and perfluoroaryl derivatives of transition metals do not react with SO_2[26]. This is traced back to a strengthened M—C bond as a result of significant contributions from the resonance structures *(a)* and *(b)*[49,50].



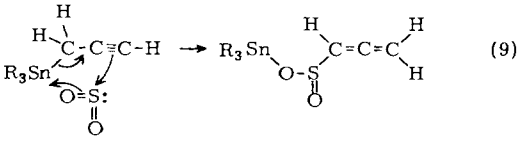
(a) *(b)*

Moreover, SO_2 is inserted preferentially into the *p*-tolylmercury bond of C_6H_5—Hg—$C_6H_4CH_3$; no reaction is observed with C_6H_5—Hg—Cl, $(C_6F_5)_2Hg$, or $(C_6Cl_5)_2Hg$, which have been found to be particularly resistant to electrophilic cleavage of the C—Hg bond[51]. These observations agree with the mechanisms given above [S_Ei; eq. (4), (5)].

Important information concerning the course of the reaction was obtained from the action of SO_2 on 2-alkenylmetal, allenylmetal, and 2-alkynylmetal compounds:



(6)



(7)

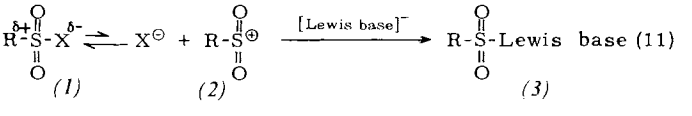
There is no doubt that reaction path (6) is favored in the case of $(CO)_5MCH_2CH{=}CRR'$ (M = Mn, R = H and CH_3, R' = CH_3; M = Re, R = R' = CH_3)[42,43]. As was shown by *Kitching et al.*[45–47], however, the insertion of SO_2 in allylstannanes (M = Sn, X = R_3) proceeds in accordance with eq. (7).

(8)

(9)

The examples (7)—(9) show that the insertion of SO_2 into 2-alkenyltin, allenyltin, and 2-alkynyltin derivatives is accompanied by rearrangement of these groups to form the alternative 2-alkenyl, 2-alkynyl, and allenyl structures respectively. Mechanisms as shown in eq. (6)—(9) may be described as S_Ei' cleavages[47]. The greatly increased reaction rates with alkenyltin, allenyltin, and alkynyltin derivatives are generally in agreement with the results of electrophilic cleavage in these organometallic systems.

The reasons for the complete absence of an S_E component of this insertion in allenetin compounds are not clear. The true reaction order with respect to SO_2 is probably greater than one, owing to donor-acceptor interactions with the metal or the unsaturated centers.



A well-established relation exists between the electrophilic cleavage of a C—Sn and of a C—Pb bond, the latter bond being more reactive. *Kitching* and *Fong*[48] found no evidence of an S_Ei' mechanism [eq. (7)] in the case of lead, since even the 2-butenyllead species are very unstable. However, the very fast reaction of the allyl complexes in comparison with the phenyl derivatives makes any other reaction path improbable.

(b) *Reaction of sulfonyl chlorides and sulfonic anhydrides with organometallic Lewis bases or neutral carbonylmetal compounds:*

$$RSO_2X + [\text{Lewis base}]^- \xrightarrow[THF]{-80\,^\circ C} RSO_2 - [\text{Lewis base}] + X^- \quad (10)$$

(R = CF_3, *p*-$CH_3C_6H_4$; X = Cl, *p*-$CH_3C_6H_4SO_3$; [Lewis base]$^-$ = $[Mn(CO)_5]^-$[52,53], $[Re(CO)_5]^-$[27], $[\pi\text{-}C_5H_5Fe(CO)_2]^-$[27,53], $[Co(CO)_3P(C_6H_5)_3]^-$[27,53]).

When a nucleophilic agent [Lewis base]$^-$ dissolved in a polar medium approaches the acyl halide or anhydride, the reaction [eq. (11)] probably proceeds by heterolysis *via* a transition state *(1)* to give the limiting form *(2)*. The intermediate cation *(2)* can then react with the nucleophile to form the derivative *(3)*, the heterolysis being the rate-determining step[53,54].

(1) *(2)* *(3)* (11)

The course of this reaction may therefore be compared with the behavior of aliphatic and aromatic acyl halides[54] or perfluorinated acid anhydrides[55] toward carbonylmetalates.

The action of organosulfonyl chlorides on mononuclear carbonylmetal compounds of the triads of groups V[56], VI[56], and VIII[27] leads, when R is electronegative (CF_3), to organosulfinato-*O,O'*-metal chlorides with bivalent metal:

$$RSO_2Cl + M(CO)_n \xrightarrow[n\text{-heptane}]{-20\,^\circ C/120\,^\circ C} RSO_2M(CO)_4Cl + (n\text{-}4)CO \quad (12)$$

(4)

$$(4) \xrightarrow[THF]{20\,^\circ C} RSO_2MCl + 4\,CO \quad (13)$$

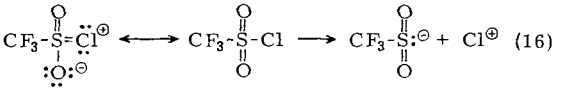
(R = CF_3; M = V, Cr, Mo, W, Fe, Ni)

The reactions proceed *via* the more or less unstable intermediates (4).

With more electropositive R (*p*-$CH_3C_6H_4$), the products are organosulfinato-*O,O'*-metal chlorides with bivalent (Ni)

or trivalent metal (Fe), depending on the oxidizability of the carbonylmetal component[56]:

$$4\,RSO_2Cl + 2\,Fe(CO)_5 \xrightarrow[THF]{20^\circ C} 2\,RSO_2FeCl_2 + 10\,CO + (RSO_2)_2 \quad (14)$$



($R = p\text{-}CH_3C_6H_4$)

CF_3SO_2Cl reacts quite differently with binuclear carbonyl complexes:

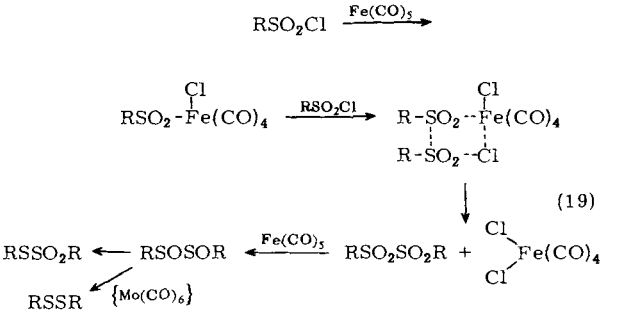
$$CF_3SO_2Cl + [\pi\text{-}C_5H_5M(CO)_n]_2 \xrightarrow{-20^\circ C} \pi\text{-}C_5H_5M(CO)_nSO_2CF_3 + \pi\text{-}C_5H_5M(CO)_nCl \quad (15)$$

($M = Fe$, $n = 2$[27]; $M = Ni$, $n = 1$[56])

Because of the strongly electron-attracting effect of the trifluoromethanesulfonyl residue on the Cl atom, heterolysis of the CF_3SO_2Cl molecule probably occurs here under the influence of a suitable reagent.

(16)

Perfluoroalkyl iodides behave similarly toward carbonylmetal and π-cyclopentadienylcarbonylmetal complexes[55, 57].



It is interesting to note that the reaction of RSO_2Cl with mononuclear carbonylmetal compounds proceeds further when tetramethylurea (TMU) is used as the solvent. *Alper* found that the reaction with $Fe(CO)_5$ leads to *S*-alkyl (aryl) thiosulfonates[58],

$$RSO_2Cl + Fe(CO)_5 \xrightarrow[TMU]{BF_3\cdot(C_2H_5)_2O} RSSO_2R \quad (17)$$

and the reaction with $Mo(CO)_6$ to disulfides[59].

$$RSO_2Cl + Mo(CO)_6 \xrightarrow[TMU]{} RSSR \quad (18)$$

According to the proposed mechanism[58], this reaction again proceeds *via* $RSO_2Fe(CO)_4Cl$ [cf. also eq. (12)]:

(19)

(c) *Reaction of metal halide compounds with alkaly metal sulfinates:*

$$R'_nMX_m + mRSO_2^- \rightarrow R'_nM(SO_2R)_m + mX^- \quad (20)$$

$$[(n\text{-}C_4H_9)_4N][M(CO_5)I] + RSO_2^- \rightarrow [M(CO)_5SO_2R]^- + [(n\text{-}C_4H_9)_4N]I \quad (21)$$

($M = Cr, W$; $R = C_6H_5$[60])

As has been shown, the preparation methods (a), (b), and (c) are not generally applicable, but supplement one another well.

3.1. Transition Metal Sulfinates

3.1.1. Transition Metals in Low Oxidation States

Of the sulfinatocarbonylmetal compounds of the triads of groups VI, VII, and VIII, only the *S* type is known, for the reasons given in Section 2.2.1.

The electron-attracting CF_3 group causes an increase in the SO_2 stretching frequencies in comparison with unfluorinated derivatives. This naturally requires a correspondingly shorter wavelength for the position of the CO absorptions, which is in fact found in every case. The spectra of the manganese and rhenium complexes are characterized by the occurrence of five absorptions in the region of terminal CO groups. The C_{4v} symmetry is so strongly distorted by the angular RSO_2^- ligands that the B_1 vibration, which is forbidden by the IR selection rules, is also present, and the band due to the E vibration is split.

Table 1. Some characteristic sulfinatocarbonylmetal complexes of the group VI, VII, and VIII triads.

3.1.2. Transition Metals in Normal and Higher Oxidation States

Sulfinato complexes of monovalent, bivalent, trivalent, and tetravalent transition metals having the general formulas RSO_2M, RSO_2MR, $(RSO_2)_2M$, $(RSO_2)_3M$, $(RSO_2)_2MR_2$, and $(RSO_2)_4M$ will be described here.

Corresponding to the Ahrland-Chatt classification[38], the RSO_2^- ligand acts as an oxygen donor (sulfinato-*O*) with the 3d metals, whereas mainly sulfinato-*S* derivatives are formed with Pd, Pt, and Hg.

Monosulfinato[19, 63], bis(sulfinato)[3, 5, 28, 31, 51, 56, 64–67], tris(sulfinato)[3, 56, 68], and tetrakis(sulfinato)[68] complexes are obtained by reaction of soluble metal halides or acetates with sodium sulfinates in water, ethanol, or THF at temperatures between 25 and 80 °C in accordance with

$$MX_n + nRSO_2Na \rightarrow nNaX + M(O_2SR)_n \quad (22)$$

(M = 3d, 4d, 5d metal; R = *p*-$CH_3C_6H_4$, C_6H_5, CH_3)

Compounds of the type RSO_2M are known[19] and have been investigated by IR spectroscopy[63] only in the group I triad, with Ag^I (cf. Table 3).

mixed, pure, and perfluorinated arylmercury arenesulfinates $R'SO_2HgR$ (*e.g.* R' = C_6H_5, R = C_6F_5) by reaction of $(R'SO_2)_2Hg$ with HgR_2.

Bonding isomers in which the sulfinato ligand is bonded *via* oxygen in one case and *via* sulfur in the other were isolated for the first time with $C_6H_5SO_2HgC_6H_5$[31, 51, 69]. The *O* type is formed by crystallization from the sulfinato-*S* complex. $C_2H_5SO_2HgC_2H_5$ is of the *S* type in the solid state, whereas the ethanesulfinate group is coordinated *via* oxygen in solution[69].

UV spectra confirm an octahedral configuration of the central ion in the bis(sulfinato)diaquametal(II) complexes (M = Co and Ni, R = C_6H_5; M = Cu, R = C_6H_5, *p*-$CH_3C_6H_4$)[64]. According to the small frequency differences between $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ (cf. Table 3), the RSO_2^- groups are bonded to the metal *via* both oxygen atoms. It cannot be established conclusively from the IR spectrum whether the ligands are linked intramolecularly or intermolecularly to the coordination center M. However, the insolubility of the bis(arenesulfinato)metals in organic solvents and even in water points to a polymeric intermolecular linkage.

Table 2. SO_2 stretching frequencies (in cm^{-1}) of some RSO_2MR complexes.

[a] Cf. Section 2.1.

Whereas dialkyl(aryl)zinc[2] and dialkyl(aryl)mercury derivatives[69] take up 1 mole of SO_2 to form RSO_2MR under certain conditions, bis-insertion occurs only with $(CH_3)_2Zn$[1, 2]. *Deacon* and *Felder*[31, 51] have synthesized

The bonding of the RSO_2^- ligands to Zn^{II}, Cd^{II}, and Hg^{II} depends on the water content of the compound[3] (cf. Table 3). The tendency to split off water increases from zinc to mercury. Since Hg^{II}, according to the Chatt-Ahrland clas-

sification[38], is one of the particularly strong b acceptors, it favors the *S*-linkage. Bonding of the RSO_2^- residue to mercury *via* both O atoms is found only in the derivatives containing water, and because of their instability, these immediately split off water to form the *S* type. The b character is considerably weakened in cadmium, while zinc even has strong a-acceptor properties. This explains why the RSO_2^- ligands are always bonded *via* one and two O atoms respectively to these last two metals.

Though the IR spectra of the sulfinatometal chlorides RSO_2MCl [cf. Section 3(b), eq. (12) and (13)] of vanadium[56], chromium[56], molybdenum[56], tungsten[56], iron[27], cobalt[56], and nickel[27,56] provide no definite information about their structures, the position of the symmetric SO_2 stretching vibration in particular indicates that the RSO_2^- group (R = CF_3, *p*-$CH_3C_6H_4$) is bonded to the metal *via* both O atoms ($CF_3SO_2FeCl(THF)_2$: $\nu_{as}(SO_2)$ = 1192 vs, 1156 s, $\nu_s(SO_2)$ = 1001 vs; $CF_3SO_2NiCl(THF)_2$: $\nu_{as}(SO_2)$ = 1192 vs, 1154 s, $\nu_s(SO_2)$ = 975 vs). The asymmetric SO_2 stretching vibrations in CF_3SO_2MCl absorb at surprisingly short wavelengths. This may be caused by coupling of the asymmetric CF_3 and SO_2 stretching vibrations, since the $\nu_{as}(CF_3)$ bands appear at relatively low frequencies. The electronic spectra indicate a pseudooctahedral environment of the central ions for $CF_3SO_2MCl(THF)_2$ (M = Fe, Ni)[27].

The sulfinatometal chlorides RSO_2MCl are formally comparable with the Grignard compounds RMgX in their composition. Their reactivity was therefore investigated, but was found to be much lower; nucleophilic transfer of the RSO_2^- group has never yet been achieved. This seems understandable when one considers that the bidentate character and the associated chelating effect result in considerable strengthening of the metal-ligand bond[56].

The bis(trifluoromethanesulfinato)metal complexes of molybdenum, iron, and nickel are obtained in a rather unusual reaction on treatment of the corresponding bis(π-cyclopentadienylmetalcarbonyls) with CF_3SO_2Cl in a polar medium such as tetrahydrofuran[56]:

$$2\,CF_3SO_2Cl + [\pi\text{-}C_5H_5M(CO)_n]_2 \xrightarrow[THF]{20\,^\circ C} MCl_2 + (CF_3SO_2)_2M + 2\,nCO + 2\,C_5H_5 \qquad (23)$$

(M = Mo, Fe, Ni; n = 3, 2, 1)

The corresponding zinc compound $(CF_3SO_2)_2Zn$ was prepared by reduction of CF_3SO_2Cl with zinc[70]. The $CF_3SO_2^-$ residue appears from the IR spectra (cf. Table 3) to be linked to the metal *via* both oxygen atoms.

Palladium(II) compounds combine with the benzenesulfinate ion to form complexes of the type $(C_6H_5SO_2)_2Pd(OH_2)_2$, $[(C_6H_5SO_2)_2PdX(OH_2)]^-$, and $[(C_6H_5SO_2)_2PdX_2]^{2-}$ (X = Cl, Br), in which the sulfinato ligand is coordinated *via* the sulfur[71] (cf. Table 4). A striking characteristic of these sulfinato complexes is their great formation tendency and the chemical stability of the aqua species. This behavior is also found for sulfito[72] and thiosulfato[73] derivatives, and is evidently characteristic of thio anions bonded *via* S. The thiosulfato and sulfito ligands greatly facilitate substitution *trans* to themselves (*trans* effect)[73,74]; the strong formation tendency of aqua species can be attributed to this effect[75].

Table 4. SO_2 stretching frequencies (in cm^{-1}) of some sulfinato complexes of noble metals (BS = $C_6H_5SO_2^-$, TS = *p*-$CH_3C_6H_4SO_2^-$).

Compound	$\nu_{as}(SO_2)$	$\nu_s(SO_2)$	Ref.	Bond type
$(BS)_2Pd(OH_2)_2$	1195 s 1103 s	1057 s	[71]	Sulfinato-*S*
$Na[(BS)_2PdCl(OH_2)]$	1189 s 1099 s	1051 s	[71]	Sulfinato-*S*
$Li_2[(BS)_2PdCl_2]$	1200 s 1103 s	1060 s	[71]	Sulfinato-*S*
$TSIr(CO)(P(C_6H_5)_3)_2Cl_2$	1240 1220	1065 1055	[76]	Sulfinato-*S*
$TSPt(P(C_6H_5)_3)_2Cl$	1205	1043	[77]	Sulfinato-*S*

The reactivity of the benzenesulfinato derivatives can be best understood by assuming that this ligand also exerts a strong *trans* effect, and the coordinated water is consequently bonded *trans* to a sulfinate group. The *cis* configuration is therefore assigned to $[(C_6H_5SO_2)_2PdX(OH_2)]^-$, $(C_6H_5SO_2)_2Pd(OH_2)_2$, and even $[(C_6H_5SO_2)_2PdX_2]^{2-}$[71].

Phosphane-substituted iridium(I)[76] and platinum(0)[77] complexes add sulfonyl chlorides to form octahedral Ir^{III} and square-planar Pt^{II} derivatives of the *S* type (cf. Table 4).

Tris(sulfinato) complexes are known at present for V, Cr, and Fe[3,68]. In contrast to *p*-$CH_3C_6H_4SO_2MCl_2$ (M = Tl, As; cf. Section 3.2[90,106]), *p*-$CH_3C_6H_4SO_2FeCl_2$ [cf. Section 3(b), eq. (14)] can undergo substitution of both Cl atoms by a sulfinato ligand, again with formation of tris(sulfinato) complexes[56].

Three SO bands with the irreducible representations $A_2 + 2E$ are observed in the IR spectra of all $(RSO_2)_3M$ derivatives (Table 5). This leads to the deduction of an octahedral configuration with D_3 symmetry, which is confirmed by the electronic spectra. The RSO_2^- ligands are linked intramolecularly *via* both O atoms to the central ions. The solubility behavior, all tris(methanesulfinato) complexes being very readily soluble in ethanol, also points to the monomeric structure.

Table 5. SO stretching frequencies (in cm^{-1}) of some tris(sulfinato) and tetrakis(sulfinato) complexes (solid, KBr).

Compound	SO stretching frequencies
$(CH_3SO_2)_3V$	970 sh (A_2), 957 vs (E), 920 vs (E)
$(CH_3SO_2)_3Cr$	964 sh (A_2), 947 vs (E), 925 vs (E)
$(CH_3SO_2)_3Fe$	967 s (A_2), 946 vs (E), 919 vs (E)
$(CH_3SO_2)_4Zr$	997 vs (E), 958 vs (E), 931 vs (B_2)
$(\pi\text{-}C_5H_5)_2Zr(O_2SCH_3)_2$	$\nu_{as}(SO_2) + \nu_s(SO_2)$ 1020 vs, 1009 vs, 972 vs, 943 w

Only mono(sulfinato) compounds of Co^{III} have so far been obtained both by insertion of SO_2 and by oxidation with RSO_2Cl[39-41], *e.g.*

$$[Co(CN)_5R]^{3-} + SO_2 \longrightarrow [Co(CN)_5SO_2R]^{3-}\,[39] \quad (R = CH_2C_6H_5) \qquad (24)$$

$$2\,[Co(CN)_5]^{3-} + RSO_2Cl \longrightarrow [Co(CN)_5SO_2R]^{3-}\,[39] + [Co(CN)_5Cl]^{3-} \qquad (25)$$

(R = CH_3, C_2H_5, C_6H_5, $CH_2C_6H_5$, *p*-$CH_3C_6H_4$, *p*-ClC_6H_4)

In all the Co^{III} sulfinates known at present, the RSO_2^- group is linked to the metal *via* the sulfur, as can be seen from Table 6 (cf. Section 2.2.1).

Table 6. SO_2 stretching frequencies (in cm^{-1}) of some mono(sulfinato-*S*)cobalt^{III} compounds (salen = *N,N'*-ethylenebis(salicylideneiminato), dmgH = dimethylglyoximato).

Compound	$\nu_{as}(SO_2)$	$\nu_s(SO_2)$	Ref.
$[CH_3SO_2Co(CN)_5]^{3-}$	1150	1035	[39]
$[C_6H_5SO_2Co(CN)_5]^{3-}$	1200	1040	[39]
$CH_3SO_2Co(salen)(OH_2)_3$	1197 s, b	1063 s	[40]
$C_6H_5SO_2Co(salen)(OH_2)$	1224 s	1062 s	[40]
$CH_3SO_2Co(dmgH)_2py$	1197	1065	[41]
$C_6H_5SO_2Co(dmgH)_2py$	1234	1058	[41]

Solvent dependence [cf. Section 3(b), eq. (12), (17)] is again found in the preparation of compounds of the types $(RSO_2)_2MR_2$ and $(RSO_2)_4M$:

$$(\pi\text{-}C_5H_5)_2ZrCl_2 + 2CH_3SO_2Na \xrightarrow[THF]{80\,^\circ C} (\pi\text{-}C_5H_5)_2Zr(O_2SCH_3)_2{}^{[68]} + 2NaCl \quad (26)$$

$$(\pi\text{-}C_5H_5)_2ZrCl_2 + 4CH_3SO_2Na \xrightarrow[ethanol]{} (CH_3SO_2)_4Zr + 2NaCl + 2C_5H_5Na{}^{[68]} \quad (27)$$

Both zirconium derivatives exist as sulfinato-*O,O'* complexes (cf. Table 5). In the case of the bis(sulfinato) product, however, intermolecular linkage of the coordination polyhedra *via* RSO_2^- bridges cannot be ruled out on the basis of IR spectroscopy.

The IR spectrum of the diamagnetic $(CH_3SO_2)_4Zr$ contains three strong SO stretching absorptions of the classes $B_2 + 2E$ with small frequency differences. A cubic configuration with D_{2d} symmetry can therefore be assigned to tetrakis(methanesulfinato)zirconium(IV).

3.2. Sulfinates of Main Group Elements

The decomposition of aluminum tris(alkanesulfinate) $(RSO_2)_3Al$ with dilute acids to obtain alkanesulfinic acids, a process that can be used even on the industrial scale, has been known for a long time[78, 79]. All the Al—C bonds are split by SO_2, the first so vigorously that a distinct decrease in the yield of sulfinic acid may be found on introduction of SO_2, corresponding to further reaction of aluminum sulfinate that is already formed with unreacted R_3Al to form $(R_2Al)_2O_2SR_2$[80]. Side reactions are best avoided by the reversed reaction principle[78]. Solvents that complex R_3Al as an ether adduct may also be used[79, 81]. Thus *Baker* and *Sisler*[81] obtained $(C_2H_5SO_2)_3Al$ in the pure state for the first time by this method. SO_2 reacts very poorly with triisobutylaluminum, since apart from steric factors, the latter acts mainly as a reducing agent on SO_2[80]. Alkylaluminum halides react without forming by-products. The conversion of a mixture of $(CH_3)_3Al$ and $AlCl_3$ ("methylaluminum sesquichloride") into methanesulfinic acid[82] is well known.

Sulfonyl chlorides react with alkylaluminum derivatives in a molar ratio of 1:1 to form the alkyl chloride and aluminum sulfinate[83]:

$$RSO_2Cl + R'AlX_2 \longrightarrow RSO_2AlX_2 + R'Cl \quad (28)$$
$$(X = R', Cl)$$

It is assumed that after the electrophilic attack of the aluminum compound on the sulfonyl chloride, the chlorine is cationically removed from the sulfur in a synchronous process, and combines with a negatively charged alkyl group of the organoaluminum compound to form the alkyl chloride.

Alkylation to form the sulfoxide takes place with aromatic sulfonyl chlorides in a molar ratio of 1:2[83]:

$$RSO_2Cl + 2R'AlX_2 \longrightarrow R_2SO + R'Cl + X_2AlOAlX_2 \quad (29)$$
$$(X = R', Cl)$$

This difference in behavior is due to the electron density on the sulfur. The aluminum sulfinate formed in the first reaction step (28) allows the alkylation of the sulfur if the electron density on this atom is reduced to a sufficient degree by an electron-attracting substituent, so that attack by the negatively charged ethyl residue is possible.

In contrast to R_3Al, only one mole of SO_2 is inserted into the C—M bond in trialkylgallium[84], trialkylindium[85], and trialkylthallium[86]. The reason for this difference in the mode of reaction probably lies in the considerably greater affinity of aluminum for oxygen, which causes a striving for the maximum possible coordination number of 6. No SO_2 insertion is observed in halogenated organogallium[87], organoindium[87], or organothallium derivatives[86].

IR spectroscopic studies by *Weidlein*[84, 85, 87, 88] suggest puckered $M_2O_4S_2$ eight-membered ring skeletons (sulfinato-*O,O'*; cf. Section 2.1) for the metal sulfinates of the third main group.

p-$CH_3C_6H_4SO_2Na$ reacts with $TlCl_3$ to form *p*-$CH_3C_6H_4SO_2TlCl_2$, and with Tl^I formate to form *p*-$CH_3C_6H_4SO_2Tl$[90], the structures of which are unknown.

Table 7. SO_2 stretching frequencies (in cm^{-1}) of some metal sulfinates of the third main group.

Compound	$\nu_{as}(SO_2)$	$\nu_s(SO_2)$	Ref.
$[(C_2H_5SO_2)_3Al]_{polym.}$	999 vs	975 vs	[81, 87, 88]

$[C_6H_5SO_2Ga(CH_3)_2]_2$	1005 vs	941 vs	[89]
$[CH_3SO_2In(CH_3)_2]$ [a]	1030 vs 999 vs	951 s	[85]
$[CH_3SO_2Tl(CH_3)_2]$ [a]	1080–965		[86]

[a] Degree of association unknown.

In contrast to the third main group, the reactivity to SO_2 increases from the lighter to the heavier elements in the organo derivatives of the fourth main group. Thus tetraorganosilanes[91] and tetraorganogermanes[91] are not attacked by SO_2, whereas organoplumbanes take up two[92–94] or three[48] moles of SO_2. In the case of tin, the insertion of SO_2 is found to depend on the organo residue. With tetra-*n*-butylstannane and tetraphenylstannane, no reaction products are isolated at a reaction temperature of $-20\,^\circ C$[95]. Since the dissociation energies of the Sn—C bond are roughly equal in tetraethyltin, tetra-*n*-propyltin, and tetra-*n*-butyltin, and are much lower than for $(CH_3)_4Sn$[96], the principal reason in the case of $(n\text{-}C_4H_9)_4S_n$ must be steric factors. The corresponding energy for $(C_6H_5)_4Sn$, on the other hand, is considerably greater[96]; in this case, SO_2 is taken up only at higher temperatures, with formation of $(C_6H_5)_2Sn(O_2SC_6H_5)_2$[97].

Of all the aromatic and saturated aliphatic organotin and organolead halides, only $(C_6H_5)_3SnCl$ and $(C_6H_5)_3PbCl$ react with SO_2, with disproportionation[97].

$$2(C_6H_5)_3MCl + 2SO_2 \xrightarrow[\text{liq. } SO_2]{60^\circ C} (C_6H_5)_2M(O_2SC_6H_5)_2 + (C_6H_5)_2MCl_2 \quad (30)$$

(M = Sn, Pb)

The diphenylmetalbis(benzenesulfinates) of Sn and Pb can also be prepared by direct reaction of the corresponding dihalides $(C_6H_5)_2MCl_2$ with benzenesulfinate and by insertion of SO_2 in $(C_6H_5)_3MO_2SC_6H_5$[97].

Eq. (30) contrasts with the insertion of SO_2 in organoaluminum halides, in which the M—Cl bond remains intact[87].

Since some arenesulfinato complexes of tin are difficult to obtain by SO_2 insertion, the reaction with sodium sulfinates has again proved useful here, particularly for the preparation of tricoordinated, pentacoordinated, and hexacoordinated tin sulfinates[98] [cf. eq. (20)].

$$MX_2 + 2NaO_2SR \xrightarrow[\text{ethanol/}H_2O]{20^\circ C} M(O_2SR)_2 + 2NaX \quad (31)$$

(M = Sn, Pb; X = Cl, NO_3; R = C_6H_5, p-$CH_3C_6H_4$)

The number of bands in the IR spectrum of $Sn(O_2SC_6H_5)_2$ (cf. Table 8) indicates that there is no equivalence in the manner in which the two sulfinato ligands are bonded. The tin atoms are evidently bonded intermolecularly *via* one RSO_2^- residue each (sulfinato-*O,O'*), whereas the second ligand is coordinated to the metal *via* one O atom (sulfinato-*O*). Taking the lone pair of electrons on the tin into account, the latter has a ψ-tetrahedral environment. This proposed structure is supported by Mössbauer spectra[98]. *Donaldson et al.*[99, 100] have suggested the same structure for tin(II) carboxylates. The IR spectrum of $(C_6H_5SO_2)_2Pb$ differs considerably from that of the corresponding tin compound. The structure thus cannot be the same as that proposed for the latter, particularly since the steric effect of the 6s electrons can be disregarded in the case of lead[99]. The small frequency difference between $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ (Table 8) indicates that *both* RSO_2^- ligands are bonded to the lead *via* oxygen (sulfinato-*O,O'*).

SO_2 acts as an oxidizing agent toward phosphorus(III) compounds[103, 104]. The course of the reaction depends on the particular P^{III} derivative in question. In many cases the reactions proceed in accordance with:

$$2P(XYZ) + SO_2 \longrightarrow 2O{=}P(XYZ) + 1/8\,S_8 \quad (32)$$

$$3P(XYZ) + SO_2 \longrightarrow 2O{=}P(XYZ) + S{=}P(XYZ) \quad (33)$$

In contrast to $TlCl_3$[90], but like $HgCl_2$[105], $AsCl_3$ reacts with camphor-10-sulfinic acid[106] with elimination of SO_2 and HCl and formation of a C—M bond (M = As; cf. also for M = Hg[5, 6, 105]). It is interesting to note that once again only one Cl—M bond is converted into a C—M bond.

Sulfur sulfinates, the so-called bis(benzenesulfonyl) and bis(*p*-toluenesulfonyl) sulfides, disulfides, and trisulfides, have been known for 100 years[107, 108]. However, it was only in 1948 that their structures were elucidated by X-ray studies[109, 110]. The designation "sulfide" is misleading here, since the bivalent sulfur is positively polarized. Thus sulfur disulfinate reacts with nucleophiles as a derivative of S^{2+}[111].

The selenium analogs $Se_n(SO_2R)_2$ are obtained *e.g.* by the following reactions[112–114]:

$$SeOCl_2 + 3NaO_2SR \rightarrow Se(SO_2R)_2 + RSO_3Na + 2NaCl \quad (34)$$

$$Se_2Cl_2 + 2NaO_2SR \rightarrow Se_2(SO_2R)_2 + 2NaCl \quad (35)$$

(R = p-$CH_3C_6H_4$, C_6H_5)

In reactions with nucleophiles, such as sodium ethylxanthate, the sulfonyl group is eliminated as a sulfinate ion. In the diselenium and triselenium derivatives, this takes place without opening of the Se—Se bonds[114].

Foss[114] has suggested unbranched S—Se—Se—S chains for the diselenium disulfinates, which are not, however, isomorphous with the corresponding disulfur disulfinates. The monoselenium disulfinates, on the other hand, have the same structure as the analogous sulfur compounds.

Tellurium disulfinates cannot be prepared by a reaction analogous to eq. (34)[115].

Table 8. SO_2 stretching frequencies (in cm^{-1}) of some sulfinato complexes of tin and lead.

4. Reactivity and Application

4.1. Elimination of SO_2 with Formation of a Carbon-Metal Bond

Since it is characteristic of acyl complexes of transition metals that they undergo decarbonylation to form the corresponding alkyl or aryl derivatives[116], it seemed

interesting to examine the question whether the analogous process, *i.e.* "desulfonylation", is possible with sulfinato complexes. Mass-spectroscopic studies on $RSO_2Mn(CO)_5$ compounds[60, 117] show that the first fragmentation yields $Mn(CO)_5SO_2^+$. The signal for $Mn(CO)_5R^+$ occurs with low intensity, *i.e.* the elimination of SO_2 accounts for only a minor part of the decomposition reactions. π-$C_5H_5Mo(CO)_3SO_2CH_2C_6H_5$[61] was the first transition metal sulfinate that was found both to be formed by insertion of SO_2 and to be degraded by desulfonylation.

Organomercury chlorides are obtained by elimination of SO_2[5, 6, 105]:

$$RSO_2H + HgCl_2 \xrightarrow{>T} RHgCl + SO_2 + HCl \qquad (36)$$

Apart from the formation of camphor-10-arsenic(III) dichloride[106], however, this method has not been used for the synthesis of organometallic derivatives of any other elements. The elimination of SO_2 from $Hg(SO_2R)_2$ in boiling toluene is suitable in many cases for the specific preparation of diarylmercuries[65]. However, this is equivalent to only a partial reaction reversal, since *e.g.* $(C_6H_5)_2Hg$ reacts with liquid SO_2 only to give $C_6H_5HgSO_2C_6H_5$[69]. On the other hand, true reversibility is found for the latter complex, which exists as two bonding isomers (sulfinato-*O* and sulfinato-*S*)[118]. Each isomer gives diphenylmercury in high yield when heated under vacuum, with no change in the bonding of the sulfinato group before the elimination of SO_2. In boiling toluene, the *p*-toluenesulfinato and benzenesulfinato derivatives $RSO_2Ir(CO)(P(C_6H_5)_3)_2Cl_2$[76] are converted into the corresponding *p*-tolyl and phenyl species. However, this type of reaction is not a generally applicable method for the preparation of aryl compounds of the group VIII triad metals, since other arylsulfinates (with R = *p*-ClC_6H_4, *p*-$O_2NC_6H_4$, and *p*-$CH_3OC_6H_4$) do not eliminate SO_2 under the same conditions[76]. Finally, *p*-$CH_3C_6H_4SO_2$-$Pt(P(C_6H_5)_3)_2Cl$ also undergoes desulfonylation, but only at 200 °C[77].

4.2. Ligand Behavior of Sulfinato Complexes

Rearrangement in the bonding of the sulfinato group can be brought about by reaction of sulfinato complexes with suitable ligands. Similar rearrangements have been observed for carbonylmanganese(I) compounds containing thiocyanate[119].

The SO_2 stretching frequencies of substituted sulfinatocarbonylmanganese(I) complexes[120] are considerably lower (cf. Table 9) than those of the unsubstituted complexes[60] (cf. Section 3.1.1). *Hartman* and *Wojcicki*[120] attribute this to further strengthening of the Mn=SO_2R π bond as compared with that in $RSO_2Mn(CO)_5$, together with a decrease in Mn—SO_2R σ character. This may be regarded as resulting from the replacement of the weak base and good π acceptor CO by a strong base and poor π acceptor, *i.e.* amine, phosphane or iodide.

The frequency difference for the SO_2 stretching vibrations in the IR spectrum of $[C_6H_5CH_2SO_2Mn(CO)_3py]_n$[120] is fairly small, and a sulfinato-*O,O'* linkage can therefore be assigned to this compound.

Table 9. SO_2 stretching frequencies (in cm^{-1}) of some substituted sulfinato complexes.

Compound	$\nu_{as}(SO_2)$ or $\nu(SO)$	$\nu_s(SO_2)$ or $\nu_{as}(SOM)$	Ref.	Bond type

$C_6H_5SO_2PdCl(py)_2$	1184	1032	[124]	Sulfinato-*S*

The substitution reactions on $RSO_2Mn(CO)_5$ surprisingly require more drastic conditions than those of $Mn(CO)_5X$ (X = Cl, Br). Examination of the CO frequencies, which are highest for $RSO_2Mn(CO)_5$, should lead one to expect the opposite. Thus factors other than the strength of the Mn=CO π bond must determine the reaction rate for

these complexes if the substitution follows a dissociation mechanism. A similar conflict between the ease with which CO is eliminated and the values of the CO frequencies was discussed earlier by *Angelici* and *Graham*[121].

If compounds of the type RSO_2MCl[27, 56], which attain a coordination number of 6 in solution only by addition of solvent molecules, are exposed to the action of bidentate chelating ligands (L), only the solvent molecules are displaced in the first reaction step:

$$RSO_2MCl \xrightarrow{+L} RSO_2MLCl \xrightarrow{+L} \underset{[ML_3][Cl, RSO_2]}{RSO_2ML_2Cl} \xrightarrow{+L} \quad (37)$$

On further addition of donor ligands, either rearrangement takes place in the bonding of the RSO_2^- group to the metal, or else an RSO_2^- or a Cl^- ion is removed[32].

The structures of the adducts (cf. Table 9) depend essentially on the choice of ligand, the ionic size of the bivalent metal, and the nucleophilic character of the RSO_2^- ligand.

Compounds of the type $(RSO_2)_2M$[56] also add bidentate ligands L:

$$(RSO_2)_2M \xrightarrow{+L} (RSO_2)_2ML \xrightarrow{+L} \underset{[ML_3][RSO_2]_2}{(RSO_2)_2ML_2} \xrightarrow{+L} \quad (38)$$

The addition parameters are the ionic size of the metal[23], the nucleophilic character of the RSO_2^- groups[23], and the solvent[122]. Whereas the reaction of the compound $(p\text{-}CH_3C_6H_4SO_2)_2Fe(OH_2)_2$ with 2,2'-bipyridine (bipy) yields the sulfinato-*O,O'* complex $(p\text{-}CH_3C_6H_4SO_2)_2Fe$bipy in tetrahydrofuran, the same reactants in pyridine give the sulfinato-*S* compound $(p\text{-}CH_3C_6H_4SO_2)_2Fe(bipy)_2$[122] (cf. Table 9). This also shows the influence of the ligand L on the character of the transition metal (cf. Section 2.2.1). By application of the solvent dependency it has also been possible to prepare the *O*- and *S*-bonding isomers of $(p\text{-}CH_3C_6H_4SO_2)_2Fe(bipy)_2$[122] and $(p\text{-}CH_3C_6H_4SO_2)_2Ni(bipy)_2$[122a].

The action of the potentially bidentate ligand ethylenediamine (en) on the sulfinato-*O,O'* complex $(p\text{-}CH_3C_6H_4SO_2)_2Mn(OH_2)_2$ leads to the ionic compound $[p\text{-}CH_3C_6H_4SO_2Mn(en)_2][p\text{-}CH_3C_6H_4SO_2]$, the cation of which can be characterized as $[p\text{-}CH_3C_6H_4SO_2Mn(en)_2][B(C_6H_5)_4]$. On reprecipitation, it changes back into the nonpolar *ionization isomer* $(p\text{-}CH_3C_6H_4SO_2)_2Mn(en)_2$[122, 123].

In the *p*-toluenesulfinato-*S*-platinum(II) complexes[33], such as *cis*- and *trans*-$[p\text{-}CH_3C_6H_4SO_2PtCl(PR_3)_2]$, $[p\text{-}CH_3C_6H_4SO_2PtCl(PR_3)]_2$, and $[(p\text{-}CH_3C_6H_4SO_2)Pt_2Cl_3(PR_3)_2]$, the sulfinato group has a *trans* effect similar to that of tertiary phosphanes. *Chatt* and *Mingos*[33] attribute this to strong electron transfer in the S—Pt σ bond. In complexes of other metals, on the other hand, it has been suggested that the sulfinato group is a weak σ donor and a strong π acceptor[26, 27, 76, 77, 120, 124].

4.3. Possible Applications of Sulfinic Acids and Sulfinates

Sulfinates find diverse applications in industrial processes. Thus in the copolymerization of butadiene and styrene in an emulsion of alkanesulfonic acid with air as the oxidizing agent and higher alkanesulfinic acids as oil-soluble reducing agents, dodecanethiol and iron(III) salts are essential for a favorable reaction course[110]. The optimum pH for fast polymerization varies with the alkanesulfinic acid (C_8 to C_{18} in the series of even, unbranched chains).

The effect of transition metal ions in the redox polymerization of vinyl acetate in solution has been investigated by *Ukita*[111]. Fe^{3+} ions are effective when the concentration of the redox catalyst (*p*-$ClC_6H_4SO_2H$/benzoyl peroxide) is low and the temperature high. Mn and Co ions influence the reaction in a similar manner. Cu^{II} salts also accelerate the polymerization even in low concentrations. The results of the investigations were interpreted as being due to a reaction between the metal ions and the benzoyl peroxide. In a process for the block and solution polymerization of vinyl acetate[113], the induction times are very short if a quaternary catalyst system containing a small quantity of an iron salt as well as an amine, a peroxide, and a sulfinic acid is used. The polymerization process becomes more controllable, and control of the continuous polymerization in particular improves. The addition of the iron salt also improves the ratio of the degrees of polymerization of polyvinyl acetate and of polyvinyl alcohol, *i.e.* the difference between the degree of polymerization of the acetate and that of the polyvinyl alcohol obtained from it by hydrolysis is decreased. This is an advantage in that a less crosslinked polyvinyl acetate whose structure corresponds more closely to that of the final polyvinyl alcohol is obtained.

The activity of catalysts (sulfinic acids combined with an oxygen donor) for the polymerization of monoolefinic systems can frequently be increased by the addition of heavy metal compounds, particularly compounds of metals that occur in several valence states, such as iron or cobalt naphthenate[114], iron(II) acetylacetonate[117], and copper salts[112, 125]. Calcium and strontium salts of aliphatic and aromatic sulfinic acids together with quaternary ammonium derivatives improve polymers of vinyl compounds[115]. Spinnable solutions of acrylonitrile-vinylidene chloride copolymers can be prepared by copolymerization in the presence of a redox catalyst system that contains the morpholinium or diethylammonium salts of *p*-chlorobenzenesulfinic acid[126].

Since solutions of acrylonitrile-vinylidene chloride copolymers containing more than 20% of chlorine readily turn yellow on heating, suitable stabilizers have been sought for a long time. It has been suggested that the sodium, potassium, or zinc salts of α-hydroxy sulfinic acids derived from formaldehydesulfoxylic acid should be used in combination with strong acids. However, the solubility of these salts in the organic solvents, *e.g.* dimethylformamide, is so low that deposition of salt crusts on the spinning nozzles occurs during the continuous spinning process[127]; moreover, they act as stabilizers only at low temperatures. Zinc salts of alkanesulfinic or arenesulfinic acids with no hydroxyl group on the α-carbon atom, on the other hand, have been found to be very suitable[127]; in contrast to the sulfoxylates, these zinc sulfinates are readily soluble in concentrations of more than 1% in dimethylformamide or dimethylacetamide at room temperature.

Silver benzenesulfinate is bactericidal, and prevents the growth of skin fungi without damaging human skin. Even

during the short duration of normal washing, soaps containing arenesulfinato complexes of silver (500 ppm) have a bactericidal effect[19].

Sodium or potassium salts of halogenated arenesulfinic acids change or regulate the growth of plant cells. For example, bean and tomato seeds germinate 5 days earlier and with better results. The falling of ripe apples is delayed by spraying with aqueous sulfinate solutions[128].

Finally, sulfinato complexes of cobalt or nickel may be added to the electrolyte in the electrolytic deposition of metal coatings in order to obtain a highly reflective, compact deposit of cobalt or nickel[18].

5. Outlook and Conclusion

The above discussions show the importance of the sulfinato complexes with regard to their structural diversity and their wide range of industrial applications. Though the catalytic activity of sulfinates has been known for more than twenty years, it is only very recently that interest has been shown in their reaction mechanism and in the elucidation of their structures. It is now possible to prepare sulfinato-*S* and sulfinato-*O* complexes as desired. Further insight into their structure should be provided in the future by X-ray analyses.

We are grateful to Dr. H. Weber, Dr. U. Kunze, Dipl.-Chem. D. Langner, and Dipl.-Chem. I. P. Lorenz for the investigations carried out by our own research group. We thank Professor Dr.-Ing. H. Behrens for his generous encouragement. Thanks are also due to the Deutsche Forschungsgemeinschaft for financial support and to the Fonds der Chemischen Industrie for a Liebig Scholarship.

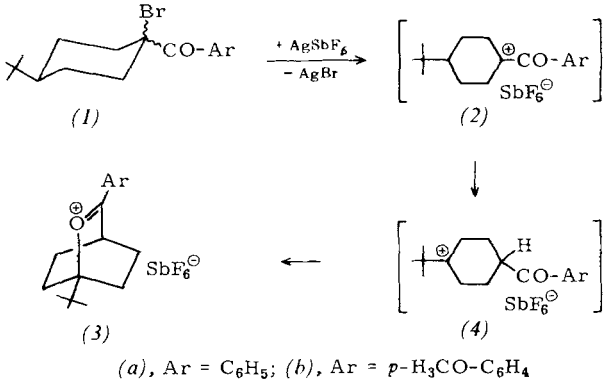
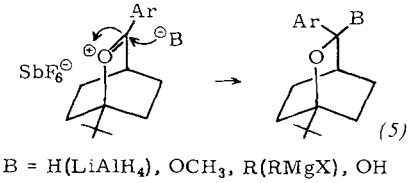
Dehalogenation of α-Haloketones *via* α-Oxocarbonium Ions to Stable Oxonium Salts



By *Jean Pierre Bégué* and *Micheline Charpentier-Morize*[*]

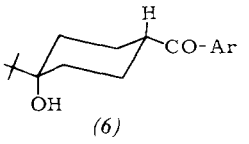
The existence of α-oxocarbonium ions has only recently been suggested in several reactions[1], including the dehalogenation of α-haloketones[2]. We describe results proving unambiguously the intermediacy of these highly reactive ions.

The two stereoisomeric ketones *(1)* [in the series *a* and *b*] were reacted with the powerful electrophile $AgSbF_6$[3]. Both epimers of *(1)* yielded the same crystalline salt, which is stable at room temperature. Its structure was deduced from its spectroscopic properties and its reactions.



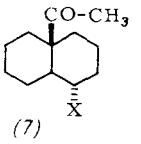
[IR of *(3a)* and *(3b)*: νC=O = 1600 cm^{-1}[4]; NMR ($CDCl_3$), *(3a)*: δ = 7.1—8.5 (5 aromatic H); 4.4 (1 H); 1.8—2.6 (4 CH_2); 1.2 (C_4H_9); *(3b)*: 7.17, 8.37 (4 aromatic H/AB system), J_{AB} = 9 Hz; 4.15 (1 H); 4.04 (OCH_3); 1.75 to 2.5 (4 CH_2); 1.19 (C_4H_9)].

Comparable oxonium ions[5] have similar spectra.



(a), Ar = C_6H_5; *(b)*, Ar = p-H_3CO-C_6H_4

The isolation of 3-aryl-1-*tert*-butyl-2-oxoniabicyclo[2.2.2]-oct-2-ene hexafluoroantimonates *(3a)* implies the initial formation of the α-oxocarbonium compounds 1-benzoyl-*(2a)* and 1-anisoyl-4-*tert*-butylcyclohexylium hexafluoroantimonate *(2b)*, leading by hydride migration (either stepwise or transannular) to the more stable carbonium compounds *(4)* and finally to the salt *(3)*.



B = H($LiAlH_4$), OCH_3, R(RMgX), OH

(3) reacts with nucleophilic reagents to give the 2-oxabicyclo[2.2.2]octanes *(5)*. Their structure is deduced from IR, NMR, and mass spectra and confirmed by the acid hydrolysis of *(5)*, B = OH, and *(5)*, B = CH_3O, to the ketone *(6)*, which loses water on treatment with iodine in xylene. Compounds similar to *(5)* have been obtained by dehalogenation of the haloketones *(7)*[6]

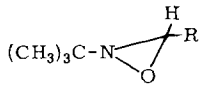
Deoxygenation of Oxaziranes by Sulfur-Containing Nucleophiles

By *David St. Clair Black* and *Keith G. Watson*[*]

Thiourea, potassium thiocyanate, potassium ethyl xanthate, and potassium selenocyanate are well known to react with oxiranes. In the case of the first three reagents[1–3], thiiranes are formed, but the last reagent[4] converts oxiranes to alkenes, *via* unstable seleniranes, from which selenium is eliminated.

We now report that oxaziranes are deoxygenated, not only by potassium selenocyanate, but also by the above sulfur-containing nucleophiles. The reactions are mild, simple and conversion to the related imine is effectively quantitative. All the above reagents are comparable in their effect, but thiourea is marginally the most convenient.



When thiourea and 2-*tert*-butyl-3-phenyloxazirane *(1a)*[5] were heated together under reflux in ethanol for six hours, *N*-benzylidene-*tert*-butylamine[5] was formed in almost quantitative yield and crystalline sulfur was also isolated in 30% yield. These results suggest that the reaction is similar to the conversion of oxiranes to thiiranes and that it proceeds *via* a thiazirane intermediate, from

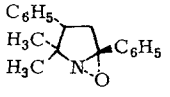
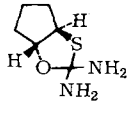
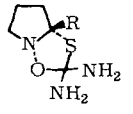
Clayton, Victoria 3168 (Australia)



which sulfur is spontaneously eliminated. Thiaziranes have recently been suggested[6,7] as reactive intermediates in the photochemical rearrangement of thiazoles[6] and isothiazoles[7,8], but are as yet unknown.



(1a), R = C_6H_5
(1b), R = CH_3



(2a), R = H

(2d)

(3)

(4)

The reaction of oxaziranes with sulfur-containing nucleophiles is influenced by stereochemical factors to a certain extent. For instance, 2-*tert*-butyl-3-methyloxazirane *(1b)*[9] remained unchanged in the presence of thiourea after twelve hours at room temperature; more vigorous conditions led to extensive tar formation. However, various fused bicyclic oxaziranes were smoothly converted to the related imines. In contrast to *(1b)*, 2,2-dimethyl-3-phenyl-6-oxa-1-azabicyclo[3.1.0]hexane *(2a)*[10] was completely deoxygenated after reaction for eight hours at room temperature. The more hindered oxaziranes *(2b)*[10] and *(2c)*[9] required a reaction temperature of 80 °C for five hours for complete deoxygenation, while compound *(2d)*[10] was only totally converted to the imine after twenty eight hours at 80 °C.

In general, the behavior of fused bicyclic oxaziranes is similar to that of simple ones, in marked contrast to the behavior of some fused oxiranes. Cyclopentene oxide is particularly resistant[2] to any reaction with thiourea or potassium thiocyanate. This result is consistent with the necessary formation of an unfavorable[11] *trans*-fused bicyclic intermediate, *e.g. (3)*, according to the postulated mechanistic pathway[2-3]. However, in the case of bicyclic oxaziranes, a *cis*-fused bicyclic intermediate, *e.g. (4)*, can always be formed, as a consequence of inversion of configuration at the nitrogen atom, even if such inversion is slow[12].

Bis(olefin)nickel(0) Complexes

By *P. W. Jolly, I. Tkatchenko,* and *Günther Wilke*[*]

The observation[1] that in 1,5,9-cyclododecatrienenickel(0) (CDT·Ni), for example, the *all-trans*-CDT can be exchanged for *all-cis*-CDT led us to attempt to replace the CDT in CDT·Ni·phosphane complexes by other olefins. We report below the preparation and characterization of the new types of bis(olefin)nickel(0) complexes *(1)—(3)*.

L = $P(C_6H_{11})_3$ for *(1a)*, R = H; *(1b)*, R = CH_3; *(1c)*, R = 3-cyclohexenyl; *(2)*; and *(3)*. L = $P(C_6H_5)_3$ for *(1d)*, R = H

Tricyclohexylphosphanebis(ethylene)nickel(0) *(1a)* is formed in 80–90% yield as an almost white precipitate when ethylene is passed into an ethereal suspension of *all-trans*-1,5,9-cyclododecatrienetricyclohexylphosphanenickel *(4)* at −20 °C. *(1a)* reacts with triphenylphosphane at 80 °C with displacement of the theoretical amount of ethylene. The structure of *(1a)* is proved by the IR spectrum [ν(C=C) at 1490 cm^{-1}] and the ^{1}H-NMR spectrum (τ = 7.22/s, $W_{h/2}$ = 4 Hz) (cf. $[(C_6H_{11})_3P]_2NiC_2H_4$, singlet at τ = 7.94[2]).

The complexes *(1b)* and *(1d)* are prepared analogously. The ^{1}H-NMR spectrum of the propene complex *(1b)* [$\tilde{\nu}$(C=C) = 1485 cm^{-1}] shows that several isomers are present in solution. The exchange reaction between propene and $(C_6H_5)_3PNi$—CDT at −20 °C leads only to separation of metallic nickel. The propene in *(1b)* is readily replaced on reaction with ethylene, with formation of *(1a)*.

(1c) and *(2)* are formed on reaction of *(4)* with vinylcyclohexene or divinylcyclobutane (DVCB), respectively, in ether at −20 °C. Both these compounds, which are white powders and extremely sensitive to air, react with CO at −78 °C with quantitative replacement of the vinylcyclohexene or divinylcyclobutane.

[*] Dr. P. W. Jolly, Dr. I. Tkatchenko, and Prof. Dr. G. Wilke
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

The bis(1,3-butadiene) complex *(3)* is obtained as a yellow, sparingly soluble compound having a somewhat sweet smell on interaction of *(4)* with liquid butadiene for 3 days at −20 °C. Replacement of the butadiene from *(3)* by triphenylphosphane at 80 °C is not quantitative: only 63–65% of the calculated amount of butadiene is found, and vinylcyclohexene, 1,5-cyclooctadiene, and divinylcyclobutane in the ratio 26:6:1 are also formed.

(3) can also be obtained from $[(C_6H_{11})_3P]_2Ni$ and butadiene, a compound $(C_6H_{11})_3PNi \cdot C_4H_6$[4] apparently being formed as intermediate; however, the nitrogen complex, $[[(C_6H_{11})_3P]_2Ni]_2N_2$[3] in toluene affords a product of composition $[[(C_6H_{11})_3P]Ni \cdot C_4H_6]_2 \cdot$ toluene. If *(3)* is treated with *(4)*, a sparingly soluble dimer, probably $[(C_6H_{11})_3P \cdot Ni \cdot C_4H_6]_2$, is precipitated. (For other properties of *(2)* and *(3)* and their relation to the mechanism of dimerization of butadiene on nickel-ligand catalysts see ref.[5].)

Experimental:

Ethylene is passed into a suspension of *(4)*, L = $P(C_6H_{11})_3$ (2.85 g, 5.7 mmole) at −20 °C until the color changes from orange to almost white (4 h). The precipitate *(1a)* is filtered off at −50 °C, washed three times with ether, and dried in a high vacuum (yield 2.0 g, 90%).

cis-Divinylcyclobutane (1 ml) is added dropwise to a suspension of *(4)*, L = $P(C_6H_{11})_3$ (3.55 g, 7.1 mmole) in ether at −20 °C. The mixture is stirred for 3 days at −20 °C and then cooled to −50 °C. The ether is removed and the white product *(2)* is washed three times with ether and dried in a high vacuum (yield 2.85 g, 90%).

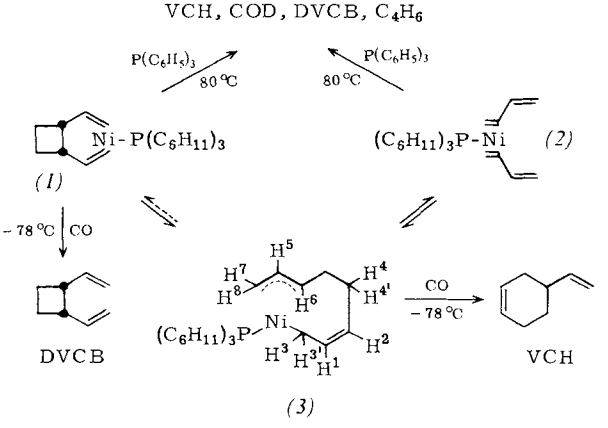
The Mechanism of the Cyclodimerization of Butadiene with Nickel-Ligand Catalysts

By *P. W. Jolly, I. Tkatchenko,* and *Günther Wilke*[*]



It has been frequently postulated that the transition metal catalyzed cyclooligomerizations of acetylene, 1,3-dienes, and olefins as well as the dismutation of olefins are concerted processes[1]. In particular the dimerization of butadiene to divinylcyclobutane (DVCB) with a nickel-ligand catalyst has been suggested to occur by a concerted mechanism[2]. This formulation, however, is in contrast to the stereochemistry of the isomers obtained from the cyclodimerization of substituted butadienes[3]. For some time now we have held the view that the dimerization is a multi-step process involving, among other intermediates, an α,ω-bisallyl-C_8-chain[4].

The isolation of $(C_6H_{11})_3P \cdot Ni \cdot DVCB$ *(1)* and $(C_6H_{11})_3PNi(C_4H_6)_2$ *(2)*[5] has presented the possibility of investigating this question experimentally and of showing that a multi-step process is involved.

Bis(butadiene)tricyclohexylphosphanenickel(0) *(2)*, a relatively thermally stable yellow compound, reacts with excess triphenylphosphane at 80 °C to give only 65% of the expected butadiene, the remainder being dimerized. In contrast the reaction in solution with CO at −78 °C gives exclusively vinylcyclohexene (VCH).

(1) reacts with CO at −78 °C to produce DVCB. If the same reaction is carried out with a sample which is first left in solution at room temperature for an hour one obtains exclusively VCH. *(2)* may be recovered unchanged from a toluene solution; under the same conditions *(1)* partly rearranges to *(2)*.

From these observations it may be concluded that *(1)* and *(2)* rearrange in solution to a common intermediate. Evidence for this is given by the ^{1}H-NMR spectra of solutions of *(1)* and *(2)* in cyclohexane—identical spectra are obtained which are in agreement with a π-allyl-σ-allyl structure *(3)* [NMR: τ = 4.35 (H^1/2 triplets, $J_{1,2}$ 9 Hz: $J_{1,3} = J_{1,3'}$ 9 Hz); 5.28 (H^2/2 triplets, $J_{1,2}$ 9 Hz; $J_{2,4} = J_{2,4'}$ 7 Hz); 5.88 (H^5/2 triplets, $J_{5,7}$ 8 Hz; $J_{5,6} = J_{5,8}$ 12 Hz) intensity 1:1:1].

Under the influence of an accelerating ligand (*e.g.* CO) ring closure occurs with formation of VCH (cf. the analogous reaction of C_{12}-bis(π-allyl)nickel with CO[6]).

It is also noteworthy that at room temperature in the *solid* state *(1)* rearranges to *(2)*. This shows itself as a color change from white *(1)* to yellow *(2)*, as a decrease in the intensity of the 1482 cm^{-1} band (coordinated C=C) and increase in the intensity of the 1600 cm^{-1} band (free C=C) of *(2)*, as well as in the products obtained by reaction with triphenylphosphane at 80 °C; the volatile hydrocarbon products obtained from freshly prepared *(1a)* and from two months old *(1b)* have different compositions.

(1a): $\sum C_8 = 74\%$, DVCB:VCH:COD = 3.6:1.8:1 as well as 26% C_4H_6
(1b): $\sum C_8 = 62\%$, DVCB:VCH:COD = 4.7:4.3:1 as well as 38% C_4H_6

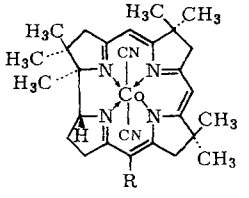
Dimethyl(methylene)ammonium Iodide[1][**]

By *Jakob Schreiber*, *Hans Maag*, *Naoto Hashimoto*, and *Albert Eschenmoser*[*]

We have recently begun to examine a possible parallelism between inversion of pyramidal nitrogen[2] and S_N2 inversion of tetrahedral carbon[3]. This problem, together with that of finding methods for introducing methyl groups into the corrin chromophore[4], has led us to investigate the behavior of (iodomethyl)trimethylammonium iodide *(1)*[5] with nucleophiles. We now describe some preparative results of these studies, namely, a simple and efficient synthesis of dimethyl(methylene)ammonium iodide *(2)*, as well as an example of its use as highly reactive "Mannich reagent"[6].

(1)



(2) *(1a)*

If a solution of the ammonium salt *(1)* (readily obtained from trimethylamine and diiodomethane[5a, 5b]) in tetrahydrothiophene dioxide is heated at *ca.* 150 °C for 10–15 min, methyl iodide distills off and, on cooling, the methyleneammonium salt *(2)* crystallizes from the solution in more than 80% yield. This salt can be recrystallized from the above solvent and sublimed without decomposition at 120 °C/*ca.* 0.05 torr; analytical and spectroscopic data (see below) confirm the structure.

Unlike the iodomethyl derivative *(1)*[7], crystalline tetramethylammonium iodide is thermostable (< 350 °C); moreover, when dissolved in tetrahydrothiophene dioxide, it does not lose methyl iodide at 200 °C to any appreciable extent. We interpret the decomposition *(1)*→*(2)* as an ($n\rightarrow\sigma/\sigma\rightarrow\pi$) fragmentation (possibly occurring concertedly [cf. *(1a)*]) and regard this type of reaction as a variant of the known ($n\rightarrow\pi/\sigma\rightarrow\pi$) fragmentation[8].

The course of the reaction *(1)*→*(2)* suggests the possibility of a new method of demethylating tertiary *N*-methylamines; preliminary experiments indicate that in such a case it is preferable to use more reactive nucleophiles, such as thiophenoxide[9], in the fragmentation step. Use of the salt *(2)* as reagent in reactions of the Mannich type[6, 10] is illustrated by formation of *(4)* from *(3)*.

(3), R = H
(4), R = CH_2-$N(CH_3)_2$
(5), R = CH_3

Stirring a solution of racemic dicyanocobalt(III)-1,2,2,7,7,-12,12-heptamethylcorrin *(3)*[11] in dichloromethane containing an excess of (undissolved) dimethyl(methylene)-ammonium iodide *(2)* for 20 hours at room temperature leads to an 85% yield of the pure, crystalline 15-(dimethylamino)methyl derivative *(4)* in a smooth electrophilic substitution reaction. Assignment of the constitution of this product rests on its characteristic NMR, IR, MS, and UV/visual spectra and is confirmed by hydrogenolytic conversion of *(4)* into the 15-methylcorrin derivative *(5)*, a compound known from earlier work[4]. The reaction sequence *(3)*→*(5)* constitutes a simple method of methylating (sterically unhindered!) meso positions of the corrin system.

Experimental[5a, 5b]:

A mixture of trimethylamine (20 g), diiodomethane (120 g), dioxane (20 ml), and anhydrous ethanol (150 ml) is kept in a closed vessel in the dark for 100 h at room temperature. The crystals formed are filtered off, washed with ethanol and then with ether, and dried for 1 h at 70 °C in a high vacuum. This affords *(1)* (98 g, 89%) as colorless crystals, double m. p.[7] *ca.* 190 °C (dec)/*ca.* 240 °C (dec); the product shows the same melting behavior after recrystallization from ethylene glycol.

A suspension of *(1)* (40.0 g) in tetrahydrothiophene dioxide (120 ml; distilled once from solid KOH and then from CaH_2) is placed in a thoroughly dry four-necked flask fitted with a stirrer and thermometer and tubes for passage of nitrogen, the exit tube leading to a cold trap. The flask is washed out with nitrogen and the reaction mixture is placed in an oil-bath heated to 160 °C whilst it is stirred and a slow stream of N_2 is passed in. The crystals dissolve rapidly at ≈130 °C, methyl iodide is conveyed by the N_2 stream into the cold trap[12], and the decomposition is complete in *ca.* 12 min (temp. ≈150 °C). On cooling in cold water, the salt *(2)* crystallizes directly from the yellow solution; it is filtered off with exclusion of moisture (N_2), washed five times with carbon tetrachloride (50-ml portions), whereupon it becomes almost colorless, and is dried in a high vacuum at 50 °C: this affords *(2)* (18.4 g, 81%),

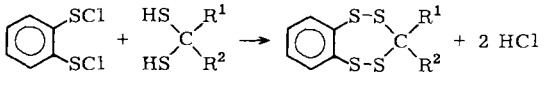
[12] The methyl iodide (b. p. 42 °C; 12.8 g, 73%) trapped at −70 °C was gas-chromatographically homogeneous.



[13] The IR spectra of the product were the same before and after sublimation. C, H, N determinations of the product before and after sublimation gave correct results.

[14] The pentadeuterio-DMSO signal at 2.54 ppm was accompanied by weak signals at 2.7 and 4.5 ppm ($\sum$ *ca.* 0.4 H) due to impurities.

Synthesis of 1,2,4,5-Benzotetrathiepins[1]

By *Franz Fehér, Franz Malcharek,* and *Klaus Glinka*[*]

1,2-Bis(chlorosulfanyl)benzene *(1)*[2] is admirably suited for cyclizing condensation with geminal dithiols *(2)*.

(1) *(2)* *(3)*

Using the dilution principle, we have obtained the 1,2,4,5-benzotetrathiepins *(3a)*, *(3b)*, and *(3c)* by treatment of *(1)* with methanedithiol *(2a)* ($R^1 = R^2 = H$)[3], 1,1-ethanedithiol *(2b)* ($R^1 = H$, $R^2 = CH_3$)[4], and 2,2-propanedithiol *(2c)* ($R^1 = R^2 = CH_3$)[5]. On recrystallization these products are obtained as colorless crystals in good yield. The composition and structures of the hitherto unknown materials *(2b)* and *(3a)–(3c)* were proved by elemental analysis and by mass and NMR spectra. Investigation of the temperature-dependence of the ^{1}H-NMR spectra of *(3a)–(3c)* are in progress.

1,2,4,5-Benzotetrathiepins (3)

100 ml each of solutions were prepared from *(1)* (0.01 mole)[2] in anhydrous carbon tetrachloride and the geminal dithiols *(2)* (0.01 mole) in anhydrous diethyl ether. The pairs of solutions were added dropwise from separate slow-yielding dropping funnels into anhydrous ether (1.8 liters) during 6–8 h, with vigorous stirring and bubbling of a slow stream of dry nitrogen through the reaction mixture. The solvent was removed in a rotatory evaporator, and the residue was treated with warm ethanol. Colorless crystals separated from the filtered ethanolic solution in the cold. *(3a)*, yield 55%, m. p. 92–93 °C, NMR: τ = 6.020 and 5.555 (CH), J = 14.3 Hz[6]. *(3b)*, yield 42%, m. p. 106 °C, NMR: τ = 7.884 and 8.546 (CH_3), 6.120 and 5.495 (CH), J_{CH_3-CH} = 6.7 Hz and 7.5 Hz, respectively. *(3c)*, yield 45%, m. p. 132 °C, NMR: τ = 7.937, 8.470, and 8.274 (CH_3).

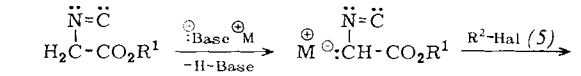
Higher Amino Acids by Alkylation of α-Metalated Isocyano-acetic or -propionic Esters[1]

By *Ulrich Schöllkopf, Dieter Hoppe,* and *Reinhard Jentsch*[*]



As can be recognized from the numerous studies of the alkylation of *N*-acylmalonic esters[2, 3], considerable preparative importance is attached to the formation of higher amino acids by alkylation of readily accessible, masked, lower α-amino acids[3]. We have now found that simple α-isocyanoalkanoic esters can be alkylated through their derivatives anionized at the α position, to yield higher α-isocyanoalkanoic acids that can be hydrolyzed to amino acids.

Dialkylated isocyanoacetic esters *(9)* (see Table) can be obtained from ethyl isocyanoacetate *(1)* and 2 equivalents of alkylating agent *(5)* in the presence of a base such as potassium *tert*-butoxide or sodium hydride in tetrahydrofuran or ether/DMSO. As a curiosity it may be mentioned that both 1,2-dibromoethane and 2-chloroethyl *p*-toluenesulfonate react with *(1)* undergoing ring closure to ethyl 1-isocyanocyclopropanecarboxylate *(10)*.

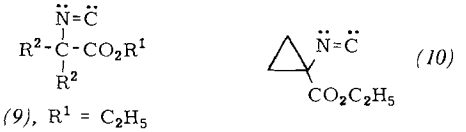
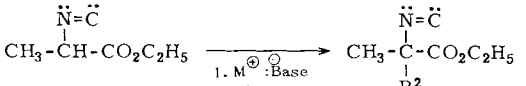
Essential intermediates are the metalated isocyano esters *(3)* [or *(4)*] and *(8)*. The intermediate alkylation products *(6)* could not as yet be isolated in preparatively satis-



(1), $R^1 = C_2H_5$ *(3)*, $R^1 = C_2H_5$

(2), $R^1 = C(CH_3)_3$ *(4)*, $R^1 = C(CH_3)_3$

(6), $R^1 = C_2H_5$ *(8)*, $R^1 = C_2H_5$



(7), $R^1 = C(CH_3)_3$

(9), $R^1 = C_2H_5$

factory yields because they react further with great rapidity to afford *(8)* and then *(9)*. However, monoalkylated products of type *(7)* can be obtained from *(2)* by way of *(4)*.

Investigations have shown that chain elongation can also be accomplished with ethyl esters of α-substituted isocyanoacetic acid, *e.g.*, with ethyl α-isocyanopropionate *(11)*, from which the ethyl α-isocyano-α-methylalkanoates *(12)* (see Table) can be obtained.

(11) *(12)*

Shaking ethyl 2-isocyanoalkanoates with ether and hydrochloric acid at room temperature converts them into *N*-formylamino esters, which yield amino acids when warmed with aqueous hydrochloric acid or amino ester hydrochlorides when kept in ethanol containing hydrogen chloride; the latter can also be obtained directly from the isocyano compounds. *N*-Formylamino acids are obtained by warming the isocyano ester in ethanolic potassium hydroxide for about 30 min and then acidifying the solution.

General experimental procedures:

Dialkylation of *(1)* with potassium *tert*-butoxide in tetrahydrofuran: A solution of *(1)* (0.02 mole) in THF (10 ml) is added dropwise, with stirring, to potassium *tert*-butoxide (0.04 mole) in anhydrous THF (25 ml) at −60 °C. Then the alkyl halide (0.042 mole) in THF (10 ml) is added at −60 to −50 °C, the cooling bath is removed, and the mixture is allowed to warm to room temperature while stirring is continued. The mixture is stirred until at least 95% of the potassium butoxide used has been consumed (*ca.* 30 min), then the solvent is distilled off at water-pump vacuum (bath-temp. 40 °C), the residue is shaken with ether (50 ml) and water (25 ml), the layers are separated, the aqueous solution is extracted once more with ether, and the combined ethereal solutions are dried over sodium sulfate and distilled.

Dialkylation of *(1)* with sodium hydride in dimethyl sulfoxide/ether: NaH (0.09 mole, suspended in 30 ml of ether) is added dropwise with vigorous stirring to a mixture of *(1)* (0.04 mole) and the alkyl halide (0.084 mole; or 0.042 mole 1,2-dibromoethane) in anhydrous DMSO (40 ml) and anhydrous ether (100 ml) under N_2 at 20–25 °C. When evolution of gas ceases, the mixture is boiled for a further 30 min, poured into ice-water (100 ml), and worked up as above except that ether-extraction is with three 50-ml portions and dissolved DMSO is removed by washing with water (50 ml). For monoalkylation of *(11)* the amounts of alkyl halide, NaH, and solvent are halved.

Monoalkylation of *(2)*: The ester *(2)* (0.04 mole) is dropped, with stirring, into potassium *tert*-butoxide (0.04 mole) in anhydrous THF (50 ml) at not more than −5 °C. This mixture is cooled to −70 °C and then precooled alkyl halide (0.04 mole) is added dropwise. This suspension is added dropwise from a dropping funnel (cooled in methanol-Dry Ice) to THF (50 ml) stirred at 50 °C. The mixture is then heated until a sample dissolved in water reacts only slightly alkaline (*ca.* 30 min), after which it is worked up as above.

Conversion into *N*-formylamino acids: Ethyl α-isocyanoalkanoate (10 mmole) is heated under reflux with KOH (0.6 g) in 90% ethanol (20 ml) for 30 min. The solvent is removed at water-pump vacuum, and the residue is dissolved in water (15 ml), if necessary with gentle warming, and acidified with concentrated hydrochloric acid (1 ml; pH = 1—2). The *N*-formylamino acid, which generally

separates as an oil, is made to crystallize in an ice-bath, filtered off, and if necessary recrystallized from ethanol or aqueous ethanol.

Conversion into an *N*-formylamino acid ester: Ethyl α-isocyanoalkanoate (20 mmole) is added to 37% hydrochloric acid (0.7 g) in ether (30 ml) at −10°C, and the layers are mixed cautiously (reaction exothermic!) and then shaken for a further 5 min, after which they are neutralized by 1 N-$NaHCO_3$ (12 ml). The organic layer is separated and the aqueous solution extracted again with ether (15 ml). The ethereal solutions are dried over sodium sulfate, and the *N*-formylamino ester is obtained in 80—100% yield by distillation or recrystallization.

Conversion into ethyl 2-aminoalkanoate hydrochloride: An ethyl 2-isocyanoalkanoate (10 mmole) in ethanol (3 ml) is added dropwise at −10°C to a saturated solution (10 ml) of hydrogen chloride in anhydrous ethanol and water (0.25 ml). The mixture is set aside at room temperature for 20 h, then the solvent is removed at water-pump vacuum with exclusion of moisture. This affords a quantitative yield of the amino ester hydrochloride, which crystallizes on cooling and can be purified by recrystallization from anhydrous ethanol, ether, or petroleum ether. Amino ester hydrochlorides are obtained analogously from ethyl *N*-formylamino esters, addition of water and cooling being unnecessary in these cases.

2-Unsubstituted Oxazoles from α-Metalated Isocyanides and Acylating Agents[1]

By *Ulrich Schöllkopf* and *Rolf Schröder*[*]

Oxazoles *(6)* carrying hydrogen on C-2 appear to be difficultly accessible by the usual synthetic methods[2]. We have found that they can be obtained conveniently by treating α-metalated alkyl isocyanides *(2)* [prepared from isocyanides *(1)* and, *e.g.*, potassium *tert*-butoxide or butyllithium] with acylating agents *(3)*. Intermediates in this

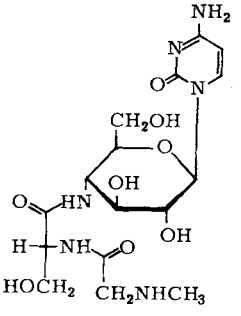
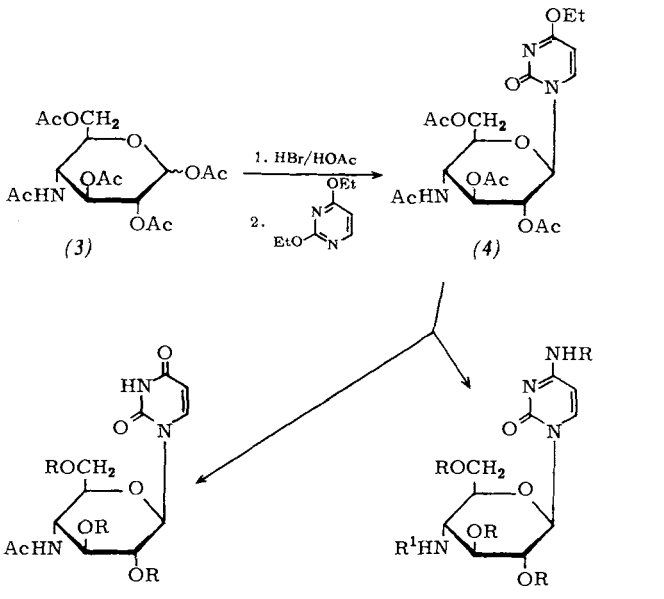
Synthesis of a Biologically Active Gougerotin Analog[1] [**]



By *Frieder W. Lichtenthaler, Günter Trummlitz, Gerd Bambach,* and *Ivan Rychlík*[*]

In continuation of our investigations aimed at detection of relations between the biological activity of antibiotics of the gougerotin and puromycin type and the structures of the individual components of these aminoacyl aminosugar nucleosides[2, 3], we have now succeeded in synthesizing the first biologically active gougerotin analog, namely a 5'-decarbamoyl-5'-hydroxymethylgougerotin *(2)*[5].

4-Acetamido-1,2,3,6-tetra-*O*-acetyl-4-deoxy-D-glucopyranose *(3)*[6] is converted into the nucleoside tetraacetate *(4)*, m.p. 118—120°C (after sintering around 110°C), $[\alpha]_D^{23} = +46°$ ($c = 1$, CH_3OH), in 36% yield, when treated with 40% HBr/glacial acetic acid for 3 h at 25°C and then with 2,4-diethoxypyrimidine. The constitution *(4)* rests on the NMR spectrum in [D_6]-DMSO (9-Hz doublet at $\tau = 2.10$, acetyl resonances at $\tau = 7.99$, 8.03, 8.14, and 8.20[7]), as well as on IR data (NH at 3310 cm^{-1}), which exclude alternative structures derived from the pyrrolidinose form of the amino sugar.



(1)

(2)

Methanolic HCl transforms *(4)*, with hydrolysis of the *O*-ethyl and *O*-acetyl groups, into 1-[4-acetamido-4-deoxy-β-D-glucopyranosyl]uracil *(5)*, a syrup, $[\alpha]_D^{23} = +8°$ ($c = 1$, CH_3OH), and by reaction with methanolic ammonia for 22 h at 95°C 1-[4-acetamido-4-deoxy-β-D-glucopyranosyl]cytosine *(7)*, dec. 290—292°C, $[\alpha]_D^{23} = +34°$ ($c = 1$, H_2O)[8], is obtained in 66% yield. These compounds are unambiguously characterized as the readily crystallizing acetates *(6)*, m.p. 255—260°C (dec.), $[\alpha]_D^{23} = +11°$ ($c = 1$, CH_3OH), and *(8)*, m.p. 294—295°C (dec.), $[\alpha]_D^{25} = +28°$ ($c = 1$, DMF)[8], which are obtained smoothly on acetylation by pyridine and acetic anhydride and afford readily interpretable NMR spectra in both $CDCl_3$ and [D_6]-DMSO.

Removal of the *N*-acetyl group from *(7)* by 4 N HCl in 3 h at 100°C and subsequent deionization lead to the free aminosugar nucleoside *(9)* which, when treated *in situ* with [*N*-(*tert*-butoxycarbonyl)sarcosyl]-D-serine azide[2b] in DMF, affords the dipeptidyl nucleoside *(10)*, dec. 136—138°C, $[\alpha]_D^{23} = +6°$ ($c = 0.4$, H_2O), in 40% yield. Treating *(10)* briefly with trifluoroacetic acid removes the t-BOC protecting group with formation of *(2)*, dec. above 155°C, $[\alpha]_D^{23} = +5°$ ($c = 0.6$, H_2O).

(5), R = H
(6), R = Ac

(7), R = H, R^1 = Ac
(8), R = R^1 = Ac
(9), R = R^1 = H
(10), R = H, R^1 = BOC-Sar-D-Ser

Like *(1)*[9], the gougerotin derivative *(2)*[5] interferes with protein biosynthesis at the peptide-chain elongation stage. In cell-free *E. coli* systems[10] *(2)* interferes with the transfer of the aminoacyl groups from *N*-acetyl-L-phenylalanyl-tRNA, oligosyl-tRNA, or the CACCA-leucine-*N*-acetate

fragment to puromycin. Further, *(2)* inhibits the bonding of CACCA-L-phenylalanine to the acceptor site of the peptidyl transferase, whereas bonding of the *N*-acetyl-leucylpentanucleotide to the donor site is stimulated.

Surprisingly the gougerotin analogs *(11)* and *(12)*[2b] proved inactive in these systems. However, steric considerations may well account for this, as indicated by comparing steric models of *(11)* and *(12)* with those of *(1)* and *(2)* — hydrogen bonds between the OH group on C-2′ and the CO group in the cytosine and between the CO group and the OH group in the serine portion are available for fixing the conformation of the molecules. Whereas the geometrical arrangements of all the important functional groups are the same in *(1)* and *(2)*, completely different steric conditions regarding incorporation at the acceptor site of the 50 S-ribosome apply in the cases of *(11)* and *(12)* owing to 1,3-bonding of the dipeptide portion and the nucleobase[11].

R = Sar-D-Ser

For the same reasons analogs of *(11)* with glycine, sarcosine, L-alanine, phenylalanine, L-lysine, and L-glutamine γ-methyl ester as aminoacyl components (which have been synthesized[12] but apparently not evaluated biologically) are likely to be inactive in these or similar systems.

Product Ratios on Gas-phase Hydration of Propene

By *Volker Schumacher* and *Kurt Dialer*[*]

Both 1-propanol *(1)* and 2-propanol *(2)* can be produced formally by addition of water to propene; according to Markovnikov's rule the isomer *(2)* is obtained preferentially. We have found that on gas-phase hydration of propene in the presence of various tungsten oxide catalysts the proportion of *(1)* formed is influenced to a surprisingly large extent by the reaction temperature; pressure and residence time are of minor importance in the range studied[1].

The Figure illustrates the observed temperature-dependence of the ratio of *(1)* to *(2)* without consideration of the other reaction parameters; equilibrium values calculated from thermodynamic data[2, 3] are included for comparison. The proportion of *(1)* increases considerably faster with temperature than predicted by thermodynamic equilibrium data. At higher temperatures it exceeds the values calculated from *Rossini*'s data[3]; this indicates a greater reliability of *Green*'s thermodynamic results[2].

Straight lines (probability of error $<1\%$) are obtained by plotting the experimental points in an Arrhenius diagram. This permits the calculation of the differences between the apparent activation energies for hydration of *(1)* or *(2)*; within the range studied (250—370 °C) these values are 23—28 kcal/mole (standard deviation ±6—12%) depending upon the catalyst used. The temperature-dependence

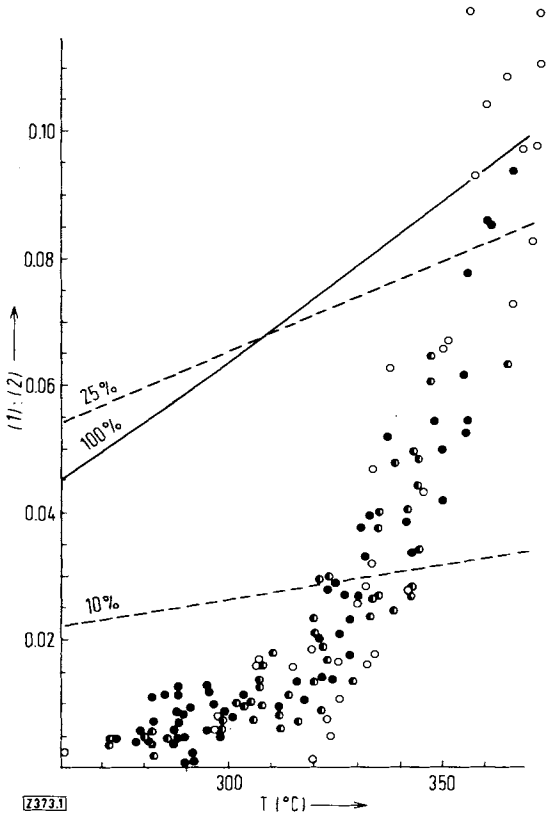

Fig. Temperature-dependence of the ratio of 1-propanol *(1)* to 2-propanol *(2)* formed on hydration of propene (pressure range 40–160 atm; residence time range 2–35 s). Catalysts: ○ 1, ◐ 2, ● 3 (see text). ----: equilibrium values (10% and 25%) according to *Green* [2]; ——: equilibrium values (100%) according to *Rossini* [3].

of the isomer equilibrium as well as the difference in formation enthalpies for the two isomers amount only to a few kcal/mole, and are thus relatively insignificant: the product ratio is primarily determined by kinetic effects.

The greatest proportion of *(1)* was obtained at >350 °C with undoped tungstic acid (catalyst 1), the ratio *(1)*: *(2)* being 0.11. Catalyst 2, in which zinc oxide was used as a promoter as described by *Runge*[4], did not appreciably increase the yield of *(1)* in the range studied. The considerable proportions of by-products, such as dipropyl ether and acetone, were reduced by addition of chromium salts (catalyst 3) without appreciably decreasing the ratio of *(1)* to *(2)*.

Symmetrical Boc-Amino Acid Anhydrides for Economical Peptide Syntheses on a Solid Phase[1] [**]

By *Theodor Wieland, Christian Birr*, and *Friedlieb Flor*[*]

In peptide syntheses on a solid phase by *Merrifield*'s method[2] the agent used for coupling the Boc-amino acids is now almost exclusively dicyclohexylcarbodiimide (Boc = *tert*-butoxycarbonyl). As maximum yields are essential[3] a three- to five-fold excess of Boc-amino acid and coupling reagent must be used at each step; and recovering the excess of precious amino acid derivative from the reaction mixture requires great effort, if it is at all possible. The mixed anhydride method often used for synthesizing peptides in solution cannot be applied to coupling on a solid phase because the slower reaction in the latter method often leads to a greater or less participation of the wrong acyl group[4]. This induced us to investigate the possibility of using symmetrical anhydrides of Boc-amino acids.

Reverting to experiments by *Wieland* and *Bernhard*[5], we worked out a generally applicable method for preparation of these reactive derivatives; the anhydrides of Boc-Ala, Boc-Phe, Boc-Val, and Boc-Pro were obtained by reaction of the Na salts of the *N*-protected amino acids with phosgene in tetrahydrofuran at −40 to −15 °C. The first three of these compounds were isolated in crystalline form. Boc-Pro anhydride was obtained only as an oil and for our projected syntheses was prepared from the triethylammonium salt in dichloromethane at −15 °C and used *in situ*. The purity of our oily product was proved by its IR spectrum, which showed the characteristic absorption bands around 1825 cm^{-1} (strong) and 1755 cm^{-1} (weak) in the same proportions as in the analytically pure, crystalline anhydrides of the other Boc-amino acids (Table 1).

Table 1. Symmetrical Boc-amino acid anhydrides of type Boc—NH—CHR—CO—O—CO—CHR—NH—Boc.

Anhydride of	M.p. (°C)	IR (cm^{-1})
Boc-Ala	103–10	1830, 1757
Boc-Phe	80–82	1832, 1759
Boc-Val	79–80	1820, 1747
Boc-Pro		1830, 1755

As a sample peptide we have synthesized, on *Merrifield* resin, a linear decapeptide[6], Phe-$(Pro)_2$-$(Phe)_2$-Val-$(Pro)_2$-Ala-Phe, which could be cyclized to well-crystalline antamanide in more than 30% yield[7, 8]. The synthesis was carried out in a "peptide synthesizer" from Schwarz Bioresearch, which had proved its value in our laboratory for the synthesis of several analogous decapeptides by the *Merrifield* technique with dicyclohexylcarbodiimide (DCCI) as coupling reagent[9]. This time our program was modified by replacing the DCCI activation step by addition of three equivalents of the required Boc-amino acid anhydride in solution in CH_2Cl_2. The program included 2 hours' shaking at 20 °C for coupling with the resin-bound peptide, but otherwise the washing program[9] was retained. An advantage of this variant is the absence of dicyclohexylurea, which may be precipitated because of its sparing solubility in many solvents.

Max-Planck-Institut für medizinische Forschung,
Abteilung Chemie
69 Heidelberg, Jahnstrasse 29 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The synthesis was effected starting from carboxyl-terminal Phe on 5 g of resin, 0.385 mmole/g of the acid being bound as ester. After each coupling step, 200 mg of resin was removed for analysis which in each case indicated homogeneity of the synthetic peptide. Fission of 3.7 g of the decapeptide resin by HBr in trifluoroacetic acid gave in all 0.9 g of material (*ca.* 60% yield)[8, 9] that afforded 33.6% of crystalline antamanide identical with the natural product in all respects. In a repetition of the decapeptide synthesis, each Boc-amino acid anhydride was not isolated but was freshly prepared shortly before the coupling and was used in that solution in tetrahydrofuran or CH_2Cl_2, being added in one portion to the reactor[10]; this actually afforded 96% of pure linear decapeptide, which also could be cyclized in 33.5% yield to antamanide with its full biological activity.

The excess of each Boc-amino acid was readily recovered from the respective filtrate in amounts exceeding 80% by hydrolysis of the anhydride with aqueous hydrogen carbonate solution. This permits economic use of any desired excess of the Boc-amino acids and may thus make it possible to realize the objective of 100% yield at each step of a polypeptide synthesis on a solid phase.

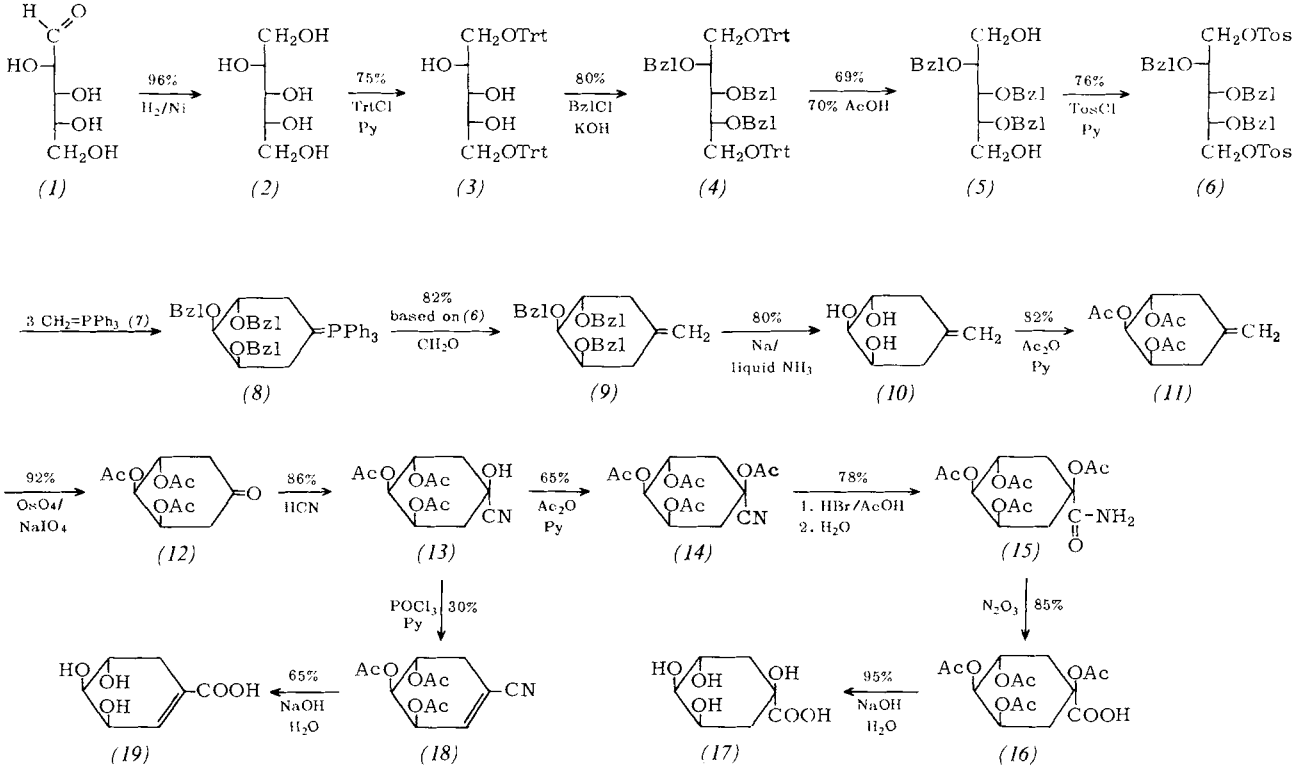
Stereospecific Synthesis of Optically Pure Quinic Acid and Shikimic Acid from D-Arabinose

By *Hans Jürgen Bestmann* and *Hans August Heid*[*]

In Memoriam Rudolf Grewe



Total syntheses of racemic quinic acid[1] and shikimic acid[2] have been reported, but hitherto no success has attended the many attempts, by numerous schools, to prepare optically pure quinic acid *(17)* and shikimic acid *(19)* from a sugar. We describe below such a synthesis (Scheme 1).

D-Arabinose *(1)* was reduced catalytically[3] by Raney nickel to the arabitol *(2)*, and this was converted[4] by triphenylmethyl chloride into the 1,5-ditrityl derivative *(3)*, which was benzylated, to give *(4)* by anhydrous KOH

[*] Prof. Dr. H. J. Bestmann and Dr. H. A. Heid
Institut für Organische Chemie der Universität
Erlangen-Nürnberg
852 Erlangen, Henkestrasse 42 (Germany)

and benzyl chloride. 70% acetic acid detritylated *(4)* to 2,3,4-tri-*O*-benzyl-D-arabitol *(5)*, which was then ditosylated[5] by *p*-toluenesulfonyl chloride in pyridine, affording *(6)*.

The cyclic ylide *(8)* was obtained from *(6)* by a method described previously by us[6] involving methylenetriphenylphosphorane *(7)* (molar ratio 1:3); in this process the third equivalent of *(7)* is required for formation of *(8)* from the corresponding phosphonium *p*-toluenesulfonate first produced[7]. A Wittig reaction of *(8)* with formaldehyde leads to the methylene compound *(9)* (boils in a rotating bulb-tube at a bath-temperature of 180—186 °C and 0.05 torr; $[\alpha]_D^{20} = -36.4°$, $c = 7.3$ in CCl_4), which is debenzylated by sodium in liquid ammonia to crystalline (1*R*,2*S*,3*R*)-5-methylene-1,2,3-cyclohexanetriol *(10)*, m. p. 147 °C, $[\alpha]_D^{20} = -19.5°$ ($c = 6.6$ in water after 48 h). Acetylation of *(10)* by acetic anhydride affords the oily triacetate *(11)*, b. p. 120 °C/0.2 torr, $[\alpha]_D^{20} = -63.8°$ ($c = 3.5$ in CCl_4), oxidation of which by $NaIO_4/OsO_4$[8] affords the ketone *(12)* which was prepared by *Grewe*[9] from naturally occurring quinic acid.

Scheme 1. Abbreviations: Ac = acetyl; Trt = trityl; Py = pyridine; Bzl = benzyl; Tos = tosyl; Ph = phenyl.

Further steps in our synthesis are based on the fundamental work of *Grewe*. *(12)* is converted in a cyanohydrin synthesis stereoselectively into the triacetylquinic acid nitrile *(13)*, which is acetylated[9] to the tetraacetyl derivative *(14)* and agrees in all its physical and spectroscopic properties with a comparison specimen prepared by *H. O. L. Fischer*'s method[10]. HBr in glacial acetic acid hydrolyzes the nitrile *(14)* to the amide *(15)*, whence liquid N_2O_3 provides the known tetraacetylquinic acid *(16)*. Hydrolysis of *(16)* by aqueous sodium hydroxide solution and subsequent treatment with an ion-exchanger affords the free quinic acid *(17)*, m. p. 161 °C, $[\alpha]_D = -43.8°$ ($c = 6$ in water), that is identical with the natural product.

The following route leads to shikimic acid: The cyanohydrin *(13)* is dehydrated by *Grewe*'s method[9] with $POCl_3$ in pyridine stereospecifically to triacetylshikimonitrile *(18)*. After hydrolysis thereof, we were able to isolate free shikimic acid *(19)* with m. p. 189 °C and $[\alpha]_D = -179.7°$ ($c = 4$ in water), which also was identical with the natural product.

Compounds *(15)*, *(16)*, and *(18)* agree in all their spectral and physical properties with authentic materials obtained from the natural materials *(17)* and *(19)*[9-11].

The synthesis described above can also be used for preparation of optically pure quinic and shikimic acid labeled with ^{14}C or tritium at various positions.

Intramolecular Photocycloaddition of 7,7'-Polymethylenedioxycoumarin[**]

By *Luc Leenders* and *Frans C. De Schryver*[*]

We recently reported the intramolecular photocycloaddition of *N,N'*-alkylenedimaleimides[1] and now wish to describe the analogous reaction of polymethylenedioxycoumarins *(1)*.

(1)

(2) *(3)*

The cyclomers formed must have an *endo*-configuration in view of the shortness of the polymethylene linkage. However, two regioisomers *(2)* and *(3)* are possible and their respective configurations have been elucidated by determination of the dipole moments[6]. The dipole moments for cyclomers *(2a)* and *(3a)*, measured in dioxane, are 6.7 and 2.0 D. The cyclomer with the greatest dipole moment can only be the isomer with a head-to-head structure *(2a)*. This is in agreement with the different solubilities of the two photoproducts in solvents with different polarities.

The configurations of the cyclomers derived from *(1b)* and *(1c)* are determined by comparison of their NMR spectra with those of *(2a)* and *(3a)* respectively. – The presence of oxygen did not inhibit the reaction.

Procedure:

In a typical photolysis, 1.092 g of 7,7'-trimethylenedioxycoumarin *(1a)* was dissolved in 300 ml dichloromethane (concentration 10^{-2} mole l^{-1}), degassed, sealed off, and irradiated in a Rayonet UV Reactor at 350 nm for 72 hours. The solvent was evaporated off on a rotary evaporator.

(1)							*(2)* + *(3)*				
			IR (ν, cm^{-1}) [b]		NMR (δ) [c]					IR (ν, cm^{-1}) [b]	
[a]	*n*	M. p. (°C)	C=O	C=C *cis*	H_A	H_B	[a]	Yield (%)	M. p. (°C) [d]	C=O	NMR (δ) [e]
(1a)	3	184–185.5	1720	3050, 1400	7.88	6.22	*(2a)*	37	241	1760	4.33
							(3a)	60	271	1752	4.08
(1b)	4	182–183.5	1717, 1708	3045, 1400, 1390	7.83	6.17	*(2b)*	42	252	1765	4.30
							(3b)	56	279	1750	4.08

							(3c)	52	291.5	1748	4.09

[a] All compounds gave correct elemental analysis data and mass spectra.
[b] In KBr.
[c] Resonance signals of the vinyl protons; these signals are doublets. All spectra were recorded in [D_6]-DMSO.
[d] All compounds sublime.
[e] Resonance signals of the four cyclobutane protons. All spectra were recorded in [D_6]-DMSO.

Direct and sensitized photodimerizations of coumarin have been reported in the literature[2]. Irradiation in solution gives a mixture of three isomers: the *endo* head-to-head dimer; the *exo* head-to-head dimer; and the *endo* head-to-tail dimer[3]. Photodimers of several substituted coumarins have also been prepared, *e.g.* 7-methoxycoumarin has been photodimerized in the solid state[4].

7,7'-Polymethylenedioxycoumarins *(1)* have been prepared in analogy with the synthesis of 7,7'-methylenedioxycoumarin[5]. The physical data of the compounds studied are reported in the Table.

The photoreactions are carried out in dichloromethane. The absorption characteristics of the —CH=CH— system in the IR and NMR spectra disappeared upon irradiation, only to be replaced by peaks that can be attributed to a cyclobutane system.

The intramolecular nature of the cycloadducts was proved by mass spectrometry.

The IR spectrum indicated that reaction was complete. The residue was taken up in dry benzene. 0.255 g (23%) isomer *(2a)* precipitated on cooling. The NMR spectrum of the residual reaction mixture shows the presence of additional 14% of isomer *(2a)*. Isomer *(3a)* was separated and purified by column chromatography on Florisil (60–100 mesh) with chloroform as eluent. The isomers were recrystallized from toluene.

A Reagent for Direct Nucleophilic Carbamoylation[**]

By *Peter Jutzi* and *Friedrich-Wilhelm Schröder*[*]

One-stage nucleophilic transfer of carbonyl groups is of practical interest in preparative chemistry, but only few examples of this type of reaction have been recorded previously[1-4]. In our studies of the reaction of carbon monoxide with element-lithium bonds[4,5] we have obtained a nucleophilic carbamoylating agent that is stable under normal conditions.

If carbon monoxide is led into a solution of lithium *tert*-butylamide *(1)*[6] in benzene/ether at about 50 °C carbon monoxide is inserted into the nitrogen-lithium bond and orange-yellow *tert*-(butylcarbamoyl)lithium *(2)* is obtained:

$$(CH_3)_3C{-}NHLi + CO \rightarrow$$
(1)

$$(CH_3)_3C{-}NH\underset{\underset{O}{\|}}{C}{-}Li \rightleftharpoons (CH_3)_3C{-}NH{-}\ddot{C}{-}OLi$$
(2)

The existence of *(2)* is proved by reaction with trimethylsilicon, -germanium, or -tin chloride, in which lithium chloride is split off and the new types of carbamoyl-substituted Si, Ge, and Sn derivatives *(3)*, *(4)*, and *(5)* are formed in yields of up to 55%:

$$(2) + (CH_3)_3ElCl \xrightarrow{-LiCl} (CH_3)_3C{-}NH{-}\underset{\underset{O}{\|}}{C}{-}El(CH_3)_3$$

El = Si, Ge, or Sn *(3), (4), (5)*

Cpd.	El	B.p. (°C/torr)	IR, $\tilde{\nu}$(C=O) (cm^{-1})	^{1}H-NMR [a] δ-C(CH_3)$_3$	δ-El(CH_3)$_3$
(3)	Si	143/760	1643	−66	−13
(4)	Ge	97/55	1634	−73	−30
(5)	Sn	46/0.01	1625	−79	−29 [b]

[a] ^{1}H-NMR spectra: *ca.* 20% solutions in CCl_4; shifts in Hz from TMS to lower field strengths.
[b] $J(^{119}Sn{-}C{-}H) = 60$ Hz; $J(^{117}Sn{-}C{-}H) = 58$ Hz.

Formation of an $>N{-}\underset{\underset{O}{\|}}{C}{-}Li$ group has so far been demonstrated only when stabilized by complex formation in its isomeric carbene form and if further reactions were carried out at −70 °C[2].

Steric reasons seem responsible for the surprising stability of the uncomplexed compound *(2)*. Thus a suspension of lithium dimethylamide in hexane also reacts with carbon monoxide, absorbing an equimolar amount of this gas in an exothermal reaction, but it was not possible to isolate a dimethylcarbamoyl derivative; treatment with chlorotrimethylsilane gave only oligomeric products and hexamethyldisiloxane.

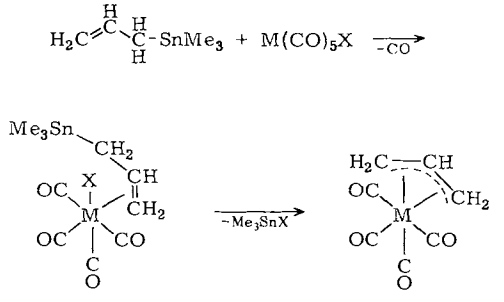
π-Allylcarbonylmetals from σ-Allylorganotin Compounds



By *E. W. Abel* and *S. Moorhouse*[*]

σ-Cyclopentadienyltrimethyltin has been shown[1,2] to form π-cyclopentadienyl derivatives of carbonylmetals. Continuing to study the utility of organotin derivatives as synthetic intermediates[3,4], we have investigated the transfer of the allyl group from σ-allyltrimethyltin to transition metals. We now report on the advantages of the method for the preparation of π-allyl derivatives of transition metals and, in particular, on the synthesis of some π-allylcarbonylmetals.

π-Allyltetracarbonylmanganese has been prepared[5] by the thermal decarbonylation of σ-allylpentacarbonylmanganese (80 °C/12 h). Such decarbonylations are not always facile, and to date π-allyltetracarbonylrhenium has not been prepared by this route[6].

In contrast, allyltrimethyltin and the pentacarbonyl halides of both manganese and rhenium react to form directly the π-allyltetracarbonylmetal in good yield under mild conditions. As noted above the decarbonylation of σ-allylmanganese pentacarbonyl requires moderately forcing conditions[5]. Thus it would appear that no σ-metal complexes are formed as intermediates in our reactions; and careful monitoring of the reaction by infrared spectroscopy at all stages has failed to indicate the presence of intermediate σ-complexes.

We propose, therefore, that as in many other ligand transferences involving organotin intermediates[3,4] the initial step is one of ligand coordination. This places the organotin group in position for an intramolecular elimination of organotin halide which converts the coordinated olefin to a π-allyl ligand (Scheme 1).

Scheme 1. M = manganese or rhenium, X = chlorine or bromine.

Similar high yield reactions occur with the dimeric $[Mn(CO)_4Br]_2$ and the anion $Mn(CO)_4Br_2^-$. In the former,

[*] Dr. E. W. Abel and S. Moorhouse
Department of Inorganic Chemistry
The University
Bristol BS8 1TS (England)

the initial step presumably involves halogen bridge fission[7] to give the olefin-coordinated intermediate, without loss of carbon monoxide, and in the latter displacement of halide ion[8] by the olefin will give the same intermediate.

In the case of many substituted-allyl organotins, the method of their synthesis gives a mixture of two isomers, but for their use in these reactions this is unimportant since the final step of organotin halide elimination gives an identical product from the two isomers. In this light the isomeric mixtures are utilized unseparated.

We have found the shelf-life of allyl-organotins to be infinite, and therefore they are excellent as easily accessible sources for the synthesis of π-allyls. The Table shows a range of allyl- and substituted-allylcarbonylmetals synthesized by this method. In addition we have found the organotin cyclopentadienyls, indenyls, and fluorenyls to be very convenient intermediates for the formation of the respective carbonylmetals having π-bonded ligands.

Table. π-Allylcarbonylmetal complexes from carbonylmetal halides and organotin compounds [a] (Me = methyl).

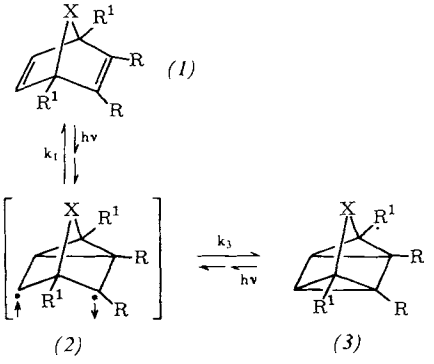
A Kinetic Procedure for Detection of Short-lived Photointermediates[**]

By *Gerd Kaupp*[*]

A kinetic model was recently developed[1, 2] that in suitable cases permits differentiation of concerted from two-step singlet photoreactions without reliance on energetic data[3]. We now report the application of this model to the elucidation of the mechanism involved in the synthesis of compounds containing the quadricyclane skeleton *(3)*. Quantum yields, qualitative fluorescence studies, solvent and substitution effects in the reversible[5] synthesis of quadricyclanes give no indication of a concerted mechanism which would be postulated on the basis of quantum-mechanical approximations for $_\pi2_s + _\pi2_s$ singlet photoadditions[6]. We have found the reaction to proceed in two steps as illustrated.



According to this scheme for a nonconcerted reaction, with a (in this case thermally inaccessible[2b, 5]) common intermediate, the sum of the quantum yields for the forward and the reverse reaction should be at most 1. On the contrary, for a concerted mechanism (proceeding *without* a common intermediate) the sum may reach 2[7].

For the case when $\Phi_{forward} + \Phi_{reverse} \leq 1$, the existence of a common intermediate is certain only if other quantum-consuming processes have been taken into account or excluded. Consideration of fluorescence data and a study of possible side reactions are pertinent to this point. On selec-

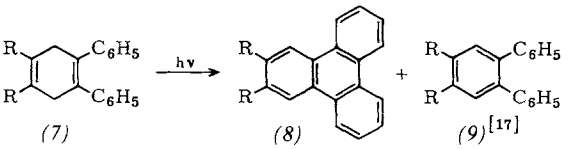
tive irradiation, *(1a)* and *(1b)* pass into *(3a)* and *(3b)*, respectively, with quantum yields of 0.55, without fluorescence or phenanthrene formation competing to a detectable extent[2b, 2c, 8] [cf. *(4a)* → *(4d)*, and *(7)* → *(8)*]. Since the

(1)

(2) *(3)*



(a), X = CH_2; R = C_6H_5; R^1 = H

(b), X = O; R-R = *o,o'*-$C_6H_4SO_2C_6H_4$; R^1 = H

(c), X = O; R-R = *o,o'*-$C_6H_4OC_6H_4$; R^1 = CH_3

sum $\Phi_{(1)\rightarrow(3)} + \Phi_{(3)\rightarrow(1)}$ is close to unity in both cases it can be concluded that within experimental error all quanta absorbed by *(1)* or *(3)* lead to formation of the intermediate *(2)*, which is deactivated to *(3)* and *(1)* in the ratio k_3/k_1.

the polycycles *(5)* and *(6)* (see Table) and by the photochemical formation of *(8)* from *(7)* (in benzene with O_2 and $5 \cdot 10^{-4}$ mol of I_2 per l)[9].

(7) *(8)* (29%) *(9)*[17] (62%)

R = CO_2CH_3

Further support for the nonconcerted mechanism of quadricyclane formation is provided by the behavior of *(1c)*[10]. This norbornadiene derivative is photolyzed smoothly to *(3c)*[2b, 18], but formation of the intermediate *(2c)* is *not* quantitative (see Table). Accordingly complete intramolecular quenching of fluorescence is not to be expected, and in fact *(1c)* provides an intense emission spectrum (see Table).

Later reports will deal with the consequences of the two-stage singlet process for preparative photochemistry, *e.g.*, the photochemistry of unbridged 1,4-cyclohexadienes[19] such as *(7)*.

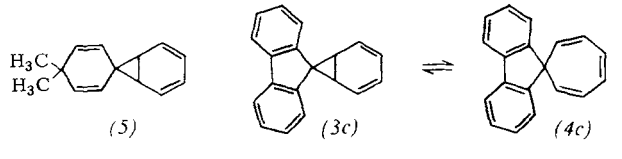
New Spironorcaradienes. — Demonstration of a Reversible Norcaradiene-Cycloheptatriene Valence-Isomerization[**]



By *Heinz Dürr* and *Helge Kober*[*]

Some time ago[1,2] we postulated that spiro-norcaradienes or -cycloheptatrienes occur as intermediates in the photolysis of unsubstituted or substituted diazo-cyclopentadienes in benzene. In the meantime two relatively unstable spiro-norcaradienes [*(3a)* and *(5)*] have been synthesized[3,4].

(3)⇌*(4)*	Yield (%)	$\Delta H^0_{(3)} - \Delta H^0_{(4)}$ (kcal./mole)	$\Delta S^0_{(3)} - \Delta S^0_{(4)}$ (cal. deg^{-1} mole^{-1})
(a), R=H	30–40 [4]	–	–
(b), R=Cl	30	+0.994	+4
(c)	8–10	+0.45	+2

(1) *(2)* *(3)* *(4)*

(5) *(3c)* *(4c)*

This paper describes the synthesis of a stable spiro-norcaradiene *(3c)* which is in equilibrium with its valence isomer the spiro-cycloheptatriene *(4c)*. The less stable *(3b)*⇌*(4b)* has also been prepared.

The valence tautomers *(3)*⇌*(4)* can be synthesized very easily by photolysis of diazo-cyclopentadienes *(1)* in benzene *(2)* at 17–20°C using a Hg high pressure lamp.

(3c)⇌*(4c)* is so stable that it can be purified by chromatography on basic aluminum oxide at ordinary temperatures (see [1,2]). Pure *(3c)*⇌*(4c)* in C_6D_6 can be kept at 100°C for 10 hours without decomposition. *(3a)*⇌*(4a)* isomerizes at room temperature within 24 hours[1,2]. The complete isomerization of *(3b)*⇌*(4b)* takes about 15 hours at 37°C.

Proof of structure is based on elementary analysis and, mainly, on spectroscopic data[1,2]. The equilibrium between the valence isomers *(3)* and *(4)* is established unequivocally by temperature dependent NMR spectra. The spectrum of *(3c)*⇌*(4c)* in CS_2 at 40°C shows the following signals: $\tau = 5.26$ (2 H/d), $J = 9.2$ Hz; 3.84 (4 H/m); 2.86 ppm (8 H/m). The doublet begins to broaden at −60°C and gives a very broad signal at −80°C. At −90°C new signals appear at $\tau = 4.8$ and 3.0 ppm, which at −100°C give rise to a broad singlet at 6.98 and a doublet at 4.77 ppm ($J = 9.5$ Hz). These signals can be assigned to the H_α-protons[5] of *(3c)* and *(4c)*, respectively. On rewarming to room temperature the original spectrum appears again. The same holds for *(3b)*⇌*(4b)*. It can be concluded from the chemical shift of the H_α-protons of the known compounds *(3a)* and *(5)* that here, too, a fast equilibrium (on the NMR time scale) exists[3–5]. Thus it is proved[5] that the spiro-compounds *(3)*⇌*(4)* undergo a fast reversible valence isomerization. Evaluation of the temperature dependent NMR-spectra[5] allows calculation of the enthalpy and entropy differences of the valence tautomers *(3)*⇌*(4)* (see Table).

Spiro[fluorene-9,7'-norcaradiene]⇌*Spiro[2,4,6-cycloheptatriene-1,9'-fluorene] (3c)*⇌*(4c)*

A solution of diazofluorene *(1c)* (10.0 g) in distilled benzene (350 ml) was photolyzed at room temperature (17–20°C) with a Philips HPK 125 W lamp (Pyrex filter). After 4 hours 80% conversion was achieved (N_2 evolution). Benzene was evaporated *in vacuo* and the residue extracted 3 times with petroleum ether (b. p. 40–80°C). After evaporation of the petroleum ether the residue was subjected to chromatography on 250 g of basic aluminum oxide. Petroleum ether eluted 800 mg (8%) [based on reacted *(1c)*] *(3c)*⇌*(4c)* as colorless crystals; m.p : 98—99°C (from ether/pet. ether); thin-layer chromatography showed only one spot; IR (KBr): 1476(w), 1454(s), 1092(m), 1042(w), 1038(w), 804(s), 791(s), 743(s), 728(s) cm^{-1}; UV($CHCl_3$): $\lambda_{max}(\varepsilon) = 302(4230)$, 287(6870), 262(11990); Raman spectrum (solid): 1554 cm^{-1} (norcaradiene band).

Tetrakis(trimethylphosphane)cobalt(0): Preparation and Reactions

By *Hans-Friedrich Klein*[*]

Only occasional complexes of zerovalent cobalt with phosphane ligands have been described so far[1, 2]. Attempts to prepare them often gave, instead, phosphane-substituted cobalt hydrides of the type $(R_3P)_4CoH$[3]. Since the CoH stretching vibration of these compounds absorbs more or less strongly according to the nature of the phosphane ligands and in some cases cannot be observed at all, the possible existence of phosphane-substituted cobalt(0) complexes under any conditions has been placed in doubt in very recent publications[3].

However, we have been able, for the first time, to obtain paramagnetic tetrakis(trimethylphosphane)cobalt(0) *(1)*, by reduction of anhydrous cobalt halides with sodium amalgam in presence of trimethylphosphane.

$$CoX_2 + 4\ (CH_3)_3P + 2\ Na(Hg) \xrightarrow[20\,^\circ C]{THF} [(CH_3)_3P]_4Co + 2\ NaX$$

(1)

After removal of volatile materials from the reaction mixture, the compound *(1)* was extracted with hexane; it crystallized at −50 °C or was sublimed at 80 °C/1 torr. In an atmosphere of nitrogen the dark brown needles decompose only at 180–185 °C and they dissolve very readily in hydrocarbons, ethers, or other apolar solvents. Cryoscopic determinations of molecular weight in benzene gave the simple formula weight. Thus in solution *(1)* shows little of the tendency to dimerize that is observed with, for instance, $Co(CO)_4$[4] and $Co(PF_3)_4$[5]. In accordance with this, NMR-spectroscopic determination of the paramagnetic susceptibility[6] (in benzene containing 5% of cyclohexane, at 30 °C) gave a magnetic moment μ of 1.70 B. M., as expected for the d^9 configuration in a tetrahedral ligand field.

The intense EPR signal[7] (at 77 °K, 1% in a toluene matrix) shows complex hyperfine structure caused by the cobalt nucleus with $I = 7/2$. The total of 16 lines corresponds to the two g factors that are expected under these conditions and they imply Jahn-Teller distortion of the tetrahedron. These details must be studied at still lower temperatures.

In the absence of a catalyst, *(1)* does not react with molecular hydrogen. However, if *(1)* is synthesized by the above reaction in a H_2 atmosphere the *(1)* produced is accompanied by some $[(CH_3)_3P]_4CoH$[8] which becomes the main product after 8 hours' reaction.

Solutions of *(1)* rapidly absorb one equivalent of nitric oxide with formation of diamagnetic nitrosyltris(trimethylphosphane)cobalt *(2)*.

$$(1) + NO \longrightarrow [(CH_3)_3P]_3CoNO + (CH_3)_3P$$

(2)

The compound *(2)* crystallizes as slightly sensitive red needles (m. p. 107–108 °C, from hexane) and can be sublimed without decomposition at 60–65 °C/1 torr. The NMR spectrum shows pseudotriplet structure for the $(A_9X)_3-C_{3v}$ system of the phosphane ligands, $|J_{AX} + J_{AX'}| = 5.8$ Hz[9]. In the IR spectrum the NO stretching vibration at 1605 cm^{-1} is at the longest wavelength so far observed for compounds of the type $L_3Co(NO)$[10].

The compound *(1)* reacts with azobenzene analogously to tetrakis(trimethylphosphane)nickel(0)[11, 12], giving a quantitative yield of azobenzenebis(trimethylphosphane)-cobalt *(3)*, which forms dark violet leaflets, m. p. 126–127 °C (dec.), from tetrahydrofuran.

$$(1) + C_6H_5\text{-}N{=}N\text{-}C_6H_5 \longrightarrow \begin{matrix} C_6H_5\text{-}N & P(CH_3)_3 \\ \| \rightarrow & Co \\ C_6H_5\text{-}N & P(CH_3)_3 \end{matrix} \quad (3) + 2\ (CH_3)_3P$$

The IR spectrum of *(3)* differs only slightly from that of the analogous nickel complex in the positions and intensities of the bands. This finding, together with the result of magnetic measurements [$\mu = 2.02$ B. M. for *(3)*], indicates coordination of the cobalt only to the azo group, without an additional σ-bond to the *ortho*-position of a benzene ring[13].

It is thus shown that not only are paramagnetic cobalt(0) compounds with phosphane ligands surprisingly stable, but also that they are amenable to replacement reactions with retention of their paramagnetic valence state.

Restricted Rotation in *N*-Silylated Hydrazines

By *Otto Josef Scherer* and *Uwe Bültjer*[*]

In continuation of our investigations concerning restricted rotation around sulfur-[1], arsenic- and antimony-nitrogen[2] bonds in compounds containing as ligand to nitrogen an organic derivative of a Group IV b element, we have studied *N*-silylated hydrazines of type *(1)*.

[*] Prof. Dr. O. J. Scherer and Dipl.-Chem. U. Bültjer
Universität Trier–Kaiserslautern
Present address: Institut für Anorganische Chemie der Universität
87 Würzburg, Röntgenring 11 (Germany)

For their replacement we used both a double reaction of metalated *N,N'*-dimethylhydrazine with organosilicon halides and fission of Si—N bonds by $(CH_3)_2SiX_2$ compounds.

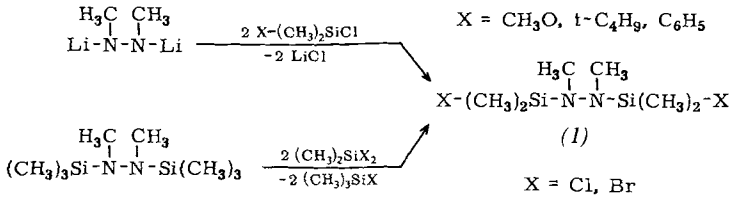

Table. Physical properties and ^{1}H-NMR data (60 MHz; 20% solution in toluene) of *N*-silylated hydrazines *(1)*.

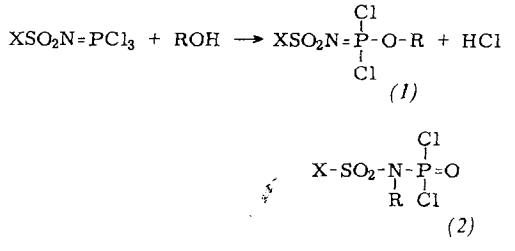
(1)	X	B. p. (°C/torr)	$\nu(CH_3)_2Si$ (Hz)	T_c (°C)[a]	$\Delta G^{\neq}_{T_c}$ (kcal/mole)
(a)	CH_3O	74–78/5			
(b)[b]	$(CH_3)_2N$	81–84/3			
(c)	*tert*-C_4H_9	98–100/0.7			
(d)	C_6H_5	120–121/0.07	2.5	7	15.4 ± 0.3[c]
(e)	Cl	46–47/1 [3]	3.7	47	17.4 ± 0.3
(f)	Br	60–61/0.5	4.2	42	17.1 ± 0.3

[a] ±2°C.
[b] *(1b)* was prepared from *(1e)* and dimethylamine.
[c] Since the width of the $(CH_3)_2Si$ signals at height is 2.0 Hz one must correct the values according to [6]; we have $k_c = 3.0$ and $\Delta G^{\neq}_{T_c} = 15.7 \pm 0.3$.

In contrast to hydrazine derivatives containing $C_6H_5CH_2$ or $(CH_3)_2CH$ groups[4], the compounds *(1)* permit for the first time a systematic variation of the ligand serving as probe in dynamic ^{1}H-NMR spectroscopic studies. In the spectra of *(1a)*—*(1c)* the protons of the CH_3 groups bound to the Si atom are isochronous not only at different concentrations and in various solvents (chloroform to −40°C, chlorobenzene to −30°C, benzene to 10°C, ethylene dichloride and *o*-dichlorobenzene to 20°C) but also in toluene to −75°C, which contraindicates that the chemical shifts of the two CH_3 signals are accidentally equivalent; however, for *(1d)*—*(1f)* they remain anisochronous [$(CH_3)_2Si$ doublet] in various solvents and at various concentrations. This might be due to hindered rotation around the N—N or Si—N bond or to an N-inversion that is slow on the NMR time scale. The latter can be excluded by the $\Delta G^{\neq}_{T_c}$ values (see Table), especially as an N-bound silyl group decreases the inversion barrier[5] by flattening the nitrogen pyramid (cf. also [2]). Hindered rotation around the Si—N bond is unlikely because the compound

$(CH_3)_2N—N(CH_3)Si(CH_3)_2Cl$

—if N-inversion is rapid only Si—N and not N—N hindered rotation can be recognized in the ^{1}H-NMR spectrum —shows only one signal for the $Cl(CH_3)_2Si$ group in toluene down to −75°C[7].



The height of the energy barrier to N—N rotation in *(1)* is apparently influenced by electronic and not by steric effects. This became clear because restricted rotation around the N—N bond of compounds *(1d)*—*(1f)* could be demonstrated only with ligands (X = Cl, Br, or C_6H_5) that are electron-attracting in aliphatic or aromatic compounds. Further, the $\Delta G^{\neq}_{T_c}$ values increase parallel to the increase in (−*I*) effect of the ligands X = Cl, Br, and C_6H_5.

(b)	X = F, R = C_2H_5	*(2b)*	31°C/0.01	95
(c)	X = Cl, R = CH_3	*(2c)*	58°C/0.01	95
(d)	X = Cl, R = C_2H_5	*(2d)*	68°C/0.01	80

The compounds *(1)* can be obtained in high yield but cannot be distilled without decomposition; they can be characterized by their NMR spectra and by elemental analysis. No ^{1}H-^{19}F coupling was observed for *(1a)* or *(1b)*. The ^{1}H- and ^{19}F-NMR spectra afford the following data for *(1a)*:

$\delta_H = -4.46$ ppm (doublet), $J_{H-P} = 17.5$ Hz, $\delta_F = -58.7$ ppm (doublet), $J_{F-P} = 4.5$ Hz.

Migration of the alkyl group has not hitherto been observed on alcoholysis of trichloroiminophosphoranes[2].

If the compounds *(1)* are heated in diethyl ether or dioxane, they rearrange to *N*-alkyl-*N*-(halosulfonyl)aminodichloro-

[7] On rapid N-inversion, Si—N hindered rotation will not be observable in the ^{1}H-NMR spectra if the compound has the *gauche* conformation (CH_3 ligand eclipsed with Cl).

phosphoric esters *(2)*. Compounds *(2a)*—*(2d)* are colorless liquids which, unlike their isomers *(1)*, distill unchanged in an oil-pump vacuum. For *(2a)* a coupling between ^{19}F and ^{1}H is observed and from the NMR spectra of this compound one obtains $\delta_H = -3.77$ ppm (2 doublets), $J_{H-P} = 10.8$ Hz, $\delta_F = -52.9$ ppm (2 quadruplets), $J_{F-P} = -4.5$ Hz, $\delta = -6.2$ ppm (2 quadruplets) [external standard: $(CH_3)_4Si$, $CFCl_3$, or 85% H_3PO_4]. The structures of the chlorosulfonyl derivatives could be confirmed by mass spectrometry: for *(2c)* there were observed, besides the molecule ion 245 (6%), the characteristic fragments at $m/e = 244$ [$FSO_2NCH_2POCl_2$ (6%)], 210 [FSO_2NCH_3POCl (100%)], 146 [NCH_3POCl_2 (91%)], 130 [NCH_3PCl_2 (36%)], 128 [$ClSO_2NCH_3$ (26%)], and 117 [$POCl_2$ (74%)]. This reaction can be applied to other (P=N) double bonds.

It was not possible to differentiate the (P=N) stretching vibration of *(1a)* and the (P=O) stretching vibration of *(2a)* in their IR spectra. For *(2a)*, bands were observed at *ca.* 2960 s, 1450 vs, 1425 vs, 1290 vs, 1220 vs, 1050 vs, 910 vs, 805 vs, 695 vs, 600 vs, 560 vs, 530 s, 515 vs, 455 m, and 400 s (cm^{-1}).

Compounds *(2)* cannot be prepared from *N*-(halosulfonyl)alkylamines and phosphorus trichloride in the presence of a tertiary amine. Compound *(2a)* reacts with $(CH_3)_3SiN(CH_3)_2$ in 1:1 molar ratio with loss of chlorotrimethylsilane:

(2a)

(3)

The product *(3)* distills unchanged at 59 °C/0.01 torr.

Preparation of (2a):

$FSO_2N{=}PCl_3$ (0.1 mol) is dissolved in CH_2Cl_2 (500 ml). Then the flask is cooled in ice, and CH_3OH diluted with CH_2Cl_2 (250 ml) is dropped in slowly with stirring. When addition is complete, the mixture is boiled under reflux for an hour, to complete removal of HCl. Finally diethyl ether (50 ml) is added and the whole is heated for about 20 minutes under reflux. The ether and CH_2Cl_2 are removed in a vacuum and the residue is distilled in an oil-pump vacuum. Yield: 21 g (90%). *(2b)* is formed as by-product.

CONFERENCE REPORTS

Macromolecular Colloquium

The Macromolecular Colloquium was held at Freiburg/Br. (Germany), February 25—27, 1971

From the lectures:

Detection of Grafting and Crosslinking of the Elastomer Phase in Two-Phase Systems

By *Lothar Bohn*[*]

It is well known that the toughness of brittle, hard materials can be improved by the incorporation of a finely divided soft phase. As an essential condition for the effect of the rubbery soft phase, it is always plain that the two immiscible polymer phases must be strongly bonded at the contact surface. Some crosslinking in the rubber phase is sometimes also regarded as important. Attempts are made to achieve adhesion between the phases, *e.g.* by graft copolymerization, polymer chains corresponding to the hard basic component being grafted onto a previously prepared rubber latex.

The method normally used in the past for the determination of the grafting and crosslinking state in such a material consists in breaking it down by trying to bring it into solution, and then determining the insoluble fraction and its swelling behavior and composition.

It will now be shown that information on grafting and crosslinking can also be obtained in the original material in the solid state. The difference in shrinkage of the glass and rubber phases on cooling from the melt can lead to "thermal stress", which affects the glass transition of the elastomer phase. This is discussed for the case of rubber-modified styrene/acrylonitrile copolymers (ABS). The importance of the "thermal stress" to the fracture mechanism, particularly to the initiation of crazing, is also discussed.

Thermodynamics of the Cooperative Transformations of Biopolymers in Solution

By *Th. Ackermann*[*]

One of the characteristics of typical biopolymers is that the thermal transformation process from a highly ordered

[*] Prof. Dr. Th. Ackermann
Institut für Physikalische Chemie der Universität
78 Freiburg, Hebelstrasse 38 (Germany)

secondary structure into the random coil arrangement, which can take place in solvents with suitable compositions, proceeds almost to completion within a relatively narrow temperature range. Some calorimetric methods for the determination of transformation enthalpies are also suitable for the direct determination of the degree of transformation as a function of the temperature.

This method is discussed in connection with the thermodynamic stability parameters characteristic of the cooperative transformations.

The transformation curve derived from these thermodynamic measurements is compared with the transformation curves obtained by optical and spectroscopic measurements for a number of examples (polynucleotides, polypeptides).

Association Behavior of Atactic and Stereospecific Polymethyl Methacrylates

By *Werner Borchard* (lecturer), *Manfred Pyrlik*, and *Günther Rehage*[*]

The stereocomplex formation observed in mixtures of stereospecific polymethyl methacrylates (PMMA) in some solvents has been investigated over a wide temperature range by viscometric and NMR spectroscopic methods. It is shown with the aid of viscosity and swelling measurements that the association of various stereospecific molecular regions also occurs in atactic and crosslinked PMMA. It can be deduced from the temperature dependence of the reduced specific viscosity and of a number of swelling curves that the stereocomplexes of different sizes are formed in the same temperature range. In dilute solutions prepared from mixtures of isotactic and syndiotactic PMMA and toluene, one observes behavior that can be explained by association that takes place mainly between coils. The observed anomalies in very dilute solutions of atactic PMMA can be explained by association within a coil. No solutions or gels in chloroform exhibit any unusual behavior.

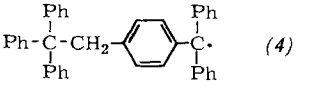
Aromatically Substituted Poly-*p*-xylylenes

By *Dietrich Braun* (lecturer) and *Ulrich Platzek*[*]

The preparation and polymerization of 1,4-α,α-diarylquinodimethanes were investigated in the course of studies on stable polyradicals.

The polymers obtained from 4-alkyltriphenylmethyl halides *(1)* and pyridine have a polydiarylxylylene structure *(3)*.



The reaction mechanism was elucidated with the aid of ESR spectroscopy for 1,4-α,α-diphenylquinodimethane *(2)*, R = H, Ar = Ar′ = phenyl. The polymerization is initiated by 4-methyltriphenylmethyl. The ESR spectra change

(1) *(2)* *(3)*

Ar = phenyl, *p*-tolyl
Ar′ = phenyl, *p*-tolyl, *o*-tolyl, α-naphthyl
R = H, CH_3
X = Cl, Br

as the polymerization proceeds, until only macroradicals having structures comparable with that of the model radical *(4)* are present.

(4)

4-Alkyltriphenylmethyls have also been detected as initiator radicals in the case of the other quinodimethanes.

The polymers can be separated by gel chromatography on polyvinyl acetate gels (Merckogel). The polyxylylenes obtained by free-radical reactions have relatively low molecular weights.

Determination of Sequence Length Distributions from the Pyrolysis of Labeled and Unlabeled Ethylene-Propylene Copolymers

By *Josef Exner*, *Michael Seeger*, and *Hans-Joachim Cantow* (lecturer)[*]

The properties of copolymers depend not only on their overall composition, but also on the distribution of the different sequences from which they are built up. The report deals with attempts to calculate the distribution of the sequences in ethylene-propylene macromolecules from the distribution of fragments obtained by thermal degradation of the copolymers.

The use of pyrolysis in investigations of this type depends on the reappearance of essential structural features of the polymer chain in the pyrolysis products. This is particularly likely to occur if the pyrolysis is carried out in such a way as to favor the formation of longer fragments. We therefore used depolymerization under a hydrogen atmosphere, with the pyrolyzer coupled to a temperature-programmed gas-chromatographic separating column[1, 2].

To allow an independent check on the sequence length distributions calculated from the experimental fragment distribution on the assumption of plausible cleavage mechanisms, we prepared copolymers with sequence structures

[*] Dr. J. Exner
Institute for Macromolecular Chemistry of the
Czechoslovak Academy of Sciences, Praha (Czechoslovakia)
1969/1970 Visiting Lecturer at Freiburg
Dipl.-Phys. M. Seeger and Prof. Dr. H.-J. Cantow
Institut für makromolekulare Chemie der Universität
78 Freiburg, Stefan-Meier-Strasse 31 (Germany)

that could be precalculated from the kinetics of polymerization. A very reliable calculation of the distribution of ethylene sequences from that of the linear fragments is possible if one simply assumes the superposition of preferential α-cleavage at the tertiary carbon with random cleavage in the ethylene sequences[1, 3]. Cleavages leading to isoalkanes are also discussed. It is shown that the sequence length distributions obtained do not depend critically on the conditions of pyrolysis and of separation.

Radio gas chromatography of the fragments from labeled copolymers considerably increases the accuracy of the analytical results. For this purpose we prepared copolymers with definite structures labeled on the α-CH_3 with tritium, and subjected the pyrolysis products to parallel determination of the carbon content with a flame ionization detector and determination of the activity with a radiation detector.

Among other things, it was found that the *n*-alkanes were active. The cleavage at the tertiary C atoms thus takes place in the chain. The activity of the *n*-alkanes in relation to their mass is roughly inversely proportional to their chain length. However, the intensities of the two greatest "iso-signals", which overlap, differ in their ratio according to the detector used. This provides information about the structure and the cleavage mechanisms of the intersequence cleavage fragments.

It appears possible to analyze the sequence structures even of terpolymers with relatively low contents of the third component.

Determination of the Polydispersity of Anionic Polystyrenes by Phase Distribution Chromatography (PDC)

By *R. H. Casper* (lecturer) and *G. V. Schulz*[*]

For the phase distribution chromatography of polystyrene, glass spheres coated with a thin film of high molecular weight polystyrene ($M = 8 \times 10^6$) are packed into a thermostated metal column (VA steel) together with cyclohexane. The polymer film swells to form a gel layer about 3000 Å thick. The polymer sample to be fractionated, whose average degree of polymerization should be about one order of magnitude lower than the degree of polymerization of the polymer film, is dissolved in cyclohexane and injected at the top of the column. The sample is then washed through the column with pure cyclohexane.

The migration of the polymer through the column can be formally described by the model of a liquid/liquid partition chromatography. Each degree of polymerization P distributes itself according to its partition coefficient $K(P)$ (ratio of the concentrations of the polymer P in the gel and in the sol phase respectively) between the stationary gel phase and the mobile sol phase. $K(P)$, and hence the elution volume, increases with falling temperature and increasing degree of polymerization. The elution volume $V_e(P)$ depends on P in accordance with the following equation:

$$V_e(P) = V_e^0 \left[1 + \frac{K(P)}{r_v} \right] \quad (1)$$

r_v = ratio of the volumes of the sol and gel phases;
V_e^0 = volume of the total sol phase in the column.

On the assumption that the two phases are in equilibrium, it is possible to determine $K(P)$ from $V_e(P)$. $K(P)$ can be calculated independently on the basis of the Flory-Huggins equation for the case of phase equilibrium. The thermodynamically calculated values agree well with the values obtained by chromatography. It can be shown both theoretically and experimentally that the dependence of the partition coefficient on P can be described by the equation:

$$K(P) = \exp(\varepsilon \cdot P) \quad (2)$$

which was used by *Brønsted* and by *Schulz*. It can therefore be concluded that the retention results from partition of the polymer between two liquid phases, and that the chromatography takes place at least approximately under equilibrium conditions.

The width of the elution curve of a polymer mixture depends on the breadth of the molecular weight distribution, as well as on the column temperature and the average degree of polymerization. Conversely, if the dispersion broadening and the type of molecular weight distribution (Poisson, Gauss, or Schulz distribution) are known, the polydispersity of the sample can be determined from the breadth of the elution curve. This assumes that the polymers pass through the column independently of one another. Under the further (experimentally verifiable) assumption that the concentration profile of a single component P on leaving the column can be described by a bell-shaped Gauss curve with variance σ, the elution curve of a polydisperse mixture with the differential mass distribution $H(P)$ is given by the equation

$$C(V) = f \int_0^x H(P) \cdot \exp\left[-\left(\frac{V - V_e^0\left(1 + \frac{K(P)}{r_v}\right)}{\sigma\sqrt{2}} \right)^2 \right] \cdot dP \quad (3)$$

(f = normalization constant). $C(V)$ is the concentration of the polymer in the eluate. According to equation (3), the variance σ_v of the elution curve $C(V)$ can be calculated for a given distribution $H(P)$ if V_e^0, σ, and ε are given, and this value can be compared with the variance of the elution curve found experimentally for a product having the same average degree of polymerization. The polydispersity of the polymer mixture is finally found from this comparison.

Measurements on anionic polystyrene samples showed that the polydispersities calculated from σ_v agree, to within the limits of accuracy, with the values found by gel chromatography and (in some cases) by Baker-Williams fractionation.

Stereochemical Control in Free-Radical Polymerizations

By *Hans-Georg Elias* (lecturer) and *Paul Göldi*[*]

No simple relationships between the constitution of a monomer and the tacticity of a polymer prepared by a free-radical reaction are known so far. For example, the

[*] Prof. Dr. H.-G. Elias and Dipl.-Ing.-Chem. P. Göldi
Dept. of Ind. and Engng. Chem.
CH-8006 Zürich, Universitätsstrasse 6 (Switzerland)

direct comparison of the syndiotacticity of polymers prepared at the same temperatures and also parameters indicating deviations from Bernoulli statistics have failed. On the other hand, the quantities T_0 and $\Delta\Delta H_0^*$, which can be determined from the temperature and solvent dependence of the ratio of the mole fractions of isotactic and syndiotactic diads formed in the polymerization, have been found to be suitable. The compensation temperature T_0 is the temperature at which the effects of the solvents just compensate one another so that the same tacticity is always obtained, irrespective of the solvent. Linear relations exist between T_0 and $\Delta\Delta H_0^*$ both for vinyl and for acrylic monomers. In the series of vinyl monomers, T_0 also depends on the size of the substituents and their interaction.

"Molecular Probes" in the Study of Polymer Structure and Interactions

By *J. E. Guillet*[*]

Recent experiments in our laboratories have shown that the technique of gas chromatography may be utilized to obtain extensive information about polymer structure and interactions in the solid phase. Although it might appear logical to apply the name "gas chromatography of polymers" to such experiments, the terminology is misleading in that the polymer is obviously not in the gas phase, nor is it undergoing a chromatographic separation. In fact the nature of the experiment has more in common with the molecular beam technique for gaseous reactions and we prefer therefore to refer to these as studies on polymers using "molecular probes".

In essence, the experiment involves sending a pulse of molecules along a narrow tube which has a thin coating of the polymer to be investigated covering the inner wall or on the surface of a suitable inert support. The probe molecules will undergo random diffusional motion in all directions, upon which is superimposed a velocity U in the forward direction maintained by a flow of inert carrier gas. In general each of the probe molecules will have a velocity component U_p perpendicular to the flow direction which will cause them to impinge on the polymer surface at the wall. If there is no interaction with the polymer there will be no alteration in the component of velocity U_f in the forward direction. On the other hand any interaction with the polymer will result in a retardation of the net translational velocity of the probe molecules along the tube direction. The strength and nature of the interaction can be deduced from this change in velocity by application of rather simple physicochemical considerations.

The use of hydrocarbon probes such as decane and hexadecane in an inverse chromatography experiment employing various polymers as stationary phases is described. It is shown that the crystalline regions of such polymers are impermeable to the probe molecules and hence the degree of crystalline order can be estimated solely from chromatographic retention data. Estimates of diffusion constants and glass transition may also be obtained.

Studies were also made of polymer transitions occurring isothermally. Using an automated injection apparatus the rate of crystallization of several samples of polyethylene and polypropylene were determined at a series of temperatures. The results agree well with data published on similar polymers obtained by dilatometric methods.

Studies of glassy polymers such as polystyrene, poly(methyl methacrylate) and polyvinylchloride show clear evidence for other transitions, such as T_g, involving changes in polymer segment mobility.

The basic expressions of gas-liquid chromatography relate the solute activity coefficient to an experimental specific retention volume. Application of these equations to polymer-containing systems is complicated by the need to define a suitable molecular weight for the polymer. The difficulty is overcome by considering the solute activity, which can be related to the experimental retention volume, without the explicit knowledge of the polymer molecular weight. Statistical thermodynamics of polymer solutions have been applied to this case, showing that experimental retention volume data may be used directly to calculate solute-solvent thermodynamic interaction parameters. These parameters can be expressed in terms of conventional Flory-Huggins concepts, leading to characteristic values of the κ parameter as illustrated for the case of *n*-alkane/polyethylene.

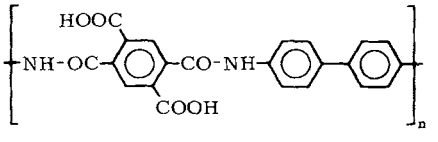
Oligomerization of Ethylene

By *G. Henrici-Olivé* (lecturer) and *S. Olivé*[*]



The oligomerization of ethylene on systems based on Ti(IV) and alkylaluminum compounds is described as an example of catalyst tailoring in homogeneous catalysis. The lecture deals with the systematic investigation of the relations between the nature of the ligands on the Ti or Al side of the catalytic complex and the properties of the product (position of the double bonds, chain length, and degree of branching of the oligomer). As a result of the findings, it is possible to direct the oligomerization in such a way as to obtain predominantly short-chain, linear α-olefins.

Influence of Triethylamine on the Viscosity of Poly(amic Acids) from Pyromellitic Dianhydride and Benzidine in Dimethylacetamide

By *A. Horvath* (lecturer) and *Bruno Vollmert*[*]

Aromatic poly(amic acids) (PAA) are structurally interesting because of their relatively immobile aromatic structural units, which may be expected to have a chain-stiffening effect. This effect is particularly pronounced when benzidine is used as the diamine component in the synthesis:

[*] A. Horvath and Prof. Dr. B. Vollmert
Polymer-Institut der Universität
75 Karlsruhe, Kaiserstrasse 12 (Germany)

On addition of triethylamine (TEA) to the dilute solutions of PAA in dimethylacetamide (DMA), the reduced specific viscosity η_{sp}/c increases depending upon the molecular weight, the PAA concentration, and the quantity of TEA added, to about twelve times the η_{sp}/c values of TEA-free PAA solutions.

The relatively pronounced increase in viscosity on addition of TEA is attributed to opening up of the coils by the intramolecular interaction of the carboxylate ions. The ions are formed by protonation of the TEA in accordance with the following equation:

$$R\text{-}COOH + N(C_2H_5)_3 \rightleftharpoons R\text{-}COO^{\ominus} + HN^{\oplus}(C_2H_5)_3$$

The η_{sp}/c values decrease with increasing PAA concentration, as is also found in aqueous solutions of polyelectrolytes. In contrast with the viscosity-titration curves of aqueous polyelectrolyte solutions, the η_{sp}/c values do not pass through a maximum with increasing addition of base, but move asymptotically toward certain limiting values. This behavior is due to the fact that the neutralization of the PAA is carried out here in an aprotic solvent with a base that is incapable of selfdissociation. An excess of TEA favors the formation of ions in accordance with the above equilibrium, but does not itself increase the ionic strength of the solution. The ionic character of the mechanisms proposed is confirmed by suitable electrical conductivity measurements.

Comparison with polymethacrylic acid having the same molecular weight in DMA, for which the increase in viscosity on addition of TEA is much smaller, shows the strong influence of the constitution of the polymer chain, *i.e.* the chain stiffness due to the constitution.

Pyro Field Ion Mass Spectrometry (PFIMS) as an Effective Method for the Determination of the Structure and Degradation Behavior of Polymers and Copolymers

By *Dieter Hummel* (lecturer), *Kurt Rübenacker, Heinz-Jürgen Düssel*, and *Theo Schweren*[*]

In PFIMS, the sample (a few µg) is pyrolyzed isothermally or in accordance with a temperature program in a gold crucible at a distance of about 5 mm from a Pt ionizing wire (2–4 µm, +8000 V). Only slight additional fragmentation occurs on ionization of the molecule-fragments on the emitter filament. An SEM[1] (currents $> 10^{-19}$ A) is used as the collector, and the spectrum is recorded with a direct-recording light (15 s for the range of masses between 10 and 300) or electron beam oscillograph (practically instantaneous).

The behavior of polymers that give large amounts of monomer and oligomers is shown for polyisobutene, polystyrene, polypropylene, and polyacrylonitrile (PAN). Polyvinyl chloride (PVC) is discussed as a particularly characteristic example of the removal of side groups with formation of polyenes and aromatic compounds. Binary copolymers allow a greatly simplified division into three groups, according to their degradation behavior: 1. Preferential rupture at the hetero linkages: breaking out of the sequences. 2. Preferential rupture in the homo sequences of one or both components: formation of characteristic hetero fragments. 3. Smooth rupture both of homo and of hetero linkages: extensive degradation to the monomers (oligomers), no preference for or discrimination against the hetero linkages. Examples discussed include polysulfones (1), vinyl chloride-propylene and α-methylstyrene-acrylonitrile (2), and α-methylstyrene-methyl methacrylate (3).

PFIMS may be particularly useful where a system (homopolymer or copolymer) can polymerize by different mechanisms to give products with different structures. This is shown for the copolymers of vinyl chloride and propylene and for the polymers of vinyl phenyl methylenedisulfone. (The latter investigations were carried out in collaboration with *H. Ringsdorf.*)

[1] SEM = secondary electron multiplier.

Conformation of Molecules in Undiluted, Noncrystalline Polymers

By *Martin Hoffmann*[*]

In amorphous rubbery polymers the molecules form statistical coils, which penetrate each other and have end-to-end distances $h = \text{const.}\ M^{0.59}$. This result is obtained from the domain sizes in microheterogeneous block copolymers of different molecular weights M, from the light scattering and the diffusion of dissolved molecules in mixtures of polymers, from the intrinsic viscosity, the structural viscosity, and the relaxation modulus of large molecules in smaller ones of the same chemical nature, as well as from the volume contraction in mixtures of polypropylene oxide with solvents. Since important theories[1,2] of the properties of amorphous polymers have hitherto assumed ideal coils ($h = \text{const.}\ M^{0.50}$) or bundled molecules they should be revised.

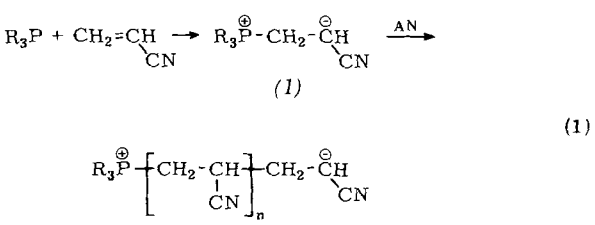
Formation of Macrozwitterions in the Anionic Polymerization of Vinyl Monomers Initiated by Tertiary Phosphanes

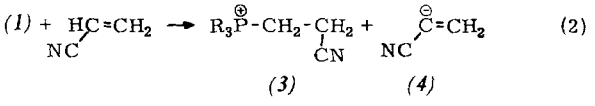


By *G. Franzmann, C. D. Eisenbach*, and *V. Jaacks* (lecturer)[*]

The formation of macrozwitterions *(2)* from acrylonitrile (AN) and a nonionic Lewis base, *e. g.* triethylphosphane [$(C_2H_5)_3P$, formerly called triethylphosphine], in accordance with equation (1) was postulated by *Horner et al.*[1] as early as 1955.

Enikolopyan et al.[2] believed that they had confirmed this by NMR spectroscopic studies. However, our investigations, in which such a polyacrylonitrile was fractionated by fractional precipitation and by gel chromatography, showed

[*] Dipl.-Chem. G. Franzmann, Dipl.-Chem. C. D. Eisenbach, and Dr. V. Jaacks
Institut für organische Chemie der Universität
65 Mainz, Jakob-Welder-Strasse 15 (Germany)



that under the usual polymerization conditions, the zwitterionic chains do not grow beyond a degree of polymerization of 1, even in polar solvents. The large amount of energy required for charge separation is presumably the reason

(1)

(2)

why the chain transfer in accordance with equation (2) occurs and only low molecular weight phosphonium ions *(3)* are formed, whereas the anions *(4)* initiate the chain growth.

(2)

The polymerization of diethyl methylenemalonate $[CH_2=C(COOR)_2]$ with triphenylphosphane in chloroform, on the other hand, proceeds by the zwitterion mechanism corresponding to equation (1). This monomer has no acidic hydrogen that could lead to transfer in accordance with equation (2). The phosphonium groups were detected and determined spectroscopically in the polymer fractions obtained by fractional precipitation and by gel chromatography. The polymers obtained contained almost one phosphonium group per polymer chain.

Molecular Weight Distribution of *n*-Component Copolymers ($n \geq 2$) in "Living Polymer" Systems

By *Fritz Horn* and *Joachim Klein* (lecturer)[*]

On the assumption that initiation is complete immediately after addition of the initiator ($k_s \gg k_w$), the chain growth in a living polymer system can be described by equation (1):

$$P_j(v) + M_i \xrightarrow{\varkappa_{ij}} P_i(v+1), \quad i = 1, 2, \ldots n \tag{1}$$

In this equation $P_j(v)$ is a polymer species having the reactive end group formed with the monomer of type j and with a degree of polymerization v; M_i is a monomer of type i in a mixture of n copolymerizing monomers; $\varkappa_{ij}$ is the propagation rate constant for the reaction of a monomer of type M_i with a polymer end group of type j.

If

$$\mathbf{u}(v,t) = (u^1, u^2, \ldots, u^n)^T \tag{2}$$

is the column vector, which gives the end group concentration of chains having a degree of polymerization v at time t, *i. e.*

$$u^i(v,t) = [P_i(v,t)] \tag{3}$$

and if the monomer concentration is assumed to remain constant, the dynamic equation for the end group concentration is

$$\dot{\mathbf{u}}(v,t) = K\mathbf{u}(v-1,t) - D\mathbf{u}(v,t) \tag{4}$$

where

$$K = \begin{bmatrix} k_{11} k_{12} \cdots k_{1n} \\ k_{21} k_{22} \cdots \\ \cdot \quad \cdot \\ \cdot \quad \cdot \\ \cdot \quad \cdot \\ k_{n1} k_{n2} \cdots k_{nn} \end{bmatrix} \quad \text{and} \quad D = \begin{bmatrix} \sum_{i=1}^{n} k_{i1} & 0 & 0 \cdots 0 \\ & & 0 \cdots 0 \\ 0 & \sum_{i=1}^{n} k_{i2} & \\ 0 & & \cdot \\ \cdot & & \cdot \\ \cdot & & \cdot \\ 0 \cdots & & \sum_{i=1}^{n} k_{in} \end{bmatrix} \tag{5}$$

In this equation, k_{ij} are the pseudo-first order constants for chain growth obtained in accordance with

$$k_{ij} = \varkappa_{ij}[M_i] \tag{6}$$

Solution of the differential equations derived from equation (4) for the first three moments

$$\sum_{v=1}^{\infty} \mathbf{u}(v,t) \cdot v^k, \quad k = 0, 1, 2$$

can provide information on a number of quantities for all times $t > 0$.

These include: 1, the concentration distribution of the end groups as a function of time; 2, the relation of the end group distribution as a function of time to the end group distribution as a function of the chain length (Markoff process); 3, the number average degree of polymerization for classes of species that are characterized by a certain end group, as well as for the material as a whole.

For other quantities that can be derived with the aid of the second moment of $\mathbf{n}$, the treatment of the problem becomes too complex for short times (degree of polymerization). However, valuable information on so-called asymptotic quantities can be easily obtained here.

These quantities include in particular the newly defined dispersion number

$$\lim_{t \to \infty} \frac{\sigma^2(t)}{\bar{v}(t)} = \Theta = \lim_{t \to \infty} (\bar{P}_w - \bar{v}) \tag{7}$$

for which it can generally be proved that $\Theta \geq 1$.

$\Theta = 1$ is valid for the homopolymerization ($n = 1$) and for exceptional cases of copolymerization ($n > 1$). The influence of the monomer concentration, which determines the quantities k_{ij} in accordance with equation (6), on the quantity Θ is discussed in more detail.

Sequence Kinetics in Polymer-Analogous Reactions by Monte-Carlo Simulation and NMR Investigation

By *Ernst Klesper* (lecturer), *Wolfram Gronski*, and *Volker Barth*[*]

If a polymer is subjected to a polymer-analogous reaction, the rate of reaction of the groups to be transformed may depend on the nature of the neighboring groups, *e.g.* on whether the immediately adjacent monomer units have already reacted. Such a cooperative effect of neighboring monomer units causes a deviation of the rates of formation of certain sequences of monomer units from the rates found in the absence of such an effect, *i.e.* in the case of random statistics of the copolymer.

The reaction of a homopolymer to form a binary copolymer was simulated by a Monte-Carlo procedure with a digital computer and by a simple dice method. The model reaction was based on the assumption that the reaction rate constants depend only on whether an unreacted monomer unit is flanked by two unreacted units, only one, or no unreacted monomer unit. The monomer units were called randomly by random numbers, and another random number was used to decide whether the unit had reacted. Alternatively, the monomer units were addressed in order, beginning at the end of the molecule, and reacted as before. It was found that the two procedures were equivalent if the rates of the model reactions were sufficiently low. Counting of the resulting model chains gave relative frequencies for the diads, triads, tetrads, and higher sequences as a function of the number of random numbers or of the conversion.

By suitable choice of the reaction rate constants for the Monte-Carlo simulation, it is possible to obtain a fit to corresponding experimental sequence frequency conversion curves. The ratios of the three experimental rate constants can be determined in this way. It is also possible, with the aid of the simulated model chains, to obtain information about the extent of reversibility of the chains, and whether the frequency even of long sequences can be precalculated with the aid of conditional probabilities of low Markoff order. To characterize the neighboring group effects, even without the determination of the rate constants, conditional probabilities representing the statistical effect of the nearest neighbors in both directions of the chain were introduced. The Monte-Carlo investigation was supplemented by formal-kinetic differential equations for polymer-analogous reactions with three rate constants, which were set up without assumptions.

For the partial hydrolysis of polymethyl methacrylate to methyl methacrylate-methacrylic acid copolymers, reaction conditions were found that led not only to random distribution but also to alternating and block-like distributions of triads. Since all triad frequencies can be determined directly by NMR spectroscopy, this polymer-analogous reaction is suitable for the investigation of the kinetics of the sequences. The alternating structure that results from hydrolysis in aqueous solution with an excess of KOH is due to retarded hydrolysis of monomer units whose neighboring monomer units have already reacted, and hence carry carboxylate groups. On the other hand, the block structure formed with a deficiency of KOH is due to acceleration of the hydrolysis by adjacent monomer units carrying carboxyl groups.

Reactivity of Pendant Vinyl Groups in Crosslinked Divinylbenzene Polymers and Styrene-Divinylbenzene Copolymers

By *Dietmar Kühnle* (lecturer) and *Werner Funke*[*]

Investigations were carried out on the reactivity of unreacted vinyl groups fixed on the network (pendant vinyl groups) in crosslinked polymers prepared by free-radical polymerization of technical grade divinylbenzene, *p*-divinylbenzene, and styrene/divinylbenzene mixtures. The reagents used were Hg(II) acetate in methanol and *n*-butyllithium in benzene.

The addition of Hg(II) acetate and of *n*-butyllithium to the vinyl groups of the polymer particles was detected by IR spectroscopy. The number of double bonds that reacted in the case of Hg(II) acetate was determined by titration of the acetic acid formed. In the experiments with *n*-butyllithium, ^{14}C-labeled *n*-butyllithium was used, and the conversion was calculated from the radioactivity of the polymer.

Unlike styrene, with which Hg(II) acetate and *n*-butyllithium react in the homogeneous phase, the reactions with the vinyl groups of the crosslinked polymer particles are heterogeneous. The addition of both reagents to the polymer particles consequently proceeds much more slowly than in the case of styrene.

The conversion reaches a final value with sufficiently long reaction times. In the case of Hg(II) acetate, this value often corresponds to quantitative conversion, whereas the reaction with *n*-butyllithium nearly always stops at much lower conversions. The substances investigated differ characteristically in their reaction rates and in their conversions. These differences can be explained by differences in the accessibility of the vinyl groups enclosed in the network. The influence of the reagents, the reaction medium, and the particle structure on the course of the reaction are discussed.

Monomer Concentration in Polymers and its Correlation with the Polymerization Rate in Heterogeneous Polymerization

By *O. F. Olaj* (lecturer), *J. W. Breitenbach*, *H. Reif*, and *K. J. Parth*[*]

Knowledge of the monomer concentration that prevails in the polymer particles under the conditions of heterogeneous free-radical polymerization should be of great importance to the understanding of the kinetics of heterogeneous free-radical polymerization.

For the experimental determination of the monomer concentration in polyvinyl chloride (PVC) in equilibrium with monomeric vinyl chloride (VC) or with mixtures of VC and the solvent 1,2-dichloroethane (DCE), a method was developed based on the measurement of the increase in the length of massive PVC rods ($[\eta] = 113$ ml/g in cyclohexanone at 25 °C) due to swelling. The relative increase in

[*] Dr. O. F. Olaj, Prof. Dr. J. W. Breitenbach, H. Reif, and K. J. Parth
Institut für Physikalische Chemie der Universität
A-1090 Wien IX, Währinger Strasse 12 (Austria)

volume $\beta(=\Delta V/V_0)$ due to swelling is 0.42 for swelling in pure VC($c_{VC}=13.6$ mole/l) at 50°C; it increases with increasing addition of DCE, and reaches a value of about 1.85 at a DCE concentration of 5.3 mole/l (corresponding to a VC concentration of 8.3 mole/l) in the swelling agent.

If the volumes are assumed to be additive, the monomer concentrations in the interior of the polymer, c^*_{VC}, can be calculated from the β values for each external concentration c_{VC}. The influence of the preferential absorption of DCE by the polymer was determined by variation of the ratio of swelling agent to polymer. The preference for the solvent DCE is relatively slight. In the range in which the polymerization in the VC-DCE systems proceeds heterogeneously practically from the outset (*i.e.* at c_{VC} between about 8 and 13.6 mole/l), the c^*_{VC} values obtained start at 4.0 mole/l in pure VC, and pass through a maximum with decreasing c_{VC} ($c^*_{VC}=5.3$ mole/l at $c_{VC}=8$ mole/l). This means that the decrease in the VC content of the swelling agent due to the addition of DCE is overcompensated at first by the increase in the uptake of swelling agent by the polymer corresponding to the higher degree of swelling. It is only at relatively high DCE concentrations that c^*_{VC} decreases with decreasing c_{VC}.

The $c^*_{VC}-c_{VC}$ curve has a striking similarity to the $v_{Br}-c_{VC}$ curve for the polymerization of VC under constant initiation conditions, which also passes through a maximum. This leads to a relatively simple formula for the description of the kinetics of the heterogeneous polymerization of VC.

The situation is different in the system polyacrylonitrile (PAN)-acrylonitrile(AN)-dimethylformamide (DMF). PAN($[\eta]=800$ ml/g in DMF at 25°C) is practically unswollen in DMF-AN mixtures up to a DMF content of about 70 vol-%, so that only vanishingly small monomer concentrations can be present in the interior of the polymer. Consequently, the correlation between the polymerization rate and the monomer concentration in the interior of the polymer cannot be so simple as in the system PVC-VC-DCE. The description of the polymerization kinetics here requires complicated formulas that take into account the extremely low monomer concentrations in the interior of the polymer.

Investigations on the Influence of Various Ions on the Radius of Gyration and Structure of tRNA in Solution

By *Ingrid Pilz* (lecturer), *Otto Kratky*, *Friedrich von der Haar*, and *Friedrich Cramer*[*]

Since the primary and secondary structures of many specific transfer ribonucleic acids (tRNAs) are largely known, a series of models for their tertiary structures have been proposed in recent years. The radius of gyration and the scattering curve can be calculated from the atomic coordinates of such a model. These data are compared with the experimental values obtained by X-ray small angle scattering measurements on the molecule in solution.

During such comparisons the following difficulty must be borne in mind: The experimental investigations are carried out in solution, and little is known about the influence of the ion- and water-shell on the radius of gyration and the structure of a polyelectrolyte such as the tRNAs. Solutions of phenylalanine-specific tRNA from yeast were therefore investigated in the presence of various ions. Only one type of ion was present in each solution. The investigations were carried out on solutions containing Li^+, Cs^+, Mg^{2+}, and Ba^{2+} ions. The influence of the ions was very pronounced. The radius of gyration of $tRNA^{Phe}$ had values of *e.g.* 23.6 Å in the presence of Li^+ ions, 26.2 Å in the presence of Cs^+ ions, and 26.3 Å in the presence of Ba^{2+} ions. These results show very clearly that the influence of the solvent must never be ignored in the comparison of experimental values with data calculated from the atomic coordinates of the molecules.

The melting behavior of the $tRNA^{Phe}$ from yeast was also investigated in the presence and in the absence of Mg^{2+} ions. The melting of the tRNA structure with rising temperature can be followed by the increase in the radius of gyration. In the presence of Mg^{2+} ions, an increase in the radius of gyration was observed at distinctly higher temperatures.

Dielectric Measurements for the Determination of Aggregation and Helix-Coil Transition in Poly-benzyl-L-aspartate and Poly-DL-phenylalanine

By *Eve Marchal*[*]

The dielectric absorption of poly-DL-phenylalanine (PDLPA) and poly-benzyl-L-aspartate (PLAB) was measured in very dilute solutions to determine association and helix-coil transition. Both polypeptides are present as associated helices in chloroform. The mode of aggregation was determined by measurement of the dipole moment and of the critical frequency. The influence of solvent polarity on the aggregates was also investigated in the case of PDLPA.

For both polymers the dissociation of the aggregates in chloroform is observed on addition of a little dichloroacetic acid, while further addition of the acid leads to the helix-coil transition. No second region of dielectric absorption that might be related to the kinetics of the transition occurs during the helix-coil transition of PLAB.

Reactivity, Modification, and Polymerization Behavior of Monomers Containing Sulfur

By *Herbert Naarmann* (lecturer) and *F. J. Feichtmayr*[*]

For the case of 2-hydroxyethyl vinyl thioether, which is readily obtainable by vinylation of 2-mercaptoethanol, relationships are shown between the reactivity of the C=C double bond and the sulfur bridge, which can be converted

[*] Dr. Herbert Naarmann and Dr. F. J. Feichtmayr
Badische Anilin- & Soda-Fabrik
67 Ludwigshafen (Germany)

into >SO, $>SO_2$, or $>\overset{\oplus}{S}-$. The scope of the reactions of 2-hydroxyethyl vinyl thioether ranges from the formation of 5-membered rings through free-radical polymerization to polyaddition. The experimental findings agree with HMO calculations on the electron distribution on the vinyl group.

Binary and Ternary Copolymerization in the System Vinyl Chloride-Butadiene-Maleic Anhydride

By *W. Ring*[*]

With free-radical initiation, the addition of small quantities of butadiene to vinyl chloride considerably reduces the polymerization rate in the initial stage. If maleic anhydride is added in small quantities as the third monomer, the polymerization rate increases again.

The accelerating effect of maleic anhydride is not due to a Diels-Alder reaction between maleic anhydride and butadiene. It results instead from modification of the copolymerization process in such a way that the retarding, slow growth step

~butadiene · + butadiene

is suppressed.

Whereas vinyl chloride and butadiene react in accordance with the rules of the conventional kinetics of free-radical copolymerization, the butadiene-maleic anhydride system exhibits a strong tendency toward alternating growth. Vinyl chloride and maleic anhydride, on the other hand, except at extreme compositions of the monomer mixture, form copolymers in which vinyl chloride is present in a molar excess.

The ternary system behaves accordingly. The molar ratio of maleic anhydride: (butadiene + vinyl chloride) in the copolymer is equal to 1:1 only at suitable monomer compositions and/or at low conversions. If these conditions are not satisfied, the copolymers obtained are deficient in maleic anhydride. Nevertheless, the partial conversion of vinyl chloride, taking into account the concentration of butadiene in the monomer mixture, is considerably higher in the presence of maleic anhydride than in the absence of the termonomer.

Reaction mechanisms are proposed, *inter alia*, in the light of recent results obtained by American and Japanese workers for polymerization controlled by donor-acceptor complexes.

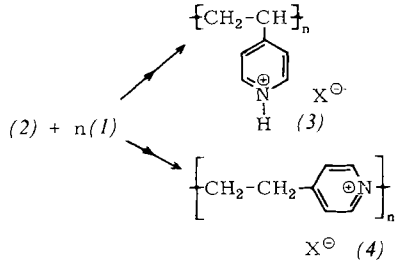
Mechanism of the "Spontaneous Polymerization" of 4-Vinylpyridinium Salts

By *Ingolf Mielke* and *Helmut Ringsdorf* (lecturer)[*]

4-Vinylpyridinium salts have already attracted wide interest because of their special polymerization properties and the associated considerations on the matrix reaction[1, 2]. The mechanism by which the monomeric salts *(1)* polymerize "spontaneously" during the synthesis or in solution has been formulated by *Kabanov et al.*[2, 3] as a nucleophilic attack of the anion on the strongly activated vinyl group, followed by anionic polymerization.



IR and NMR spectroscopic and titrimetric investigation of the reaction course has shown that the polymerization is initiated by 4-vinylpyridine as the nucleophile [eq. (1)][4, 5].

(1)

(1) X = Cl, Br, ClO_4

The course of growth in the polymerization is strongly dependent on the anion, the solvent, and the concentration of the salt[6]. Depending on the reaction conditions, it leads to vinyl polymers having the structure *(3)* or to polyadducts having the structure *(4)*, which have the pyridinium ring in the main chain [eq. (2)].

(2)

According to viscosity measurements on 4-ethylpyridinium salts the change in the reaction mechanism may be due to micelle formation at high monomer concentration and polymerization in the oriented media.

These results also necessitate a check on the course of the "matrix polymerization" of 4-vinylpyridine on polyacids[1].

The Influence of Proline on the Conformation of a Polypeptide Chain

By *Manfred Rothe* (lecturer), *Rainer Theysohn*, *Jan Mazánek*, *Michael Kostrzewa*, *Wolfgang Schindler*, and *Rolf Steinberger*[*]

The special structural and steric properties of peptide-bound proline are investigated by use of definite linear and cyclic oligopeptides of proline and glycine and of proline alone. Their conventional and solid-phase synthesis is described mainly in relation to peculiarities and difficulties that arise from the conformation.

Conformation-dependent physical properties such as IR, UV, CD, and NMR spectra are investigated in detail for the free linear peptides and for those protected on the N and C ends, particularly with reference to criteria for the chain length required for helix formation and the influence of the end groups. The study of the solvent dependence of the configuration of the peptide group in oligoprolines led to the detection of *cis* linkages and to the isolation of *cis*-peptides with uniform configurations.

In the case of cyclic peptides particularly interesting points are the conformations of medium-sized rings with rigid arrangements of the amino acids, as in the cyclodipeptide c-Pro-Pro, the cyclotripeptide c-Pro-Pro-Pro, and the cyclotetrapeptide c-Pro-Gly-Pro-Gly, in comparison with the conformations of the more flexible cyclohexapeptides c-Pro-Pro-Gly-Pro-Pro-Gly and c-Pro-Gly-Gly-Pro-Gly-Gly and of the corresponding polymers, which are also ordered and relatively rigid.

Energy and Entropy Parameters of Different Species of Carbanions from the Polymerization Kinetics and from Conductivity Measurements on Polystyryl-sodium in Polar Organic Solvents

By *M. Chmelíř*, *B. J. Schmitt*, and *G. V. Schulz*[*]

The anionic polymerization of vinyl monomers exhibits two kinetically unusual effects: 1, In solvents having different polarities, the polymerization rate varies by up to five orders of magnitude under otherwise identical conditions; 2, the temperature dependence of the propagation constant appears to be in total conflict with the Arrhenius equation.

The following model was proposed in 1965 for the solution of the resulting problems[1]. The carbanion end group exists in three well-defined forms (contact ion pair, solvent-separated ion pair, and free anion), which add monomer with rate constants that differ by orders of magnitude. The solvent and the temperature influence primarily the equilibria between these three species and hence the polymerization rate. Their direct influence on the rate constants does not go beyond that of the usual solvent effects.

Experimental and theoretical methods have been developed to determine the equilibrium and the rate constants for the three species as a function of the temperature from the polymerization kinetics[2] in various solvents. This gives the enthalpy and entropy differences between the species, as well as the dissociation constants and the Arrhenius parameters of their propagation constants. Conductivity measurements on "living" polymers in various solvents over a wide temperature range lead to dissociation constants that agree with those found kinetically. They prove the existence of the three types of the carbanion end group and allow the determination of the thermodynamic parameters of the corresponding equilibria.

Synthesis of Polymer Gels with Covalently Incorporated Nucleoside Residues and Their Use for the Separation of Nucleic Acid Structural Units

By *H. Schott* (lecturer) and *Gerd Greber*[*]

Nucleoside derivatives with one or two methacryloyl substituents in the sugar residue were prepared by acylation of the nucleosides uridine, adenosine, cytidine, and guanosine with methacryloyl chloride. Free-radical copolymerization of these mono-unsaturated and di-unsaturated nucleoside derivatives gives crosslinked gels with covalently incorporated nucleoside residues, which swell both in water and in DMSO/$CHCl_3$(2:3). With the aid of these U, A, C, and G gels, it was possible to separate nucleoside mixtures and mixtures of nucleic acid structural components by the affinity chromatography principle, since the nucleic acid structural components interact specifically with the nucleoside residues fixed on the gel by base-pairing mechanisms. The importance of hydrogen bonds and of the stacking effect to the observed specific base pairings is discussed on the basis of the separation results.

Diolefin Polyreaction in the Homogeneous Phase

By *Jürgen Hinz*, *Wolfgang Gebert*, and *Hansjörg Sinn* (lecturer)[*]

The reaction of butyllithium with isoprene in diethyl ether yields methyloctenyllithium compounds, which give 36% of 2-methyl-1-octene and the *cis-trans* isomers of 3-methyl-2-octene in the ratio 63:1.

On removal of the diethyl ether from the methyloctenyllithium by distillation after repeated addition of *n*-heptane, the hydrocarbons are found in a ratio of 26:74, whereas after renewed addition of diethyl ether, the ratio of 36:64 is found again.

The methyloctenyllithium compounds thus undergo reversible solvent-dependent rearrangement. Considerable 1,4 addition of isoprene to butyllithium also takes place in diethyl ether.

[*] Dr. J. Hinz, Dipl.-Chem. W. Gebert, and Prof. Dr. H. Sinn
Institut für Angewandte Chemie der Universität
2 Hamburg, Papendamm 6 (Germany)

Whereas the rate constants

$k_s = 1.6 \times 10^{-4}\,l\,mole^{-1}s^{-1}$ and $k_w = 1.5 \times 10^{-2}\,l\,mole^{-1}s^{-1}$

are found at -10 °C for the polyreaction of isoprene with butyllithium as the initiator, the corresponding values for the polyreaction of butadiene are

$k_s = 4.5 \times 10^{-5}\,l\,mole^{-1}s^{-1}$ and $k_w = 2.4 \times 10^{-3}\,l\,mole^{-1}s^{-1}$

The kinetically detectable association behavior of polyisoprenyllithium is described by

$K_3 = 1.86 \times 10^{-9}\,mole^2\,l^{-2}$

and

$K_6 = 2.80 \times 10^{-21}\,mole^5\,l^{-5}$

while the values for polybutadienyllithium are

$K_3 = 2.98 \times 10^{-9}\,mole^2\,l^{-2}$

and

$K_6 = 2.76 \times 10^{-20}\,mole^5\,l^{-5}$

The assumption that 1,4 linkage always occurs first, and that the product then isomerizes under the reaction of the initiator, is supported by the increase in the content of compounds having the 1,4-*cis* structure with decreasing initiator concentration:

Initiator concentration (mole/l)	1,4-*cis* structure	
	isoprene	butadiene
3×10^{-2}	80%	35%
5×10^{-5}	95%	70%
$< 10^{-5}$	98%	–

The rearrangement demonstrated resolves the conflict between the postulated primary step and the structure of the products obtained.

Investigations on Fragments of Phenylalanine-Specific tRNA

By *Rainer Thiebe*[*]

The transfer ribonucleic acids (tRNAs) constitute a group of relatively small molecules among the nucleic acids. Their molecular weights are in the region of 25000—30000, corresponding to chain lengths of 75—87 nucleotides.

In the course of protein biosynthesis, amino-acylated tRNAs are bonded to messenger RNA. The linkage of the amino acids to the tRNA is catalyzed by an enzyme. The tRNA is bonded to the messenger RNA by hydrogen bonds. The esterification is extremely specific; each tRNA can be coupled to only one of the 20 amino acids by the enzyme. Thus corresponding to the 20 amino acids, there are at least 20 tRNAs[1].

Some pure tRNAs have been isolated and sequenced. A number of rules can be deduced from a comparison of the primary structure of the tRNAs analyzed so far. These rules and some experimental observations point to a certain similarity in the tertiary structure.

The questions in which we are primarily interested are as follows: What is the reason for the high specificity with which the tRNA is recognized by the enzyme? Is this determined by the entire structure or only by a certain region? If it is a certain region, which?

A number of relatively large fragments of a tRNA have been prepared by chemical and enzymatic methods. Experiments have been carried out with individual isolated fragments and with combinations of fragments in an effort to answer the above questions. It was shown by omission or modification of various regions of the tRNA that a large part of the molecule is not necessary for the specific recognition by the enzyme[2].

A second set of problems is concerned with the steric structure of tRNAs. Whereas the final solution will probably be obtainable only by X-ray analysis, we have been able to contribute to the solution of a part of the problem by optical measurements on fragments. Experimental confirmation has been found in this way for the model of the secondary structure, which was originally based on theoretical considerations[3].

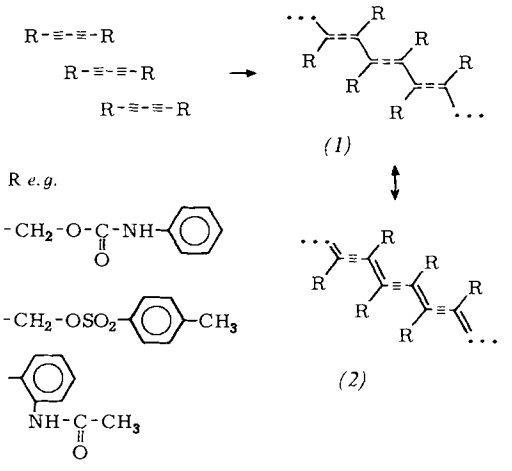
Topochemical Polymerization of Monomers with Conjugated Triple Bonds

By *G. Wegner*[*]



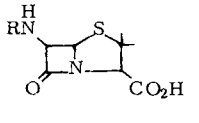
Many monomers containing two conjugated triple bonds polymerize in the crystalline state when heated to temperatures below their melting point or when exposed to visible or UV light to give deeply colored crystalline polymers.

Diacetylenes of this type with substituents that can form directional coordinate bonds are particularly reactive. Substituents of this nature favor a ladder-like arrangement of the monomer molecules in their crystal lattice. The rungs of the ladder are formed by the conjugated triple bonds, and the side-pieces with the aid of the coordinate bonds between the substituents. In such an arrangement, pairs of triple bonds of adjacent molecules approach to a distance of at least 3 Å from each other. The polymerization takes place along the ladder by successive tilting of each rung or by shearing of the entire ladder. Polymers with three cumulated double bonds per repeating unit and with a continuous conjugated main chain are formed from the conjugated triple bonds according to a 1,4 addition. On the basis of X-ray data, the main chain can be described either as a substituted poly-*trans*-butatriene *(1)* or as a mesomeric polybutenyne *(2)*.

Neither the shape nor the lattice of the monomer crystals generally changes in the topochemical polymerization of diacetylenes. Polymers with very high molecular weights can be obtained. The polymer crystals "as polymerized" exhibit strong dichroism with respect to the fiber axis (direction of strongest absorption) and are electrically

[*] Dr. G. Wegner
Institut für Physikalische Chemie der Universität
65 Mainz, Jakob-Welder-Weg 15 (Germany)

conducting. The specific resistances are around $10^9-10^{13}\,\Omega$ cm ($E_a = \approx 0.8-1.0$ eV), depending on the substituents on the main chain.



The reaction leading from monomers with conjugated triple bonds to linear high polymers can also be applied to crystallizable polymers with conjugated triple bonds in the repeat unit. It then acts as a topochemical crosslinking reaction.

Recent Advances in Penicillin Chemistry

By *J. H. C. Nayler*[*]

The penicillins contain a common nucleus consisting of fused β-lactam and thiazolidine rings, with different acylamino side-chains at C-6. Benzylpenicillin (penicillin G) *(1a)* and phenoxymethylpenicillin (penicillin V) *(1b)* are still produced industrially by growing a Penicillium mold in the presence of phenylacetic acid and phenoxyacetic acid respectively, but the newer "semisynthetic" penicillins are prepared *via* the parent amine of the series, 6-aminopenicillanic acid (6 APA) *(1c)*. This substance was first isolated in 1957 from fermentations to which no side-chain precursor had been added, but it is now obtained more conveniently by removing the phenylacetyl side-chain from penicillin G *(1a)* with a bacterial enzyme. Simple chemical hydrolysis ruptures the β-lactam amide bond preferentially, but an ingenious procedure for directing the attack on the secondary amide function of the side-chain has been devised recently. A penicillin ester is treated under very mild conditions with phosphorus pentachloride followed by an alcohol, and very mild acid hydrolysis of the resulting imidate gives 6 APA *(1c)* and the alkyl phenylacetate.

(1b), R = $C_6H_5OCH_2CO$
(1c), R = H

[*] Dr. J.H.C. Nayler
Beecham Research Laboratories
Brockham Park, Betchworth, Surrey (England)

Thousands of semi-synthetic penicillins have been prepared by acylation of 6 APA. Those derived from sterically hindered acids have the advantage of not being inactivated by the β-lactamases produced by many bacteria, and are particularly useful in treating staphylococcal infections. Valuable activity against Gram-negative bacteria is shown by α-aminobenzylpenicillin (ampicillin) and α-carboxybenzylpenicillin (carbenicillin). Their preparation involves temporary protection of the side-chain substituent, and the methods used are compared and contrasted with those employed in peptide synthesis.

In contrast to the many useful antibiotics produced by modifying the penicillin side-chain, modification of the nucleus usually reduces antibacterial activity. However, the cephalosporins represent a related group of β-lactam antibiotics in which a dihydrothiazine ring replaces the thiazolidine ring. Cephalosporins are prepared at present from cephalosporin C *(2)*, a metabolite of a Cephalosporium mold, by replacing the aminoadipyl side-chain with other acyl groups. Much attention is however being given to the chemical conversion of penicillins into cephalosporins, and this aspect of penicillin chemistry is likely to become increasingly important.

Institut für Organische Chemie der Technischen Hochschule
51 Aachen, Prof.-Pirlet-Strasse 1 (Germany)

In comparison with the values reported by *Sauer et al.*[1] for the reactivity of maleic anhydride *(1)* toward dienes, the dichloro derivative *(2)* is a distinctly poorer dienophile. However, in the case of the carbonates *(3)* and *(4)*, the dichloro derivative *(3)* exhibits a greater dienophile activity than the chlorine-free parent compound *(4)*.

The relatively positive entropy of activation of the reactions with vinyl carbonate compared to other compounds is worthy of note. Since no dependence of the rate constants on the solvent could be observed, it can be assumed that the molecule *(4)* requires a less ordered transition state than the usual dienophiles. Correlation of the activation energies E_A with the frequencies of the double bond in the IR or Raman spectrum or with the values for the total bond order determined by means of an EHT calculation with inclusion of the 3p electrons does not give linear relationships.

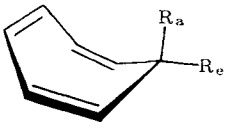
Stereochemical Investigation of Carbanion and Carbenoid Formation from Conformationally Rigid Cycloheptatriene Derivatives



By *Werner Tochtermann*[*]

For 1,2,3,4-tetraphenyl-9*H*-tribenzo[*a,c,e*]cycloheptenes the boat conformation is "frozen" at room temperature ($\Delta G^{\neq} > 30$ kcal/mol for ring inversion of the seven-membered ring). Such compounds are thus suitable for a study of the reactivity of diastereotopic substituents on C-9 of the system and permit predictions about the relation between conformation and reactivity among benzologous cycloheptatrienes.

Remarkable differences of conformational origin were found in solvolytic experiments with conformational isomers of type *(1a)* and *(1b)*: only *(1b)* reacted readily with nucleophiles, and then with retention of conformation, *(1a)* being on the contrary relatively inert. On reaction with potassium *tert*-butoxide in [D_6]-dimethyl sulfoxide, tetraphenyltribenzocycloheptatriene *(2)* undergoes selective exchange of H_a for D, giving the monodeuterated hydrocarbon *(3b)*. The small amount of di- and tri-deuteration (determined mass-spectroscopically) permits the conclusion that the rate of exchange of H_e can be compared with that of the bridgehead hydrogens of triptycene; H_a, however, behaves similarly to the methylene-hydrogen atoms of diphenylmethane.

Reaction of the dichloro compound *(4)* with *n*-butyllithium at −100 °C apparently leads with high preference to the carbenoid *(5b)*, as shown by formation of *(6a)* on addition of deuterium oxide.

(1a), R_a = H; R_e = Cl
(1b), R_a = Cl; R_e = H
(2), R_a = H; R_e = H
(3b), R_a = D; R_e = H
(4), R_a = Cl; R_e = Cl

(5a), R_a = Cl; R_e = Li
(5b), R_a = Li; R_e = Cl
(6a), R_a = D; R_e = Cl
(7b), R_a = COOH; R_e = Cl

(5b), with its quasiaxial C—Li bond, couples with great rapidity, similarly to diphenylmethyllithium derivatives, with alkyl halides, *e.g.*, with added *n*-propyl bromide. With *(5a)*, however, one would expect rather a rapid coupling of *n*-butyllithium with the reactive quasiaxial C—Cl_a bond; such products could be detected only in small quantities by mass spectroscopy. Carboxylation of *(5b)* leads to the chloro carboxylic acid *(7b)*, whereas according to the literature[1] the conformationally mobile chloro(diphenyl)-methyllithium affords diphenylglycolic acid owing to hydrolysis of the C—Cl bond during working up. *(5b)* is also formed on metalation of *(1a)*.

A consideration of models reveals that the greater reactivity of R_a than of R_e may rest on stabilization of the transition state of the C—R_a cleavage by partial overlap with the π electrons of the neighboring benzene rings.

[1] *D. F. Hoeg, D. I. Lusk,* and *A. L. Crumbliss,* J. Amer. Chem. Soc. *87*, 4147 (1965).

Steel embrittlement by hydrogen absorption has been studied by *C. D. Kim* and *B. E. Wilde* by electrochemical methods. To evaluate the steady-state surface concentration the adsorbed hydrogen is oxidized rapidly by an anodic pulse. With the aid of a membrane-permeation method the rate of hydrogen absorption into the iron lattice was measured: on one side of the membrane a steady-state hydrogen concentration is maintained, on the other side hydrogen is oxidized immediately. On an iron surface polarized cathodically in 10^{-4} M NaOH + 0.1 M Na_2SO_4 with current densities of 10—300 μA cm^{-2} surface coverages were 5—12% of a monolayer. The permeation method yielded a value of about 5 sec^{-1} for the hydrogen absorption rate constant in iron. The current densities used would effect corrosion rates of 0.1—4 mm/year. / J. Electrochem. Soc. *118*, 202 (1971) / –Hz.

[Rd 329 IE]

The kinetics of decomposition of aqueous perchloric acid at 295—322 °C in the concentration range often used in electrochemical work (1.1—6.6 mole/l) was studied by *M. P. Henderson, V. I. Miasek,* and *T. W. Swaddle*. The overall reaction is

$$2\,HClO_4 = H_2O + Cl_2 + 3.5\,O_2$$

Cl_2 is in equilibrium with $Cl^{\ominus}$ and HOCl. The initial reaction rate is to the power 3.5 of the perchloric acid concentration; the rate coefficient is $3.1 \cdot 10^{-7}$ $l^{2.5} mole^{-2.5} s^{-1}$ at 300 °C, and the overall activation energy 84 kcal $mole^{-1}$. The reaction is accelerated by its product $Cl^{\ominus}$ and decelerated modestly by $HSO_4^{\ominus}$. The reaction

$$2\,HClO_4 = H_2O + ClO_4 + ClO_3$$

is assumed to be the rate-determining step in the decomposition; ClO_4 and ClO_3 undergo fast reactions leading, finally, to Cl_2 and O_2. The chloride acceleration is thought to be due to the alternative reaction path

$$H^{\oplus} + HCl + ClO_4^{\ominus} = H_2O + Cl + ClO_3.$$

For application as an inert electrolyte the decomposition can be neglected for 1 M $HClO_4$ at 250 °C and for 0.2 M $HClO_4$ at 300 °C, if experiments of about a day's duration are involved. / Can. J. Chem. *49*, 317 (1971) / –Hz.

[Rd 330 IE]

The kinetics of disilane pyrolysis at initial pressures of 23 to 100 torr and 283—340 °C were investigated by *M. Bowrey* and *J. H. Purnell*. Product analysis by gas chromatography showed that initially only mono- and trisilane are formed. Secondary reactions also yield the isomeric tetrasilanes, solid $(SiH_2)_n$, and hydrogen. A detailed analysis of the experimental data excludes the occurrence of SiH_3 radicals as intermediates; the reactive species is silene SiH_2 (presumably in a bent singlet state). SiH_2 does not insert into Si—Si bonds nor into C—H or C—Si bonds, as was found by co-pyrolysis experiments with the methylated monosilanes. Insertion only takes place into Si—H bonds. Rate constants of these insertion reactions could be evaluated for several straight-chain, branched, and methylated silanes. They are practically independent of temperature. The enthalpy of formation of SiH_2 at 298 °K amounts to 247.5 kJ $mole^{-1}$. / Proc. Roy. Soc. *A 321*, 341 (1971) / –Hz.

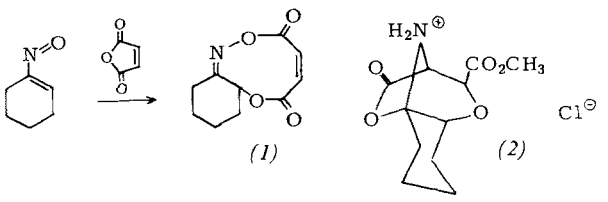
[Rd 331 IE]

A new versatile method for the evaluation of electron affinities of molecules has been developed by *J. J. deCorpo* and *J. L. Franklin*. Both the appearance potential and the average translational energy of negative ions are measured in a mass spectrometer. The negative ions are formed by reactions of the type

$RX + e = X^- + R$ (dissociative electron attachment).

If the heats of formation of the reactants and products are known, (adiabatic) electron affinities can be calculated. The method was applied to the evaluation of the electron affinities of the halogen molecules formed by reactions of the type mentioned above starting with carbon tetrahalides. The values are in the range 2.5—2.9 eV; no trend can be recognized in the series from F_2 to I_2. / J. Chem. Phys. *54*, 1885 (1971) / –Hz.

[Rd 332 IE]



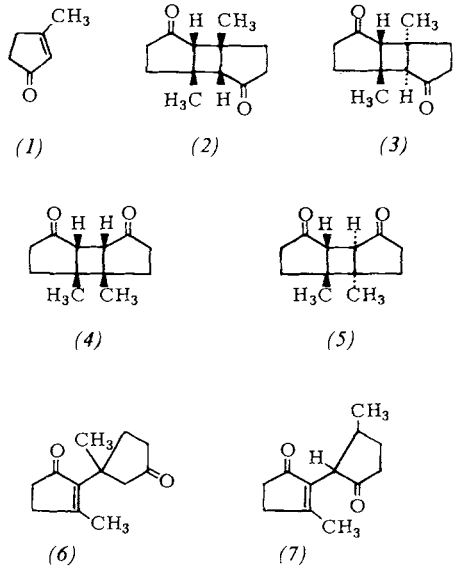
Hydrogen atoms in UV irradiated acid aqueous solutions of indole and 3-β-hydroxyethylindole were detected by *J. Feitelson via* scavenging with isopropanol: molecular hydrogen is formed and the hydroxyisopropyl radical disproportionates yielding isopropanol and acetone. It is known that the excited singlet state of indole releases solvated electrons into the solution, and that protons are effective quenchers of indole fluorescence. The pH dependence and the influence of oxygen on the yield of hydrogen atoms indicate that fluorescence quenching by protons is not effected by direct electron transfer from excited indole to H^+; the hydrogen atoms are formed by reaction of solvated electrons with protons. / Photochem. and Photobiol. *13*, 87 (1971) / –Hz.

[Rd 333 IE]

The molecular structure of gaseous chlorine isocyanate, ClNCO, has been determined by *H. Oberhammer* by electron diffraction. ClNCO was prepared by thermal depolymerization of trichloroisocyanuric acid. The scattering intensities could be interpreted equally well by two different structural models. One contains a linear NCO group, and the N—C and C—O distances differ widely from those found with similar molecules. The other model has an NCO group bent by about 10°, and the bond lengths are in the ranges expected. The rotational constants known from microwave spectroscopy solve the problem favoring the second model with the bond distances (in Å units) Cl—N 1.700 ± 0.002, N—C 1.227 ± 0.005, C—O 1.156 ± 0.006 and the angles ClNC 118.2 ± 0.6° and NCO 171.0 ± 2.1°. Semiempirical MO calculations also indicate a bent NCO group with the Cl atom in *trans* position to the O atom. / Z. Naturforsch. *26a*, 280 (1971) / –Hz.

[Rd 334 IE]

Reaction of nitrosocyclohexene with maleic anhydride leads, according to a report by *G. Just* and *W. Zehetner*, not to the expected Diels-Alder adduct but to the 1:1 adduct *(1)*. Nitrosocyclohexene is prepared by treating α-chlorocyclohexanone oxime with triethylamine in benzene at room temperature. On adding maleic anhydride the blue color disappears with formation of *(1)*, m. p. 205—208 °C (dec.). This 1:4 addition of anhydrides to nitrosoolefins seems to be of a general nature. With dimethyl acetylenedicarboxyl-



(1) (2)

ate or tetracyanoethylene, no identifiable product was obtained. On prolonged standing in presence of 0.5 N methanolic HCl, compound *(1)* undergoes a novel rearrangement quantitatively to give the salt *(2)*, m. p. 180 °C (dec.). / Chem. Commun. *1971*, 81 / –Ma.

[Rd 335 IE]

The photodimerization of 3-methyl-2-cyclopenten-1-one *(1)* (in benzene, 20 °C, Hg high-pressure vapor lamp, $1 > 300$ nm) has been investigated by *G. Mark, H. Matthäus, F. Mark, J. Leitich, D. Henneberg, G. Schomburg, F. v. Wilucki,* and *O. E. Polansky. (1)* is the first α,β-unsaturated cyclic ketone whose irradiation in solution affords all four possible *cis*-coupled cyclobutane isomers [compounds *(2)*—*(5)*]. Two dimers, *(6)* and *(7)*, having an oxocyclopentylcyclopentenone skeleton were also formed in the

Active Carbon. Manufacture, Properties and Applications. By *M. Smišek* and *S. Černý*. Elsevier Publishing Company, Amsterdam–London–New York 1970. 1st Edit., vii, 479 pp., *ca.* DM 97.—.

Active carbon has long been known in the form of carbo animalis, blood charcoal, *etc.*, but it was only at the beginning of this century that it was first manufactured on a commercial scale. It soon found a wide field of applications as an adsorbent and as a catalyst or catalyst support. Depending on the way in which it is produced, active carbon may have narrow or wide pores; the first type is better suited to the adsorption of gases or vapors, and the second to the adsorption of dissolved substances.

The present book is a revised and improved translation of a volume originally published in 1964 in Czech, in which other authors were involved in the writing of certain chapters. It deals with the manufacture and many of the applications of active carbon, and the theory of adsorption and the various equations for describing adsorption isotherms, together with methods for measuring the pore volume and the pore radius distribution, are all given in detail. However, the reader will seek in vain for *de Boer*'s recently developed t-method for the determination of pore size distribution. Although eight pages are devoted to the catalytic oxidation of hydrogen sulfide on active carbon, there is no mention of the process for the separation of sulfur dioxide from flue gases by means of active carbon.

The authors have taken some trouble to give as comprehensive a survey as possible of the current knowledge on active carbon. In a book of this size, however, details can only be handled very briefly. Because of its limited subject matter, the book will only be of use to a relatively small circle of specialists.

H. P. Boehm [NB 965 IE]

Chemie und Technologie der Silicone (Chemistry and Technology of Silicones). By *W. Noll*. Verlag Chemie, Weinheim 1968. 2nd Edit., xvi, 612 pp., 124 illustrations, 115 Tables, bound, DM 98.—.

The first edition appeared in 1960[1] and the present second edition in 1968. It is characteristic of the rapid overall growth in the chemistry and technology of macromolecular substances that after eight years this book, dealing with a specific field, required a fundamental revision, amplification, and extension; we should be thankful that this has in fact been done. This is particularly true of the chemistry of the low-molecular organosilicon compounds, the technology of silicone rubbers, and the copolymers obtained by various methods. The diligence and thoroughness with which the revision has been carried out can be seen by a comparison of the literature references, which are given at the end of each chapter and (in the new edition) listed on the contents page. Unfortunately, there is no author index to enable the work of a given author to be located.

The author is justified in pointing out in the foreword that the extension of Chapter 4 (present length *ca.* 50 pages, as opposed to 20 previously) on the chemistry of low-molecular organosilicon compounds, which have indeed been the starting-point for further developments, was particularly necessary. Here and in Chapter 7 (Copolymers) there are very informative tables.

The value of this book, which concentrates on essentials, can be seen by comparing Chapter 7 (Other Organosilicon Polymers, 42 pp.) with "Organosilicon Heteropolymers and Heterocompounds" (Plenum Press, New York, 1970, 568 pp.), the English translation of the monograph by *Borisov*, *Voronkov* and *Lukevits*, in which no summarizing survey is given.

For the many readers who are interested in polymeric organosiloxanes, Chapter 6 is still very important. This chapter gives a survey of the fundamentals of chemical and steric structure, the types of bonding, the effect of substituents, the Si—C bonding (comparison with C—C bonding), and the intermolecular forces. This survey leads to a better understanding of the overall properties and thus of the technical and operational behavior.

The very high standard of presentation of the book could be improved still further if certain important concepts (*e.g.* configuration, tacticity, conformation) were used consistently.

The book is strongly recommended to all those interested in the chemistry and technology of macromolecular substances.

Werner Kern [NB 960 IE]

Fortschritte der Verfahrenstechnik (Advances in Process Technology). Edited by *W. Springer*. Verlag Chemie, Weinheim 1969. 1st. Edit., xxvii, 1243 pp., 93 illustrations, 31 Tables, linen binding, DM 260.—.

The publication explosion in the field of chemical engineering continues, and it is becoming increasingly difficult to obtain an overall picture of progress in this branch of engineering. The annual publication of "Fortschritte der Verfahrenstechnik" is an attempt to meet this need, and now we have the eighth volume containing the literature for 1966–1967.

The very fact of the delay in publication (the first annual volume covered the period 1952–1953 and appeared as 1954) shows that the subject specialist cannot expect this type of compilation to act as a report on recent progress in his own particular field (computer-based SDI systems are far more suitable for this purpose) but rather to give him a survey of advances in subjects related to but different from his own. The individual sections of the latest volume fulfil this task with varying degrees of success. For example, the newly instituted Section 8, "Methods of Optimization", meets the above requirements and does it extremely well. On the other hand Section 7, "Technical Reactions and Reactors", still retains an arrangement which not only makes it difficult to get a comprehensive view of the topic, but also does not make use of the advances made in the systematics of this topic in the meantime (*e.g.* reaction analysis as opposed to reactor design).

If individual sections are omitted from time to time (*e.g.* in the present volume "Physics of High and Ultrahigh Pressures" and "Distillation and Rectification") in order to arrive at long-term critical evaluations rather than just a simple arranging and listing, then this is all to the

[1] Cf. Angew. Chem. *74*, 914 (1962).

good; Section 24, "Mechanical Separation of Liquids", which has reappeared in Volume 8, appears to the present reviewer to be a step in this direction.

The overall arrangement of the volume, with sections on Theory of Flow (Section 1), Rheology (Section 2), High-Pressure Technology (Section 3) *etc.* on the one hand and Flotation (Section 22), Mixing in the Viscous, Intrinsically Viscous, Multiphase, Paste, Powder, and Granular States (Section 26b), *etc.* on the other shows how difficult it is to achieve a logical division of the entire field. A search for research results in a specific topic will often necessitate reference to several sections of the book, and will often reveal the presence of duplicate entries.

The collection of over 11000 literature references has been assembled with much care. The note on abstracts of certain of the references in the "Verfahrenstechnische Berichte" is useful. Like its predecessors, this volume will help many chemists and engineers to gain a general picture of recent developments in the field of process technology; it is only a pity that the high ofice will prevent many from purchasing their personal copres

Hanns Hofmann [NB 959 IE]

The Chemistry of Indoles. Organic Chemistry, a Series of Monographs, Vol. 18. By *R.J. Sundberg*. Academic Press, New York–London 1970. 1st ed., x, 489 pp., £ 11.45.

The book provides a 500 page review of the advances made in indole chemistry between about 1950 and 1969, with reference to 1357 publications.

The author has made an excellent job of dividing up the great volume of subject matter and making the book readable and interesting. The main aspects of indole chemistry are presented in ten chapters containing many formulas and reaction schemes. The chapters deal with: 1. Electrophilic Substitutions on the Indole Ring; 2. General Reactions of Substituted Indoles; 3. Synthesis of the Indole Ring; 4. Synthesis of Special Indole Derivatives; 5. Oxidation, Degradation, and Metabolism of the Indole Ring; 6. Rearrangements, Ring Expansion, and Ring Opening Reactions of the Indoles; 7. Hydroxyindoles and their Derivatives; 8. Aminoindoles; 9. Ketones, Aldehydes, and Carboxylic Acids Derived from Indole; 10. Naturally Occurring Derivatives of Indole and the Indolines, and their Physiological and Medical Importance.

The first few chapters are divided according to mechanism, and an excellent idea of the reactivity of the indole ring is therefore gained from many examples. Where possible, the reactions found for indole are compared with those of other groups of substances. The presentation is assisted by a large number of tables.

The author places great value on the clarification of every reaction, and he is critical of any results that seem uncertain to him. Syntheses are placed in the forefront of the discussion.

It was obviously necessary to limit the discussion of indole alkaloids, their synthesis, and their biosynthesis. Preference has been given here to reactions that take place on the indole ring itself.

The author has succeeded in abstracting all the essentials from a subject matter that has now grown almost beyond comprehension.

The reviewer considers the book to be particularly successful, and recommends it to all chemists who are concerned with indoles, as well as to all libraries in the field. The book is essential to everyone whose work involves the synthesis of indoles.

Hans Plieninger [NB 956 IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz*. Vol. 18: Lipid Metabolism. Elsevier Publishing Company, Amsterdam-London-New York 1970. 1st edit., xv, 398 pp., numerous figures, bound Dfl. 75.—.

Lipids, once neglected by biochemists because of their complex behavior and analytical difficulties, are nowadays at the center of interest on account of their important role in the structure and function of biological membranes. Their metabolism is the preparatory stage for these physiological tasks. In animals this begins with resorption after the ingestion of food, mobilization of free fatty acids from the depots, and transport of the triglycerides in the plasma, leading *via* biosynthesis in the liver and other organs, especially nerve tissue, to breakdown by β-oxidation. In addition to this, bacteria and plants have their own individual lipid metabolism.

The chapters and compilations of this volume of "Comprehensive Biochemistry"[*], which roughly follow the scheme set down are once more written by competent authors practised in the art of writing surveys. The coordination of the chapters is somewhat careless, so that a number of repetitions and overlaps occur, and some authors use different nomenclature. However, the efforts made by the editors to obtain the necessary degree of cooperation from the authors should not be underestimated: an apologetic and reproachful note reveals that delays by a few of the authors—obviously overburdened by other literary duties—had a deleterious effect not only on the completion but also on the unity of the volume. This explains the gaps in the book, namely the lack of chapters on fat synthesis in higher organisms, fatty acid oxidation, steroid metabolism and end oxidation. The latter had already been moved from Vol. 17 to Vol. 18 for the same reason, and it is now intended to produce a special volume, which will not make the handbook, already expensive in itself, any cheaper. In the chapters offered, however, the metabolism of simple and complex lipids is very comprehensively, but critically covered and fairly selectively documented up to 1968. The length of the sections is not always in accordance with the biological importance of the material, but all contain a great deal of information so that the volume deserves a plade at the side of the others.

Chemistry through the Language Barrier. By *E. Emmett Reid*. Johns Hopkins Press, Baltimore–London 1970. 1st ed., xi, 138 pp., bound £4.75.

In this book, which has the subtitle "How to scan chemical articles in foreign languages with emphasis on Russian and Japanese", it is the author's aim to pass on his technique for reading information from foreign-language publications without learning the language. Since only 55.9% of all publications are written in English, the English-speaking chemist must encounter a large number of articles that are not in English.

The author builds up his method for the understanding of foreign-language publications, particularly the experimental part, from the assumptions that numbers, chemical formulas and equations, and names of compounds are the

same or similar in all languages and that in order to understand scientific articles it is more important to know the field of science than to be familiar with the language. The peculiarities of the following languages, collected in language groups, are described in a space of 64 pages: Italian, French, Romanian, Spanish, Portuguese (Romance group); Dutch, Swedish, Danish, Norwegian, German (Germanic group); Hungarian, Finnish, Czech, Polish, Russian (Slavic group); Japanese. Examples of texts are given for each language, with explanations. Special space is devoted to the introductions to the peculiarities of Russian and Japanese (presentation of the Russian alphabet, table of the Japanese Katakana and Hiragana [phonetic characters]). The 74 page Appendix consists of a multilingual vocabulary of the words of greatest importance to the chemist, and a list of Chinese characters used in Japanese texts for words such as acid, atom, to boil, *etc.* Despite the tips given by the author, it will not be easy to obtain information in this way, particularly since abstracting periodicals present the information in a more easily understandable manner, and there is a growing tendency for the journals to include English summaries of the articles. However, the book should be useful to the reader who is interested in languages.

Christian Weiske [NB 954 IE]

Physical Principles and Techniques of Protein Chemistry, Part A. From the Molecular Biology series. An International Series of Monographs and Textbooks. Edited by *S. J. Leach*, Academic Press, New York–London 1969. 1st Edit., xii, 530 pp., numerous figures, $ 24.00.

Some fifty years' research into proteins has resulted not only in an increase of knowledge of their structure and function, but also in an extension of the methods used for their study. In addition to chemical and biochemical methods, physical methods are being used with increasing success. Although in many cases only an expert can master them, some degree of familiarity with their physical foundations, their range of applications, and in particular with the interpretation of the results obtained is a necessity for any chemist working in the protein and peptide fields. Any new information source is desirable, and for this very reason this collection of papers under the editorship of *S. J. Leach* is to be welcomed.

The present volume (Part A) contains: 1. Electron microscopy of globular proteins *(E.M. Slayter)*; 2. X-Ray methods *(D.B. Fraser* and *T. P. MacRae)*; 3. UV absorption *(J.W. Donovan)*; 4. Fluorescence of proteins *(R. F. Chen, H. Edelhoch,* and *R. F. Steiner)*; 5. Perturbation and flow techniques *(B.H. Haysteen)*; 6. Dielectric relaxation *(S. Takashima)*; 7. Electrical birefringence and dichroism *(K. Yoshioka* and *H. Watanabe)*; 8. Electrophoresis *(R.J. Cann)*; 9. Analytical gel filtration *(D.J. Winzer)*.

Both the authors and the editor have succeeded in taking into account the current significance of the methods under discussion. Practical hints are given even for the methods used by non-specialists, and specific methods, where the greatest emphasis is on the range of applications, are carefully distinguished. The way in which the articles are distributed between the two volumes is somewhat less satisfactory; the present reviewer would have thought it more logical to collect related topics (*e.g.* spectroscopy) into one volume.

It will only be possible to estimate the importance of the book for scientific work when the second volume has appeared. In the meantime we can certainly say that a good and profitable book has been added to the "Molecular Biology" series.

New Routes to Multicomponent Oxide Glasses

By Helmut Dislich[*]

Multicomponent oxide glasses can be produced not only by melting methods but also by hydrolysis and condensation of alkoxide complexes with several metals. This requires temperatures only up to the transformation range of the glass in question, usually 500–600 °C. The process does not pass through the molten phase. It is possible to obtain glasses or polycrystalline substances, depending on the composition. The method is particularly suitable for the production of thin, transparent multicomponent oxide layers of almost any composition on substrates. Some of these layers provide protection against climatic attack or against oxidation.

1. Introduction

It is generally known, though rarely mentioned, that glass is the oldest thermoplastic. There is no reason to think of the materials and methods of organic chemistry in connection with glass, since the ASTM definition of glass is "an inorganic product of fusion, which has cooled to a solid state without crystallizing"[1].

The concept of the "vitreous state" will not be discussed here. The wisdom of including a production process (melting) in the definition seems questionable, since the definition then depends on the state of the art at the time of its formation. It results from the fact that for 4000 years, glass has been produced almost exclusively by melting, and from the technical importance that is attached to the further development of the melting process and of fused glasses. However, unfused glasses are also known. *Mackenzie*[2] has compiled an annotated list of unconventional routes leading to glass (Table 1).

The simplest method is hydrolysis; *Schroeder*[5] prepared vitreous layers of individual and mixed oxides (SiO_2, TiO_2, and others) by hydrolysis and polycondensation of metal alkoxides. However, single-oxide glasses are special cases, and if one wishes to carry out investigations and to obtain information about glass in general, the methods used must also be suitable for the preparation of complicated multicomponent glasses such as occur in industry.

[*] Dr. H. Dislich
Organisch-Chemisches Laboratorium des Jenaer Glaswerkes
Schott und Gen.
65 Mainz, Postfach 2480 (Germany)

The first step in this direction was made by the use of at least one hydrolyzable metal compound in the preparation of a multicomponent glass; this allowed the use of a lower melting temperature[6]. *Roy*'s "gel method"[7] ultimately also aims in this direction. In this method, silica sols and metal carbonates, hydroxides, nitrates, *etc.* are combined to form gels, from which glasses are obtained below the liquidus temperature but above the transformation temperature. No details are known, but layers of multicomponent glasses will presumably not be obtainable in this way.

Table 1. Unconventional routes to glass (after [2]).

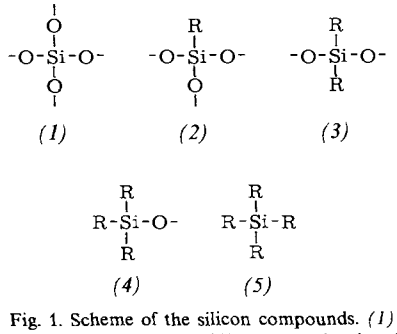
Glass production in solid state: (a) Shock-wave treatment (b) Neutron bombardment
Glass production from the vapor phase: (a) Direct methods, *e.g.* evaporation of crystalline Al_2O_3 and deposition of a noncrystalline Al_2O_3 film, recently also simultaneous evaporation of several individual oxides, which deposit as a glass film [3] (b) Indirect methods, *e.g.* vapor-phase hydrolysis of $SiCl_4$ to SiO_2. (c) Preparation of multicomponent glass films by the "Chemical Vapor Deposition" process [4].
Glass production from solution: (a) Oxide films produced anodically from aqueous electrolytes (b) Hydrolysis of *e.g.* metal alkoxides

Multicomponent glasses have not so far been obtained at temperatures not exceeding the transformation point. This seems a desirable achievement, for the following reasons.

1. It would no longer be possible to describe the glass structure merely as the structure of a supercooled melt, as has been common until now, since no temperature ranges in which crystallization occurs at a measurable rate are traversed during cooling. Since the properties of a glass are known to depend on its past history, glasses with novel "histories" would be available for investigation.

2. The axiom "glass is a product of fusion" would be replaced by *Mackenzie*'s definition[2]: "Glass is a noncrystalline solid", or by *Krebs*': "Glass in the wider sense can be defined as a solid with dense packing of the atoms, in which crystalline arrangements do not extend beyond a few interatomic distances".

3. Preparation below the transformation temperature would provide at least a possibility of obtaining glasses that cannot be obtained at higher temperatures because of an excessively strong tendency to crystallize.



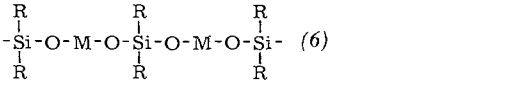
Since hydrolytic methods are well suited to the production of layers, it would be possible to apply coatings of multicomponent glasses to substrates that are stable up to the transformation temperature of the glass to be applied. This is only very rarely possible by other methods.

Nothing much can be said at present about points 1 and 3. Points 2 and 4 are in the forefront at present, and particularly the route by which multicomponent oxide glasses and also crystalline multicomponent oxides can be prepared. This is where organic chemistry plays its part, for it provides this route. There is much here that is old, insofar as the starting materials are hydrolyzable metal compounds, particularly metal alkoxides, which can be readily degraded to the metal oxide. The novelty is the advantage that is taken of the strong tendency of alkoxides of various elements to react *with one another*. These reactions lead to "alkoxo salts", which are often very complicated, and which are then degraded by hydrolysis and polycondensation to multicomponent oxide glasses and crystalline multicomponent oxides.

2. Position and Statement of Problem

Let me first recall the old silicate-silicone comparison (the contents of the following lines are based on *W. Noll*'s book[8]).

The smaller the number of organic residues R in Figure 1, the more pronounced is the silicate character of the corresponding polymers; the type *(1)*, which is the only one



(1) *(2)* *(3)* *(4)* *(5)*

Fig. 1. Scheme of the silicon compounds. *(1)*: Structural unit of the silicate network; *(2)—(4)*: structural units of the silicone polymers; *(5)*: "pure" organosilicon compound.

with which we shall be concerned, must be regarded as a structural unit of an "inorganic polymer".

The search for heat-resistant plastics led to attempts to use the principle of the Si—O framework of the silicates, but instead of the tetrafunctional group *(1)*, which leads to highly crosslinked products, the groups *(2)–(4)*, whose functionality can be read off directly, were incorporated. The resulting successes of silicone chemistry are well known.

On the whole, attempts to extend the structural principles of silicate chemistry farther into organosilicon chemistry by transition to heteroorganopolysiloxanes *e.g.* of the type *(6)*[*] (M = *e.g.* B, Al, Ti, Sn, Pb, P, As[8]) have so far been technically less successful. The investigations, which are

(6)

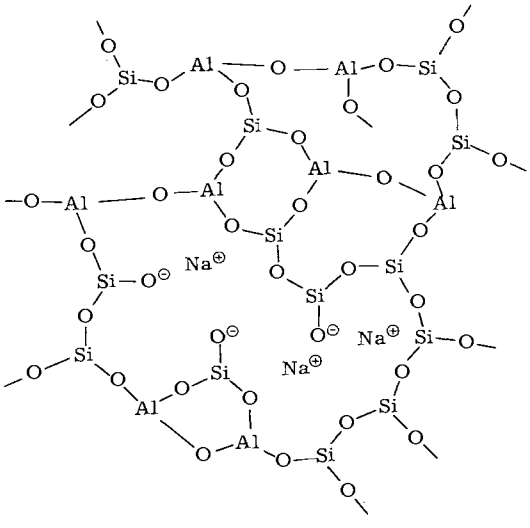


Fig. 2. Section of the structure of a multicomponent glass. Silicon forms a fourth bond to oxygen in the third dimension.

intended to yield polymers that can be processed at low temperatures, have not yet been completed. Such polymers are not highly crosslinked; the functionality of the monomers is limited by the incorporation of groups R. Polymers of this type often have more or less irregular compositions, and this makes the "starting material/end product" correlation very difficult[9].

Silicate glasses are highly crosslinked, but are nevertheless thermoplastics. Their thermoplasticity, unlike that of organic polymers, is due to the rupture of principal valences in the network as a result of thermal motion at high processing temperatures. The structural groups in silicate glasses correspond to type *(1)* above in the case of silicon, and to the analogous type having the highest functionality in the case of the other metals. Figure 2 shows a section from the structure of a multicomponent glass containing some of these groups.

The simplest case is silica glass, which can be prepared[5] from esters of silicic acid by hydrolysis and polycondensation, formally in accordance with

[*] Shown with bivalent M for simplicity.

$$Si(OR)_4 + 4\ H_2O \longrightarrow [Si(OH)_4] + 4\ ROH$$

$$[Si(OH)_4] \xrightarrow{-2\ H_2O} SiO_2$$

though the reaction undoubtedly proceeds *via* polyorganoxysiloxanes, and not *via* $Si(OH)_4$.

In the practical application of this "structural unit principle" for the production of multicomponent glasses and crystalline multicomponent oxides, the metal alkoxides provide a good source of monomeric structural units with maximum functionality. The maximum functionality is a necessary (but not sufficient) condition, since all the organic groups must be split off to obtain pure oxide systems. This is trivial in the case of a single metal alkoxide. When many metal alkoxides are present together, the following questions are of interest:

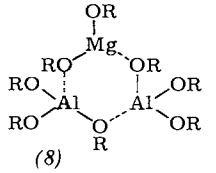
1. Can a multicomponent glass be prepared by the hydrolysis and polycondensation methods commonly used in organosilicon chemistry *without going through the molten phase*?

2. Can crystalline multicomponent oxides be prepared in the same way from the reactive metal alkoxides?

The first efforts were concerned with known multicomponent glasses and crystalline multicomponent oxides. This has the advantage over the heteroorganopolysiloxanes *(6)* that the end products can also be obtained by another route, *e.g.* by melting, and it is therefore possible to compare the properties of the products obtained by the known method and by the new route.

3. Some Known Reactions of Metal Alkoxides

Metal alkoxides have been known for a long time, and have been studied intensively and systematically during the last twenty years, particularly by *Bradley*[10,11] and *Mehrotra*[12], who cite hundreds of original articles in their reviews[10-12]. Reference should also be made to[13].



These reactions of the metal alkoxides are particularly important to the following discussion:

1. Many metal alkoxides react readily with one another to form complex metal alkoxides, the "alkoxo salts". The stability of these salts increases with the difference in the electrochemical characters of the two metals. The complexes may be heteropolar, *e.g. (7)*, or homopolar, *e.g. (8)*.

$$Al(OR)_3 + KOR \longrightarrow [Al(OR)_4]K$$

(7)

$$2\ Al(OR)_3 + Mg(OR)_2 \longrightarrow$$

(8)

2. All metal alkoxides can be more or less readily hydrolyzed, as illustrated earlier for $Si(OR)_4$.

3. During the hydrolysis, condensation reactions take place with formation of polyorganoxymetaloxanes, some of which are polymeric, *e.g. (9)* and *(10)*.

$$M(OR)_x + H_2O \rightarrow M(OH)(OR)_{x-1} + ROH \quad (9)$$

$$M(OH)(OR)_{x-1} + M(OR)_x \rightarrow (RO)_{x-1}MOM(OR)_{x-1} + ROH \quad (10)$$

$$2\,M(OH(OR)_{x-1} \rightarrow (RO)_{x-1}MOM(OR)_{x-1} + H_2O \quad (10)$$

The end product of the hydrolysis, after elimination of water from OH groups by heating, is the metal oxide, which may be regarded as a macromolecule built up from three-dimensionally linked metaloxane chains —M—O—M—O—.

Other reactions that sometimes complicate the situation, but do not fundamentally change it, can be indicated briefly by some typical examples (Fig. 3).

$$>B\text{-}OH + RO\text{-}Si\lessdot \longrightarrow >B\text{-}O\text{-}Si\lessdot + ROH$$

$$>B\text{-}OH + HO\text{-}Si\lessdot \longrightarrow >B\text{-}O\text{-}Si\lessdot + H_2O$$

$$>Al\text{-}OR + HO\text{-}Si\lessdot \longrightarrow >Al\text{-}O\text{-}Si\lessdot + ROH$$

$$\geqslant Ti\text{-}OR + HO\text{-}Si\lessdot \longrightarrow \geqslant Ti\text{-}O\text{-}Si\lessdot + ROH$$

$$\geqslant Si\text{-}OR + HO\text{-}P(=O)\lessdot \longrightarrow \geqslant Si\text{-}O\text{-}P(=O)\lessdot + ROH$$

$$\geqslant Si\text{-}OR + R^1OH \longrightarrow \geqslant Si\text{-}OR^1 + ROH$$

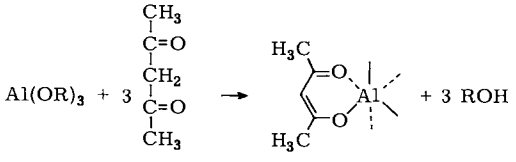


Fig. 3. Examples of crosslinking by metaloxane formation.

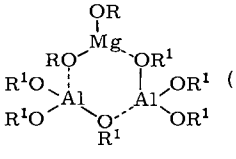

4. Preparation of Crystalline Multicomponent Oxides

Though we are interested mainly in glasses, we shall first consider the crystalline multicomponent oxides, since the reaction is much more straightforward, particularly in the case of spinel, which has only two components. The preparations are carried out in a temperature range in which the above reactions take place, *i.e.* up to about 500 °C. Reactions that take place in the melt, *i.e.* at much higher temperatures, do not occur.

4.1. Preparation of Magnesium-Aluminum Spinel

Magnesium methoxide is allowed to react with aluminum *sec*-butoxide in a molar ratio of 1:2 in alcohol. The magnesium aluminum alkoxide *(11)* is formed in solution [eq. (1)][13].

$$Mg(OR)_2 + 2\ Al(OR^1)_3 \longrightarrow$$

(1)

(11), $R = CH_3$, $R^1 = CH(CH_3)_2$

The choice of the organic residues is a matter of purely practical importance, since they are removed later in any case.

On evaporation of the solvent in the presence of atmospheric moisture, hydrolysis occurs [eq. (2)].

$$Mg[Al(OR)(OR^1)_3]_2 + 8\,H_2O \rightarrow \underset{(11)}{} \; Mg[Al(OH)_4]_2 + 2\,ROH + 2\,R^1OH \quad (2)$$

The resulting lumps of gel are then heated to 620 °C to induce the condensation, which undoubtedly also takes place in part even at room temperature [eq. (3)].

$$Mg[Al(OH)_4]_2 \rightarrow Mg[AlO_2]_2 + 4\,H_2O \quad (3)$$

4.2. Identification of the Magnesium-Aluminum Spinel

The small, hard, white lumps obtained were identified by X-ray diffraction analysis as spinel (crystallite size 100 Å). The principal reflections of spinel appear (though they are very broad) on heating at 250 °C, and become more pronounced on heating at 400 °C. The lattice constant at 20 °C is 8.084 Å (literature value 8.080 Å).

The product prepared by the alkoxide method at 620 °C absorbs water from the air on prolonged standing; this water can be rapidly removed by reheating to 620 °C. A product heated to 1150 °C no longer exhibits this water absorption. The X-ray diffraction diagram also becomes sharper. The crystallite size is then about 950 Å. The polycrystalline material contains MgO and Al_2O_3 in a ratio of 1:1.08.

The spinel is thus formed at temperatures far below those normally used for such syntheses. Whereas Mg and Al alkoxides react with one another even at room temperature, high temperatures are necessary for the normal reaction of salts or oxides. We allowed $Mg(NO_3)_2 \cdot 6\,H_2O$ to react with $NH_4Al(SO_4)_2 \cdot 12\,H_2O$, and found that spinel formation started only above 850 °C. According to *Hüttig et al.*[14], the formation of the zinc-aluminum spinel also begins at 850 °C, while the material consists entirely of spinel only at 1150 °C.

Bratton[15] uses lower temperatures. $Al(OH)_3$ and $Mg(OH)_2$ are precipitated together at 100 °C. Spinel is formed when the precipitate is heated at 350–400 °C (Fig. 4).

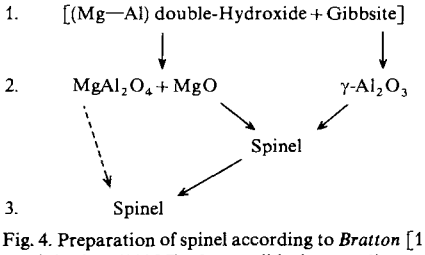

Fig. 4. Preparation of spinel according to *Bratton* [15]. 1: Simultaneous precipitation (100 °C); 2: possible intermediate stage (350—400 °C); 3: crystallization of spinel (> 400 °C).

The route *via* the alkoxides seems more direct; no crystalline phases other than spinel are formed even at low temperatures.

Hard, glass-clear spinel layers can also be applied to substrates by the method described in Section 7 (dipping method).

5. Scope of the Method

The formation of the spinel evidently depends on the prior reaction of the components in accordance with eq. (1), so that a sort of cocondensation occurs after hydrolysis instead of homocondensation. The latter possibility, which appears, from literature data, to be more common[16], would yield mixtures of single oxides instead of a homogeneous multicomponent oxide. Part of the metal alkoxides may naturally undergo condensation reactions with elimination of alcohol even at room temperature, but this is of no importance to the final result, since the reaction continues *via* the polyorganoxymetaloxane stage *(11)*. The temperatures mentioned are evidently necessary for the removal of the last traces of water from hydroxyl groups bonded to metal.

The process should be applicable to other elements if the metal alkoxides react with one another, as they do in most cases. For example, we have prepared eucryptite [LiAl(SiO$_4$)] in this way from lithium ethoxide, aluminum *sec*-butoxide, and $Si(OR)_4$. After this work had been concluded *Mazdiyasni, Dollof,* and *Smith*[17] reported the preparation of $BaTiO_3$, $SrTiO_3$, and $SrZrO_3$ as polycrystalline material by a similar method; this underlines the scope of the method. (Investigations on a similar basis are also being carried out at the ETH Zürich[18].)

This therefore provides a relatively convenient route to multicomponent oxides that are difficult or perhaps almost impossible to obtain by other methods, and also offers the possibility of obtaining substances of high purity. Very pure metals may be used in the preparation of the metal alkoxides, the alkoxides themselves or their reaction products may be recrystallized, and even distilled in some cases, and the reactions proceed under comparatively mild conditions, so that contamination from the walls of the vessel can be avoided. The method may also be of value for doping.

Finally, there is practically no other method that allows the preparation of thin layers of multicomponent oxides having almost any desired composition on substrates (see Section 7). The method is particularly elegant for this purpose, since the action of atmospheric moisture (hydrolysis) and the removal of the condensation products water and alcohol can be achieved without difficulty in the case of thin layers (a few tenths of a μm). The preparative difficulties in the production of polycrystalline material are sometimes considerable, since the diffusion paths are long and difficult to control, unlike those in thin layers. This can lead, with rising temperatures, to pyrolysis with separation of carbon before the hydrolytic removal of the OR groups is complete. Though this does not interfere with the necessary determination of the nature of the material obtained, the product is not obtained in the pure state. However, an improvement can generally be achieved by the use of different experimental conditions, often established only by laborious trial and error.

5.1. Preparation of Borosilicate Glass

Unlike the organic polymers, which are versatile in spite of restriction to a few elements, the inorganic polymers, *i.e.* the glasses, owe their versatility to the fact that their composition can include practically any element from the periodic system.

To prepare a multicomponent glass, the various components must be made to react with one another. In the melting method, favorable conditions are provided by heating the starting materials until they melt; the various components then react with one another, possibly with elimination of gases such as CO_2. The melt may then, for example, be poured into a mold, where it cools and solidifies to form a glass.

Since a multicomponent glass containing silica can be regarded, on the basis of its structure (Fig. 2), as a crosslinked "polymultimetaloxanesiloxane", it seemed interesting to us to look for a practical route that would also justify this description. As in the spinel case, metal alkoxides should combine here to form an alkoxo complex, which is converted by hydrolysis and polycondensation *via* "polyorganoxymultimetaloxanesiloxanes" into the glass, which contains no organoxy groups, and is in fact the "polymultimetaloxanesiloxane".

To provide a better grasp, an example of a practical procedure will now be described. A three-neck flask is fitted with a stirrer and a reflux condenser, and the following ingredients are introduced in succession with stirring, nitrogen being passed over the mixture at the same time: 50 g of ethanol (dry) + 0.5 g of 2,4-pentanedione; 102 g of $Si(OCH_3)_4$, 5.3 g of $Al(O\text{-}sec\text{-}C_4H_9)_3$, 10.5 g of $NaOCH_3$ (solution in methanol corresponding to 172 g of Na_2O/l), and 1.4 g of KOC_2H_5 (solution in methanol corresponding to 218 g of K_2O/l). The precipitate formed on addition of the aluminum *sec*-butoxide is brought into solution by stirring and heating at 70 °C. 11.2 g of H_3BO_3 dissolved in 120 ml of boiling ethanol is then added. The precipitate that forms dissolves within 5 minutes. The dark yellow solution contains about 160 g of oxides (80.9% SiO_2, 12.7% B_2O_3, 3.6% Na_2O, 2.2% Al_2O_3, 0.6% K_2O) per liter.

The diluted solution containing 30 g of oxide/l is left open to the air in a beaker. It sets to form a gelatinous mass, which is then heated for 9 hours at 150 °C. During this heating, it cracks and breaks up into small yellow crumbs, which become colorless, glass-clear, and hard when heated at 530 °C. Small black impurities that sometimes form (see above) are sorted out. This preparation route is illustrated in Figure 5.

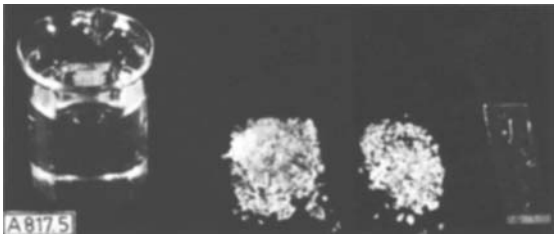

Fig. 5. Preparation of a borosilicate glass from hydrolyzed alkoxides. From left to right: starting solution, crumbs obtained by hydrolysis at 20 °C, crumbs obtained from these by heating at 550 °C, glass obtained from these on pressing at 2800 atm.

5.2. Proof that the Product is a Borosilicate Glass

Though the presence of clear, transparent fragments allows little doubt as to the nature of the product, the properties of a product prepared in this way must be compared with those of a fused glass in order to provide rigorous proof that a glass has in fact been formed in the region of the transformation temperature, without fusion. A portion of the glass-clear crumbs was therefore pressed into transparent plates at 630 °C and 100 t (this can be achieved more easily at 650–700 °C), and another portion was fused at 1600 °C. The investigations described below were carried out on the crumbs, the molded plates, and the fused pieces, and show that glass has in fact been formed (see Table 2).

Table 2. Chemical composition of the borosilicate glass (values in wt.-%).

Glass	SiO_2 (%)	B_2O_3 (%)	Al_2O_3 (%)	Na_2O (%)	K_2O (%)
Unfused	86.85	5.91	2.62	3.92	0.66
Fused	87.99	4.97	2.62	3.67	0.67

The reason for the greatly reduced B_2O_3 content in comparison with that in the original solution is that part of the B_2O_3 escapes as esters of boric acid. It should be remembered that 10–15% of the B_2O_3 used in the melting method can also escape with the flue gases.

The residual water content can be determined by IR spectroscopy (OH band at 2.9 μm).

Unfused glass contains 0.036% of H_2O after a fragment has been heated for 50 h at 550 °C and pressed at 650 °C. If the same glass is heated for 4 h at 700 °C under a high vacuum before pressing, 0.029% of water can still be detected. Fused glass contains 0.023% of H_2O (for comparison, Duran 50, which is fused on a large scale, contains 0.033% of H_2O).

The water is thus very extensively removed during the normal condensation at 550 °C (followed by heating for a short time at 650 °C during pressing).

The residual carbon content of an unfused glass is 0.0002%, which is surprisingly low in view of the fact that the glass was made from alkoxides. The hydrolysis is thus practically quantitative, despite the strong crosslinking.

The hydrolysis resistance of unfused glass in accordance with DIN 12111 is 0.007 mg of Na_2O/g of coarsely ground glass (= hydrolytic class 1), while that of fused glass is 0.005 mg of Na_2O/g of coarsely ground glass (= hydrolytic class 1). Physical and optical properties are shown in Table 3.

The temperature function of viscosity was tested qualitatively by heating a fragment under constant load and observing it with the aid of a microscope. Deformation begins at 675 °C. The temperature function of viscosity corresponds to that of similar borosilicate glasses.

The agreement of the properties shows that the product does not consist of single oxides or a number of two-component oxides, but of a homogeneous multicomponent system, *i.e.* a borosilicate glass.

Let us now briefly compare the procedure for the hydrolytic condensation with that for the melting process. The batch is replaced by a mixture of compounds that react readily with one another. Homogenization is replaced by

dissolution in a common solvent. The reaction, which starts only at high temperatures in the melting process, begins here at room temperature (complex formation) and continues with the action of atmospheric moisture with hydrolytic elimination of alcohol, which is comparable to the thermal elimination of CO_2 from a carbonate. The condensation reaction with elimination of water takes place at the same time; this reaction requires temperatures up to the transformation range of the glass. The pouring of a fused glass into a mold is replaced by pressing of the glass crumbs to form a transparent molding in the transformation range.

Table 3. Physical and optical properties of the unfused and of the fused glass.

Glass	Density D_{20} (g/cm³)	Coefficient of expansion	Transformation temperature (°C)	Hardness to scratching
Unfused	2.28	32×10^{-7}	590	scratches window glass and apparatus glass 20
Fused	2.27	32×10^{-7}	610	scratches window glass and apparatus glass 20

Glass	Refractive index n_d 20	ν_d	X-ray diffraction analysis
Unfused	1.477	65	contains no crystalline phases
Fused	1.474	66	contains no crystalline phases

This last step is obviously more difficult than a melting process. Moreover, because of the simultaneous reaction of five components, it is not so easy to explain the path as in the case of the two-component system of spinel. Since the initial and final states are known with certainty, we could write a formal reaction equation, but we shall not do so here. A first glimpse is provided by following the IR spectrum of a film of borosilicate glass 0.5 μm thick on a barium fluoride plate during its formation. After 30 min at 100 °C, a pronounced metal-OH band is observed at 3 μm, which is stronger after 30 min at 250 °C. After 30 min at 530 °C, the metal-OH groups have been consumed by condensation, and can no longer be detected, at least in this thin layer. A band at 3.4 μm is attributable to the CH_3 and/or CH_2 vibration of the OR residues that have not yet been removed (or of the free alcohol). It is present after heating at 100 °C, but has disappeared at 250 °C, when hydrolysis has progressed to an advanced state. The boric acid band is situated at 7.2 μm and the Si—O vibration at 9.4 μm. The characteristic of the curve corresponds to that of a Duran 50 film (though the boric acid content of the latter is considerably higher) and to that of a vapor-deposited layer of borosilicate glass.

6. Conclusions

According to all the observations reported, a multicomponent oxide glass can no longer be regarded exclusively as an "inorganic product of fusion" (ASTM definition), but can also be considered with equal right as a "multipolycondensation product" prepared by hydrolysis and polycondensation reactions from compounds containing metal-OC groupings. Neither of these features is fundamentally essential or necessary to the definition. It is important and interesting, however, that practically no difference can be detected between a fused and a condensed glass by the investigation methods used. It may be possible, by more refined methods, to find differences due to the past history of the material, which could lead to further knowledge about glasses.

An important point as far as the method is concerned is that it is now possible to prepare a glass "from below", *i.e.* by approaching the glass state from a lower temperature. It is therefore no longer necessary to pass through the temperature range of maximum crystallization rate. With this release from the danger of crystallization during cooling, it should now be possible to establish whether a given composition that can be prepared by this method forms a glass or a crystalline phase. The method may also be of use in the study of phase separation phenomena.

7. Multicomponent Glass Layers on Substrates

It has only recently become possible to apply thin multicomponent glass layers to substrates by simultaneous vapor deposition of individual oxides under vacuum[3]. A particularly important step is the development of special "vapor deposition glasses", with which homogeneous glass layers suitable for technical use can be produced directly[19]. Glass layers can also be applied by the chemical vapor deposition process[4].
